Abstract—The composition of an equilibrium vapor–gas mixture in the range 700–1100 K was estimated for the reaction of arsenic trichloride with hydrogen taken in excess of a = 1.0–2.5 as compared to the stoichiometry. The temperatures of the onset of arsenic condensation (dew point) were found. Kinetic parameters of the chemical reaction were determined. Optimal conditions for the reduction of arsenic trichloride with hydrogen were refined and conditions for the condensation of arsenic with the minimum fraction of the amorphous modification were found.

DOI: 10.1134/S1070427207010016

The reaction of gaseous arsenic trichloride with hydrogen is one of the most important stages of the preparation of high-purity elemental arsenic [1–4]. Systematic study of $AsCl_3$ reduction with hydrogen is required for the development of physical and chemical principles for producing high-purity arsenic from an unconventional raw material, products of the detoxication (utilization) of chemical weapons (lewisite). The feasibility of organizing industrial production of high-purity arsenic-containing compounds on the basis of lewisite has been substantiated in [5–7].

It was found by studying thermodynamic and kinetic features of the $AsCl_3$ reduction with hydrogen [8–10] that the degree of conversion of arsenic trichloride is sufficiently high even at temperatures above 600 K and small hydrogen excesses against a stoichiometry. The chemical equilibria for real reaction conditions were simulated in [11].

This paper deals with an experimental study of the reduction of $AsCl_3$ with hydrogen. Appreciable attention is given to the process kinetics, and also to the optimization of conditions for the production of high-purity arsenic from unconventional raw materials, products of lewisite detoxication and wastes from nonferrous metallurgy.

EXPERIMENTAL

First we made a thermodynamic estimation of the arsenic trichloride reduction with hydrogen:

$$AsCl_{3g} + 1.5H_{2g} \rightleftarrows 0.25As_{4g} + 3HCl_g, \quad (1)$$

$$K_{eq} = \exp(-\Delta G_T^0/RT). \quad (2)$$

Such representation of the $AsCl_3$ transformation to arsenic is admissible, as it was shown previously [5, 7] that As_4 is the main arsenic species in the vapor phase at temperatures below 1100 K in the presence of a hydrogen excess $\alpha < 5$ against the stoichiometry. Equilibrium constants (2) of reaction (1) were calculated for the range 700–1100 K and an excess (α = 1–2.5) of hydrogen against the stoichiometry by two known methods:

$$\Delta G_T^0 = \Delta H_{298}^0 - T\Delta S_{298}^0 + \sum [n_i(H_T^0 - H_{298}^T)_i] - T\sum [n_i(S_T^0 - S_{298}^T)_i], \quad (3)$$

$$\Delta G_T^0 = \Delta H_{298}^0 - T\Delta\Phi_T^{**}, \quad (4)$$

where $\Delta\Phi_T^{**}$ is the reduced thermodynamic potential.

Both methods give similar K_{eq} values varying from 3.4×10^4 to 6.0×10^4 atm$^{0.75}$ for ΔG_T^0 varied from 60 to 100 kJ mol^{-1}. From the resulting K_{eq} values, we estimated the composition of the equilibrium vapor–gas mixture for a total pressure of 1 atm in the reaction zone. The calculated data are given in Fig. 1, which shows that the calculated partial pressures P_{eq} of arsenic vapor are practically independent of the process temperature and decrease by a factor of 1.7 with increasing α from 1 to 2.5. The partial pressure

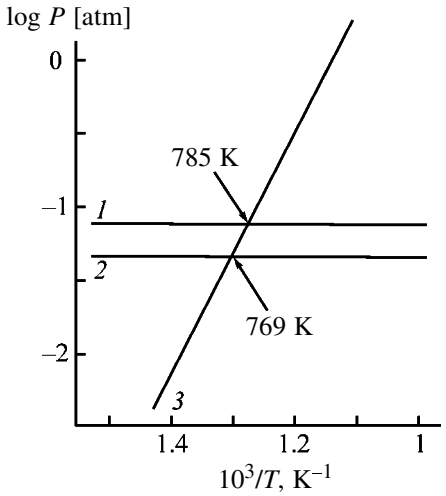

Fig. 1. Temperature dependence of arsenic pressure P under equilibrium conditions. α: (*1*) 1.0 and (*2*) 2.5; (*3*) saturated vapor pressure of arsenic.

of hydrogen decreases by a factor of 1.26 with increasing temperature from 700 to 1100 K at $\alpha = 1$, but at $\alpha > 1.5$ it becomes practically temperature-independent. The equilibrium concentration of $AsCl_3$ remains insignificant at all α values and decreases as α increases, confirming a high degree of $AsCl_3$ conversion to arsenic (Table 1).

The temperature dependence (5) of the saturated vapor pressure of arsenic over solid arsenic [8] is also shown in Fig. 1.

$$\log P\,[\text{atm}] = -8140/T + 9.244. \quad (5)$$

It is seen that the straight line crosses the horizontal lines of P_{As} in points corresponding to 785 and 769 K for $\alpha = 1$ and 2.5, respectively. These are the temperatures that are "dew points" for the initial proportions of the reactants and correspond to the conditions of the onset of arsenic condensation and to the lower temperature boundary of correct thermodynamic calculations for reaction (1). At lower temperatures, reaction (6) occurs, and the homogeneous process becomes heterogeneous.

$$AsCl_{3g} + 1.5H_{2g} \rightleftarrows As_s + 3HCl_g. \quad (6)$$

Thus, we can expect that $AsCl_3$ will be reduced by reactions (1) and (6) simultaneously below the dew point. In this case, the contribution of reaction (6) increases as the temperature decreases and can be estimated from expression (7).

$$D = (P_{eq} - P)/P_{eq}, \quad (7)$$

where P_{eq} is the equilibrium pressure of arsenic vapor for reaction (1). The process can be considered as passing homogeneously (1) in the gas phase with the subsequent condensation of arsenic vapor:

$$As_{4g} \rightleftarrows 4As_s. \quad (8)$$

The kinetics of $AsCl_3$ reduction with hydrogen was studied on an installation schematically shown in Fig. 2. The main element of the installation is a quartz reactor consisting of two sections. A high-temperature zone is constructed as a system of three coaxial cylinders ensuring a preset residence time of the reaction mixture ($AsCl_3 + H_2$) at a certain temperature.

A water-cooled condenser ensuring the deposition of arsenic in the form of a compact coarsely crystalline ingot is arranged in the low-temperature zone of the reactor. The reactor is placed inside a multizonal resistance heating unit where the required temperature of the reaction and arsenic condensation zones is created.

We used two methods for the determination of the degree of arsenic trichloride conversion to elemental arsenic: (1) direct monitoring of the $AsCl_3$ content in gaseous reaction products by sampling and subsequent analysis of the samples and (2) determination of the amount of the resulting elemental arsenic from the loss of a certain amount of the starting $AsCl_3$.

The first method makes it possible to reduce the experiment duration and to make several parallel analyses with a single portion of $AsCl_3$. The second method is more labor-consuming; however, it provides an integral characteristic of the process kinetics in the H_2–$AsCl_3$ system where the effect of fluctuations of process conditions will be leveled off. In this case, however, an essential complication is permanent formation of finely dispersed amorphous modification of arsenic, which is partially carried away from the condenser by a gas stream. Therefore, it is necessary to take into account the amount of elemental arsenic precipitated in the absorbing system.

We used a combined technique in the experiments,

Table 1. Degree of arsenic trichloride conversion to arsenic η as a function of temperature and hydrogen excess

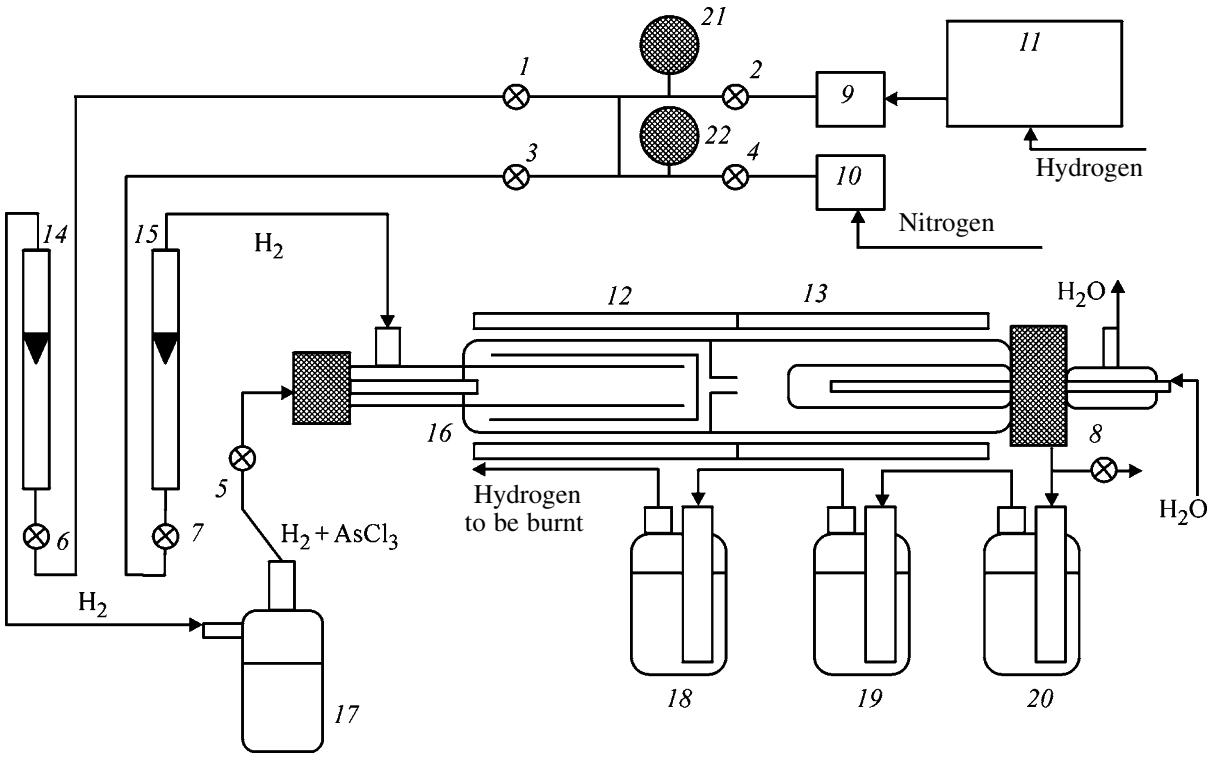

Fig. 2. Scheme of a pilot installation for studying kinetics of $AsCl_3$ reduction with hydrogen: (*1–8*) control stopcocks, (*9, 10*) gas pressure regulators for pressure adjustment, (*11*) installation for diffusion purification of hydrogen, (*12, 13*) heaters of high-temperature and low-temperature zones, (*14, 15*) flow meters, (*16*) reactor for arsenic trichloride reduction with hydrogen, (*17*) vessel with $AsCl_3$, (*18–20*) vessels for absorption of hydrogen chloride and residual arsenic trichloride, and (*21, 22*) manometers.

determining the total amount of unchanged $AsCl_3$ for the entire experiment duration with a sufficiently large amount of the starting substance (about 200 g). As a result, the advantages of the second method were realized and the error originating from incomplete collection of elemental arsenic formed was decreased. To check the correctness of the results obtained, we measured in addition the total amount of chlorine in the system for absorption of gaseous reaction products.

To describe the kinetics of the arsenic trichloride reduction, we used the approach developed in [8, 12, 13]. The rate of reaction (1) is determined by equation (9).

$$r = \mathrm{d}c/\mathrm{d}t = kc^X c_\mathrm{H}^Y, \quad (9)$$

where r is the reaction rate (mol l^{-1} s^{-1}); k, the reaction rate constant; c and c_H, concentrations of arsenic trichloride and hydrogen in the vapor–gas mixture (M); X and Y, partial reaction orders with respect to arsenic trichloride and hydrogen.

The reaction rate constant in a series of experiments can be calculated from the $AsCl_3$ residual concentration at a fixed residence time of the reaction mixture in the reaction zone. We found the residence time (chemical reaction duration) from expression (10)

$$t_\mathrm{r} = V_\mathrm{a}T_0/(Q_1 + Q_2)T_\mathrm{r}, \quad (10)$$

where t_r is the reaction duration (s); V_a, volume of the reaction zone (l); T_0, absolute temperature (K); Q_1 and Q_2, flow rates of vaporous $AsCl_3$ and gaseous hydrogen, respectively, reduced to the normal conditions (l s^{-1}); and T_r, reaction temperature (K). Generally the average value of T_r was determined by the graphical integration of the temperature variation along the reaction zone.

The concentrations of components in the starting vapor–gas mixture were calculated by formulas (11) and (12).

$$c_0 = T_0/V_0(1 + 1.5\alpha)T_\mathrm{r}, \quad (11)$$

$$c_{\mathrm{H}(0)} = 1.5\alpha T_0/V_0(1 + 1.5\alpha)T_\mathrm{r}, \quad (12)$$

where α is the ratio of the amount of hydrogen fed (mol) to its stoichiometric amount; V_0, volume of 22.4 l, which is occupied by 1 mol of ideal gas under normal conditions.

To determine the partial reaction orders and the reaction rate constant, it is necessary to solve rate

equation (9). Let us introduce a dimensionless variable f, the fraction of unchanged $AsCl_3$, defined by expression (13):

$$f = c/c_0. \quad (13)$$

Then, taking into account expression (14), we can write down the rate equation of the chemical reaction in form (15):

$$c_H = 1.5\alpha c, \quad (14)$$

$$df/[f^X(f + \beta)^Y] = -1.5^Y k c_0^{(X+Y-1)} dt, \quad (15)$$

where $\beta = \alpha - 1$. In view of the fact that at $t_r = 0$ $f = 1$, the integral form of the rate equation is

$$\int_f^1 df/[f^X(f + \beta)^Y] = 1.5^Y k c_0^{(X+Y-1)} t_r. \quad (16)$$

The integration of the left-hand side of Eq. (16) represents a certain problem, as the form of the integral depends on X and Y values, and only when X and Y are equal to integer and(or) half-integer numbers the integral can be expressed in elementary functions. In this connection, the problem was solved in such a way as to obtain an array of experimental concentrations of unchanged $AsCl_3$ by varying independent variables and to determine the partial reaction orders and the temperature dependence of the reaction rate constant on this basis.

The ranges of variation of the independent parameters were as follows: temperature of the reaction zone T_r = 886–1071 K, reaction duration τ = 5–28 s, and excess of hydrogen against the stoichiometric amount α = 1.02–4.03. The ranges of variation of these variables were chosen on the basis of the examination of real process modes and the data of [8, 10].

Typical experimental and calculated data are given in Table 2. To determine partial reaction orders, we used the method of finding a minimum of the dependence of the standard deviation of the reaction rate constant (and also of its logarithm) on X and Y calculated by Eq. (16) for each series of the experiments satisfying the requirement T_r = const. The application of such a procedure gave the following reaction orders with respect to arsenic trichloride and hydrogen: X = 1.86 and Y = 2.78. The order of reaction (1) in the system $AsCl_3$–H_2 is 4.6, suggesting its complicated mechanism.

Using the X and Y values obtained, we solved Eq. (16), calculated the reaction rate constant for the whole array of the experimental data, and determined its temperature dependence (17).

$$\ln k = B - A/T, \quad (17)$$

where A = 15287 and B = 36.509.

The apparent activation energy E is approximately 127 kJ mol^{-1}. The frequency factor K_0, determined in the collision theory from the relationship $\ln K_0 = B$, is 7.17×10^{15} (mol l^{-1})$^{-4.6}$ s^{-1}. We note that the reaction rate constant at 800 K exceeds 3.6×10^7 and increases to approximately 1.7×10^9 (mol l^{-1})$^{-4.6}$ s^{-1} at 1000 K. The degree of arsenic trichloride conversion under these conditions exceeds 99% at the residence time of

the mixture in the reaction zone longer than 15 s and at a hydrogen excess $\alpha > 1.5$.

The data obtained allowed us to calculate the degree of arsenic trichloride conversion η (%). The results of this calculation satisfactorily agree with the experiment (Table 2). The relative difference between the calculated and experimental data does not exceed 40% when estimating the fraction of unchanged $AsCl_3$ and 4% when determining the degree of its conversion. The rate constants of $AsCl_3$ reduction with hydrogen were used to optimize operation conditions for the production of high-purity arsenic on a pilot installation.

The calculation results are plotted in Fig. 3. It is seen that the maximal capacity of about 3 g min^{-1} of arsenic at the preset 99.9% conversion and temperature of 1100 K is reached at $\alpha = 3.4$. When choosing the reaction temperature, the possibility of contamination of the desired arsenic by apparatus impurities should be taken into account. In particular, at temperatures exceeding 1100 K the resulting arsenic contains an increased amount of silicon. The decrease in temperature below 900 K results in an appreciable decrease in the reaction rate. The increase in the hydrogen excess over 3.4 reduces the output capacity. In practice, the reduction of arsenic trichloride with hydrogen is carried out with a hydrogen excess of 1.5–2, as at $\alpha > 2$ the fraction of amorphous arsenic appreciably increases because of higher rates of the gas mixture at the reactor outlet and, as a consequence, greater breakthrough of arsenic vapor into the cold part of the reactor where arsenic condenses in the amorphous state.

We determined the optimal temperature of the condensation zone from the viewpoint of minimizing the amount of amorphous arsenic. We performed a series of experiments in which the temperature in the zone of the maximal thickness of the product layer was varied and the fraction of amorphous arsenic was determined. The results are given in Fig. 4, which shows that, at temperatures higher than 700 K, the amorphous arsenic fraction increases considerably (from 7.2 to 22% at $T > 730$ K). In the range 700–670 K, this fraction varies only slightly. Thus, the optimal temperature range where the residual pressure of arsenic is lower than 5×10^{-3} atm is 670–705 K.

To decrease arsenic removal in the form of aerosols from the reactor, it is necessary to use a trapping system. In our case, we used a special unit in which the direction of the gas stream changes and residual amorphous arsenic is trapped by a system of bubble absorbers. The amount of arsenic removed from the

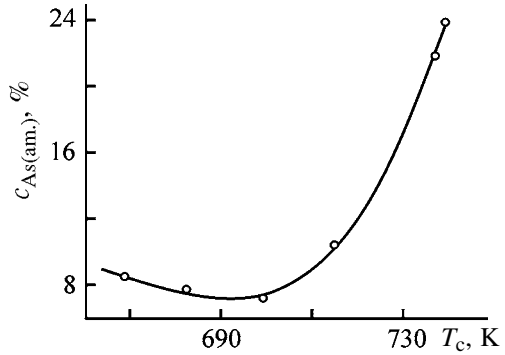

Fig. 4. Dependence of the amorphous arsenic content $c_{As(am.)}$ on the temperature T_c of the condensation zone.

condensation zone does not exceed 1.5%.

The found conditions for the reduction of arsenic compounds with hydrogen were used as the basis for constructing a pilot installation for the production of high-purity arsenic from such unconventional raw materials as products of the detoxication of chemical weapons (lewisite) and waste from nonferrous metallurgy.

The content of impurities in samples of high-purity arsenic prepared from lewisite is shown in Table 3. The impurity contents were monitored by spectral analysis with excitation of the spectrum in a dc arc and by atomic-emission spectroscopy with excitation of the spectrum in an inductively coupled plasma discharge. The high detection limit of impurities (up to 10^{-8} wt %) was reached by applying extraction preconcentration of impurities in the sample preparation stage.

It should be noted that the purity of amorphous and crystalline arsenic modifications is practically the same. Nevertheless, from the viewpoint of conveni-

Pb	<5.0	<5.0	1.0

ence in the technology of semiconductor materials, amorphous arsenic is further sublimed to convert it to the crystalline form. The arsenic thus obtained is of 99.9999 wt % purity (6N grade) and is highly competitive with products of leading companies from the United States (Johnson Matthey) and Japan (Furukawa) produced from the traditional raw material, arsenic ores.

The use of high-purity arsenic obtained from unconventional raw materials ensures high and reproducible parameters for commercially produced single crystals of gallium arsenide and for epitaxial structures based on it.

CONCLUSIONS

(1) The composition of an equilibrium vapor–gas mixture was estimated for the reaction of $AsCl_3$ with hydrogen in the range 700–1100 K. The degree of $AsCl_3$ conversion varies from 97.3 up to 97.9% at the amount of hydrogen relative to the stoichiometry α = 1 and approaches 100% as α exceeds 1.5.

(2) The reaction order (X = 1.86, Y = 2.78), rate constant ($\ln k = 36.509–15287/T$), and apparent activation energy (E = 127 kJ mol^{-1}) were determined.

(3) The optimal conditions of the arsenic trichloride reduction with hydrogen were determined experimentally: temperature in the reaction zone 1050–1100 K, temperature in the condensation zone 670–705 K, residence time of vapor–gas mixture in the reaction zone 20–25 s, and hydrogen excess α = 1.5–2.0.

(4) The degree of $AsCl_3$ conversion to arsenic was shown to be no less than 99.99%, and the minimal amount of amorphous As, 7.2 %.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation of Iron–Aluminum Powders from Aqueous Solutions and Their Physicochemical Properties

A. F. Dresvyannikov, M. E. Kolpakov, and O. A. Lapina

Kazan State Technological University, Kazan, Tatarstan, Russia

Abstract—Iron and iron–aluminum powders were obtained by the reduction of Fe(III) to α-Fe, occurring on a dispersed aluminum support. Their physical and mechanical properties were studied, and the possibility of obtaining compact samples with a lower bulk density as compared to known analogs, an elevated strength, and a high porosity was examined.

DOI: 10.1134/S1070427207010028

Increasing researchers' activity is focused on a search for procedures for preparing new nano- and microdimensional materials with unique physical and physicochemical properties. One of approaches consists in the precipitation of a metal layer from solutions of its compounds on microparticles of another metal. Such processes can be of interest also for recovery of metals from liquid and solid industrial media, their utilization, and production of metal-clad and alloyed metal powders with special properties [1].

One of urgent problems is the preparation of alloys and composites based on a binary iron–aluminum system exhibiting elevated strength and corrosion resistance. It was suggested previously to obtain this system from an aqueous solution by depositing iron on aluminum microparticles. It was found that iron(0) is deposited from such solutions in two steps: Fe(III) → Fe(II) → Fe(0), with simultaneous dissolution of aluminum support and formation of an α-iron layer on its surface [2]. As a result, dendrite spherical particles with large internal cavities and pores are formed, which determines low bulk density of the powder. The amount of residual aluminum is readily controlled by treating the precipitate with an alkali solution and can be made as low as tenth fractions of percent.

The surface of the precipitated particles is covered by spherulites of various sizes, which, in turn, bear nanodimensional spherical nuclei. Various sparingly soluble oxo and hydroxo compounds can be formed on the aluminum surface in the process; therefore, it is of interest to estimate the phase composition and structure of the deposits. Furthermore, it is important to reveal regular trends in the behavior of these objects under mechanical (pressing) and thermal (sintering) actions.

EXPERIMENTAL

The synthesis of iron–aluminum powders is based on the electrochemical reduction of iron(III) ions on an aluminum support suspended in solution. The resulting precipitate was separated from the mother liquor by magnetic separation, washed with double-distilled water to neutral reaction, and dried in a vacuum at 60°C.

The chemical and phase compositions of the samples were determined with a DRON-2 X-ray diffractometer. To decrease the noise from scattering of the primary X-ray beam in air, we used FeK_α long-wave radiation with a β-filter. The X-ray patterns were recorded under the following conditions: a voltage of 30 kV, a current of 15 mA, goniometer slits of 1–1–1×8 mm^2, and range of recording angles 2θ from 20° to 160°. Compact samples were pulverized prior to measurements.

The X-ray patterns were treated using the MAUD 1.999 multifunction software [3, 4]. Annealed copper foil was used as a reference for comparing line profiles (determination of coherent scattering areas and microstresses).

The analysis and microphotographing of particles of the starting aluminum and resulting precipitates were carried out on a Philips SM XL-30 TMP electron scanning microscope in the following mode: scale ΔE = 10 keV (0–500), collection time 100 s,

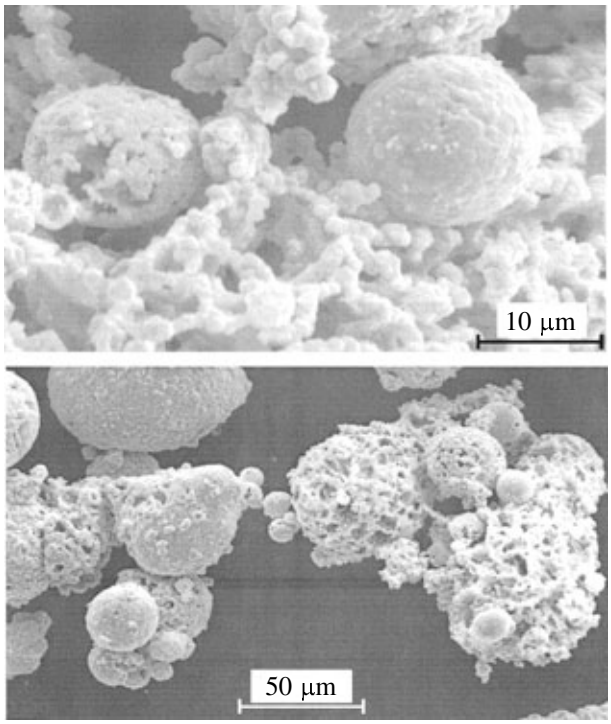

Fig. 1. Photomicrographs of particles of deposited iron.

and $E_{el.probe}$ = 30 keV. The microprobe area was varied from 20×30 to 50×75 μm^2.

The specific porosity of preliminarily evacuated (0.01 mm Hg) samples was determined by mercury porosimetry on a Milestone-200 instrument under pressures from 0.7 to 199 MPa.

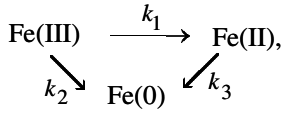
The fractal dimension D was determined by processing the mercury porometry data using Neimark's equation [5]

$$D = 2 + d(\log \int_0^V P dV)/d\log P = 2 + d[\log f(P)]/d\log P, \quad (1)$$

where $f(P) = \int_0^V P dV$, V is the mercury intrusion, and P is the applied voltage.

Physicochemical characteristics of powders and compact samples made of them were estimated according to Russian and international standards currently in force [6].

It was found previously that the iron(III) reduction in aqueous solutions on a dispersed aluminum matrix occurs in two steps: Fe(III) → Fe(II) → Fe(0) [7]. As two products, iron (II) ions and iron(0), are formed in the course of the iron(III) reduction, we used the relative selectivity method [8] to elucidate the reaction mechanism. On the basis of thus obtained experimental data we suggest the following scheme of transformations of iron redox species in the course of reaction of iron(III) with aluminum [9]:



where k_1, k_2, and k_3 are the rate constants of the corresponding steps (s^{-1}).

In this case, the total process is described by the following system of rate equations [10]:

$$[Fe(III)] = [Fe(III)]_0 \exp[-(k_1 + k_2)t], \quad (2)$$

$$[Fe(0)] = [Fe(III)]_0 \{k_2(k_1 + k_2)^{-1} \{1 - \exp[-(k_1 + k_2)t]\} + [1 - k_3(k_3 - k_1)^{-1} \exp(-k_1 t) + k_1(k_3 - k_1)^{-1} \exp(-k_3 t)]\}, \quad (3)$$

$$[Fe(II)] = [Fe(III)]_0 - [Fe(III)] - [Fe(0)]$$

or

$$[Fe(II)] = [Fe(III)]_0 \{1 - \exp[-(k_1 + k_2)t] - k_2(k_1 + k_2)^{-1} \{1 - \exp[-(k_1 + k_2)t]\} - [1 - k_3(k_3 - k_1)^{-1} \exp(-k_1 t) + k_1(k_3 - k_1)^{-1} \exp(-k_3 t)]\}, \quad (4)$$

$$\alpha = m[Fe(0)]/m_0[Fe(III)] = \{k_2(k_1 + k_2)^{-1} \{1 - \exp[-(k_1 + k_2)t]\} + [1 - k_3(k_3 - k_1)^{-1} \exp(-k_1 t) + k_1(k_3 - k_1)^{-1} \exp(-k_3 t)]\}. \quad (5)$$

The iron(0) precipitate is formed on the surface of aluminum particles with the preservation of the shape and geometric sizes of a source matrix, i.e., aluminum is dissolved, and simultaneously spherical nuclei of metallic iron are formed. The main amount of aluminum is dissolved in the course of time, and the forming particles represent practically hollow spheres with a large number of spherical subindividuals on the surface, pores, and nuclei inside them (Fig. 1). This is also indirectly proved by the abnormally low bulk density of the resulting powders (1.25 ± 0.01 g cm^{-3}). Iron is precipitated nonuniformly on aluminum particles, i.e., particles completely covered by the deposit and particles that have not entered into the reaction coexist in any reaction step.

As in this case self-similarity of iron–aluminum particles predetermines a complicated contour of the

surface, we determined the fractal dimension of particles by mercury porosimetry [5]. Figure 2 shows curves of mercury intrusion obtained by the above-mentioned method for three objects: dispersed aluminum, the synthesized composite iron–aluminum powder, and then iron powder obtained by etching the latter with an alkali. According to these curves, particles of dispersed aluminum exhibit a low porosity, the main part of pores being large. This is caused by the history of the aluminum powder (prepared from a melt), which determines predominantly smooth shape of the particles. We can note that the total volume of pores in iron–aluminum particles is larger by a factor of approximately three than that of aluminum particles; however, the pore sizes are smoothed out in this case. When residual aluminum is removed by etching the precipitate in NaOH solution (3.0 M), the total porosity slightly increases. Figure 2 shows that this change is connected mainly with increasing volume of large pores, whereas the total volume of small pores changes to a considerably lesser extent.

The examination of mercury intrusion curves using Neimark's equation [5] shows that the fractal dimension of aluminum microparticles is 2.04 ± 0.002 (a smooth surface). The fractal dimension of iron–aluminum particles is 2.87 ± 0.02, which is characteristic of rough objects. The latter result is caused by specific features of corrosive dissolution of aluminum in a chloride-containing medium and by features of the conjugate process of iron isolation. The greatest value corresponds to iron particles obtained by an additional treatment of iron–aluminum composite powders with an alkali; for them, D is 3.00 ± 0.02, which is a theoretical limit for a surface dimension. It is characteristic for samples with the maximal porosity and roughness of the external and internal surfaces.

Table 1 shows that powdered sample no. 1, which was prepared according to the suggested technique,

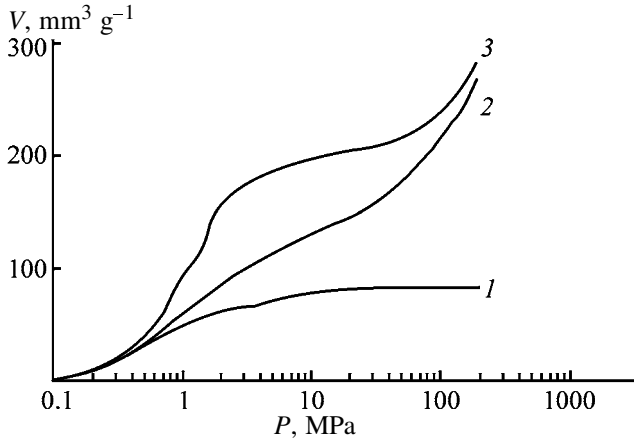

Fig. 2. Experimental curves of mercury intrusion for microparticles of (*1*) aluminum, (*2*) iron–aluminum samples, and (*3*) iron. (*V*) Pore volume and (*P*) pressure.

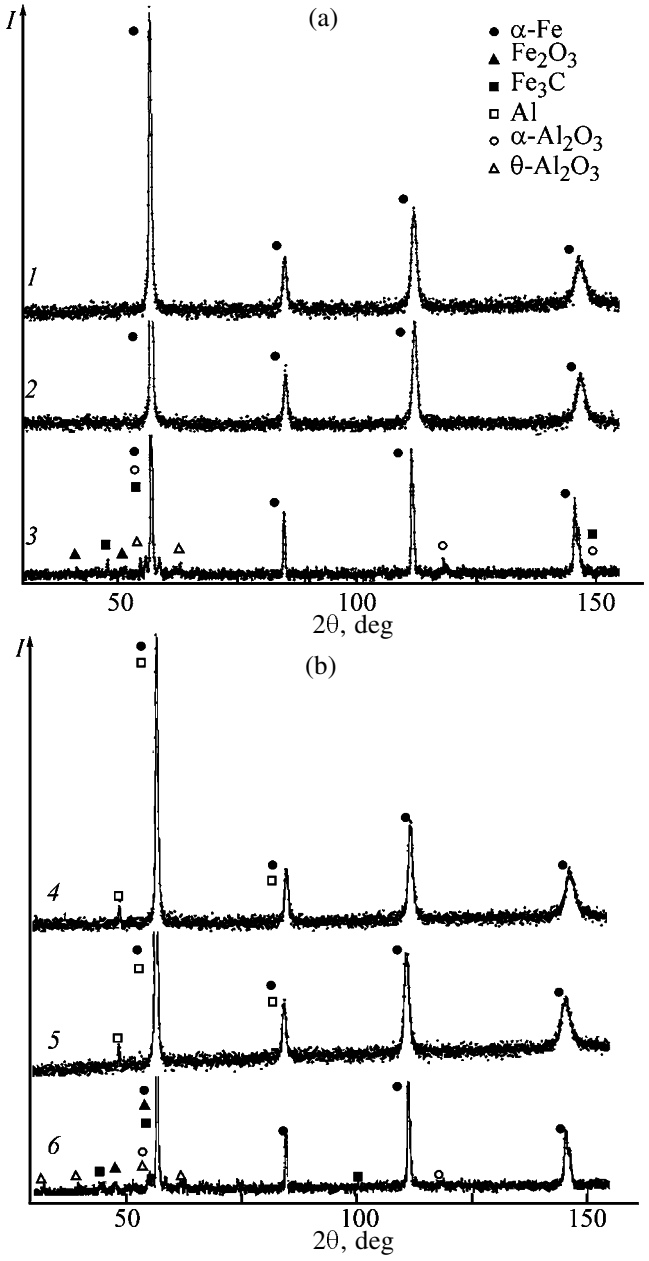

Fig. 3. X-ray patterns of (a) dispersed iron and (b) iron–aluminum composite. (*I*) Intensity and (2θ) Bragg angle. (*1–6*) Sample nos. in Table 1.

contains only one phase of α-Fe. After pressing aluminum "appears" in sample no. 2, apparently forming a thin layer on the internal surface of hollow particles of iron powder and outcropping on the external surface upon a strong deformation. In the X-ray patterns (Fig. 3, curve *2*), separate peaks of aluminum are very weak. It is interesting that iron crystallites become larger as a result of the mechanical action accompanied by aluminum outcrop.

When samples are sintered, aluminum transforms into various modifications of its oxide (Table 1, sample no. 3). X-ray phase analysis reveals the presence of two phases, θ-Al_2O_3 and α-Al_2O_3 (corundum). Apparently, the character of thermomechanical treatment strongly affects the structure, composition, and physicochemical properties of the object under study. The presence of moisture in pores of a source powder, most likely, leads to the reaction of water with metallic aluminum yielding α- and θ-Al_2O_3 on heating.

The presence of organic binding agents (sodium stearate), introduced before pressing and filling the pores of the initial sample, results in the formation of a Fe_3C phase. The presence of atmospheric oxygen in combination with moisture on the surface and in internal pores of the sample promotes partial transformation of iron into Fe_2O_3 (hematite).

The above-described processes significantly affect the fine structure of the samples under study. As iron is deposited, a significant amount of gas separates out and enters into the deposit together with iron [9]; therefore, hydrogen absorption along with polarization is the main cause of defects forming in the structure of the deposited iron and determining its stressed state [11]. It is seen that the sizes of α-iron crystallites somewhat increase after pressing (Table 1, sample no. 2), though their shape remains unchanged, and microstresses decrease, most likely, due to rearrangement of the internal load. After sintering in an ammonia atmosphere, the sizes of α-iron crystallites considerably increase and microstresses decrease. Apparently, in this case the grain size grows and the amount of lattice defects decreases.

Similar results were obtained on testing sample nos. 4 and 5 containing residual aluminum. Unlike sample nos. 1 and 2, after pressing the sizes of crystallites and their shape remain practically unchanged, and microstresses change only slightly. The crystallite sizes in these samples considerably decrease after sintering (Table 1, sample no. 6), and microstresses are relieved; however, in contrast to sample no. 3, they still remain relatively high.

According to the quantitative analysis, sample nos. 4 and 5 contain almost equal amounts of aluminum, i.e., pressing causes almost no changes. Sintering (Table 1, sample no. 6) gives a result close to that for sample no. 3, but differing from it by a larger amount of α-Al_2O_3.

It should be emphasized that microparticles formed by iron deposition from solution on an aluminum support are practically always spherical, and their size only slightly differs from that of the starting sample.

Table 2. Physicomechanical properties of dispersed and compact samples

Strength of pressed material after sintering, MPa	194.6 ± 4.9 (ρ = 4.78 g cm^{-3})	122.4 ± 1.4 (ρ = 4.56 g cm^{-3})	No data

The granulometric study of iron powders obtained by the synthesis that was performed with a close-cut fraction of dispersed aluminum (85 ± 15 μm) shows that the narrow particle-size distribution is preserved [10].

Samples prepared by cold pressing of the resulting iron–aluminum powdered composite are characterized by a low mechanical strength. First of all, this is attributable to a difference in parameters of the components of the object under study and to its highly defective crystal lattice, which is indirectly indicated by a zero line rise in the X-ray pattern (Fig. 3, curve *5*).

The study of rheological characteristics of the objects under study has shown that the density of both the bulk powder and pressed briquettes is essentially lower than that prescribed by the standard [6] (Table 2), which is apparently caused by the formation of framework structures as a result of accretion of separate particles during the synthesis. The formation of such structures for iron powders and, as a consequence, a low density of the objects under study after pressing are responsible for the high porosity of the sintered samples.

This factor is very important; it determines the properties of composites prepared from such materials [12]. For example, the application of porous antifriction materials allows the service life of friction units to be considerably prolonged owing to their capacity to keep liquid lubricant in pores for a long time, which makes the parts self-lubricated.

The strength of the pressed samples results both from mechanical engagement and a weave of surface protrusions and imperfections of powder particles and from the action of interatomic adhesive forces, the degree of their action increasing as the contact area increases. Table 2 shows that the strength of the pressed sample of "pure" iron powder is considerably higher than that of the sample made of iron–aluminum powder. This is attributable to a more developed system of internal pores in powder particles, which are formed on leaching. Under the external loading, hollow particles are deformed in an unusual way, the ratio of the surface area of a particle to its volume increases, and surface films of adsorbed impurities are broken off. Flattened-out metal particles contact each other with freshly formed surfaces to give blocks of a complicated shape tightly engaged with each other. The strength of the blocks increases on sintering of these samples; however, it appears a little lower than that for analogs obtained from industrially produced iron powders [6]. This is attributable to the presence of hydrogen in the deposit, which is absorbed during the formation and growth of nuclei of α-iron and increases its brittleness [11].

At high pressure (>600 MPa) and temperature (>1000°C), aluminum reacts with chemically bound and adsorbed water in the medium of gaseous ammonia to form an iron matrix structured by aluminum oxides (α- and θ-Al_2O_3) and having no strong internal stresses. The presence of a significant amount of aluminum oxides in sample no. 6 (Table 1) seems to promote the formation of a strengthened dispersed structure due to a fairly uniform distribution of the oxides in the iron matrix reached during caking. It defines an increase in the mechanical strength of materials prepared by sintering.

CONCLUSIONS

(1) Particles of an iron–aluminum composite prepared by iron deposition from an aqueous solution on a dispersed aluminum support represent practically

hollow spheres with a large number of spherical subindividuals on the surface, pores, and nuclei inside them, which gives rise to unique physical properties of the dispersed metal.

(2) The resulting objects have a dendritic structure; the fractal dimension of the surface of the synthesized binary iron–aluminum systems was calculated from the data of mercury porosimetry.

(3) The powders have characteristics that make it possible to obtain pressed samples having, compared to the existing analogs, lower bulk density (by approximately 30%), higher strength (by a factor of 2–3), and high porosity and corrosion resistance.

(4) The heat treatment (sintering) of the samples synthesized in solution and containing iron and aluminum promotes the formation of new phases of α- and θ-Al_2O_3 as a result of dehydroxylation of aluminum hydroxo compounds formed in the reactions of aluminum with capillary and adsorbed water.

Abstract—Information model of plasmochemical processes for synthesis of nano- and ultradispersed oxide materials was developed on the basis of the CALS concept (Continuous Acquisition and Life cycle Support) for the example of ultrapure tin oxides.

DOI: 10.1134/S107042720701003X

Modern CALS technologies [1] were used to develop an information model of the plasmochemical process for synthesis of ultrapure nano- and ultradispersed oxides. The process was thermodynamically modeled in a wide range of temperatures, pressures, and component ratios. A system for computerized quality management (CQM system) [2] was used for analytical monitoring of the target oxide materials.[1]

Ultrapure oxide materials are widely used in the most promising and science-intensive fields of Russia's economy [3]. In manufacture of ultrapure oxides, it is exceedingly important that a by-product of synthesis should not contaminate the target products or interact with process equipment, thereby taking up an additional amount of impurities. A promising way to tackle with this problem is application of low-temperature plasma, which makes it possible to create a set of modern apparatus with the minimum microimpurity background [4]. One more advantage of this technique is that it can yield ultra- and even nanodispersed powders, which is virtually impossible with other methods.

Low-temperature plasma enables studies and process operations at temperatures of 2×10^3–2×10^4 K, various pressures, and residence times of 10^{-5}–10^{-3} s. Low-temperature plasma can be successfully employed in those cases when the equilibrium is shifted to high temperatures; a high yield is achieved under strongly nonequilibrium conditions; the reaction rates markedly grow with temperature.

In the course of plasmochemical synthesis, the aggregative state of any starting substance, as well as its physical and chemical properties, are changed. The following reaction scheme has found wide application in plasmochemical synthesis: A → B + C, where A is a starting substance, B is an ultrapure product, and C is by-product of synthesis. It is important in this case that by-product C should not contaminate the ultrapure substance and should not interact with the process equipment to preclude additional contamination.

Numerous researchers have used chlorides and organoelement compounds as starting substances. The advantage of chlorides consists in their more convenient introduction into the plasma flare, compared with heterogeneous systems. However, synthesis with chlorides yields the following by-products: HCl, ClO, $MeCl_{n-1}$, where n = 2–4 [4]. These products strongly impair the purity of the finished product. With organoelement compounds as starting substances, one of the most undesirable by-products of synthesis is carbon [5].

The plasmochemical technology includes a number of units and process operations. A study of the be-

[1] The system was developed at Institute of Chemical Reagents, Federal State Unitary Enterprise on the basis of the CALS technology.

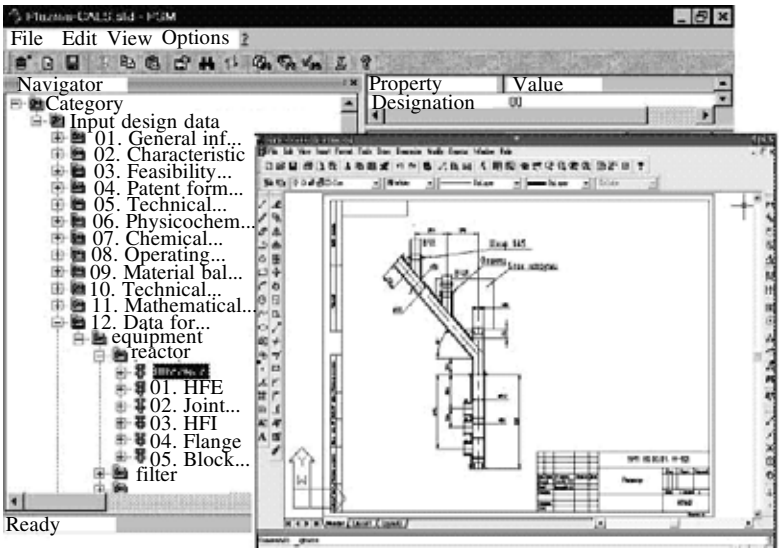

Fig. 1. Element of the CALS project: plasmochemical reactor for synthesis of ultrapure tin oxide.

havior of microimpurities in plasmochemical synthesis of ultrapure substances (oxides) furnished data on the influence exerted by limiting apparatus-related and process factors on the purity of the finished product [3]. Analysis of these data shows that the finished product is contaminated to the greatest extent in stages of trapping, discharge, and packaging.

In one of the first studies in this field, nano- and ultradispersed tin oxide was obtained [6]. Ultrapure tin oxide is a widely demanded chemical product used in manufacture of special kinds of glass and ceramics. A large number of enamels contain tin oxide, without which manufacture of acid- and fire-resistant chemical apparatus would be impossible. It is clear in this context that tin oxide should possess a certain granulometric composition and specific surface area and should contain less than 0.01% microimpurities. Modern ceramic technology has started to consume nanopowders. Naturally, the existing multistage industrial technology developed at the end of 1930s could not yield nanosized tin oxide. In addition, this multistage technology consumes large volumes of hydrochloric acid and requires neutralization and many days' stage-by-stage calcination [6].

A single-stage technology producing a nanosize (30–100 nm) tin oxide powder was developed. This could be only done with the use of plasmochemistry, one of the most promising tools of modern chemical technology.

The plasmochemical process was developed in the framework of the most modern and promising computer-support system, CALS technology (Continuous Acquisition and Life cycle Support) [1]. The CALS concept is based on a set of unified information models and on standardization of access ways to information and its adequate interpretation in conformity with international standards (ISO-10303 STEP). This provides unified methods for control over processes and enables interaction between all those involved in the development process. According to prognoses of foreign specialists, soon after 2005 it will be impossible to sell at the foreign market any high-tech products without electronic documentation conforming to international CALS standards (ISO-10303 STEP) [1]. Thus, use of CALS technologies is a must for promising domestic projects. With account of this circumstance, a number of promising processes have been reconsidered in terms of the CALS concept: syntheses of biologically active additives [7] and ultrapure materials [8].

In the development of a plasmochemical process for synthesis of ultrapure tin oxide, a type scheme (application protocol) "Input design data" was created in the framework of the CALS project (Fig. 1).

In conformity with the chemical industry's standard, the structure of the input data includes 17 necessary sections [8]. All these sections are incorporated in the CALS project. In the screen form (Fig. 1), additional subitems are only displayed in section no. 12 (data for calculation and choice of the process equipment). However, additional, specific to chemical industry, information is actually input into the CALS project for all the sections.

A designer's electronic description conforming to the STEP standard (Fig. 1) contains the structure and

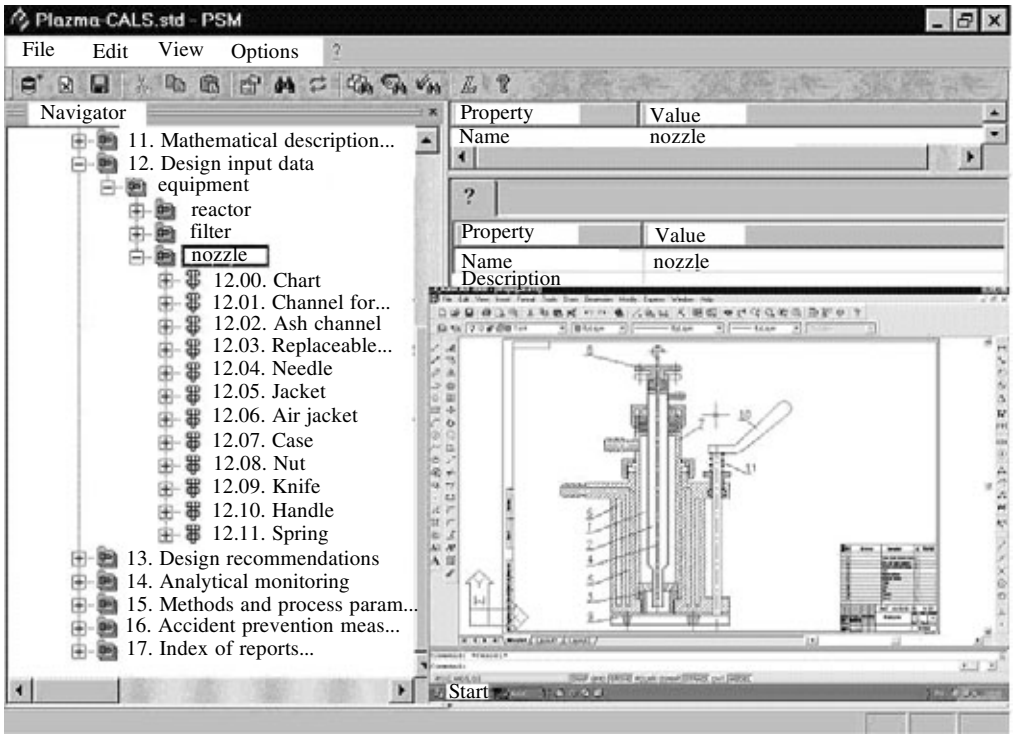

Fig. 2. Element of the CALS project, pneumatic nozzle for feeding of liquid-phase starting reagents into the reactor.

alternative configurations of an article, geometric models and drawings, properties and characteristics of the constituent parts. The STEP standard can be applied in several ways.

(1) Data can be stored as an exchangeable text file. In this form, the data can be conveniently transferred among automated systems having an appropriate converter for STEP files.

(2) Data structures can be created in a finished PDM system by its appropriate adjustment and by development of necessary visual applications. The already available solutions can be employed. Information is processed using PDM STEP suite 2.5 software developed at the Research Center for CALS technologies [9]. The use of the international CALS standard for defining the data structure and programmed access interfaces enables parallel work with information from different fields of technology and allows integration with information systems of any kind. This development potentiality is not presently observed for any other PDM system [9].

The versatile plasmochemical installation being developed can feed into the reactor (Fig. 1) not only the starting solid product via a powder feeder, but also liquid-phase reagents (chlorides and alkoxides) via a special jet (Fig. 2).

The versatility of the installation makes it possible to obtain ultradispersed oxides of Group II and III light and transition metals (aluminum, beryllium, cadmium, magnesium, scandium, yttrium, and zirconium). These products belong to a promising scientific area "Ceramic glassy materials and superhard materials."

Section no. 11 (mathematical description of the process) of the CALS project (Fig. 1) presents the results obtained in simulating the plasmochemical synthesis of ultrapure tin oxide. Analysis of chemical and heat-and-mass exchange processes at elevated temperatures leads to severe difficulties already in the stage of formulation of the simulation problem. It is appropriate to use thermodynamic simulation methods as a first approximation [6]. These methods presume that, in the processes under consideration, the working body forms a conditionally closed, isolated system in which a local thermodynamic equilibrium (LTE) is attained. In this approximation, the state of the system is only determined by the content of chemical elements in the system and by values of two parameters of state. The use of the thermodynamic equilibrium approximation is justified by the high concentration of energy in the volumes under consideration and by the resulting high rates of conversion processes, which instantaneously bring the system in the LTE state.

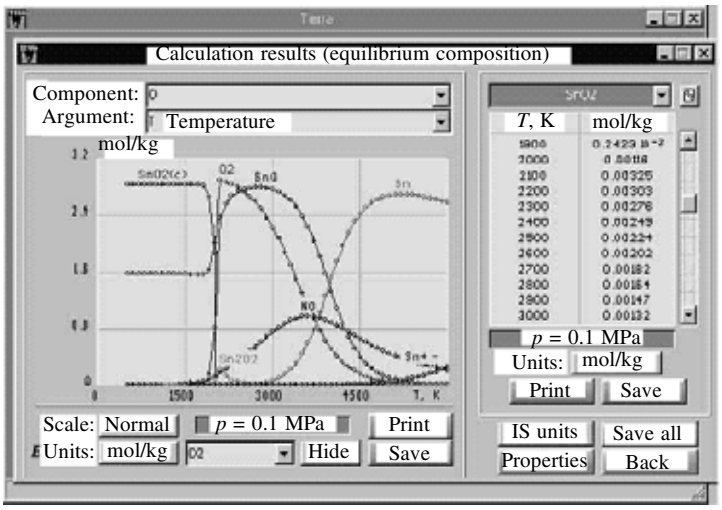

Fig. 3. Screen form of the results of thermodynamic simulation of the plasmochemical synthesis of ultrapure tin oxide.

A calculation of equilibrium for isolated multicomponent thermodynamic systems can be reduced to a problem of determination of a state with the minimum entropy. Therefore, to compose the sought-for system of equations, it is necessary to find an analytical relationship between the entropy of a unit mass of the working body and the thermodynamic parameters determining its composition, properties, and existence conditions.

In the general case, a gaseous system is constituted by neutral and electrically charged (ionized) components of the gas phase and separate condensed phases. The equation of state for an ideal gas is valid for the gas phase as a whole and for each of its components. The condensed phase will be considered single-component and immiscible. The content of the components of the gas phase (i = 1, 2, ..., k) and of separate condensed phases (l = 1, 2, .., L) in the system will be expressed in moles per unit mass, n_i and n_l. The entropy of such a system is given by

$$S = \sum_{i=1}^{k} S_i^{(p_i)} n_i + \sum_{l=1}^{L} S_l n_l = \sum_{i=1}^{k} [S_i^0 - R_0 \ln (R_0 T n_i/\nu)] n_i + \sum_{l=1}^{L} S_l^0 n_l,$$

where $S_i^{(p_i)}$ is the entropy of ith component of the gas phase at a partial pressure $p_i = R_0 T n_i/\nu$ at which it will be in the equilibrium state; S_l, entropy of lth condensed phase, dependent only on temperature; ν, specific volume of the whole system; S_i^0, standard entropy of ith component of the gas phase at temperature T and pressure equal to 1 physical atmosphere.

Determination of the parameters of the equilibrium state consists in finding all the dependent variables, including the number of moles of the components and the number of phases at which S reaches a maximum. This problem of a search for the extremum of the entropy of the system with account of constriction equations was solved using Astra-4 software developed at Bauman Higher Technical School in Moscow [10].

A thermodynamic calculation of the equilibrium states of the system is performed in a wide range of basic parameters of the plasmochemical process: starting component ratios, temperatures, and pressures (Fig. 3). A thermodynamic simulation makes it possible to choose the synthesis conditions, analyze the environmental safety of the production process, and assess the mechanism of thermal dissociation of the starting compounds.

The CALS technology and thermodynamic simulation were used to develop a pilot installation for single-stage synthesis of tin oxide. Powdered metallic tin is continuously fed into a plasmochemical reactor. In the reactor, the powder comes into an oxygen-containing plasma jet with a mass-average temperature of 4500 K. Depending on the feeding rate of the starting tin powder, flow rate of the plasma-forming gas, and input power, nanodispersed (0.03–0.1 μm) and ultradispersed tin oxide powders (0.1–0.3, 0.3–0.7, 0.7–1.2, 1.2–3, 3–7, 7–15, and 15–40 μm) can be obtained.

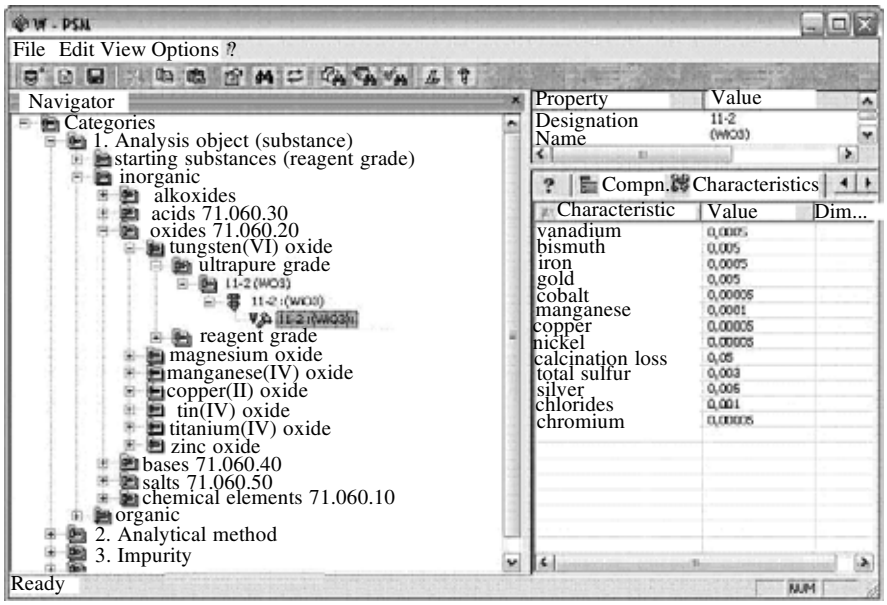

Fig. 4. Element of the CALS project of a CQM system for the example of ultrapure tungsten oxide of the 11-2 brand.

Industrial use of this project will make it possible to completely eliminate the inefficient, environmentally unsafe, and health-hazardous technology for manufacture of tin oxide at Russian chemical plants. The new technology is totally free of any harmful discharges. However, the most important factor is that it yields a fundamentally different product with high consumer's properties, which can well compete in the world market of ultrapure materials.

Recently, the requirements to the substance purity have become markedly more stringent and the number of parameters characterizing the quality of a product (ultrapure products) has increased. Simultaneously, the requirements to methods for analytical control of ultrapure substances have become more stringent. These problems can be only solved on the basis of a modern CQM system.

The CQM system developed has a hierarchic database structure (Fig. 4). Three main information categories are distinguished: (i) substance being analyzed, (ii) analytical methods and technical means of analysis and sample preparation, and (iii) output and standardizing documentation. Each category includes several subcategories for systematization of data in accordance with criteria appropriate for each category. Thus, the category substance includes the following groups: organic–inorganic, acids–salts–oxides (Fig. 4), and other classes of chemical compounds and simple substances.

CONCLUSION

Implementation of CALS technologies and modern computerized quality management systems in development of science-intensive plasmochemical processes raises the productivity and diminishes the expenditure of time and material resources. This is achieved by simplified access to information, reorganization of the working activities (without change of the tasks to be accomplished), computerization of the working environment, and significant improvement of relationships between partner designers.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Mechanochemical Activation in Manufacture of Defluorinated Forage Phosphate

S. V. Antipov and M. T. Sokolov

Belarussian State Technological University, Minsk, Belarus

Received May 4, 2006

Abstract—The effect of preliminary mechanochemical activation of phosphate rock on the temperature of hydrothermal calcination and degree of defluorination in manufacture of defluorinated forage phosphates conforming to GOST (State Standard) 23999–80 was studied. A mechanism of mechanochemical activation of phosphate raw materials, associated with changes in thermodynamic properties of the activated system, was suggested.

DOI: 10.1134/S1070427207010041

Phosphorus is a structural element of a living body. Its deficiency in rations weakens the resistance ability of the living mass, impairs the milk productivity, and disrupts the reproductive capacity. Phosphorus is second to protein in importance for animal feeding.

At present, the overwhelming majority of methods for processing of phosphorus-containing raw materials are either energy-intensive (thermal), or require use of inorganic (mostly sulfuric) acids, which leads to formation of a difficultly utilizable waste, phosphogypsum [2]. A topical problem is that of development of a simple power-saving technology for manufacture of this product. A possible way to obtain forage phosphates could be a method based on acid-thermal processing of natural phosphates [3]. This method consists in that, prior to hydrothermal defluorination, natural phosphate is treated with phosphoric acid. Such a treatment leads both to an increase in the content of the valuable component (P_2O_5) and to a deeper defluorination. A significant disadvantage of this method is, in the authors' opinion, the rather high defluorination temperature (1200–1350°C).

Of particular recent practical and theoretical interest is activation of chemical processes by mechanochemical activation [4–6]. The mechanochemical activation consists in initiation and acceleration of chemical transformations of reactants under a mechanical impact leading to deformation of the structure of solid reagents [4]. The plastic deformation of a solid commonly not only changes its shape, but also leads to accumulation of defects in the solid, which changes its physicochemical properties, including reactivity [5, 6].

The aim of our study was to examine the influence exerted by mechanochemical activation of phosphate raw materials on parameters of hydrothermal defluorination in manufacture of defluorinated forage phosphates.

EXPERIMENTAL

An analysis of the market of phosphate raw materials from the standpoint of a Belarussian manufacturer demonstrated that it is the most feasible either to use phosphate rock from CIS countries (Kingisepp, Polpino, Verkhnekamsk, Egor'evsk deposits) or to develop deposits in Belarus (Mstislavl, Lobkovichi, Orekhovskoe, and Prigranichnoe deposits). The chemical composition of primary concentrates from some of these deposits is listed in Table 1.

In the experiments, phosphate rocks from Polpino and Kingisepp deposits were used as phosphorus-containing raw materials. As activators served apparatus of various types: dismembrator and vibrational, planetary, and drum ball mills. The best results were obtained with activators of planetary and drum types. A ground phosphate rock was activated in a planetary or drum mill for 5–60 min. The activated mixture was treated with boiled-down (or not boiled-down) wet-process phosphoric acid (WPA, nWPA) to a molar ratio $CaO/P_2O_5 = 2.5$. The resulting plastic paste was granulated by extrusion through dies with various die aperture diameters. Weighed portions of humid grains were subjected to hydrothermal calcination at 900–1200°C. The results obtained in our study are listed in Tables 2 and 3.

Table 1. Chemical composition of phosphate rock

Phosphate rock	Content, wt %						
	CaO	P_2O_5	SiO_2	Al_2O_3	Fe_2O_3	F	calcination loss
Verkhnekamsk	37.50	21.83	14.23	4.60	3.90	2.10	15.84
Egor'evsk	31.52	19.90	22.20	5.80	5.00	1.77	13.81
Polpino	29.40	18.55	33.60	1.61	2.29	2.5	12.05
Mstislavl (flotation concentrate)	45.67	28.04	5.30	1.12	1.51	3.41	14.95
Kingisepp	41.42	27.71	11.39	1.16	1.84	2.21	14.27

Table 3. Content of phosphorus soluble in 0.4% HCl relative to its total content

Type of phosphate rock and stages of its treatment	Content, %, at indicated thermal treatment time, min		
	20	40	60
Polpino ground phosphate rock + WPA → activation → hydrothermal calcination at 900°C	91.4	93.0	92.1
Polpino ground phosphate rock + hydrothermal calcination at 900°C	95.5	97.8	94.8

It follows from Tables 2 and 3 that the defluorination yielding a product conforming to GOST (State Standard), i.e., that with $c_F \le 0.2$ wt %, without preliminary activation occurs at 1200°C and higher. The time of hydrothermal calcination is 60 min. The results of run nos. 3–8 (Table 2) show that defluorination performed without activation of the phosphorus-containing mixture is less intensive and the residual content of fluorine exceeds the value conforming to GOST. Use of a preliminary mechanochemical activation makes it possible to perform hydrothermal calcination at temperatures of about 900°C, with the calcination time equal to 20–40 min, depending on temperature. At present it is difficult to answer the question as to what is preferable in practice, calcination at 900°C for about 40 min or at 1000°C for 20 min. An answer

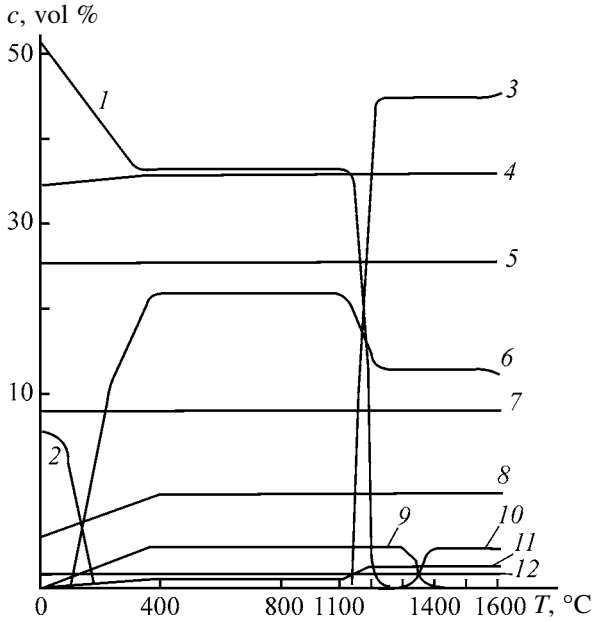

Fig. 1. Results of a thermodynamic analysis of the system constituted by phosphate rock, WPA, and H_2O. (*c*) Content and (*T*) temperature. (*1*) $Ca_{10}F_2(PO_4)_6$, (*2*) H_3PO_4, (*3*) $Ca_3P_2O_8$, (*4*) SiO_2, (*5*) H_2O, (*6*) $Ca_2P_2O_7$, (*7*) CO_2, (*8*) $AlPO_4$, (*9*) Fe_2O_3, (*10*) Fe_3O_4, (*11*) HF, and (*12*) O_2.

can be provided by an additional study aimed to find the minimum energy expenditure with account of the specific output capacity of the apparatus.

The defluorinated forage phosphate has the form of light porous grains. The content of P_2O_5 soluble in 0.4% HCl is higher than 33%, with the relative content of assimilable P_2O_5 exceeding 96%. The degree of defluorination is 90–95%, and the residual content of fluorine in the samples is less than 0.2%, which completely conforms to GOST 23999–80.

To elucidate how mechanochemical activation affects properties of phosphate rock, we thermodynamically analyzed the defluorination process by a calculation method. The analysis was performed using Astra-4 software package [7] for the system constituted by phosphorite rock, wet-process phosphoric acid, and water. The calculation demonstrated that defluorination is thermodynamically probable at temperatures of about 1200°C (Fig. 1).

As already noted, about the same defluorination temperatures (1200°C) were observed in a study of nonactivated phosphate rock on an experimental laboratory installation (Tables 2, 3). Thus, the preliminary mechanochemical activation of phosphate rock, performed prior to its thermal treatment, made it possible, all other conditions being the same, to lower the defluorination temperature from 1200 to 900°C.

In the study, the heat effect of dissolution of activated and nonactivated phosphate rock was calorimetrically determined in a calorimeter with an isothermal sheath. A 5% solution of hydrochloric acid served as a solvent. The calorimeter constant was found by the electric method.

The following processes occur upon introduction of a solid into the solvent: the crystal lattice of the substance disintegrates ($\Delta H_{disint} > 0$), ions pass into solution, are hydrated ($\Delta H_{hydr} < 0$), and interact with HCl. Depending on the relative values of ΔH_{disint}, ΔH_{hydr}, and ΔH of interaction with HCl, the substance dissolution may be either endothermic ($\Delta H > 0$) or exothermic ($\Delta H < 0$).

The experimental data we obtained show that dissolution of both activated and nonactivated phosphate rock is accompanied by heat release ($\Delta H < 0$), with the amount of heat released in dissolution of phosphate rock in hydrochloric acid exceeding by approximately 12–19% that in dissolution of a nonactivated sample (at equal sample weights).

The values of ΔH_{hydr} and ΔH of interaction between ions and HCl are the same for both phosphate rock samples, and, therefore, the difference between the heats of solution is due to that between changes in the enthalpy of crystal lattice disintegration, ΔH_{disint}. The value of ΔH_{disint} for the crystal lattice of activated phosphate rock exceeds that for nonactivated phosphate rock. This is quite understandable, because, in the course of mechanical activation, a solid undergoes first elastic, and then plastic and breaking deformation. As a result, ΔH_{disint} decreases.

Because the internal energy of a solid increases in the course of mechanical activation, it was assumed that thermodynamic characteristics of an activated substance differ from those of a nonactivated sample; the specific heat of the activated phosphate rock is somewhat lower that of the nonactivated substance.

Under real conditions, an activated system comes into equilibrium with the environment ($T_{amb} = T_{a.s}$) via relaxation (dissipation) processes, but a part of the energy received in the course of activation remains and leads to changes in thermodynamic properties.

As an example, we performed a thermodynamic analysis of the following reaction:

$$Ca_{10}F_2(PO_4)_6 + SiO_2 + H_2O = 3Ca_3(PO_4)_2 + CaSiO_3 + 2HF. \quad (1)$$

Taking into account the above assumption and the fact the amount of heat released in dissolution of

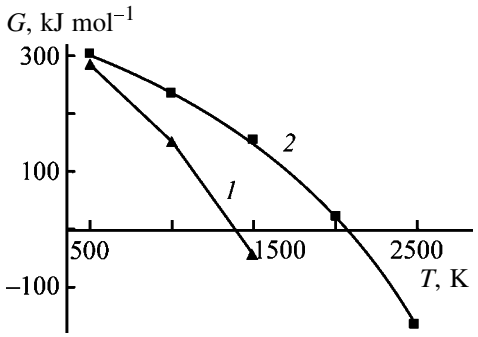

Fig. 2. Changes in the Gibbs energy, ΔG, vs. temperature T for (*1*) activated and (*2*) nonactivated systems.

activated phosphate rock in hydrochloric acid exceeds by approximately 12–19% that released in dissolution of a nonactivated substance, we lowered the value of the coefficient in formula (2) for activated phosphate rock [for SiO_2 and $Ca_{10}F_2(PO_4)_6$] by 15%:

$$c_p = a + bT = cT^{-2}. \quad (2)$$

For $Ca_{10}F_2(PO_4)_6$, $c_p = 946.38 + 120.91 \times 10^{-3}T - 204.4 \times 10^5 T^{-2}$; for SiO_2 (α-quartz), $c_p = 46.98 + 34.33 \times 10^{-3}T - 11.3 \times 10^5 T$.

The Gibbs energies of the processes involving the activated and nonactivated systems are plotted in Fig. 2. These quantities were calculated by the formula

$$\Delta G_T^0 = \Delta H_{298}^0 - T\Delta S_{298}^0 - T(M_0\Delta a + M_1\Delta b + M_{-2}\Delta c). \quad (3)$$

Figure 2 shows that a decrease in the specific heat leads to a pronounced change in the occurrence conditions of reaction (1) and that the temperature (at ΔG_T^0) is substantially lower than that for the reaction involving the starting raw material. A similar behavior was observed in experiments with activated phosphate rock.

CONCLUSIONS

(1) The experimental and calculated results of the study suggest that mechanochemical activation of the phosphate component of phosphate rock may become an efficient method for improving the conventional techniques for processing of phosphate raw materials.

(2) Preliminary mechanochemical activation in manufacture of defluorinated forage phosphates makes it possible, in particular, to lower the temperature of hydrothermal calcination by 300°C.

(3) The mechanochemical activation in the process studied affects the thermodynamic properties of the starting raw material.

Abstract—Methods for phase stabilization of ammonium nitrate were sought for in order to considerably expand the application area of this oxidizing agent in various-purpose self-combustible formulations, including that in a new generation of gas-generating formulations for automobile air bags. New methods for stabilization of ammonium nitrate were studied and, in particular, a search was made for organic compounds that can stabilize ammonium nitrate even at their low content. The mechanism of phase state stabilization of ammonium nitrate by compounds of this kind was examined.

DOI: 10.1134/S1070427207010053

The existence of five polymorphic modifications of ammonium nitrate (AN) and, accordingly, four phase transitions (°C): –17 (V $\rightleftarrows$ IV), +32.3 (IV $\rightleftarrows$ III), 84.2 (III $\rightleftarrows$ II), and 125.2 (II $\rightleftarrows$ I) strongly hinders use of AN in energetic formulations. This is due to the fact that the composite structure disintegrates in prolonged storage at varying temperature because of the occurrence of phase transitions with a change in volume and, as a result, articles undergo mechanical disintegration with uncontrollable changes in the combustion pattern. It is natural to find and introduce into the AN structure a minor additive that preserves AN in one of the modifications in the working temperature range, from –50 to +100°C for gas-generating formulations used in automobile air bags (AAB). Stabilizers of this kind have been found for some application areas of AN. These are potassium nitrate, ammonium sulfate, and ammonium phosphates [1, 2]. However, these stabilizers cannot be used in AAB because of the formation of condensed (which results in that a formulation ceases to be smokeless) or toxic (compounds of sulfur or halogens) combustion products. Phase state stabilizers for AN to be used in AAB should not contain any elements other than C, H, N, and O. In most cases, arbitrarily chosen additives penetrate into interblock spaces of crystallites and virtually do not affect the course of phase transitions. The only exception are minor additives of salts in which either the cation or the anion is close in volume to those in ammonium nitrate. In this case, isomorphic substitution of ions occurs in the AN lattice in cocrystallization or in fusion of salts, i.e., a substitution solid solution is formed [3]. If potassium nitrate is used as stabilizer, it should be introduced in an amount of no less than 8% [4] for reliable phase stabilization of AN at temperatures in the range from –50 to +100°C. However, the formulation ceases to be smokeless upon introduction of the potassium salt.

There are indications that AN can be stabilized with a number of organic pigments, most of which are either sulfonic acids or salts of sulfonic acids with metal cations [5]. Many of the compounds suggested contain chlorine or bromine. Only few of diazo or triphenylmethane dyes satisfy the requirements to the elemental composition, but all of these compounds were found to be inefficient in a thorough experimental analysis.

To develop a new generation of smokeless environmentally safe gas-generating formulations for AAB, we conducted a search for phase-state stabilizers for AN, based on organic compounds that contain no elements other than C, H, N, and O.

It seems attractive to stabilize AN by isomorphic introduction of an anion into the lattice. However,

the choice of anions comparable in size with the nitrate anion is extremely narrow. The anions NO_2^- and CO_3^{2-} are unacceptable because of the low stability of ammonium carbonate and nitrite. The azide, cyanate, and oxalate anions could not be introduced into the AN lattice by fusion or cocrystallization from solution, which is presumably due to the strong difference in the configurations of the anions. Only the formate anion could form isomorphous solutions in the AN lattice both in joint crystallization and in fusion [6]. An X-ray study of single crystals of a solid solution of salts demonstrated that the sample was close in composition to $2NH_4NO_3 \cdot NH_4HCO_2$. Unfortunately, the effect of introduction of the formate ion into the lattice was found to be considerably weaker than that upon substitution of the ammonium cation with potassium. The temperature of the IV $\rightarrow$ III phase transition could only be shifted by 20–30°C, which is apparently insufficient for working with composites.

An additional important way to stabilize the phase state of AN is its cocrystallization with salts or organic compounds in order to create mixed crystals or cocrystallizates. These crystals are new chemical compounds with a new lattice other than those of the starting pair of compounds and with different properties. They may exhibit no phase transitions inherent in the starting compounds or may show quite different phase transitions with widely different transition temperatures and volume changes. We found that AN does tend to form cocrystallizates, but cocrystallizates with positive oxygen balance could not be formed. In addition, all the cocrystallizates obtained have very low melting points. For example, a 1 : 1 cocrystallizate with aminotetrazole melts at 40°C. The best of all was a mixed crystal with ammonium formate of the composition $5NH_4NO_3 \cdot 3NH_4CHO_2$ [6], but it passes into the plastic state at higher temperatures. In addition, the oxygen balance of this compound is negative [this quantity is considered positive if O/(2C + 0.5H) > 1, and negative if this parameter is smaller than unity]. A search of AN cocrystallizates with organic compounds is a rather complicated task because of the necessity for obtaining a mixed crystal with a positive oxygen balance, i.e., the mass content of AN in the binary system constituted by AN and an organic compound should be commonly (depending on the oxygen balance of the latter) not smaller than 50–80%.

In this study, we examined the possibility of phase stabilization of AN by another method, with modifier substances that affect phase transformations by a mechanism different from those in the two techniques described above. In what follows we deliberately use two rather close terms "modifier" and "stabilizer." Substances of the first type affect to a certain extent the structure of AN and its phase transitions, whereas substances of the second type exert just stabilizing influence, which consists in that AN is in a smaller number of phase states in the temperature range under study. The experience gained when studying the effect of organic dyes and arenesulfonates on the phase state of AN and that acquired in a search for cocrystallizates made it possible to formulate the following principles governing the choice of substances that expectedly affect the phase state of AN, be it the true phase stabilization or only hindrance to a phase transition (i.e., transformation to the metastable state).

(1) The structure of a modifier should be close to that of AN in crystal-chemical parameters: interplanar spacings of the modifier should coincide to the maximum possible extent with those in AN itself. This should be manifested in the experiment in a nearly complete coincidence of X-ray diffraction patterns of the composite alloy and starting AN, whereas the modifier itself should be virtually not seen in the X-ray diffraction pattern at all.

(2) Additional interactions of the orbital and(or) electrostatic type, or additional hydrogen bonds except those already existing in the starting products, should appear between the atomic planes of the modifier and those of AN. Also possible is formation of a complex, with charge transfer in the solid phase. Introduction of atomic planes of the modifier into the initial lattice of AN and the additional intermolecular interaction between the ions of the starting material and modifier molecules (monitored by UV and IR spectra) distort the electrostatic field of AN and change the total energy of the structure, which leads to a significant change in the course of phase transitions in the composite material.

Thus, we had to select stabilizers by a search for molecular structures similar to that of AN. This, naturally, could be done by introducing some functional groups into certain original molecular skeletons. The choice of these latter could be rather wide, but we had to take into account the fact that the potential stabilizer should also be a combustible in a formulation for AAB, and the most acceptable compounds for accomplishing the task in hand are those with high thermal stability, comparatively low content of hydrogen, and comparatively high content of nitrogen. Therefore, we studied as starting skeletons nitrogen-containing heterorings, and especially derivatives of purine and pyrimidine bases, which well satisfy the above requirements. In the study, we oriented to com-

pounds with a suitable set of functional groups; for most of the compounds we studied (>50), no evidence about their crystal-chemical parameters was available. Particular attention was given to compounds containing carbonyl, imino, amido, and amino groups, and especially the first two of these, in which both orbital interactions of the carbonyl group with the nitrate ion and formation of hydrogen bonds would be expected. We assumed that the electron density of the nitrate anion, concentrated on lone electron pairs, which are not involved in chemical bonding and occupy a higher energy position, can be donated to a vacant, lying lower in energy, orbital of the carbonyl group of the stabilizer molecule. In this case, the interacting orbitals have the same symmetry. The unique capacity of the carbonyl group as electron acceptor in molecules was reported in [7]. The natural additional conditions were at least partial solubility of a modifier in AN and absence of chemical interaction up to 160–170°C.

EXPERIMENTAL

Minor additives of substances were mostly introduced into AN by fusion at a temperature close to the melting point of AN. This method is the most efficient because the solubility of modifier substances in molten AN, as a rule, exceeds that in organic solvents and, what is more, polar solvents can compete with ammonium nitrate in formation of hydrogen bonds. The following experimental techniques were used: X-ray phase analysis (computer-controlled DRON-2 diffractometer, phase identification in transitions in the temperature range from –50 to +100°C by analysis of X-ray diffraction patterns with preliminary calculation of theoretical X-ray diffraction patterns of polycrystals of all the phases from atomic coordinates obtained in an X-ray diffraction study of single crystals), DTA (MOM derivatograph, Hungary, heating rate 0.6 deg min^{-1}), and, in some cases, studies of UV spectra on a Specord M40 spectrophotometer in the spectral range 200–900 nm and IR spectra on a Specord IR75 spectrophotometer at 4000–700 cm^{-1}.

X-ray phase studies and differential thermal analysis. As regards the influence exerted on the phase state, three groups of stabilizer substances can be distinguished: (a) the X-ray diffraction pattern of an alloy is identical to that of a mechanical mixture; (b) X-ray diffraction pattern of the alloy retains lines characteristic of each of the components being fused, but there are slight changes in the positions or relative intensities of the peaks; and (c) X-ray diffraction pattern of the alloy shows significant changes manifested in that the modifier peaks disappear or a set of entirely new peaks appears, which corresponds to the formation of a new mixed crystal. Situation (a) commonly (with rare exceptions) does not lead to changes of phase states and most frequently means that the substances are either not mixed in fusion or stratify upon cooling. Situation (b) most frequently indicates that new hydrogen bonds are formed, which undoubtedly affects the phase state of AN. However, this influence is not strong and requires introduction of considerable amounts of a modifier. Situation (c) indicates that a strong interaction occurs between the nitrate anion and modifier molecule, in addition to formation of hydrogen bonds. This is the case when the crystal-chemical parameters of the substances being fused are close and additional intermolecular interactions arise between the atomic planes of the partners. Even a new mixed crystal can be formed.

(only those interplanar spacings in the stabilizer which coincide with the interplanar spacings in AN are given). The best coincidence of the interplanar spacings is observed for trihydroxypurine (uric acid, UA). Complete coincidence is impossible for the natural reason of differences between lattices of different compounds, but the best coincidence is necessary for obtaining a doped product. Widely known is the nearly complete coincidence of the interplanar spacings of γ-iron (high-temperature phase of iron) and iron carbide Fe_3C (cementite), whose fusion yields martensite with carbon content of less than 6.67% [8]. The nature of doping of the alloys is presumably the same for different types of substances: an additive does not form its own phase until its certain amount is introduced into the main substance. Only a minor amount of an additive can be introduced into the alloy before its presence starts to be seen in the X-ray diffraction pattern. The substance introduced into the alloy is distributed in the form of very small clusters among those crystalline blocks of AN which show coincidence of their interplanar spaces with those between similar atomic planes in the additive. Table 2 lists the interplanar spacings of alloys with varied UA content and, for comparison, full data for UA and AN crystals. The maximum amount of UA, which can be dissolved in AN without any visible indications of its presence, is about 13–15 wt %. The composition of an alloy containing 18.9 wt % UA (stoichiometry for complete burning of the composite to CO_2 and H_2O) shows presence of a minor amount of the intrinsic UA phase (Table 2). The atomic planes with coinciding interplanar spacings of the crystalline blocks of the alloy and of the constituent components show different interplanar spacings and peak intensities, compared with the starting components.

Having different mechanisms of influence on the phase states, all these compounds produce the same result. As shown by DTA measurements for AN fused with barbituric acid, melamine cyanurate, trihydroxypurine, guanine, and isatin, the V → IV transition is shifted to temperatures below –50°C, whereas in pure AN it occurs at –17°C. The IV → III transition is not

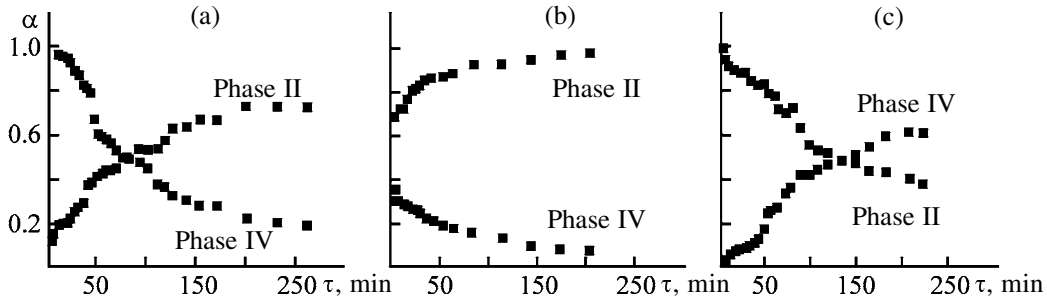

Fig. 1. Kinetics of phase transitions in an alloy of composition 90 wt % AN + 10 wt % UA. (α) Degree of conversion and (τ) time. (a) Direct transition IV → II at 53°C, (b) direct transition IV → II at 54°C, and (c) reverse transition II → IV at 46°C.

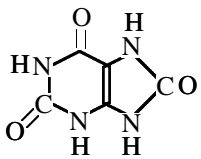
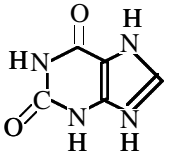
observed, phase IV directly transforms into phase II in the temperature range 45–55°C, and phase II remains stable up to 117–120°C, whereas in pure UA phase III transforms into phase II at 84.2°C. The method of quantitative X-ray phase analysis of polycrystals was used to examine the kinetics of direct and reverse IV → II transitions in an alloy containing 10 wt % UA and 90 wt % AN. The study was performed in a specially designed temperature chamber for DRON-2 diffractometer, which makes it possible to record variation of the phase ratio with time at a constant temperature. We measured the integral intensities of peaks corresponding to certain phase and then performed normalization to an internal reference. The normalized values of integral intensity, obtained at different prescribed instants of time, were related to the integral intensity at the initial instant of time. Further, we plotted kinetic curves describing the time dependence of the degree of conversion in direct and reverse transitions. To plot the kinetic curves, we followed the variation of three or four reflections in the starting and final phases. The direct transition (IV–II) was studied at two temperatures, 53 and 54°C, in the isothermal mode (Figs. 1a, 1b). At 53°C, the transition does not come to an end in 4 h. At 54°C, the transition occurs at higher rates and is complete in 3.5 h. It was shown that the conversion of phase IV into phase II occurs directly from a crystal to crystal, rather than via an intermediate state, because the sum of the initial and final phases is close to unity at any degree of conversion. The reverse transition was performed at 46°C, it occurred with a significant delay in time and temperature, and here, as also in the case of the direct transition, the sum of the initial and final phases is close to unity (Fig. 1c). Such a behavior of stabilized AN samples differs from that of pure AN, for which the transition of the initial phase to the new phase (transition IV → III and back) occurs via a certain intermediate (X-ray amorphous) state, which then forms the new phase [4]. In individual AN, a transition directly from phase IV to phase II can also be observed, and this occurs in the nearly total absence of moisture [9]. It was shown in [10, 11] that the phase transformation of a single crystal of one phase (IV) into a single crystal of another phase (II) and back is possible in the same single crystal without its disintegration. In this case, the structural transformation of phase IV into phase II reduces to a rotation of the NH_4^+ cation about the twofold axis by an angle of 90° and to an increase in the lattice constants, with the system of initial hydrogen bonds rearranged to give a new system.

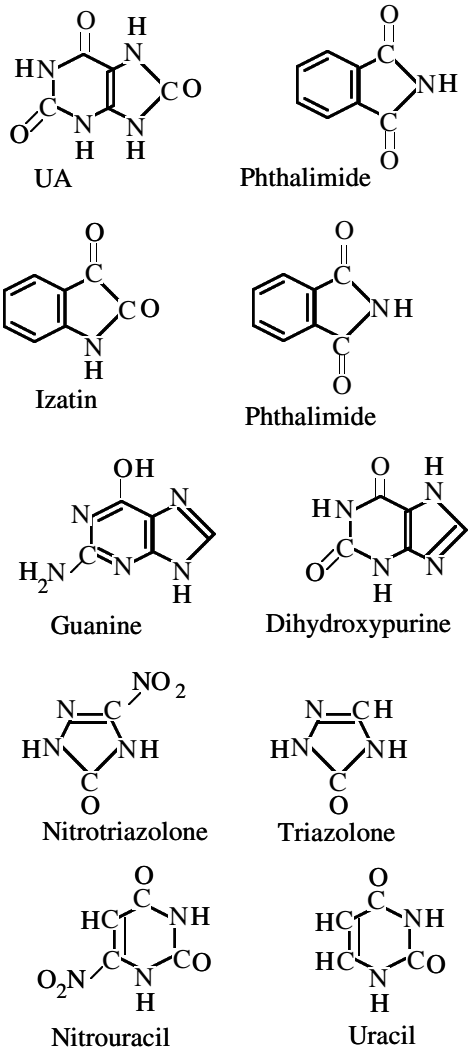
When studying the stabilization of the phase state of AN, we found that the structure of, and differences between the functional groups present in the modifier molecule affect the stabilization efficiency. The strongest effect was observed in the presence of a carbonyl group and an imino group in the ring. We also observed the influence exerted by the position of the imino and carbonyl groups in the molecule. For example, AN is stabilized by isatin with neighboring carbonyl groups in the five-membered ring, whereas phthalimide, which is isomeric to isatin, but has carbonyl groups separated by an imino group, has no effect on the phase state of AN. Introduction of the electronegative nitro group enhances the effect of a substance on the phase state of AN. Below, we present, for clarity, structures of nine different substances tested as possible phase-state stabilizers for AN. In each of the six pairs of possible modifiers, the structures are closely similar, but the left-hand substance is a stabilizer, and the right-hand one is not:



UA



Dihydroxypurine



Spectral studies (UV and IR). Trihydroxypurine (UA) was found to be one of the best phase-state stabilizers for AN, and, therefore, we made an attempt to elucidate the mechanism of intermolecular interaction stabilizing this system by spectroscopic methods.

Samples for UV spectral measurements were prepared in the form of an emulsion in Vaseline oil, deposited as a thin layer on quartz plates. Samples for IR measurements were prepared as emulsions in Vaseline oil and hexachlorobutadiene (an important advantage of the latter is the absence of absorption bands in the range of vibrations of N–H bonds in the compounds under study). The emulsion was deposited as a thin layer on NaCl plates (with KBr plates, an interaction of AN with the material of the plates was observed).

The UV spectrum of AN contains a strong band peaked at ~200 nm and a weak shoulder at 222 nm, which corresponds to the $\pi \rightarrow \pi^*$ transition in the anion. The spectrum of UA exhibits three bands: the strongest band peaked at ~200 nm, the weakest broad band at 227 nm, and two overlapping medium-intensity bands at 290 and 305 nm. The UV spectrum of the alloy retains bands at ~200 and 227 nm. The bands at 290 and 305 nm, which may be associated with the $n \rightarrow \pi^*$ transition in the carbonyl groups of UA, are substantially weakened. It should be noted that a new weak band peaked at ~550 nm appears in the spectrum of the AN + UA alloy. This band can be attributed to a charge-transfer complex formed in interaction of frontier orbitals of the nitrate anion and UA molecule. The bands in the UV spectrum of the alloy, assigned to the $n \rightarrow \pi^*$ transition in the carbonyl groups, are markedly weakened, which can be attributed to donation of electron density from the highest occupied orbital of the nitrate anion to the lowest unoccupied orbital of the carbonyl group. This is possible if the orbitals are close in energy and have the same symmetry. The IR spectra of AN and UA have rather close vibration frequencies in the range of vibrations of N–H bonds, and the spectrum of the alloy has the form close to a simple sum of the spectra of the components. This means that the energetics of the systems of hydrogen bonds in AN and UA are close and remain virtually unchanged on passing to an alloy.

An unambiguous interpretation of the stabilizing action of intermolecular interaction as resulting from the appearance of charge-transfer complexes for the case of IV $\rightarrow$ II transitions in the alloy is not always possible. Presumably, the phase stabilization of alloys may result from appearance of other types of interaction between the nitrate anion and stabilizer molecule. We examined intermolecular interactions in an alloy of AN with barbituric acid (BA). Comparative analysis of the IR spectra of the starting components and the alloy reveals the disappearance of the bands at 3175 and 3080 cm^{-1}, associated with stretching vibrations of N–H bonds in barbituric acid, on passing to the alloy, which suggests that BA molecules form in the alloy a new system of hydrogen bonds. A new band at 3000 cm^{-1}, absent in the spectra of the starting components, appears in the spectrum of the alloy. The strong depression of the frequency of N–H vibrations suggests that BA molecules form in the alloy a more stable network of hydrogen bonds than the N–H···O=C network in the starting BA. At the same time, the vibration frequencies of the ammonium ion, 3125 and 3030 cm^{-1}, remain virtually unchanged on passing to the alloy. This suggests that BA molecules in the alloy mostly interact with nitrate ions. The assumption is confirmed by UV spectral data. The UV

spectrum of barbituric acid contains three broad absorption bands peaked at ~200, 220, and 256 nm. Four bands are observed in the spectrum of the alloy. The bands at ~204 and 220 nm are formed by superposition of the corresponding bands of the components. The band at 263 nm is associated with the $n \rightarrow \pi^*$ transition in the carbonyl groups of barbituric acid. Its shift to longer wavelengths (from 256 to 263 nm) is probably due to disruption of the system of hydrogen bonds N–H···O=C in the alloy. It should be noted that a new broad low-intensity absorption band appears in the UV spectrum of the alloy at 312–385 nm. This band can be attributed to a charge-transfer complex formed by the BA molecule and the nitrate ion. It should be noted, however, that bands of this kind commonly lie at longer wavelengths.

An important question is whether or not this action leads to a thermodynamically stable phase state of An or to a sufficiently stable in the course of time, but metastable state. The IV $\rightleftarrows$ II phase transition for the AN–UA system is reproduced in multiple transformations without any noticeable hysteresis. This, however, does not confirm the thermodynamic stability of the system. Upon exposure at 110°C for 400 h (standard test for thermal stability of the given class of formulations), followed by storage for a year under hermetically sealed conditions, the AN–UA alloys retain their properties. However, such a statement cannot be made for all of the systems studied. For example, AN modified with barbituric acid ceases to be phase-stabilized after the same test (400 h at 110°C).

As for AN samples stabilized with UA, cracks start to appear in compacted pellets subjected to multiple cyclic changes in temperature in a wide range only after several tens of such cycles, whereas the same pellets of a nonstabilized preparation totally disintegrate into powder after one to three cycles.

CONCLUSIONS

(1) A study of ammonium nitrate alloys with minor additions of organic substances demonstrated that compounds close to NH_4NO_3 in crystal-chemical parameters affect the phase state of ammonium nitrate.

(2) It was shown that a substance exerts a stabilizing influence on the phase state of ammonium nitrate if it contains functional groups that are involved in intermolecular interactions of orbital and electrostatic types and form new hydrogen bonds.

(3) It was determined that the most effective groups of this kind are carbonyl, amino, and imino groups, and especially those of carbimino and carbamino types. A high stabilization efficiency was observed for derivatives of purine and pyrimidine bases and similar nitrogen-containing heterocyclic compounds.

(4) Substances (trihydroxypurine, isatin, guanine, barbituric acid, etc.) that provide at a content of 2–5 wt % partial phase stabilization of ammonium nitrate were found. With these stabilizers, it exists in the temperature range from –50 to +100°C in only two phases, with a single phase transition at about 50°C, which leads to a manyfold increase in the stability of compacted samples to multiple cyclic changes in temperature.

Abstract—An approach to express screening of promising hydrocarbon propellants, based on the calculation of the specific impulse of an engine from the results of quantum-chemical calculation of their heats of combustion, was suggested. The approach ensures high accuracy irrespective of the composition and structure of the compounds under consideration. Polycyclic and framework hydrocarbons with small rings were suggested as promising propellants.

DOI: 10.1134/S1070427207010065

The development of new hydrocarbon propellants for environmentally clean rockets is a priority research field, because the use of energetic propellants increases the pay load of carrier rockets and makes their launch more cost-efficient.

One of approaches to enhancing the performance of hydrocarbon propellants is increasing their density by using cyclic and framework compounds [1–7]. Such propellants are usually prepared by hydrogenation of dicyclopentadiene followed by catalytic rearrangement of the product from the *endo* to *exo* form, which is required for decreasing the melting point. Such propellants as, e.g., JP-10, RJ-4, and RJ-41 with a density of 0.94 g cm^{-3} were prepared by this procedure. With norbornane taken as starting compound, a propellant (RJ-5) with a still higher density, 1.08 g cm^{-3}, was prepared. Another way to increase the density is the condensation of dicyclopentadiene with adamantane derivatives; however, this leads to a significant increase in the melting point.

To enhance the performance of hydrocarbon propellants, their heat of combustion is increased, in particular, by using structurally strained hydrocarbons containing three- and four-membered rings [8]. These compounds contain fragments with strongly distorted C–C bond angles, which leads to appreciably larger heats of formation and hence higher heats of combustion. The suggested propellants based on 1-methyl-1,2-dicyclopropylcyclopropane [9] and dicyclobutyl [10–13] are characterized by record-breaking heats of combustion.

We believe that the use of polycyclic and framework hydrocarbons with small rings as propellants can further enhance the energy characteristics of rockets owing to high density and increased heat of combustion of such propellants.

Studies on synthesis and determination of the characteristics of new fuels require considerable expenses; therefore, it is appropriate to start searching for compounds having the required properties with the calculation of the relevant physicochemical characteristics. With the modern computers, the existing quantum-chemical methods allow quick screening of the potentially promising compounds with incommensurably lower time and money expenses compared to experimental studies. This approach also allows calculation of the characteristics of difficultly available and even hypothetical substances.

Various empirical additive schemes for calculating the heat of combustion require the knowledge of such molecular parameters as the bond energies or force constants. Additive schemes give particularly inaccu-

rate results when applied to compounds of different types, e.g., in going from normal hydrocarbons to cyclic hydrocarbons, especially those with small rings. Therefore, such calculations do not ensure the level of versatility and accuracy required for comparing the parameters of compounds with diverse chemical structures. Molecular mechanics methods suffer from the same drawback.

Since the heat of combustion of the compounds of interest varies in a relatively narrow range (10% at maximum and 2–3% in most cases), the only method giving the reliable and comparable data is direct ab initio calculation of the heat of combustion.

The overall reaction equation for the combustion of hydrocarbon propellants in oxygen at a stoichiometric component ratio,

$$C_nH_m + (n + m/4)O_2 = m/2H_2O + nCO_2, \quad (1)$$

corresponds to the real calorimetric experiment. Although the error in calculating the heat of combustion, as will be shown below, is 4–8 kJ mol^{-1} and somewhat exceeds the error of experimental determinations, the calculation accuracy attained is quite sufficient for comparing the power intensity of various hydrocarbons.

The calculations reported in this paper were performed ab initio using the GAMESS program package [14] which allows, in particular, calculation of the total energies of molecules and of the correlation and thermodynamic corrections to them. The molecular geometries were fully optimized within the framework of the restricted Hartree–Fock (RHF) method in the TZV(*d*,*p*) basis set [15] with the polarization *d* functions on the C atoms and *p* functions on the H atoms. To determine the thermochemical correction at 25°C, the harmonic vibration problem [16] was solved in the same approximation. For the molecular geometry corresponding to the total energy minimum in the TZV(*d*,*p*) basis set, the electron correlation was taken into account according to the Møller–Plesset perturbation theory (MP2) [17, 18] in a wider basis set, TZV(2*df*,2*p*). Several test calculations of small molecules showed that the geometry optimization in this basis set did not lead to appreciable decrease in the total energy. The oxygen molecule in the ground triplet state was calculated by the restricted open-shell Hartree–Fock (ROHF) method, and the MP2 electron correlation correction for this molecule was determined according to [19]. The required total energies with the MP2 correction, calculated in the TZV(2*df*,*p*) basis set (in atomic energy units) are as follows: H_2O –76.3204, CO_2 –188.3156, and O_2 –150.1218. The thermochemical corrections to their enthalpies at 25°C are 70.43, 42.80, and 20.64 kJ mol^{-1}, respectively.

The calculated heats of combustion in oxygen of saturated hydrocarbons of different chemical structures and several unsaturated hydrocarbons in the gas phase are listed in the table.

To evaluate the accuracy of calculating the heat of combustion within the framework of the above-described scheme, we calculated the total energies of aliphatic hydrocarbons for which these quantities are well-known. As follows from the table, the relative errors of the calculated heats of combustion of the homologous series of hydrocarbons (from methane to octane) are within 0.12–0.37%. Appreciably higher accuracy is attained for molecules containing small rings. In this case, the error does not exceed 0.1% and in most cases is within 0.03–0.04%. The experimental heats of combustion presented in the table refer to the gas phase.

Note that, when comparing the power intensity of various compounds, the heat of combustion is usually referred to 1 g of the combustible but not of the fuel (combustible + oxidant), which can lead to wrong conclusions when choosing the most efficient fuel. Indeed, assume that combustion of fuel of mass m results in evolution of Q J of heat. Then, neglecting the thermal dissociation of combustion products, we can determine the velocity of their outflow v from the law of energy preservation:

$$mv^2/2 = \eta Q, \quad (2)$$

where η is the engine efficiency factor.

Hence,

$$v = (2\eta H)^{1/2} \quad (3)$$

(Glushko's formula), where

$$H = Q/m \quad (4)$$

is the heat of combustion per unit mass of the fuel (J kg^{-1}), which, as seen from formula (3), is the major factor determining the outflow rate and hence the engine thrust.

Let us illustrate these reasonings by a simple example. Judging from the specific heat of combustion per kilogram of combustible h, methane is the most efficient (see table); however, its H value is relatively low, determining its moderate power characteristics as propellant. In the combustion of methane,

$$CH_4 + 2O_2 = CO_2 + 2H_2O, \quad (5)$$

* For the gas phase.
** Calculation by Glushko's formula (8) at $\eta = 0.556$.
*** Bold dots denote hydrogen atoms located over the molecular plane.
**** Because of the large molecular size, the calculations were performed in a somewhat less accurate basis set TZV(*df*,2*p*), which leads to ~1-s underestimation of the specific impulse.

the oxygen consumption is 3.9891 mass units per mass uinit of methane. Therefore, for complete combustion of methane in oxygen, we have

$$H = h/(1 + 3.9891) = 49657/4.9891 = 9953 \text{ kJ kg}^{-1}.$$

Similarly, in combustion of, e.g., dicyclobutane,

$$C_8H_{14} + 11.5O_2 = 8CO_2 + 7H_2O \quad (6)$$

the oxygen consumption is as low as 3.339 mass units per mass unit of the combustible; hence,

$$H \approx h/(1 + 3.339) = 44561/4.339 = 10269 \text{ kJ kg}^{-1}.$$

Thus, although the heat of combustion per kilogram of combustible (h) of methane, 49.657 kJ kg^{-1}, appreciably exceeds that of dicyclobutyl, 44.561 kJ kg^{-1}, methane is less efficient because of the lower heat of

combustion per kilogram of fuel (H): 9953 kJ kg^{-1} against 10 269 kJ kg^{-1} for dicyclobutyl. Note that the reasonings given here and below refer exclusively to the stoichiometric ratio of the fuel components, combustible and oxidant. Actually, to attain the maximal performance of a specific type of propellant, the optimal amounts of the oxidant are determined experimentally, and they are usually appreciably lower than the stoichiometric amount. In this case, our approach to assessing the performance of propellants can be used as a preliminary estimate.

To convert the specific heat of combustion of a hydrocarbon h to the specific heat of combustion of a fuel H, it is convenient to use a formula following from Eq. (1):

$$H = h(11.91 + x)/(43.66 + 8.936x), \quad (7)$$

where $x = m/n$ is the H/C atomic ratio in the given hydrocarbon C_nH_m.

An important conclusion follows from Eq. (7): With a decrease in the H/C ratio x in a hydrocarbon, the conversion factor from h to H increases. Thus, a propellant with a low hydrogen content can exhibit a higher specific impulse, even despite lower power intensity h per kilogram of the hydrocarbon.

By multiplying the outflow velocity of gaseous products v from formula (3) by the fuel consumption rate (kg s^{-1}), we obtain the tractive force in newtons. In the literature on rocket engines, the specific impulse p_{sp}, measured in kilogram-force (kgf) units and equal to the tractive force at a fuel consumption rate of 1 kg s^{-1}, is commonly used. Conversion of formula (3) to p_{sp} gives

$$p_{sp} = (2\eta H)^{1/2}/g, \quad (8)$$

i.e., the dimension of p_{sp} is kgf kg^{-1} s or simply s after the "cancellation" of kgf and kg, which is a common practice. The results of calculation by formula (8) are given in the table. The efficiency factor η was taken equal to 0.556 to bring the calculated and experimental [10–12] specific impulses of dicyclobutyl to coincidence; this value of η was also applied to calculate the specific impulses of all the other compounds listed in the table. Thus, the parameter η plays the role of a calibration factor taking into account, to a first approximation, the nonstoichiometric ratio of the combustible and oxidant, partial dissociation of combustion products, etc. It is assumed that these factors affect the specific impulse of the examined substances to approximately the same extent as that of dicyclobutyl.

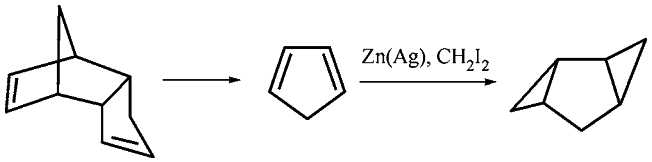
The specific impulses given in the table range from 336.4 for adamantane to 366.3 for stereoisomer III of tricyclo[4.1.0.0^{2,4}]heptane (no. 17). Note that the specific impulses of adamantane and JP-10 propellant are close to that of kerosene, 337.9 s [10–12]. The natural terpenes α- and β-pinene present in turpentine exhibit higher specific impulse, 341.4–341.8 s. Still higher values, 345–350 s, are attained, e.g., with 2,6-dimethyltricyclo[3.1.1.0^{3,6}]heptane (no. 22), norbornadiene (no. 36), tricyclo[3.1.0.0^{2,6}]hexane (no. 30), and bicyclo[2.1.0]pentane (no. 27). Note that tetracyclo[3.3.1.-0^{2,4}0^{6,8}]nonane (no. 8) suggested in [23] as a promising aviation fuel, according to our calculations, has a specific impulse of 345.1 s, only slightly exceeding that of dicyclobutyl (344.5 s).

The highest values of the specific impulse (exceeding 350 s) are characteristic of such strained framework hydrocarbons as quadricyclane (no. 31), spiropentane (no. 33), bicyclobutane (no. 25), cubane (no. 32), tricyclo[2.1.0.0^{2,5}]pentane (no. 26), and prismane (no. 29). Many of these compounds are hypothetical and have not been synthesized up to now. The synthesis of the other compounds of this group is extremely difficult and labor-consuming, and it can hardly be realized on the commercial scale in the near future. Furthermore, such compounds have high molecular symmetry and hence should have high melting point at relatively low boiling point, which is hardly acceptable for propellants.

The three series of stereoisomers of tricyclo-[3.2.0.0^{2,4}]heptane (nos. 18, 19), tricyclo[5.2.0.0^{2,5}]-nonane (nos. 12–14), and tricyclo[4.1.0.0^{2,4}]heptane (nos. 15–17) deserve particular consideration. As seen from the table, in going from the "transoid" chair-like to "cisoid" boat-like molecular configuration, the specific impulse increases by only 0.5–1.6 s. However, a striking result was obtained with the "skewed" isomers: the specific impulse increased by 6.8 s for tricyclo[5.2.0.0^{2,5}]nonane III (no. 14) and even by 20.8 s fir tricyclo[4.1.0.0^{2,4}]heptane III (no. 17) (relative to the coresponding transoid structures). Compound no. 17 even exceeds prismane (no. 29) in the specific impulse, being a "champion" among the structures chosen.

Analysis of data in the table, taking into account the set of requirements to propellants (melting and boiling points, density, viscosity, stability, etc.) shows that the most promising for further experimental studies are terpene derivatives (nos. 20, 21) and tricycloheptanes (nos. 15–17), the more so as the raw materials for their synthesis (turpnetine oil and cyclopentadiene) are cheap and readily available.

For primary estimation of properties of potentially promising propellants, we synthesized laboratory samples of some of them. Tricyclo[4.1.0.0^{2,4}]heptane was prepared by the Simmons–Smith reaction [26] used for obtaining three-membered hydrocarbon rings. Cyclopentadiene prepared by thermal depolymerization of dicyclopentadiene was treated with methylene iodide in the presence of silver-plated zinc dust; in the process, it was smoothly converted to tricyclo[4.1.0.0^{2,4}]heptane:

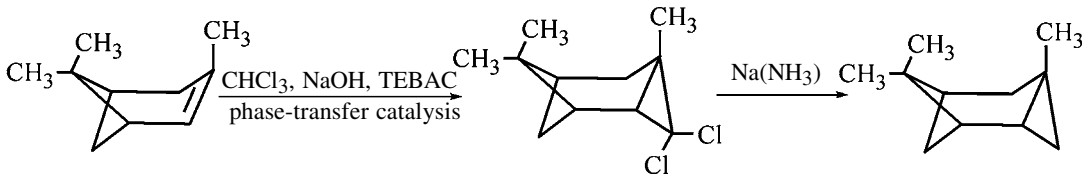


The product was identified by ^{1}H NMR spectroscopy as transoid stereoisomer I of tricyclo[4.1.0.0^{2,4}]-heptane (no. 15); its calculated specific impulse is 345.5 s. The compound synthesized has a density of 0.908 g cm^{-3} (0.8912 according to [25]); its freezing point is below –103°C, and the boiling point is 104°C (103°C [25]). Unfortunately, the other stereoisomers (nos. 16, 17) were not detected in the product.

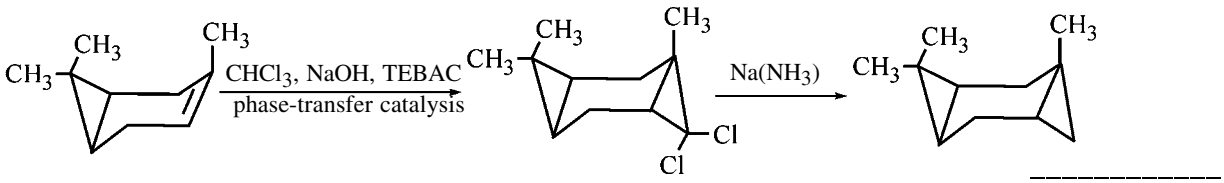
Apparently, the purposeful synthesis of highly strained stereoisomers like nos. 14 and 17 requires a higher level of preparative organic chemistry. Such a synthesis may involve the use of coordinating matrices or catalysts ensuring formation and preservation of the required strained steric configuration.

For chemical modification of natural terpenes, it appeared feasible to use a two-step synthesis scheme involving addition of dichlorocarbene to the double bond of the substrate under phase-transfer conditions (with triethylbutylammonium chloride, TEBAC, as phase-transfer catalyst), followed by reductive dehalogenation of the intermediate product with sodium in liquid ammonia. This scheme is preferable over the Simmons–Smith reaction because of the availability of the reagents and solvents and high yield and purity of the products.

With α-pinene used as precursor, this scheme leads to 4,7,7-trimethyltricyclo[4.1.1.0^{2,4}]octane (no. 20) whose calculated specific impulse is 342.4 s:



and from carene, 1,4,4-trimethyltricyclo[5.1.0.0^{3,5}]octane (no. 21) having the same specific impulse is obtained:



Since the above-described two-step synthesis with individual turpentine components occurs very smoothly and with high product yields, we made an attempt to use as starting reagent turpentine oil, a multicomponent mixture of natural terpenes. By so doing, we obtained a propellant with a density of 0.882 g cm^{-3}, freezing point below –90°C, and boiling onset point of 186°C. The expected specific impulse should be 342–343 s.

CONCLUSIONS

(1) Evaluation of the specific impulse of a rocket engine, based on quantum-chemical calculation of the heat of combustion of hydrocarbon propellants, is an efficient approach to their express screening. This approach ensures high accuracy when applied to hydrocarbons of diverse compositions and structures.

(2) The use of polycyclic and framework hydrocarbons with small rings as propellants can ensure further enhancement of the power characteristics of rocket engines due to high densities and high heats of combustion of such compounds.

(3) The power characteristics of strained polycyclic hydrocarbons essentially depend on their steric configuration. For example, the stereoisomers of tricyclo[4.1.0.0^{2,4}]heptane differ in the specific impulse by more than 20 s.

(4) Strained polycyclic and framework hydrocarbons selected according to the calculation results were synthesized by addition of carbenes to double bonds of natural terpenes and cyclopentadiene. The products obtained exhibit increased specific umpulse and density; they also meet other requirements to propellants.

Abstract—The solubility of individual fullerenes C_{60} and C_{70} and a fullerene mixture enriched in higher fullerenes (C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%) in higher isomeric carboxylic acids was studied within the 20–80°C temperature range; the corresponding solubility polytherms are presented.

DOI: 10.1134/S1070427207010077

This paper continues our previous studies [1] and deals with the solubility polytherms of individual fullerenes (C_{60} and C_{70}) and a mixture enriched in higher fullerenes (C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%) in higher isomeric carboxylic acids (HICA). Such information is of interest for developing efficient methods of fullerene separation and enrichment.

The development of a process for the extraction separation and purification of fullerenes (mainly C_{60} and C_{70}) [2] based on the difference in their solubility in aromatic solvents becomes important for prechromatographic enrichment. Experimental data on solubility polytherms, quite necessary for this purpose, are very limited [3–9] for binary systems C_{60} or C_{70}–solvent (aromatic as benzene, toluene, *o*-xylene, 1,2-dichlorobenzene and nonaromatic as CCl_4, hexane, etc.) and are virtually lacking for more complex systems, e.g., two fullerenes in one solvent, or one fullerene in a binary solvent, etc. In particular, there are no data on the solubility polytherms for the most important ternary systems C_{60}–C_{70}–solvent. The solubility diagrams of the C_{60}–C_{70}–toluene system at 25°C and C_{60}–C_{70}–*o*-xylene system at 80°C, that we reported in [1], are the only exception.

Analysis of data on solubility of individual fullerenes (C_{60}, C_{70}) in organic solvents revealed the following features [4, 7, 8, 10–13]:

(1) Solubilities of C_{60} and C_{70} are of one order, but can be several times different. Exactly the difference in the solubilities can underlie the most efficient method of fullerene separation.

(2) Fullerenes are practically insoluble in polar solvents and poorly soluble in acyclic saturated hydrocarbons (they are the more soluble, the greater the number of carbon atoms in solvent molecule); this indicates insufficient role of the solvation mechanism of dissolution.

(3) The maximal solubility of fullerene is observed in solvents whose specific enthalpy of solution related to the volume of solvent molecule is close to the corresponding value of the fullerene molecule. Aromatic hydrocarbons and their derivatives can be examples of such solvents.

The influence of external parameters (e.g., temperature) on the solubility is manifested differently for individual fullerenes. This can be illustrated by the corresponding polytherms [4, 8, 13]. In contrast to C_{70}, for C_{60} the temperature dependence of the solubility in a series of solvents (CS_2, *o*-xylene, toluene, etc.) is nonmonotonic with its descending branch being due to the thermal decomposition of associates (C_{60} solvates) accompanied by an increase in the energy of fullerene interaction with solvent molecules and, correspondingly, by the shift of the phase equilibrium in direction to the solid phase. In [14], an anomalous effect of a sharp increase in the solubility of C_{60} with increasing pressure at 298.2 K was observed, although the solubility usually decreases for molecular crystals. Such a substantial difference in

dependences of the solubilities on the external conditions demonstrates complex character of solubility of fullerenes as a phenomenon and, in particular, the existence of various competitive mechanisms of their dissolution.

In this study, we used a mixture of α,α'-branched higher isomeric carboxylic acids with C_9–C_{11} carbon chains (HICA) as a fullerene solvent. It should be noted that the dissolving power of HICA only weakly depends on the size of the hydrocarbon substituent in the acid molecule. Therefore, in practice, in particular, in separation of rare-earth metals, mixtures of organic acids rather than individual acids are usually used [15].

EXPERIMENTAL

The following reagents were used in the study: fullerenes C_{60} and C_{70} of 99.9 and 99 wt % purity, respectively, with the content of the main determinable impurities (C_{70} in C_{60} and C_{60} in C_{70}) of about 0.1 wt %; a fullerene mixture enriched in higher fullerenes (C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%) produced by ILIP Closed Joint-Stock Company (St. Peresburg, Russia); analytically pure grade *o*-xylene; and a technical mixture of higher isomeric carboxylic acids HICA.

HICA was purified by repeated washing with hydrochloric acid to remove metals. *o*-Xylene purity was monitored spectrophotometrically and refractometrically (with an IKR-20 refractometer; $n^{20} = 1.5054$).

The solubility was measured within the 20–80°C temperature range by an isothermal saturation method. Initially, solutions of C_{60}, C_{70}, and fullerene mixture in HICA were prepared (substantial excess of fullerene was taken in all cases). Then solutions were subjected to saturation in a temperature-controlled shaker (thermostating error ±0.05°C) for 8–10 h at each temperature. Preliminary experiments showed that this time was sufficient to attain the phase equilibrium in the HICA–fullerene system. The solution was separated from the precipitate by filtration through a Schott filter with a porosity of 16.

The C_{60} and C_{70} concentrations after each step of saturation were determined spectrophotometrically on a Specord-32 spectrophotometer at λ 335.5 and 472.0 nm. Aliquots of C_{60}, C_{70}, and fullerene mixture in HICA were taken and then diluted with *o*-xylene. Pure HICA diluted with *o*-xylene to the same degree as for fullerene solution in HICA was used as a reference solution. This procedure is dictated by substantial difficulties in recovery of fullerenes from HICA for subsequent analysis, in particular, due to high HICA boiling point of about 250°C. The fullerene concentrations were calculated using empirical equations for solutions in *o*-xylene [16]:

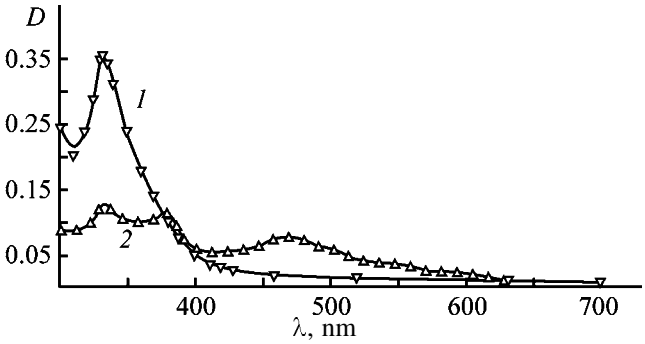

Fig. 1. Optical spectra in HICA of individual fullerenes (*1*) C_{60} and (*2*) C_{70}. Concentration of C_{60} 0.083 g l^{-1}, dilution with *o*-xylene 1 : 21; concentration of C_{70} 0.16 g l^{-1}, dilution with *o*-xylene 1 : 15; reference solution: HICA in *o*-xylene with the same dilution. (*D*) Optical density and (λ) wavelength; the same for Fig. 2.

$$c(C_{60}) = 13.10(D_{335} - 1.808D_{472}), \quad (1)$$

$$c(C_{70}) = 42.51(D_{472} - 0.0081D_{335}), \quad (2)$$

where D_{335} and D_{472} are optical densities of solutions referred to a solution thickness of 1 cm, and $c(C_{60})$ and $c(C_{70})$ are the concentrations of the corresponding fullerenes (mg l^{-1}).

The concentration of the fullerene mixture enriched in higher fullerenes after each step of saturation was performed by HPLC on a LYuMAKhROM liquid chromatograph (LUMEX, St. Petersburg, Russia) with detection through light absorption at λ 254 nm [17].

The electronic absorption spectra of solutions of individual fullerenes and enriched fullerene mixture in HICA are shown in Figs. 1, 2. In these spectra, solvatochromic effects (sharp change in the optical spectrum at moderate change in the solution concentration or solvent composition) characteristic of two-component mixtures (acetonitrile–toluene, benzene–methanol, benzene–hexane, etc.) and suggesting tendency toward formation of fillerene clusters [18] do not appear. Thus, fullerene solutions in HICA are similar to solutions in aromatic solvents (*o*-xylene, benzene, toluene, *o*-dichlorobenzene). This justifies the use of empirical equations (1) and (2) in this case. Such insensitivity of the absorption spectrum of fullerenes at λ = 335 nm to the solvent is observed only for dilute solutions, whereas for λ = 472 nm it is also observed in substantially more concentrated solutions.

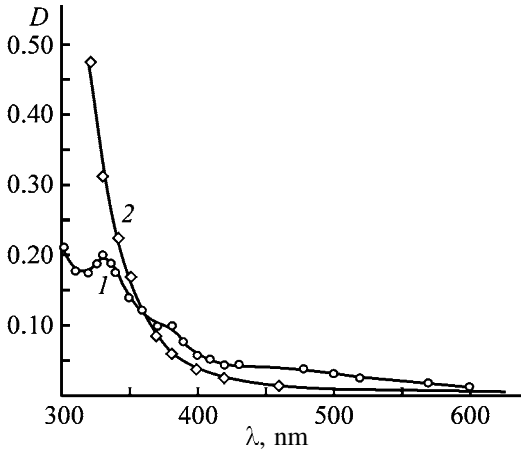

Fig. 2. Optical spectra of (*1*) the mixture enriched in higher fullerenes (C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%) in HICA and (*2*) HICA. Fullerene concentration 0.168 g l^{-1}, dilution with *o*-xylene 1 : 51, reference solution: HICA in *o*-xylene with the same dilution. HICA in *o*-xylene (dilution with *o*-xylene 1 : 21, comparison solution is *o*-xylene).

The measured polytherms of fullerene solubility in HICA are shown in Figs. 3a–3c.

The curve of C_{60} solubility in HICA (Fig. 3a) is characterized by the initial sharp increase in the solubility followed by gradual saturation. Such type of the solubility polytherm shows that in this case nonsolvated fullerene C_{60} is the equilibrium solid phase [8].

The curve shape in Fig. 3b is characteristic for C_{70} (monotonic increase in the solubility) and is in good agreement with reference data [8] on solubility polytherms in solutions in *o*-xylene, toluene, and CS_2.

An attention is paid to lower solubility of C_{60} as compared to C_{70} (by a factor 3) in HICA, which is caused by higher polarizability of the latter due to lower symmetry of the molecular structure. Let us consider the character of intermolecular interactions in the HICA–C_{70} system. In this case, only induction and dispersion components contribute to the intermolecular interactions (polar molecular–nonpolar molecule) [19]: $U(r) = U_{ind} + U_{disp}$. The dispersion forces appear due to fast fluctuations of the electron density in the molecule, inducing an electric moment in the neighbouring molecule; this results in interaction between atoms. Induction forces are caused by polarization of C_{70} molecule in the electric field of the HICA molecule having a permanent dipole moment. As a result, the method for the prechromatographic separation of fullerenes, based on the above-found difference in the solubility of the individual fullerenes, can be suggested.

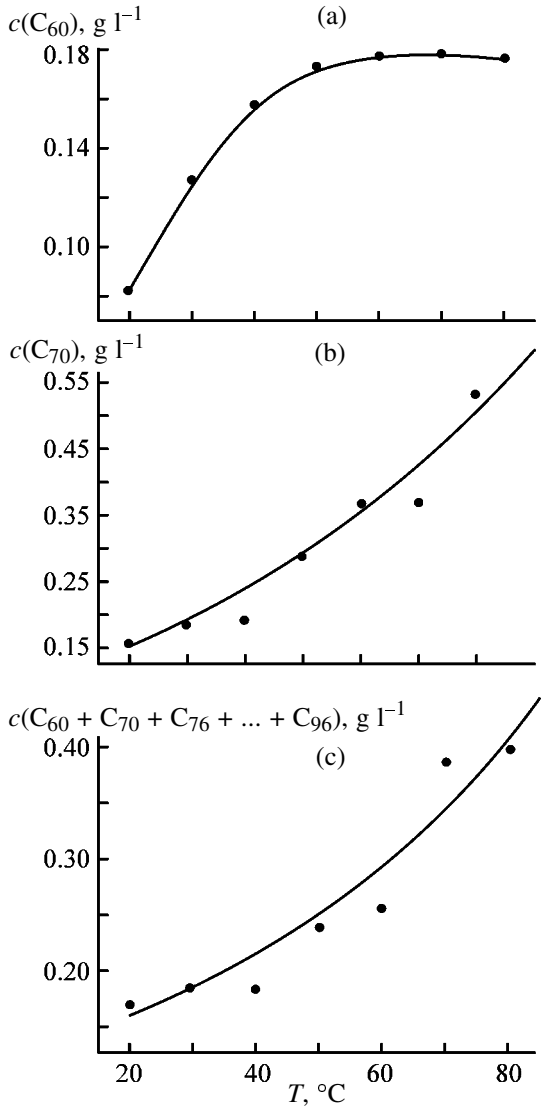

Fig. 3. Polytherm of solubility in HICA of (a) C_{60}, (b) C_{70}, and (c) C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%. (*c*) Fullerene concentration and (*T*) temperature.

CONCLUSIONS

(1) Solubility polytherms of fullerenes C_{60} and C_{70} and of the mixture containing C_{60} 38.8, C_{70} 33.0, $C_{76–78}$ 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3% in a mixture of higher isomeric carboxylic acids were measured and characterized within the 20–80°C temperature range.

(2) Comparatively high solubility of light fullerenes in higher isomeric carboxylic acids was found. It monotonically increases with temperature to ~0.5 g per liter of acid at 80°C.

(3) Suitability of higher isomeric carboxylic acids

as solvents in prechromatigraphic separation of light fullerenes was demonstrated.

Abstract—Equilibrium vapor pressure of water over mechanically and chemically treated cellulose is determined by the effusion method at 298, 303, and 308 K. Thermodynamic characteristics of water desorption from cellulose are determined.

DOI: 10.1134/S1070427207010089

Currently a great body of experimental data has been gained on the interaction of cellulose with water [1–5]. It is commonly accepted that only amorphous domains in the cellulose structure are involved in this interaction. Furthermore, the thermodynamic state of sorbed water differs from that in the bulk of the liquid, which is reflected in, e.g., decrease in the diffusion coefficient, spin–spin relaxation time, and freezing temperature [6]. This difference was also confirmed by the model calculations of the structure and properties of water in thin layers and small volumes [7]. It was demonstrated that the change in the characteristics of water in limited volumes is caused primarily by rearrangement of the hydrogen bonds. In small pores and capillaries (<50 Å in diameter), water cannot take the structure typical of bulk liquid water. The computer simulation data [7] show that, in thin films with a thickness well comparable with the diameter of the water molecules, disjoining pressure oscillations occur, playing the role of a hydration pump.

Cellulose-bound water may considerably influence the properties of cellulose-based materials, e.g., medical products. Therefore, it is important to know how various methods of mechanical treatment (crushing) influence the sorption properties of cellulose, what amount of water is sorbed or desorbed at various relative humidities and temperatures, and, at last, what is the thermodynamic state of cellulose-bound water in relation to the moisture content.

The goal of this study is to develop an accurate and time-saving method for determination of the equilibrium water vapor pressure over cellulose.

EXPERIMENTAL

Desorption of water from mechanically and chemically treated cellulose was studied using the effusion technique. Sulfite cellulose [TU (Technical Specifications) 5411-003-0025-3497–94] was mechanically treated on an extruder or shock-reset machine. The chemical treatment involved hydrolysis of cellulose for 2 h at 365 K in 10% HNO_3. As known, using the effusion technique, desorption isotherms of solvents can be obtained over the entire range of the relative vapor pressure at low time consumption. In this study, this technique was used to examine water desorption from cellulose materials.

Determination of the vapor pressure by the Knudsen's effusion technique is based on measuring the vapor effusion rate from a cell to a vacuum through an orifice in the membrane [8]. A great diversity in design characteristics of the existing effusion installations originates from a wide spectrum of research objectives. In our case, the design criteria were maximal simplicity and availability of equipment in combination with high precision and reproducibility of results. The experimental effusion installation was designed on the platform of a VOU-1A vacuum unit providing the residual pressure in the system no higher than 1×10^{-4} mm Hg. A cylindrical effusion cell (4 cm^3 in volume) was placed in an electric furnace. The temperature of the cell was controlled to within 0.1 K using a thermocouple assembly and a TRM-34 double-circuit thermoregulator. Additionally, the effusion cell was equipped with an electromagnetic valve hermetically closing the effusion hole until the desired temperature was attained. A cellulose sample (~100 mg), vacuum-dried at 338–343 K to constant weight, was wetted in a glass ampule with a small portion of distilled water (on the basis of 500 mg of water per gram of cellulose) and placed in the effusion cell. The cell was hermetically sealed, weighed, and allowed to stand in an air bath oven at the temperature of the

planned effusion experiment for at least 24 h. The cell was placed in a furnace heated to the desired temperature; the system was evacuated and allowed to stand at the preset temperature for at least 120 min. Then the orifice was opened, and the effusion experiment started. After completion of the experiment, the orifice was closed; the system was filled with air, and the ampule with the sample was weighed again. From the weight loss, effusion time, and temperature, we estimated the vapor pressure by the Knudsen equation:

$$P_k = (\Delta m/\alpha\beta S_h\tau)(2\pi RT/M)^{1/2}, \quad (1)$$

where Δm is the weight loss through effusion; α, condensation coefficient; S_h, orifice area; β, Clausing coefficient characterizing the resistance to mass transfer; τ, effusion time; R, gas constant; T, temperature; and M, molecular weight of the substance.

Following [9, 10], we used naphthalene and benzoic acid as reference compounds. The requirements to reference compounds for calorimetry of vaporization (availability, usability, high purity, and safety) essentially coincide with those to reference compounds for calorimetry of other processes such as combustion and dissolution. However, in calorimetric study of vaporization, it is needed to have quite a set of such compounds with the vapor pressures ranging over a broad interval, insofar as the fact that the method provides accurate results in a certain temperature range by no means guarantees the same accuracy over another temperature range. Many researchers prefer naphthalene, because, like other aromatic compounds, it can be quite easily purified using such methods as recrystallization, sublimation, zone melting, directional crystallization, and chromatography. Using these methods allows reduction of foreign impurities, e.g., anthracene, by several orders of magnitude. Benzoic acid is also often used as a reference. It was recommended by IUPAC, as having well-defined and reproducible melting and evaporation points.

In this study, benzoic acid (mp 395.5 K) and naphthalene (calorimetrically pure grade, mp 353.43 K) were further purified using fractional sublimation in a high vacuum. The middle fraction was used for making calibrations. Calibration with naphthalene was carried out over the temperature range from 298 to 318 K at an effective orifice area ($S_{eff} = \beta S_h$) of 2.21×10^{-7} and 2.7×10^{-8} m^2; and by benzoic acid, from 323 to 348 K at S_{eff} 8.48×10^{-7} and 2.21×10^{-7} m^2. We used a specially designed tool, which allowed making regularly round-shaped effusion holes up to 0.01 mm in diameter in 0.1-mm Al foil. The orifice areas were measured microscopically at a magnification of 200. The Clausing coefficient β was estimated as recommended in [8]. The experimental heats of sublimation of naphthalene and benzoic acid (72.4 ± 0.6 and 89.8 ± 0.7 kJ mol^{-1}, respectively) were well consistent with the recommended values [9, 10].

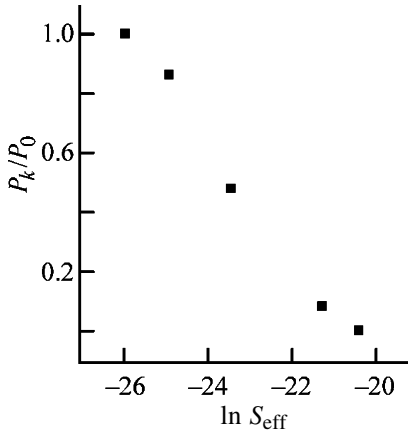

Fig. 1. Water vapor pressure in the Knudsen cell as a function of the effective area of the effusion hole ($S_{eff} = \beta S_h$) at 298 K. (P_k) Vapor pressure estimated by the Knudsen equation (1) and (P_0) saturated vapor pressure at 298 K.

Despite the advantage of the effusion technique, as a time-saving method, over, e.g., the isopiestic method, it has some limitations. It is well known that the applicability of the effusion method is limited to a pressure of 10 Pa and an effusion hole radius of 1 mm. This is caused by the fact that the condition of molecular flow is met if the free path of the molecules in the effusion cell significantly exceeds the hole diameter. However, there are examples in the literature for the application of the effusion technique to measuring pressures considerably exceeding 10 Pa. In these cases, various corrections should be introduced to take into account the deviation from the molecular flow mode. Furthermore, it was demonstrated in [8, 9] that, at a sufficiently small diameter of the effusion hole, all the limitations of the method, originating from the effusion mode deviation from the molecular flow, are eliminated; the condensation coefficient α becomes equal to unity, and the measured vapor pressure no longer depends on the effusion hole area and can be accepted equal to the true saturated vapor pressure.

Figure 1 shows the water vapor pressure estimated by the Knudsen equation (1), as influenced by the effusion hole size (at $\alpha = 1$). As seen, with decreasing orifice area, the estimated vapor pressure approaches the true value. Therefore, for the effusion cell used in this study, the estimated water vapor pressure corre-

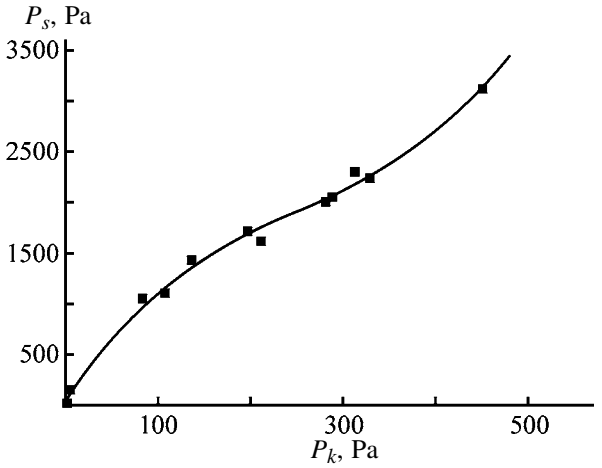

Fig. 2. Calibration curve for determination of the true water vapor pressure P_s from the experimental P_k values obtained using the effusion technique at 298 K.

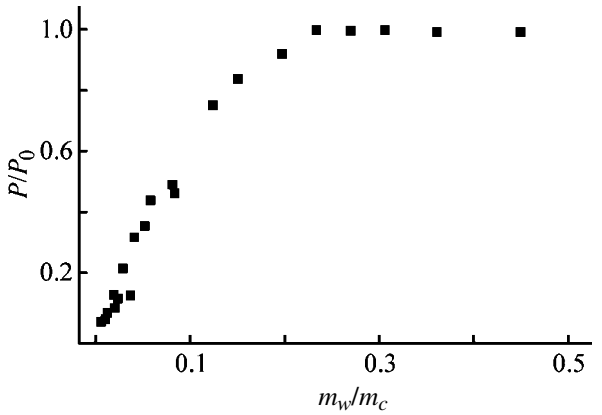

Fig. 3. Primary data obtained in the effusion experiment on desorption of water from cellulose sample I at 298 K. (m_w/m_c) Water content in cellulose and (P/P_0) relative vapor pressure of water.

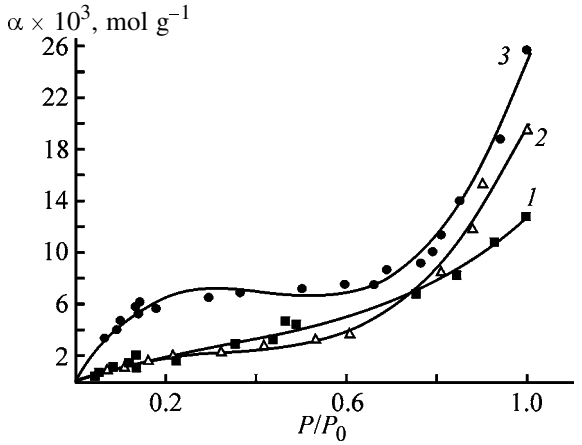

Fig. 4. Water desorption isotherms from cellulose samples (*1*) I, (*2*) II, and (*3*) III at 298 K. (a) Equilibrium sorption of water on cellulose and (P/P_0) relative vapor pressure of water; the same for Fig. 5.

sponds to the true value at a hole diameter of about several hundredth parts of millimeter and smaller. At such a small size of the effusion hole, the sensitivity of the method, and, therefore, its accuracy, decrease.

Therefore, there are certain difficulties in using the effusion method for studying water desorption over a wide pressure range. First, the correction factors used to take into account the deviation from the molecular flow mode are empirical, being dependent on the investigated system and the design of the effusion cell. Second, decrease in the orifice area results in deterioration in the sensitivity and accuracy of the method. Third, as will be demonstrated below, in the system in hand, the condensation coefficient α is pressure-dependent, so that its application becomes questionable in our case. To obviate complications inherent in the effusion method in the range of high relative water pressures, employing all the advantages of the method in measuring low pressures, we acted as follows. We prepared aqueous solutions of sulfuric acid of various concentrations and measured the water vapor pressures over these solutions using the effusion method (effective orifice area 8.206×10^{-10} m^2). The results were used to construct calibration curves coupling the vapor pressure obtained by the Knudsen method P_k with the true water vapor pressure P_s corresponding to a given concentration of sulfuric acid [11]. An example of such a calibration curve, obtained at 298 K, is presented in Fig. 2. As seen, this is not a straight line, but a curve which can be extrapolated by a third-order polynomial with a correlation factor of 0.995. The calibration curves obtained at 303 and 308 K are similar. Even at low pressures, the curve deviates from linearity, and, as the pressure increases, the function P_s vs. P_k becomes much more complex, which can be attributed to alteration in the vapor flow mode from the effusion hole.

Using the above procedure, we obtained desorption isotherms of water from the cellulose samples at 298, 303, and 308 K. The water vapor pressure was determined to within 10%. Figure 3 shows the primary data obtained in the effusion experiment and then used for construction of the desorption isotherms. In the experiment, we determined the water vapor pressure over a cellulose sample wetted with water. The moisture content in cellulose, at which the equilibrium vapor pressure P started to deviate from the saturated vapor pressure P_0 at a given temperature (in other words, when P/P_0 started to deviate from 1), corresponded to the maximal sorption of water on cellulose.

Figure 4 shows the water desorption isotherms from cellulose treated mechanically using an extruder

(sample I) or shock-reset machine (II), or chemically with dilute HNO_3 (III). For comparison, Fig. 5 shows the water desorption isotherms from sample I, obtained at 298 K using both the effusion and isopiestic (sample is kept in a desiccator at a fixed humidity) methods. The isopiestic experiments were carried out over the relative vapor pressure range P/P_0 = 1–0.0003. A cellulose sample of about 100 mg, vacuum-dried at 338–343 K to constant weight, was brought into the isopiestic equilibrium with aqueous sulfuric acid of a fixed concentration, for which the water vapor pressure over the solution is known [11]. The experiment was carried out in an air bath oven. The temperature was controlled to within 0.1 K. The equilibration time was from 7 to 21 days. The amount of sorbed water was determined gravimetrically. The same method was used to control the equilibrium conditions in the system.

The results obtained by both methods are in satisfactory agreement, even though the isopiestic method gives slightly overestimated values for water sorption, particularly, in the range of low relative pressures, which is probably due to longer time required for establishment of the sorption equilibrium in the isopiestic experiments. Previously we studied the equilibrium in the system water–cellulose using an MI-1201 mass spectrometer modified for performing effusion experiments [12]. Data on the H_2O^+ intensity in the mass spectrum suggested that, in the effusion experiment, the time required for establishment of the equilibrium is 90–120 min, depending on the moisture content and temperature of cellulose samples.

The dependence of the relative water vapor pressure at a given sorption value on the reciprocal temperature was then used to estimate the thermodynamic parameters of water desorption by the Clapeyron–Clausius equation (2)

$$[\ln(P/P_0)]_a = -A/T + B, \qquad (2)$$

where P/P_0 is the relative water vapor pressure corresponding to the given sorption of water a at the temperature T; $A = \Delta H_{des}/R$ and $B = \Delta S_{des}/R$ (ΔH_{des} and ΔS_{des} are the enthalpy and entropy of desorption); and R, gas constant.

The enthalpies and entropies of desorption of water from the cellulose samples are presented in Figs. 6a and 6b. The heat effects of water desorption from cellulose samples II and III at low sorption values are about 10–20 kJ mol^{-1}, decreasing to zero with increasing sorption, which is typical of the cellulose–water system. In this case, the entropy of the system is practically independent of the amount of sorbed water, differing only slightly from zero, suggesting that the interaction in the system is accompanied by ordering of the water molecules and disordering of the cellulose segments. Sample I stands out against a background of the other samples. For sample I, the enthalpy of water desorption at low sorption is about

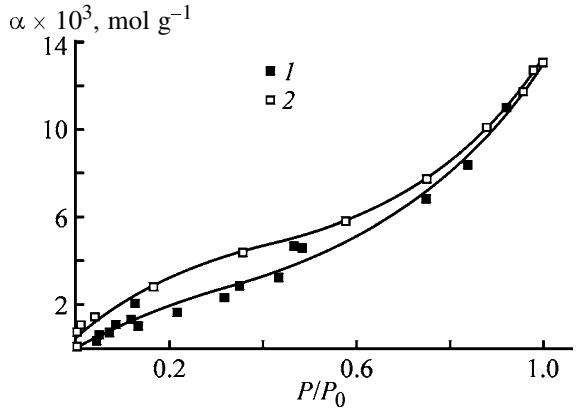

Fig. 5. Water desorption isotherms from cellulose sample I, obtained by (*1*) effusion and (*2*) isopiestic methods.

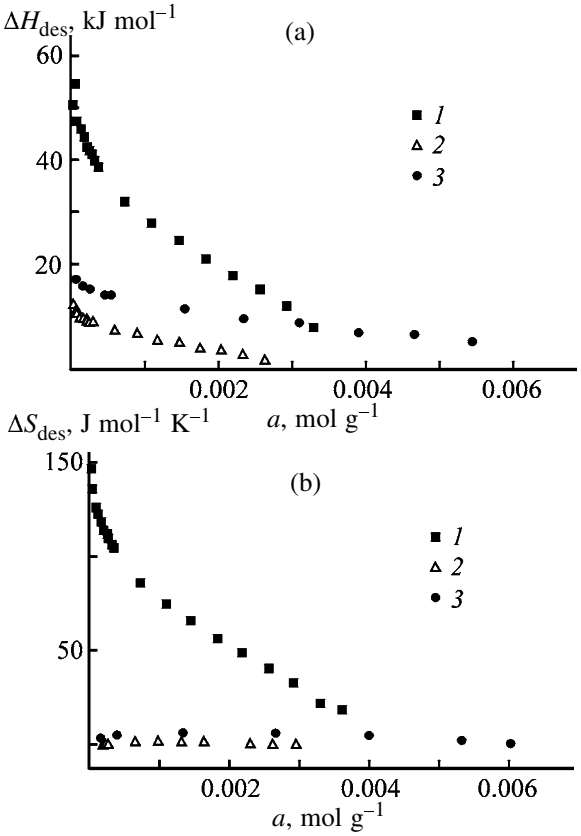

Fig. 6. (a) Enthalpy and (b) entropy of water desorption from cellulose samples (*1*) I, (*2*) II, and (*3*) III. (ΔH_{des}) Enthalpy and (ΔS_{des}) entropy of water desorption from cellulose, and (*a*) equilibrium sorption of water on cellulose.

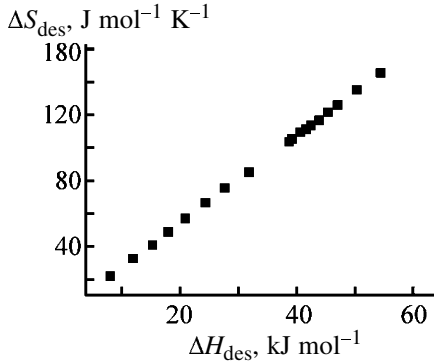

Fig. 7. Thermodynamic compensation effect in water desorption from cellulose sample I. (ΔH_{des}) Enthalpy and (ΔS_{des}) entropy of water desorption from cellulose.

55 kJ mol^{-1}, and the entropy of desorption changes in parallel to the enthalpy, i.e., the thermodynamic compensation effect takes place here (Fig. 7).

The compensation or isokinetic theory is widely used in physicochemical research. According to this theory, the enthalpy–entropy compensation originates from changing nature of the solute–solvent interaction due to a specific reaction, the relationship between the enthalpy and entropy being linear. Aguerre [13] applied this approach to the study of sorption of water on foodstuffs. He derived an equation relating the equilibrium sorption of water to its activity and the temperature, and demonstrated a linear correlation to occur between the enthalpy and entropy for a series of foodstuffs. It was demonstrated also that the penetration of water across the grape peel is a rate-controlling stage of drying, i.e., the resistance to water loss is provided primarily by the cell membrane [14]. The water loss can be decelerated through optimization of the storage conditions (temperature and humidity).

It may be suggested from the observed abnormally high heat effects of water desorption from sample I in combination with the thermodynamic compensation effect that the interaction of water with this sample differs from that with other samples. Among the reasons could be chemical interaction of water with some impurities introduced into cellulose during pretreatment, changing number of hydration centers and characteristics of the micropores; transformation of the crystalline domains, etc. By now we cannot fix the key factor. Nevertheless, the study of the conditions and factors controlling water desorption from cellulose is of crucial importance. In studying the water sorption on cellulose materials, it is necessary to take into account the history of the sample. There is no doubt that data on the equilibrium sorption of water are significant for optimization of drying and storage of foodstuffs and medical products. In this context, the effusion technique shows promise as an express method for characterization of desorption of water as well as other solvents.

CONCLUSIONS

(1) With precision calibration systems, the effusion method can be used for determination of the equilibrium water vapor pressure over cellulose.

(2) The experimental isotherms of water desorption from cellulose, obtained by the effusion method, are well consistent with those obtained using the isopiestic technique.

(3) Determination of the equilibrium water vapor pressure at various temperatures using the effusion method allows estimation of the thermodynamic characteristics of water desorption from cellulose.

Abstract—The sorption of organic dyes of various molecular weights (from 100 to 700 amu) from aqueous solutions on minerals and on sea and lake bottom sediments was studied.

DOI: 10.1134/S1070427207010090

In the modern stage of development of human society, various aspects of human health are closely associated with the environmental problems. There is no doubt that the environmental pollution and deterioration of food and drinking water negatively affect the human health. Therefore, an urgent problem is the development of techniques allowing the elimination of these detrimental effects. One of approaches to solution of this problem is based on detoxication of human body by introducing specific sorbents ensuring its inner ecological purity (endoecological purity).

One of promising directions in the modern environmental science is the development of techniques for sanitation of human body by introduction of specific sorbents recovering toxic, ballast, and potentially detrimental compounds of endogenic and exogenic kinds. High-performance biocompatible sorbents based on polymeric materials are successfully used today for medical treatment of human body [1–3]. These medical sorbents include various carbon materials [1–9]. Activated carbons are used as application materials stabilizing the growth of tumor cells [8] and accelerating the healing of infected wounds, burns, and chilblains [2, 8, 10].

Recently the market of medical and cosmetic application materials was replenished owing to appearance of new biologically active dispersed minerals and other compounds taken from bottom sediments of the Black and Azov seas. These materials were found to contain the specific natural curative organomineral complex. The preparation of new domestic medical compositions based on these raw materials and development of effective techniques for their production is an urgent problem.

In this study we examined the sorption of organic dyes simulating the exo- and endogenic organic pollutants on clay minerals and bottom sediments collected from the Black Sea at different depths (200–2100 m) and also from limans and lakes located in the southern Ukraine.

The sorption power and selectivity of sorbents for organic pollutants are mainly determined by the size ratio of sorbent pores and organic pollutant molecules whose size, in turn, correlates with their molecular weight [10, 11].

It is known that the molecular weight of toxic organic compounds varies within a broad interval from several hundreds to tens thousands atomic units [12]. Therefore, purposeful choice of the optimal enterosorbent for removing particular organic pollutant from a living body requires understanding of correlation between the sorption power of the sorbent and the pollutant molecular weight.

EXPERIMENTAL

Since enterosorption is usually applied for detoxication of human body poisoned with organic compounds with the molecular weight below 1000, in our experiments we tested as simulating compounds organic dyes with the molecular weight (*MW*) from 100 to 700.

The sorption of organic dyes (Methylene Blue, *MW* = 320; Methyl Orange, *MW* = 324; Methyl Violet, *MW* = 410; Orange-Yellow, *MW* = 450; Bromocresol Purple, *MW* = 540; Bromphenol Blue, *MW* = 670; Congo Red, *MW* = 700; and creatinine,

Structural and sorption characteristics of bottom sediments of various origins

Sample no.	Sampling site	Sorption of nitrogen, $cm^3\ g^{-1}$	S_{sp} by N_2 sorption, $m^2\ g^{-1}$	Pore radius, Å	S_{mi}, $m^2\ g^{-1}$	V_{mi}, $cm^3\ g^{-1}$
1	Kuyal'nitskii liman, Odessa	36	36	20; 30	22	0.08
2	Lake Velikoe, Berdyansk	32	11	20	11	0.01
3	Station 5795, Black Sea bottom	14	20; 35	11	11	0.02

MW = 113) from aqueous solutions was studied under static conditions. The dye concentration in the solutions ranged from 0.1 to 1.5 $g\ l^{-1}$. The ratio of solid and liquid phases was 1 : 150. The initial and equilibrium dye concentrations were determined on a KFK-3 photocolorimeter. The creatinine content was determined on an SF-16 spectrophotometer.

The natural materials used as enterosorbents were as follows: minerals palygorskite and vermiculite and three samples of bottom sediments with different specific surface areas S_{sp} taken from the Black Sea, Kuyal'nitskii liman, and Lake Velikoe (see table).

The pore structure of the bottom sediments under consideration was studied with a NOVA 2000 E high-performance gas analyzer. In these experiments, the low-temperature sorption and desorption isotherms of nitrogen were obtained at 77 K and the pore size distribution was calculated. The specific surface area, micropore surface area S_{mi}, micropore volume V_{mi}, and pore radius r (Å) were calculated by the BET technique (MULTI POINT, BET, BJH etc.) with the correlation factor of 0.999.

Figure 1a shows the sorption and desorption isotherms of nitrogen plotted as A (specific sorption) vs. P/P_s (relative vapor pressure). The integral distribution of the pore volume with respect to pore radii for the sample of liman bottom sediments is shown in Fig. 1b. Our results listed in the table indicate that the tested samples of the liman, sea, and lake bottom sediments are microporous materials. Their pores have the size of about 20 Å, the specific volume of micropores of 0.01–0.08 $cm^3\ g^{-1}$, and the micropore surface area S_{mi} of 11–36 $m^2\ g^{-1}$. The sorption of dyes of higher molecular weight (Congo Red and Methyl Violet) was studied on palygorskite and vermiculite having more developed surface structure [13]. The sorption isotherms of organic dyes on palygorskite and vermiculite are shown in Figs. 2a and 2b. Figures 3a and 3b show the sorption of organic dyes on bottom sediments. It is seen that sorption of dyes on clay minerals (Figs. 2a and 2b) significantly depends on their molecular weight. This effect is apparently caused by the fact that the accessibility of the sorbent pore volume for dye molecules depends on their size. This hypothesis is consistent with the sorption isotherms of Methylene Blue on bottom sediments

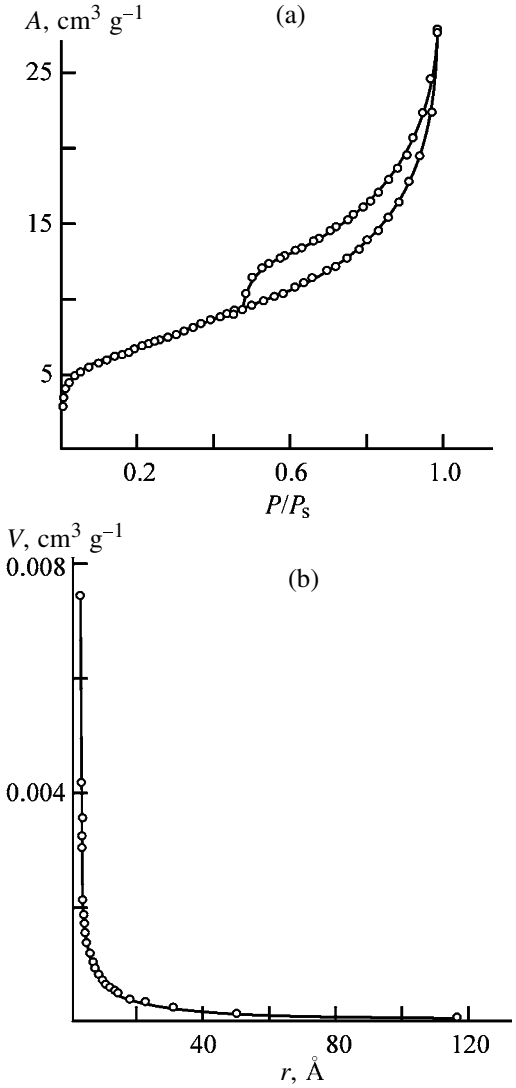

Fig. 1. (a) Sorption and desorption isotherms of nitrogen on sample no. 1 at 77 K and (b) the integral distribution of the pore volume V with respect to the pore radii for sample no. 1. (P/P_s) Ratio of the equilibrium pressures of sorbed and liquid nitrogen at 77 K. (A) Specific sorption of nitrogen.

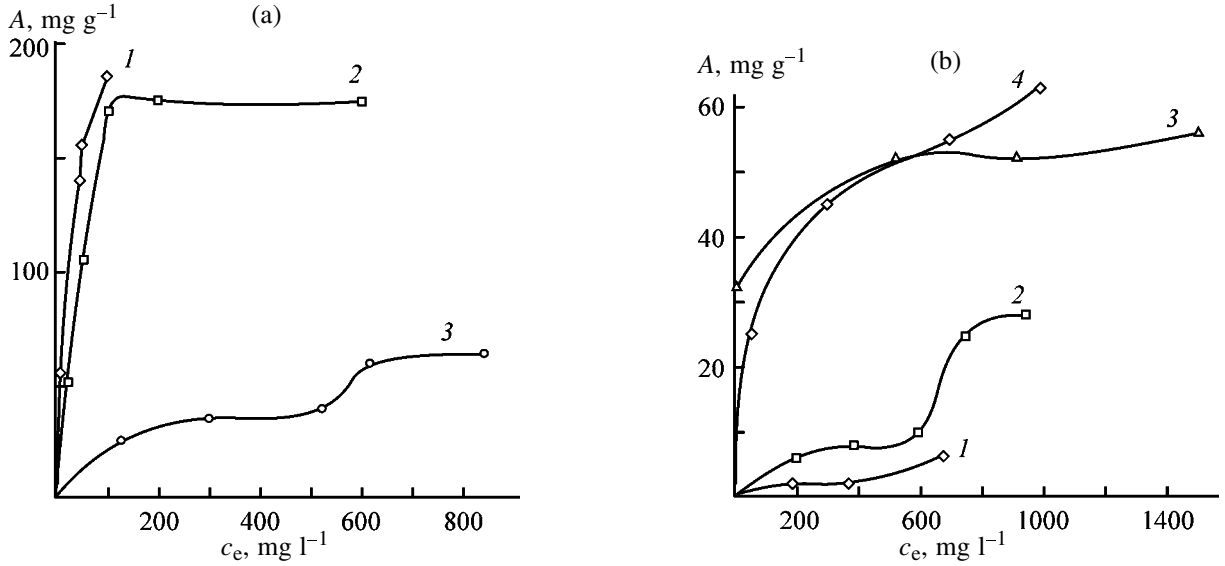

Fig. 2. Sorption isotherms of organic dyes from aqueous solutions on (a) palygorskite and (b) vermiculite. (*A*) Dye concentration in the sorbent; (c_e) equilibrium dye concentration in the aqueous phase; the same for Fig. 3. Dyes: (a) (*1*) Methylene Blue, (*2*) Methyl Violet, and (*3*) Congo Red; (b) (*1*) Bromophenol Blue, (*2*) Congo Red, (*3*) Methyl Violet, and (*4*) Methylene Blue.

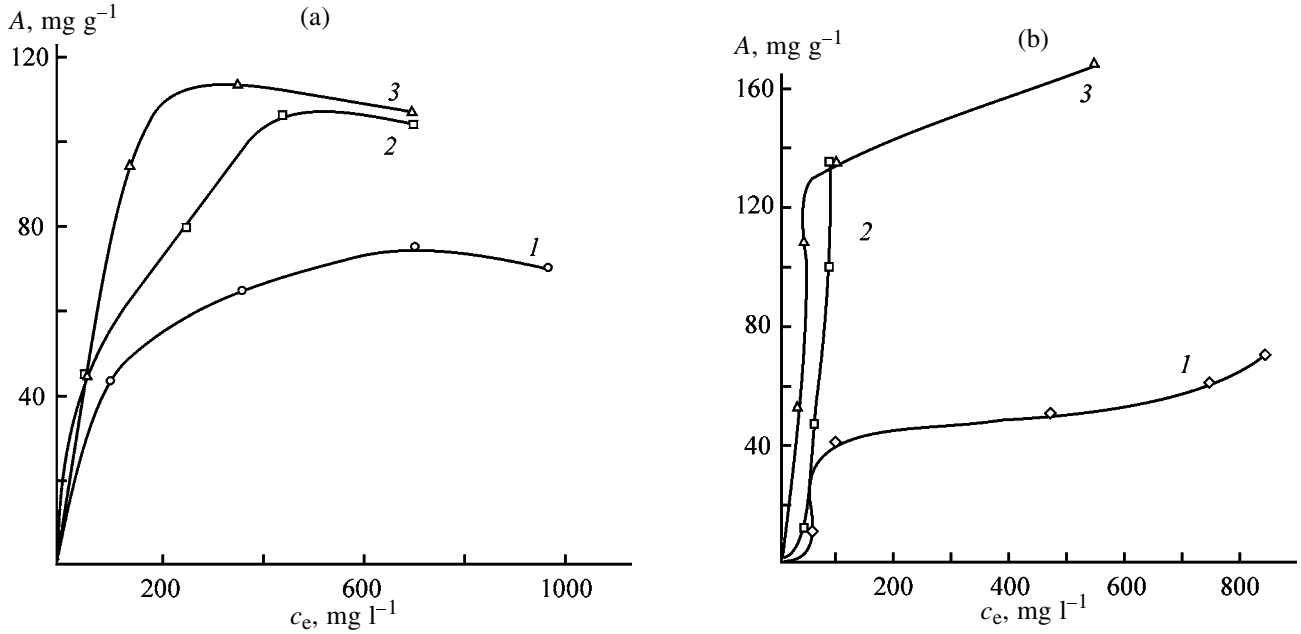

Fig. 3. Sorption isotherms of (a) Methylene Blue and (b) Methyl Orange from aqueous solutions on bottom sediments. Bottom sediments (see table): (*1*) no. 3, (*2*) no. 2, and (*3*) no. 1.

(Fig. 3): in going from liman bottom sediments (sample no. 1, S_{sp} = 36 $m^2 g^{-1}$) to sea bottom sediments (sample no. 3, S_{sp} =14 $m^2 g^{-1}$), the sorption of Methylene Blue decreases by a factor of approximately two. The pattern of sorption of creatinine was similar.

The sorption isotherms show that the specific sorption of dye *A* on bottom sediments decreases with decreasing its concentration in the aqueous phase. However, even at low concentrations of the dye in the aqueous solution, comparable with the content of an organic toxicant in a poisoned organism, the bottom sediments ensure sufficiently effective sorption of dyes.

The experimental values of sorption *A* allow calculation of the distribution factor K_d (ml g^{-1}) of dye between the sorbent and aqueous solution, which is determined as the ratio of the dye concentration in the sorbent to its equilibrium concentration in the aqueous

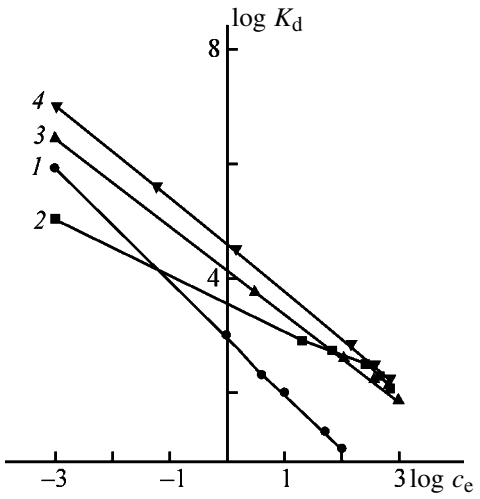

Fig. 4. The log–log plot of the distribution factors K_d of organic dyes between the sorbent and aqueous solutions vs. the equilibrium concentration of dyes in the aqueous solution. Sorbents: (*1*) palygorskite, (*2*) sample no. 3, (*3*) sample no. 2, and (*4*) sample no. 1 (see table).

phase. In other words, the distribution factor is equal to the equilibrium sorbate volume that contains the sorbate (dye) in the amount equal to its content in 1 g of the sorbent at equilibrium.

Figure 4 shows the plots of $\log K_d$ vs. $\log c_e$ in sorption of the dyes on palygorskite and bottom sediments under consideration. Taking into account that the maximal permissible concentration of stable organic pollutants in a human body is approximately 10^{-3} mg l^{-1} ($\log c_e = -3$), the mutual arrangement of straight lines in Fig. 4 allows us to expect that the detoxication efficiency of the sorbents under consideration for organic pollutants will increase in the order sample no. 3 < palygorskite < sample no. 2 < sample no. 1. The distribution factors of dyes between aqueous solution and sorbents are as large as several hundred thousands, i.e., these sorbents can be used as antidotic and neutralizing components of medicinial preparations and food additives.

The mechanism of sorption of dyes is sensitive to the sorbent kind. For example, palygorskite sorbs dyes owing to the large surface area of colloid clay particles (100 m^2 g^{-1}). In sorption on bottom sediments, the dye molecules are accommodated in pores whose size changes in the course of sorption due to swelling [14] and increase in the interplanar spacings [13].

The considered mechanisms of fixation of dyes ensure strong immobilization of organic pollutants on the sorbents concerned. Therefore, these natural materials can be used as enterosorbents suitable for treating human body to remove organic pollutants.

The sorption power of the sorbents under consideration is dependent on the organic pollutant concentration in the aqueous solution. For example, activated carbon better sorbs organic pollutants from their concentrated solutions (1–100 mg l^{-1}) [15, 16]. On the contrary, the clay mineral palygorskite and bottom sediments better sorb organic pollutants at their low (<1 mg l^{-1}) and ultralow (<10^{-2} mg l^{-1}) concentrations. In these systems, the distribution factor of Methylene Blue reaches 100 000 ml g^{-1}. These results suggest that activated carbons in combination with bottom sediments can be used as a food additive accelerating the removal of organic toxins from living body subjected to poisoning due to prolonged nega- tive environmental impacts and technogenic disasters.

CONCLUSIONS

(1) The sorption of organic dyes on sea and lake bottom sediments and also on minerals palygorskite and vermiculite was studied in relation to the organic dye molecular weight.

(2) The decrease in sorption of organic dyes with an increase in their molecular weight is caused by microporous structure of sorbents.

(3) At low and ultralow concentrations of dyes in aqueous solutions (1–10^{-2} mg l^{-1}), they are sorbed by mineral sorbents and bottom sediments most efficiently.

(4) The clay minerals sorb organic dyes with the distribution factors reaching several hundred thousands and therefore show much curative promise.

Abstract—Sorption of Cu(II), Pb(II), Cd(II), and Zn(II) from aqueous solutions on two-component organosilicas was studied as influenced by sorbent composition, contact time, ratio of solid and liquid phases, solution pH, nature and concentration of heavy metal ions, and content of modifying agent. The degrees of sorption of these metal ions from aqueous solutions using organosilicas modified with aluminum(III) added into the siloxane matrix or with copper(II) grafted to the sorbent surface layer were compared.

DOI: 10.1134/S1070427207010107

Deterioration of the environment in both East and West Europe owing to anthropogenic factors and ecological accidents and disasters puts forward a requirement of treatment of aquatic media to remove inorganic ecological toxic agents (heavy metals). Among heavy metals, ions of copper(II), lead(II), cadmium(II), and zinc(II) whose toxicity increases in the order Cu(II) < Zn(II) < Pb(II) < Cd(II) [1] are of particular importance. It is known that silica-containing natural sorbents (clays, zeolites, aluminosilicates [2–5]) and synthetic sorbents (silica gel and its modified forms [6]) are used in water treatment to remove heavy metal ions. However, certain drawbacks are typical for these materials: nonselective sorption, insufficient efficiency of sorption of various heavy metal ions in the wide pH range, and, hence, relatively narrow range of their operation. Low maximum permissible concentrations (MPCs) of heavy metals and their ability to form complexes with organic compounds put forward certain requirements to the disperse sorption materials for treatment of aqueous and aqueous salt solutions to remove heavy metals. These requirements are as follows: selectivity of sorption by modification with metal ions, which increases the number of active ion-exchange and complexing centers on the sorbent surface, nontoxicity of sorption materials, their stability in a wide pH range, presence of various functional organic groups that interact with heavy metal ions, etc.

As compared to modern silica-containing sorbents used in water treatment to remove heavy metals, two-component organosilica sorbents (silicopolymethylsiloxanes) have certain advantages such as rigidity of the polymeric skeleton, insolubility in water and organic solvents, and chemical stability in aqueous and aqueous salt solutions at pH changing from 1 to 9. The surface silanol ≡Si–OH and methylsilyl ≡Si–CH_3 groups in two-component organosilica sorbents act as centers of specific adsorption of both molecular and ionic compounds [7]. It should be noted that the data on recovery of heavy metals from solutions using organosilica sorbents are scarce and nonsystematic. Voronkov et al. [8] showed that complexing sulfonic silicopolymethylsiloxanes are fairly efficient in treatment of potable and waste waters to remove heavy metal ions at pH 1–3. Chen et al. [9] estimated the sorption capacity for Sb(III), Bi(III), and Ag(I) of ion exchangers with organosiloxane structure, which are hydrolytically stable in the acidic medium.

In this work we studied the degree of recovery of heavy metal ions from aqueous solutions as influenced by various metal ions added to modify the structure of silicopolymethylsiloxanes.

As organosilica sorbents (OSs) we used silicopolymethylsiloxanes with various ratios of the silanol and methylsilyl groups (wt %), namely, 30 : 70 (OS-30), 50 : 50 (OS-50), and 70 : 30 (OS-70), and also their forms modified with metal ions: OS-30(Al), OS-30(Al,Cu), OS-50(Cu), OS-70(Cu), with the content of copper and aluminum differing by a factor of 2 (1.6 and 3.2 g g^{-1}, respectively). Various methods were used to introduce metal ions into the organosilica structure. For example, aluminum was incorporated in

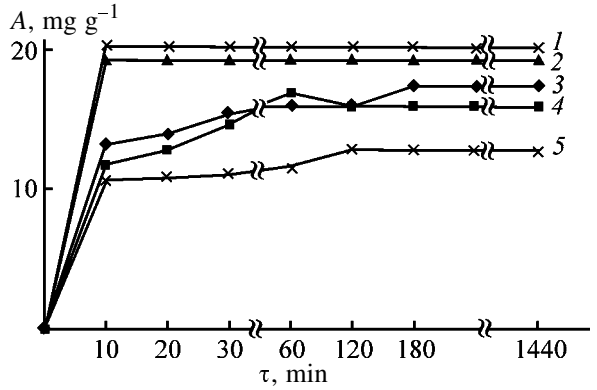

Fig. 1. Kinetic curves of sorption *A* of heavy metal ions on (*1–4*) OS-30(Al) and (*5*) OS-50 sorbents from aqueous solutions; c_{in} = 200 mg l^{-1} and s : l = 1 : 100; (τ) contact time. (*1, 5*) Pb(II), (*2*) Cd(II), (*3*) Cu(II), and (*4*) Zn(II).

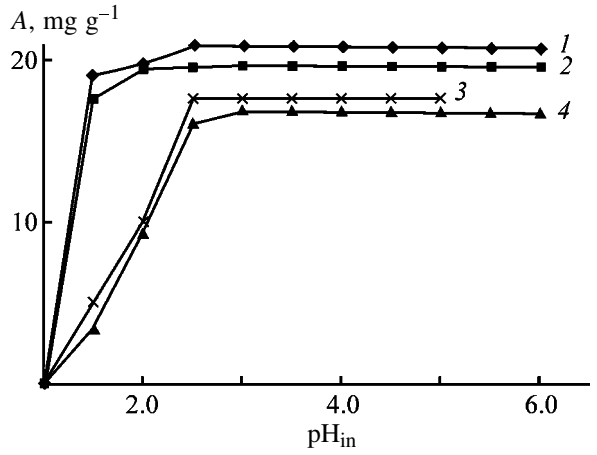

Fig. 2. Sorption *A* of heavy metal ions on OS-30(Al) sorbent as influenced by pH_{in} of the aqueous solutions; c_{in} = 200 mg l^{-1}, s : l = 1 : 100, τ = 3.5 h. (*1*) Pb(II), (*2*) Cd(II), (*3*) Cu(II), and (*4*) Zn(II).

the siloxane chain in the stage of coprecipitation of the initial sodium silicate and methylsiliconate in the course of organosilica synthesis [10]. The silica surface was modified with copper(II) by its contact with a solution of copper ammoniate using the procedure given elsewhere [11]. The structural and sorption characteristics of the resulting complexes (specific surface area and sorption pore volume for benzene and water) were determined using a Nova-2200E device (Guantachrom Corp.) and by a gravimetric procedure. The solution acidity and suspension pH were recorded with a 150M pH-meter, and pH of the surface zero charge was measured by the published procedure [12]. The content of the heavy metal ions in aqueous solutions before and after sorption was determined by atomic-absorption analysis on a C-115MT spectrophotometer using the supplied PC software. The sorption of heavy metal ions was studied under the static conditions in the concentration range from 50 to 1000 mg l^{-1} and ratio of the solid and liquid (s : l) phases from 1 : 100 to 1 : 300. The sorption of heavy metal ions and degree of their recovery were calculated in mg g^{-1} and %, respectively.

Solutions of heavy metal ions were prepared by dissolution of weighed portions of $CuSO_4 \cdot 5H_2O$, $Pb(CH_3COO)_2 \cdot 2H_2O$, and $Cd(NO_3)_2 \cdot 4H_2O$ in water. The kinetics of the metal ion sorption was studied at s : l = 1 : 100 and at initial concentrations exceeding many times MPC for potable water.

The IR spectra of the organosilica sorbents and their forms modified with aluminum(III) were recorded on a Specord-M80 spectrophotometer in the 4000 – 400 cm^{-1} range.

The resulting kinetic curves of sorption of heavy metal ions from aqueous solutions using the initial and modified organosilicas show that modification of OS-30 sorbent with aluminum(III) decreases the time of equilibrium attainment from 120 to 10 min and increases the sorption of lead(II) by a factor of 1.7 as compared to the initial sorbent (Fig. 1, curves *1–5*). The time of equilibrium attainment correlates with the sorption of heavy metal ions on OS-30(Al) sorbent [Pb(II) > Cd(II) > Cu(II) > Zn(II) (Fig. 1)] and agrees with the previous experimental data on the sorption kinetics of copper(II) and zink(II) ammoniates on OS-30(Al) [13]. In contrast to Cd(II) and Pb(II), for copper(II) and Zn(II), along with a fast section of the kinetic curve when 70–75% of heavy metal ions are recovered from the aqueous solutions in several minutes, we also observe a section of slow sorption with the time of equilibrium attainment of 2–3 h (Fig. 1, curves *3, 4*). The data obtained previously in [14] showed that, at high s : l ratios (>1 : 20), the sorption in silicopolymethylsiloxane is predominantly diffusion-controlled. Hence, this fact suggests that, at given s : l ratio from 1 : 100 to 1 : 300, the rate of recovery of heavy metal ions by organosilica sorbents would be determined by chemical kinetics. In this case, not only ion exchange but also specific interactions of complexing metal ions, such as Cu(II) and Zn(II), with the active centers on the sorbent surface [15] should be taken into account.

The pH dependences of the sorption of the heavy metal ions on OS-30(Al) sorbent show that sorption of lead(II) and cadmium(II) sharply increases at pH 1–2 (Fig. 2). Already at pH > 2, the sorption is maximal and remains constant with increasing pH to 7. At the same time, for copper(II) and zinc(II) the sorption increases to a maximum in the pH range from 1 to 3;

Degree of recovery of the heavy metal ions from aqueous solutions as influenced by modification of organosilica sorbents with Al(III) and Cu(II). Initial concentration of the heavy metal ions 200–250 mg l^{-1}, pH 4.8–5.2, contact time 3.5 h

* Cu 3.2 mg g^{-1}.
** Cu 1.6 mg g^{-1}.

it also remains constant with increasing pH to 7 (Fig. 2). In this case, in contrast to silica and natural aluminosilicates, sorption of the heavy metal ions on OS-30(Al) is accompanied not by acidification of solutions after their contact with the sorbent, but by increase in the solution pH by 0.2–0.9 unit depending on the metal ion [16, 17]. Changes in solution pH after sorption using the sorbent modified with Al(III) amount to 1, 0.5, 0.4, and 0.3 for Pb(II), Cd(II), Cu(II), and Zn(II), respectively, and correlate with variations in the degree of recovery of the heavy metal ions.

The sorption curves of the heavy metal ions on OS-30(Al) are similar to the sorption curves of these metals on silica gel with chelating groups grafted to the silica surface [18]. Two sections in the kinetic curves of Cu(II) and Zn(II) sorption indicate that their recovery on OS-30(Al) can occur not only through the ion exchange but also through the specific interaction with negatively charged ≡SiO groups on the sorbent surface (Fig. 1, curves *3, 4*). Addition of aluminum(III) and copper(II) coordinated with the surface silanol groups in the organosilica structure increases the sorbent selectivity. As seen from the table, the degree of recovery of the heavy metal ions correspondingly increases. As seen, irrespective of the modifying metal, the series of the degree of recovery of heavy metal ions on OS-30(Al), OS-30 (Al, Cu), and OS-70(Cu) are similar and correlate with the ionic radii of the sorbates [19]: Pb(II) 1.32 > Cd(II) 0.97 > Cu(II) 0.96 > Zn(II) 0.83 Å. For OS-30, OS-50, and OS-50(Cu), these series are different, which may be due to certain features of the surface chemistry of these sorbents owing to different amounts of active hydroxy groups in their composition.

The effect of the nature of heavy metal ions on their sorption is confirmed by a change in the shape of the sorption isotherms of Cu(II) and Zn(II) belonging to the classical Langmuir type L2 with a saturation section (plateau) in accordance with the Giles classification as compared to the H2 isotherms typical for sorption of Pb(II) and Cd(II) on OS-30(Al) and OS-30(Al, Cu) (Fig. 3). The H2 type of isotherms suggests that sorption is fairly high even at low equilibrium metal concentrations; with increasing concentration, the surface adsorption layer with new active centers for interaction with heavy metal ions is formed.

Our experimental data on the effect exerted by modification of two-component organosilica sorbent with Al(III) on the degree of recovery of heavy metal ions allow the following conclusions. Aluminum(III),

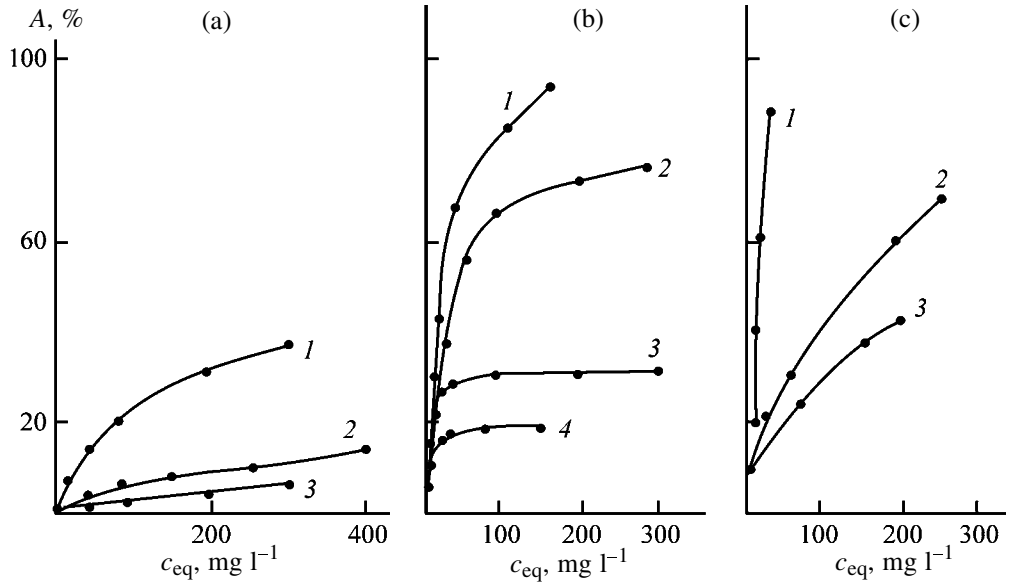

Fig. 3. Isotherms of sorption A of heavy metal ions on organosilica sorbents from aqueous solutions; s : l = 1 : 100, pH 4.8–5.2. (c_{eq}) Equilibrium concentration of the heavy metal ions in solutions. (a) OS-30, (b) OS-30(Al), and (c) OS-30(Al, Cu). (*1*) Pb(II), (*2*) Cd(II), (*3*) Cu(II), and (*4*) Zn(II).

when incorporated in the sorbent structure, probably polarizes the silanol groups [20], provides appearance of the negative charge, and increases its acidic and complexing properties and thus, its ion-exchange power. The selectivity of sorption of the heavy metal ions on the organosilica sorbents modified with Al(III) ions of acceptor type or with copper(II) ions containing *d* electrons is probably due to the increase in the amount of acid groups on the sorbent surface containing mobile protons, similarly to silica gel modified with Al(III) [21]. Introduction of aluminum(III) in the siloxane chain and formation of the ≡Si–O–Al–O–Si≡ bond are confirmed by the elemental analysis showing that the content of silicon decreases in the order OS-30 (42.4) > OS-30(Al) (37.0) > OS-30(Al, Cu) (36.1%). This suggests isomorphic substitution of aluminum for silicon, which is confirmed by the IR spectroscopic data for OS-30 modified with Al(III). For example, with a twofold increase in the aluminum content, the intensity of the bending vibrations of the OH groups at 1640 cm^{-1} increases, whereas the intensity of the strong stretching vibrations of the ≡Si–O–S≡ group in the 1100–1000 cm^{-1} range decreases and shifts toward lower frequencies. The frequency of the bending vibrations of the ≡Si–O bond at 400–500 cm^{-1} and its intensity slightly decrease. It is known that the absorption band of the hydroxy group in the aluminosilicate system is observed at 3610 cm^{-1} [22], and the observed shift of the vibration band of the OH groups from 3610 to 3500 cm^{-1} on passing from OS-30 to OS-30(Al) corresponds to an increase in the concentration of the hydroxy groups with increased proton mobility. This confirms our assumption that the modification of organosilica enhances its ion-exchange properties with respect to heavy metal ions in aqueous solutions.

CONCLUSIONS

(1) Kinetic characteristics of organosilica sorbents and degree of Pb(II), Cd(II), Cu(II), and Zn(II) recovery from aqueous solutions are improved with introduction of aluminum(III) or copper(II) ions into the siloxane matrix or sorbent surface layer, respectively.

(2) Depending on the nature of the modifying agent and ratio of the solid and liquid phases, for lead(II) and cadmium(II) the maximal recovery of 98–100 and 88–100%, respectively, is observed at pH 2–7, and for copper(II) and zinc(II) the highest recovery of 75.2–99.5 and 65.7–98.3%, respectively, is attained at pH 3–7.

(3) As seen from the IR spectroscopic data, the content of hydroxy groups with elevated proton mobility increases upon modification of two-component organosilica with acceptor aluminum(III) ions and, as a result, these sorbents effectively recover heavy metal ions from aqueous solutions.

Abstract—Cellulose diacetate ultrafiltration membranes for separation of protein–carbohydrate raw materials are fabricated, and their performance characteristics (porosity, permeability, and selectivity) are examined.

DOI: 10.1134/S1070427207010119

Among the common methods for increasing the food and biological values of dairy products is introduction of additional amounts of protein and deficient amino acids, e.g., lysine and threonine. For this purpose, components derived from the secondary dairy material, whey, are widely used.

Whey is a natural by-product from manufacture of cheese, cottage cheese, and dairy-proteinic concentrates; it is classed with secondary dairy products. Data on the composition of whey are given in the table.

Whey contains fat and protein particles (suspended), and also lactose and minerals.

Ultrafiltration is widely used in processing dairy products [1]. In ultrafiltration, retention is caused primarily by the screening effect. However, adsorption of particles on the membrane surface also contributes significantly. Commercial membranes UAM-500 used for ultrafiltration of whey are not mechanically strong and exhibit practically no adsorption properties. Furthermore, their formulation includes such plasticizers and additives as formamide and magnesium perchlorate, whose contact with foodstuffs is undesirable.

In this study we examined the adsorption of proteins on ultrafiltration membranes based on cellulose diacetate (CDA) or, in any case, on cellulose acetate with the degree of substitution $\gamma \leq 240$, modified with charcoal (it was introduced to increase the adsorption capacity and improve the mechanical characteristics of the membranes).

In fabricating CDA ultrafiltration membranes by the dry-wet formation procedure, we used two fractions of charcoal: fine (85 μm) and coarse (160 μm), which were obtained by screening through Capron sieves. The mean degree of polymerization of CDA was 220–250.

Polymer macromolecules used for fabricating membranes should be sufficiently rigid or be capable of forming supramolecular structures. This is necessary, first, to obtain a loose matrix in formation of asymmetric membranes, and, second, to eliminate glass transition in the polymer during exploitation of the membranes, thus preventing their deformation under pressure. Cellulose esters meet these requirements in full measure. Furthermore, an important criterion is the inertness of a polymer against the components to be separated.

Thus, it appears quite reasonable to use cellulose acetate as a material for ultrafiltration membranes.

The membranes were produced from 5, 7, and 10% CDA solutions in acetone. A fixed amount of charcoal was added to the acetone solution, and the mixture was thoroughly stirred. To study the protein adsorption on the membranes, we used a blood substitute (10% albumin stabilized with NaCl). The adsorption was studied interferometrically [2]. The experimental isotherm of the excess adsorption of albumin on the charcoal-filled membranes is shown in Fig. 1.

Composition of whey

Whey	Content, %				
	ash	fat	protein	lactose	minerals
Sweet	6.5	0.20	0.70	4.50	0.50
Acid	6.0	0.20	0.80	4.20	0.60

Previously we reported on the adsorption of albumin on $NaHCO_3$-modified membranes [3] (Fig. 1, curve *1*). In the case of charcoal-filled membrane (Fig. 1, curve *2*), the adsorbate–adsorbate interaction is stronger as compared to the adsorbate–adsorbent interaction, as demonstrated by the convex shape of the isotherm against the concentration axis.

The experimental data were analyzed using the excess Gibbs functions [4]: we constructed the dependences of the chemical potential of the sorbent $\Delta\Phi$ and Gibbs energy ΔG on the albumin concentration (Fig. 2).

Our results show that the adsorption capacity for albumin of the charcoal-filled membranes is higher by a factor of 100 than that of the $NaHCO_3$-filled membranes. Therefore, the charcoal-filled membranes can be recommended for separating protein mixtures.

The membranes were also characterized by their porosity (pore size distribution was not examined) and performance characteristics (permeability and selectivity) as influenced by the porosity. The porosity was determined by electron microscopy on a Hitachi HU-12A microscope (resolution 50 Å).

The porosity of the membranes is plotted in Fig. 3 as a function of the filler content for two fractions of charcoal (85 and 160 μm). Various amounts of charcoal (0.25, 0.5, 0.75, and 1 g) were added into variously concentrated polymer solutions in acetone, and the charcoal content c was expressed in wt %.

Figure 3 shows that the porosity depends on the concentration of the initial polymer solution. The membranes obtained from a 5% solution demonstrate higher porosity: 18.42 and 15.35% in the membranes filled with the coarse and fine fractions of charcoal, respectively. The porosity depends also on the filler content (the higher content, the higher the porosity) and on the filler particle size (the coarser the particles, the higher the porosity).

The ultrafiltration was carried out on a laboratory unit at a pressure of 0.3–0.5 MPa. Figures 4a–4c show the permeability of the membranes as a function of the porosity.

The membranes fabricated from 7% CDA with fine charcoal particles and from 10% CDA with both fine and coarse charcoal particles demonstrated zero permeability for both water and whey.

Our results show (Fig. 4) that the permeability depends on the porosity (it increases with increasing porosity). Therefore, we obtained membranes with a large number of through pores. The permeability depends also on the CDA concentration in the initial acetone solution (the highest permeability was observed in the membranes prepared from a 5% solution). Finally, the permeability for water is higher than that for the whey.

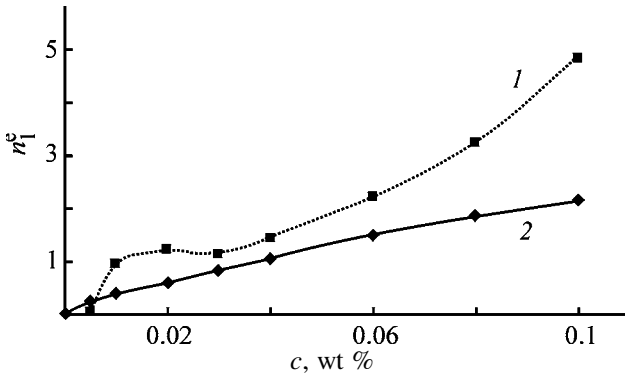

Fig. 1. Isotherms of albumin adsorption on membranes modified with (*1*) $NaHCO_3$ ($n_1^e \times 10^{-5}$) and (*2*) charcoal ($n_1^e \times 10^{-3}$). (n_1^e) Excess adsorption and (c) initial albumin concentration.

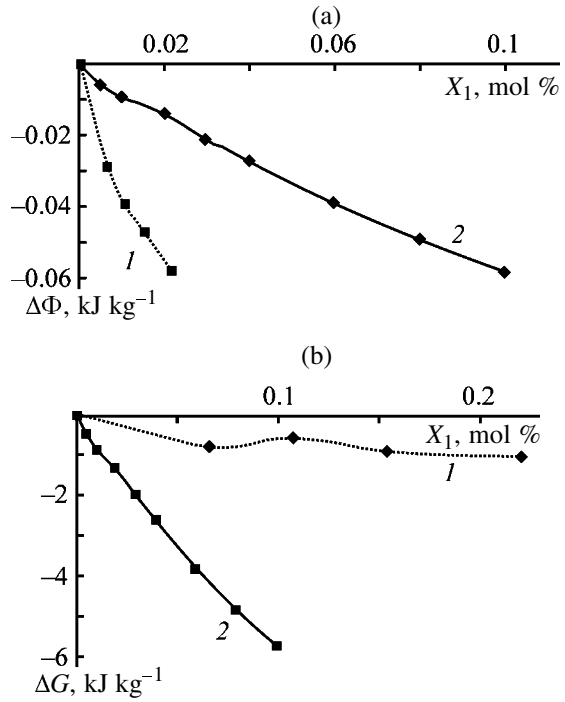

Fig. 2. (a) Chemical potential of the sorbent $\Delta\Phi$ and (b) Gibbs energy ΔG vs. the albumin concentration X_1 for membranes modified with (a) (*1*) $NaHCO_3$ ($X_1 \times 10^{-2}$%) and (*2*) charcoal, and (b) (*1*) $NaHCO_3$ ($X_1 \times 10^{-3}$%, $\Delta G \times 10$) and (*2*) charcoal.

The membrane selectivity with respect to albumin was determined by the Kjeldahl method [5]. The results were plotted as selectivity vs. filler content

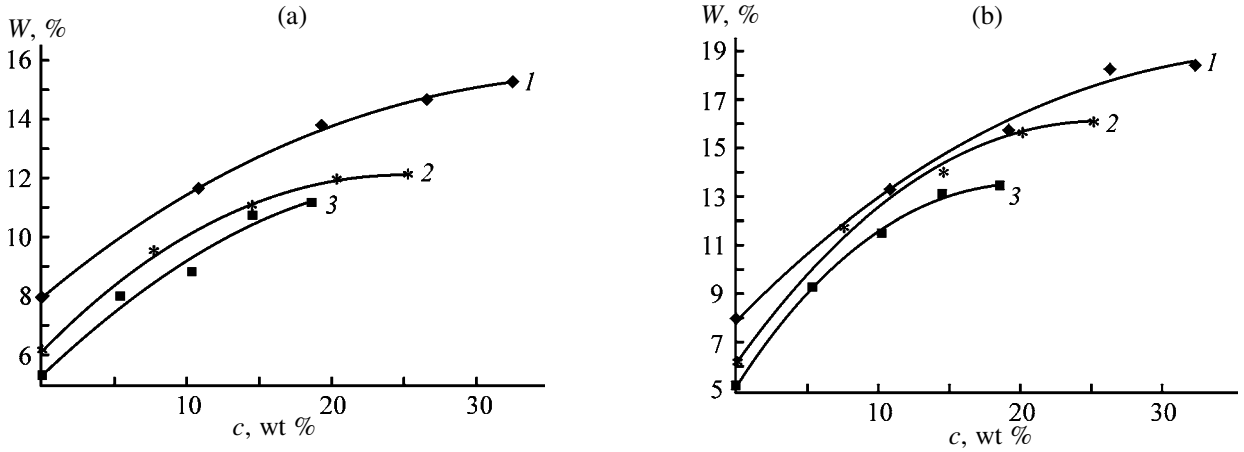

Fig. 3. Porosity W as a function of the filler content c in membranes modified with (a) fine (85 μm) and (b) coarse (160 μm) fractions of charcoal. CDA concentration in the initial acetone solution (%): (*1*) 5, (*2*) 7, and (*3*) 10.

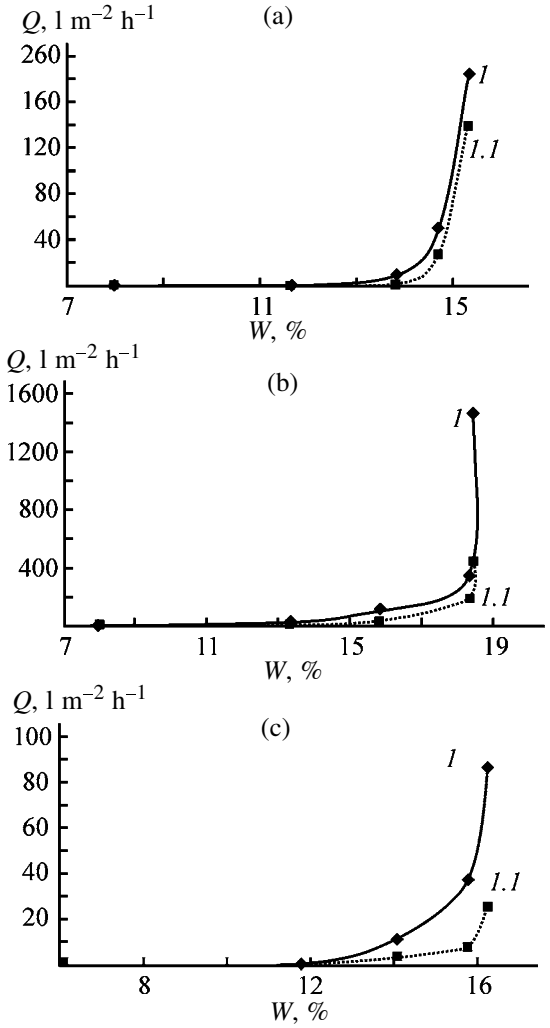

Fig. 4. Permeability Q as a function of the porosity W in membranes fabricated from (a, b) 5% and (c) 7% CDA in acetone. Filler: (a) fine (85 μm) and (b, c) coarse (160 μm). Permeability: (*1*) water and (*1.1*) whey.

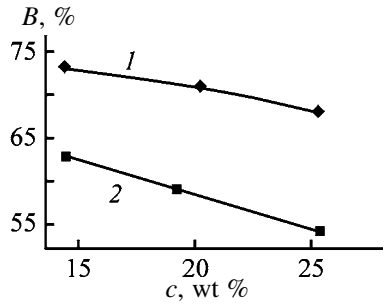

Fig. 5. Selectivity B as a function of the filler (coarse fraction 160 μm) concentration c. CDA concentration in acetone (%): (*1*) 5 and (*2*) 7.

(Fig. 5). The selectivity decreases with increasing permeability. The highest selectivity was observed in the membranes prepared from 5% CDA solutions with coarse charcoal filler (15 wt %) and porosity of 15%. However, the selectivity decreases with increasing CDA concentration in the initial solution. Our results show that the membranes prepared from 5% CDA solution are optimal by all the characteristics (porosity, permeability, and selectivity).

The permeability of the investigated membranes for water and the whey ranged from 0.17 to 24.45 and from 0.07 to 7.2 l m^{-2} min^{-1}, respectively. For commercial UAM-500 membranes, the permeability for water and the whey is 21.3 and 0.32 l m^{-2} min^{-1}, respectively. The selectivity of the membranes studied ranged from 50 to 75%, whereas that for UAM-500 membranes is 62%.

CONCLUSIONS

(1) Modification of cellulose acetate membranes with charcoal allows considerable improvement of the adsorption properties of the membranes for albumin:

sorption capacity increases by a factor of 100 against the $NaHCO_3$-modified membranes.

(2) Introduction of charcoal particles promotes the formation of through pores in the membrane structure, thus increasing its permeability; the total porosity of the membranes studied ranged from 13 to 18%. As a result, the permeability of the membranes for water and the whey increases by 3 and 7 $l\,m^{-2}\,min^{-1}$, respectively, as compared to commercial membranes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Theoretical Foundations and Technology of Electrochemical Production of Lead Chrome Pigment from Electroplating Waste

T. V. Goreva and Yu. P. Khranilov

Vyatka State University, Kirov, Russia

Received September 4, 2006

Abstract—An electrochemical method was developed for production of lead chrome pigment from Cr(VI)-containing spent solutions of electroplating shops and lead battery scrap.

DOI: 10.1134/S1070427207010120

Electroplating shops are one of the main sources of environment pollution with compounds of toxic nonferrous metals, including chromium. There exist tens of various processes using chromium(VI) compounds. These are passivation of zinc coatings, anodizing, chromium-plating, etching of copper, chemical and electrochemical polishing, chemical oxidizing, enameling, etc. [1]. As impurities (Cr^{3+} cations and cations of a metal being treated and a coating metal) are accumulated, solutions cease to be usable, which requires their treatment (regeneration) or discharge to sewage works. In this context, collection of spent solutions and recovery of chromium compounds from these solutions are economically and environmentally important.

The most efficient method is that of full regeneration of spent solutions via removal of the impurities being accumulated and recycling of regenerated solutions into the electroplating process. However, integrated treatment to remove all impurities requires, because of their wide diversity, a gross material and energy expenditure and is frequently economically unfeasible.

There exist methods for recuperation of spent chromium-containing solutions (SCCS) with a minimum regenerating processing for their secondary industrial use in other, less demanding technologies. In [1], recommendations were given as to how SCCS should be use to prepare working process solutions containing Cr(VI) compounds. However, this method requires that plants should possess a set of processes employing Cr(VI) compounds and well developed techniques for analysis of SCCS and newly prepared working solutions.

Here we suggest an alternative procedure of SCCS utilization. It consists in processing of these solutions into lead chromate (main component of lead chrome pigment used as a pigment in paint-and-varnish industry) [2]. It is suggested to use starter battery scrap as source of lead. On disassembly of the batteries, the active paste of negative electrodes is utilized to a sufficient extent. Crushing of the paste and its successive dissolution in NaOH and CH_3COOH solutions yields a lead acetate solution for chemical synthesis of lead chrome pigment by interaction with purified SCCS. The metallic component of the battery scrap (plate-connection buses, terminals, element connectors, fragments of negative-plate grids) is remelted into anodes for electrochemical synthesis of lead chrome pigment, based on anodic dissolution of lead in Cr(VI)-containing solutions:

$$2Pb + Cr_2O_7^{2-} + H_2O \rightarrow 2PbCrO_4 + 2H^+ + 4e.$$

Previous studies [3–5] of the electrochemical synthesis of lead chrome pigment have been carried out with a flowing-through electrolyte of constant composition, prepared from pure salts, and a pure lead anode. The technique being developed employs an electrolyte prepared from SCCS. It is recommended to use an anode fabricated from a lead–antimony alloy produced in remelting of the metallic parts of battery scrap, rather than from pure lead.

EXPERIMENTAL

When developing the technique, we examined the following issues: method and mode of SCCS treatment to remove cationic contaminations; type and concentration of the agent activating the anodic dis-

solution of lead, introduced into the electrolyte composition; admissible Cr(IV) concentrations in SCCS; electrolysis mode; verification of the resulting recommendations on real SCCS, with an anode made of a lead–antimony alloy.

The most dangerous among cationic contaminants of SCCS are Cr^{3+} and Fe^{3+} ions, which is due to their interaction in electrolysis with the alkali formed at the cathode. The simplest and most economical is the method of alkaline treatment of SCCS. The residual concentrations of Cr(III) and Fe(III) (both as hydrated cations and as hydroxo complexes), as well as those of Cu(II), Al(III), and Zn(II), which can be contained in SCCS, were calculated by the equation [6]

$$[M] = [M^{n+}] + \Sigma M(OH)_m^{n-m} = [M^{n+}](1 + \Sigma K_m[OH^-]^m),$$

were $[M^{n+}]$ is found from the solubility product of the corresponding hydroxides [7], and K_m are stability constants of the corresponding complexes [7].

The results of the calculation are shown in Fig. 1.

These data show that, as the pH of spent solutions is brought to 7, the concentrations of all kinds of ions, except Zn^{2+}, decrease to values lower than 10^{-5} M. This provides a high degree of purification. However, the expenditure of chemicals for alkalization can be diminished by bringing the pH of SCCS to 5. At this pH value, a high degree of purification to remove Fe^{3+} and Al^{3+} can be achieved, and Cr^{3+}, Cu^{2+}, and Zn^{2+} ions will precipitate as poorly soluble chromates.

In electrochemical synthesis of lead chrome pigment, lead ions are delivered to a solution from the dissolving lead anode. Preliminarily, we studied the anodic behavior of lead in chromium-containing solutions by galvanostatic and potentiodynamic methods. As objects of study served potassium dichromate (PD) and chromium(VI) oxide (ChO) solutions of varied concentrations. A P5848 potentiostat was used; chronovoltammetric (CVA) curves were measured at a potential sweep rate of 2 mV s^{-1}.

As shown by galvanostatic measurements, the electrode is rapidly passivated in pure dichromate solutions (0.025–0.1 M) even at i = 0.01–0.05 A dm^{-2}. The maximum current densities in voltammograms linearly increase as the chromium(VI) concentration in solution decreases and do not exceed 0.06 A dm^{-2}. The calculated thickness of the passive $PbCrO_4$ film on reaching the peak current in the CVA curves is 0.07–0.13 μm. Thus, lead chrome pigment cannot be synthesized in pure potassium dichromate and chromium(VI) oxide solutions at an industrially acceptable

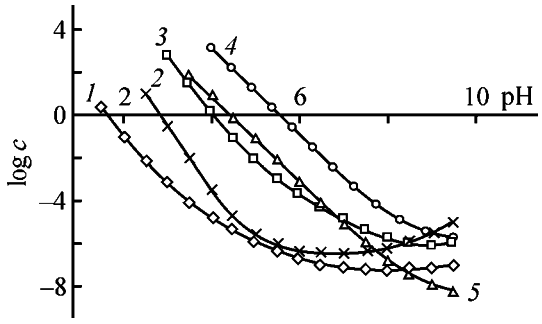

Fig. 1. Calculated pH dependence of the impurity concentration c in the solution: (*1*) Fe(III), (*2*) Al(III), (*3*) Cr(III), (*4*) Zn(II), and (*5*) Cu(II).

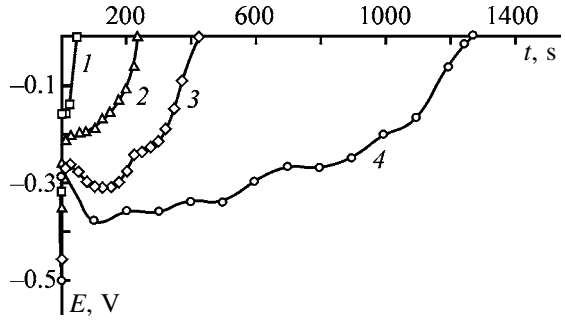

Fig. 2. Galvanostatic curves measured in a potassium dichromate solution. (*t*) Time and (*E*) potential. Sodium acetate concentration (M): (*1*) 0.1, (*2*) 0.2, (*3*) 0.4 (i = 0.1 A dm^{-2}), and (*4*) 0.6 (i = 1 A dm^{-2})

rate, which indicates that an additive that would favor dissolution of the lead anode should be introduced into the solution. As additives of this kind can serve chemical compounds whose anion gives a soluble salt with lead (NO_3^-, BF_4^-, CH_3COO^-). In [4], the behavior of a lead anode in solutions of sodium nitrate, acetate, and diphosphate, and in those simultaneously containing precipitating salts (potassium dichromates) and a depassivating additive, was studied and sodium nitrate was recommended as an agent activating the anodic process. In our case, sodium acetate is recommended as an activator. This is due to its buffer properties, which stabilizes the pH value during electrolysis. In addition, our preliminary experiments demonstrated that nitric acid formed in electrolysis of solutions containing sodium nitrate leads to spalling of the lead anode and contamination of the product.

The galvanostatic (Fig. 2) and CVA (Fig. 3) curves measured in model solutions with a sodium acetate additive demonstrated that, as the activator concentration is raised to 0.6 M and more, the operation of the lead anode at sufficiently high, for industrial purposes, current densities becomes possible. This is indicated in galvanostatic measurements by a steep rise in the transient time upon an increase in the sodium acetate

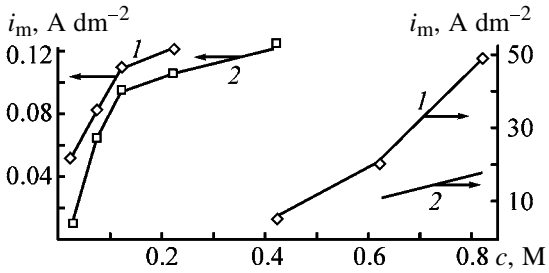

Fig. 3. Peak current density i_m vs. the sodium acetate concentration c in (*1*) 0.1 M solution of chromium(VI) oxide and (*2*) 0.05 M potassium dichromate solution.

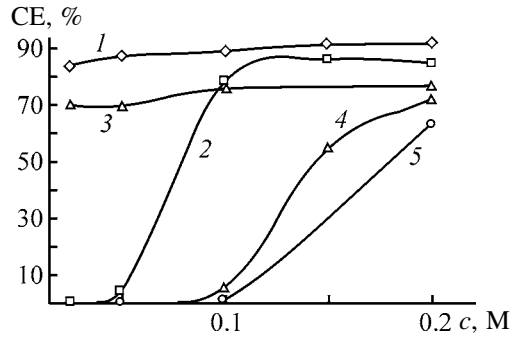

Fig. 4. Variation of the current efficiency CE by oxygen with increasing passivator concentration c in solutions. Q = 2 A h dm^{-2}, sodium acetate concentration 0.6 M. Solution: (*1*) potassium dichromate without sodium acetate, (*2*) potassium dichromate with sodium acetate, (*3*) chromium oxide without sodium acetate, (*4*) chromium oxide with SA, and (*5*) real SCCS based on chromium oxide with sodium acetate.

concentration from 0.1 to 0.6 M. It can be seen from the CVA curves that introduction of sodium acetate makes faster the anodic dissolution of lead, first only slightly, and then, at activator concentrations of 0.6 M and more, by more than two order of magnitude. Thus, the experiments we carried out make it possible to recommend a sodium acetate concentration of 0.6–0.8 M for performing the electrolysis.

The lower peak currents in solutions based on potassium dichromate (Fig. 3) point to a stronger passivation of the lead anode in these solutions. This is accounted for by the higher pH value of dichromate solutions, compared to solutions based on chromium(VI) oxide. It follows from the ionic equilibria of the type

$$Cr_2O_7^{2-} + 2OH^- \rightleftarrows 2CrO_4^{2-} + H_2O$$

that, as pH increases, the fraction of chromate ions, which directly cause precipitation of lead chromate, in solution grows.

Oxygen is evolved at the anode simultaneously with lead chromate formation. To obtain information about the role of oxygen in the anodic process, we measured potential–time curves in the galvanostatic mode at i = 4 A dm^{-2} and electrolysis time of 30 min and simultaneously determined the volume of the evolved oxygen with a gas-collecting buret. The current efficiency was found from the volume of evolved oxygen, reduced to normal conditions. To prevent transfer of oxygen to the solution, it was preliminarily air-saturated before a run. As shown by the study, the potential is shifted in the initial period of active anodic dissolution of lead in the E–t curves in the positive direction and reaches the oxygen evolution potential. After the maximum value is attained, the potential starts to decrease, which is accompanied by its fluctuations resulting from the knocking-off of the viscous near-anode film of lead chromate by gas bubbles.

The revealed fact of a weaker passivation of lead in chromium(VI) oxide solutions, compared with potassium dichromate solutions, is in agreement with the results obtained in a study of the oxygen evolution (Fig. 4, curves *1* and *3, 2* and *4*). The sodium acetate additive depassivates the anode and thereby suppresses oxygen evolution at low Cr(VI) concentrations (curves *2, 4*). At chromium(VI) oxide concentrations exceeding 0.1 M and chromium(VI) concentrations higher than 0.05 M, the oxygen evolution rate steeply increases, so that exceeding these concentrations in industrial electrolysis is not recommended. Measurements of the volume of oxygen evolved from a real spent solution based on chromium(VI) oxide, diluted to different concentrations in terms of chromium(VI), yielded results consistent with those obtained in experiments with model solutions (Fig. 4, curves *5* and *4*).

Experiments on prolonged electrolysis of solutions with various Cr(VI) concentrations and addition of 0.6 M of sodium acetate made it possible to determine the range of working current densities (2.5–12.5 A dm^{-2}) at which the process can be performed with high efficiency and confirmed the recommended limiting Cr(VI) concentration (≤0.1 M) for solutions to be used in electrochemical synthesis of chrome pigment.

It is known [2] that, depending of the solution pH, chrome pigments of different modifications (predetermining the color of the product) are obtained. Experiments in which the pH value was determined in the course of electrolysis made it possible to recommend to carry out the process until the solution is 80–90% depleted of Cr(VI). Under these conditions, the pH value does not exceed 8–9, which corresponds to for-

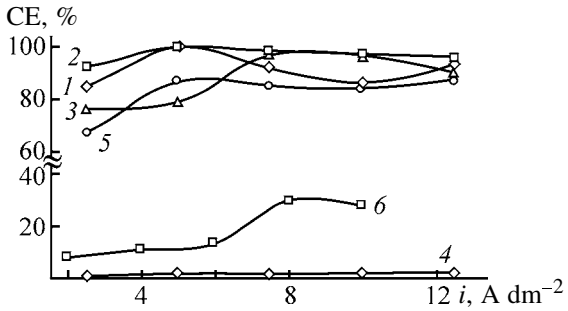

Fig. 5. Effect of the current density i on the CE by lead chromate in solutions of chromium(VI) oxide and potassium dichromate. Sodium acetate concentration 0.6 M, 100% depletion of Cr(VI). Concentration (M): chromium(VI) oxide: (*1*) 0.05, (*2*) 0.1, (*3*) 0.15, and (*4*) 0.2; potassium dichromate: (*5*) 0.05 and (*6*) 0.1.

mation of a neutral lead chromate of the monoclinic modification [2].

The assumption that an alloy of lead and antimony can be used as the anode was confirmed by polarization curves measured on lead and the alloy under comparable conditions. The presence in the alloy of a eutectic phase, which is more weakly passivated in dichromate solutions, predetermines the shift of the zero-current potential of the alloy in the negative direction, relative to the potential of lead. On applying an anodic polarization, the lead chromate film formed on the alloy is less compact than that on lead, which leads to an increase in the peak current and, consequently, to a higher anode dissolution rate. In the case of industrial electrolysis, it is recommended to place an alloy anode in a sheath in order to preclude contamination of the product with antimony.

The recommendations we made were confirmed by experiments on prolonged electrolysis in a solution prepared from an SCCS of the following composition (g l^{-1}): CrO_3 201, H_2SO_4 33.7, and HNO_3 98.3, and made it possible to obtain a high-quality deposit of lead chromate with high current efficiency.

The technology we developed includes the following stages: collection and accumulation of SCCS, with composition homogenization; treatment of SCCS, with pH brought to 5–7; preparation of the filtrate for electrolysis [dilution to a Cr(VI) concentration of 0.1 M and addition of sodium acetate]; electrolysis to 80–90% depletion of Cr(VI); filtration of the electrolyte; and drying of chrome pigment. After the electrolysis, the electrolyte is subjected to partial evaporation (which can be done in a natural way if the process is performed in the batch mode), after which the solution volume is brought to its initial value by introduction of purified SCCS. With the process organized in this way, sodium acetate can be recycled.

CONCLUSIONS

The following technological recommendations for performing an electrochemical synthesis of lead chrome pigment from spent chromium-containing solutions were experimentally substantiated: treatment to remove cationic contaminations with a NaOH solution, with pH brought to 5–7; Cr(VI) concentration in the electrolyte not exceeding 0.1 M; sodium acetate concentration in the electrolyte 0.6–0.8 M; current density range 2.5–12.5 A dm^{-2}; 80–90% depletion of the electrolyte of Cr(VI). The recommendations were confirmed by synthesis of chrome pigment from a real spent chromium-containing solution.

Abstract—An ammonia–chloride electrolyte containing 2,2'-bipyridine for preparing CdTe deposits on a glassy carbon electrode with a particle size of 3–5 nm was developed. The joint electroreduction of Cd(II) and Te(IV) ions was studied by voltammetry.

DOI: 10.1134/S1070427207010132

The existing methods for preparing semiconductor compounds with a particle size of 2.5–25 nm are labor-consuming and involve large number of operations. To such methods belong pyrolysis of organic reagents, dispersion sputtering on heated substrates, and chemical deposition from colloids with intense agitation and subsequent utilization of a stabilizer [1–6]. The disadvantages of these methods consist in complexity of a process, difficulty in obtaining a narrow size distribution of particles, and necessity of additional operations to prevent subsequent aggregation.

Here we suggest an electrochemical method of preparation of a CdTe semiconductor compound with a grain size of 3–5 nm. The advantages of the electrochemical method are that it allows control of synthesis parameters through change in electrochemical parameters, uses simple equipment, and involves complex formation with heterocyclic amines for stabilizing ultradispersed aggregates, which allows preparation of stable metal colloid systems.

Acid electrolytes (pH 0–2) are widely used for electrochemical deposition of CdTe films [7–10]. However, previous studies [11–13] demonstrated the possibility of using ammonia–chloride buffer electrolytes. This made it possible to improve properties of the formed films by decreasing the amount of elemental tellurium codeposited with CdTe, to increase the electrodeposition rate, and to prevent corrosion.

This study is concerned with electrodeposition of the CdTe films from ammonia–chloride buffer electrolytes containing 2,2'-bipyridine. The effect of the grain size of films on the volt–ampere characteristics of CdTe semiconductor under illumination was studied.

EXPERIMENTAL

The electrochemical processes occurring on a glassy carbon electrode upon deposition of CdTe were studied by voltammetry. The composition and properties of the deposits obtained were investigated by physical methods. These involved XPA, electron microscopy, and electron probe analysis. Also, the optical volt–ampere characteristics taken on a Z-curve tracer upon scattered illumination were analyzed. As electrolyte we used ammonia–chloride buffer solutions with pH 8.4 and 9.2, ionic strength $\mu = 2$, and high buffer capacity $\pi = 0.4$, which virtually eliminated variations of pH in a near-electrode layer in the case of discharge of both molecular oxygen and Te(IV) anions (TeO_3^{2-} and $HTeO_3^-$). The volt–ampere curves were measured in a three-electrode Pyrex glass cell with separated cathode and anode compartments. As working electrode we used a glassy carbon electrode with an apparent surface area of 0.07 cm^2. As auxiliary electrode served a platinum electrode with an apparent surface area of 1.5 cm^2. The potentials were measured relative to a silver chloride reference electrode in a saturated potassium chloride solution. The voltammetric studies were performed using a PI-50.1.1 potentiostat, with *I–E* curves recorded with a PDA-1 *XY* recorder.

The cathodic volt–ampere curve obtained in a solution containing 3.8×10^{-4} M Te(IV) (Fig. 1a) shows a region of limiting current, which is due to the reduc-

tion of Te(IV) to Te^0 by reactions (1) and (2),

$$HTeO_3^- + 2H_2O + 4e \rightarrow Te^0 + 5OH^-, \quad (1)$$

$$TeO_3^{2-} + 2H_2O + 4e \rightarrow Te^0 + 4OH^-, \quad (2)$$

with a current peak at the potential $E_m = -0.6$ V and a cathodic current peak at $E_p = -0.9$ V, which is due to the further reduction of elemental tellurium to telluride by reaction (3):

$$Te^0 + 2e \rightarrow Te^{2-}. \quad (3)$$

The ammonium ions, NH_4^+, along with water molecules, can serve as proton-donating molecules. When the direction of the potential sweep is changed in the anodic region, elemental tellurium is oxidized to Te(IV) ($E_p = 0.09$ V).

On introduction of Cd(II) ions into the electrolyte studied, the electroreduction potential of Te(IV) ions is strongly shifted to negative potentials ($\Delta E \geq 300$ mV, Fig. 1b), which corresponds to electroreduction of TeO_3^{2-} and $HTeO_3^-$ anions by the reactions

$$TeO_3^{2-} + 3H_2O + 6e \rightarrow Te^{2-} + 6OH^-, \quad (4)$$

$$HTeO_3^- + 3H_2O + 6e \rightarrow HTe^- + 6OH^-. \quad (5)$$

The effect observed is associated with a decrease in proton-donating ability of a near-electrode layer caused by adsorption of ammonia complexes of cadmium $Cd(NH_3)_4^{2+}$, which, unlike NH_4^+ cations, exhibit no proton-donating ability. This impedes the electrochemical reactions involving TeO_3^{2-} anions, which proceed solely in the presence of proton-donating ions near the electrode.

The complex cations of cadmium react with telluride ions:

$$Cd(NH_3)_4^{2+} + Te^{2-} \rightarrow CdTe + 4NH_3, \quad (6)$$

which results in the formation of CdTe in the near-electrode layer.

We found that CdTe obtained by the electrolysis is the electrochemically active compound and undergoes stepwise oxidation. The anodic volt–ampere curves at reverse sweep of the potential contain two anodic current peaks, at –0.1 and +0.13 V (Fig. 1b). To the anodic peak at $E_1 = -0.1$ V corresponds the reaction

$$CdTe + 4NH_3 - 2e \rightarrow Cd(NH_3)_4^{2+} + Te^0, \quad (7)$$

and to that at $E_2 = +0.13$ V, the reaction

$$Te^0 - 4e \rightarrow Te(IV). \quad (8)$$

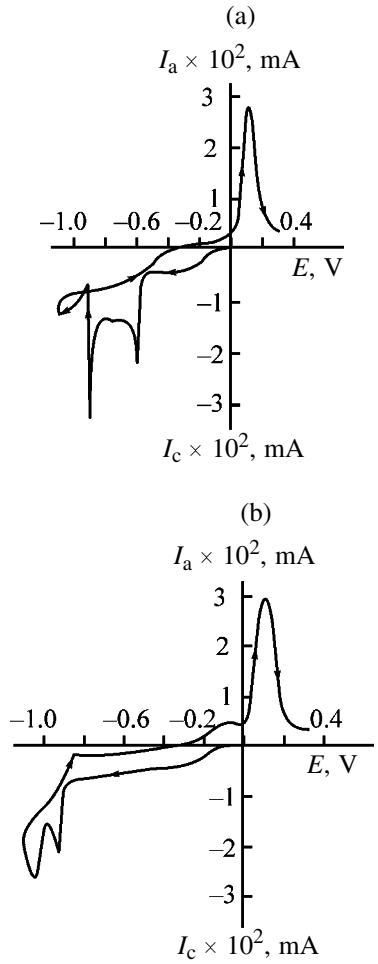

Fig. 1. Cathodic and anodic volt–ampere curves obtained on a glassy carbon electrode in an ammonia–chloride buffer electrolyte (pH 8.4, $\pi = 0.4$, and $\mu = 2$). (a) $c_{Te(IV)} = 3.8 \times 10^{-4}$ M and (b) $c_{Te(IV)} = c_{Cd(II)} = 3.8 \times 10^{-4}$ M. (*I*) Current and (*E*) potential; the same for Fig. 2.

We analyzed how variation of the ratios of the anodic peak currents, which are determined by contributions of CdTe and Te(0) formed on the electrode surface on changing concentration of cadmium ions in the electrolyte, affects the possibility of occurrence of the reaction

$$Te(IV) + 2Te^{2-} \rightarrow 3Te^0. \quad (9)$$

The potentiodynamic curves in oxidation of the CdTe films electroplated from ammonia–chloride buffer electrolytes as functions of the concentrations of the components were analyzed, and the data obtained were used to choose the optimal conditions for electrodeposition of this compound.

To stabilize the size of the CdTe crystals and create conditions for formation of colloid solutions in a near-

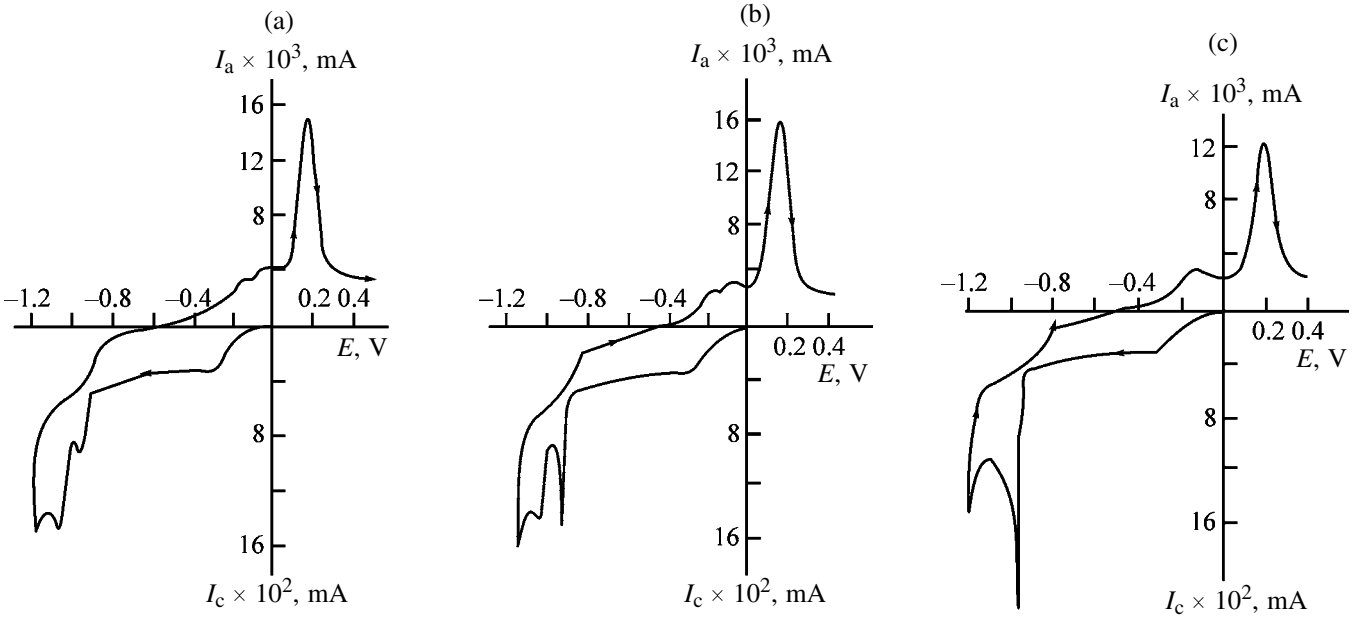

Fig. 2. Volt–ampere curves in joint discharge–ionization of Te(IV) and Cd(II) ions on a glassy carbon electrode in an ammonia–chloride buffer electrolyte with pH 9.2 at varied concentration of 2,2'-bipyridine. $c_{Cd(II)} = c_{Te(IV)} = 3.8 \times 10^{-4}$ M. c_{bipy}, M: (a) 1.8×10^{-4}, (b) 3.6×10^{-4}, and (c) 1×10^{-3}.

electrode space, we used in the study the electrolyte containing 2,2'-bipyridine, which exhibits high adsorption power and forms thermodynamically stable complexes differing in the compositions of the inner and outer coordination spheres. The effect of 2,2'-bipyridine on the electroreduction of Te(IV) and Cd(II) ions on a glassy carbon electrode was established at varied pH values. The above effect on the deposition of CdTe from an ammonia–chloride buffer electrolyte at pH 9.2 is demonstrated in Fig. 2.

The addition of 2,2'-bipyridine to an ammonia–chloride buffer electrolyte shifts the reduction wave related to reaction (1) and the peak at the limiting current of this wave associated with reaction (2) toward negative potentials (Fig. 2). In this case, 2,2'-bipyridine acts as organic surfactant displacing water molecules from the surface. As a result, the amount of the proton-donating ions at the electrode surface decreases. The Te(IV) ions do not form complexes with 2,2'-bipyridine.

At the same time, 2,2'-bipyridine, as the ligand incorporated into the inner coordination sphere, affects the electroreduction of Cd(II). The $[Cd(dipy)_3]TeO_3$ complexes with tellurite in the outer coordination sphere are formed as the 2,2'-bipyridine concentration increases. The electroreduction of Te(IV) anions from these complexes on a glassy carbon electrode is accelerated owing to a decrease in negative charge of the anion. This makes the electroreduction potentials of Te(IV) anions and Cd(II) ions closer. It should be taken into account that the concentration of the Cd^{2+} and Te(IV) ions increases owing to adsorption of the outer-sphere complexes, which allows the current to be increased. Thus, for obtaining CdTe with prescribed qualitative and quantitative characteristics, it is possible to create conditions at which the concentrations of Te(IV) and Cd(II) in the near-electrode space and on the electrode surface can be controlled by varying the 2,2'-bipyridine concentration in joint electroreduction of Te(IV) and Cd(II).

The optimal concentrations of 2,2'-bipyridine in an ammonia–chloride buffer solution with pH 8.4 were determined, ensuring the best conditions for the formation of CdTe deposits on a glassy carbon electrode, at which the electrodeposited CdTe virtually does not contain inclusions of elemental tellurium. The X-ray diffraction patterns of the films plated from these solutions contain solely reflections associated with CdTe, whose crystals have regular cubic structure (Fig. 3).

The effect of the pH of the buffer electrolyte within the pH range 8.4–10.0 at a constant buffer capacity ($\pi = 0.4$) and $\mu = 2.0$ was examined. In an ammonia–chloride solution with pH 9.2, CdTe is not electrodeposited at $E = -1.1$ V. At the same time, on addition of 2,2'-bipyridine, an X-ray amorphous CdTe film

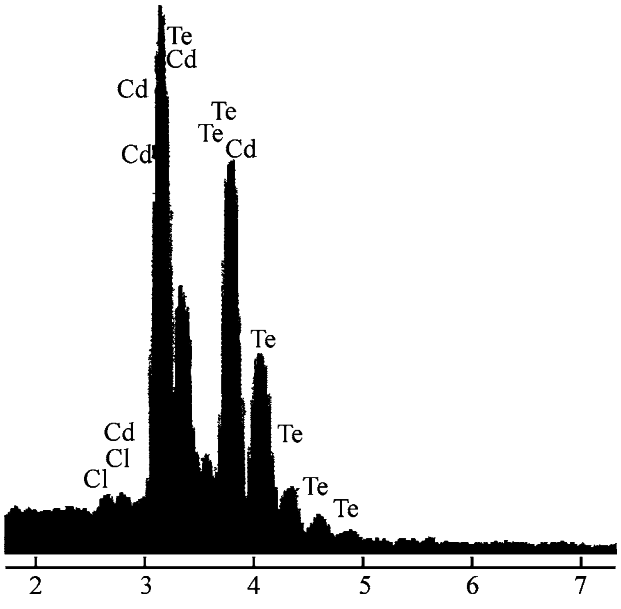

Fig. 4. Energy spectrum of the CdTe film.

Volt–ampere characteristics under illumination of the deposits plated from ammonia–chloride electrolytes at various pH values

pH	c_{dipyr}, M	Grain size, nm	Short-circuit current, μA
8.4	2.9×10^{-4}	5–10	4
	4.4×10^{-4}		5
	5.4×10^{-4}		20
	1×10^{-3}		40
9.2	2.9×10^{-4}	3–8	140
	1×10^{-3}	3–5	700

is formed. Its stoichiometric composition was confirmed by electron probe analysis; it was free of Te(0) impurities (Fig. 4).

The film has strong adhesion to the substrate. The grain size of the nonannealed samples, as determined with an electron microscope, was 5–10 nm for films obtained from an ammonia–chloride electrolyte with pH 8.4, and 3–5 nm for those obtained from an electrolyte with pH 9.2. The CdTe films with an area of 1 cm^2, annealed at 450°C for 10 min, were checked for the sensitivity to visible radiation (see table).

All the deposits give the typical volt–ampere characteristics, indicative of absorption and conversion of light. The samples plated from ammonia–chloride buffer electrolyte with pH 9.2 in the presence of 1×10^{-3} M 2,2'-bipyridine have the best characteristics. The filling coefficient of the loading characteristics was 75%.

CONCLUSIONS

(1) A decrease in the limiting current and the shift of the potential of reduction of Te(IV) ions on a glassy carbon electrode in the buffer solutions studied at low concentrations of Cd(II) ions are due to the occurrence of the surface reactions at the electrode–electrolyte interface, which depend on the concentration of the NH_4^+ proton-donating ions near the charged surface of the electrode.

(2) CdTe obtained by the electrolysis exhibits electrochemical activity and is oxidized in two steps to tellurium(IV) ions, giving two peaks of the anodic current at −0.1 and +0.13 V.

(3) The origin of the peaks in the anodic volt–ampere curves was determined. The possibility of identification of the products of electrochemical reactions obtained by joint electrodeposition of Te(IV) and Cd(II) was demonstrated.

(4) Raising pH of the solutions studied decreases the size of the CdTe grains. The buffer solutions with pH 9.2, $\pi = 0.4$, and $\mu = 2.0$ are optimal for obtaining films with a grain size of 3–5 nm. The formation of the stochiometric CdTe crystals containing no foreign impurities and Te^0 was established.

(5) The effect of the grain size on volt–ampere characteristics under illumination was demonstrated. Decreasing the grain size to 3–5 nm increases the short-circuit current to 700 μA.

Abstract—Kinetics of the anodic processes occurring upon V_2O_5 electrodeposition from $VOSO_4$ solutions containing Na^+ ions was studied by the method of polarization curves. The mechanism of their formation was suggested, based on the analysis of the morphology of the deposit surface.

DOI: 10.1134/S1070427207010144

The conditions of preparation of electrolytic V_2O_5 (e-V_2O_5) by the anodic deposition from aqueous solutions of $VOSO_4$, including those containing Na^+ ions, were considered in [1, 2]. Electrolytic V_2O_5 is a promising cathode material for lithium batteries [3, 4]. Owing to the formation of a compound of the type of $Na_xV_2O_5$, exhibiting higher electrochemical activity and high stable reversible capacity on repeated cycling, e-V_2O_5 plated in the presence of Na^+ ions is of particular interest [5, 6]. In the above studies, inadequate attention was given to the possible mechanisms of the electrolytic formation of oxide molecules and to the associated processes of phase transformations and formation of a molecular crystalline deposit. This was the subject of our study.

The study was performed by the method presented in [2]. The partial polarization curves of the V_2O_5 deposition were constructed on the basis of the current efficiencies at constant I_a. The morphology of the surface of the anodic deposits was studied by the atomic-force microscopy with a nanoscope.

The total and partial polarization curves recorded in anodic deposition of V_2O_5 in the coordinates I_a–E_a and E_a–$\log I_a$, respectively, are shown in Figs. 1a and 1b. In both cases, the total curves consist of lower and higher ascending branches separated by a certain plateau. The lower branches are arranged in order of increasing anode potential to fit the increase in the concentration of Na^+ ions in the solution. The decreasing order of the limiting currents I_a at the inflection points is the same. The higher branches are shifted relative to lower segments in the inverse order along the potential axis. Evidently, the lower portions of the curves mainly reflect the character of variations of the rate of the V_2O_5 deposition at weakly competing reaction of oxygen discharge. With feeding rate of the VO^{2+} ions in a near-electrode layer decreased, the anodic polarization increases, and the lower portions of the curves give way to transition plateaus and then to the higher ascending portions. In the process, the rate of the O_2 evolution becomes dominating and is the higher, the higher the concentration of the Na^+ ions in the solution (Figs. 1a, 1b, curves *2, 3*). The fact that the higher portoins of the curves are arranged in the inverse order with respect to their lower portions is associated with a decrease in oxygen overvoltage corresponding to a decrease in the rate of the V_2O_5 formation and hence to the weaker shielding of the anode surface by the deposit. The above conclusion is also confirmed by the fact that the slope of the total E_a–$\log I_a$ dependences decreases with increasing Na^+ concentration in the solution (Fig. 1b, curves *1–3*). At 0.4 M concentration of the Na^+ ions, the higher portions of the total and partial curves of the O_2 evolution virtually merge together (Fig. 1b, dashed), which shows that the rate of the V_2O_5 deposition under the corresponding conditions approaches zero.

The fact that the total and partial E_a–$\log I_a$ curves of the V_2O_5 deposition are strictly linear (Fig. 1b) allows the processes studied to be considered in terms of the electrochemical kinetics [7]. The slopes of the partial curves of the V_2O_5 deposition (Fig. 1b, curves *1'–3'*, lower portions) increase only slightly with increasing concentration of the Na^+ ions in the solution. Their abnormally high values (0.48, 0.52, and 0.54 V) are likely due to the considerable concentration polarization accompanying electrode processes under the conditions considered [8]. Probably, in the given case, the change in the $dE_a/d\log I_a$ value is also due to the filling of the anode surface by adsorbed oxygen, oxide molecules, and by the mutual influence of the simultaneously occurring anodic processes [7]. Also, it should be taken into account that the outer surface of the double layer, consisting mainly of VO^+ ions, is rather diffuse because of the lack of the elec-

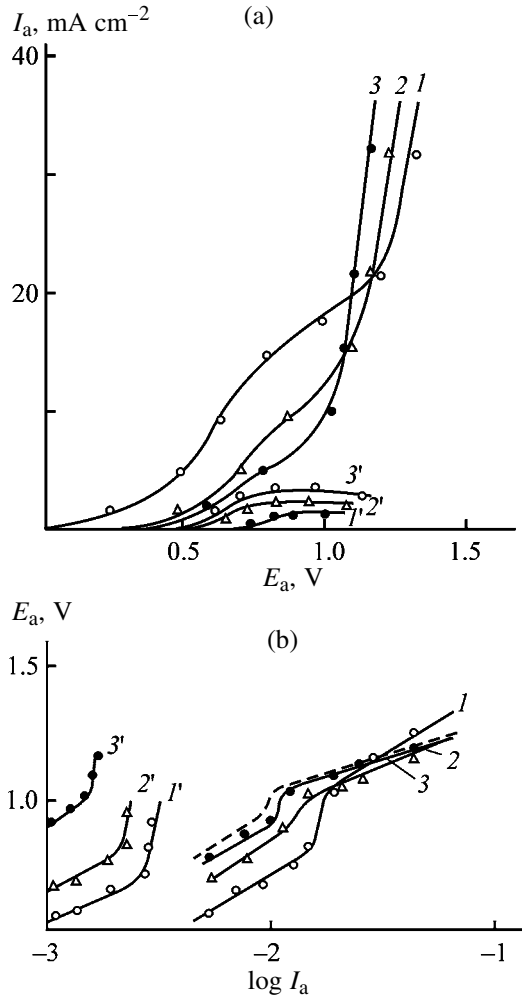

Fig. 1. (*1*–*3*) Total and (*1*'–*3*') partial dependences of the anode potential E_a on (a) anodic current density I_a and (b) $\log I_a$ in V_2O_5 deposition from a 0.25 M solution of $VOSO_4$ in the presence of Na_2SO_4. 80°C, pH 1.8–2.0. trostatic interaction and of the influence of surface phenomena caused by adsorption and evolution of oxygen. Hence, it is probable that the transfer coefficient $\beta \ll 0.5$, which, correspondingly, results in the increased slope.

Thus, the factor largely determining the character of the V_2O_5 deposition is oxygen evolution. In terms of the latest theoretical concepts, oxygen is evolved on the anode through chemisorbed layer of its atoms [9]:

$$2[M + H_2O - 2e \rightarrow (M\text{–}O) + 2H^+] \quad (1)$$

$$(M\text{–}O) + (M\text{–}O) \rightarrow 2M + O_2 \quad (2)$$

$$2H_2O - 4e \rightarrow O_2 + 4H^+ \quad (3)$$

If reactions (1) and (2) actually occur, then the V_2O_5 deposition from a pure $VOSO_4$ solution can be presented by the following reaction equations:

$$M + H_2O - 2e \rightarrow (M\text{–}O) + 2H^+ \quad (4)$$

$$VO^{2+} + (M\text{–}O) - e \rightarrow VO_2^+ + M \quad (5)$$

$$VO_2^+ + VO_2^+ + H_2O \rightarrow V_2O_5 + 2H^+ \quad (6)$$

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+ \quad (7)$$

From the energy standpoint, such a mechanism seems quite correct, because adsorbed oxygen atoms may serve as an electron-transferring bridge. In this case, the exact value of the overvoltage in discharge of VO^{2+} ions cannot be determined because of superposition of side factors. At the same time, the standard potential of the V_2O_5 formation [Eq. (7)] and the potential of the start of its deposition on the anode are close, showing that the above value is comparatively low.

The presence of Na^+ ions may promote formation of OH^- ions in the near-electrode layer upon the discharge of water molecules. The OH^- ions can impede partial acidification of the latter layer by accumulation of SO_4^{2-} ions in it. In all probability, this may occur at a low concentration of Na_2SO_4 (0.05 M). Apparently, this effect is responsible for a certain increase in the rate of the V_2O_5 formation [2]. At a high concentration of Na_2SO_4 (0.2–0.4 M), acidification of the near-electrode layer becomes substantial, and the probability of the influence of OH^- ions on the anodic process is virtually reduced to zero. In this case, the anode potential considerably increases, which causes the rates of the V_2O_5 deposition and O_2 evolution to change in favor of the latter process.

The effect of Na^+ ions is clearly revealed in the character of the formation of V_2O_5 phases. Comparison of the morphology of the surface of anodic deposits formed from a pure $VOSO_4$ solution and from that containing Na_2SO_4 (Figs. 2a and 2b, respectively) shows that their structures differ considerably. The former deposits have the amorphous-crystalline structure with a developed surface relief formed by comb-shaped V_2O_5 deposites. The latter deposits have a pronounced crystalline structure characterized by compact and ordered arrangement of crystal growth steps. The mechanism of normal stacking of two-dimensional molecular-crystalline aggregates is assumed for probable nucleation and growth of crystals constituting the latter structure. Energetically, this may be facilitated by the three-dimensional structure of V_2O_5 molecules. Evidently, Na^+ ions suppress the sorption activity of V_2O_5 molecules and restrict the

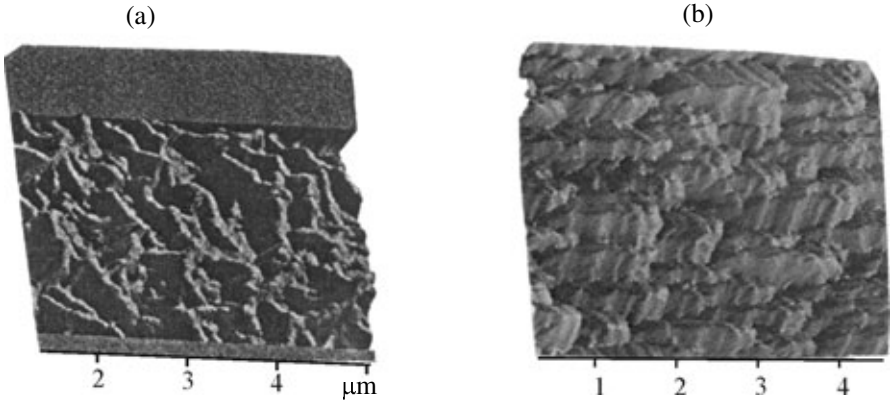

Fig. 2. Morphology of the surface of V_2O_5 electroplated (a) from pure $VOSO_4$ solution and (b) from a $VOSO_4$ solution containing 0.4 M Na_2SO_4; the electrolysis parameters are the same as in Fig. 1.

effect of H_2O molecules on the crystal nucleation and growth in this case.

The nucleation of V_2O_5 crystals starts at a certain potential, which exceeds its steady-state value under the electrolysis conditions. This is, in particular, confirmed by the fact that the anode potential, while switching on current, sharply increases and then gradually decreases to a constant value, which is determined by filling of the anode surface by a V_2O_5 layer. Evidently, this overpotential, along with the inevitable influence of concurrent factors, adsorption of oxygen and H_2O, can be assigned to the additional energy loss resulting from the change in the free surface energy upon appearance of a new phase.

According to X-ray structural and spectral analyses, Na^+ ions and V_2O_5 form a compound of the type of $Na_xV_2O_5$ (x = 0.23–0.28), which is classed with vanadium bronzes [5]. The additional energy consumption for the formation of a new phase is compensated by the heat liberated during the reaction and by the heat of phase transition. As a result, the phase overvoltage in the total energy balance of the electrode process is virtually reduced to zero.

Thus, the anodic deposition of V_2O_5 upon electrolysis from a $VOSO_4$ solution containing Na^+ ions undergoes marked qualitative changes, which are revealed in a decrease of the rate of the oxide deposition and in an increase of the anodic polarization. Simultaneously, the character of the V_2O_5 electrocrystallization changes, i.e., the amorphous-crystalline structure of the anodic deposit transforms into the pronounced crystalline structure.

CONCLUSIONS

(1) The possible mechanisms of the anodic deposition of V_2O_5 from a $VOSO_4$ solution with and without Na^+ ions were considered on the basis of analysis of the I_a–E_a and E_a–$\log I_a$ dependences. The competing evolution of O_2 exerts a decisive effect on the mechanism of the formation of the anodic deposit.

(2) In the presence of Na^+ ions, the rate of the O_2 evolution increases, thus changing the ratio of the formation rates of V_2O_5 and O_2.

(3) According to X-ray structural analysis, Na^+ ions and V_2O_5 form on the anode a compound of the type of $Na_xV_2O_5$. In the presence of Na^+ ions, V_2O_5 with pronounced crystalline structure is deposited on the anode.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Treatment of Tin in Alkaline Electrolytes

Abstract—Processes of the formation of anodic films on the surface of tin in sodium hydroxide solutions were studied. The optimal conditions of the high-speed anodization, at which conversion coatings with high corrosion resistance can be formed, were determined.

DOI: 10.1134/S1070427207010156

The standard processes for tinplate production involve the step of surface finishing, which is performed in solutions of chromic acid or sodium dichromate [1, 2]. These compounds are highly toxic and hence environmentally hazardous. Active search for the ways to decrease toxicity of the solutions used is stimulated by the environmental standards becoming more and more stringent in many countries. Unfortunately, the developed electrolytes have a complex composition, and surface finishing in them is, as a rule, power-consuming and inefficient [3–5], making their use in the tinplate technology unfeasible. Alternative to traditional chromate coatings may be films formed by anodic treatment of tin in alkaline electrolytes [6–12]. To implement the anodization process in practice, it is necessary to know factors affecting formation of stable films.

Therefore, this study is concerned with the formation of anodic films on tin and with their functional properties.

EXPERIMENTAL

The processes occurring during anodic polarization of Sn were studied by voltammetry with linear potential sweeping. The potential sweep rate was 0.01 V s^{-1}. The electrochemical measurements were performed in solutions of sodium hydroxide (ultrapure grade). The voltammograms were recorded with a PI-50-1.1 potentiostat [13]. Prior to the measurements, the surface of the working electrode was treated by the method suggested in [9].

To determine the corrosion resistance of the anodic films, we recorded the spontaneous activation curves [9–11] in solutions containing 3 wt % NaCl, 0.5 M NaOH, and 0.5 M H_2SO_4, with acetic and citric acids used as buffer solutions. As a criterion of protective ability we used the activation time τ_a during which the film is destroyed in a corrosion-active medium, which results in the shift of the potential to a steady-state value corresponding to the nonoxidized surface. The traditional method [14] of testing the film stability in boiling sulfide-containing solutions of acetic acid was also applied. Testing was performed in a solution containing 0.52 M CH_3COOH + 0.01 M Na_2S (I) and under more rigorous conditions, in a solution containing 2.08 M CH_3COOH + 0.01 M Na_2S (II). The protective properties of the conversion coatings were judged by the appearance of dark brown tin sulfide compounds.

All potentials of the working electrodes were measured in a saturated solution of potassium chloride and are given relative to a silver chloride reference electrode (EVL1-M3.1). The electrolyte temperature was maintained constant with a U-4 ultrathermostat.

The polarization curves in the cathode direction, taken on a tin electrode preanodized at different potentials, are presented in Fig. 1. As seen, the anodic current peaks and a cathodic peak at $E \approx -1.1$ V are present in the voltammograms after the anodizing in the range of potentials from -0.92 to -0.52 V (Figs. 1a–1c). After the treatment at the more positive potentials, from -0.32 to -0.08 V (Figs. 1d–1f), the peak corresponding to the formation of Sn(IV) compounds was not recorded; the peaks of both the anodic dissolution and cathodic reduction were not found after the anodization at $E \geq -0.08$ V. The similar dependences are observed in the cyclic votammograms of the Sn–NaOH system.

Evidently, the revealed trends can be accounted for

by the fact that oxidation of tin to Sn(IV) yields tin hydroxide as intermediate [15–18], which is reduced at $E \approx -1.1$ V. It follows from the results obtained in studying the surface of a tin electrode by X-ray photoelectron spectroscopy [19] that the anodic film consisting of Sn(II) and Sn(IV) is dehydrated at more positive potentials ($E > -0.5$ V). Apparently, the oxides forming in the process are electrochemically stable and are not cathodically reduced in the range of potentials from –1.1 to –0.5 V.

It can be suggested that the increase in the concentration of Sn(IV) oxide, which is more stable than Sn(II) compounds, in the surface film should increase its corrosion resistance and that films obtained by tin anodization can be used as protective coatings. Apparently, industrial anodization of tin coatings should be performed under the conditions precluding formation of hydrated tin(II) oxides. To control the process of the anodic treatment and to optimize its conditions, it is necessary to reveal factors facilitating formation of corrosion-resistant coatings. The region of intense dissolution, wherein the anodic current peaks and the amount of electricity corresponding to them increase, is made broader with increasing concentration of hydroxide ions or the electrolyte temperature. To decrease the dissolution rate of the passive films, the anodization was performed in the electrolytes with a low concentration of hydroxide ions and at lower temperature.

The functional properties of the conversion films on tin are improved upon introduction of film-forming inorganic substances into the electrolyte [20, 21]. In this connection, we studied the effect of additions of sodium carbonate, tungstate, silicate, and phosphate on the anodic voltammograms of a tin electrode.

In the presence of sodium carbonate, the anodic current peaks and the associated amount of electricity Q do not noticeably change in comparison with the case when a 0.5 M NaOH solution is used. On the contrary, on addition of sodium tungstate, silicate, or phosphate, the current density peaks and Q decrease. In this case, for the reactions occurring in the region of oxygen evolution, in the presence of tungsten, silicate, or phosphate ions the overvoltage increases in comparison with that in a NaOH solution.

Nonetheless, the effects revealed are weak and do not allow unambiguous conclusion about the protective properties of the films. Therefore, the other methods allowing control of the film properties are required for the optimization of the processes of tin anodization in alkaline electrolytes. Evidently, it is

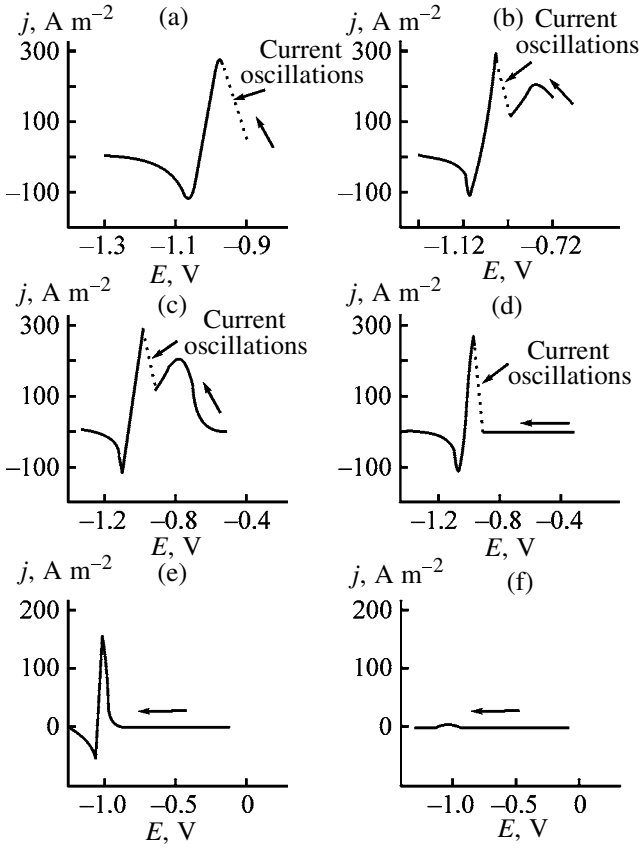

Fig. 1. Voltammograms taken in a 0.5 M NaOH solution at 298 K on a tin electrode anodized for 10 s at various potentials. (j) Current density and (E) potential. E, V: (a) –0.92, (b) –0.72, (c) –0.52, (d) –0.32, (e) –0.12, and (f) –0.08.

reasonable to use the corrosion resistance of the films as the optimization criterion. The times of activation in a 0.5 M NaOH solution of tin electrodes anodized at E = 3.0 V for 2 s in a 0.5 M NaOH solution containing 0.5 M of different additives are given below:

Additive	–	CO_3^{2-}	WO_4^{2-}	SiO_3^{2-}	PO_4^{3-}
τ_a, s	64	64	160	735	105

Our results show that the addition of sodium carbonate does not noticeably change the activation time τ_a in comparison with the pure electrolyte. In the presence of sodium tungstate or phosphate, the activation time of the anodized tin electrode somewhat increases. Nonetheless, the conversion coatings formed by high-speed anodization in a solution containing 0.5 M NaOH + 0.5 M Na_2WO_4, in that containing 0.5 M NaOH + 0.5 M Na_3PO_4, 0.5 M NaOH, or in that containing 0.5 M NaOH + 0.5 M Na_2CO_3 do not inhibit the formation of tin sulfide compounds under the standard conditions of the testing. Evidently, the corrosion resistance of the anodic films obtained from

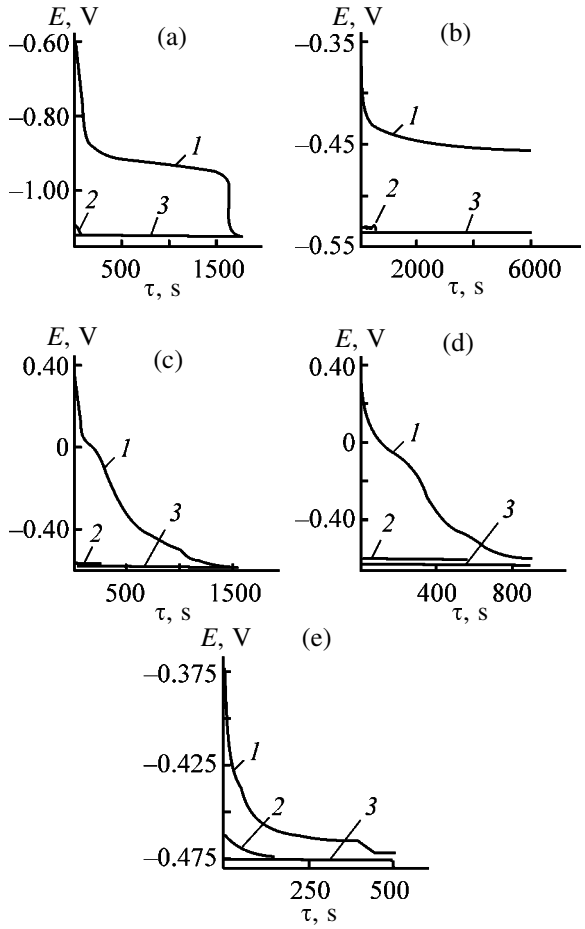

Fig. 2. Curves of spontaneous activation of a tin electrode in solutions containing (a) 0.5 M NaOH, (b) 3% NaCl, (c) 0.5 M CH_3COOH + 0.5 M CH_3COOK, (d) 0.5 M $C_6H_5O_7H_3$ + 0.5 M $C_6H_5O_7Na_3$, and (e) 0.5 M H_2SO_4 after the preliminary treatment by different methods. (*E*) Potential and (τ) time. Treatment method: (*1*) anodization in silicate-containing alkaline electrolyte for 2 s [11], (*2*) cathodic chromation for 2 s [2], and (*3*) no treatment.

the above electrolytes does not meet the existing requirements.

The activation time τ_a of a tin electrode anodized in a solution containing 0.5 M NaOH + 0.5 M Na_2SiO_3 exceeds by about an order of magnitude the activation time of this electrode anodized in a pure electrolyte. The films formed by high-speed anodization in silicate-containing alkaline electrolytes inhibit formation of tin sulfide compounds not only under the traditional (mild) conditions but under the more severe conditions as well.

Significant improvement of the corrosion resistance of the anodic films formed in silicate-containing electrolytes is accounted for by incorporation of silicon inclusions into the coating being formed, which is confirmed by the results of qualitative analysis. Probably, tin silicates are formed on a tin electrode [22].

Organic compounds can also be used to control the properties of oxide–hydroxide coatings. For example, when polyethylene glycol, which is selectively adsorbed on the oxidized surface of tin, is added to the anodizing electrolyte, the activation time can increase by a factor of approximately 2. Probably, the presence of polymer flocculants favorably changes the colloid-chemical conditions of formation of the oxide–hydroxide film and causes the activation time to increase.

Based on the trends revealed, for high-speed anodization of tin coatings we developed an electrolyte containing (M) NaOH 0.25–0.50 and Na_2SiO_3 0.25–1.0, to which 1–2 g l^{-1} of polyethylene glycol can be added [11]. The composition (M) 0.25–0.5 NaOH and 0.75–1.0 Na_2SiO_3 is optimal. The corrosion-resistant conversion coatings are formed in this electrolyte at current densities of 500–1000 A m^{-2} and temperatures not exceeding 298 K.

The comparative tests of the protective properties of the films obtained by the anodic treatment in silicate-containing electrolytes and of those obtained by the traditional method of the cathodic chrome plating [2] showed that the activation time of chrome-plated electrode is considerably shorter than that of the anodized electrode (Fig. 2). In this case, the potentials of the electrodes anodically treated in silicate-containing alkaline solutions are more positive in comparison with the potentials of chromated samples (Fig. 2, curves *1, 2*). The closeness of the potentials of the chromated and unmodified electrodes shows that films forming upon this treatment are porous (Fig. 2, curves *2, 3*). Moreover, the stability of the suggested anodic films in sodium chloride solutions is considerably improved on storage of the anodized samples [24].

The tests performed in a traditional solution containing 0.52 M CH_3COOH + 0.01 M Na_2S, recommended in [14], showed that both the samples oxidized in chromate media and those anodized in silicate-containing alkaline electrolytes contain no tin sulfides, which indicates that the films formed are continuous. Evidently, with increasing acetic acid concentration to 2.08 M, the dissolution rate of the oxide–hydroxide coatings increases. The samples subjected to preliminary chemical treatment or to the cathodic chrome plating, tested in a solution containing 2.08 M CH_3COOH + 0.01 M Na_2S, are coated with SnS. The films obtained by the high-speed treatment (τ_a = 2 s) in the solutions containing silicate ions and polyethylene glycol impede the formation of sulfide com-

pounds on the surface of anodized samples, which confirms the high protective properties of the coatings obtained.

Thus, the corrosion resistance of the conversion coatings formed on tin by the high-speed anodic treatment not only satisfies to the current regulations but also surpasses well that of the traditional chromate coatings.

CONCLUSIONS

(1) Films highly stable in aggressive media owing to the formation of a conversion coating containing the oxide SnO_2 as major component can be obtained by the anodic treatment of tin in alkaline electrolytes.

(2) The corrosion resistance of the conversion coatings formed by the high-speed anodic treatment can be improved by addition into an anodizing electrolyte of alkali metal silicate, tungstate, or phosphate and (or) an organic compound that is selectively adsorbed on hydrated tin oxides. Improvement of the protective properties of anodic films in the presence of Na_2SiO_3, Na_3PO_4, and Na_2WO_4 is associated with the incorporation of SiO_3^{2-}, PO_4^{3-}, and WO_4^{2-} into the forming coating. Among the compounds used, the most effective additive is sodium silicate.

(3) The recommendations to preparation of a high-speed anodizing electrolyte were developed. The optimal composition of the electrolyte and the conditions of the anodic treatment were determined.

(4) The protective properties of the films formed by the suggested process conform to the existing standards and not only compare well with the traditional chromate coatings but even considerably surpass them.

Abstract—Effect of strontium on the corrosion-electrochemical behavior of the Al + 6% Li alloy was studied.

DOI: 10.1134/S1070427207010168

One of the most important present-day goals in manufacture of structural materials is the necessity for improving their strength and anticorrosion characteristics. Aluminum and its alloys are used in various areas of modern technology, and, in this context, the problem of corrosion control to prolong the service life of equipment becomes increasingly important.

A study of the electrochemical behavior of aluminum in neutral and alkaline–salt solutions is of indubitable importance, because it can reveal specific features of how the metal is activated on the background of comparatively high rates of the anodic process [1].

Studies of this kind are also of theoretical interest, because, despite the available publications on the electrochemistry of aluminum, many processes occurring on aluminum in solutions of varied nature have no unambiguous theoretical interpretation based on reliable experimental results. Experimental data on the effect of the solution pH in a wide range of concentration on the anodic behavior of aluminum are scarce. The mechanisms of corrosion and anodic dissolution of aluminum in neutral electrolytes are insufficiently understood [2].

Alloying of aluminum alloys with lithium leads to a significant decrease in the density of an alloy and raises its strength, heat resistance, and elastic modulus. In this case, depending on the nature of a third alloying component, the density of Al–Li alloys decreases by approximately 11% and the elastic modulus, by 4%, compared to D16 alloy. Alloys of the Al–Li system have been used to develop industrial alloys VAD-23, 1420, 1430, 1450, etc., which exceed D16T alloy in corrosion resistance and approach AMg6M alloy in this regard. These alloys are used to fabricate half-finished presswork and rolled products. To improve the corrosion resistance of aluminum alloys with lithium, they are additionally alloyed with manganese, cadmium, or zirconium [3].

Based on the concept of improvement, by alloying with anodic microadditives, of the corrosion resistance of alloys that can be passivated, we examined in this study the effect of strontium additives on the electrochemical behavior of an aluminum–lithium alloy containing 6% Li [4, 5]. As is known, the standard potential of the Sr/Sr^{2+} system is –2.89 V [6]. Thus, strontium is an anode with respect to the Al + 6% Li alloy whose stationary potential is –1.020 V.

EXPERIMENTAL

We prepared alloys from A995 aluminum, LE1 lithium, and StM1 metallic strontium. The alloys were obtained in corundum crucibles in a resistance furnace at 750°C under a layer of a flux of the composition (wt %): NaCl 32.5, KCl 32.5, and LiCl 35. Taking into account the anodic properties of strontium and its solubility in the aluminum–lithium alloy, we chose the following relative concentrations of the alloying component (wt %): 0.01, 0.05, 0.10, and 0.50. The study was performed using a PI-50-1 potentiostat with an LKD-4 self-recorder in a 3, 0.3, or 0.03% NaCl

solution at a potential sweep rate of 2 mV s^{-1} by the procedure described in [7]. A silver chloride electrode served as reference. All the potentials are given relative to this electrode. The results obtained are listed in Tables 1–3.

As is known, the corrosion behavior of metals and alloys can be judged from various electrochemical characteristics. The steady-state value of the free-corrosion potential and the type of its dependence on the test time can give important evidence concerning the behavior of a metal in a corrosion medium. As a rule, a large shift of the corrosion potential in the positive direction indicates that the rate of the anodic reaction may decrease due to passivation. Thereby, it can be tentatively predicted that a system of this kind will be more corrosion-resistant under natural working conditions [8]. The time dependence of the free-corrosion potential of the starting Al + 6% Li alloy and alloys with varied content of strontium (Fig. 1) indicates that a sharp shift of the potential to more positive values is observed during the first minutes after an alloy is submerged in the electrolyte solution. In this case, the free-corrosion potential stabilizes in 40 min for the unmodified alloy and in 20–30 min for modified alloys, which points to their rather strong passivation under the action of strontium additives. For example, the corrosion potential of the unmodified alloy kept in a 3% NaCl solution for 1 h is –1.020 V, whereas for the alloy containing 0.50% Sr, it is –0.840 V. A similar tendency is observed in all the three media we studied. However, the variation of

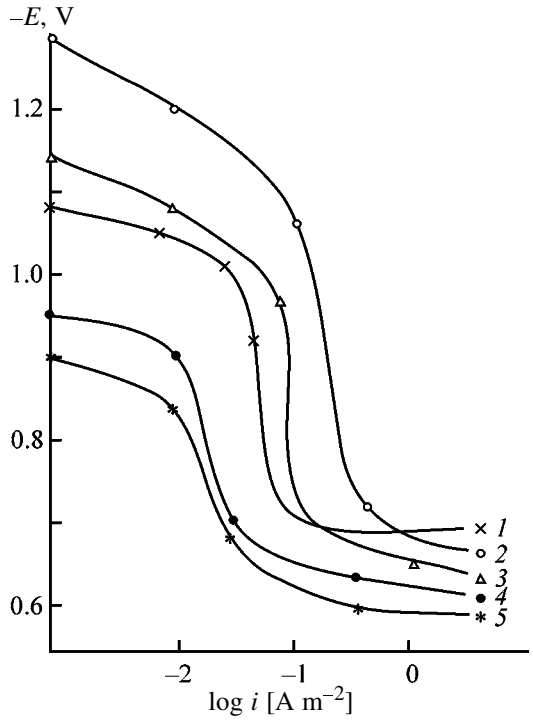

Fig. 2. Potentiodynamic anodic polarization curves (potential sweep rate 2 mV s^{-1}) of (*1*) Al + 6% Li alloy and (*2*–*5*) that containing strontium. Electrolyte: 3% NaCl solution; 298 K. (*E*) Potential and (*i*) current density.

the free-corrosion potential depends on the strontium content in a different way. At 0.05 wt % strontium in the alloy, the free-corrosion potential is more negative that that of the starting alloy. Further increase in the concentration of strontium makes the free-corrosion potential more positive, compared with that of the starting alloy.

Addition of the alloying component in amounts of 0.01–0.05 wt % shifts the corrosion potential of the starting alloy in the positive direction. As the concentration of chloride ions increases, the corrosion potential shifts in the negative direction, which indicates that the corrosion resistance of alloys decreases as the medium becomes more corrosive (Table 1). This is confirmed by a calculation of the corrosion rate of the alloys from the cathodic branch of potentiodynamic curves. The results of this calculation are listed in Table 3.

It can be seen that addition of the alloying components in an amount of up to 0.05 wt % decreases the corrosion rate of the alloys by a factor of approximately 3–3.5 in media with 0.3 and 3% NaCl and by a factor of 2 in a medium with 0.03% NaCl.

Table 3 lists the pitting potentials of the alloys in relation to the concentrations of the NaCl electrolyte and the alloying additive. As the concentration of chloride ions increases, the pitting potential shifts, similarly to the corrosion potential of the alloys, in the negative direction. In an electrolyte with 0.03% NaCl, addition of strontium leads to an increase in the pitting potential of the alloys, thereby making them more pitting-resistant. In the rest of the media studied, such a behavior is not observed.

Figure 2 shows anodic polarization curves of the alloys of the Al–Li–Sr system, measured in 3% NaCl solution after a preliminary cathodic treatment. Thus, any influence of an oxide film was ruled out. As can be seen in Fig. 2, the polarization curves of the alloys containing 0.01–0.05 wt % strontium lie to the right of the curve for the starting alloy, and the curves of the alloys with 0.1–0.5 wt % Sr lie below the curves of the unmodified alloy.

Analysis of the anodic curves of the alloys, measured in other media, shows that, as the NaCl solution is diluted (the effect of the chloride ions of the medium becomes weaker), the width of the passive region, ΔE_{pas}, increases from 300 (in a 3% NaCl solution) to 700 mV (in 0.03 and 0.3% NaCl solutions). Consequently, the alloy samples under study are more passive in the solution with the lowest content of chloride ions, i.e., more resistant to corrosion-induced degradation. This is also evidenced by the fact that E_p shifts in the positive direction as the solution is diluted.

In view of the fact that various-purpose articles are cast under industrial conditions from liquid aluminum alloys containing 3–8% lithium, it was of interest to study oxidation of binary aluminum–lithium alloys that serve as a basis in the development of more complex formulations. A study of the oxidation of binary alloys containing 5–6% lithium demonstrated that alloys of more complex composition can be developed using these alloys. The effect of strontium on the oxidizability of the alloys was examined for the example of an alloy containing 6% lithium.

To study the kinetics of oxidation of alloys of the systems Al–Li and Al–Li–Sr under isothermal conditions, we used the thermogravimetric method based on continuous weighing of the molten metal [9]. The change in the mass was judged from the extension of a spring, with a KM-8 cathetometer. The true oxidation rate was calculated from tangents drawn from the origin of coordinates to the alloy oxidation curves by the formula $K = g/s\Delta\tau$. The apparent activation energy of oxidation was calculated from the slope of the straight line describing the dependence $\log K$–$1/T$.

0.1	723	9.75	25.48
	793	14.17	

We studied the kinetics of oxidation of liquid alloys of the aluminum–lithium system in the temperature range 973–1023 K. The compositions of the alloys we studied are listed in Table 4.

As the temperature becomes higher, the specific mass of a sample, g/s, increases with time. The oxidation of liquid aluminum is intensive during the first 20 min and the oxidation curves are linear. Further, the oxidation process becomes hindered and the curves become parabolic because of the formation of a protective oxide layer mostly composed of γ-Al_2O_3. The oxidation rate of aluminum at temperatures of 973–1023 K is in the range from 20.0×10^{-4} to 34.38×10^{-4} kg m^{-2} s^{-1}. The apparent activation energy of oxidation is 74.48 kJ mol^{-1}.

The oxidation of liquid Al–Li alloys containing 0.1, 1.0, 5.0, and 10.0 at. % Li was studied at 973 and 1023 K. The process follows the linear law and then, as a dense oxide film is formed, the curves become parabolic. As the temperature increases and the lithium content grows, the oxidation rate increases. The true oxidation rate becomes higher, which is, in turn, accompanied by a decrease in the apparent activation energy of oxidation (Table 4).

The kinetic and energy parameters of oxidation of Al + 6% Li alloys containing 0.01, 0.05, and 0.1 wt % strontium are listed in Table 5. The oxidation of the alloy with 0.01 wt % strontium was studied at 723 and 793 K. During the first 10 min, we observed a steep increase in the oxidation rate of the sample, which reached a value of 46 mg cm^{-2}, and then a slight increase in the specific mass of the sample, which is presumably due to the protecting capacity of the oxide film. However, at a large thickness of this film, the maximum value of $\Delta g/s$ was 55 mg cm^{-2}, and the apparent activation energy was as high as 33.44 kJ mol^{-1}.

The kinetic oxidation curves of the Al + 6% Li alloy containing 0.05 wt % strontium demonstrate that the oxidation of the alloy follows the parabolic

law with diffusion hindrance, and the process is complete by the 15th–20th minute. The true oxidation rate changes from 5.59 to 8.70 kg m^{-2} s^{-1}, and the apparent oxidation energy reaches a value of 31.85 kJ mol^{-1}.

The alloy with 0.1 wt % strontium was subjected to oxidation at 723 and 793 K. The kinetic curves of this alloy are described by the parabolic law. The oxidation process is complete by 25th minute of interaction between the metal and atmospheric oxygen. The true oxidation rate is 9.75×10^{-4} and 14.17×10^{-4} at 723 and 793 K, respectively, and the apparent activation energy is 25.48 kJ mol^{-1}.

CONCLUSIONS

(1) The corrosion-electrochemical behavior of alloys of the Al–Li–Sr system in a NaCl electrolyte was studied by the potentiometric method. It was shown that alloying with strontium makes the corrosion rate of the alloys 2–3 times lower, depending on the concentration of the NaCl electrolyte.

(2) The effect of chloride ions on electrochemical characteristics of aluminum–lithium alloys modified with strontium was examined by the potentiodynamic method. It was shown that a 10- or 100-fold decrease in the concentration of chloride ions makes the corrosion rate of the alloys lower and shifts the electrode potentials in the positive direction.

(3) A study of the anodic behavior of aluminum–lithium alloys modified with strontium demonstrated that the pitting resistance of the alloys increases with the strontium concentration, which is evidenced by a shift of the pitting potential in the positive direction for the alloys with 0.1 wt % strontium. The highest pitting resistance is observed for the alloys in a medium with NaCl content of 0.03 and 0.3%.

(4) The kinetics of oxidation of aluminum–lithium alloys modified with strontium was studied by the method of thermogravimetry, and it was found that the oxidation process follows the parabolic law. Addition of up to 0.05 wt % strontium to the Al + 6% Li alloy enhances its oxidation resistance. Further increase in the strontium concentration leads to a rise in the oxidation rate of the basic alloy.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Use of Membrane Electrolysis for Recovery of Heavy Metal Ions

D. Yu. Turaev

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received March 30, 2006

Abstract—Use of membrane electrolysis for recovery of heavy metal ions from cyanide electrolytes at a zinc- and cadmium-plating shop, with subsequent processing of zinc- or cadmium-plated articles in solutions containing Cr(VI) compounds, was studied.

DOI: 10.1134/S107042720701017X

The method of membrane electrolysis makes it possible to regenerate solutions for cadmium and zinc passivation and to diminish discharge of cadmium ions, Cr(VI) compounds, and cyanide ions into wastewater of electroplating shops.

The maximum permissible concentrations (MPC) for fishery basins of cadmium, Cr(VI), and cyanide ions are 0.005, 0.02, and 0.05 mg l^{-1}, respectively [1].

To diminish the discharge of heavy metal ions into wastewater of electroplating shops, it has been suggested to prolong the working life of the solution for zinc and cadmium passivation via its regeneration by membrane electrolysis. The regeneration precludes one-time or batch discharges of this solution. Recovery of ions of heavy metals, cadmium and Cr(VI), and cyanide ions from catching baths (baths for batch washing) maintains their low concentration and diminishes their discharge into wastewater [2, 3].

EXPERIMENTAL

We chose as objects of study industrial solutions and electrolytes whose composition is presented in the table. Our study was performed on installations using the membrane electrolysis and having the form of two-chamber electrolyzers in which the cathode space (catholyte) is separated from the anode space (anolyte) by an ion-exchange membrane.

The regeneration of the solution for passivation of zinc or cadmium coatings (see table, solution no. 1) consists in that zinc and cadmium ions are recovered and Cr(III) and Cr(VI) are oxidized when electric current is passed. To preclude reduction of Cr(VI) at the cathode to Cr(III) by the reactions

$$Cr_2O_7^{2-} + 14H^+ + 6e = 2Cr^{3+} + 7H_2O, \quad (1)$$

$$CrO_4^{2-} + 8H^+ + 3e = Cr^{3+} + 4H_2O, \quad (2)$$

it is necessary to separate the cathode space with a 1.0 N sulfuric acid solution (catholyte) from the anode space, bath with the solution being regenerated (anolyte), with a cation-exchange membrane, e.g., of the MK-40 type. The virtually total absence of nitrate and chloride ions in the solution being regenerated allows use of anodes with high overvoltage of oxygen evolution, fabricated from lead coated with a lead dioxide layer or from platinum-plated titanium. When electric current is passed, ions of hydrogen, zinc, cadmium, and Cr(III), present in the solution being regenerated, migrate into the cathode space, in which the main cathodic reaction is the multistage process of reduction of hydroxonium ions to hydrogen gas:

$$2H_3O^+ + 2e = H_2 + 2H_2O. \quad (3)$$

As the pH value of the catholyte, cathode current density, and concentration of cadmium and zinc ions increase, deposition of these ions at the cathode in

Nominal composition of solutions

Component	Concentration, g l^{-1}, in solution				
	no. 1	no. 2	no. 3	no. 4	no. 5
CrO_3		100–150			300
H_2SO_4	8–10	8–10		20	15
$Na_2Cr_2O_7$	100–150			100	
CdO			35–45		
NaOH			20–30		
NaCN			90–130		
HNO_3		50–70			140

the form of a metal becomes possible:

$$Cd^{2+} + 2e = Cd, \quad (4)$$

$$Zn^{2+} + 2e = Zn. \quad (5)$$

The zinc and cadmium deposited onto the cathode are etched-off from the cathode in an H_2SO_4 solution in a separate vessel.

In the course of regeneration, Cr(III) ions are accumulated in the catholyte because electrolysis is performed under the conditions that preclude recovery of chromium at the cathode in the form of a metal. An increase in the concentration of Na^+ ions leads to a gradual rise in the solution pH in the cathode space. At a solution pH exceeding 5, the deposition of zinc and cadmium at the cathode is virtually completely terminated because of the formation of zinc and cadmium hydroxides and their precipitation in the cathode space. Addition of H_2SO_4 to the catholyte to dissolve zinc and cadmium hydroxides favors deposition of zinc and cadmium at the cathode in the form of metals.

The main anodic reaction is oxidation of water molecules to oxygen gas:

$$2H_2O = 4H^+ + O_2 + 4e. \quad (6)$$

Cr(III) ions formed in the working bath in the course of passivation are oxidized in the aqueous solution at an anode fabricated from platinum-plated titanium or from lead dioxide to dichromate ions, which enter into the composition of the passivating solution, with hydrogen ions formed:

$$2Cr^{3+} + 7H_2O = Cr_2O_7^{2-} + 14H^+ + 6e. \quad (7)$$

The migration of zinc, cadmium, and Cr(III) ions from the solution being regenerated maintains, together with reactions (6) and (7), the necessary concentration of hydrogen ions in the passivation solution.

The method of membrane electrolysis was introduced into industrial practice for regeneration of solutions for passivation of zinc and cadmium coatings (solution no. 1 containing 113 g l^{-1} of $Na_2Cr_2O_7$ and 9.8 g l^{-1} of H_2SO_4). On passing 427.1 A h of electricity, 4.7 g of zinc and 2.0 g of cadmium was recovered into the catholyte (1.0 N H_2SO_4 solution) in the form of ions, with the electric power consumption equal to 4.09 kW h. At a current strength of 5 to 10 A, the voltage across the installation varied from 7 to 16 V. The calculated transport numbers for zinc and cadmium ions were found to be small, 0.009 and 0.0022, respectively, which can be attributed both to migration of competing hydrogen and sodium ions and to the low initial concentration of zinc and cadmium cations, equal to 1.2 and 0.19 g l^{-1}, respectively. Despite the comparatively high electric power consumption, 870 and 2045 kW h kg^{-1} for zinc and cadmium ions, respectively, the recovery of these ions from the passivation solution precludes their discharge into wastewater.

The membrane electrolysis was used to recover cadmium and cyanide ions from a catching bath for article washing after cadmium plating in a cyanide electrolyte (solution no. 3). In this case, we used two cathodes fabricated from steel and connected in parallel. The first cathode and its cathode space were separated from the catching bath by an MK-40 cation-exchange membrane. The second cathode is mounted, together with the anode, directly in the catching bath, with the anode fabricated from graphite (or platinum-plated titanium) and placed between the two cathodes.

Only the reduction of water occurs at the cathode separated from the solution by the cation-exchange membrane:

$$2H_2O + 2e = 2OH^- + H_2. \quad (8)$$

Simultaneously with reaction (8), a sodium hydroxide solution is accumulated in the cathode space. As the sodium hydroxide concentration reaches approximately 50% of its concentration in the cadmium-plating bath, it is used to adjust the bath.

At the cathode directly introduced into the catching bath, there occurs, together with reaction (8), reduction of cadmium(II) from its complex cyanide compound:

$$Cd(CN)_4^{2-} + 2e = Cd + 4CN^-, \quad (9)$$

The metallic cadmium formed at the cathode as a loose deposit can be reused in cyanide cadmium plating in two ways: (i) as a soluble anode fabricated by remelting the cadmium powder and (ii) for adjustment of the electrolyte for cyanide cadmium plating with cadmium oxide produced by calcination of the cadmium powder with free access of air.

In the course of electrolysis, cyanide and hydroxide ions are oxidized at the anode:

$$CN^- + 2OH^- = CNO^- + H_2O + 2e, \quad (10)$$

$$2CNO^- + 8OH^- = 2CO_3^{2-} + N_2 + 4H_2O + 6e, \quad (11)$$

$$4OH^- = 2H_2O + O_2 + 4e. \quad (12)$$

When a graphite anode is used, it is gradually oxidized:

$$C + 6OH^- - 4e = CO_3^{2-} + 3H_2O. \quad (13)$$

It can be seen from Eqs. (10) and (11) that the oxidation of cyanide ions is accompanied by consumption of hydroxide ions, which leads to a decrease in the concentration of free alkali. At a too low concentration of the alkali, cyanide ions undergo hydrolysis to give free hydrocyanic acid:

$$CN^- + H_2O \rightarrow HCN + OH^-. \quad (14)$$

To suppress hydrolysis, it is necessary to monitor the pH value in the catching bath and to add NaOH when necessary.

With the apparatus employing the method of membrane electrolysis and installed in the catching bath (bath for batch washing), we obtained from the catholyte, after cadmium plating in a cyanide electrolyte [solution no. 3, containing (g l^{-1}): CdO 36, NaCN 108, and NaOH 23], 15 l of a NaOH solution of concentration 9.7 g l^{-1} (at the initial concentration of 0.58 g l^{-1}), and 24.0 g of powdered cadmium was deposited on the cathode mounted directly in the catching bath. In this case, the expenditure of electric power for both processes, formation of the NaOH solution and deposition of metallic cadmium, was 3.76 kW h. The low concentration of NaOH in the working bath, equal to 20–30 g l^{-1}, makes it possible to use the resulting alkali solution for adjustment of the working bath in terms of sodium hydroxide, and the metallic cadmium powder deposited at the steel cathode can be recycled in cyanide cadmium plating. Owing to use of membrane electrolysis, the cadmium(II) concentration in the catching bath is maintained at 0.4 g l^{-1}, and that of cyanide ions (in terms of sodium cyanide), at 0.3 g l^{-1}. This diminishes the loss of cadmium(II) into washing water by a factor of approximately 80, and that of sodium cyanide, by a factor of 360, compared with a catching bath from which cadmium and cyanide ions are not recovered.

To recover Cr(VI) ions from the catching bath, in order to obtain a solution containing chromic acid, after passivation and brightening, it is necessary to separate the cathode space, catching bath, from the anode space by a specially treated MA-40 anion-exchange membrane. An untreated MA-40 membrane cannot be used because it is blocked in the course of electrolysis as a result of the reaction of Cr(VI) compounds with the anion-exchange resin, with the current rapidly decreasing virtually to zero. A treatment (modification) of the MA-40 membrane in a solution with peroxydisulfate ions makes it possible to perform electrolysis at a current density through the membrane of about 1–2 A dm^{-2} and voltage across the electrodes not exceeding 16 V [4]. Stainless steel is used as a cathode, and platinum-plated niobium, as anode.

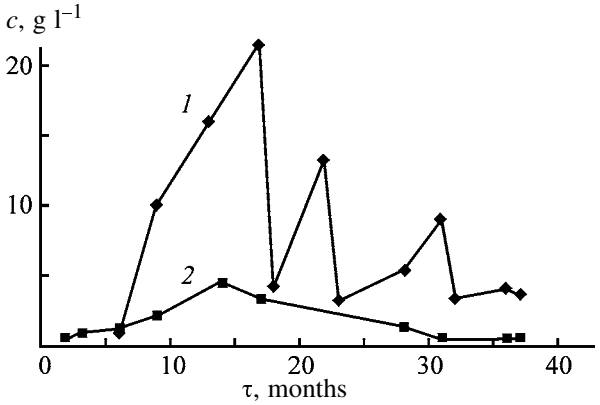
When electric current is passed, chromate, dichromate, sulfate, and nitrate ions migrate from the cathode space into the anode space. Hydrogen ions move in the opposite direction because of the nonideal selectivity of the anion-exchange membrane.

The main cathodic process is reduction of Cr(VI) compounds in the form of chromate and dichromate ions to Cr(III) ions by reactions (1) and (2), which leads, together with reaction (3), to a considerable consumption of hydrogen cations. As a result, the pH value of the catholyte increases and formation of a mixture of zinc, cadmium, and Cr(III) chromates and hydroxides and its precipitation become possible.

The main anodic process is oxidation of water to oxygen gas, reaction (6). If a solution from the catching bath is used when first putting the installation in operation to impart electrical conductivity to the solution in the anode space, then reaction (7) will occur at the anode, together with reaction (6). The solution accumulated in the anode space contains chromic, sulfuric, and nitric acids and is used only for adjusting the brightening bath.

This method has been introduced into industrial practice in the form of an apparatus that employs the method of membrane electrolysis and is installed in the catching bath (catholyte) for recovery of metal ions after brightening of zinc and cadmium coatings [in solution no. 2 containing (g l^{-1}): CrO_3 105, H_2SO_4 9.5, HNO_3 54]. In the course of electrolysis, Cr(VI) compounds (with a concentration of 8–12 g l^{-1} in terms of CrO_3) are recovered from the catching bath, which diminishes their discharge into wastewater. A solution containing 14.7 g l^{-1} of CrO_3 (against the initial concentration of 10.4 g l^{-1}) is obtained in the anolyte. The apparent transport number, determined for chromate ions, is 0.0735, and the electric power expenditure, 54.8 kW h kg^{-1} CrO_3. These values are characteristic of dilute solutions.

In a similar way are recovered chromium(VI) compounds from the washing water of the catching bath in which articles are washed after brightening in solution no. 5 and passivation in solution no. 4. This method has been introduced into industrial practice. It can give a solution containing chromic acid, which can be used to adjust the brightening bath. The results ob-



Recovery of chromium(VI) compounds from the washing water of a catching bath. (*c*) Cr(VI) concentration and (τ) time. Chromium(VI) concentration: (*1*) in anolyte and (*2*) in the catching bath.

tained are shown in the figure. It can be seen (curve *2*) that the maximum concentration of chromium(VI) in the catching bath did not exceed 5 g l^{-1}, and the minimum concentration is about 0.5 g l^{-1} and is maintained at this level for a long time. Accordingly, the loss of toxic chromium(VI) compounds into the next washing bath with running water decreased by a factor of approximately 80–300, compared with the bath having no installation based on membrane electrolysis. The decrease in the concentration of chromium(VI) in the anolyte (see figure, curve *1*) is due to discharge of a part of the solution containing the accumulated chromic acid in a concentration of approximately 18 to 42 g l^{-1} in terms of CrO_3 from the anolyte and filling of the free volume with tap water. The right-hand part of the figure is characterized by a more intensive, compared with that in the right-hand part, operation mode, i.e., longer working periods of the installation and more frequent discharging of a part of the anolyte and its use for adjusting the zinc and cadmium brightening bath in CrO_3. As a result, the chromium(VI) concentration in the washing water in the catching bath steadily decreases. Further considerable decrease in the chromium(VI) concentration in wastewater can be achieved by mixing the washing waster from an electroplating shop with household sewage.

CONCLUSIONS

(1) Membrane electrolysis can be used to recover cadmium ions from low-concentration solutions.

(2) Methods for recycling of an alkali solution and cadmium powder recovered from the catching bath after cadmium-plating in a cyanide electrolyte by membrane electrolysis were suggested.

(3) A method for modification of the MA-40 anion-exchange membrane was suggested. This method enables use of this membrane for recovery of chromium(VI) compounds from catching baths by membrane electrolysis, with their subsequent recycling in the form of a solution containing chromic acid.

(4) It was demonstrated that application of membrane electrolysis in an electroplating shop enables a closed cycle for toxic components, with these components recycled and discharge of heavy metal ions and poisonous compounds, such as cadmium, chromium(VI), and cyanide ions, into wastewater of an electroplating shop substantially diminished.

Abstract—Effect of pulsed electric discharges on aqueous solutions of chromium(VI) in a reactor with an aluminum or iron charge was studied. A mechanism of the occurring processes was suggested. Changes in the pH values of the aqueous solutions of chromium(VI) and the composition and yield of the products formed were determined. The possibility of water treatment to remove chromium by this method was demonstrated.

DOI: 10.1134/S1070427207010181

Recently, publications have appeared devoted to the electric-discharge method for water treatment in reactors with a metallic charge in the form of grains or shavings [1–10]. The experimental conditions used in these studies differed in the reactor design, in the position, shape, and composition of electrodes, and in the composition and concentration of solutions. All these factors affect the composition of dispersion products and efficiency of impurity removal, and, therefore, no adequate model of the occurring processes has been developed. The scientific interest in this issue is due to the particular conditions of occurrence of chemical reactions in a pulsed electric discharge (PED), their kinetics and mechanism. It is apparent, in particular, that different kinds of impurities are involved in different types of reactions: redox, acid–base, ion-exchange, chemisorption, coprecipitation, etc. At the same time, the type and parameters of discharges predetermine both the reaction conditions and the kind of reactants. For example, the electrode material can be involved in the reaction in the case of a zero-barrier discharge, and the fraction of PED energy expended for electric erosion (EE) of the electrode and heating, evaporation, and ionization of the medium may vary as the electrical parameters change.

Previously, we studied the removal of As(V) impurity from water [2] and demonstrated that the results obtained can be understood in terms of a mechanism including stages of oxidation of the eroded metal with water and oxygen, with sorption of arsenate ions by the forming iron hydroxide.

This study is a continuation of [1, 2] and is devoted to analysis of chemical reactions and of the dependence of the yields of the products formed in these reactions on pH and Cr(VI) concentration in the case of PED treatment of metallic charges in aqueous solutions.

EXPERIMENTAL

The study was performed on the experimental installation described in [1]. The electrical parameters used were as follows: voltage pulse width τ_p = 10 μs; pulse repetition frequency f = 300 Hz; voltage U = 500 V for iron charge and U = 1000 V; maximum current I = 250–400 A; pulse energy E = 0.5 J.

The solution was treated in a reactor of 10×10 cm^2 area and 20 cm height. The reactor was filled with a charge to a height of 2.5–3 cm. Model $K_2Cr_2O_7$ solutions of various concentrations (10 to 400 mg l^{-1}) in distilled water were used in the study. The suspension produced upon the PED treatment of the solution was analyzed for the total content of dispersed iron, Fe_{tot}, and in particular for Fe(II) and Fe(III) by dissolving an aliquot in hydrochloric acid [11]. The content of Fe(0) in the suspension was determined by volumometry, and the concentration of Cr(VI) in the filtrate was found after separating the solid precipitate [11]. The composition of the solid precipitate was determined by X-ray phase analysis (XPA). The XPA data were interpreted using the JCPDS (International Centre for Diffraction Data) database.

Table 1. Content of iron in various forms in the suspension produced in EE of shavings in water and Cr(VI) solution. Initial chromium(VI) concentration in model solutions, $c_{Cr(VI)}$ = 50 mg l^{-1}; PED treatment time 60 s

System	pH	Content, wt %		
		Fe(0)	Fe(II)	Fe(III)
Fe + water	2.5	44	3	53
	5.5	87	3.7	9.3
Fe + Cr(VI) solution	2.5	32	28	40
	5.5	51	35.5	13.5

Table 1 lists data on the content of Fe(0), Fe(II), and Fe(III) in the suspension. It can be seen that the presence and involvement of Cr(VI) leads to oxidation of a large amount of iron. As the pH value decreases, the fraction of oxidized iron in the suspension grows. The extent of iron oxidation by chromium(VI) to Fe(II) exceeds that to Fe(III). The PED treatment of an iron charge in distilled water gives a black solid precipitate. A study of the precipitate by XPA demonstrated that it contains Fe(0) and Fe(II) and Fe(III) oxides.

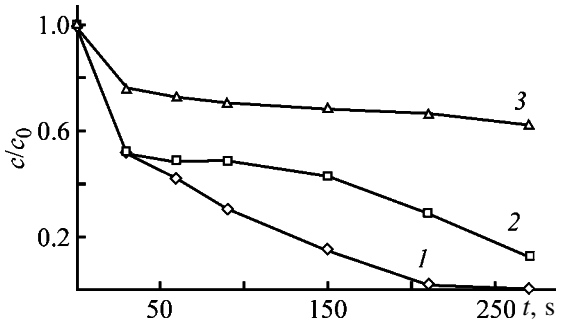

Fig. 1. Degree of Cr(VI) extraction from water vs. time t of PED treatment of various charges at c_0 = 25 mg l^{-1}. (c_0, c) Initial and running Cr(VI) concentrations. Charge: (*1*) iron shavings, (*2*) iron grains, and (*3*) aluminum shavings.

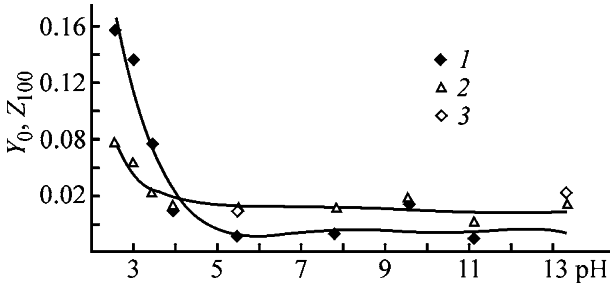

Fig. 2. Fraction of reduced Cr(VI) vs. the solution pH. (Y_0) Fraction of chromium(VI) that reacted before PED treatment and (Z_{100}) relative yield of chromium(VI) reduced during the PED treatment for t = 100 s and c_0 = 50 mg l^{-1}. (*1*) Y_0, extrapolation of the equation $Y(t) = Y_0 + \beta t$; (*2*) Z_{100}, after PED treatment for 100 s; and (*3*) Y_0, experiment (without PED).

Figure 1 shows curves describing the decrease in the Cr(VI) concentration in solution under PED treatment for different charges: Al and Fe shavings and Fe grains. The process is the most efficient with Fe shavings. The reduction yield per unit mass of eroded metal is the same for iron shavings and grains. In contrast to the case of spherical grains, use of shavings leads to enhanced erosion, which, in turn, accelerates chemical reactions of Cr(VI) reduction. Although aluminum is more thermodynamically active than iron, it is less efficient in the reaction with the solution.

There exists an initial region of fast Cr(VI) reduction by the metal (Fig. 1), which occurs via a reaction without any discharge. After the initial interaction, the reaction stops. The extent of this region can be found both in experiments without RED and from curves measured under EE conditions. In doing so, the following circumstance can be used for taking into account the oxidation before the PED treatment: after the initial interaction, the chromium(VI) concentration in solution varies virtually linearly, so that the fraction of reacted chromium(VI) is given by

$$Y = 1 - c_{Cr(VI)}/c_{0Cr(VI)} = Y_0 + \beta t. \quad (1)$$

Figure 2 (curve *1*) shows the dependence of the fraction of chromium(VI), Y_0, reduced by iron without PED on the pH value. The fraction of chromium(VI) reacted before the PED treatment is independent of pH in the range 4–13.5. At pH values lower than 4, this fraction sharply increases. The points obtained directly in the experiment are close to those found by extrapolation.

Measurements of $c_{Cr(VI)}$ on switching off PED also demonstrated that further reduction of Cr(VI) is terminated, i.e., the iron surface formed upon erosion is rapidly passivated.

Because it is assumed that reactions involving H^+ and OH^- ions occur in the course of iron erosion in water (Table 2), changes in the pH value were measured in the course of the experiment (Table 3). It can be seen that, in the case of iron erosion in water, pH increases to approximately 9.0 (Table 3). It follows from Table 3 that the pH value increases upon PED treatment of acid and neutral solutions of Cr(VI) salts, and this effect becomes insignificant in the case of PED treatment of alkaline solutions (pH ≥ 11).

Table 2. Chemical reactions in EE of an iron charge in water and Cr(VI) solution

Reaction		$\Delta\varphi^0$,* V
pH > 3.5		
$Fe + 2H_2O = Fe(OH)_2 + H_2$	(1)	+0.9
$2Fe + 6H_2O = 2Fe(OH)_3 + 3H_2$	(2)	+0.8
$2Fe + 2H_2O + O_2 = 2Fe(OH)_2$	(3)	+1.2
$4Fe + 6H_2O + 3O_2 = 4Fe(OH)_3$	(4)	+0.85
$2CrO_4^{2-} + 3Fe + 8H_2O = 2Cr(OH)_3 + 3Fe(OH)_2 + 4OH^-$	(5)	+0.81
$CrO_4^{2-} + Fe + 4H_2O = Cr(OH)_3 + Fe(OH)_3 + 2OH^-$	(6)	+0.70
pH < 3.5		
$Fe + 2H^+ = Fe^{2+} + H_2$	(7)	+0.44
$2Fe + 6H^+ = 2Fe^{3+} + 3H_2$	(8)	+0.06
$4Fe + 4H^+ + O_2 = 4Fe^{2+} + 2H_2O$	(9)	+1.67
$4Fe + 12H^+ + 3O_2 = 4Fe^{3+} + 6H_2O$	(10)	+1.3
$Cr_2O_7^{2-} + 14H^+ + 3Fe = 2Cr^{3+} + 3Fe^{2+} + 7H_2O$	(11)	+2.23
$Cr_2O_7^{2-} + 14H^+ + 2Fe = 2Cr^{3+}\ 2Fe^{3+} + 7H_2O$	(12)	+2.12
$Cr_2O_7^{2-} + 14H^+ + 6Fe^{2+} = 2Cr^{3+} + 6Fe^{3+} + 7H_2O$	(13)	+0.61

* $\Delta\varphi^0$, standard change in the potential.

Table 3. Changes in the pH value in extraction of Cr(VI) from model solutions by PED with an iron charge. Initial chromium(VI) concentration $c_{Cr(VI)}$ = 50 mg l^{-1}, time of PED treatment 110 s

Solution	Solution pH							
	K_2CrO_4			$K_2Cr_2O_7$				H_2O
Before PED treatment	7.84	9.6	11.15	2.55	3	3.47	3.95	5.5
After PED treatment:								
suspension	11.5	11.26	11.25	4.43	5.1	6.94	8.5	9.13
filtrate	11.1	10.82	11	5.48	5.8	6.95	8.2	8.95

The effect of pH on the erosion of iron and reduction of chromium(VI) under a PED treatment is illustrated by Figs. 3 and 4.

In accordance with the previously obtained results [1], the mass of eroded iron is proportional to $t^{0.72}$ (Fig. 3). The linearization was made using the equation $m = k_2 t^{0.72}$ [1]. The pH dependence of the effective erosion constant k_2 is shown in Fig. 4.

The yield of Fe erosion as a function of pH passes through a maximum at pH ~7. This circumstance was taken into account when studying the effect of pH on the reaction of Cr(VI) with eroded iron: for comparison we took masses of reacted chromium(VI) per unit mass of eroded iron. Figure 5 shows examples of how the pH value affects the kinetics of interaction between Cr(VI) and iron. It can be seen that the relative yield of chromium(VI) reduction, $Z_t = (m_0 - m)_{Cr}/m_{Fe} =$

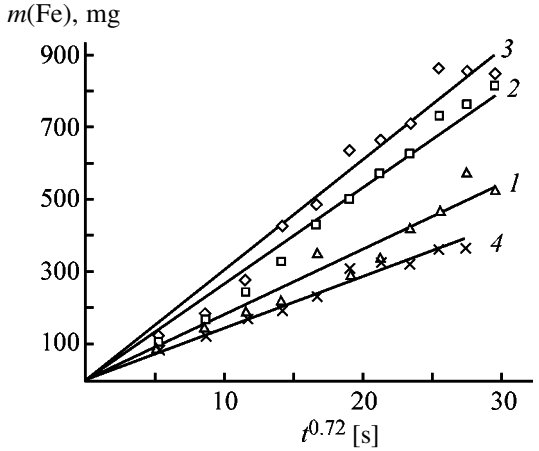

Fig. 3. Amount of eroded Fe, m(Fe), vs. treatment time $t^{0.72}$ under PED at different pH values. pH: (*1*) 3.95, (*2*) 5.5, (*3*) 7.84, and (*4*) 13.33.

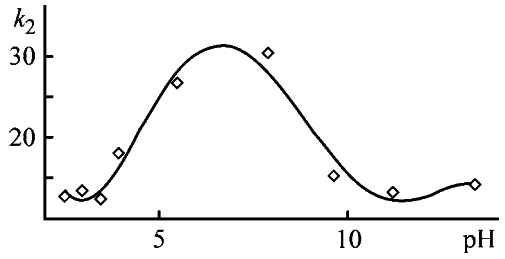

Fig. 4. Specific erosion constant of iron shavings, k_2, vs. pH.

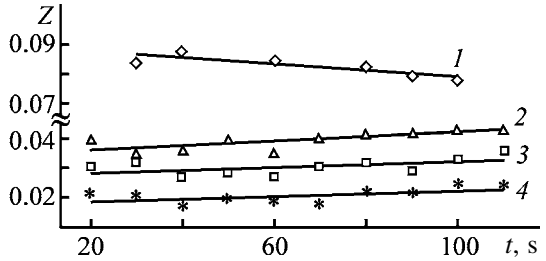

Fig. 5. Relative yield of the reaction, $Z = (m_0 - m)_{Cr}/m_{Fe} = Z_0 + \alpha t$, vs. the PED treatment time t at different pH values. Initial chromium(VI) concentration c_0 = 50 mg l^{-1}. pH: (*1*) 2.55, (*2*) 3.47, (*3*) 7.84, and (*4*) 11.15.

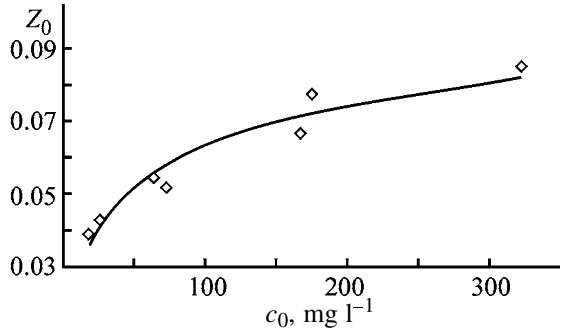

Fig. 6. Relative initial yield of Cr(VI) reduction, Z_0, vs. the initial chromium(VI) concentration c_0 in solution.

$Z_0 + \alpha t$, weakly and nearly linearly varies as the time of PED treatment increases (the coefficient α at t is small).

The pH dependences of the relative yield Z_t at different treatment times are qualitatively the same and similar to that of the yield Y_0 before the PED treatment (Fig. 2). In Fig. 5, a dependence of this kind is shown for t = 100 s. It can be seen that the yield Z_{100} is weakly dependent on pH in the range 3.5–13.5 and steeply increases at pH < 3.5.

Figure 6 shows how the initial relative yield Z_0 depends on the starting concentration of the Cr(VI) solution at pH 5.5. In the absence of PED, the surface of iron and aluminum is covered with oxohydroxide films. In the case of Al, the films are thinner and denser. In the presence of oxidizing ions, $Cr_2O_7^{2-}$ and CrO_4^{2-}, the film may become thicker and denser via formation of oxohydroxides and other Cr(III) compounds. This hinders and terminates the reaction, i.e., additional passivation of the metal may occur. For Al this effect is more pronounced, which can be seen in Fig. 1. At pH 5.5, the initial yield of Cr(VI) reduction is approximately 0.06 mol of Cr per mole of Fe in the case of iron and 0.05 for aluminum. Outside the range of the initial steep rise, this difference is considerably stronger: the yields are 0.02 and 0.005, respectively. These differences are apparently due to the thickness and density of passivating films and to the fact that the film is formed faster in the case of Al. It can also be seen that the fraction of a utilized metal is small because of the passivation. If it is assumed that the specific surface area of the eroded metal is about 10.0 $m^2\ g^{-1}$, which is characteristic of electric-explosion-produced powders, about 0.1% of atoms will lie on the particle surface and, consequently, several tens of iron monolayers and several aluminum monolayers will react with chromium(VI). Thus, two processes noticeably contribute to the formation of a passivating film: interaction of surface metal atoms with Cr(VI) and water.

In a PED treatment of metallic charges in water or aqueous solutions, the metal is heated at places of discharges to a high temperature and its micro- and nanoparticles are ejected into the liquid. The particles are rapidly cooled and, in the process, react with neighboring molecules and ions. Also reacts the metal situated at places of particle detachment. As a result, the reaction surface of the metal strongly increases, compared with its initial value (by a factor of $\geq 10^4$), and just this circumstance leads to an increase in the fraction of reacted impurity, compared with the case of a reaction without discharges. Because of the change in the configuration of discharge gaps, the amount of eroded iron varies with time in proportion to $t^{0.72}$, rather than linearly. For the aluminum charge, this dependence is linear [1], which was taken into account in experimental data processing (Figs. 3, 4). In this case, the fraction of the eroded metal that enters into the reaction is determined by the thickness and density of the passivating film, both intrinsic, formed in interaction with water and oxygen dissolved in the liquid, and that constituted by products of impurity reduction. Upon a PED treatment of an iron charge in distilled water, the pH value increases to approximately 9. It should be noted that pH 9.0 is the equilibrium value for a $Fe(OH)_2$ solution in water, saturated at 298 K [12]. Although iron(II) and (III) hydroxides are formed in erosion according to the data

presented, the concentration of dissolved iron is determined by the more soluble component, $Fe(OH)_2$.

Thus, the experimental data obtained indicate that reactions (1)–(4) occur simultaneously in EE in distilled water (Table 2). In accordance with the potential presented, iron is predominantly oxidized to $Fe(OH)_2$ in the experiment. Upon acidification of water, the advantageousness of iron oxidation to Fe(II) becomes even more pronounced, which is due to a decrease in the potential of reaction (8). The high pH-independent potential of the Fe^{3+}/Fe^{2+} couple (φ^0 = 0.77 V) precludes additional oxidation of Fe^{2+} with such oxidizing agents as H^+ and H_2O. As a result, there occurs gradual oxidation with O_2 as it is dissolved in water from the atmosphere. It can be seen that, as pH varies (Figs. 3, 4), the yield of Fe erosion passes through a maximum at about pH 7. The erosion is a physical process related to conductivity of intergrain spaces, and, therefore, such a behavior of the erosion yield can be attributed to the apparent change in the solution conductivity, which must pass through a minimum at pH 7. Apparently, the fraction of PED energy released into the solution will increase with the solution conductivity, whereas the energy expenditure for heating and dispersion of the metal will decrease.

The degree of iron oxidation in the reaction products and their composition are determined by both thermodynamic and kinetic factors. The former can be evaluated by the standard electrode potentials φ^0 [13] for electrodes in an alkaline medium (V): $Fe(OH)_2/Fe$ = –0.896, $Fe(OH)_3/Fe$ = –0.79, $Fe(OH)_3/Fe(OH)_2$ = –0.58, and $CrO_4^{2-}/Cr(OH)_3$ = –0.086. Here, the potential for a freshly precipitated chromium(VI) hydroxide is used. These values point to a somewhat higher thermodynamic probability of iron oxidation to Fe(II) by Eq. (5). At a chromium(VI) concentration in solution of 50 mg l^{-1}, the potentials of reactions (5) and (6) decrease by 0.22 V at pH 7 and remain virtually unchanged at pH 13, so that both reactions are thermodynamically probable for freshly formed precipitates. And even a decrease in the chromium(VI) concentration by additional three orders of magnitude does not change the sign of the difference of these potentials, which indicates that deep purification of water is possible. The oxidation to Fe(II) is also kinetically advantageous, because transfer of a smaller number of electrons is necessary in this case. The existence of this pathway is also evidenced by the above pH value of 9, established after the PED treatment.

In the acid medium, the φ^0 values for the electrodes are important (V): Fe^{2+}/Fe = –0.44, Fe^{3+}/Fe = –0.062, and $Cr_2O_7^{2-}/Cr^{3+}$ = +1.33. These data indicate that two alternative pathways of interaction are possible: reactions (11) and (12). As in the alkaline medium, oxidation to Fe(II) is kinetically advantageous. However, reaction (11) can be followed by additional oxidation of Fe(II) by reaction (13). This liquid-phase reaction is kinetically more probable than oxidation of $Fe(OH)_2$ to $Fe(OH)_3$ by reaction (5) in an alkaline medium, because the latter occurs in the solid phase. It was experimentally demonstrated (Table 1) that the contribution from these reactions depends on pH of the starting solution: as pH becomes lower, the yield of Fe(III) increases from 13.5 to 40%, whereas that of Fe(II), contrariwise, decreases from 35 to 28% because of the occurrence of reaction (13).

It can also be seen that the yield of oxidation of eroded iron in the presence of Cr(VI) exceeds that in the case of erosion in pure water. This indicates that reactions (5), (6), and (10)–(13) occur, with reactions (5), (6), and (11) predominant. Measurements of the solution pH in PED (Table 3) demonstrated that, in accordance with reactions (5), (6), and (10)–(13), pH increases upon discharge treatment of Cr(VI)-containing solutions. The yield of the reduction of Cr(VI), based on metal unit mass, under PED for 100 s (Fig. 2, curve *2*; Fig. 5) is virtually independent of pH in the range 3.5–13.5. The steep rise in the yield at pH < 3.5 is due to a change of the reaction mechanism from that described by Eqs. (5) and (6) to that by (11). The independence of the yield from pH in the range 3.5–13.5 indicates that reaction (5) is irreversible under the experimental conditions. Some information about iron passivation in PED in a solution of a chromium(VI) salt was obtained by determining the dependence of the relative yield of the reaction on the initial concentration of the salt (Fig. 6). This dependence is weak, described by a flattening-out curve, which confirms that a passivating film is formed, because a linear or superlinear dependence would be expected in its absence. At the same time, the yield somewhat increases as the concentration becomes higher, which points to a low, but still noticeable permeability of the passivating film and to involvement of chromium(VI) compounds in its formation.

In conclusion, the energy expenditure for treatment of wastewater to remove the chromium(VI) impurity will be calculated. Let the energy expenditure for iron erosion be 0.067 kW h mol^{-1} [1], and the yield of chromium(VI) removal, 0.02 mol Cr per mole of Fe, as shown above. Then, 0.4 kW h of electric energy will be necessary for removal of 300 mg l^{-1} of chro-

mium(VI) from 1 m^3 of wastewater at pH > 3.5. This value is tens of times lower than that consumed in treatment of a grained iron charge with high-voltage (3–15 kV) electric discharges [3, 4]: 90 MJ m^{-3} at c = 100 mg l^{-1}. This difference is possibly due to expenditure of the PED energy both for metal erosion and for evaporation and ionization of the solution in intergrain spaces. In this case, in accordance with the mechanism suggested, the expenditure for erosion purifies water by removing impurities and that for evaporation and ionization either does not lead to purification, or purification occurs by a less efficient mechanism.

CONCLUSIONS

(1) In treatment of Cr(VI) solutions with pulsed electric discharges in a reactor with an aluminum or iron charge, the eroded metal directly interacts with the impurity via dispersion of a metal, disintegration of the passivating film, and oxidation of the metal to the corresponding hydroxides.

(2) The efficiency of the interaction with Cr(VI) depends on the rate of formation of the passivating film, pH value, and initial concentration of the solution: it is 0.02–0.03 mol Cr(VI) per mole of eroded Fe.

(3) The yield of chromium(VI) reduction is virtually independent of pH in the range 3.5–13.5 and sharply increases at pH < 3.5. This is due to a change of the reaction mechanism: from oxidation of iron to give solid hydroxides to its oxidation to simple ions, Fe(II) and Fe(III), in solution.

(4) The possible energy expenditure for wastewater treatment to remove Cr(VI) ions at c = 300 mg l^{-1} is about 1.5 MJ m^{-3}, which makes this method promising for practical use.

Abstract—The features of formation of organic–inorganic cross-linked structures prepared by copolymerization of *n*-butyl methacrylate with 3-(trimethoxysilyl)propyl methacrylate, followed by hydrolysis of the trimethoxysilane groups of the copolymers and condensation of the resulting silanol groups, were studied. The quantitative composition of the functional groups of the cross-linked copolymers was determined. The physicomechnaical and mechanical properties of the copolymers were studied in relation to the copolymer composition and conditions of hydrolytic condensation.

DOI: 10.1134/S1070427207010193

Cross-linking polymer systems containing reactive oligomers and polymers are conventionally used for preparing films, coatings, and polymer articles by so-called reaction molding. The advantage of this process is that cross-linking of the polymer and molding of the article are combined in one step, with the three-dimensional cross-linked structure of the polymer improving the mechanical, thermal, and other properties of the article.

This approach was widely used mainly in thermosetting systems prepared by the polycondensation mechanism. At the present time, copolymers with different functional groups (hydroxy, carboxy, epoxy, etc.) are used for preparing cross-linked systems. Usually low-molecular-weight cross-linking additives are introduced into these systems, i.e., these systems are "double-packed composites" since the cross-linking agent can be introduced into the reaction mixture only prior to its use, which is inconvenient for industrial processes. Systems cross-linked without cross-linking additives, or more precisely, by cross-linking agents contained in the environment, are more promising. For examples, reactive copolymers with isocyanate functional groups are cross-linked under the action of atmospheric moisture. The disadvantage of isocyanate systems is their high toxicity. More attractive in this respect are copolymers with alkoxysilane functional groups cross-linked by the following reactions:

$$\equiv SiOR + HOH \rightarrow \equiv SiOH + ROH,$$

$$\equiv SiOH + \equiv SiOH \rightarrow \equiv SiOSi\equiv + HOH,$$

$$\equiv SiOH + \equiv SiOR \rightarrow \equiv SiOSi\equiv + ROH,$$

to form organic and inorganic (≡SiOSi≡) cross-links. These copolymers are used for preparing organic–inorganic cross-linked structures from epoxy resins [1], polyurethanes [2], and polycarbonates [3]. Condensation cross-linking of polymers involves at least three steps: polycondensation of the monomer to obtain the oligomer; addition of alkoxysilane fragment to the terminal groups of the oligomer using functionalized trialkoxysilanes; and cross-linking of the system by hydrolytic condensation.

Hybrid cross-linking polymerization is simpler from the technological point of view, since preparation and functionalization of the polymer are com-

bined in one step. Preparation of organic–inorganic cross-linked polymers from acryl copolymers containing 3-(trimethoxysilyl)propyl methacrylate (TMPM) chains $CH_2=C(CH_3)C(O)OCH_2CH_2CH_2Si(OCH_3)_3$ was studied in [4–6].

It was noted [5, 7] that not all functional groups are involved in hydrolytic condensation, i.e., the system contains the methoxy and silanol groups, and the siloxane bonds as the condensation product. It is clear that the properties of a copolymer and its possible application fields will depend on its functional composition. However, no quantitative data on the content of functional groups in similar systems were reported. To predict the polymer properties, it should be taken into account that the cross-linked structure in the examined systems is formed not only by cross-linking of silanol groups but also by formation of hydrogen bonds between the silanol groups and electron-donor fragments of macromolecules [4, 8]. It should also be noted that inorganic micro- or nanofragments with polysiloxane structure can be formed under definite conditions in the polymer matrix by condensation of the ≡SiOH groups. However, this process can be almost completely suppressed under definite copolymerization conditions. Chan and Chu [4] showed that the polymerization system became heterogeneous only at more than 40 mol % content of TMPM in the initial monomer mixture. Similarly, the inorganic phase in a mixture of polymethyl methacrylate and tetraethoxysilane (TEOS) is formed only when the content of TEOS in the system exceeds 20 wt % [8].

The aim of this study was to examine formation of organic–inorganic cross-links in the course of copolymerization of *n*-butyl methacrylate (BMA) with TMPM in relation to the content of TMPM units in the copolymer and conditions of hydrolytic condensation. We also determined the quantitative composition of functional groups in the intermediate and final products and studied their properties.

EXPERIMENTAL

We used BMA [Russia, GOST (State Standard) 16756–71] and TMPM (Fluka) containing 99% main compound. The monomers were distilled in a vacuum prior to use. The solvents were benzene (analytically pure grade, GOST 5955–75) dried over calcium hydride and chloroform [chemically pure grade, TU (Technical Specifications) 2631-066-444493/79-01] used as received.

Polymerization was initiated by benzoyl peroxide recrystallized from ethanol.

Hydrolytic condensation was catalyzed by 0.1 N H_2SO_4 (titration standard), *p*-toluenesulfonic acid (TSA) (Merck), and dibutyltin dilaurate (DBTDL) (Sigma–Aldrich).

Copolymerization of BMA with TMPM was performed in a benzene solution at the monomer : solvent ratio of 1 : 5, initiator concentration of 1% relative to the copolymer weight, and 70°C in sealed glass ampules under nitrogen atmosphere for 48 h.

The copolymerization kinetics was studied by gas-chromatographic analysis on a Tsvet-800 chromatograph with a flame ionization detector. A 2-m column 4 mm in diameter was packed with Inerton-Super (grain size 0.125–0.160 mm) containing 5% Carbowax 20M. The flow rates of the carrier gas (helium) and hydrogen and air used for detection were 20, 20, and 200 ml min^{-1}, respectively. The column programmed temperature was in the range from 80 to 140°C. The content of components in the reaction mixture was determined using toluene as an internal reference.

The morphology of the copolymers prepared by hydrolytic condensation was studied by atomic force microscopy (AFM) on a Solver P47 Pro scanning probe microscope (NT-MDT, Russia) in the tapping mode in air. The samples were scanned in the topographical survey and phase contrast modes. The difference in the surface composition was determined from the change in the phase shift of the amplitude–frequency parameter of the cantilever caused by adhesion interactions [9].

The films were prepared at 25°C and 50–60% air humidity on a Teflon support or, to accelerate hydrolysis of $\equiv SiOCH_3$ groups, on the water surface.

Hydrolytic condensation was studied by FTIR spectroscopy. For this purpose, the changes in the intensity of the IR bands at 820, 1000–1200, and 3500 cm^{-1} were monitored. The content of the silanol groups ≡SiOH was determined from the integral intensities of their stretching vibrations at 3500 cm^{-1}, measured after subtraction of the spectrum of the freshly prepared initial sample. The content of the $\equiv SiOCH_3$ groups was determined from the integral intensity of the band at 820 cm^{-1}, measured after subtraction of the spectrum of completely hydrolyzed samples with the similar composition. The initial and completely hydrolyzed samples were used as references for calculation of the absorption coefficients. Since the siloxane bands overlap with other bands, the concentration of siloxane groups was calculated form the difference in the initial and current concen-

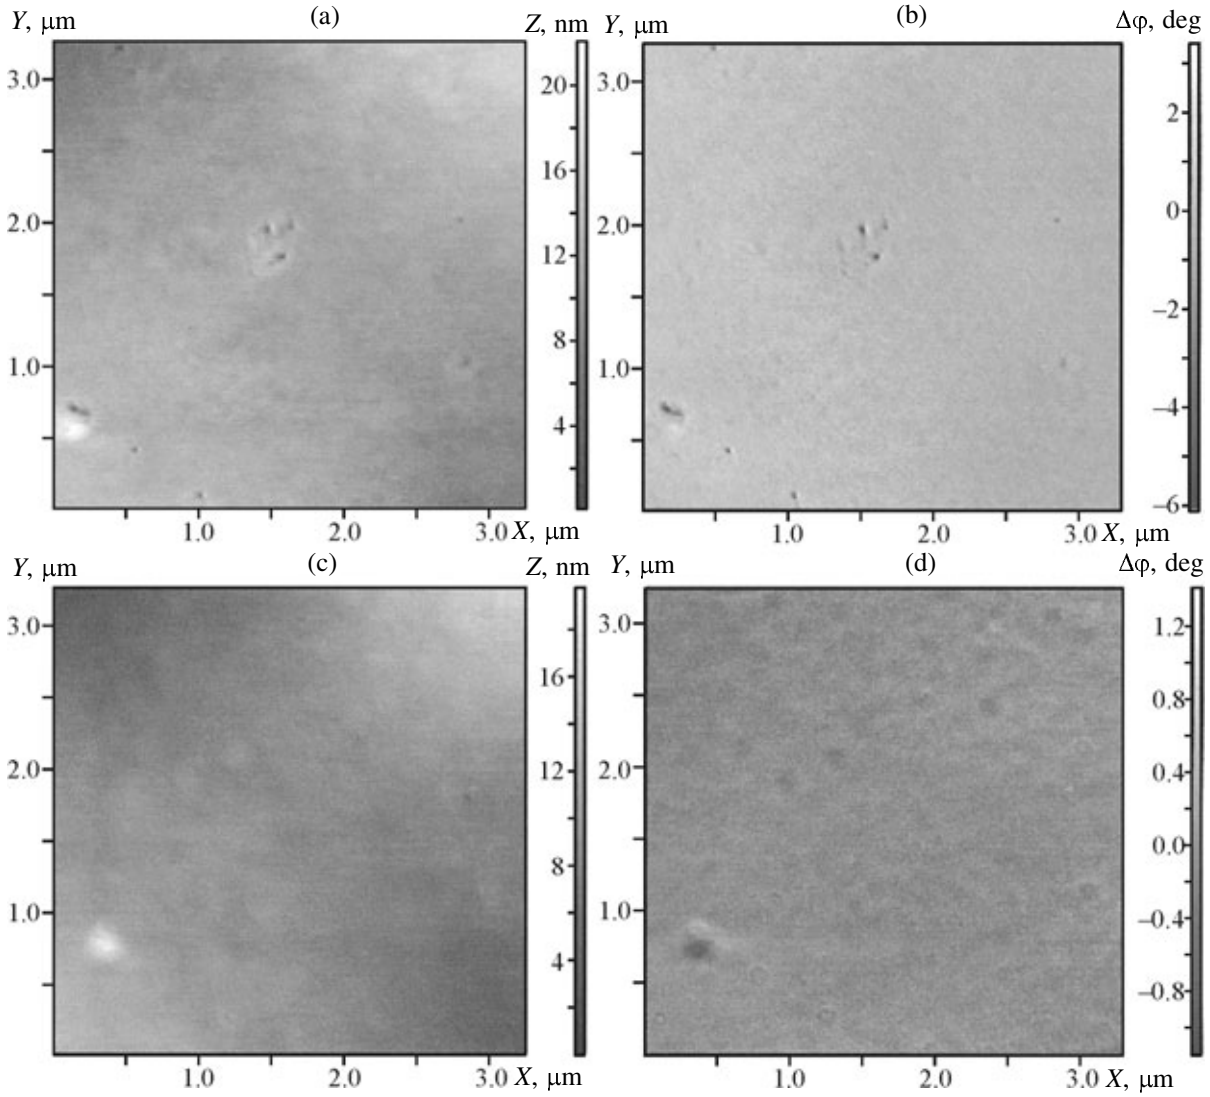

Fig. 1. AFM pattern of the films of BMA–TMPM copolymer (72.4 : 27.6 mol %) after hydrolytic condensation on heating from 25 to 120°C in the presence of DBTDL (0.539×10^{-2} mmol g^{-1} of the copolymer). (*X, Y*) Scanning range, (*Z*) height, and (Δφ) phase shift of the amplitude–frequency parameter of the cantilever. tration of the ≡$SiOCH_3$ groups and the concentration of the silanol groups.

The chemical composition of the polymer films was determined by FTIR spectroscopy using a multiple attenuated total internal reflection (MATIR) attachment.

The degree of swelling of the films in chloroform at 25°C was determined gravimetrically.

The glass-transition point of the polymers T_g was measured by differential scanning calorimetry on a DSC-60 calorimeter (Shimadzu) at a heating rate of 10 deg min^{-1} in the range 50–100°C.

The mechanical properties of the films were measured by the conventional procedures (GOST 12589–78) on an RTM-1T universal tensile-testing machine (Orientec, Japan).

To prevent formation of inorganic polysiloxane inclusions in the polymer matrix, copolymerization was performed at the content of TMPM in the monomer mixture lower than 30 mol %. The results of AFM examination of the film surface (Figs. 1a and 1b) shows that the copolymer structure is homogeneous even at the maximal content of the TMPM units in the copolymer (27.6 mol %). We obtained the AFM patterns of the copolymer films prepared by hydrolytic condensation in the course of gradual heating from 25 to 120°C. As shown below, under these conditions

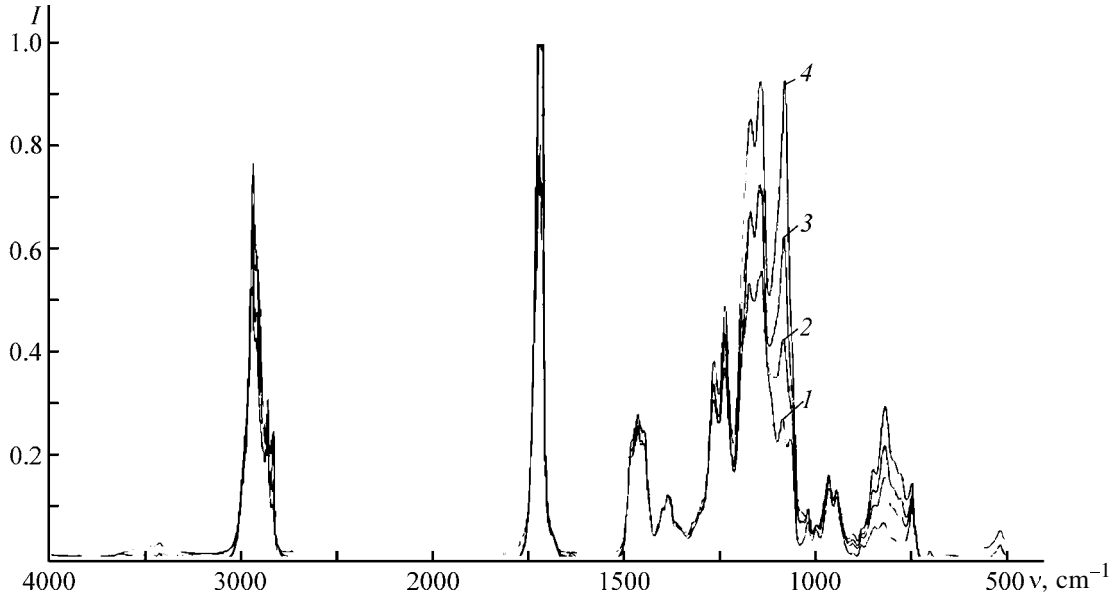

Fig. 2. IR spectra of BMA–TMPM copolymer containing (*1*) 6.0, (*2*) 12.5, (*3*) 19.7, and (*4*) 27.6 mol % of the TMPM units. (*I*) Intensity and (ν) wavenumber; the same for Figs. 4 and 5.

the degree of condensation of the silanol groups is maximal. No areas of the films having different adhesion to the cantilever were observed in the pattern measured in the phase contrast mode, which suggests the homogeneous structure of the film.

The AFM pattern of the film section (Figs. 1c and 1d) also shows that the bulk chemical composition of the copolymer is uniform. In addition, as determined by scanning of the section in the phase contrast mode (Fig. 1d), the copolymer consists of spherical globules grown together. The globule size is approximately 300 nm.

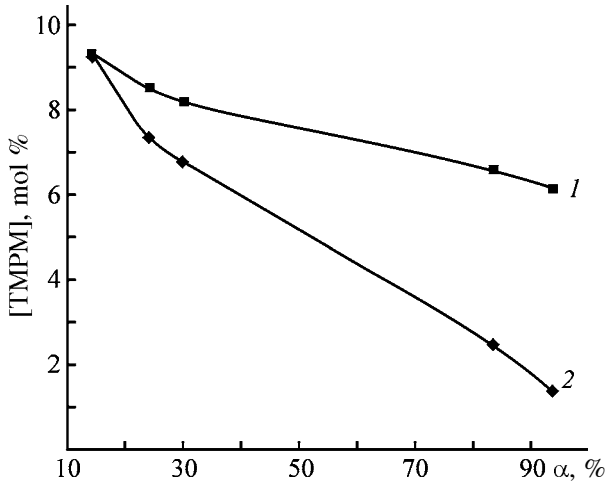

Fig. 3. (*1*) Total and (*2*) current content of TMPM units in BMA–TMPM copolymer as a function of the total conversion of a BMA + TMPM monomer mixture α. TMPM content in the initial monomer mixture 6.0 mol %.

In what follows, the copolymer properties will be discussed from the standpoint of formation of the three dimensional cross-linked structure of the copolymer containing inorganic cross-links.

The IR spectra of the copolymers with different content of the TMPM units are shown in Fig. 2. The samples were prepared on a Teflon support in the absence of catalysts and without heat treatment. The intensity of the bands at 820–1085 cm^{-1} assigned to the stretching vibration of the $-OCH_3$ groups of the TMPM units increases with an increase in the content on these units in the copolymer. In addition, a small silanol band at 3500 cm^{-1} suggests hydrolysis of the $\equiv SiOCH_3$ groups during formation of the films in air.

We recorded the IR spectra of the copolymers prepared at almost complete monomer conversion. The change in the copolymer composition in the course of copolymerization is shown in Fig. 3. In all copolymerization steps, the copolymer is enriched in the TMPM units as compared to the composition of the initial monomer mixture. The dependence of the total copolymer composition on the monomer conversion supports this conclusion. Calculation of the current copolymer composition shows that the content of the TMPM units in the copolymer at low monomer conversions is higher by a factor of 1.5 than the content of this monomer in the initial monomer mixture, whereas the copolymer formed in the final copolymerization steps contains less than 1.5 mol % TMPM. These data suggest nonuniform copolymer composi-

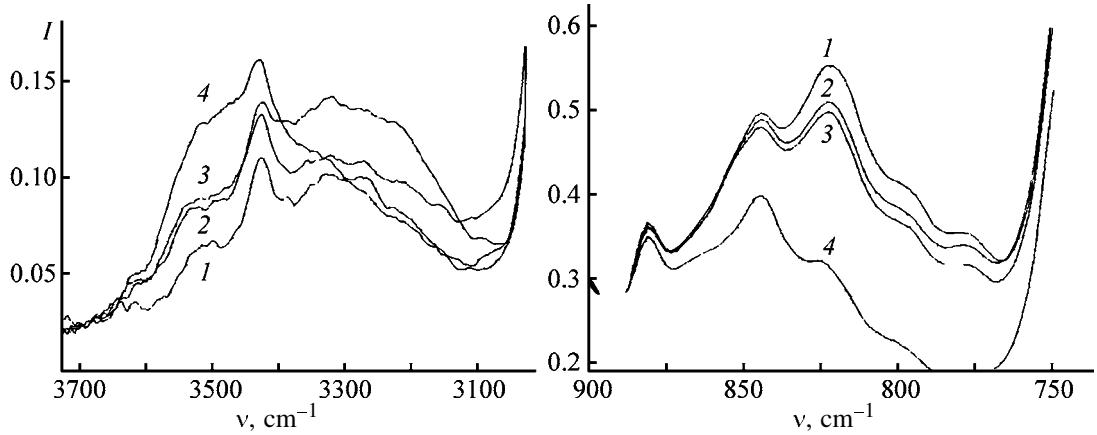

Fig. 4. IR MATIR spectra of BMA–TMPM copolymer (94.0 : 6.0 mol %) films (copolymer–support interface) formed on (*1*) Teflon and (*2–4*) water supports (*1, 2*) in the absence of catalyst and in the presence of (*3*) H_2SO_4 and (*4*) TSA.

tion, which can result in its nonuniform cross-linked structure.

The copolymers prepared at all the examined ratios of the monomers are soluble, despite consumption of the $\equiv SiOCH_3$ groups in the course of film formation. It should be noted that the IR spectra of copolymers formed on Teflon and water surfaces are similar even when the aqueous phase contains an inorganic acid catalyzing hydrolytic condensation.

To understand this phenomenon, let us consider the MATIR IR spectra of the samples (Fig. 4). The intensity of the band at 3500 cm^{-1} in the spectra of the films prepared on the water surface is substantially higher than that of the films prepared on the Teflon support. The opposite pattern was observed for the band at 820 cm^{-1}. It should be noted that the intensity of the band at 3500 cm^{-1} in the IR MATIR spectra appreciably increases when the polymer films is formed on the surface of the aqueous phase containing a strong organic acid (TSA). Thus, the $\equiv SiOCH_3$ groups of the films are hydrolyzed mainly at the copolymer–support interface. Propagation of this process in the bulk of the film is controlled by diffusion, since the surface copolymer layer structured by hydrogen bonds prevents diffusion of water in the bulk of the film. The number of covalent siloxane cross-links formed in this step is negligible since the copolymer remains soluble. This assumption is confirmed by an increase in the content of silanol groups in the bulk of the film with a decrease in its thickness.

The IR spectra of the samples were recorded immediately after their preparation. When the films are kept in an acid aqueous solution (pH 2.2), the conversion of the $\equiv SiOCH_3$ groups into the $\equiv SiOH$ groups increases. In this case, the intensity of the band of the silanol group at 3500 cm^{-1} increases with time. The mechanical strength of the films formed from soluble copolymers is low. When the content of TMPM units in the copolymer increases from 6.0 to 19.7 mol %, the ultimate tensile strength decreases from 7.1 to 4.2 MPa and the relative elongation increases from 200 to 275%.

To obtain polymers with the best performances, the conversion of the functional groups should be increased. For this purpose, we increased the reaction temperature and used an effective catalyst. At elevated temperatures the water diffusion in the bulk of the film increases owing to both an increase in the free volume in the copolymer and the rupture of the network of hydrogen bonds. To catalyze the hydrolytic condensation, compounds having increased affinity for the polymeric matrix are preferable. This assumption is confirmed by the fact that the hydrolytic condensation catalyzed by TSA is faster that that catalyzed by sulfuric acid having lower affinity for the copolymer. In the subsequent experiments, we used oil-soluble DBTDL as a catalyst of hydrolytic condensation.

The influence of the temperature and time of heat treatment of the copolymers on their properties and the processes occurring in the reaction mixture in the absence of the catalyst is shown in Table 1. It is seen that cross-linking of the copolymer by condensation of silanol groups in ineffective in the absence of the catalyst. Even under the most rigid conditions, no more that 10% of silanol groups formed by complete hydrolysis of $\equiv SiOCH_3$ groups are converted into the siloxane bonds. It should be noted that the dependences of all the examined properties on the temperature and time of heat treatment are abnormal. The cross-link density naturally increases after the heat

treatment in modes 1 and 2. This is indicated by an increase in the content of silanol groups, T_g, and film strength and by a decrease in the degree of swelling and specific elongation of the film. All these transformations suggest restriction of the segmental mobility of the macromolecules, mainly owing to formation of a large number of hydrogen bonds between the ≡SiOH hydroxy groups and probably carbonyl groups of BMA or TMPM [8]. In the final heat treatment step (conditions 3), all the examined parameters change in the opposite direction despite additional formation of ≡SiOSi≡ cross-links.

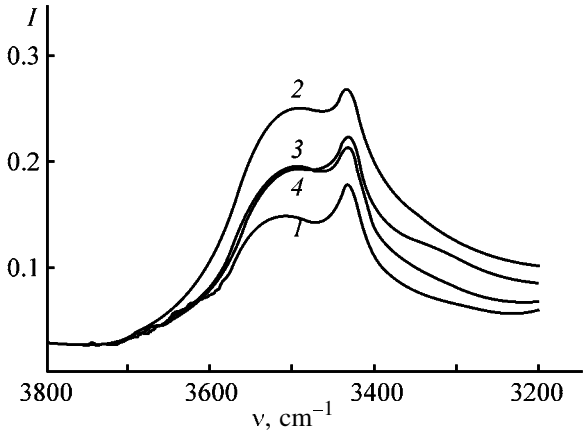

Fig. 5. IR spectra of the films of BMA–TMPM copolymers (94.0 : 6.0 mol %) subjected to hydrolytic condensation at room temperature in the presence of (*1*) 0.539×10^{-2}, (*2*) 0.792×10^{-2}, (*3*) 1.585×10^{-2}, and (*4*) 3.169×10^{-2} mM DBTDL.

We are not able to give unambiguous explanation of these effects. It is possible that microzones with an increased content of hydrolyzed TMPM units can be formed in the copolymers owing to their nouniform composition. The presence of these zones can prevent macromolecules from taking the equilibrium conformation and can change the free volume of the polymer system, thus affecting the physicochemical and mechanical properties of the copolymers. It is known [8] that introduction of silica in polymethyl methacrylate by the sol–gel procedure (hydrolytic condensation of TEOS) decreases T_g by 10–15°C. The decrease in the mechanical strength of cross-linked films win increasing content of the TMPM units in the copolymer confirms this assumption (Table 2). The siloxane cross-links formed in this step are not numerous and enhance the mechanical strength insignificantly. Our calculation shows that more than 100 carbon atoms are located, on the average, between two ≡SiOSi≡ cross-links. It is significantly higher than the size of the statistical segment in methacrylate polymers [10]. Thus, a small number of the covalent cross-links insignificantly affects T_g.

Introduction of DBTDL in the reaction system catalyzes hydrolytic condensation. As seem from the IR spectra (Fig. 5), the reaction performed at room temperature in the presence of DBTDL is relatively fast. The insoluble copolymer is formed at the catalyst concentration of 0.0079 mmol g^{-1}. At this concentration, the ≡SiOCH$_3$ groups are completely consumed and the intensity of the absorption band at 3500 cm^{-1} becomes maximal. At higher DBTDL concentration, the silanol groups are involved in condensation processes to a greater extent and their content in the copolymer decreases.

Table 3. Degree of swelling in chloroform of BMA–TMPM copolymers (94.0 : 6.0 mol %) prepared at different concentration of the catalyst and in different heat treatment modes

	0	1	2
0.792	250	128	198
1.585	235	140	258
6.339	290	264	363

The heat treatment in the presence of the catalyst additionally accelerates the polycondensation. It is seen from the degree of swelling of the films prepared under these conditions (Table 3). As in the absence of the catalyst, the dependence of the degree of swelling on the heat treatment temperature passes through a minimum under relatively mild conditions (heat treatment conditions 1). This can be due to the fact that the appropriate ratio between hydrogen and covalent bonds is attained in the earlier steps of the process. It should be noted that the degree of swelling of the copolymer prepared in all the heat treatment modes increases with increasing the DBTDL concentration. We cannot explain this fact using the above-considered arguments. As seen from Table 4, the content of the silanol groups and hence the probability of hydrogen bond formation in the samples prepared in all the heat treatment modes increase with increasing the catalyst concentration. This phenomenon deserves a separate consideration. We can only suggest that chloroform used as the solvent can compete for hydrogen bond formation with other components of the reaction system.

Table 4 shows that the role of inorganic cross-links increases under more rigid conditions of hydrolytic condensation. However, since the concentration of the ≡SiOH groups is high in the course of the overall process, formation of hydrogen bonds between macromolecules is possible in all the condensation steps. Thus, the organic–inorganic network of the copolymer consists of both inorganic cross-links and hydrogen bonds. However, the relative contributions of processes leading to these intra- and intermolecular cross-links remains unclear.

The mechanical properties of the copolymers are summarized in Table 5. It should be noted that some of cross-linked copolymers withstand substantial deformation before failure. Since these experiments were performed at temperatures below T_g of the copolymers, high deformations are caused by the state of induced elasticity. Hence, to understand the copolymer properties, the possibility of formation of this state in relation to the copolymer composition and

conditions of hydrolytic condensation should be considered.

When the degree of hydrolysis and condensation of all copolymers increase, the strength of the products increases and their elasticity decreases. This is quite natural, since presence of small number of cross-links restricts the segmental mobility of the macromolecules. However, displacement of some macromolecular fragments under a load (induced elasticity) results in partial ordering of macromolecules and strengthening of the material. At high concentration of cross-links in the sample, the segmental mobility is impossible and the films readily undergo brittle failure. In this case, not only the specific elongation but also the strength of the samples decrease, since all parts of the macromolecules are fixed and their additional ordering is impossible. Probably this is the case for the examined systems also. The strong induced deformation decreases with increasing TMPM content in the copolymer. The higher the content of the units of this monomer in the copolymer, the lower the temperature and the catalyst concentration corresponding to sharp deterioration of the elastic and mechanical properties. It should be taken into account that randomly distributed heterogeneous regions resulting in intermolecular interaction of the functional groups can be formed in the copolymer. This concerns formation of both covalent cross-links and hydrogen bonds. This effect should be the most pronounced in the copolymers with a high content of the TMPM units. The AFM pattern of the material with the globular structure (Fig. 1) confirms this assumption. The heterogeneous regions can concentrate the stress, which results in brittle failure of the material.

The properties of the copolymers with the minimal (6.0 mol %) TMPM content differ. Previously we discussed interesting effects appearing in these systems. When the organic–inorganic cross-linked structure of these copolymers is formed at a low catalyst concentrations and moderate temperatures, the strength of the samples can be substantially increased with preservation of their high elasticity.

As noted above, the cross-linked copolymers contain a large amount of free silanol groups. This is a known phenomenon. Similar systems cured by a sol–gel procedure also contain residual silanol groups

[5, 7]. On the one hand, the presence of the residual SiOH groups in a copolymer allows preparation of polymer coatings with a high adhesion to particular supports. For this purpose, high-strength copolymers with poor elastic properties (e.g., copolymers containing 12.5 mol % TMPM) can be used. Coatings formed by these copolymers on a glass cannot be separated without failure from the support. On the other hand, the properties of materials containing residual silanol groups can be changed in the course of their prolonged operation. On prolonged storage, the elasticity of some films decreases without changing their strength. Hence, these copolymers are unsuitable for film preparation and can be used for preparing coatings and bulk articles.

CONCLUSIONS

(1) Hydrolysis of $\equiv SiOCH_3$ groups in the course of preparation of organic–inorganic cross-linked copolymers of *n*-butyl methacrylate and 3-(trimethoxysilyl)propyl methacrylate is substantially faster than condensation of the ≡SiOH groups. Conversion of ≡SiOH groups into the siloxane bonds is incomplete even at high temperatures.

(2) Cross-linking of the copolymers containing large number of the residual silanol groups involves simultaneous formation of covalent inorganic cross-links and hydrogen bonds between the macromolecules.

(3) The dependences of physicochemical and mechanical properties of the copolymers cross-linked by the covalent and hydrogen bonds on the heat treatment temperature passes through extrema with gradual accumulation of the siloxane cross-links in the polymeric matrix.

(4) Copolymers with a high content of the ≡SiOH groups can be used for preparing coatings cross-linked in the course of their formation on surfaces reactive with respect to the silnaol groups.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Orientational Ordering of Polymer Chains near the Surface and Asymmetry of the Statistical Segment of Macromolecules

G. M. Pavlov

Fock Research Institute of Physics, St. Petersburg State University, St. Petersburg, Russia

Received September 13, 2006

Abstract—The parameter of the orientational order of polymer chain fragments near the substrate (film) surface in relation to the degree of asymmetry of the statistical segment of the macromolecule was discussed in terms of the model of adsorption of rigid cylinders on the substrate surface. The theoretical parameters of the orientational order were analyzed and compared with the experimental data for films of polysaccharides, sulfated phenyl-containing polymers, and polytrimethylsilylpropynes.

DOI: 10.1134/S107042720701020X

The properties of polymer films and polymers at interfaces have been the subject of numerous studies [1–4]. Spontaneous ordering of the macromolecules near the surface in films prepared by free evaporation of the solvent from solutions is examined by the polarized-beam technique at oblique incidence [5, 6]. The theory of Cherkasov–Vitovskaya–Bushin [5] provides a quantitative interpretation to the birefringence observed in films and estimates the parameter of the orientational order of the polymer chain fragments near the surface as

$$S_0 = (3\langle\cos^2\theta\rangle - 1)/2, \quad (1)$$

where θ is the angle between the normal to the film (substrate) surface and the long axis of the statistical segment of the macromolecule.

We found that the orientational order parameter S_0 is unambiguously dependent on the length of the statistical segment characterizing the equilibrium rigidity of the macromolecular chains forming the polymer film [7–10].

Published data [1, 2, 11–13] suggest that formation of the surface layers of polymer films from solutions under solvent evaporation involves adsorption of the macromolecules on the substrate surface and that the contact of the polymer with the substrate surface is energetically favorable. In this case, the molecule and its constituting segments tend to be arranged in a way ensuring the largest area of contact with the surface. Then the arrangement of the chain segments with respect to the substrate surface is dependent on their geometric shape/asymmetry, rather than equiprobable. The polymer chain in solution will be modeled in this study as a cloud of identical statistically independent segments (cylinders); each of them will have a length A and will be characterized by the axial ratio $p = A/d$ ($d = 2r$ is the diameter of the cylinder, and r, its radius). The energy of adsorption (adhesion) E_a of the polymer segment on the flat surface of the substrate will be taken proportional to the area s of the contact of the segment with the surface: $E_a = \alpha_a s$, where α_a is the surface density of the adsorption (adhesion) energy. We will assume that α_a is identical for the end faces and lateral surface of the cylinder, as well as in the series of homologous polymers. Then, the probability of the orthogonal arrangement of the cylinder simulating the statistical segment of the polymer chain will be proportional to the area of its base. The probability of the parallel arrangement of the cylinder will be proportional to the area of contact between the lateral surface of the segment and the substrate surface, which will be calculated as $s = A l_c$, where l_c is the effective cross-sectional dimension of the contact (a priori unknown). In this case, the parameter $\langle\cos^2\theta\rangle$ can be calculated as

$$\langle\cos^2\theta\rangle = (\pi r^2\cos^2\theta + Al_c\cos^2\pi/2)/(\pi r^2 + Al_c)$$
$$= \pi r^2/(\pi r^2 + Al_c) = [1 + (2l_c p/\pi r)]^{-1}, \quad (2)$$

which yields

$$S_0 = (3\langle\cos^2\theta\rangle - 1)/2 = [1 - p/\pi(r/l_c)]/[1 + 2p/\pi(r/l_c)] \quad (3)$$

for the orientational order parameter S_0.

Length of the statistical segment A, cross-sectional diameter of the macromolecules d, asymmetry of the segment p for selected sulfated phenyl-containing polymers (nos. 1–3) and polysaccharides (nos. 4–10), and the orientational order parameter of the polymer chain fragments near the surface S_0, determined by the polarized-beam technique with oblique incidence in the films of the corresponding polymers

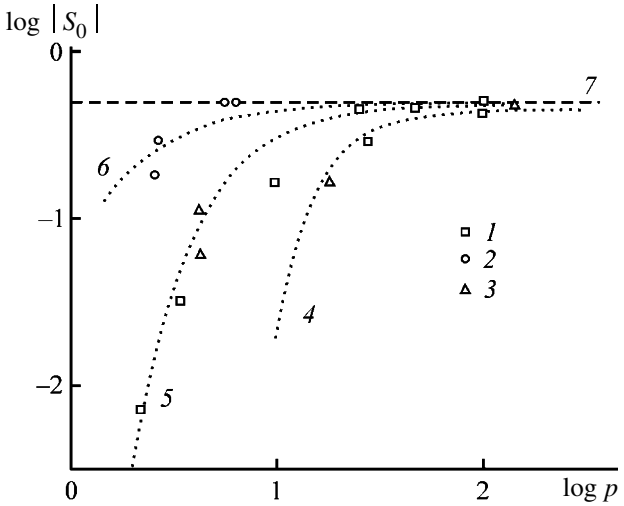
** The parameter S_0 was estimated accurately to within 10%.

The condition for the predominantly planar ordering of the segments on the surface, when $S_0 < 0$, is $Al_c > \pi r^2$, i.e., the area of contact of the lateral surface of the cylinder with the substrate surface should exceed the area of its end face. In this case, at high degrees of asymmetry of the statistical segment, when $p \to \infty$, the parameter S_0 tends to a limiting value: $S_0 \to -0.5$, corresponding to the ideal planar packing of the segments near the surface. In the case when $\pi r^2 > Al_c$, $S_0 > 0$, and the segments near the surface exhibit orthogonal ordering (the directrix of the cylinder makes an angle $\theta < 57°$ with the normal to the substrate surface).

When $\pi r^2 \gg Al_c$, the order parameter tends to another limit, $S_0 \to 1$, corresponding to the ideal orthogonal packing of the segments near the surface. Thus, expression (3) describes both types of the possible orientation ordering of the segments with respect to the surface (planar and orthogonal) in relation to the r/l_c ratio. Virtually all linear polymers exhibit planar ordering of the chains near the surface, i.e., $\pi r^2 > Al_c$.

The parameter S_0 is governed both by the asymmetry of the statistical segment p and the dimensionless ratio r/l_c. The plot of the module of S_0 vs. p in the log–log coordinates breaks down into a number of curves shifting to the right along the p axis with increasing r/l_c (see figure). The smaller the surface area of contact of the segment with the surface, the greater the degree of asymmetry of the segment corresponding to the same degree of the orientational order in the surface layer of the polymer film.

Testing the calculated dependences $S_0 = f(p, r/l_c)$ is best conducted via comparison with the experimental data for films formed under identical conditions, which excludes possible uncontrollable impact of additional factors (substrate, solvent) on the properties of the near-surface layers. Let us consider the birefringence of the films formed on glass from solutions of water-soluble polysaccharides and water-soluble sulfated phenyl-containing polymers (see table). The



Module of the orientational order parameter $|S_0|$ in relation to the asymmetry of the statistical segment p in the log–log coordinates. (3)], corresponding to r/l_c of (*4*) 3, (*5*) 1, and (*6*) π^{-1}. Straight line *7* corresponds to the limiting value of the orientational order parameter $S_0 = -0.5$ for the planar ordering.

table presents the parameters A, d, and p and their corresponding errors, as well as the parameter S_0. For references to original works, in which the lengths of the statistical segment A and the molecular diameter d were determined, see [7–10, 14]. It should be noted that the polysaccharide series holds a record on the scope of possible lengths of the statistical segment of linear chains (see table) and, hence, its asymmetry.

The figure compares the theoretical dependences $S_0 = f(p, r/l_c)$ calculated by relationship (3) with the experimentally estimated parameters S_0 and p. Also, the figure presents the data from studies [15, 16] concerned with the surface birefringence of the films of polytrimethylsilylpropynes prepared on cellophane substrates under evaporation of their solutions in toluene or CCl_4.

The experimental points obtained for the films formed from water-soluble sulfated aromatic polymers and polysaccharides are intermediate between the curves corresponding to the dimensionless parameter $1 \le r/l_c \le 3$. For polytrimethylsilylpropyne chains, the best agreement between the experiment and the theory is observed in the case when the contact area of the polymer chain segment with the substrate satisfies the condition $l_c \approx \pi r$. This means that the polytrimethylsilylpropyne chains are relatively better oriented at interfaces, which, in turn, can provide an explanation to the unique gas-separation properties of membranes thereof [17].

It should be noted that comparison of our experimental results with the relationship (3) allows estimating the contact surface area $s = Al_c$ of the polymer segment with the rigid flat surface of the substrate. For the water-soluble polymer/substrate systems examined, the surface area of contact of the statistical segment varies within 0.4–300 nm^2, depending on the thermodynamic rigidity of the polymer chains. The contact surface area for the statistical segments of the chains of polytrimethylsilylpropynes is relatively larger: $s \approx \pi Ar$. We will note that a larger or a smaller cross-sectional dimension of the contact l_c can mean that some polymer/solvent/substrate systems have a higher or a lower adsorption (adhesion) energy compared to other systems. In other words, the cross-sectional dimension of the contact is an effective parameter which needs to be reduced to the corresponding surface density of the adhesion energy in comparison of various polymer/solvent/substrate systems. The resulting structure of the macromolecules near the surface is dictated by the competition of the entropy factor, to a first approximation depending on the asymmetry p, and the energy factor governed by l_c.

Naumova and Grishchenko [18] assumed that the orientational ordering of rigid impenetrable cylinders near the surface is governed by purely steric factors and obtained for the order parameter

$$S_0 = (1 - p)/(1 + 2p). \quad (4)$$

Evidently, relationship (4) is a special case of relationship (3) at $l_c = \pi r$.

CONCLUSION

The relationship $S_0 = [1 - (pl_c/\pi p)]/[1 + (2pl_c/\pi p)]$ was obtained, which, along with the degree of asymmetry of the statistical segment of the macromolecules p, contains the ratio of the cross-sectional dimension of the contact between the segment of the macromolecule and the substrate surface l_c to the segment radius r.

Abstract—Nanocomposites based on a thermoplastic polyimide, poly{1,3-bis(3',4-dicarboxyphenoxy)benzene [4,4'-bis(4"-*N*-phenoxy)diphenyl sulfone]imide}, and synthetic magnesium silicate nanoparticles with montmorillonite structure were prepared from melts. Efficient modification of the surface of the initial nanoparticles with (aminoethylaminomethyl)phenethyltrimethoxysilane was performed.

DOI: 10.1134/S1070427207010211

At present one of the most efficient approaches to the development of new polymeric materials is the preparation of hybrid nanocomposites of polymers with inorganic nanoparticles, i.e., with inorganic particles of size no more than 100 nm. It should be noted that the polymeric materials formed on both molecular and supramolecular levels from organic (polymer) and inorganic (nanoparticles) components are absolutely new polymeric systems and not a simple "sum" of these components. This fact is confirmed in a series of experimental studies [1, 2]. It is known [3–8] that lamellar silicates, when added as fillers, strongly enhance characteristics of the resulting polymeric materials, e.g., they improve the strength, crack resistance, softening point, and heat resistance of polymers and decrease their coefficient of linear thermal expansion, gas permeability, etc.

Polyimides (PIs) are highly thermally stable polymers widely used in various branches of industry, such as electrical engineering and electronics. Polymer–inorganic nanocomposites based on PI thermoplastics and natural lamellar silicate montmorillonite were prepared and studied in [9–12]. For example, PI nanocomposites prepared from natural montmorillonite modified with various organic compounds [11, 12] exhibit elevated barrier and mechanical properties as compared to unfilled PIs. At the same time, composites with natural montmorillonite filler have certain drawbacks associated with heterogeneity of the chemical, phase, and disperse composition of the filler [13–15]. The use of synthetic nanoparticles eliminates these drawbacks.

Lamellar silicates are capable of isomorphic substitution of atoms in their structure, allowing direct synthesis of nanoparticles of given composition. The choice of the composition and size of nanoparticles is dictated by the destination of the resulting composites. Thus, synthetic nanoparticles with given characteristics provide preparation of polymeric composites with required properties.

In this study we prepared nanocomposites based on polyimide thermoplastics and synthetic magnesium silicate montmorillonite (MMT-Mg) synthesized under the hydrothermal conditions [13] and examined the mechanical characteristics of these materials.

EXPERIMENTAL

Synthetic magnesium silicate montmorillonite was used as a filler to prepare composites based on polyimide matrices. Montmorillonite was prepared under the hydrothermal conditions given elsewhere [13]. The size of the resulting particles was about 50 nm, and the composition of the resulting magnesium silicate montmorillonite (analog of natural saponite) was $Mg_3Si_4O_{10}(OH)_2 \cdot nH_2O$.

The hydrophobicity and affinity for polymeric materials of the MMT-Mg nanoparticles were improved by modification of their surface with (aminoethyl-

aminomethyl)phenethyltrimethoxysilane (hereinafter, silane). A weighed portion (1 g) of MMT-Mg nanoparticles was preliminarily dispersed in ethanol (50 ml) using an ultrasonic bath (20 kHz) for 1 h. Then, the resulting dispersion was mixed with silane (0.2 ml) und ultrasonic treatment was performed for an additional 10 min. The resulting dispersion in the ethanolic solution of silane was centrifuged, the precipitate was additionally washed with ethanol for 30 min to remove excess silane not consumed in the reaction with MMT-Mg nanoparticles, and the mixture was centrifuged. The resulting MMT-Mg nanoparticles treated with silane were dried to remove ethanol in a vacuum at 60°C for 5 h.

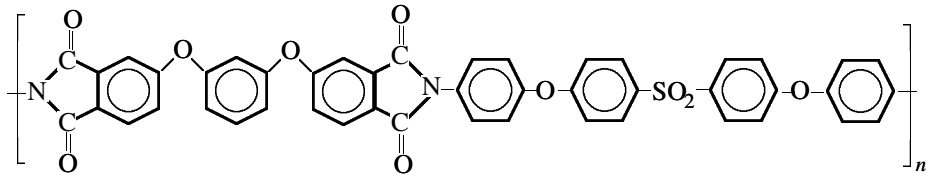
The efficiency of the nanoparticle surface treatment with silane was monitored by X-ray diffraction (XRD) analysis on a MiroMax007 device (Rigaku Denki Co. Ltd, Japan). The increase in the distance between the silica layers in MMT-Mg after its treatment with silane was determined from the shift of the (001) reflection toward smaller angles θ, and the corresponding interlayer spacing d was calculated using the Bragg equation:

$$D = \lambda/2\sin\theta,$$

where λ = 1.54 Å (wavelength of CuK_α radiation).

The thermogravimetric analysis (TGA) of the MMT-Mg samples before and after treatment with silane was performed on a Perkin–Elmer 7 device under nitrogen atmosphere; the sample weight was 5–10 mg, and the heating rate, 10 deg min^{-1}.

As a polymeric matrix we used, poly{1,3-bis(3',4-dicarboxyphenoxy)benzene [4,4'-bis(4"-*N*-phenoxy)-diphenyl sulfone]imide} (PI P-SOD) [13] of the following structure:



The P-SOD + 10 wt % MMT-Mg/silane mixture was prepared on a Haake Minilab microblender, which allows combining a small amount (5 g) of the molten polymer with MMT-Mg/silane powder (0.5 g). Blending was performed at 340°C for 20 min at a screw rotation rate of 100 rpm.

The block samples for mechanical tests were prepared from both unfilled of PI P-SOD and P-SOD + 10 wt % MMT-Mg/silane composite using a microinjector (DACA Instruments); the melt temperature was 360°C, the mold temperature, 90°C, and injection pressure, 100 atm.

The mechanical properties (bending strength σ, bending elastic modulus E, and ultimate bending strain ε) of block samples P-SOD polyimide and nanocomposites based on it were determined on a 1958U-10-1 tensile-testing machine (Russia). For mechanical tests, the samples of polyimide and composite were prepared as $1 \times 5 \times 20$ mm plates. The bending properties were studied at room temperature under the mode of active loading at a rate of 10^{-3} m min^{-1}. The shear Young's modulus G' of the block samples was determined with an MK-002 torsional balance wheel (Institute of Macromolecular Compounds) in the mode of freely damping torsional oscillations (oscillation frequency ~0.5 Hz) at room temperature.

Modification of the surface of lamellar silicates is an important stage of the preparation of nanocomposites based on them. Treatment of silicates with organic compounds makes their surface more hydrophobic, improves the compatibility of nanoparticles with the polymer, and increases the interlayer spacing to simplify exfoliation of the silicate filler in the polymer matrix [1, 2]. Since the main process occurring at interaction of the polymers with lamellar silicates is the exchange adsorption, the behavior of the exchanging cations (Na^+, K^+, Ca^{2+}) localized between the silica layers is of particular importance. High cation-exchange capacities determine the simplicity and completeness of modification of the clay materials. In turn, the cation-exchange capacity is determined by the composition and structure of the lamellar material. Isomorphic substitution of aluminum atoms for silicon and of magnesium, iron, and some other elements for aluminum in tetrahedral and octahedral positions of the structure provides formation of the surface negative charge and improves the cation-exchange capacity of the lamellar silicate.

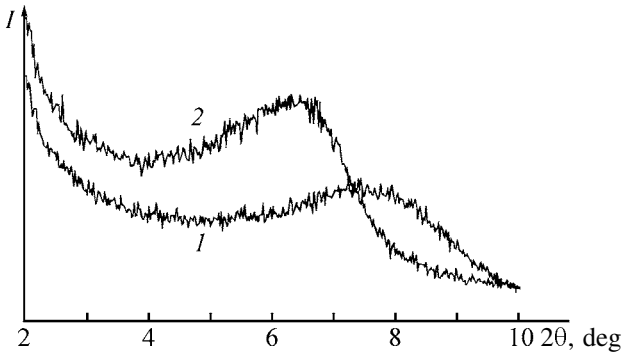


Fig. 1. XRD patterns of (*1*) initial MMT-Mg and (*2*) MMT-Mg modified with silane. (*I*) Intensity and (2θ) Bragg angle.

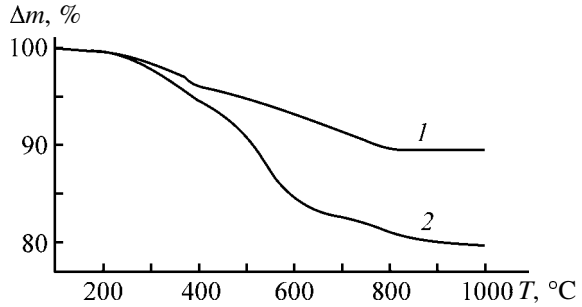

Fig. 2. TGA curves of (*1*) initial MMT-Mg and (*2*) MMT-Mg modified with silane. (Δ*m*) Weight loss and (*T*) temperature.

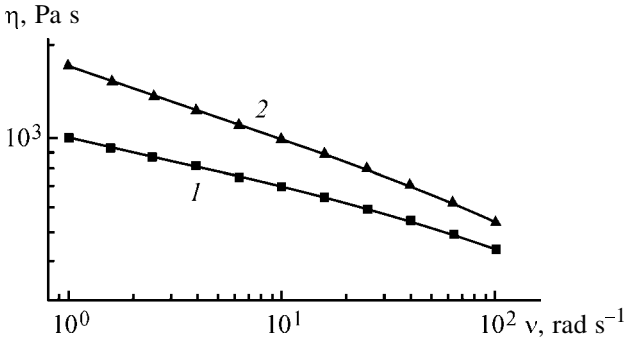

Fig. 3. Viscosity η of melts: (*1*) PI P-SOD and (*2*) nanocomposite PI P-SOD + 10 wt % MMT-Mg/silane as a function of frequency ν; temperature 360°C, deformation amplitude 1%.

In the absence of isomorphic substitution, as in the case of MMT-Mg studied in this work, the crystallochemical charge of the particle surface should be neutral and the cation-exchange capacity should be close to zero. From this viewpoint, the composition of montmorillonite is not optimal. At the same time, synthetic montmorillonite exhibits adsorption capacity allowing efficient modification of its surface with organic compounds. This is due to the fact that the surface of lamellar silicates, along with exchanging cations, contains wide assortment of active adsorption centers of various nature [16, 17]. Along with exchanging cations and coordination-unsaturated magnesium and aluminum ions, they can include single and geminal OH groups at the silicon atoms at the edges of tetrahedral and octahedral layers, uncompensated bonds at the crack surfaces, etc. [17].

The XRD patterns of the initial MMT-Mg and of MMT-Mg treated with silane are shown in Fig. 1. As seen, the reflection at 2θ = 7.55° (d_{001} 11.7 Å) characterizing the basal distance between the silicon–oxygen layers in the initial montmorillonite shifts toward smaller angles after treatment with silane. The reflection at 2θ = 6.31° corresponds to an increase in the interlayer spacing to 13.8 Å. Thus, treatment of the initial sample with silane increases the interlayer spacing, which confirms formation of a hybrid organic–inorganic material.

As seen from the TGA data (Fig. 2), the MMT-Mg samples treated with silane exhibit relatively high heat resistance; intensive weight loss is observed in the 230–250°C range, which allows their use for modification of heat-resistant polyimide matrices. It should be noted that low stability of aliphatic amines often used in modification of the lamellar silicate surface [3–8] is the main drawback hindering their use for preparing nanocomposites based on polyimides.

Compounding of silane-MMt-Mg nanoparticles modified with PI P-SOD in a microblender only insignificantly increases the polyimide viscosity at 360°C (Fig. 3). For example, filling of PI P-SOD with MMT-Mg/silane (10 wt %) increases the viscosity of the polyimide matrix by a factor of 1.5, which allows preparation of high-quality nanocomposite samples using the DACA microinjector without increasing temperature of the melt or press mold. Small increase in the melt viscosity can be probably explained by a small size (50 nm) of the MMT-Mg nanoparticles. In contrast, coarser natural montmorillonite with the particle size more than 100 nm, when added to the polymeric matrix, strongly increases the viscosity of the polymer melt [4, 5]. Increased viscosity of the resulting composites complicates their molding.

The mechanical characteristics of samples of polyimide thermoplastics and nanocomposites based on P-SOD and filled with MMT-Mg nanoparticles modified with silane are listed in the table. Addition of MMT-Mg/silane (10 wt %) into the PI P-SOD matrix increases the bending strength σ_f of the composite from 170 to 195 MPa and, especially, its bending elastic modulus E_f and shear elastic modulus G' from 2.3 to 3.2 GPa and from 1.3 to 1.8 GPa, respectively. This increase in the strength and hardness of the poly-

Mechanical properties of polyimide thermoplastics and nanocomposites prepared from PI P-SOD and nanoparticles of synthetic MMT-Mg modified with silane*

Sample	σ_f, MPa	E_f, GPa	ε_f, %	G', GPa
ULTEM-1000	180 ± 3	2.7	>10	1.4
P-SOD	170 ± 4	2.3	>10	1.3
P-SOD + 10wt % MMT-Mg/silane	195 ± 7	3.2	5	1.8

* (ε_f) Bending strength, (E_f) bending elastic modulus, (χ_f) ultimate bending strain, (G') shear elastic modulus.

imide composite confirms the reinforcing effect of MMT-Mg nanoparticles owing to anisotropic platelike shape of the nanoparticles and their strong binding with the P-SOD matrix. For comparison, the properties of thermoplastic ULTEM-1000 polyamide (GE, the United States), whose test samples were prepared by a similar procedure using a DACA microinjector, are also listed in the table. As seen, the strength and elastic characteristics of commercial ULTEM-1000 composite are slightly higher than those of PI P-SOD thermoplastics, but they are lower than those of P-SOD + 10 wt % MMT-Mg/silane nanocomposite. Slight decrease in the ultimate bending strain ε_f of the nanocomposite is probably due to insufficiently uniform distribution of the MMT-Mg nanoparticles in the PI P-SOD matrix and formation of submicron particle aggregates, which can initiate formation of critical microcracks in the composite bulk.

CONCLUSIONS

(1) The surface of magnesium silicate nanoparticles with montmorillonite structure was modified using (aminoethylaminomethyl)phenethyltrimethoxysilane. As a result, the basal spacing between the silicon-oxygen layers increased from 11.7 to 13.8 Å, which confirms the efficiency of the surface modification.

(2) Nanocomposites based on thermoplastic polyimide poly{1,3-bis(3',4-dicarboxyphenoxy)benzene [4,4'bis(4"-*N*-phenoxy)diphenyl sulfone]imide} and magnesium silicate nanoparticles modified with silane were prepared.

(3) Filling of the polyimide matrix with magnesium silicate nanoparticles modified with silane (10 wt %) increases the nanocomposite strength by 15% and its bending elastic modulus and shear elastic modulus by a factor of 1.4.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Thermogravimetric Study of Lithium Tetraalkoxyborates

Z. T. Dmitrieva and N. A. Khomchenko

Institute of Petroleum Chemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received March 16, 2006

Abstract—Properties of lithium tetraalkoxyborates Li[*t*-$C_4H_9OB(OR)_3$] (R = *n*-C_4H_9 to *n*-C_8H_{17}, *n*-$C_{12}H_{25}$) were studied by differential thermogravimetry. The kinetic parameters and heat effects of thermal decomposition of lithium tetraalkoxyborates in air and inert gas atmosphere as functions of the carbon chain length were determined.

DOI: 10.1134/S1070427207010223

Our previous studies [1–5] by mass spectrometry, rheometry, NMR spectroscopy, and small-angle X-ray scattering showed that lithium tetraalkoxyborates Li[$B(OR)_4$] (R = C_4H_9–$C_{16}H_{33}$) in the solid state and in hydrocarbon liquids are polyassociated through Li···O bonds and van der Waals bondings between alkyl groups R···R with the formation of three-dimensional chelate structures. In liquids with low permittivity, compounds swell similarly to polymers with the formation of thermodynamically stable structured systems [6–8]. After mechanical breakdown under the action of shear stress in various deformation modes, the supramolecular structure of solutions and gels is restored without changes in rheological properties [3, 4, 8, 9].

Due to thixotropic properties, hydrocarbon gels of compounds are used, for instance, in the technology of hydraulic fracturing of low-permeability gas- and oil-bearing strata in order to increase their filter-output. The thermodynamic parameters of thermal desorption show high affinity of lithium tetraalkoxyborates for hydrocarbons [10].

In this study, to obtain additional information on the stability of associative intermolecular interactions and of Li[*t*-$C_4H_9OB(OR)_3$], e.g., under conditions of stratal temperature, we examined these compounds by differential thermogravimetry.

EXPERIMENTAL

Thermal decomposition (pyrolysis) and thermal oxidative decomposition of Li[*t*-$C_4H_9OB(OR)_3$] (R = *n*-C_4H_9 to *n*-C_8H_{17}, *n*-$C_{12}H_{25}$) were performed in a platinum crucible in an argon flow (10 l h^{-1}) and in air, respectively, at a heating rate 5 deg min^{-1} on a MOM derivatograph (Hungary). Lithium tetraalkoxyborates were synthesized in a flow of dry inert gas by the reaction of boron trialcoholates with lithium *t*-butylate in dry pentane and without diluent. The purity of compounds obtained was checked by elemental microanalysis and IR and ^1H NMR spectroscopy.

The parameters of the formal kinetics of the thermal transformation were obtained with appropriate computer software under the assumption that the thermal transformation obeys the Arrhenius law

$$K = A\exp(-E/RT)$$

and involves the pyrolysis reaction only [11]. With regard to the kinetics of decomposition of polymeric materials [12], we assumed that the pyrolysis of lithium *t*-butoxytrialkoxyborates is also described by the

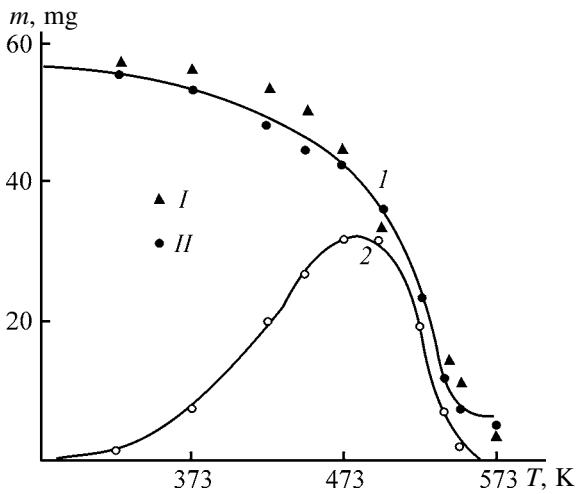

Fig. 1. Change in weight *m* (TG) in the course of Li[*t*-$C_4H_9OB(OC_7H_{15})_3$] pyrolysis. (*T*) Temperature. (*1*) Experimental TG of pyrolysis: (*I*) by one-stage scheme and (*II*) by two-stage scheme; (*2*) accumulation of an intermediate, calculated by the two-stage scheme.

C_8H_{17}	34.8	373–448	9.8×10^{-5}–6.4×10^{-4}	125.1	448–573 (548)	1.5×10^{-5}–2.4×10^{-2} (7.1×10^{-3})
$C_{12}H_{25}$	76.9	423–498	3.1×10^{-5}–8.3×10^{-4}	158.0	498–573 (533)	2.5×10^{-7}–3.7×10^{-5} (3.0×10^{-6})

first-order equation. The calculated dependences of the compound weight loss with temperature (TG curves) well coincide with experimental thermograms of the compound pyrolysis (Fig. 1). The pyrolysis parameters were calculated using a two-stage scheme (Table 1). The DTA curves recorded in an inert atmosphere are characterized by a large endothermic effect with two ill-resolved maxima within the 403–423 and 473–498 K ranges, whose position depends on the R length (Figs. 2a, 2b). The first of them is accompanied by uniform weight loss (the TG curve descends at a constant rate). The second endotheric effect is characterized by an extremum in the DTG curve at 518–548 K corresponding to the maximal reaction rate. The pyrolysis is completed by the exothermic effects within the 480–673 K range for Li[*t*-$C_4H_9OB\cdot(OC_7H_{15})_3$] (Fig. 2a, Fig. 3, curve *1*) and within the 528–688 K range for Li[*t*-$C_4H_9OB(OC_{12}H_{25})_3$] (Fig. 2b, Fig. 3, curve *2*) without weight change, which can be assigned to rearrangement of the unit cell of the inorganic residue after the compound thermal decomposition. With lengthening of R, both the maximum of this effect and the maximum of heat absorption shift to higher temperatures.

In the first stage of the thermal decomposition, lengthening of R reduces the weight loss rate (Table 1). The slower pyrolysis of bulkier compounds is probably caused by an equilibrium between the elimination of alkyl radicals and their recombination with both decomposed compound and with each other with the formation of the condensed phase because of

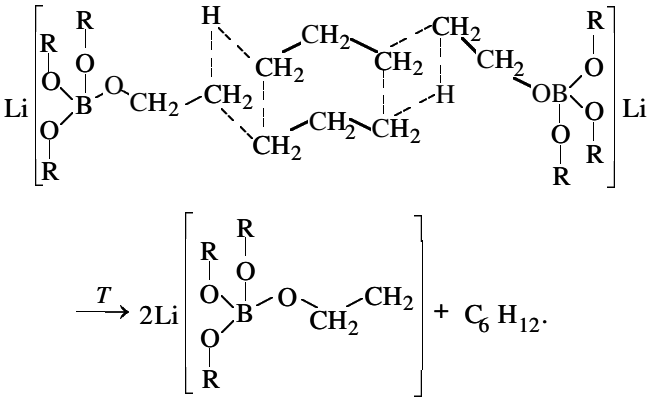
Table 2. Dependence of the weight loss in two-stage pyrolysis of Li[*t*-$C_4H_9OB(OR)_3$] compounds on the size of R

First stage			Second stage		
T, K	R	Δ*m*, %	*T*, K	R	Δ*m*, %
348–473	C_4H_9	31.5	473–530	C_4H_9	48.5
398–448	C_5H_{11}	29.2	448–548	C_5H_{11}	46.9
348–423	C_6H_{13}	24.5	423–547	C_6H_{13}	67.3
373–453	C_7H_{15}	20.2	453–553	C_7H_{15}	72.1
373–448	C_8H_{17}	13.8	448–573	C_8H_{17}	79.2
423–498	$C_{12}H_{25}$	5.1	498–573	$C_{12}H_{25}$	81.6

insufficiently high temperature (348–498 K). Under these conditions, the equilibrium dissociation–association of Li···O coordination bonds can still occur. This process itself does not change the shape of the weight loss curve, but affects the thermal stability of the peripheral part of the associate by means of the orientation effect. The distribution of the weight losses in the first and second stages of the compound pyrolysis depending on R size is listed in Table 2. The first stage of the pyrolysis presumably involves elimination of hydrocarbon fragments through which alkyl substituents interact in the intermolecular associate:



The longer R, the larger set of associates through the alkyl substituents is formed and the stronger is the R···R intermolecular interaction [1, 10]. In this case, the pyrolysis should be accompanied by a set of parallel and consequtive reactions of cleavage of C–C and C–H bonds with the formation of different hydrocarbons and active intermediates. This assumption does not contradict the kinetic parameters of the pyrolysis of lithium *t*-butoxytrialkoxyborates. The rate constant of weight loss decreases, and the activation energy of thermal decomposition increases with lengthening of R. In the series from C_4H_9 to $C_{12}H_{25}$, ΔE_a of the pyrolysis changes more sharply in the first stage than in the second stage (Table 1). In associated hydrocarbon chains, the energy of C···C bonds and the number of such bonds should increase in proportion to the R length because of intermolecular R···R interactions. Correspondingly, ΔE_a increases with increasing the length of R. The trend in variation of the activation entropy of decomposition at 423 K in going from Li[*t*-$C_4H_9OB(OC_4H_9)_3$] to Li[*t*-$C_4H_9OB(OC_{12}H_{25})_3$] ($\Delta S_a$ = –0.26 ans –0.16 kJ mol^{-1} K^{-1}, respectively) shows that the size of R largely governs the number of degrees of freedom of the system.

The second stage of the pyrolysis has an explosive character with the maximal rate of weight loss within a narrow temperature range (Figs. 2a, 2b, DTG curves). The activation energy increases by a factor of 2–6 as compared to the first stage and slightly changes with the length of R (Table 1). Under these conditions, there is no dissociation–association equilibrium, and fragments with short R are accumulated. At a definite temperature, they simultaneously decompose with the rupture of nonassociated C–C, C–O, and partially B–O bonds. The total weight loss of compounds is 80–90%, which corresponds to the composition LiBO + $LiBO_4$. Both stages formally proceed with the same overall reaction rate. The leveling of the kinetic parameters of thermogravimetry is probably caused by superposition of many independent reactions with different periods of maximal rates. This is especially characteristic for the first stage of the process.

In air, compounds undergo oxidative thermal decomposition also in two stages with the total weight loss of 85–94% within the 558–575 and 607–689 K ranges corresponding to maximal reaction rates (Fig. 4). In the first stage, the weight loss amounts to 38–40%. As follows from the analysis of the heat absorption (DTA curves) and weight loss (DTG and TG) curves, the thermal stability of lithium *t*-butoxytrialkoxyborates in air is higher than that in an inert gas (Figs. 2, 4). Thermal oxidative decomposition even in the first stage of the process occurs at higher temperature than thermal decomposition in an inert atmosphere. The thermograms show that in air noticeable weight loss begins at higher temperature than in an inert gas (Ar). This can be due to the fact that in the first stage of thermal oxidation the loss of air sorbed on the crystal surface is compensated by addition of oxygen and carbon monoxide to the compound molecule. Obviously, oxygen and carbon monoxide primarily interact with coordination-unsaturated lithium cation with the formation of new compounds. Therefore, the thermal stability of the complexes

Table 3. Kinetic and thermodynamic characteristics of thermal oxidative decomposition of Li[*t*-$C_4H_9OB(OR)_3$]

R	First stage			Second stage			ΔH	Q
	ΔE_a, kJ mol^{-1}	T_{max}, K	$k_1 \times 10^{-4}$, s^{-1}	ΔE_a, kJ mol^{-1}	T_{max}, K	k_2, s^{-1}	kJ mol^{-1}	
C_3H_7	25.3	531	7.0	24.7	597	–	7578.5	7930.4
C_4H_9	24.9	557	9.0	80.7	607	4.7×10^{-3}	10811.0	9257.1
C_7H_{15}	84.4	449	1.5	133.2	613	4.5×10^{-2}	12682.5	15003.4
$C_{12}H_{25}$	80.2	575	1.3	173.4	689	3.1×10^{-3}	–	25120.7

increases, whereas their heat absorption ability substantially decreases.

During thermal oxidative decomposition, the heat absorption ability of compounds is compensated by the heat release due to formation of new bonds because of oxidation. The comparison of the pronounced endothermic maximum in the DTA curves in an inert atmosphere (Fig. 1, curves *1, 2*) with the exothermic effect in curve *3* recorded in air shows that a large amount of heat is released during oxidation of lithium tetraalkoxyborate. Thus, the absorbed heat is almost completely compensated by the released heat. This results in the fact that the temperature corresponding to the maximum of the exothermic effect (617 K) of the complete decomposition of the oxidized compounds coincides with the temperature (613 K) of maximal rate of the weight loss (Fig. 4), whereas in the case of pyrolysis these processes do not coincide (Fig. 2): the exothermic effect (573 K) appears after the intense weight loss at 530–540 K. In the thermograms of the thermal oxidative decomposition of compounds, similarly to pyrolysis, the exothermic maximum appears at a constant weight (Fig. 3). Due to coordination unsaturation of the lithium cation, the structure of lithium *t*-butoxytrialkoxyborates contains a stored energy, which is manifested as additional heat release in the course of thermal oxidation.

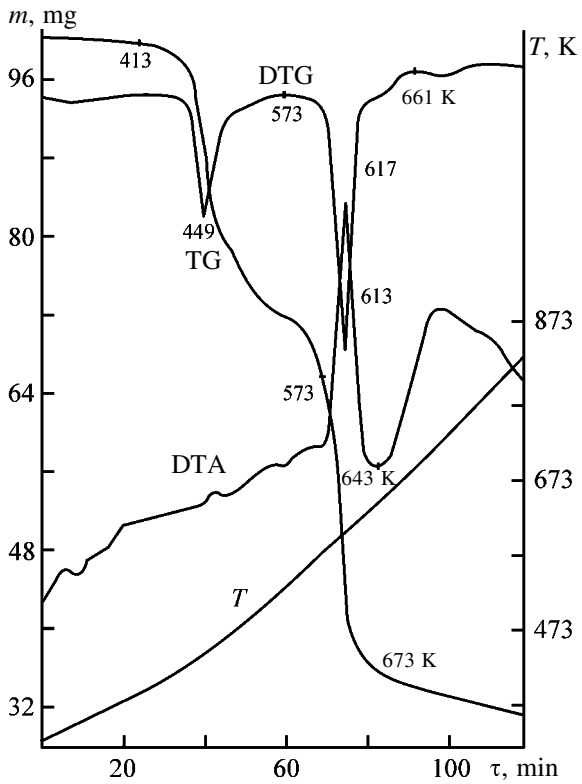


Fig. 4. Thermograms of Li[*t*-$C_4H_9OB(OC_7H_{15})_3$] in air. DTA 1/3, DTG 1/10, TG 100, m = 97 mg, v_h 5 deg min^{-1}.

The thermal effects ($-\Delta H$) of the oxidative decomposition of compounds in air, calculated from the DTA curves relative to a reference (*D*-glucose), are close to the heats of combustion Q found by calorimetry (Table 3). Increase in the heat effect with lengthening of R is proportional to the number of new bonds formed during oxidation. The positive heat of melting, increasing with decrease in the length of R, makes a certain correction to correlation of the heat effect with the length of R. The dependence of the kinetic parameters of the Li[*t*-$C_4H_9OB(OR)_3$] oxidative thermal decomposition on the length of R (Table 3) is similar to that observed for the pyrolysis (Table 1).

CONCLUSIONS

(1) Kinetic and thermodynamic parameters of the pyrolysis and thermal oxidative decomposition of lithium *t*-butoxyltrialkoxyborates were determined; the dependences of these parameters on the length of alkyl substituents were determined.

(2) The activation energy of lithium *t*-butoxytrialkoxyborate thermal decomposition increases with lengthening of R, which suggest strengthening of cooperative intermolecular R···R dispersion interactions.

(3) In contrast to activation energy, the rate constants of the pyrolysis and thermal oxidative decomposition are only slightly sensitive to the compound size.

(4) Thermal analysis of lithium *t*-butoxytrialkoxyborates in an inert gas and in air showed that the compound stability is higher under the conditions of thermal-oxidative decomposition.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Di(4-isopropenylphenoxy)alkanes as Cross-Linking Comonomers in Three-Dimensional Copolymerization with Styrene

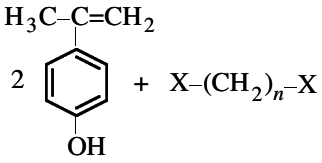
Abstract—Di(4-isopropenylphenoxy)alkanes were synthesized by condensation of 4-isopropenylphenol with symmetrical dihaloalkanes in the presence of KI promoter. Three-dimensional polymeric structures were prepared by compolymerization of these monomers with styrene.

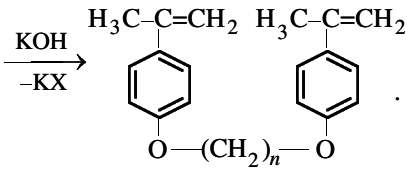
DOI: 10.1134/S1070427207010235

Copolymerization of various monomers with polyfunctional comonomers is a way to construct polymer networks and impart to them imporant service characteristics [1]. Many modern high-tech processes for preparing polymeric sorbents, photoresists for microelectronics and laser engineering, specialty composites, supported coordination catalysts, etc. [2–6] are based on this procedure.

Both thickly and thinly cross-linked polymers are required depending on destination [7]. In most cases, the required functional properties are imparted by polymer-analogous transformations. In particular, a cross-linked three-dimensional framework of the styrene–divinylbenzene copolymer is modified by introducing ionic groups (e.g., SO_3H groups by sulfonation). It should be noted, however, that the preparation of such cross-linked copolymers often involves problems associated with the high reactivity of the cross-linking comonomer (divinylbenzene), heat release in the process, and impossibility of controlling the network density in the products. This negatively affects the physicochemical properties and compositional homogeneity of the product.

Previously [8] we demonstrated that di(4-isopropenylphenoxy)alkanes are efficient as cross-linking comonomers in the copolymerization with styrene. These monomers are prepared by condensation of 4-isopropenylphenol with symmetrical dihaloalkanes in isopropanol in the presence of a base catalyst:





where n = 1–4; X = Cl, Br, I.

The starting compound, 4-isopropenylphenol, was prepared by cracking of 4,4'-isopropylidenediphenol in the presence of a base catalyst according to [9]; reagent grade dihaloalkanes were freshly distilled before use.

The condensation readily occurs at 80°C in the presence of KI promoter at the molar ratio 4-isopropenylphenol : dihaloalkane = (2–3) : 1. The yield of the desired compounds (white solids) ranged from 42.5 to 91.0% depending on particular dihaloalkane.

The structures of the di(4-isopropenylphenoxy)alkanes obtained were proved by spectral data. The ^1H NMR spectra were recorded on a Bruker spectrometer (300 MHz), and the IR spectra, on a Specord 75-IR spectrometer.

In this study we examined the behavior of these compounds in radical three-dimensional copolymerization with styrene depending on various factors (temperature, monomer ratio, reaction time) and determined some functional properties of the cross-linked copolymers obtained.

EXPERIMENTAL

To find conditions for preparing three-dimensional copolymers with preset physicochemical properties,

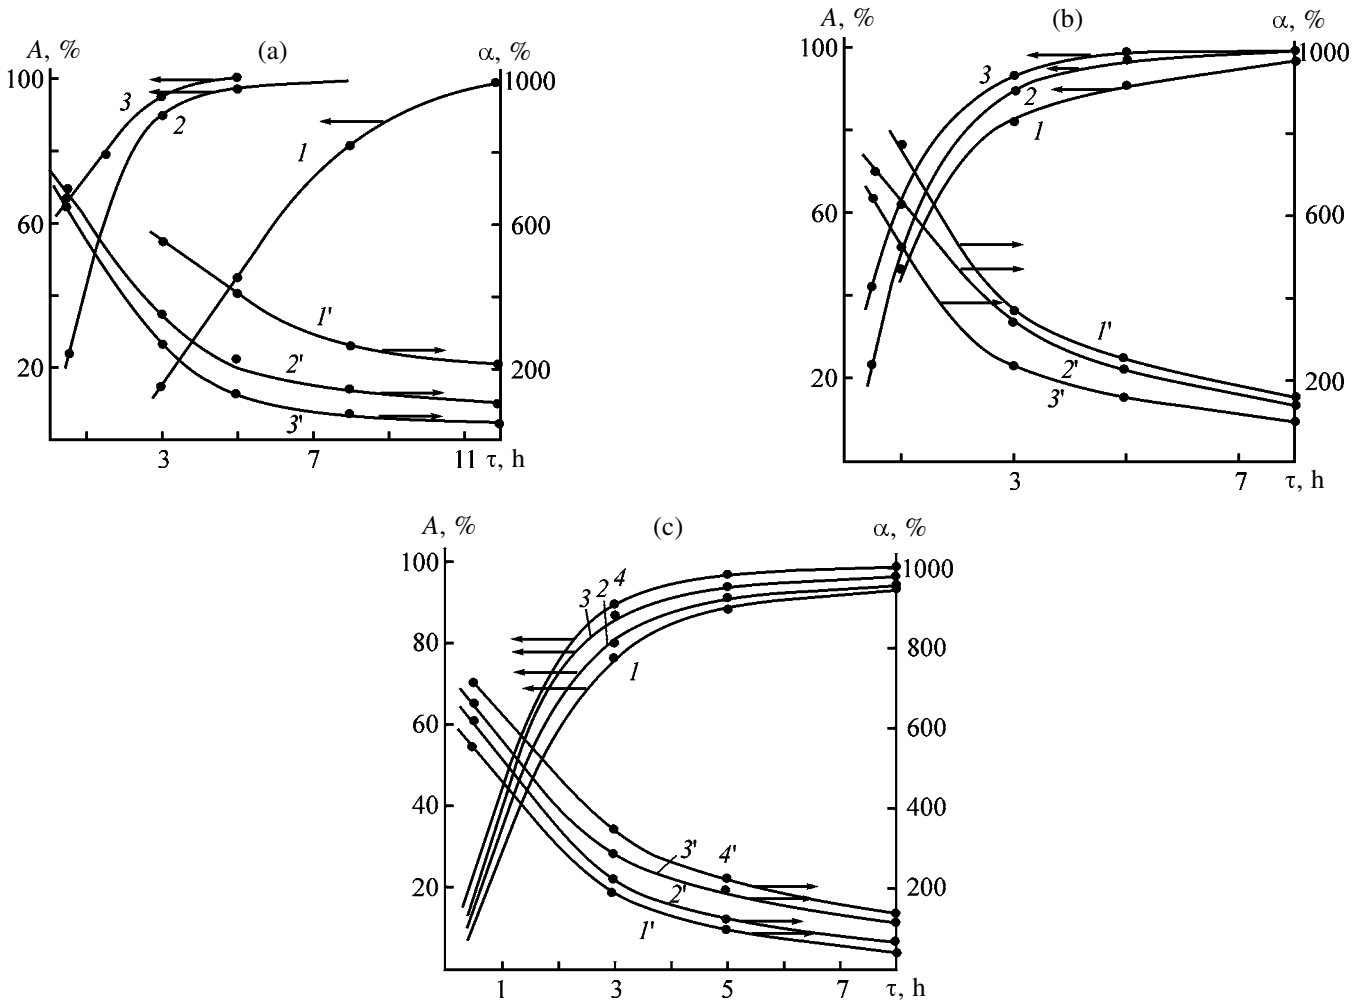


Fig. 1. Influence of (a) temperature, (b) amount of 1,4-di(4-isopropenylphenoxy)butane, and (c) kind of di(4-isopropenylphenoxy)alkane on the gel fraction yield *A* and degree of swelling of the cross-linked copolymer α. (τ) Time. 1,4-Di(4-isopropenylphenoxy)butane concentration, mol %: (a) 1; (b) (*1*, *1*') 0.5, (*2*, *2*') 1, and (*3*, *3*') 2. Temperature, °C: (a) (*1*, *1*') 80, (*2*, *2*') 100, and (*3*, *3*') 140; (b, c) 100. (c) (*1*, *1*') di(4-isopropenylphenoxy)methane, (*2*, *2*') 1,2-di(4-isopropenylphenoxy)ethane, (*3*, *3*') 1,3-Di(4-isopropenylphenoxy)propane, and (*4*, *4*') 1,4-di(4-isopropenylphenoxy)butane.

we chose the copolymerization of styrene with 1,4-di-(4-isopropenylphenoxy)butane as example and examined the effect of various factors on the copolymerization course, gel fraction yield, and degree of swelling of the cured three-dimensional copolymers. The aim of these studies was not only to replace divinylbenzene in the copolymerization with styrene, but also to obtain polymeric matrices of a different structure. Major attention is given today to the development of new ion exchangers with improved physicochemical properties, especially of ion exchangers in which the ionic groups are accessible to large organic ions and metal ions.

The copolymerization was performed in sealed glass ampules in the bulk. The reaction rate was judged from the gel fraction yield and degree of swelling of the cross-linked copolymer in benzene. The gel fraction yield was determined by extraction of the sol fraction with refluxing benzene in a Soxhlet apparatus.

Figures 1a–1c illustrate the influence of temperature and of the amount and kind of the cross-linking monomer on the yield of the cross-linked copolymers and degree of their swelling. As seen from Fig. 1a (curves *1*–*3*), with an increase in temperature from 80 to 140°C the reaction rate grows; at 100°C, the gel fraction yield in 5 h is about 97%. However, further increase in temperature from 100 to 140°C exerts a less significant effect. Curves *1*'–*3*' show that the degree of swelling of the copolymers regularly decreases with an increase in temperature to 140°C. On the contrary, the cross-linked copolymers prepared at relatively low temperatures show larger swellability.

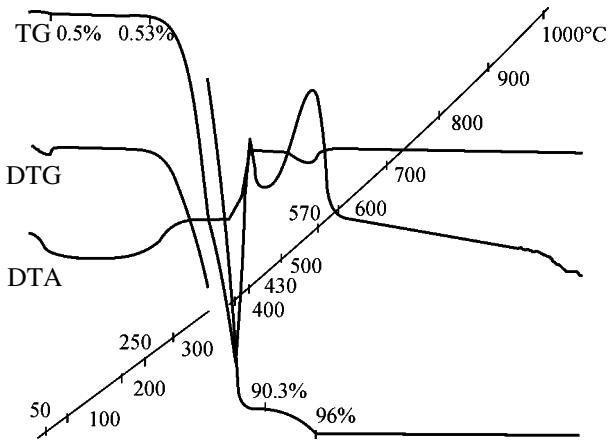

Fig. 2. Derivatogram of a sample of cross-linked 1,4-di(4-isopropenylphenoxy)butane–styrene copolymer.

Thus, the temperature strongly affects the formation of cross-linked structures with a controllable network density, i.e., relatively thickly cross-linked structures are formed at relatively high temperatures, and thinly cross-linked structures, at lower temperatures.

At the temperature that appeared to be optimal (100°C), we examined the effect of the amount of the cross-linking comonomer, 1,4-di(4-isopropenylphenoxy)butane, on the gel fraction yield and degree of swelling (Fig. 1b). With an increase in the content of this monomer from 0.5 to 1 and 2 mol %, the reaction rate noticeably increased; the gel fraction yield in 3 h was 81.8, 90.3, and 93.5%, respectively. At the reaction time increased to 8 h, the yield of the cross-linked copolymers reached 98–99%. An increase in the content of the cross-linking monomer from 1 to 2 mol % leads to a certain decrease in the copolymer swellability (curves *1'–3'*).

The structure of the cross-linking monomer strongly affects the gel fraction yield and swellability of the copolymers (Fig. 1c). Curves *1–3* show that the copolymerization rate noticeably grows with an increase in the number of methylene groups in the cross-linking monomer from 1 to 4. The swellability of the cross-linked copolymers, as expected, increases in the same order (curves *1'–3'*), i.e., the structure of the resulting three-dimensional copolymer (and hence the properties of sulfonic cation exchangers derived from it) can be controlled by choosing appropriate cross-linking monomer.

The heat resistance of the cross-linked copolymers was evaluated by thermal analysis (reference Al_2O_3, heating rate 5 deg min^{-1}). The results of the thermogravimetric and differential thermal analyses show that all the cross-linked copolymers prepared, irrespective of the structure of the cross-linking comonomer, undergo major transformations in a relatively narrow temperature range, 320–430°C. The mass loss at 430°C is about 90%, and the thermal oxidative degradation is complete at 430–600°C (Fig. 2).

The cross-linked copolymers synthesized were used as framework matrices for preparing sulfonic cation exchangers. Sulfo groups were introduced by treatment with 5% oleum at 90°C for 3 h, following the standard protocol [10]. The exchange capacity of these sulfonic cation exchangers was 5.2–5.4 mg-equiv g^{-1}, which is suitable for practical applications.

CONCLUSION

The di(4-isopropenylphenoxy)alkanes synthesized can act as cross-linking monomers in the copolymerization with styrene. The process yields three-dimensional copolymers with a controllable network density, showing promise as matrices for preparing sulfonic cation exchangers for various applications.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of a Lignocellulose Material from Wastes

E. V. Udoratina and V. A. Demin

Institute of Chemistry, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia

Received September 4, 2006

Abstract—A powder lignocellulose material was prepared from waste paper and characterized. Waste paper is partially hydrolyzed with peroxomonosulfuric acid. Physicochemical characteristics, functional composition, and the IR spectra of the resulting samples were studied. The parameters of supramolecular structure were estimated from the evidence of the IR spectra.

DOI: 10.1134/S1070427207010247

Interest in the use of fibrous secondary material (waste paper) for production of various types of paper products grows steadily. Reprocessing of waste paper into paper and cardboard reduces water consumption, release of detrimental gases into the environment, and saves many hectares of forests. A search for new applications of waste paper is an urgent problem.

The chemical and physical structure of secondary fibers undergoes irreversible transformations during reprocessing (milling and drying). The majority of pores and capillaries are destroyed, and the fiber surface contracts and is keratinized, which prevents swelling of the fiber [1]. The mechanical characteristics of the paper from wastes are deteriorated. Along with this, waste paper fiber is of interest as a raw material for production of powder materials (PMs).

In recent years, powder celluloses find increasing application in various branches of industry. They are used as fillers, stabilizers, binding and filtering materials, and chromatographic media. Powder materials can be prepared from various raw materials, including unbleached cellulose and wood pulps, containing lignin and lignocarbohydrate complex, by treatment with hydrolyzing and oxidizing agents causing partial degradation of cellulose to limiting values of the degree of polymerization.

Unbleached cellulose fiber containing lignin is used for production of various types of cardboard and can be incorporated into the composition of newsprint. Therefore, spent cardboard package and newspapers can be considered as the secondary raw materials for production of powder lignocellulose material.

The aim of this study was to examine the possibility of utilization of package cardboard and newsprint as cellulose raw materials for production of powder forms of cellulose and powder lignocellulose sorbents.

EXPERIMENTAL

The milled initial material was hydrolyzed with peroxomonosulfuric acid (PMA), prepared by mixing of concentrated H_2O_2 solution and concentrated sulfuric acid, in a solution containing 10% H_2SO_4 and 1% H_2O_2. The treatment temperature was 100°C, duration, 3–4 h, and solid-to-liquid ratio, 1 : 30. The resulting material was washed to neutral reaction, included with a 1 : 1 acetone : ethanol mixture, and dried in air. The dried samples were milled to obtain homogeneous samples [2].

The resulting powder lignocellulose materials were characterized by functional analysis performed by the common procedures of wood chemistry. The content of carboxy groups was determined by the chemisorption method based on the exchange reaction of COOH groups with an 0.2 M solution of calcium acetate [3]. To a weighed portion of raw material after decationation (treatment with 0.1 M HCl for 1 h at room temperature and washing with distilled water) and drying to absolutely dry state we added a solution of calcium acetate (solid-to-liquid ratio 1 : 100) and kept for 2 h and room temperature. Potentiometric titration of the sample solution was performed with an 0.05 M NaOH solution to pH 7.8 (pH of the initial 0.2 M solution of calcium acetate) after separation of the material on a Schott filter.

The content of carbonyl groups was determined by the reaction of the sample with hydroxylamine hydrochloride to form oximes; the released equivalent

Table 1. Physicochemical characteristics of lignocellulose powders

Sample	Content of groups, %		DP	$-q_{max} \times 10^{-3}$, C g^{-1}
	COOH	CHO		
LCP:				
from cardboard	0.80	0.25	150	26.40
from newsprint	1.81	0.39	145	40.51
from deciduous unbleached cellulose	0.23	0.11	140	5.62
from coniferous unbleached cellulose	0.28	0.10	220	–
from TWP	1.42	0.57	120	37.59
MCC	0.14	0.04	250	–

amount of hydrochloric acid was determined by the potentiometric titration with sodium hydroxide solution [4]. The decationated weighed portion of absolutely dry sample was kept for 2 h at room temperature in a freshly prepared 0.3 M ethanol solution of hydroxylamine hydrochloride, filtered, and titrated with 0.05 M NaOH to pH of the initial $NH_2OH \cdot HCl$ solution 3.25–3.30.

The content of carboxy and carbonyl groups (%) was calculated by the formula

$$X = \frac{VNM \times 100}{g},$$

where V is the volume of the titrant solution spent for titration of the sample (ml), N is the normality of the titrant solution (g-equv l^{-1}), M is the molecular weight of carboxy and carbonyl groups, respectively (g mol^{-1}), and g is the weighed portion of absolutely dry material (mg).

The error of determination was approximately 3%. The degree of polymerization (DP) of the powder materials was evaluated from their intrinsic viscosity in Cadoxen solutions using the equation $[\eta] = DP^{0.94} \times 7.1 \times 10^{-3}$ [5].

To evaluate the accessibility of functional groups of powder lignocellulose materials we studied their electrical surface characteristics. The total surface charge of lignocellulose powders (LCPs) q_{max} was measured by the potentiometric back-titration and calculated by the published procedure [6]. To a 2% suspension of the powder in an electrolyte solution (1×10^{-3} M NaCl), 1 ml of 0.1 M HCl was added, and the mixture was titrated with 5×10^{-2} M NaOH.

The supramolecular structure of the resulting powder materials was characterized by IR spectroscopy (MIR 8000 Fourier spectrometer). The samples were pelletized with KBr. The spectra were processed by the method of baselines and normalized using the internal reference, the band at 2900 cm^{-1} (C–H stretching vibrations of methyl and methylene groups) [7]. The standard error in evaluation of the relative optical density for each absorption band was ±5%.

Some physicochemical characteristics of LCPs prepared from various types of raw materials, involving waste paper (newspaper and cardboard), are presented in Table 1. The yield of target products from secondary raw materials was 63–66%. For comparison, the characteristics of commercial microcrystalline cellulose from cotton raw materials (Biisk) are presented.

The minimal content of functional groups, carbonyl and carboxy, is observed in the sample of microcrystalline cellulose (MCC), which is thus the most inert (with respect to ionogenic groups) material. Lignocellulose powders from thermochemical wood pulp (TWP) and from newsprint (waste paper) contain the maximum amount of carboxy and carbonyl groups (1.4–1.8% COOH and 0.4–0.6% CHO groups). The amount of functional groups is significant in the LCP from waste cardboard (0.80% COOH and 0.25% CHO groups) and is low, close to that in ordinary unbleached cellulose, in LCP from coniferous and deciduous unbleached celluloses. It seems likely that the higher the amount of lignin-containing intermediate products in the initial raw materials, i.e., wood pulp in which the lignin content can reach 30–33%, the higher the content of functional groups in the sample. The treatment used results in breakdown of the fibrous structure of the initial raw materials and degradation of cellulose, as suggested by the low degrees of polymerization of the resulting products (200 and less).

The higher the content of carboxy groups in the powder material, the higher the total surface charge of its particles $-q_{max}$. The sample from unbleached

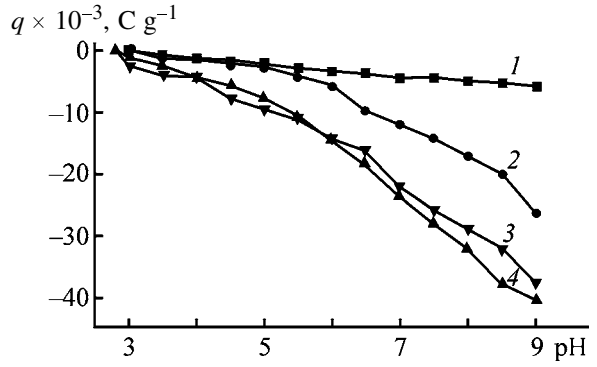

Fig. 1. Total surface charge q as a function of the type of LCP and pH value of aqueous suspension. LCP: (*1*) from unbleached deciduous kraft cellulose, (*2*) from cardboard, (*3*) from thermomechanical pulp, and (*4*) from newsprint.

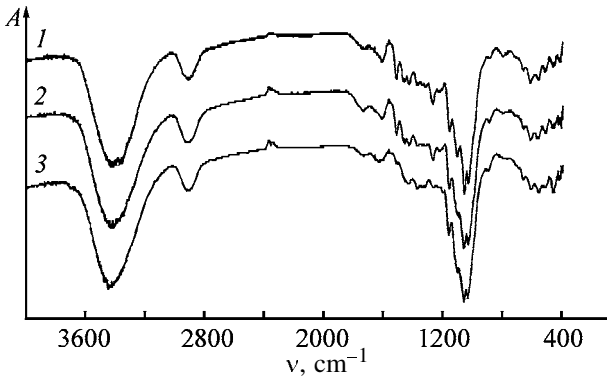

Fig. 2. IR spectra of powder lignocellulose materials. (*A*) Transmission and (ν) wavenumber. (*1*) TWP; waste paper: (*2*) newsprint and (*3*) cardboard.

deciduous kraft cellulose has the minimum charge of the surface throughout the entire pH range of aqueous suspension: $-q_{max}$ is approximately 5620 C g^{-1} (at pH 9). The negative surface charge of LCP prepared from cardboard is higher by a factor of approximately 4.5 and at the same pH, $-q_{max}$ = 26400 C g^{-1}. The negative surface charge of LCP from TWP and newsprint is higher than the above value by a factor of 1.4–1.5 ($-q_{max}$ 37 590 and 40507 C g^{-1}, respectively). The dependence of the negative surface charge on the type of LCP and pH of the aqueous suspension is shown in Fig. 1.

The IR spectra of lignocellulose powders from (1) thermomechanical wood pulp and waste paper raw materials, (2) newsprint, and (3) cardboard, are presented in Fig. 2. The IR spectra contain the characteristic bands of celluloses. In the range of stretching vibrations of OH groups there is a broad band with a maximum at approximately 3400 cm^{-1}. The band at approximately 2900 cm^{-1} is also strong. In the range 900–1500 cm^{-1}, there are absorption bands forming a complex pattern with several maxima.

The resulting samples contain residual lignin and hemicelluloses. The presence of these components is suggested by the corresponding absorption bands. Hemicelluloses can be revealed from the band at 1730 cm^{-1} (stretching vibrations of the C=O groups in ester fragments) [7] and lignin, from the bands at 1595–1500 cm^{-1} corresponding to the skeleton vibrations of the benzene ring and characteristic band at 1460 cm^{-1} (bending modes of the CH groups) [8].

The IR spectra show that in the resulting samples almost all hydroxyls are involved in hydrogen bonds, which is suggested by the shape of the absorption band in the range 3000–3700 cm^{-1} (ν_{OH}). This absorption band can be characterized by the position of the maximum ν_{OH}(max), values of the symmetry index a/b (the ratio of the widths of the high- and low-frequency wings of the absorption band at half-maximum), and the ratio of the optical densities at 3570 and 3330 cm^{-1} D_{3570}/D_{3330} [9].

The characteristics of the state of hydroxy groups and the relative optical densities of some analytical absorption bands are also presented in Table 2. For comparison, data for unbleached deciduous cellulose and MCC are presented.

The maximum of the absorption band of stretching modes of OH groups in the spectra is practically unchanged. The newsprint sample has the lowest symmetry index a/b (ν_{OH}) 0.60, which suggests formation of a dense network of strong hydrogen bonds; the TWP sample has the highest symmetry index, i.e., the sample is characterized by a fairly loose network of hydrogen bonds.

The ordering index (analog of the crystallinity index in X-ray diffractometry) is determined from the ratio of optical densities at 1375 (bending modes of CH groups) and 2900 cm^{-1}. For powder materials it is higher than that for unbleached cellulose. This means that in hydrolysis the fraction of the amorphous part decreases and the fraction of crystalline part increases. For LCP from cardboard, this effect is observed to a greater extent.

The content of crystalline and amorphous parts in the sample can also be judged from the ratio of the intensities of the band at 1430 cm^{-1} (bending modes of CH_2 groups), related to the crystalline areas, and the band at 900 cm^{-1}, related to amorphous areas (C–O stretching modes in amorphous area). This ratio increases from 1.27 for the initial cellulose to 2.08 for "classic" MCC (Table 2), which suggests an increase in the fraction of the crystalline phase, i.e., formation of a more ordered structure of MCC. In the samples of

Table 2. Variation of frequencies and intensities of the absorption bands in the IR spectra of powder celluloses from various types of raw materials

LCP type	Characteristic of the state of hydroxy groups			Relative optical densities of analytical absorption bands	
	ν_{OH}(max), cm^{-1}	a/b (ν_{OH})	D_{3570}/D_{3330}	D_{1375}/D_{2900}	D_{1430}/D_{900}
Unbleached cellulose	3432	0.83	0.76	1.39	1.27
MCC	3430	0.69	0.48	1.41	2.08
TWP	3430	0.70	0.33	1.52	2.69
Newsprint	3434	0.60	0.44	1.46	3.30
Cardboard	3449	0.64	0.59	2.02	2.65

LPC from waste paper, the crystallinity index is higher than that for MCC (2.65–3.30).

CONCLUSIONS

(1) Powder lignocellulose materials prepared from waste paper of different origins have different physicochemical characteristics.

(2) It was shown by chemical analysis that the resulting samples are characterized by a high content of carboxy and carbonyl groups, 0.80–1.81 and 0.25–0.57%, respectively. They have significantly higher ion-exchange activity of surface functional groups (primarily, COOH) than the powders from cellulose.

(3) The IR spectra of lignin-containing powder materials suggest that the hydrolysis of the initial waste paper and thermomechanical wood pulp results in formation of a more reactive microcrystalline structure than that of microcrystalline cellulose from cotton raw materials.

Abstract—The effect of *C*-phenyl-*N*-*tert*-butylnitrone on the features of radical copolymerization of *N*-vinylpyrrolidone with methyl methacrylate and styrene was examined. Nitrone exerts virtually no effect on the relative activities of the comonomers. At the same time, *C*-phenyl-*N*-*tert*-butylnitrone as a potential source of nitroxyl radical makes it possible to prepare copolymers of *N*-vinylpyrrolidone with methyl methacrylate and styrene to high conversions without gel effect, to control the molecular-weight characteristics of the copolymers, and to prepare block copolymers.

DOI: 10.1134/S1070427207010259

Polyvinylpyrrolidone (PVP) and its copolymers find diverse applications: from blood plasma substitutes to propellant additives [1, 2].

The requirements to copolymers for medicobiological purposes are more stringent than those to general-purpose polymers. First, these copolymers should be nontoxic in amounts ensuring the therapeutic effect. Second, medicinal preparations should have a definite molecular mass M and a narrow molecular-mass distribution (MMD), because the pharmacological effect essentially depends on these parameters. In particular, the molecular mass should not be too large to provide spontaneous excretion. Finally, environmentally clean methods for efficient commercial production of such preparations should be developed.

Therefore, a search for efficient ways to control the copolymerization of *N*-vinylpyrrolidone (VP) with vinyl monomers is a key problem of *N*-vinylpyrrolidone chemistry.

The goal of this study was the development of procedures for preparing gradient copolymers of VP with methyl methacrylate (MMA) and styrene (ST), and also block copolymers derived from them with controllable composition and molecular-mass characteristics in the presence of *C*-phenyl-*N*-*tert*-butylnitrone (PBN) as one of effective chain-terminating agents under the conditions of radical initiation, maximally similar to the industrial conditions [3–5].

EXPERIMENTAL

C-Phenyl-*N*-*tert*-butylnitrone was prepared by the procedure described in [6]. The solvents, initiator [azobis(isobutyronitrile), AIBN], and monomers (VP, ST, MMA) were purified by standard procedures [7–9]; VP met the requirements of TU (Technical Specifications) 6-09-2991–78. The physicochemical constants of all the compounds were in agreement with published data. The (co)polymers were prepared from the freshly distilled monomers. The samples were prepared as follows: The monomer was placed in glass ampules, degassed by threefold freezing–pumping–thawing, and polymerized at a residual pressure of 1.3 Pa. The polymerization progress was monitored gravimetrically, dilatometrically [10], and thermographically [11].

When plotting the kinetic curves of the copolymerization from thermographic data, we used the running heats of copolymerization, calculated from the published heats of homopolymerization of VP (64.3 ± 1.9 kJ mol^{-1}) [12], MMA (55.6 ± 1.1 kJ mol^{-1}) [13], and ST (69.4 ± 0.8 kJ mol^{-1}) [13], taking into account the running compositions of the copolymers.

The copolymers obtained were purified to remove residual initiator and monomers by twofold reprecipitation from chloroform into hexane. The VP homopolymer was washed out with distilled water.

The intrinsic viscosity of VP–MMA and VP–ST copolymers was determined in chloroform at 25°C [14]. The molecular-mass characteristics of the copolymers were examined by GPC on a chromatograph equipped with five Styrogel columns with pore diameters of 1×10^5, 3×10^4, 1×10^4, 1×10^3, and 250 Å (Waters, the United States). An R-403 differential refractometer (Waters) was used as detector, and THF was the eluent. Close-cut polystyrene (PS) references were used for calibration. For VP–ST copolymers, M was calculated using the constants K and α for PS. Conversion of the mean M values from the polystyrene references to the examined VP–MMA copolymers was done using standard formulas for poly(methyl methacrylate) (PMMA) [15].

The composition of the copolymers was determined by IR spectroscopy with an Infralum FT-80 spectrophotometer. The spectra were measured in the range 5500–550 cm^{-1} with an accuracy of ± 0.05 cm^{-1}. Stretching vibration bands of the carbonyl groups of VP (1675 cm^{-1}) and MMA (1725 cm^{-1}) were chosen as analytical bands, because of transparence of the solvent ($CHCl_3$) in this range and good resolution of these bands. As calibration plots we used the concentration dependences of the optical density of PVP and PMMA solutions in chloroform, plotted using solutions of exactly known concentration. The absorption intensity was determined using the baseline method [16]. The spectra of the copolymers were recorded similarly to those of the homopolymers. The content of carbonyl fragments in VP–MMA copolymers was determined from calibration plots, and that in VP–ST copolymers, from the calibration plot for PVP.

The effective relative activity constants in the VP–MMA and VP–ST copolymerization were determined by the Kelen–Tudös [17] and "fitted curve" [18] methods.

Block copolymerization was performed in a solution of PS macroinitiator in VP at 70°C and in solution of PVP macroinitiator and ST in dioxane at 80°C. The mixture was evacuated by the same procedure as in the common copolymerization. The product of the polymerization involving the macroinitiator was separated into three fractions (homo-PS, homo-PVP, and block copolymer) by sequential dissolution of the polymer in cyclohexane and water. The separation completeness was checked by IR spectroscopy.

N-Vinylpyrrolidone readily polymerizes by the radical polymerization mechanism, and its polymers have valuable properties. It should be noted, however, that published data on the VP activity in copolymerization even with such common monomers as MMA and ST are rather contradictory [19–21]. Therefore, we considered it necessary to estimate the relative activity constants for the comonomer systems VP–MMA and VP–ST, and also to examine the effect of PBN on these parameters. The copolymerization was performed in a wide range of compositions of the monomer mixtures, from 5 to 95 mol % VP.

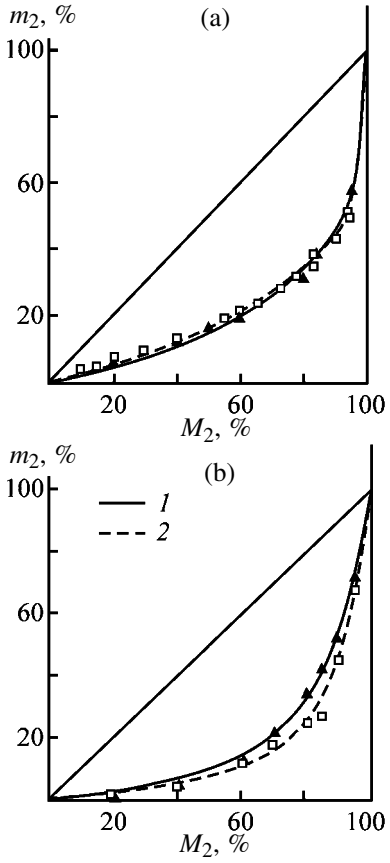

Fig. 1. Composition curves for (a) MMA–VP and (b) ST–VP copolymers prepared at (a) 60 and (b) 80°C. (M_2) *N*-Vinylpyrrolidone content in the monomer mixture and (m_2) its content in the copolymer. Initiator AIBN (0.8 mol %); the same for Figs. 2 and 3. PBN concentration, mol %: (*1*) 0 and (*2*) 0.1.

An IR spectroscopic analysis of the copolymer compositions showed that, irrespective of the monomer ratio in the starting mixture, the copolymer is always enriched in the more active monomer, either MMA or ST. Such a pattern is observed for samples prepared both in the presence of PBN and without it. The dependences of the copolymer composition on that of the monomer mixture are shown in Fig. 1.

These data show that addition of PBN exerts no effect on the composition of VP–MMA copolymers. The composition curves obtained in the presence of

Fitted curve	0.17 ± 0.05	10.2 ± 1.2	0.13 ± 0.04	14.2 ± 1.4

PBN and without it virtually coincide (Fig. 1a). Thus, in this case the coordination interaction of propagating radicals with nitroxyls does not noticeably affect the copolymer composition. The enrichment in MMA units is due to the higher activity of this monomer.

In contrast to the VP–MMA system, in the VP–ST system the composition curves obtained in the presence of PBN and without it are somewhat different (Fig. 1b). In the presence of PBN, the enrichment of the copolymer with styrene is still more pronounced.

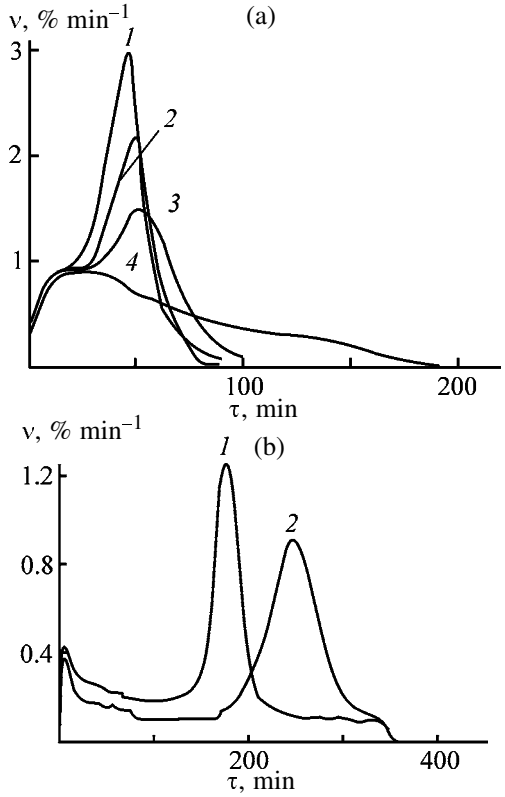

Fig. 2. Differential kinetic curves of the copolymerization of VP with (a) MMA and (b) ST in the presence of PBN at (a) 60 and (b) 80°C. (ν) Polymerization rate and (τ) polymerization time. PBN concentration, mol %: (a) (*1*) 0, (*2*) 0.01, (*3*) 0.05, and (*4*) 0.10; (b) (*1*) 0 and (*2*) 0.05.

The results of determining the relative activities of the monomers by the above methods are given in Table 1. It is seen that the relative activities determined by the two procedures show good agreement with each other and with published data [20, 21]. Certain differences in the results obtained by the two methods can be attributed to the fact that the Kelen–Tudös method takes into account variation of the monomer mixture composition with increasing conversion, and the copolymer composition is averaged over the conversion range from zero to the final value, whereas in the fitted curve method the copolymer is considered as obtained exclusively at the initial monomer concentrations.

The relative activities of the monomers and the dependences of the copolymer composition on that of the monomer mixture indicate that addition of PBN does not affect the activity of the monomers in the VP–MMA copolymerization and slightly enhances the activity of styrene in the VP–ST copolymerization.

The effect of PBN on the kinetic features of copolymerization of VP with MMA and ST and on the molecular-mass characteristics of the copolymers was examined at monomer molar ratios of 50 : 50 and 80 : 20, respectively.

We found that PBN affected the kinetics of AIBN-initiated copolymerization of VP with MMA and ST in the bulk at 60 and 80°C, respectively. Figure 2 shows the differential kinetic curves of the copolymerization in the presence of PBN at these temperatures. It is seen that addition of PBN in an amount comparable with that of the initiator appreciably decreases the

gel effect (Fig. 2). At the same time, as follows from the integral kinetic curves shown in Fig. 3, addition of nitrone in various concentrations also considerably decreases the overall polymerization rate and limiting conversion.

For example, in the copolymerization of VP with MMA and ST without PBN additions, the dependence of the conversion on time is S-shaped, which is characteristic of the polymerization with a gel effect, whereas in the presence of PBN the conversion increases in time more uniformly, without rate splashes and pronounced self-acceleration (Fig. 3).

To estimate additionally the kinetic parameters of the polymerization at small conversions, we analyzed dilatometrically the initial portions of the kinetic curves. We found that PBN does not noticeably affect the initial rate of MMA–ST homopolymerization, but in its presence the VP homopolymerization rate decreases considerably (by two orders of magnitude) relative to the process performed with the traditional initiator without additives (Table 2, run nos. 1–9). The kinetic data derived from the initial portions of the VP–MMA and VP–ST copolymerization curves indicate that addition of PBN in various concentrations to the polymerizing system does not noticeably affect the copolymerization rate compared to the process initiated by AIBN only (Table 2, run nos. 10–15), as in the case of the homopolymerization of MMA and ST. The essential difference in the effect of PBN on the homopolymerization of the VP, MMA, and ST and on the copolymerization of VP with MMA and

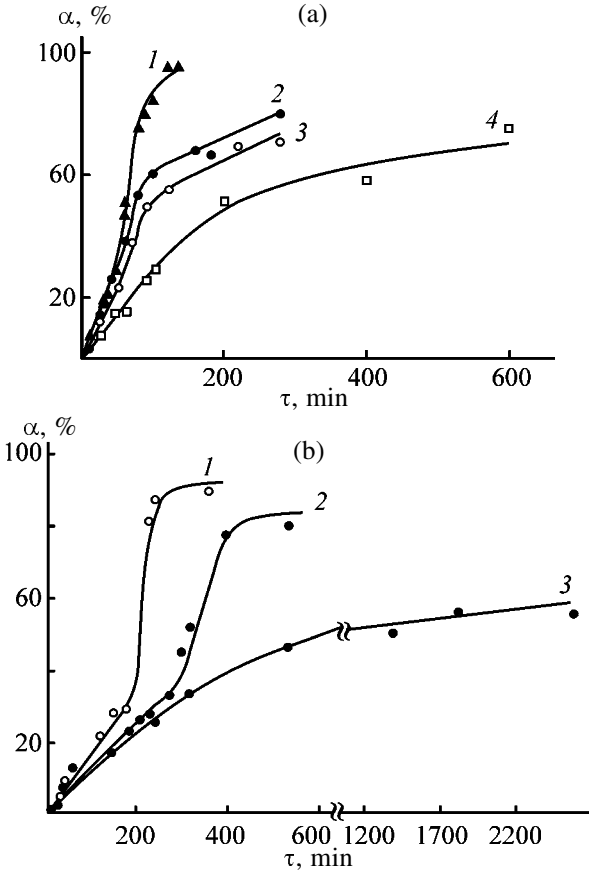

Fig. 3. Integral kinetic curves of the copolymerization of VP with (a) MMA and (b) ST in the presence of PBN at (a) 60 and (b) 80°C. (α) Conversion and (τ) polymerization time. PBN concentration, mol %: (a) (*1*) 0, (*2*) 0.1, (*3*) 0.2, and (*4*) 1.0; (b) (*1*) 0, (*2*) 0.05, and (*3*) 0.10.

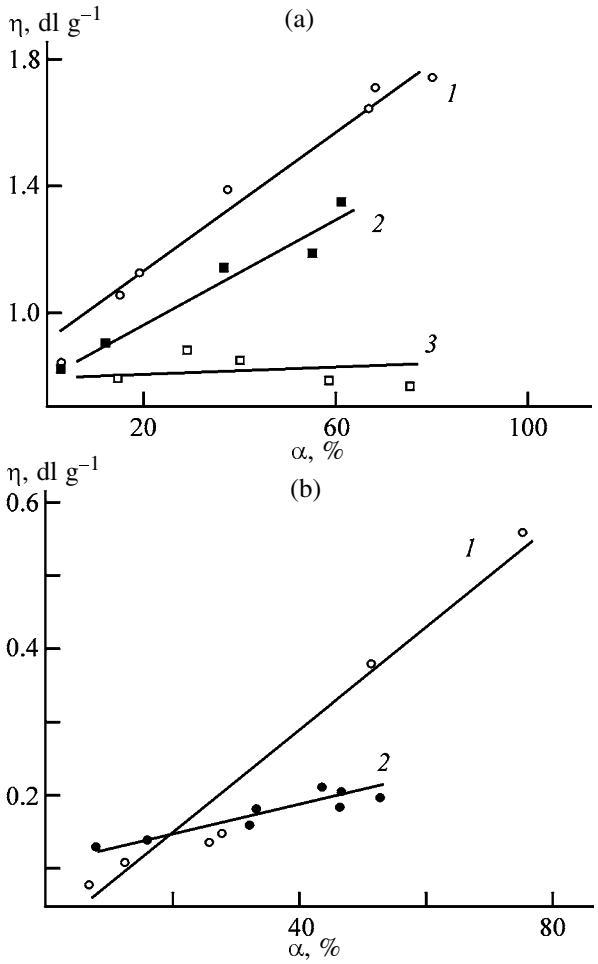

Fig. 4. Intrinsic viscosity η of copolymers of VP with (a) MMA and (b) ST as a function of conversion α. Initiator AIBN, 0.8 mol %; samples prepared at (a) 60 and (b) 80°C. PBN concentration, mol %: (a) (*1*) 0.1, (*2*) 0.2, and (*3*) 1.0; (b) (*1*) 0.05 and (*2*) 0.10.

ST may be due to large difference in the monomer activities and in the accepting power of PBN relative to the arising secondary (VP or ST terminal unit) and tertiary (MMA terminal unit) propagating radicals [22]. Since, as determined above, the relative activities of components of the VP–MMA and VP–ST pairs differ by several orders of magnitude, the first step of the copolymerization yields macroradicals enriched in the more active monomer, MMA or ST. Correspondingly, as in the case of the homopolymerization of MMA and ST, addition of PBN does not strongly affect the initial copolymerization rate.

We found that PBN as a potential source of stable radicals can efficiently control not only the kinetic parameters of the copolymerization of VP with MMA and ST, but also the molecular-mass characteristics of the (co)polymers.

In contrast to the copolymers prepared by common (noncontrolled) radical polymerization, for which the dependence of M on conversion shows a pronounced jump corresponding to an increase in the intrinsic viscosity at the instant of the gel effect, addition of PBN to the polymerizing system results in linear growth of the intrinsic viscosity of the VP–MMA and VP–ST copolymers with the conversion (Fig. 4). In the case of the VP and MMA copolymers prepared in the presence of excess PBN (1.0 mol %), the intrinsic viscosity does not noticeably change with the conversion and remains constant throughout the process (Fig. 4a, curve *3*).

The GPC studies of the copolymers show that the MMD cuurves of the samples prepared in the presence of PBN are unimodal, in contrast to the copolymers prepared in the presence of AIBN without PBN (Figs. 5a, 5b); with an increase in the polymerization time, the MMD maxima regularly shift toward higher MM. These data indicate that the copolymerization is accompanied by a continuous increase in M_n of the copolymer with the conversion. The polydispersity coefficients of the copolymers somewhat increase with the conversion, but remain considerably lower than those of the copolymers prepared in the presence of AIBN without PBN additions (Table 3).

Since the monomers in the pairs chosen essentially differ in the activity, at the end of the copolymerization, with the exhaustion of the active monomers (MMA and ST), VP homopolymer can accumulate in the system, which can lead to MMD broadning and to the growth of the polydispersity coefficient at high conversions.

To quantitatively determine the PVP content in the copolymers, we separated PVP with distilled water and determined the molecular-mass parameters of the washed copolymers (Table 4). We found that the samples synthesized in the presence of the traditional initiator AIBN to high conversions contained appreciable amounts of PVP. This fact accounts for the appearance of the second mode in the copolymers at high conversions (Figs. 5a, 5b), which is not observed in the washed samples. The copolymers prepared in the presence of PBN contain virtually no PVP. Thus, addition of PBN allows preparation of copolymers free of impurities of VP homopolymer.

The composition of the copolymers obtained at different conversions was studied by IR spectroscopy (Table 5). At the initial monomer molar ratio VP : MMA = 50 : 50, the copolymer composition varies with the conversion.

* The molecular masses were calculated using the constants K and α for PMMA.

** The molecular masses were calculated using the constants K and α for PST.

The data obtained (Table 5) show that the polymer formed in the initial steps of the process is enriched in MMA units relative to the starting monomer mixture. However, the average composition of the copolymer varies with the conversion, and the relative content of VP units increases. This trend is observed with the copolymers prepared both in the presence of PBN and without it.

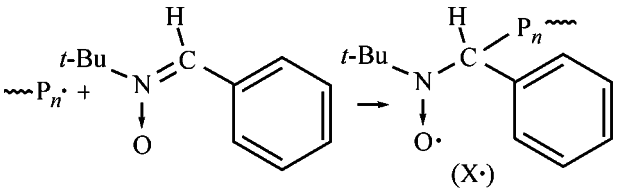
* Monomer molar ratio in the starting mixture 50 : 50, 60°C.
** Monomer molar ratio in the starting mixture 80 : 20, 80°C.

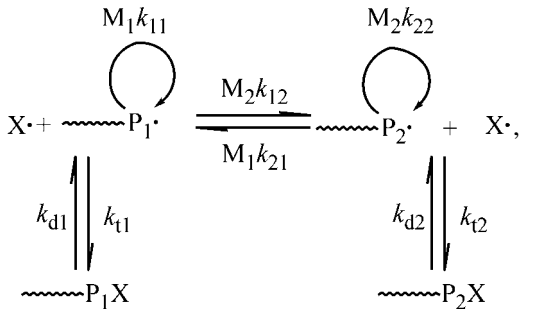
A similar trend is observed in the copolymerization of VP with styrene (Table 5).

It is known [3–5] that PBN is an effective agent for controlled polymerization of ST and some other monomers. To prove the realization of the pseudoliving mechanism in the copolymerization of VP with MMA and ST in the presence of PBN, we prepared block copolymers PVP-σ-PS and PS-σ-PVP. As macroinitiators of the block copolymerization we used PVP prepared by controlled polymerization in the presence of 0.2 mol % PBN and 0.8 mol % AIBN at 60°C and PS prepared at 70°C in the presence of 0.8 mol % PBN and 0.8 mol % AIBN. To determine the relative content of the homopolymers, we fractionated the copolymers by sequential selective extraction; the results are given in Table 6. The GPC data show that the MMD of the PVP-σ-PS block copolymer is unimodal (Fig. 5c).

Our results suggest that, as in the case of other vinyl monomers [3–5], a decrease in the gel effect is due to formation in the system of stable nitroxyl radicals X$^{\bullet}$ [Eq. (1)] and their subsequent participation in the chain propagation:



(1)



(2)

where M_1 and M_2 are the molecules of the respective monomers; X$^{\bullet}$, nitroxyl radical; P$^{\bullet}$, propagating radical; k_{d1} and k_{d2}, dissociation rate constants of adducts P_1X and P_2X, respectively; k_{t1} and k_{t2}, rate constants of the recombination of the nitroxyl radical X$^{\bullet}$ with the macroradicals $P_1^{\bullet}$ and $P_2^{\bullet}$, respectively; and k_{11}, k_{22}, k_{12}, and k_{21}, rate constants of chain propagation (addition of macroradical to the corresponding monomer).

The reinitiation by equilibrium reaction (2) leads to the realization of the reversible inhibition mechanism. The occurrence of reinitiation is also suggested by data on the synthesis of VP–ST block copolymers in the presence of AIBN and PBN.

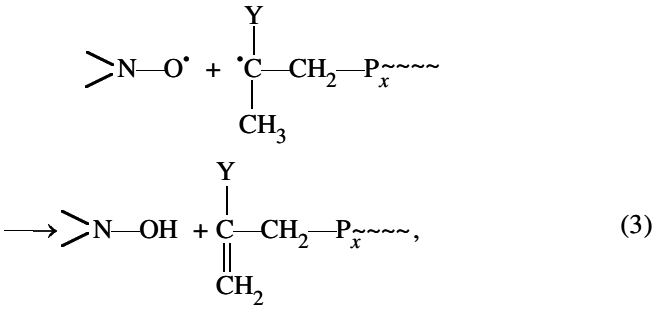
Our results show that the chosen monomer pairs VP–MMA and especially VP–ST are examples of systems prone to damped copolymerization in the presence of nitroxyls. More difficultly dissociating adducts P_2–X containing a VP unit at the terminus of the polymeric macroradical are inevitably accumulated in the course of the process. Macroradicals with MMA or ST terminal units, prone to reversible recombination–dissociation, remain active in the polymerization. Addition of active monomers does not reduce the activity, but addition of a VP molecule increases the

Table 6. Postpolymerization in the systems ST + PVP (80°C) and VP + PST (70°C)

Macro-initiator	τ, h	*T*, °C	Conversion, %	Content in polymerization product, %			Characteristics of block copolymer	
				PST	PVP	block copolymer	$M_n \times 10^{-3}$	M_w/M_n
PVP	25	80	22	26	45	29	221	2.1
PST	68	70	13	32	Absent	68	–	–

probability of transition of the chain to the dormant state, which inhibits its propagation. Thus, chains with MMA or ST terminal units propagate faster. This leads to an increase in the content of active monomers in the copolymer and allows preparation of gradient copolymers in which the composition varies from one end of the macromolecule to the other.

It is not improbable that stable nitroxyl radicals formed in the system can react with propagating macroradicals not only through recombination, but, in the case of MMA, also through disproportionation:



(3)

where Y is a functional group.

Reaction (3) allows control of the kinetic parameters of the copolymerization. In this case, however, a "dead" polymer is formed in the system, which results in deviations from the ideal pseudoliving polymerization mechanism and, in particular, in increased polydispersity.

CONCLUSIONS

(1) *C*-Phenyl-*N*-*tert*-butylnitrone as a potential source of stable radicals directly participates in the chain propagation in the copolymerization of *N*-vinylpyrrolidone with methyl methacrylate and styrene, actively affecting both the initial rate and the overall reaction kinetics, inhibiting the autoacceleration step.

(2) Additions of *C*-phenyl-*N*-*tert*-butylnitrone control the molecular-mass characteristics of macromolecules and allow the synthesis under mild conditions (60–80°C) of low-molecular-weight copolymers derived from *N*-vinylpyrrolidone, which are the most demanded by parmaceutical industry.

(3) *C*-Phenyl-*N*-*tert*-butylnitrone does not affect the composition of copolymers of *N*-vinylpyrrolidone with methyl methacrylate and styrene under the examined conditions.

Abstract—Oxidative degradation of the organic matter of shungite rock from the Zazhogino deposit (Karelia, trans-Onega region) with various reagents was performed. The composition of the products obtained was studied by IR Fourier spectroscopy and gas chromatography–mass spectrometry. The set of the compounds identified reflects the structure and origin of the macromolecular network and mobile phase of shungite.

DOI: 10.1134/S1070427207010260

Oxidative degradation is relatively widely used for determining the features of chemical composition and structural organization of macromolecules of various caustobioliths [1–9]. In this study we examined the chemical composition of the organic matter (OM) of shungite rock (SR) from the Zazhogino deposit (Karelia, trans-Onega region) by oxidative degradation with various reagents.

EXPERIMENTAL

The starting shungite rock ground in a ball mill to a particle size of 70–90 μm was charged into a Teflon vessel and thoroughly stirred for 6 h at 20°C with 40% HF. The resulting slurry was allowed to settle, and the solid phase was repeatedly washed with water to pH ~7 by decanting, vacuum-filtered on a Büchner funnel, and dried to constant weight at 100°C, after which the OM content in SR was determined by thermal gravimetric analysis of the resulting OM-enriched product. According to the elemental analysis, treatment of the initial SR with aqueous HF increased the OM content from 30.21 to 82.00 wt %. The elemental composition of SR OM (wt % daf) is as follows: C 95.45, H 0.30, N 0.60, and O + S 3.65.

Oxidation of SR OM with an alkaline solution of ammonium peroxodisulfate was performed as follows. A 100-ml three-necked flask with a power-driven stirrer and a thermometer was charged with 10 g of the enriched SR and 50 ml of 16 wt % aqueous NaOH. The resulting suspension was heated to 60°C with vigorous stirring, after which 5 g of dry $(NH_4)_2S_2O_8$ was added in small portions through the third neck. In so doing, intense foaming was observed because of the release of ammonia and oxygen. After 1 h, the temperature was raised to 90°C, an additional 5 g of $(NH_4)_2S_2O_8$ was added, and the mixture was stirred at 90°C for 2 h, after which the third portion (5 g) of $(NH_4)_2S_2O_8$ was added. Then the mixture was stirred at 90°C for 3 h more, cooled to room temperature, and vacuum-filtered through a glass frit no. 4; the residue of the enriched SR was washed with distilled water to neutral reaction, dried in a vacuum oven to constant weight, and weighed. The weight of the solid obtained was 8.50 g.

The brown filtrate was combined with wash waters and extracted in a separating funnel with CH_2Cl_2 (4 × 50 ml). The combined extracts were dried over anhydrous $MgSO_4$, and the solvent was distilled off on a water bath. The residue was dissolved in a small amount of chloroform, the solution was quantitatively transferred into a weighed bottle, and the solvent was evaporated in an oven at 70°C. The resulting extract was dried in a vacuum oven to constant weight. The yield of the CH_2Cl_2 extract was 0.04 wt % relative to SR OM.

The remaining red-brown filtrate was acidified with 34.6 wt % HCl to pH 2–3. In so doing, vigorous evolution of CO_2 was observed, and the solution became light brown. It was evaporated to dryness on a water bath, and the residue was thoroughly triturated in an agate mortar with acetone and kept in a stoppered weighing bottle for 3 h. The dark orange acetone extract was separated by decanting, and the solid residue was additionally extracted with two portions of refluxing acetone. The acetone extracts were combined, and the solvent was distilled off. The resulting brown residue was triturated in a weighing bottle with a 1 : 1 (by volume) mixture of CH_2Cl_2 and Et_2O. In so doing, the solid partially dissolved. The solution was separated by decanting, quantitatively transferred into a weighed bottle, and evaporated to constant weight. The yield of the light yellow CH_2Cl_2–Et_2O extract from the acetone extract was 1.07 wt % based on SR OM. The brown residue of the acetone extract, insoluble in CH_2Cl_2–Et_2O, was dried in a vacuum oven to constant weight. Its yield based on SR OM was 7.77 wt %. For the analysis by gas chromatography–mass spectrometry (GC–MS), the CH_2Cl_2–Et_2O extract from the acetone extract and the residual amount of the acetone extract were methylated with diazomethane in ether.

All the products obtained were studied by IR Fourier spectroscopy and GC–MS [10–14].

In the experiments on SR OM oxidation with HNO_3, a 50-ml three-necked flask equipped with a power-driven stirrer, a thermometer, and a dropping funnel was charged with 10 g of enriched SR, and 23 ml of a 50 wt % HNO_3 solution was gradually added with careful stirring through the dropping funnel. After adding HNO_3, the mixture was slowly heated with vigorous stirring to 60°C and kept at this temperature for 3 h. In so doing, slight foaming and evolution of nitrogen oxides were observed. After 3 h, the mixture was cooled to room temperature and filtered through a glass frit no. 4. The residue of the enriched SR was repeatedly washed with distilled water to pH ~7 and dried to constant weight; its weight was 8.25 g.

The filtrate was evaporated to dryness on a water bath to obtain an orange-brown solid. It was thoroughly triturated with chloroform in an agate mortar, and the mixture was quantitatively transferred into a weighing bottle with a ground-glass stopper and allowed to stand at room temperature for 3 days. Then the yellow chloroform solution was separated by decanting from the undissolved solid residue, and the residue was washed twice with chloroform by decanting; the chloroform extracts were combined, and the solvent was distilled off on a water bath. The extract was finally dried in a vacuum oven to constant weight. The yield of the chloroform extract was 0.16 wt % based on SR OM. For GC–MS analysis, the extract was methylated with diazomethane in ether; characteristic odor of carboxylic acid esters was noted. The methylation products were dissolved in CH_2Cl_2, and the solution was evaporated; yellow needle-like crystals were obtained, which were analyzed by IR Fourier spectroscopy and GC–MS [10–14].

In the experiments on SR OM oxidation with potassium permanganate in alkali solution, a 50-ml three-necked flask equipped with a power-driven stirrer, a reflux condenser, and a thermometer was charged with 12 g of enriched SR, 12 g of $KMnO_4$, and 50 ml of 6 M aqueous NaOH. The mixture was heated to 90°C with moderate stirring and stirred at this temperature for 3 h. After that, the mixture was cooled to room temperature and vacuum-filtered through a glass frit no. 4; the residue of the enriched SR was washed with distilled water to neutral reaction and dried in a vacuum oven to constant weight. The weight of the residue was 11.52 g. The dark orange filtrate was neutralized with 3 M HCl to pH ~7. The solution became yellow, and a yellow precipitate formed. The solution and precipitate were extracted without their separation with chloroform (4 × 50 ml) in a dropping funnel. The combined chloroform extracts were dried over anhydrous $MgSO_4$, after which the solvent was distilled off on a water bath. The resulting extract was finally dried in a vacuum oven in a weighing bottle to constant weight. The yield of the chloroform extract was 0.10 wt % based on SR OM. Its chemical composition was characterized by IR Fourier spectroscopy [10–13].

In the IR Fourier spectrum (Fig. 1) of the CH_2Cl_2 extract of the alkali fraction from peroxodisulfate oxidation of SR OM, we identified the absorption bands of the following structural fragments (ν, cm^{-1}):

alkanes: ν_{CH_3} (2960.0, 2876.0), ν_{CH_2} (2921.9, 2848.6), ν_{CH} (tertiary, 2896.9), δ_{-CH_2-} (1465.7), δ_{C-CH_3} (antisymmetric, 1450.0), $\delta_{-C(CH_3)_2-}$ (1386.6–1380.0, 1370–1365.0), ρ_{CH_2} (750.0–713.5);

alkenes: $\nu_{CH=CH-}$ (3047.2–3010.0), $\delta_{-CH=CH-}$ (out-of-plane, 970.0–960.0), $\delta_{-CH=CH-}$ (in-plane, 1310.0–1290.0), $\delta_{C=C}$ (nonconjugated, 1680.0–1620.0), $\delta_{C=C}$ (conjugated with benzene rings, 1620.0);

aromatic rings: $\nu_{=C-H}$ (3030.0, 3047.2); $\nu_{C=C}$ (in-plane skeleton vibrations, 1580.0, 1550.6, 1530.0, 1510.0, 1600.0); conjugated rings (1580.0, 1450.0,

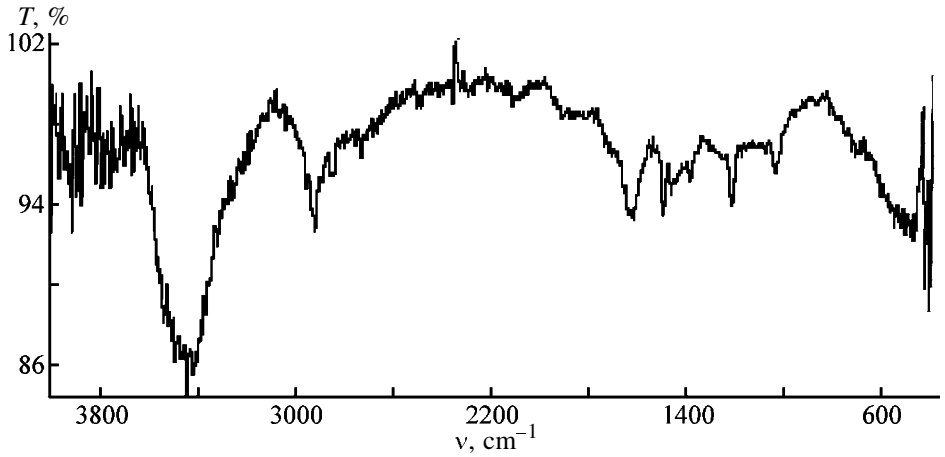

Fig. 1. IR Fourier spectrum of the CH_2Cl_2 extract of the alkali fraction from oxidative degradation of SR OM with ammonium peroxodisulfate. (*T*) Transmission and (ν) wavenumber; the same for Figs. 3, 4, 6, 8 and 9.

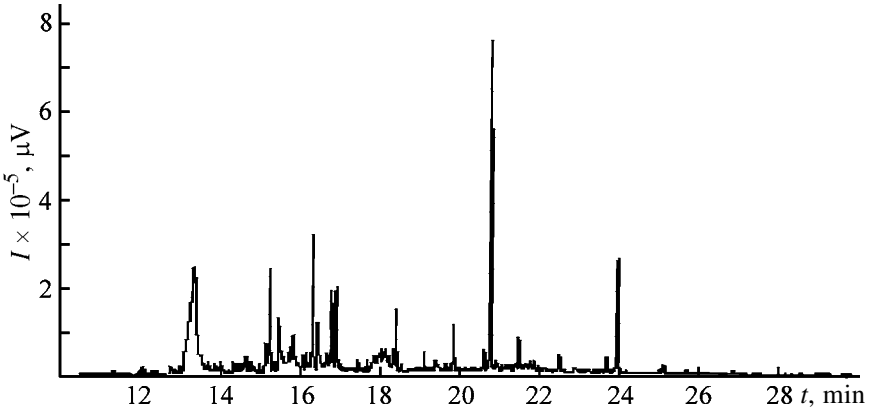

Fig. 2. Chromatogram of a CH_2Cl_2 extract of the alkali fraction from oxidative degradation of SR OM with ammonium peroxodidulfate. (*I*) Intensity and (*t*) time; the same for Figs. 5 and 7.

1465.7); aromatic rings, mainly fused (1620.0, 1680.0, 1580.0–1550.6, 1550.6–1465.7);

cyclic carboxylic acid anhydrides (1822.5, 1784.0); ν_{O-H} (phenols, alcohols, 3656.7–3595.0); ν_{O-H} (phenols, 1216.9, 1410.0–1310.0); δ_{O-H} (primary alcohols, 1039.5, 1050.0, 1350.0–1260.0); δ_{O-H} (in-plane, 1386.6); δ_{O-H} (out-of-plane, 690.3, 650.0); carboxylic acids (3000.0–2500.0, 1620.0, 1465.7, 1386.6, 1300.0–1200.0); acid amides (3000.0–3251.7, 3265.2, 1620.0, 3411.8, 3442.6, 3465.8, 1216.9, 1280.0); ketones (1730.0, 1720.0); aliphatic ethers (1125.0); aromatic and alkyl aromatic ethers (1083.8–1039.4);

pyrrole, indole, pyridine, piperidine, quinoline heterorings (3319.2–3384.7, 3367.4, 3490.8, 1465.7, 1498.5, 1216.9, 1280.0, 713.5, 750.0).

In this extract, we identified by GC–MS (Fig. 2) alkanes (heptadecane, octadecane, eicosane, tricosane, tetracosane, hexacosane heptacosane) and an alkene, 2,6,10,15,19,23-hexamethyltetracosa-2,6,10,14,18,22-hexaene.

In the IR Fourier spectrum of the residue of the acetone extract of the acid fraction from oxidative degradation of SR OM with ammonium peroxodisulfate (Fig. 3), we identified the absorption bands of the following fragments (ν, cm^{-1}):

alkanes: ν_{CH_3} (2958.5, 2873.6), ν_{CH_2} (2925.7, 2854.4), δ_{-CH_2-} (1465.0), $\delta(C-CH_3)$ (symmetric, 1380.0–1370.0), $\rho_{-(CH_2)_4-}$ (rocking, 750.0–720.0);

alkenes: $\nu_{CH=CH-}$ (3031.8–3006.7), $\delta_{CH=CH-}$ (out-of plane, 979.7–960.4), $\nu_{CH=CH_2}$ (vinyl, 3093.5–3078.1, 3031.8–3006.7), $\rho_{-CH=CH_2}$ (conjugated with benzene ring, 1633.5);

phenols, alcohols, ν_{O-H} (free –OH group, 3650.0–3590.0); intramolecular hydrogen bond (3579.5–3444.5); chelate compounds (3203.5–2500.0); δ_{O-H} and ν_{C-O} (primary alcohols, 1050.0, 1350–1260.0,

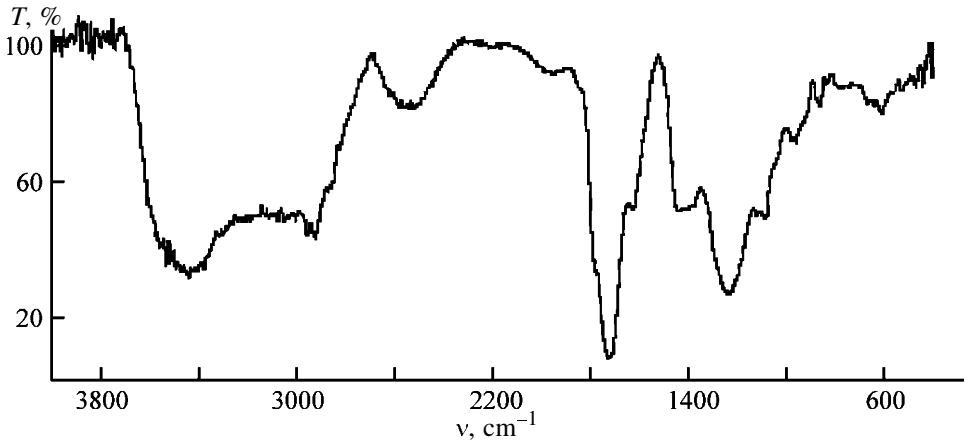

Fig. 3. IR Fourier spectrum of the residue of the acetone extract of the acid fraction from oxidative degradation of SR OM with ammonium peroxodisulfate.

1050.0, 1359.6–1230.4, 1260.0); open-chain unsaturated ketones (–CH_2–CO–CH_2–, 1280.0–1230.4); diketones (1630.0–1540.0); quinones (1645.1–1630.0); carboxylic acids ($\nu_{C=O}$): saturated aliphatic (1737.6–1700.0), aromatic (1700.0–1680.0); esters ($\nu_{C=O}$): normal saturated (1750.0–1737.6), unsaturated (1737.6–1720.0), acetates (1260.0–1230.4);

pyrrole, indole, pyridine, piperidine, quinoline, thiophene heterorings (3022.2, 3064.6–3000.9, 3000.9–3049.2, 1645.1, 3307.6–3394.4, 3352.0, 3473.5, 3409.8, 1440.6, 1230.4, 752.1); primary amines (3195.7, 3352.0, 3487.0, 3409.8); secondary amines (3448.4–3409.8, 3320.0–3270.0, 3195.7–3126.3); sulfur-containing groups: –S–H (2621.0–2530.3), –S–S– (410.7–528.3).

In the methylated residue of the acetone extract of the acid fraction from oxidative degradation of SR OM with ammonium peroxodisulfate, we identified by GC–MS (Fig. 5) the following compounds: alkanes (dodecane, tetradecane, pentadecane, hexadecane, octadecane, eicosane, docosane, tetracosane, heptacosane, octacosane); alkenes (1-tetradecene, 1-hexadecene, 1-octadecene, 1-nonadecene, 2,6,10,15,19,23-hexamethyltetracosa-2,6,10,14,18,22-hexaene); cycloalkane (cyclodecane); esters of saturated, unsaturated, and polybasic carboxylic acids (hexadecanoic, 14-methylpentadecanoic, octadec-7-enoic, octadec-9-enoic; tetramethyl benzenetetracarboxylate; hexamethyl benzenehexacarboxylate).

In the IR Fourier spectrum of the methylated CH_2Cl_2–Et_2O extract form the acetone extract of the acid fraction from oxidative degradation of SR OM with ammonium peroxodisulfate (Fig. 6), we identified the following absorption bands (ν, cm^{-1}):

alkenes: $\nu_{-CH=CH-}$ (3045.3–3001.0), $\delta_{-CH=CH-}$ (out-of-plane, 983.5–960.0); $\delta_{-CH=CH-}$ (in-plane, 1320.0–1290.0);

aromatic ($\nu_{=C-H}$, 3031.8), mainly fused (3031.8–3080.0, 1643.1, 1442.5, 1178.3–1100.0, 720.0–757.9), naphthenic (2925.7, 2954.6, 1442.5, 983.5) and aromatic rings (720.0–825.4, ill-resolved triplet);

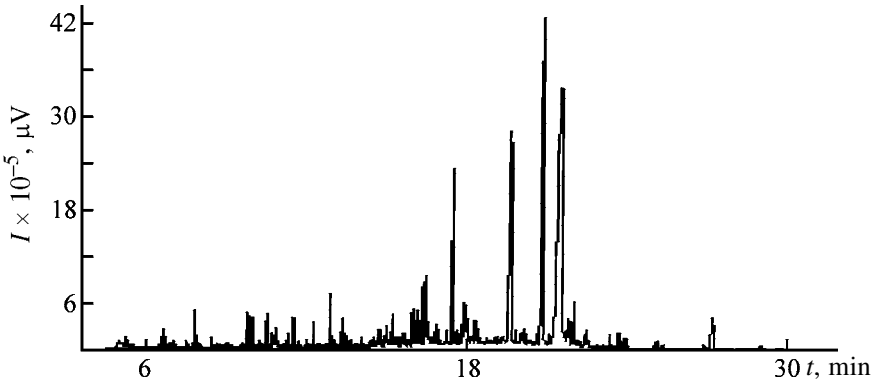

Fig. 7. Chromatogram of the methylated CH_2Cl_2–Et_2O extract from the acetone extract of the acid fraction from oxidative degradation of SR OM with ammonium peroxodisulfate.

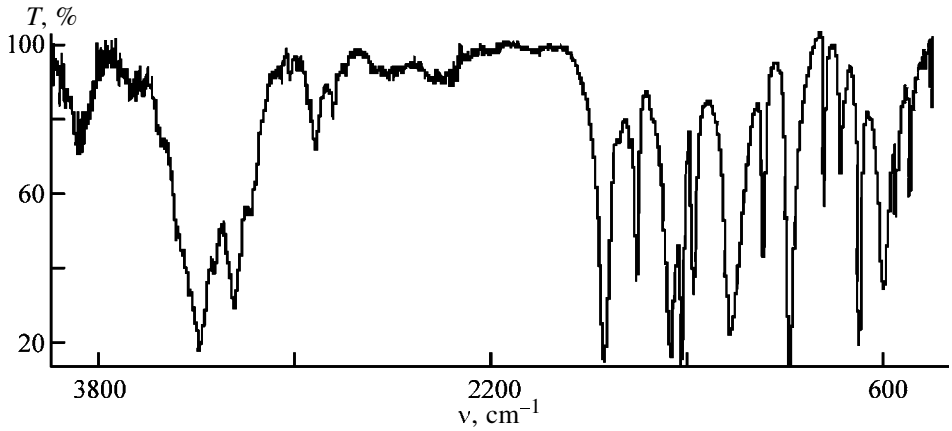

Fig. 8. IR Fourier spectrum of the methylated chloroform extract from oxidative degradation of SR OM with nitric acid.

phenols, alcohols (3633.6–3580.0, 3211.2–3250.0, 1410.0–1310.0, 1242.0–1178.3); quinoid groups (1643.1, 1660.0, 1680.0); ketones (1720.0–1739.6, 1178.3); carboxy groups of aliphatic and aromatic acids (1705.0–1739.6, 3580.0–3500.0, 3519.8, 3546.8, 1800.0–1739.6, 1359.6–1242.0, 1080.0–1178.3);

pyrrole, indole, pyridine, quinoline, furan heterorings (3170.0–3134.0, 1560.0, 1410.0–1310.0, 1178.3–1242.0, 720.0, 757.9, 825.4, 3300.0–3355.8, 3431.0, 3473.5, 1411.7); conjugated pyrrole rings of porphyrins and chlorophylls (3519.8, 3487.0, 3134.0, 3045.3, 1560.0, 1018.2, 700.0–757.9); sulfides and disulfides (1411.7, 1359.6, 588.1, 472.4, 451.2, 428.0).

In the methylated CH_2Cl_2–Et_2O extract from the acetone extract of the acid fraction from oxidative degradation of SR OM with $(NH_4)_2S_2O_8$, we identified by GC–MS (Fig. 7) the following compounds: alkanes (dodecane, tetradecane, hexadecane, octadecane, eicosane, tetracosane, heptacosane, nonacosane); complete methyl esters of mono-, di-, and polycarboxylic acids (tetradecanoic, hexadecanoic, propanedioic, butanedioic, thiophenetetracarboxylic, benzenehexacarboxylic).

In the IR Fourier spectrum of the methylated chloroform extract of products of SR OM oxidation with 50% HNO_3 (Fig. 8), we identified the absorption bands of the following structural fragments (ν, cm^{-1}):

alkanes: ν_{CH_3} (2948.9, 2889.1), ν_{CH_2} (2920.0, 2848.6), δ_{CH_2} (1459.9), $\rho_{(CH_2)_n}$ (775.2);

alkenes: $\nu_{-CH=CH-}$ (3060.7–2995.9), $\delta_{-CH=CH-}$ (out-of-plane, 979.7), $\delta_{-CH=CH-}$ (in-plane, 1310.0–1290.0), $\delta_{C=C}$ (nonconjugated, 1680.0–1606.5, 1637.3);

aromatic rings ($\nu_{=C-H}$), mainly fused (3000.0, 3060.7, 3024.1); δ_{C-H} (out-of-plane, 775.2, 842.7); naphthenic (2920.0, 2948.9, 1459.9, 979.7) and hydroaromatic rings (775.2, 842.7, 979.7);

phenols, alcohols (3635.5–3583.4, 3247.8–3203.5, 1410.0–1310, 1220.7–1089.6), δ_{O-H} (alcohols, 1419.4–1371.2, 1089.6); quinones (1637.3, 1680.0); ketones (1735.7, 1180.0); aliphatic and aromatic acids (1735.7–1700.0, 3583.4–3500.0, 3514.0, 3521.7,

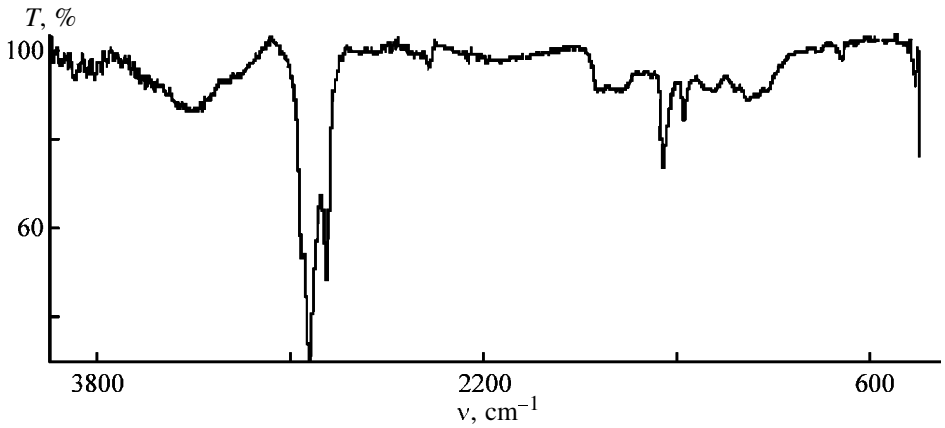

Fig. 9. IR Fourier spectrum of the chloroform extract from oxidative degradation of SR OM with potassium permanganate in alkali solution.

3529.4, 3566.0, 3583.4, 1800–1735.7, 1371.2–1220.7, 1220.7–1089.6);

esters ($\nu_{C=O-O-}$) with acetate group conjugated with benzene ring (1750.0–1735.7); ethers, ν_{C-O-C} (symmetric, 1089.6; antisymmetric, 1220.7);

pyrrole, indole, quinoline, furan heterorings (3180.0–3105.1, 1580.0, 1410.0–1310.0, 1220.7–1089.6, 3379.0–3307.6, 3431.0, 3425.3, 3465.8, 3485.0, 1419.4, 1459.9); conjugated pyrrole rings of porphyrins and chlorophylls (3514.0, 3521.7, 3485.0, 3105.1, 3060.7, 3024.1, 1560.0, 1220.7, 700.0–775.2); sulfides and disulfides (1419.4, 1459.9, 1371.2, 593.9, 696.1, 491.7, 441.5, 426.1).

In this extract from products of SR OM oxidation with 50% nitric acid, we identified by GC–MS eicosane, pentacosane, octacosane, methyl hexadecanoate, 2-methyl-7-phenylindole, 1,1-dicyano-2-methyl-3-(*p*-cyanophenyl)propene.

In the IR Fourier spectrum of the chloroform extract from products of SR OM oxidation with an alkaline solution of potassium permanganate (Fig. 9), we identified the absorption bands of the following structural fragments (ν, cm^{-1}):

alkanes: $\nu^{as}_{CH_3}$ (2960.0), $\nu^{s}_{CH_2}$ (2865.0), $\delta^{as}_{CH_3}$ (1461.8), $\delta^{s}_{CH_2}$ (1377.0), $\nu^{as}_{CH_2}$ (2921.9), $\nu^{s}_{CH_2}$ (2850.5), CH_2 (scissor, 1461.8), $\rho_{-(CH_2)_n}$ (rocking, 728.9, 719.3);

aromatic rings (3030.0, 3060.0, 3097.4, 1540.9, 1506.2, 1558.3, 1654.7);

alcohols, phenols (3583.4–3515.9); ν_{C-O} (phenolic, 1220.0, 1261.2); ν_{O-H} (alcohol, 1040.0); δ_{O-H} (1261.2); quinones (1654.7–1680); diketones (1710.6); carboxylic acids (3010.0–2500.0, 1710.6, 1461.8, 1300.0–1200.0);

pyrrole, indole, pyridine, quinoline heterorings (3328.8–3369.3, 3413.7, 3433.0, 3467.7, 1461.8, 1377.0, 1377.0–1261.2, 719.3, 728.9).

CONCLUSIONS

(1) Each of the oxidants tested gives rise to a complex set of products among which carboxylic acids, alcohols, phenols, ketones, and quinones prevail. *n*-Alkanes, alkenes, and cycloalkanes were also identified.

(2) Hydrocarbons, especially alkanes and alkenes, and also aliphatic saturated and unsaturated carboxylic acids, identified by gas chromatography–mass spectrometry in methylated extracts, are presumably coextracted from the network matrix of shungite macromolecules, i.e., are components of the mobile phase reflecting the lipid composition of ancient unicellular algae. The detection of benzenetetra- and benzenehexacarboxylic acids shows that the organic matter of shungite rock has a highly fused structure; in the course of oxidative degradation, these acids could form from pyrene, coronene, and fullerene fragments of its macromolecular network.

(3) According to the results obtained, separate highly condensed aromatic fragments are presumably linked with each other by polymethylene, cycloalkane, indole, furan, thiophene, and other bridges.

Received April 27, 2006

Abstract—A mechanism of formation of fulleroid nanoparticles in shungites, adequate to the principal structural features of these particles (a cavity filled with nothing but water traces, the absence of the catalyst nanoclusters, and some other) was suggested.

DOI: 10.1134/S1070427207010272

Natural mineral shungite is extremely promising from the viewpoint of nanocarbon science and applications. Some of these applications, e.g., water treatment, are known for at least 300 years, while others, e.g., coke substitution or addition to building materials, are now under development [1, 2] or research [3].

Fullerene and carbon nanotube (CNT) science treats shungite as an important natural material unique in containing fulleroid particles such as multilayer fullerenes and, probably, true fullerenes. Data on the presence of true fullerenes are contradictory. The first encouraging results obtained in mass-spectrometric experiments [4] were disproved by the results of extraction with conventional organic solvents, but those studies were underlain by the views on the molecular character of the bond for fullerenes in shungites. Covalent and donor–acceptor compounds of fullerenes, yielded by their reactions with nucleophilic molecules, are being actively studied today. It is believed that specifically the chemical character of the bonding of fullerenes in shungites complicates their detection [5].

By contrast to fullerenes, the existence of fulleroid particles as multilayer globules, nanotubes, nanobarrels, and onion-like nanocarbons with an internal cavity is beyond question, and they were repeatedly observed [6, 7]. Like carbon in shungites on the whole, fulleroid structures are rigidly connected to the aluminosilicate matrix [7]: Both phases are uniformly distributed even in particles prepared by micrometer grinding. Along with noncrystalline carbon and aluminosilicates, shungite contains a small amount of a bituminous organic material.

The richest in carbon (up to 90 %) is shungite-I [8]; however, it is fairly expensive, and its deposits are extremely limited. Evidently, more promising is shungite-III containing 30–40% carbon [8, 9] (with the remaining 60–70% accounted for primarily by aluminosilicates). The total resources of the shungite rocks of the Onega basin exceed 1 bln tons, and the explored reserves of the largest Zazhoginskoe deposit are estimated at ca. 150 mln tons.

Typical electron micrographs of the nanostructures of shungite-III were obtained after chemical recovery of the carbon component (the resulting material was named MNS, modified nanoshungite). The sequence of the operations in removal of the mineral components was described in [10]. The samples were analyzed on a JEM-100S (JEOL, Japan) transmitting electron microscope at a magnification of 10^4–10^5. Figure 1 shows one of compact accumulations of the nanoparticles, irregularly distributed over the bulk of the material. The micrograph shows a closed-end multilayer CNT with a cavity, comprising numerous layers, with the channel diameter of ca. 3 nm, outside diameter of 20 nm, and length of ca. 0.2 μm, as well as nanobarrels with a cavity and onion-like nanocarbons without cavity. All the nanostructures are clearly separated from the silicate matrix.

The morphology of the carbon filling the inter-

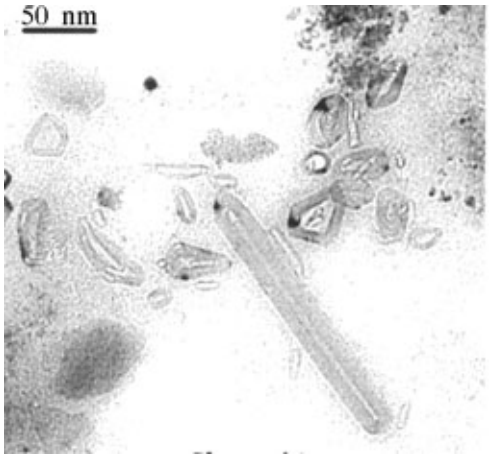

Fig. 1. Tunneling electron micrograph (TEM) of the chemically modified shungite-III.

globular space in nonsplit shungite still remains to be examined. Published data characterize it as a carbon material resistant to graphitization up to very high temperatures [7, 8].

The task of developing a model of formation of fulleroid particles (FPs) in shungites is clearly not as broad as the global geological problem of formation of shungite rocks. The model we propose here, rather, provides an alternative treatment of the mechanism of formation of FPs (or globules), that is, not underlain by the concept of the organic nature of the initial carbon.

Up to now, two hypotheses of formation of shungites, biogenic and abiogenic, were proposed [8, 9]. They fundamentally differ but are similar in treating the globular structure of the matter, characteristic of shungites, as due to the presence in the prehistoric carbon substance of long polymeric molecules with flexible linear segments. Under the action of intramolecular forces, these molecules can roll themselves into balls which subsequently turn into globules. This rolling is driven by the tendency of the molecules to minimize the free surface energy caused by the "projecting" active groups [11, 12]. Basically, the only difference between the biogenic and abiogenic hypotheses consists in how they treat the nature of carbon which in both cases is assumed to be organic. Various versions of the biogenic hypothesis consider as organic substance Cyanophyceae, naphthoids, or bitumen–resin substances. The abiogenic hypothesis also considers various types of hydrocarbons in organosilicate complexes. A common feature is that these complexes gradually replace the previously formed silicate and aluminosilicate rocks. A special place is occupied by the model of formation of FPs by a mechanism similar to that in formation of carbon black particles in the flame synthesis of fullerenes by oxidation of methane [13].

Formation of globules from carbonization of some organic substances was unambiguously established long before arising of science of nanotubes. The globules were observed, e.g., in glassy carbons [11], where polyvinyl alcohols or phenol–formaldehyde resins can act as the initial products. Later, carbonization of specially selected organic substances was applied in synthesis of CNTs as well [14]. Importantly, such carbon materials are synthesized, however, under specific conditions in the absence of aluminosilicates. Therefore, in the absence of real simulation experiments with a substance close to shungite, only those versions of arising of fulleroid particles have a right to exist that do not at all appeal to the assumed organic nature of the initial carbon.

It is essential that the hypothetical mechanism of formation of the shungite FPs takes into account a number of the morphological features distinguishing these particles of shungites from the nanoparticles obtained by the chemical and arc syntheses.

(1) The particles have a cavity filled with nothing but, probably, water or its traces.

(2) There are no clear metal nanoclusters encapsulated inside the fulleroid layers.

(3) The fulleroid layers around the nanoparticles can have topological breaks, i.e., the surface typically does not have a fullerene nature in the strict sense of the word.

(4) The fullerene particles exist both in shungite-III containing ca. 60% aluminosilicates and in shungite-I, where the content of aluminosilicates can be no higher than several per cent.

General geological views on magma [15] and a typical chemical composition of shungite suggest that our considerations can start from a combination of the main components, carbon–aluminosilicate–water, if we will consider the following sequence of events. Carbon, molten in the aluminosilicate rock, rises from the interior of the Earth and is cooled. The melt also contains certain amount of water completely dissolved in it. Gradual decrease of pressure and lowering of temperature to a certain value T_{boil} result in supersaturation of the melt with the water separated out in the bulk of this melt as bubbles (the aggregation state at temperatures close to 1000°C can be only steam, since the critical point of water corresponds to a pressure of ca. 200 atm and temperature close to

300°C). As temperatures promising for synthesis of the nanostructures markedly exceed 300°C, water can be considered as steam throughout the synthesis of the nanostructures, even if this steam will be able of condensation upon further cooling.

A larger decrease in temperature results in separation of the melt components, since the solubility of carbon in SiO_2 attains the limiting value. This leads to supersaturation of the melt with carbon, which precipitates at the separation temperature T_{separ}. The bubble boundary becomes a natural site for precipitation of carbon from the melt as a solid phase. The shape of the nucleus during precipitation of carbon is similar to the fulleroid surface island on the surface of the catalytic particle (CP) (or nanodrop) [16, 17] (Fig. 2a). We showed in [17] that, in the case of a nanodrop, precipitation of the island (Fig. 2a, surface *1*) does not necessarily result in appearance of a nanotube. At high energies A of the van der Waals interaction of the catalyst atom with the fulleroid surface, encapsulation of the CP inside this surface (Fig. 2a, surface *3*) is more favorable than formation of a nanotube nucleus (Fig. 2a, surface *2*). A special place occupied by the iron group (or palladium group) elements is due specifically to the fact that they have a minimal A (Fig. 3), and the fulleroid island can fairly easily be detached from the catalyst surface and turn into CNT. Moreover, these elements are characterized by an optimal combination of A with the energy difference of the carbon–carbon chemical bond E_{CC} in graphite and carbon–melt(metal) atom bond $E_{M–C}$. This difference is specifically responsible for separation of the carbon atom from the melt and its incorporation into the fulleroid surface. For other elements (e.g., silicon), the parameter A is much higher (Fig. 3), but this does not hinder nucleation of the island, if we do not consider further detachment of such an island from the melt. Also, if $E_{M–C}$ somewhat exceeds E_{CC}, the growth of the perimeter and the spread of the island are energetically favorable. For silicon, the energy $E_{M–C} \equiv E_{Si–C}$ was estimated by the PM3 semiempirical quantum-chemical method at $E_{Si–C} \approx 12$ eV, while E_{CC}, at ≈ 6.5 eV.

Realization of the above-described sequence of events requires the following prerequisites. The solid carbon–melt phase segregation should occur before solidification of the melt as a whole, i.e., the condition $T_{boil} > T_{separ} > T_{solid}$ (where T_{solid} is the solidification temperature) should be satisfied. Also, the carbon content in the melt should decrease along the line of separation of the solid carbon phase rather than of sublimation of the excess carbon in the form of CO.

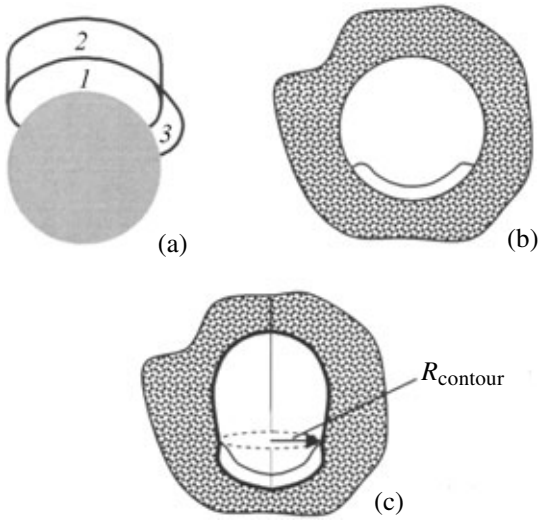

Fig. 2. (a) (*1*) CNT nucleus on the catalytic nanodrop surface, (*2*) CNT nucleus generated by the primary CNT nucleus, and (*3*) further spread of the island over the surface; (b) a fulleroid island on the internal surface of the nanobubble under assumption of a nondeformable surface; and (c) fulleroid island on the internal surface of the nanobubble (of the liquid surface of the melt).

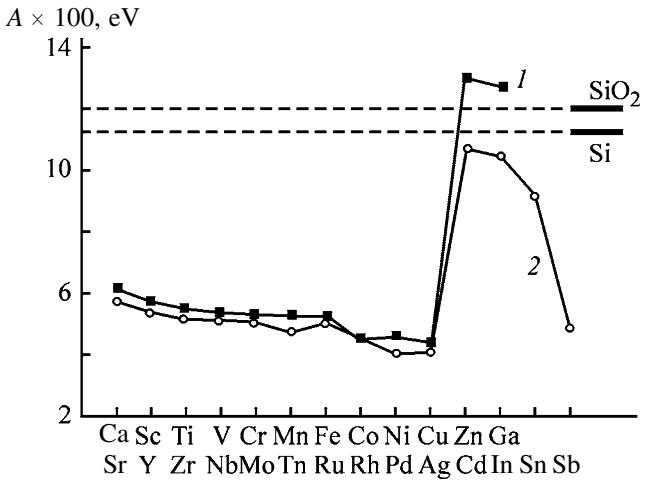

Fig. 3. Van der Waals interaction energy A of period III and IV atoms with the graphene plane. Period: (*1*) III and (*2*) IV. Dashed lines: energies of interaction of silicon and silicon dioxide SiO_2 with the graphene plane.

The phase diagram of the water–SiO_2 system was discussed in [18]; it is shown in Fig. 4 for the pressure of 1 atm. It is seen that, at the water content $c \geq$ (6–7) wt % and temperature $T \geq 1200$°C, the steam bubbles begin to evolve from the melt, and this pattern is preserved to at least 2000°C. The crystal phase, in which SiO_2 is transformed under cooling to 1200–1000°C (depending on the pressure), can have various modifications, e.g., quartz, tridymite, and cristobalite.

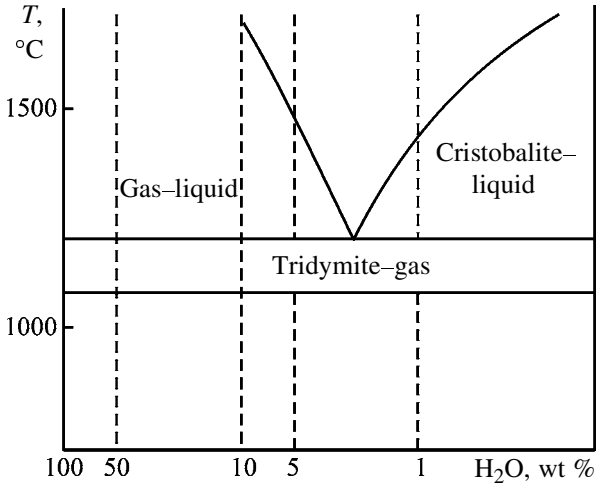

Fig. 4. Phase diagram of the water–SiO_2 melt system [18] at a pressure of 1 atm.

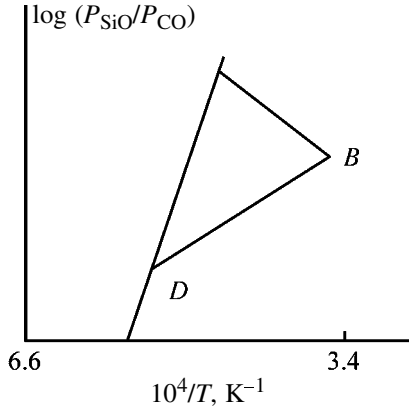

Fig. 5. A characteristic shape of equilibrium phase diagrams of the Si–C–O system [19]. (T) Temperature.

At pressures above 2 atm, the melt solidifies only as quartz; however, the pressure does not markedly affect the behavior at high temperatures.

The range of the conditions corresponding to specifically SiO_2 and C as condensed phases was identified in [19]. The schematic phase diagrams of the Si–O–C system are plotted in the $\log(P_{SiO}/P_{CO})$ vs. T coordinates, where the oxides SiO and CO are the components that are constantly present in the gas phase. A characteristic diagram is shown in Fig. 5; this pattern depends on the total pressure. To the left from the point D, the condensed phases are really SiO_2 and C, and to the right (along the DB line), a carbide phase SiC appears in the system. Taking into account the diagrams presented in [19] for pressures of 0.1, 1.0, and 10 atm, the $\log(P_{SiO}/P_{CO})$ vs. P, atm, and T, K, dependence to the left from the point D can be represented as

$$\log(P_{SiO}/P_{CO}) = -3.08 \times 10^4 T^{-1} + 14.864 - 1.702 \log P, \quad (1)$$

and the temperature at the point D, as

$$T = \frac{10^4}{5.4 - 0.621 \log P}. \quad (2)$$

Since no carbide traces were revealed in shungites, the evolution of the melt actually proceeds to the left from point D. Equation (1) suggests that the temperature corresponding to the onset of an appreciable decrease in the solubility of carbon is no less than 1700 K. Below this temperature, the gas phase should become virtually purely carbonic, and this could be due to faster evaporation of carbon compared to silicon (in the form of SiO), which is accompanied by the escape of "excess" carbon from the melt. In fact, relationship (1) suggests a gas phase, not limited by the total volume of the bubbles, and the absence of water. The steam occurring inside the bubble hinders the escape of carbon, and it should be condensed in a solid phase.

Thus, water plays a dual role. The steam pressure favors precipitation of the solid phase of carbon. At the same time, water as a component of a fluid–silicate melt causes the solidification temperature to decrease [15]. For example, it is known that, in the absence of volatile components, fluids, the solidification temperature of aluminosilicate slags is near 1500°C. At a significant content of water, the solidification temperature decreases to 1100–1200°C, and the condition $T_{boil} > T_{separ} > T_{solid}$ can be well satisfied.

Unfortunately, it is a difficult task to compare with a fairly high accuracy the activation energies of reduction of silicon dioxide with carbon and of precipitation of the fulleroid island. In the latter case, the free energy of the island–bubble–melt system can be estimated as [17]:

$$\Delta G_g = m(\beta + 6\Delta E_{SiO_2\text{–}C}) - g(wT + A), \quad (3)$$

where m and $g = 6m(m + 2)$ are the numbers of the rings of pentagonal cells (pentagons) and hexagonal cells (hexagons) (if the shape of the island boundary is taken close to a circumference and its size, equal to the number of the rings of the polygons around the central hexagon) and of atoms in the island, respectively; the term βm takes into account the spheroidal segments of the CNT surface and distortion of the bond angles when the island is bent to the nanodrop surface; $\beta = \alpha_{NT}\pi\Psi/3$, $\alpha_{NT} \approx 1$ eV, is the distortion energy per hexagon row in the tubular part of the nanotube; and, Ψ, ratio of the width of the ring of the hexagons to the length of the C–C bond, $a \approx 1.5$ Å.

At $\Omega = \beta - 12(wT + A) + 6\Delta E_{SiO_2-C} < 0$, the ΔG_g function monotonically decreases at any size of the island. Clearly, this does not suggest barrier-free formation of the islands. Equations of type (3) correspond to a smoothened curve ΔG_g, when the local maxima associated with the onset of filling of the next ring of the hexagons are neglected (Fig. 6). Since the growth of a projection begins with the cleavage of the radical–metal bond having the energy E_{SiO_2-C} (the run of the ΔG_g curve is shown qualitatively in Fig. 6), such local maxima can be taken into account by adding the term γE_{SiO_2-C} to the expression for the global maximum $(\Delta G_g)_{max}$ of the ΔG_g curve ($0 < \gamma < 1$ is a free parameter). At $\Omega < 0$, this maximum is of the order of

$$(\Delta G_g)_{max} = \gamma E_{M-C}. \quad (4)$$

Clearly, at $\Omega < 0$, the nucleation of the smallest island (e.g., one of the hexagons) should be analyzed; in this case, expression (3) is inapplicable. As to the activation barrier in nucleation of such an island, we will only mention that it is of the order of γE_{SiO_2-C}. It hardly exceeds considerably the activation energy of a reaction such as $SiO_2 + C_{(sol)} = SiO + CO$.

Consideration of the mechanism of nucleation of fulleroid islands on the internal surface of a nanobubble should take into account the fact that the island can effectively expand over the surface in the absence of catalytic atoms as well. Then the situation with the CNT nucleation is partly similar to the growth of the CNT of the cathodic deposit, observed in arc synthesis of fullerenes [20]. Fullerene molecules can serve as a CNT nucleus. These molecules can be partially broken down when deposited onto the lateral surface of the cathode (with a temperature close to 1300 K). The preserved part of the fullerene can easily become a CNT nucleus, since there is no need in detachment of its central part from the cathode surface, associated with overcoming at least van der Waals forces. A close mechanism, even not connected with fullerenes, can also be realized in uncatalyzed electrochemical growth of CNTs [21].

An insignificant influence of the metal catalyst on formation of FPs in shungite is suggested by the absence of the catalyst macroparticles in the electron micrographs. The role of the metal as a catalyst of the CNT growth at the atomic level was analyzed so far only hypothetically [22–24] and was not confirmed experimentally. Therefore, it is extremely difficult to suggest a true form of the metal capable of catalyzing formation of the FPs.

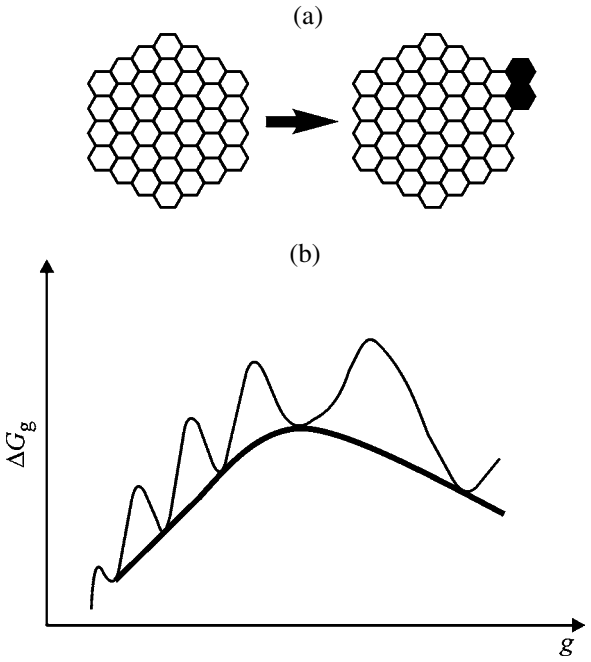

Fig. 6. (a) Initial stage of formation of the next ring of hexagons in the island and (b) oscillating pattern of the true curve of the Gibbs energy ΔG_g as a function of the number of atoms in the island g.

Another prerequisite to precipitation of the solid carbon phase as an island is the presence of atomic carbon in the melt. At $\Delta \log f_{O_2}$ from approximately –2 to –3 (f is the fugacity), carbon is dissolved specifically in the atomic form, although the melt contains only insignificant amounts of both carbonate ions and "silicide" carbon linked by the Si bonds, Si–C [25]. Under identical conditions, the inevitably occurring hydrogen also exists mainly as water. At $\Delta \log f_{O_2}$ from approximately –4 to –6, the situation changes radically (the dissolved carbon forms in the melt a C–H bond, typical for alkanes, e.g., CH_4). The model discussed is applicable specifically to the former case.

Thus, the model of nucleation of the fulleroid island on the internal surface of the bubble seems to be consistent. The following relationships in nucleation and growth of such an island can be assumed.

(1) The arising fulleroid surfaces can have diverse shapes. The reason is that, under expansion of the island, the total surface energy is determined by at least two factors: the surface energy of the bubble and the stress of bending of the island to the melt surface. The latter factor arises because the bending area is represented mainly by hexagonal cells with strongly distorted bond angles. The number of pentagonal cells, capable of lowering the stress, can be only such that, upon subsequent incorporation of the pen-

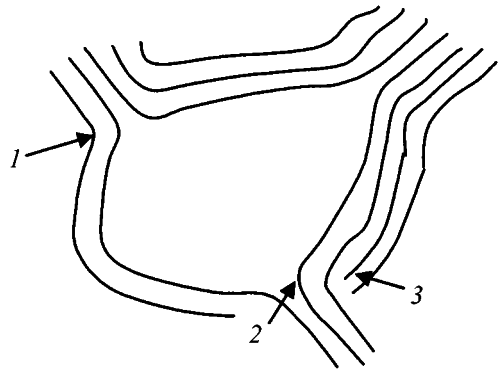

Fig. 7. Topological breaks of the fulleroid surface being formed and nucleation of the stack structures.

tagon into the surface, the total curvature corresponds to that of the melt surface. The tendency of the island to minimize the stress of bending to the melt surface can be responsible for gradual deformation of the bubble into an irregular dumbbell or, further, into a nanotube, nanocone, or flattened nanoparticle. In the general case, a functional of the type

$$\oint dS' \sigma = (\alpha_{NT}/6a)2\pi R_{contour}$$

should be minimized. Here, the integral is taken over the surface free from the island; $R_{contour}$ is the radius of the line of bending of the island to the melt surface (Fig. 2c), and σ, surface tension on the melt–steam interface. The integral is of the order of $\pi\sigma R^2$, and the second term, of $2\pi(\alpha_{NT}/6a)R$. Thus, at $R \leq \alpha_{NT}/3a\sigma$, the total surface energy is weakly sensitive to the shape of the bubble, and the morphology of the FPs is determined by the condition of the minimal stress of bending of the island. At $\sigma \sim 200$ erg cm^{-2}, this yields $R \sim 5$ nm, which is somewhat less than the nanoparticle size. However, it is clear that this condition implies a series of possible morphologies of the island–melt boundary system, slightly differing in the energy and entropy, which, moreover, tend both to the spherical and edged shapes. Indeed, as mentioned above, it is convenient to represent the expansion of the island along the surface of the boundary with the melt as an increase in the number of the rings of the polygons (mainly, hexagons), formed in sequence around the initial nucleation area, rather than in the number of polygons. If the frequency of the occurrence of pentagonal distortions in the external rings corresponds to the curvature of the nanobubble, the shape of the first fullerene surface should approximately correspond to that of the fullerene with the characteristic size identical to that of this nanobubble. Such a fullerene should be very large: The number of atoms in the fullerene is related to its diameter D_{ful} approximately as $N \sim 20 + 2(\pi/6 \times 3^{1/2})(D_{ful}/a)^2$; hence, at the bubble diameter close to 15 nm, $N \sim 40\,000$. It is known that, with growing size, the fullerene tends from the spherical to the edged shape. Therefore, even under assumption of the perfect fulleroid surface in shungite, its shape should be edged, rather than spherical.

(2) In fact, the fulleroid surface of shungite is imperfect and has topological breaks [7, 8]. The model considered here treats this as due to the fact that, in the problem of the cavity, geometrically "inverted" with respect to the problem of the nanodrop, local precipitation of carbon at some point of the cavity does not decrease the supersaturation with carbon on the opposite side of the cavity. Some islands can start to grow simultaneously, and, strictly speaking, their contact with one another does not necessarily involve cross-linking, especially at low temperatures.

(3) The fullerene particles growing around the bubbles should have a multilayer structure. The subsequent layers are formed from the side of the areas more distant from the nanobubble. Clearly, graphitization initiated by a small amount of local sources (bubbles) results in formation of ever more defective fulleroid layers. With increasing distance from the initial globule, the fulleroid layers change their structure ever more profoundly and resemble a "stack." The model considered here attributes this to the fact that simultaneous and independent growth of several islands results in formation of fulleroid surfaces sharply turned to one another (e.g., areas *1* and *2* in Fig. 7). For each subsequent layer growing on such a break, the breakage of the plane can be thermodynamically as favorable as its bending (Fig. 7, area *3*). Formation of one break of this kind apparently suggests the growth of subsequent layers, whereby a stack structure is formed.

The assumption that the stacks begin to dominate over the fulleroid layers with increasing distance from the globule can be verified by the results of experiments on vibrocavitational treatment of shungite [3], when chemically treated shungite is placed into a field of a standing sound wave of a very small power (ca. 60 W per bath volume of ca. 0.5 l) in water. The field was created by plates oscillating with a sound frequency in antiphase with one another. The total treatment time was 2.5 h. The resulting suspension was left to stand, whereupon both fractions were analyzed, namely, that deposited to the bottom of the vessel with the suspension and the floating, emerged onto

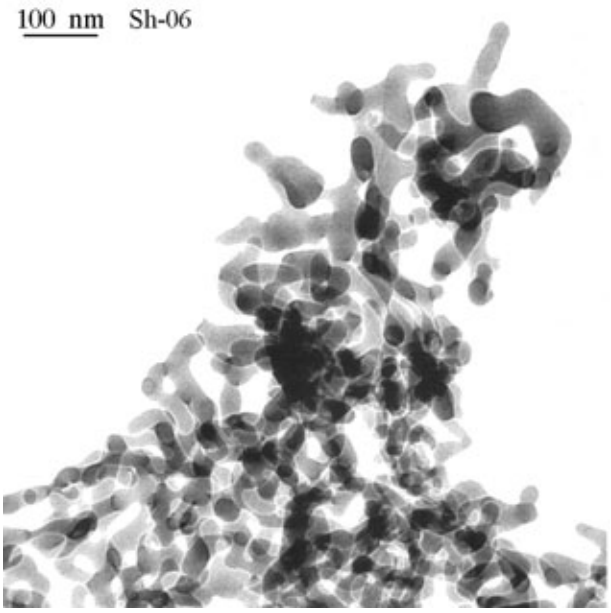

Fig. 8. TEM images of the material yielded by vibrocavitational treatment of the chemically pretreated shungite-III.

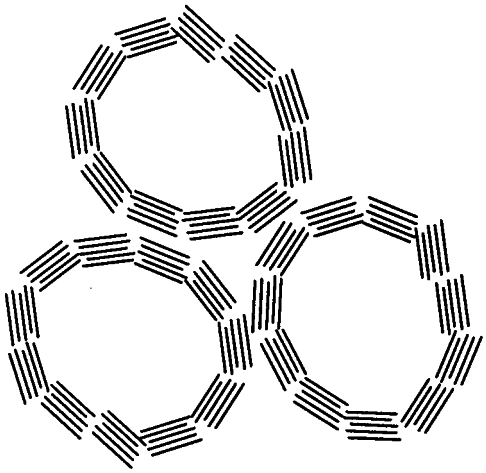

Fig. 9. Aggregation of the stack structures destroyed by vibrocavitational treatment into a new nanoporous structure.

the surface. Vibrocavitational treatment yields two types of macroparticles: with the same morphology as the initial material and a specific nanoporous carbon with numerous globules, absolutely different from the initial material. Figure 8 shows typical electron micrographs of such nanoporous carbon having one of the two slightly different morphologies. The structure consists of numerous nanopores 5–20 nm in size and short appendices 30–100 nm in size.

Such structures can be formed by the following mechanism. In the course of vibrocavitational treatment, a part of the graphitized stacks not fixed by the aluminosilicate matrix (the result of chemical etching of aluminosilicates) is "thrown out" into a water dispersion. Such stack behaves as a specific "quadrupole" towards another analogous stack: During coagulation, the energy of interaction, associated with the torn-off edges of the graphite stacks, tends to decrease, if the stacks are arranged in the edge-to-edge fashion (Fig. 9). The newly formed structure tends to reduce the surface energy, thereby yielding a globule.

CONCLUSIONS

(1) Formation of fulleroid particles in shungites can be interpreted in terms of a model absolutely analogous to that interpreting the formation of fulleroid structures on the surface of the nanoparticles of a metal catalyst, supersaturated with carbon.

(2) In terms of the model, the fulleroid particles arise from precipitation of carbon from the aluminosilicate melt, supersaturated with carbon during cooling.

(3) The natural surface of precipitation of the islands of the fulleroid surface is the internal surface of the bubbles of steam evolving from the same melt at a higher temperature (1500–1800°C).

(4) The natural structural motif arising from precipitation of carbon from the melt is represented by graphitized stacks with torn-off graphene layers. These stacks can release during chemical degradation of the aluminosilicate matrix and the subsequent vibrocavitational treatment with water.

(5) A water dispersion of such graphitized stacks is an effective medium for nucleation of a nanoporous carbon material.

Abstract—Formation of transparent crystallites embedded in the deposited substrate obtained in a reactor for arc synthesis of fullerenes was studied. An X-ray diffraction analysis of the substrate was made.

DOI: 10.1134/S1070427207010284

The interest in mono- and polycrystalline diamond-like materials is due to their unique properties. The materials are synthesized both by chemical vapor deposition onto a hot (800–1200 K) support and by structural transformation of carbon under conditions of high temperature and pressure. Fullerene molecules can be used as a starting carbon material in both the first and second approaches to synthesis of diamond-like structures [1, 2].

The aim of our study was to examine processes in which various kinds of carbon are formed in arc sputtering of a graphite rod and to find the conditions necessary for a diamond-like structure to be produced.

EXPERIMENTAL

An uncooled metallic support *1* was mounted in a reactor for electric-arc synthesis of fullerenes (Fig. 1) at a distance of 1–10 cm from the arc. We used as electrodes rectangular graphite rods of length 10 cm and 2×4 to 4×6 mm in cross section. The electrodes were annealed by passing dc current of 50–70 A through short-circuited electrodes for 8–10 h at a residual pressure in the reactor on the order of 10^{-2} Pa or in a helium atmosphere. The working pressure of 2×10^4 Pa provides the maximum yield of fullerenes for the given reactor. In the curse of sputtering, the arc current was 100–150 A at a voltage across the discharge gap equal to 20–25 V. The completion of the sputtering process was judged by visual inspection.

The substrate deposited on the support was examined by X-ray diffraction analysis and microphotography. The X-ray diffraction analysis was made on a DRON-UM1 X-ray diffractometer (MoK_α radiation monochromated with a Zr filter) modified for work with substances in condensed and polycrystalline states, with the possibility of obtaining X-ray diffraction patterns at diffraction angles θ of 1°–50° by the Debye–Scherrer scheme.

* The support melted.
** No substrate formed.

Data in Table 1 suggest that the formation of crystallites (Fig. 2) is governed both by the support material and by the distance from the graphite evaporation zone to the support. The possible critical parameters of the process are the following: (a) composition of the carbon vapor near the support, (b) support temperature, (c) existence of zones of a melted metal on the support surface, and (d) chemical nature of the interaction between carbon and the support material.

The composition of the carbon vapor formed near the support is governed by the following factors. Graphite evaporated by the arc method forms a flow of a carbon vapor in which carbon clusters condense. The vapor composition is determined by the following processes [3]: first stage, $C_i + C_j \rightarrow C_k$, where *i, j* are integers in the range from 2 to *k*/2; second stage, $C_{k1} + C_{k2} \rightarrow C_{60}$.

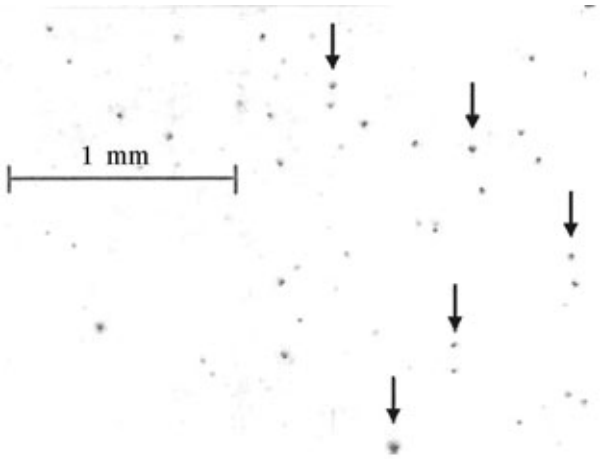

Fig. 2. Micrograph (negative) of a typical substrate obtained after the synthesis is complete. Arrows point to crystallites.

The reverse process, disintegration of vibrationally excited clusters, is suppressed via collision transfer of excitation to inert gas atoms.

Afanas'ev et al. [4] estimated the size of the zone in which C_{60} is formed at approximately 2.5 cm, and the time in which clusters are formed, at ~2.5×10^{-4} s at a vapor flow velocity of about 10^4 cm s^{-1}. In accordance with this estimate, the distances from the graphite evaporation zone to the support were chosen in such a way that the compositions of the carbon vapor near the support were strongly different. In particular, the vapor was represented by species with markedly different properties: small carbon fragments (1 cm from the evaporation zone), "hot" fullerene and nonfullerene clusters (3 cm from the evaporation zone), and "cold" clusters (10 cm from the evaporation zone).

In our opinion, the absence of crystallites at a relatively large distance from the support indicates that they are formed on the support, rather than in the gas phase. This circumstance makes the process under study similar to the CVD technique. Obraztsov et al. [5] noted that various structures were formed, depending on the gas composition and support temperature, and reported the ranges of support temperatures (800–1000°C) and hydrocarbon concentrations (≤5%) in which diamonds were effectively formed. It may be assumed that, placing a support at a distance of 3 cm from the arc, we should obtain process parameters that are in agreement with [5]. It can be stated, in particular, that the support temperature markedly exceeds the melting point of zinc in the experiment with zinc-plated iron as the support material at distances from the graphite evaporation zone of 1 and 3 cm.

The existence of nucleation centers on the support used is an important factor for formation of diamond crystallites. The corresponding carbide (e.g., SiC formed on a silicon support [6]) most frequently acts as a center of this kind. In the case under study, the chemical properties of the supports are strongly different. For aluminum [7], formation of both a composite material Al/C_{60} and aluminum carbide Al_4C_3

would be expected. Zinc rather easily forms a carbide, ZnC_2. By contrast, copper difficultly reacts with carbon [9–11]. This is presumably one of the reasons why crystallites are not formed on the copper support.

The X-ray diffraction patterns in Fig. 3 characterize changes in the structure of the carbon material in the course of the experiment. The experimentally obtained diffraction patterns are compared with published data in Table 2. It can be readily seen that the starting carbon material (pattern *1*) corresponds to graphite, for which the strongest reflection is that from the (002) plane (interplanar spacing 0.336 nm, θ 12.2°). X-ray diffraction pattern *2* corresponds to the substrate sputtered under the experimental conditions and collected from an uncooled zinc-plated support. Apparently the substrate is composed of a mixture of various kinds of carbon. In agreement with published data [12], pattern *2* contains a broad halo of amorphous carbon, on whose background low-intensity diffraction peaks can be seen. The peak at 12.2° can be attributed to recrystallized graphite present in the substrate. It is noteworthy that the relative intensities of the reflections at 12.2° and 20.5° for dispersed substrate markedly differ from those for the starting graphite. The noticeable increase in the relative intensity of the reflection at 20.5° [interplanar spacings of 0.203 nm for the (101) plane of graphite and 0.206 nm for the (111) plane of diamond] may indicate that a diamond-like phase appears in the substrate obtained. The presence of the fullerene fraction in the substrate has been demonstrated previously by spectroscopy, HPLC, and mass spectrometry [13–16]. Disordered fullerenes present in the substrate appear as a shoulder in X-ray diffraction pattern *2* at 3.3°–5.7° (d = 0.715–1.233 nm) [7, 16]. The fact that peaks appear on annealing the substrate in air at 500°C is due to partial removal (via oxidation and structural rearrangements) of the amorphous carbon fraction. In addition, as can be seen from the X-ray diffraction pattern *3* of the sample, the annealing is accompanied by a decrease in the relative amount of the fullerene fraction in the sample. By contrast, the relative amount of graphitized carbon markedly increases. The graphitization of various kinds of carbon is presumably the most frequent result obtained in annealing of carbon materials [17]. The set of reflections of the annealed substrate partly belongs to various kinds of crystalline carbon (Table 2). Despite the exceedingly wide variety of different forms of carbon, some peaks at 14°–18° and 26°–32° can be attributed to zinc oxide ZnO (hexagonal lattice, a = 0.325 nm, c = 0.52 nm, according to [18, 19] and JCPDS file 36-1451). The formation of this product, which is the known white pigment, changes the color of the annealed sample and indirectly confirms the above considerations concerning the involvement of zinc in the nucleation of crystallites.

An analysis of the X-ray diffraction patterns suggests, with a sufficient certainty, that the crystallites we observed in the sputtered substrate belong to a diamond-like fraction of carbon. This conclusion can be indirectly confirmed by the high refractive index and high hardness of the crystallites obtained. The average size of the crystallites, measured using a set of photographs, is about 0.05 mm. Taking into account the fact that the duration of the arc sputtering of the starting graphite rod is about 10 min, we can estimate the growth rate of the crystallites to be approximately 0.3 mm h^{-1}. Such a crystal growth rate is abnormally high, because the growth rate commonly does not exceed 10 μm h^{-1} for a diamond-like structure [20]. In our case, the higher rate of formation of the diamond-like phase is possibly due to presence of fullerenes in the carbon vapor being deposited onto the support.

CONCLUSIONS

It was shown that conversion of carbon to a diamond-like phase may accompany electric-arc synthesis of fullerenes. The formation of crystallites (average crystallite growth rate 0.3 mm h^{-1}) depends on the support material and on the distance between the support and the graphite evaporation zone. According to qualitative estimates, crystallites with an average size of about 0.05 mm have high hardness and high refractive index.

Abstract—Extraction, washing, back extraction, and precipitation of Th(IV) from the backwash in the hydrochloric acid processing of perovskite are studied. Process conditions are optimized to obtain a concentrate with a ThO_2 content of about 85 wt %.

DOI: 10.1134/S1070427207010296

Integrated hydrochloric acid technologies for processing rare-metal raw materials are being developed at the Institute of Chemistry, Kola Scientific Center, Russian Academy of Sciences [1–5]. The presence of Th(IV), U(VI), and Ra(II) in rare-earth metal titanoniobates (loparite, perovskite) makes it necessary to treat the chloride process solutions to remove these radionuclides. In processing perovskite containing up to 40 wt % CaO, this task is complicated by the fact that high concentration of $CaCl_2$ present in the process solutions strongly influences both recovery of target components and treatment of waste solutions. At the same time, there is steadily growing interest in the use of Th(IV) as a fuel component for the future nuclear power engineering [6]. Kosynkin et al. [6] recommended to recover Th(IV) as a coproduct, the more so as the treatment to remove radionuclides is a necessary element of any technology for processing radionuclide-containing raw materials.

This paper concerns preparation of Th(IV) concentrate from perovskite containing 0.07–0.14 wt % ThO_2. After hydrochloric acid breakdown of perovskite (see [4] for its composition), hydrolytic precipitation of Ti(IV), Nb(V), and Ta(V), and concentration by evaporation, the composition of the resulting process solution was as follows (g l^{-1}): HCl 70–90, $CaCl_2$ 430–470, ThO_2 0.54–1.38, Ln_2O_3 25–30 (here and hereinafter Ln_2O_3 refers to the sum of REE oxides), Fe_2O_3 27–32 [Fe(II) + Fe(III) recalculated to Fe_2O_3], TiO_2 1–5, ZnO 0.5–1.5, Al_2O_3 2–6, and V_2O_5 0.1–0.4. Previously we have optimized the conditions for removal of Fe(III) by extraction with octanol; we also tested various extractants for Th(IV), and the best results were obtained with tributyl phosphate (TBP) [4, 7].

Table 1 summarizes data on TBP extraction of Th(IV) from solutions of the above-specified composition. From the starting solution (100–300 ml), Fe(III) was first extracted with octanol at $V_o : V_w$ = 1 : 1, and then Th(IV) was extracted in single stage with TBP (pure grade) at $V_o : V_w$ = 1 : 1. The degree of Th(IV) recovery in this stage was 92–94%. The extract was washed with water, and Th(IV) was backwashed from the organic phase with water or 10 g l^{-1} HCl. The backwash was neutralized to the desired pH with aqueous NaOH. Further details of the experimental procedure, including analytical control, were reported elsewhere [4].

In the experiments we varied the factors controlling separation of Th(IV) from Ln(III) and other associated components (Table 1). In run no. 4 we obtained a concentrate with a ThO_2 content of about 60 wt %. In run no. 3, the Th(IV) recovery in the extraction, washing, back extraction, and precipitation steps was 93.2, 95.0, 93.2, and 75.5%, respectively; the total degree of recovery from the starting solution to the concentrate was 62.3%.

However, our attempts to increase the ThO_2 content of the concentrate above 60 wt % failed, which was caused by the instability of the parameters characterizing both the recovery of Th(IV) and the composition of the concentrate. The reason was the high $CaCl_2$ concentration in the starting solutions. In fact, the back extraction and washing were carried out not

with water, but with aqueous $CaCl_2$, which was caused by Ca(II) transfer from the extract to the corresponding aqueous phases. For example, the $CaCl_2$ concentration in the aqueous phase after washing was 311–362 g l^{-1} and higher. At the same time, changing $CaCl_2$ concentration in the system strongly influences the component distribution between the phases. It should be pointed out that this effect becomes clearly pronounced only above a sufficiently high $CaCl_2$ concentration, which is accompanied by abrupt increase in the component recovery. Above this critical concentration, even slight change in the $CaCl_2$ concentration strongly affects the extraction efficiency, causing the above-mentioned instability in the composition of both intermediate solutions and concentrate.

According to our and published data [8], at a $CaCl_2$ concentration in the starting solution up to 200–250 g l^{-1}, the Ca(II) recovery to TBP is insignificant (<2%). With increasing the $CaCl_2$ concentration to above 500 g l^{-1}, the degree of Ca(II) extraction rapidly increases to 12% and higher. Similar data on the effect of the $CaCl_2$ concentration were obtained also for other components of the investigated system. We demonstrated that the Th(IV) recovery is insignificant at $[CaCl_2]$ < 300 g l^{-1}. With increasing $[CaCl_2]$, the degree of Th(IV) extraction rapidly increases to 80% and higher at $[CaCl_2]$ = 450 g l^{-1}. According to [8], at $[CaCl_2] \le 220–330$ g l^{-1}, the Mn(II) and Co(II) distribution coefficients are low, but they rapidly increase to 20 and 140, respectively, with increasing $[CaCl_2]$ to 540–610 g l^{-1}. It is clearly seen from all the above data that the minimal concentration at which $CaCl_2$ starts to strongly influence the recovery of components is 200–300 g l^{-1}. Since in washing and back extraction Ca(II) readily passes into the aqueous phase, in these stages (particularly in washing) also the Ca(II) concentration has a considerable effect on the extraction behavior of the components. In this respect, it would be interesting to study in more detail the reasons for such an abrupt change in the nature of the effect of $CaCl_2$ concentration on the extraction properties of the system, particularly, in comparison with chlorides of metals in an oxidation state other than +2.

During this study, we also observed a significant effect of $[CaCl_2]$ on pH values of Th(IV) and Ln(III) precipitation. For example, with increasing $[CaCl_2]$ from 35 to 442 g l^{-1}, pH of the onset of precipitation of Th(IV) and Ln(III) decreased from 3.9 and 6.1 to 2 and 5, respectively.

We performed additional experiments with the aim to increase the Th(IV) content of the concentrate. Table 2 shows that, with a decrease in $V_o : V_w$ by half, the recovery of major foreign elements, Ln(III) and Ca(II), becomes several times lower.

In this case, the extraction of Th(IV) also decreased to 78%. However, this extraction efficiency is sufficient to practically completely remove Th to the organic phase using a 4–5-step cascade operating in the continuous countercurrent mode. The low degree of Ln(III) and Ca(II) extraction allows elimination of the washing stage, i.e., the operation responsible for deterioration of the stability of the process parameters. Using back extraction at $V_o : V_w$ = 1 : 1, followed by neutralization of the backwash to pH ~5, we obtained a concentrate with the following content (wt %) (ac-

Table 2. Effect of $V_o : V_w$ on extraction of Th(IV) and major impurities*

$V_o : V_w$	Degree of recovery, %		
	Th(IV)	Ln(III)	Ca(II)
1 : 1**	92–94	9–13	10–14
0.5 : 1	78	2.6	~5

* See text for the composition of the initial solution.

** Degree of recovery obtained in the experiments described in Table 1.

cording to X-ray spectrum analysis): ThO_2 84.8, CuO 6.2, CaO 0.2, Al_2O_3 3.6, CeO_2 1.1, SiO_2 0.7, TiO_2 0.4, Nb_2O_5 0.6, MnO_2 0.9, and Fe_2O_3 1.4 [presence of Cu(II) originates from an occasional contamination of perovskite with copper–nickel concentrate]. The Th(IV) recovery from the starting solution to the concentrate is about 76%, and that from the backwash to the precipitate, ~97%.

It is easy to increase the Th(IV) content of the concentrate to >95 wt %, e.g., by treating with dilute HCl to remove Cu(II), Ca(II), Al(III), and Fe(III). The quality of the concentrate can be further improved to above 98 wt % of the Th content by introducing the stage of precipitation of Al(III), Ce(IV), Ti(IV), Nb(V), and other elements from the backwash at pH 2–3 prior to precipitation of Th(IV).

Also we tested TBP in dodecane (as analog of kerosene) as an extractant. Introduction of 25 vol % of dodecane into the extractant remarkably improves the phase separation. In this case, the extraction of Th(IV) decreases by only several percents. Octanol and benzene can also be used as diluents, but from the safety measures standpoint, it is preferable to use dodecane.

CONCLUSIONS

(1) To obtain a Th-rich concentrate, the necessary condition in extraction is to decrease $V_o : V_w$ to (0.5–0.6) : 1. In this mode, the coextraction of Ln(III) and Ca(II) strongly decreases, allowing recovery of a product with a ThO_2 content of about 85 wt %.

(2) It is advisable to perform back extraction of Th(IV) from the organic phase at $V_o : V_w = 1 : (1–1.5)$, and its precipitation from the backwash, at pH ~5.

BRIEF COMMUNICATIONS

A Simple Procedure for Evaluation of the Critical Pressure of Molecular Inorganic Compounds

I. B. Sladkov and N. A. Semenov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received December 19, 2006

Abstract—A procedure was suggested for evaluation of the critical pressure of molecular inorganic compounds from a single experimental characteristic of a substance, its boiling point.

DOI: 10.1134/S1070427207010302

The critical pressure is a fundamental constant of a substance and is used as the initial parameter for evaluation of many physicochemical characteristics (saturated vapor pressure, heat of vaporization, surface tension of liquid, calculations by the equations of the state of real gases, etc.) [1]. The experimental data on the critical pressure are very limited; therefore, estimation of the critical pressure by calculations becomes an important problem. Here we present a method allowing estimation of the critical pressure from the minimum number of readily available initial data.

From the expression for the critical factor of compressibility

$$z_c = P_c V_c / RT_c$$

it follows that the critical pressure is

$$P_c = z_c RT_c / V_c. \quad (1)$$

When the critical temperature T_c is expressed in K, critical volume V_c is expressed in $cm^3\ mol^{-1}$, and the universal gas constant R is taken equal to 8.314 $J\ mol^{-1}\ K^{-1}$, an evaluation gives the critical pressure P_c expressed in MPa. However, Eq. (1) cannot be used in practice since all the initial parameters are difficult to determine.

For practical use of Eq. (1) it should be considered that the critical factor of compressibility lies in fairly narrow limits: for the majority substances it lies in the limits of 0.25–0.30. The analysis of a large body of experimental data on the critical factor of compressibility (50 substances, whose characteristics are taken from [2]) shows that its average can be taken equal to 0.280. This allows one variable in Eq. (1) to be excluded:

$$P_c = 0.28\,RT_c / V_c. \quad (2)$$

In addition, we can pass from the difficult-to-determine values of critical temperature and volume to the readily available parameters of the boiling point. We can do this using the relations given in [3]:

$$T_c = T_b/(0.667 - 0.055f^{0.5}), \quad (3)$$

$$V_c = V_b(0.05f + 2.69), \quad (4)$$

$$V_b = (-6.2f + 31.2)\prod^{0.54}, \quad (5)$$

where f is the deciding factor of thermodynamic similarity,

$$f = \ln T_b - 1.1 \ln \prod - 4,$$

T_b is the standard boiling point (K), V_b is the molar volume of liquid in the boiling point ($cm^3\ mol^{-1}$), and $\prod$ is the parachor ($J^{1/4}\ cm^{5/2}\ mol^{-1}$).

The parachor $\prod$ is evaluated by the additive method based on stoichiometric formula of the compound [2].

Eqs. (2)–(5) allows evaluation of the critical pressure from the only one experimental characteristic of a substance, its boiling point, instead of difficult-to-determine values of critical temperature and critical volume.

The suggested procedure for evaluation of the critical pressure was checked on the body of data for 50 molecular compounds [2]. Among them are sub-

Error of evaluation of the critical pressure by Eqs. (2)–(4) for some substances

Substance	Calculation	Published data	Discrepancy, %
MoF_6	5.17	4.94	3.8
$SiCl_4$	3.66	3.73	–1.9
$GeBr_4$	4.24	4.20	0.9
BI_3	4.99	5.00	–0.2
$CBrF_3$	3.93	3.97	–1.2
$SiHBr_3$	4.40	4.36	0.9
PBr_3O	5.36	5.39	–0.6
$SeOF_2$	10.89	10.84	0.4
VCl_3O	5.14	5.17	–0.6
OsO_4	8.18	8.61	–4.9

stances of various chemical classes and various polarities: hydrides (B_2H_6, N_2H_4), fluorides (PF_3, MoF_6, PtF_6, UF_6, ReF_6), chlorides (CCl_4, $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, BCl_3, PCl_3, $AsCl_3$, $SbCl_3$, S_2Cl_2, $HgCl_2$, HCl), bromides (BBr_3, $SnBr_4$, $GeBr_4$, PBr_3, $TiBr_4$), iodides (BI_3, SiI_4, SnI_4), mixed halides (CCl_3F, CCl_2F_2, $CClF_3$, CBr_2F_2, $SiBrCl_3$, $SiBr_2Cl_2$, $PFCl_2$, PCl_2F, $PBrF_2$, PBr_2F), hydrohalides ($CHClF_2$, $SiHBr_3$), oxohalides (PCl_3O, PBr_3O, SCl_2O, $SeOF_2$, WCl_4O, VCl_3O, ClO_3F), and oxides (SO_2, OsO_4).

The results of calculations by Eqs. (2)–(5) for various substances are presented in the table. For 50 substances, the average absolute error of evaluation of the critical pressure by the suggested procedure was 2.4% (the maximum error did not exceed 10%). When the evaluation for these substances is performed by Eq. (2) using the experimental values of T_c and V_c, the error is 1.9%.

Thus, substitution of boiling point for critical parameters decreases the accuracy of estimating the critical pressure by only 0.5%. When the experimental values of molar volume of liquid in the boiling point V_b are known, Eq. (5) can be excluded from the calculation scheme; in this case, the accuracy does not decrease at all (1.9%).

It should be borne in mind that, among 50 substances used, there were no associated liquids (NH_3, H_2O), for which the evaluation error significantly increases.

CONCLUSION

A new calculation procedure allowing reliable estimation of the critical pressure from the minimum number of available initial data is suggested.

BRIEF COMMUNICATIONS

Determination of the Number of Transport Units from Data on Equilibria in Binary Mixtures

V. N. Pavlechko

Belarussian State Technological University, Minsk, Belarus

Received January 18, 2006

Abstract—Relations for analytical determination of the number of transport units are suggested. These relations contain coefficients found from experimental data on equilibria in binary mixtures. Examples for four binary mixtures are considered.

DOI: 10.1134/S1070427207010314

The number of transport units (NTU) is an important characteristic of mass transfer. These numbers can be used as an independent quantity that reflects the driving force of the mass-transfer process, with its kinetics expressed in terms of the height of transport units [1], or as an auxiliary quantity in determining the efficiency of a mass-transfer stage [2].

Expressions used to determine NTU depend on the adopted mass-transfer model and on properties of a mixture being separated. Their applicability is limited to the range in which the parameters being analyzed were studied [3]. Frequently, the known methods for NTU calculation yield strongly different results, poorly consistent with experimental data, for the same mixtures [4], which necessitates development of new models that are valid in a somewhat different range of properties or mode parameters [5].

The numbers of transport units can be analytically determined if the equilibrium line is straight for the range under consideration. This assumption is valid for a limited portion of the equilibrium line or for strongly dilute solutions. Values of NTU can also be determined by numerical methods in the case when expressions for equilibrium curves are known. Occasionally, NTUs are found graphically, because the known equation

$$N = \int_{y_{in}}^{y_{fin}} dy/(y^* - y), \quad (1)$$

(y is the mole fraction of the readily volatile component in the vapor phase) cannot be solved analytically because the integrand is unknown. The minimum labor intensity and acceptable accuracy can be only provided by analytical techniques.

The equilibrium dependence of the content of the readily volatile component in the vapor and liquid phases can be represented as the equation

$$y^* = \frac{Ax + B}{Cx + D}x, \quad (2)$$

where x is the mole fraction of the readily volatile component in the liquid; coefficients A, B, C, and D are found from experimental data.

This enables generalization of the factual material and makes it possible to obtain equilibrium relations for a wide variety of mixtures being separated. In particular, the coefficients of Eq. (2) have been found for some solutions, with the content of the readily volatile component expressed in mole fractions: $A = 0.24$, $B = -2$, $C = 1$, and $D = 0.03$ for water and furfural [6]; $A = 1.35$, $B = -0.1$, $C = 0.58$, and $D = 0.67$ for toluene and benzene [7]; $A = 1$, $B = 1.5$, $C = 1.8$, and $D = 0.7$ for acetic acid and water; and $A = 3$, $B = 8$, $C = 10$, and $D = 1$ for water and methanol. These values of the coefficients provide an acceptable accuracy in the whole range of concentration, with the exception of the water–furfural mixture, for which they are valid in the range from zero to the azeotropic point ($x = 4$ mol %).

Relations (1) and (2) and the working-line equations

$$x = x_{fin} + V/L(y - y_{in}), \quad (3)$$

where L and V are the molar flow rates of the liquid

and vapor, respectively, give Eq. (4) (with V/L denoted for brevity as k, $x_{fin}L/V - y_{in}$, as E, and $x_{fin}V/L - y_{in}$, as E'):

$$N = \int_{y_{in}}^{y_{fin}} dy/(y - y) = C[2(Ak - C)]^{-1} \ln \left| y_2 + [(C - 2Ak^{-1})E' + Dk - B]y(C - Ak)^{-1} - (AkE^2 + BE)(C - 2Ak)^{-1} \right|_{y_{in}}^{y_{fin}}$$
$$+ (Ak - C)^{-1}[C^2E + D(Ck^{-1} - A)/2 + (BC - AD)/2] [(CE + B - Dk)^2 + 4D(C - A)E]^{-1/2} \ln \left| \{2y(C - Ak^{-1}) + (C - 2Ak^{-1})E - B + Dk^{-1} - [(B - Dk^{-1} + CE)^2 + 4D(C - A)E]^{1/2}\} \right.$$
$$\left. \times \{2y(C - Ak^{-1}) + (C - 2Ak^{-1})E - B + Dk^{-1} + [(B - Dk^{-1} + CE)^2 + 4D(C - A)E]^{1/2}\}^{-1} \right|_{y_{in}}^{y_{fin}}. \quad (4)$$

For the stripping part of the column, at low x_{in} and y_{fin}, the term E can be neglected. Then expression (4) can be simplified:

$$N = \int_{y_{in}}^{y_{fin}} dy/(y - y) = (Ak/C - 1)^{-1} \ln \left| y_2 - (B - Dk^{-1}) \times (C - Ak)^{-1} \right|_{y_{in}}^{y_{fin}} + (Bk/D - 1)^{-1} \ln \left| 1 - (B - Dk^{-1}) \times [y(C - Ak)]^{-1} \right|_{y_{in}}^{y_{fin}}. \quad (5)$$

Formula (4) provides high calculation accuracy for both low and high component concentrations. Calculations by the simplified formula (5) provide an acceptable accuracy only for low concentrations, with the calculation accuracy largely determined by the ratio of the flow rates of the liquid and vapor. The upper limit of component concentrations in the vapor and liquid phases at which the simplified expression can be used depends on the ratio of the compositions and molar flow rates of the vapor and liquid. As the difference $(x_{fin}L/V - y_{in})$ approaches zero, the applicability range of dependence (5) becomes wider. At higher component concentrations, this formula leads to gross errors and its application is unfeasible in this case.

CONCLUSIONS

(1) The numbers of transport units can be calculated for binary mixtures by the formula derived at known analytical equilibrium dependences containing four coefficients determined from experimental data.

(2) Use of a simplified formula to determine NTU is justified only at low concentrations of the readily volatile component. The applicability range of the simplified relation depends on the ratios of the compositions and molar flow rates of the vapor and liquid phases.

Abstract—The reaction of chitosan with hydrogen peroxide in homogeneous medium and the influence of iron(II) sulfate, copper(II) chloride, and disodium ethylenediaminetetraacetate on oxidative degradation of chitosan were studied by the rheology method.

DOI: 10.1134/S1070427207010326

Materials based on chitosan (CS) with various molecular weights are widely used in medicine [1, 2]. For production of chitosan oligomers, hydrogen peroxide can be used, [3] and the oxidation is accompanied by visible chemiluminescence [4].

Here we studied the influence of variable-valence metal ions on oxidative degradation of chitosan under the action of hydrogen peroxide by the rheology method.

EXPERIMENTAL

In the experiments we used chitosan of Far-Eastern crab {poly[(1→4)-2-amino-2-deoxy-β-*D*-glucose], RIG Production Association, TU (Technical Specifications) 6-09-05-397–75}. Milled CS (particle size less than 0.6 mm) was treated with 1 N HCl four times for 3 h at room temperature until the supernatant became colorless. The precipitate was filtered off and kept for 1.5 h in 2 N NaOH. Then, the precipitate was washed with distilled water to neutral reaction and ash free CS was dried at room temperature to constant weight. The molecular weight (*MW*) of CS was (1.5–2.0) × 10^5; moisture content, 11%; and degree of deacetylation, 74.5% [5]. Elemental composition (%): C 44.0, H 7.5, N 7.9, O 42.6, and ash traces.

The rheological characteristics of hydrochloric acid solutions of CS were studied in the temperature range 273–333 K at pH 4.5 on a modified Rheotest-2.1 viscometer equipped with a special accessory with a cylinder–cylinder working unit. The thermodynamic characteristics of the solutions were evaluated from the viscosity determined at a shear rate $D = 1200\ s^{-1}$. The experimental error was 3%.

The dependence of the viscosity of CS solutions on the shear rate is shown in Fig. 1. As seen, at [CS] = 5.8×10^{-2} M (recalculated to elementary unit), its aqueous solutions acidified to pH 4.5 behave as non-Newtonian fluids, for which a decrease in the viscosity is observed throughout the studied range of the shear rate. On addition of hydrogen peroxide to a CS solution in the temperature range 273–333 K, the viscosity decreases (Fig. 2), which is caused by oxidative degradation of CS. We did not observe noticeable changes in the IR spectrum of the product in comparison with the initial CS. It is likely that, similarly to published data [6], treatment with hydrogen peroxide induces oxidative degradation with the rupture of glycoside bonds in the CS molecule.

It is well known that variable-valence metals catalyze decomposition of hydrogen peroxide [7]:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + OH^\bullet.$$

Therefore, we studied the influence of Fe^{2+} and Cu^{2+} ions on the oxidative degradation of CS under the action of H_2O_2. Addition of variable-valence metal salts into CS solutions causes the viscosity of the solutions to decrease by a factor of 1.5–2 (Fig. 2, curves *2, 3*). The decrease in the viscosity of the CS solutions in the presence of metal salts can be caused by variation of the ionic strength of the chitosan solutions. Upon subsequent addition of hydrogen peroxide into the reaction medium, the viscosity of the solutions decreases significantly, suggesting oxidative degradation (Fig. 2, curves *5, 6*). As seen from the table, variation of the activation parameters of viscous flow of CS solutions is insignificant. However, after oxidative degradation the Gibbs energy of viscous flow of the CS solutions decreases in the order CS+ H_2O_2, CS + Cu^{2+} + H_2O_2, CS + Fe^{2+} + H_2O_2. Variation of the enthalpies of viscous flow of CS solutions are significantly larger for the system CS + Cu^{2+} + H_2O_2, which is apparently caused by higher complexing power of copper(II) ions compared to iron(II) ions [8]. The decrease in the enthalpy of viscous flow of chitosan solution in the presence of iron(II) ions and hydrogen peroxide is caused by significant influence of iron ions on the oxidative degradation of chitosan.

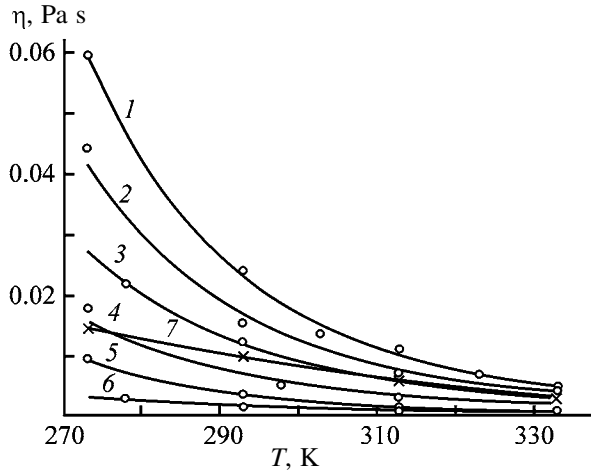

Fig. 2. Viscosity of CS solutions η as a function of temperature T in the reaction with hydrogen peroxide in the presence of variable-valence metal ions. [CS] = 5.84×10^{-2} M. (*1*) Solution without additives; concentration (M): (*2*) [Cu^{2+}] = 5×10^{-3}; (*3*) [Fe^{2+}] = 5×10^{-3}; (*4*) [H_2O_2] = 2.94×10^{-1}; (*5*) [Cu^{2+} = 5×10^{-3}, [H_2O_2] = 2.94×10^{-1}; (*6*) [Fe^{2+}] = 5×10^{-3}, [H_2O_2] = 2.94×10^{-1}; and (*7*) [Fe^{2+}] = 5×10^{-3}, [Na_2EDTA] = 5×10^{-3}.

It is well known [4] that salts of ethylenediaminetetraacetic acid form complexes with metal ions; therefore, addition of sodium ethylenediaminetetraace-

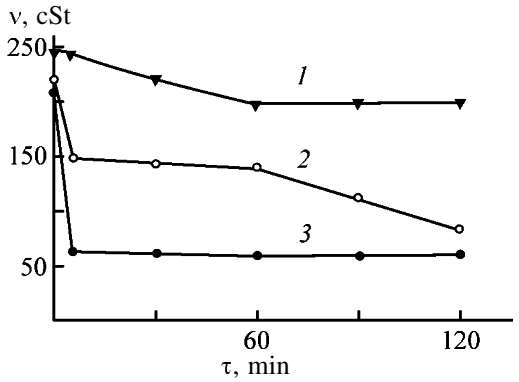

Fig. 3. Influence of variable-valence metal salts on oxidative degradation of chitosan under the action of hydrogen peroxide. T = 25°C, [CS] = 5.84×10^{-2} M. (ν) Intrinsic viscosity and (τ) time. (*1*) [CS] : [H_2O_2] = 1 : 10, (*2*) [CS] : [Cu^{2+}] : [H_2O_2] = 1 : 0.1 : 10, and (*3*) [CS] : [Fe^{2+}] : [H_2O_2] = 1 : 0.1 : 10.

tate (Na_2EDTA) into the reaction mixture decreased the influence of Fe^{2+} ions on oxidative degradation of CS under the action of H_2O_2 (Fig. 2, curve *7*).

Variation of the intrinsic viscosity in the course of oxidative degradation of CS under the action of hydrogen peroxide in the presence of variable-valence metal ions is shown in Fig. 3. As seen, the time of oxidative degradation and average molecular weight of oligomers in the presence of iron(II) are significantly lower than those in the presence of copper(II). This is caused by higher efficiency of generation of OH radicals in decomposition of hydrogen peroxide in the presence of iron(II) ions [7].

CONCLUSIONS

(1) Oxidative degradation is the main process in the reaction of hydrochloric acid solutions of chitosan in the range 273–333 K.

(2) Addition of variable-valence metal ions makes shorter the reaction time and allows preparation of chitosan oligomers with a lower molecular weight.

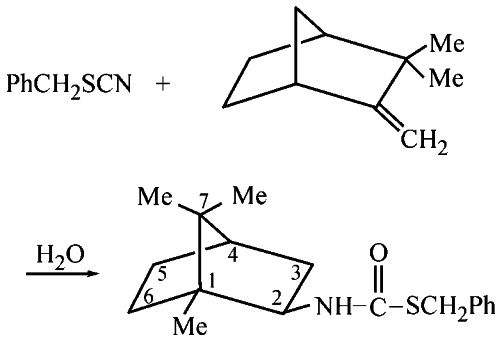
Abstract—The reaction of benzyl thiocyanate with camphene in the presence of heteropoly acids, 12-phosphotungstic and 12-silicotungstic, at 65°C was studied. *S*-Benzyl (1,7,7-trimethylnorbornyl)thiocarbamate was prepared in 66% yield.

DOI: 10.1134/S1070427207010338

Previously [1] we reported on the reactions of a series of thiocyanates with a natural terpene, camphene, in the presence of concentrated sulfuric acid, yielding the coresponding N-substituted thiocarbamates. We examined the possibility of using heteropoly acids (HPAs) for catalyzing this reaction. It is of fundamental importance for catalysis that HPAs have high Brønsted acidity, considerably exceeding that of common mineral acids and traditional acid catalysts [2].

By the reaction of benzyl thiocyanate with camphene in the presence of the most typical tungstic heteropolyacids, $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$, we prepared a new camphene derivatives, *S*-benzyl (1,7,7-trimethylnorbornyl)thiocarbamate:



It should be noted that benzyl thiocyanate does not react with camphene in the presence of sulfuric acid as catalyst [1].

The reaction was performed in acetic acid, taking into account published data on related syntheses of N-substituted thiocarbamates [1]. Heteropoly acids of the Keggin structure in acetic acid are relatively weak electrolytes dissociating by the first step only [3], but in the acidity they exceed by 2–5 pK units the traditional acid catalyst, sulfuric acid [4].

The initial camphene : thiocyanate molar ratio was 1 : 1.48. The reaction was performed with water additions, because without water the HPA precipitates. It should also be noted that small amounts of water allow the reaction to be performed at a relatively low temperature.

It is known [5] that camphene can isomerize in acid-catalyzed reactions; as a result, several compounds are usually formed. Comparison of the ^{13}C NMR spectrum of the purified product with those of various camphene derivatives [5] allowed identification of the compound obtained.

Analysis of the mother liquor revealed formation of small amounts of isobornyl acetate and isoborneol along with the major product, benzyl (1,7,7-trimethylnorbornyl)thiocabamate. These by-products were identified by GLC using authentic samples.

We optimized the concentrations of the acids used, reaction temperature, and reactant weight ratio. We found that the reaction mixture, when heated above 65°C, undergoes tarring (as judged from its color and amount of the bottoms), which considerably decreases the yield of the target product.

The heteropoly acid $H_4SiW_{12}O_{40}$ also actively catalyzes the reaction in question. On the whole, however, it does not surpass in performance $H_3PW_{12}O_{40}$. This fact is consistent with close strength of these acids. It is known that the strength of heteropolytungstic acids depends on the nature of the central atom insignificantly [2].

EXPERIMENTAL

The synthesis was performed for 2–8 h at various temperatures in a temperature-controlled glass reactor equipped with a reflux condenser. After the reaction completion, the mixture was extracted with diethyl ether in an amount equal to a half of the volume of the aqueous phase. The organic phase was washed with 10% NaOH and then with water to neutral reaction of the wash waters, after which it was dried for 24 h over Na_2SO_4. The organic layer was analyzed by GLC. To obtain pure samples of the product, the solvent was removed at reduced pressure. The crystalline residue was repeatedly recrystallized from *n*-hexane until the melting point became constant.

The heteropoly acids of the 12th series $H_3PW_{12}O_{40}$ and $H_4SiW_{12}O_{40}$ (pure grade commercial products) were used without additional purification. The starting optically active camphene {$[\alpha]_{580}^{22}$ +12.5° (*c* 11.6, $CHCl_3$)}, which initially contained 10% tricyclene (GLC data), was brought to 99% purity by recrystallization from EtOH, mp 50°C (published data [6]: mp 50°C). Acetic acid was purified by distillation of the ultrapure grade acid on a 0.3-m distillation column. Commercial chemically pure grade (97% purity) benzyl thiocyanate was used without additional purification. Technical-grade isoborneol was brought to 96% purity (GLC data) by fractional recrystallization from ethanol. Diethyl ether, ethanol, and *n*-hexane (chemically pure grade) were purified by standard procedures [7]. Isobornyl acetate was prepared by the procedure described in [8].

The purity of the starting substances was checked and the reaction products analyzed by GLC on a Chrom 5 chromatograph equipped with a flame ionization detector and a 30000 × 10-mm column; stationary phase polyphenylmethylsiloxane-4 (15%) on Chromaton N-AW-DMSC (0.20–0.25 mm), column temperature 180–190°C, carrier gas (nitrogen) pressure 2.5 atm. As internal reference we used *N*-(1,7,7-trimethylnorbornyl)propionamide.

The ^{13}C NMR spectra (32 MHz) were recorded on a Bruker AC-200 spectrometer using the solvent ($CDCl_3$) signal as internal reference (δ 7.24, δ_C 76.90 ppm).

The elemental composition of the compound obtained was determined from the high-resolution mass spectrum taken with a Finnigan MATINCOS 50 mass spectrometer. For recording the IR spectra, samples were prepared as KBr pellets or mulls in mineral oil.

A solution of 0.2 g (1.34 mmol) of benzyl thiocyanate and 0.12 g (0.88 mmol) of camphene in 3 ml of acetic acid was added to 1.34 g (0.46 mol) of $H_3PW_{12}O_{40}$ wetted with water (0.2 ml, 11.11 mmol). The mixture was heated for 4 h at 65°C. White crystals of benzyl (1,7,7-trimethylnorbornyl)thiocarbamate were obtained; yield 0.18 g (66% based on the initial amount of camphene), mp 87°C.

CONCLUSIONS

(1) Benzyl (1,7,7-trimethylnorbornyl)thiocarbamate was prepared in 66% yield by the reaction of benzyl thiocyanate with camphene in the presence of heteropoly acids. With sulfuric acid as catalyst, this compound is not formed at all.

(2) Isoborneol and isobornyl acetate are formed in this reaction as by-products.

Abstract—Ester interchange of 4- and 5-methoxycarbonyl-2-sulfobenzoic acid imides with glycols was studied.

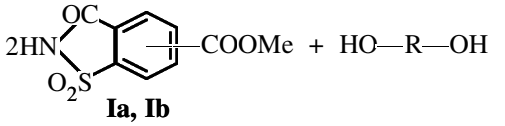
DOI: 10.1134/S107042720701034X

Trimellitic acid esters are used as monomers for heat-resistant polymers, poly(ester imides) [1]. Babe et al. [2] reported on diester diimides prepared by ester interchange of trimellitimide methyl ester with glycols. Recently we reported on diester disulfimides derived from saccharinmonocarboxylic acids and aromatic diols [3].

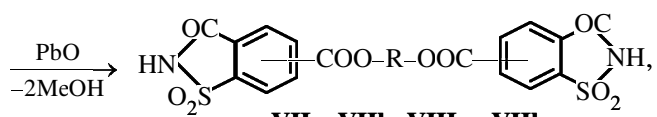
Here we report on imides of 4- and 5-methoxycarbonyl-2-sulfobenzoic acids (**Ia**, **Ib**) and on a series of diester disulfimides **IIa**–**VIIIa** and **IIb**–**VIIIb** derived from these imides. Compounds **IIa**–**VIIIa** and **IIb**–**VIIIb** are of interest as potential monomers for preparing poly(ester sulfimides).

Imides **Ia** and **Ib** were prepared from imides of 2-sulfo-1,4- and 2-sulfo-1,5-benzenedicarboxylic acids, respectively, and anhydrous methanol in the presence of sulfuric acid as catalyst [4]. Yield 76%, mp 164–165°C. The IR spectra of **Ia** and **Ib** contained characteristic absorption bands of the saccharin ring at 1720 (>C=O), 1300–1250 (>SO_2), and 1120–1100 cm^{-1} (>NH).

Diester disulfimides **IIa**–**VIIIa** and **IIb**–**VIIIb** were prepared by ester interchange of **Ia** and **Ib** with various aliphatic glycols:



Ia, Ib



VIIa–**VIIb, VIIIa** –**VIIb**

where R = $(CH_2)_2$ (**IIa**, **IIb**), $(CH_2)_3$ (**IIIa**, **IIIb**), $CH(Me)CH_2$ (**IVa**, **IVb**), $(CH_2)_4$ (**Va**, **Vb**), $(CH_2)_6$ (**VIa**, **VIb**), $(CH_2)_2O(CH_2)_2O(CH_2)_2$ (**VIIa**, **VIIb**), $CH_2CH(OH)CH_2$ (**VIIIa**, **VIIIb**).

Diester disulfimides **IIa**–**VIIIa** and **IIb**–**VIIIb** were synthesized in excess glycol; the ratio of imide **Ia** or **Ib** to glycol was 1 : 3. Lead(II) oxide was used as catalyst; the mixture was gradually heated in the temperature range 80–170°C. The reaction time was 3–4 h. The reactions with glycols containing a longer hydrocarbon chain between hydroxy groups occurred at lower temperatures.

The compositions of diester disulfimides **IIa**–**VIIIa** and **IIb**–**VIIIb** were determined by elemental analysis (see table), and their structure was confirmed by IR spectroscopy. The IR spectra contained characteristic absorption bands at 1760–1720 (C=O of saccharin ring), 1370–1300 and 1200–1180 (SO_2), 1300–1250 and 1120–1100 (C–O–C of ester group), and 3350–3310 cm^{-1} (N–H) [5].

EXPERIMENTAL

The IR spectra were recorded on a Specord M-80 spectrophotometer from liquid films in the range 3700–700 cm^{-1} using KBr prisms. The boiling points of glycols and solvents agreed with reference data [6].

Ethylene glycol bis(2-sulfo-1,4-benzenedicarboxylic acid imide) ester IIa. A mixture of 24.1 g (0.1 mol) of methyl ester of imide **Ia** and 1.2 g of PbO in 31 g (0.5 mol) of 1,2-ethanediol was heated with stirring to 170–175°C over a period of 3–4 h. The resulting mixture was dissolved in acetone, and the product was precipitated with distilled water. The grayish-white crystalline product was dried at room

temperature and vacuum-dried to constant weight; mp 208–210°C.

Compounds **IIIa**–**VIIIa** and **IIb**–**VIIIb** were prepared similarly.

CONCLUSION

Diester disulfimides derived from 4- and 5-methoxycarbonyl-2-sulfobenzoic acid imides, showing promise as monomers for preparing polyester imides, were synthesized in a high yield (76–88%).

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Nikolai Aleksandrovich Menshutkin (to 100th Anniversary of His Death)

DOI: 10.1134/S1070427207010351

N.A. Menshutkin is, together with his closest associates from St. Petersburg University, A.M. Butlerov (1828–1886) and D.I. Mendeleev (1834–1907), among the most prominent Russian chemists of the second half of the XIX century. N.A. Menshutkin's research in chemical kinetics actually initiated application of physicochemical techniques in organic chemistry. The textbook *Analiticheskaya khimiya* (Analytical Chemistry), written by N.A. Menshutkin, presented a novel approach to a study of this discipline, ran into 16 editions, was the main manual of analytical chemistry during many years, and was translated into German and English. The scientist made a major contribution to the organization of laboratories at St. Petersburg University and Polytechnic Institute and development of chemical education in Russia.

Nikolai Aleksandrovich Menshutkin was born on October 12 (24), 1842, in St. Petersburg into a rather wealthy trader's family. His father, hereditary honorary citizen, paid a considerable attention to education of his children. The scientist-to-be received his initial education at one of the best St. Petersburg boarding schools, where he studied from the age of six. Beginning at the age of ten, he was also educated in St. Petersburg, at the technical department of the St. Peter principal German school. Already during this period, N.A. Menshutkin's abilities and high sense of responsibility manifested themselves. In December 1857, he successfully, the first among the graduates, finished the school and, in the next year, being under 16, he entered, having passed an examination, the natural department of the physicomathematical faculty of St. Petersburg University. In those years, lectures on inorganic and analytical chemistry were delivered by A.A. Voskresenskii (1809–1880, corresponding member of St. Petersburg Academy of Sciences since 1864), professor of a number of higher school institutions of St. Petersburg and a prominent scientist in the field of organic chemistry. Lectures on organic chemistry were delivered by Prof. N.N. Sokolov (1826–1877), a talented pedagogue and scientist, one of founders of Russia's first chemical journal [1]. Sokolov paid a considerable attention to students

Nikolai Aleksandrovich Menshutkin (1906).

and was held in deserved high respect by students. N.A. Menshutkin left very warm reminiscences about his teacher [2]. Under Sokolov's influence, N.A. Menshutkin exhibited a particular interest in chemistry from the first years of education at the University. Being a second-year student, he established a chemical laboratory at his home.

In the spring of 1862, N.A. Menshutkin successfully finished the University with a candidate degree from the physicomathematical faculty and a solid intention to be engaged in research and pedagogical activities in the field of chemistry. In those years, Russia's universities, including St. Petersburg University (founded in 1819), provided a fundamental training in general theory, but possessed a very limited number of laboratories. In order to primarily improve his experimental abilities, N.A. Menshutkin went, after the example of his numerous colleagues, abroad, to Germany, having chosen the University of

Tübingen, one of the oldest in Europe (founded in 1477). For more than a year, the Russian scientist was trained on methods for qualitative and quantitative analysis at the laboratory of Prof. A. Strecker (1812–1871), a known organic chemist mostly interested in natural compounds. At the same laboratory, N.A. Menshutkin carried out his first scientific study, published in France in 1864.

At the end of March 1864, N.A. Menshutkin moved to Paris, to the laboratory a known chemist, Prof. A. Wurtz (1817–1884, member of Paris Academy of Sciences since 1867, president of this academy in 1881–1884, foreign corresponding member of St. Petersburg Academy of Sciences since 1873), at Ecole de Medicine and spent there a year. Scientists from many countries, including Russia, worked at different times at Wurtz's laboratory. Among the known Russian scientists, those who improved their skills at this laboratory included P.P. Alekseev (1840–1891), F.F. Beilstein (1838–1906), A.M. Butlerov, G.G. Gustavson (1843–1908) A.M. Zaitsev (1845–1904), A.L. Potylitsyn (1845–1905), and others [3, 4].

N.A. Menshutkin commenced, on his own initiative, studies of phosphorous acid and its derivatives. The results obtained were published in French chemical journals and formed the basis of his master's dissertation. In the spring of 1865, the young scientist left Paris and again went to Germany, to Marburg University (founded in 1527), to Prof. A.W.H. Kolbe (1818–1884), a prominent German organic chemist. At Kolbe's laboratory, N.A. Menshutkin completed the experimental part of his dissertation work and published one more article in the same area: on the action of anhydrous ethanol on phosphorus trichloride. In August of the same year, the scientist returned to homeland with a finished dissertation.

In the spring of 1865, N.A. Menshutkin successfully passed examinations at St. Petersburg University for master's degree in chemistry, and at the very beginning of 1866, submitted dissertation "On Hydrogen of Phosphorous Acid that is Incapable of Substitution with Metals under Conditions Ordinary for Acids." In conformity with the existing regulations, the complete text of the dissertation was published as a separate brochure (St. Petersburg, 1866). Based on a vast body of experimental data, N.A. Menshutkin was the first to establish that only two out of the three hydrogen atoms contained in phosphorous acid H_3PO_3 can be substituted with a metal. He noted that "this hydrogen is involved only in those reactions which are successful with alcohols." This study was of particular methodological and general scientific interest and was distinguished by a new formulation of the problem. In March 1866, N.A. Menshutkin defended his dissertation, with Mendeleev and Voskresenskii as opponents. After master's degree was conferred on N.A. Menshutkin and he delivered trial lectures, he became a privatdocent at St. Petersburg University.

In the 1866/67 academic year, N.A. Menshutkin commenced his pedagogical activities at the University and was soon elected a permanent docent at the chair of chemistry. Among his duties was teaching of analytical chemistry and management of the analytical department of the chemical laboratory. In addition to a course of lectures on analytical chemistry, N.A. Menshutkin also delivered a special course of organic chemistry (alcohols). Simultaneously, the scientist commenced work on his doctoral dissertation. Already at the beginning of 1869, he published as a separate edition (St. Petersburg, 1869) and submitted his doctoral (chemistry) dissertation "Synthesis and Properties of Ureides." The dissertation was defended in April 1869, and the opponents, Mendeleev and Butlerov, noted the high scientific level and the experimental skills of the defendant. On defending the dissertation, N.A. Menshutkin was elected an extraordinary professor and continued teaching of the same disciplines. In 1876, he was appointed ordinary professor. In 1871, the young scientists occupied for three years the position of the secretary of the faculty; in 1874, he was elected to this position for a second term. In 1879, N.A. Menshutkin was elected dean of the physicomathematical faculty (till 1887). During all these years, he was intensively engaged in all the faculty's activities.

In 1885, N.A. Menshutkin abandoned teaching of analytical chemistry and headed the department of organic chemistry, teaching exclusively this discipline. In 1891, the degree of honored professor was conferred on the scientist. In 1893, in view of his prolonged service, N.A. Menshutkin occupied the position of a supernumerary professor of the University.

A major N.A. Menshutkin's achievement was the organization, beginning in 1867, of systematic practical studies in qualitative and quantitative chemical analysis, which were obligatory for all students of the natural department of the physicomathematical faculty. To simplify mastering of chemical analysis, N.A. Menshutkin published an original textbook *Analiticheskaya khimiya* (Analytical Chemistry) in 1871. As noted [5] by M.I. Usanovich (1894–1981), a known historian of chemistry, *Osnovy khimii* (Fundamentals of Chemistry) (1st edition in 1868–1871) by Mendeleev and *Analiticheskaya khimiya* (Analytic-

Chemical laboratory of St. Petersburg University (1894).

al Chemistry) by N.A. Menshutkin, published nearly simultaneously, laid the foundation of the chemical education in Russia and were many times republished during the authors' life and posthumously. In 1877, *Analiticheskaya khimiya* was translated into German and published in Leipzig; its third German edition was published in 1892. In 1895, the book was published in English in London and New York.

Beginning with the 10th edition in Russia (1908), *Analiticheskaya khimiya* was remade and supplemented by the author's son, B.N. Menshutkin (1874–1938), a chemist and science historian, a professor of St. Petersburg Polytechnic Institute (in 1902–1938). An N.A. Menshutkin's disciple, Prof. D.N. Monastyrskii (1875–1959), was actively involved [6, 7] in preparing the last, 16th edition of the book for publication.

Having passed to teaching of organic chemistry, N.A. Menshutkin prepared for publication *Lektsii po organicheskoi khimiii* (Lectures on Organic Chemistry). All the four editions of these lectures (1884, 1891, 1896, 1901) strongly differ, which reflects the development of science and the evolution of authors' views. In 1878, N.A. Menshutkin delivered for the first time at St. Petersburg University a course of lectures on the history of science. Based on these lectures, he later published *Ocherk razvitiya khimicheskikh vozzrenii* (Essay on the Evolution of Chemical Concepts) (St. Petersburg, 1888), the first original work of the Russian scientist in the field of the history of chemistry. The essay begins from deeply ancient past and covers a period of time extending to the 1880s. It, in particular, analyzes publications devoted to kinetic patterns and chemical affinity, which appeared by that time. The essay only disregards the theory of electrolytic dissociation by S.A. Arrhenius (1859–1927, foreign corresponding member of St. Petersburg Academy of Sciences since 1903, honorary member of the Academy of Sciences of the USSR since 1926, 1903 Nobel Prize Laureate in Chemistry), which was only in the initial stage of its development by that time. It is known, however, that, in contrast to Mendeleev and D.P. Konovalov (1856–1929, academician of the Academy of Sciences of the USSR since 1923), a professor of St. Petersburg University, N.A. Menshutkin' attitude toward the concepts put forward by Arrhenius was positive and he presented these ideas in third edition of *Analiticheskaya khimiya* (St. Petersburg, 1893) [8].

N.A. Menshutkin have done great services to St. Petersburg University in the construction of a chemical laboratory. The new University's statutes and regulations adopted in 1884 envisaged a significant expansion of laboratory studies in teaching of natural sciences. In this context, Mendeleev, Butlerov, and N.A. Menshutkin substantiated, in a special memorandum, the necessity for creating an absolutely new chemical laboratory at the University. In 1890, the Ministry of Finance suggested to St. Petersburg University to make up an estimate of expenditure for construction of the new laboratory. N.A. Menshutkin was appointed head of a commission organized at the

physicomathematical faculty and intended to prepare the estimate and a working design of the chemical laboratory. In the summer of 1891, N.A. Menshutkin and A.F. Krasovskii, an academician of architecture involved in the construction, were sent to a business trip abroad, where they visited laboratories of quite a number of higher-school institutions in Germany, Austria–Hungary, and Switzerland. Already in the autumn of 1891, the work on the design and estimate of the new chemical laboratory was complete; the construction of the new building was commenced in the spring of 1892 and was finished by the autumn of 1894. N.A. Menshutkin was a member of the construction commission; on October 16, 1894, he delivered a brilliant speech at the opening ceremony of the laboratory [9]. Assessing the extent of development of chemical science in Russia in the XIX century, N.A. Menshutkin noted that "the success of chemistry in the last quarter century is largely due to works of Russian scientists."

At the turn of the XX century, after a decision was made to organize a polytechnic institute in St. Petersburg, N.A. Menshutkin and other known chemists, Mendeleev, P.I. Walden (1863–1957, professor of Riga Polytechnic Institute, academician of St. Petersburg Academy of Sciences since 1910), and N.S. Kurnakov (1860–1941, professor of the Mining Institute, academician of St. Petersburg Academy of Sciences since 1913) took part, by invitation of the Ministry of Finance, in the work of a commission for making up curricula for the metallurgical department and the electrochemical subdepartment of the institute being organized. The commission was head by the Finance Minister of Russia, S.Yu. Vitte (1849–1915). In July 1901, Walden was appointed dean of the metallurgical department of the Polytechnic Institute. It was presumed that he would also occupy the position of the professor of general chemistry [1, 10]. However, already in October of the same year, Walden reported that he could not accept this appointment in view of circumstances and recommended N.A. Menshutkin as a dean. At the beginning of 1902, Walden was elected director of Riga Polytechnic Institute.

On November 1, 1901, N.A. Menshutkin was appointed, and later elected, dean of the metallurgical department and also headed the chair of analytical and organic chemistry. A major N.A. Menshutkin's achievement as dean of the metallurgical department was that he invited most prominent, worldwide-known specialists to teach basic disciplines. Kurnakov was invited as professor of general chemistry. A graduate from the Mining Institute, Kurnakov occupied there the position of a professor of inorganic chemistry already beginning in 1893. The well-equipped laboratories of the Polytechnic Institute enabled Kurnakov to commence extensive experimental studies in the field of physicochemical analysis of metallic and salt systems and to develop a prominent research area. On Kurnakov's initiative, supported by other professors of chemistry, students of the metallurgical department were entitled, for the first time in the practice of Russia's technical higher school institutions, to defend either the design of a plant or the results of an experimental study performed at the final stage of their education.

V.A. Kistyakovskii (1865–1952, academician of the Academy of Sciences of the USSR since 1929) was to deliver lectures on physical chemistry and theoretical electrochemistry. The author of quite a number of well-known studies in the theory of electrolyte solutions, he, having graduated from St. Petersburg University, worked in Germany and was a follower of concepts put forward by Arrhenius and J.H. van't Hoff (1852–1911, foreign corresponding member of St. Petersburg Academy of Sciences since 1895, 1901 Nobel Prize Laureate in chemistry). In 1903–1904, Kistyakovskii equipped at the Polytechnic Institute the first Russia's laboratory of physical chemistry, which not only provided the teaching process, but also made it possible to commence various experimental studies in the field of electrochemistry, corrosion of metals, and nature of the liquid state. The position of an ordinary professor of geology and mineralogy was occupied, by N.A. Menshutkin's invitation, by F.Yu. Levinson-Lessing (1861–1939, academician of the Academy of Sciences of the USSR since 1925). He was a professor at Yur'ev (now Tartu, Estonia) University and headed the chemical direction in petrography in Russia. Technical electrochemistry and mineral technology were to be taught in 1902 by P.P. Fedot'ev (1864–1934, corresponding member of the Academy of Sciences of the USSR since 1933), an experienced technologist-engineer, the author of a number of monographs in technical chemistry. The studies at the St. Petersburg Polytechnic Institute commenced on October 2, 1902. As a member of the construction commission and dean of the metallurgical department, N.A. Menshutkin paid a considerable attention to completion of the construction of the chemical building and equipment of laboratories.

N.A. Menshutkin's scientific activities have been described in detail [10–14]. The central place is occupied by studies in chemical kinetics, commenced in 1877. The first series of works was devoted to the

Chemical building of St. Petersburg Polytechnic Institute (1902).

relationship between the structure of organic compounds and the esterification rate. The scientist accumulated a large body of factual data and demonstrated for the first time that the esterification rate can give information about the structure of organic compounds. For example, methanol shows the highest reaction rate when involved in reactions to give esters. Any other alcohol with a higher molecular weight shows a lower esterification rate. The reaction rate decreases in a similar way when the molecular weight of an acid involved in the esterification increases. For studies of the effect of isomerism of alcohols and acids on formation of esters, N.A. Menshutkin was awarded the N.N. Sokolov Prize by the Russian Physicochemical Society in 1878.

In the second series of kinetic studies, commenced in 1887, N.A. Menshutkin systematically analyzed for the first time the effect of indifferent solvents on the rate of chemical reactions. All textbooks on chemical kinetics give as example N.A. Menshutkin's evidence that the rate of the reaction between triethylamine and ethyl iodide is 742 times faster in benzyl alcohol, compared with hexane. The final series of N.A. Menshutkin's studies in kinetics of chemical reactions was devoted to the effect of side chains and cyclic structure on the rate of reactions between organic compounds.

N.A. Menshutkin devoted about 30 years of his life to kinetic research, with the last studies carried out at the Polytechnic Institute [10, 16]. In 1904, N.A. Menshutkin received the highest award of St. Petersburg Academy of Sciences, Lomonosov Prize, for his research in the field of chemical kinetics. The scientist's achievements were recognized by the whole world's chemical community. The list of N.A. Menshutkin's publications as of 1895, composed by him, is contained in the biographic dictionary of St. Petersburg University's professors and teachers [15]. The full list of the scientist's publications is included in B.N. Menshutkin's book about his father [10].

Together with carrying out intensive pedagogical and scientific work, N.A. Menshutkin was permanently engaged in various kinds of social activities. In 1868, he was, together with Mendeleev, N.N. Beketov (1827–1911), V.V. Markovnikov (1837–1904), and other known chemists, among those who founded the Russian Chemical society. N.A. Menshutkin composed the statutes of the Society, was permanent editor of the Transactions of the Society, and made 82 reports at its meetings. Having a perfect knowledge of main European languages, N.A. Menshutkin annually published in *Zhurnal Rossiiskogo fiziko-khimicheskogo obshchestva* (Journal of the Russian Physicochemical Society) tens of summaries of the most interesting foreign studies. N.A. Menshutkin repeatedly occupied various elected positions at the Russian Physicochemical Society and was president of the Society in 1906.

N.A. Menshutkin was a permanent participant of congresses of Russian natural scientists and physicians, the first of which was held in St. Petersburg at the end of 1867, was member of the Organizing Committees of a number of congresses, and chairman of the XI congress (1901).

In 1892, N.A. Menshutkin was actively involved in the activities of zemstvo (local self-government) institutions in Luga uezd of St. Petersburg guberniya and

Zemstvo of St. Petersburg guberniya, where he represented Luga uezd. Beginning in 1894 and till the end of his life, N.A. Menshutkin was a member of the Nobiliary assembly of St. Petersburg guberniya, and represented Luga uezd.

Unsatisfied by programs of political parties that appeared in Russia after the Manifesto of October 17, 1905, N.A. Menshutkin and a group of professors from the Polytechnic Institute organized, with the participation of a number of prominent public figures of St. Petersburg, a new political party, party of democratic reforms. Its program was close to that of the constitutional-democratic party (kadets). The principal points of the program of the party of democratic reforms were presented in [10]. In the political orientation of the program, this party can be characterized as a left-center party.

Nikolai Aleksandrovich Menshutkin died on January 22 (February 5), 1907, of cerebral hemorrhage. An outstanding Russian chemist, public figure, broadly educated and talented person, he was among the most advanced professors of St. Petersburg and Russia.

BOOK REVIEWS

Gamburg, Yu.D., *Gal'vanicheskie pokrytiya. Spravochnik po primeneniyu* (Application Reference Book of Electroplated Coatings)

Moscow: Tekhnosfera, 2006, 216 pp.

DOI: 10.1134/S1070427207010363

Deposition of various kinds of electroplated coatings and the electroplating technology constitute the most rapidly developing part of applied electrochemistry. The new reference book for this area, written by one of the leading Russian electrochemists, is of indubitable interest. The book is intended for a wide audience of users and is, simultaneously, a reference book and a textbook. The latter is favored by the manner of presentation.

The book comprises a preface, four chapters, brief list of recommended literature, and list of principal designations. In the preface (pp. 14, 15), the author emphasizes that the technology of deposition of metal and alloy coatings has not changed fundamentally during the 150 years of its history, but has substantially developed owing to the success and advances of the electrochemical science. As a result, the application area of electroplating in a wide variety of modern technologies has strongly expanded.

Chapter 1 (pp. 16–28) considers the application areas of electrochemical coatings and their purpose and choice. Coatings are classed, the electrochemical processes occurring in their deposition are described in a popular manner, and principles that underlie the choice of a coating material, coating thickness, and deposition technique are noted. The whole body of evidence is of a most general nature. Chapter 2 (pp. 29–99) presents the electrochemical foundations of coating deposition processes. The author managed to combine modern scientific approaches to complex electrochemical processes with the simplicity and understandability of presentation. All the mathematical relations used are commented to a sufficient extent. Stages of electrochemical processes, current distribution over the electrode surface, metal deposition modes, and specific features of the electrodeposition of alloys are described in detail. A special section is devoted to analysis of the most frequently occurring disruptions of coating deposition processes.

Chapter 3 (pp. 100–160), which occupies the central position in the reference book, summarizes evidence concerning the technology of deposition of metal and alloy coatings. On describing procedures used to prepare the base surface for coating deposition (degreasing, etching, etc.), it considers deposition of coatings composed of copper, silver, gold, zinc, tin, nickel, chromium, iron, low-melting metals, platinum metals, and a large number of alloys. A small section is devoted to use of the electroless reduction of metals in coating deposition.

Chapter 4 of the reference book is devoted to methods for analysis of coating properties: mechanical: plasticity, hardness, internal stresses, and adhesion to the base surface; electrical: resistivity and contact resistance; and quite a number of other important parameters: porosity, thickness, corrosion resistance, solderability, hydrogenation, etc. The techniques employed to study the coating properties are described in the reference book by Yu.D. Gamburg in more detail and more thoroughly, compared with previous publications by other authors. The list of recommended literature (p. 214) contains three reference books, six monographs, five reviews, and two textbooks.

The book by Gamburg produces quite a favorable impression. It can be of use both for technologists and engineers working with electroplated coatings and for students specialized in technology of electrochemical industries.

BOOK REVIEWS

Medvedev, A.S., *Vyshchelachivanie i sposoby ego intensifikatsii* (Leaching and Methods for Intensification of This Process)

Moscow: Mosk. Gos. Inst. Stali i Splavov, 2005, 240 pp.

DOI: 10.1134/S1070427207010375

Hydrometallurgical processes presently occupy an important place in manufacture of a large number of nonferrous metals, including aluminum, zinc, uranium and thorium, tungsten and molybdenum, tantalum and niobium, zirconium and hafnium, rare-earth metals, gold and silver, platinum-group metals, indium, thallium, rhenium, and others. In some countries, hydrometallurgical processes are employed to manufacture a considerable amount of copper, nickel, cobalt, and zinc. The main procedure predetermining the extent of metal recovery from ores and secondary raw materials in their hydrometallurgical processing is leaching, i.e., selective dissolution of one or several components of a raw material with an aqueous solvent (water or solutions of acids, alkalis, and salts).

The monograph by A.S. Medvedev, totally devoted to leaching and methods for intensification of this process, comprises a preface, three chapters, conclusion, and bibliographic list containing 304 references. The preface (pp. 4–6) describes specific features of the leaching process. Chapter 1 (pp. 7–74) is devoted to theoretical foundations of leaching processes. The author describes the thermodynamics and kinetics of leaching and presents a number of examples illustrating kinetic features of the processes. Chapter 2 (pp. 75–178) describes quite a number of preparatory procedures that intensify leaching. To these belong thermal, mechanical, ultrasonic, and radiation treatments. Despite the specific nature of each kind of treatment, their common feature is that they give rise to structural defects in solids and disrupt the structure of liquids. The presentation is accompanied by a large number of examples. Particular attention is given to description of the influence exerted by mechanical treatment of minerals on their structure and reactivity. Chapter 3 (pp. 179–218) discusses methods for mechanical, ultrasonic, and radiation treatment of pulp in the course of leaching. The brief conclusion (pp. 219–221) summarizes the main results obtained in analyzing the methods for intensification of leaching.

The monograph by Medvedev is provided with an extensive bibliography (pp. 222–239), but, unfortunately, most of references are to publications older than 30 years. The number of references to studies published later than 1995 does not exceed 10 (out of 304).

The book summarizes and analyzes a vast body of experimental data on leaching of widely diverse materials. It seems, however, that the author's desire to make scientific to the maximum possible extent the presentation of purely technological information is not always successful. It is hardly necessary to invoke Einstein's or Landau's concepts for explaining the effect of additives on leaching of scheelite, tungstite, or uranium ore or to calculate the "probability of a fluctuation changing the entropy of an equilibrium system" (p. 71).

The book by Medvedev has been published in the series "Metallurgy and Materials Science in the XXI Century," devoted to the 75th anniversary of the foundation of Moscow Institute of Steel and Alloys (Technological University). The book is primarily intended for technologists-engineers and research workers of metallurgical and chemical industries. It may also be of use for teachers, postgraduate students, undergraduates of metallurgical and chemical-technological higher-school institutions.

Received September 4, 2006

Abstract—Behavior of a skeleton silicate, nepheline, in the reaction of fluorination with ammonium hydrofluoride was studied by means of differential-thermal, X-ray phase, and chemical analyses, IR spectroscopy, and scanning electron microscopy.

DOI: 10.1134/S1070427207020012

As shown by numerous studies [1–8], use of fluoride metallurgy may favor a more intensive development of a closed technology for processing of mineral raw materials and a transition to conditioning of waste or its components into products compatible with ecologically safe technologies.

However, practical development of hydrofluoride methods for processing of various ores and concentrates requires more detailed and specific evidence about mechanisms and kinetics of interaction of both ores and rock-forming minerals with NH_4HF_2. It has been found, in particular, that many ore minerals are fluorinated under more severe conditions, compared with silicates [1, 7]. This offers an opportunity to perform desilicification of concentrates, e.g., at lower temperatures (below the melting point of ammonium hydrofluoride), without evolution of NH_4F into the gas phase in the first stage.

It was shown in [4] that decomposition of island silicates is the most difficult process. Complete fluorination of such minerals with NH_4HF_2 is achieved in Teflon autoclaves at 200°C. At the same time, it has been found [8] that the structure of magnesium silicates has no noticeable effect on the fluorination process.

It is, therefore, of indubitable interest to study specific features of interaction between a set of silicate minerals of varied structure with ammonium hydrofluoride.

In this study, the behavior of powdered nepheline in the reaction of fluorination was examined. Nepheline (simplified formula $Na_3K[AlSiO_4]_4$) is a mineral with aluminosilicate tetrahedra (skeleton silicate), which belongs to the hexagonal crystal system. The structure of minerals that belong to the nepheline group is based on a tetrahedral skeleton of the type of high-temperature tridymite, in which half of Si atoms are substituted by Al and lattice voids are filled with alkali metal cations neutralizing the negative charge of the skeleton [9].

A nepheline concentrate containing (wt %): SiO_2 44.28, Al_2O_3 29.48, and Na_2O 13.28, and the monomineral fraction of nepheline from a rock sample from the Khibiny massif were used in the study. As the fluorinating agent served twice recrystallized ammonium hydrofluoride NH_4HF_2 of analytically pure grade.

The thermogravimetric analysis was carried out on a Q-1500D derivatograph (Hungary) in air in the dynamic and quasi-isothermal modes. The X-ray phase analysis (XPA) of the reaction products was made on a DRON-2 diffractometer with Cu_{K_α} radiation. The IR spectral study was performed on a UR-20 instrument.

The surface of particles of nepheline powder and reaction products was analyzed by means of digital scanning electron microscopy (SEM) on a computerized LEO-420 electron microscope (Germany) [10].

To study the degree of decomposition of the mineral after leaching, the solid residue was spectro-

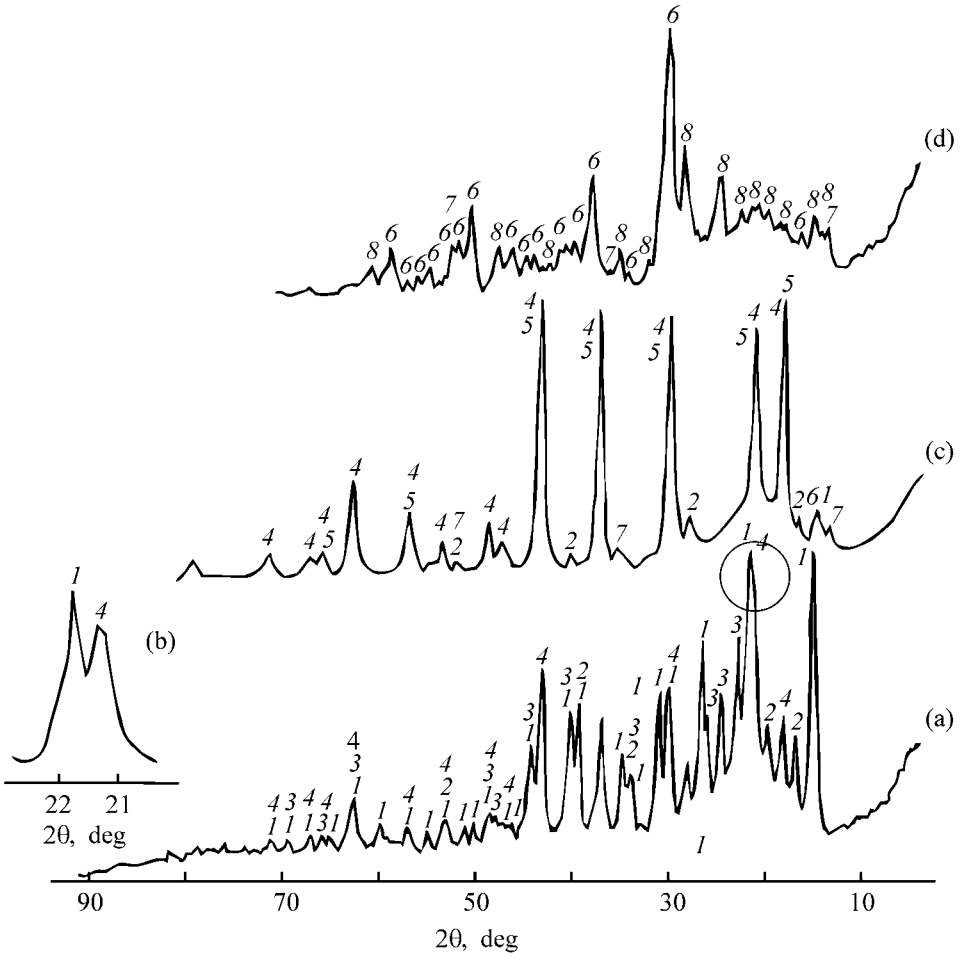

Fig. 2. X-ray diffraction patterns of products formed in the reaction of nepheline with ammonium hydrofluoride upon isothermal keeping at different temperatures. (2θ) Bragg angle; the same for Fig. 5. Keeping temperature (°C): (a, b) 150, (c) 275, and (d) 345. Reflection: (*1*) $(NH_4)_3SiF_7$, (*2*) $(NH_4)_3AlF_6$, (*3*) NH_4F, (*4*) $(NH_4)_2NaAlF_6$, (*5*) $(NH_4)_2SiF_6$, (*6*) $Na_5Al_3F_{14}$, (*7*) NH_4AlF_4, and (*8*) $NaAlF_4$. The measurement at Bragg angles 2θ = 20°–23° with a step of 0.02° made it possible to resolve reflections belonging to $(NH_4)_3SiF_7$ and $(NH_4)_2NaAlF_6$ (b).

photometrically analyzed for the content of silicon (SF-46) by determining the blue complex with Mohr's salt.

Figure 1a shows a derivatogram of the mixture of nepheline and NH_4HF_2, taken in the 1 : 7 molar ratio. The DTA curves exhibit a number of endo- and exo-

thermic effects. The fluorination process starts at temperatures exceeding 40°C and becomes considerably more intensive upon the melting of ammonium hydrofluoride (endothermic effect with a minimum at 120°C). The interaction accompanied by loss of mass ends in a strong exothermic effect peaked at 345°C. Further, no loss of mass occurs in the temperature range 350–500°C.

The thermogravigram obtained in the quasi-isothermal mode shows a set of plateaus (Fig. 1b). To determine the composition of intermediate reaction products, experiments with slow heating (at about 1 deg min^{-1}) and isothermal keeping for 1.5 h at 150, 275, and 345°C were performed.

In the X-ray diffraction pattern of the mixture kept at 150°C, the compounds $(NH_4)_2SiF_6$ and $(NH_4)_3AlF_6$ were identified and reflections were observed that can be attributed to $(NH_4)_2NaAlF_6$ [11] (Figs. 2a, 2b). According to [11], the last compound decomposes at 240–360°C by the scheme

$$5(NH_4)_2NaAlF_6 = Na_5Al_3F_{14} + 2NH_4AlF_4 + 8HF\uparrow + 8NH_3\uparrow,$$

$$NH_4AlF_4 = AlF_3 + HF\uparrow + NH_3\uparrow. \quad (1)$$

At 275°C, the compounds $(NH_4)_2SiF_6$ and $(NH_4)_3AlF_6$ and a minor amount of NH_4AlF_4 were found. Trace amounts of chiolite $Na_5Al_3F_{14}$, formed in thermal decomposition of $(NH_4)_2NaAlF_6$, which begins under these conditions (Fig. 2c), were observed. At 345°C, $Na_5Al_3F_{14}$, $NaAlF_4$, and NH_4AlF_4 are identified (Fig. 2d).

Figure 3a shows the IR spectrum of a nepheline sample. The absorption bands at 472, 513, 700, 1000, and 1090 cm^{-1} correspond to vibrations of the crystal lattice of the mineral [12]. Figure 3b shows the spectrum of a mixture of nepheline and ammonium hydrofluoride kept at 150°C for 2 h. The spectrum contains bands at 1230 and 1440 cm^{-1}, which are associated with deformation vibrations of $[NH_4]^+$ and HF_2^- ions [13]. The bands at 3040 and 3145 cm^{-1} correspond to stretching vibrations of the $[NH_4]^+$ ion. The bands at 480 and 730 cm^{-1} are associated with vibrations of the $[SiF_6]^{2-}$ octahedron in the compound $(NH_4)_3SiF_7$. The bands at 410 and 580–590 cm^{-1} correspond to vibrations of the $[AlF_6]^{3-}$ octahedron. No bands related to nepheline or other silicates are observed in the spectrum, and, consequently, silicon is completely bound into silicon heptafluorosilicate.

Thus, the stages of fluorination of the nepheline powder and subsequent decomposition of intermediate products can be represented by the equations

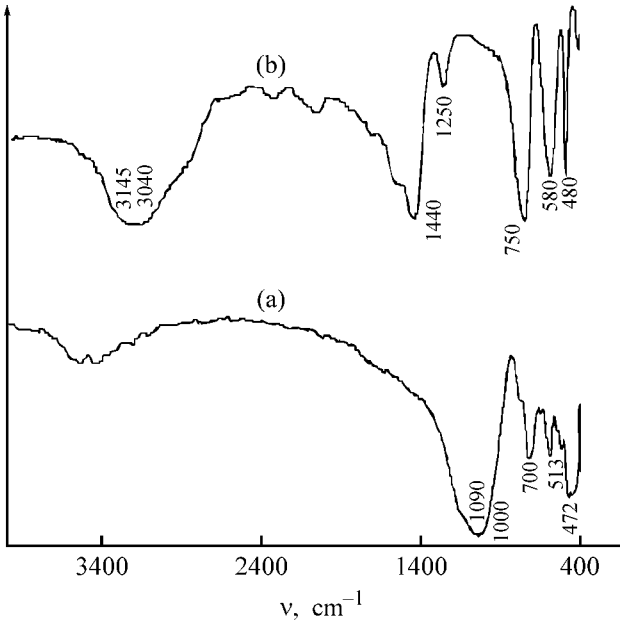

Fig. 3. IR spectra of (a) nepheline and (b) a mixture of nepheline and NH_4HF_2 at 150°C. (ν) Wave number.

$$(1 + n)NaAlSiO_4 + 6.5(1 + n)NH_4HF_2 = n(NH_4)_3AlF_6 + (1 + n)(NH_4)_3SiF_7 + (NH_4)_{2-n}Na_{1+n}AlF_6 + 1.5(1 + n)NH_3 + 4(1 + n)H_2O, \quad (2)$$

$$(NH_4)_3SiF_7 = (NH_4)_2SiF_6 + NH_3\uparrow + HF\uparrow, \quad (3)$$

$$(NH_4)_2SiF_6 = SiF_4\uparrow + 2NH_3\uparrow + 2HF\uparrow, \quad (4)$$

$$(NH_4)_{2-n}Na_{1+n}AlF_6 = (1 + n)Na_5Al_3F_{14} + (1 + n)NaAlF_4 + (2 - 4n)NH_4AlF_4 + (10 - 2n)NH_3\uparrow + (10 - 2n)HF\uparrow, \quad (5)$$

$$(NH_4)_2AlF_6 = NH_4AlF_4 + 2NH_3\uparrow + 2HF\uparrow. \quad (6)$$

The scheme presumes that sodium is in a certain excess with respect to aluminum in the compound $(NH_4)_{n-2}Na_{1+n}AlF_6$.

To elucidate the mechanism of the first stage, a mixture of nepheline particles with ammonium hydrofluoride, taken in a molar ratio of 1 : 0.5 and kept at 150°C for 1.5 h, was subjected to SEM analysis (Fig. 4). The deficiency of ammonium hydrofluoride with respect to the stoichiometry of reaction (2) enables a more detailed examination of changes in the surface morphology of particles of the mineral and reaction products. It can be seen that nepheline grains are covered by reaction products, with the characteristic cracking of the newly formed phases. The depth

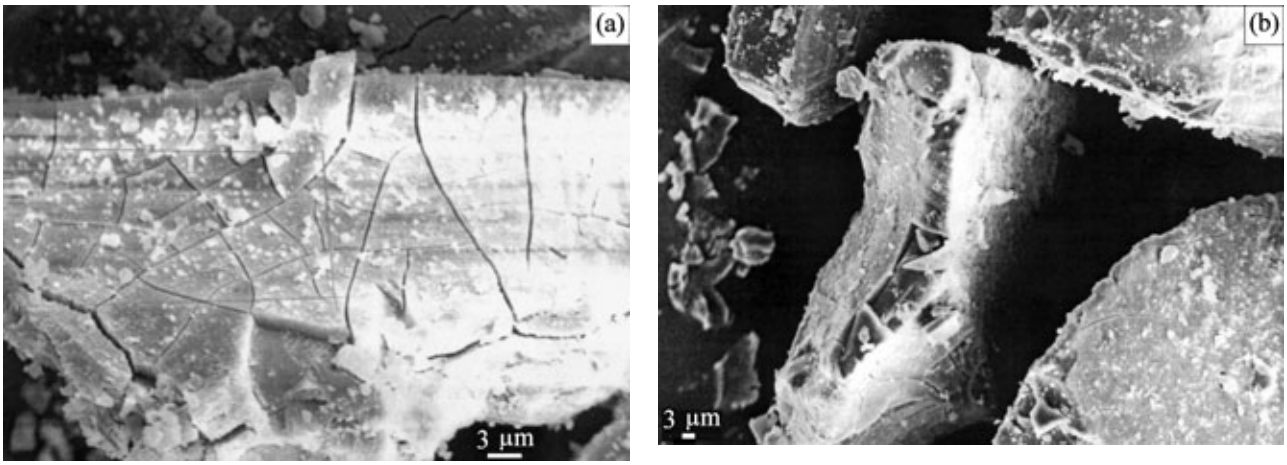

Fig. 4. SEM micrographs of particles of a mixture of nepheline and reaction products on keeping the mixture at 150°C. (a) Cracking of the reaction products on the nepheline surface and (b) depth of interaction.

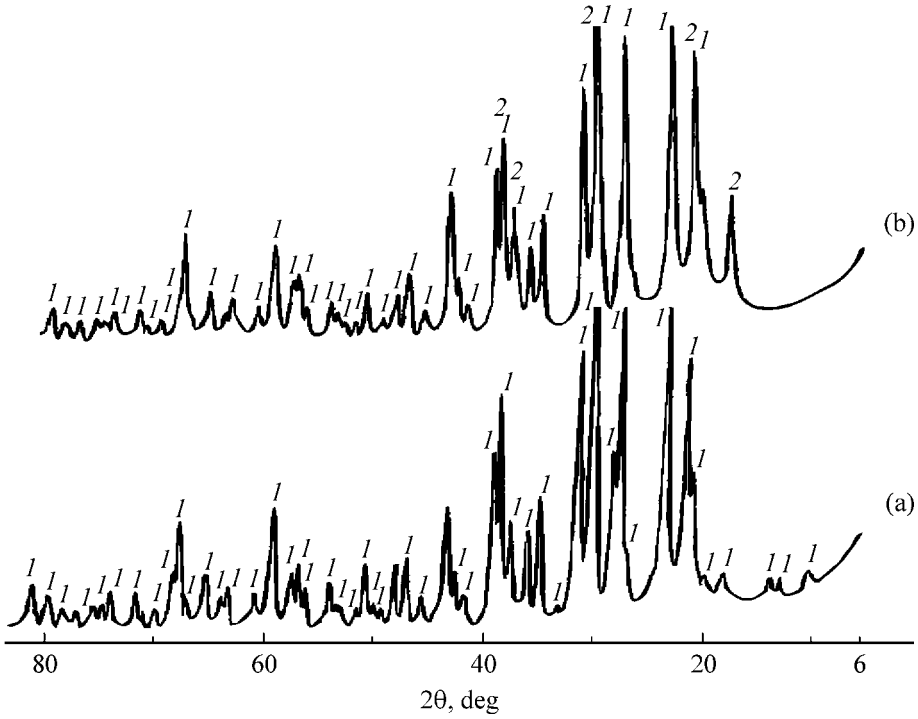

Fig. 5. X-ray diffraction pattern of (a) nepheline and (b) 1 : 0.5 mixture of nepheline and NH_4HF_2, kept at 150°C. Reflection: (*1*) nepheline and (*2*) a phase isostructural with $(NH_4)_2NaAlF_6$.

of interaction can be traced (Fig. 4). Thus, it may be assumed that the fluorination process is limited by diffusion within the layer of a solid product. XPA was used to determine the composition of the reaction products. It was found that, in addition to the nepheline reflections, a compound isostructural with $(NH_4)_2NaAlF_6$ is identified (Fig. 5). It is noteworthy that reflections associated with $(NH_4)_3SiF_7$ are not observed in the diffraction pattern. Thus, it may be assumed that the fluorination of nepheline begins with disintegration of aluminum-oxygen tetrahedra, with Na^+ contained in the structural voids entering into the composition of the hexafluoroaluminate being formed.

The kinetics of nepheline fluorination was studied in the temperature range 130–170°C. The specific surface area of nepheline was 0.21–0.26 $m^2\ g^{-1}$. Kinetic curves were plotted by measuring the loss of mass. The conversion was calculated by the equation

$$\alpha = \Delta m/m_{theor}. \quad (7)$$

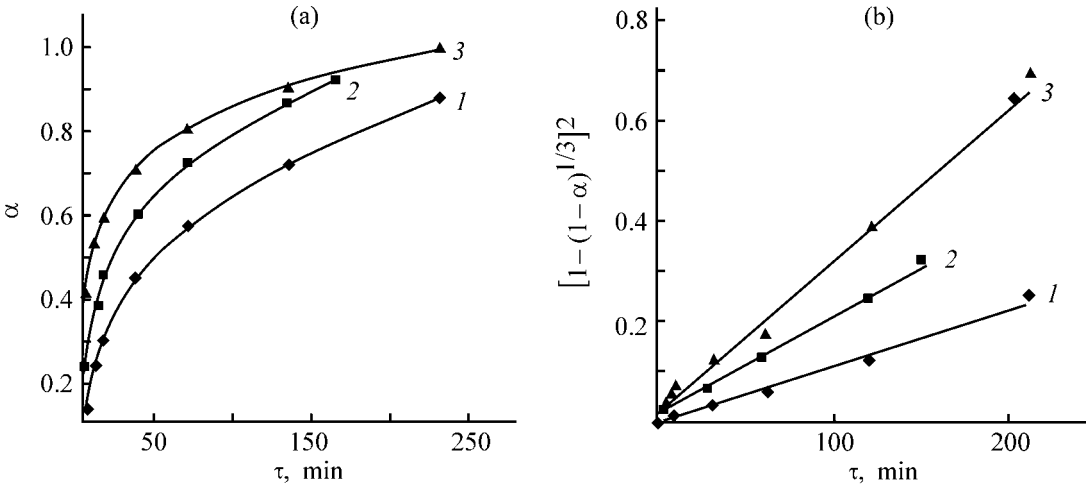

Fig. 6. (a) Degree of nepheline decomposition, α, vs. time τ and (b) kinetic curves of fluorination, plotted in the coordinates $[(1 - (1 - \alpha)^{1/3})^2]$–τ. Temperature (°C): (*1*) 130, (*2*) 150, and (*3*) 170.

The variable Δm was found as the difference of masses, initial and obtained as a result of a reaction in the stock; m_{theor} was calculated using the reaction equation corresponding to the initial stage of fluorination. Control runs, in which the residual amount of nepheline in the mixture was determined by chemical analysis, yielded closely similar results. The run of the curves indicates that, for all the temperatures studied, the duration of the autocatalytic process and its contribution to the overall balance of the process, are negligibly small (Fig. 6a). This, in particular, may take place at a sufficiently high probability of nucleation of a new phase on the surface of a crystalline body. All the transformations occur during the averaged front (The reaction rate decreases because the front motion toward the particle center is accompanied by a decrease in the area of the phase boundary.). The fraction of nepheline fluorinated at 130°C in 210 min, in melting of ammonium hydrofluoride, is 87%; at a temperature raised by 20°C, the conversion of nepheline is 92%; and at 170°C, nepheline is virtually completely transformed into a mixture of fluorides.

With account of the results of SEM diagnostics, the kinetic data were processed using the parabolic equation of a shrinking sphere

$$[1 - (1 - \alpha)^{1/3}]^2 = k\tau,$$

which is used in kinetics to describe topochemical reactions occurring simultaneously over the entire surface (Fig. 6b) [14]. The slope of the curves was used to find the apparent rate constants of fluorination; the apparent activation energy E_a^* was calculated by the Arrhenius equation, with the initial values of the pre-exponential factor found by the least-squares procedure for the linearized form of this equation. The calculated kinetic parameters of the nepheline fluorination process are given below:

$$E_a^* = 35.922 \text{ kJ mol}^{-1}$$

Temperature, °C	130	150	170
Rate constant, min^{-1}	0.0697	0.1218	0.1832

The process occurs under the ionic-diffusion control. Thus, an increase in the degree of cracking of the mineral and in the number of defects in the crystal lattice makes the reaction rate faster.

CONCLUSIONS

(1) The process of nepheline fluorination was studied using a set of physicochemical methods. It was found that, initially, aluminum-oxygen tetrahedra disintegrate, with Na^+ contained in voids of the structure entering into the composition of the hexafluoroaluminate $(NH_4)_{2-n}Na_{1+n}AlF_6$ being formed.

(2) Intermediate reaction products were identified and the temperatures of their formation and thermal decomposition were determined.

(3) Kinetic studies of nepheline fluorination demonstrated that, in the temperature range 130–170°C, transformations occur in the averaged-front mode. It was found that the process occurs under the ionic-diffusion control. The apparent activation energy is 35.9 kJ mol^{-1}.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrolysis of Aluminum Sulfates in the Presence of Ammonium Sulfite

V. A. Matveev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received September 4, 2006

Abstract—Hydrolysis of aluminum sulfate and potash alum in the presence of an ammonium sulfite additive in the temperature range T_{boil}–200°C was studied. A possible reaction mechanism was suggested. The composition and structure of the precipitates formed were determined and certain differences in their morphology were noted. Recommendations for practical implementation of the method of hydrolytic recovery of aluminum from solutions of its sulfate salts were given.

DOI: 10.1134/S1070427207020024

Hydrolysis of aluminum sulfates is the most widespread method for recovery of aluminum(III) from solutions in sulfuric acid processing of aluminum-containing raw materials into alumina [1–5]. It has been found that aluminum sulfates can be arranged in order of increasing susceptibility to hydrolysis as follows: aluminum sulfate < ammonium alum < sodium alum < potash alum [6].

The effect of additions of ammonium, sodium, and potassium sulfates on the hydrolysis of aluminum sulfate has been studied [7, 8]. It was shown that the cations can be arranged in order of increasing effect on the degree of hydrolysis as follows: $H^+ < NH_4^+ < Na^+ < K^+$. It was noted that the ionic radii increase in the same order, which suggests that the solubility of basic aluminum salts decreases as the ionic radius of cations becomes larger.

The effect of temperature has been studied in detail. It was found that a noticeable precipitation of the basic aluminum sulfate is observed only at $T >$ 200°C. For example, according to [6], the degree of hydrolysis of potash alum $KAl(SO_4)_2$, which is the most susceptible to hydrolysis, does not exceed 84% at 240°C. The process is hindered by accumulation of sulfuric acid in solution.

High-temperature hydrolysis involves a large power expenditure and requires an intricate equipment (autoclaves working under a pressure $P > 30$ atm). This is one of the principal reasons why the hydrolytic recovery of basic aluminum salts from sulfate solutions has not been implemented in practice so far. Therefore, it is a topical task to develop procedures that would increase the degree of aluminum(III) extraction into a precipitate of a basic salt, with a simultaneous pronounced decrease in the hydrolysis temperature.

In this study, the hydrolysis of aluminum sulfate (AS) and potash alum (PA) in the presence of ammonium sulfite was examined.

Ammonium sulfite was obtained by bubbling sulfur dioxide through a concentrated solution of ammonium hydrate. As the solution was saturated, ammonium sulfite monohydrate $(NH_4)_2SO_3 \cdot H_2O$ precipitated, which was confirmed by chemical, X-ray phase, and IR spectroscopic analyses. According to [9], ammonium sulfite obtained by various methods contains up to 9–9.4% ammonium sulfate. Therefore, it was taken that the content of the main substance in the resulting salt is 95 wt %. The solution containing 10 wt % ammonium sulfite had pH = 8.2–8.4.

For the experiments, we prepared AS and PA (analytical grade) solutions containing 80 g l^{-1} of Al_2O_3, which is characteristic of solutions obtained by processing aluminosilicate raw materials. The expenditure of ammonium sulfite varied from 0.5 to 2 mol per mole of Al_2O_3. The experimental temperature range was from T_{boil} to 200°C (the boiling points of AS and PA solutions were 103 and 105°C, respectively). The duration of the process at the boiling points of the solutions was 4 h. Hydrolysis at 125, 150, 175, and

200°C was carried out in autoclave bombs, into which 40 ml of a solution was charged and a necessary amount of ammonium sulfite was added. Then the bombs were kept at a prescribed temperature for 1.5 h. The solutions were agitated by tumbling rotation of the bombs. After the process was complete, the autoclave was cooled and the precipitate formed was filtered off, thoroughly washed, and dried to constant weight at 105°C. The precipitates and solutions were analyzed for the content of Al_2O_3. The experimental data listed in the table clearly demonstrate that ammonium sulfite most strongly affects the hydrolysis of aluminum sulfates. No basic aluminum sulfate was precipitated on heating an aluminum sulfate solution up to 200°C.

The addition of ammonium sulfite results in a sharp shift of the reaction equilibrium toward hydrolysis. At the minimum expenditure of the sulfite (0.5 mol per mole of Al_2O_3), a precipitate is formed even at the boiling point of the solutions. At the same temperature, an increase in the expenditure of ammonium sulfite from 0.5 to 2.0 mol per mole of Al_2O_3 results in that the degree of hydrolysis grows by a factor of 2.1–4. At the boiling point (103°C) and an expenditure of ammonium sulfite equal to 1.0 mol per mole of Al_2O_3, a higher degree of hydrolysis (42.7%) is reached, compared with the case of hydrolysis of aluminum sulfate at 230°C, but in the absence of ammonium sulfite (23.2%) [7]. The fullest and technologically acceptable recovery of aluminum(III) into a precipitate of the basic sulfate salt (90.8–93.0%) occurs at an expenditure of ammonium sulfite equal to 2.0 mol per mole of Al_2O_3 and 175–200°C. It is apparent that a virtually complete hydrolysis of aluminum sulfate can be achieved by further raising the temperature.

It is seen from the data obtained that the effect of ammonium sulfite on the PA hydrolysis is more clearly pronounced than that in hydrolysis of aluminum sulfate. At the boiling point (expenditure of ammonium sulfite equal to 1–2 mol per mole of Al_2O_3), the recovery of aluminum(III) into a precipitate of the basic salt reaches 75–88%; the degree of hydrolysis is 86–94% at 125°C and a virtually complete recovery of aluminum(III) into a precipitate of the basic salt is reached at 150°C and higher temperatures.

The role of ammonium sulfite in the hydrolysis of aluminum sulfates is as follows. In an aqueous solution, aluminum sulfate and potash alum are hydrolyzed in accordance with the equation

$$Al_2(SO_4)_3 + 2nH_2O \rightleftarrows Al_2(OH)_{2n}(SO_4)_{3-n} + nH_2SO_4, \quad (1)$$

where $0 < n \leq 3$.

The forming sulfuric acid reacts with ammonium sulfite introduced into a solution in accordance with the equation

$$nH_2SO_4 + n(NH_4)_2SO_3 \rightarrow n(NH_4)_2SO_4 + nH_2O + nSO_2\uparrow, \quad (2)$$

with the weaker sulfurous acid displaced and ammonium sulfate formed. Being unstable, sulfurous acid readily decomposes into H_2O and SO_2. A part of SO_2, which corresponds to its solubility at a given temperature, remains in the solution, whereas its main part is discharged into the gas phase. As a result, the acid is not accumulated in the solution, and the equilibrium of reaction (1) is shifted toward hydrolysis of aluminum salts.

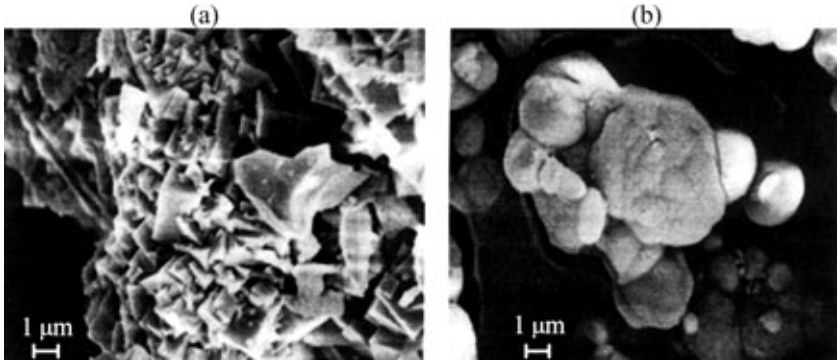

Fig 1. Micrographs (×10000) of basic aluminum sulfates obtained in hydrolysis of potash alum; (a) in the absence of ammonium sulfite and (b) in the presence of ammonium sulfite.

Summing up the left- and right-hand parts of Eqs. (1) and (2), we obtain the following equation of the hydrolysis reaction.

$$\begin{aligned} &Al_2(SO_4)_3 + n(NH_4)_2SO_3 + nH_2O \\ &\rightarrow Al_2(OH)_{2n}(SO_4)_{3-n} + n(NH_4)_2SO_4 \\ &\quad + nH_2SO_3,\ (nH_2O + nSO_3), \end{aligned} \tag{3}$$

where $0 < n \leq 2$.

In this scheme, one of the conditions for a shift of the equilibrium toward hydrolysis is satisfied: the forming sulfuric acid is continuously bound into a neutral compound.

When there is no free sulfuric acid, ammonium sulfite enters into an exchange reaction directly with aluminum sulfate or potash alum in accordance with the equation (for the example of aluminum sulfate)

$$\begin{aligned} &Al_2(SO_4)_3 + n(NH_4)_2SO_3 \\ &\rightarrow Al_2(SO_4)_{3-n}(SO_3)_n + n(NH_4)_2SO_4 \end{aligned} \tag{4}$$

($0 < n \leq 2$) to form aluminum sulfate-sulfite, which is hydrolyzed by the reaction

$$\begin{aligned} &Al_2(SO_4)_{3-n}(SO_3)_n + 2nH_2O \\ &\rightarrow Al_2(OH)_{2n}(SO_4)_{3-n} + nH_2O + nSO_2\uparrow. \end{aligned} \tag{5}$$

The overall reaction equation is similar to Eq. (3):

$$\begin{aligned} &Al_2(SO_4)_3 + n(NH_4)_2SO_3 + nH_2O \\ &\rightarrow Al_2(OH)_{2n}(SO_4)_{3-n} + n(NH_4)_2SO_4 \\ &\quad + nH_2SO_3,\ (nH_2O + nSO_2\uparrow), \end{aligned} \tag{6}$$

where $0 < n \leq 2$.

According to this scheme, the process goes through a stage of formation of an intermediate salt that is more susceptible to hydrolysis than the starting aluminum sulfate or PA.

As the reactions of ammonium sulfite with sulfuric acid and aluminum sulfate or potash alum occur simultaneously and yield the same products, it is impossible to determine the priority of a particular reaction pathway.

The composition of the basic salts formed in hydrolysis of aluminum sulfate and potash alum in the presence of ammonium sulfite is close to the formula $(H_2O, NH_3, R_2O) \cdot 3Al_2O_3 \cdot 5SO_3 \cdot 9H_2O$, where R is Na or K. According to the X-ray phase analysis, all the basic sulfates formed have a similar structure analogous to that of natural rock alum. The basic salt produced in hydrolysis of aluminum sulfate is an isomorphous mixture of ammonium and hydrogen rock alums, and that formed in hydrolysis of potash alum is potassium rock alum with a minor admixture of ammonium rock alum.

The electron micrographs of basic aluminum sulfates formed in hydrolysis of potash alum in the absence (Fig. 1a) and presence (Fig. 1b) of ammonium sulfite show different shapes of the resulting particles. According to the crystal-optical analysis, the particles obtained in the first case are polycrystalline formations with a refractive index $N = 1.575$. A slight tendency for individual grains to have a rounded oval shape is seen. In the second case, the overwhelming part of particles are isometric (rounded) grains with $N = 1.510$.

The study performed is of technological importance. It is shown for the first time that aluminum sulfates can be hydrolyzed with virtually complete precipitation of aluminum(III) basic salts at compara-

tively low temperatures (150°C), which allows the process to be carried out in standard chemical apparatus working at pressures of up to 6 atm. The suggested method of hydrolysis also furnishes a real opportunity for preparation of basic aluminum sulfates with a decreased content of iron. Furthermore, there are prerequisites for regeneration of ammonium sulfite and its recycling.

CONCLUSIONS

(1) A study of the effect of ammonium sulfite on the hydrolysis of aluminum sulfate and potash alum in the temperature range from T_{boil} to 200°C demonstrated that the role of ammonium sulfite consists in that it reacts both with the forming sulfuric acid and directly with aluminum sulfate or potash alum. In the first case, sulfuric acid is bound, whereas in the second, intermediate compounds more susceptible to hydrolysis, compared with the starting salts, are formed. As a result the reaction equilibrium is shifted toward a fuller hydrolysis.

(2) Parameters of the hydrolysis process were determined: at an expenditure of ammonium sulfite equal to 1–2 mol per mole of Al_2O_3 at 150°C, potash alum is almost completely hydrolyzed. In hydrolysis of aluminum sulfate under similar conditions, the recovery of aluminum(III) into a precipitate of a basic sulfate reaches almost 86%.

(3) It was found that all the basic aluminum salts formed are similar in composition and structure to the natural mineral rock alum.

(4) The comparatively low hydrolysis temperature and the possibility of using the standard equipment create real prerequisites for implementation of the method in sulfuric acid processing of alumina-containing raw materials.

Abstract—Cerium(III) extraction with oleic acid in *o*-xylene from nitrate solutions was studied. The extraction mechanism and the dependence of the distribution ratio on pH and composition of the organic and aqueous phases were examined. The thermodynamic characteristics of extraction were calculated.

DOI: 10.1134/S1070427207020036

The best studied among extractants used for recovery of REEs from nitrate solutions are organophosphorus compounds, mainly tributyl phosphate. However, with sulfuric [1] and hydrochloric [2–4] acids are more effective in leaching of lean ores and technologically produced raw materials and TBP is inefficient with these media [5].

REEs are present in acid solutions in the form of anionic complexes $[M(An)_x]^{3-zx}$, where An is anion, and x is the anionic charge equal to 1 or 2 [6]. Therefore, REEs are commonly recovered from acid solutions with anion-exchange extractants, mainly with carboxylic acids [7].

In this study, the characteristics of cerium(III) extraction with oleic acid from nitrate solutions were determined and compared with those of tributyl phosphate and trialkylbenzylammonium nitrate.

In our experiments, cerium(III) was extracted from aqueous nitrate solutions of Ce(III) with a concentration of 0.01 mol kg^{-1}, which is close to the REEs concentration in process solutions formed in extractive recovery of REE from depleted and technogenic raw materials. An 0.5 M solution of oleic acid in *o*-xylene was used as extractant. The dissociation constant of oleic acid is 1.25×10^{-6} [8]. The required pH was adjusted by adding sodium hydroxide or nitric acid. The REE concentration in the initial and equilibrium solutions was determined photometrically with Arsenazo III [9].

The cerium(III) concentration in the organic phase was determined from the difference between its concentrations in the initial solution and equilibrium aqueous phase with account of the difference between the volumes (weights) of the organic and aqueous phases

$$c_{org} = (c_0 - c_{aq})\frac{m_{aq}}{m_{org}} = (c_0 - c_{aq})\frac{V_{aq}}{V_{org}\rho_{org}}, \qquad (1)$$

where c_{org} and c_{aq} are the equilibrium concentrations (mol kg^{-1}) of metals in the organic and aqueous phases, respectively; c_0, REE concentration in the initial aqueous solution (mol kg^{-1}); V_{aq}/V_{org}, volume ratio of the aqueous and organic phases equal to 50 : 5; and the organic phase density $\rho_{orq} = 0.86 \pm 0.1$ g cm^{-3}.

The distribution ratio was calculated by the equation

$$D = c_{org}/c_{aq}. \qquad (2)$$

The data on cerium(III) extraction with 0.5 M oleic acid in *o*-xylene from nitrate solutions within the pH range 3–3.5 are listed in Table 1.

Table 1. Distribution ratios of Ce(III) D_{Ce} at various pH (initial Ce(III) concentration 0.014 mol kg^{-1}, pH 5)

pH	$c_{aq} \times 10^3$	$c_{org} \times 10^2$	D_{Ce}
	mol kg^{-1}

4.5	4.7	9.3	19.70
4.8	1.7	12.3	71.67
5.0	1.3	12.7	98.89
5.5	0.6	13.4	235.00

Table 2. Distribution ratio of cerium(III) as a function of oleic acid concentration c_{ol} in the organic phase (initial Ce(III) concentration 0.014 mol kg^{-1}, pH 5)

c_{ol}, M	$c_{aq} \times 10^3$	$c_{org} \times 10^2$	D_{Ce}
	mol kg^{-1}		
0.1	4.7	2.2	4.60
0.2	3.1	4.9	15.69
0.3	2.7	8.0	29.10
0.4	1.8	11.4	63.21
0.5	1.4	14.6	103.28

The distribution ratios of Ce(III) were studied at constant pH 5.0 ± 0.1 in relation to the oleic acid concentration in the organic phase at the molar ratio of oleic acid and the metal equal to 4. The oleic acid concentration in the organic phase was varied by its dilution with *o*-xylene. The distribution ratios of Ce(III) at various oleic acid concentrations in the organic phase are listed in Table 2.

In special experiments, we found that the distribution ratio of cerium is not influenced by the nitrate concentration in the aqueous phase. This means that the cerium-containing extractable complex contains no nitrate anions. Oleic acid poorly dissociates in the organic phase. Therefore, extraction of Ce(III) can be regarded as consisting of the following steps: oleic acid first passes into aqueous phase where it dissociates to form cerium(III) oleate insoluble in water (pL = 12 [8]), but is readily soluble in the organic phase. Therefore, the extraction of cerium with oleic acid can be described by the equation of the following heterogeneous reaction:

$$M^{3+} + zH_2O + (3 - z)R^- \rightleftarrows M(OH)_zR_{3-z(org)} + zH^+. \quad (3)$$

The extraction constant is determined by the following equation

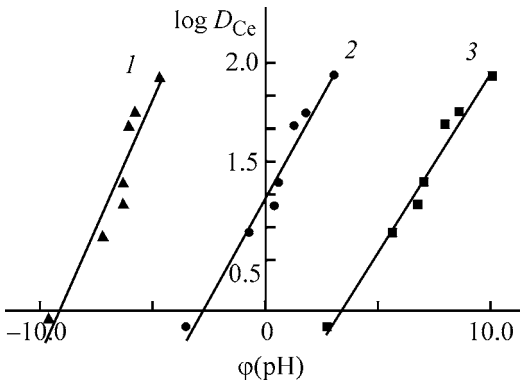

Fig. 1. Plot of the logarithm of the Ce ($\log D_{Ce}$) distribution ratio vs. φ(pH) [Eq. 10)] at z (*1*) 0, (*2*) 1, and (*3*) 2.

$$K = \frac{c_{org} a_{H^+}^z}{c_{aq} \gamma_{\pm} [R^-]^{3-z}} = \frac{D a_{H^+}^z}{\gamma_{\pm} [R^-]^{3-z}}, \quad (4)$$

where $\gamma_{\pm}$ is the mean ionic activity coefficient of REE nitrate in the equilibrium aqueous phase, and $[R^-]$ is the oleate anion concentration dependent on pH [8]:

$$[R^-] = \frac{[HR]_{org} K_d}{a_{H^+}}, \quad (5)$$

where K_d is the dissociation constant of oleic acid.

The concentration of the nondissociated oleic acid species in the organic phase $[HR]_{org}$ is determined by the equation

$$[HR]_{org} = c_{extr} - (3 - z)c_{org} - [R^-]_{org}, \quad (6)$$

where c_{extr} is the total extractant concentration in the organic phase; c_{org}, REE concentration in the organic phase; and $(3 - z)c_{org}$, concentration of the oleate anion bound in the extractable complex.

The equilibrium concentration of free oleate anions is determined by the equation obtained by joint solution of Eqs. (5) and (6):

$$[R^-]_{org} = \frac{c_{extr} - (3 - z)c_{org}}{\left(1 + \frac{a_{H_{aq}^+}}{K_d}\right)}. \quad (7)$$

On substitution of Eq. (7) in Eq. (4), the following equation is obtained:

$$K = \frac{D a_{H_{aq}^+}^z \left(1 + \frac{a_{H_{aq}^+}}{K_d}\right)^{3-z}}{\gamma_{\pm} [c_{extr} - (3 - z)c_{org}]^{3-z}}. \quad (8)$$

On taking the logarithm, Eq. (8) is converted to the form

$$\log D = \log K + z\,\mathrm{pH} - (3 - z)\log\left(1 + \frac{a_{H_{aq}^+}}{K_d}\right) + (3 - z)\log [c_{extr} - (3 - z)c_{org}] + \log \gamma_{\pm}. \quad (9)$$

Then, using the experimental D values listed in Table 1, we plotted the dependences of $\log D_{Ce}$ on

$$\varphi(\mathrm{pH}) = z\,\mathrm{pH} + (3 - z)\log [c_{extr} - (3 - z)c_{org}] - (3 - z)\log\left(1 + \frac{a_{H_{aq}^+}}{K_d}\right), \quad (10)$$

for z = 0, 1, and 2 (Fig. 1).

In accordance with Eq. (9), these dependences are linear at $z = 0$, 1 and 2 and are described by the following equations with $R^2 = 0.93$

$$\log D = 0.52\varphi(\mathrm{pH}) + 4.72 \quad (z = 0), \qquad (11)$$

$$\log D = 0.41\varphi(\mathrm{pH}) + 1.11 \quad (z = 1), \qquad (12)$$

$$\log D = 0.37\varphi(\mathrm{pH}) - 1.29 \quad (z = 2). \qquad (13)$$

We calculated from the absolute term in Eqs. (11)–(13), taking into account (9), the extraction constant and the Gibbs free energy of cerium(III) extraction with oleic acid at a certain z. The mean ionic activity coefficients of cerium(III) nitrate in the equilibrium aqueous phase, $\gamma_{\pm}$, used in the calculations, were estimated in the framework of the Debye–Hückel theory from the ionic strength of the solution. The ionic strength of the equilibrium aqueous phase was determined taking into account the cerium(III) nitrate concentration and also HNO_3 and NaOH amounts added to adjust the required pH. The calculated thermodynamic characteristics of cerium(III) extraction with oleic acid are as follows:

$\log K = 4.72$ ($z = 0$), $K = 5.2 \times 10^4$, $\Delta_r G = -26.9$ kJ mol^{-1},

$\log K = 1.11$ ($z = 1$), $K = 12.9$, $\Delta_r G = -6.3$ kJ mol^{-1},

$\log K = -1.29$, ($z = 2$), $K = 0.05$; $\Delta_r G = 7.4$ kJ mol^{-1}.

These results show that the extraction constant of Ce(III) with oleic acid, calculated at $z = 2$, is much less than the experimental value. Therefore, the assumption that $z = 2$ was rejected.

The thermodynamic characteristics of cerium(III) extraction with oleic acid can also be determined from the plots of $\log D_{Ce}$ vs. the following function of the extractant concentration $\varphi(c_{ol}) = (3 - z)\log[c_{extr} - (3 - z)c_{org}]$. These plots at $z = 0$ and 1 are shown in Fig. 2.

It was found that, at $z = 1$, $\log D_{Ce}$ is a linear function of $\varphi(c_{ol})$ with $R^2 = 0.97$:

$$\log D = 1.2\varphi(c_{ol}) + 3.59. \qquad (14)$$

The slope in Eq. (14) shows that the solvate number of the extractable complex is 2. The extraction constant and the Gibbs free energy of cerium(III) extraction were calculated from the absolute term of (14), taking into account Eq. (9). These values were as follows: $\log K = 0.51$, $K = 3.2$, and $\Delta_r G = -2.9$ kJ mol^{-1}.

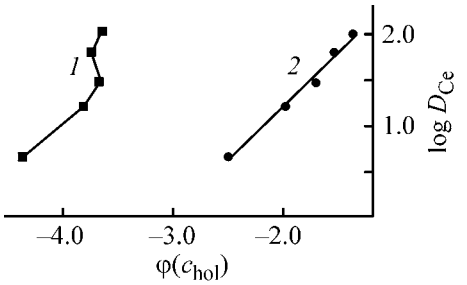

Fig. 2. Logarithm of the distribution ratios of cerium(III) ($\log D_{Ce}$) vs. $\varphi(c_{ol})$ at z (*1*) 0 and (*2*) 1.

Thus, both the approaches used for mathematical processing of experimental data on cerium(III) extraction with oleic acid resulted in consistent thermodynamic characteristics. The average extraction constant and Gibbs free energy of Ce(III) extraction were found to be: $K_{extr} = 8 \pm 4$ and $\Delta_{extr} G = -4.6 \pm 1.7$ kJ mol^{-1}. The solvate number of Ce(III) in the extractable complex, determined by both methods, is 2.

The Ce(III) extraction with oleic acid can be described by the equation of a chemical reaction

$$(CeOH)^{2+}_{aq} + 2R^-_{org} = CeOHR_{2(org)}, \qquad (15)$$

where the $(CeOH)^{2+}$ cation is formed by hydrolysis:

$$Ce^{3+} + H_2O = [CeOH]^{2+} + H^+. \qquad (16)$$

The Gibbs free energy of this reaction, $\Delta_h G$, calculated from reference data, is 53.98 kJ mol^{-1}.

The Gibbs free energy of the solvation reaction [Eq. (15)] was calculated from the difference between the Gibbs free energies of extraction of Ce(III) and its hydrolysis: $\Delta_{solv} G = \Delta_{extr} G - \Delta_h G = -58.6 \pm 1.7$ kJ mol^{-1}.

The characteristics of cerium(III) extraction with 20% TBP in *o*-xylene, 0.5 M trialkylbenzylammonium nitrate (TABAN) in *o*-xylene, and 0.5 M oleic acid in *o*-xylene are listed in Table 3.

Table 3 shows that, in cerium(III) extraction from nitrate solutions at pH 5, the highest extractive power

Table 3. Characteristics of extraction of cerium(III) nitrate with various extractants

Extractant	pH	D	$-\Delta_r G^0_{298}$, kJ mol^{-1}	Solvate number
TBP [10]	5	9.0 ± 0.4	5.92 ± 0.03	2
TABAN [5]	3	35 ± 4	8.9 ± 0.3	2
Oleic acid	5	100 ± 3	58.6 ± 1.7	2

is exhibited by oleic acid. This fact confirms the assumption that cerium(III) in the aqueous phase forms positively charged hydroxocomplexes at pH 5. In more acidic media (pH 3), cerium(III) forms anionic complexes and, therefore, its extraction with a salt of a quaternary ammonium base is more efficient.

CONCLUSIONS

(1) At pH 5, Ce(III) occurs in aqueous nitrate solutions in the form of hydroxo complexes $Ce(OH)^{2+}$.

(2) In extraction of Ce(III) with oleic acid at pH 5, the solvate number in the extractable complex is 2, i.e., cerium(III) is extracted in the form of hydroxo complexes $Ce(OH)^{2+}$ coordinated with two oleate anions.

(3) The thermodynamic characteristics of extraction of cerium(III) from aqueous nitrate solutions with oleic acid are calculated.

(4) In extraction of cerium(III) from nitrate solutions at pH 5, the extractive power of oleic acid exceeds that of tributyl phosphate and trialkylbenzylammonium nitrare.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Silver Cementation with Magnesium in Cyanide Solutions

O. I. Kuntyi, G. I. Zozulya, and O. G. Kurilets

Lvivska Politekhnika National University, Lviv, Ukraine

Received July 29, 2006

Abstract—Contact precipitation of silver with a magnesium powder from 0.0025–0.01 M solutions of the system $[Ag(CN)_2]^-$–CN^- in the hydrodynamic mode was studied. The dependence of the silver cementation rate in the initial stage on the concentration of the $[Ag(CN)_2]^-$ complex and on the surface area of the cementing agent was examined, and the relationship of the temperature factor with the depolarization of silver reduction on microcathodes and acceleration of magnesium dissolution on microanodes was analyzed.

DOI: 10.1134/S1070427207020048

A number of techniques for recovery of gold and silver from ores and secondary raw materials are based on hydrometallurgical processes [1–3]. Analysis of publications devoted to this issue [3] shows that the cyanide method is the most widespread in the world practice of leaching-out of these metals. Further, metallic gold and silver (M) are precipitated from the resulting solutions by cementation with zinc [1, 2] by the reaction

$$2[M(CN)_2]^- + Zn \rightarrow 2M + [Zn(CN)_4]^{2-}. \quad (1)$$

The formation of the cyanide complex $[Zn(CN)_4]^{2-}$ by the main reaction results in binding of free cyanide ions CN^-. Side reactions (2) and (3), whose share exceeds that of the main reaction, also lead to binding of CN^- anions:

$$Zn + 4CN^- + 2H_2O \rightarrow [Zn(CN)_4]^{2-} + H_2 + 2OH^-, \quad (2)$$

$$2Zn + 8CN^- + O_2 + 2H_2O \rightarrow 2[Zn(CN)_4]^{2-} + 4OH^-. \quad (3)$$

In view of the fact that the actual consumption of zinc is tens of times that theoretically calculated for cementation [2], its use as a cementing metal makes difficult the technological cycle of leaching, cementation, leaching, etc. Furthermore, it is necessary to recover zinc from spent solutions after the reduced metals are isolated and CN^- ions are neutralized. Because the concentration of zinc is low, this process is not economically feasible.

Similar complications arise if zinc is used as a cementing metal in noncyanide leaching solutions, with thiosulfate or thiocarbamide. Therefore, cementation with metals whose ions do not form complexes with ligands, the main components of leaching solutions, aluminum [4–6] and magnesium [7–9], have become more intensive in the last decade.

The aim of this study was to examine the possibility of using magnesium for contact precipitation of silver from cyanide solutions that model solutions for leaching of ores, scrap metal, and spent electrolytes and washing water formed in silver plating. This study proceeds with systematic examination of the recovery of nonferrous and precious metals from solutions by cementation with magnesium [7–9].

EXPERIMENTAL

Contact precipitation of silver was carried out in the system $[Ag(CN)_2]^-$–CN^-. Solutions for cyanide leaching of ores and secondary raw materials were modeled and kinetic and electrochemical features of the process, as well as the morphology of the reduced metal, were analyzed. Solutions containing equimolar amounts of $[Ag(CN)_2]^-$ complexes and free cyanide ions CN^- were prepared from $AgNO_3$ and NaCN. The cementation was carried out in a thermostated glass container with a solution volume of 0.1 l in the atmosphere nitrogen at 20–40°C, with vigorous mechanical stirring. A magnesium powder with average particle size of $0.42 \times 0.15 \times 0.04$ mm, scrap metal of the 1.0–1.1-mm fraction, and a magnesium disk 30 mm in diameter were used for the experiments. Before each experiment, the disc was trimmed with a fine emery paper, degreased with alcohol, and its

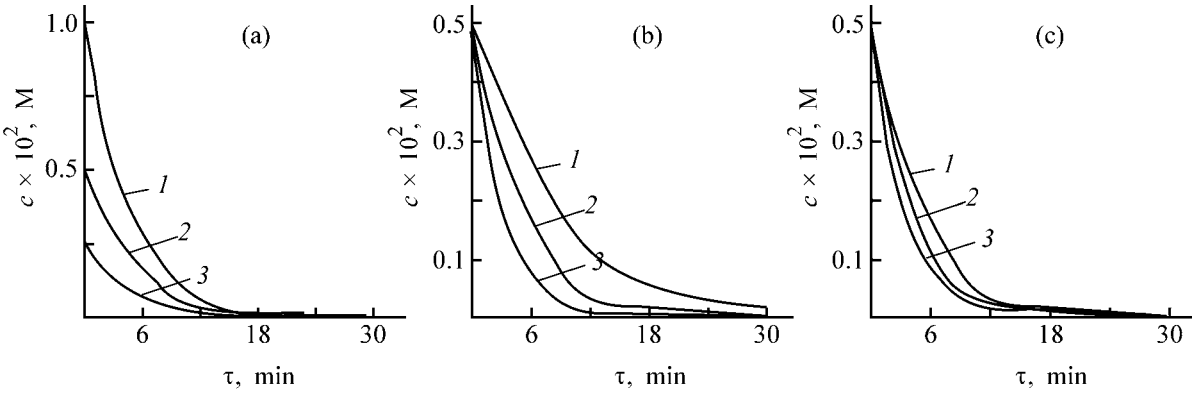

Fig. 1. Variation of the silver concentration c with time τ in cementation with a magnesium powder in solutions of the system $[Ag(CN)_2]^-$–CN^- in relation to (a) initial content of silver cyanide complex c_0(Ag), (b) magnesium powder weight m(Mg), and (c) temperature. (a) T = 20°C, m(Mg) = 0.10 g. c_0(Ag) (M): (*1*) 0.01, (*2*) 0.005, (*3*) 0.0025. (b) T = 20°C, c_0(Ag) = 0.005 M. m(Mg) (g): (*1*) 0.05, (*2*) 0.10, (*3*) 0.15. (c) c_0(Ag) = 0.005 M, m(Mg) = 0.10 g. T (°C): (*1*) 20, (*2*) 30, (3) 40.

lateral surface was insulated with a Teflon tape. During the cementation, samples of a solution were periodically taken and analyzed for the silver content by atomic-adsorption spectroscopy (AAS-IN atomic-absorption spectrophotometer in an air–propane–butane flame at a wavelength of 328.1 nm).

After the cementation was complete, the powders, scrap metal, and disc were washed with water and acetone, dried in air at 80°C, weighed, and examined with an optical microscope equipped with a digital camera. On separating the precipitate, the content of magnesium ions in solution was determined by titration with Trilon B.

It was found that the rate of cementation with powdered magnesium in solutions of the system $[Ag(CN)_2]^-$–CN^- is directly proportional to the content of the complex. For example, the cementation rate in 0.0025, 0.005, and 0.01 M solutions of the $[Ag(CN)_2]^-$ complex at 20°C is 0.00044, 0.00077, and 0.00186 mol min^{-1}, respectively, during the initial 2 min, when a virtually linear time dependence of the silver concentration is observed (Fig. 1a). Thus, the contact precipitation of silver with magnesium in cyanide solutions can be considered a first-order pseudoreaction ?(pseudo-first-order reaction)? in the initial stage.

The cementation rate is also virtually directly-proportional to the surface area of the magnesium powder in the initial stage (Fig. 1b). For example, the cementation rate in a 0.005 M $[Ag(CN)_2]^-$ solution is, during the first 2 min, 0.00040, 0.00077 and 0.00121 mol min^{-1}, respectively, for a magnesium powder weight of 0.05, 0.10, and 0.15 g. This agrees with the general dependence of the contact precipitation rate of a metal on the surface area of a cementing agent in contact with a solution [10].

The temperature factor is of no importance for acceleration of the silver cementation (Fig. 1c). For example, the cementation rate increases by about 15% in the initial stage for 0.005 M solutions in the range 20–30°C and by about 25% in the range 30–40°C. This behavior can be accounted for by acceleration of electrode processes associated with depolarization of process (4) at microcathodes [11], and also by acceleration of reaction (5) at microanodes; in addition, heating promotes diffusion:

$$[Ag(CN)_2]^- + e \rightarrow Ag + 2CN^-, \quad (4)$$

$$Mg \rightarrow Mg^{2+} + 2e. \quad (5)$$

In a wide range of concentrations of the cyanide complex $[Ag(CN)_2]^-$, silver films (Figs. 2a–2d) or compact metal formations (Figs. 2e–2i) appear on the smooth magnesium surface. This is primarily attributable to a strong cathodic polarization of silver in cyanide electrolytes [11]. Silver films are not homogeneous, which is caused by the electrochemical nonuniformity of the magnesium surface. For example, outgrowths, which are known to have an increased energy [12], are formed in prolonged cementation at crystallite boundaries on smooth magnesium samples (discs) (Figs. 2a, 2b). The heterogeneity of the silver precipitate is considerably more pronounced on the surface of magnesium scrap (Figs. 2c, 2d) and especially on powder particles (Figs. 2e, 2f). In the last case, the corrugated surface and internal stresses are reasons for the increased electrochemical (energy-related) heterogeneity, which leads to a high current density on microcathode and microanode parts and,

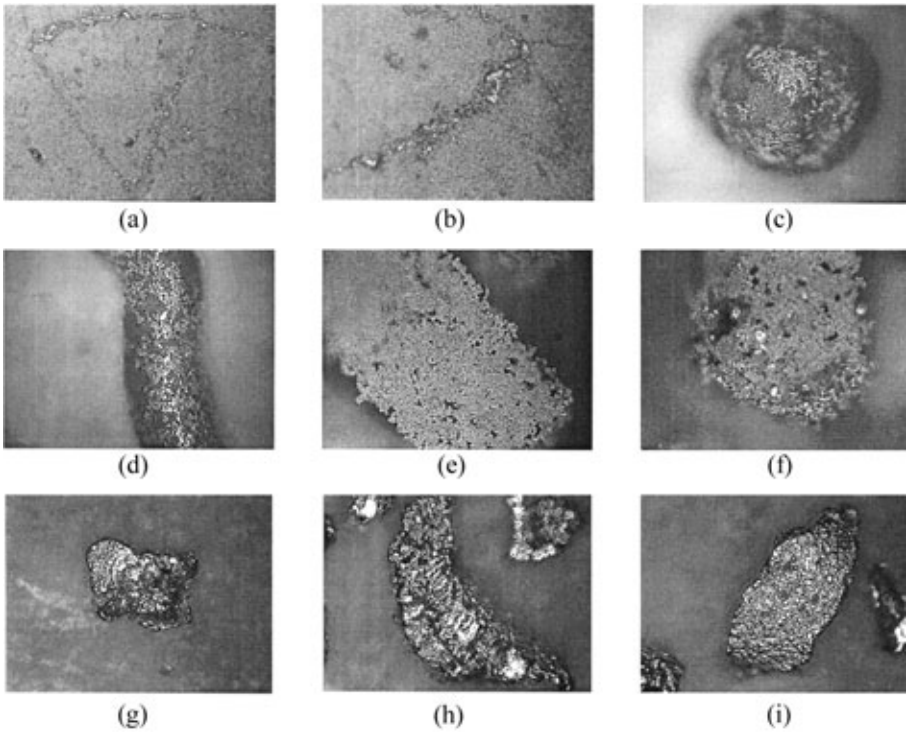

Fig. 2. Micrographs of the surface of (a, b) magnesium discs, (c, d) scrap, (e, f) powder, and (g–i) silver formations upon contact precipitation at 20°C from a 0.005 M $[Ag(CN)_2]^-$ + 0.005 M CN^- solution. Magnification: (a, g–i) 100; (b, e, f) 200; (c, d) 50.

accordingly, to a high cementation rate. Furthermore, the corrugated surface of magnesium powder particles precludes formation of solid silver films, which is characteristic of the contact precipitation from solutions of complex salts [10] and is observed on the magnesium disc (Figs. 2a, 2b). Therefore, the microanode parts are not blocked by a bulk silver precipitate reduced on microcathodes. These latter are formed as outgrowths during cementation (Fig. 2f), which are agglomerated in anodic dissolution of magnesium. After the cementing agent is completely consumed, the silver particles formed reproduce particles of magnesium powder or their fragments (Fig. 2g–2i).

Thus, the contact precipitation of silver with a magnesium powder from cyanide solutions enables complete utilization of magnesium as a cementing metal. The specific expenditure of magnesium is only determined by microcathod?ic reactions of silver reduction (4) and side reaction (6), because reactions similar to (2) and (3) do not occur:

$$2H_2O + 2e \rightarrow H_2 + 2OH^-. \quad (6)$$

As demonstrated by the experimental results, the practical expenditure of magnesium on reaching a 99% extraction of silver is 150–300% of the theoretical value, i.e., 0.17–0.34 g per gram of reduced silver.

No precipitation of magnesium hydroxide was observed during the cementation and a long time after its completion, which is due to the low concentration of Mg^{2+} formed by microanod?ic reaction (5) and to a comparatively low alkalinity of the medium. The precipitation of $Mg(OH)_2$ from a 0.01 M solution begins at pH 10.4 and is complete at pH 12.4 [13]. In the model solutions under study, this value does not exceed 10.5. Thus, the precipitation of silver from cyanide solutions with a magnesium powder makes it possible to obtain a pure reduced metal, with cyanide ions not bound by ions of the cementing agent.

CONCLUSIONS

(1) Compact silver films are deposited from solutions of the system $[Ag(CN)_2]^-$–CN^- on a smooth magnesium surface, and monolithic silver particles are formed on a corrugated surface.

(2) The rate of silver cementation with a magnesium powder is directly proportional to the concentration of the complex $[Ag(CN)_2]^-$ and to the surface area of the cementing agent in the initial stage of the process. The temperature factor is associated with

the depolarization of silver reduction on microcathodes and with the acceleration of magnesium dissolution on microanodes.

3. The specific expenditure of magnesium for a 99% extraction of silver is 0.17–0.34 g per gram of reduced silver, which corresponds to a 150–300% dissolution of the cementing agent relative to the theoretical value. No magnesium hydroxide is formed during the cementation and a long time after its completion, which makes it possible to obtain pure silver precipitates.

Abstract—New rhodium selenochlorides $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$ whose structure is based on the cluster "cubane" $[Rh_4(\mu_3\text{-}Se)_4]$ and products of their thermal transformations were obtained. The catalytic properties of the compounds on various carbon and silica supports in oxidative carbonylation of methane in the gas phase and their dependence on the catalyst preparation technique, type of support, and size of its nanopores were analyzed.

DOI: 10.1134/S107042720702005X

The ability to coordinate in the inner coordination sphere both organic and inorganic ligands creates a wide variety of complex compounds of rhodium, with the resulting opportunity to use these systems to develop catalytic systems with controllable functional properties. Possibly promising objects as catalysts for organic synthesis are chalcogenide and chalcohalide compounds of rhodium, synthesized in nonaqueous organic media without use of expensive templates [1, 2], and products of thermal destruction of these compounds. In systems of this kind, activation and conversion of reagents may occur not only at the central metal atoms, but also at chalcogenide sites. As a result, rhodium chalcohalides may be of particular interest for direct synthesis of complex substances from simple molecules. Single-stage synthesis of alcohols, aldehydes, acids, and esters from methane, carbon monoxide, and oxygen is a possible alternative to the multistage and energy-intensive processing of natural gas, which includes stages of steam reforming of methane into a mixture of H_2 and CO (3 : 1), high-temperature conversion of a mixture of H_2 and CO (2 : 1) into methanol, and subsequent synthesis of aromatic oxygen-containing compounds from methanol [3].

The reaction of oxidative carbonylation of methane to give acetic acid was first performed in the liquid phase under elevated pressure [4], but carrying out the reaction in a heterogeneous catalytic system under atmospheric pressure is a simpler and more attractive method [5–8]. In this case, no aggressive and toxic solvents are used and liquid reaction products are easily removed from the reaction mixture.

In this study, catalysts prepared by deposition of new cluster-type rhodium selenochlorides onto silica and porous carbon materials in the reaction of oxidative carbonylation of methane to give oxygen-containing compounds were examined.

EXPERIMENTAL

Rhodium selenochlorides were synthesized in the medium of Se_2Cl_2, with rhodium(III) chloride $RhCl_3 \cdot 4H_2O$ used as a reaction form. In this medium, selenium can be present in various states and oxidation levels: as neutral molecules Se_2Cl_2, anions, Se^{2-}, chain anions Se_n^{2-} or molecules Se_n^0, selenium dioxide SeO_2, and selenyl dichloride $SeOCl_2$. For this reason, the first stage of synthesis was performed at 80–90°C in the course of 120 h ($RhCl_3 \cdot 4H_2O$: Se_2Cl_2 = 1 : 10) in an open reactor to enable release of the gaseous products, H_2Se and HCl. In the second stage, the reactor was sealed and the heating was continued at 100°C in two different temperature modes:

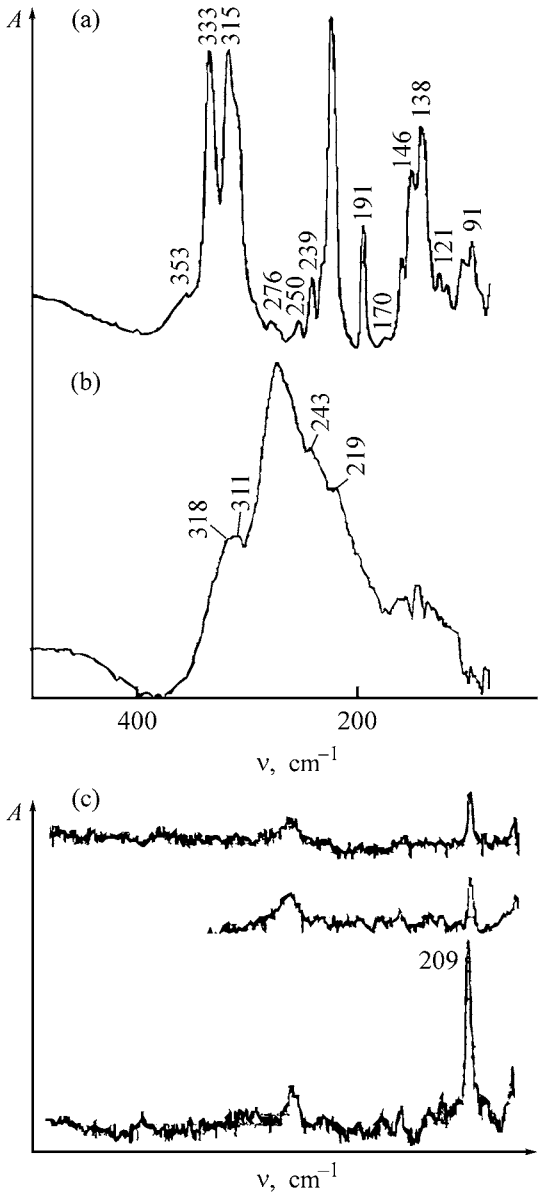

Fig. 1. IR spectra: (a) $Rh_4Se_{16}Cl_{10}$, $Rh_4Se_{18}Cl_{10}$ and (b) Rh_3Se_3Cl, Rh_3Se_5Cl; (c) variation of the relative intensities of lines of the Raman spectrum of $Rh_4Se_{18}Cl_{10}$ in the course of 2 h. (*A*) Absorption and (ν) wave number.

with cyclic heating–cooling (60–80 h) and with continuous heating (180 h). The forming solid products, $Rh_4Se_{16}Cl_{10}$ (**1**) and $Rh_4Se_{18}Cl_{10}$ (**2**), were yielded by the following reactions

$$4RhCl_3 \cdot 4H_2O + 12H_2O + 15Se_2Cl_2 = Rh_4Se_{16}Cl_{10} + 32HCl + 6Se + 8SeO_2,$$

$$4RhCl_3 \cdot 4H_2O + 12H_2O + 23Se_2Cl_2 = Rh_4Se_{18}Cl_{10} + 32HCl + 16Se + 8SeOCl_2 + 4SeO_2.$$

The thermal decomposition products, Rh_3Se_3Cl and Rh_3Se_5Cl, were obtained in 40 h at 345 and 320°C in accordance with the reactions

$$3Rh_4Se_{16}Cl_{10} \xrightarrow{345^\circ C} 4Rh_3Se_3Cl + 13Se_2Cl_2 + 10Se,$$

$$3Rh_4Se_{18}Cl_{10} \xrightarrow{320^\circ C} 4Rh_3Se_5Cl + 13Se_2Cl_2 + 8Se.$$

Rhodium selenochlorides were studied using a set of mutually complementary physicochemical techniques: vibrational and X-ray photoelectron (XPS) spectroscopies; X-ray phase, thermal, and elemental chemical analyses. It was found that the complexes contain the structural fragments μ-Se^{2-}, μ-Se_2^{2-}, μ_3-Se^{2-}, Cl^-_{term}, and Cl^-_{bridge}, as well as coordinated Se_2Cl_2 molecules.

A thermographic study was performed on an MOM Q-1500 instrument (Hungary) in the temperature range 20–1000°C (sample heating rate 5 deg min^{-1}, sensitivity 250 μV, sample weight 0.5–1 g) in special cuvettes under a constant lowered pressure, with gaseous decomposition products condensed in liquid nitrogen. To isolate solid thermolysis products, the starting compounds were kept at the temperatures of the effects recorded in the thermograms (345 and 320°C) for 40 h to constant weight of the solid residue.

For all the compounds formed both by direct synthesis and by thermal destruction, a chemical elemental analysis was made. The content of the metal was determined gravimetrically upon reduction of weighed portions of the compounds in a flow of hydrogen at 20–1000°C; that of chlorine, by argentometry in alkaline solutions through which gases evolved in reduction by hydrogen were passed; and that of selenium, from the difference.

IR spectra of the compounds suspended in Nujol were recorded on Nicolet Magna-IR 750 and Specord M-80 spectrometers,[1] and Raman spectra, on a DFS-24 spectrometer with a He–Ne laser excitation source (632.8 nm).

XPS spectra were measured with a modified ES-2402 electron spectrometer. An X-ray gun with a magnetic anode ($E_{Mg\,K_\alpha}$ = 1253.6 eV, P = 300 W) served as excitation source.

The catalytic properties of the samples were studied by passing a gas mixture with component ratio

[1] The authors are grateful to B.V. Lokshin and Z.S. Klemenkova, staff members of INESS (Moscow), for assistance in IR spectral measurements.

$CH_4 : CO : O_2 = 10 : 4 : 1$ through a quartz reactor with an inner diameter of 10 mm. The catalyst volume was 1.0 cm^3. The experiments were performed under atmospheric pressure in the temperature range 400–600°C at a volumetric flow rate of 6000 h^{-1}. The specific surface area of the samples, S_{BET}, was found by the method of thermal desorption of nitrogen. The starting substances and gaseous reaction products (CH_4, CO, O_2, CO_2) were analyzed with an LKhM-80 gas chromatograph equipped with a heat-conductivity detector. Liquid reaction products were frozen-out in a trap at a temperature of –70°C and then analyzed on a Khrom-5 chromatograph with a flame-ionization detector and a column packed with Separon-BD sorbent.

The vibrational spectra of $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$ are identical. The spectra contain a complex set of frequencies repeated in the IR and Raman spectra (Figs. 1a, 1c). The broad band at 360–350 cm^{-1} (IR), and the strong band at 350 cm^{-1} (Raman) are associated with stretching vibrations of the Se–Cl bond in the Se_2Cl_2 molecule. The frequencies 334, 315, 307 cm^{-1} (IR) and 331, 319, 310 cm^{-1} (Raman) can be attributed to stretching vibrations of the Rh–Cl and Rh–μ_3–Se^{2-} bonds. The weak bands at 274, 251, and 239 cm^{-1} (IR) and the lines at 269, 255, and 240 cm^{-1} (Raman) lie in the range of vibrations of the Se–Se bond in chain and annular Se_n molecules. From the whole set of frequencies of deformation vibrations, which lie below 200 cm^{-1}, the following frequencies can be distinguished: 146, 138 cm^{-1} (IR) and 149, 138 cm^{-1} (Raman). These frequencies correspond to deformation vibrations of the SeSeCl bonds in the individual Se_2Cl_2 molecule (149 and 135 cm^{-1}). Particular attention is attracted by the strong band at 215 cm^{-1} (IR) and the line at 209 cm^{-1} (Raman). The intensity of this line in the Raman spectrum sharply decreases under the action of laser light, whereas the intensities of the other lines remain unchanged (Fig. 1c). This frequency can be attributed to vibrations of the $(Se–Se)^0$ group coordinatively bound to rhodium. This group lies as a kind of dumbbell over faces of the cubane core. Relatively weakly bound μ-Se_2 fragments can be split-off under the action of laser light, with the cubane structure preserved.

The IR spectra of the products of thermal decomposition, Rh_3Se_3Cl and Rh_3Se_5Cl, are identical (Fig. 1b), but strongly differ from the IR spectra of the starting rhodium selenochlorides, $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$, which points to profound changes in the original molecular structure. The doublet at 318 and 311 cm^{-1} corresponds to vibrations of Rh–Cl and Rh–μ_3-Se^{2-}. The broad absorption band peaked at 270 cm^{-1} is associated with vibrations of the Rh–Se^{2-} and Se–Se bonds, which indicates that selenide bridges μ-Se^{2-} and "perselenide" fragments μ-Se_2^{2-} appear in the structure.

Table 1. Rh3$d_{5/2}$ XPS spectra of rhodium selenochlorides

Se3d FWHM = 1.5 eV	I of component a	I of component b	I of component c
	at E_b, eV		
	306.4	308.3	309.6
$Rh_4Se_{16}Cl_{10}$ $Rh_4Se_{18}Cl_{10}$	–	–	1.0
Rh_3Se_3Cl Rh_3Se_5Cl	–	1.0	–
Rh_3Se_5Cl/F1	0.2	0.8	–

The Rh3$d_{5/2}$ XPS spectra of the compounds $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$, Rh_3Se_3Cl and Rh_3Se_5Cl, and of Rh_3Se_5Cl on a carbon support are presented in Table 1 and Fig. 2. The spectra were analyzed by decomposition into components by the Gauss–Newton method. The Rh3$d_{5/2}$ XPS spectra of the compounds $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$ (Fig. 2a) have a single component (c) with Rh3$d_{5/2}$ E_b = 309.6 eV, which indicates that rhodium is present in the oxidation state +3. The spectra of the thermal decomposition products Rh_3Se_3Cl and Rh_3Se_5Cl (Fig. 2b) contain a single component (b) with Rh3$d_{5/2}$

Rh_3Se_5Cl				

E_b = 308.3 eV, which may be due both to a significant decrease in the number of chlorine atoms substituted by selenium and to a lowering of the oxidation state of rhodium.

The Cl$2p_{3/2}$ spectra of the starting rhodium selenochlorides (Table 2) contain two components with Cl$2p_{3/2}$ E_b 197 and 198 eV, which can be attributed, according to published data [9], to a bridging chloride atom in the polymeric structure of rhodium selenochlorides. The Se3*d* spectra of rhodium selenochlorides (Table 3) have three components, which points to three different energy states of selenium in these molecules. To the μ_3-Se^{2-} group is attributed the peak at Se3*d* E_b = 55.9 eV. This energy somewhat exceeds the corresponding value for selenides MSe with Se3*d* E_b = 53.3–54.5 eV [9] and is caused by a decrease in the amount of negative charge on the selenium atom bonded to three, rather than one, metal atoms. The component Se3*d* E_b = 56.5 eV is attributed to –Se–Se– chain fragments with zero charge and is larger than that in elementary selenium, in which Se3*d* E_b = 55.5 eV because of the complexation. The higher-lying line Se3*d* E_b = 57.0 eV must be associated with the Se_2Cl_2 molecule, in which the strong "electrophile," chlorine, makes greater the positive charge on selenium atoms, with the complexation acting in the same direction.

Selenium derivatives are characterized by formation of multinuclear complexes whose structure is based on a cubane-like core [$Rh_4(\mu_3$-Se$)_4$] [10]. The "cubane" structure [$Rh_4(\mu_3$-Se$)_4$] is due to a specific electronic structure of the selenium atom, which has free, comparatively low-lying *d*-orbitals capable of additional bonding [11]. Therefore, analysis of the vibrational and XPS spectra suggests that the structure of the compounds obtained is $Rh_4(\mu_3$-Se$)_4(\mu$-$Se_2)_3Cl_4(Se_2Cl_2)_3$ and $Rh_4(\mu_3$-Se$)_4(\mu$-$Se_2)_4Cl_4(Se_2Cl_2)_3$. The intensity ratio of the lines in the Se3*d* spectrum, 0.23 : 0.53 : 0.24, approximately corresponds to the selenium distribution among the fragments.

The Se3*d* spectra of the thermal decomposition products, Rh_3Se_3Cl and Rh_3Se_5Cl, have two components with Se3*d* E_b = 54.6 and 55.3 eV. The binding energy of 54.6 eV is typical of metal selenides. This means that the charge on selenium is close to –2e and confirms the conclusion furnished by vibrational spectroscopy, according to which the molecules of the starting selenochlorides undergo a deep transformation in thermal decomposition to give "selenide" fragments μ-Se^{2-} and μ-Se_2^{2-}. The value of 55.3 eV can be attributed to the μ_3-Se^{2-} fragment.

On heating rhodium selenochlorides, Se_2Cl_2 molecules and Se_2 "dumbbells" are eliminated and the remaining molecular structure is constituted by the μ_3-Se fragment linking three rhodium atoms, between which the fragments μ-Se and μ-Se_2 are situated. The structure of the compounds can be represented as $Rh_3(\mu_3$-Se$)(\mu$-$Se)_2Cl$ and $Rh_3(\mu_3$-Se$)(\mu$-$Se)_2(\mu$-$Se_2)Cl$.

The compositions of these compounds might indicate that rhodium is in the oxidation state +1 and μ-SE and μ-Se_2 fragments have zero charges. However, the IR and XPS spectra more likely correspond to selenide fragments μ-Se^{2-} and μ-Se_2^{2-}. In this case, rhodium retains the oxidation state +3.

A decomposition of the Rh$3d_{5/2}$ XPS spectrum of a sample synthesized in Se_2Cl_2 in the presence of a carbon support gave two lines indicating that there exist two different states of rhodium (Fig. 2c, Table 1). Presumably, the line Rh$3d_{5/2}$ E_b = 308.3 eV with the highest intensity (b) belongs to rhodium which is possibly in the oxidation state Rh^{2+} in a ligand environment of selenium and chlorine, and the low-lying weak line Rh$3d_{5/2}$ E_b = 306.4 eV is associated with Rh^0 (a), i.e., with metallic rhodium. The second line lies at somewhat lower energies, compared with Rh$3d_{5/2}$ E_b = 307.2 eV for pure metallic rhodium, which may be due to interaction of adsorbed rhodium with the carbon of the substrate. The presence of three lines in the spectrum indicates that the thermal decomposition of $Rh_4Se_{18}Cl_{10}$ in the presence of carbon

supports yields three potentially possible catalytically active centers.

Tests with various catalyst supports (SiO_2, Al_2O_3, ZrO_2, TiO_2, MgO) in synthesis of rhodium selenochlorides demonstrated that only carbon materials are stable in Se_2Cl_2.

Catalysts containing rhodium compounds on carbon supports (SKT-1 carbon: S1, S_{sp} = 700 $m^2 g^{-1}$; spherical enterosorbent: S2, S_{sp} = 1400 $m^2 g^{-1}$; and two fractions of fullerene black: F1, S_{sp} = 20 $m^2 g^{-1}$ and F2, 65 $m^2 g^{-1}$, produced by pyrolysis of styrene and a copolymer of divinylbenzene) were prepared by the following four methods. The first included impregnation of carbon supports with an aqueous solution of $RhCl_3$ and subsequent thermal decomposition at 120°C for 5 h and 320°C for 40 h (method I). The second was based on thermal decomposition of a mechanical mixture of a preliminarily synthesized $Rh_4Se_{18}Cl_{10}$ and carbon supports (method II). In the third technique, rhodium selenochloride $Rh_4Se_{18}Cl_{10}$ was synthesized on the surface of carbon supports and then subjected to thermal destruction (method III). Finally, the fourth procedure included mechanical mixing of the thermal decomposition product Rh_3Se_5Cl with carbon supports (method IV).

The thermal decomposition of samples prepared using methods II and III was carried out at 320°C for 40 h.

The data on the catalytic activity of the samples are listed in Table 4. The first set of catalysts was prepared by ordinary impregnation of carbon supports with an aqueous solution of rhodium chloride (method I). Tests of impregnated samples in oxidative carbonylation of methane revealed that CO_2 is the only reaction product.

It was found in a study of catalysts containing rhodium selenochlorides that methanol and acetic and propionic acids are formed in addition to the main reaction product, CO_2 (Table 4). A comparison of the data in Table 4 demonstrated that the activity and

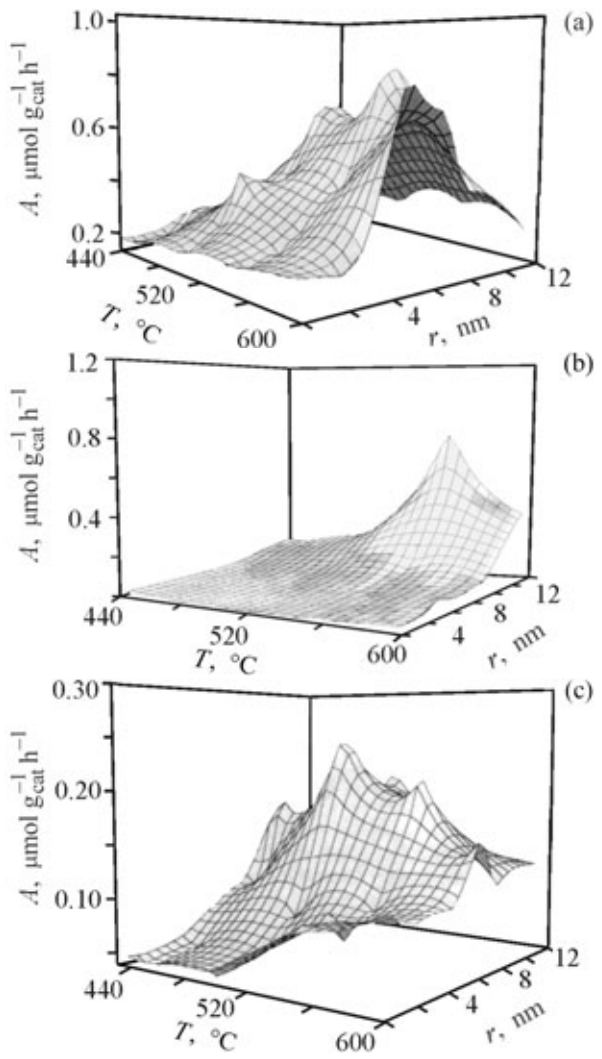

Fig. 3. Output capacity of Rh_3Se_3Cl/SiO_2 catalysts for (a) methanol, (b) ethanol, and (c) acetic acid in relation to the process temperature *T* and support pore size. (*A*) Output capacity and (*r*) pore radius.

selectivity of rhodium selenochlorides on carbon supports largely depends on the catalyst preparation technique. This result can be illustrated by the example of a catalyst deposited on an S1 support by three different methods. It can be seen from Table 4 that C_2-oxygenates are formed on the samples synthesized by methods II and IV, but the quantitative composition of the products depends on the catalyst preparation method. A higher output capacity for acetic acid (0.971 μmol $g_{cat}^{-1} h^{-1}$) is observed in the case when the support is mixed with the thermal destruction product (method IV), compared with the starting selenochloride (method II). Only ethanol is found in liquid reaction products formed on a sample synthesized by introducing a support into the starting reaction mixture $RhCl_3 \cdot 4H_2O : Se_2Cl_2 = 1 : 10$ (method III). A test in the reaction of samples prepared by method IV on other carbon supports demonstrated that acetic acid and alcohols are formed on all the catalysts, but the output capacity of the process depends on the nature of a carbon support.

Table 5. Texture characteristics of silica supports

Support	*S*, $m^2 g^{-1}$	Pore volume, $cm^3 g^{-1}$	Pore diameter, nm
KSK	270	0.76–0.93	12–15
KSS-3	520	0.920	7
KSS-4	650	0.76	5
KSS-5	500	0.71	3
ShSM	720	0.40	1.1–1.2

The data obtained show that the widest variety of reaction products (methanol, ethanol, acetic and propionic acids) is observed when the catalyst is prepared by mechanical mixing of the thermal destruction product Rh_3Se_5Cl with carbon support S2, spherical enterosorbent.

The next series of experiments was devoted to catalytic properties of rhodium selenochlorides on silica supports, synthesized by their mechanical mixing with Rh_3Se_3Cl, which is a product of thermal destruction of a cluster selenochloride $Rh_4Se_{16}Cl_{10}$, and of samples prepared by impregnation of the KSS-5 support with rhodium trichloride and its mixture with ammonium metavanadate. As supports for rhodium selenochlorides served the following silicas: KSS-5, KSS-4, KSS-3, ShSM, and KSK, which differ in specific surface area, volume, and average pore size (Table 5).

It has been shown previously that pure silica supports are inactive in oxidative carbonylation of methane carbonylation and insignificant amounts of methyl acetate (0.05–0.5 μmol $g_{cat}^{-1} h^{-1}$) are formed on samples prepared by introduction of ammonium metavanadate in template synthesis of MCM-41 mesoporous silica [8]. Only gaseous products, carbon oxides, were formed on catalysts prepared by impregnation of the supports KSS-5, KSS-4, KSS-3, ShSM, and KSK supports with a rhodium trichloride solution. Trace amounts of acetic acid (0.02 μmol $g_{cat}^{-1} h^{-1}$) were found on a catalyst synthesized by joint deposition of rhodium trichloride and ammonium metavanadate onto a KSS-5 silica, with the catalyst strongly carbonized in the course of the reaction. Methanol, ethanol, and acetic acid were formed in oxidative carbonylation of methane on samples prepared by mixing Rh_3Se_3Cl with silicas. Figure 3

shows how the output capacity of the catalysts for methanol, ethanol, and acetic acid depends on the process temperature and support pore size. As can be seen in Fig. 3a, the highest output capacity for methanol (1.5 μmol $g_{cat}^{-1} h^{-1}$) is observed on the Rh_3Se_3Cl/KSS-3 sample with a support pore size of 3 nm. Acetic acid is mostly formed on Rh_3Se_3Cl/KSS-4 and Rh_3Se_3Cl/KSS-5 samples with a pore size of 7–8 nm. As the support pore size increases to 12 nm, ethanol becomes the main liquid product of the process.

It was shown in [12] that single-stage synthesis from methane and carbon monoxide yields methanol in the presence of nitrogen(II) oxide as oxidizing agent and iron(III) phosphate as catalyst, and methyl acetate upon addition of highly dispersed Rh_2O_3 to the catalyst. A conclusion was made on the basis of these data that presence of a single active center ($FePO_4$) on the catalyst surface leads to activation of methane to give a methyl radical and, subsequently, C_1-oxygenate. Presence of a second closely lying active center (Rh_2O_3) enables carbonylation and makes it possible to obtain longer-chain C_2–C_3-oxygenates.

It was experimentally demonstrated that oxygen-containing products are formed in oxidative carbonylation of methane either on a rhodium selenochloride or in the joint presence of rhodium and vanadium oxides. The formation of acetic acid on the rhodium-vanadium catalyst can be attributed, by analogy with [12], to presence of two active centers responsible for activation of methane and its subsequent carbonylation into acetic acid. Use of rhodium selenochloride instead of rhodium and vanadium oxides can improve the output capacity for acetic acid by more than an order of magnitude. In addition, the reaction of oxidative carbonylation of methane yields ethanol and ethanol.

A detailed study of the structure of active centers of the reaction of oxidative carbonylation of methane on rhodium selenochlorides is beyond the scope of this study. The suggested structure of both the starting rhodium selenochlorides, $Rh_4(\mu_3\text{-}Se)_4(\mu\text{-}Se_2)_3Cl_4(Se_2Cl_2)_3$ and $Rh_4(\mu_3\text{-}Se)_4(\mu\text{-}Se_2)_4Cl_4(Se_2Cl_2)_3$, and products of their thermal transformations, $Rh_3(\mu_3\text{-}Se)(\mu\text{-}Se)_2Cl$ and $Rh_3(\mu_3\text{-}Se)(\mu\text{-}Se)_2(\mu\text{-}Se_2)Cl$, leads to a conclusion that the starting reagents are activated not only on rhodium atoms, but on selenium as well. The subsequent transformations of the activated complex and the qualitative composition of the reaction products strongly depend both on the nature of a support and on its texture characteristics. This makes it possible to regard nanovoids in porous silicas and carbon materials as nanoreactors whose size affects the selectivity of oxidative carbonylation of methane on rhodium selenochlorides [13]. It should be noted that none of the catalyst samples containing rhodium seleno-chlorides was carbonized in the tests, in contrast to the catalyst prepared by impregnation with rhodium trichloride and ammonium metavanadate.

CONCLUSIONS

(1) New cluster-type cubane-like rhodium selenochlorides $Rh_4Se_{16}Cl_{10}$ and $Rh_4Se_{18}Cl_{10}$ were synthesized and products of their thermal transformations, Rh_3Se_3Cl and Rh_3Se_5Cl, were obtained. An analysis of the vibrational (IR, Raman) and Rh3$d_{5/2}$, Se3d, and Cl2$p_{3/2}$ XPS spectra of these compounds suggested the following structure of the rhodium selenochlorides obtained: $Rh_4(\mu_3\text{-}Se)_4(\mu\text{-}Se_2)_3Cl_4(Se_2Cl_2)_3$ and $Rh_4(\mu_3\text{-}Se)_4(\mu\text{-}Se_2)_4Cl_4(Se_2Cl_2)_3$, based on the "cubane" core $[Rh_4(\mu_3\text{-}Se)_4]$.

(2) The catalytic properties of $Rh_4Se_{18}Cl_{10}$ and a product of its thermal destruction, Rh_3Se_5Cl, deposited on various carbon supports were studied in the reaction of oxidative carbonylation of methane. It was shown that, in contrast to samples prepared by impregnation of supports with rhodium trichloride, rhodium selenochlorides exhibit catalytic activity in carbonylation of methane. The output capacity of the process for methanol, ethanol, and acetic acid depends on the method of catalyst preparation and type of a carbon support.

(3) A study of the catalytic properties of a mechanical mixture of rhodium selenochloride Rh_3Se_3Cl and silicas with various texture characteristics demonstrated that support nanopores can be regarded as nanoreactors whose size affects the output capacity and selectivity of oxidative carbonylation of methane.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Concentration and Temperature of Eutectic Points in Glucose–Water and Saccharose–Water Systems, Determined by the Method of Fractional Melting of Ice

I. G. Chudotvortsev and O. B. Yatsenko

Voronezh State University, Voronezh, Russia

Received September 26, 2006

Abstract—Method based on fractional melting of ice was used to determine the concentration and temperature of eutectic points in aqueous systems with glucose and saccharose.

DOI: 10.1134/S1070427207020061

Presently, aqueous systems are studied at low temperatures by specialists from many fields of science and technology, with particular attention given to aqueous solutions of electrolytes. A number of models have been constructed for describing solutions of this kind. For example, changes in the solution structure near 0°C are commonly described in terms of hydration. The negative hydration of many ions is replaced by positive hydration, and the structuring effect of these ions on water becomes stronger at lower temperatures [1]. Below 0°C, a number of effects difficultly described in terms of the classical concepts of solutions are observed near eutectics. In particular, there is evidence that solutions are transformed into microheterogeneous systems under these conditions [2].

Aqueous solutions of nonelectrolytes at low temperatures have been studied to a considerably lesser extent. No general theory satisfactorily describing the structure of aqueous solutions of nonelectrolytes has been developed so far, especially for temperatures below 0°C.

Information about phase diagrams of aqueous systems of nonelectrolytes also remains incomplete. Most of data represented in reference and scientific publications refer to solutions of electrolytes, such as metal chlorides and sulfates. The published evidence concerning aqueous solutions of nonelectrolytes at temperatures below 0°C is extremely scarce.

Meanwhile, the behavior of solutions of this kind in phase transitions gives deeper insight into the structure of water at low temperatures, which is a topical scientific problem, which has not been completely resolved until now. Knowledge of phase diagrams is, in addition, necessary for solving a number of technological problems, e.g., those associated with separation and purification of components.

Determining the concentration of eutectics of complex aqueous-organic systems, such as water–glucose, by direct methods, i.e., by gradual cooling of a solution of prescribed concentration, is hindered for a number of reasons. First, solutions of organic substances are susceptible to supercooling. Second, many of these solutions show a gradually sloping run of the liquidus line with a shallow eutectic, which hinders accurate determination of the eutectic concentration.

The method of fractional melting of ice has already been applied to determine eutectics in complex aqueous systems. It has been used to determine eutectics in systems constituted by water and glycine, triglycine sulfate, thiourea, lysine, and lysine hydrochloride [3–5].

An advantage of this method is that it is based on melting of ice ingots, rather than on cooling of a solution. Consequently, this makes it possible to eliminate errors associated with the supercooling characteristic of systems with such components.

EXPERIMENTAL

The experiments were carried out with a solution of a substance under study, with a certain concentration and volume of 10 to 40 cm^3. Further, the solution in a cylindrical plastic vessel was cooled in a freezer

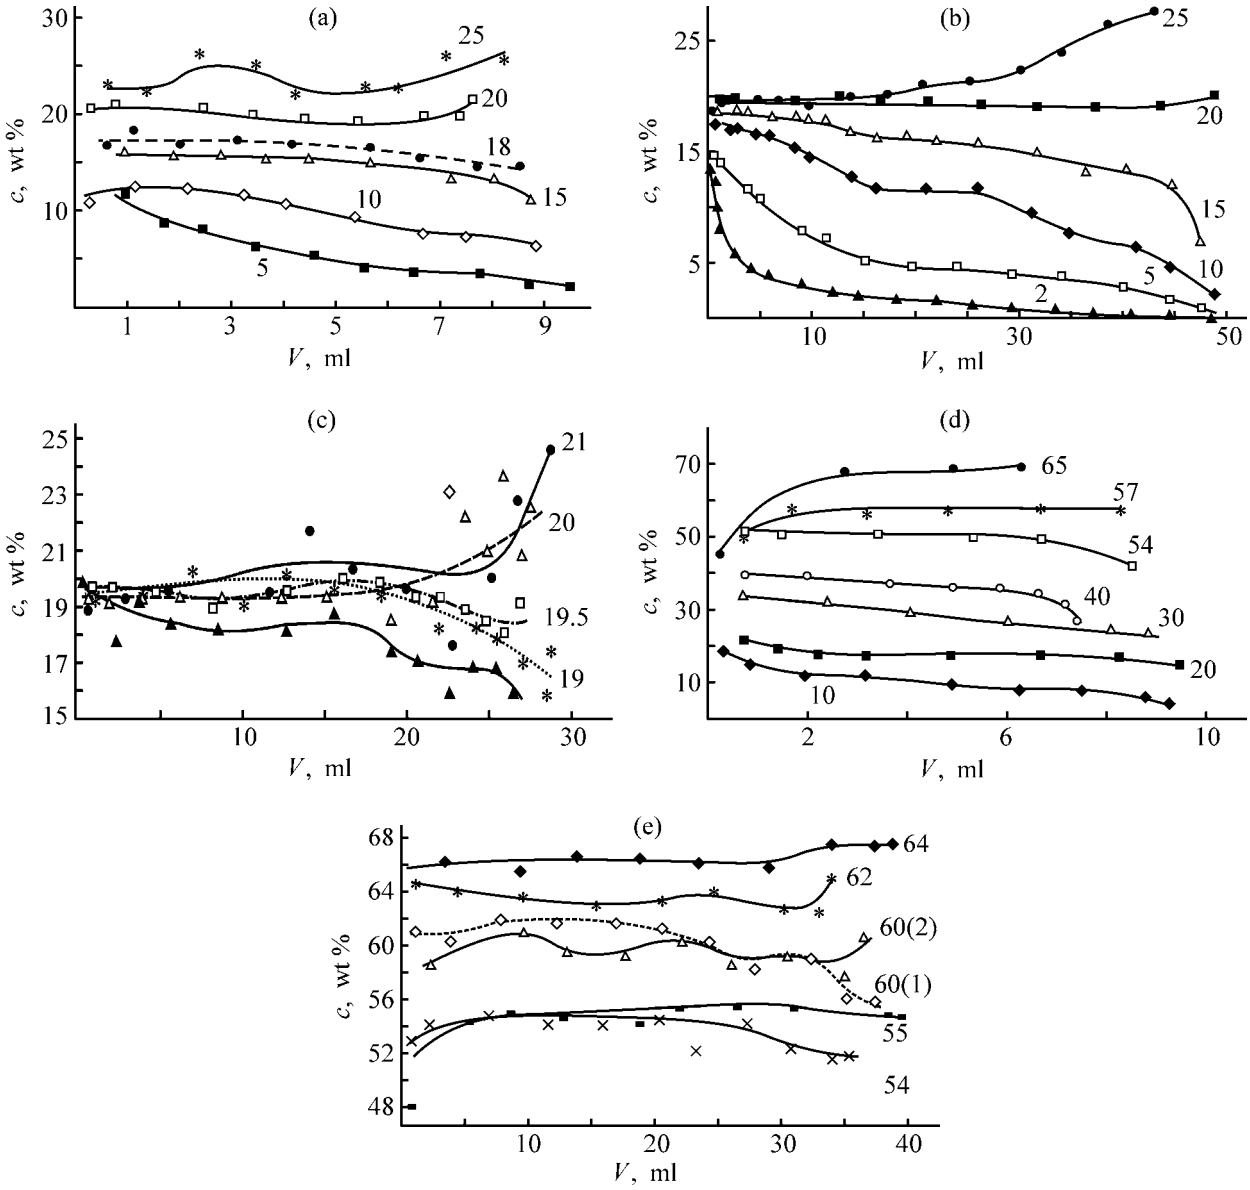

Fig. 1. Concentration c vs. melt volume V in the systems (a) glucose–water, (b) H_2O–NH_4Cl (eutectic concentration 19.6 wt %), (c) glucose–water with the volume of the starting solution equal to 30 ml, (d) saccharose–water (10 ml), and (e) saccharose–water (40 ml). Samples with concentrations of 56 and 58 wt % behave similarly to the composition with 60 wt % and, therefore, are not represented in Fig. 1e. *Digits at curves* are the concentrations (wt %) of the starting solutions from which ice was crystallized.

to –30°C and kept at this temperature for 24 h. After that, the resulting ice ingot was extracted from the freezer and melted at room temperature. As a melt was formed, it was sampled with a micropipette. The solute concentration was determined by refractometry in each of the melt fractions. The data obtained were used to plot the dependence of the substance concentration in the melt on its total volume. The volume of the fractions was varied in different experiments from 0.5 to 5.0 ml, depending on a particular task.

The greatest body of information can be obtained from the type of component distribution among melt fractions (Figs. 1a–1e). These plots show how the solute concentration varies in the course of melting of the ice crystallized from a solution of prescribed concentration.

In fractional melting of ice ingots (Fig. 1a) crystallized from solutions with a concentration of 5 wt %, the first fractions of the melt are enriched in glucose (with respect to the initial concentration). The glucose concentration in the subsequent fractions decreases. In melts formed from ingots with a higher initial concentration (10, 15, and 18 wt %), no noticeable enrichment is observed in the initial stage, with the concentration gradually decreasing. Contrariwise, the melting curve of the ingot crystallized from a solution with a concentration of 20 wt % goes up in the last fractions. The curve for a melt with a concentration of 25 % shows steps and the glucose concentration in the last fractions steeply increases. Simultaneously, growth of glucose crystals is observed, which is characteristic of supereutectic concentrations.

The general type of the component distribution in this system remains the same as that for water–salt systems (Fig. 1b).

In both cases, the most important specific feature is that the run of the dependences is not the same for super- and subeutectic concentrations. The eutectic concentration in the water–NH_4Cl system is 19.6 wt % [6]. It can be seen that, for the melting curves of ingots with concentrations of 15 wt % and lower, the content of the solute in the last fractions of the melt steeply falls. By contrast, the last fractions are enriched in the solute at a concentration of the starting solution equal to 25 wt %. The curve for 20 wt % shows a minor rise in the very last fraction. Thus, the type of the component distribution changes at the eutectic concentration. Owing to this effect, the method of fractional melting of ice can be used to determine the compositions of eutectics.

The data obtained (Figs. 1a, 1b) confirm that the processes occurring in fractional melting of ice have the same nature for electrolyte and nonelectrolyte solutions.

Analysis of the curves (Fig. 1a) suggests that concentrations of up to 18 wt % are subeutectic for the glucose–water system. The eutectic point lies within the range 18–20 wt %.

To find more precisely the position of the eutectic, an experiment with a larger melt volume (30 ml) was carried out. The results obtained are shown in Fig. 1c. It can be seen that no noticeable change in concentration is observed at the beginning of fractional melting for most of samples. For ingots crystallized from the solutions with 18 and 19 wt %, the concentration markedly decreases as the volume of melted ice becomes larger. By contrast, a pronounced rise is observed in last fractions for samples with 20 and 21 wt %. The curve for the composition with 21 wt % shows wide scatter of points, which is due to strong fluctuations of the melt composition, which are accompanied by growth of glucose crystals.

The distribution at 19.5 wt % is the closest to the eutectic distribution: the decrease in the substance content of the last fractions is less noticeable than that for 19 wt % and gives way to a rise in the last fraction.

It should be noted that the initial portions of all the curves are horizontal and lie in the range 19 and 20 wt %.

Thus, the eutectic concentration in the water–glucose system is 19.5 ± 0.5 wt %.

The results of similar experiments for the saccharose–water system are presented in Fig. 1d. As also in the case of glucose, first fractions of the melt formed in melting of ice ingots crystallized from low-concentration solutions (10 to 40 %) are enriched in the solute; as the concentration of the starting solution increases, the enrichment becomes less pronounced. By contrast, last fractions show a noticeable increase in concentration. At the same time, the concentration grows along the entire plot for the saccharose solution with an initial concentration of 65 wt %. Consequently, the eutectic point lies in the concentration range 54–65 wt %. Characteristically, the solution with 57 wt % behaves as the closest to the eutectic. Therefore, the interval between 54 and 65 wt % was chosen for further experiments with a solution volume of 40 ml.

The general pattern of component distribution for the saccharose–water system in the region close to the eutectic (Fig. 1e) is markedly different from that for the same distribution in the glucose–water system (Fig. 1c). On the one hand, solutions with concentrations of 54 wt % and (to a lesser extent) 55 wt % show a decrease in concentration in the course of melting, and the content of the substance increases in last fractions for solutions with concentrations of 62 and 64 wt %, which gives reason to identify these compositions as sub- and supereutectic, respectively.

On the other hand, all the solutions behave in approximately the same way in the range 55–62 wt %. A nonmonotonic dependence of the concentrations on the melt volume is observed, with characteristic minima and maxima.

Statistical processing of the results smoothes the run of the curves, but does not change the pattern as a whole. Both an increase and a decrease in concentration in last fractions are observed for the same con-

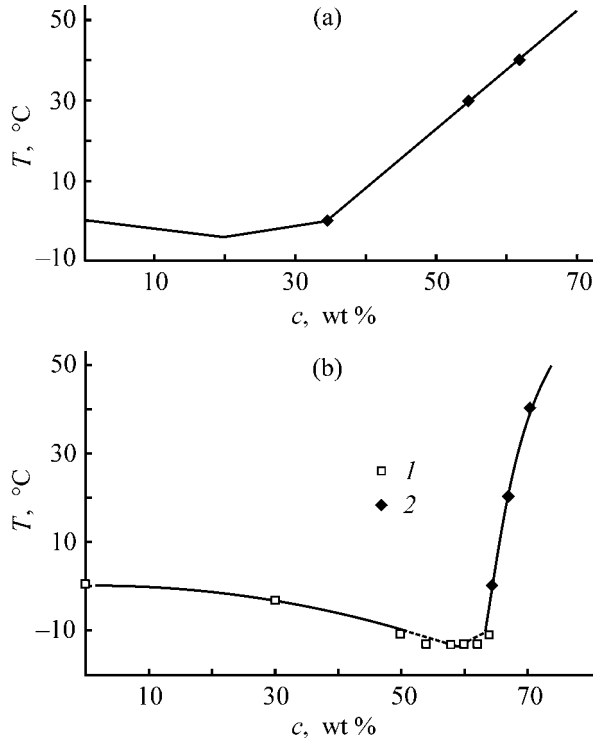

Fig. 2. Phase diagrams of the systems (a) glucose–water and (b) saccharose–water. (a) T_{eu} = –4.5°C, c_{eu} = 19.5 wt %; (b) T_{eu} = –13°C, $c_{eu} \approx$ 58.5 wt %. (*1*) Points obtained by solution cooling and (*2*) published data; the eutectic concentration was found by the fractional melting method. (*T*) Temperature and (*c*) concentration.

centrations (e.g., 60 wt %) (Fig. 1e). Thus, the lower and upper boundaries of the eutectic region could be determined: 55 and 62 wt %. The point at 58.5 wt % corresponds to the middle of this interval.

The unusual behavior of this system is also confirmed by the initial portions of the curves in Fig. 1e. For the glucose–water system (Fig. 1c), all the curves originate from a narrow interval of less than 1%, whereas for the saccharose–water system, this is not observed. The curves do not originate from any definite point, being distributed over the entire range under study. This behavior distinguishes saccharose not only from glucose, but also from other substances previously studied by the authors [3–5].

The anomalous behavior in the saccharose–water system is also confirmed by direct experiments aimed to determine the temperature of the eutectic point. In these experiments, the eutectic temperature was found by cooling a solution of prescribed concentration until the onset of its crystallization.

The composition with a concentration of 19.5 wt % was studied in this way in the glucose–water system. The eutectic temperature was found to be –4.5°C.

The saccharose–water system was examined not only at a concentration of 58.5 wt %, determined to be eutectic, but over the entire range under study. It was found that crystallization in the range 54–62 wt % onsets at the same temperature (–13°C). This certainly may be due to the susceptibility of this system to supercooling. At the same time, the fact that the results obtained in determining the concentration distribution in the melt in fractional melting (Fig. 1e) and in experiments aimed to find the eutectic temperature coincide may indicate that there is an "anomalous" region in the phase diagram of the saccharose–water system, e.g., a nearly horizontal fragment of the liquidus line near the eutectic.

It should also be mentioned in this context that, according to some data [7], aqueous saccharose solutions tend to pass to the glassy state at high concentrations.

The phase diagrams of the systems glucose–water and saccharose–water are shown in Figs. 2a, 2b. The solubilities of the substances in the supereutectic region were taken from the literature [6], and the eutectic points were found in the experiments described above. For the saccharose–water system, the portion near the eutectic is plotted as a dashed line, because the run of the equilibrium liquidus line in the vicinity of the eutectic point is ambiguous.

CONCLUSIONS

(1) It was shown that the processes occurring in crystallization and melting of ice have a common nature for aqueous solutions of electrolytes and nonelectrolytes.

The method of fractional melting of ice was used to determine the temperatures and concentrations of eutectics in the systems under study: glucose–water (c_{eu} = 19.5 wt %, T_{eu} = –4.5°C) and saccharose–water (c_{eu} = 58.5 wt %, T_{eu} = –13°C).

(2) An anomalous behavior near the eutectic point was observed in the saccharose–water system: solutions with concentrations of 55–62% behave identically both in fractional melting of ice and in cooling of a solution until the onset of crystallization. At the same time, the component distribution in the saccharose–water system at other concentrations is similar to that for the rest of the systems studied.

(3) It was demonstrated that the advantage of the method of fractional melting of ice consists in

that it can avoid errors associated with solution supercooling.

Abstract—Phase diagrams in ternary liquid systems hexane–*o*-xylene–DMF were studied at 298.15–333.15 K. Critical points in these systems were determined. The fullerene C_{60} distribution in the ternary liquid systems with constant and variable compositions of two organic phases was studied at variable fullerene concentration.

DOI: 10.1134/S1070427207020073

Extraction separation and purification of fullerenes (primarily C_{60} and C_{70}) prior to their chromatographic isolation is a topical problem [1–5].

Experimental data on the fullerene distribution in liquid–liquid systems with phase separation are very limited and often contradictory. Generally, data are available only for binary systems constituted by fullerene (C_{60} or C_{70}) and a solvent [aromatic (benzene, toluene, *o*-xylene, 1,2-dichlorobenzene) or nonaromatic (CCl_4, hexane)] [6–13], but not on the mutual solubility of two different fullerenes in one solvent or of an individual fullerene in a mixed solvent, except for data reported in [1–5]. Some of the systems investigated contained water as a component of the system, with complicates the extraction because of the long time of phase separation or limitations on the solubility of fullerenes in liquid phases [1–5].

Data on the phase diagrams in the ternary liquid system hexane–*o*-xylene–DMF at various temperatures as well as on the fullerene distribution between two liquid phases of different compositions are lacking in the literature. Since these data are practically significant, we examined in this study the extraction of fullerenes in multicomponent liquid systems with phase separation.

EXPERIMENTAL

In the experiments, we used solvents of analytically pure grade: hexane ($\rho_{298.15}$ = 0.6548 g cm^{-3}), *o*-xylene ($\rho_{298.15}$ = 0.8760 g cm^{-3}), and DMF ($\rho_{298.15}$ = 0.9440 g cm^{-3}). The binodal curves for the ternary systems were constructed using Alekseev's visual polythermal method [14]. The component concentrations in the coexisting phases were determined with gas chromatographs Model 3700 (Khromatograph, Moscow) and LKhM-8MD (carrier gas N_2, Chromaton N-AW-DMCS, stationary phase PEG-6000).

The compositions of the coexisting phases in volume percent were converted to weight fractions, taking into account the solution densities. The binodal curves were approximated by third- or fourth-order polynomials. The phase diagrams of the ternary liquid system were constructed using the second-type Roseboom triangle (Figs. 1 and 2). The orthogonal coordinates represent the weight fractions of two components of the ternary system (for the third component, $\omega_3 = 1 - \omega_1 - \omega_2$). The weight fractions of the components were determined to within 0.001–0.002, and the temperature, to within 0.2 K.

We used fullerene C_{60} of 99.8% purity. The content of fullerene in the coexisting phases was determined spectrophotometrically on an SF-16 instrument with 1-cm quartz cells [15]. To study the fullerene distribution between two organic phases, a 1–2 g l^{-1} stock fullerene solution in *o*-xylene was introduced into the hexane–DMF binary solvent at various component ratios. The total time of mixing, phase separation, and thermostating was 15–30 min, the time of phase separation being within 3 min. In separate experiments,

homogeneous fullerene solutions in *o*-xylene–DMF mixtures of various compositions were obtained and then contacted with various volumes of hexane.

The hexane–*o*-xylene and DMF–*o*-xylene binary mixtures form homogeneous solutions, while the hexane–DMF binary mixtures form a liquid two-phase system over the entire experimental temperature range from 298.15 to 333.15 K (Fig. 1). At $T < 340.9$ K (bp of hexane), we failed to determine the upper critical temperature of mixing for the DMF–hexane binary system. Further increase in temperature results in evaporation of hexane from the liquid phase, rather then in homogenization in the binary system.

The hexane–*o*-xylene–DMF ternary system has a region of homogeneous liquid solutions (*B*) and a two-phase region (*A*) bounded by a binodal curve at a given temperature (Fig. 1). The area of region *A* is minimal at 298.15 K. Analysis of the nodes in the ternary liquid systems at various temperatures, e.g., at 298.15 K (Fig. 2) shows that, in region A, one of the coexisting phases is enriched in DMF at fairly close concentrations of *o*-xylene and hexane (phase I), and the other is enriched in hexane at fairly close concentrations of DMF and *o*-xylene (phase II). At the critical points, the DMF and *o*-xylene concentrations are also close, being, however, considerably lower than the hexane concentration. For example, at 298.15 K, the composition of the system corresponding to the critical point is as follows (weight fractions): DMF 0.19, *o*-xylene 0.22, and hexane 0.59.

Figure 3 shows the isotherm of the C_{60} distribution between phases I and II at the following compositions (weight fractions): phase I (Fig. 2, node 5): DMF 0.276, *o*-xylene 0.266, and hexane 0.542.; phase II: DMF 0.076, *o*-xylene 0.070, and hexane 0.886. The extraction isotherm was obtained at a constant volume ratio of the three liquid components at various fullerene concentrations in the starting *o*-xylene solution. The extraction isotherm is virtually linear (Fig. 3). The distribution coefficient is independent of the fullerene concentration in both phases, being equal to 0.88 ± 0.02. Figure 3 shows also the distribution of C_{60} between phases I and II along different nodes (see Fig. 2, nodes *2*–*5*). The fullerene concentrations in these phases were determined by treating the solutions of C_{60} in *o*-xylene–DMF mixtures with various volumes of hexane. The resulting values are fairly close to those obtained in studying the fullerene distribution at a constant phase composition. The mean distribution coefficient was estimated to be 0.97 ± 0.11. Therefore, regardless of the composition of the coexisting phases, the mean distribution coefficient of

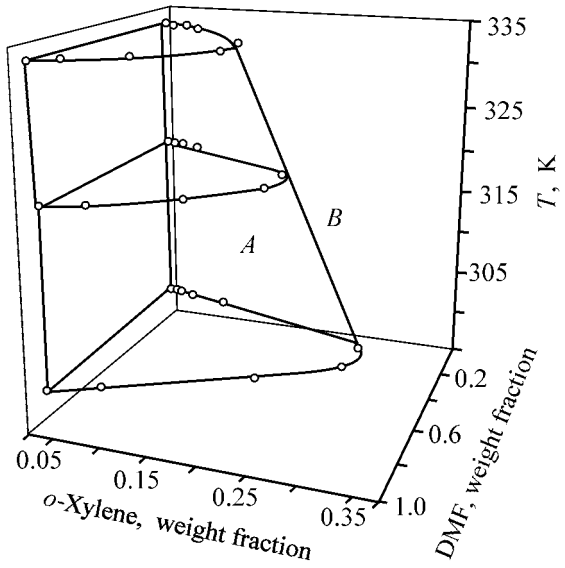

Fig. 1. Phase diagram of the ternary system hexane–DMF–*o*-xylene at various temperatures. (*T*) Temperature, (*A*) region of heterogeneity and (*B*) region of homogeneity; the same for Fig. 2.

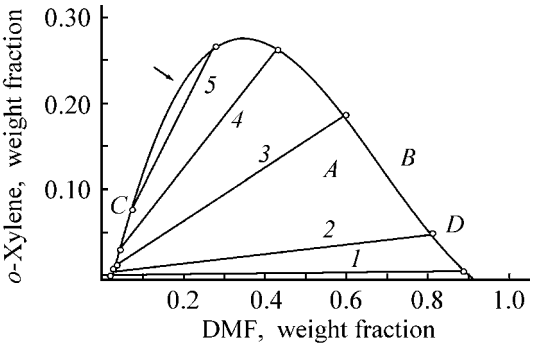

Fig. 2. Section of the phase diagram at 298.15 K. (*1*–*5*) Nodes and (*CD*) binodal curve; the arrow indicates the critical point.

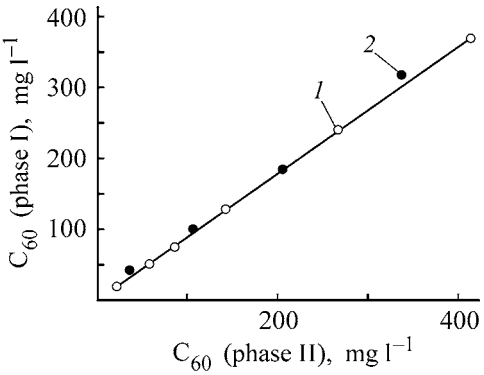

Fig. 3. Fullerene C_{60} distribution between phases I and II. Phases I and II are enriched in DMF and hexane, respectively. Composition of the coexisting phases: (*1*) corresponds to node *5* in Fig. 2 and (*2*) variable; corresponds to nodes *2*–*5* in Fig. 2.

C_{60} is about 0.92, which is close to the statistical distribution. The extraction system investigated makes it possible to work with fullerene concentration in both phases of up to 500 mg l^{-1}.

CONCLUSIONS

(1) The hexane–dimethylformamide binary system has limitations on the mutual solubility of the components. An increase in temperature from 298.15 to 333.15 K has no significant effect on the mutual solubility.

(2) The phase diagram of the ternary liquid system hexane–dimethylformamide–*o*-xylene consists of the region of homogeneous solutions and the region of two-phase liquid systems (systems with phase separation). One of the coexisting phases (I) is enriched in dimethylformamide at fairly close concentrations of *o*-xylene and hexane, and the other (II), in hexane at fairly close concentrations of dimethylformamide and *o*-xylene. The two-phase region is minimal at 298.15 K. The critical points of the system are determined.

(3) The distribution of fullerene C_{60} is considered at its various concentrations in the ternary liquid system, using the section with constant composition of the coexisting phases and sections with variable phase composition. The extraction isotherm of fullerene C_{60} is virtually linear under the experimental conditions, and the mean distribution coefficient of C_{60} between the two liquid phases is about 0.92.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Concentration Dependence of the Boiling Point of Binary Equidistant Solutions

A. N. Marinichev

St. Petersburg State University, St. Petersburg, Russia

Received December 26, 2006

Abstract—A concentration dependence of the boiling point of binary equidistant mixtures in isobaric conditions was revealed. The dependence is a solution to a second-order inhomogeneous difference equation describing the autoregression properties of solutions.

DOI: 10.1134/S1070427207020085

Binary solutions of volatile organic substances whose concentrations (e.g., in mole fractions of one of their components) are arranged in increasing order, with the same constant increment, form the so-called equidistant series. For example, a series of this kind is constituted by a set of concentrations of eleven mole fractions of a component x of the mixture: 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, and 1. If values of an experimentally measured property (e.g., boiling point T, composition of the vapor phase, density, refractive index) are known for each concentration, ordered data of this kind can be named equidistant. A similar situation occurs in analysis of, e.g., boiling points of substances that form homologous series (alkanes, alkenes-1, alkyl arenes, etc.). It was shown in [1] that the boiling points of such series are well described by a first-order difference equation

$$T(n + 1) = aT(n) + b. \quad (1)$$

Here a and b are constants whose values are found by processing an array of equidistant data by the least-squares method; n are numbers of homologues in an equidistant series or the number of carbon atoms, or the number of some structural fragments, which varies along the series.

A large body of ebulliometric equidistant binary data can be found in the literature devoted to phase equilibria: the reference book [2] contains such experimental data for more than 60 systems. The reference book [3] presents in the equidistant form for a number of systems verified data obtained in processing of experimental information by finding parameters of the concentration dependence of the activity coefficients on the basis of an appropriate interpolation equation (mostly these are one-, two-, or three-parameter Redlich–Kister equations), with or without account of the nonideality of the vapor phase. If equidistant data on boiling points are available, the possibility of their description by various-order difference equations can be analyzed. It should be noted here that equations of type (1) cannot, as a rule, be used to derive satisfactory concentration dependences, because deviations of calculated values from those found experimentally markedly exceed the errors in determining the boiling points.

Below, we discuss equidistant isobaric data on boiling points of binary systems, presented on the centigrade scale with an accuracy, as a rule, as good as tenths of a degree, both with a monotonic run of the boiling points and with azeotropes corresponding to the minimum and(or) minimum of the boiling point. As the basic relation we take the following second-order difference equation

$$T(n + 2) = aT(n) + bT(n + 1) + c, \quad (2)$$

where $n = 10x + 1$; a, b, and c constants found by the least-squares method.

Relation (2) is known in the literature [4] as the Yule–Walker equation; it was used for the first time in spectral analysis. At the same time, this equation apparently characterizes an autoregression in which each term of the equidistant series (beginning from the third term), figuratively speaking, possesses "memory" about two nearest preceding terms, with the contributions of these latter determined by "weighting" coefficients a and b.

We illustrate finding the coefficients of Eq. (2) by equidistant data for the methanol–*N*,*N*-dimethyloxyethylamine system [2] with a monotonic variation of the boiling point: 134.2, 112.9, 102.2, 94.9, 88.8, 83.3, 78.4, 74.4, 70.7, 67, 64.6. Let us construct an array of nine sets, each containing three nearest values $\{T_i, T_{i+1}, T_{i+2}\}$, i = 1, ..., 9. The values of the autoregression coefficients and their standard deviations calculated by the least-squares method are found to be: $a = -0.20 \pm 0.06$, $b = 1.11 \pm 0.06$, and $c = 4.0 \pm 1.1$. It is noteworthy that, in this case, the coefficient of determination (designated as $r2$ in Excel electronic tables, and just these tables were used in the calculations) was found to be rather large: $r2$ = 0.9995, which points that the data are very well correlated by Eq. (2).. Further, we find the roots Z_1 and Z_2 of the quadratic equation $Z^2 = a + bZ$ (Z_1 = 0.8811 and Z_2 = 0.2275), calculate the so-called basis functions of the type Z_j^n (j = 1 and 2), and write the solution to Eq. (2) as

$$T_{\text{calc}}(n) = C_0 + C_1 Z_1^n + C_2 Z_2^n. \quad (3)$$

To find the parameters C_0, C_1, and C_2 (as least-squares estimates relative to the values of the basis functions), we used the entire array of boiling temperatures (for n 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11). This equation can also be represented as a linear combination of two exponential functions of the molar fraction x of methanol, with a free term C_0:

$$T_{\text{calc}}(x) = C_0 + C_1 \exp(-k_1 x) + C_2 \exp(-k_2 x),$$

where $k_1 = -(1/10)\ln Z_1$, $k_2 = -(1/10)\ln Z_2$ are parameters in the exponents.

It should be noted that the calculated boiling points of pure components can be found from the last equation at x = 0 and x = 1 to be, respectively, $C_0 + C_1 + C_2$ and $C_0 + C_1 \exp(-k_1) + C_2 \exp(-k_2)$. At the same time, the free term C_0 is related to the autoregression parameters a, b, and c by the expression $C_0 = c/(1 - a - b)$. If, thus, the boiling points of the pure components are known, we have three linear equations with three unknowns C_0, C_1, and C_2, which makes an alternative way of their calculation. In addition, the calculated values of the parameters can be used to find the azeotrope composition x_{az} by the formula

$$x_{\text{az}} = \frac{\ln\left(-\dfrac{k_2 C_2}{k_1 C_1}\right)}{k_2 - k_1}. \quad (4)$$

Finally, we obtain, after simple rearrangements, the equation

$$T_{\text{calc}}(x) = 43.42 + 74.88 \exp(-1.266x) + 15.9 \exp(-14.8x). \quad (5)$$

The free term C_0 was calculated from the autoregression parameters to be 43.76, which is quite acceptable with account of the temperature determination error (±0.5°C) in the system under study. The expression under the logarithm sign in Eq. (4) is negative, which confirms the absence of an azeotrope in the system under discussion.

For the azeotropic case (with a minimum of the boiling point), we consider data on boiling points for the system constituted by methanoic acid and butyl methanoate [2]: 107, 105.85, 104.7, 103.6, 102.55, 101.5, 100.55, 99.7, 99.1, 99.1, 100.8. For these data, the coefficient $r2$ found with Eq. (2) is 0.9993. After similar calculations, the final result is represented by the following equation:

$$T_{\text{calc}}(x) = 66.31 + 40.692 \exp(-0.2905x) + 0.000144 \exp(10.25x). \quad (6)$$

The boiling point and the azeotrope composition can be readily found from Eqs. (4) and (6) to be 98.97°C and 0.853 (mole fraction of the acid). For solutions with molar fractions of the acid equal to 0.05 and 0.95, the calculated boiling points of 106.41 and 99.62°C are very close to those found experimentally: 106.4 and 99.55°C, respectively.

Let us consider the binary system constituted by methanol and 2-methyl butadiene-1,3 [2], which also shows a minimum of the boiling point: 34.1, 31.6, 30.6, 30.5, 30.6, 31, 31.7, 34.1, 37.6, 44.7, 64.7. It was found, when determining the autoregression coefficients, that $r2$ = 0.990. On performing calculations similar to those described above, we have

$$T_{\text{calc}}(x) = 30.73 + 0.0059 \exp(8.658x) + 13.342 \exp(-13.83x). \quad (7)$$

The boiling point and the azeotrope composition calculated by Eqs. (4) and (7) are 30.86°C and 0.303 (mole fraction of methanol). It can be readily seen that the calculated boiling point of the azeotrope is not equal to the minimum boiling point, but coincides with it within the determination error.

The system constituted by propenic acid and methyl-3-methyloxypropanoate [2] has an azeotrope with a maximum of the boiling point. Data on boiling points of pure components (with x = 0 and x = 1) are unavailable. Let us use data on the boiling points:

Calculated values of $T_{calc} - T$ for each solution composition (x, mole fraction of the first component) and the average value $|\overline{T_{calc} - T}|$, found by Eqs. (5)–(12)

144.6, 146, 146.9, 147.5, 147.8, 147.5, 147, 146, 144.3 for the following nine solutions: 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9. It was found, when determining the autoregression parameters, that $r2 = 0.985$, and the following equation was obtained for the calculated boiling point:

$$T_{calc}(x) = 150.82 - 0.2105\exp(3.721x) - 8.028\exp(-3.033x). \quad (8)$$

According to Eq. (8), the azeotrope corresponding to the maximum temperature boils at 147.7°C and has a molar fraction of the acid equal to 0.535 [with Eq. (5), this value is 0.509 and corresponds to a boiling point of 149.2°C]. Such a strong difference between the azeotrope compositions and the corresponding boiling points is probably due to errors in the experimental data. The boiling points of pure components, calculated by Eq. (8) for $x = 0$ and $x = 1$, are 142.6 and 141.7°C, respectively.

Let us consider the extent to which availability or lack of data on the boiling points of pure components affects the accuracy of prediction of the boiling points (K) and azeotropic properties. This will be done for the example of verified equidistant data on boiling points (K): 354.03, 352.46, 351.36, 350.61, 350.15, 349.94, 349.96, 350.22, 350.77, 351.72, 353.25, in the azeotropic system constituted by benzene and 2,2,3-trimethyl butane [3]. For this system, the boiling points are known to within hundredths of a degree. The dependence of type (2) for the data set including the boiling points of the pure substances has $r2 = 0.99992$. The final equation, which is a solution to the corresponding difference equation, can be represented as

$$T_{calc}(x) = 348.21 + 0.083\exp(4.066x) + 5.735\exp(-3.299x). \quad (9)$$

If we disregard the boiling points of the pure substances, the equation of type (2) is characterized by a value $r2 = 0.9998$ and the concentration dependence is described by an equation similar to (8):

$$T_{calc}(x) = 348.10 + 0.098\exp(3.913x) + 5.828\exp(-3.253x). \quad (10)$$

The exclusion of the information about pure components from the data set being processed somewhat improves the agreement between the calculation and the experiment: the boiling point found for benzene by Eq. (4) is 353.22 K (experimental value 353.25 K), and that for 2,2,3-trimethyl butane, 354.03 K (354.03 K). For the binary azeotrope, the calculated boiling point and mole fraction of pyridine are 349.921 K and 0.547 for Eq. (9) and 349.917 K and 0.545 for Eq. (10). Apparently, it is difficult to give preference to one of these equations for data with so small error in temperatures (hundredths of a degree).

The results obtained in calculating the boiling points for the systems under discussion by Eqs. (5)–(10) are presented in the form of the differences $T_{calc} - T$ for each solution composition x (see table). The average absolute values of these differences demonstrate

a good agreement between the experimental and calculated data. Equations (4)–(10) can also be used for interpolation purposes, i.e., for calculation of boiling points at any intermediate value of x and for prediction of azeotropes.

In processing of equidistant data by the method under discussion, the value of $r2$ is important in calculation of the autoregression parameters. If $r2 < 0.9$ for some set of data (with a complex concentration dependence of the boiling point in the presence of, e.g., several azeotropes), it can be stated that an equation of type (2) should not be used for these data. In this case, it may be appropriate to use a third-order difference equation. In the examples presented above, the roots of the quadratic equation were real and positive. If, however, one of the real roots is negative, the corresponding term in the dependence $T_{calc}(x)$ will contain a factor $(-1)^x$, and the calculated values may be complex. If the roots of the quadratic equation are complex-conjugate, i.e., $Z_{1,2} = u \pm vI$ (I is imaginary unity), then Eq. (3) can be written as follows [5]:

$$T_{calc}(n) = C_0 + \rho^n[C_1 \cos(\varphi n) + C_2 \sin(\varphi n)], \quad (11)$$

where $\rho^2 = (u^2 + v^2)$ is squared modulus, and $\varphi = \arccos(u/\rho)$, argument of the complex root. Then the basis functions for making least-square estimates of the parameters C_0, C_1, and C_2 are products of the exponential function ρ^n by the appropriate trigonometric function. This actually exhausts all the possible variants of solutions to the second-order difference equation of type (2), because the case of multiple roots seems to be exceedingly improbable in practice.

Let us consider as an example of application of Eq. (11) equidistant data on boiling points (°C) in the benzene–perfluorobenzene system, selected from an array corresponding to normal pressure [2]: 79.06, 80.34, 80.46, 80.4, 80.21, 79.95, 79.7, 79.51, 79.44, 79.54, 79.94. This system has two azeotropes: with a minimum and a maximum of the boiling point. In determining the autoregression coefficients, it was found that $r2 = 0.977$. As expected, the roots of the quadratic equation were complex-conjugated, and, therefore, the calculation equation (11) took, on making appropriate rearrangements, the following form:

$$T_{calc}(x) = 79.993 - \exp(-0.2842x) \times [0.030\cos(6.39x) - 0.590\sin(6.39x)]. \quad (12)$$

Both the azeotropes found using (12) had the following compositions (in mole fractions of benzene) and the corresponding boiling points: 0.247 and 80.48°C, and 0.738 and 79.45°C. The experimental values for these azeotropes were as follows: 0.240 and 80.45°C, 0.8168 and 79.35°C. The results of the calculations are listed, and compared with the experiment, in the table.

Abstract—Theoretical and correlation equations for calculation of multicomponent systems were considered in terms of a previously developed theory of ion–ion interactions in steady- and nonsteady-state processes for the example of ammonium sulfate-nitrate solutions formed from effluent gases of thermal power plants.

DOI: 10.1134/S1070427207020097

Effluent gases of thermal power plants contain a significant amount of sulfur dioxide (~7 g m^{-3}) and nitrogen oxides (~1.5 g m^{-3}), which are discharged into the atmosphere and contaminate air, soil, and water basins. Previously a new technology for manufacture of ammonium sulfate–nitrate (ASN) fertilizers from these contaminants has been developed [1–3]. The technology includes introduction of gaseous ammonia, electron-beam processing of dusty effluent gases, absorption of the forming SO_3 and NO_2 by water, concentration of ASN solutions, evaporation, and granulation.

Development of new technologies and choice of the optimal ways of utilization of industrial waste require that thermodynamics, kinetics, and various physicochemical parameters should be known. The technology suggested requires particularly reliable and authentic data on physicochemical properties of concentrated solutions of inorganic substances.

The theory of interparticle interactions in steady-state processes in concentrated electrolyte solutions [4] and some implications of this theory [5] were used to suggest methods for determination of physicochemical parameters of multicomponent systems. The following properties of the solutions were analyzed: density, specific heat, thermal conductivity, water vapor pressure over solution, activity of water, surface tension, dynamic viscosity coefficient, electrical conductivity, and boiling and freezing points.

The present study is devoted to analysis of the physicochemical properties of solutions of multicomponent systems based on $(NH_4)_2SO_4$ and NH_4NO_3, with minor additions of NH_4HSO_3, NH_4HSO_4, $(NH_4)_2SO_3$, and NH_4NO_2. The concentrations of the components in solutions was varied from 10 to 70 wt % at an $(NH_4)_2SO_4/NH_4NO_3$ ratio equal to 4 and temperatures of 25–80°C.

The density of a multicomponent solution was calculated by the formula

$$\rho = \rho_0 + \sum_{i=1}^{h} c_i (A_{1i} + A_{2i} t + A_{3i} c_i), \qquad (1)$$

where ρ is the solution density (kg m^{-3}); ρ_0, water density (kg m^{-3}); h, number of solution components; c, electrolyte concentration (wt %); t, temperature (°C); and A_{ij}, coefficients found by processing by methods of regression analysis of the authors' own data and those published in the literature for a large number of electrolytes [5]. The values of these coefficients for the components of the ASN solution are listed in Table 1.

The density of water (kg m^{-3}) on the saturation line at 0–150°C was calculated with a relative error of 4.8×10^{-3}% by the formula

$$\rho_0 = 999.810745 + R_1 t^* + R_2 t_*^{1.5} + R_3 t_*^2 + R_4 t_*^{2.5} + R_5 t_*^3 + R_6 t_*^{3.5} + R_7 t_*^4 + R_8 t_*^{4.5}, \quad (2)$$

where $t^* = 0.01t$, $R_1 = 15.910174$, $R_2 = -73.840671$, $R_3 = 141.693443$, $R_4 = -297.162815$, $R_5 = 160.758796$, $1R_6 = 146.727674$, $R_7 = -194.580793$, $R_8 = 58.847919$.

The results obtained in calculating the density of the ASN solution are listed in Table 2.

The specific heat of the multicomponent solution, C_p (J kg^{-1} K^{-1}) can be calculated by the formula

$$C_p = C_{p0} + \sum_{i=1}^{k} (B_{1i} + B_{2i} c_i + B_{3i} t + B_{4i} t^2) c_i. \quad (3)$$

Here, C_{p0} is the specific heat of water (J kg^{-1} K^{-1}); $\tilde{c}_i$, concentration of ith component in a binary isopiestic solution (wt %); t, temperature (°C); c_i, concentration of ith component in the multicomponent solution (wt %); k, number of the solution components; and B_{ni}, coefficients found by processing by methods of regression analysis of the authors' own data and those published in the literature for a large number of electrolytes [6, 7]. The values of these coefficients for the components of the ASN solution are listed in Table 3.

The specific heat of water (J kg^{-1} K^{-1}) on the saturation line at 0°C ≤ t < 40°C was calculated with a root-mean-square and average relative calculation errors of 3.95 J kg^{-1} K^{-1} and 0.035%, respectively, by the formula

$$C_{p0} = 4.21703 - 0.068372 t_*^{0.5} - 0.193808 t_*^{1.5} + 0.340252 t_*^2, \quad (4)$$

where $t_* = 0.01t$.

In the temperature range 40°C ≤ t < 250°C, the specific heat of water was found by the formula

$$C_{p0} = 4.178232 - 0.200822 t_*^{2.5} + 0.551896 t_*^{1.3} - 0.435824 t_*^{3.5} + 0.123167 t_*^4. \quad (5)$$

The value of $\tilde{c}_i$ was calculated as

$$\tilde{c}_i = E_i^{-1} \sum_{j=1}^{k} E_j c_i. \quad (6)$$

Here E_i is a coefficient characterizing the vapor pressure over solution, which can be found from the dependence [5, 7]:

$$E_i = (1 - a_w^s) c_i^s, \quad (7)$$

where a_w^s and c_i^s are, respectively, the activity of water and the mass fraction of a saturated solution of a separate component of the system under consideration at a given temperature.

30	0.569	0.576	0.590	0.602	0.613	0.621	0.627

The results obtained in calculating the specific heat of the ASN solution are listed in Table 4.

The thermal conductivity of multicomponent electrolyte solutions was calculated by the formula

$$\lambda = \lambda_0\left(1 + \sum_{i=1}^{k}\beta_i c_i\right). \quad (8)$$

Here, λ is the thermal conductivity of the solution (W m^{-1} K^{-1}); λ_0, thermal conductivity of water (W m^{-1} K^{-1}); c_i, concentration of ith component in the multicomponent solution (wt %); k, number of solution components; and β_i, coefficients found by processing by methods of regression analysis the authors' own data and those published in the literature for a large number of electrolytes [8]. The values of these coefficients for the components of the ASN solution are listed in Table 5.

The thermal conductivity of water on the saturation line at temperatures of 0 to 135°C was approximated with a root-mean-square calculation error S_λ = 0.29 W m^{-1} K^{-1} and average relative calculation error Δ = 0.03% with the polynomial

$$\lambda_0 = 10^{-3}(L_0 + L_1T^* + L_2T_*^{1.5} + L_3T_*^{2.5} + L_4T_*^3), \quad (9)$$

where L_0 = 560.971778, L_1 = 178.153112, L_2 = 59.731618, L_3 = –245.008302, L_4 = 124.973313, T^* = 0.01t, and t is temperature (°C).

The results of calculation of the thermal conductivity of an ASN solution are listed in Table 6.

The water vapor pressure (Pa) over a multicomponent electrolyte solution was calculated by the equation

$$P = P_0\exp\left(2.3026\sum_{i=1}^{k} m_i P_i^*\right), \quad (10)$$

where P_0 is the water vapor pressure over pure water (Pa); m_i, mass concentration of the electrolyte in

the solution (mol kg^{-1}); k, number of solution components; and P_i^*, correction for the decrease in the water vapor pressure over the multicomponent electrolyte solution.

The water vapor pressure over pure water on the saturation line is calculated with root-mean-square and average relative errors of 39.54 Pa and 0.006% by the formula

$$P_0 = P_c \exp B. \quad (11)$$

Here, P_c is the critical pressure equal to 2.2064×10^7 Pa and B is given by

$$B = T_c A/T, \quad (12)$$

where T_c is the critical temperature equal to 647.14; T, temperature (K); and A is found from the following dependence at temperature of 0 to 100°C:

$$A = A_0 + A_1 T_*^{1.5} + A_2 T_*^3 + A_3 T_*^{3.5}, \quad (13)$$

$A_0 = -0.595684$, $A_1 = -11.039345$, $A_2 = 17.449275$, $A_3 = -16.028445$,

$$T^* = 1 - T/T_c. \quad (14)$$

The value of P_i^* in Eq. (10) was found using the formula

$$P_i^* = W_{0i} + W_{1i} t_i + W_{2i} m_i + W_{3i} t_i^2 + W_{4i} t_i m_i + W_{5i} t_i^2 m_i, \quad (15)$$

where the coefficients W_{ji} are found by processing by methods of regression analysis of the authors' own data and those published in the literature for a large number of electrolytes [5]. The values of these coefficients for the components of the ASN solution are listed in Table 7.

The results obtained by calculating the water vapor pressure over an ASN solution are listed in Table 8.

The activity of water can be calculated by theoretical and semiempirical equations reported in [4, 5], where various calculation examples were demonstrated. In view of the limited volume of the present communication, the following formula can be recommended in the given case

$$a_w = \exp(2.3026 \sum_{i=1}^{k} m_i P_i^*). \quad (16)$$

Table 9. Activity a_w of water over an ASN solution

$(NH_4)_2SO_4$	15.434	0.744	12.29	0.0	0–50	20–90	3.54	1.72

The results obtained by calculating the activity of water over the ASN solution are listed in Table 9.

The surface tension of a multicomponent solution can be calculated by the formula [8]:

$$\sigma = \sigma_0 + 0.049(1 - a_w), \quad (17)$$

where σ is the surface tension of the multicomponent electrolyte solution (N m^{-1}); σ_0, surface tension of water (N m^{-1}); and a_w, activity of water in the multicomponent solution.

The surface tension was calculated with high accuracy for the entire range of existence of water from the data of [9]:

$$\sigma_0 = B\left(\frac{T_0 - T}{T_0}\right)^m \left[1 + b\left(\frac{T_0 - T}{T_0}\right)\right], \quad (18)$$

where $B = 235.6 \times 10^{-3}$, $T_0 = 647.15$, $m = 1.256$ $b = -0.625$.

The results of calculation of the surface tension of ASN solutions are listed in Table 10.

The dynamic viscosity coefficient η (Pa s) of a multicomponent solution was calculated by the formula

$$\eta = \eta_0 \exp V, \quad (19)$$

$$V = \sum_{i=1}^{k} c_i(A_{0i} + A_{1i}t + A_{2i}c_i + A_{3i}t^2),$$

where η_0 is the dynamic viscosity coefficient of water (Pa s); k, number of electrolyte components in the solution; c_i, mass fraction of ith component in the multicomponent solution (%); t, temperature (°C); and A_{ij}, found by processing by methods of regression analysis of the authors' own data and those published in the literature for a large number of electrolytes [10, 11]. The values of these coefficients for the components of the ASN solution are listed in Table 11.

The viscosity of water, η_0 (Pa s), on the saturation line in the temperature range 0–350°C was calcu-

lated with root-mean-square and average relative calculation errors of, respectively, 1.19 (Pa s) and 0.07% in the temperature interval 0–200°C by the formula

$$\eta_0 = S_0 + S_1 t + S_2/t + S_3 \exp(-0.1t) + S_4/t^2 + S_5\sqrt{t} + S_6 \ln t, \quad (20)$$

where S_0 = 4496.839782, S_1 = –4.644252, S_2 = –7025.494506, S_3 = –159.419139, S_4 = 4104.442382, S_5 = 316.705387, and S_6 = –1486.934219.

The results of a calculation of the dynamic viscosity coefficient of ASN solutions are listed in Table 12.

The electrical conductivity Λ (S cm^2 mol^{-1}) of a multicomponent electrolyte solution can be calculated using the following theoretical equation [4–6]:

$$\Lambda = \frac{1}{c_{kg}} \sum_{i=1}^{k} \nu_i c_{ki} [\Lambda_i (1 - L_i) + K_{1i} c_{ki}^2]. \quad (21)$$

Here, c_{kg} is the total molar concentration of the equivalent of the solution components (g-equiv dm^{-3}); k, number of electrolyte components in the solution; ν_i, number of like charges of the electrolyte molecule; c_{ki}, molar concentration of each electrolyte component (mol dm^{-3}); Λ_i^0, limiting molar electrical conductivity of each component of the multicomponent solution in water (S cm^2 mol^{-1}); L_i, parameter of ith component in the solution; and K_{1i}, correction factor for ith component of the solution [4, 5].

In turn, Λ_i^0 was found using the formula

$$\Lambda_i^0 = \lambda_i^0 + \lambda_j^0, \quad (22)$$

where λ_i^0 and λ_j^0 are the limiting electrical conductivities of cations and anions in water (S cm^2 mol^{-1}).

The limiting molar electrical conductivities of cations and anions in water were calculated using expressions reported in [5].

The parameter L_i was found using the equation

$$L_i = V_{0i} + V_{1i} t + V_{2i} c_{ki} + V_{3i} t c_{ki} + V_{4i} (t c_{ki})^2 + V_{5i} c_{ki}^{0.7} + V_{6i} c_{ki}^{0.7} + V_{7i} (t c_{ki})^{0.5}, \quad (23)$$

where t is temperature (°C), and V_{ij} are coefficients found by processing by methods of regression analysis of the authors' own data and those published in the literature for a large number of electrolytes [5].

The correction factor K_{1i} was determined by the formula [5]:

$$K_1 = -3.161 \times 10^{17} \frac{(\nu_k z_i)^2 \alpha_a}{\eta_0 \varepsilon (\varepsilon T)^3 (6 - \alpha_a^2)}, \quad (24)$$

where ν_k is the number of ions in the electrolyte molecule; z_i, cation charge; α_a, theoretical parameter [4, 6]; η_0, viscosity of water (Pa s); ε, dielectric constant; and T, temperature (K).

The value of α_a was found using the expression derived in [4]:

$$\alpha_a = \sinh(\beta/a), \quad (25)$$

where β is calculated by the formula

$$\beta = \frac{1.6718 \times 10^{-3} |z_i z_j|}{\varepsilon T}. \quad (26)$$

The value of ε can be calculated with a standard deviation of 0.33 in ε units by the equation [12]:

$$\varepsilon = 1 + (a_1/T^*)\rho + (a_2/T^* + a_3 + a_4 T^*)\rho_*^2 + (a_5/T^* + a_6 T^* + a_7 T_*^2)\rho_*^3 + (a_8/T_*^2 + a_9/T^* + a_{10})\rho_*^4, \quad (27)$$

where

$$T^* = T/298.15, \ \rho^* = \rho_0/1000, \quad (28)$$

and ρ_0 is the density of water (kg m^{-3}).

Table 13. Electrical conductivity Λ of ASN solutions

c, wt %	Λ, S cm^2 mol^{-1}, at indicated temperature, °C						
	25	30	40	50	60	70	80
10	32.81	35.92	42.14	48.47	54.98	61.74	68.78
20	31.13	33.96	39.59	45.27	51.10	57.12	63.38
30	29.36	31.93	37.04	42.17	47.43	52.87	58.52
40	27.69	30.04	34.70	39.39	44.20	49.18	54.37
50	26.15	28.31	32.59	36.91	41.36	45.99	50.82
60	24.74	26.74	30.70	34.72	38.88	43.21	47.75

The coefficients a_i have the following values: a_1 = 7.62571, a_2 = 244.003, a_3 = –140.569, a_4 = 27.7841, a_5 = –96.2805, a_6 = 41.7909, a_7 = –10.2099, a_8 = –45.2059, a_9 = 84.6395, a_{10} = –35.8644.

Equation (27) is applicable under the following conditions: temperature 273.15–823.15 K, density 0–1150 kg m^{-3}, pressure 0–500 MPa. The value of a in Eq. (25) is found by the formula

$$a = \chi_f(a_i + a_j), \quad (29)$$

where χ_f = 1 for electrolytes of the symmetric type and χ_f = 2 for those of the asymmetric type, and distances from the ion center to the oxygen of water for ions in solution and the effective radii of polyatomic ions a_i and a_j (nm) can be found in [5].

The results of calculation of the electrical conductivity of ASN solutions are listed in Table 13.

The boiling point T_b (K) of a multicomponent solution can be calculated with an accuracy acceptable for practical purposes by the modified formula [5]:

$$T_b = 500.2238/[(24.6536 + \ln a_w)^{1/2} - 3.6249], \quad (30)$$

$$0 < t < 215°C, \; S_{T_b} = 0.6 \text{ K},$$

where S_{T_b} is the root-mean-square calculation error (K).

Equation (30) is solved by the method of iterations. First a_w (0.99) is set and T_b is calculated. This value of T_b is used to find a_w, using formulas (10)–(16) or some others. Then, T_b is again calculated [calculation of the vapor pressure over solution with the use of coefficients in formulas (13) and (15) allows a slight extrapolation beyond 100°C]. The number of iterations is 2. Making this number larger impairs the calculation accuracy. Instead of calculating a_w, it is possible to use its experimental values reported in [13] at temperatures below 100°C for many tens of electrolytes, with the activity of water at T_b found by means of a linear approximation. The results of calculation of the boiling points of ASN solutions are presented below (°C):

c, wt %	10	20	30	40	50	60
T_b, °C	100.86	101.97	103.28	105.16	107.97	112.42

The freezing temperature of a multicomponent solution, T_f (K) is commonly found in the entire range of activities of water, using the equation [5]:

$$T_f = \frac{555.316}{2.76375 - \sqrt{\ln a_w^{(25)} + 0.53398}}, \quad (31)$$

where $\ln a_w^{(25)}$ is the activity of water over solution at 25°C.

The applicability of formula (31) is limited by the lower bound of the interval $|\ln a_w^{(25)}| < 0.53398$, because the expression within the square root should be positive.

The results of calculation of the freezing point of ASN solutions are presented below (°C):

c, wt %	10	20	30	40	50
T_f, °C	–2.58	–5.95	–10.54	–17.19	–27.79

The whole set of the physicochemical studies performed enabled optimal consideration of heat-and-mass exchange processes in the technology for manufacture of a complex integrated fertilizer based on ammonium sulfate and nitrate with microelements from effluent gases discharged by thermal power plants.

CONCLUSIONS

(1) The previously developed theory of ion–ion interactions in steady- and nonsteady-state processes in concentrated electrolyte solutions was used to derive new equations for calculation of physicochemical properties of multicomponent systems of electrolyte

solutions: density, specific heat, thermal conductivity, water vapor pressure over solution, activity of water, surface tension, dynamic viscosity coefficient, boiling and freezing points, and electrical conductivity.

(2) New correlation equations were suggested for determining the density of water, specific heat, thermal conductivity, water vapor pressure over solution, dynamic viscosity of water on the saturation line in a wide range of temperatures and pressures. These equations provide the minimum calculation errors.

(3) The physicochemical properties of ammonium sulfate-nitrate solutions were calculated for a mass fraction of the components equal to 10–70% in the temperature range 25–80°C. This made it possible to recommend the equations under consideration for determining these properties for other multicomponent systems of electrolytes as well.

(4) The set of the physicochemical studies performed enabled optimal consideration of heat-and-mass exchange processes that occur in manufacture of a complex integrated fertilizer based on ammonium sulfate and nitrate with addition of microelements from effluent gases of thermal power plants.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Temperature Dependence of the Diffusion Coefficient of Copper(II) Chloride in Porous-Glass Membranes

V. N. Pak and E. S. Stromova

Hertzen Russian State Pedagogical University, St. Petersburg, Russia

Received October 23, 2006

Abstract—Diffusion transport of a 0.5 M aqueous solution of $CuCl_2$ was studied in a set of porous-glass membranes with predominant pore radii of 4.5 to 70 nm in the temperature range 25–70°C. Raising the temperature causes a rise in diffusion coefficients and their gradual equalization, which eliminates their dimension dependence on the radius of membrane channels.

DOI: 10.1134/S1070427207020103

It is well known that the diffusion coefficients D of many substances, which characterize transport of their aqueous solutions across finely porous hydrophilic membranes, are lower than the values for free solutions [1, 2]. The hindrance to diffusion mobility, created by the effect of the surface, must be the stronger, the narrower the cross-section of transport channels. A quantitative verification of this concept is possible, but requires experiments with a number of membranes of the same chemical nature, with structural parameters that are variable and can be rather precisely set. This is possible in the case of porous glasses produced by acid etching of liquated glasses of the sodium–borosilicate system, followed by alkaline etching [3–5]. It has been found previously [6–10] that, in a number of cases, the dimension dependence of the diffusion coefficient on the pore radius in porous-glass membranes has the form

$$D = D_\infty \exp(-K_w r^{-1}), \quad (1)$$

where D_∞ corresponds to a free solution (at $r \to \infty$), and K_w characterizes the effective thickness of the near-wall structured solution layer with a limited diffusion.

If relation (1) is steadily satisfied, prospects arise for use of the dimension parameter K_w as a characteristic of the structuring effect of the silica surface on boundary layers of aqueous solutions of a wide variety of compounds. In addition, determining the temperature dependence of the parameter K_w can give a rather reliable notion of the thermal stability of the structure of thin water layers modified by the silica surface [6]. However, information on diffusion in porous glasses [11–14], and especially on its dimension and temperature dependences, is available only for a limited number of systems [6–10]. To supplement and refine this information, we studied the effect of temperature on the diffusion mobility of $CuCl_2$ in a number of porous glasses with effective pore radii in the range 4.5–70 nm. The possibility of direct photometric determination of Cu^{2+} cations in aqueous solutions and the negligible amount of their sorption by the silica surface in an acid medium [15] markedly facilitate the formulation and solution of the problem and make it possible to distinguish the membrane pore radius and temperature as the principal factors responsible for the value of the diffusion coefficient.

EXPERIMENTAL

Porous-glass membranes were prepared in the form of thin (1 mm) discs of diameter 25 mm. The pore radii r_p and the porosity δ of porous glasses were set by preliminary thermal treatment and by the conditions of the subsequent acid-alkaline etching of a DV-1M sodium-borosilicate glass [3–5]:

r_p, nm	4.5	6.5	10	19	25	30	38	45	70
δ, $cm^3\ cm^{-3}$	0.313	0.345	0.436	0.389	0.512	0.480	0.429	0.313	0.569

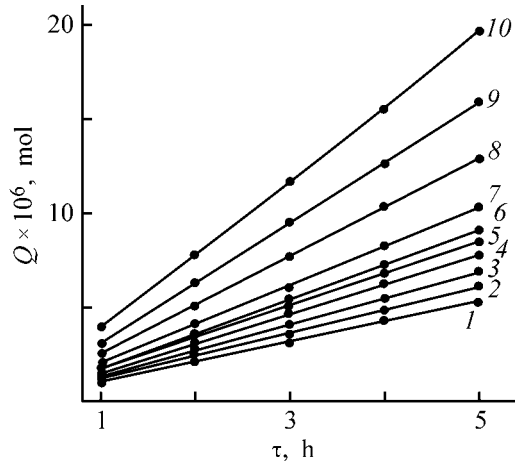

Fig. 1. Amount Q of $CuCl_2$ transferred across a membrane with a pore radius of 38 nm vs. time τ. Experimental temperature T (°C): (*1*) 25, (*2*) 30, (*3*) 35, (*4*) 40, (*5*) 45, (*6*) 50, (*7*) 55, (*8*) 60, (*9*) 65, and (*10*) 70; the same for Fig. 4.

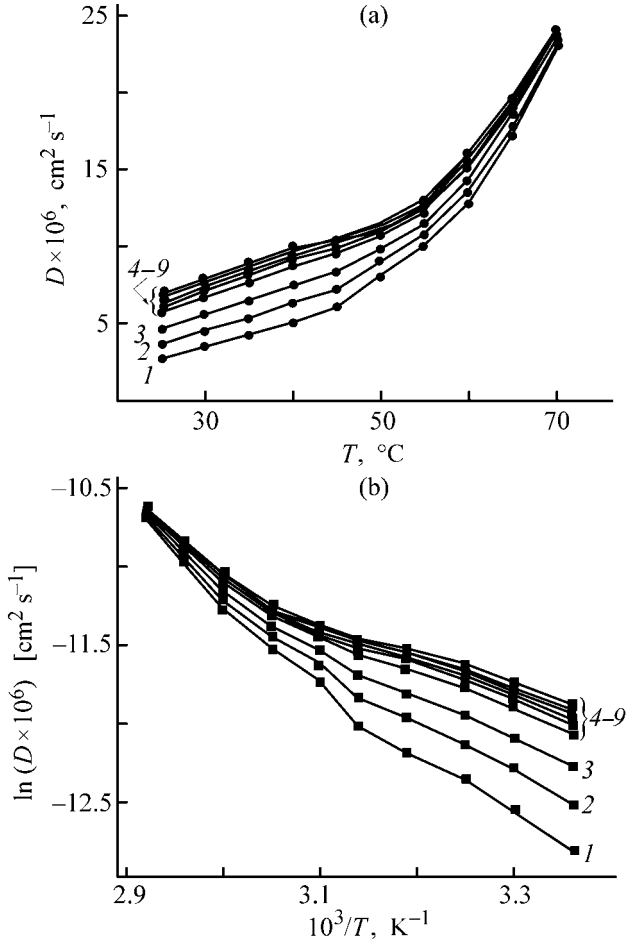

Fig. 2. (a) Dependence of the diffusion coefficient D of $CuCl_2$ in porous-glass membranes on temperature T and (b) the same dependence plotted in the Arrhenius coordinates. Membrane channel radius r_p (nm): (*1*) 4.5, (*2*) 6.5, (*3*) 10, (*4*) 19, (*5*) 25, (*6*) 30, (*7*) 38, (*8*) 45, and (*9*) 70.

As in our previous studies [6–10], we examined the diffusion by fixing membranes between two cells, one of which (receiver) was filled with twice-distilled water, and the other (feeder), with a 0.5 M aqueous solution of $CuCl_2$. The dynamics of the diffusion transport was judged from the results of a direct photometric determination of aqua complexes of Cu^{2+} (λ_{max} = 800 nm, ε = 11.32 mol cm^{-1} l^{-1}). The experiments were carried out with permanent agitation of the system and thermostating of the system in the temperature range 25–70°C. The time in which a steady diffusion flow across the membranes was attained depended on temperature and pore structure parameters of porous glasses. However, a linear time dependence of the amount of the salt, Q, that passed across the membranes was recorded in all cases after 1 h. In calculations of the diffusion coefficient D, the concentration gradient was taken to be

$$\Delta c/h = (c_{in} - c_{out})/h - c_{in}/h, \quad (2)$$

where h = 1 mm is the membrane thickness, and c_{in} = 0.5 M is the concentration of the $CuCl_2$ solution before the membrane, which markedly exceeds, in all cases, the running concentration c_{out} of the solution in the receiving cell.

In the case of a steady-state process, we considered justified application of the first Fick law, according to which the diffusion flux was represented as

$$dQ/d\tau = DS\delta c_{in}/h, \quad (3)$$

with the free cross-section of the membrane taken equal to its geometric area S, with a correction for the porosity δ.

Selected experimental results demonstrating the steady state of the process and the general, on the whole, type and extent of the influence exerted by temperature on the rate of the diffusion transport of $CuCl_2$ are shown in Fig. 1 for a porous glass with a pore radius r_p = 38 nm. The temperature dependences of the diffusion coefficient in a set of membranes, calculated using these and similar data, are shown in Fig. 2a. The most pronounced decrease in the salt mobility, which characterizes the hindrance to diffusion in the near-boundary layer of the pore solution [6–10], is observed in pores with small radius $r_p \le 20$ nm and is reliably recorded at moderate experimental temperatures. The "rigidity" of the network of hydrogen bonds in the near-wall water, imposed by the silica surface, diminishes, on the whole, the mobilities of pore solution components by hindering the diffusion transport of the salt. We believe that,

in the given case, we can reliably conclude that the structural constituent of forces, specifically, hydrogen bonds exerts a dominating influence on the rate of the membrane transport. As for the increase in the diffusion coefficients with temperature, it is accompanied by their progressive convergence to become virtually coinciding, with $D = (2.35 \pm 0.05) \times 10^{-5}$ cm^2 s^{-1} at 70°C.

The dependences obtained (Fig. 2a) characterize the activation of the thermal mobility of the pore solution, which overcomes the structuring effect of the membrane channel walls. The disintegration of the boundary layers of the solution is, thus, complete as a temperature of approximately 70°C is reached. This agrees with the known concept [1, 16, 17] that, near this temperature, the properties of water in narrow pores of silica cease to be different from those of the bulk liquid.

It should be noted that the D–T dependences are not linearized in the Arrhenius equation coordinates (Fig. 2b). This is a reflection of the pronounced structural and energetic inhomogeneity of the pore solution, preserved up to a temperature of 70°C, at which the properties of the solution in the membranes are completely equalized, irrespective of the size of transport channels. Nevertheless, the run of the $\ln D$–T^{-1} dependences clearly demonstrates that the energy expenditure substantially increases in the course of a gradual thermal disintegration of the near-wall layers of the solution. This can be additionally confirmed by estimating the conditional activation energies E^* of diffusion, with the gently and steeply sloping portions of the $\ln D$–T^{-1} dependences approximated by straight lines. The results presented in Fig. 3 clearly demonstrate both a significant rise in E^* in the range of disintegration of the near-wall layers of the solution and a general enhancement of the hindrance to diffusion in small-radius pores.

The dependences of the diffusion coefficient of $CuCl_2$ on the pore radius of porous-glass membranes are shown in the explicit form in Fig. 4a. The fact that the experimental data are described by Eq. (1) suggested in this study is confirmed by the clearly pronounced linearity of their plots in the $\ln D$–$1/r_p$ coordinates in the entire temperature range 25–70°C (Fig. 4b). The thus revealed "dimensional" behavior of D on the whole corresponds to the generally exponential type of the dependence of the structural forces on the boundary layer thickness [1, 16, 17].

The asymptotics of Eq. (1) reflects the physically justified conditions: $D \to D_\infty$ at $r_p \to \infty$ and $D \to 0$ at $r_p \to 0$ and shows that the rule $D = 0.368D_\infty$

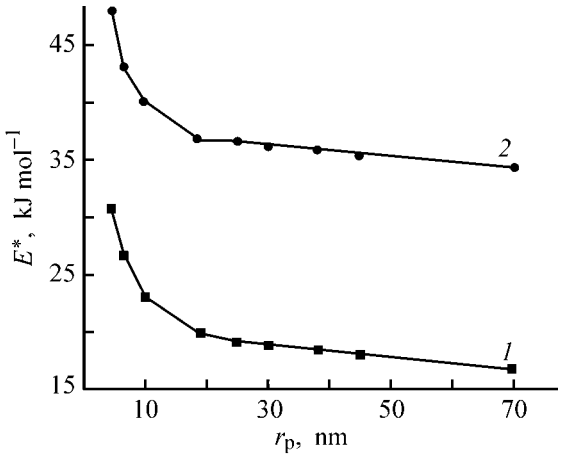

Fig. 3. Activation energy E^* of diffusion vs. the membrane channel radius r_p on (*1*) gently and (*2*) steeply sloping portions of the $\ln D$–T^{-1} dependence.

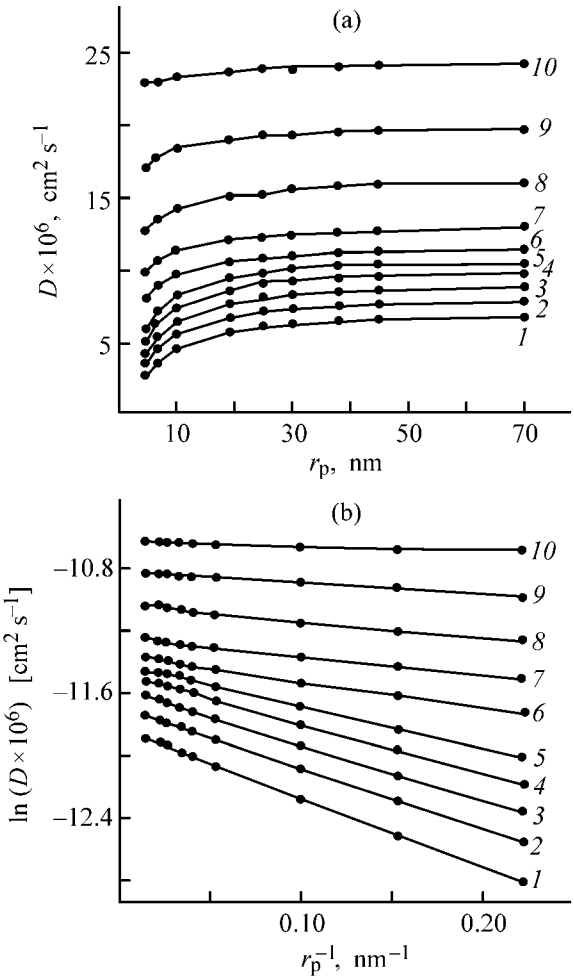

Fig. 4. Dependence of the diffusion coefficient D of $CuCl_2$ in porous-glass membranes on the transport channel radius r_p and (b) its linearization in the coordinates of Eq. (1).

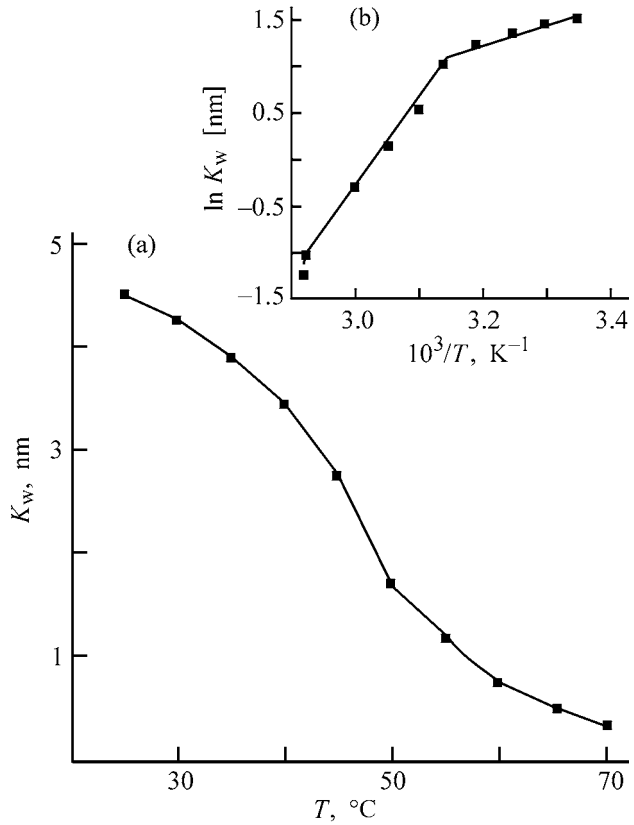

Fig. 5. (a) Dependence of the dimension parameter K_w on temperature T and (b) linearization of its two portions.

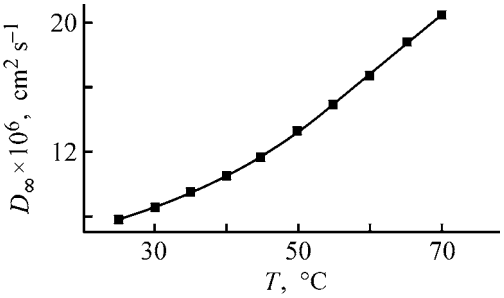

Fig. 6. Limiting diffusion coefficient D_∞ vs. temperature T.

is satisfied at $r_p = K_w$, i.e., the "long-range-action" parameter of the surface is numerically equal to the pore radius of the glass membrane in which the diffusion coefficient of the solute is approximately 2.7 times smaller than its value in a free solution. Processing of the isotherms obtained (Fig. 4b) gives values of K_w and D_∞. The temperature dependence of K_w (Fig. 5) in fact characterizes the rate of thermal disintegration of the boundary layer of the pore solution. As in the D–T case, two portions can be distinguished in the K_w–T curve, and these portions are satisfactorily linearized in the coordinates of the Arrhenius equation. The relative values of the calculated activation energies $E_1^* = 19.6$ kJ mol^{-1} and $E_2^* = 77.0$ kJ mol^{-1} indicate that thermal disordering of the peripheral region of the pore solution, subject to a weak influence of the silica surface, proceeds easily, whereas disintegration of its part adjacent to the membrane channel walls is strongly hindered.

The values of D_∞ estimated by extrapolation are, as a rule, close to the diffusion coefficients in free solutions [6–10]. Thus, the results obtained when measuring the rate of membrane transport in a set of porous glasses give a knowledge of both the diffusion coefficient D of $CuCl_2$ in water, which cannot be found in the literature, and its temperature dependence (Fig. 6). An estimate of the activation energy of diffusion, based on the data of Fig. 6, gives a value $E^* = 19.2$ kJ mol^{-1}, which virtually coincides with that found for the peripheral part of the pore solution in a porous glass with $r_p = 70$ nm. This is in an agreement with the fact that the room-temperature diffusion coefficients are close: the value $D = 6.9 \times 10^{-6}$ cm^2 s^{-1} is 91% of $D_\infty = 7.6 \times 10^{-6}$ cm^2 s^{-1} for a membrane with as channel radius of 70 nm. Thus, there is reason to believe that the structuring of an aqueous solution of $CuCl_2$ in a porous glass exponentially decays away from the surface and its influence extends to boundary layers of thickness of about 70 nm.

CONCLUSIONS

(1) A reduction in the channel radius of porous glasses from 70 to 4.5 nm is accompanied by a substantial decrease in the diffusion coefficient of copper(II) chloride in its membrane transport. The general run of the D–r_p dependences is consistent with the concept that there exists a near-wall layer of the pore solution, with a limited diffusion mobility.

(2) The activation of the thermal mobility of a $CuCl_2$ solution in silica membranes on raising the temperature of the experiment to 70°C leads to total disintegration of the boundary layer, with the structuring effect of the surface on the diffusion transport of the salt eliminated.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Optical Properties of a Perfluorosulfonic Membrane Modified with Co^{2+} Cations

E. N. Brazhnikova and V. N. Pak

Hertzen Russian State Pedagogical University, St. Petersburg, Russia

Received December 8, 2006

Abstract—A perfluorosulfonic membrane was modified with Co^{2+} cations. A comparative study of the thermal stabilities of the starting (hydrogen) and cobalt(II)-containing forms of the membrane was carried out. Optical electronic spectroscopy was used to characterize color transformations accompanying sorption–desorption of water by the modified membrane.

DOI: 10.1134/S1070427207020115

Perfluorosulfomic membranes (PFSM) belong to a special type of porous fluorocarbon polymers containing grafted sulfo groups. In accordance with the existing concepts [1–3], a continuous system of spherical voids about 4 nm in diameter, connected by narrow channels with a diameter of approximately 1 nm, is formed in the PFSM skeleton constituted by fluorocarbon and ether chains. In turn, the functional sulfo groups with protons (or cations) neutralizing their charge are situated on void walls and provide the hydrophilicity of the membranes. The high transparency, accessibility of the pore space, and clearly pronounced cation-exchange capacity predetermine the possibility of directed modification of PFSM to impart necessary optical properties to these membranes. For example, studies have been carried out of luminescent and spectral properties of a number of complex compounds of transition and rare-earth metals [4–6], uranyl ion [7], and dyes [8] fixed in PFS membranes by the ion-exchange mechanism. Proceeding with these investigations, we tested whether a system for visual monitoring of humidity can be created on the basis of a PFSM modified with Co^{2+} ions.

EXPERIMENTAL

MF-4SK membranes of domestic manufacture, with a thickness of 0.25 mm and linear dimensions of 1×3 cm, were cleaned by boiling in concentrated nitric acid for 2–3 h, with the subsequent thorough washing with distilled water to zero reaction to NO_3^- ions. The content of accessible sulfo groups was determined as follows [6]: membranes of known mass were submerged in an aqueous NaOH solution for 24 h to provide complete substitution of protons of the sulfo groups by sodium cations, and then the alkali was titrated with hydrochloric acid and $[-SO_3H]$ was found from the difference of its concentrations before and after contact with PFSM. The membranes were modified at a fixed s : 1 ratio by keeping samples with a mass of about 0.1 g in 10 ml of aqueous $Co(NO_3)_2$ solutions with a concentration of 0.1 to 3.5 M for 24 h, with the subsequent thorough washing with distilled water. The content of irreversibly sorbed Co^{2+} cations was determined gravimetrically on drying the starting and modified PFSM to constant weight at 120°C. It is important to note that incomplete removal of the weakly retained form of Co^{2+} and, the more so, of residual amounts of the impregnating solution from the pore space led to formation of cobalt oxide particles in heating of the membranes, which diminished or completely eliminated the characteristic optical properties. The adsorption of water by pure and modified membranes was controlled at relative vapor pressures in the range $p/p_0 = 0.1–0.8$ by the desiccator method with the use of sulfuric acid solutions. The optical absorption of the membranes in the visible spectral range was recorded on an SF-56 spectrometer.

The content of sulfo groups in the membrane was, according to the results of titration, $[-SO_3H] = 0.84$ mmol g^{-1}. The ion-exchange modification of PFSM samples with Co^{2+} cations under the conditions specified above occurred on the background of their considerable molar excess (12- to 420-fold) over sulfo groups of the membranes. It is all the more characteristic that the content of irreversibly sorbed cobalt

was found to be independent of the solution concentration and was $[Co^{2+}] = 0.22 \pm 0.04$ mmol g^{-1} in all cases. This result suggests that the electrically neutral sorbed form $(–SO_3)_2Co$, in whose formation is involved approximately 0.44 mmol g^{-1} of sulfo groups of the membrane, i.e., about 52% of their total content, is firmly fixed and water-stable. In this case, the remaining 48% of functional groups are "single" because of the nonuniformity of their distribution in the support voids, and the salt-type exchange form $(–SO_3)Co(NO_3)$, produced with their participation is hydrolytically unstable and is removed in membrane washing.

The replacement of protons in a considerable part of sulfo groups in PFSM with Co^{2+} cations leads to a noticeable suppression of water adsorption in the whole range of pressures (Fig. 1). Thus, hydration of fixed cations to give $=Co(H_2O)_n$ aqua complexes can compensate to an only insignificant extent for the loss of the adsorption activity, caused by substitution of sulfo groups in the membrane. In addition, the modification of PFSM results in a substantial decrease in the pore volume V_p from 0.20 to 0.15 cm^3 g^{-1}. Relating the quantity ΔV_p to the content of cobalt in the membrane makes it possible to estimate the effective volume occupied by a hydrated cation by $\Delta V_p/[Co^{2+}]N_A = 0.38$ nm^3 (N_A is the Avogadro number), which gives in the spherical model approximation a reasonable value of the cation radius $r = 0.45$ nm.

It is important to note that, despite the contraction of the internal space, modification of the membrane strongly improves its thermal stability. For example, it has been found [6] that, in the case of a hydrogen form of PFSM, irreversible changes of the pore structure begin even at a temperature of 100–105°C. Figure 2 shows as an example the results demonstrating the decrease dynamics of V_p to a residual value of 0.1 cm^3 g^{-1} in the course of heating of a pure membrane in air at 120°C. It is not improbable that, in this case, there occurs irreversible condensation of sulfo groups, the most probable at places of narrowing of the hydrophilic voids of PFSM:

$$2(–SO_3H) \rightarrow –\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}–O–\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}– + H_2O. \qquad (1)$$

In the case of a membrane modified with Co^{2+} cations, the contraction of the pore volume occurs at temperatures higher than 200°C and is observed only upon a prolonged thermal treatment (Fig. 3); for example, short (for 10–15 min) treatments even at 250°C are not accompanied by any recordable change in the pore space. The most probable reasons for the improvement of the thermal stability of the porous structure are the firm fixation and valence saturation of cobalt(II) in the grafted aqua complexes, which

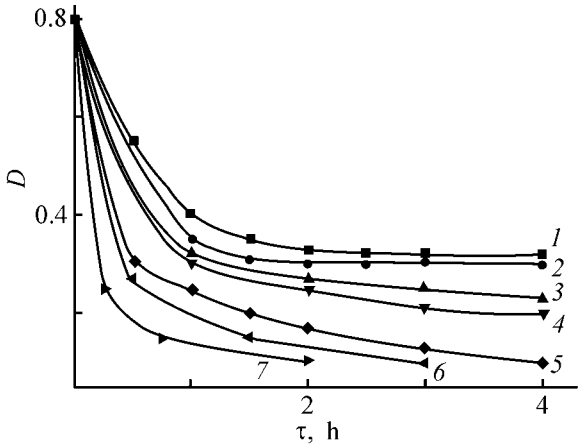

Fig. 5. Optical density *D* at a wavelength of 580 nm vs. the keeping time τ of a dehydrated modified membrane in the atmosphere with varied relative humidity. Relative humidity: (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, (*4*) 0.4, (*5*) 0.5, (*6*) 0.75, and (*7*) 0.95.

rule out any possibility of their "cross-linking" to form Co–O–Co bonds.

The spectrum of a modified membrane saturated with moisture contains a broad band peaked at about 517 nm (Fig. 4), whose position and profile are closely similar to those of the well-known spectrum of a pink octahedral complex $Co(H_2O)_6^{2+}$ and correspond to the main single-electron transition $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ [9, 10]. Heating of a sample at 100–120°C is accompanied by a weak long-wavelength shift (λ_{max} = 530 nm) and an insignificant increase in the intensity of the absorption band. These minor spectral changes are, nevertheless, manifested in the appearance of a clearly pronounced violet coloration of the membrane. Further increase in temperature gives rise to a more complex spectrum with a peak at 570 nm and two shoulders at 540 and 610 nm (Fig. 4), preserved in the temperature range 150–200°C. As a result, the membrane becomes light blue. And finally, at temperatures exceeding 200°C, we observe an additional shift and sharp enhancement of the intensity of the spectrum having a clearly pronounced three-component structure (peaks at 545, 580, and 620 nm), which makes the sample bright blue.

The transformations we observed undoubtedly reflect the generation of several structural forms, which appear as the starting hexacoordinated state $=Co(H_2O)_4$. In this case, the transition from pink to violet coloration, caused by an insignificant change of the spectrum at 100–120°C, is in all probability due to a slight distortion of the configuration of grafted $=Co(H_2O)_4$ complexes upon removal of water molecules (outer sphere) adsorbed on these complexes. In turn, it is reasonable to believe that the strong changes of the membrane spectrum with further rise in temperature are due to successive desorption of coordinatively bound water molecules

$$=Co(H_2O)_4 \rightarrow =Co(H_2O)_3 + H_2O,\ T = 150\text{–}200^\circ C, \quad (2)$$

$$=Co(H_2O)_3 \rightarrow =Co(H_2O)_2 + H_2O,\ T > 200^\circ C, \quad (3)$$

which results in that the membrane color changes to light and intense blue, respectively. The long-wavelength shifts of the spectral bands in Fig. 4, observed in the course of dehydration, correspond, on the whole, to a decrease in the coordination number of the Co^{2+} cations and to the resulting weakening of the splitting effect of ligands on its 3*d*-states.

Despite the similar types of coloration, we observed noticeable differences between the spectra of a dehydrated Co(II) : PFS membrane and a dehydrated blue form of a cobalt(II)-containing silica gel (widely used humidity indicator). For the latter, the doublet band peaked at 620 and 670 nm has been attributed to the $[CoO_4]$ tetrahedron; however, it was not specified whether or not the T_d symmetry is observed in this case [11, 12]. It should be noted, in this context, that not only reliable interpretation of spectra (assignment of peaks to electronic transitions), but even their comparative analysis are hindered in the case in question because it is very difficult to take into account the strong influence exerted by the type and extent of distortion of the structure of Co(II) complexes on the splitting of terms of excited states [9, 10].

On bringing a dehydrated membrane in contact with water vapor, we observed reverse transitions of coloration, whose completeness and occurrence duration depend on the relative humidity p/p_0. Figure 5

shows a set of kinetic dependences obtained by recording the optical density D at λ_{max} = 580 nm for a sample heated to 250°C and kept in an atmosphere with p/p_0 = 0.1–0.95. The transition of the indicator membrane color from blue ($D_{580} \approx 0.85$) to pink ($D_{580} \approx 0.15$) is complete at p/p_0 of 0.95, 0.75, and 0.5 in 1, 2, and 3 h, respectively. At moderate and low humidities p/p_0 = 0.4–0.1, only a transition from blue to light blue can be observed, with complete restoration of the pink coloration taking days under these conditions. The results we obtained point to an enhanced stability of the intermediate form of the grafted complex $=Co(H_2O)_3$, which is clearly manifested in the process of both sorption and removal of coordinatively bound water. At the same time, the noticeable slowness of the optical "response" is primarily due to the diffusion hindrance of water molecules in the nanosize channels of PFSM. Nevertheless, under certain conditions and with account of the dynamics of color variation, a Co(II)-containing PFS membrane may be of use as a compact means of qualitative visual determination of the humidity of gaseous media.

CONCLUSIONS

(1) Ion-exchange modification of a perfluorosulfonic membrane in aqueous $Co(NO_3)_2$ solutions is accompanied by firm sorption of Co^{2+} cations in an amount of 0.22 ± 0.04 mmol g^{-1}.

(2) Modification of the membrane significantly improves of the thermal stability of its pore structure, with the stability threshold increasing from 100 to 200°C.

(3) Four reliably visually distinguishable forms of hydrated Co^{2+} cations (pink, violet, light blue, and blue) in the membrane occur in sorption–desorption of water, which creates prerequisites for use of the membrane for determining the humidity of gaseous media.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Empirical Method for Calculation of Thermodynamic Potentials of Organic Substances

Yu. E. Zevatskii and D. V. Samoilov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received June 4, 2006; in final form, December 2006

Abstract—A method for establishing relationships between various physicochemical properties of organic substances is developed. The method is based on the concept of linear deviations of physicochemical parameters calculated by additive techniques from experimentally determined values for some broad groups covering various classes of organic substances. The deviations from linearity are analyzed for the example of thermodynamic potentials of 1055 organic substances.

DOI: 10.1134/S1070427207020127

The relationship between the structure of organic substances and their reactivity is one of the most fundamental problems of modern chemistry. At present, the reactivity of organic compounds is evaluated by reactivity indices (RI) based on local electronic (hardness, softness, electronegativity, polarizability, delocalization) and pseudothermodynamic (chemical potential, entropy, electronic temperature) properties of a molecule [1, 2]. These local parameters are determined by formal equations in quantum-chemical calculations in terms of the electron density functional (EDF) theory.

The main advantage of this approach is its presumed versatility, i.e., applicability to any group of reagents or reaction series. The main commonly accepted disadvantages are as follows: use of the isolated-molecule approximation (which, e.g., gives no way of taking into account the effect of medium), not quite clear physical meaning of these local properties, and a pronounced dependence of the calculation accuracy on the choice of initial conditions.

There also exists an empirical method of correlation analysis (CA), suggested long ago by Hammett [3]. This method is based on the chemical similarity and linear free energy (LFE) principles and on application of the mathematical formalism of polylinearity [4], which remains an effective way to evaluate the reactivity of substances and their physicochemical properties.

This is indicated by publications of the last 10 years, which are devoted to evaluation of the inductive effect of substituents [5], development of criteria for a quantitative description of free-radical reactions [6], thermodynamic substantiation of the experimentally observed nonlinearity of the Brønsted equation for CH-acids by CA and of the hard soft acid base (HSAB) principle [8, 9], and by a review of correlation methods of analysis and prognostication of reactions of nucleophilic substitution [10]. The correlation analysis and the LFE principle have been successfully used in a number of studies concerned with the effect of substituents, including those of the organoelement type, on the ionization potentials of amines [11], sulfides [12], and phosphines and other organophosphorus compounds [13].

The key issue is that thermodynamic potentials of reactions are to be known for applying the CA technique. This is because this method is based on the commonly known simple relationship of the equilibrium constants K and rate k of a reaction with, respectively, the enthalpy H and activation energy E_a of the reaction (Vant-Hoff and Arrhenius equations) and on models that relate these kinetic parameters with thermodynamic characteristics. These relationships make it possible to express, using the CA method, the effect of substituents on the reaction center and physicochemical properties on a universal energy scale. Therefore, improvement of methods for calculation of thermodynamic parameters of compounds for prognostication of their reactivity is a topical task for physical organic chemistry.

Thermodynamic potentials have been recently used not only in theoretical and physical organic chemistry,

but also in neighboring research areas: geochemistry [14], biological docking [15, 16], colloid chemistry [17], and chemical industry [18]. Particular importance has been acquired by development of reliable and efficient techniques for prognostication of the heat of evaporation [19–22], mostly for the purpose of finding new effective and ecologically safe cooling agents [20–22]. For these reasons, techniques for calculation of various thermodynamic parameters continue to be improved.

A comparative analysis of the most important additive methods for calculation of the enthalpy of formation and other molecular parameters has been made earlier [23]. As a result, a conclusion was made that each of the methods considered has a number of advantages and disadvantages over other techniques; however, all of them give deviations from experimental data. The discrepancies are small, but exceed the measurement errors of the corresponding quantities. In this context, it has been suggested that the existing gap between the values calculated by additive schemes and those found experimentally (nonlinear effect or defect) is of not only quantitative, but also qualitative nature, which has its own physical meaning. This circumstance was mentioned long ago in the classical monograph by Pal'm [4]. Following this suggestion, dependences of deviations from linearity (defects) of one parameter on another parameter were analyzed with account of the results of [24] in order to improve the accuracy of additive methods. It was found that defects of different quantities also linearly depend on each other, and do so with a considerably larger correlation coefficient. As a result, the correlation coefficients were improved for the dependences of polarizability, enthalpy of atomization, and ionization potential on the defect of the volume.

However, an analysis of the input data used in [23, 24] demonstrated that the correlation coefficient is only seemingly improved on passing from additive schemes for molecular parameters themselves to additive schemes for their defects. This is mainly due to the purely mathematical effect of "smoothing" of deviations in subtraction of sums of atomic parameters, which frequently exceed the quantities themselves by more than an order of magnitude. Apparently, the dependences of the sum of atomic values of one parameter on another parameter are represented by an ideal straight line for homologous series and a degenerate point for isomers with the same empirical formula. Therefore, the correlations of defects, calculated for series of this kind, will certainly have a larger coefficient than the initial correlations of molecular parameters.

Taking into account the urgent need for improvement of methods for calculation of thermodynamic parameters, we carried out, similarly to [23], a comparative analysis of mutual correlations of the values and defects of linearity of the standard enthalpy (ΔH_f, kJ mol^{-1}), entropy (ΔS_f, J mol^{-1} K^{-1}), Gibbs energy of formation (ΔG_f, kJ mol^{-1}), and isobaric specific heats (C_p, J mol^{-1} K^{-1}) for 1055 organic compounds, with the above thermodynamic quantities regarded as independent parameters. We chose among these compounds, with account of the above comments, series of compounds that are certainly not homologues or isomers, but have similar chemical properties (which are characteristic of functional groups) or the same structural fragment (nucleus).

We took as input data the table of standard thermodynamic constants [25], in which all values of the parameters listed above were not available for all the compounds represented in the table. The phase for which a thermodynamic parameter was determined was denoted by superscripts s, l, and g for the solid, liquid, and gaseous states, respectively.

Preliminarily, we found the sum of the atomic constituents of a thermodynamic quantity under consideration for all the molecules:

$$\Sigma g_i X_i. \quad (1)$$

Here, g_i is the stoichiometric coefficient of ith atom in the molecular formula, and X_i is the experimentally determined value of the corresponding thermodynamic parameter of the atom in the gas phase [26].

We introduced the value of the defect of a molecular parameter as the difference between the experimentally found values δX [25] and the sum of atomic constituents

$$\delta X = X - A\Sigma g_i X_i. \quad (2)$$

Initially, the dimensionless coefficient A was taken to be unity.

Further, we considered correlations of the experimental values of the molecular parameters under study with each other in all the possible combinations (66 pairs). We excluded from consideration the dependences of the same thermodynamic quantity in different phases (12 pairs). This is so for it is apparent that the sums (1) of atomic values, used for calculations, were the same because they belong to the gas phase by definition. For the remaining 54 combinations, we compared the correlation coefficients between the experimental values [25], atomic sums (1), and defects of these thermodynamic quantities by Eq. (2).

To find series of substances and pairs of quantities for which the correlation can be really achieved on passing from experimental values to defects, we used the following scheme for each of the groups we chose.

(1) We considered correlations of the molecular parameters under study with each other in the combinations specified above. In most cases, the correlation coefficient did not exceed 0.8.

(2) Of all the possible pairs of thermodynamic parameters, we chose those whose dependence on each other was constituted for the given group of substances by more than five points.

(3) We analyzed the types of dependences of the sums of atomic parameters on each other for different series of compounds. In those cases when the correlation coefficient was unity (straight line in the plot), the series were excluded as being "unsuccessful."

(4) We chose those combinations in which the correlation coefficient for the dependence of the defects of the given pair of quantities δY and δX by Eq. (2) exceeded that for their atomic sums (1). This definitely indicated that there is a real relationship between the defects for the chosen pair of thermodynamic quantities. For the chosen dependences of δY on δX, we optimized coefficient A in Eq. (2) for δX. We considered optimal that value of A_X at which the correlation coefficient was improve to the maximum possible extent, compared with that for the atomic sums. The values of A_X were within the range 0.17–15 for all the cases we analyzed (Table 1).

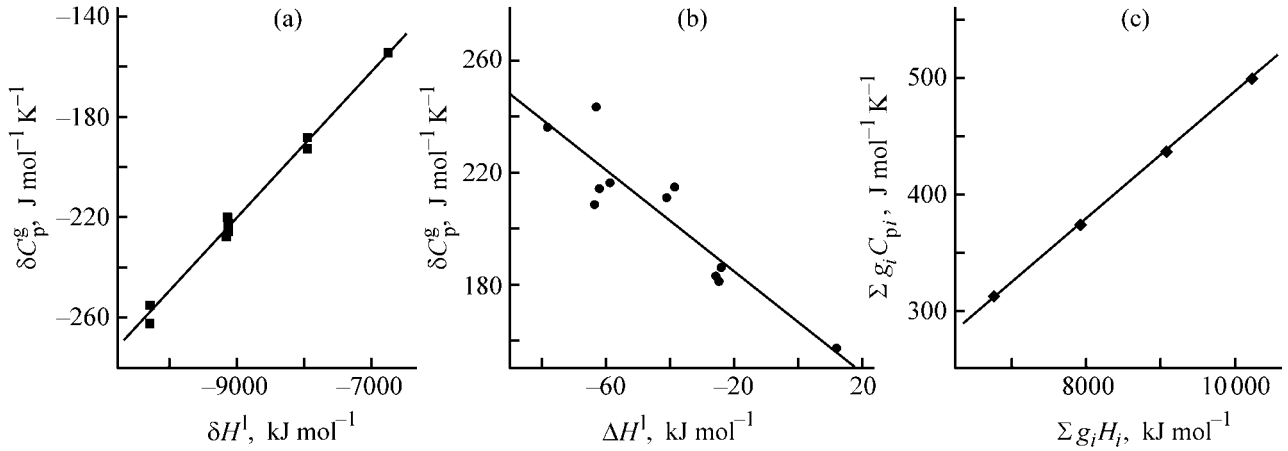

Fig. 1. Dependences for group 1. Dependence: (a) of the defect of the isobaric specific heat in the gaseous state, δC_p^g on the defect of the standard enthalpy of formation in the liquid state, δH^l; (b) of the isobaric specific heat in the gaseous state, C_p^g on the standard enthalpy of formation in the liquid state, H^l; and (c) of the specific heat $\Sigma g_i C_{pi}$ on the standard enthalpy of formation, $\Sigma g_i H_i$; the dependences were calculated by the additive formula (1); the same for Fig. 3.

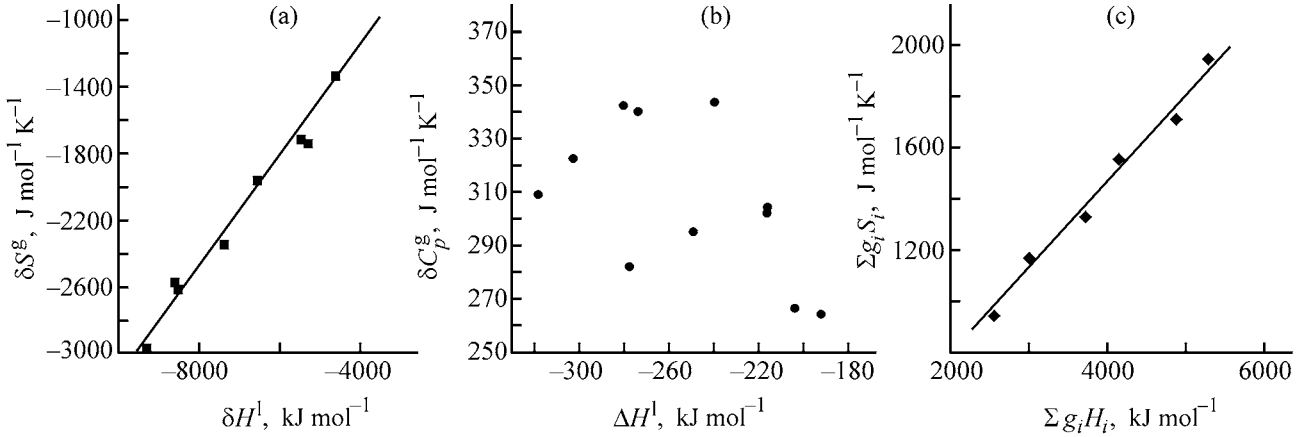

Fig. 2. Dependences for group 9. Dependence: Dependence: (a) of the defect of the entropy of formation in the gaseous state, δS^g on the defect of the standard enthalpy of formation in the liquid state, δH^l; (b) of the entropy of formation in the gaseous state, ΔS^g on the standard enthalpy of formation in the liquid state, H^l; and (c) of the entropy of formation, $\Sigma g_i S_i$, on the standard enthalpy of formation, $\Sigma g_i H_i$; the dependences were calculated by the additive formula (1).

Using the procedure described above, we found strong correlations between the defects of thermodynamic parameters for the following groups of substances: (1) alkyl derivatives of benzene; (2) halo, hydroxy, and alkyl derivatives of benzene; (3) all derivatives of benzene; (4) carboxylic acids and their derivatives (amides, nitriles, esters); (5) six-membered heterorings with one and two nitrogen atoms; (6) noncyclic monoatomic alcohols, thiols, esters, sulfides; (7) cyclic esters, sulfides; (8) all alcohols, esters, thiols, sulfides; and (9) monoatomic alcohols, ethers, aldehydes, ketones of the C_1–C_8 group.

As regards the applicability of the method under consideration, these groups can be accepted as series. Groups 1 and 9 are of particular interest in that they are, on the one hand, combinations of exclusively partial functional homologous series, and on the other hand, combinations of exclusively partial series of isomers. For these groups, the dependence of the sums of atomic parameters on each other is a straight line formed by several degenerate points (Fig. 1c) or two straight lines (Fig. 2c).

Consequently, despite that each of the partial series constituting the groups is unsuccessful, we markedly improved the correlation by considering these series together. In most cases, the remaining groups also included such combinations of unsuccessful series, but, in addition, contained a considerable number

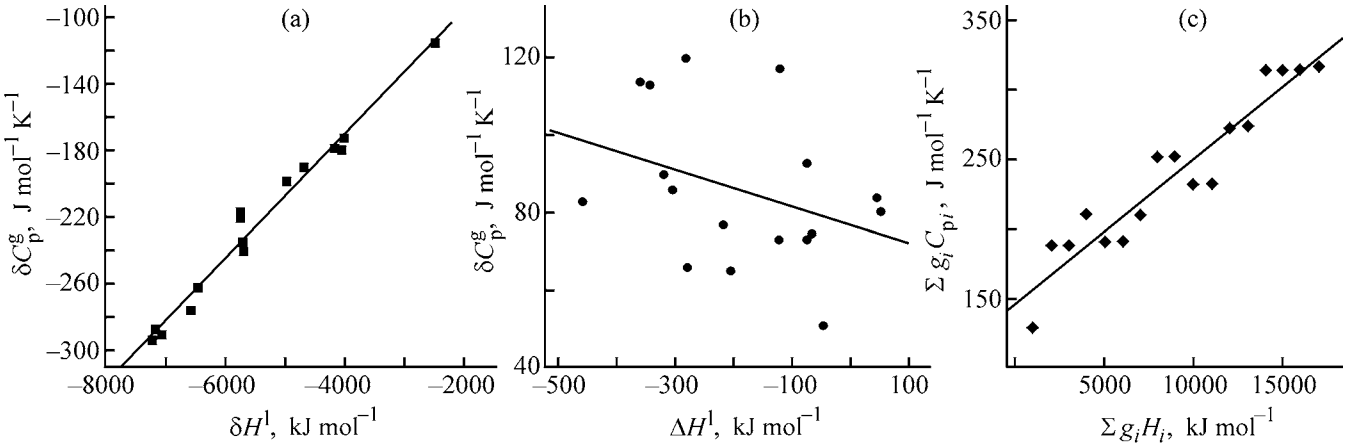

Fig. 3. Example of dependences for group 8.

of compounds not entering into any of these series (Fig. 3).

The parameters of the correlations and the optimized coefficients A_X for all the dependences of parameters in the selected groups of substances, processed using the procedure described above, are listed in Table 1. The correlation coefficients of the experimental X and Y in the dependence

$$Y = d_{ex}X + b_{ex} \quad (3)$$

are designated as r_{ex}; the correlation coefficients of the sums of the atomic values in the dependences

$$\Sigma g_i Y_i = a_{at}\Sigma g_i Y_i + b_{at} \quad (4)$$

are denoted by r_{at}; a and b are the coefficients in the equations

$$\delta Y = a\delta X + b, \quad (5)$$

where δY and δX are the defects of the corresponding quantities, given by Eq. (2); and r is the correlation coefficient.

The unknown values of one of the thermodynamic parameters, Y, was calculated within the chosen series and the improvement of correlations for the known values in this series, at a known value of the other parameter X, was verified using the equation

$$Y = \Sigma g_i Y_i + a(X - A_X\Sigma g_i X_i) + b. \quad (6)$$

The table containing 1010 calculated values of thermodynamic potentials for 365 organic compounds can be found on the Internet [27].

Table 2 lists the results of calculation of the standard entropies of formation in the gas phase, ΔS^g,

which cannot be found in [25], from experimental values of ΔH^g for the compounds that are contained simultaneously in groups 7 and 8.

CONCLUSIONS

(1) A method was suggested, which is a variety of correlation analysis, modified by taking into account sums of contributions of atomic parameters to the molecular parameter. This is particularly important in practical regard in those cases when significant deviations from the principle of linearity of free energies are observed when studying the reactivity of series of compounds.

(2) It was demonstrated that the method makes it possible to calculate, within the series of substances that were specified in the study, an unknown thermodynamic potential from another, known, one by the relations established.

(3) Nine series exhibiting strong correlations of deviations for certain thermodynamic quantities were found. The coefficients obtained were used to calculate 1010 values for 365 organic substances for which no experimental data could be found in the literature.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Properties of Enzymatically Modified Flax Fiber

Abstract—The influence of enzymatic modification on the sorption properties of a short flax fiber with respect to the Cu(II) ions was examined. The optimal parameters were determined for treatment of natural cellulose-containing sorbent with various enzymatic preparations, $B_{1\,mix}$, NCE, and protease, which affords the maximal sorption capacity of the sorbent and the shortest time required for establishment of equilibrium. IR spectroscopy was applied to examine changes in the structure of the substrate via rupture of inter- and intramolecular bonds in its constituent biopolymers under the action of the enzymes.

DOI: 10.1134/S1070427207020139

In the context of development of resource-saving processes, of particular interest is development of sorption methods for removal of heavy metal ions from aqueous solutions of varied nature, including food media. The easy accessibility and low cost of the waste from agroindustrial and wood-processing sectors make them promising sorbents for this purpose [1–3].

Such sorbents, however, typically exhibit poor kinetic characteristics and a comparatively low sorption capacity. This makes the search for a procedure for treatment of cellulose-based polymers to increase their sorption capacity and decrease the sorption time an important avenue in the development of new sorbents. Various methods [4–9] have been suggested for treatment of cellulose-containing sorbents, including mechanical, physical, chemical, and physicochemical methods (wet grinding, freezing, plasma activation, treatment with sodium polysulfides, coloration with active dyes, grafting of amino acid residues, etc.). In our opinion, enzymes and enzymatic preparations (EPs) are promising for treatment of sorbents.

Today, wide application of biotechnological methods in solving specific practical problems is limited by the lack of a databank covering the specific features of the influence exerted by both individual enzymes and EPs on various substrates. This makes examination of the impact of enzymes and their formulations on biopolymers an important step in this direction. Shibashova et al. [10] and Cheshkova et al. [11] reported on biochemical modification of cellulose and flax materials for textile industry.

We examined here the sorption properties with respect to the copper(II) ions of natural cellulose-containing material, short flax fiber, in relation to the conditions of the enzymatic treatment.

EXPERIMENTAL

We examined a short flax fiber, a secondary processing product of flax industry, with the composition, wt %: cellulose, 75–78; hemicellulose, 9.4–11.9; lignin, 3.8; pectins, 2.9–3.2; waxy substances, 2.7; nitrogen-containing substances calculated for proteins, 1.9–2.1; and mineral substances, 1.3–2.8 [12].

We also used enzymatic preparations[1] $B_{1\,mix}$ and NCE, as well as the alkaline protease manufactured in Russia. The enzymatic complex NCE comprises cellulases, pectinases, and esterases, and $B_{1\,mix}$, cellulases, pectinases, esterases, and hemicellulases. Both EPs are beige powders with a specific odor. The alkaline protease is produced in the form of 0.2–1.0-mm light gray or light beige granules. The proteolytic activity of the preparation is 50000 units g^{-1}, in accordance with TU (Technical Specifications) 64-13-19–89 (bacteria, fungi). Solutions containing Cu(II) were prepared by dissolving $CuSO_4 \cdot 5H_2O$ of chemically pure grade.

[1] Developed by gene engineering at the Chair of Enzymology, Moscow State University.

The short flax fiber was modified in aqueous solutions of EPs at the solution/sorbent ratio of 5–50 and enzyme concentration of 1–10% of the sorbent mass for 1–3 h at 25–40°C, whereupon the sorbent was filtered off, washed with distilled water, and dried.

The copper ion sorption was examined under static conditions from aqueous solutions of copper sulfate.

The sorption kinetics was studied by the method of a limited volume of solution. To a series of test tubes containing weighed portions of the polymer m = 0.1 g we added V = 0.01 l of the reference solution with the initial concentration $c_0 = 1.5 \times 10^{-4}$ M and kept for 0.5–3 h with stirring at a constant temperature (293 K). The solutions were intermittently filtered; in the filtrate, we determined the residual concentration of the metal ions and, under the equilibrium conditions, the equilibrium concentration of the metal ions in solutions c_{eq}, by the atomic absorption spectroscopy on a Saturn instrument.

The sorption power of the polymer was evaluated by the sorption capacity A

$$A = (c_0 - c_{eq})V/m.$$

The IR spectra of samples of the natural and treated flax fiber were measured by the reflection technique. The spectra were recorded on an Avatar 360 FT-IR E.S.P. spectrometer in the range 400–4000 cm^{-1}.

Important characteristics of polymeric sorbents are the sorption capacity and the time required for attainment of the sorption equilibrium [13]. Our kinetic examinations showed that, in sorption of the Cu(II) ions with a short flax fiber, the equilibrium is established within 40 min. The sorption capacity of the natural polymer is 10.1×10^{-3} mol kg^{-1} (Fig. 1). Thus, similarly to other cellulose-based materials, the flax fiber is a sorbent with poor sorption and kinetic characteristics.

Hydrophobic components present in this fiber and, in particular, lignin and waxy substances, hinder adsorption of aqueous solutions of the reactants (copper ions) and decelerate their penetration deep inside the fiber. Hence, improving the sorption characteristics of the short flax fiber requires removing hydrophobic substances. Therefore, we examined the equilibrium and kinetic characteristics of the polymer in relation to the procedure of treating short flax fiber by enzymatic preparations of varied nature.

The impurity components that are the most difficult to remove from natural plant fibers are waxy substances. They contain a natural mixture of esters,

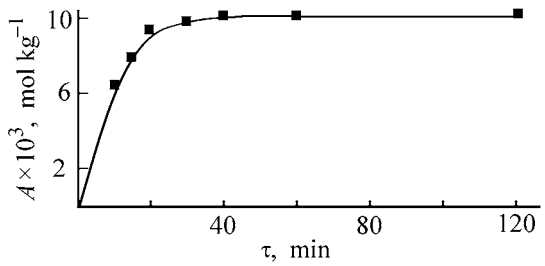

Fig. 1. Kinetics of sorption of Cu(II) ions by native flax fiber. (A) Sorption capacity and (τ) process time.

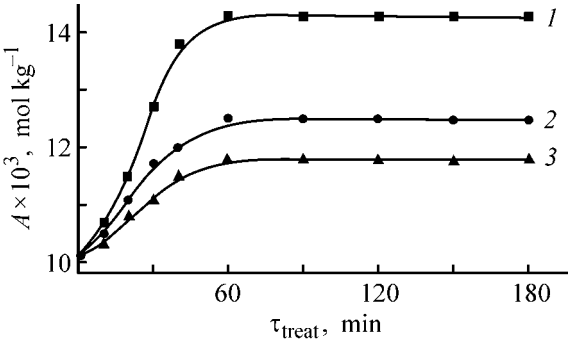

Fig. 2. Sorption capacity A vs. the time of treatment of a short flax fiber, τ_{treat}, with (*1*) $B_{1\,mix}$, (*2*) NCE, and (*3*) protease solutions. EP solution concentration 2% of the sorbent mass; temperature of the EP solutions 25°C, EP solution/sorbent ratio 50.

free saturated and unsaturated fatty acids, various high-molecular-weight alcohols, and some hydrocarbons. These substances prevent wetting of the fibers with aqueous solutions, thereby making them water-resistant. The esterase enzymes used in this study hydrolyze ester bonds and thus can destruct waxy substances.

Modification of the flax fiber with an enzymatic formulation containing pectinases, hemicellulases, and cellulases disturbs the stable system of cellulose–lignin–polysaccharides intermolecular bonds via hydrolytic degradation of the components of the carbohydrate complex (pectins, hemocelluloses) and partial degradation of cellulose, which is responsible for the removal of lignin from the fiber [11].

To determine the best conditions for treatment of the sorbent with EPs, we varied the following parameters: time of treatment of the sorbent with the EP solutions, EP solution concentration, EP solution/sorbent ratio, and EP solution temperature.

Figures 2–5 show how the sorption properties of the natural sorbent are influenced by treatment of the short flax fiber with EPs. The time of sorption of copper(II) ions by the short flax fiber treated

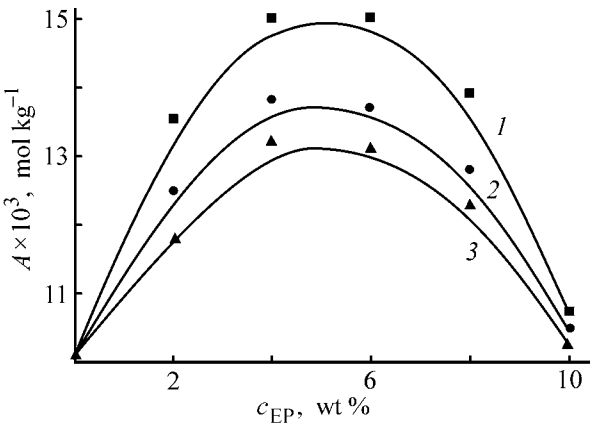

Fig. 3. Sorption capacity A of the short flax fiber vs. the content c_{EP} of (*1*) $B_{1\,mix}$, (*2*) NCE, and (*3*) protease in the solution used for treatment. Temperature of the EP solutions 25°C; EP solution/sorbent ratio 50; treatment time 60 min.

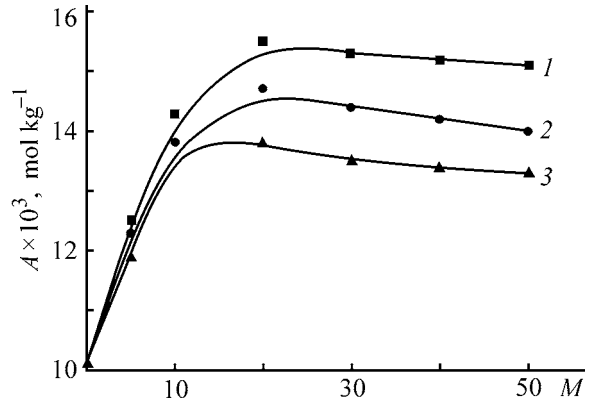

Fig. 4. Sorption capacity A of the short flax fiber vs. the EP solution/sorbent ratio M in treatment with solutions of (*1*) $B_{1\,mix}$, (*2*) NCE, and (*3*) protease. Treatment time 60 min; EP solution concentration 5% relative to the sorbent mass; temperature of EP solutions 25°C.

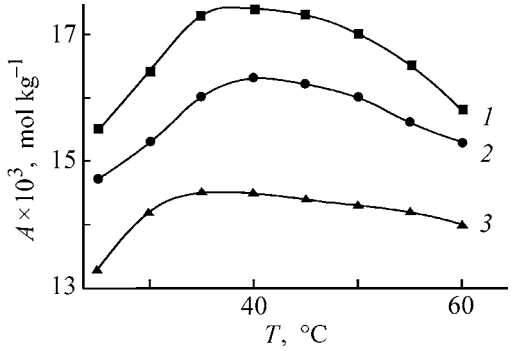

Fig. 5. Sorption capacity A of the short flax fiber vs. temperature T of the solutions of enzymes (*1*) $B_{1\,mix}$, (*2*) NCE, and (*3*) protease during treatment. Treatment time 60 min; EP solution/sorbent ratio 20 for $B_{1\,mix}$ and NCE, and 10 for protease. EP solution concentration 5% relative to the sorbent mass.

with the EP solutions decreases by half relative to that for the untreated sorbent. Therefore, the sorption time in all the experiments with the treated sorbent was not longer than 20 min.

The plots of the sorption capacity of the short flax fiber as a function of the time of enzymatic treatment (Fig. 2) suggest that the optimal time of treatment of the substrate is 60 min for all the EPs examined.

The enzyme concentration is known to substantially affect the rate of the enzymatic reaction, which is at maximum at the saturating concentration of the substrate. Under an excess of the substrate, the initial rate of the enzymatic reaction will vary with the enzyme concentration. Therefore, the concentration of the EP solutions for treating the short flax fiber was varied within 1–10% of the sorbent mass.

Figure 3 shows plots of the sorption capacity of the short flax fiber vs. the concentration of the EP solutions during sorbent treatment, which exhibit a weakly pronounced maximum at concentrations of 2–7% relative to the sorbent mass.

Figure 4 shows plots of the sorption capacity of the short flax fiber vs. the EP solution/sorbent ratio M for $B_{1\,mix}$, NCE, and protease. It is seen that the sorption capacity of the treated short flax fiber for copper(II) ions insignificantly changes at M = 5–50. The best results for enzymatic preparations $B_{1\,mix}$ and NCE were obtained at the EP solution/sorbent ratio of 20. In the case of protease, the maximal sorption capacity for the copper(II) ions is observed at the ratio of 10.

The optimal temperature affording the maximal activity for most of enzymes lies within 37–50°C, but some enzymes have a temperature optimum beyond this range. Temperature typically exerts a complex influence on the enzyme activity, depending on numerous factors: affinity of the enzyme for the substrate, ionization of the reaction components, rate of cleavage of the enzyme–substrate complex, formation of enzyme–activator or enzyme–inhibitor complex, and denaturation of the enzymatic protein [14].

Figure 5 shows plots of the sorption capacity of the short flax fiber vs. the temperature of the enzyme solution during treatment. Heat treatment of flax with the enzyme solutions at 20–60°C noticeably affects the sorption capacity of the short flax fiber. There is a broad maximum at 30–55°C. Our results are consistent with the published data on the optimal temperature limits of the activity of the enzymes.

Thus, our experiments showed that the imfluence exerted by the EPs examined on the sorption capacity

Optimal parameters of treatment of the short flax fiber with EP

EP	τ_{treat}, min	EP solution concentration, % relative to the sorbent mass	EP solution/sorbent ratio	T_{treat}, °C	$A \times 10^3$, mol kg^{-1}
No treatment	–	–	–	–	10.1
$B_{1\,mix}$	60	2	20	35	17.4
NCE	60	2	20	35	16.3
Protease	60	4	10	35	14.5

of the short flax fiber varies as follows: protease < NCE < $B_{1\,mix}$.

The optimal parameters of treatment of the short flax fiber with the EP solutions are listed in the table.

Treatment of the sorbent under the optimal modification conditions increases its sorption capacity for copper ions by 43–72% and decreases the sorption time by half relative to the natural samples. The maximal effect is achieved in the case when the short flax fiber is treated with a complex enzymatic preparation $B_{1\,mix}$, comprising cellulases, hemicellulases, pectinases, and esterases. Treatment with protease increases the sorption capacity of the sorbent to the smallest extent.

The observed decrease in the time required for attainment of the sorption equilibrium in the heterogeneous system constituted by the short flax fiber and a copper(II) sulfate solution and the increase in the sorption capacity of the modified sorbent can be accounted for by the simultaneous changes in the carbohydrate, protein, and lipid complexes of flax during its treatment with the enzymatic preparation. This leads to an increase in its porosity and hydrophilicity, as well as in the number and accessibility of the functional groups that can bind heavy metal ions.

These changes are also reflected in the IR spectra of samples of the short flax fiber. The natural flax is a mixture of polymers containing various functional groups with donating properties: carboxy, ether/ester, and hydroxy groups. The IR spectrum of the initial flax fiber exhibits a characteristic set of absorption bands of cellulose enriched in lignin. The spectrum contains intense absorption bands associated with stretching vibrations of the C=O, C–O–C, and OH bonds [15].

Comparison of the IR spectra of the initial and modified samples of the flax fiber (Fig. 6) demonstrates a certain decrease in intensity and resolution of the bands of the flax fiber treated with the enzyme. The observed decrease in the intensity of the broad absorption band at 3100–3600 cm^{-1}, associated with stretching vibrations of the hydrogen-bonded hydroxy groups, can be attributed to a decrease in the intensity of the intermolecular interaction via hydrogen bonds of cellulose and incrusting substances due to removal of pectins and hemicelluloses [16].

In the spectra of the flax treated with enzymes with different substrate activities, the absorption bands at 2917 and 2852 cm^{-1} decrease in intensity relative to the initial flax This can be due to changes in the structure of the substrate. These changes are observed near the characteristic absorption bands of mono- and polyphenols, i.e., lignin and tanning substances. For example, at 3000–2800 cm^{-1} there are absorption bands associated with stretching vibrations of the C–H bonds in the alkyl groups.

In the range 1800–1600 cm^{-1}, the IR spectra of the initial flax contain prominent absorption bands at 1740, 1664, and 1646 cm^{-1} due to the presence of carboxy groups of substrates of varied nature.

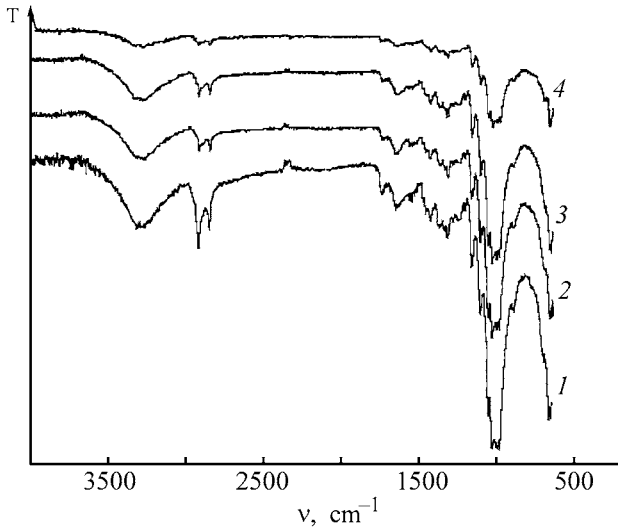

Fig. 6. IR spectra of (*1*) initial flax fiber and (*2*, *3*, *4*) flax fiber treated with (*2*) protease and (*3*, *4*) enzymatic preparations (*3*) NCE and (*4*) $B_{1\,mix}$. (T) Transmission and (ν) wavenumber.

In the spectra of the samples of the flax modified with the enzymatic formulation, the band at 1740 cm^{-1} decreases in intensity. Decreases in the intensity and diffuseness of absorption for the samples of the treated flax in this spectral region can be due to removal of the pectins from the fiber.

The bands at 1600–1510 cm^{-1} are associated with the absorption due to skeleton vibrations of the aromatic structures; the spectrum of the native flax exhibits closely lying bands at 1568 and 1560 cm^{-1} and a band at 1520 cm^{-1}. In the spectra of the fiber treated with the enzymes, this configuration of the bands is less prominent.

In the region 1210–830 cm^{-1} in the spectra of the sample of the flax treated with the enzymatic formulation, the intensity of the absorption bands associated with vibrations of the CC and CO bonds decreases relative to the native substrate.

It should be noted that the most pronounced changes in the spectra of the samples of the modified flax are observed for the flax treated with $B_{1\,mix}$, and the least prominent changes, for the flax treated with protease. These data are consistent with the trends in variation of the sorption capacity of the modified sorbents.

CONCLUSIONS

(1) Modification of the short flax fiber with an enzymatic formulation increases its sorption capacity by 43–72%. The maximal effect is achieved with the complex enzymatic preparation $B_{1\,mix}$.

(2) The time required for attainment of the sorption equilibrium in the aqueous solution of the system copper(II) sulfate–short flax fiber modified with various enzymes is 20 min, which is half that for the untreated polymer.

(3) The improvement of the equilibrium and kinetic characteristics of the natural polymer can be accounted for by the change in its structure due to degradation of inter- and intramolecular bonds of the biopolymers of the flax under the action of the complex of enzymes, as well as to an increased accessibility of cellulose and loosening of its structure. This is confirmed by the IR spectra of a sample of the natural flax fiber and fibers treated with various enzymes.

Abstract—The possibility of recovering cadmium deposited on fibrous carbon electrodes from ammonium washing solutions formed in cadmium plating via operation of a short-circuited electrochemical system or anodic dissolution was examined. A polarization study of electrode processes that occur on a renewable graphite microelectrode in ammonium solutions of varied composition was carried out. The change in the properties of fibrous carbon electrodes in their cyclic use in electrodeposition–recovery of cadmium and the possibility of their repeated use were analyzed.

DOI: 10.1134/S1070427207020140

Owing to their specific properties, cadmium coatings are used for protection of articles in aggressive media (high humidity or tropic conditions) [1–3]. Cadmium(II) is to be removed from washing solutions formed in cadmium plating for detoxication of these solutions and recycling of cadmium into the electroplating process. Electrolysis is a way to simultaneously solve these two problems. With account of the low concentration of cadmium(II) in washing solutions, it is preferable to use electrolysis with 3*D* flow-through electrodes and, in particular, with electrodes made of fibrous carbon materials (FCM) [4].

In the recent decades, electrolysis with fibrous carbon electrodes (FCE) has been successfully used to recover noble and nonferrous metals in hydrometallurgy and electroplating [4, 5]. The use of FCM for electrolytic recovery of nonferrous metals from washing solutions formed in electroplating is due to the necessity for regeneration of carbon electrodes and recycling of the recovered metal into main process. An important issue is that of changes in the FCM properties during their cyclic use in electrodeposition–recovery and of the influence exerted by these changes on the parameters of both the processes. No systematic studies have been performed in this area. The results of previous studies [6–9] suggest that use of FCM in cyclic processes will strongly affect their properties. However, no unambiguous conclusion can be made about whether these changes exert positive or negative influence on the main process of metal electrodeposition because of the scarcity of the available data.

This study was undertaken in order to examine experimentally the possibility of recovery of cadmium deposited on FCE, changes in the FCE properties in an electrodeposition–regeneration cycle, and influence exerted by these changes on the main process for the example of electrolytic processing of washing ammonium solutions formed in cadmium plating.

EXPERIMENTAL

Industrial cadmium-plating ammonium electrolytes of two compositions were chosen for study. Solution no. 1 contained (g l^{-1}): $CdSO_4$ 50, $(NH_4)_2SO_4$ 150, H_3BO_3 25 (pH 5); and solution no. 2: $CdSO_4$ 50, $(NH_4)_2SO_4$ 250, urotropin 20, NF dispersant 75 ml l^{-1} (pH 6) [2, 3]. Supporting electrolytes contained all the components listed above except cadmium. The electrode polarization was carried out using a TES-14 dc power supply in the galvanostatic mode, with the solution circulated by a pmp-304 peristaltic pump through the FCE volume and an intermediate tank at a rate of 0.2 ml cm^{-2} s^{-1} [9]. The solution was delivered to

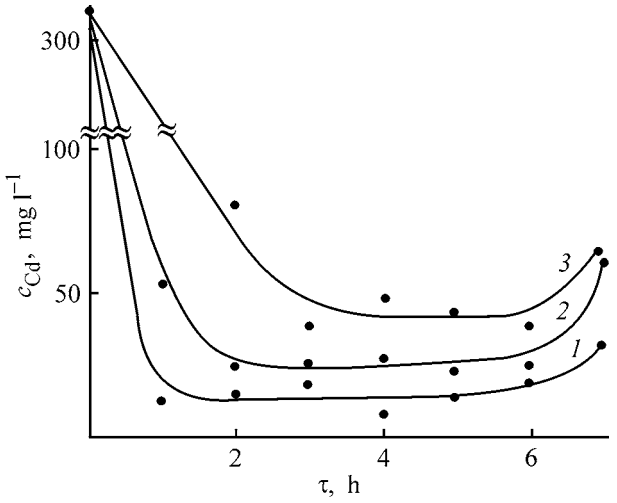

Fig. 1. Kinetic curves of electrolytic recovery of cadmium(II) from electrolyte no. 1 in modeling of the electrolytic recovery of cadmium(II) from a catching bath. Initial cadmium(II) concentration 330 mg l^{-1}, dilution factor n = 20, interval between washings 15 min. (c) Cd(II) concentration, and (τ), time. Rise in the cadmium(II) concentration upon a single washing (mg l^{-1}): (*1*) 27, (*2*) 54, and (*3*) 81.

an electrode with a back current lead from the back side with respect to the counter electrode. The FCE was made of NT-1 carbonized carbon graphite material, its geometric area was 2 cm^2. A perforated titanium or platinum plate served as a current lead, and a platinum wire, as a counter electrode. To measure changes in the mass and electrical conductivity of the FCE electrode, it was washed with distilled water and dried at 80–100°C. The steady-state electrode potential of a cadmium plate and FCE in the electrolytes were measured relative to a saturated silver chloride reference electrode and recalculated to the hydrogen scale, without drying of the FCE.

The electrical conductivity of FCE was measured with a VM-509 ac bridge and the steady-state electrode potential, with an OR-265/1 pH-meter, using the procedure and setup described in [4]. Polarization curves were measured in the potentiodynamic mode with an RA-2 polarograph on a graphite microelectrode 2 mm in diameter with a surface freshened in the electrolyte solution [10], with a potential sweep rate of 50 mV s^{-1}.

The efficiency of electrolytic recovery of cadmium was evaluated by the degree of recovery, $\alpha = (c_0 - c_\tau)/c_0$; current efficiency by cadmium, $C_E = [(c_0 - c_\tau)VF]/I\tau M_{eqiv}$; and electric power consumption $W = IU\tau/(c_0 - c_\tau)V$. Here c_0 and c_τ are the initial and final cadmium concentrations in solution (g l^{-1}); V, solution volume (l); F, Faraday constant (26.8 A h mol^{-1}); I, current (A); U, cell voltage (V); τ, experiment duration (h); and M_{equiv}, molar mass of the metal equivalent. The cadmium(II) concentration in solution was determined by the atomic-absorption method.

Figure 1 demonstrates the results of experiments on modeling of the electrolytic recovery of cadmium(II) from a catching bath for an automated cadmium-plating line. A portion of the cadmium-plating electrolyte was introduced at regular intervals of time (15 min) into a solution circulated between the electrolyzer and the intermediate tank, which models a catching bath. The Cd(II) concentration in the solution modeling a single washing of articles changed by 27 to 81 mg l^{-1}. The electrolytic recovery of cadmium(II) was carried out at a current density of 750 A m^{-2}. The kinetic curves presented in Fig. 1 reflect the change in the cadmium(II) concentration in a solution before introduction of a portion of the cadmium-plating electrolyte. It can be seen that the time in which a constant cadmium(II) concentration in solution is attained and the level of this constant concentration increase with the amount of the electrolyte introduced in a single washing. The fact that a constant cadmium(II) concentration in solution is reached shows that, under the chosen electrolysis conditions, the whole amount of cadmium(II) introduced in article washing is recovered by electrolysis between two successive washings. Depending on the introduced amount of electrolyte modeling washing of articles with different surface areas, this concentration is 10–35 mg l^{-1} before deposition of a certain amount of cadmium onto FCE. After that the efficiency of cadmium electrodeposition decreases, which is characterized by an increase in its concentration in solution. Evidently, the main reason for the decrease in the process efficiency is that the reaction surface area and the rate of electrolyte circulation decrease because of the plugging of the pore space in FCE by the deposited metal.

The amount of cadmium deposited per 1 g of FCE varies with the electrolyte composition and is determined by the deposit structure and by the localization of cadmium within the FCE volume, which are governed by specific features of cadmium electrodeposition from the electrolytes under consideration. In the case of metal electrodeposition onto FCM cathodes, the overvoltages of hydrogen evolution on FCM and on a metal being deposited are important for the metal distribution throughout the electrode volume [4]. The overvoltage of hydrogen evolution on cadmium is 1.1 V, and that on graphite, 0.8 V [1, 11]. Therefore, the overgrowth of the electrode with cadmium predominantly occurs on the metal deposited during

the initial stage of electrolysis. No less important is the solution pH, which is responsible for the stability of ammine complexes of cadmium; at pH > 5, $Cd(NH_3)_2^{2+}$ complexes predominate in the solution ($K_n = 1.8 \times 10^{-5}$) [2, 12]. In addition, electrolyte no. 2 contains cadmium(II) complexes with urotropin and a surfactant additive, and, therefore, the electrodeposition of cadmium from this electrolyte should be characterized by a higher polarizability [2, 3]. Thus, the varied content of components of the supporting electrolyte, inherent to washing solutions, should affect the polarization characteristics of the cathodic process in cadmium-plating electrolytes.

The polarization curves characterizing cadmium(II) discharge on a graphite microelectrode at different dilutions of the supporting electrolyte and a constant cadmium(II) concentration in the solution (300 mg l^{-1}) are shown in Fig. 2. The polarization curves have four characteristic portions. The first of these (portion *II*) ranges from the steady-state potential to a sharp rise in current, which is associated with cadmium(II) reduction. This portion apparently corresponds to oxygen reduction, and the fourth portion, to intense hydrogen evolution. For both the electrolytes, the reduction of cadmium(II) is determined by a clearly pronounced plateau of the limiting current (third portion), whose length is about 500 mV for electrolyte no. 1 and 300 to 500 mV for electrolyte no. 2 and increases with the dilution of the solution. For both the electrolytes, the height of the plateau of the limiting current is proportional to the cadmium(II) concentration in a solution.

For electrolyte no. 1, the run of the polarization curve is little affected by dilution of the supporting electrolyte, with the potential of the onset of cadmium deposition only somewhat shifted in the positive direction. For electrolyte no. 2, a strong effect is observed. In this case, the potential of the onset of cadmium deposition is shifted in the positive direction, the length of the plateau characterizing cadmium deposition at the limiting current becomes longer, and the limiting current itself also increases. In addition, electrolyte no. 2 possesses a higher electrical conductivity (0.21 Cm cm^{-1}), which is approximately 1.5–1.7 times that of electrolyte no. 1. Therefore, electrodeposition of cadmium from electrolyte no. 2 is characterized by a higher polarizability, which is clearly seen in curve *1* in Fig. 2b.

It was shown experimentally that, in the case of electrolytic recovery of cadmium(II) from electrolyte no. 1, cadmium is deposited on FCE on the front (closer to the counter electrode, anode) side of the electrode, whereas in the case of recovery from electrolyte no. 2, it is localized on the back (closer to the current lead) side of the electrode. The electrolytic deposits of cadmium also differ in structure. In

the case of electrodeposition from electrolyte no. 1, the deposit is porous, its adhesion to the surface of carbon fibers is weak, and deposit scales off. The cadmium deposit formed from electrolyte no. 2 is less porous and covers each fiber of the FCE. The amount of cadmium deposited on FCE from electrolyte no. 1 does not exceed 4.5 g per 1 g of FCE, the deposit grows on fibers in the direction of the electrolyte bulk and falls-off into the solution. In the case of cadmium(II) electrodeposition from electrolyte no. 2, cadmium is deposited on the back side of the electrode and then grows into the electrode, with the amount of deposited cadmium equal to 6.0–6.5 g per 1 g of FCE.

Cadmium deposited on FCE should be regenerated and recycled into the electroplating process. A promising way to achieve this objective is anodic dissolution.

The anodic polarization curves reflecting cadmium dissolution show that cadmium dissolves without any difficulties in both the electrolytes and the potentials corresponding to a steep rise in the anodic current are close (Fig. 2). The results obtained in studying the anodic dissolution of the cadmium deposit on FCE in the supporting solutions of electrolyte nos. 1 and 2 at different anode current densities are listed in Table 1. It can be seen that cadmium well dissolves in both the solutions and the degree of dissolution increases with the current density.

If anodic polarization of an FCE by a metal is performed without separation of the electrode spaces, dissolved cadmium is deposited on the cathode to give an electrolytic powder of cadmium.

If the electrode spaces are separated with an ion-exchange membrane and the anodic dissolution is performed in the supporting solution of the corresponding electrolyte, a solution of the cadmium-plating electrolyte can be obtained. Such a procedure for recycling of cadmium deposited on the FCE can be performed in the same electrolyzer that is used for electrolytic recovery of cadmium. It follows from the data of Table 1 that, depending on the anode current density, the current efficiency by cadmium exceeds 100% by a factor of 1.2–4.5 for both the electrolytes. The rate of anodic dissolution depends on the current density only slightly. If, however, the rate of the anodic dissolution of cadmium is calculated for a 100% current efficiency the rate is 4–4.5 times lower at low current densities and increases as the current density becomes higher. The electric energy expenditure for dissolution of 1 g of cadmium is low; its values differ by a factor of 5–8 for current densities of 50 and 200 A m^{-2}. If the energy expenditure for dissolution of 1 g of cadmium is calculated for a current efficiency of 100%, the difference tends to zero. The aforesaid shows that there occurs a concurrent reaction accompanied by dissolution of cadmium. Such a reaction may be cadmium dissolution through operation of a short-circuited electrochemical system (SES) constituted by FCE, cadmium, and electrolyte solution.

Measurements of the steady-state electrode potentials of cadmium (E_{Cd}) and FCE (E_{FCE}) in solutions of electrolyte nos. 1 and 2 demonstrated (Fig. 3) that E_{FCE} is independent of the electrolyte dilution, whereas E_{Cd} depends on the electrolyte dilution for cadmium and components of a supporting solution. For electrolyte no. 2, this dependence is more pronounced (curves *1*, *4*). The difference between the steady-state potentials of cadmium and FCE for both the electrolytes remains considerable (850–950 mV). Therefore, cadmium deposited on FCE must dissolve in the supporting ammonium electrolyte via SES operation.

The process of cadmium dissolution via SES operation can be independently used for cadmium regeneration, because it is a simpler cadmium regeneration technique, which has been effectively used previously for regeneration of zinc and palladium deposited on FCE [13]. The studies performed demonstrated that cadmium deposited on FCE dissolves in the supporting solution of the corresponding electrolyte at a considerable rate (Fig. 4). Solutions containing 35–40 g l^{-1} $CdSO_4$ were obtained as a result of the cadmium dissolution through SES operation. These solutions can be used for preparation of cadmium-plating electrolytes.

In the course of cadmium regeneration, FCE undergoes cyclic cathodic and anodic polarizations. It has been shown previously [6–9] that the FCE properties can be considerably changed in the process. Therefore, it was necessary to study how the properties of fibrous carbon electrodes change after several cycles of cadmium electrodeposition–regeneration. The results obtained in measuring the mass and the electrical conductivity of FCE after several cycles of cadmium electrodeposition–dissolution are listed in Table 2.

It follows from the data of Table 2 that, when cadmium is dissolved in a cycle through operation of a short-circuited electrochemical system, the mass of FCE and its electrical conductivity decrease. This is due to electrode processes occurring in the cathodic and anodic periods of the polarization. The decrease in the FCE mass may also be due to mechanical disintegration of carbon fibers. The electrical conductivity decreases by a factor of 1.7–2. More significant changes in the FCE properties are observed after cadmium is regenerated via anodic dissolution. The FCE mass increases, whereas the electrical conductivity decreases by a factor of 6–12, depending on the electrolyte composition. This is due to the formation of oxide groups on the surface of carbon fibers during the anodic cycle and also to the possible interaction of the electrolyte components with the FCM fibers [6, 7]. The less pronounced changes in the electrical conductivity and FCM mass in electrolyte no. 2 may be due to adsorption of the electrolyte components (urotropin and NF dispersant) on the FCE surface.

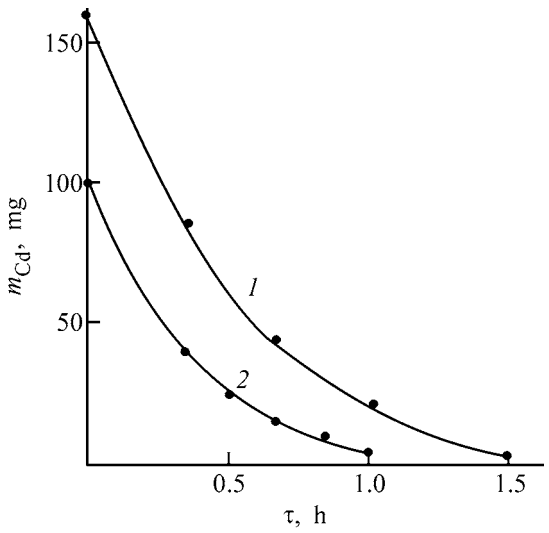

Fig. 4. Kinetic curves of dissolution of cadmium deposited onto FCE through SES operation in the supporting solutions of electrolyte nos. (*1*) 2 and (*2*) 1. Solution volume 100 ml. m_{Cd} Mass of soluble Cd, τ time.

The change in the FCE properties can affect the process of cadmium electrodeposition. Figure 5 shows the results obtained in studying the cadmium electrodeposition on FCE samples on performing five cycles of cadmium electrodeposition–dissolution. It can be seen that the parameters of the electrolytic recovery of cadmium on fibrous carbon electrodes on their cycling in electrolyte no. 1 are not deteriorated significantly, with only a 10–15% decrease in α_{Cd} observed during cadmium recovery via anodic dissolu-

(α) Degree of Cd(II) recovery, (τ) time. (*1*) Initial FCM; FCM after five cycles of cadmium electrodeposition–dissolution (*2*) through SES operation, and (*3*) via anodic dissolution.

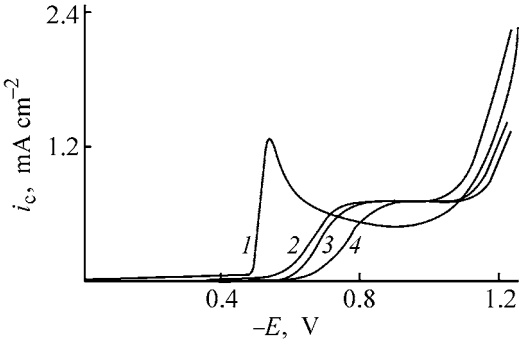

Fig. 6. Polarization curves of cadmium(II) recovery in cyclic cathodic–anodic polarization of a graphite microelectrode in electrolyte nos. (*1*) 1, cycles 1–5; and 2: (*2*) 1st cycle, (*3*) 2nd cycle, and (*4*) 3rd–5th cycles.

tion (Fig. 5a). The mass of cadmium deposited per unit FCE mass changed only slightly, compared with that of the starting material.

As for the results obtained in electrolyte no. 2, the parameters of cadmium electrodeposition on the electrodes used in five cadmium electrodeposition–dissolution cycles are improved (Fig. 5b). The adhesion of deposited cadmium to the surface of carbon fibers becomes considerably better, the deposit is more uniformly distributed across the electrode thickness, and the amount of cadmium deposited per 1 g of FCE increases to 7–7.5 g.

It is known that the efficiency of the electrochemical process in 3*D* flow-through electrodes is characterized by a distribution of the potential, polarization, and local current densities across the electrode thickness. The change in the distribution of the electrochemical process across the thickness of the FCM electrode, which is responsible for the change in the efficiency of cadmium electrodeposition in the cyclic deposition–dissolution, may be due to presence of such components as urotropin and NF dispersant in electrolyte no. 2. Presumably, the positive effect of urotropin and NF dispersant on the electrolytic recovery of cadmium from ammonium electrolytes is accounted for by the interaction of these components with the surface of carbon fibers of the electrode during its cyclic polarization. To verify this suggestion, special polarization studies were carried out. A graphite electrode was preliminarily subjected to up to five cycles of cathodic–anodic polarization in electrolyte nos. 1 and 2 containing 300 mg l^{-1} of cadmium(II).

It follows from Fig. 6 that cyclic treatment of FCE in a solution containing no urotropin and NF dispersant (electrolyte no. 1) has virtually no effect on the run of the polarization curve (Fig. 6, curve *1*). In a solution containing urotropin, the polarization curve is shifted toward electronegative potentials already after the first cycle, the slope of the second portion of the polarization curve markedly increases (Fig. 6, curve *3*), and, consequently, the polarizability is enhanced, too. Renewal of the electrode surface by cutting in a solution "returns" the polarization curve to the initial state, i.e., makes the run of the polarization curve similar to that measured in the initial solution without any cyclic treatment (curve *2*). The most significant changes in the cathodic portion of the curve are observed during the first three cycles of polarization (curves *3*, *4*), which is probably due to adsorption of urotropin and NF dispersant on the surface of carbon fibers. Further increase in the number of po-

larization cycles has no effect on the cathodic polarization curve.

CONCLUSIONS

(1) It was demonstrated that cadmium(II) can be electrolytically recovered from ammonium solutions formed in catching baths on a fibrous carbon electrode. The structure of the electrolytic deposit of cadmium and its distribution across the electrode thickness depend on the solution composition. The amount of cadmium deposited per 1 g of the fibrous carbon material is 4.5–6.5 g.

(2) The polarization study showed that the current of cadmium(II) reduction depends on the composition and dilution of the solution; presence of organic substances (urotropin, NF dispersant) shifts the potential of the onset of cathodic reduction of cadmium in the negative direction and leads to a decrease in the limiting current of reduction of cadmium(II) ions and in the length of the plateau of the limiting current. The anodic process proceeds without any hindrance.

(3) The possibility of regeneration of cadmium deposited on a fibrous carbon electrode through operation of a short-circuited electrochemical cell or via anodic dissolution was demonstrated. Solutions containing 35–40 g l^{-1} $CdSO_4$ were obtained. In the case of cadmium regeneration via anodic dissolution, an electrolytic powder of cadmium can also be obtained.

(4) A change in the mass and electrical conductivity of fibrous carbon electrodes in their cycling in electrodeposition–dissolution of cadmium was found. The most pronounced changes were observed in cadmium recovery via anodic dissolution: the mass of the electrode subjected to five cycles increased by 7–8%, whereas its electrical conductivity decreased by a factor of 6–12, depending on the solution composition.

(5) It was found that the characteristics of cadmium(II) electroreduction on fibrous carbon electrodes are not deteriorated upon their cycling. The degree of electrolytic recovery of cadmium from solutions containing organic components is 20–30% higher, the structure of the deposit and its distribution across the electrode thickness of the electrode are better, with up to 7.5 g of cadmium deposited per 1 g of electrode.

Abstract—Cyclic voltammetry, chronopotentiometry, and gravimetry were used to study the electrochemical oxidation of copper in an ionic liquid, 1-butyl-3-methyl imidazolium bromide monohydrate.

DOI: 10.1134/S1070427207020152

Ionic liquids, room-temperature molten salts (RTMS) composed of dialkyl imidazolium cations (R,R'-Im-) and complex metal-containing anions, e.g., chloroaluminate ionic liquids R,R'-ImAlCl_4, are regarded as promising media for carrying out various catalytic reactions of organic synthesis, electrodeposition of metals, etc. [1–4]. Considerable attention is given to synthesis and study of compounds that belong to this group of ionic liquids. Ionic liquids containing $[InCl_4]^-$, $[NiCl_4]^{2-}$, $[CuCl_2]^-$, and $[ZnCl_3]^-$ anions are known and have been characterized [5–7]. Commonly, salts of this kind are prepared by simple mixing of appropriate halide salts of a metal and dialkyl imidazolium to give a considerable number of metal-containing anions of various compositions dependent on the molar ratio of the starting components. For example, mixing of $ZnCl_2$ and 1-ethyl-3-methyl imidazolium chloride can give complex anions $[ZnCl_3]^-$ and $[ZnCl_4]^{2-}$, as well as polynuclear complex anions $[Zn_2Cl_5]^-$ and $[Zn_3Cl_7]^-$ [7]. The presence of $[CuCl_2]^-$, $[Cu_2Cl_3]^-$, and $[Cu_3Cl_4]^-$ anions has been revealed in chlorocuprate ionic liquids [6].

The applicability of metal salt solutions in ionic liquids in electrochemical deposition of thin films of various metals has been studied [8–10]. Particular researchers' attention has been given to the electrodeposition kinetics and quality of metal deposits, with the anodic processes accompanied by dissolution of the corresponding metal electrodes virtually not understood at all. A study of the anodic behavior of metals in RTMS is of interest because these processes largely determine the operation stability of a galvanic cell and the corrosion resistance of materials. It is known that various processes are possible in anodic oxidation of metals, including dissolution and formation of passivating films.

The aim of this study was to examine the kinetics of anodic oxidation of copper in a halide ionic liquid, 1-butyl-3-methylimidazolium bromide monohydrate.

EXPERIMENTAL

The ionic liquid [BMIm]Br was synthesized by the procedure described in [11] from *N*-methyl imidazole (Acros organics, 99%) and freshly distilled bromobutane (pure grade). This liquid has the form of brown crystals with a melting point of 65°C and decomposition temperature of 275°C (thermographic data, 1000 D derivatograph), in agreement with published data [12]. Its monohydrate (molar ratio [BMIm]Br : H_2O = 1 : 1) is in the liquid state at room temperature (concentration of bromide ions 5.49 M and water content 6.5%, as determined by the Fisher method). The composition was confirmed by elemental analysis (CPNS) (Flash EA 1112 instrument).

Found (%): C 39.97, H 7.65, N 12.19.

$C_8H_{17}N_2BrO$.

Calculated (%): C 40.51, H 7.17, N 11.81.

Copper of M0b (oxygen-free) brand served as a metal under study. The electrode was fabricated in the form of a 0.2-cm^2 plate with insulated nonworking surface. Platinum was used as auxiliary elec-

trode. A platinum electrode served as reference in the [BMIm]Br · H_2O melt. In the case of RMTS, this electrode is regarded as a reference quasi-electrode and is widely used in polarization studies in electrolyte media of this kind [13].

The following electrochemical research methods were used in the study: cyclic voltammetry, chronoammetry (PI-50.1 potentiostat), and gravimetric analysis (Sartorius ME215S analytical balance with a weighing accuracy of 1×10^{-5} g) for determining the current efficiency by the metal. The study was carried out at a temperature of 18 ± 0.2°C.

Experimental details are described in figure captions.

The electrochemical window of a naturally aerated melt of 1-butyl-3-methyl imidazolium bromide monohydrate was measured on a platinum electrode (Fig. 1, curve *1*). This window is presumably limited by oxidation of bromide ions at anodic potentials and by reduction of the cation at cathodic potentials and is approximately equal to 1.9 V. It was noted in [1] that presence of water in hydrophilic RTMS leads to a significant narrowing of the electrochemical window to values comparable with those obtained in the present study.

It can be seen in Fig. 1, curves *2*, that the electrode processes involving the copper electrode and products of its oxidation occur at potentials of electrochemical stability of components of the BMImBr salt, and the electrochemical response of H_2O is negligible, compared with the reduction currents of the products of the anodic reaction. Therefore, it was assumed that presence of water has no significant effect on the mechanism of anodic oxidation of copper in the electrolyte under study.

The steady-state potential E_{st} of the copper electrode relative to the platinum electrode is $-(0.70 \pm 0.03)$ V. The cyclic voltammograms of the copper electrode, measured in [BMIm]Br · H_2O are shown in Fig. 1 (curves *2*). It can be seen that, in anodic polarization, the current steadily grows and the forward and return portions of the polarization curve coincide at positive potentials (as far as the anodic boundary of the electrochemical window). As the potential sweep direction is changed and the polarization curve enters the region of negative potentials, it can show one or two cathodic current peaks. Their number depends on the limiting anodic polarization potential. The processes characterized by the first and second cathodic waves C_1 and C_2 reflect the reduction of the anodic product formed at more positive anodic potentials

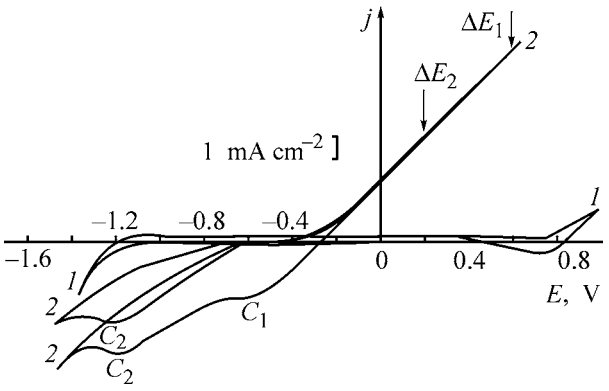

Fig. 1. Cyclic voltammograms measured on (*1*) platinum and (*2*) copper electrodes in [BMIm]Br · H_2O. Potential sweep rate 5 mB s^{-1}. (*E*) Potential and (*j*) current density.

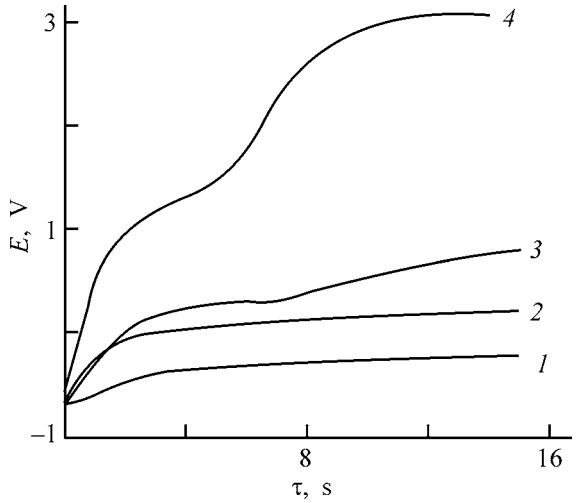

Fig. 2. Chronopotentiogram of a copper electrode in [BMIm]Br · H_2O. (*E*) Potential and (τ) time. Current density (mA cm^{-2}): (*1*) 0.99, (*2*) 2.05, (*3*) 5.31, and (*4*) 9.58.

ΔE_1 and at smaller anodic polarization ΔE_2, respectively. Thus, it follows from Fig. 1 and from the theory of chronovoltammetry [14] that two irreversible processes of electrochemical oxidation of copper may occur in the potential range studied.

Both the electrode processes are recorded under the conditions of a galvanostatic anodic polarization of the copper electrode (Fig. 2). As the current density *j* increases, the second wave appears in the chronopotentiogram, which is due to a decrease in the transient time in which the potential of the electrode process occurring at more positive potentials is reached. The slopes of the *E*–τ curves ($\Delta E/\Delta\tau$, where τ is time) for the first and second waves are close (0.010–0.011 V min^{-1}), which is due to the formation of anodic products that do not passivate the electrode.

The following results were obtained by determining the anodic current efficiency and visually examin-

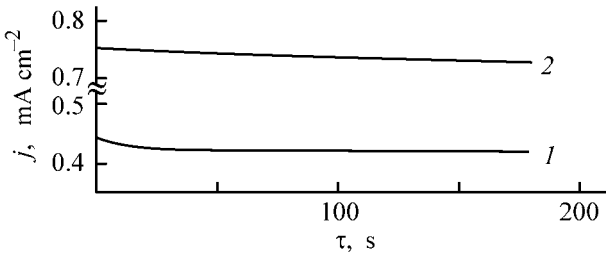

Fig. 3. Chronoammograms of a copper electrode in [BMIm]Br · H_2O under polarization. (*j*) Current density and (τ) time. Polarization ΔE (V): (*1*) 0.43 and (*2*) 0.56.

ing the state of the electrode surface upon the galvanostatic polarization. At the potentials of the first wave (current density of up to 5 mA cm^{-2}), the anodic current efficiency by Cu(I) is at the 100% level. The slope of the Tafel curve is 0.126 V, which points to an irreversible transfer of an electron in the ionization of copper. It should be noted that no phase film of a poorly soluble compound CuBr is formed on the surface of copper in the course of anodic polarization and bromide ions form stable complex compounds with Cu(I) cations [15]. With account of this circumstance, the following electrode reaction characterizing the anodic dissolution of copper is the most probable:

$$Cu + 2[BMIm]^+Br^- \rightarrow [BMIm]^+[CuBr_2]^- + [BMIm]^+ + e. \quad (1)$$

In this range of potentials, the electrode surface is corroded, but a thin white CuBr film is present on the surface [16]. Presumably, the film is formed by the dissolution-deposition mechanism, because it is easily removed from the metal surface. In this case, CuBr may be formed in decomposition of a complex compound on the active surface of the electrode by the reaction

$$[BMIm]^+[CuBr_2]^- \rightleftarrows [BMIm]^+Br^- + CuBr\downarrow. \quad (2)$$

Presumably, reversible formation of polynuclear complex compounds [3] may occur, under the conditions of supersaturation of the near-electrode space by the substance $[BMIm]^+$ $[CuBr_2]^-$, e.g.,

$$2[BMIm]^+[CuBr_2]^- \rightleftarrows [BMIm]^+[Cu_2Br_3]^- + [BMIm]^+Br, \quad (3)$$

followed by their decomposition

$$[BMIm]^+[Cu_2Br_3]^- \rightleftarrows [BMIm]^+[CuBr_2]^- + CuBr\downarrow. \quad (4)$$

The exchange current j_0 was determined by chronopotentiometry for the irreversible process occurring at anodic potentials ranging from E_{st} to $\Delta E \approx 0.9$ V (cathodic current wave C_2). The current–time curves in Fig. 3 were transformed to $j(\tau^{1/2})$ plots. The portions *j*, intercepted on the current axis by these plots, are related to j_0 by [17]:

$$j = \frac{j_0 z F (E - E_{st})}{RT},$$

where *z* is the number of electrons; *F*, Faraday number; *E*, preset potential; *R*, universal gas constant; and *T*, temperature.

The value of j_0 was found to be 3×10^{-5} A cm^{-2}, which also points to the irreversibility of the electrochemical process under study.

The second wave in the *E*–τ curve is associated with the appearance of a black substance $CuBr_2$ [16] in the near-electrode zone. This substance does not block the reaction surface of the electrode and its gradual dissolution in [BMIm]Br results in that the coloration changes from yellow-brown (color of molten [BMIm]Br) to green. An experiment demonstrated that $CuBr_2$ solutions in [BMIm]Br are green in the presence of a minor amount of water, as also is a solution of products formed in anodic oxidation of copper in this liquid, which may be due to formation of a partly hydrated compound $[BMIm]^+[CuBr_3]^-$.

As the current density increases and the potentials corresponding to the second wave are reached (Fig. 2), the current efficiency by Cu(I) decreases to 50–70% and less, which is probably due to oxidation of Cu(I) to Cu(II). Therefore, the second process occurring on the copper electrode in the potential range under study can be represented by the reactions

$$[BMIm]^+[CuBr_2]^- + Br^- \rightarrow CuBr_2 + [BMIm]^+Br^- + e, \quad (5)$$

$$CuBr + Br^- \rightarrow CuBr_2 + e. \quad (6)$$

It should also be noted that the ionic liquid containing products of electrochemical dissolution of copper at the potentials of the first wave does not change its coloration in the initial stage. However, its color changes to green upon its prolonged contact with air, and the electronic absorption spectrum becomes similar to that obtained after anodic dissolution of copper, which is presumably also due to the reaction Cu(I) → Cu(II). It should be noted that reactions (2) and (4) are written as possible, because a semitransparent CuBr film is manifested in the *E*–τ curve (Fig. 2).

CONCLUSIONS

(1) The study demonstrated that two irreversible electrode processes occur in the potential range under study on a copper electrode in $[BMIm]Br \cdot H_2O$. These processes are accompanied by formation of a well-soluble compound $[BMIm]^+[CuBr_2]^-$, which is rather stable under the experimental conditions and is oxidized to $CuBr_2$ at more positive potentials and upon interaction with the atmospheric oxygen.

(2) Electrochemical oxidation of metals in ionic liquids can be regarded as a possible way to obtain ionic liquids with complex metal-containing anions.

ACKNOWLEDGMENTS

The study was carried out in the framework of the Program of basic research no. 9 (OKhMN, Russian Academy of Sciences) "New Approaches to Improvement of the Corrosion Resistance and Radiation Hardness of Materials and Radioecological Safety," (2006, project no. 1).

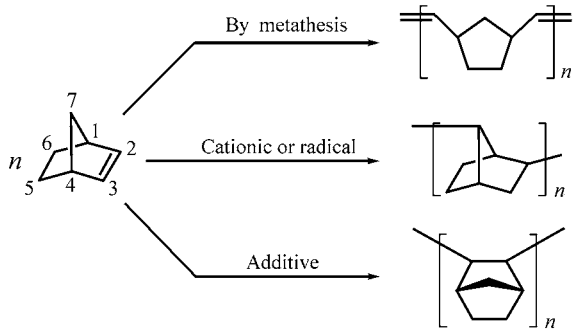
Abstract—Catalytic systems based on palladium carboxylates and boron trifluoride etherate were studied in the reaction of additive polymerization of nonbornene. The system $Pd(OAc)_2$ + $25BF_3OEt_2$ exhibits a high activity, up to 154 100 kg of nonbornene per mole of Pd per hour.

DOI: 10.1134/S1070427207020164

Polymerization of cyclic olefins under the action of metal-complex catalysts has been arousing a considerable interest recently. Nonbornene (bicyclo-[2.2.1]heptene-2) can polymerize via metathesis or by radical, cationic, and additive mechanisms (Scheme 1). Additive polymerization occurs with cleavage of the double bond and yields polymers containing unchanged cyclic structures in the backbone chain. Polymers of this kind show good thermal and chemical stability, are amorphous, exhibit high transparency in the IR, visible, and UV spectral ranges, and have low refractive index, narrow range of decomposition temperatures, and small dielectric constant. These factors make them promising for deposition of coatings in electronics, manufacture of telecommunication materials, optical lenses, substrates for plastic displays, photoresistors for chips and displays, and insulators for semiconductors [1, 2].



Scheme 1. Variants of nonbornene polymerization.

Data on additive polymerization, published by the year of 2000, were reviewed by Makovetskii [1] and Janiak [2]. In the last six years, a vast body of new information on metal-complex catalysts for this process has appeared in the literature. All the known catalysts can be conventionally divided into two groups: individual complexes of transition metals, mostly of the cationic type, and commonly neutral complexes used in combination with cocatalysts, mostly with methylaluminoxane (MAO) or tris(pentafluorophenyl) borate $B(C_6F_5)_3$ and with triethylaluminum (TEA) or without this compound. However, the production cost of organoaluminum or organoboron cocatalysts is high. Moreover, MAO is named a "black hole" because of its indeterminate structure. Therefore, development of less expensive and structurally simpler cocatalysts is an important task for chemical industry.

It has been shown previously [3–10] that systems based on bis(acetylacetonato)palladium Pd(acac) and boron trifluoride etherate BF_3OEt_2 are active catalysts for di- and oligomerization of ethylene and propylene [3–5], selective dimerization of styrene [6], telomerization of diene hydrocarbons with secondary amines [7], positional isomerization of hexene-1 [8], and additive polymerization of nonbornene and alkyl nonbornenes [9, 10]. The present communication reports on a study of the additive polymerization of nonbornene under the action of new catalytic systems based on palladium carboxylates of general formula $Pd(RCOO)_2$, combined with BF_3OEt_2.

EXPERIMENTAL

Nonbornene was polymerized in 10-ml glass reactor with a magnetic rabble in the atmosphere of

nitrogen. A solution of nonbornene and a Pd(II) complex in toluene was allowed to stand at a required temperature for 15 min; polymerization was initiated by introduction of BF_3OEt_2. After the reaction was complete, the polymers formed were precipitated with ethanol acidified with hydrochloric acid, separated by filtration, and dried in a vacuum (6 h at 80°C).

NMR spectra of solutions in $CDCl_3$ were recorded on a Bruker AMX-500 instrument with working frequencies of 500 MHz for ^1H and 125 MHz for ^{13}C. IR spectra were recorded on a Nicolet FT-IR spectrometer. The viscosity was measured at 25°C with an Ubellohde viscometer. Gel-permeation chromatography (GPC) was performed on a WATERS 150 HPLC instrument with 300 × 7.5-mm columns packed with 10-μm MIXED-B (135°C polystyrene standards); 1,2,4-trichlorobenzene served as a solvent. Thermal analyses were made on a DSC Q100 instrument at 10–800°C and a heating rate of 10 deg min^{-1}.

Toluene (Sigma-Aldrich, 99.8%) was used as a solvent without additional purification. Pd(II) carboxylates were synthesized by a procedure described in [11] and recrystallized from benzene.

In standard experiments, the amount of Pd was 1.0×10^{-6} mol, with the mol/mol ratios B : Pd = 25 and nonbornene : Pd = 5.104 (4.71 g); reaction time 30 min; temperature 25°C; solvent toluene; total volume of the reaction mixture, 7 ml.

In the study of how the amount of the cocatalyst in the system $Pd(OAc)_2$ + nBF_3OEt_2 on the process of nonbornene polymerization, the atomic ratio B : Pd was varied from 5 to 60 at 25°C at a constant concentration of Pd(II). The results obtained are listed in Table 1. As the B : Pd ratio is raised from 5 to 20, both the polymer yield and the intrinsic viscosity (and, accordingly, the molecular weight) steeply increase. The maximum conversion of the substrate into target products is reached at B : Pd = 25. The highest intrinsic viscosity [η] of the polymer is obtained at B : Pd = 40. Further increase in the B : Pd ratio to 60 leads to a slight decrease in conversion and intrinsic viscosity. This decrease may be due to partial destruction of active centers.

Such a dependence of the activity on the ratio between a cocatalyst and a transition metal rather widely occurs in metal-complex catalysis and is frequently accounted for by formation of an active complex from an inactive precursor and cocatalyst under equilibrium conditions, when the number of active centers grows with the B : Pd ratio [12]. In the present study, the mechanism of interaction between $Pd(OAc)_2$ and BF_3OEt_2 in the presence of nonbornene was not analyzed in detail. Therefore, the equilibrium between the inactive and active complexes can be represented in the general form as

$$Pd(OAc)_2 + BF_3OEt_2 \rightleftarrows \text{Active complex}.$$

The formation of α-alkylpalladium complexes via incorporation of coordinated alkenes at the Pd–OAc bond and further β-elimination to form a Pd–H bond have been described in detail in the literature [13]. Therefore, it can be assumed that catalytically active Pd hydrides are also formed in the $Pd(OAc)_2$ + BF_3OEt_2 system in the presence of nonbornene. The effect of the nature of carboxylate ligands at Pd on the nonbornene polymerization is illustrated by Table 2.

As can be seen from Table 2, the nature of carboxylate ligands at Pd(II) has no effect, within experimental error, on the nonbornene conversion into

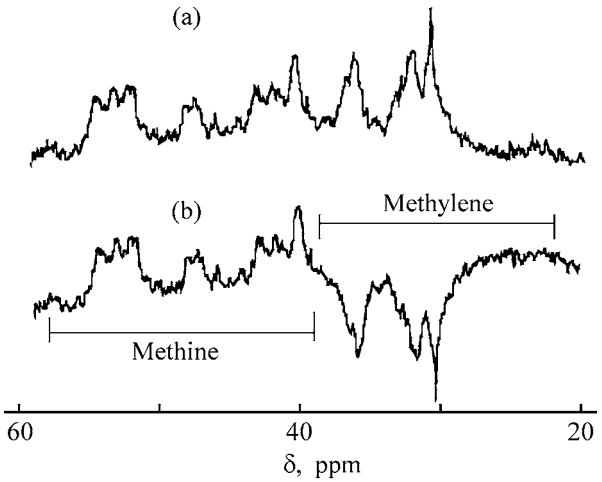
polymers. These data may indicate that the active complexes formed in these systems are of a homogeneous nature. A nearly linear dependence of the intrinsic viscosity of the polymers on the acidity of the carboxylate ligand is observed in this case. The nature of this dependence is the subject of a separate study.

Raising the temperature to 65°C for the $Pd(OAc)_2$ + $25BF_3OEt_2$ system leads to a significant decrease in the nonbornene conversion to 17.4% and in the polymer viscosity to 0.19 dl g^{-1}. The decrease in conversion on raising the temperature points to the low thermal stability of the system. The decrease in the intrinsic viscosity of the polymers at higher temperatures can be attributed to a faster rise with temperature in the rate constant of chain termination, compared with the rate constant of chain growth.

To study the effect of the amount of monomer on the nonbornene polymerization, several experiments were carried out with nonbornene : Pd molar ratios of 25000 to 100000 at a constant Pd(II) concentration. It was shown that the nonbornene : Pd ratio has no effect on the nonbornene conversion into polymers. This indicates that the reaction is zeroth-order with respect to the monomer. The intrinsic viscosity decreases from 1.45 to 1.18 dl g^{-1} as the nonbornene : Pd ratio is raised from 25000 to 100000. The possible reason is that the diffusion of the monomer toward an active center is hindered at high monomer concentrations by the poor solubility of the growing polymer chain. In this case, the termination of a chain and initiation of a new one become preferable.



^{13}C NMR spectra of polynonbornene: (a) full spectrum and (b) DEPT 135° spectrum. (δ) Chemical shift.

The effect of the Pd(II) concentration on the nonbornene polymerization in the presence of the $Pd(OAc)_2$ + $25BF_3OEt_2$ system at a constant monomer concentration is illustrated by Table 3. An increase in the amount of Pd(II) is accompanied by a rise in the nonbornene conversion and a decrease in the intrinsic viscosity of polymers. At an amount of Pd(II) equal to 1.0×10^{-5} mol, the catalytic activity is as high as 154100 kg of nonbornene per mole of Pd per hour. This activity is comparable with the best published data [16–19] and exceeds by approximately a factor of 7 that achieved for the $Pd(acac)_2$ + $25BF_3OEt_2$ system [9]. It should be noted that an exothermic effect starts to be observed beginning with an amount of Pg(II) equal to 3.0×10^{-6} mol. At a Pd(II) content of 1.0×10^{-5} mol, the reaction is strongly exothermic and the reaction mixture instantaneously becomes a solid white mass.

The structure of the resulting nonbornene was studied by NMR and IR spectroscopies. The data obtained demonstrated that the structure corresponds to that of the additive polymer. The ^1H NMR spectrum contains no resonances associated with C=C bonds. The IR spectrum does not contain, either, bands at 1620–1680 cm^{-1}, associated with double bonds, but there are strong absorption bands at 1452–1474 cm^{-1}, associated with δ_{H-C-H} deformation vibrations of the bridging CH_2 groups of the nonbornene ring [20]. The ^{13}C NMR spectra of polynonbornene are shown in the figure. The NMR signals were assigned in ac-

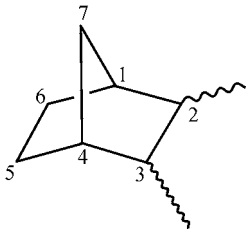
cordance with the following numbering of carbon atoms:



The resonance peaks at 28–34 ppm are related to nonbridging CH_2 groups (C_5 and C_6). The bridging CH_2 groups (C_7) show signals at 34–38 ppm. The nodal CH groups (C_1 and C_4) appear as signals at 38–45 ppm. The signals at 45–55 ppm belong to the CH groups (C_2 and C_3) of the backbone chain of the polymer. The absence of resonances at 20–24 ppm indicates that the polymer chain has the exo configuration [21].

The signal from the C_7 atom appears as a group of strong resonances at 34–38 ppm. This indicates that the microstructure of the polymer is a combination of *rr* and *mr* triads with low diisotacticity [22]. The absence of *mm* triads is confirmed by the fact that there is no resonance signal at 39 ppm [21].

The data obtained in analyses by derivatography, differential-scanning calorimetry (DSC), and GPC for selected samples are listed in Table 4. The molecular-weight distribution (MWD) $Q = M_w/M_n$ in polymerization under the standard conditions is close to 2, which is the theoretical value of the Flory–Schultz distribution for the ideal polymerization with chain termination. This value shows that the active complexes are of the single-center, highly homogeneous nature. The deviation of MWD to larger values at high palladium(II) concentrations and high temperatures may be due both to destruction of active centers and to an increase in the rate of chain termination. The thermal decomposition temperature T_d of the polymers varies from 313 to 324°C, and the glass-transition temperature T_g, from 240 to 262°C.

CONCLUSIONS

(1) The catalytic system $Pd(OAc)_2$ + $25BF_3OEt_2$ shows high activity in additive polymerization of nonbornene, up to 154 100 kg of nonbornene per mole of Pd(II) per hour.

(2) The results of ^{13}C NMR studies demonstrate that the microstructure of the polymers formed is a combination of *rr* and *mr* triads with low diisotacticity.

(3) The value of the molecular-weight distribution of polymers obtained under the standard conditions indicates that the active complexes are of the single-center, highly homogeneous nature.

CATALYSIS

Simulation of Oxidation of Carbon Particles at the Surface of Mixed Oxide Catalysts

A. A. Ostroushko, M. Yu. Sennikov, and M. O. Tonkushina

Research Institute of Physics and Applied Mathematics, Gor'ky Ural State University, Yekaterinburg, Russia

Received August 3, 2006

Abstract—A model of catalytic oxidation of a cylindrical carbon particle was suggested. The model considers the rate of layer-by-layer burning of the particle, variation of its geometry, and remote action of the catalyst. A software for calculations was developed; the data obtained correlate well with the experimental data for catalysts based on lanthanum cesium vanadate. The kinetics of carbon oxidation on catalysts of varied nature was compared.

DOI: 10.1134/S1070427207020176

The reactions of catalytic oxidation of carbon [1] are of practical significance for, in particular, treatment of exhaust gases in industry and transport. One of the main aspects providing a successful development of thermal catalytic devices is the knowledge of the kinetics and mechanism of the above reactions. It is important to understand, for example, how the oxidation of carbon particles on the whole, proceeds on the filter-catalyst [2, 3]. At the same time, for optimization of the oxidation conditions, there is need to have a notion of the behavior of individual particles. Here, we report on theoretical simulation and experimental modeling of their behavior.

Carbon particles of two shapes, cylindrical and spherical, can be selected as model. Here we consider the oxidation of individual particles with the shape close to cylindrical by atmospheric oxygen at the catalyst surface. This corresponds to the optimal mode of the device operation at which the burning rate of particles is comparable with the rate of their deposition, i.e., no layer covering the catalyst surface and deteriorating its performance is accumulated. These conditions can be more easily created when using reverse gas flows through the catalytic device of a batch operation cycle. We assume that individual particles are relatively small, so that the catalyst surface can be considered to be flat. Cylinder-shaped particles contact with the catalyst through the base of cylinder. We assume that the oxidation of small particles proceeds mainly at the catalyst surface.

For experimental modeling of the behavior of carbon particles we used compact samples of the corresponding shape prepared from carbon-graphite mixture used, for example, for production of electrodes for manganese–zinc power cells. We performed pyrolytic synthesis of mixed oxide catalysts of the composition $Cz_{0.3}La_{0.7}VO_{4\pm y}$ [1] and $La_{0.75}Ag_{0.25}MnO_{3\pm y}$ [4]. The catalysts were prepared in the form of pellets and sintered for 6 h at 650 and 900°C, respectively. The pelletized carbon samples were pressed against the catalyst pellets with a springing attachment and annealed isothermally in air. After annealing, the weight change was monitored. To take into account the possible contribution of removal of volatile products and noncatalytic oxidation to the weight loss of carbon, we performed concurrent blank experiments without a catalyst.

In oxidation of particles, an important parameter is variation of their shape with time. The configuration of the area of carbon oxidation was studied by the microscopic method. In particular, variation in the sample shape is fairly conveniently recorded by photographing the sample from one side or in cross section. In this case, we can model a spherical particle by considering variation of the cross-section of a round rod contacting with the catalyst through the generatrix of the cylindrical surface.

Let us consider a model of oxidation of a cylindrical particle. As assumed previously [1, 2, 5, 6], a catalyst accelerates the burning process both when in direct contact with carbon and at a certain distance from it. To verify this assumption, we performed the following experiment. For contact annealing, we took a catalyst pellet with a smaller diameter than that of the carbon pellet. This case simulates a situation when a particle or carbonaceous agglomerate with a fairly large diameter contacts with a peak on

the rough catalyst surface. This is quite possible in using mixed oxide catalysts applied onto foamed materials [4, 7–10]. The experiment showed that the oxidation area of carbon extends in fact around the catalyst pellet to a noticeable distance (Fig. 1), in our case, on the average, to 170–180 μm. To describe the process of particle burning, consideration must be given, on the one hand, to the decrease in its thickness due to the contact action and, on the other hand, to the variation of the shape and sizes due to the remote action of the catalyst.

In consideration of the carbon oxidation, we proceeded from the presence of two main stages of chemical conversion: initial formation of carbon monoxide CO and its conversion into carbon dioxide CO_2. In this case, the contact action on carbon oxidation is apparently caused by accelerated formation of CO in the contact area, which is due in part to the formation of unstable carbonate complexes [1, 11]. The remote action can be assigned to the existence of the outer area of exothermic oxidation of CO, which raises the effective temperature in the vicinity of the carbon surface and thereby accelerates the first stage of carbon oxidation. In the dependences of the weight loss of the samples on time with heating, this remote action is manifested in changes in the run of the curves describing the overall oxidation rate (Fig. 2). In the case of the remote action, the surface area of the particle subjected to oxidation increases with time due to the appearance of an additional area of oxidation on the side surface of the sample (particle). At even higher temperatures, the as yet disregarded noncatalytic oxidation has a pronounced effect on oxidation of carbon materials.

A mathematical model of the process can be developed in a general form. For example, in the cross section of a carbon pellet, the angle between its surface adjacent to the catalyst and tangent to the surface formed as a result of the remote action can be arbitrary and varying with time, which should complicate the model. An experimental observation of the variation of the shape of a sample being oxidized allows us to simplify the model and make it more adequate to actual processes. In particular, it was found that the surface of the remote action can be regarded with a good accuracy as the generatrix of a truncated cone. In this case, in the cross section of the pellet the angle between the generatrix and the pellet, base remains constant and close to 45°. In such a situation, it is reasonable to assume that the rate of motion of this generatrix into the particle is constant. Naturally, the surface area accessible for the remote action increases with time until the expanded generatrix of the cone reaches the upper base of the initial cylinder. One more important fact is that the area of the remote action can spread to a distance larger than the particle thickness. It seems likely that the unburnt part can shield the backside of carbon particles from the remote action of the catalyst. The condition occurence of both mechanisms of catalytic action is that the rate of motion of the carbon oxidation front due to the contact action is lower than that due to the remote action; otherwise the generatrix of a truncated cone should not be observed. It is believed that at higher temperatures, when both processes occur, the boundary of contact burning moves also linearly. These are the boundary conditions for construction of a model of oxidation of a cylindrical particle.

With the aim to perform model calculations of burning of carbon particles contacting with the catalyst surface in the Maple 9 environment, we developed a software in which, according to the scheme (Fig. 3), the following designations were made: *C*, rate con-

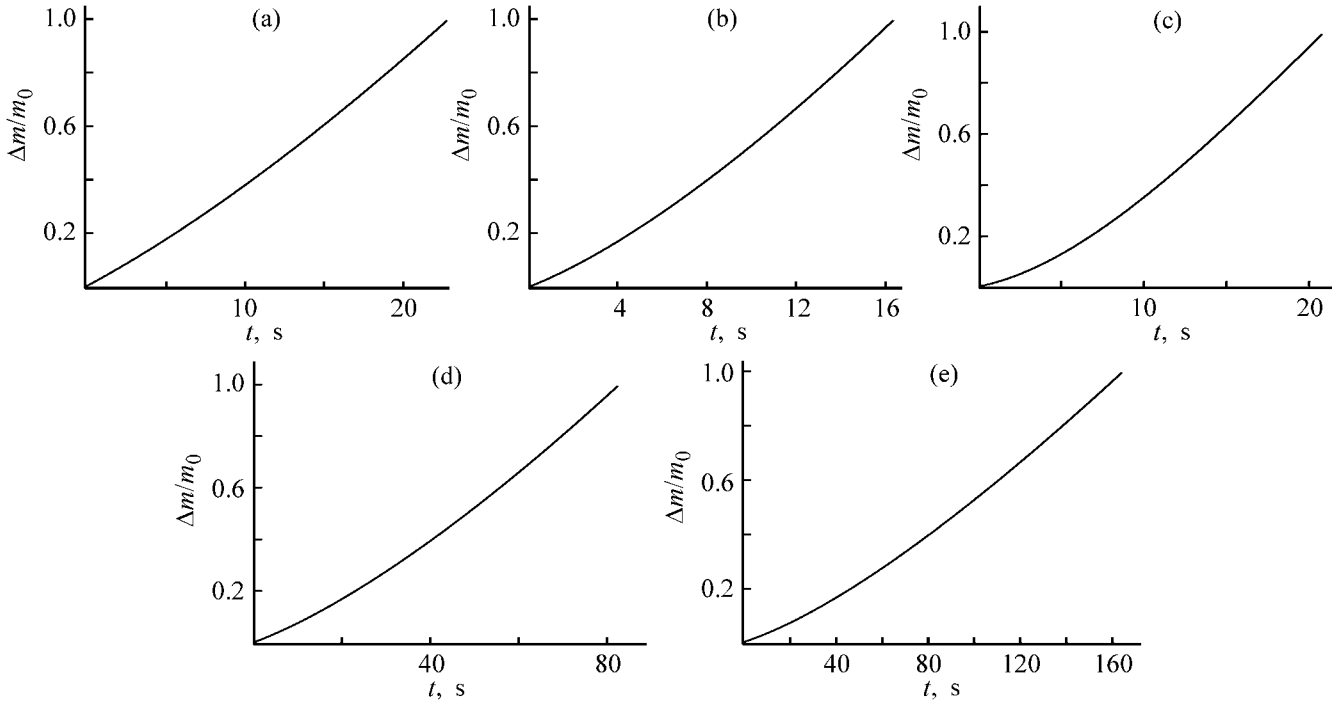

Fig. 4. Calculated curves of the relative weight loss $\Delta m/m_0$ in catalytic oxidation of quasicylindrical carbon particles at the catalyst surface. (t) Time. Radius and height of particles, μm: (a–c) 1, (d) 5, and (e) 10. Rate constants H and C, respectively, μm s^{-1}: (a) 0.33, 0.017; (b, d, e) 0.033, 0.033; and (c) 0.017, 0.033.

stant of remote oxidation at given temperature, μm s^{-1}; H, rate constant of contact oxidation at the same temperature, μm s^{-1}; R, particle radius, μm; L, initial height of the particle, μm; h, thickness of the layer burnt due to contact action in a time t; and c, thickness of the layer burnt due to the remote action in a time t,

$$h = Ht, \quad (1)$$

$$c = Ct \quad (2)$$

at a linear dependence of the thickness of the burnt layer due to each processes.

In the calculations, we considered V_0 (initial particle volume, μm^3) and V_t (particle volume after a some time when a part of the material was burnt), based on the model configuration

$$V_t = \Pi[R^2(1 - z - h) + zR^2 - Rz^2 + z^3/3] \quad (3)$$

(z is shown in Fig. 3), and also V_b (volume of the burnt part of the material):

$$V_b = \Pi[R^2h + Rz^2 - z^3/3]. \quad (4)$$

Variation of the volume is in direct proportion to the weight loss by the particle (sample).

The results of calculation for various ratios of the burning rates of particles by each mechanism are presented in Fig. 4 and Table 1. The ratio of the burning rates of a particle by the mechanism of contact and remote actions can vary with temperature, since these processes have different activation energies. It is believed that the contact action predominates at relatively low temperatures and the remote action, with heating. A comparison of the shapes of the experimental dependences for the weight loss by the pellet in the contact and remote actions of the catalyst (Fig. 2) with the calculated curves gave a good correlation, which suggests that the model suggested is valid. The experiments confirmed that at relatively low temperatures virtually only contact oxidation at

500	0.63	

a constant rate occurs on vanadate catalysts, which is accompanied by the linear weight loss and is satisfactorily described by the equation with x values close to 1:

$$m^x = Kt, \quad (5)$$

where m is the total weight loss of the sample in a time t and K is the effective rate constant.

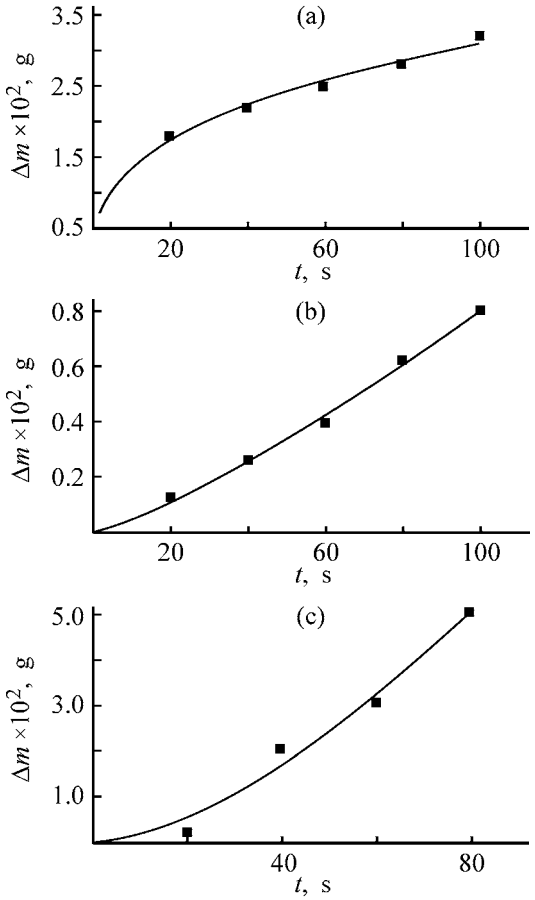

Fig. 5. Kinetic curves for weight loss Δm by carbon samples in the presence of the catalyst $La_{0.75}Ag_{0.25}MnO_{3 \pm y}$ at (a) 400, (b) 450, and (c) 500°C.

The exponent x in these equations is governed by the oxidation mechanism [1]. With heating, a component corresponding to the remote action of the catalyst appears and the formal value of x decreases.

The developed software allows calculation of the oxidation of particles with an arbitrary height-to-diameter ratio even in the case when the oxidation of particles due to the contact and remote action is not described by a linear law. In this case, the experimentally determined actual dependences $h = f(t)$ and $c = f_1(t)$ can be used. In a similar manner, we can describe the oxidation of spherical particles that take, due to the remote action, an egg-like shape with a cut-off bottom end, which is caused by the contact oxidation. This was confirmed experimentally. Observation of the oxidation of a cylindrical sample, initially brought in contact with the catalyst through the generatrix of the cylinder, can be conveniently used for calculating the configuration of spherical particles. In the course of burning, the round cross-section of the sample changes, which is recorded photographically.

Based on the fact that the catalysts of varied nature can accelerate each stage of carbon oxidation to different extents, we performed comparative experiments. Along with the oxidation on the vanadate catalyst with a monazite structure, we performed experiments with catalysts in the system Ag–La–Mn–O. Typically, these catalysts contain perovskite phases doped with silver [12–15] and also a certain amount of metallic silver and manganese oxides. Such compositions are very active in deep oxidation of gaseous products (organic substances of various classes, carbon monoxide, etc.).

A comparison of the kinetics of carbon oxidation at 400–500°C on the catalysts of the $Cs_xLa_{1-x}VO_{4 \pm y}$ and $La_{0.75}Ag_{0.25}MnO_{3 \pm y}$ types confirmed that the catalyst nature is an extremely important factor in this case. The experimental data obtained for the total weight loss were described satisfactorily by power dependences of type (5), irrespective of the mechanism of the catalyst action.

As mentioned above, the oxidation mechanism for vanadate catalyst changes with heating. At relatively low temperatures, the contact action predominates, and with heating the remote action is manifested. The system Ag–La–Mn–O at relatively low temperatures (400°C) is presumably characterized by a stronger hindrance associated with the substance transfer in the gas phase (Table 2, Fig. 5), compared to the vanadate catalyst. In this case, virtually no area of remote burning of the pellets was observed, as in the case of vanadate catalysts at low temperatures.

The differences in the influence of the catalysts can be caused by the fact that the system Ag–La–Mn–O is less able to exert the contact action manifested in the first stage of carbon oxidation to CO and, at the same time, significantly accelerates oxidation of CO to CO_2. As in the preceding case, the oxidation mechanism changes as the temperature of the experiments increases, which is suggested by the changed shapes of the dependences of pellet weight loss on time. It is likely that the appearance of a sufficient amount of CO results in local heating and initiation of the "remote" mechanism manifested in the formation of an additional burning front at an angle of 45° to the catalyst surface. The overall oxidation abruptly accelerates with time.

The activity of catalysts based on cesium vanadate promoted with cesium sulfate and without promoter [1] in CO oxidation was determined using a Katakon 1.1 flow-circulating reactor and a Testo-350 XL electronic gas analyzer. The content of CO in the gas–air mixture was 0.2 vol %, and the feeding rate, 6.3 l h^{-1}; in this case, the specific load on the catalyst was 1500 h^{-1}. For dosing of the mixture, we used a gas cylinder with 20.3 vol % CO in nitrogen. As a result, we found that the vanadate phases actually have poorer catalytic characteristics with respect to CO (Fig. 6) in comparison with doped perovskites [4, 5, 15]. It is likely that the presence of cesium sulfate as a promoter results in a decrease in the effective surface area of the catalyst with heating due to the possible appearance of a local eutectic melt [1], which results in decrease in the degree of CO conversion. The specific surface area of promoted and unpromoted samples was 0.25 and 0.52 $m^2 g^{-1}$, respectively (Tristar-3000 equipment was used), while perovskite catalysts have a surface area of approximately 20 $m^2 g^{-1}$.

In addition, the difference in the type of behavior of the catalytic systems studied may be due to the possible contact reduction of silver, initially originally contained in the perovskite structure, by carbon, which was found experimentally as a silver film covering the catalyst pellet after contact annealing. This can hinder transfer of gaseous products to the contact area. In this case, the previous assumptions on the advisability of using combined blocks containing catalysts of different compositions [1–3] are confirmed. In particular, vanadate catalysts can remove carbonic products from exhaust gases, with further, more efficient, purification on perovskites.

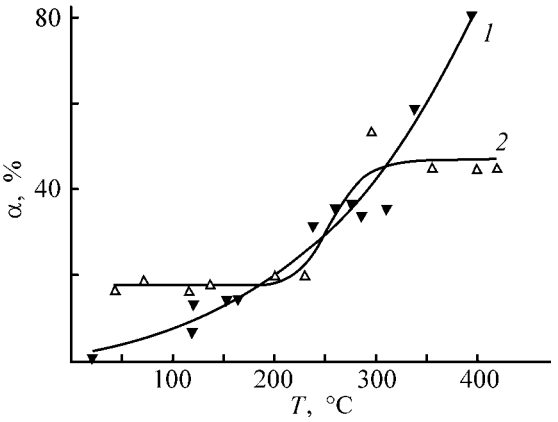

Fig. 6. Degree of CO conversion α vs. temperature *T*. Catalyst: (*1*) $Cs_{0.1}La_{0.9}VO_4$ (R^2 = 0.9653) and (*2*) $Cs_{0.1}La_{0.9}VO_4$ + 10% Cs_2SO_4 (R^2 = 0.9445).

CATALYSIS

Adsorption of Chlorobenzene on V_2O_5/Al_2O_3 Catalyst under Dynamic Conditions

L. D. Asnin, A. A. Fedorov, and Yu. S. Chekryshkin

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received June 6, 2006

Abstract—Frontal chromatography was used to study the adsorption dynamics and adsorption equilibrium of chlorobenzene on a 5% V_2O_5/Al_2O_3 catalyst at temperatures of 50 and 100°C. The mixed-diffusion model was employed to describe the elution curve and evaluate the effective coefficients of external mass exchange and diffusion within transport pores.

DOI: 10.1134/S1070427207020188

Vanadium oxide catalysts exhibit high activity in reactions of deep oxidation of chloroaromatic compounds [1–4], which makes them attractive for development of systems for detoxication of gas discharges containing compounds of this kind. Oxides of aluminum, titanium, and zirconium and various double oxides have been studied as supports for vanadium oxide [1–6], with mostly titanium oxide used in recent years [1, 3, 5, 7, 8]. Comparative studies of V_2O_5/Al_2O_3 and V_2O_5/TiO_2 catalysts have shown that the latter is more active in oxidation of 1,2-dichlorobenzene [1] and benzene [6]. At the same time, vanadium(V) oxide supported by Al_2O_3 shows a no less activity in oxidation of chloroethylene than catalysts on other supports [4]. The data of [9–11] suggest that vanadium-aluminum oxide catalysts provide a conversion of chloroaromatic compounds that is sufficient for industrial purposes. An advantage of aluminum oxide over titanium oxide is the larger specific surface area of the former. This circumstance becomes particularly important in the case of the adsorption-catalytic method for elimination of toxic contaminants, in which the catalytic stage proper is preceded by the stage of substance concentration on the surface of an adsorbent-catalyst. Thus, catalysts with a more developed surface will provide a higher specific capacity of the reactor-adsorber. Another important factor that predetermined the choice of a support was the existence of a well-developed domestic industry for manufacture of aluminum oxide for catalytic purposes [12].

The mechanism of oxidation of chlorobenzenes on the surface of the V_2O_5/Al_2O_3 catalyst has been studied at elevated temperatures by means of IR spectroscopy and thermal desorption method [2, 11, 13]. In [14], data on the adsorption equilibrium and adsorption thermodynamics in the system constituted by chlorobenzene and 5% V_2O_5/γ-Al_2O_3 at partial pressures of the adsorbate of up to 18 Pa in the temperature range 190–240°C were reported. No studies have been carried out in the practically important temperature range below 100°C. Data on dynamic characteristics of adsorption and catalyst capacity in concentrated gas media, necessary for development of adsorption-catalytic processes, are not available in the literature. The present study was aimed to close this gap.

EXPERIMENTAL

The measurements were made by means of frontal chromatography on a Tsvet-530 chromatograph with a flame-ionization detector, connected to a Power-Graph 2.0 computerized data acquisition unit via E24 analog-to-digital converter (L-card, Moscow). Nitrogen additionally dried with aluminum oxide and CaA zeolite was used as carrier gas. Prior to use, chlorobenzene (analytically pure grade) was dried over a freshly calcined NaA zeolite. A gas–vapor mixture was obtained by passing the carrier gas through a glass saturator thermostated at 0°C. The mass flow rate of chlorobenzene, Q, was found from the loss of mass by the saturator. If Q and the volumetric flow rate of the carrier gas, φ, are known, the chlorobenzene concentration in the gas flow can be calculated by

$$c_0 = Q/\omega.$$

A 1.975-g portion of the catalyst (0.63–0.80-mm fraction) was charged into an absorbing cartridge having the form of a brass tube of length L = 5 cm and inner diameter of 0.9 cm. Before carrying out the ex-

periments, a sample was conditioned in a flow of the carrier gas at 140°C for 5 h. The catalyst was prepared by deposition of V_2O_5 in an amount of 5% relative to the support mass from an aqueous solution of NH_4VO_3 of pure grade, drying at 100°C, and subsequent calcination in air at 450°C for 5 h. Technical-grade aluminum oxide was used as a support. The parameters of the support and the catalyst, measured by the method of low-temperature adsorption of nitrogen on a Micromeritics ASAP 2400 installation, are presented in Table 1 and Fig. 1.

As a measure of the adsorption activity of a catalyst were used the breakthrough (a_{br}) and equilibrium (a_{eq}) adsorption capacities. The value of a_{br} was calculated from the time at which chlorobenzene appears at the outlet of the absorbing cartridge. The equilibrium capacity was found as the area of the figure delimited by the elution curve plotted in the c–V coordinates and the horizontal line $c = c_0$, where c is the chlorobenzene concentration at the outlet of the absorbing cartridge; c_0, chlorobenzene concentration in the flow; and V, volume of the gas–vapor mixture passed through the absorbing cartridge (c_0 and V at room temperature and normal pressure). In both cases, a correction was made for the dead volume, determined with methane. Each measurement was repeated no less than two times.

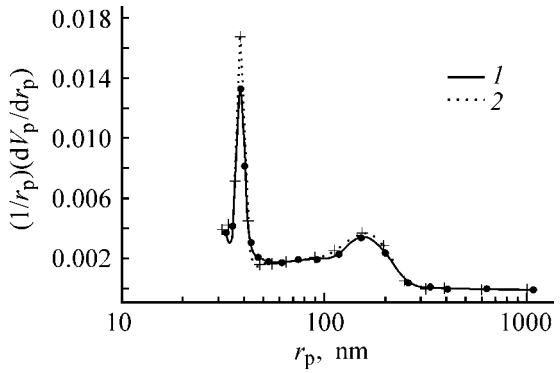

Fig. 1. Pore size distribution for samples of (*1*) catalyst and (*2*) support. (r_p) Pore radius and (V_p) pore volume.

In the adsorption isotherm, the equilibrium concentration c_{eq} reduced to the temperature and average pressure in the absorbing cartridge corresponds to a_{eq}.

As shows comparison of the structural parameters of the support and catalyst, deposition of 5% vanadium oxide does not change the type of the porous structure (the catalyst remains mostly mesoporous), but leads to a slight decrease in the pore volume, with the deposition of vanadium oxide occurring in both macro- and mesopores. According to [15–17], vanadium(V) oxide is deposited on the surface of metal oxide supports in the form of a monolayer.

Table 2 lists the data obtained in measurements of the breakthrough and equilibrium adsorption capaci-

ties. It can be seen that a_{br} is virtually independent of the gas flow rate, but strongly depends on the adsorbate concentration in the gas phase. The equilibrium adsorption capacity exceeds the breakthrough capacity by approximately a factor of 1.15, and this ratio is independent of experimental conditions. Thus, about 13% of the sorbent capacity remains unused in the dynamic mode. On raising the temperature from 50 to 100°C, the sample capacity becomes three times lower, all other conditions being the same.

As follows from Table 2, the reached filling of the catalyst surface is far from the range of monolayer filling, but does not correspond, either, to the linear portion of the adsorption isotherm (Fig. 2).

The data obtained are well linearized in the coordinates of the Langmuir equation. At the same time, it cannot be suggested that the conditions of the Langmuir model (adsorption on a uniform surface) are, indeed, satisfied. This is so because, as demonstrated previously [14], the chlorobenzene adsorption on the V_2O_5/γ-Al_2O_3 catalyst is described at small degrees of filling by the Freundlich adsorption isotherm. Two explanations of this contradiction are possible. The first of these consists in that deviations from the Langmuir model are not noticeable in a narrow range of the data obtained, which covers θ values of 0.11 to 0.21. At the same time, it has been noted [19] that the fraction of highly active adsorption centers on the surface of V_2O_5/γ-Al_2O_3 is small, on the order of 10^{-2}%. After a certain degree of filling is reached, the thermodynamic adsorption parameters start to decrease, as the amount of adsorption increases, at a considerably lower rate. The same conclusion can be based on the results of studies concerned with the adsorption of chlorobenzene and benzene on aluminum oxide and vanadium oxide catalyst [14, 20]. Hence, it seems reasonable to suggest that, after "particularly active" adsorption centers are filled, the surface becomes quasi-uniform and the adsorption equilibrium on such a surface is described by the Langmuir isotherm. It was reported in the review [21] that a phenomenon of this kind is observed in various adsorption systems containing chlorobenzenes and a polar adsorbate (water or pyridine). Pyridine acts as a catalytic poison that blocks strong-adsorption centers, upon which the surface of a solid becomes quasi-uniform and the interaction of the target adsorbate with the adsorbent is described in terms of the Langmuir model.

Lukin and Novosel'skii [22] derived, based on the model of a mixed-diffusion adsorption dynamics, suggested by Akulov and co-authors [23], an expression describing the elution curve in the case of the Langmuir isotherm. This expression has the form of the Shilov equation:

Table 3. Dynamic adsorption parameters at T = 100°C

v,* cm min^{-1}	c,* g dm^{-3}	$K = \Gamma/v$, min^{-1}	K[Eq. (1)], min^{-1}	β_e, s^{-1}	$D \times 10^2$, cm^2 s^{-1}
59	0.0124	15.5	15.5	293	0.30
115	0.0065	11.5	11.4	97	0.29
113	0.0127	8.0	7.9	274	0.40
173	0.0040	8.9	9.0	33	0.36
174	0.0083	6.4	6.4	326	0.37

* Reduced to the temperature and pressure in the absorbing cartridge.

$$t = KL - t_0, \quad (1)$$

where

$$t_0 = K_1 z_1 + K_2 z_2,$$

$$z_1 = \ln(1/y) - 1 + h\ln[(1 - y)/y],$$

$$z_2 = 1.5(1 - y)^{1/3} + y - 1.4 + h\left\{1.5\ln[1 + (1 - y)^{1/3} + (1 - y)^{2/3}] - \sqrt{3}\arctan\{[2(1 - y)^{1/3} + 1)]/\sqrt{3}\} - 0.5 + 3.464\pi\right\},$$

$y = c/c_{eq}$, and h is the parameter of the Langmuir equation written in the dimensionless form:

$$a/a_{eq} = [(1 + h)y]/(h + y).$$

The coefficient K has the same meaning as that in the ordinary Shilov equation and characterizes the mo-

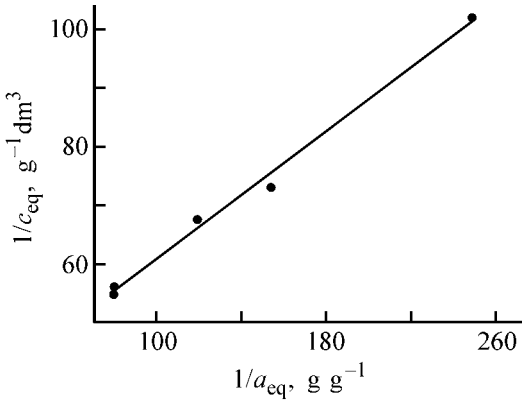

Fig. 2. Isotherm of chlorobenzene adsorption a_{eq} on the V_2O_5/Al_2O_3 catalyst at 100°C. (c_{eq}) Equilibrium adsorbate concentration in the gas phase.

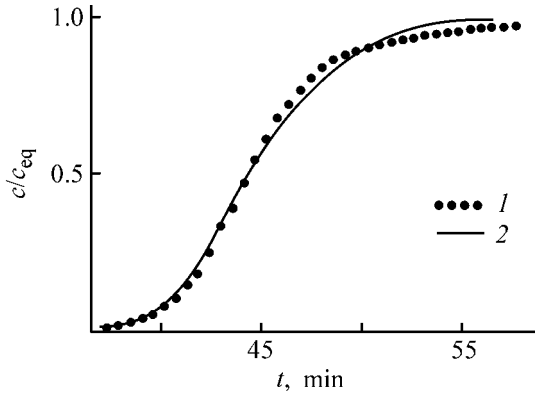

Fig. 3. (*1*) Experimental elution curve and (*2*) that calculated by Eq. (1). T = 100°C, v = 173 cm min^{-1}, c_{eq} = 0.0047 g dm^{-3}. (*c*) Chlorobenzene concentration at the outlet of the absorbing cartridge and (*t*) time.

tion velocity of the adsorption front along the layer. The parameters K_1 and K_2 are related to the external-mass-exchange coefficient β_{ex} and diffusion coefficient D in transport pores and to the catalyst grain radius R by the following expressions

$$K_1 = \Gamma/\beta_e, \quad K_2 = \Gamma R^2/3D.$$

The adsorption coefficient $\Gamma = a'_{eq}/c_{eq}$ is expressed in terms of the adsorption calculated per unit cartridge volume.

Because the dependence of t on variables z_1 and z_2 is linear, the parameters of Eq. (1) can be found by the least-squares procedure and, consequently, the dynamic coefficients can be calculated (Table 3). Figure 3 shows an example of approximation of the experimental data with the theoretical elution curve. The applicability of the model employed is also indicated by the fact that the protective-action coefficients K obtained by regression analysis coincide with their theoretical values $K = \Gamma/v$, where v is the linear flow velocity calculated per full cross-section of the tube.

The coefficient β_e varies within an order of magnitude, commonly has smaller values at lower adsorbate concentrations, and, presumably, is independent of the flow velocity. Close values of the external-mass-exchange coefficient (about 100 s^{-1}) were observed in the case of benzene adsorption on AU-1 and AU-2 carbons under similar experimental conditions [24].

The effective inner-sphere-diffusion coefficient randomly fluctuates around a certain average value, which suggests that concentration-dependent effects, e.g., the surface diffusion [22], exert no influence on the transport within pores. The value of D is approximately two orders of magnitude smaller than that of the "normal" diffusion coefficient of chlorobenzene in nitrogen (D_0 = 0.12 cm^2 s^{-1} as calculated by the Fuller–Schettler–Gidding equation [25]). It was noted in [24] that the D/D_0 ratio approximately gives the specific volume of transport pores, being equal to 3% in the case in question. The so small fraction of transport pores can be understood on the assumption that transport pores are macropores, whereas mesopores have a closed structure. The presence of two peaks in the pore size distribution curve in Fig. 1 does not contradict this assumption.

CONCLUSIONS

(1) The 5% V_2O_5/Al_2O_3 catalyst prepared on an industrial support has high adsorption parameters and can be recommended for adsorption-catalytic purification of gas discharges. The excess of the equilibrium adsorption capacity over the breakthrough capacity is independent, within the range studied, on experimental conditions and is about 13% for the given granulometric composition of the catalyst.

(2) The mixed-diffusion model was successfully used to describe the dynamics of chlorobenzene adsorption, which made it possible to evaluate the coefficients of external mass transfer and transport diffusion. The order of magnitude of the first coefficient is consistent with the known published data on the range of variation of this quantity. The low ratio between the effective diffusion coefficient in transport pores and the normal diffusion coefficient indicates that the volume fraction of transport pores in the samples is small.

Abstract—Zirconiun dioxide promotes the catalytic activity of a dealuminated mordenite in *n*-butane isomerization. A method is suggested for preparing, without any solvents, a sulfated mordenite-zirconium catalyst active at relatively low temperatures.

DOI: 10.1134/S107042720702019X

Isomerization of *n*-butane is one of the most important processes of petrochemical industry in production of alkylates and other valuable products [1, 2]. To perform this reaction, different heterogeneous catalysts have been suggested. Among them the chlorinated platinum-alumina catalysts, metallozeolites, and sulfated zirconium dioxide are of particular interest [1–8]. Each of these catalysts has advantages and disadvantages. For instance, chlorinated platinum-alumina catalyst require a thorough pretreatment of the raw material and are environmetally unfavorable. Isomerization with metallozeolites is performed at high temperatures; they are favorable in isomerization of C_5 and C_5–C_6 paraffins. Sulfated zirconium dioxide is active at relatively low temperatures. However, additional studies are required to improve the stability and reproducibility of its catalytic properties.

Due to cellular structure and possibility of purposeful modification of the physicochemical properties, zeolites are promising catalysts for *n*-butane isomerization. It was shown in [9, 10] that dealumination of H-mordenite enchances its isomerization activity. The activity of dealuminated H-mordenite can be further raised by choosing appropriate promoters [11, 12].

In this study, we examined the catalytic properties of binary mordenite-zirconium and ternary sulfated mordenite-zirconium catalysts to find the probable synergism of such systems and to develop on their base low-temperature catalysts of *n*-butane isomerization.

EXPERIMENTAL

The catalysts were prepared from dealuminated H-mordenite with the SiO_2/Al_2O_3 ratio of 17 (sample HM_{17}). To promote HM_{17} with zirconium dioxide, we used impregnation and mechanical mixing of the zeolite with $ZrO(NO_3)_2$ or $ZrO(OH)_2$, with subsequent decomposition of the mixture at 823–873 K [the samples were denoted as $a\,ZrO_2/HM_{17}$ (impregnation) and HM_{17}–$a\,ZrO_2$ (mixing), where a is the ZrO_2 content, wt %]. The samples obtained were sulfated by their treatment with 2 M solution of $(NH_4)_2SO_4$. Catalysts were molded with aluminum hydroxide as a binding agent, dried at 383–393 K, and calcined at 823–873 K.

The conversion of *n*-butane was studied in a flow-type apparatus at atmospheric pressure within the 433–523 K range. A 2 cm^3 portion of cylindrical catalyst granules 1–3 mm in size was charged into a quartz reactor and activated in an air flow at 773 K for 3 h. After the experiments, the catalyst was regenerated under the same conditions. After activation or regeneration, catalysts were cooled in an N_2 flow to the reaction temperature, and *n*-butane was started to be delivered at a flow rate of 300 ml h^{-1}. No carrier gas was used.

The induction period of the reaction was 20–30 min, depending on the experimental conditions. During this time, the isobutane yield reached the maximum and then decreased to a constant value. The data reported in this paper are related to 20th minute of the reaction run. The reaction products were monitored chromatographically, and catalysts, by powder X-ray

diffraction (DRON-3M X-ray diffractometer) and thermal analysis (Q-1500D derivatograph).

Zirconium dioxide synthesized by decomposition of $ZrO(NO_3)_2 \cdot 2H_2O$ and calcination of $ZrO(OH)_2$ hydrogel precipitated with NH_4OH solution shows low activity in *n*-butane isomerization. Sulfation of ZrO_2 preliminarily calcined at 823–873 K does not raise the isobutane yield. The active catalyst is formed after treatment with an $(NH_4)_2SO_4$ solution of $ZrO(OH)_2$ dried at room temperature. In this case, the *n*-butane conversion is 22.0% at 493 K; the yield of isobutane reaches 16.9% (the residue consists of propane and *n*- and isopentanes).

Impregnation of dealuminated mordenite HM_{17} with $ZrO(NO_3)_2$ aqueous solution, with further calcinations at 823 K, substantially improves the catalyst activity, which appears in a rise in the isobutane and isopentane yield and in a decrease in the optimal temperature of the reaction. That is, ZrO_2 has a promoting effect on the activity of dealuminated mordenite.

It should be noted that, in contrast to HM_{17}, whose sulfation does not substantially affect its isomerization activity, $a ZrO_2/HM_{17}$ samples (a = 2.5–10.0 wt %) show after sulfation a higher activity in *n*-butane isomerization at relatively low temperatures. These data show that, in contrast to ZrO_2, which directly promotes HM_{17}, sulfate ions raise the activity of dealuminated mordenite only when the latter contains zirconium dioxide. The data obtained are listed in Table 1.

Depending on the ZrO_2 content in mordenite-zirconium and sulfated mordenite-zirconium catalysts, the *n*-butane conversion and the total yield of isoparaffins (isobutane and isopentane) pass through maxima. As can be seen from the figure, the maximal activity of the catalysts prepared by impregnation is observed for samples containing 5.0–7.5 wt % ZrO_2.

The same extremal dependences are observed for catalysts prepared more simply by mechanical mixing of HM_{17} and $ZrO(NO_3)_2 \cdot 2H_2O$ without any solvent, followed by molding with a binding agent, drying, and calcination. A comparison of samples containing from 5 to 20 wt % ZrO_2 showed that the HM_{17}–10 wt % ZrO_2 catalyst has the highest activity in *n*-butane isomerization. The corresponding data are listed in Table 2.

It should be noted that such an extremal dependence of the activity on the ZrO_2 content is observed for the catalysts prepared by mechanical mixing of HM_{17} with a $ZrO(OH)_2$ hydrogel synthesized by precipitation from $ZrOCl_2 \cdot 8H_2O$ solution with aqueous

the sample prepared from ZrO(OH) hydrogel (Table 2, sample 6).

The difference in the properties of mordenite-zirconium catalysts prepared by impregnation or mechanical mixing is also manifested in that sulfation of impregnated catalysts $a ZrO_2/HM_{17}$ calcined at 823 K raised their activity, while sulfation of the HM_{17}–$a ZrO_2$ (mixed catalysts) samples calcined at the same temperature does not substantially affect the activity.

The three-component catalyst HM_{17}–10% ZrO_2–4% SO_4^{2-} prepared by simultaneous mixing of HM_{17}, $ZrO(NO_3)_2 \cdot 2H_2O$, and $(NH_4)_2SO_4$ followed by thermal treatment under the above standard conditions has a higher isomerization activity. At 463–493 K, the yield of isobutane and isopentane on this catalyst was 19.2–26.0 and 2.3–4.9%, respectively, at an *n*-butane conversion of 36.3–51.6%. The yield of the main by-product of the reaction, propane, decreases substantially faster as compared to the isobutane yield, and the selectivity of the reaction correspondingly increases.

Taking into account the data obtained, we studied the conversion of *n*-butane on a catalytic apparatus with two series-connected reactors. In this case, a higher yield of isoparaffins and selectivity can be reached at lower temperatures. The data on *n*-butane conversion and the yield of isoparaffins after the first and second reactors at various temperatures are listed in Table 3. As seen, the yield of isobutane in the two-reactor system at 448–463 K increases to 25.3–28.9% at a small decrease in the isopentane yield. The reaction selectivity with respect to isoparaffins increases to 75% due to a substantial decrease in the propane yield. These results are of certain interest because the catalyst used contained no precious metals (Pt, Pd) and was prepared by a simple and convenient method at atmospheric pressure and without any carrier gas. Such catalysts can be used as a basis for preparation of more active catalysts for isomerization of *n*-paraffins.

The high catalytic activity of sulfated ZrO_2 promoted with various metals (Mn, Fe, Ga, Pt, etc.) was discussed in a number papers [6–8, 13–17]. In this study, we showed that zirconium compounds promote the activity of dealuminated mordenite, whereas sulfation does not affect isomerization activity of mordenite itself, but substantially improves that of the mordenite-zirconium catalysts. This fact suggests that the promoting effect of sulfate ions is caused by the presence of ZrO_2 in the catalysts. At the same time, it should be noted that dealuminated mordenite is not only a support for ZrO_2 and SO_4^{2-}, but is the dominating component of the mordenite-zirconium catalysts, as indicated by the attainment of the maximal catalytic activity at small concentrations of ZrO_2 and SO_4^{2-} and by the preservation of the same features of the reaction before and after promotion of HM_{17}. The parallel variation of the yields of propane, isobutane, and isopentane with time can be caused by the bimolecular mechanism of the reaction. However, this matter requires a further study.

The thermal analysis of the systems HM_{17}, 5% ZrO_2/HM_{17} and 4% SO_4^{2-}/5% ZrO_2/HM_{17} and of samples prepared by mechanical mixing (HM_{17}–10% ZrO_2 and HM_{17}–10% ZrO_2–6% SO_4^{2-}) does not show any substantial difference in their thermal behavior. Only one endothermic peak at 388 K, caused by elimination of adsorbed water, exists in the DTA curve of HM_{17}. After impregnation of HM_{17} with $ZrO(NO_3)_2$, this peak shifts to 398 K and a weak endothermic peak appears at 628 K.

These facts are probably caused by dehydration and decomposition of the zirconium salts. The high-temperature peaks of sulfate decomposition were not found, probably, because of the small amounts of sulfate groups in the samples examined.

The X-ray diffraction patterns show that the crystal structure of H-mordenite is preserved after dealumination and promotion with zirconium dioxide. In the diffraction patterns of a powder with the composition 7.5% ZrO_2/HM_{17} and ZrO_2, prepared by decomposition of $ZrO(NO_3)_2 \cdot 2H_2O$ at 873 K, reflections characteristic of tetragonal ZrO_2 at $2\theta = 30^\circ$ were observed [18]. Based on the data obtained, we can suggest that impregnation of HM_{17} with a $ZrO(NO_3)_2$ aqueous solution, followed by thermal treatment at 823–873 K, yields a mixed mordenite-zirconium system with a higher isomerization activity at relatively low temperatures because of the interaction between the decomposing zirconium salt and HM_{17}. This process affects the specific texture and acid–base properties of the catalytic mixture.

CONCLUSIONS

(1) The promoting effect of ZrO_2 on the catalytic activity of dealuminated mordenite in isomerization of *n*-butane was found.

(2) It was shown that the sulfated mordenite-zirconium catalyst prepared by a simple and convenient method shows high activity in *n*-butane isomerization at atmospheric pressure and relatively low temperatures.

Abstract—Catalytic oxidation of a mixture of low-molecular-weight sulfides with atmospheric oxygen was studied. The catalytic activity of poly(cobalt phthalocyanine) in this process is higher than that of monomeric cobalt phthalocyanine.

DOI: 10.1134/S1070427207020206

The use of the gas condensate of the Karachagansk deposit in natural gas processing increased the sulfur content in the isopentane and pentane fractions to 0.02 and 0.2 wt %, respectively [1]. The total sulfur content of the isopentane and pentane fractions used in production of synthetic rubbers should not exceed 0.003 and 0.01 wt %, respectively [2].

An analysis of pentanes for sulfur-containing compounds showed the presence of mercaptans and sulfides [1]. The mercaptan fraction consists mainly of ethyl isopropyl, and butyl mercaptans. The sulfide fraction contains dimethyl sulfide as the major component and a minor amount of methyl ethyl sulfide.

One of the procedures for removing sulfur-containing compounds is their catalytic oxidation with atmospheric oxygen [2]. Therefore, a search for effective catalysts for this reaction is a topical problem.

EXPERIMENTAL

The amount of sulfide sulfur in the pentane–isopentane fractions ranges from 35 to 50 wt % relative to the total sulfur content [3]. The efficiency of desulfurization by alkali treatment and demercaptanization in the presence of cobalt disulfophathalocyanine decreases when both sulfides and mercaptan are present in the substrate [4]. We studied comparatively the oxidation of a mixture of sulfur-containing compounds in the presence of cobalt(II) phthalocyanine [PhCo(II)] and its polymer [PPcCo(II)] as catalysts. For this purpose, we used isooctane solutions of a mixture of sulfides with a sulfide sulfur content of 0.052–0.059 wt % and of a sulfide-mercaptan mixture with a mercaptan sulfur content of up to 0.055 wt %. The phthalocyanine complexes were used in the form of a suspension or a solution in aqueous sodium hydroxide. The PPcCo(II) and PcCo(II) concentration in the alkaline solution was 0.025 and 0.033 wt %, respectively. A suspension or a solution (50 ml) of the phthalocyanine complex and a solution of sulfur-containing compounds in isooctane (100 ml) were placed in a 250-ml conical flask. Air was bubbled through a glass tube. The mixture was vigorously stirred for 30 min at 40°C and then the sulfide sulfur content in isooctane was determined.

Sulfur-containing compounds were analyzed by gas chromatography–mass spectrometry on a Finnigan 4021 spectrometer. The total sulfur content of the pentane–isopentane fraction was determined in accordance with GOSTs (State Standards) 22986–78 and 13380–81. The experimental results are presented in Table 1. It is seen that PPcCo(II) is a more efficient catalyst for oxidation of low-molecular-weight sulfides that PcCo(II). At the same time, the catalytic activity of poly(metal phthalocyanines) (PPcM) in oxidation may be lower, higher, or equal to that of the monomers (PcM) [5]. The reasons for this phenomenon were not understood. However, the catalytic activity of PPcM was believed to be due to structural features of the intermediates and to the influence of the reaction medium.

Because the PcM–S bond formed by σ electrons of the sulfur atom and donation of d_π-electrons of the metal ion to the unoccupied σ-orbital of the sul-

fur atom is strong [6, 7], the PcM–$S(CH_3)_2$ complex should be stable. In the presence of molecular oxygen a PcM–$S(CH_3)_2$–O_2 complex can be formed. Decomposition of this complex yields the initial catalyst and dimethyl sulfoxide.

The high catalytic activity of PPcCo(II) in oxidation of sulfides by atmospheric oxygen can be due to an undistorted planar structure of the phthalocanine rings in the polymeric chain and, hence to a higher stability of intermolecular complexes of PPcCo(II) as compared to those of PcCo(II) [5]. It should be noted that the degree of sulfide oxidation catalyzed by both PPcCo(II) and PcCo(II) increases in the presence of mercaptans, which can be probably due to involvement of mercaptans and their derivatives in the formation of the intermolecular complexes [7–9].

Based on the experimental results, we developed an industrial installation for removal of sulfur-containing compounds from the pentane–isopentane fraction in the presence of PPcCo(II) (see figure). Raw material, stabilized sulfurous naphtha (C_5–C_6 fraction), is fed by a pump *2* from receiver *1* to a preliminary washing column *3*. The column is washed with 6% NaOH solution to remove traces of hydrogen sulfide. The prewashed petrol (100 volumes) is mixed with 6–10% NaOH solution (12–15 volumes). The mixture is bubbled with air using a compressor *4* and then is fed into a mixer *6* equipped with nine flow-measuring diaphragms. The turbulence produced in the course of passage of the naphtha, alkali, and air through the diaphragm holes provides a good contact between these components. Mercaptan passes into the alkaline solution and is oxidized to the disulfide [1, 2] which is extracted into the hydrocarbon phase. Sulfides are oxidized mainly to the corresponding sulfoxides. Since low-molecular-weight sulfoxides are readily soluble in water, the major portion of these compounds formed in the system passes into the alkaline solution. The residence time of the system in the mixer is sufficient for the reaction completion. The reaction mixture is fed from the mixer to a settler *7* where the sodium hydroxide solution is separated and recycled with a pump *8* to mixer *6*. The NaOH

Table 2. Distributiion of DMSO between hydrocarbon and aqueous phases (initial aqueous phase: 10% NaOH solution)

DMSO concentration in initial solution, wt %	Hydrocarbon : aqueous solution weight ratio	Hydrocarbon	Total sulfur content of the hydrocarbon phase, wt %
1	1 : 3	*n*-Hexane	0.0012
25	1 : 3	″	0.0029
50	1 : 3	″	0.0082
5	1.4 : 1	Isopentane	0.0007
9	1.3 : 1	″	0.0016
20	1.2 : 1	″	0.0024
33	1 : 1	″	0.0020
19	1.1 : 1	″	0.0025

solution circulating through the mixer contains 0.01–0.005 wt % PPcCo(II). This complex is added from a vessel *5* at regular intervals.

To remove traces of the alkali emulsion, the hydrocarbon fraction is passed through filter *9*. Then the hydrocarbon fraction containing oxidized sulfur compounds is fed into a distillation column *10* (15 TP, reflux ratio 3). Pentane and isopentane fractions are taken from the top of the column. The total sulfur content in these fraction meets the requirements of TU (Technical Specifications) 38.101 790–79.

The boiling points of the oxidation products, disulfides and sulfoxides, are higher than those of the initial mercaptans and sulfides and, hence, these products can be separated by distillation. Low-boiling sulfoxides (C_5–C_6) are readily soluble in water and are removed by washing.

The main sulfur-containing compound present in the pentane fraction examined, dimethyl sulfide, is oxidized to dimethyl sulfoxide. Dimethyl sulfoxide can be distributed between the aqueous alkali and the hydroxarbon fraction. Dimethyl sulfoxide (DMSO) can be accumulated in the aqueous phase in the course of multiple circulation of the oxidizing agent. Hence, its content in the hydrocarbon fraction should also increase. To determine the maximal DMSO content of the aqueous phase, we studied phase equilibria in the hydrocarbon–DMSO–NaOH solution system. Hydrocarbons were isopentane and *n*-hexane. The DMSO distribution was estimated from the total sulfur content in the hydrocarbon fraction.

The experimental results listed in Table 2 show that, even at a very high concentration of DMSO in the aqueous phase, the total sulfur content of the hydrocarbon fraction is not higher than hundredth of a persent. The distribution coefficient of DMSO between the aqueous and hydrocarbon fractions is 100. Thus, isopentane meeting the TU can be obtained at the DMSO content in the aqueous phase lower than 10%.

CONCLUSIONS

(1) It was shown that the catalytic activity of poly(cobalt(II)phthalocyanine) in oxidation of a sulfide mixture by atmospheric oxygen is higher than that of monomeric cobalt(II) phthalocyanine. The conversion of a sulfide mixture increases in the presence of mercaptans.

(2) A flow sheet was developed for removal of sulfur-containing compounds from pentane–isopentane fractions by oxidation with atmospheric oxygen in the presence of poly(cobalt(II) phthalocyanine).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidative Destruction of Dinitrophenols by Fenton's Reagent in the Presence of Inorganic Salts

A. A. Solov'ev, M. A. Pashina, and O. E. Lebedeva

Belgorod State University, Belgorod, Russia

Received August 3, 2006

Abstract—The influence of inorganic salts on the kinetics of oxidation of 2,4- and 2,6-dinitrophenols by Fenton's reagent, hydrogen peroxide, in the presence of iron(II) ions was studied.

DOI: 10.1134/S1070427207020218

Nitro derivatives of phenol are basic chemicals in production of some dyes and explosives and are widely used in agriculture as compounds having a multipurpose pesticide effect. However, by their toxicity for warm-blooded animals, compounds of the nitrophenol series are offensive and highly toxic substances with a cumulative effect. Water treatment to remove nitro derivatives of phenol is an important environmental problem.

Complete oxidation of organic contaminants (so-called mineralization) is considered to be the most reliable procedure of their inactivation. Oxygen, ozone, and hydrogen peroxide can serve as oxidants [1]. Hydrogen peroxide is an environmentally safe oxidant convenient in use. However, its oxidizing potential is insufficient to oxidize many persistent contaminants. More effective are oxidizing systems in which radical species are generated from H_2O_2. The best known system is Fenton's reagent: hydrogen peroxide in combination with iron(II) ions. Hydroxy radicals are formed by the scheme [2]

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^{\cdot} + OH^{-}.$$

Along with organic contaminants, inorganic salts, such as chlorides, sulfates, nitrates, and phosphates, are present in natural and waste water. However, only several studies have been devoted to the influence of these salts on the Fenton process, and only low concentrations of salts have been examined. For example, phenol, 2-chlorophenol, and 2-nitrophenol were oxidized with Fenton's reagent in solutions of sodium chloride and sulfate; the concentrations of salts did not exceed 20 mM [3]. The influence of inorganic ions on the oxidation of phenol was studied in [4]; the concentration of anions was 100 mg l^{-1}.

Here we studied mineralization of 2,4- and 2,6-dinitrophenols with Fenton's reagent in the presence of high concentrations of inorganic salts.

EXPERIMENTAL

We used 2,4- and 2,6-dinitrophenols of analytically pure grade without additional purification.

In all experiments, we studied the oxidation of 2,4- and 2,6-dinitrophenols at 23°C in an aqueous solution with a volume of 25 ml. The substrate concentration was constant and equal to 0.25 mM. Calculated amounts of H_2O_2 and $FeSO_4$ solutions were added to the test solution. The H_2O_2 concentration was varied from 4 to 16 mM, and the $FeSO_4$ concentration, from 0.125 to 0.5 mM. The experiment was carried out during for 60 min. The course of the process was monitored by measuring the optical density of the solution on a KFK-3-01 photometer at a wavelength of 345 nm. The pH was measured with a Mettler Toledo pH meter. In all runs, the pH value was kept equal to 3.0.

The initial pH value is one of the key parameters in the optimization of processes in the system H_2O_2–Fe^{2+}–substrate. Oxidation of most of organic compounds, among them such stable as chlorophenols, under the action of Fenton's reagent proceeds more efficiently at the initial pH 2.7–3.5 [5–9]. The dependence observed is caused by the influence of acidity on the rate of H_2O_2 decomposition and on the state of iron(II) ions in the solution and, hence, on their catalytic characteristics.

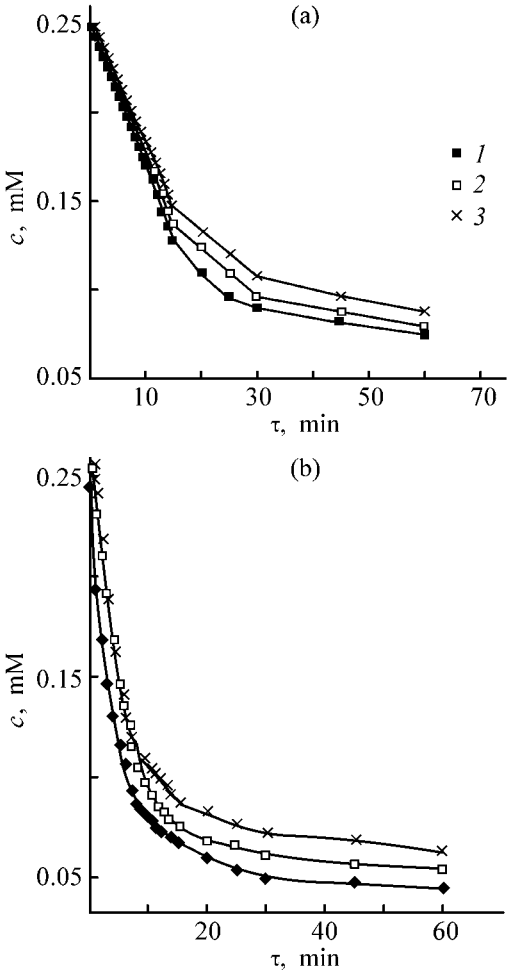

Fig. 1. Variation of the concentration c of (a) 2,4-dinitrophenol and (b) 2,6-dinitrophenol in the course of oxidation by Fenton's reagent in aqueous solutions of sodium nitrate. (τ) Time; the same for Fig. 2. Concentration of $NaNO_3$, mM: (*1*) 0, (*2*) 0.1, and (*3*) 1.0.

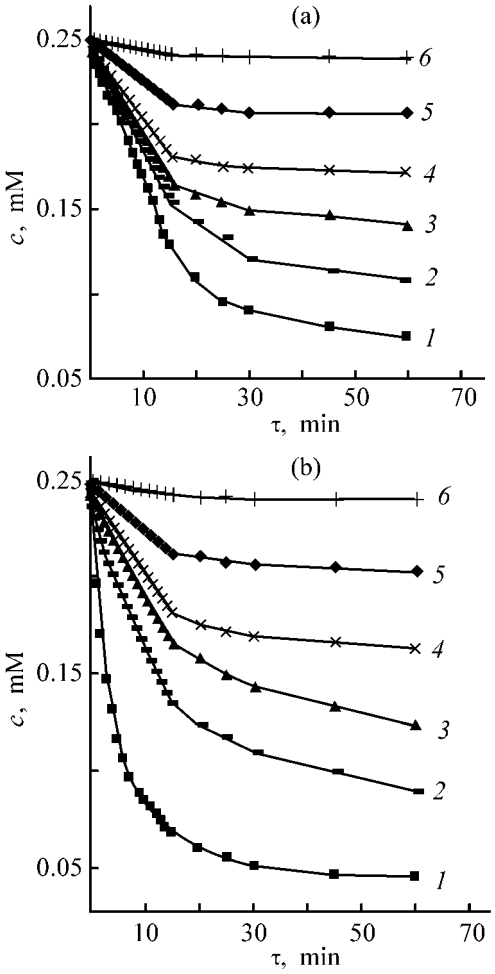

Fig. 2. Variation of the concentration c of (a) 2,4-dinitrophenol and (b) 2,6-dinitrophenol in the course of oxidation by Fenton's reagent in aqueous solutions of sodium chloride. Concentration of NaCl, mM: (*1*) 0, (*2*) 0.1, (*3*) 0.3, (*4*) 0.5, (*5*) 0.7, and (*6*) 1.0.

In the first series of experiments, we determined the optimal conditions of decomposition of dinitrophenols and the concentrations of H_2O_2 and iron(II) ions, because the oxidation mechanism depends on the $H_2O_2 : Fe^{2+}$: substrate ratio [10]. The experimental results showed that the optimal concentration of H_2O_2 for decomposition of dinitrophenols is 8 mM at a Fe^{2+} concentration of 0.25 mM. These conditions were maintained in all the subsequent experiments when studying the influence of inorganic salts on the decomposition of dinitrophenols.

It should be noted that the assortment of salts that can be used in the study is rather narrow, since organic anions are excluded due to ease of their oxidation by Fenton's reagent and fluorides, phosphates, and other anions of weak inorganic acids or acids of medium strength shift the solution pH to the alkaline region, making Fenton's reagent inefficient. In this context we used salts of strong acids.

The kinetic curves of oxidation of dinitrophenols by Fenton's reagent in 0.1 and 1 M $NaNO_3$ aqueous solutions are shown in Figs. 1a and 1b. The curves obtained do not significantly depart from the curves of oxidation of the corresponding substrates in distilled water. Ammonium nitrate does not affect the oxidation of dinitrophenols either. The kinetic parameters typical for the process in distilled water are kept in the presence of 0.1–1.0 M NH_4NO_3.

A different situation arises with addition of chloride ions into the solution. As can be seen from Figs. 2a and 2b, the rate of oxidation of dinitrophe-

nols in the presence of NaCl significantly decreases, whereas in an 1 M NaCl solution, the substrates are not oxidized: the concentrations of dinitrophenols do not noticeably vary.

Figures 2a and 2b show that, as the NaCl concentration increases, the kinetics parameters of the process regularly vary. The initial rate of the process and the final degree of conversion depend linearly on the NaCl concentration, with the linear dependence observed for both dinitrophenols (Figs. 3a, 3b).

It can be assumed that chloride ions, rather than sodium ions, are the main inhibiting species, because $NaNO_3$ does not exhibit this effect. Substitution of Cs^+ ions for Na^+ ions does not essentially alter the influence of the salt on the course of the process. The curves obtained in the presence of CsCl are similar to those obtained with of NaCl. Data for CsCl are described by the same linear dependence as that in the case of NaCl.

To explain the results obtained, it necessary, first and foremost, to check whether H_2O_2 is consumed in side processes, including those involving trace contaminants. The experiment showed that the H_2O_2 concentration in NaCl solutions without dinitrophenols and iron(II) ions remains constant for a long time.

According to published data, one of the reasons why anions affect the oxidation by Fenton's reagent is that iron complexes are formed. It was appropriate to study one more anion able to form complexes. The next series of experiments was performed in solutions of sodium sulfate. We revealed no noticeable inhibiting effect of sodium sulfate similar to that of chloride ions. The resulting kinetic curves do not significantly depart from the curve of oxidation of the corresponding substrate by Fenton's reagent in distilled water.

A more probable assumption is that chloride ions are oxidized by Fenton's reagent in the systems studied in parallel with oxidation of dinitrophenol. It has been noted that Fenton's reagent has a high redox potential (2.8 V [11]).

It should be noted that Bali and Catalkaya [4] studied only low concentrations of anions (1–3 mM) and reported only the inhibiting effect of phosphate ions, byt no noticeable influence of chloride or sulfate ions on phenol oxidation by Fenton's reagent was not revealed.

The nature of the cation of an inorganic salt does not affect the oxidation of dinitrophenols. It is likely that, in these studies, ammonium cations are not oxidized or are extremely weakly oxidized by Fenton's reagent, even though ammonium is a possible reducing agent similarly to chloride ions. In any case, the presence of NH_4NO_3 in the system does not affect the course of oxidation of dinitrophenols.

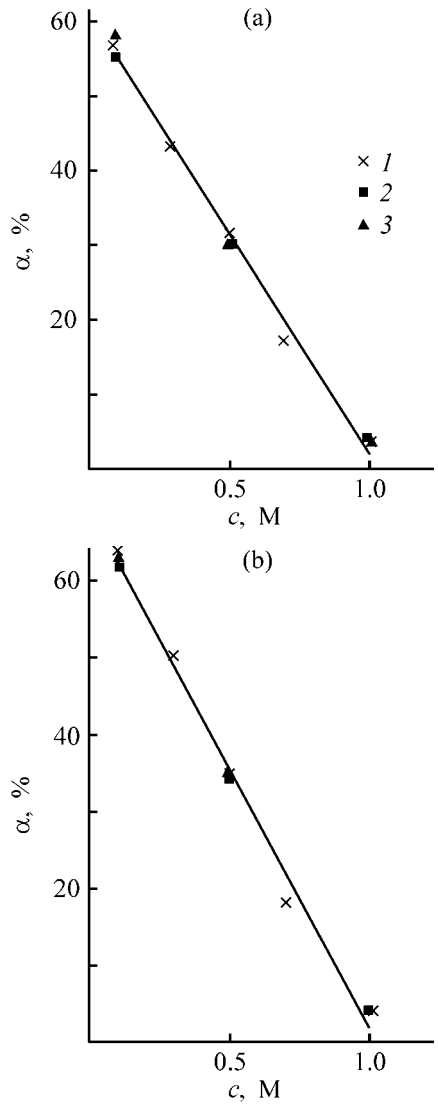

Fig. 3. Degree of conversion α of (a) 2,4-dinitrophenol and (b) 2,6-dinitrophenol in oxidation by Fenton's reagent for 60 min vs. salt concentration *c*. Salt: (*1*) NaCl, (*2*) NH_4Cl, and (*3*) CsCl.

The reducing power of ammonium ions is not manifested when they are added to the system in the form of ammonium chloride. Oxidation of dinitrophenols is inhibited at the same concentrations as in the case of sodium and cesium chlorides, i.e., inhibition is caused by the presence of chloride ions. Data for NH_4Cl are described by the same dependence as data obtained for sodium and cesium chlorides.

CONCLUSIONS

(1) 2.4- and 2,6-Dinitrophenols are oxidized by Fenton's reagent in the presence of inorganic salts under comparable conditions. Sodium, cesium, and ammonium cations, as well as nitrate and sulfate anions, do not noticeably affect the oxidation of dinitrophenols.

(2) The presence of impurities of fluoride, phosphate, and other anions of weak acids or acids of medium strength in water shifts the solution pH to the range in which Fenton's reagent is ineffective.

(3) The presence of chloride ions in water inhibits the oxidation of dinitrophenol by Fenton's reagent, probably due to a competing oxidation of chloride ions.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Bisacylated Diethylenetriamines as Extractants for Nonferrous Metals from Hydrochloric Acid Solutions

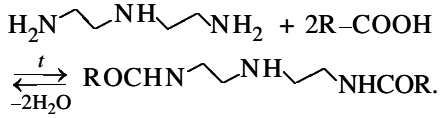
Abstract—A series of bisacylated polyethylenepolyamines with linear and α- and α,α'-branched substituents were synthesized. The effects of the number of the nitrogen atoms in the polyethylenepolyamine fragment of the reagent and of the length and branching of its alkyl radicals on the extractant distribution between the organic and aqueous phases was studied. The performance characteristics of the extractants, such as the loss with the aqueous phase, hydrolytic stability, back extraction conditions for nonferrous metals, and $\beta_{Zn(II)/Fe(III)}$ and $\beta_{Zn(II)/Cu(II)}$ partition coefficients, were examined.

DOI: 10.1134/S107042720702022X

Previously we have reported the extraction characteristics of certain bisacylated polyethylenepolyamines (PEPAs) with respect to some nonferrous and noble metals [1–3]. The goal of this study is to optimize the number of nitrogen atoms and the structure of the alkyl substituents in bisacylated polyethylenepolyamines for extraction of nonferrous metals and also to determine the performance characteristics of the most efficient extractants from this series.

EXPERIMENTAL

The PEPAs and other organic reagents used were distilled prior to use: ethylenediamine (bp 117–118°C), diethylenetriamine (59–60°C/2 mm Hg), triethylenetetramine (142°C/8 mm Hg), tetraethylenepentamine (167–170°C/8 mm Hg), caprylic acid (105–107°C/5 mm Hg), 2-ethylhexanoic acid (89–90°C/5 mm Hg), and narrow fractions of α,α'-branched fatty carboxylic acids: ~C_9 (116–120°C/4 mm Hg) and $C_{13,15}$ (205–210°C/8 mm Hg). The fraction of higher isomeric acids VIK-1 (propionic acid telomeres), narrow fractions of synthetic α,α'-branched fatty carboxylic acids ~C_9 and ~$C_{12,14,16}$ (Kaustik Production Association, Sterlitamak), and lauric acid (pure grade) were used without additional purification. Bisacylated PEPAs (BAPs) were synthesized by the following scheme [1]:



The reagents synthesized are listed in Table 1. The reagents with linear and α-branched substituents are paraffin-like compounds, and those with α,α'-branched substituents, viscous liquids. All the reagents are readily soluble in alcohols, aromatic hydrocarbons, and chloroform (0.1–0.5 M) and moderately soluble in saturated hydrocarbons (<0.1 M). The BAPs obtained were identified by the strong amide **I** and amide **II** bands in the IR spectra and by the low-field peaks of the sp^2-hybridized atoms of the amide groups in the ^{13}C NMR spectra (Table 2). The lack of imidazoline derivatives, the most probable by-products in the synthesis of BAPs, was confirmed by the UV and IR spectra [4].

The electronic spectra were recorded on a Specord M40 spectrophotometer over the range 50000–11000 cm^{-1}; the IR spectra of the films, on a Specord M80 instrument, and the ^{13}C NMR spectra, on a Bruker AM-300 instrument ($CDCl_3$, TMS).

As diluents we used toluene and *n*-octanol (analytically pure grade) without additional purification. Addition of *n*-octanol (15 vol %) eliminates the formation of interfacial films.

Table 1. Formulas, number, full names, and molecular weights of reagents

Reagent	Formula of acylating acid	BAP	Moleculat weight
	ROCHN⌒⌒NHCOR

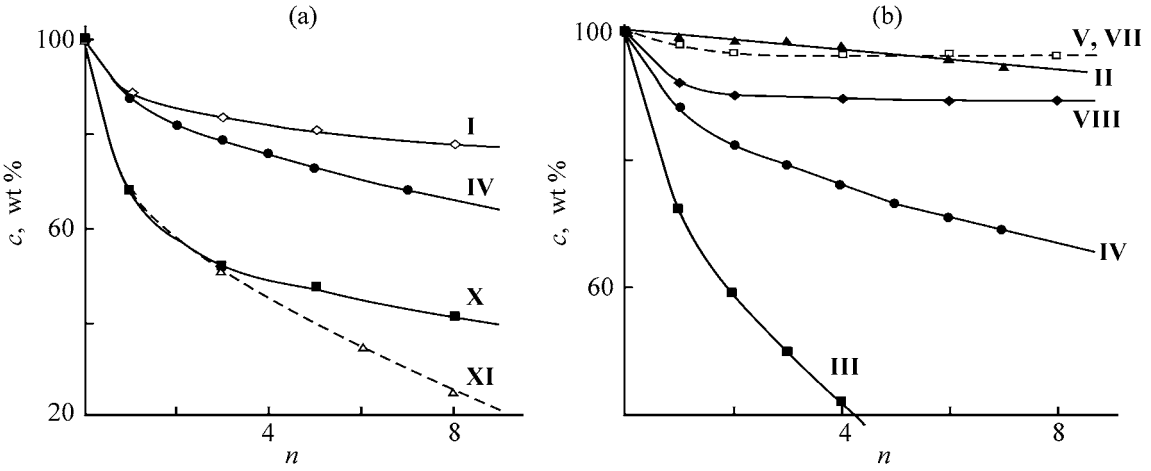

Fig. 1. Distribution of reagents between the organic phase and 1 M HCl. Initial concentration of the reagent in the organic phase 0.1 M (corresponds to 100%), diluent 15% octanol in toluene (30% octanol in toluene for **XI**). (*c*) Concentration of the reagent in the organic phase and (*n*) number of washing runs.

To remove the unchanged starting acids, the solutions of reagents were washed with three portions of equivalently concentrated NaOH, and then with 0.1 M HCl, to remove residual PEPA (until disappearance of the blue coloration upon adding 0.1 M copper chloride). Finally, the extractant was washed with 1 M NaCl.

Iron(III) in the raffinate and backwash was determined chelatometrically with Na_2EDTA in the presence of sulfosalicylic acid, and Zn(II), Cu(II), Mn(II), Co(II), and Ni(II), with Murexide in the presence of ammonia buffer.

Initially, the BAP concentration was monitored pH-metrically using an OP-211/1 pH meter with a combined glass electrode in 90% isopropanol (0.5 M $NaClO_4$). Then we found that, with all the BAPs that are capable of extracting Zn, the Zn(II) : ligand ratio at saturation was 1 : 2, which allowed determination of the reagent concentration using the simpler and less time consuming extraction method.

Equal volumes (5–10 ml) of the organic and aqueous phases were brought contact in temperature-controlled separating funnels at 20.0 ± 1.0°C. The extractant concentration was 0.1 M, and the working concentration of a metal, about 3×10^{-2} M (in the concentrated Zn solution, 0.2 M). The HCl concentration was varied from 0.05 to 9.0 M. The extraction equilibrium in the system was attained in 45–60 s. Therefore, the contacting time of the phases was chosen to be 5 min. The phase separation was observed immediately after the termination of the mixing.

The extractant distribution between the organic and aqueous phases was studied using the above extraction procedure. In this case, a fixed volume of the extractant solution of a known concentration (~0.1 M) was contacted with the equal volume of 0.1 M HCl. The aqueous phase was separated, and a part of the organic phase was used for extraction of Zn ($[Zn^{2+}]$ = 0.2 M, [HCl] = 5 M). Finally, the reagent concentration in the organic phase was determined. Then the cycle was repeated.

In the hydrolytic tests, an extractant (10 ml of 0.1 M solution) was stirred with a magnetic stirrer for a fixed time at 60.0 ± 0.2°C with 10 ml of 1.75 M sulfuric acid. Then the mixture was placed in a separating funnel and washed with 1 M NaCl. The organic phase was separated, and its volume was adjusted to 10 ml at 20°C by adding the diluent. The extractant concentration was determined by the extraction method.

The extraction–back extraction experiments were carried out as follows. Equal volumes of 0.1 M solution of an extractant and 3×10^{-2} M solution of the Zn(II) salt in 1.8 M HCl were shaken for 5 min. The raffinate was separated and analyzed for residual Zn(II). Back extraction was carried out with three portions of 1.75 M sulfuric acid at o : w = 2 : 1 by shaking for 2 min. Finally, the organic phase was washed with 1 M NaCl.

With increasing acidity of the aqueous phase, BAPs undergo protonation, and the solubility in water of all the previously synthesized BAPs increases [1]. To optimize the performance characteristics of the extractants of this series, we varied the number of nitrogen atoms in the PEPA fragment and also the length and branching of the alkyl radicals (Table 1). Then the extractants were tested for the distribution between the organic phase and 1 M HCl (Fig. 1).

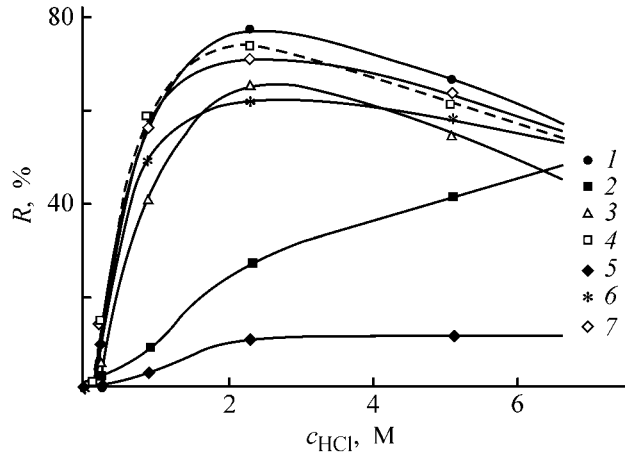

Fig. 2. Extraction power of the extractants *R* vs. the length and branching of their hydrocarbon radical in extraction of Zn(II) (0.032 M). Initial concentration of the extractants 0.1 M; diluent 15% octanol in Nefras (commercial solvent based on butylbenzene). (c_{HCl}) HCl concentration. Extractant: (*1*) **II**, (*2*) **III**, (*3*) **IV**, (*4*) **V**, (*5*) **VI**, (*6*) **VII**, and (*7*) **VIII**.

Figure 1a presents data for the extractants differing in the PEPA fragment only. As expected, bisacylated ethylenediamine **I** containing no amino groups does not extract nonferrous metals (NFMs) over the HCl concentration range 0.5–0.6 M. Therefore, despite the lowest solubility in water, BAP with the ethylenediamine fragment was not further examined in this study. Protonated reagent **XI**, when contacted with 1 M HCl, practically totally separated into a third phase, which vanished only when the fraction of octanol in the diluent was raised to 30%.

Figure 1 shows that, as the number of the nitrogen atoms in the PEPA fragment of BAPs becomes larger, the solubility of their protonated forms does increase. The lowest solubility in water can be expected for diethylenetriamine derivatives. The effect of the length and branching of the hydrocarbon radical on the solubility of bisacylated diethylenetriamines (BADs) is shown in Fig. 1b. Unfortunately, we failed to obtain a narrow fraction of the α,α'-branched acid C_8. Therefore, the results for individual isomers **II** and **III**, obtained on the basis of the linear and α-branched acids, respectively, were compared with those for **IV** synthesized from a very narrow fraction of α,α'-branched acids (primarily C_9). Here the lowest solubility was observed for **II**, i.e., for the reagent with linear substituents. An increase in the length of the linear alkyl radical (**IX**) results in a higher emulsifying power of the reagent: in the systems with **IX**, the phases were not separated even in 24 h. We were able to extract Zn(II) from saturated solutions with **IX**, since the phase separation is facilitated near the limit of the extractant capacity, but we faced difficulties in separating the phases in back extraction and washing with 1 M HCl. For these reasons, the curve for **IX** is lacking in Fig. 1.

Table 3. Characteristics of the hydrolytic stability of the extractants in 1.75 M sulfuric acid at 60°C

Heating time, h	Extractant concentration after heating, % of the initial value			
	II	**III**	**IV**	**VIII**
0.5	98	–	–	–
1.0	94	95	98.5	100
2.0	90	93.5	99	100
3.0	86.5	94	98	100
4.0	83	93	99	100

An increase in the length of the branched alkyl radical [**V**, **VII**, **VIII**] significantly suppesses the transfer of BADs to the aqueous phase. The initial part in the curves can be attributed to the presence of small amounts of more soluble monoacylated diethylenetriamines, and, in the case of **VIII**, of lower-molecular-weight homologues, e.g., **IV**. After three washings, the concentrations of **V**, **VII**, and **VIII** remained unchanged: no transfer of BADs to the aqueous phase was observed.

The extraction properties of BADs are illustrated in Fig. 2 by an example of extraction of Zn(II) from HCl. The lowest extraction power is shown by the most water-soluble BADs (**III** and **VI**).[1] Generally, variation of the alkyl radical only slightly influenced the extraction characteristics of the reagents.

Since BADs were suggested to be used for extraction of NFMs from HCl solutions, followed by back extraction with dilute sulfuric acid, we studied the resistance of these reagents to acid hydrolysis. To be able to compare the results with published data [5], we carried out hydrolysis at 60°C (Table 3). Previously, we have shown [6] that, in base hydrolysis of imidazolines, introduction of a branched substituent into the α-position relative to the reactive center hampers addition of the hydroxide ion, thus decelerating the hydrolysis. The results of this study are well consistent: the highest hydrolytic stability is observed for the reagents with α,α'-branched substituents, and the lowest stability, for those with linear substituents.

[1] Reagent **VI** is readily soluble in water and HCl (~0.2 M). For this reason, the curve for this reagent is lacking in Fig. 1.

Table 4. Selectivity characteristics of the reagents

Extraction conditions (M)	V		VII		VIII	
	$\beta_{Zn/Fe}$	$\beta_{Zn/Cu}$	$\beta_{Zn/Fe}$	$\beta_{Zn/Cu}$	$\beta_{Zn/Fe}$	$\beta_{Zn/Cu}$
o : w = 1 : 1, [HCl] = 1, $[Cu^{2+}] = [Fe^{3+}] = 0.2$, $[Zn^{2+}] = 0.021$	–	–	145	650	55	440
o : w = 1 : 1, [HCl] = 1, $[Cu^{2+}] = [Fe^{3+}] = 0.2$, $[Zn^{2+}] = 0.0021$	–	–	240	1700	130	1000
o : w = 1 : 5, [HCl] = 1.8, $[Cu^{2+}] = [Fe^{3+}] = 0.2$, $[Zn^{2+}] = 0.021$	30	330	55	635	19	370

Table 5. Performance characteristics of the reagents in HCl

Reagent	Phase separation time in extraction (back extraction), min	Extraction capacity for Zn (5% solution), g l^{-1}	Conditions of back extraction
V	30–40 (3–5)	3.1–3.5	1.8 M H_2SO_4, two steps: (I) 85–90% and (II) 10–15%; washing time 2 min
VII	40–90 (2–5)	2.7–3.2	
VIII	~1(2–5)	3.3–3.7	100% back extraction in a single step, washing time 2 min

Table 6. Evolution of the reagent concentration in the organic phase in the extraction–back extraction cycles (% of the initial)

Extraction cycle no.	Concentration, %			Extraction cycle no.	Concentration, %		
	V	**VII**	**VIII**		**V**	**VII**	**VIII**
1	100	100	100	4	–	–	99
2	–	–	100	5	100	100	99
3	100	100	100	6	–	–	98
				7	100	100	98

A decrease in the HCl concentration in the aqueous phase to 0.5 M deteriorates the phase separation, and a third phase is formed. As the HCl concentration is raised to 9 M, reagents **VII** and **VIII** are totally separated into the third phase. Therefore, it is practical to use BADs for extraction of NFMs at HCl concentrations from 0.8–1.0 to 8.5 M. In this range, for reagents **VII**, **VIII**, and **X**, the extraction of NFMs decreases in the order Zn(II) > Fe(III) > Cu(II) > Co(II) > Mn(II) > Ni(II)[2] (Fig. 3).

At an HCl concentration of about 2 M and lower, all the BADs are selective for Zn(II) (Table 4). Nonferrous metals are totally backwashed with dilute sulfuric acid (0.2–2 M) in 1–2 steps.

In the case of **VIII**, back extraction with water is quite efficient (Table 5), while reagents **V** and **VII** form poorly settled emulsions with water.

Since the best results in extraction of NFMs from HCl were obtained with reagents **V**, **VII**, and **VIII**, they were tested in extraction–back extraction cycles. With **V** and **VII**, the reagent concentration in the organic phase remained unchanged in at least seven cycles. In the case of **VIII**, the recovery of Zn(II) regularly decreased as a result of the loss of the extractant (Table 6). Taking into account some un-

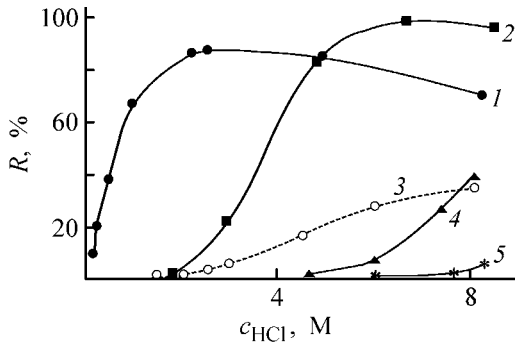

Fig. 3. Recovery of nonferrous metals R with 0.11 M solution of **VIII** in toluene vs. the HCl concentration c_{HCl}. Initial metal concentration ~0.03 M.

[2] Reagent **VIII** does not extract Ni(II).

certainties, the loss factor for a 0.1 M solution of **VIII** was estimated at 0.12–0.13 g l^{-1} per cycle, which can be attributed to the presence of some lower-molecular-weight homologues. However, the loss can be considerably reduced by changing sulfuric acid for water in back extraction of NFMs. The advantages of the systems with **VIII** are the more rapid phase separation (Table 5) and the fact that, even in the absence of octanol, this reagent does not form a third phase.

CONCLUSIONS

(1) Diethylenetriamines bisacylated with α,α'-branched acids ~C_{11}–C_{14} show promise as extractants for nonferrous metals from hydrochloric acid solutions.

(2) These reagents are virtually insoluble in the aqueous phase, demonstrate no tendency toward formation of emulsions, are stable against sulfuric acid hydrolysis, and extraction systems with them relatively rapidly settle. Nonferrous metals can be quantitatively backwashed with dilute sulfuric acid.

(3) At HCl concentrations ≥0.5 M and total chloride concentrations in the aqueous phase $c \leq 2$ M, these extractants are selective for Zn(II).

Abstract—A new procedure was developed for preparing carbon films with magnetic metal nanoparticles by thermolysis of a polymer precursor. The conditions for preparing carbon films with required surface concentration of the metal nanoparticles and hence with dielectric or metallic properties were determined.

DOI: 10.1134/S1070427207020231

The unabated interest in nanoheterogeneous structures consisting of a matrix and metal nanoparticles as a filler is caused by their unusual dielectric, magnetic, chemical, and biological properties [1, 2], which, in turn, are due to the size effects. The properties of these composites can be changed by using an insulating or conducting matrix with different concentrations of metal nanoparticles.

Nanoheterogeneous systems are characterized by interesting mechanisms of charge transport, in particular, quantum corrections to the conductivity [3, 4] and tunnel effects and giant magnetoresistance [5, 6]. The materials can be used in practice for production of gas sensors, magnetic field transducers, magnetic memory units with superhigh packing density of the components, etc. [7, 8]. Metal nanoparticles are widely used as catalysts not only for conventional reactions but also for growth of carbon nanotubes [9, 10] and onion-like structures [11].

Films and, especially, thin films occupy a prominent place among composites containing metal nanoparticles. The properties of these films are determined mainly by the properties and transformations of their surface. Carbon films containing metal nanoparticles are promising materials for micro- and nanoelectronics.

One of the procedures for preparing carbon films containing metal nanoparticles is thermolysis of metal-containing polymer precursors [12, 13]. The conductivity of films prepared by this method can be varied in a wide range (from dielectric to metal) by changing the thermolysis temperature. However, it is difficult to prepare monodisperse metal particles by this method (especially at high annealing temperatures) and to control the content of metal nanoparticles in the carbon matrix.

The aim of this study was to prepare dielectric and conducting thin carbon films with a required content of magnetic metal nanoparticles from a polymer precursor.

EXPERIMENTAL

The procedure for preparing carbon films with required content of metal nanoparticles consists of three steps.

The fist step involves preparation of thin polymer films, introduction of an appropriate transition metal ion (e.g., Co^{2+}, Ni^{2+}, Cu^{2+}, etc.) into the film, and thermolysis of the polymer precursor. The second step is treatment of the metal-carbon film with an aqueous solution of palladium chloride. The third (final) step is treatment of the film containing palladium nanoparticles with a nickel-plating solution.

The first step can be conventionally subdivided in three steps: (I–1) preparation of thin polymer films, (I–2) introduction of inorganic cations into the films, and (I–3) thermolysis of metal salts of the polymer in a vacuum.

We used starch as an initial polymer. Starch macromolecules were modified with nitro ester and carboxy groups [14]. The modified starch is soluble in ethers, esters, and alcohol-ether mixtures. Because the coefficient of spreading of a polymer solution over the water surface is positive [14] ($S > 0$ is the neces-

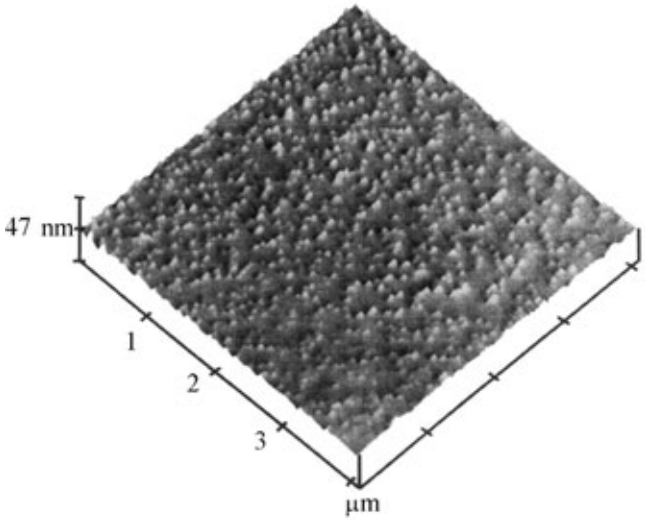

Fig. 1 AFM image of a surface of the carbon film containing Co nanoparticles. The cobalt salt of CNS was heated at 350°C.

sary thermodynamic conditions for complete spreading of a solution), the polymer solution is spread over a water surface.

Metal cations were introduced into a polysaccharide molecule by ion exchange of protons of its –COOH groups with the appropriate metal cation by the procedure described in our previous paper [14].

Thin films of carboxylated nitrostach (CNS) were prepared by dropping a polymer solution in isoamyl acetate on the water surface. A drop was completely spread to form a thin film solidified after removal of the solvent. The resulting film was put on a solid support made of polycor or sapphire. The film thickness calculated from the drop volume (0.02 ml), solution concentration (10 g/100 ml), film diameter (9 cm), and CNS density (1.58 g cm^{-1}) was 200 nm.

Sorption of metal cations and, in particular, cobalt(II) was performed by immersion of a supported CNS film in a 0.125 M aqueous solution of cobalt(II) acetate for 2 h at 20 ± 0.2°C.

The polymer films modified with cobalt(II) cations were isothermally heated at 350–700°C in a vacuum for 30 min. The heating rate was 10 deg min^{-1}. Under these conditions, the polymer degrades to form a carbon matrix containing cobalt nanoparticles produced by thermolysis of the cobalt carboxylate groups with simultaneous cobalt reduction

$$Co^{2+} \rightarrow Co. \quad (1)$$

The cobalt atoms are agglomerated into clusters which grow to form larger metal nanoparticles. Since the content of the –COOH groups in CNS was 16.0 wt %, the metal content of the carbon matrix was approximately 6.5 mol %. After the thermolysis, the film thickness decreased by approximately a factor of 5, whereas the parameters of the film in the plane did not noticeably change.

Clusters with an average size of 10–50 nm are formed in the carbon film in the course of low-temperature thermolysis (350–500°C). Their distribution in the carbon matrix was analyzed by atomic-force microscopy (AFM) (Fig. 1). As can be seen from Fig. 1, the nonuniformity of the surface of the carbon film does not exceed 1–2 nm. However, the profile of the cobalt-containing carbon films is nanogranular: the height difference along the film surface reaches 15–20 nm. Clearly, this is due to the formation of cobalt nanoparticles.

As can be seen from Fig. 1, the distance between cobalt clusters substantially exceeds the cluster size (a micrograph of a carbon film containing 6.5 mol %) cobalt is shown in Fig.1; the limited exchange capacity of the polymer matrix does not allow preparation of carbon films with a higher cobalt content).

The cluster size increases after heat treatment at temperatures of 700°C and higher. The conductivity of the carbon and metal-containing carbon films annealed at these temperatures substantially increases [15] and is determined mainly by the properties of the carbon matrix. The indirect influence of metal nanoparticles on the conductivity of the carbon matrix can consist only in their catalytic effect on the formation of the carbon structure. Previously, we have observed similar effect for carbon fibers containing cobalt particles [16].

Thus, although cobalt nanoparticles are formed by low-temperature thermolysis of a cobalt salt of CSN, the cobalt content in the thus obtained films is limited.

The carbon matrix is structured after a high-temperature treatment. However, in this case, the size of the metal particles substantially increases and their distribution in the carbon film becomes random. In other words, carbon films with close packing of cobalt nanoparticles cannot be prepared by thermolysis of the cobalt salt of CNS. To raise the metal content, the second step is used. This step involves treatment of a carbon film prepared by low- and/or high-temperature thermolysis with a 10^{-3} M aqueous solution of palladium(II) chloride for 15 min. Under these con-

ditions, almost all cobalt particles present in the carbon matrix react with palladium chloride in accordance with the equation

$$Co + PdCl_2 = CoCl_2 + Pd. \quad (2)$$

Cobalt chloride is washed out with distilled water from the carbon film, whereas palladium particles formed by reaction (2) are retained in the matrix. This is confirmed by an X-ray fluorescence microanalysis: the cobalt peaks disappear and palladium peaks appear after this treatment.

It is known [17] that palladium particles actively catalyze almost all reactions of electroless deposition of metals from aqueous solutions. Palladium nuclei (5 nm) exhibit the highest catalytic activity. When the particle size increases over 5 nm, the catalytic activity decreases. The catalytic activity of 15-nm Pd particles is very low [18]. Palladium particles formed in the film by reaction (2) actively catalyze nickel deposition from a nickel–plating solution, which suggests their small size. The third step is treatment of the palladium–containing film with a nickel–plating solution.

Carbon films containing palladium particles can be also prepared by direct thermolysis of palladium salt of CNS, which would eliminate the second step. However, as shown by Ermolenko et al. [19], the carbon matrix is not structured in this case and palladium particles are subject to autocoalescence (especially at temperatures of 700°C and above), which affects their catalytic activity.

Thus, the second step consists in introduction into the carbon matrix of palladium nanoparticles catalyzing electroless nickel deposition from a nickel-plating solution. The composition of the nickel-plating solution (solution a: $NiCl_2 \cdot 6H_2O$ 30 g l^{-1}; solution b: $NaH_2PO_2 \cdot H_2O$ 10 g l^{-1}, $Na_3C_6H_5O_7$ 88 g l^{-1}, NH_4Cl 50 g l^{-1}, and 25% NH_4OH 25 ml) was taken from [20]. When the palladium-modified carbon film is treated with a mixture of solutions a and b taken in a 1 : 4 ratio, nickel is reduced on catalytically active palladium nanoparticles by the reaction

$$2Ni^{2+} + H_2PO_2^- + 6OH^- \rightarrow 2Ni + PO_4^{3-} + 4H_2O. \quad (3)$$

The film was nickel-plated at 35°C for 5–15 min. As determined by scanning electron microscopy, the nickel content of the film increases with the plaiting time.

As can be seen from Fig. 2, treatment of the palladium-modified carbon film with the nickel-plating solution for 15 is sufficient for a dense layer of nickel nanoparticles to be formed. The morphology and composition of the particles were determined by scanning electron microscopy and X-ray fluorescence microanalysis.

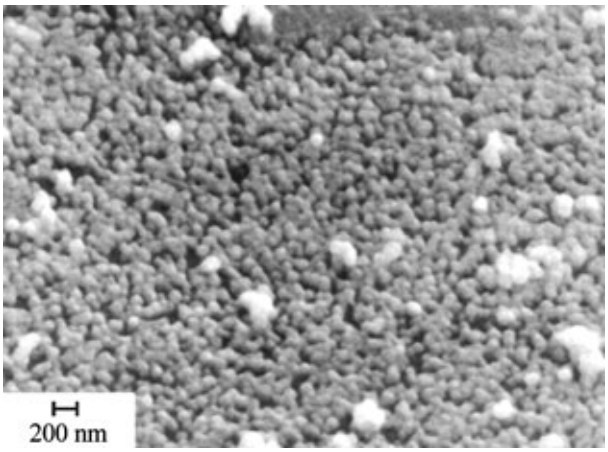

Fig. 2. Scanning electron micrograph of nickel nanoparticles on the surface of carbon film. Treatment with the nickel plating solution for 15 min; the same for Fig. 4.

In addition, the temperature dependences of a 2*D* film of nickel nanoparticles formed in the carbon matrix in different preparation steps were measured in the range 4.2–300 K. Changes in the temperature dependences of the film conductivity prepared by gradual increase in the time of treatment with the nickel-plating solution were also analyzed. To perform the electrical measurements, Al contacts were applied onto the film surface by thermal evaporation through metallic templates. The temperature dependence of the film resistance was measured by the conventional four-probe procedure.

The room-temperature resistance of the cobalt-containing carbon film prepared in the first step and of the films containing palladium particles prepared by treatment with a palladium chloride solution is approximately several tens of megaohms. The resistance substantially increases at temperatures below 100 K. The $R(T)$ dependences for both samples can be described by the Mott law typical of the variable-range hopping conductivity [21]:

$$R(T) = BT^{-1/2}\exp(T_0/T)^{1/4}, \quad (4)$$

where B is a constant independent of temperature, and T_0 is a parameter proportional to the density of states in the vicinity of the Fermi level.

The fact that the $R(T)$ dependences for the films containing cobalt and palladium nanoparticles are similar suggests that the conductivity of these films

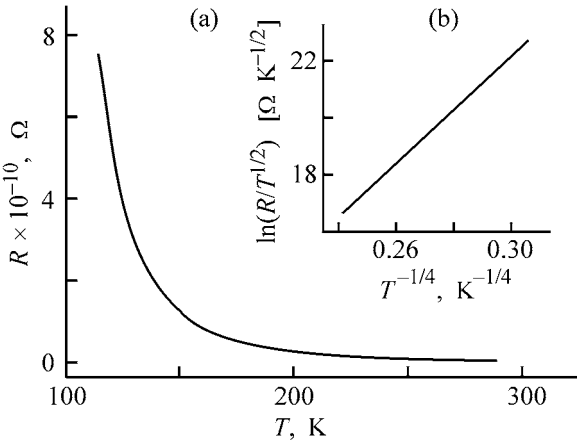

Fig. 3. (a) Resistance R of a nickel-carbon film vs. temperature T and (b) temperature dependence of the resistance plotted in the Mott coordinates. Time of nickel plating 5 min.

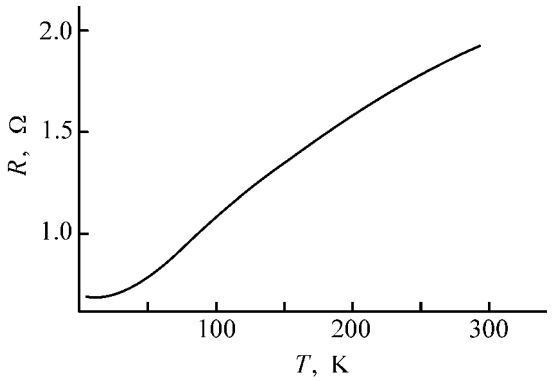

Fig. 4. Resistance R of a carbon film containing nickel nanoparticles vs. temperature T.

is due to the carbon matrix and replacement of cobalt nanoparticles with palladium nanoparticles by reaction (2) has no effect on the structural properties of the matrix and on the formation of percolation conductivity pathways.

The palladium-containing films treated with the nickel-plating solution for a short time (up to 5 min) also have a high room-temperature resistance, and the temperature dependence of their resistance is described by the Mott law. When the treatment time is increased to 10 min, the film resistance decreases. However, the temperature coefficient of resistance remains negative, i.e., the nickel-palladium-carbon films prepared under these conditions behave as insulators. An increase in the time of treatment with the nickel-plating solution to 15 min not only decreases the film conductivity to several ohms but also changes the sign of the temperature coefficient to positive. In other words, an insulator–metal transition caused by an increase in the surface concentration of nickel naonoparticles to form a granular nickel film is observed.

The temperature dependence of the resistance of a carbon film containing nickel nanoparticles in the range 290–115 K is shown in Fig. 3a as an example. This film was prepared under the following conditions: thermolysis temperature of the cobalt-containing film 700°C and time of the treatment with nickel-plating solution 5 min. As can be seen from Fig. 3b, this dependence is linear in the $\ln(R/T^{1/2})$–$T^{1/2}$ coordinates, which suggests prevalence of the variable-range hopping conductivity described by Eq. (4).

The $R(T)$ dependence for the carbon film containing nickel nanoparticles prepared by the same procedure, but at a nickel plating time of 15 min, is shown in Fig. 4. The $R(T)$ dependence is characterized by the positive temperature coefficient of resistance and a residual conductivity at low temperatures, which is typical of metals.

CONCLUSIONS

(1) The procedure for preparing thin carbon films containing surface nickel nanoparticles involves the following steps: (1) thermolysis of the solid polymer precursor (salt of carboxylated nitrostarch) in a vacuum; (2) reduction of palladium ions with nickel nanoparticles by treatment of the nickel-containing carbon film with an aqueous solution of palladium chloride; (3) deposition of magnetic nickel nanoparticles on catalytically active palladium particles present in the carbon film.

(2) The possibility of preparing carbon films with required surface density of nickel nanoparticles and the conductivity ranging from dielectric to metal was demonstrated. The surface concentration of nickel nanoparticles was controlled by the time of treatment with the nickel-plaiting solution.

Abstract—The kinetics of formation of water-soluble copolymers of acrylamide and ammonium acrylate with various molecular properties by copolymerization in concentrated aqueous solutions at 60°C in the presence of potassium persulfate initiator was studied by dilatometry.

DOI: 10.1134/S1070427207020243

Owing to their valuable properties, water-soluble polymers are widely used in various branches of industry. Moreover, their production and application exclude toxic, inflammable, and explosive solvents, strongly decrease the volume of noxious substances discharged into the environment, and improve the hygienic working conditions [1]. These water-soluble polymers include polyacrylamide, its derivatives, and copolymers of acrylamide (AA), which are effectively used in water treatment, papermaking, mining operations, and petroleum production [1, 2]. Copolymers of AA with acrylic acid and its salts are frequently prepared by copolymerization of monomers [2, 3] or by partial hydrolysis of polyacrylamide [4]. It is advisable to use concentrated aqueous solutions. Previously, we have studied polymerization of acrylic acid in the presence of sodium hydroxide [5] and copolymerization of AA with sodium acrylate in concentrated aqueous solutions [6].

In this study we examined copolymerization of AA with ammonium acrylate (AmA) in concentrated aqueous solutions at 60°C in the presence of potassium persulfate initiator (PP).

EXPERIMENTAL

In our study, we used an 18% aqueous solution of AmA and a 42.8% aqueous solution of AA, prepared by the biocatalytic method at the Moscow–Stockhausen–Perm Joint-Stock Company; PP twice recrystallized from water, sodium hydroxide and acetone of analytically pure grade, and ultrapure helium. All the working solutions were prepared using distilled water.

Copolymerization was performed in 12-ml glass dilatometers (low conversion) and in 50-ml sealed weighing bottles (deep conversion). First, aqueous solutions of AA and AmA were mixed in a flask, the required solution pH was adjusted using an aqueous solution of sodium hydroxide, and the required volume of distilled water was added to attain the required concentration. Then, using a Schott filter, helium was bubbled through the reaction mixture to remove oxygen acting as a polymerization inhibitor. An aqueous solution of PP was added and the reaction mixture was transferred with a syringe into a dilatometer and weighing bottle, which were then placed in a thermostat and kept at 60°C. At low conversion, copolymerization was monitored by the shift of the meniscus of the reaction mixture in a dilatometer capillary, using a KM-8 cathetometer, and copolymerization to deep conversion was performed for 1 h. Then the resulting copolymers were precipitated with a large excess of acetone and dried in a vacuum at 50°C to constant weight.

The process kinetics was monitored dilatometrically. From the dilatometric data, we obtained the kinetic dependences, which in all the cases were linear, and then calculated the initial rates of polymerization v_0 from their slopes at low conversions ($X < 2\%$). The conversion X (%) was calculated from the following expression:

$$X = \Delta V/(VK) \times 100,$$

where V and ΔV are the initial volume of the reaction mixture in the dilatometer and its change with time, respectively; and K is the contraction factor of copolymerization, $K = K_1\omega + K_2(100 - \omega)$. Here K_1 and K_2 are the contraction factors for AA and AmA, respectively; and ω is the content of AA in the initial monomer mixture.

The factors K_1 and K_2 were determined using the equation

$$K_1,\ K_2 = (\rho_p - \rho_m)/\rho_p,$$

where ρ_p and ρ_m are the densities of the polymer and monomer, respectively.

The conversion was calculated using the correction factor:

$$K' = K[1 + \alpha_m(T_1 - T_2)],$$

where α_m is the cubic expansion coefficient of the monomer solution, and T_1 and T_2 are, respectively, the temperatures at which the experiment was performed and the dilatometer was filled.

The values of α_m were calculated as follows:

$$\alpha_m = (1/V)(dV/dT),$$

where dV is the change in the volume of the reaction mixture; V, initial volume; and dT, temperature range corresponding to the volume change dV.

The content of the ionic units was determined by a potentiometric procedure [7] using a pH-121 pH-millivoltmeter equipped with an ESL-63-07 working glass electrode and an EVL-1M3 silver chloride reference electrode.

The viscometric measurements were carried out in a 0.5 M NaCl solution at 30°C, using an Ubbelohde viscometer (d_c = 0.56 mm). The intrinsic viscosities [η] were evaluated from the experimental dependences of the reduced viscosity η_{sp}/c_p on the copolymer concentration c_p; $[\eta] = \lim(\eta_{sp}/c_p)$ at $c_p \to 0$. Then, from the [η] values and the content of the ionic groups in AA–AmA copolymer, we calculated the viscosity-average molecular weight of copolymers ($\overline{M}_\eta$) by the Mark–Houwink–Kuhn equation:

$$[\eta] = K''M^{\alpha},$$

where K'' and α [8] were varied depending on the content of AmA ionic units in the copolymer.

Copolymerization of AA (M_1) with AmA (M_2) was carried out in 18% aqueous solutions at 60°C in the presence of PP initiator ($c = 7.4 \times 10^{-4}$ M). In the experiments, copolymerization proceeded under the homogeneous conditions at any conversions and no spontaneous copolymerization was observed.

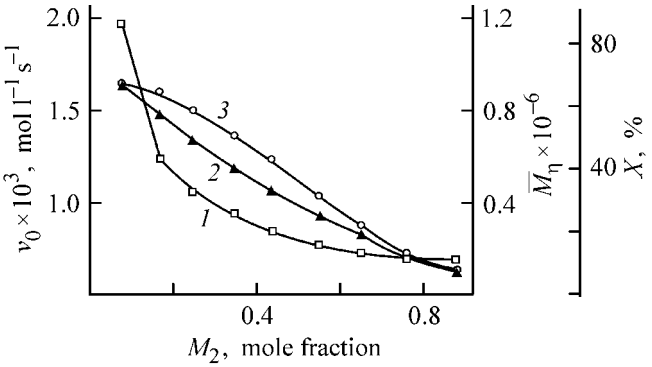

Fig. 1. (*1*) Viscosity-average molecular weight, (*2*) initial copolymerization rate v_0, and (*3*) yield of copolymer X vs. the AmA mole fraction in the initial monomer mixture M_2.

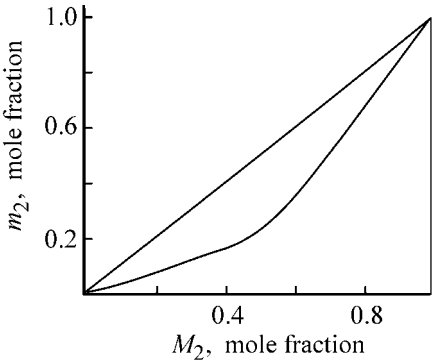

Fig. 2. Mole fraction of the ionic AmA units in the AA–AmA copolymer m_2 at low conversion ($X < 3$) vs. the mole fraction of AmA in the initial monomer mixture M_2.

First, we examined the effect of the composition of the initial monomer mixture on the copolymerization of AA with AmA. Figure 1 shows the dependences of v_0, $\overline{M}_\eta$, and copolymer yield on the content of the ionic monomer M_2 in the initial monomer mixture. It is seen that v_0, $\overline{M}_\eta$, and the copolymer yield decrease as M_2 increases. The data on v_0 indicate that, under the given experimental conditions, the reactivity of AA in the course of copolymerization is higher than that of AmA. In accordance with $\overline{M}_\eta$, the higher-molecular-weight compounds were obtained in the mixtures enriched with AA. The highest yield of the copolymer is also observed in the monomer mixtures enriched with AA.

The dependence of the current composition of the copolymer prepared by copolymerization of AA and AmA at low conversion ($X < 2\%$) on the composition of the initial monomer mixture is shown in Fig. 2. As seen, copolymers enriched in AA are

Table 1. Relative activities of AA (r_A) and AmA (r_B) in copolymerization in aqueous solutions

Equation	$[M_1 + M_2]$, %	r_A	r_B
Fineman–Ross	18	2.25 ± 0.03	0.15 ± 0.03
Kelen–Tudo	18	2.2 ± 0.03	0.1 ± 0.03

Table 2. Properties of the resulting copolymers as influenced by the total monomer concentration in the reaction mixture

$[M_1 + M]_2$, %	m_2, mol %	[η], $cm^3\ g^{-1}$	$\overline{M}_\eta \times 10^{-6}$	Yield, %
30.4	46.0	300	0.38	99.3
22.8	35.6	220	0.30	63.3
15.2	31.2	200	0.27	36.7

formed in a wide range of compositions of the initial monomer mixture, which is due to higher reactivity of AA in the course of copolymerization as compared to AmA. The relative monomer activities were determined from Fig. 2 as the quantitative parameters of the monomer reactivity in copolymerization:

$$r_A = k_{AA}/k_{AB} \text{ (for AA) and } r_B = k_{BB}/k_{BA} \text{ (for AmA).}$$

The values of r_A and r_B, determined using various procedures, are listed in Table 1. As seen, these values well agree with each other and, in all the cases, $r_A > r_B$, which confirms the higher reactivity of AA in copolymerization as compared to AmA.

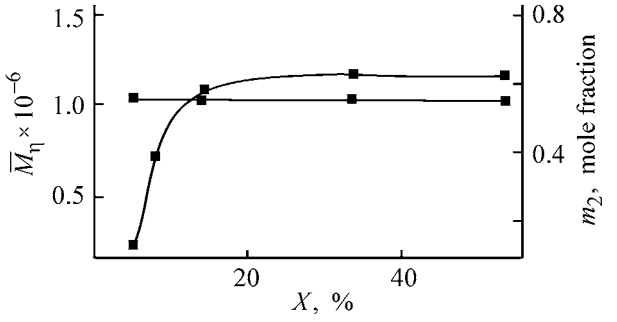

Fig. 3. (*1*) $\overline{M}_\eta$ and (*2*) mole fraction of the AmA ionic units in the AA–AmA copolymer m_2 vs. the conversion X in copolymerization of AA and AmA.

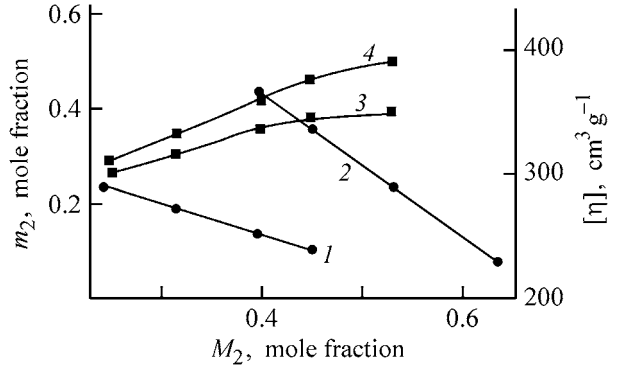

Fig. 4. (*1*, *2*) Intrinsic viscosity [η] and (*3*, *4*) mole fraction m_2 of the AmA units in copolymer vs. the AmA mole fraction in the initial monomer mixture M_2 at pH (*2*, *3*) 10 and (*1*, *4*) 12.

The dependence of the AA copolymerization with AmA on the conversion under given experimental conditions is shown in Fig. 3. As seen, the copolymer composition remains unchanged in the course of copolymerization; a similar phenomenon has been observed previously for other systems (e.g., in copolymerization of AA with dimethylaminoethyl methacrylate [9]). This fact can be attributed to formation of aggregates (micelles) with external hydrophilic and internal hydrophobic groups in concentrated aqueous solutions of the copolymer. Owing to the electrostatic repulsion between like-charged AmA monomer and its units on the micelle surface, penetration of the AmA species inside the micelle to react with a macroradical is hindered. With increasing conversion, the decrease in the AA content in copolymerization is compensated for by the preferential penetration of the AA molecules inside the micelles; as a result, the composition of the monomer mixture near macroradicals in the course of the reaction and, thus, the copolymer composition remain constant.

As seen, $\overline{M}_\eta$ increases with the conversion (Fig. 3, curve *1*). This is obviously due to the increasing viscosity of the reaction mixture in copolymerization, which decreases the probability of the chain termination.

The effect of the total monomer concentration in the initial mixture on the running composition of copolymers was evaluated at a mole fraction $[M_2]$ = 0.25, other experimental conditions being equal. As can be seen from Table 2, with the total monomer concentration the AmA content in the reaction solution increases; the resulting increase in the ionic strength of the solution weakens the electrostatic repulsion between the AmA monomer and macroradical, and the forming copolymer becomes enriched in AmA units. It also follows from the data in Table 2 that the yield of copolymer also increases with the total monomer concentration in the initial mixture.

The effect of the reaction mixture pH on the copolymerization was evaluated at different compositions of the initial monomer mixture, other experimental conditions being equal (Fig. 4). As seen,

as the AmA content in the initial mixture increases at pH 10 and 12, m_2 increases (Fig. 4, curves 3 and 4) and [η] decreases (Fig. 4, curves *1* and *2*) owing to a decrease in the copolymer molecular weight, which well agrees with the experimental data in Fig. 1 (pH 8). Comparison of the experimental data at M_2 = const shows that, on going from pH 10 to pH 12, [η] decreases (Fig. 4, curves *1* and *2*) and m_2 increases (Fig. 4, curves *3* and *4*). The observed increase in m_2 is due to a rise in ionic strength of the solution upon addition of NaOH.

To determine the overall rate equation of copolymerization in the system in question, experiments were carried out at various concentrations of the monomers and initiator, other conditions being equal. The results obtained are shown in Fig. 5. As seen, v_0 increases with [AA], [AmA], and [PP]. The reaction orders with respect to monomers and initiator were determined from the slopes of the curves (Fig. 5). As a result, we determined the empirical equation of the overall rate of copolymerization of AA and AmA in aqueous solution:

$$V = K_c[\mathrm{AA}]^{1.5}[\mathrm{AmA}]^{1.4}[\mathrm{PP}]^{1.0},$$

where K_c is the rate constant of copolymerization.

The reaction orders with respect to the monomers exceeding unity are probably due to the increasing viscosity of the initial solutions, which agrees with published data [2]. The reaction order with respect to the initiator suggests monomolecular termination of the kinetic chains in copolymerization in concentrated aqueous solutions, which is due to the increasing viscosity of the reaction mixture.

The effect of temperature on the copolymerization of AA and AmA was studied at 40 and 60°C, other conditions being equal. Figure 6 illustrates the dependences of the content of AmA units in copolymer m_2 (curves *1* and *2*) on the content of AmA monomer in the initial monomer mixture at various temperatures. As seen, at the temperatures examined [η] decreases with increasing M_2 (curve *3* and *4*) owing to a decrease in the copolymer molecular weight, whereas m_2 increases (curves *1* and *2*). This increase in m_2 with temperature in probably due to a decreasing ionization of the ionic groups of AmA monomer and its units in macromolecules [3], which decreases electrostatic repulsion between AmA and macroradical, i.e., promotes enrichment of the copolymer with ionic units (passing from curve *1* to curve *2*, Fig. 6). Comparison of the experimental data at M_2 = const shows that, at smaller content of the AA units in copolymers

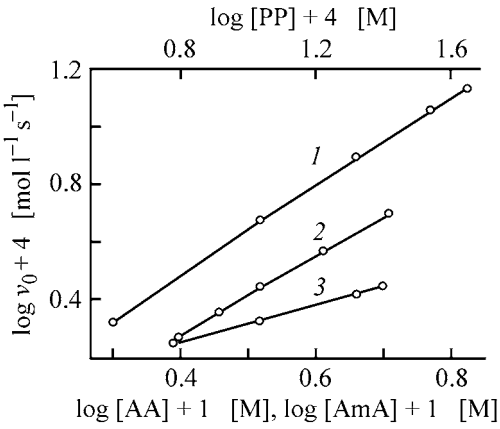

Fig. 5. Initial rate of copolymerization of AA and AmA v_0 vs. concentration of (*1*) AA, (*2*) AmA, and (*3*) PP (log–log plots). Concentration, M: (*1*) [AmA] 2.01 and [PP] 7.4×10^{-4}; (*2*) [AA] 6.03 and [PP] 7.4×10^{-4}; and (*3*) [AA] = [AmA] = 2.01.

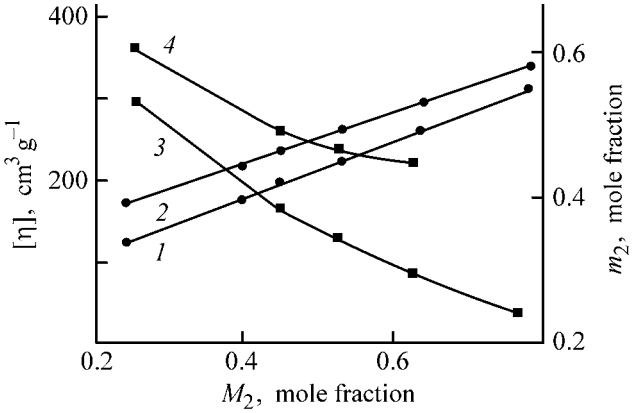

Fig. 6. (*1*, *2*) Mole fraction of AmA units in copolymer m_2 and (*3*, *4*) intrinsic viscosity of solutions [η] vs. the AmA mole fraction in the initial monomer mixture M_2 in copolymerization of AA and AmA at (*1*, *4*) 40 and (*2*, *3*) 60°C.

prepared at 60°C, smaller [η] and lower molecular weight are observed (Fig. 6, passing from curve *3* to curve *4*).

CONCLUSIONS

(1) Macromolecular copolymers were prepared from acrylamide and ammonium acrylate with a mole fraction of the ionic units of 0.01 to 0.55, viscosity-average molecular weight of $(0.03–1.15) \times 10^6$, and intrinsic viscosity of 40–360 cm^3 g^{-1} by copolymerization in concentrated aqueous solutions at 60°C in the presence of potassium persulfate initiator.

(2) The initial copolymerization rate increases with the concentrations of acrylamide, ammonium

acrylate, potassium persulfate, and monomer mixture ($M_1 + M_2$).

(3) The molecular weight of the copolymer increases as the concentration of acrylamide, monomer mixture, and conversion increase, and as the concentration of initiator and the solution pH decrease (from 12 to 10) and as the temperature is lowered from 60 to 40°C.

(4) The content of the ionic units in the copolymer increases with an increase in the concentrations of ammonium acrylate and monomer mixture and in pH (from 10 to 12) and with a decrease in temperature from 60 to 40°C and is almost independent of conversion.

(5) The copolymer yield grows as the concentrations of acrylamide and monomer mixture increase and pH decreases from 12 to 10.

Abstract—The influence exerted by copolymers of the C_9 fraction of liquid pyrolysis products of petroleum raw materials with maleic anhydride and by their esterification products, added to paper pulp, on the main paper properties was examined.

DOI: 10.1134/S1070427207020255

Sizing of paper pulp is one of important steps in production of sized kinds of paper; it allows control over the hydrophobic properties of the product. Presently sizing is performed in an acidic medium by adding a sizing emulsion (or dispersion) and a coagulant solution to the paper pulp, after which the paper sheet is formed on the frame of the paper-making machine [1].

The most commonly used sizing materials are rosin and products of its modification. However, active efforts are made today to develop synthetic sizing materials that would not only allow the characteristics of sized paper to be varied in a wider range, but also impart to the paper some specific properties that cannot be imparted by rosin sizing. In particular, polymeric adhesives enhance the mechanical strength of paper [2] and the resistance of its surface to picking, inhibit its aging [3], enhance its acid and alkali resistance [4], and improve its printing properties [5]. Furthermore, polymeric adhesives do not absorb UV radiation in the range 350–370 nm and thus do not decrease the efficiency of optical brighteners [6].

The copolymer of maleic anhydride (MA) with styrene (Styromal) and products of its esterification have been fairly well studied and tested as synthetic additives in paper production. Along with styrene–MA copolymers, polymers containing units of acrylic acid, its esters, or acrylonitrile are also used for preparing synthetic adhesives. Copolymers of styrene with MA are classed with nonreactive anionic synthetic sizing materials, despite that they exhibit no sizing effect when taken alone and can be used only in a mixture with a rosin adhesive [1]. Therefore, it would be more adequate to consider such products as modifying additives.

As an analog of Styromal, we tested as an additive to paper pulp the copolymer of MA with C_9 hydrocarbon fraction of liquid pyrolysis products (CPM) whose main polymerizable components are styrene, its derivatives, and dicyclopentadiene.

The goal of this study was to examine the effect of additions of CPMs and their ester derivatives on the hydrophobic, strength, and special properties of paper.

It is known that nonreactive synthetic sizing materials and, in particular, polymeric adhesives, do not form strong chemical bonds with cellulose fibers [2]. The effect of paper sizing is based on the mechanism of fixation of coagulated particles on the fiber surface via adsorption-electrostatic interactions, similar to the mechanism of sizing with rosin products [1]. Therefore, we compared the properties of paper with CPM additions to those of the unsized paper and paper sized with ZhM rosin adhesive (adhesive paste from modified oleoresin rosin) in acidic medium (pH 4.8–5.2). Because direct interaction of copoly-

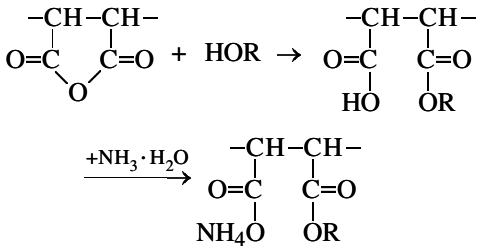
mer particles bearing a negative charge with cellulose fibers, also charged negatively, is impossible, it is necessary to add a coagulant (most commonly aluminum sulfate) to the paper pulp to attain the hydrophobizing effect.

Copolymers of the C_9 fraction and MA in the form of ammonium salts were introduced into sulfite pulp before casting the paper sheet. We found that the copolymers under consideration, like Styromal, show no sizing properties but enhance the mechanical strength of paper sheet. Table 1 shows that even at 0.5% concentration of the copolymer in the system the strength of the paper sheet (dry breaking strength and breaking length) are 20–30% higher than those of the paper without additives and paper sized with ZhM rosin adhesive. The wet strength of paper remains similar to that of the unsized paper. It is of interest that the strength does not grow as the amounts of the additive and coagulant [$Al_2(SO_4)_3$] increase.

A turbidimetric analysis demonstrated that aqueous solutions of copolymers **1** and **2** (Table 1) contain particles with mean diameters of 186 and 104 nm, respectively. The rosin emulsion of ZhM contains dispersed phase particles of smaller size, 93 nm. The electrolytic coagulation of copolymer solutions with $Al_2(SO_4)_3$ occurs more slowly than that of the ZhM rosin emulsion. A 2 : 1 weight ratio of the coagulant to the additive is preferable; at a higher content of $Al_2(SO_4)_3$ (3 : 1, 4 : 1), the coagulation decelerates. A higher strength was obtained with copolymer **2** (0.5% of a.d.f., Table 1), which, compared to copolymer **1**, was characterized by lower MA content and smaller size of dispersed phase particles.

To make CPMs more hydrophobic, we studied their esterification with 1-tetradecanol (myristyl alcohol) and alcohol fractions $C_{12}H_{25}OH$–$C_{16}H_{33}OH$ and $C_{16}H_{33}OH$–$C_{21}H_{43}OH$. To vary the hydrophilic–hydrophobic balance of macromolecules, the MA : alcohol molar ratio in the esterification was varied from 1 : 1 to 1 : 4. The esterified copolymers were converted to the salt form by treatment with aqueous ammonia:



An IR study of the esterified CPMs showed that the anhydride groups are virtually completely converted in the course of esterification. The neutralization of the esterified copolymer is accompanied by partial base hydrolysis of the ester. The yield of the reaction product is virtually quantitative. The products obtained were tested as additives to paper pulp prepared from sulfate pulp [GOST (State Standard) 7269–86], sulfite pulp (GOST 3914–74), and MS-1 waste paper. The quality of paper specimens was evaluated by their hydrophobicity (extent of sizing determined by the stroke method and absorbency in one-sided wetting), strength (dry and wet breaking strength, breaking length, energy absorption and elongation at break), and special properties (wet strength).

Studies of CPMs showed that the maximal yields of the copolymers were attained at an equimolar ratio of MA to monomers of the C_9 fraction in the starting mixture. The MA content in such copolymers was about 30 wt %. Therefore, we chose these substrates to be tested in esterification first. We found that the esterification performed at the molar ratio of MA in copolymer to tetradecanol from 3 : 1 to 2 : 1, followed by neutralization, yielded water-soluble prod-

Table 2. Properties of CPMs esterified with tetradecanol (solvent cyclohexanone, 150°C, 3 h, MA content in the starting copolymer 30 wt %)

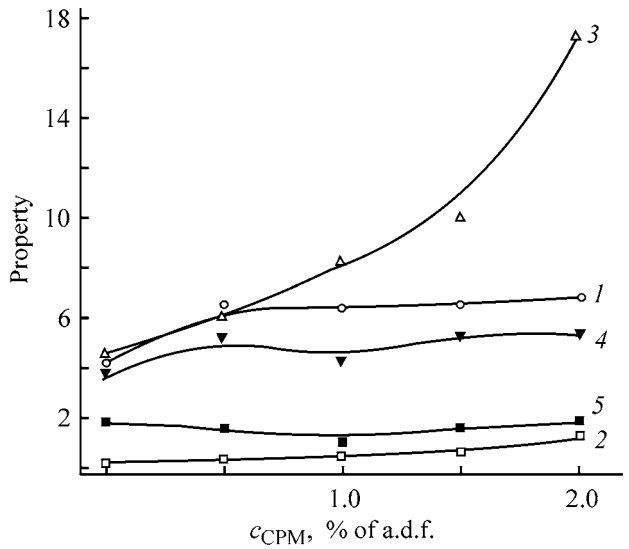
* MA content of the starting copolymer 21 wt %, molar ratio of MA in CPM to alcohol in esterification 4 : 1.

ucts (Table 2). At the equimolar ratio, the products obtained did not dissolve in water even on boiling.

Our studies showed that, like unmodified CPMs, the esterified CPM derivatives exhibit no sizing effect. Table 3 shows that, with the copolymers containing 30 wt % MA and esterified with tetradecanol, the wet breaking strength and wet strength of the paper sheet are considerably lower (by a factor of 1.5–3.0) than those of the paper specimen sized with a rosin adhesive. The dry breaking strength and the elongation and energy absorption at break for the paper specimens containing the synthesized additives are similar to those of the unsized paper and paper sized with ZhM adhesive. We found that it is preferable to use as an additive to paper pulp the esterified copolymer with a lower acid number (CPM **4**) at its 0.5% content in the system and additive : coagulant ratio of 1 : 2.

We found that addition of the esterified copolymer with a lower MA content (21 wt %, molar ratio MA : alcohol = 4 : 1) to the paper pulp in an amount of 1.5 wt % of a.d.f. imparts to the paper a wet strength comparable with that of the paper impregnated with rosin adhesive. Furthermore, the dry strength of the thus obtained paper sheet, even at the additive content as low as 0.5%, is higher than that of the paper sized with rosin adhesive and unsized paper. This additive is fairly versatile, as it improves the properties of paper prepared both from sulfate and sulfite pulps and from waste paper (Table 4).



Properties of a paper sheet based on sulfite pulp vs. the concentration (c_{CPM}) of the esterified copolymer (CPM **6**, MA content in the starting copolymet 32 wt %, molar ratio MA : alcohol in esterification 1.5 : 1) in the paper pulp. CPM **6** : $Al_2(SO_4)_3$ ratio 1 : 2. Property: (*1*) dry breaking strength, kgf; (*2*) wet breaking strength, kgf; (*3*) wet strength, %; (*4*) breaking length, mm; and (*5*) breaking elongation, %.

Similar results were obtained upon addition to the paper pulp of copolymers with a higher MA content (30 wt %), esterified with tetradecanol at the molar ratio MA : alcohol = 1.5 : 1. Using the copolymers with an MA content of about 20 wt %, esterified with tetradecanol at the molar ratio MA : alcohol = (1.5–2) : 1, we obtained paper specimens whose wet strength exceeded that of the paper sized with the ZhM rosin adhesive [ZhM content 1.5%, ratio ZhM : $Al_2(SO_4)_3$ = 1 : 3]. As in the preceding cases, the optimal concentration of the copolymer was 0.5 wt % of absolutely dry fiber, and the additive : coagulant ratio was 1 : 2.

An examination of paper specimens prepared using copolymers esterified with different alcohols ($C_{14}H_{29}OH$, alcohol fractions $C_{12}H_{25}OH$– $C_{16}H_{33}OH$ and $C_{16}H_{33}OH$–$C_{21}H_{43}OH$) showed that the paper sheet characteristics were virtually independent of the hydrocarbon chain length in the alcohol molecule in the interval from $C_{12}H_{25}$ to $C_{21}H_{43}$. Replacement of ammonium salts of the esterified copolymers with their sodium salts had no appreciable effect on the paper properties, either. It should be noted that an increase in the concentration of the additive in the system, as a rule, does not lead to proportional changes in the properties of the paper sheet obtained (see figure).

EXPERIMENTAL

CPM ammonium salts were prepared by adding to 3 g of the copolymer 6 ml of 10% aqueous ammonia (molar ratio NH_3 : MA = 4 : 1). The mixture was refluxed until the copolymer fully dissolved. Excess ammonia and water were distilled off on a rotary evaporator at 60–70°C (15–20 mm Hg). The resulting product was dried at 90–100°C in a vacuum (2 mm Hg) to constant weight.

Esterification of the copolymers was performed in the bulk or in a cyclohexanone solution. A glass vessel equipped with a power-driven stirrer, a thermometer, and a reflux condenser was charged with 3 g of the copolymer (MA content 30 wt %), 15 ml of cyclohexanone (if the reaction was performed in solution), and 1 g of tetradecanol (molar ratio MA : alcohol = 2 : 1). In some experiments, pyridine was used as esterification catalyst. The mixture was heated to 140–150°C with vigorous stirring for 3 h, after which cyclohexanone was distilled off in a vacuum (90–100°C, 2 mm Hg). The product was washed with several portions of diethyl ether to remove the unchanged tetradecanol. The washed copolymer was vacuum-dried (90–100°C, 2 mm Hg) to constant weight. The yield of the esterified copolymer was up to 98 wt %.

The acid number of the esterified copolymers was determined by direct titration with phenolphthalein as indicator; a 0.1–0.2-g sample was dissolved in 10 ml of acetone, 10 ml of water was added, and the mixture was titrated with 0.1 N KOH.

The mean particle diameter and kinetic features of the electrolytic coagulation of the copolymers and rosin emulsion were determined by turbidimetric examination of 0.04% aqueous solutions with a KFK-2 photoelectric colorimeter.

Paper specimens (70 g m^{-2}) were prepared on a Rapid–Ketten paper-casting apparatus. Fibrous pulp was first unraveled in a BM-3 disintegrator and then milled in a laboratory roll by a standard procedure to the Schopper–Riegler freeness of 40° (concentration of milled fibrous suspension 1%). To prepare paper specimens, a 2% aqueous solution of the salt form of the MA–C_9 fraction copolymer and then a 0.5% solution of aluminum sulfate were added to 220 cm^3 of the fibrous suspension containing 2.2 g of a.d.f. The copolymer content was varied from 0.5 to 2.0 wt % of a.d.f., and the $Al_2(SO_4)_3$ content, from 1 to 6% of a.d.f.; the additive : coagulant weight ratios were 1 : 2, 1 : 3, and 1 : 4.

The hydrophobic properties of paper specimens were evaluated by the degree of sizing (stroke method,

GOST 8049–91) and by absorbency in one-sided wetting (GOST 12605–82). The strength and special properties of paper specimens were evaluated by the dry and wet breaking strength (GOST 135225.1–79) and wet strength (GOST 8049–62). The breaking length, breaking elongation, wet strength, and dry and wet bending strength were determined with Lorentzen a. Wetter devices.

CONCLUSIONS

(1) The influence exerted by additions of esterified and nonesterified copolymers of C_9 fraction and MA to paper pulp on the properties of paper sheets was examined. Addition of the unmodified copolymers enhances the paper strength, and addition of esterified copolymer enhances both the strength properties and wet strength. Some strength characteristics considerably exceed those of the paper with additions of the ZhM rosin adhesive. The modified and unmodified copolymers exhibit no sizing effect. The optimal concentration of the additives is 0.5 wt % of absolutely dry fiber, and the optimal additive : coagulant weight ratio is 1 : 2.

(2) Paper with the best properties is obtained when esterified copolymers with a lower MA content (about 20 wt %) and copolymers with the molar ratio MA : alcohol = (1.5–2) : 1, which are more hydrophobic, are used as additives. The hydrophobicity of the products can be increased both in the copolymerization step (synthesis of copolymers with a low MA content) and by esterification with long-chain alcohols.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Mixed Cellulose Ethers by the Reaction of Short Flax Fibers and Cotton Linter with Monochloroacetamide

Abstract—The conditions of preparation of mixed cellulose ethers containing carboxy and amino groups by the reaction of samples of short flax fiber and cotton linter with monochloroacetamide were examined. The influence of the amino groups of the mixed cellulose ethers on the rheological properties of their aqueous solutions was elucidated.

DOI: 10.1134/S1070427207020267

An increased interest is presently attracted by self-associated polymer systems based on biodegradable and environmentally safe natural polymers. These systems include water-soluble compounds of cellulose and, in particular, its ethers: carboxymethyl cellulose in the form of a sodium salt (NaCMC), methyl cellulose (MC), hydroxyethyl cellulose (HEC), methoxypropyl cellulose, etc. Most of the above-mentioned ethers possess a set of valuable properties: water solubility, lack of toxicity, and good thickening power. They find wide application in food industry, perfumery, oil extraction, and medicine [1]. The principal raw materials for preparation of the ethers are wood and cotton varieties of cellulose. Large-capacity waste from flax production, short flax fibers and the hardwood part of the flax stem (flax boon) can serve as an alternative source of cellulose for preparation of its various ethers.

Among ionic compounds of cellulose, the most extensively used is carboxymethyl cellulose; it serves as a thickening and structuring agent in production of adhesives, lacquers, paints, detergents, and toothpastes. Chemical modification of CMC is one of the ways to modify the properties of this widespread ether. Introduction of new functional groups (in this case, amide) into CMC macromolecules implies changing the physicochemical properties of a new cellulose compound.

The physicochemical properties of the resulting ether are influenced by the nature of the initial polymer, namely, the molecular weight, chemical composition, presence of associated substances, structural uniformity, and fiber morphology.

Here, we examined the conditions of synthesis of cellulose ethers by the reaction of cotton and flax cellulose with monochloroacetamide (MCAA). It can be assumed that new cellulose compounds containing carboxy and amide groups exhibit ion-exchanging properties.

Carboxymethyl cellulose amides (CMCAs) can be prepared by the reaction of CMC acid chlorides with amines [2–4] and by the reaction of CMC in the acid form (HCMC) with amines [5]. By contrast to the above-mentioned methods of preparation of CMCAs, we studied here the conditions of synthesis without employing high temperatures and such reagents as dimethylformamide, $SOCl_2$, benzene, and xylene. The synthesis conditions and the apparatus in our experiments were identical to those in preparation of NaCMC.

EXPERIMENTAL

As initial materials served cotton linter with a degree of polymerization DP_η = 1500 and pretreated short flax fibers with DP_η = 3700. The flax fibers were treated by boiling for 3 h in the cooking solution of composition NaOH : $Na_2S_2O_3$: H_2O (at a fiber : NaOH : $Na_2S_2O_3$ ratio of 1 : 1.2 : 0.7) in a nitrogen medium [6]. Such a treatment removes most of associated substances (hemicelluloses, lignin, pectins)

from the flax fibers, with a minor decrease in the DP of cellulose.

The cellulose compounds were synthesized by the reaction

$$Cell(OH)_3 + NaOH + ClCH_2{-}\overset{\overset{O}{\|}}{C}{-}NH_2$$

$$\xrightarrow{T = 60^\circ C,\ i\text{-PrOH}} Cell(OH)_{(3-x)}(OCH_2{-}\overset{\overset{O}{\|}}{C}{-}NH_2)_x + NaCl.$$

The initial samples were stirred in isopropyl alcohol, whereupon 30% aqueous NaOH was introduced, and the resulting mixture was stirred at room temperature for another 1 h. Next, MCAA was introduced, and the reaction was run at T = 55°C. Upon completion of the reaction, the liquid was decanted, 70% methanol was added, and the resulting mixture was stirred, whereupon the liquid was decanted and the product was washed with 70% aqueous ethanol to neutral pH [6, 7]. The removal of NaOH was monitored by phenolphthalein coloration, and the removal of Cl^- ions, by the reaction with an $AgNO_3$ solution. The washed samples were dried to constant weight in a vacuum desiccator at T = 60°C. The nitrogen content was determined by the Kjeldahl method [8]. The degree of substitution, DS, with respect to the carboxy groups was calculated as

$$DS_{Na} = \frac{Na\% \times 162}{2300 - Na\% \times 80},$$

where Na is the sodium content of the polymer, wt %.

The amount of Na was determined by conductometric back-titration of the CMCA samples. The solubility of CMCA was calculated by the formula

$$S = \left(100 - \frac{g_2 - g_3}{g_1}\right) \times 100,$$

where g_1 is the mass of the polymer sample, g; g_2, mass of the precipitate with the filter, g; and g_3, mass of the filter, g.

A weighed portion of the polymer (with due account of its moisture content) was placed in distilled water (in an amount corresponding to 1% solution), and the mixture was stirred for several hours at room temperature. The resulting solution was filtered through a weighed (dried to constant weight at T = 105°C) Schott filter no. 2. The precipitate was washed with water and dried to constant weight.

The table lists the conditions of synthesis of mixed cellulose ethers and selected characteristics of the products. It is seen that, for all the resulting cellulose ethers, the number of carboxy groups substantially exceeds that of amide groups. Hence, a number of side chemical reactions proceed during synthesis.

Conditions of synthesis of mixed cellulose ethers and their solubility in water (washing of the samples with EtOH)

Reaction time, h	Content, %		Degree of substitution with respect to Na	Solubility in water, %
	N	Na		
Short flax fibers				
2.0	0.60	4.87	0.41	77.0
3.5	0.55	5.13	0.43	73.0
5.0	0.50	4.64	0.40	77.0
Cotton linter				
2.0	1.30	4.84	0.41	83.0
3.5	1.60	5.32	0.53	93.0
5.0	0.69	5.60	0.50	82.0

(1) Hydrolysis of the initial MCAA, yielding sodium monochloroacetate, which reacts with cellulose, to give NaCMC and NaCl [1]:

$$ClCH_2{-}\overset{\overset{O}{\|}}{C}{-}NH_2 \xrightarrow{NaOH,\ H_2O} ClCH_2{-}\overset{\overset{O}{\|}}{C}{-}ONa + NH_3,$$

$$Cell(OH)_3 + NaOH + ClCH_2{-}\overset{\overset{O}{\|}}{C}{-}ONa$$

$$\xrightarrow[NaOH]{T = 60^\circ C,\ i\text{-PrOH},} Cell(OH)_{(3-x)}(OCH_2{-}\overset{\overset{O}{\|}}{C}{-}ONa)_x + NaCl.$$

(2) Hydrolysis (saponification) of the resulting CMC amide (more precisely, of the mixed cellulose ether), to give NaCMC:

$$Cell(OH)_{(3-x)}(OCH_2{-}\overset{\overset{O}{\|}}{C}{-}NH_2)_x$$

$$\xrightarrow{NaOH} Cell(OH)_{(3-x)}(OCH_2{-}\overset{\overset{O}{\|}}{C}{-}ONa)_x + NH_3.$$

The side reactions decrease the yield of the main product. The sodium content in the samples is no higher than 5.32% (DS_{Na} = 0.53), and the maximal content of nitrogen is 1.6%.

The chemical analysis data (content of nitrogen and carboxy groups) were confirmed by the IR Fourier spectra of the mixed cellulose ethers, measured on an FS-88 Bruker IR Fourier spectrometer (KBr pellets).

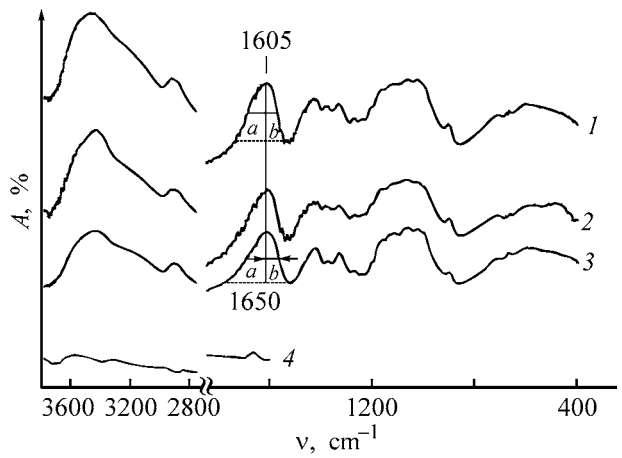

Fig. 1. (*1*, *2*) IR Fourier spectra of the mixed cellulose ethers prepared from (*1*) flax fibers and (*2*) cotton linter, (*3*) IR spectrum of refined commercial NaCMC, and (*4*) difference spectrum obtained by subtracting the spectrum of NaCMC from spectrum *2*. (*A*) Absorption and (ν) wavenumber.

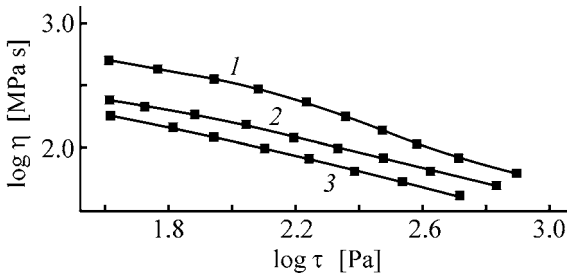

Fig. 2. Flow curves of 1.0% aqueous solutions of the mixed ethers of cellulose based on cotton at (*1*) 20, (*2*) 30, and (*3*) 40°C. Reaction time 2 h. (η) Viscosity and (τ) shear stress; the same for Fig. 3.

Figure 1 shows as an example the IR spectra of the mixed cellulose ethers prepared from cotton linter and flax fibers at 55°C and a reaction time of 3.5 h. Also, Figure 1 presents for comparison the IR spectrum of commercial refined NaCMC. The IR spectra of all the cellulose ethers synthesized in this study are similar to spectra *1* and *2*.

Spectral features characteristic of refined cotton cellulose include a broad absorption band at 3000–3700 cm^{-1}, associated with OH groups of the polymer, both free and linked by intra- and intermolecular hydrogen bonds, and absorption at 2900 cm^{-1}, associated with the CH_2 and CH groups of the polymers. The band at 2900 cm^{-1} in the spectrum of refined cellulose is nearly symmetrical [9]. The IR spectrum of NaCMC contains a band at 1597–1605 cm^{-1}, associated with antisymmetrical vibrations of the ionized carboxy groups COO^- [1]. Upon convertion of NaCMC to the H form, an absorption band at 1740 cm^{-1}, associated with the COOH groups, appears along with a shoulder at 1647 cm^{-1} [5]. For the CO groups of amide, an absorption band at 1650 cm^{-1} is characteristic (amide **I**), as well as a band at 1515–1570 cm^{-1}, associated with the bending vibrations of the NH groups (amide **II**) [10].

The content of the amide groups in the samples synthesized is not high (see table) compared to that of the COONa groups, whose absorption bands occur in close proximity. Therefore, we analyzed the IR spectra to reveal the amide groups in the products by two procedures. The first procedure consisted in analyzing the change in the ratio of the left-to-right parts of the half-width of the band at 1605 cm^{-1} by the technique suggested for analyzing changes in the system of hydrogen bonds in cellulose ethers [1]. It is believed that the total absorption band is composed of the contributions made by the COONa group (1605 cm^{-1}) and the CO groups of amide I (1650 cm^{-1}). For refined NaCMC, the *a*/*b* ratio of the band half-widths was estimated at 2.0, while that for all the samples of the mixed cellulose ethers, at 2.3–2.8. The broadening of the left part of the absorption band suggests the presence of the CO groups of amide.

The second procedure consisted in obtaining the difference (subtraction) spectra by subtracting the IR spectrum of NaCMC from that of the mixed cellulose ethers synthesized. Figure 1 shows as an example the difference spectrum obtained by subtracting spectrum *3* from spectrum *2* (curve *4*). Near 1650 cm^{-1}, there is a characteristic absorption band of amide **I**. It should be noted that the absorption band at 1515–1570 cm^{-1} (amide **II**) is 2–3 times less intense than that at 1650 cm^{-1} [10]. Thus, the absence of the absorption band associated with amide **II** can be attributed to the small number of amide groups in the samples synthesized.

Thus, our IR Fourier spectroscopic examination confirmed the presence in the samples of carboxy and amide groups, revealed by the chemical and physicochemical methods of analysis of the mixed cellulose ethers synthesized.

Since CMC is widely used in the form of aqueous solutions, we carried out a comparative examination of the rheological properties of moderately concentrated (1.0 wt %) aqueous solutions of the mixed ethers synthesized from flax and cotton cellulose. Figure 2 shows as an example the flow curves of 1% aqueous solution of mixed ether of cotton cellulose. For all the remaining samples we obtained similar flow curves; these are partial flow curves of non-New-

tonian fluids. Based on the temperature dependences of the viscosity, we calculated the heats E_a of activation of viscous flow of the solutions. These parameters were calculated for temperatures within 20–40°C. For solutions of the ethers based on cotton, E_a varies within 32.0–40.0 kJ mol^{-1}, and for the samples based on flax fibers, within 40.0–55.0 kJ mol^{-1}. For NaCMC solutions, E_a was estimated at 20.0 kJ mol^{-1}.

Figure 3 shows the flow curves of equiconcentrated solutions of CMCAs synthesized from cotton and flax fiber cellulose. For comparison, Fig. 3 shows the flow curve of an aqueous solution of commercial NaCMC obtained by the reaction of cotton linter with monochloroacetic acid. The conditions of synthesis for NaCMC (in isopropanol at 55°C) are identical to those for CMCAs.

The difference in the viscosity of the solutions is due to that in the molecular weights of the initial polymers, as well as to the presence in the mixed cellulose ethers of amide groups contributing to formation of a hydrogen bond system in concentrated solutions of polymers. It should be noted that commercial NaCMC has a higher DS_{Na}, which, in turn, increases the water solubility of the ether [1].

To elucidate how the time of synthesis of the cellulose ethers influences the viscosity of their aqueous solutions, we plotted the viscosity of the solutions of the mixed ethers vs. the reaction time at identical shear stresses ($\log \tau = 2.2$). Figure 4 shows that the viscosity of the mixed ethers of both flax and cotton cellulose we examined tends to decrease with increasing reaction time. The decrease in viscosity is presumably due to oxidative degradation of the glycoside bonds in the cellulose macromolecules (in an alkaline medium in the presence of atmospheric oxygen [1]) and to the change in the ratio of the numbers of carboxy to amide groups (see table).

CONCLUSIONS

(1) Mixed cellulose ethers were synthesized by the reaction of cellulose with monochloroacetamide.

(2) Chemical, physicochemical, and IR Fourier spectroscopic examinations confirmed the presence of carboxy and amide groups in the resulting cellulose compounds. The number of the functional groups and their ratio depend on the reaction time.

(3) Rheological properties of 1 wt% aqueous solutions of the mixed cellulose ethers were examined.

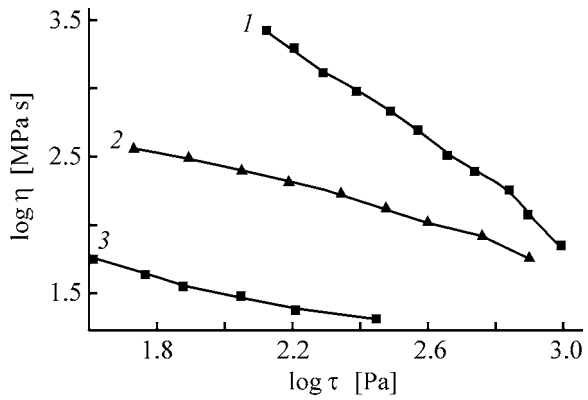

Fig. 3. Flow curves of 1.0 wt % aqueous solutions of the mixed ethers of cellulose based on (*1*) flax (DS_{Na} = 0.43), (*2*) cotton (DS_{Na} = 0.53), and (*3*) commercial NaCMC (DS_{Na} = 0.58). Temperature 20°C.

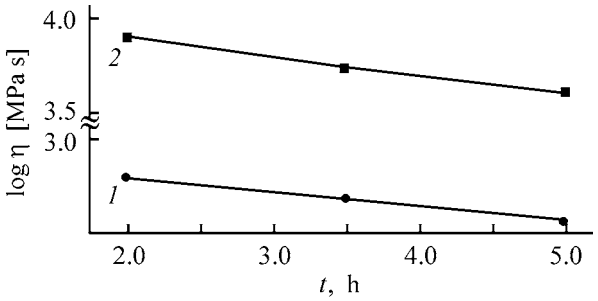

Fig. 4. Viscosity η of 1.0 wt % aqueous solutions of mixed ethers of cellulose based on (*1*) cotton linter and (*2*) short flax fibers (at 20°C $\log \tau = 2.2$) vs. the synthesis time *t*.

Aqueous solutions of the mixed ethers have a higher viscosity than the commercially produced carboxymethyl cellulose. This difference is due to that in the molecular weights of the ethers synthesized and commercial carboxymethyl cellulose, as well as to the presence in the mixed cellulose ethers of amide groups contributing to formation of the hydrogen bond system in concentrated solutions of the polymers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification with Maleic Acid of the Copolymer from By-Products of Polybutadiene Production and Use of the Modified Copolymer for Protective Treatment of Wood Fiberboards

Abstract—Modification with maleic acid of a styrene-containing polymeric material prepared from by-products of polybutadiene production was studied.

DOI: 10.1134/S1070427207020279

Many wastes from petrochemical enterprises, including synthetic rubber plants, contain numerous reactive compounds.

It is known that butadiene dimers and trimers, on the one hand, are by-products in some petrochemical processes involving butadiene and, on the other hand, can be valuable raw materials for various organic and petrochemical syntheses and for production of polymeric materials [1, 2]. A process for production of styrene-containing low-molecular-weight polymeric materials from these by-products has been commercially implemented [3, 4]. However, the polymeric materials thus obtained contain no functional groups, which restricts their possible applications.

The problems of chemical modification of synthetic polymers, rubber stocks, and vulcanizates are given much attention today from both scientific and practical viewpoints. Introducing functional groups into the copolymers and finding new fields of their applications are important problems.

In this study, we examined the possibility of using for impregnation of wood materials a low-molecular-weight copolymer prepared from unsaturated compounds of recycled toluene distillation bottoms (TDB) from polybutadiene production, modified with maleic acid (MA). The interest in maleic acid as a modifying agent is based on the fact that maleic acid is a by-product in the production of phthalic and maleic anhydrides. Therefore, this process not only allows modification of polymeric materials prepared from by-products of polybutadiene production, with new properties imparted to the resulting compounds, but also provides utilization of production waste.

Maleic (*cis*-butenedioic) acid can be dehydrated to obtain maleic anhydride. Maleic acid and its esters readily isomerize into fumaric acid and its derivatives under the action of heat, light, and catalysts. Maleic acid is widely used for preparing various surfactants. Certain amount of MA is used in food industry for preparing tartaric acid [5].

EXPERIMENTAL

We examined how the MA content of the reaction mixture, temperature, and process duration affect the properties of the styrene-containing polymeric material based on unsaturated TDB (bound styrene content 75–80 wt %).

The modification was performed as follows. A reactor was charged with 100 g of 70% toluene solution of a low-molecular-weight styrene-containing polymeric material based on unsaturated TDB, and MA was added in various ratios to the starting polymer. The best modification conditions were determined by using the method of experiment design. We examined the effects of such factors as MA content, temperature, and process duration using the 4×4 Latin square plan [6]. For each factor, we took four levels of variation: factor A (MA dosage), 0, 3.0, 6.0, and 9.0 wt %; factor B (process temperature), 120, 150, 180, and 210°C; and factor C (process duration), 8, 16, 24, and 32 h. The reaction progress was monitored by analytical methods from the variation of the mean molecular

* (y_i) Bending strength, MPa; (y_i') water absorption in 24 h, %; (y_i'') swelling in thickness in 24 h, %.

molecular weight and of the bromine and acid numbers on the above factors are as follows:

for the molecular weight $\overline{M}_v$,

$$Y = 2.92 \times 10^{-7} \times (1562 + 69a)(1439 + 2.6b)(1322 + 63c - 1.5c^2);$$

for the bromine number, (g Br_2) (100 g)$^{-1}$,

$$Y' = 3.96 \times 10^{-3}(17.34 - 0.32a) \times (19.31 - 2.07 \times 10^{-2}b)(16.22 - 1.625 \times 10^{-2}c);$$

and for the acid number, (mg KOH) g^{-1},

$$Y'' = 2.32 \times 10^{-2}(4.07 + 0.884a) \times (-9.48 + 0.19b - 5.367 \times 10^{-4}b^2) \times (0.708 + 0.682c - 1.58 \times 10^{-2}c^2).$$

Thus, an increase in the MA content and temperature leads to a rise in the mean molecular weight of the product, described by first-order equations. This fact can be attributed to the cross-linking in the system through Diels–Alder addition of MA to the macromolecules [7] and addition of MA to sites of double bond cleavage in the polymeric chains. It is important that MA can behave at high temperatures as a cationic catalyst and can accelerate the cross-linking. The influence of the reaction duration on the modification can be described by a second-order equation with a maximum, indicating that degradation processes become prevalent after approximately 20 h.

The acid number steadily grows with an increase in the MA content of the reaction mixture. However, the influence of the temperature and process duration on the acid number is described by second-order equations with maxima. This may be due to partial dehydration of MA and its transformation into maleic anhydride. The extent of this process increases with temperature. It is known that active dehydration of MA starts at ≥130°C, and at 150°C an equilibrium with 50% conversion is attained in 0.3 h [5, 8].

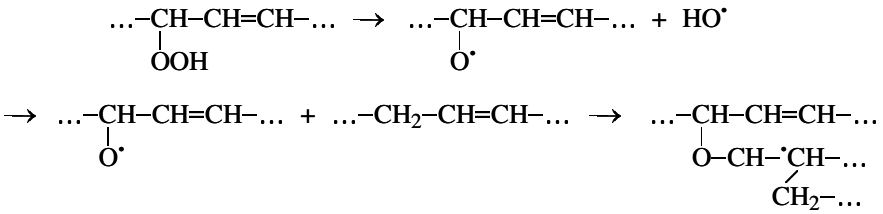
Thus, by varying the MA content, process duration, and temperature, it is possible to control the properties of the resulting products so as to meet consumer's requirements.

Functionalization of the styrene-containing polymeric material prepared from by-products formed in polybutadiene production opens new prospects for its application, such as production of rubber by emulsion (co)polymerization and protective treatment of wood materials with the aim to enhance their resistance to water and moisture and their mechanical strength.

We examined the application of the MA-modified product to treatment of wood fiberboards (WFBs). In so doing, we used the fourth-order 4×4 Greco-Latin square plan [6]. As the major factors exerting the strongest effect on the WFB properties we chose the impregnation duration (factor A; 30, 60, 90, 120 s), impregnating formulation temperature (factor B; 25, 50, 75, 100°C), heat treatment temperature (factor C; 120, 140, 160, 180°C), and heat treatment time (factor D; 1, 3, 5, 7 h). The following WFB parameters were monitored: bending strength, water absorption, and swelling in thickness. The matrix of the Greco-Latin square plan is given in Table 2.

The WFB treatment was performed as follows. Dried and weighed specimens were placed in an impregnation bath containing a polymeric material modified with MA, with addition of ~10 wt % drier, and kept for a prescribed time at a prescribed temperature according to the experimental plan. For impregnation we took the polymeric material modified with 6.0 wt % MA for 24 h. The impregnated WFB specimens were withdrawn from the bath, predried, and subjected to a heat treatment, after which they were cooled to room temperature and weighed. The copolymer content of the specimens was determined gravimetrically from the weight gain.

Addition of a drier accelerates both formation and decomposition of hydroperoxides. The reactions involving atmospheric oxygen actively occur in the surface layers. The oxygen access into the bulk of the formulation is limited, which leads to decreased contribution of oxidative processes and increased contribution of high-temperature polymerization. The last process is activated by various radicals present in the system ($R^{\cdot}$, $RO^{\cdot}$, $ROO^{\cdot}$, see scheme).



The film formation is inevitably accompanied by oxidative degradation yielding compounds that contain carbonyl, carboxy, and hydroxy groups. This leads to a further increase in the content of functional groups capable of reacting with active groups of lignin and cellulose. The probability of occurrence of such reactions is particularly high in surface layers under the conditions of film formation with a better efficient access of atmospheric oxygen.

By computer processing of the experimental results we obtained regression equations describing the effect of the main process parameters on the properties of the WFB specimens:

for the bending strength, MPa,

$$Y = 1.53 \times 10^{-5}(36.5 + 0.052a) \times (40.5 - 0.0028b)(35.7 + 1.17c)(14.5 + 0.174d);$$

for the water absorption in 24 h, %,

$$Y' = 1.77 \times 10^{-4}(19.1 - 0.0173a) \times (19.3 - 0.0236b)(18.0 - 0.065c)(19.6 - 0.0117d);$$

and for the swelling in thickness in 24 h, %,

$$Y'' = 4.87 \times 10^{-4}(14.4 - 0.022a) \times (13.45 - 0.0116b)(13.14 - 0.11c)(15.85 - 0.021d).$$

These dependences are plotted in Fig. 2. They show that the following conditions ensure the best characteristics of the modified fiberboards: impregnation duration of 30 s, impregnating–formulation temperature of 100°C, heat treatment temperature of 180°C, and heat treatment duration of 7 h. However, the effect of the impregnation duration in the examined interval on the WFB properties is insignificant. This is caused by the fact that WFBs have low density, and the MA-modified copolymeric material readily penetrates into the WFB structure within a short

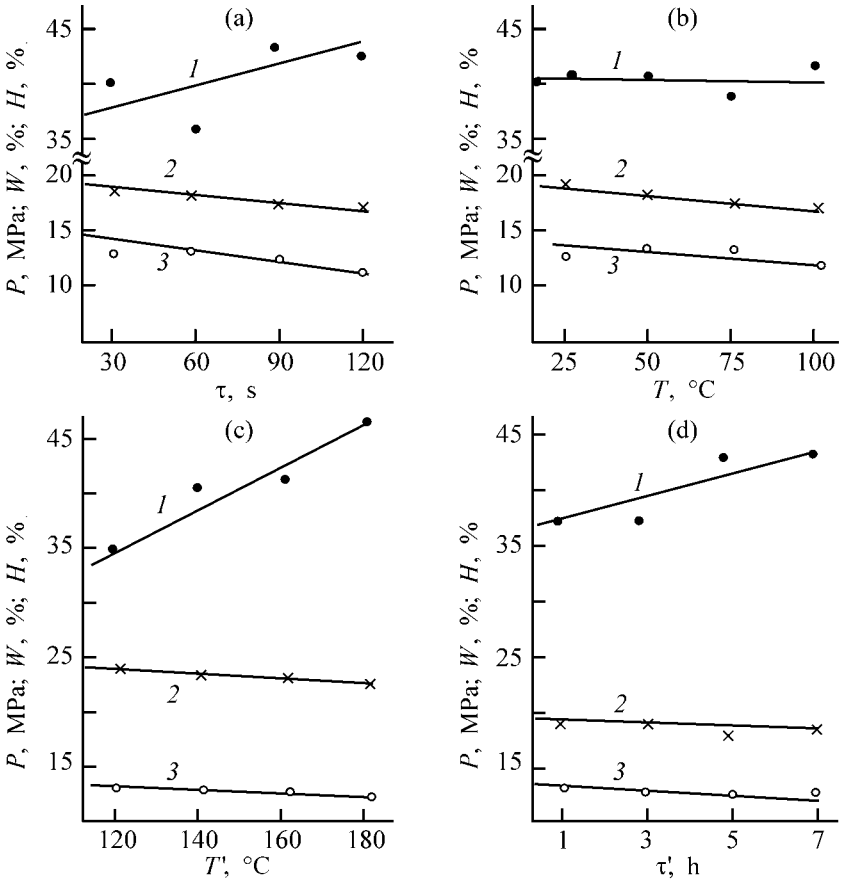


Fig. 2. Influence of (a) impregnation duration τ (30, 60, 90, 120 s; factor A), (b) impregnating formulation temperature T (25, 50, 75, 100°C; factor B), (c) heat treatment temperature T (120, 140, 160, 180°C; factor C), and (d) heat treatment duration τ (1, 3, 5, 7 h; factor D) on the parameters of WFB treated with the MA-modified polymeric material. (*1*) Water absorption W, (*2*) swelling in thickness H, and (*3*) bending strength P.

time. The effect of the impregnating–formulation temperature is also insignificant. To save power, it is advisable to perform the impregnation without heating. The strongest influence is exerted by the duration and especially by the heat treatment temperature, because cross-linking processes faster at elevated temperatures. Furthermore, at elevated temperatures maleic acid can undergo dehydration to maleic anhydride, and both can react with the wood components. Thus, elevated temperature and longer time of the heat treatment make possible the occurrence of a number of consecutive, parallel, and consecutive-parallel processes. The resulting 3*D* cross-linked copolymeric framework and its chemical bonding with the wood fiber impart to WFB not only increased hydrophobicity but also enhanced strength.

The content of the modified copolymeric material in the WFBs, influenced by the conditions of the impregnation and subsequent heat treatment, varied in a relatively narrow range, in most cases from 12 to 14.5% relative to the WFB weight.

Comparison of the experimental values with those calculated by the above-given regression equations for the corresponding conditions (Table 3) shows their good agreement.

The experimental results and the general physicomechanical and physicochemical concepts suggest the existence of an intimate correlation with a positive effect between the water absorption and swelling in thickness and between the water absorption and bending strength. These quantities are plotted in

Table 3. Experimental characteristics of WFB specimens treated with the MA-modified polymeric material

Parameter	Experiment	Calculation
Bending strength, MPa	44.8	47.1
Water absorption, %	15.9	17.1
Swelling in thickness, %	11.6	12.3

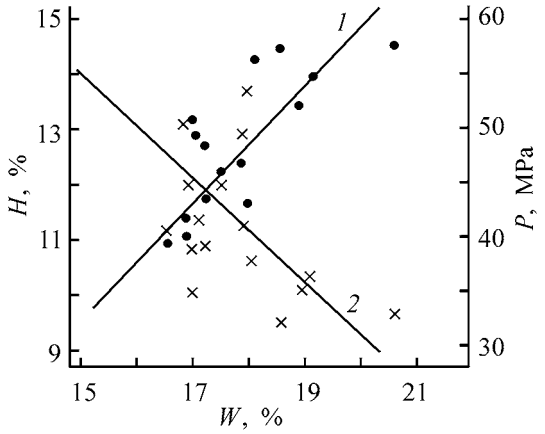

Fig. 3. (*1*) Swelling in thickness *H* and (*2*) bending strength *P* of WFB specimens as functions of the water absorption *W*.

Fig. 3; indeed, there is a positive correlation of the swelling in thickness and bending strength with the water absorption.

Visual examination of cuts of WFBs impregnated with the MA-modified copolymeric material shows that this material is uniformly distributed in the bulk of the fiberboard, filling the production defects and micro- and macropores. The resulting copolymeric framework of the MA-modified copolymeric material and products of its reaction with wood components reduces the release of formaldehyde from articles in which phenol– or urea–formaldehyde resins were used as binders.

The use of copolymeric materials prepared from petrochemical production wastes and by-products can not only improve of the properties of items but also solve environmental problems.

CONCLUSIONS

(1) Modification with maleic acid of a low-molecular-weight styrene-containing copolymer from by-product formed in polybutadiene production allows preparation of a material with an increased content of oxygen-containing functional groups.

(2) The copolymers modified with maleic acid can be used for protective treatment of wood materials with the aim to impart to them increased hydrophobicity and mechanical strength.

Abstract—Pentaerythritol-based block copolymers of ethylene and propylene oxides were synthesized and characterized as surfactants and demulsifiers.

DOI: 10.1134/S1070427207020280

The wide diversity of oil production and treatment processes, and the large number of properties of the produced oil makes a search for new high-performance demulsifiers a topical task [1]. Presently, the most efficient demulsifiers are nonionic surfactants such as alkylene oxide block copolymers [1–4]. Nonionic surfactants are mostly synthesized from glycols, amines, synthetic fatty acids, and phenols.

Alkylene oxide block copolymers based on polyhydric alcohols have not been adequately explored as demulsifying surfactants [1–4].

Therefore, we prepared in this study polyoxyalkylated derivatives of pentaerythritol and characterized their surfactant and demulsifying properties.

EXPERIMENTAL

Oxyalkylated pentaerythritols were synthesized using the conventional anionic polymerization route [5]. First, we synthesized a prepolymer by adding four moles of propylene oxide (PO) to the starting reagent. Then PO and ethylene oxide (EO) were successively added. Hydroxyalkylation was carried out at 135–150°C and 1.0–1.6 atm in the presence of a base catalyst.

As a result, we prepared a series of block copolymers with various hydrophobic to hydrophilic group ratios (Table 1). Sample nos. 1–7 have hydroxyethyl terminal groups, and sample nos. 8–14, hydroxypropyl groups.

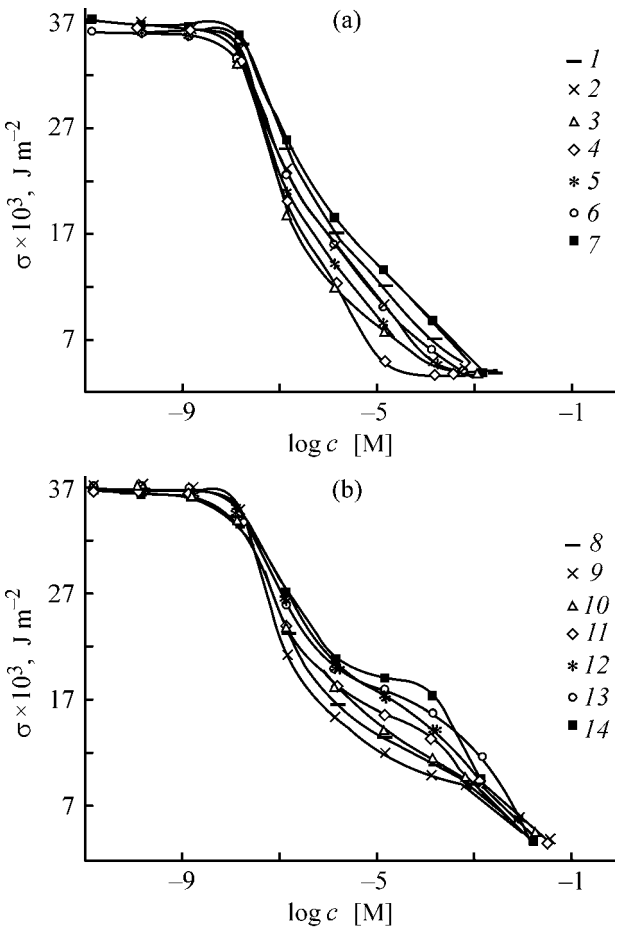

Fig. 1. Isotherms of surface tension at toluene/water interface for the samples with (a) EO and (b) PO terminal groups. (σ) Surface tension and (*c*) concentration. The *curve numbers* correspond to the numbering in Table 1.

The characteristic of the block copolymers that reflects the addition of ethylene oxide is the cloud point of their aqueous solutions. When dissolved in water, nonionic substances form hydrates through hydrogen bonding between water molecules and ether oxygen atoms of the polyethylene glycol residue [5]. Heating ruptures the hydrogen bonds, and the solution becomes turbid (solute separates out as suspended droplets). Cooling makes the solution clear again [4, 5]. The cloud points of the samples are listed in Table 1. Since the cloud point of several samples was above 100°C, 1% solutions of the block investigated copolymers were prepared in 10% NaCl [4].

Table 1 shows that the cloud point increases with the number of the hydroxyethyl units, i.e., the number of hydrogen bonds between the EO units and water molecules grows.

To determine the molecular weight of the samples, we measured the hydroxyl number by the procedure involving esterification of the hydroxy groups with acid chlorides or anhydrides. The theoretical and experimental hydroxyl numbers are also listed in Table 1.

The difference between the experimental and theoretical hydroxyl numbers can be attributed to the formation of polyethylene glycols and to the resulting the broad molecular-weight distribution in the products obtained. As the number of the hydroxyethyl groups added increases, the main reactions are accompanied by side reactions. This makes more pronounced the difference between the experimental and theoretical data.

Among the significant characteristics of surfactants is their ability to reduce the surface tension at the interface between the solution and a gas or another liquid. The interfacial tension of the nonionic surfactant solutions at the toluene/water interface was measured by the ring detachment (Du Nouy) method using a LAUDA tensiometer. In this method, the force acting on an immersed body is measured electronically. Figure 1 shows the surface tension isotherms of the toluene solutions of the nonionic surfactants at the toluene/water interface.

As we pass from infinitesimal concentrations to the critical micelle concentrations (CMC) two portions are observed in the surface tension isotherms, These portions differ in the extent to which the surface tention varies with the nonionic surfactant concentration in the solution.

It is known that, in mixtures of ethers with different numbers of glycol residues, compounds with shorter polyglycol chains form micelles at a lower concentration, compared to longer-chain compounds [4, 6, 7]. Therefore, the surface tension isotherms level out smoothly in our case, and the critical micelle concentration range is extended. For sample nos. 8–14 (Fig. 1b), the increase in the EO content in the molecule is reflected in the occurrence of an additional nearly horizontal portion suggesting the presence in the sample of an admixture of nonionic surfactants with a lower molecular weight, formed in the final oxypropylation stage. Sample nos. 1–7 (Fig. 1a) do not contain such admixtures, because ethylene oxide added in the final stage "landed" on the target block copolymer, forming polyethylene glycol side products to a lesser extent. The resulting polyethylene glycols are composed of the starting compound (pentaerythritol) and various amounts of ethylene oxide. These compounds demonstrate a weak surface activity.

From the surface tension isotherms we estimated the adsorption Γ, limiting adsorption Γ_m, work of

adsorption W_a, landing area of the molecule S_m, and CMC [8–10].

The adsorption Γ (g-mol m^{-2}) was determined from the slope of the tangent to the initial portion of the isotherm. The slope $d\sigma/d\log c$ was then substituted in the Gibbs equation [9]:

$$\Gamma = -(1/2.3RT)(d\sigma/d\log c).$$

The limiting adsorption Γ_m (g-mol m^{-2}) was found from the slope of the second linear portion of the isotherm, in which the limiting adsorption is attained. Again the slope $d\sigma/d\log c$ was substituted in the Gibbs equation [9]:

$$\Gamma_m = -(1/2.3RT)(d\sigma/d\log c).$$

The landing area of the molecule, S_m (m^2), was estimated from the limiting adsorption [9]:

$$S_m = 1/(\Gamma_m N),$$

where N is the Avogadro number (6.022057×10^{23} mol^{-1}).

The work of adsorption, W_a (kJ mol^{-1}), is among the most significant characteristics of surfactants. This parameter represents the energy gain in the transfer of a mole of a surfactant from the bulk to the interface [9]:

$$W_a = RT\ln(\Gamma/\delta c),$$

where δ is the adsorption layer thickness determined taking into account the range of intermolecular forces at the interface and equal to 12×10^{-10} m for the toluene/water interface [8, 11].

The maximal work of adsorption of the surfactants under study was estimated at the maximum dilution by extrapolation to zero concentration, i.e., for the case of ideal solution. The CMC values were also determined from the surface tension isotherms ploted in the coordinates σ–$\log c$ (Table 2).

Using data of Table 2, we plotted the dependences of CMC, landing area of the molecule, S_m, and work of adsorption W_a on the degree of oxyethylation (Figs. 2, 3). The resulting dependences are well consistent with the data from [5, 8, 9, 12]. The surface tension at the water/toluene interface only slightly depends on the degree of oxyethylation (Table 2), because the molecular weight of the resulting samples is

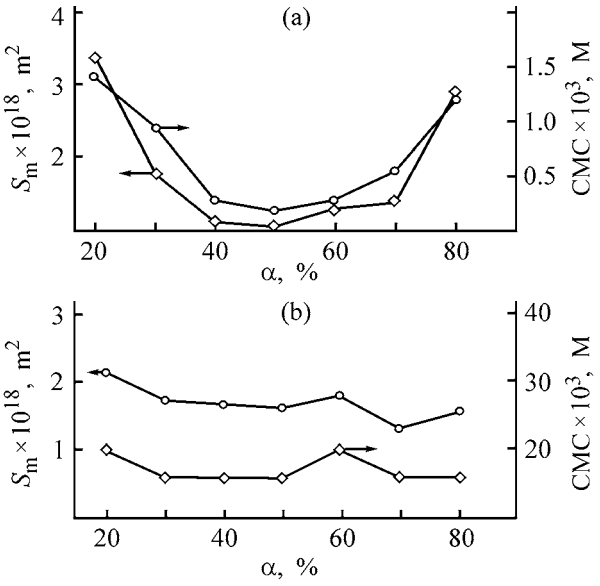

Fig. 2. Landing area of the molecule, S_m, and CMC vs. the degree of oxyethylation, α, in sample nos. 1–14. α is taken from Table 1; the same for Fig. 3.

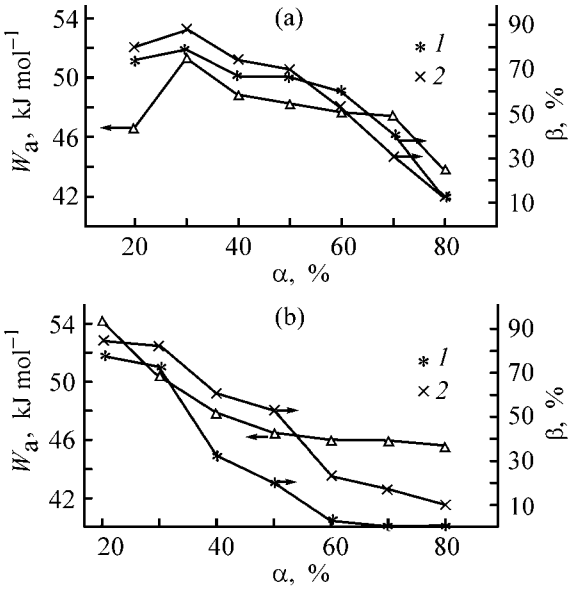

Fig. 3. Work of adsorption W_a vs. the degree of oxyethylation α in sample nos. 1–14. Oil field: (*1*) Novo-Suksinskoe and (*2*) Peschanoe.

constant, and the PO : OE ratio only changes. The different solubilities in toluene and water of nonionic surfactants of the same molecular weight only slightly affect the surface tension. It has been demonstrated previously [13] that the surface tension is significantly affected by an increase in the molecular weight of a nonionic surfactant and changes in the EO : PO ratio in the molecule.

Figure 2 shows that there is a minimum in the CMC–α dependence, which is due to different solubilities of the samples in toluene and water. The occurrence of the maximum in the most hydrophobic sample nos. 7 and 8 suggests that they have the highest solubility in toluene. Among the most hydrophilic anionic surfactants, the maximum is shown by sample nos. 1 and 12. Sample nos. 13 and 14 are even more hydrophilic, but their CMC is lower, which can be attributed to a larger amount of lower-molecular-weight anionic surfactants in their composition, formed by side reactions.

The landing area of the molecule at the toluene/water interface also shows a minimum coincident with that in the CMC dependence. The arrangement of the molecule at the interface depends on its solubility in each phase. The most hydrophobic molecule is entirely distributed in the toluene phase, as well as a part of the hydrophilic block. In this case, both the landing area and CMC are at a maximum. Minima in the dependences are observed for sample no. 4 with equal amounts of the PO and EO blocks. In this case, the landing area is at a minimum, since the molecule of the indicated block copolymer is equally soluble in both phases, and no retraction of the hydrophobic and hydrophilic blocks occurs. The landing area of the compounds with the PO terminal groups also shows a minimum corresponding to the sample having equal amounts of the PO and EO blocks. However, sample nos. 13 and 14 have low landing areas because they contain large amounts of side products.

The dependences of the demulsifying efficiency of surfactants on the landing area of the molecule and CMC have been analyzed previously in [5, 10–12] for the compounds in which the hydrophobic blocks were represented by long alkyl radicals. For these compounds, correlations were found. In our case, nonionic surfactants are block copolymers, and no correlations were found between their demulsifying efficiency and landing area and CMC.

It was interesting to study the effect of the work of adsorption on the demulsifying efficiency.

The demulsifying efficiency was studied using the conventional bottle sampling method with artificial and natural emulsions. The artificial emulsion with 30% watering was prepared from anhydrous coal-bearing oils from the Novo-Suksinskoe oil field (oil well no. 1090, Tatneft' Joint-Stock Company) using a simulated stratal water. The natural emulsion was taken from the Peschanoe oil field (Archneftegeologiya Joint-Stock Company). The data obtained in testing the samples for the demulsifying efficiency are listed in Table 1. These data were plotted in Fig. 3 against the work of adsorption taken from Table 2.

Figure 3 shows that the most efficient demulsifiers are the samples with an EO group content from 32 to 40% in the series with EO terminal groups and from 20 to 30% in the series with PO terminal groups. The decrease in the demulsifying efficiency directly correlates with the decreasing work of adsorption.

CONCLUSIONS

(1) Pentaerythritol-based block copolymers of ethylene and propylene oxides with various hydrophobic to hydrophilic part ratios demonstrate a surface and demulsifying activity.

(2) The critical micelle concentration, landing area of the molecule, work of adsorption, and demulsifying efficiency were determined as functions of the degree of oxyethylation of the samples. The highest demulsifying efficiency was observed for the compounds with a content of the hydroxyalkyl groups of 32–40 and 20–30 wt % in the series with hydroxyethyl and hydroxypropyl terminal groups, respectively.

Abstract—Copolymers of 1-vinyl-1,2,4-triazole and 5-vinyltetrazole with 1,1,5-trihydrooctafluoropentyl methacrylate and 1,1,7-trihydrododecafluoroheptyl methacrylate were prepared under the conditions of radical initiation. These copolymers were used for modification of the surface of a glassy carbon electrode, and the effect of the modification on the electrochemical behavior of the electrode in anodic oxidation of dopamine and NO was studied. The possibility of enhancing the selectivity of the electrochemical sensor for monitoring NO in biological media was demonstrated.

DOI: 10.1134/S1070427207020292

Nitrogen(II) oxide exhibits a broad spectrum of biological effects [1], and the NO functions in mammal bodies critically depend on its concentration [2]. Numerous methods have been developed for determining NO in biological systems [3], but the electrochemical method allowing on-line determination of the NO concentration is justly considered to be particularly efficient. Electrochemical redox reactions of NO can be performed in model buffer solutions on smooth unmodified metal or glassy carbon electrodes [4], but the development of an electrochemical sensor for measuring the NO concentration in biological media requires enhancing the selectivity of the working electrode. Among interfering species are both anions (NO_2^-, NO_3^-) and cations (e.g., dopamine).

The common procedure for eliminating the effect of anions is modification of the working electrode surface with a Nafion polymeric cation-exchange membrane [5, 6]; however, higher electrode selectivity can be attained by applying multilayer electrode coatings based on polyfunctional polymeric materials. Polymers combining in their structure azole rings and fluorinated fragments can be one of the components of such selective membranes. Synthesis of copolymers of 1-vinyl-1,2,4-triazole with fluorinated alkyl methacrylates [7] and preparation of materials for medicine based on these copolymers [8] have been reported. 1,2,4-Triazole rings impart to the copolymers hydrophilicity, chemical and hydrolytic stability, and complexing ability, whereas fluorinated fragments should enhance the mechanical strength of the copolymer film coatings and their adhesion to other fluorinated polymers and, in particular, to Nafion, which is very important in preparation of high-selectivity multilayer coatings for an amperometric sensor.

In this study, we prepared copolymers of 1-vinyl-1,2,4-triazole (VTr) and 5-vinyltetrazole (VT) with 1,1,5-trihydrooctafluoropentyl methacrylate (8-FAMA) and 1,1,7-trihydrododecafluoroheptyl methacrylate (12-FAMA), and examined the influence exerted on the electrochemical behavior of NO by film coatings based on these copolymers, applied onto the electrode surface.

EXPERIMENTAL

The starting monomers were prepared and purified by published procedures: VTr [9], bp 41–42°C/10 Pa, n = 1.5100; 8-FAMA [10], bp 71°C/1.73 kPa, n = 1.3570; 12-FAMA [10], bp 100°C/1.73 kPa, n = 1.3490. VT was recrystallized from chloroform, mp 126°C. The polymerization initiator [azobis(isobutyronitrile, AIBN] and solvents (DMF, acetone, diethyl

ether) were purified by standard procedures. The copolymerization of monomer mixtures was performed to maximal conversion in ampules under argon at 60°C in DMF solution containing AIBN. The copolymers were isolated by precipitation into water, reprecipitated, and vacuum-dried to constant weight. The composition and structure of the copolymers were determined by elemental analysis and IR spectroscopy. The viscosity of the copolymers in DMF was determined with an Ubbelohde viscometer at 20°C. The degree of swelling of the copolymers in water was determined gravimetrically using films prepared by evaporation of 1–3% solutions of the copolymers in acetone or dimethylformamide, cast on a glass surface. To make the films based on VT copolymers hydrophilic, they were additionally kept for 3–5 min in 0.1 M NaOH, with the subsequent drying in a vacuum. The degree of swelling (%) was calculated by the formula

$$K_{sw} = [(M_h - M_0)/M_0] \times 100,$$

where M_h is the weight of the swollen hydrogel, and M_0, that of the dry polymer.

The IR spectra of the copolymers were recorded on a Specord M-60 spectrometer; samples were taken as mulls in mineral oil and thin films.

The main voltammetric measurements were performed as described in [11, 12]. In addition, we used for voltammetric analyses an installation based on an EP20A potentiostat and a PR-8 programmer. Measurements were performed in a three-electrode glass cell with a working volume of 15 ml. The reference electrode was a BAS RE-1B silver chloride electrode, and the auxiliary electrode was a platinum grid. The surface area of the working glassy carbon (GC) electrode was 7.1 mm^2.

In the study, we used $FeSO_4 \cdot 7H_2O$ (chemically pure grade), KNO_2 (chemically pure grade), KH_2PO_4 (ultrapure grade, recrystallized), NaOH (chemically pure grade), HCl (analytically pure grade), 5% aqueous–alcoholic solution of Nafion (Aldrich), and 0.5% solution of dopamine (Ferane). As supporting electrolytes we used 0.1 M phosphate and phosphate–alkaline buffer solutions [11]; their pH was varied from 2.0 to 9.0. The majority of electrochemical measurements were performed at pH 7.4.

Nitrogen(II) oxide prepared according to [13] was introduced into the system as described in [11, 12]; the concentration of the saturated NO solution was 2 mM [14].

Before each experiment, the GC electrode was pretreated by polishing the working surface with alumina powder, after which the electrode was kept in an ultrasonic bath for 7 min to remove solid particles from the surface and washed with double-distilled water. The glassy carbon electrodes were modified with Nafion and/or synthesized copolymers of VTr with 8-FAMA and 12-FAMA at various ratios of monomeric units. The surface of the working GC electrode with Nafion was modified as described in [11, 12]. A similar procedure was used for modifying the GC electrode with the azole-containing copolymers synthesized. A 10-μl portion of a 5% solution of a copolymer in acetone was applied onto the electrode surface. The coating was dried for 40 min at room temperature and then for 40 min at 60°C. To prepare multicomponent coatings, the electrode was first coated with Nafion, after which it was dried and the modifying copolymer layer was applied over the Nafion film.

The cell and other glassware were treated with a hot mixture of concentrated sulfuric acid with 30% hydrogen peroxide solution, which was followed by washing with hot tap water and then with double-distilled water. To provide an inert atmosphere, the solution in the electrochemical cell was bubbled with argon for 10 min.

The potential sweeping rate in various potentiodynamic experiments was varied from 0.002 to 0.500 $V\ s^{-1}$. The potentials are given vs. the silver chloride electrode. The measurements were performed at room temperature.

The elemental and spectral analyses and turbidimetric titration show that joint polymerization of vinylazoles with fluorinated methacrylates under the conditions of radical initation yields copolymers. The IR spectra of copolymers of VTr with 8- and 12-FAMA are identical to those given in the literature [7]: The absorption bands of the vinyl groups of the comonomers at 1650 and 964 cm^{-1} are lacking, but there are bands characteristic of the 1,2,4-triazole moiety (1508, 1450, 1100 cm^{-1}), carbonyl group (1740 cm^{-1}), and CF_2 groups (420–970 cm^{-1}). The IR spectra of the copolymers of VT with 8- and 12-FAMA contain, along with the above-noted bands of the fluorinated monomers, also the bands characteristic of the N–H-unsubstituted tetrazole ring [15] at 2200–3500, 1560, and 1250 cm^{-1}.

The results of the copolymerization and analysis of the products are given in the table. The copolymerization of VTr with 8- and 12-FAMA, as noted

Copolymerization of vinylazoles (M_1) with fluorinated alkyl methacrylates (M_2) ([AIBN] = 5×10^{-3} M, $[M_1] + [M_2]$ = 2 M, DMF, 60°C, 8 h)

previously [7], is characterized by a decrease in the yield of the polymeric product with an increase in the VTr content of the starting mixture and by enrichment of the copolymers with the units of the fluorinated monomer, which indicates that the vinylazole is less reactive. The viscosity of the copolymers grows with an increase in the content of VTr units. For the copolymerization systems with VT, there is no apparent correlation between the yield of the reaction product and the composition of the starting mixture. The ratio of the comonomer units in the polymeric product differs insignificantly from that in the starting mixture, i.e., the copolymerization of VT with fluorinated methacrylate is approximately azeotropic.

The copolymers prepared are colorless powders whose solubility strongly depends on the structure of units of the vinylazole comonomer and on their content. For example, copolymers of VTr with 8- and 12-FAMA, with the mole fraction of vinylazole units less than 0.5, are soluble in DMF, acetonitrile, and acetone, whereas the copolymers with a higher VTr content are soluble only in DMF. DMF is the common solvent for the copolymers of VT with 8- and 12-FAMA, irrespective of their composition. The 1,2,4-triazole ring shows very weak base properties; therefore, the polymeric products containing the triazole ring exhibit no polyelectrolytic behavior, despite the capability to swell in water. The degree of swelling of the films prepared from the VTr copolymers grows with an increase in the content of vinylazole units and varies within 18–150%. The N–H-unsubstituted tetrazole ring is a typical acid; therefore, the copolymers containing VT units behave as polymeric acids. This is manifested in the formation of polymeric salts in the reactions of the copolymers with alkalis. The water affinity of the copolymers considerably increases upon ionization. The water absorption by samples of VT–12-FAMA copolymer films treated with NaOH ranges from 70 to 350%. The hydrated films preserve a fairly high mechanical strength. The compatibility with water of the films based on the synthesized copolymers of vinylazoles with fluorinated methacrylates makes them promising as an electrode coating for determining the NO concentration in aqueous solutions.

When preparing model solutions, we added to the buffer solution typical anionic and cationic substances that could interfere with the determination of NO: solutions of KNO_2 and dopamine, respectively, taking into account that their oxidation can mask the oxidation of NO. It is known that, even without a modifier, the redox response of dopamine is influenced by the electrode material, mechanical and/or electrochemical pretreatment of the surface, composition and ionic strength of the supporting electrolyte [16], and other factors associated with the conditions of electrochemical measurements [17, 18]. Therefore, to obtain the initial data, we studied the electrochemical behavior of dopamine (35 μM) on the unmodified

GC electrode (Fig. 1). An anodic current peak corresponding to the oxidation of dopamine under these conditions is observed at E = +0.15 V. To this peak corresponds a reduction current peak in the cathodic branch, suggesting reversibility of the electrochemical oxidation of dopamine. This is confirmed by the fact that, at potential sweeping rates as low as 0.002–0.010 V s^{-1}, the difference between the maximum potentials of the anodic and cathodic peaks (ΔE) is about 30 mV, and the anodic and cathodic currents in these peaks increase in proportion with the square root of the potential sweeping rate ($V^{0.5}$). The latter dependence holds through the entire range of sweeping rates examined, from 0.002 to 0.500 V s^{-1}, which is clearly seen in Fig. 2. The above-noted features allow us to characterize the redox transformations of dopamine as a quasireversible two-electron process typical of biologically active substances of the quinone nature [19].

The voltammograms of dopamine on the unmodified GC electrode were recorded in supporting electrolytes with different pH values. We found that ΔE of the redox peaks of dopamine remained constant in the pH range 3.0–9.0, with both cathodic and anodic peaks shifting toward less positive potentials with increasing pH. This trend suggests that protons are involved in electrochemical transformations of dopamine. In the pH range 3.0–8.0, the dependences for both peaks are linear, with a slope of 60 mV per pH unit. This slope suggests that the ratio of the number of protons involved in the redox process to the number of electrons transferred is 1 : 1 [19]. Taking into account the above assumptions that two electrons are transferred in the redox reaction of dopamine, the overall reaction equation can be written as

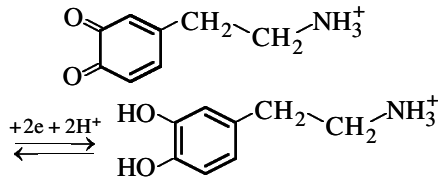

Figure 3 shows that, at high pH values (>8), the slopes of the E–pH dependences decrease. According to [20], such a decrease in the slope is observed in oxidation of dibasic acids at pH values close to pK_1. Indeed, for dopamine, pK_a is 8.9 [21]. Then at pH > 8 the contribution of the partially deprotonated reduced form of dopamine becomes significant:

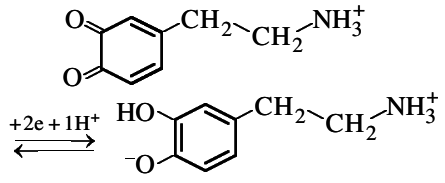

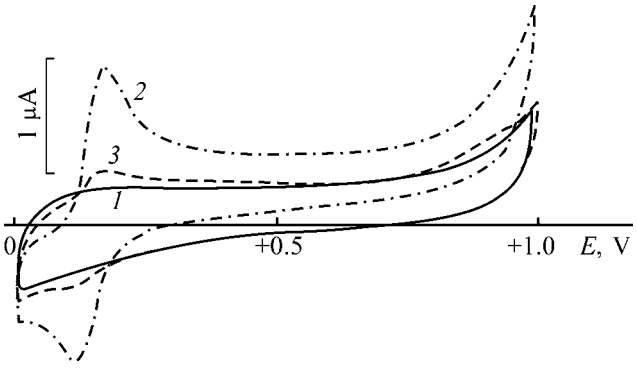

Fig. 1. Voltammograms measured on an unmodified GC electrode in a 0.1 M phosphate buffer solution (pH 7.4) at a sweeping rate of 20 mV s^{-1}. (*E*) Potential (vs. silver chloride electrode); the same for Figs. 3–5. (*1*) Straight supporting electrolyte; (*2*) 35 μM dopamine, first cycle; and (*3*) 35 μM dopamine, after cycling.

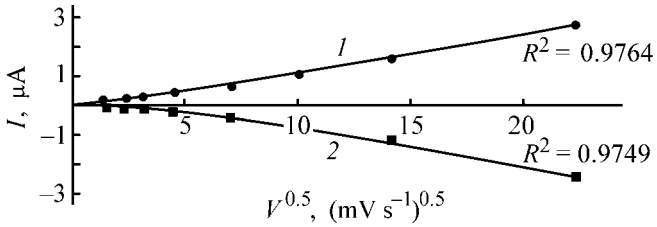

Fig. 2. Currents I of (*1*) anodic and (*2*) cathodic peaks vs. the potential sweeping rates V for voltammograms measured on an unmodified GC electrode in a solution containing 35 μM dopamine. Supporting electrolyte: 0.1 M phosphate buffer, pH 7.4.

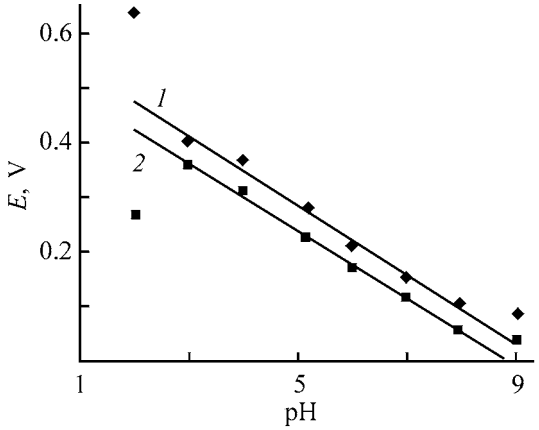

Fig. 3. Potentials of (*1*) anodic and (*2*) cathodic peaks of the voltammograms measured on the unmodified GC electrode vs. pH of a 0.1 M phosphate supporting electrolytes containing 35 μM dopamine (V = 20 mV s^{-1}). E_a^p = –0.0628pH + 0.5966, R^2 = 0.9878; E_c^p = 30.0612pH + 0.5415, R^2 = 0.9973.

At pH < 3, ΔE no longer meets the conditions of a quasireversible electron transfer and increases to several hundreds of millivolts. This fact suggests that the mechanism of electrochemical transformations

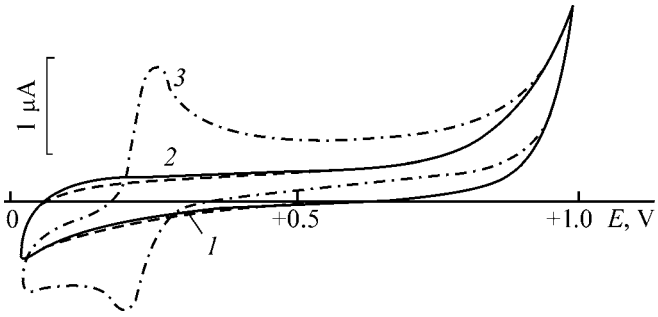

Fig. 4. Voltammograms measured at V = 20 mV s^{-1} on a GC electrode modified with 1-VTr–8-FAMA (*1*) before and (*2*) after adding dopamine (35 μm) to 0.1 M phosphate buffer solution (pH 7.4). Copolymer composition (molar ratio) 0.44 : 0.56. Curve *3* was measured under conditions similar to curve *2* but after removing the modifier from the electrode surface.

of dopamine on glassy carbon changes in in going to strongly acidic solutions. Similar phenomena were noted previously [22].

One more feature of the electrochemical behavior of the system under consideration is manifested after multiply repeated potential cycling. The redox responses of dopamine in the first cycle (curve *2*) and after prolonged potential cycling (curve *3*) are compared in Fig. 1. In the latter curve, the anodic and cathodic current peaks corresponding to the reversible electrochemical transformations of dopamine become considerably less pronounced than those in the first cycle. Furthermore, one more anodic current wave appears in curve *3* at potentials of +0.8 to +1.0 V. This anodic process is apparently irreversible, because no corresponding current peaks or waves are observed in the cathodic branch of the curve. These phenomena can be attributed to further transformations of products formed in the first (reversible) step of oxidation of the pyrocatechol fragment of the dopamine molecule. It is known [23] that such products, can not only be electrochemically reduced to the initial form, but also can be involved in side chemical processes, including reaction with water (hydroxylation) or with the initial reduced form (coupling).

The above features of the electrochemical behavior of dopamine show that the unmodified GC sensor electrode is unsuitable for determining the NO content in the presence of dopamine. Since dopamine is oxidized at considerably less positive potentials than those of NO oxidation (from +0.7 to +0.9 V [11, 12]), the presence of dopamine in solution will cause a considerable increase in the background current of the sensor operating in the amperometric mode. Furthermore, appearance, accumulation, and side reactions of dopamine oxidation products lead to formation of substances that are oxidized in the range of potentials overlapping with that of NO oxidation. Moreover, these side processes will apparently lead to an appreciable degradation of the electrode surface. In the context of searching for ways to improve the stability and selectivity of a sensor for NO determination, dopamine seems to be a good model simulating the presence in solution of cations interfering with the electrochemical determination of NO in biological systems.

To eliminate the interfering effect of dopamine in the determination of NO, the surface of the working GC electrode was modified with copolymers of VTr with 8-FAMA and 12-FAMA. We tested eight samples of the copolymers with different ratios of the monomeric units.

After the modification, the electrode was kept for 24 h in a 0.1 M phosphate buffer solution (pH 7.4) and transferred into an electrochemical cell filled with the same buffer solution, to measure cyclic voltammograms. After obtaining the background curve, dopamine was added to a concentration of 35 μM, and the measurement was repeated. Then the voltammogram was measured in the same solution but on the unmodified electrode, after removing the polymeric coating from the working surface (Fig. 4). The voltammograms recorded similarly for all the eight samples (Fig. 4) clealry show that coating the GC electrode surface with the copolymers considerably decreases the currents corresponding to reversible redox transformations of dopamine under the conditions examined, as compared to the unmodified electrode. An increase in the content of hydrophilic VTr units in the copolymer decreases the sensitivity of the working electrode to dopamine, which is protonated at physiological pH values. However, when the content of hydrophilic groups becomes higher than a certain critical value (specific to each type of copolymers), the polymer films swell too strongly (see table), which impairs the mechanical properties of the modified coatings.

We also modified the GC electrode by successive application onto its working surface of films of Nafion and the copolymers synthesized. Such multilayer multicomponent coating is necessary for preparing a sensor electrode suitable for NO determination in real systems containing both anionic and cationic interfering components. We measured cyclic voltammograms in the buffer solution and after adding dopamine to its maximal concentration of 35 μM. Under the same conditions, we recorded the curves after adding KNO_2 (7 mM) and

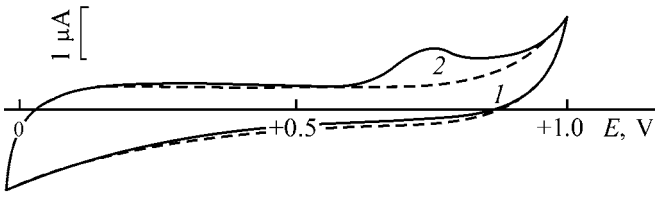

Fig. 5. Voltammograms measured at $V = 20$ mV s^{-1} on a GC electrode modified successively with Nafion and 1-VTr– 8-FAMA (*1*) before and (*2*) after saturating the solution with NO. Solution composition: 0.1 M phosphate buffer solution (pH 7.4), KNO_2 (7 mM), and dopamine (35 μM); copolymer composition (molar ratio) 0.33 : 0.67.

after saturating the solution with NO by its bubbling for 10 min. The voltammograms obtained (Fig. 5) show that the bilayer modifying coatings used do not interfere with the anodic oxidation of NO. The background curve does not change after adding KNO_2 and dopamine in the above-indicated concentrations.

CONCLUSIONS

(1) VTr–8-FAMA copolymers with the mole fraction of vinylazole units of 0.33–0.44 are effective modifiers of the electrode surface, which fully suppress the interfering effect of dopamine and, probably, of other cationic species. The modified electrode remains active in the electrochemical oxidation of NO.

(2) Good adhesion of copolymers with fluorinated and azole-containing units to a Nafion film allows preparation of multilayer coatings promising for the development of a selective electrochemical sensor for measuring the NO concentration in biological media.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Immobilization of Proteolytic Enzymes Trypsin and α-Chymotrypsin to Cellulose Matrix

N. E. Kotel'nikova, S. A. Mikhailova, and E. N. Vlasova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received June 5, 2006; in final form, November 2006

Abstract—Trypsin and α-chymotrypsin were immobilized on a microcrystalline cellulose matrix by adsorption interaction with cellulose. The adsorption of enzymes was determined as a function of their concentration and the pH of solutions. Mechanisms of enzyme binding to functional groups of cellulose were suggested.

DOI: 10.1134/S1070427207020309

The adsorption of proteins and, in particular, enzymes on solid interfaces and interactions between surfactants and enzymes at liquid | solid interfaces are processes of significance in our daily life and in such fields as medicine, food processing, biotechnology, etc. Adsorption acquires particular importance in biological systems because enzymes in them are mostly in the immobilized state on surfaces of cell membranes and subcellular structures. In fact, the conjugates of proteins and interfaces are heterogeneous systems and, taking into account their biological activity, they are heterogeneous biocatalysts [1]. Polymer fibers and films, including polysaccharides, are widely used as carriers of such biocatalysts. The immobilization of physiologically active compounds of protein nature is a convenient method for developing biomedical preparations that can be inserted into the injured zone and can stay in it for an indefinite period. They continuously emit an active preparation into the environment to achieve its high local concentration. The most widespread immobilization method is attachment of an enzyme to a polymer support by covalent, ionic, or adsorption bonds.

Cellulose, due to its unique properties, is of particular interest among other polysaccharides and is widely applied for various purposes. In this study, microcrystalline cellulose (MCC) was used as matrix for immobilization of enzymes. It exhibits specific properties, and its powder morphology makes it possible to use it in processes for which fiber celluloses are unsuitable [2]. There is a positive experience in applying this cellulose as a matrix to prepare conjugates with drugs, with synthetic polymers (for instance, with PVP and its complexes [3, 4]), and also for immobilization of human serum albumin (HSA) [5].

Proteolytic enzymes trypsin and α-chymotrypsin have the key position in the system of digestive enzymes. There is poor information in the literature about preparation of heterogeneous biocatalysts based on cellulose and these enzymes [6, 7]. Modified, e.g., oxidized, cellulose has been mainly used [8]. In this study, adsorption interaction between enzymes and cellulose matrix was performed to immobilize enzymes on MCC. Enzyme adsorption mostly depends on the surface properties of adsorbent, such as its chemical structure, hydrophilicity or hydrophobicity, charge, and porosity. Adsorption is also determined by the chemical composition, structure, and other properties of enzymes themselves. All these factors determine the properties of their conjugates with the matrix and, primarily, the activity of enzymes or their tendency to inactivation.

The goal of this study was to examine immobilization of trypsin and α-chymotrypsin on MCC by their adsorption interaction and the properties of the resulting adsorption complexes MCC–enzymes (ACs). Their preparation is not only of practical interest. From the scientific viewpoint, formation of the complexes with retention of the enzymatic activity may serve as a model for preparation of a peculiar kind of "glycoproteins," in which polysaccharides (cellu-

lose) molecules are bound to polypeptide chains of protein.

EXPERIMENTAL

The powdered microcrystalline cellulose used as a matrix for immobilization of enzymes contained no more than 2.0 wt % water. Its particle size was <0.05 mm. The viscosity-average degree of polymerization DPv of MCC was 190. The volume of pores, their radius, and specific surface area determined by water vapor sorption were 2.16 $cm^3\ g^{-1}$, 20 μm, and 230 $m^2\ g^{-1}$, respectively. The content of aldehyde end groups in cellulose chains was 3.2×10^{-5} mol g^{-1}, and that of carboxy groups on the surface of cellulose macromolecules, 5.8×10^{-6} mol g^{-1} [9].

Crystalline bovine trypsin was taken from SPOFA (Czech Republic), and crystalline bovine α-chymotrypsin, from Samson-Med Ltd. (Russia). The main characteristics of enzymes are listed in Table 1.

The enzymatic activity of trypsin was determined by the Erlanger method [12] from the hydrolysis rate of a low-molecular-weight substrate, *p*-nitroanilide of *N*,α-benzoyl-*D*,*L*-arginine (BAPNA). The enzymatic activity of α-chymotrypsin was determined with respect to a low-molecular-weight substrate, ethyl ether of *N*-benzoyl-*L*-tyrosine (BTEE) (both enzymes from Sigma, the United States). The rate of enzymatic hydrolysis was determined with the aid of a Specord UV VIS 20 spectrometer (Carl Zeiss, Germany). The relative activity of immobilized enzymes in ACs and in solutions after desorption was calculated with respect to the enzymatic activity of the pristine enzymes.

Trypsin and α-chymotrypsin were immobilized from solutions by adsorption onto the cellulose matrix under isothermal conditions at 15°C with continuous stirring. Cellulose feeds (m) were 0.1 g in 30 ml of enzyme solution. Solutions were separated from ACs by filtration through a Schott filter with a porosity of 16. The resulting ACs were vacuum-dried at 40°C. The initial (c_0) and equilibrium (c_{eq}) concentrations of the enzymes in solutions were determined by the Lowry method [13] and by direct measurement of the optical density of solutions on a Specord UV VIS 20 spectrometer at a wavelength λ = 280 nm. The content of the adsorbed enzyme (adsorption value *A*, mg g^{-1}) was calculated from the equation

$$A = (c_0V_0 - c_{eq}V_{eq})/m,$$

where V_0 and V_{eq} are the volumes of the filtrates before and after adsorption.

Table 1. Main characteristics of trypsin and α-chymotrypsin [10, 11]

Constants	Bovine trypsin	Bovine α-chymotrypsin
Molecular mass, kDa	23.8	25
pH of optimum activity	7–8	8
Isoelectric point p*I*	10.6	8.1
pH range of stability	Acid	Acid
Relative activity, %	76	84
K_{bound} $(Ca^{2+}) \times 10^{-4}$, 1 mol^{-1}	11.0	0.92

To obtain the dependence of the content of the adsorbed trypsin on pH of its solution (in the pH range from 4.8 to 12.0), we used its 2.3 and 4.0 mg ml^{-1} solutions in a buffer. For α-chymotrypsin adsorption, we used its 1.1 and 2.6 mg ml^{-1} solutions. To obtain the kinetic dependences, we used trypsin and α-chymotrypsin solutions of the same concentrations at pH 8.2 (in case of trypsin) and at pH 8.0 (in case of α-chymotrypsin). To obtain the adsorption isotherms, we used trypsin solutions in the concentration range from 0.5 to 7.2 mg ml^{-1} and those of α-chymotrypsin in the concentration range from 0.5 to 4.5 mg ml^{-1} at the same pH values. Buffer solutions with pH 4.0–6.3 were prepared by titration of a 0.1 M solution of trisubstituted sodium citrate $Na_3C_6H_5O_7$ with a 0.5 M solution of HCl. Buffer solutions with pH 7.0–10.3 were prepared by titration of 0.05 M solution of tris(hydroxymethyl)aminomethane $[(HOCH_2)_3CNH_2]$ with 1 M HCl. Buffer solutions with pH 11.0–12.0 were prepared by the method described in [14]. All the buffer solutions were filtered before use through a Schott filter with a porosity of 16.

The enzymes were desorbed from ACs containing various amounts of adsorbed enzymes at buffer solution pH 2.0 and 8.2. The desorption conditions and procedures for treatment of feeds after desorption, sample drying, and determination of enzyme concentration were similar to those used in the adsorption study. The desorption (*D*) was calculated in percent of the enzyme adsorption. The content of enzyme strongly bound to MCC was designated as the residual adsorption (Ar, mg g^{-1}).

To study the chemical composition of ACs and enzymes by IR Fourier spectroscopy, samples were prepared in KBr pellets. Transmission spectra were recorded on a Bruker IFS 88 IR Fourier spectrometer (Bruker, Germany) with a 4 cm^{-1} resolution. Differential spectra of enzymes in ACs were obtained by subtraction of the MCC spectrum from the AC spectra.

Wide-angle X-ray scattering was applied to study the supramolecular structure of ACs. X-ray diffraction patterns were obtained with a DRON-48 diffractome-

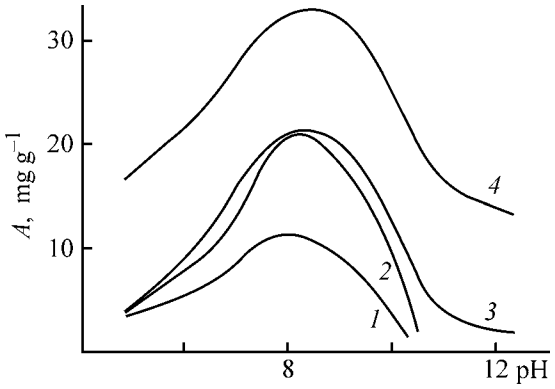

Fig. 1. pH dependence of the maximum adsorption A of (*1*, *2*) α-chymotrypsin and (*3*, *4*) trypsin on MCC. c_0, mg ml^{-1}: (*1*) 1.1, (*2*) 2.6, (*3*) 2.3, and (*4*) 4.0; the same for Fig. 2.

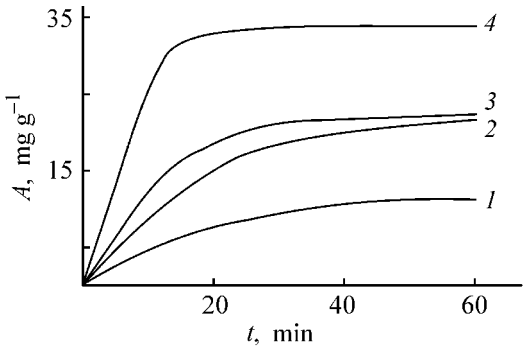

Fig. 2. Adsorption kinetics of (*1*, *2*) α-chymotrypsin and (*3*, *4*) trypsin. (*t*) Time.

ter (Burevestnik NPO, USSR) with a Geiger counter for recording the intensity of reflected beams at any 2θ angle. The samples were prepared as isotropic discs 10 mm in diameter by compacting powder samples at a pressure of 100 kg cm^{-2}. The diffraction patterns were recorded under the following conditions: Cu_{K_α} radiation monochromatized with a Ni filter, voltage 3.5 kV, current 8 mA, goniometer rate 2 deg min^{-1}, and time constant 3.5. The crystallinity indices of ACs were calculated by the Segal method [15], and the size of cellulose crystallites, by the Scherrer method [16].

Table 2. Rate constants (k_1, k_2) of adsorption of trypsin and α-chymotrypsin from solutions onto MCC

Enzymes	c_0, mg ml^{-1}	A, mg g^{-1}	$k_1 \times 10^3$	$k_2 \times 10^3$
			min^{-1}	
Trypsin	2.4	21	7.5	–
	4.0	33	8.5	–
α-Chymo-	1.1	11	12.6	3.5
trypsin	2.6	21	15.3	2.4

Changes in the morphological structure of MCC during adsorption were studied by scanning electron microscopy (SEM) with a Jeol JCM-35 CF (Jeol, the United Kingdom) scanning electron microscope. To obtain micrographs, samples of pristine cellulose and ACs were preliminarily placed on an aluminum support coated with a carbon layer in a special chamber and were sprayed using a gold target in an inert gas atmosphere. The electron micrographs were obtained at a magnification of 40 to 2000 at a 15 kV voltage.

The pH of solutions of enzymes profoundly affects their adsorption. Figure 1 shows the dependence of the maximum adsorption values for trypsin and α-chymotrypsin on the pH of the medium. The maximum A for trypsin (21 and 33 mg g^{-1} at the initial concentration C0 of solutions 2.3 and 4.0 mg ml^{-1}, respectively) is reached at pH 8.0–8.5, and that for α-chymotrypsin (11 and 21 mg g^{-1} at the initial concentration of solutions 1.1 and 2.6 mg ml^{-1}, respectively), at pH 7.9–8.2. These results are in agreement with the data on adsorption of these enzymes onto other polymer adsorbents [8, 17, 18]. MCC has a negative surface charge in the pH range 3.5–11.0 due to dissociation of its surface carboxy groups [9]. The isoelectric point for trypsin is 10.6 [10]. Consequently, trypsin molecules are positively charged in the pH range 8.0–8.5. In this case, the electrostatic factor contrib- utes to the adsorption interaction in the pH range <10.6. The isoelectric point of α-chymotrypsin is 8.1 [11]. Hence, α-chymotrypsin molecules are not charged in the pH range 7.9–8.2. In contrast to trypsin, the contribution of electrostatic factor to the adsorption interaction with MCC should be lower in the case of α-chymotrypsin.

Kinetic dependences of the adsorption of trypsin and α-chymotrypsin onto cellulose at different initial enzyme concentrations are shown in Fig. 2. The dependences have a shape typical of adsorption from solutions on porous surfaces. The adsorption is a two-stage process. The first stage proceeds at a high rate, and in the second stage the rate becomes much lower. The equilibrium trypsin adsorption is attained in 30 min, with the rate of the second stage close to zero. The equilibrium α-chymotrypsin adsorption is attained in 50 min, with the adsorption terminated in the second stage. The rate constants of enzyme adsorption onto cellulose were calculated from the semilog kinetic plots, according to the pseudo-first-order rate equation (Table 2). It should be noted that the rate constants of trypsin adsorption onto cellulose are comparable with those of adsorption of a synthetic polymer, PVP, onto MCC [3] and

three-four times lower than those of HSA adsorption onto MCC [5]. The rate constants of α-chymotrypsin adsorption onto cellulose are higher than those of PVP and are comparable with those of HSA.

Adsorption isotherms of trypsin and α-chymotrypsin are shown in Fig. 3. The S-shaped dependences can be referred to type IV and can be satisfactorily described by Freundlich equations [19]. This is in agreement with the results of immobilization of enzymes on other matrices described in [8, 18, 20]. An analysis of Freundlich constants calculated from the isotherms plotted in log-log coordinates showed that the capacity of MCC to adsorb those enzymes is 8–10 times that to adsorb serum albumin [5] and comparable with its capacity to adsorb PVP [3]. The S-shape is known to be characteristic of adsorption that combines physical sorption and chemisorption of enzymes [19]. The occurrence of enzyme chemisorption was confirmed by IR spectroscopy (see below).

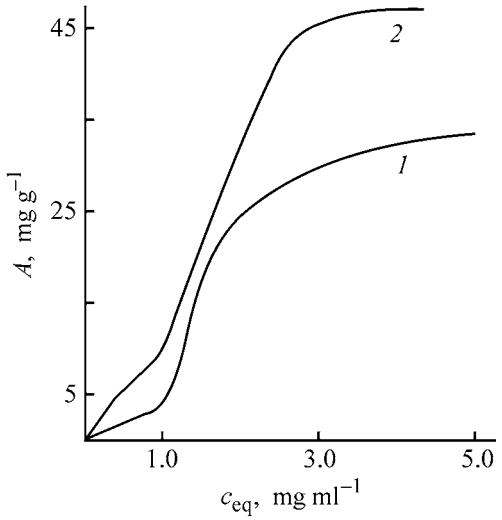

Fig. 3. Adsorption isotherms of (*1*) trypsin and (*2*) α-chymotrypsin to MCC. (*A*) adsorption and (c_{eq}) equilibrium enzyme concentration.

A study of desorption of both enzymes from the ACs demonstrated that the desorption *D* only slightly depends on the pH of the medium (Table 3). In the case of trypsin, *D* increases proportionally to the content of the enzyme adsorbed. However, in the case of α-chymotrypsin, *D* depends on the content of the adsorbed enzyme to a lesser extent. It is important that both enzymes are not completely released from the cellulose matrix. The maximum value of *D* for trypsin is 69 wt %, which is in agreement with the data reported in [8]. The amount of trypsin retained in the matrix is constant (~10 mg g^{-1}), i.e., ~1% of the AC mass. In contrast to trypsin, α-chymotrypsin is retained in the cellulose matrix to a greater extent. The maximum value of *D* is 18 wt %, and the amount of retained α-chymotrypsin is as high as 41 mg g^{-1}. Consequently, the results of enzyme desorption from the AC indicate that a part of immobilized enzymes is strongly bound to the cellulose matrix.

The relative enzymatic activities of the enzymes in AC and in solutions after desorption, calculated relative to the enzymatic activity of pristine enzymes, are also listed in Table 3. The enzymatic activity of trypsin solutions after the desorption (carried out at pH 2.0 and 8.2) is low (lower than that of pristine trypsin) and depends on the amount of desorbed trypsin only in the case of desorption at pH 8.2. This is probably caused by autolysis of trypsin, which can take place both in solutions and on the cellulose matrix directly during the adsorption.

The relative enzymatic activity of α-chymotrypsin desorbed from AC at pH 2.0 and 8.2 is 70%. It is much higher than that of adsorbed trypsin. In this case,

Table 3. Desorption of enzymes from ACs and their relative activity *A*

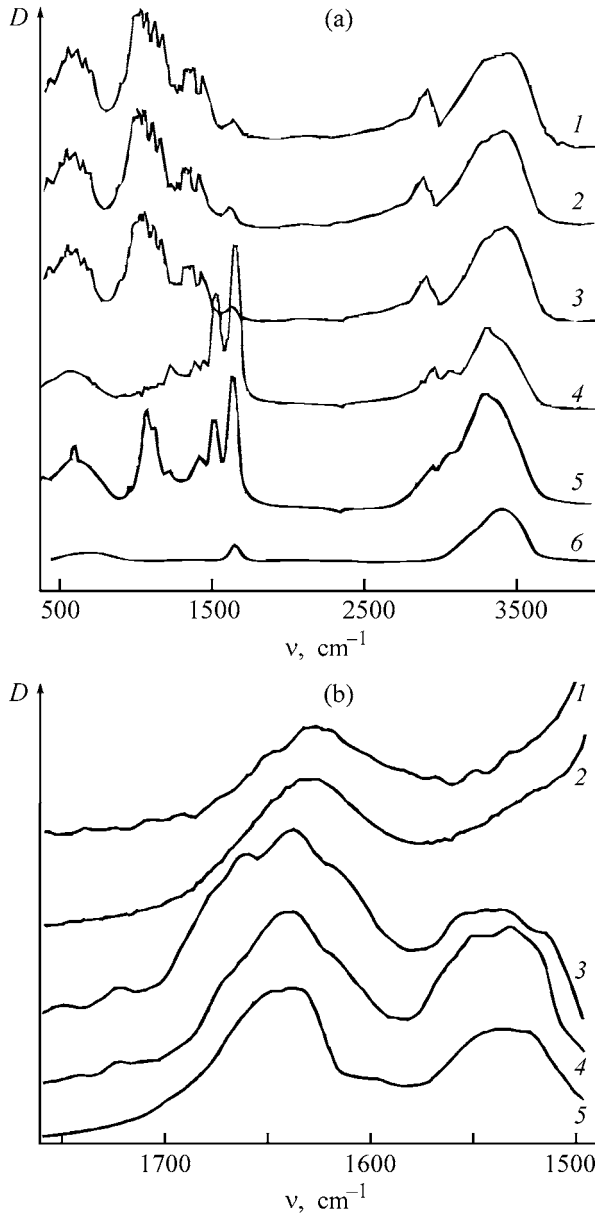

Fig. 4. IR Fourier spectra. (*D*) Absorption and (ν) wavenumber. (a) wavelength range 400–3700 cm^{-1}; (*1*) MCC, (*2*) AC MCC–trypsin (A = 21 mg g^{-1}), (*3*) the same AC after desorption of trypsin (A_r = 10 mg g^{-1}), (*4*) α-chymotrypsin, (*5*) trypsin, and (*6*) water; (b) wavelength range 1500–1775 cm^{-1}; (*1*) MCC and (*2*) AC MCC-trypsin (A = 21 mg g^{-1}); differential spectra of (*3*) trypsin and (*4*) α-chymotrypsin; (*5*) pristine trypsin.

the enzymatic activity is independent of the content of enzyme in AC.

Thus, the resulting data on the isolation of both trypsin and α-chymotrypsin from ACs, carried out under conditions simulating the physiological pH range in gastrointestinal tract, show that ACs MCC–trypsin and MCC–α-chymotrypsin can be applied to control the functions of gastrointestinal tract, both in stomach (pH 2.0) and in the upper part of the intestines (pH 8.2). Their enzymatic properties will be manifested most strongly in the latter case.

It is known that, in protein adsorption on solid surfaces under heterogeneous conditions, the surface influences protein binding and its structure as well as proteins influence the adsorption matrix. For instance, in the case of adsorption of HSA onto MCC, conformational changes of protein molecules occur, but also the morphological structure of cellulose greatly changes [5]. An X-ray diffraction study of cellulose–enzyme ACs has shown that MCC keeps the structure of cellulose I. The crystallinity index is 0.80 both in the pristine MCC and in the AC. It is known that the shape and intensity of the 040 reflection can serve as criteria of crystallite order [21]. The decrease by half in the intensity of the 040 reflection in ACs suggests that the shape of cellulose crystallites in AC changes and their packing becomes more defective. This fact confirms that the enzyme adsorption affects the supramolecular structure of the cellulose matrix.

The IR spectra of trypsin and α-chymotrypsin (Figs. 4a, 4b) contain characteristic absorption bands peaked at about 1640–1645 (amide I), 1532 (amide II), 1142–1087 (in the spectrum of trypsin) and 1236 (in the spectrum of α-chymotrypsin) (amide III), 590 cm^{-1} (amide V), as well as bands peaked at about 2900 (C–H stretching vibrations) and 3300 cm^{-1} (N–H stretching vibrations) [22]. The spectra show that the chemical composition of the pristine cellulose in the ACs does not change. The differential spectra of enzymes, obtained by subtracting MCC spectra from those of the ACs (in the ranges 1500–1750 cm–1, Fig. 4b and 3000–3600 cm^{-1}), indicate that immobilized enzymes remain in the ACs. This confirms the conclusion that a part of enzymes is strongly bound to the matrix. The position and shape of the amide I and amide II absorption bands in differential spectra of trypsin and α-chymotrypsin are sensitive to changes in the conformation of enzymes. Their analysis shows that the absorption band peaked at 1532 cm^{-1} changes only slightly as compared to that of pristine enzymes. The change in the shape of the absorption band in the range 1620–1680 cm^{-1}, specifically, its splitting into three bands, in the differential spectra of both enzymes is more noticeable (Fig. 4b). These changes are probably due to interaction between enzymes and cellulose. However, the overlapping of some absorption bands in the range 3000–3600 cm^{-1}, for instance, the amide I band in the spectra of enzymes and

the HOH bending band of adsorbed water in cellulose, the broad absorption band of OH groups of cellulose, peaked at 3410 cm^{-1}, and that of NH groups of enzymes, peaked at 3250 cm^{-1}, do not allow any unambiguous conclusion on the mechanism of component interaction. The revealed presence of a considerable amount of unremovable water bound both to the enzyme and to the cellulose matrix is in agreement with data obtained by other authors, according to which water can form stable cluster systems when strongly bound to enzymes and cellulose [23–25].

Thus, the results of an IR study indicate that immobilized trypsin and α-chymotrypsin are strongly bound to the cellulose matrix and interact with cellulose. This is in agreement with the conclusions based on the adsorption isotherms.

Changes in the morphological structure of cellulose also occur during enzyme immobilization on cellulose fibers. According to the results obtained by scanning electron microscopy (Figs. 5a–5d), the pristine cellulose fibers (Fig. 5a) become swollen and partly destroyed. The fibrillar order on the fiber surface is disturbed; the fibers are destroyed in transverse and longitudinal directions (Fig. 5b). This is especially noticeable after partial desorption of adsorbed enzymes (Figs. 5c, 5d).

Thus, immobilization of enzymes on a cellulose matrix is accompanied by mutual effect of enzymes on the supramolecular and morphological structure of cellulose and of cellulose on some properties of enzymes, for instance, their solubility.

To elucidate the mechanism of enzyme binding to the cellulose matrix, the content of enzymes immobilized on cellulose and retained after desorption was correlated to the amount of cellulose chains and, correspondingly, to that of the main reactive (carboxy and aldehyde) groups of cellulose (Table 4).

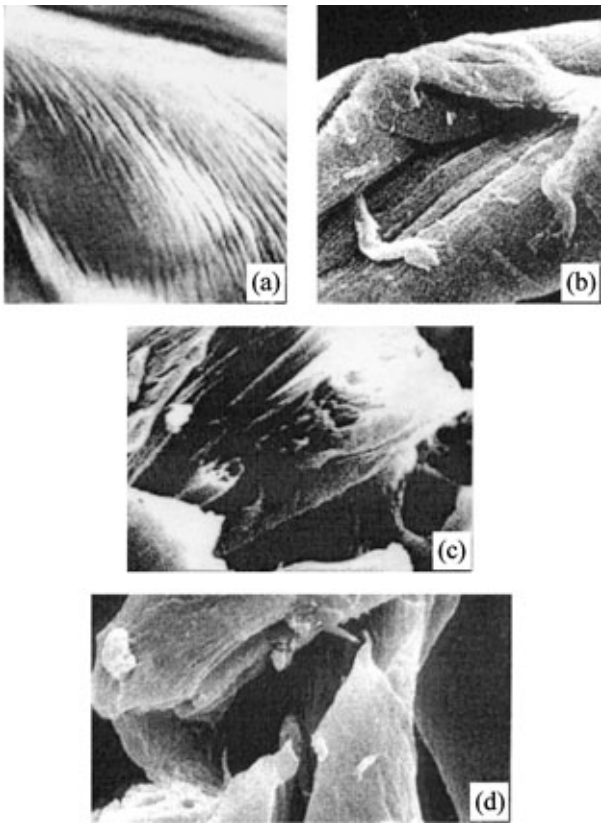

Fig. 5. Electron micrographs of (a) MCC fiber, (b, c) AC of MCC containing immobilized (b) trypsin or (c) α-chymotrypsin, and (d) MCC fiber after desorption of trypsin from AC MCC–trypsin.

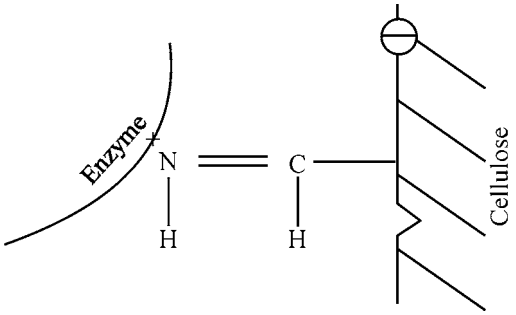
Table 4. Molar ratio of enzymes and functional groups of cellulose in ACs MCC–trypsin or MCC–α-chymotrypsin with varied content of immobilized enzymes

Sample no.*	A, mg g^{-1}	Amount of cellulose chains and functional groups of cellulose capable to be bound with 1 mol of enzyme			Sample no.*	A, mg g^{-1}	Amount of cellulose chains and functional groups of cellulose capable to be bound with 1 mol of enzyme		
		cellulose chains	–HC=O groups	–COOH groups			cellulose chains	–HC=O groups	–COOH groups
Trypsin					α-Chymotrypsin				
1	3.0	256	191	45	6	7.0	116	116	21
2	13.0	59	59	11	7	18.0	45	45	8
3	21.0	36	36	7	8	49.0	17	17	3
4	33.0	23	23	4	9	38.0	21	21	4
5	9.9	77	77	14					

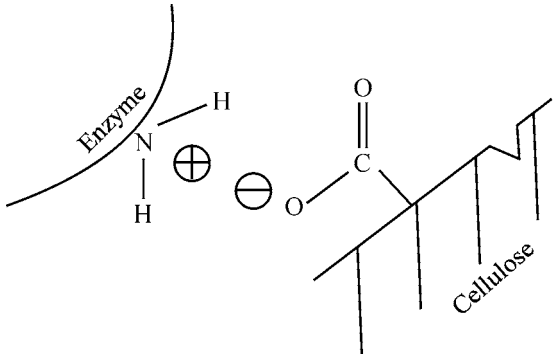
* Samples 1–4 and 6–8 are ACs MCC–trypsin and MCC–α-chymotrypsin, respectively; samples 5 and 9 are the same ACs after desorption of enzymes from samples 4 and 8, respectively.

Table 4 confirms the conclusion that α-chymotrypsin is retained in the cellulose matrix to a greater extent than trypsin. The macromolecule of immobilized α-chymotrypsin is strongly bound by a smaller amount of cellulose chains than that of trypsin (compare samples 5 and 9), i.e., α-chymotrypsin is more labile with respect to cellulose.

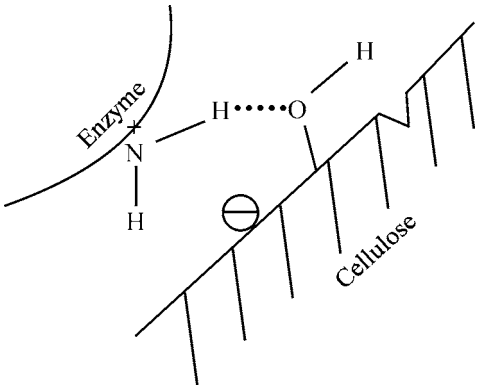
According to these results, three possible ways of formation of cellulose-enzyme complexes can be suggested. Stable bonds between cellulose and enzymes are formed owing to the interaction of amino groups of enzymes with aldehyde end groups of cellulose and surface carboxy groups, as well as due to binding of amino groups to hydroxy groups of the cellulose surface (schemes 1–3).



Scheme 1.



Scheme 2.



Scheme 3.

The surface of MCC is very hydrophilic because it is enriched in hydroxy groups. This favors multipoint interaction between the amino groups of enzymes and the hydroxy groups of cellulose (scheme 3). This process does not exclude binding of both cellulose macromolecules and enzymes to water molecules, as described in [23–25].

CONCLUSIONS

(1) Adsorption isotherms are described by the Freundlich equation.

(2) Adsorption of enzymes is partly reversible. The content of immobilized trypsin strongly bound to cellulose is 10 mg g^{-1} and that of α-chymotrypsin attains 41 mg g^{-1}.

(3) It is shown by wide-angle X-ray scattering and scanning electron microscopy that enzyme adsorption promotes changes in the supramolecular and morphological structure of the cellulose matrix.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Immobilization of Urease on the Silica Gel Surface by Sol–Gel Method

Abstract—The possibility of "double immobilization" of urease on silica gel, involving enzyme incorporation into the polysiloxane polymer prepared by sol-gel procedure on the surface of an inorganic support was studied. The optimal composition and thickness of the polysiloxane film, providing relatively high activity of urease, were determined.

DOI: 10.1134/S1070427207020310

One of the main problems of biotechnology is development of new simple and practically feasible methods for immobilization of enzymes to prepare stable and highly active heterogeneous biocatalysts for commercial use [1]. Among modern procedures of enzyme immobilization, the sol–gel method and, especially, the procedure based on hydrolytic polycondensation of alkoxysilanes [2] seems promising. In this mode, an enzyme can be immobilized both by sorption on preliminarily prepared polysiloxane supports and by incorporation into polysiloxane matrices in the course of the above reaction [3, 4]. In the first case, we frequently obtained porous materials with fairly developed surface and pores of certain diameter. The parameters of the pore structure of these matrices directly affect the degree of enzyme binding and the preservation of its activity [5, 6]. In the second case, a certain (frequently large) fraction of the enzyme is completely incorporated into the siloxane support and, thus, becomes inaccessible for the substrate [7]. To eliminate this disadvantage, the procedure of so-called double immobilization of enzymes on the surface of porous silica gel by the sol–gel procedure was suggested [8, 9]. This approach for preparing biocatalysts is based on the uniform distribution of a solution containing alkoxysilanes and enzyme on the surface of the inorganic support. Subsequent hydrolytic polycondensation in the supported solution leads to the formation of polysiloxane layer (PL) containing an enzyme on the silica gel surface.

This method is rather simple and does not require expensive supports and reagents. In this study, which continues our systematic investigations, we attempted to develop a procedure for double immobilization of urease on the silica gel surface and to study the activity and stability of the immobilized enzyme as influenced by the nature of alkoxysilanes and the component ratio.

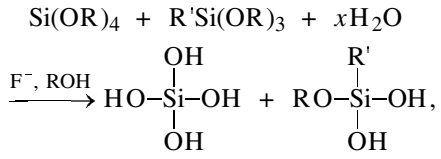
EXPERIMENTAL

The experiments were performed using the hydrolase class enzyme, specifically, soybean urease (Jack beans, EC 3.5.1.5) with an activity of 46.2 units mg^{-1} at pH 7 (Fluka). The sol–gel procedures were carried out using tetraethoxysilane $Si(OC_2H_5)$ (TEOS, 98%), 3-mercaptopropyltrimethoxysilane $(CH_3O)_3Si–(CH_2)_3SH$ (MPTMS, 99%), methyltriethoxysilane $(C_2H_5O)_3SiCH_3$ (MTES, 995), and dimethyldiethoxysilane $(C_2H_5O)_2Si(CH_3)_2$ (DMDES, 99%); all the chemicals were purchased from Aldrich (United States). Porous Davesil silica gel (Aldrich, S_{sp} 300 $m^2 g^{-1}$, d 0.015 μm) was used as a support. We also used a 0.06 M phosphate buffer (pH 7), 0.05 M solution of sodium ethylenediaminetetraacetate (analytically pure grade Na_2EDTA), 2 M solution of chemically pure grade urea, 4% aqueous solution of polyvinyl alcohol (PVA), and 0.01 M solution of NH_4F as a catalyst for hydrolytic polycondensation.

Urease was immobilized by hydrolytic polycondensation on the silica gel surface of alkoxysilanes

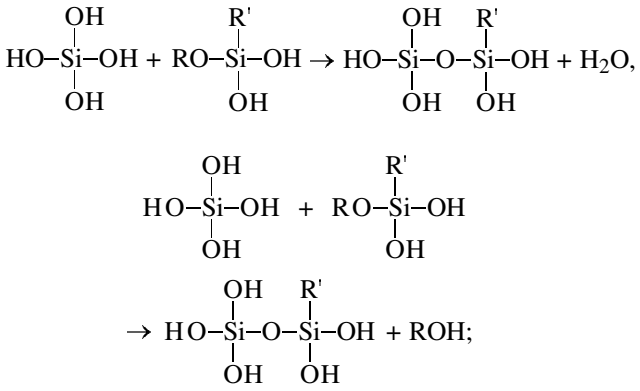
preliminarily mixed in the required ratios in the presence of a catalyst (fluoride ions), PVA, and urease:

Hydrolysis of alkoxysilanes

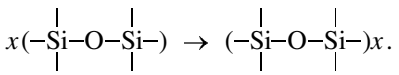


where R = CH_3, C_2H_5; R' = functional group;

Condensation



Polycondensation



The volume ratio of the initial solution and silica gel was selected so as to eliminate formation of a supernatant liquid fraction. The suspension was thoroughly mixed and placed in a refrigerator (4°C) for subsequent hydrolysis of alkoxysilyl groups and condensation of the resulting silanol groups, (silanol groups on the silica gel surface are also involved in this process). The activity of the immobilized urease was measured at regular intervals. For example, the component ratio in the preparation of a sample was as follows: TEOS 0.15 cm^3, MTES 0.05 cm^3, DMDES 0.05 cm^3, PVA solution 0.05 cm^3, NH_4F 0.01 cm^3, urease solution (20 mg of urease in a phosphate buffer at pH 7) 0.25 cm^3, and silica gel 1.5 g.

For comparison, urease was directly immobilized in the initial silica gel by equilibrium adsorption from a phosphate buffer solution (pH 7) or by its wetting with the urease solution in the phosphate buffer, with subsequent drying of the sample in a refrigerator and washing with water. The washing water

Table 1. Activity of urease immobilized on silica gel by adsorption from a buffer solution

after urease immobilization on the silica gel surface was analyzed for the content of urease, and the degree of urease immobilization was determined from the difference between the initial content of urease and its concentration in the wash water. The content of urease in the wash water was evaluated from its enzymatic activity, taking into account that the specific activity of urease in the wash water was similar to that in the native sample (46.2 units g^{-1}).

The enzymatic activity of urease in the wash water and of immobilized urease A_{im} was determined by the kinetic method from the rate of urea hydrolysis catalyzed by urease. The rate of the urea hydrolysis was evaluated from the amount of ammonia formed during a certain period of time. The concentration of the ammonium cations was determined colorimetrically with the Nessler reagent [10]. Conversion of 1 μmol of urea per minute of the enzymatic reaction was taken as a unit activity of the urease. In all the cases, the activity was determined as the average of three parallel runs; the measurement error of the urease activity did not exceed 10%.

The retention of the immobilized urease was evaluated using the following expression:

$$A_{pr} = A_{im} \times 100/46.2m,$$

where A_{pr} is the preserved urease activity (%); A_{im}, activity of immobilized urease units g^{-1}); and m, weight of the native urease contained in 1 g of the sample (mg).

The data on the activity of urease immobilized on the Devisil silica gel surface by equilibrium and nonequilibrium adsorption from the buffer solution are listed in Table 1. As seen, the evaporation of the urease solution provides irreversible immobilization (90–

Table 2. Activity of urease immobilized on silica gel by the sol–gel method as influenced by the composition of the initial reaction mixtures

Initial components of the polysiloxane layer	Alkoxysilanes added, $cm^3\ g^{-1}$	Urease added, $mg\ g^{-1}$	A_{im}, units g^{-1}	A_{pr}, %
TEOS : PVA = 2.5 : 1	1.0	38.0	0.2	0.6
TEOS : MPTMS : PVA = 2,5 : 0.1 : 1	1.0	41.0	0.2	0.6
TEOS : MTES : PVA = 4 : 1 : 1	1.0	36.0	1.4	4.0

TEOS : MTES : DMDES = 3 : 1 : 1	0.5	20.0	3.5	10.0

100%) of the enzyme in the silica gel. At the same time, only a small fraction of the enzyme (10–26%) is irreversibly retained on the silica gel surface in the case of equilibrium adsorption. However, the enzymatic activity of immobilized urease is very low in both cases.

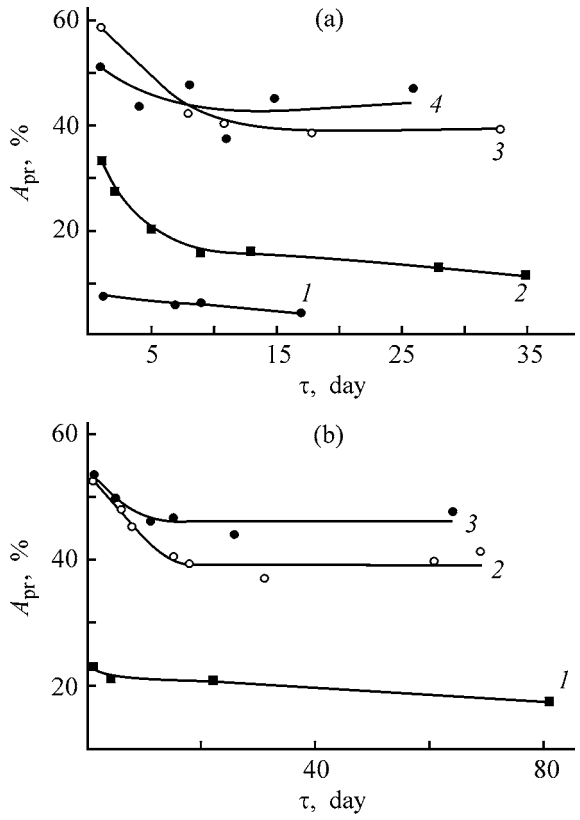

Fig. 1. Preserved activity A_{pr} of urease immobilized in polysiloxane layer on silica gel vs. time τ for (a) three-component TEOS : MTES : DMDES and (b) two-component TEOS : MTES systems. Alkoxysilanes added ($cm^3\ g^{-1}$): (a) (*1*) 1.0, (*2*) 0.5, (*3*) 0.25, and (*4*) 0.16; (b) (*1*) 0.4, (*2*) 0.3, and (*3*) 0.13.

The data on the urease activity in the samples prepared by double immobilization with various systems are listed in Table 2. As seen, the activity and the preservation of the activity of immobilized urease increase upon introduction of the hydrophobic groups (methylsilyl or dimethylsilyl) into the polysiloxane layer. These groups at the silicon atom in alkoxysilanes, especially $=Si(CH_3)_2$, hinder formation of a 3*D* matrix network, because they cannot be involved in condensation. These groups also cannot form hydrogen bonds with amino residues of urease. As a result, the enzyme binding should be weaker [11]. Hence, the effect of the polysiloxane matrix on the structure of immobilized urease will be smaller. The effect of PVA is probably the same: on mixing with alkoxysilanes, it prevents formation of the 3*D* network of the polysiloxane matrix [6]. As a result, the activity of urease in the films prepared on the silica gel surface in the presence of PVA is higher by a factor of 1.5 as compared to the samples prepared without PVA.

The data listed in Table 2 suggest that the preservation of the activity of immobilized urease also depends on the ratio of the volume of alkoxysilanes and weight of the support. The effect of this factor was studied in detail for the example of two-component TEOS : MTES and three-component TEOS : MTES : DMDES systems. The results are shown in Figs. 1 and 2. As can be seen from Figs. 1a and 1b, the activity of immobilized urease slightly decreases in the initial period of the samples storage (about 10 days) in both systems in most cases. In this time, the polysiloxane layer probably undergoes further structuring in which a certain fraction of urease either loses its enzymatic activity or gets encapsulated and becomes inaccessible. Moreover, as the ratio of the liquid and solid phases decreases, i.e., as the polysiloxane layer becomes thinner, the activity of immobilized enzyme increases.

It has been found previously that the activity of urease immobilized in polysiloxane xerogels by adsorption is determined by the pore structure of the matrix and, in particular, by the pore diameter [7]. However, the structural and adsorption properties of silica gel (Table 3), determined from the isotherms of nitrogen adsorption, show that formation of PL on the sorbent surface does not significantly affect the parameters of the pore structure of the resulting samples as compared to the initial silica gel. Thus, the variation of the activity of urease immobilized in PL on the silica gel surface with the ratio of the volume of alkoxysilanes and weight of silica gel is governed by some other factor.

Obviously, the smaller the volume of alkoxysilanes per gram of silica gel, the thinner the resulting polysiloxane layer. Assuming that the reaction solution of alkoxysilanes is uniformly distributed over the silica gel surface, we can calculate from its volume and specific surface area the thickness of the resulting layer. The ratio of the solid and liquid phases used in this study provides formation of the polysiloxane layers with a thickness from 0.4 to 3.3 nm. On drying, the layer thickness will decrease. At the same time, the resulting PL may be discontinuous (islet-like), rather than uniform. In this case, the layer (islet) will be thicker. Taking into account the diameter of the urease molecule (about 5 nm) [12] we can assume that a greater fraction of the enzyme is accessible for the substrate in a thin polysiloxane layer. With increasing layer thickness, the probability of urease encapsulation grows, which decreases its activity to values typical of xerogels (Table 4).

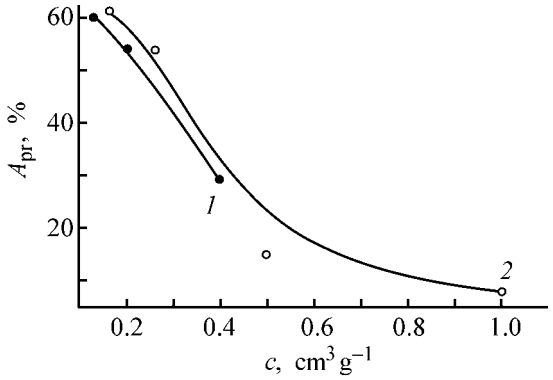

Fig. 2. Preserved activity A_{pr} of immobilized urease for (*1*) TEOS : MTES and (*2*) TEOS : MTES : DMDES systems vs. the content c of alkoxysilanes used for preparing PL on the silica gel surface; samples stored for 20 days at 4°C.

In conclusion, we can compare the activity of urease immobilized in the polysiloxane layer on the silica gel surface with the activity of urease incorporated into the polysiloxane xerogel in the course of its preparation by the sol–gel method [7] (Table 4). As can be seen from Table 4, the activity of immobilized

* Urease was immobilized in the course of xerogel preparation by the sol–gel method.

urease strongly decreases on passing from film-forming samples to samples of polysiloxane xerogels with immobilized urease. The decrease in the urease activity on passing form film-forming samples to xerogels with incorporated enzyme can be accounted for by the fact that the enzyme is almost completely incorporated in the matrix in the latter case; as a result, the enzyme not only loses its activity but becomes inaccessible to the substrate [7]. At double immobilization, significantly smaller amounts of alkoxysilanes are used for the enzyme binding, and it occurs in the fine polysiloxane layers and, in most cases, is accessible to the substrate. Moreover, introduction of hydrophobic groups into these layers decreases the number of hydrogen bonds between the enzyme molecule and matrix surface. As a result, the effect of the rigid polysiloxane matrix on the enzyme being immobilized decreases, which should improve the preservation of the urease activity. The decrease in the activity of urease immobilized in xerogels, compared to the samples of urease immobilized in a thin polysiloxane layer, was predictable, whereas the relatively low activity of urease adsorbed on silica gel (Table 1) was unexpected. In sorption of urease on the silica gel surface, the interaction of the enzyme with the surface silanol groups is probably of the type many-point [13, 14], which causes its rigid linking and hence deactivation. As a result, only an insignificant fraction of the adsorbed urease retains its activity in enzymatic reactions. A similar pattern has been observed for similarly immobilized alcohol dehydrogenases and glucose oxidases [9].

CONCLUSION

An efficient sol–gel method was developed for immobilization of urease in polysiloxane layer on the silica gel surface. The activity of urease immobilized by this procedure is determined by the composition and thickness of the film; it increases upon addition of the hydrophobic (methyl) groups and polyvinyl alcohol and with decreasing thickness of the polysiloxane layer.

BRIEF COMMUNICATIONS

Specific Feature of Synthesis and Technological Scheme for Manufacture of Nonstoichiometric Hydroxo Chromium(III) Formates

G. V. Kiseleva, S. V. Smirnov, and B. P. Sereda

Ural State Forestry University, Yekaterinburg, Russia

Received March 1, 2006; in final form, July 2006

Abstract—Specific features of the hydrothermal interaction between chromium(VI) oxide and formic acid to give water-soluble nonstoichiometric hydroxo chromium(III) formates with compositions from the range $Cr(OH)_{0.66}(HCOO)_{2.34}$–$Cr(OH)_{1.55}(HCOO)_{1.45}$ were studied. These compounds can be used in formulations for chromium-plating electrolytes and tanning agents.

DOI: 10.1134/S1070427207020322

Chromium(III) sulfate is the most accessible and least expensive among water-soluble chromium(III) compounds applied in chemical technology. Use of chromium(III) sulfate leads to a substantial contamination of wastewater, because methods for removal and utilization of chromium(III) are mostly based on its binding into poorly soluble compounds, with further separation from the aqueous phase, whereas sulfate ions remain in solutions and are accumulated to concentrations exceeding those established by regulations. It has been shown previously that reduction of chromium(VI) compounds in formic acid can give hydroxo chromium(III) formates having rather high solubility and exhibiting properties that enable their effective use, instead of chromium(III) sulfate, in formulations for chromium-plating electrolytes and tanning agents. [1, 2]. Chromium can be rather simply bound into poorly soluble compounds in wastewater purification by pyrolysis, because formate ions decompose at high temperatures to give carbon(IV) oxide and water [3].

This study is concerned with specific features of synthesis of nonstoichiometric hydroxo chromium(III) formates from chromium(VI) oxide and formic acid. The compounds were synthesized by the known procedure [4]. The course of the reactions was monitored, which the initial concentrations, reactant ratios, temperature, and mixing rate of substances varied. The results of the laboratory studies were used to develop a technological scheme tested under real industrial conditions.

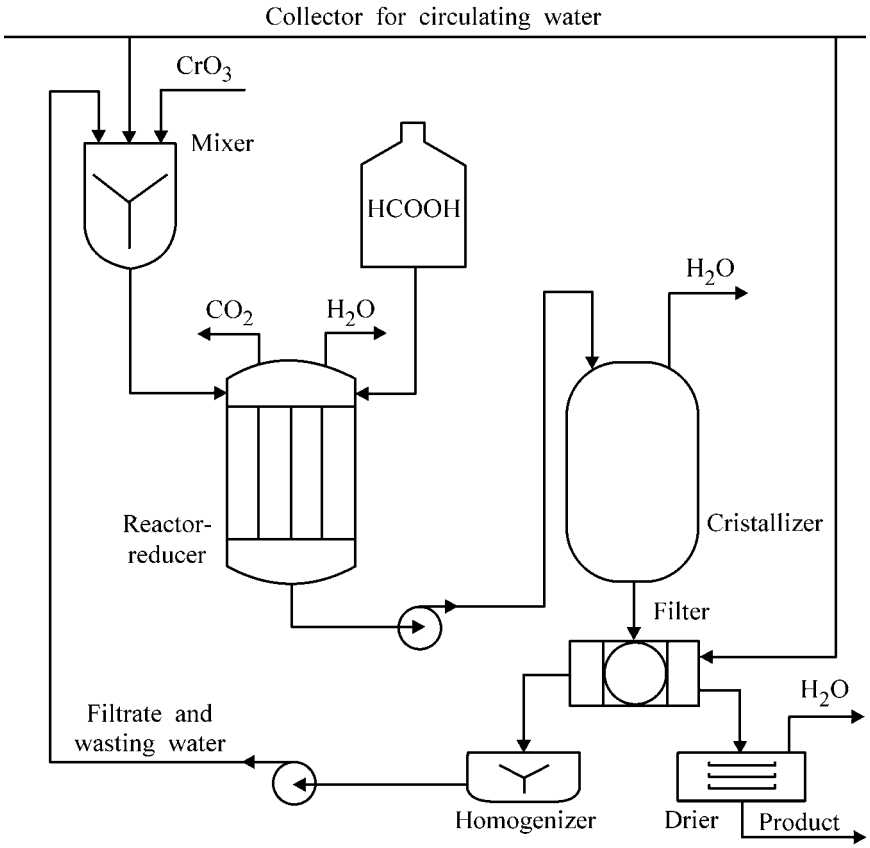
EXPERIMENTAL

The choice of chromium(III) oxide as a raw material is due to the fact that this compound is the main product formed in processing of natural chromium compounds [5]. Formic acid simultaneously acts as an agent that reduces chromium(VI) and an anion in the formation of basic formate salts. Hydroxo chromium(III) formate is formed by the reaction

$$2CrO_3 + 7HCOOH = 2CrOH(HCOO)_2 + 3CO_2\uparrow + 4H_2O. \quad (1)$$

The reaction was performed in an aqueous solution at temperatures of 313–368 K, initial chromium(VI) oxide concentrations of 0.85 to 1.65 mol dm^{-3}, and CrO_3/HCOOH ratios of 0.16–0.34. The mixing rates of the reactants and the duration of separate studies of synthesis were chosen empirically by visual inspection and on the basis of data furnished by chemical analysis of intermediate phases and synthesis products. The cationic complexes of chromium(III), formed in reduction, undergo hydrolysis dependent on the concentration, pH value, and temperature of the solution. As result, the forming hydroxo chromium(III) formates contain different amounts of hydroxo groups per mole of chromium(III). With account of the acid-neutralizing capacity h, Eq. (1) can be transformed to

$$CrO_3 + (4.5 - 3h)HCOOH = Cr(OH)_{3h}(HCOO)_{3-3h} + 1.5CO_2 + (3 - 3h)H_2O, \quad (2)$$



Technological scheme of synthesis of hydroxo chromium(III) formates.

where h can theoretically take values ranging from zero for the neutral salt to unity for chromium(III) hydroxide.

It was found that water-soluble hydroxo chromium(III) formates, which can be used in technologies involving preparation of aqueous solutions, formed at h in the range 0.22–0.50 and correspond to the end compositions $Cr(OH)_{0.66}(HCOO)_{2.34}$ and $Cr(OH)_{1.55}(HCOO)_{1.45}$. A statistical processing of the experimental data produced regression equations relating the product yield η and the acid-neutralizing capacity h to the initial mass concentration c_1 of chromium(VI) oxide (g dm^{-3}) and the mass fraction c_2 of the initial HCOOH [percent relative to stoichiometry (1)]:

$$\eta = 0.60c_1 + 0.64c_2 - 0.004_4c_1c_2, \quad (3)$$

$$h = 0.45c_1 + 0.31c_2 - 0.004c_1c_2. \quad (4)$$

An optimization of Eqs. (3) and (4) with respect to the yield of the product and its solubility in water demonstrated that the best initial parameters are the concentration of 120–160 g dm^{-3} CrO_3 and the amount of HCOOH equal to 150% relative to the stoichiometry.

It was found in calorimetric studies that reaction (1) is exothermic and 155.6 kJ of heat per 1 dm^3 of a solution is released in interaction of 1 mol of CrO_3 with the stoichiometric amount of HCOOH [1]. To preclude boiling-up and spraying of the reaction mass, a limiting mixing rate of reactants was set and the temperature of the reaction mass was lowered by heat removal from the reactor walls. Lowering the temperature to below 350 K at sufficiently high mixing rates of the reactants results in thickening of the reaction mixture and hinders its agitation.

Synthesis of the target process by reaction (2) with a prescribed acid-neutralizing capacity comprises two processes: reduction of chromium(VI) oxide by formic acid upon mixing of the reactants and formation of formate salts of hydroxo chromium(III) in hydrothermal treatment of the reaction mass. At 363–370 K, the duration of the reduction stage is 180–210 min. At synthesis temperatures below 340 K, reaction fails to provide complete reduction of chromium(VI) in 8 h, which results in an increase, in particular, in the duration of sample fil-

tration. A rather complex, extremal dependence of the acidity index of the samples on the temperature of the stage of thermal treatment. At 300–315 K, compounds with average h fluctuating within the range from 0.4 to 0.5. Below 300 K, the acidity index decreases because of the weakening of hydrolysis and enhancement of the competing effect of formate ions, and above 315 K, because of the decreasing stability of hydroxo complexes. At 313 and 370 K, the average values of h are 0.25–0.27. Thus, hydroxo chromium(III) formates with a prescribed acidity factor can be obtained by varying the solution treatment temperature. The duration of the complex formation stage depends on temperature and is 30–420 min.

The final stage of synthesis of the target product involves crystallization of the samples by cooling the reaction mass formed upon the thermal treatment and by keeping it under constant agitation at temperatures of 293–303 K for 360–7200 min. Hydroxo chromium(III) formates are produced in the form of a polydisperse precipitate with irregular elongated crystals. The average transverse size and length of the most representative fraction are 45 and 700 μm, respectively.

The conditions of synthesis of hydroxo chromium(III) formates, found in this study, were tested at a chromium industry plant. The synthesis of the target product (see scheme) included the following main stages.

(1) Dissolution of chromium(VI) oxide in water mixed with the filtrate produced at a subsequent stage and washing water formed at the stage of recovery of formate compounds of hydroxo chromium(III) from a suspension.

(2) Reduction of chromium(VI) with formic acid at 363–370 K and controlled rate of reactant mixing.

(3) Treatment of the reaction mass at a prescribed temperature of 300 to 370 K in order to form formate salts of hydroxo chromium(III).

(4) Crystallization of the target product by cooling the reaction mixture and keeping the suspension formed at 293–303 K.

(5) Separation of the suspension into the liquid and crystalline phases, with the washing water and the filtrate delivered to the initial stage, at which an aqueous solution of chromium(VI) oxide is prepared.

(6) Drying and packaging of the product.

A reactor-reducer with enameled walls of the reaction zone served as the technological apparatus under plant conditions. The reactor was equipped with electric heater, stirrer, Nutsch filter, and shelf drier.

Results of industrial tests of the procedure for synthesis of hydroxo chromium(III) formates

Starting reagents		Composition of hydroxo chromium(III) formates		η, %
CrO_3 c_1, g dm^{-3}	HCOOH c_2, mass fraction, %	h	$HCOO^-$ index $(1 - h)$	
100	150	0.18	0.51	62.0
120	150	0.22	0.55	88.7
120	200	0.20	0.56	87.3
140	150	0.20	0.55	67.9
160	150	0.18	0.55	95.8

The results obtained in a set of experiments performed under industrial conditions are listed in the table. The plant tests confirmed the results of the laboratory experiments. Minor changes in the composition of the products have virtually no effect on their service characteristics, which is confirmed by tests of the samples synthesized in formulations for chromium-plating electrolytes.

CONCLUSIONS

(1) The optimal conditions of chromium(VI) oxide reduction by formic acid and synthesis of water-soluble hydroxo chromium(III) formates with prescribed acidity index were determined. The composition of formate salts of hydroxo chromium(III) is determined by the temperature of hydrothermal treatment of the reaction mass and corresponds to $Cr(OH)_{0.66}(HCOO)_{2.34}$–$Cr(OH)_{1.55}(HCOO)_{1.45}$.

(2) It was found that crystallization of samples near room temperature gives a polydisperse precipitate with elongated crystals, whose transverse size and length are 45 and 700 μm, respectively.

(3) A procedure for synthesis of hydroxo chromium(III) formates under industrial conditions was suggested.

Synthesis of High-Purity Trialkylgermanethiols

M. G. Voronkov, R. G. Mirskov, and S. N. Adamovich

Favorksii Irkutsk Institute of Chemistry, Siberian Division, Russian Academy of Sciences, Irkutsk, Russia

Received December 26, 2006

Abstract—A procedure was developed for preparing high-purity trialkylgermanethiols by the reaction of hexaalkyldigermoxanes with hydrogen sulfide.

DOI: 10.1134/S1070427207020334

Trialkylgermanethiols R_3GeSH (**I**) (R = Alk) are promising chemicals for fine organometallic synthesis and precursors for plasmochemical deposition of thin dielectric layers containing germanium and sulfur atoms.

Henry and Davidson [1] prepared triarylgermanethiols by reacting triarylhalogermanes with hydrogen sulfide in the presence of pyridine. However, this procedure appeared to be unsuitable for preparing the related alkyl compounds **I**.

Vyazankin et al. [2] prepared previously unknown trialkylgermanethiols **I** in 49.5% yield by heating trialkylgermanes with sulfur at 140°C for 4 h in an inert atmosphere. The drawbacks of their procedure are the relatively low yield of **I**, difficult synthesis of the starting trialkylgermanes, and use of high temperatures and inert gases.

For applications in microelectronics, compounds **I** of ultrahigh purity should be prepared. To this end, we developed a procedure for preparing high-purity trialkylgermanethiols in high yield by the reactions of hexaalkyldigermoxanes (which are readily prepared by hydrolysis of trialkylhalogermanes) with hydrogen sulfide at room temperature:

$$R_3GeOGeR_3 + 2H_2S \rightarrow 2R_3GeSH + H_2O,$$

where R = C_2H_5 or C_4H_9.

Triethylgermanethiol. Hydrogen sulfide was bubbled for 2 h at 20°C through a flask containing 16.8 g (0.05 mol) of hexaethyldigermoxane, until the mixture became turbid. After a 1-h pause, hydrogen sulfide was bubbled for an additional 0.5 h. In the process, the mixture spontaneously warmed up to 50°C and then cooled to room temperature. By vacuum distillation we isolated 15.4 g (80%) of triethylgermanethiol, bp 47–48°C (6 mm Hg), d_{20}^4 = 1.1249, n_D^{20} = 1.4900. Published data [2]: bp 86°C (35 mm Hg), d_{20}^4 = 1.1270, n_D^{20} = 1.4852.

Found, %: C 37.44, H 8.45, Ge 37.57, S 16.52.
$C_6H_{16}GeS$.
Calculated, %: C 37.40, H 8.40, Ge 37.60, S 16.60.

^{1}H NMR ($CDCl_3$, HMDS), δ, ppm: 1.81 (CH_3), 2.02 (CH_2), 3.6 (SH); IR, ν, cm^{-1}: 2555 (ν_{S-H}), 408 (ν_{Ge-S}).

Tributylgermanethiol was prepared similarly from 10 g (0.02 mol) of hexabutyldigermoxane; yield 7.2 g (65%), bp 104–106°C (3 mm Hg), d_{20}^4 = 1.0219, n_D^{20} = 1.4810.

Found, %: S 11.37.
$C_{12}H_{28}GeS$.
Calculated, %: S 11.57.

According to GLC analysis, the products purified by vacuum distillation on a quartz column contained no traces of organic impurities. The content of metals (Na, K, Ca, Fe, Ni, Co, etc.), according to atomic absorption analysis, did not exceed 10^{-5}–10^{-6} wt % for each metal.

CONCLUSION

A procedure was developed for preparing high-purity trialkylgermanethiols for micro- and optoelectronics technology in 65–80% yields by reactions of accessible hexaalkylgermoxanes with hydrogen sulfide for 3 h at room temperature, followed by isolation of the products by fractional distillation in a vacuum.

Abstract—Synthesis of electrolytic manganese dioxide on a heated anode was studied. The specific energy of chemical power cells fabricated using this dioxide in the Zn–Mn system is as high as 100 W h kg^{-1}.

DOI: 10.1134/S1070427207020346

The research aimed to improve the galvanic cell with a cathode paste composed of manganese dioxide (MD) is concentrated on making higher the operation speed and energy density of the cells [1]. As regards mass production, raising the specific energy of chemical power cells (CPC) is, naturally, of primary importance.

This communication describes a method for synthesis of electrolytic MD of improved quality and presents the results of tests of CPC fabricated from the electrolytic manganese dioxide (EMD) synthesized by anodic oxidation of manganese(II) ions from an electrolyte heated to 90–95°C. A significant disadvantage of this technique is that the resulting EMD contains, in addition to the γ-modification of MnO_2, its other modifications, which are inactive in the Zn–Mn system of CPC [2].

The novelty of the previously developed technique [3] consists in that EMD is synthesized at a heated anode. This makes it possible to heat to a higher temperature the electrosynthesis zone, in which an anodic deposit of MnO_2 of mostly γ-modification crystallizes. The higher temperature of EMD synthesis favorably affects the quantitative yield of the necessary γ-modification of manganese dioxide at the expense of other modifications (β-, α-, ...).

EXPERIMENTAL

The electrolytic synthesis of MD was carried out on an anode made of platinum-plated VT1-0 titanium. The anode comprising 10 titanium plates (25 mm wide and 300 mm long) welded in series to form a labyrinth was heated with 80–200-A ac current. The heating was controlled by varying the applied voltage, commonly 3–5 V at currents of up to 100 A. The anode temperature was measured with a thermometer introduced into a tube welded in the anode. VT1-0 titanium plates served as cathodes.

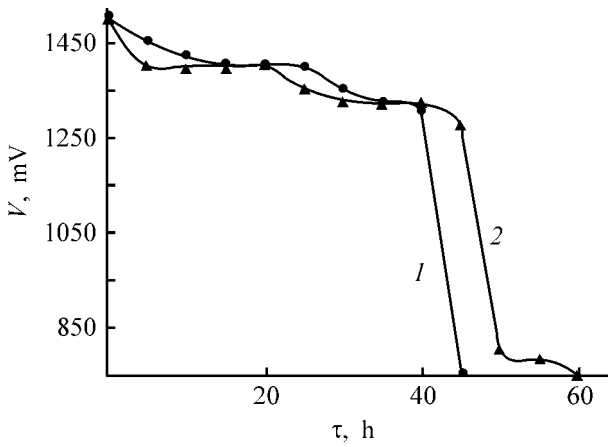
The electrolyte was of the commonly used composition (100–200 g l^{-1} of manganese sulfate) [4]. It was not specially heated; its temperature varied, depending on the circulation rate ?between leaching and electrolysis procedures, from 30 to 95°C.

When determining the specific energy of CPC, discharge curves were recorded with a self-recorder connected to an unconventional electrolytic cell with a zinc anode 25 mm in diameter and 2.5 g of EMD with addition of 20% carbon black. A solution of $ZnCl_2$ and NH_4Cl served as electrolyte. The cell load was 10 or 56 Ω. The CPC discharge was continued until the cell voltage decreased to 700–750 mV.

The chemical power cell fabricated from this kind of EMD has a specific energy (in the Zn–Mn system) of 100 W h kg^{-1}, which markedly exceeds that of commercial CPC of the same type (see table).

Phase composition of electrolytic manganese dioxide and specific energy of CPC based on this manganese dioxide in the Zn–Mn system

EMD	Anode temperature in synthesis, °C	Phase composition of EMD	Specific energy in the Zn–Mn system, W h kg^{-1}
Comparison sample	80–90	γ-,α-,β-	45–60 [5]
	No data	No data	80 [6]
Trial sample:			
1	90	γ-,α-,β-	60
2	105	γ-,α-,β-	70
3	110	γ-	100



Discharge curves of CPC. (V) Voltage and (τ) time. (*1*) Standard Varta R6P AA · UM.3 · 1.5 V and (*2*) trial sample Uran-1 R6 (316) 1.5 V.

A trial batch of EMD was produced on a pilot installation with an electrolysis bath holding about 40 l of electrolyte and platelike platinum-plated titanium anodes of the labyrinth type (10 series-connected 300-mm-long and 25-mm-wide plates) at a current density of 100–300 A m^{-2}. Titanium plates served as cathodes. The electrolyte (100–200 g l^{-1} $MnSO_4$, 10 g l^{-1} H_2SO_4) was purified to remove admixtures of nonferrous metals and iron by successive hydrolytic precipitation of iron and ion-exchange precipitation of nonferrous metal ions on an An-35 chelate ion-exchange resin at pH 3–4 to a level of 1–2 mg l^{-1}. The platelike labyrinth anode was heated with an ac current of mains frequency, with a voltage not exceeding 10 V. The heating level was controlled by varying the current in the range from 80 to 200 A. About 900 g of manganese dioxide was obtained in three batches differing in the extent of anode heating. It was found that the maximum heating (with a current of about 200 A) leads to partial conversion of the dioxide into Mn_2O_3, which is undesirable. The best results were obtained in the case of heating with a current of 80–100 A. The quality of the resulting manganese dioxide was judged from its phase composition and capacity of CPC in discharge to 750 mV. The previously obtained EMD samples [3] are virtually totally composed of the γ-modification of manganese dioxide and have capacities in the range from 90 to 116 A h kg^{-1} (cf 65 A h kg^{-1} for a cell with Japanese EMD) at a discharge current density of 20 A m^{-2}.

The EMD obtained was used to fabricate a trial batch of chemical power cells at Svirskie promyshlennye seti (Svirsk Industrial Power Supply) plant.[1] The discharge characteristics of these CPC [Uran-1 R6 (316) 1.5 V trial sample] (see figure) show that the electric energy produced on a load of 56 Ω is 1.1 A h per cell, which corresponds to the output capacity of commercial CPC of the same design (Standard Varta R6P AA · UM.3 · 1.5 V) under comparable conditions.

CONCLUSIONS

It was demonstrated that raising the anode temperature in synthesis results in that mostly the γ-modification of electrolytic manganese dioxide is formed. As a result, the specific energy of a chemical power cell increases.

Abstract—The reaction of dextran polyaldehyde with iron(III) chloride was studied. The dependences of the Fe^{3+} content in the resulting complex on the number of aldehyde groups in polysaccharide and pH of the solution were found.

DOI: 10.1134/S1070427207020356

Metal complexes with polysaccharides and their derivatives are of growing importance in medicine and pharmacy. For instance, polypher is well known as a blood substitute [1]. New blood substitutes with hemostimulating and antianemic function, Rondferrin, Spaceferron, Neorondex, and Microdez, which are complexes of dextran with Fe^{2+}, Fe^{3+}, Co^{2+}, and Cu^{2+}, respectively [2, 3], differ from the existing analogues in good bio- and hemocompatibility and more pronounced and prolonged action. Magnetic complexes based on polysaccharide derivatives with Fe, Ca, Zn, Co, Ni, and Cu oxides are used in roentgenologic studies [4]. These complexes are very stable during prolonged storage and are not toxic, when introduced in blood as X-ray contrast substances. In this context, we studied reactions of dextran polyaldehyde (DPA) with iron(III).

Dextran polyaldehyde was prepared by oxidation of dextran with sodium meta-periodate, separated, and analyzed as in [5]. Samples containing 0.55–0.84 mol of aldehyde groups per mole of the monomeric fragment (C_{sa}) were used.

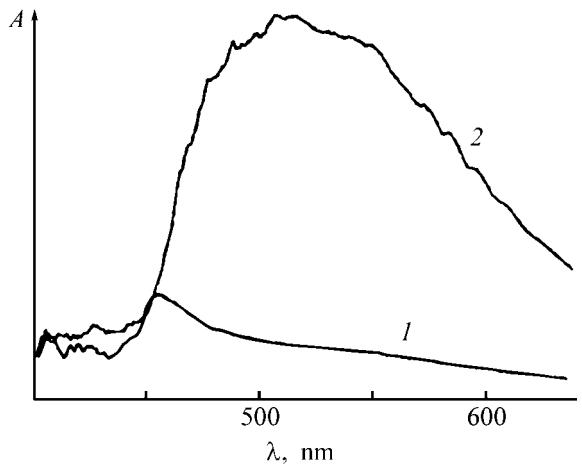
The reaction of DPA with iron(III) chloride was performed in water at 18–23°C; 1.2–3.6 mol of salt was taken per mole of aldehyde groups: 0.2 g DPA was dissolved in 3 ml of 0.04 – 0.48 M NaOH within 30 min, and then 2 ml of a 5–15 wt % $FeCl_3$ solution in 0.1 M HCl was added. On doing so, the reaction mixture immediately became reddish-brown. The reaction product was precipitated with acetone, filtered, washed with acetone (to remove iron chloride) and ethyl ether, and dried in a vacuum at a residual pressure of 20–25 mm Hg at 61°C.

The compound synthesized is beige amorphous powder soluble in water and insoluble in ethanol, acetone, and ethyl ether. The complex is fairly stable; it does not decompose during reprecipitation from aqueous solution or dialysis for 24 h at pH < 7.

The IR spectra of DPA and of iron(III) complex with DPA strongly differ in the intensity of absorption bands. In the spectrum of the complex, bands at 1370–1420 and 1620 cm^{-1} are substantially stronger than those in the DPA spectrum, suggesting a considerably larger amount of the aldoenol form in the first case. In addition, there is no band at 1270 cm^{-1} belonging to hydrated aldehyde group in the spectrum of the complex.

A peak at 321 nm is observed in the UV spectrum of the complex in 0.1 M HCl, in contrast to the initial substances which do not absorb light in this spectral range. Similar absorption at 310 nm in the spectra of DPA alkaline solutions is attributed to aldoenol fragments.

The spectrum of the DPA complex with iron(III) compared to that of the Fe(III) salt solution of the same concentration, exhibits a new peak at 510–520 nm. In the spectrum of the initial DPA, this peak is absent. The reaction product was characterized by the degree of substitution, C_{sFe} (number of iron ions per monosaccharide unit), which was calculated from the results of determination of the iron content by potentiometric titration with ascorbic acid [6] and spectrophotometrically with sulfosalicylic acid in ammonia solution [7]. The values of C_{sFe} obtained by these two methods differ by no more than 2%. The degree of substitution varied from 0.11 to 0.32.



Electronic spectra of the reaction mixture after addition of $FeCl_3$ solution to a DPA solution (*1*) with preliminary neutralization of DPA alkaline solution and (*2*) without neutralization. (*A*) Absorption and (λ) wavelength.

We also found that $C_{s\,Fe}$ strongly depends on the pH of the initial DPA solution. Complexes characterized by the 510–520 nm band are formed only when iron(III) chloride is mixed with DPA in alkaline solutions. At pH < 7, only substances with a weak band at 455 nm (but not at 510–520 nm) are formed. The same substances are also formed when an alkaline solution of DPA is neutralized before addition of the Fe(III) salt solution (see figure).

Table 1. Influence of the alkali concentration c_{NaOH} on the number of enol groups per monosaccharide unit of dextran polyaldehyde (C_{sa} = 0.55)

c_{NaOH}, M	Number of enol groups per monosaccharide unit	Number of aldehyde groups converted into enols, %
0.0034	0.029	4.60
0.0051	0.040	6.79
0.0068	0.070	11.43
0.0092	0.085	13.41
0.0136	0.100	16.15

Table 2. Influence of the alkali concentration c_{NaOH} in the initial DPA solution on the content of iron reacted

c_{NaOH}, M	C_{sa}, mol mol^{-1}	Number of aldehyde groups reacted, %
0.040	0.11	17.3
0.079	0.13	20.6
0.119	0.14	22.2
0.159	0.17	27.0
0.318	0.21	33.2
0.477	0.27	42.9

It is known that DPA aldehyde groups can exist in different forms in aqueous solutions; at pH < 4, DPA has the aldehyde structure, whereas at pH > 5.2 the aldoenol structure appears. At pH 4.0–5.2, hydrated or hemiacetal structures are probably stable [8–10].

Neishlos et al. [11] showed that individual (dry) DPA also contains an aldoenol form, whose content increases with the pH of the solution in which dextran is oxidized with periodate.

Taking this fact into account, we suggested, similarly to [9], that just the aldoenol forms of DPA, which appear in the course of polyaldehyde dissolution in aqueous alkali, form coordination bonds with the metal ion.

To determine the conditions of iron(III) introduction into the polymer, we studied the effect of alkali concentration in the solution on the content of enol groups in DPA. A solution containing 0.2 g of DPA and $(2.38–9.52) \times 10^{-4}$ M NaOH was conductometrically titrated with 0.1 M HCl. The titration curve has two inflections corresponding to equivalence points. The calculated number of the equilibrium enol groups per each monomeric unit and the percentage of aldehyde groups converted into enols are listed in Table 1.

As expected, the degree of conversion of aldehyde groups into enol groups increases with the alkali concentration (Table 1), which makes higher the ligand reactivity. Indeed, the more concentrated alkaline solution is used, the larger amount of iron(III) reacts with DPA (Table 2), which confirms the reaction of iron(III) ions with the DPA aldoenol form. The dependence of the number of iron moles per mole of the DPA monomeric fragment on the alkali concentration is linear: $y = 0.354x + 0.1$ ($R^2 = 0.988$, $n = 6$).

However, other types of iron bonding with the polysacchride are possible in the substances obtained. For instance, products of Fe(III) reaction with DPA aqueous solutions (pH ≤ 7) are characterized by a peak at 455 nm and contain up to 0.05 mol of iron per monosaccharide fragment.

To determine the influence of DPA and excess complexing agent on the yield of the target product, we studied the dependence of the iron(III) content in the complex on the number of aldehyde groups in

Table 3. Influence of the number of aldehyde groups in the polysaccharide on the iron(III) content in the reaction product (0.2 g of DPA in 2 ml of 0.48 M NaOH and 2 ml of 10% $FeCl_3$ solution in 0.1 M HCl)

Number of aldehyde groups per monomeric unit of DPA	Fe^{3+} content (mol) per monomeric unit of reaction product
0.52	0.23
0.63	0.26
0.75	0.28
0.84	0.32

Table 4. Influence of the $FeCl_3$ excess on the iron(III) content in the reaction product (0.2 g of DPA in 2 ml of 0.48 M NaOH, C_{sa} = 0.55)

c_{FeCl_3}, %	$FeCl_3$ excess, mol per mol of aldehyde groups	Fe^{3+} content per monomeric unit of reaction product
5	1.2	0.25
7.5	1.8	0.27
10	2.4	0.27
15	3.6	0.26

the polysaccharide and on the concentration of iron(III) chloride (Tables 3, 4).

As expected, the iron content of the reaction product linearly increases with the number of aldehyde groups in the polymer ($y = 0.27x + 0.09$, $n = 4$, $R^2 = 0.97$), being independent of the concentration of the complexing agent.

CONCLUSIONS

(1) Dextran polyaldehyde reacts with iron(III) in aqueous alkaline solutions to form stable complexes.

(2) The content of iron(III) in the complex linearly depends on the alkali concentration and on the number of aldehyde groups in the polysaccharide.

Received July 18, 2006

Abstract—The possibility of preparing monoesters derived from sucrose and tall oil fatty acids was examined.

DOI: 10.1134/S107042720702036X

Esters derived from carbohydrates and higher fatty acids (so-called fat–sugars) are promising nonionic surfactants used in various branches of industry and in medicine [1–3]. A wide variety of different procedures for their preparation have been reported. Some procedures involve esterification of carbohydrates (in particular, sucrose) with acid chlorides and anhydrides [1], which are difficultly available. More promising are chemical and biochemical methods based on ester interchange of methyl or ethyl esters of higher fatty acids with carbohydrates or their acetates [1, 4–6]. The search for the best conditions for performing this reaction is still continued [2, 3].

As ester interchange catalysts are used alkali metals or their alloys, hydroxides, carbonates, and alkoxides [1, 2]. The most frequently used solvents are dimethylformamide, dimethyl sulfoxide, dimethylacetamide, *o*-xylene, etc. [1, 2]. The reaction is performed at temperatures ranging from 60 to 190°C at atmospheric or reduced pressure, or in an inert gas atmosphere. The isolation and purification methods depend on the structure and degree of substitution of the resulting esters [1].

Methyl and ethyl esters of higher fatty acids can be prepared by esterification of fats and oils with the corresponding alcohol. A promising source of fatty acids is tall oil, a by-product of kraft pulp production. The main components of tall oil fatty acids (TOFAs) are unsaturated acids: oleic, linoleic, and linolenic [7].

The goal of this study is preparation of fat–sugars by ester interchange of TOFA methyl esters with sucrose, catalyzed by a suspension of potassium carbonate in methanol.

It is known that the most reactive in acylation of carbohydrates are primary OH groups, and in the case of sucrose, mainly those in the 6-position of the glucoside moiety [4]. An effective base catalyst of ester interchange is potassium methoxide generated in the system K_2CO_3–CH_3OH [8].

The choice of solvents and of the sequence of their use for synthesis and purification depends on the structure of a desired ester. As it is difficult to find a specific solvent for the esters to be obtained, it was suggested to successively remove the impurities and starting compounds by different solvents. The procedure suggested allowed isolation of only monoesters of sucrose and TOFAs. The product is a noncrystallizing light yellow greasy substance.

EXPERIMENTAL

The ^1H NMR spectrum of the sucrose monoester obtained was recorded on a Bruker AC-200 spectrometer (200 MHz) from a 5% solution in $CDCl_3$; the chemical shifts were determined relative to internal TMS.

To monitor the reaction progress and assess the purity of the products, we used TLC on Silufol UV 254 plates {eluent 1: *n*-butanol–acetic acid–diethyl ether–water, 9 : 6 : 3 : 1 [9]; eluent 2: petroleum ether (40–70°C)–diethyl ether–acetic acid, 75 : 25 : 1 [5]}.

TOFAs (from Segezha Pulp and Paper Combine) were additionally purified by vacuum distillation; the fraction boiling in the range 170–205°C (1 mm Hg) was collected. Methyl esters of TOFAs were prepared by refluxing the acids with a threefold excess of methanol in the presence of *p*-toluenesulfonic acid [10]. The suspension of K_2CO_3 in CH_3OH was prepared according to [8].

Monoesters of sucrose and TOFAs. To a solution of 0.15 mol of sucrose in 250 ml of DMF, we added

0.05 mol of TOFA methyl esters and a suspension of 1.0 g of K_2CO_3 in 20 ml of CH_3OH. The mixture was stirred for 20 h at 95°C under a pressure of 160 mm Hg, after which it was cooled to room temperature. Analysis of the reaction mixture revealed the presence of the major component, monoester, and a small impurity of esters with a higher degree of substitution, and also of the unchanged TOFA methyl esters. The mixture was washed with three portions of petroleum ether to remove the unchanged TOFA methyl esters, and the solvents were distilled off in a vacuum. The residue was dissolved in a two-phase mixture of 220 ml of chloroform and 50 ml of water; the aqueous phase was separated and extracted with two portions of chloroform. All the chloroform extracts were combined and dried over $MgSO_4$; the solvent was distilled off on a rotary evaporator. The residue was extracted with methanol (3×150 ml); in so doing, only the monoesters of sucrose and fatty acids dissolved. The solvent was distilled off, and the product was dried in a vacuum; yield of esters 72%. The TLC analysis showed the absence of impurities of the starting TOFA esters and of esters with a higher degree of substitution. ^{1}H NMR spectrum, δ, ppm: 0.89 t (3H, CH_3), 1.20–2.75 m (2H, CH_2), 5.34 m (CH=CH), 3.60 m (1H, O–CH–C/O–CH_2–O), 5.30 m (1H, O–CH–O), 4.50 s (4H, OH), 4.05 d (2H, C–CH_2–O–CO).

CONCLUSION

A procedure was developed for preparing monoesters of sucrose and TOFAs in 72% yield, using the K_2CO_3–CH_3OH catalytic system.

Polyfunctional Additives to Oils, Based on Sulfonated Oligomers

A. I. Akhmedov and D. Sh. Gamidova

Kuliev Institute of Chemistry of Additives, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received October 16, 2006

Abstract—Studies in the field of development of polymeric oligoalkenesulfonate additives derived from sulfonated oligomers and exhibiting multifunctional effect when added to petroleum oils are summarized.

DOI: 10.1134/S1070427207020371

Among the first additives used in motor oils are various sulfonates prepared by sulfonation of petroleum oils, followed by reactions of the resulting sulfo acids with various oxides or hydroxides of Group II metals [1]. These sulfonates are used as detergent and dispersing additives to motor oils.

The functional properties of sulfonate additives depend on the chemical nature of a petroleum oil being sulfonated, i.e., on the content of aromatic hydrocarbons; such additives do not improve other performance characteristics of petroleum oils. Therefore, it would be appropriate to replace petroleum oils as sulfonation substrates with oligomers or cooligomers of various vinyl monomers. These oligomers, owing to the nonvolatility, chemical affinity for petroleum products, and mutual miscibility with them, and also to the possibility of widely varying their chemical nature, allow purposeful synthesis of polymeric additives with prescribed performance characteristics and are indispensable in functionalization reactions.

The polymeric additives prepared by such procedure not only preserve the main functional characteristics of sulfonates but also improve the viscosity–temperature properties of petroleum oils, making larger their viscosity index. This is a pressing problem for Baku oils whose viscosity index is low.

This paper summarizes the results of studies performed at the Institute of Chemistry of Additives, National Academy of Sciences of Azerbaijan, in the field of development of polymeric additives based on sulfonated oligomers. The sulfonation was performed both with oleum and with chlorosulfonic acid. The products were neutralized with various amines, and also with magnesium or calcium oxide or hydroxide [2, 3].

As starting compounds were used cooligomers of α-olefins (isobutylene, 1-hexene, 4-methyl-1-pentene) with styrene, α-methylstyrene, dicyclopentadiene, or indene, and also cooligomers of vinyl butyl ether with styrene. Introduction of cyclic fragments into cooligomers creates an additional reaction center for the sulfonation and makes the products resistant to oxidation.

Copolymerization of α-olefins and vinyl *n*-butyl ether with styrene and of α-olefins with the other comonomers was performed in the presence of $AlCl_3$ at 5–20°C; the content of the comonomer units was 10–20 wt %; the molecular weight of the binary cooligomers obtained was 1000–2000.

The sulfonation of the cooligomers was performed by the standard procedure. Depending on particular requirements, the sulfonation products were neutralized so as to obtain ash-free and ash additives.

The compositions and structures of the compounds obtained were studied by IR and ^{1}H NMR spectroscopy and by elemental analysis. The presence of aromatic fragments was confirmed by the IR absorption band at 1610 cm^{-1}. The content of aromatic units in the cooligomers was determined by ^{1}H NMR spectroscopy from the integral intensity of signals of the aromatic ring protons (δ 6.6 ppm).

As the studies showed, a decrease in the molecular weight impairs viscosity–temperature properties of petroleum oils and leads to an increased consumption of the cooligomer for thickening, which is not economically profitable. At the same time, additives with molecular weight exceeding 2000 are less stable thermally.

When present in an amount less than 10%, the comonomer units in the cooligomer affect the performance characteristics of the additives insignificantly. At the same time, at the content of comonomer units

exceeding 30%, the solubility of the additives in petroleum oils decreases.

We found that the main function of the cooligomers is to act as ligands, which makes it possible to impart to them solubility in petroleum oils. Therefore, the specific chemical nature of the cooligomers is not essential in the synthesis of sulfonates and sulfonamides. The choice of particular oligomer is governed by the availability of the raw materials for its synthesis and by the amount of its production in Azerbaijan. Preference is given to cooligomers of C_6 α-olefins with styrene as low-cost and readily available compound; introduction of such additives into oils increases their viscosity index to an extent exceeding by 5–7 points that attained with the other additives. In the preparation of sulfonates, $Ca(OH)_2$ is used as a neutralizing agent.

The resulting calcium oligoalkenesulfonates contain 1.2–1.8% Ca and 1.5–2.0% S; the alkali number of the additive is 40–60 (mg KOH) g^{-1}.

Laboratory tests of the sulfonate additives in petroleum oils gave the following results: detergent properties 0–0.5 point; anticorrosion properties 3–5 g cm^{-2}; decrease in viscosity 1.5–2% upon thermal degradation. The viscosity index of the initial oil increases by 10–15 points.

The synthesis of oligoalkenesulfonates and sulfamides can be described by the reactions

$$\text{R–H} \xrightarrow{SO_3} \text{R–SO}_2\text{OH},$$
$$\text{R–H} \xrightarrow{HOSO_2Cl} \text{R–SO}_2\text{Cl},$$
$$\text{R–SO}_2\text{OH} \xrightarrow{Me(OH)_2} (\text{R–SO}_3)_2\text{Me},$$
$$\text{R–SO}_2\text{OH} \xrightarrow{R'\text{–NH}_2} \text{R–SO}_2\text{NH–R}',$$
$$\text{R–SO}_2\text{Cl} + \text{NH}_3 \rightarrow \text{R–SO}_2\text{NH–R}',$$

where R is a cooligomer radical, and R', radical in amines.

Thus, oligoalkenesulfonates acting as multifunctional additives to petroleum oils were prepared from cooligomers of α-olefins and vinyl butyl ether with vinylaromatic and carbocyclic monomers. The nature of the starting comonomer and the synthesis conditions are chosen on the basis of particular requirements to the quality of the sulfonates.

The use of the synthesized oligoalkenesulfonates as additives to petroleum oils allows development of lubricating formulations meeting the modern requirements to motor oils with respect to the viscosity–temperature and other performance characteristics.

CONCLUSIONS

(1) Sulfonation with oleum or chlorosulfonic acid of cooligomers of α-olefins (isobutylene, 1-hexene, 4-methyl-1-pentene) with styrene, α-methylstyrene, dicyclopentadiene, or indene, and of cooligomers of vinyl n-butyl ether with styrene, followed by neutralization with various amines and with magnesium or calcium oxide or hydroxide, was studied, and multifunctional polymeric additives were obtained.

(2) The major function of the cooligomers is to act as ligands, which makes it possible to impart to them solubility in petroleum oils. The chemical nature of the starting cooligomers in the synthesis of sulfonates and sulfamides is insignificant. Their choice is based on specific requirements to the quality of the sulfonates.

BOOK REVIEWS

Kulifeev, V.K., Miklushevskii, V.V., and Vatulin, I.I., *Litii* (Lithium),

Moscow: Mosk. Inst. Stali Splavov, 2006, 240 pp.

DOI: 10.1134/S1070427207020383

Lithium is among the most important metals whose role in modern technology steadily grows. The monograph by V.K. Kulifeev and co-authors notes that the world's production of lithium and its compounds (in terms of the metal) was 17 100 tons in 2004. The annual-average rise in world's consumption of lithium and its compounds was 7–8% in the last 10 years. Lithium is virtually irreplaceable in nuclear technology, manufacture of ultralight alloys, and modern chemical power cells.

The book by Kulifeev and co-authors comprises an introduction, nine chapters, and reference list for the entire monograph. The brief introduction (pp. 3, 4) describes the important and steadily growing role of lithium in modern technology and notes that domestic monographs devoted to chemistry and technology of lithium [Ostroushko, Yu.I. et al., *Litii, ego khimiya i tekhnologiya* (Lithium: Chemistry and Technology), Moscow: Atomizdat, 1960, 200 pp.; Plyushchev, V.E. and Stepin, B.D., *Khimiya i tekhnologiya soedinenii litiya, rubidiya i tseziya* (Chemistry and Technology of Compounds of Lithium, Rubidium, and Cesium), Moscow: Khimiya, 1970, 358 pp.) have become largely outdated and fail to reflect the modern development level of lithium industry. A small first chapter (pp. 5–16) considers the world's production and main application fields of lithium and its compounds. In 1990, our country was second in manufacture of lithium and its compounds only to the United States. Later, the internal demand for lithium diminished and the manufacture of lithium decreased fivefold, with the lithium products obtained mostly exported. By now, the manufacture of lithium in Russia from domestic raw materials has been terminated and all the acting plants work with imported raw materials. The second chapter (pp. 17–54) considers the physical and chemical properties of lithium and its compounds and alloys. The third chapter (pp. 55–77) describes minerals containing lithium compounds. The fourth chapter (pp. 78–101) discusses the state of mineral resources of lithium in foreign countries, Russia, and CIS countries. The fifth chapter (pp. 102–123) contains evidence about dressing of lithium ores of industrial importance. The sixth chapter (pp. 124–171), which seems to occupy the central place in the monograph, describes methods for processing of lithium ores and concentrates and for manufacture of such compounds as lithium hydroxide and chloride.

The seventh chapter (pp. 172–205) describes techniques for manufacture of metallic lithium. The authors do not specify present places and scale of lithium is production by carbothermic and metallothermic reduction. It is unclear whether there are prospects for application of these methods in the XXI century. At the same time, the electrolytic method is described very superficially. No data are presented on refining of electrolytic lithium. Primary attention is given to production of lithium by aluminothermic reduction of lithium aluminates. Such an exotic method is not considered in the foreign literature among the possible alternative thermal methods for manufacture of lithium [see, e.g., a review of new technologies for manufacture of lithium in J. of Metals (JOM), 1998, May, pp. 24–26].

The eighth chapter (pp. 206–228) is devoted to secondary metallurgy of lithium. No data on the scale of manufacture of secondary lithium are presented by the authors. In the discussion of the possible utilization of lithium power cells, nothing is said about whether collection of these cells is really feasible. A very brief ninth chapter (pp. 229–233) gives notion of basic safety rules to be observed when working with lithium. The bibliographic list (pp. 234–237) contains references to 63 Russian and 17 foreign publications, which seems to be apparently insufficient.

The book is published in the series Metallurgy and Materials Science of the XXI Century, timed with the 75th foundation anniversary of Moscow State Institute (Technological University) of Steel and Alloys. The polygraphy of the book deserves the highest appraisal, but, as regards the content of the book, there is no escape from making a number of critical remarks. Not all sections of the book create favorable impression, the structure of the monograph seems to be questionable as regards its title, and the directly

relevant literature is far from being represented in full measure.

The impression created by the second chapter is impaired by quite a number of annoying inaccuracies in the description of thermodynamic quantities. The section "Lithium Compounds with Silicon" (pp. 50–54) is very poorly written; the diagrams of state of the systems Li–Pb, Li–Al, Li–Ge, and Li–Cu, presented in this section, are not commented at all. The diagram of state of the system Li–Si, shown in Fig. 2.12, is not consistent with the text. Technologically important alloys of lithium with potassium and magnesium are not mentioned. The highly detailed description of lithium-containing minerals is hardly appropriate (ch. 3). This evidence can be found in full measure in specialized publications. A question arises whether it is worthwhile to describe in such detail dressing and processing of ores from Russia's deposits, when none of them is presently in service, and whether use of these deposits in the XXI century is economically feasible.

It seems that the metal itself, its compounds and methods for their production, and modern and promising application areas should occupy the central place in a monograph having the "Lithium" title. The monograph fails to pay due attention to lithium alloys and their specific features, production of the metal by electrolysis, electrochemistry and thermodynamics of this process, and interaction of lithium with an electrolyte. Metallothermic reduction methods for production of lithium are described very one-sidedly, nothing is said about the scale of manufacture of lithium power cells in Russia, there is not even mention of lithium-ion batteries, intercalation phenomena, application areas of the Li–Pb alloy, and methods for changing the isotope composition.

Naturally, it is impossible to cover in a comparatively small book such a wide variety of issues, but the information value of the monograph could have been made considerably higher by extending the bibliographic list. A large number of monographs, reviews directly devoted to lithium, and its rather promising application areas remained out of the authors' sight. For example, no mention is made of the following publications: Shpil'rain, E.E. and Yakimovich, K.A., *Gidrid litiya* (Lithium Hydride), Moscow: Izd. Standartov, 1972, 108 pp.; Bystrov, P.I. et al., *Zhidkometallicheskie teplonositeli teplovykh trub i energeticheskikh ustanovok* (Liquid-Metal Heat Carriers for Heat Tubes and Power Installations), Moscow: Nauka, 1988, 263 pp.; Kedrinskii, I.A. et al., *Litievye istochniki toka* (Lithium Power Cells), Moscow: Energoatomizdat, 1992, 240 pp.; Kedrinskii, I.A. and Yakovlev, V.G., *Li-ionnye akkumulyatory* (Li-Ion Batteries), Krasnoyarsk: Platina IPK, 2002, 268 pp.; Borgstedt, H.U. and Mathews, Ch.K., *Applied Chemistry of the Alkali Metals*, New York: Plenum, 1987, 282 pp.; and reviews: *Zh. Fiz. Khim.*, 1983, no. 9, pp. 529–546; *Zh. Prikl. Khim.*, 1994, no. 12, pp. 1937–1950; *Zh. Prikl. Khim.*, 1996, no. 4, pp. 529–546.

The on the whole useful monograph by Kulifeev and coauthors should have been titled *Litii: Mineral'nosyr'evye resursy i ikh pererabotka* (Lithium: Mineral Resources and Their Processing). This title would be consistent both with the structure of the book and with the contents of its main chapters.

Vladimir Stepanovich Shpak (to His 98th Birthday)

DOI: 10.1134/S1070427207030019

On February 20, 2007, was celebrated 98th birthday of Vladimir Stepanovich Shpak, Academician of the Russian Academy of Sciences, advisor of the Director General of Prikladnaya Khimiya Russian Scientific Center, Editor-in-Chief of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry), and member of the Editorial Board of *Zhurnal Prikladnoi Khimii*. Hero of Socialist Labor, Honored Scientist and Technologist of the Russian Soviet Federative Socialist Republic, and Honored Chemist, V.S. Shpak has made an outstanding contribution to the creation of quite a number of chemical industries, strengthening of the defense potential of the country, and development of the rocket-and-space technology. Among the large number of congratulations received by Shpak is that from the Chairman of the Federation Council of the Federal Assembly of the Russian Federation, S.M. Mironov.

Editorial Board and Editorial Staff of *Zhurnal Prikladnoi Khimii* and numerous colleagues heartily congratulate dear Vladimir Stepanovich Shpak on his birthday and wish him cheerfulness and health.

GOVERNMENTAL TELEGRAM

Highest governmental. Notification by telegraph. To Academician V.S. Shpak, Editorial Office of *Zhurnal Prikladnoi Khimii*, Mendeleevskaya liniya 1, St. Petersburg.

"Dear Vladimir Stepanovich, please accept my congratulations on your birthday. You have worked a long way up in science. Your whole life is a remarkable example of devotion to the chosen profession and persistence and aspiration in goal achievement. Your contribution to the development of domestic science and advanced technologies has been deservedly appreciated by the State. I wish you, Vladimir Stepanovich, sound health, active longevity, and well-being.

Chairman of the Federation Council of the Federal Assembly of the Russian Federation and Chairman of *Spravedlivaya Rossia (Rodina/Pensionery/Zhizn')* [Just Russia (Motherland/Pensioners/Life)] party,

S. M. Mironov."

Editorial Board and Editorial Staff of *Zhurnal Prikladnoi Khimii*

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Physicochemical Properties of a Microelement Fertilizer with Amino Acids

R. Paleckiene, A. Sviklas, and R. Šlinkšiene

Kaunas Technological University, Kaunas, Lithuania

Received June 19, 2006

Abstract—The physicochemical properties of the initial components and products were studied with the aim of production of a microelement fertilizer with an amino acid concentrate. The physicochemical properties of the amino acid concentrate and its influence on the stability and sorption properties of fertilizers enriched in microelements were studied.

DOI: 10.1134/S1070427207030020

Intensification of agriculture requires using not only effective mineral fertilizers containing macro- and microelements [1, 2], but also physiologically active substances, growth stimulants. In the past years, much attention was given to testing as growth stimulants various synthetic and natural physiologically active substances: citric acid, humates, amino acids, etc. [3–6].

The use of amino acids is most often recommended under critical conditions of plant growth: after transplantation, in the flowering period, and also at climatic stresses (night frosts, drought) or plant diseases. Amino acids are particularly effective in fertilizers when used in combination with microelements [7–12].

In this study we examined the physicochemical properties of the amino acid concentrate (AAC) and its effect on the stability and sorption properties of fertilizers enriched in microelements.

As AAC we used Naturamin-WSP product (DAYMSA, Spain), and as fertilizer, ARVI-micro product (ARVI and Co., Lithuania) containing ammonium sulfate and microelements.

The compositions of substances were determined by chemical and physicochemical methods of analysis. The nitrogen concentration was determined by standard methods [13, 14]. The solid substances were examined by IR spectroscopy, thermal analysis, and X-ray phase analysis [15–18]. The IR spectra were recorded on a Spectrum GX FTIR spectrometer (Perkin–Elmer); samples were prepared as KBr pellets. Thermal analysis was performed by differential scanning calorimetry (DSC) with a Du Pont Instruments 990 Thermal Analyzer at a heating rate of 10 deg min^{-1}. X-ray phase analysis was performed with a DRON-6 diffractometer (Ni-filtered Cu radiation, range of diffraction angles 0°–166.5°, relative error ≤0.5%).

Naturamin-WSP amino acid concentrate was prepared by chemical hydrolysis of proteins, collagen, and keratin. The chemical formula of the product depends on the ratio of free amino acids and oligopeptides. Naturamin-WSP product is a concentrate of water-soluble amino acids containing 80% free amino acids and 12.8% nitrogen; the total weight fraction of organic matter is 90%.

Naturamin-WSP concentrate is a homogeneous mixture of microgranules; it contains 17 amino acids in amounts shown in Fig. 1.

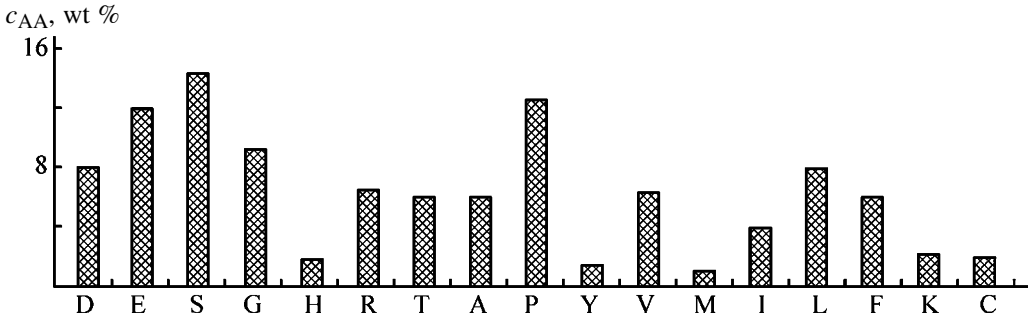

Fig. 1. Content of amino acids c_{AA} in Naturamin-WSP: (D) aspartic acid, (E) glutamic acid, (S) serine, (G) glycine, (H) histidine, (R) arginine, (T) threonine, (A) alanine, (P) proline, (Y) tyrosine, (V) valine, (M) methionine, (I) isoleucine, (L) leucine, (F) phenylalanine, (K) lysine, and (C) cysteine.

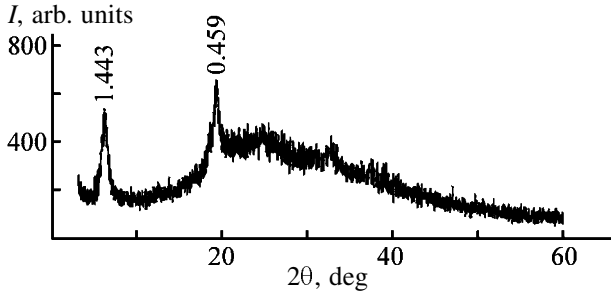

Fig. 2. X-ray diffraction pattern of Naturamin-WSP amino acid concentrate: (*I*) intensity and (2θ) Bragg angle; the same for Fig. 6.

The X-ray diffraction pattern of Naturamin-WSP is shown in Fig. 2; the TG and DSC curves, in Fig. 3; and the IR spectrum, in Fig. 4.

The X-ray diffraction pattern of ACC amino acids (Fig. 2) is typical of amorphous compounds. Only the reflections at 1.443 and 0.449 nm of similar intensity are pronounced; other reflections cannot be identified.

The DSC and TG curves of ACC (Fig. 3) show that, starting from 70°C, Naturamin-WSP loses moisture (TG curve) and remains virtually stable up to ~210°C. At 214.1°C, a pronounced endothermic effect is observed, followed by weight loss. Further heating causes decomposition of the substance (DSC curve exhibits exothermic peaks at 339.0 and 350.0°C, and endothermic peaks at 293.5 and 305.4°C). In the crystalline state, amino acids exist in the form of bipolar ions; their IR spectra (Fig. 4) are similar irrespective of the position of carboxy and amino groups and of the functional substituent. The NH_2 bands are observed at 3500–3000 cm^{-1}; a characteristic C=O band, at 1590–1650 cm^{-1}; and bands of CH, NH_2, and COO^- groups, in the range 1520–450 cm^{-1}.

We studied gravimetrically [13] the sorption of water on AAC under ambient conditions (20–22°C, humidity 25–37%) and in a desiccator over water (~21°C, humidity ~98%). The dynamic curves of water sorption by AAC are shown in Fig. 5.

Under ambient conditions (Fig. 5, curve *1*), AAC takes up a small amount of water (up to 5% in 69 days). Small oscillations of the dynamic curves arise from fluctuations of the ambient temperature and humidity. In a desiccator over water, AAC concentrate absorbs water more actively. Point *a* in curve *2* corresponds to the limiting content of water after which AAC starts to dissolve. Point *b* corresponds to the appearance of mold. Thus, AAC is a hydrophilic substance, and the water absorption depends on the humidity of the medium. This property should be evaluated when using amino acids in production of mineral fertilizers.

For agrochemical and economic reasons, we prepared fertilizers based on ARVI microfertilizer and Naturamin-WSP AAC. ARVI microfertilizer containing 14% nitrogen consists of ammonium sulfate and microcomplex (Mg, S, Mn, Cu, Zn, B, Mo). To this substance we added 1, 3, and 4% AAC and mechanically mixed the components. Therefore, it was necessary to study possible interactions between the components and the stability of the composition. The separate components, ARVI microfertilizers, and ARVI microfertilizers with various additions of AAC were subjected to X-ray diffraction, thermal, and IR analyses (Figs. 6–8).

In the X-ray diffraction pattern of ammonium sulfate (Fig. 6, pattern *1*), we identified its characteristic reflections at 0.519, 0.433, 0.389, 0.314, 0.305,

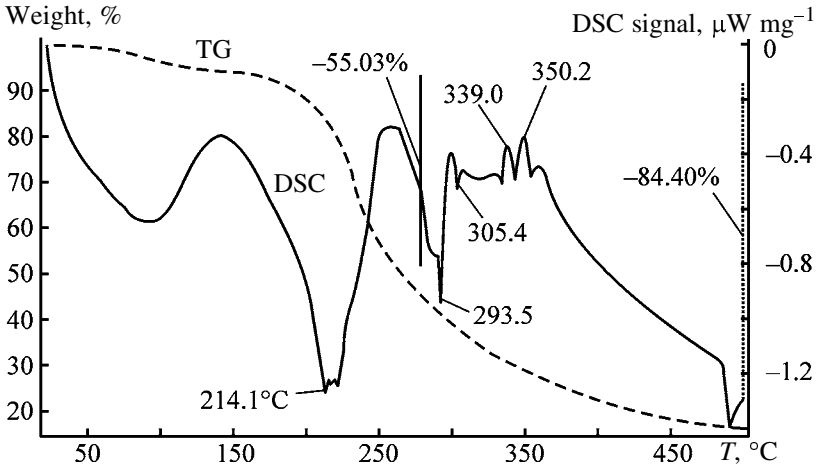

Fig. 3. DSC and TG curves of Naturamin-WSP AAC; (*T*) temperature; the same for Fig. 7.

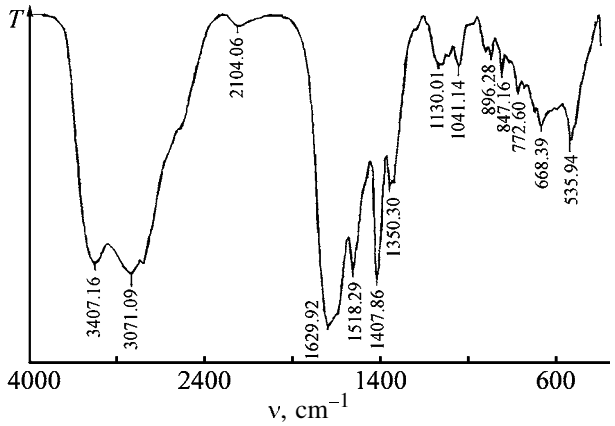

Fig. 4. IR spectrum of Naturamin-WSP AAC: (*T*) transmission and (ν) wavenumber; the same for Fig. 8.

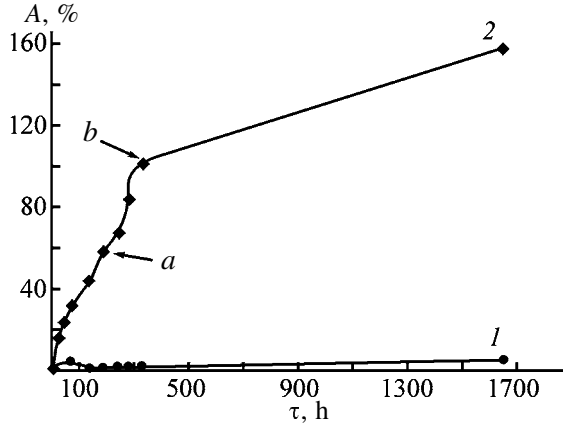

Fig. 5. Dynamic curve of water sorption *A* by AAC (*1*) under ambient conditions and (*2*) in a desiccator over water. (τ) Time; the same for Figs. 9 and 10.

0.299, 0.266, 0.252, 0.232, 0.217, 0.194, 0.177, and 0.164 nm. The microcomplex consists of sulfates of microelements and their crystal hydrates, and also of boric acid; therefore, its diffraction pattern (Fig. 6, pattern *2*) contains reflections of magnesium, manganese, copper, and zinc sulfates and of boric acid at 0.754, 0.598, 0.534, 0.470, 0.447, 0.421, 0.378, 0.341, 0.317, 0.299, 0.287, 0.267, 0.225, 0.220, 0.209, 0.195, and 0.179 nm. The diffraction pattern of ARVI microfertilizer (Fig. 6, pattern *3*) contains reflections of ammonium sulfate and the microcomplex. The diffraction patterns of ARVI microfertilizer with addition of 1, 3, and 4% AAC (Fig. 6, patterns *4*–*6*) exhibit reflections of ammonium sulfate, sulfates of microelements, and AAC. No new reflections are observed, which indicates that the mixture is stable and no chemical reactions occur between the fertilizer components.

The results of thermal analysis are given in Fig. 7. The DSC curve of ammonium sulfate (Fig. 7a) dem-

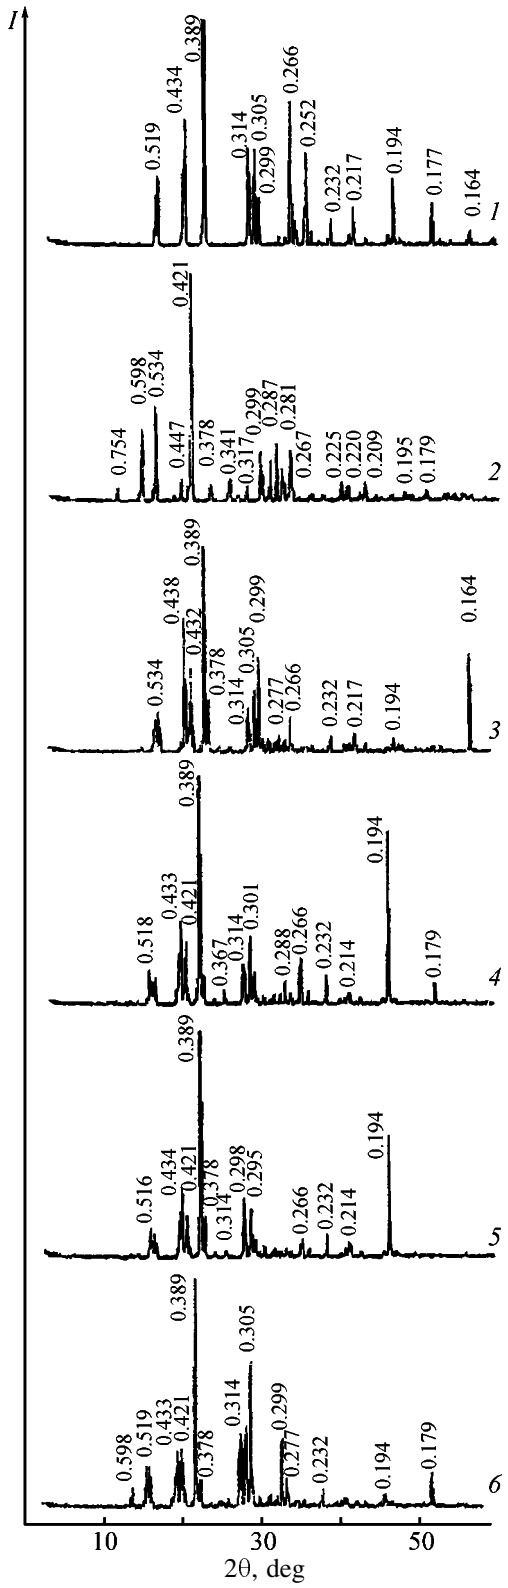

Fig. 6. X-ray diffraction patterns of (*1*) ammonium sulfate, (*2*) microcomplex, (*3*) ARVI microfertilizer, and (*4*–*6*) the same + 1, 3, and 4% AAC, respectively.

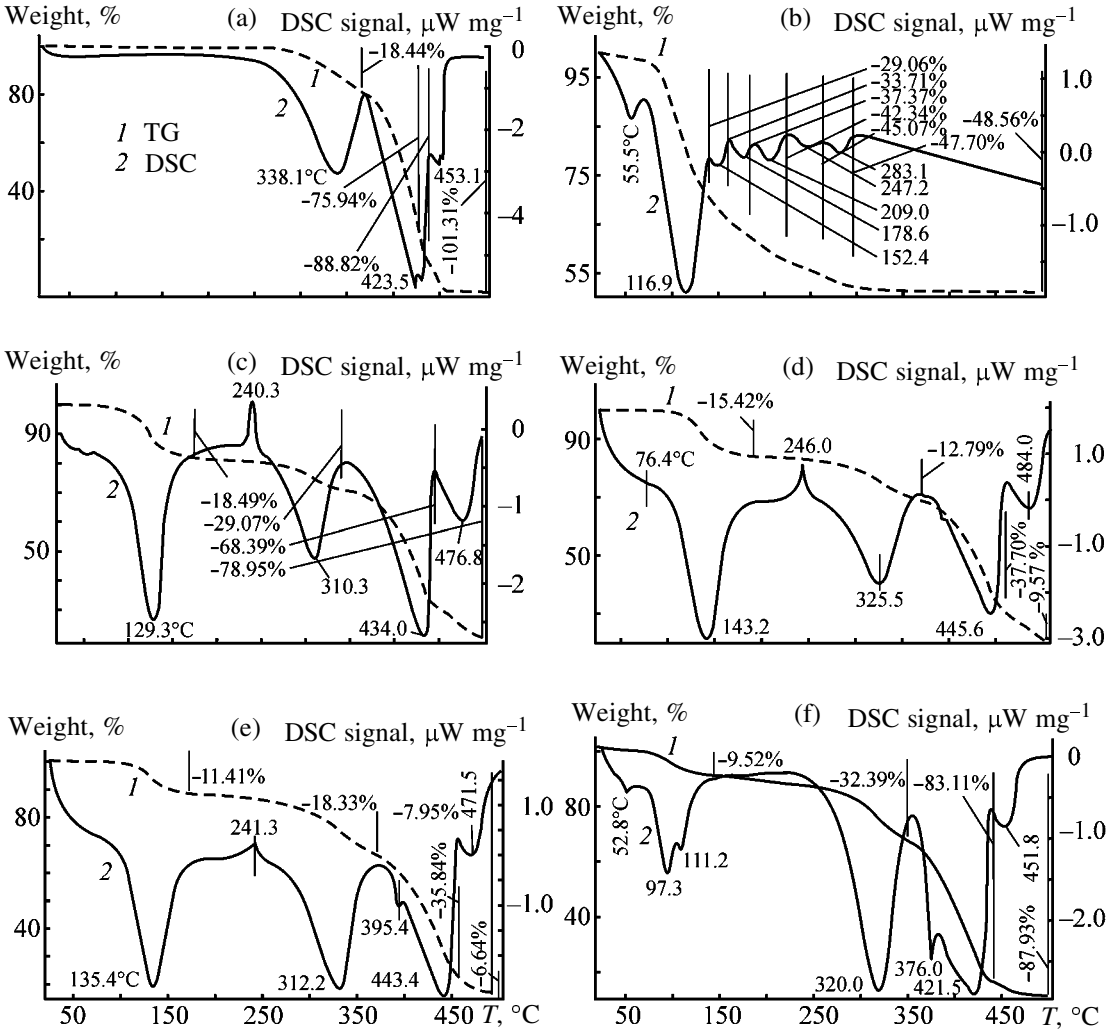

Fig. 7. (*1*) TG and (2) DSC curves of (a) ammonium sulfate, (b) microcomplex, (c) ARVI microfertilizer, and (d–f) the same + 1, 3, and 4% AAC, respectively.

onstrates endothermic decomposition of the compound into gaseous ammonia and an acidic salt, NH_4HSO_4. The decomposition starts at about 300 and is complete at 455°C. The weight loss observed in the TG curve is consistent with the elimination of ammonia.

The DSC curve of the microcomplex (Fig. 7b) exhibits an endothermic peak at 55.5°C indicative of the dehydration of boric acid to metaboric acid HBO_2 followed by further dehydration to boron oxide B_2O_3. A pronounced endothermic effect at 116.9°C corresponds to the onset of dehydration of magnesium, manganese, copper, and zinc sulfate crystal hydrates. The effect is complete at 283.1°C. The anhydrous salts remain stable up to 600°C. A continuous weight loss starting about 100°C corresponds to the dehydration.

Thermal analysis of ARVI microfertilizer (Fig. 7c) reveals a total endothermic effect (DSC curve) in combination with weight loss (TG curve) from the initial components, ammonium sulfate and the microcomplex. The DSC and TG curves of ARVI microfertilizer with 1, 3, and 4% AAC (Figs. 7d–7f) exhibit the same peaks as in the curves for the separate components. Some changes in the peak intensities and positions (some of peaks overlap) are natural and insignificant; thus, mixing of the components involves no chemical reactions, and no new chemical compounds are formed.

The IR spectra of the initial substances, ARVI microfertilizer, and ARVI microfertilizer with additions of AAC are shown in Fig. 8. In the IR spectrum of ammonium sulfate (Fig. 8, curve *1*) there are characteristic absorption bands of the NH_4^+ ion at 3000, 2000, and 1400 cm^{-1} and of the SO_4^{2-} ion at 1150–450 cm^{-1}. Since the microcomplex contains a number

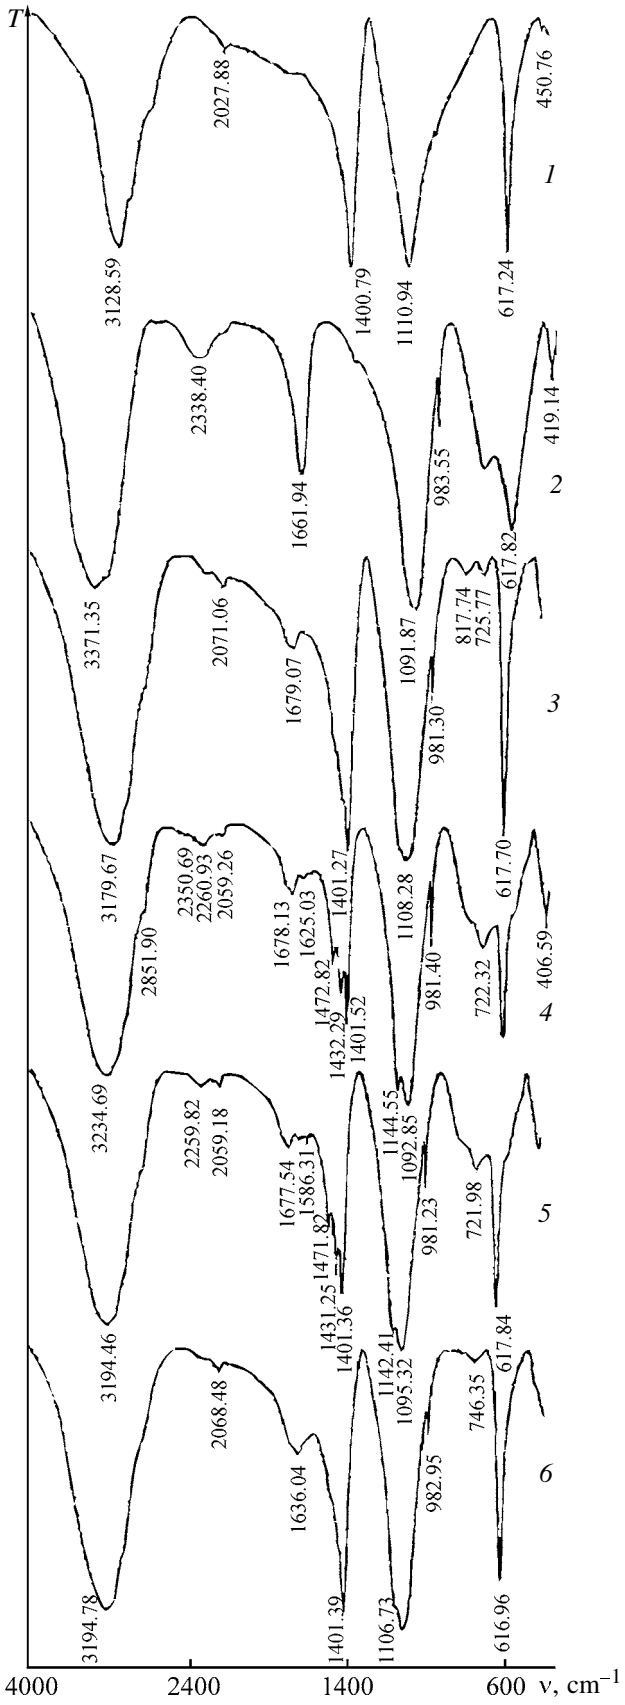

Fig. 8. IR spectra of (*1*) ammonium sulfate, (*2*) microcomplex, (*3*) ARVI microfertilizer, and (*4–6*) the same + 1, 3, and 4% AAC, respectively.

of sulfates, in its IR spectrum there are strong absorption bands of SO_4^{2-} at 1150–450 cm^{-1}. Also present are bands of boric acid at 1490–1428 cm^{-1} and a weak band at 2400–3000 cm^{-1} assignable to the bridging BH group.

The IR spectrum of ARVI microfertilizer (Fig. 8, spectrum *3*) exhibits characteristic absorption bands of both ammonium sulfate and the microcomplex.

The IR spectra of ARVI microfertilizer with AAC additions are shown in Fig. 8, curves *4–6*. The spectra exhibit characteristic absorption bands of ammonium sulfate, microcomplex, and AAC. In the frequency range 3500–3000 cm^{-1} there are absorption bands of the NH_2 group, and a band at 1590–1650 cm^{-1} corresponds to the C=O bond. Bands at 1520–450 cm^{-1} are characteristic of the NH_2, CH_2, and COO^- groups. All the absorption bands in spectra *4–6* are observed at the same (or slightly shifted) positions as in the spectra of the separate components (ammonium sulfate, microcomplex, AAC); therefore, we can conclude that no chemical reactions occur in ARVI microfertilizers.

To evaluate the sorption properties, we examined the hygroscopicity of the separate components, ARVI microfertilizers, and ARVI microfertilizers with AAC additions under the same conditions as in the above-described AAC tests. The dynamic sorption curves are shown in Figs. 9 and 10.

Experiments on the water absorption under ambient conditions (Fig. 9; 20–22°C, 25–37% humidity) show that only ammonium sulfate (Fig. 9, curve *6*) slightly absorbs water, whereas the other components and fertilizers with AAC (curve *2–5*), especially the microcomplex (curve *1*), even lose moisture.

In a desiccator over water (~21°C, ~98% humidity), all the samples show a linear dependence of the water absorption on time (Fig. 10). In 192 h, the samples start to dissolve, and on samples with AAC a mold appears in 336 h. The lowest water absorption is shown by the microcomplex (curve *1*). All the other substances (ammonium sulfate, ARVI microfertilizers, ARVI microfertilizers with 1, 3, and 4% AAC) take up considerably larger amount of water. The dynamic sorption curves of the fertilizers with AAC resemble that of ammonium sulfate (Fig. 10, curve *2*), which is the major component of the fertilizers.

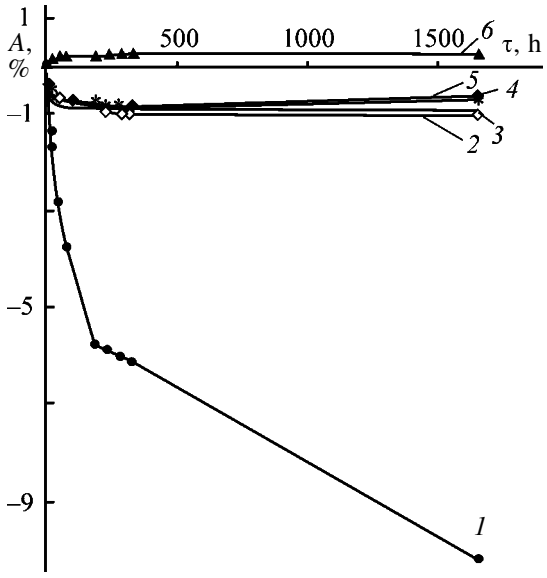

Fig. 9. Dynamic curves of water absorption *A* under ambient conditions by (*1*) microcomplex; (*2*) ARVI microfertilizer; (*3*–*5*) the same + 1, 3, and 4% AAC, respectively; and (*6*) ammonium sulfate.

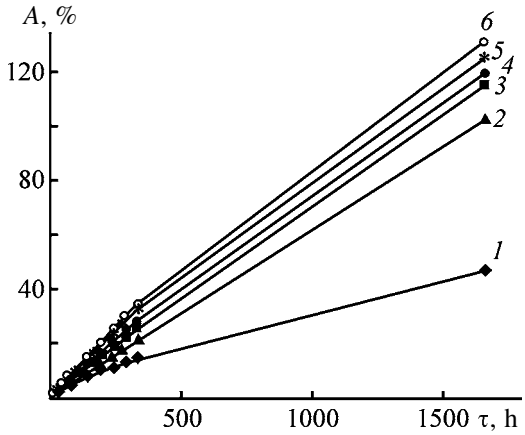

Fig. 10. Dynamic curves of water absorption *A* in a desiccator over water by (*1*) microcomplex, (*2*) ammonium sulfate, (*3*) ARVI microfertilizer, and (*4*–*6*) the same + 1, 3, and 4% AAC, respectively.

CONCLUSIONS

(1) Data obtained by instrumental methods show that no chemical reactions between the components occur in ARVI microfertilizer with additions of amino acid concentrate. The amino acid concentrate decreases the thermal stability of the fertilizers. Traditional conditions of granulation, drying, and storage are quite suitable for the fertilizers in question.

(2) Studies of water absorption under various conditions show that microelement fertilizers based on ammonium sulfate and containing amino acid concentrate do not change their physical properties.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Organic–Inorganic Hybrids in the System Ruthenium Tris(diimine) Complexes–Silica

Abstract—Organic–inorganic composites in which ruthenium(II) complexes are covalently bound to the silicate matrix were prepared by the sol–gel method. The physicomechanical and optical properties of the monolithic samples obtained were studied.

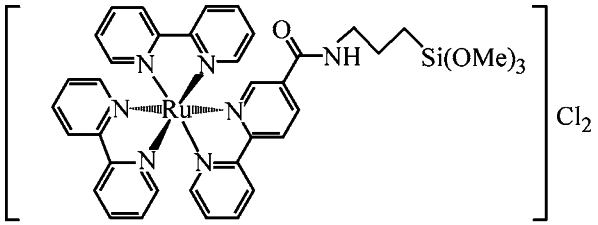
DOI: 10.1134/S1070427207030032

The majority of transition metals form stable complexes with 2,2'-bipyridine, 1,10-phenanthroline, their derivatives, and related compounds [1]. The diversity of electronic transitions in these compounds, due to accessibility of the *d* and *f* electronic sublevels of transition metals in combination with conjugated π-electron systems of ligands, gives rise to interesting photophysical, photochemical, and electrochemical properties [2–6]. Complexes of the type $[RuL_3]^{2+}$ exhibit a unique combination of these properties with high thermal and chemical stability [7]. Large interest in these compounds is caused by prospects for their use in the fields of photochemistry, photophysics, electrochemistry, chemiluminescence, and electroluminescence (especially after the discovery in 1976 of the catalytic effect of ruthenium complexes on decomposition of water into elements under the action of visible light [7]).

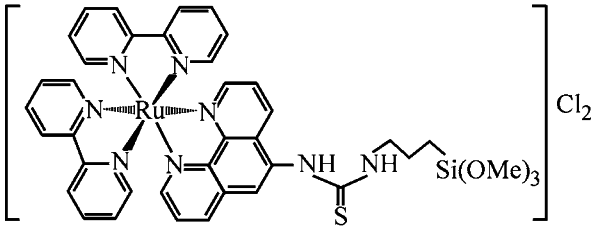
The practical use of photophysical and electrochemical properties of such structures involves their incorporation into an organic or inorganic matrix. Various organic polymers (polymethacrylates, polyurethanes, polyamides, polyimides, polybenzimidazoles, etc.) can be used as matrix [8–13]. The stability and uniformity of films, coatings, fibers, and other materials thus obtained are mainly determined by the possibility of chemical bonding between the system components, i.e., of formation of a covalent bond between the matrix and ligands of the complex (or at least one of them) [14, 15]. There are several synthetic strategies for preparing a ruthenium complex chemically bound with a polymer chain. The majority of researchers believe that, from the viewpoint of attaining chemical stability and high deformation and strength characteristics, the best choice is synthesis of a polymer chain containing 2,2'-bipyridine-type units, followed by complexation with Ru^{2+} derivatives. In so doing, however, some problems arise: The viscosity of polymer solutions considerably increases as a result of cross-linking of polymer chains upon formation of the Ru^{2+} complex, and the polymer becomes less soluble, which can lead to formation of a nonuniform material. Therefore, the metal concentration in the polymer–metal complex rarely exceeds 1%.

A good solution to this problem is replacement of a polymer matrix by an inorganic SiO_2 matrix prepared by the organic sol–gel method: hydrolysis of tetraalkoxysilanes followed by polycondensation of the hydrolysis products [16]. In so doing, the organic complex of ruthenium is added into the initial system, and the sol–gel process yields a hybrid material with intermolecular binding of the organic ($[RuL_3]^{2+}$) and inorganic (SiO_2) components of the system [17–19]. This intermolecular binding is due to van der Waals and hydrophobic–hydrophilic interactions of the components; naturally, it is relatively weak [20]. Therefore, the physicomechanical properties of the hybrids obtained in the $[RuL_3]^{2+}$–SiO_2 system are unsatisfactory. Furthermore, clusterization of the molecules of the organic component in the course of sol–gel synthesis will disturb the uniformity of the material. Apparently, the prospects of this strategy are associated with the synthesis of nanocomposites in which the organic and inorganic components of the system will be chemically bound with each other.

To prepare such nanohybrid structures, we used ruthenium complexes containing a trimethoxysilyl group in the side chain of one of the ligands (Scheme 1).



Ia



IIa

Scheme 1. Ruthenium complexes.

Our goals were to synthesize such complexes, to incorporate them into a silica matrix prepared by hydrolytic polycondensation of tetramethoxysilane, and to study the physicomechanical and optical properties of the materials obtained.

EXPERIMENTAL

The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DPX-300 device (operating frequencies 300.13 and 75.5 MHz, respectively; internal reference TMS). The UV spectra were measured on an SF-2000 spectrometer, and the luminescence spectra, on a Lyumeks device. Thermal analysis was performed with a Q-1500 D derivatograph. The reaction mixtures were analyzed and the product purity checked by TLC on Silica Gel 60 F254 and Armsorb TSKh-AN-UF 254 plates. Substances were separated by column chromatography on Silica Gel 60 (0.040–0.063 μm) and alumina L 40/350 (40–250 μm). In the syntheses we used $[Ru(bipy)_3]Cl_2$, 5% Pd/C, thiophosgene, and 3-aminopropyltrimethoxysilane (Aldrich). *cis*-[Bis-(2,2'-bipyridine)dichlororuthenium] [7], 5-nitro-1,10-phenanthroline [21], and ruthenium complexes **Ib**–**Id** [22, 23] were prepared by previously described procedures.

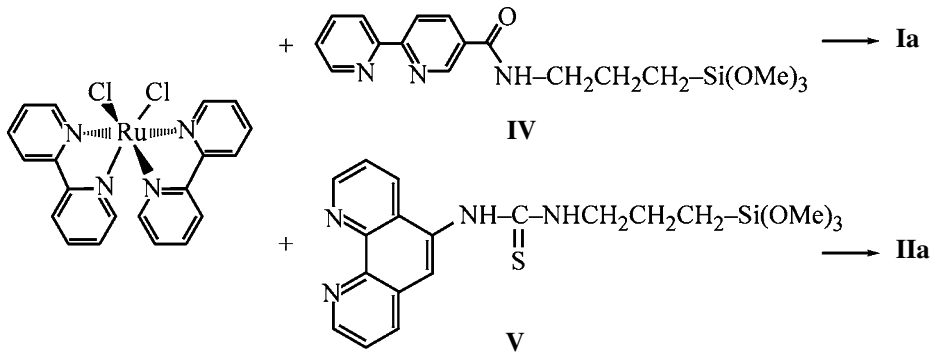
$[Ru(bipy)_2(phenNO_2)]Cl_2$ (IIb). A suspension of 600 mg of bis(2,2'-bipyridine)dichlororuthenium **III** and 1.1 equiv of 5-nitro-1,10-phenanthroline in 40 ml of water was refluxed for 1 h to complete conversion of **III** (TLC monitoring on alumina). The resulting solution was cooled and filtered; the filtrate was evaporated to dryness in a water-jet-pump vacuum, and the residue was dissolved in 1 ml of methanol and reprecipitated into 20 ml of absolute diethyl ether. Yield 90%.

^{1}H NMR spectrum [$(CD_3)_2SO$], δ, ppm: 9.50 s (1H), 9.10 m (2H), 8.35 d (2H), 8.30 d (2H), 8.25 t (2H), 8.15 t (2H), 8.05 m (2H), 7.80 d (2H), 7.65 m (4H), 7.40 t (2H).

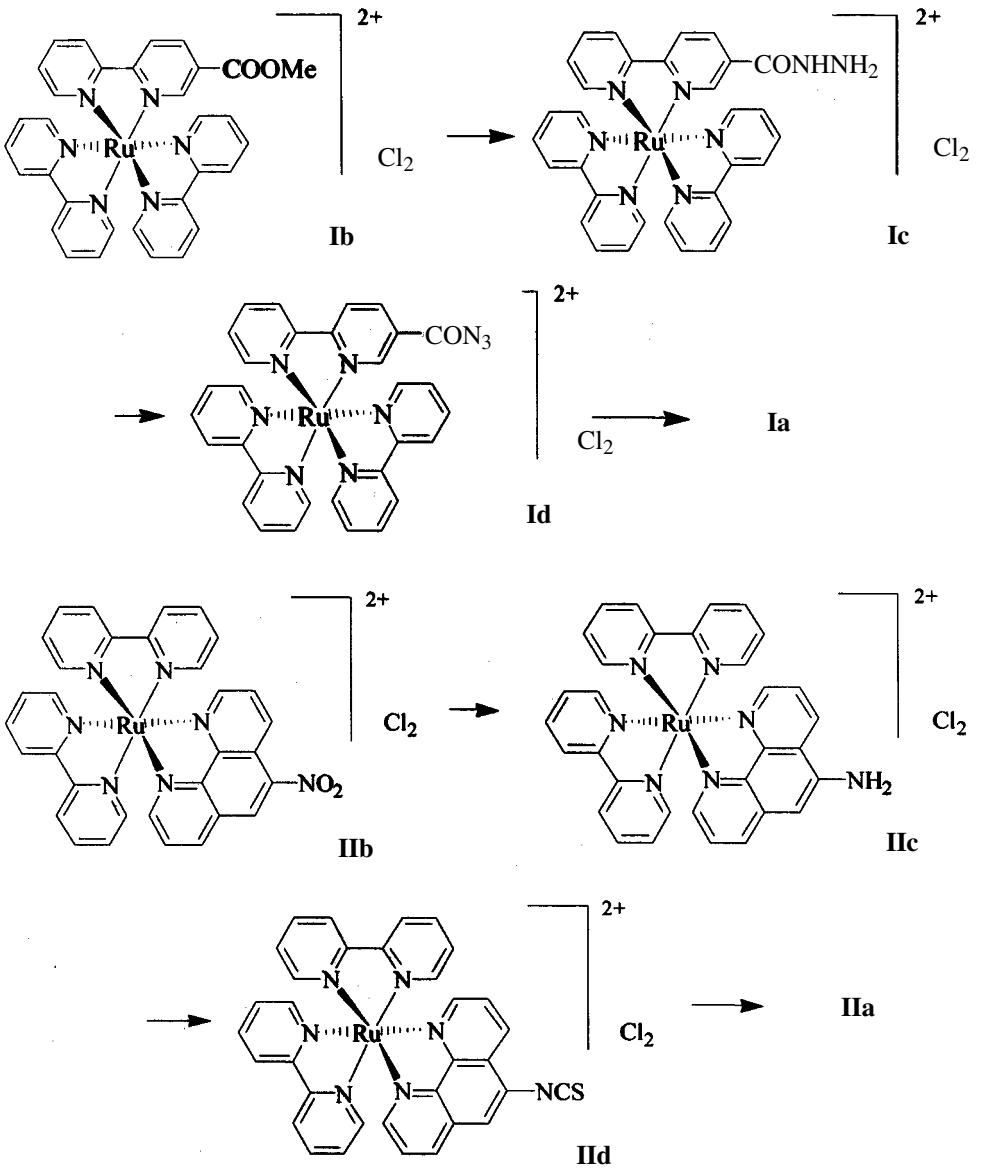
$[Ru(bipy)_2(phenNH_2)]Cl_2$ (IIc). A solution of 0.5 g of **IIb** in 12 ml of water was hydrogenated at room temperature and atmospheric pressure with stirring in the presence of 170 mg of the palladium catalyst. After the uptake of the theoretical amount of hydrogen (24 h), the catalyst was filtered off, and the resulting yellow-orange solution was used in further synthesis without isolation of the amino derivative. To confirm the structure of **IIc**, a sample of **IIb** was hydrogenated in DMF-d_7. ^{1}H NMR spectrum [$(CD_3)_2NCDO$], δ, ppm: 8.95 m (6H, $H^{3,3'}$-bipy, $H^{4,7}$-phen), 8.30 m (3H, $H^{6,6'}$-bipy, H^8-phen), 8.17 t (2H, $H^{4,4'}$-bipy), 8.07 t (2H, $H^{4,4'}$-bipy), 7.95 d (1H, H^3-phen), 7.85 m (4H, $H^{6,6'}$-bipy, $H^{5,5'}$-bipy), 7.67 t (2H, $H^{5,5'}$-bipy), 7.62 s (1H, H^6-phen), 7.47 m (2H, $H^{2,9}$-phen). ^{13}C NMR spectrum [$(CD_3)_2NCDO$], δ, ppm: 124.9, 126.1, 127.5, 127.6, 132.3, 133.6, 137.9, 138.1, 146.7, 147.2, 151.8, 152.4, 152.8, 157.1.

$[Ru(bipy)_2(phenNCS)]Cl_2$ (IId). A solution of NaOAc in 5 ml of water was added to a solution of **IIc** in water, cooled to –5°C, after which a solution of thiophosgene in 2 ml of acetone was added dropwise with vigorous stirring over a period of 5 min. After 15 min (TLC monitoring), the solution was evaporated in a vacuum, and the residue was separated chromatographically on alumina, eluent methylene chloride–methanol, 10 : 1. Yield 50% based on the starting complex with nitrophenanthroline. ^{1}H NMR spectrum [$(CD_3)_2SO$], δ, ppm: 8.90 m (4H, $H^{3,3'}$-bipy), 8.75 d (1H, H^7-phen), 8.55 d (1H, H^4-phen), 8.12 m (6H, $H^{4,4'}$-bipy, $H^{3,8}$-phen), 7.78 m (5H, $H^{6,6'}$-bipy, H^6-phen), 7.58 m (4H, $H^{5,5'}$-bipy), 7.40 m (2H, $H^{2,9}$-phen). ^{13}C NMR spectrum [$(CD_3)_2SO$], δ, ppm: 125.4, 125.5, 126.2, 126.7, 128.7, 129.8, 132.1, 134.8, 136.3, 138.7, 138.9, 144.2, 148.1, 151.8, 152.2, 157.4, 157.7.

Ruthenium complexes **Ia** and **IIa** can be prepared by two routes. The first route involves condensation of $Ru(bipy)_2Cl_2$ with appropriate derivative of 2,2'-bipyridine (**IV**) or 1,10-phenanthroline (**V**) (Scheme 2).



Scheme 2. Synthesis of ruthenium complexes



Scheme 3.

Synthesis of **IV** and **V** involves no serious problems and was described previously [23]. Unfortunately, in anhydrous medium (absolute methanol), required to prevent possible hydrolysis, the reactions of formation of **Ia** and **IIa** are slow and do not go to completion. We found that the reaction $Ru(bipy)_2Cl_2 + L \rightarrow [Ru(bipy)_2L]Cl_2$ occurs considerably faster and with a higher yield in the presence of water, even if the ligand L is insoluble in water.

It is extremely difficult to prepare pure compounds **Ia** and **IIa** by this route, because common methods of column chromatography are unsuitable for their purification.

The second pathway involves direct transformation of functional groups in the complexes $[Ru(bipy)_2 \cdot (bipy')]Cl_2$ and $[Ru(bipy)_2(phen')]Cl_2$ (Scheme 3).

This route allows preparation of the desired complexes **Ia** and **IIa** in a higher yield and by less labor-consuming procedures, because transformations of functional groups in ruthenium complexes require considerably milder conditions than formation of the complexes themselves.

Complexes **Id** [22] and **IIb**–**IId** were isolated and characterized in the course of the synthesis. Because of easy hydrolysis of trimethoxysilyl groups, compounds **Ia** and **IIa** were synthesized directly in the sol–gel system. Their structure was confirmed by NMR spectroscopy; for this purpose, the reactions of azide **Id** and isothiocyanate **IId** with 3-aminopropyltrimethoxysilane were performed in DMSO-d_6.

To perform sol–gel synthesis of nanohybrids, to a mixture of tetramethoxysilane (TMOS) (1 equiv), acetic acid (1 equiv), and water (4 equiv) we added a methanol solution of **Ia** or **IIa**, prepared by mixing **Id** or **IId** with 3-aminopropyltrimethoxysilane taken in an equivalent amount. Compound **IIa** is formed immediately; formation of **Ia** requires keeping the solution at room temperature in the absence of atmospheric moisture for 3 days.

The resulting solutions were placed in hermetically stoppered polypropylene test tubes and kept at 55°C for 2 days. Then the hermetic stoppers were replaced by stoppers with holes (hole diameter about 1 mm), and wet gels were dried for 2 h at 55, 2 h at 70, 2 h at 80, and 17 h at 90°C. The temperature was raised at a rate of 3 deg h^{-1}. After that, the gels were transferred into glass test tubes equipped with stoppers with holes and were heated to 90 (15 deg h^{-1}) and then to 120°C (3 deg h^{-1}); at 120°C, the samples were kept for 12 h.

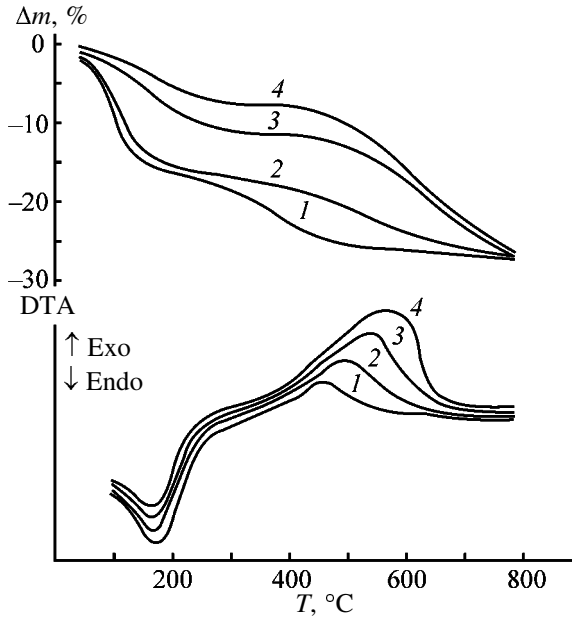


Fig. 1. Curves of thermal analysis of composites: (*1*) **1a**, (*2*) **1b**, (*3*) **1c**, and (*4*) **1d**. (Δm) Weight loss and (T) temperature.

With 1, 5, 10, and 20% complex **Ia**, we prepared composites **1a**–**1d**, respectively, and with the same amounts of **IIa**, composites **2a**–**2d**, respectively. Hybrids **3a**–**3d** containing the same amounts of commercial $[Ru(bipy)_3]Cl_2$ were prepared as references.

All the hybrids **1a**–**1d**, **2a**–**2d**, and **3a**–**3d** are monolithic transparent cylinders with the color gradually changing from yellow for **1a**–**3a** to red-brown for **1d**–**3d**. The composition and structure of the SiO_2 gel prepared by the organic sol–gel method under similar conditions are described in detail elsewhere [16]. Introduction of Ru(II) complexes into the SiO_2 matrix is accompanied by a gradual increase in the density from 1.38 for **1a** to 1.68 g cm^{-3} for **Id**, and in the microhardness from 100 to 165 kg mm^{-2}, respectively. Similar changes in the density and microhardness, though less pronounced, occur in formation of composites **2a**–**2d** and **3a**–**3d**. According to the results of thermal analysis of composites **1c**–**3c**, the formation of hybrids **1c** and **2c** in which the Ru(II) complexes are linked with the inorganic matrix by a chemical bond is accompanied by a considerable increase in their thermal stability compared to **3c**. It should be particularly emphasized that, in contrast to **3c**, the total content of volatile impurities in hybrids **1a**–**1d** and **2a**–**2d** remains constant, i.e., introduction of an organic component into the sol–gel system is accompanied by displacement of a part of water and methanol sorbed by the gel matrix (Fig. 1).

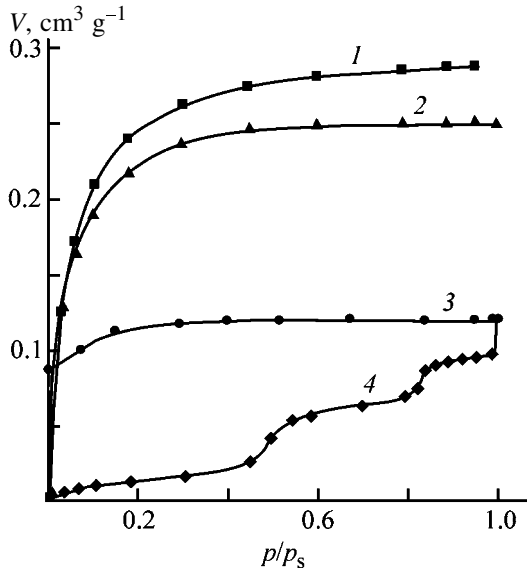

Fig. 2. Isotherms of ethanol adsorption–desorption at 18°C on composites (*1*) **1a**, (*2*) **1b**, and (*3*, *4*) **1d** (adsorption and desorption, respectively). (*V*) pore volume and (p/p_s) ratio of the ethanol vapor pressure to its saturated vapor pressure.

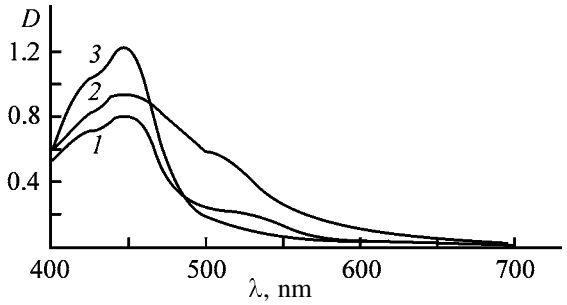

Fig. 3. Absorption spectra of composites (*1*) **1b**, (*2*) **2b**, and (*3*) **3b**. (*D*) Optical density and (λ) wavelength.

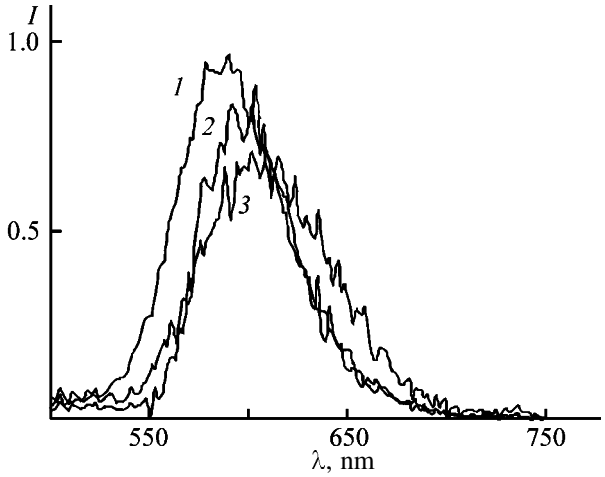

Fig. 4. Luminescence spectra of composites (*1*) **1b**, (*2*) **2b**, and (*3*) **3b**. (*I*) Normalized intensity (relative to I_{max}) and (λ) wavelength.

Figure 2 shows the isotherms of ethanol adsorption–desorption on composites **1a**, **1b**, and **1d**. From these curves, we can calculate the specific surface area of the composites and the mean pore size [24]:

Composite	**1a**	**1b**	**1d**
S, $m^2\ g^{-1}$	500	440	30
r, nm	0.8	0.7	–

The calculated specific surface areas of hybrids **2a**–**2d** are close to those of **1a**–**1d**.

Apparently, with an increase in the content of organic component in hybrids formed by chemical binding of system components with each other, the number and size of pores in the SiO_2 matrix decrease, and at a 15–20% concentration of the Ru complex the matrix becomes monolithic.

The absorption spectra of the composites (Fig. 3) are very similar, although their maxima are red-shifted by approximately 3–5 nm. All the complexes synthesized show a strong luminescence in the range 550–650 nm (excitation with a xenon lamp, λ = 450 nm) (Fig. 4).

It should be noted that in composites **1**–**3** the concentration quenching of the luminescence is not decisive, in contrast to the lanthanide complex–silica system in which even a minor increase in the Ln(III) concentration, leading to clusterization of the molecules of the complex (for hybrids formed without chemical bonding between the system components), is fatal.

CONCLUSIONS

(1) New metal–polymer Ru(II) complexes in the form of organic–inorganic hybrids, with the organic and inorganic components linked by a chemical bond, were synthesized.

(2) The use of an inorganic SiO_2 matrix as a polymeric base allows control of the content of the Ru(II) complex in the composite, significant improvement of the physicomechanical properties of the material, enhancement of its heat resistance, and simplification of the synthesis of the initial polymeric structures.

Abstract—Terbium(III) chloride (1.5–150 μmol g^{-1}) was encapsulated in porous glass by impregnation of the support with aqueous solutions of various concentrations. The concentration dependences of the luminescence parameters and luminescence quenching in the course of water vapor adsorption in the salt intercalates were analyzed.

DOI: 10.1134/S1070427207030044

Porous glasses (PGs) with a pore size of 2–100 nm [1, 2] can be used as supports for preparing and stabilizing nanoparticles of various compounds [2–7]. Particular interest in the size-dependent optical properties of nanocomposites based on PGs is determined by their transparence in a wide wavelength range. Impregnation of PGs with solutions of optically active components of various concentrations with subsequent solvent removal is a simple and reliable procedure providing profound fragmentation and immobilization of small particles of various salts and complexes on the silica surface [4–7]. Owing to pronounced luminescence, microsecond lifetime of the excited states, and fixed positions of the excited levels, rare-earth elements (REEs) are interesting guest compounds. Porous glasses modified with REE compounds are systems with individual optical properties, which can be used as components of various photoluminescence, electroluminescence, light-converting, and sensor devices. Essentially, PGs act as nanoreactors determining the size specificity of the occurring processes and thus the properties of the resulting composites. Here we analyze the potentialities of this approach by the example of size features of luminescence of terbium(III) chloride encapsulated in PG.

EXPERIMENTAL

As a support we used finely dispersed glass with the particle size of 0.05–0.07 mm (predominant pore radius 4.5 nm, porosity 0.166 $cm^3\ g^{-1}$, and specific surface area 80 $m^2\ g^{-1}$). The PG modification was performed by impregnation with aqueous solutions of terbium chloride (0.01–1.0 M) and subsequent drying of the impregnated glasses at 120°C. The content of terbium in the support was determined photocolorimetrically with Arsenazo [8] using the solution prepared by boiling of the sample in water to transfer the terbium salt into the aqueous phase. The required concentration of $TbCl_3$ in PG can be attained at maximal and reproducible filling of the pore volume with the impregnation solution. The actually attainable molar content of salt Q introduced into PG is determined by the salt concentration c and pore volume ε:

$$Q = c\varepsilon\gamma, \quad (1)$$

where $\gamma < 1$ is a coefficient reflecting the deviation from the ideal filling of the pore volume.

The effective value was determined as the ratio of the salt content in PG to its highest content calculated at $\gamma = 1$. Our experimental data showed that the average value $\gamma = 0.9$ corresponds to the ratio of the through (open) and difficultly accessible (blind) pores, or to the fraction of the total PG pore volume in which the terbium chloride solution is distributed in the course of impregnation.

The spectra of the dry powder samples and those with adsorbed water were recorded using sealed quartz tubes 5 mm in diameter. The luminescence in the visible range and lifetimes of the excited state were recorded at room temperature using a device based on a KSVU-1 spectrometer interfaced with a computer and equipped with an FEU-100 photoelectron multiplier [9]. The luminescence was excited with an LGI21 pulse nitrogen laser ($\lambda = 337$ nm, $\tau = 10$ ns) and was recorded at the right angle to the laser beam. Samples with various content of adsorbed water on the initial and impregnated glasses in the range of relative humidity p/p_0 from 0.1 to 0.8 were prepared

by their keeping over solutions of sulfuric acid of the required concentrations.

The luminescence spectra of $TbCl_3$/PG samples with the content of terbium chloride Q = 1.5–150 μmol g^{-1}, recorded after drying at 120°C, are shown in Fig. 1. In all the cases, the band of the hypersensitive transition $^5D_4 \rightarrow {}^7F_4$ (λ_{ma}) dominates in the luminescence spectra of terbium(III) [10]. Additional weak bands at 590, 625, and 680 nm are also typical for $TbCl_3$ and correspond to the transitions from the lowest excited level $^5D_4$ to the $F_{1,3,4}$ levels of the Tb(III) cation [10]. It should be noted that even minimal concentrations of intercalate in the support (~0.04 wt %) provide reliably recordable green luminescence.

The nature of accumulation and distribution of the salt species on the through pore surface can be analyzed from the changes in the integral intensity I of the band of the main transition $^5D_4 \rightarrow {}^7F_4$ and lifetimes of the excited state τ* in the series of $TbCl_3$/PG samples (Fig. 2). With increasing intercalate content Q, I and τ* both increase and reach maximal values at Q = 120 μmol g^{-1}. Probably, the main portions of the dependences shown in Fig. 2 correspond to the monotonic increase in the amount of isolated luminescence centers uniformly distributed over the support surface. Their aggregation, causing concentration quenching of the luminescence, is essential only at relatively high intercalate concentrations and becomes a decisive factor only at Q = 120 μmol g^{-1}. The known specific surface area of 80 $m^2\,g^{-1}$ allows evaluation of the topographic density of $TbCl_3$ distribution over the silica surface:

$$n = QN_A/S, \quad (2)$$

where N_A is the Avogadro number. For example, at Q = 120 μmol g^{-1}, n is equal to one formula unit (molecule) of $TbCl_3$ per 1 nm^2, which well agrees with the concept of the monolayer coverage of the support surface with the intercalate. This fact suggests maximal (molecular) dispersion and predominantly tangential distribution of $TbCl_3$ at its accumulation in PGs. Strong interaction of the salt species with the glass surface due to the electron-acceptor power of amorphous silica [10] hinders aggregation of $TbCl_3$ molecules in three-dimensional networks of the cluster type, which, in turn, determines the monotonic increase in the luminescence intensity and lifetime of the excited state in the main sections of their dependences on the $TbCl_3$ content (Fig. 2). It should be noted that predominantly monolayer distribution of some metallic and oxide intercalates in PGs were found previously by electric resistivity measurements [4, 12, 13].

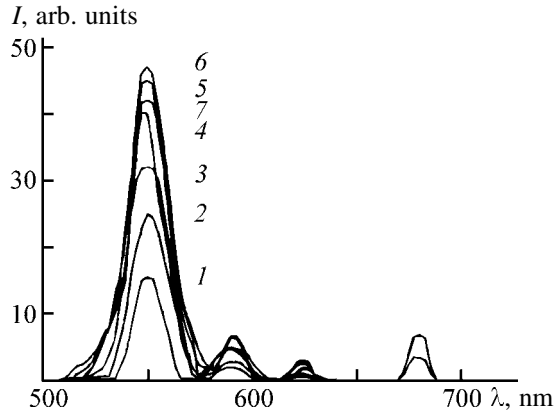

Fig. 1. Luminescence spectra of modified porous glasses with various content of $TbCl_3$. (*I*) Intensity and (λ) wavenumber. Content of $TbCl_3$, μmol g^{-1}: (*1*) 1.5, (*2*) 15, (*3*) 30, (*4*) 60, (*5*) 90, (*6*) 120, and (*7*) 150.

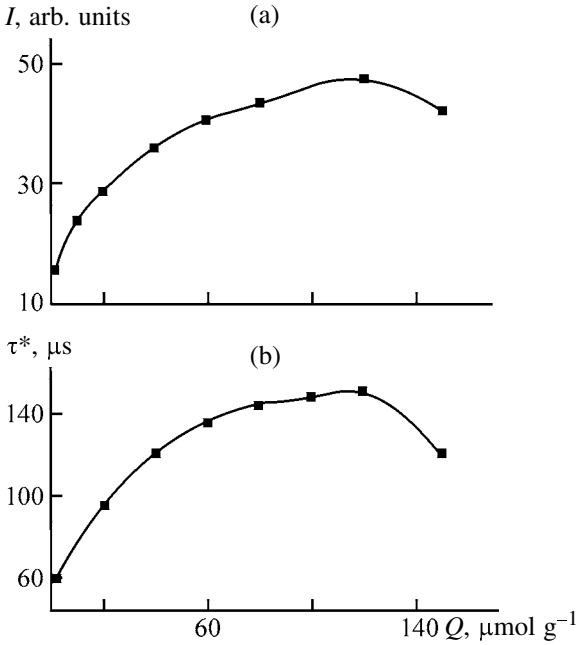

Fig. 2. (a) Intensity of the hypersensitive transition band I and (b) lifetime of the excited state τ* as functions of the $TbCl_3$ content Q in porous glass.

The features of luminescence quenching with water can give additional information on the state of salt species in porous glass. It should be noted that impregnation of PGs with $TbCl_3$ does not noticeaboly affect the water adsorption. The adsorption isotherms of the initial and impregnated samples with the $TbCl_3$ content changing from 1.5 to 150 μmol g^{-1} are so close (Fig. 3) that we failed to reveal any regular trends in their variation. We assume that $TbCl_3$

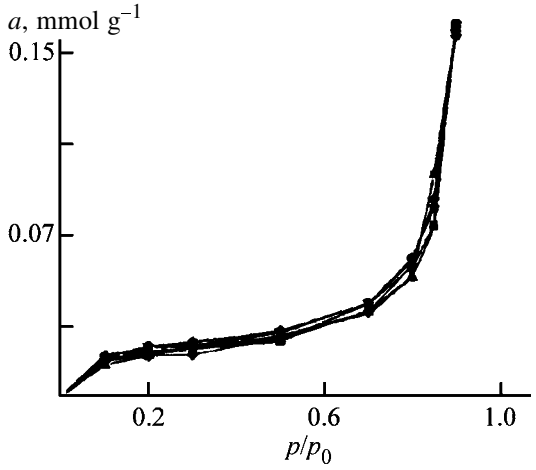

Fig. 3. Isotherms of water adsorption on the initial and modified porous glasses (for explanation, see text). (*a*) Adsorption and (p/p_0) relative humidity.

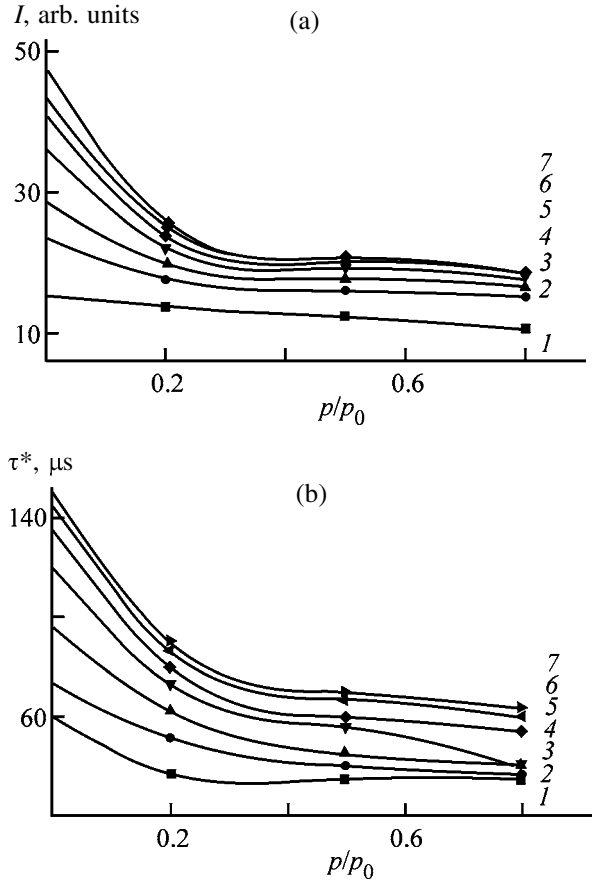

Fig. 4. (a) Luminescence intensity I and (b) lifetime of the excited state τ^* in a series of $TbCl_3$/PG samples as functions of the relative humidity p/p_0. Content of $TbCl_3$, μmol g^{-1}: (*1*) 1.5, (*2*) 10, (*3*) 20, (*4*) 40, (*5*) 60, (*6*) 90, and (*7*) 120.

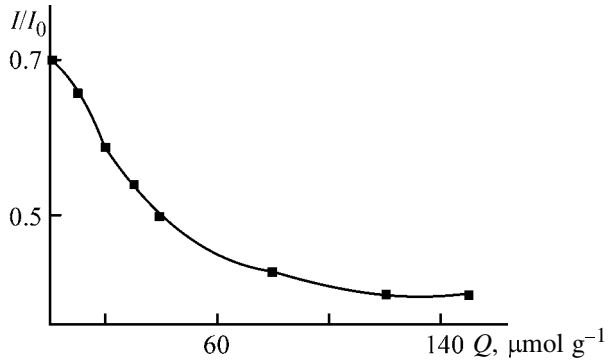

Fig. 5. Normalized intensity of the hypersensitive transition band I/I_0 at $p/p_0 = 0.8$ as a function of the $TbCl_3$ content Q in porous glass.

molecules with their affinity for water compensate the decrease in the adsorption activity of silanol groups on the glass surface, caused by their shielding.

The dependences of the intensity of the $^5D_4 \rightarrow {}^7F_4$ transition band and lifetime of the excited state on the relative humidity for a series of $TbCl_3$/PG samples are shown in Fig. 4. As seen, the main luminescence quenching is observed in the initial stage of adsorption. This fact suggests that water molecules are incorporated in the coordination sphere of Tb^{3+}, which determines the nonradiative loss of the energy of the excited state as a result of its interaction with high-frequency vibrations ν_{OH} [10]. Moreover, the most intense quenching is observed for samples with a high content of terbium(III) chloride. This feature is additionally illustrated by the dependence of normalized intensity I/I_0 (reflecting the extent to which the initial intensity decreases upon attainment of the relative humidity $p/p_0 = 0.8$) on the intercalate content (Fig. 5). Thus, the number of centers excluded from the luminescence process owing to water desorption decreases by 30% with a decrease in Q from 150 to 1.5 μmol g^{-1}. Such a behavior probably reflects the specificity of distribution of water molecules over the adsorption centers of silica and modifying agent. Therefore, small amounts of $TbCl_3$ in porous glass only slightly participate in the adsorption, which predominantly proceeds on the free surface OH groups. However, with increasing degree of the surface filling, intercalate molecules begin to dominate in water adsorption, which causes an increase in the quenching of their luminescence.

CONCLUSION

The maximal intensity of the luminescence of terbium(III) chloride in porous glass is attained at its

content of 120 μmol g^{-1}, which is close to that at monomolecular filling of the support surface. The concentration dependences of the luminescence and the features of its quenching in the presence of adsorbed water are consistent with the concept of molecular fragmentation and uniform distribution of the impregnated salt over the support surface.

Received October 12, 2005; in final form, April 2006

Abstract—The conditions of complexation of 1,2-diacylhydrazines (H_2L) $C_6H_5C(O)NHNHC(O)R$, where R = C_6H_5 or CH_3, with Cu(II) ions in alkaline solutions were studied. The composition of the complexes formed by precipitation of Cu(II) from alkaline solutions, $(CuOH)_2L$ and CuL, was determined. The possibility of afterpurification of solutions with a low Cu(II) content by pneumatic flotation using H_2L was examined.

DOI: 10.1134/S1070427207030056

1,2-Diacylhydrazines $RC(O)NHNHC(O)R$ (H_2L) are tetradentate ligands and form stable flotation-active complexes ML with ions of Cu(II) and other nonferrous metals in ammonia or alkaline solutions [1, 2]. Replacement of alkyl radicals in symmetrical 1,2-diacylhydrazine molecules by phenyl radicals enhances the acid properties of the reagent, so that poorly soluble complexes of 1,2-dibenzoylhydrazine (DBzH) with Cu(II) are formed in ammonia solutions at pH 5–8 [3].

The goal of this study was to examine the conditions of complexation of 1,2-diacylhydrazines $C_6H_5 \cdot C(O)NHNHC(O)R$, where R = C_6H_5 or CH_3, with Cu(II) ions in alkaline solutions and the possibility of using these reagents for afterpurification of wastewater to remove Cu(II) after precipitation of the major amount of Cu(II) in the form of $Cu(OH)_2$.

EXPERIMENTAL

1,2-Dibenzoylhydrazine was prepared as described in [4], by thermal decomposition of $2C_6H_5COOH \cdot N_2H_4 \cdot H_2O$ [4]; 1-acetyl-2-benzoylhydrazine (BAH) was prepared similarly by the reaction of benzhydrazide with concentrated acetic acid. The main substance content in the reagent samples was 97% as determined by conductometric titration on an OK-102/1 conductometer (Hungary) with a bell-shaped OK-0902P electrode [5]. The optical density of solutions was measured on SF-26 and KFK-2 spectrophotometers, and pH, on an EV-74 pH meter with glass and silver chloride electrodes. The IR spectra were recorded in mineral oil on a Specord M 80 spectrophotometer. The derivatograms were taken on an MOM Q-1500D derivatograph (Hungary). The Cu(II) concentration in solution was determined by an extraction-photometric method with sodium diethyldithiocarbamate [6].

Complexation of reagents with Cu(II) ions was studied by the precipitation method, because the precipitates formed are insoluble in water and common solvents. Figure 1 (curve *4*) shows that the maximal

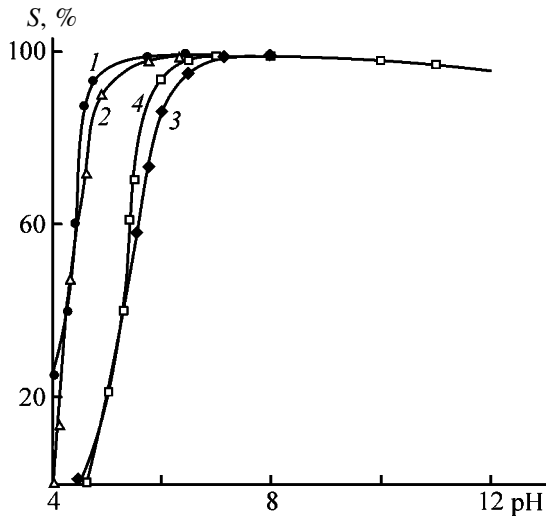

Fig. 1. pH dependences of the recovery *S* of Cu(II) ions with (*1*) DBzH, (*2*) BAH, and (*3*) DPH, and (*4*) in the form of $Cu(OH)_2$ without adding reagents. $c_{Cu(II)} = 63.5$ mg l^{-1}, $c_{H_2L} = 10^{-2}$ M in EtOH; [Cu(II)] : [H_2L] = 1 : 1, $\tau = 5$ min.

degree of precipitation of Cu(II) in the form of $Cu(OH)_2$ under the action of alkali is 99.8% in the pH range 7.0–10.0. The 99.9% precipitation of Cu(II) in the presence of DBzH was observed at pH 5.5 (curve *1*); in the presence of BAH, at pH 6.3 (curve *2*); and in the presence of dipropionylhydrazine (DPH), at pH 7 (curve *3*). These differences can be accounted for by considering the dissociation of 1,2-diacylhydrazines:

$$H_2L \xrightleftharpoons{pK_{a_1}} HL^- \xrightleftharpoons{pK_{a_2}} L^{2-}. \quad (1)$$

The acid properties of the reagents under consideration increase in the order DPH (pK_{a_1} 11.21 ± 0.04, pK_{a_2} 12.5 ± 0.3 [7]) < BAH (pK_{a_1} 9.37 ± 0.03, pK_{a_2} 10.9 ± 0.2) < DBzH (pK_{a_1} 9.22 ± 0.04, pK_{a_2} 10.8 ± 0.3 [3]). Therefore, the complexation of Cu(II) with DPH occurs in neutral and weakly alkaline solutions, whereas BAH and DBzH form complexes with Cu(II) even at pH 4.5–5.

We calculated the amount of H^+ (moles) released in complexation of DBzH and BAH with Cu(II) at varied pH_{eq} and constant concentration ratio Cu(II) : H_2L = 1 : 1 by slope analysis in the coordinates log ε–pH_{eq}, where ε is the sorption ratio [$\varepsilon = S_i/(1 - S_i)$]. Equations (2) and (3) wre obtained by the least-squares method for BAH and DBzH, respectively:

$$\log\varepsilon = 1.8 \pm 0.1 \quad (r = 0.9995,\ n = 4,\ P = 0.95), \quad (2)$$

$$\log\varepsilon = 1.7 \pm 0.1 \quad (r = 0.9995,\ n = 4,\ P = 0.95). \quad (3)$$

Hence, Cu(II) ions form with DBzH and BAH the complexes CuL in which the ligand is double-deprotonated.

The composition of the complexes was confirmed by potentiometric titration. For this purpose, a 100-ml beaker was charged with 5.0 ml of a 0.9×10^{-3} M solution of $CuSO_4$ and 60 ml of a 1 : 1 EtOH–H_2O mixture. The resulting solution was titrated with 1×10^{-3} M solutions of potassium salts of the reagents. The complexation with DBzH and BAH occurred in steps; the bends in the curve were observed at Cu(II) : H_2L concentration ratios of 2 : 1, 1 : 1, and 1 : 2 (Fig. 2).

Then we isolated complexes at the Cu(II) : H_2L concentration ratios of 1 : 1 and 2 : 1 in alkaline solutions. A 250-ml beaker was charged with 50 ml of a 1×10^{-2} or 2×10^{-2} M solution of $CuSO_4$, 1.6 ml of a 1×10^{-1} M KOH solution was added, and 50 ml of a 1×10^{-2} M solution of DBzH or BAH in ethanol

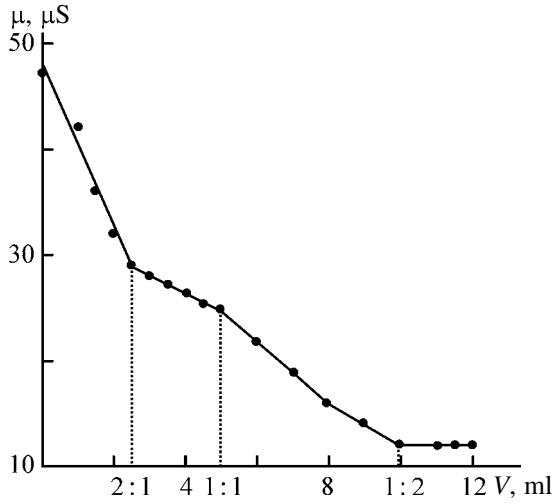

Fig. 2. Electrical conductivity μ of a $CuSO_4$ solution as a function of the precipitant (BAH) solution volume *V* (alkaline medium). $c_{Cu(II)} = 0.9 \times 10^{-3}$ M, $c_{BAH} = 10^{-3}$ M.

was added with stirring. The mixture was allowed to stand for 20 min. The precipitates were filtered off, washed on the filter with ethanol and hot water, and dried in air.

With DBzH and BAH at a Cu(II) : H_2L concentration ratio of 2 : 1 we obtained green precipitates, and at the 1 : 1 ratio, brown precipitates insoluble in water and common organic solvents, which is characteristic of polymeric compounds.

Analysis of the precipitates for Cu(II) gave the following results, wt %: [Cu(II)] : [DBzH] = 1 : 1, 20.75 and 2 : 1, 28.82; [Cu(II)] : [BAH] = 1 : 1, 25.9 and 2 : 1, 33.87. The composition of the complexes corresponds to the following formulas [calculated Cu(II), wt %]: $[Cu(C_6H_5OCNNCOC_6H_5)]$, 21.06; $[(CuOH)_2 \cdot (C_6H_5OCNNCOC_6H_5) \cdot 2H_2O]$, 29.20; $[Cu(C_6H_5O \cdot CNNCOCH_3)]$, 26.51; and $[(CuOH)_2(C_6H_5OCNN \cdot COCH_3) \cdot 2H_2O]$, 34.05.

To determine the structure of the complexes, we recorded their IR spectra. As compared to the starting DBzH and BAH, the IR spectra of the complexes do not contain stretching vibration bands of the C=O and N–H bonds, but contain bands at 1395–1404 cm^{-1} corresponding to stretching vibrations of C–O single bonds. The bands at 1520–1535 cm^{-1}, absent in the spectra of the starting diacylhydrazines, can be assigned to stretching vibrations of the C=N bonds [8]. Thus, the IR spectra confirm that Cu(II) ions form complexes with the reagent molecules in the double-deprotonated enol form. The spectra of the 2 : 1 complexes, in contrast to those of the 1 : 1 complexes,

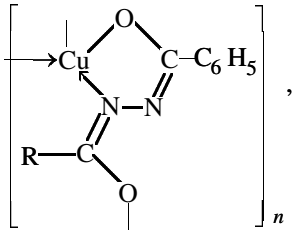
Calculated solubility products SP and molar solubilities S of the complexes CuL with reagents $C_6H_5C(O)NHNHC(O)R$ in alkaline solutions

R	$c_{Cu} \times 10^4$, M	$c_{H_2L} \times 10^4$, M	S_i, %	$[Cu]^b_{eq} \times 10^6$, M	pH_{eq}	$c_{L^{2-}} \times 10^{12}$, M	$c_{Cu^{2+}} \times 10^6$, M	–log SP	$S \times 10^9$, M
CH_3	8.9	8.9	99.8	1.57	7.0	1.8	1.57	17.6	1.70
C_6H_5	10.0	10.0	99.9	1.26	6.5	0.1	1.26	18.9	0.35

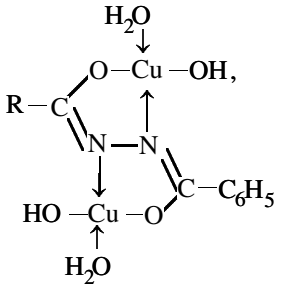
also contain absorption bands in the range 3350–3520 cm^{-1} corresponding to stretching vibrations of hydroxy groups and water of crystallization. The presence of water of crystallization is also confirmed by thermal analysis of the complexes. The DTA curve exhibits endothermic peaks in the interval 170–210°C with maxima at 180°C for the Cu–BAH (2 : 1) complex and at 190°C for the Cu–DBzH (2 : 1) complex, assignable to the loss of water of crystallization.

On the basis of the above facts, the suggested structures of the 2 : 1 and 1 : 1 complexes can be presented by formulas (4) and (5), where R = CH_3 or C_6H_5.

The complexation of DBzH and BAH with Cu(II) ions in alkaline solution at a component ratio of 1 : 1 can be described by Eq. (6).



(4)



(5)

$$Cu^{2+} + H_2L + 2OH^- \rightleftarrows CuL\downarrow + 2H_2O. \quad (6)$$

To calculate the equilibrium concentrations of Cu^{2+} and L^{2-}, we used data from [9].

The solubility products SP and molar solubilities S of the complexes, calculated from data in Fig. 1, are given in the table. It is seen that the molar solubilities of the precipitates of the complexes are lower than that of $Cu(OH)_2$ (1.8×10^{-7} M [10]) by two orders of magnitude. Therefore, Cu(II) ions are recovered from alkaline solutions in the form of complexes with the ligands in question more completely than in the form of $Cu(OH)_2$.

We found that, at the initial Cu(II) concentration of 57 mg l^{-1}, precipitation of the complexes at the 1 : 1 component ratio reduces the residual Cu(II) concentration to 0.08 mg l^{-1} with DBzH and 0.1 mg l^{-1} with BAH. However, to precipitate Cu(II), large amounts of the reagent should be added [2.8 mg of BAH per milligram of Cu(II)], and the reagent is not regenerated. Therefore, it was interesting to examine the possibility of additional recovery of Cu(II) ions from solutions with their low content [after precipitation of Cu(II) in the form of $Cu(OH)_2$] by pneumatic flotation with BAH.

To a solution containing 3 mg l^{-1} of Cu(II) [after precipitation of $Cu(OH)_2$ with NaOH], we added BAH in 0.1 M KOH or in ethanol at the [Cu(II)] : [BAH] ratio of 1 : 1 or 1 : 2; the mixture was stirred for 1–2 min. The precipitates, Cu(II) complexes with the reagents, passed into the foam and were removed from the solution. The flotation installation and the experimental conditions were similar to those described in [11]. The experiments were performed at 20±2°C. The sample of the purified solution was taken through a sampler and analyzed for the residual Cu(II) content by the extraction-photometric method [6]. The degree of additional recovery of Cu(II) at pH 9 was 83.8 and 95%; the residual concentration of Cu(II) ions was 0.5 and 0.15 mg l^{-1}, respectively, which is below MPC for household water [12].

CONCLUSIONS

(1) Conditions for complexation of Cu(II) with 1,2-dibenzoyl- and 1-benzoyl-2-acetylhydrazines in the course of precipitation were optimized. The 1 : 1 and 2 : 1 complexes of Cu(II) with H_2L were isolated from alkaline solutions (pH ~9) and identified.

(2) Replacement of one phenyl radical in 1,2-dibenzoylhydrazine by the acetyl radical increases the solubility of the complex and decreases the degree of recovery of Cu(II) ions.

(3) 1-Acetyl-1-benzoylhydrazine is suitable for afterpurification of wastewater by pneumatic flotation after precipitation of Cu(II) with alkali in the form of $Cu(OH)_2$.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Lead and Copper Ions on Synthetic Apatite Samples Produced by Melt Thermal Process

Abstract—The possibility of using calcium fluoro- and hydroxylapatites synthesized in a NaCl–KCl salt melt as sorbents of heavy metal ions from aqueous solutions was analyzed. The sorption products formed were identified by chemical and X-ray phase analyses and diffuse reflection spectroscopy.

DOI: 10.1134/S1070427207030068

To the class of apatites belong compounds of the composition $M_{10}(ZO_4)_6X_2$, where M most frequently stands for Ca, Sr, Ba, Eu, Pb, Cd, and other ions with a charge of +2; Z = P, V, and other ions with a formal charge of +5; and X = OH, F, Cl, Br, and other ions with a charge of –1. In recent years, a considerable success has been achieved in basic research and development of technologies for production of apatite materials with prescribed properties, which initiated efforts aimed at their large-scale industrial production [1, 2]. Calcium fluoroapatite (CaFAp) and, especially, calcium hydroxylapatite (CaHAp) are close in chemical composition and structure to the inorganic component of bones, and, therefore, are promising as artificial biologically compatible implants. They are capable of isovalent substitution of calcium ions in a wide range of compositions, which enables their use as supports for luminescent materials and hosts for disposal of radioactive wastes. At the same time, this property of apatite is negatively manifested as the ability of the bone tissue to accumulate toxic heavy metals (lead, cadmium, mercury, etc.) upon prolonged exposure of vertebrate organisms (including humans) to an environment containing increased concentrations of these toxicants.

In this study we examined the possibility of using apatites produced by melt thermal process (synthesis in a NaCl–KCl salt melt) as sorbents of certain heavy metals (lead, copper) from aqueous solutions.

EXPERIMENTAL

The previously developed melt thermal process, applied to synthesis of apatites, combines the main advantages of "dry" (short process duration) and "wet" (completeness of the reaction and sufficiently high dispersity of the products formed) techniques. Apatites were produced by the reaction of an intimate mixture (stock) of the starting compounds: CaF_2 (in the case of CaFAp) or $Ca(OH)_2$ (in the case of CaHAp), CaO, $CaCO_3$, and KPO_3 in a NaCl–KCl melt of equimolar composition at an approximately 1 : 1 mass ratio of the stock and the eutectic mixture in an Alundum crucible in open air at 700°C. The synthesis duration did not exceed 2 h. The product was formed as a cake having the shape of the crucible, which was readily detached from the latter. The cake was removed from the crucible, ground, and washed several times with distilled water to a weakly alkaline reaction (pH 7.58), after which it was dried in an oven at $T \approx 150$°C. The resulting material had the form of a white fluffy powder. The yield of the product was about 98%, and its mass, about 50 g. The phase composition of the apatites obtained was determined by X-ray phase analysis (XPA) on a DRON-3 installation by the standard technique. According to XPA data, all the samples obtained were highly crystalline and contained only the phase of the corresponding apatite. The specific surface area of the powders was estimated at approximately 10 $m^2\ g^{-1}$, which corresponds to an average particle size of about 0.1 μm. The particle size distribution was not studied in detail.

To study the sorption of Pb^{2+} ions, two 50-ml portions of 1 M solution of $Pb(NO_3)_2$ were prepared by dissolving weighed portions of anhydrous $Pb(NO_3)_2$ in distilled water in volumetric flasks of appropriate capacity. The concentration of the solutions was checked by titration. The content of Pb^{2+} ions in the

solutions was determined by direct chelatometric titration in a weakly acidic medium (pH ~5) in the presence of Xylenol Orange indicator. An acetate buffer solution was used to maintain constant pH. A standard (0.05 M) solution of Na_2EDTA served as a titrant. To an aliquot of the solution were added 5 ml of the buffer solution and 2 drops of a 0.1% solution of the indicator, and the mixture was titrated with a solution of Na_2EDTA until the coloration changed from pink to yellow. The analysis yielded a concentration of 0.1005 M, which is close to the preset value. The solution pH indicated a weakly acidic medium (4.55). The pH was measured with a pH-121 instrument with a glass working electrode and a silver chloride reference electrode.

To study the sorption, a 2.0000-g portion of the apatite obtained was placed in a beaker and the solution prepared was added. In order to prevent evaporation of water, the vessel was hermetically sealed with a polyethylene film. The sorption was studied under static conditions with intermittent (twice in 24 h) manual agitation at a temperature of about 20°C. It was noticed that the pH of the medium changed only slightly during sorption (to 4.99 for CaFAp and 5.15 for CaHAp by the end of the process). The concentration of Pb^{2+} ions in solutions brought in contact with the sorbents was determined in 24 and 72 h; the volume of the solution samples taken was 5.0 ml. According to chemical analysis data, the content of Pb^{2+} ions in solution after sorption on CaHAp is considerably lower than that after sorption on CaFAp (see table). The absolute value of sorption, Γ (mmol g^{-1}), was calculated by the formula

$$\Gamma = \frac{c_0V_0 - cV}{m_0},$$

where c_0 and c are the initial and running concentrations of Pb^{2+} ions in the solution (M); V_0 and V, initial and running volumes of the solution (ml); and m_0, initial mass of the sorbent (g).

These data were used to plot time dependences of the Pb^{2+} sorption on CaFAp and CaHAp (Fig. 1, curves *1a* and *1b*). It can be seen that the sorption equilibrium is not attained during the experiment.

To elucidate the mechanism of sorption of Pb^{2+} ions, the content of Ca^{2+} ions in the solutions under study was determined upon the completion of the process by a procedure similar to that for Pb^{2+}. This was done at pH > 10 after Pb^{2+} ions were precipitated with potassium iodide as PbI_2. An analysis demonstrated that a considerable amount of Ca^{2+} ions appeared in the solutions under study. This amount is not equivalent to the decrease in the content of Pb^{2+} ions in solution. For example, the concentration of Ca^{2+} ions is lower by a factor of 3.5 for CaFAp and by a factor of more than 5 for CaHAp, compared with the decrease in the concentration of Pb^{2+}. This fact indicates that the ion exchange plays an important, but not a key role in Pb^{2+} sorption from solution; it is inconsistent with the statement that the sorption process has an ion-exchange nature [5] and confirms the data obtained in [6]. The sorption products obtained were separated from the solutions by filtration and kept in an oven at 70°C to constant weight. A significant gain in the sorbent mass, Δm, due to sorption of Pb^{2+} is observed, with the value of Δm for CaHAp markedly exceeding that for CaFAp. A chemical analysis demonstrated that lead(II) is present in the sorption products, with its content being in satisfactory agreement with the mass gain of apatite samples and Γ values (see table).

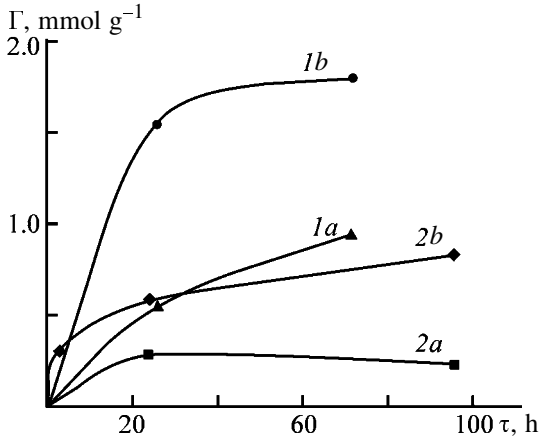

Fig. 1. Kinetic curves of sorption Γ of (*1*) Pb^{2+} and (*2*) Ca^{2+} ions on (*a*) CaFAp and (*b*) CaHAp. (τ) Time.

The products formed in sorption of Pb^{2+} ions by the apatites were studied, upon thorough drying, by XPA and diffuse reflection spectroscopy (DRS). The X-ray diffraction patterns of the starting sorbents significantly change after sorption (Figs. 2a, 2b). According to XPA data, the phases of the starting apatites undergo partial decomposition, with separate phases formed on the basis of PbFAp and PbHAp (see table). Presumably, this is due to the substantially larger radius of Pb^{2+} ions (0.126 nm), compared with Ca^{2+} ions (0.104 nm), which hinders incorporation of Pb^{2+} ions into the structure of the calcium apatite. In addition, strong absorption bands characteristic of Pb^{2+} compounds appear in the DRS spectra in the UV range (Fig. 3, curves *2a*, *2b*). It should be noted

Summary data on sorption of heavy metal ions on apatites

M^{2+}	Sorbent	$c_{M^{2+}}$ final	$c_{Ca^{2+}}$ in solution	Δm of sorbent, g (%)	Content of M^{2+} in sorbent, wt %	Phase composition of sorbent

that the intensity of the absorption band for the product of Pb^{2+} sorption on CaHAp markedly exceeds that for the product of Pb^{2+} sorption on CaFAp, even though there is no complete correlation between the band intensities and Pb^{2+} contents of the sorption products.

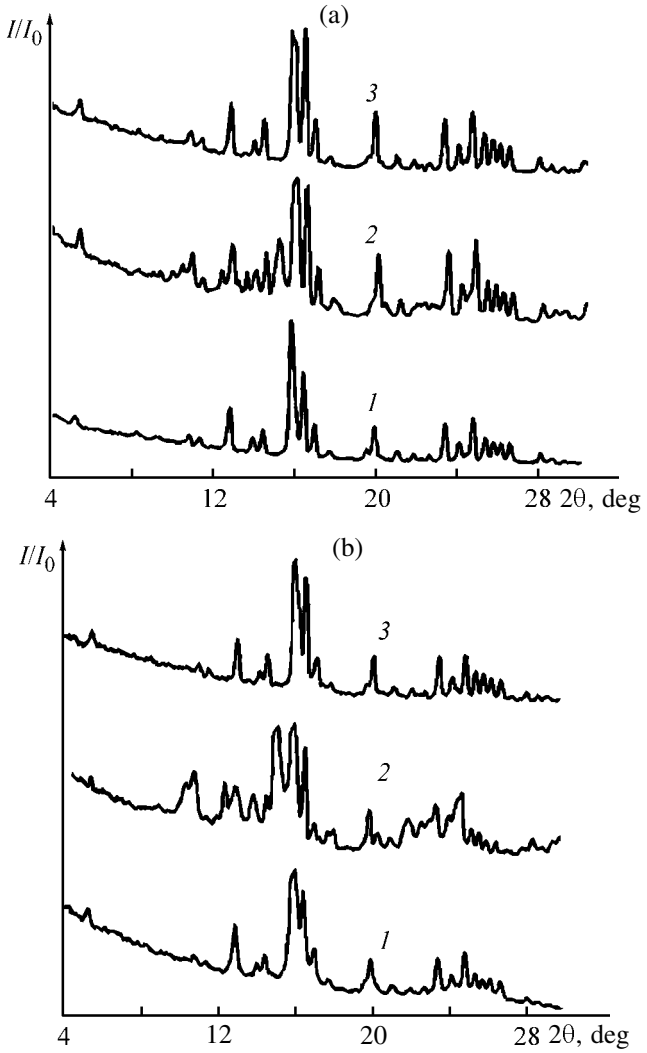

Fig. 2. X-ray diffraction patterns of (*1*) starting sorbent [(a) CaFAp and (b) CaHAp] and products of sorption of (*2*) Pb^{2+} and (*3*) Cu^{2+}. (I/I_0) Relative intensity and (2θ) Bragg angle.

Preliminary experiments demonstrated that Cu^{2+} ions are sorbed by the apatites to a lesser extent than Pb^{2+} ions. Therefore, 4.00-g portions of CaHAp and CaFAp powders were taken to study the sorption of Cu^{2+} ions. To the sorbents we added 100 ml of a 0.1 M $CuSO_4$ solution prepared by dissolving a weighed portion of $CuSO_4 \cdot 5H_2O$ in distilled water in a volumetric flask. The concentration of Cu^{2+} ions, $c_{Cu^{2+}}$, in the solutions was photometrically determined on an SF-26 spectrophotometer at a wavelength of 810 nm, which corresponds to the absorption maximum of $[Cu(H_2O)_4]^{2+}$ ions. According to chemical analysis data, the concentration of Cu^{2+} ions in a solution that was brought in contact with CaHAp is

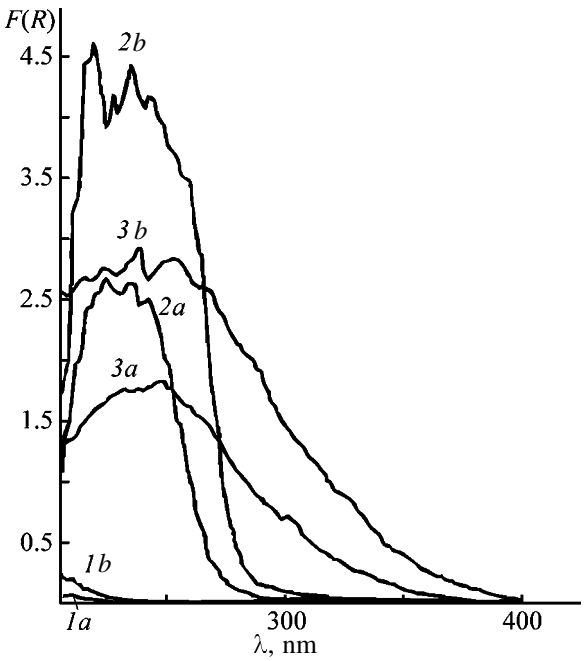

Fig. 3. Diffuse reflection spectra of (*1*) starting apatites and products of sorption of (*2*) Pb^{2+} and (*3*) Cu^{2+} ions on (*a*) CaFAp and (*b*) CaHAp in the UV range. [$F(R)$] Kubelka–Munk function and (λ) wavelength.

lower than $c_{Cu^{2+}}$ in a solution with CaFAp (see table). The concentrations of Cu^{2+} in solutions that were brought in contact with the sorbents were determined in 24 and 96 h.

The values of Cu^{2+} sorption were calculated by a formula similar to that presented above. Data on the sorption of Cu^{2+} ions from an aqueous solution on CaFAp and CaHAp are listed in the table, and the time dependences of Γ are shown in Fig. 1, curves *2a* and *2b*. This evidence indicates that the sorption on CaHAp is more effective, compared with that on CaFAp. On the whole, the sorption of Cu^{2+} on apatites is considerably weaker than that of Pb^{2+}. In addition, an interesting specific feature of Cu^{2+} sorption on CaFAp is that the saturation range is reached.

According to XPA, the sorption of Cu^{2+} ions does not change the phase composition of the starting apatites and only distorts their lattices. Figures 2a and 2b show that the X-ray diffraction pattern of the product of Cu^{2+} sorption on CaHAp is closely similar to that of the starting CaFAp and of the product of Cu^{2+} sorption on CaFAp. This fact can be explained as follows. The ionic radius of Cu^{2+} (0.080 nm) is markedly smaller than that of the Ca^{2+} ion (0.104 nm), and, therefore, partial substitution of Ca^{2+} by Cu^{2+} ions is possible in the structure of CaHAp. This should lead to contraction of its lattice, with its structure becoming more similar to that of CaFAp. Analogous distortions of the CaFAp structure upon sorption of Cu^{2+} ions must be less pronounced because of the considerably smaller value of sorption.

As in the case of Pb^{2+} sorption, strong but broadened absorption bands characteristic of Cu^{2+} compounds appear in the DRS curves of dried products of Cu^{2+} sorption on apatites in the UV range (Fig. 3, curves *3a* and *3b*). Their intensity qualitatively correlates with the content of Cu^{2+} in the products of sorption on the apatites, which is considerably (6–10 times) lower than that of Pb^{2+} (see table). The change in the mass of the sorbents upon sorption is also considerably smaller in the last case (see table). This is due, on the one hand, to the close atomic masses of Cu and Ca and, on the other hand, to the lower sorbability of Cu^{2+} ions, compared with Pb^{2+}. Presumably, the mechanism of Pb^{2+} sorption with disintegration of the structure of the starting sorbents is more effective than the mechanism of Cu^{2+} sorption via incorporation into the apatite structure. A similar conclusion was made in [7]. In addition, a certain role is presumably played by differences in the degrees of hydration of Pb^{2+} and Cu^{2+} ions. This parameter is considerably larger for Cu^{2+}, which also hinders sorption.

CONCLUSIONS

(1) It was found that sorption of Pb^{2+} ions on calcium fluoro- and hydroxylapatites leads to formation of separate phases based on lead apatites. In the case of sorption of Cu^{2+} ions on the apatites, the ions are incorporated into the structure of the apatites, with its subsequent distortion.

(2) It was demonstrated that the efficiency of sorption on the hydroxylapatite markedly exceeds that on the fluoroapatite. This makes it possible to recommend hydroxylapatite, including (and especially) that of natural origin, as a promising sorbent of ions of toxic heavy metals from aqueous media.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Chromium(VI) on Ion-Exchange Resins and Sorbents

S. L. Alekseeva, S. N. Bolotin, and T. G. Tsyupko

Kuban State University, Krasnodar, Russia

Received June 6, 2006; in final form, September 2006

Abstract—Sorption of Cr(VI) on AV-17 and EDE-10P anion exchangers, KU-2 and KB-4 cation exchangers, activated charcoal, and foamed graphite (STRG) is studied.

DOI: 10.1134/S107042720703007X

Transition metals are persistent cumulative pollutants of natural waters. Generally, they demonstrate a strong tendency to hydrolysis and complexation, forming products stable in water [1]. Among the most toxic pollutants are chromium compounds (natural Cr concentration in natural waters is relatively small, 0.1–0.6 $\mu g\ l^{-1}$) [1]. Technogenic Cr compounds can remain migrationally active in aquatic systems for a long time [2].

Treatment of natural and waste waters to remove Cr salts is complicated by its very complex redox chemistry and complexation with natural compounds [3]. It is often necessary to remove chromium in water pretreatment and also in analytical practice (in the stage of preconcentration of an analyte to eliminate the interfering effect of Cr). For these purposes, ion exchange is widely used. Therefore, optimization of ion-exchange procedure to remove Cr compounds, including decision on the ion-exchange resin and sorbent, is a topical problem.

Vishnevskaya et al. [4, 5] reported on the interaction of Cr(III) and Cr(VI) with the sites of various cation- and anion-exchange resins in the course of static sorption. It was concluded from the ESR spectra of the Cr-containing resins that, in these systems, the ion exchange is accompanied by redox reactions of Cr.

In this study we examined the mechanisms of ion exchange of Cr(III) and Cr(VI) on AV-17 and EDE-10P anion exchangers and KU-2 and KB-4 cation exchangers, and also of their sorption on activated charcoal and foamed graphite (STRG) in the dynamic mode (laminar flow mode).

In the experiments we used potassium dichromate solutions with Cr concentrations of 1.0, 1.5, and 2.0 $mg\ l^{-1}$ (pH 5.5 and 6.0). The experiments were conducted in the dynamic mode using the laminar flow mode. The solutions were passed through the columns at a velocity of 1 $cm\ min^{-1}$. The eluate was analyzed for Cr(III) and Cr(VI) photometrically using the standard procedure [2] based on the reaction of hexavalent chromium with diphenylcarbazide under acid conditions to form a red-violet compound containing Cr(III) and diphenylcarbazone. In this method, the Cr concentration should be within 0.01–1.0 $mg\ l^{-1}$, and dilution or preconcentration was used to adjust the Cr concentration to this range.

pH was measured on an EV-U4 ion meter with an ESL-63-07 glass electrode using an Ag/AgCl reference electrode.

The ESR spectra were recorded on a RADIOPAN SE/X 2543 instrument. The magnetic field was determined using a JTM-6 built-in NMR magnetometer. The samples after sorption were kept in air to constant weight.

Figure 1 shows the elution curves of Cr(VI) for anion exchangers AV-17 (Fig. 1a) and EDE-10P (Fig. 1b), and cation exchangers KU-2 (Fig. 1c) and KB-4 (Fig. 1d). In the former two cases, the shape of the curves is classical: initially the Cr(VI) concentration in the eluate is nearly zero, and then it increases to reach that in the starting solution.

AV-17 anion-exchange resin contains only one kind of sites (quarternary ammonium groups), whereas EDE-10P is a polyfunctional resin with the hydroxyl as a counterion. It may be suggested that, depending on pH, the dichromate is absorbed from the

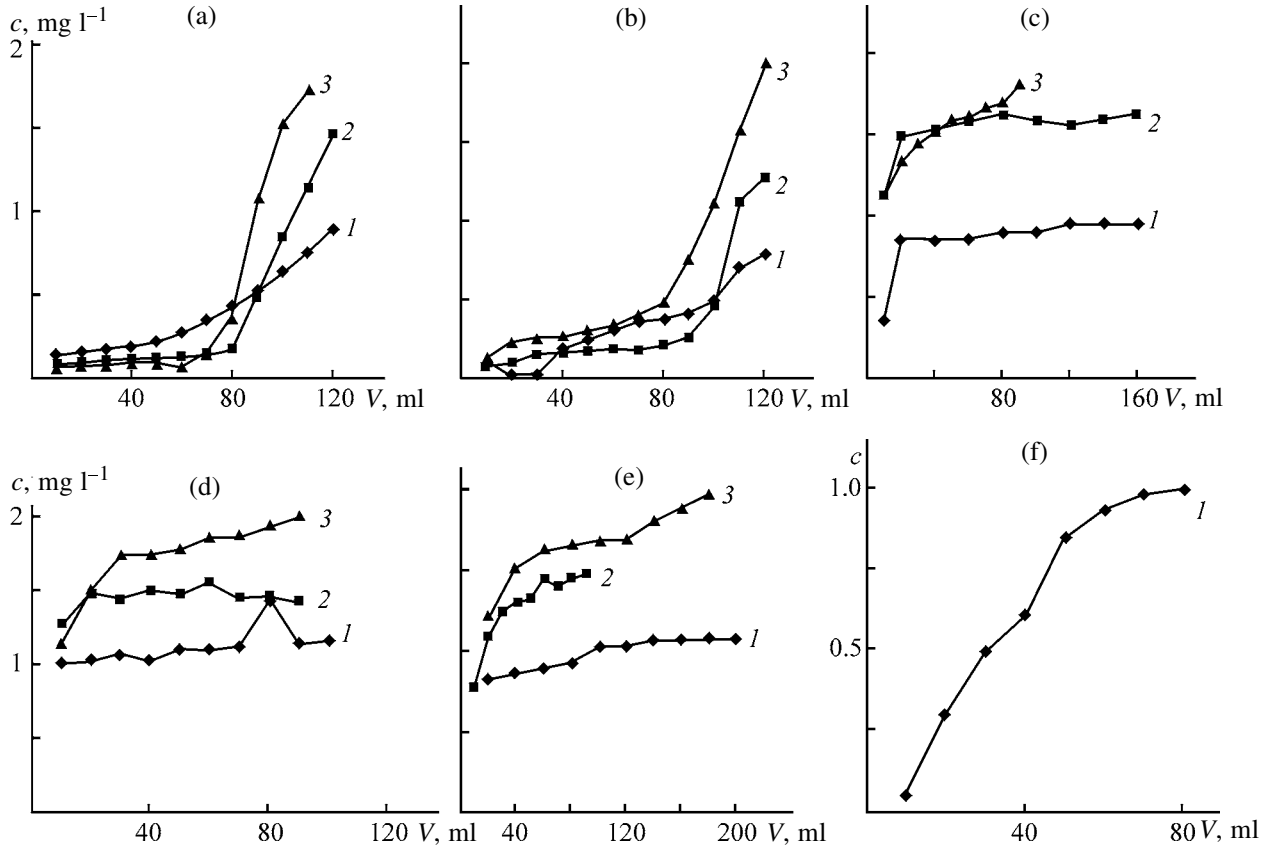

Fig. 1. Cr(VI) concentration c in the eluate. Initial $K_2Cr_2O_7$ concentration, mg l^{-1}: (*1*) 1.0, (*2*) 1.5, and (*3*) 2.0. Columns: (a) AV-17, (b) EDE-10P, (c) KU-2, (d) KB-4, (e) activated charcoal, and (f) STRG. (*V*) Eluate volume.

solution according to the following reactions:

$$2ROH + K_2Cr_2O_7 = R_2Cr_2O_7 + 2KOH,$$

$$4ROH + K_2Cr_2O_7 + H_2O = 2R_2CrO_4 + 2KOH.$$

This is supported by the fact that the dynamic exchange capacity is practically independent of the starting solution concentration.

At the same time, for these ion exchangers, we detected Cr(III) in the eluate, and its concentration increased with increasing concentration of the starting solutions. Evidently, in sorption of the dichromate ions from weakly acidic solutions, in the interfacial diffuse layer, Cr(VI) can be reduced to Cr(III) by the organic matter of the resin:

$$Cr_2O_7^{2-} + 14H^+ + 6e = 2Cr^{3+} + 7H_2O.$$

In studying the static sorption of potassium dichromate on an anion-exchange resin, Vishnevskaya et al. [4, 5] demonstrated the appearance of Cr(III) in the resin phase. Their thought is that the reduction of Cr(VI) can occur only in the resin phase. In this study we obtained similar results for the dynamic mode of sorption. The occurrence of Cr(III) in the eluate suggests that, after reduction of the adsorbed complex containing the dichromate ions, Cr(III) is partially eluted from the resin.

Figures 1c and 1d show that the sorption of the dichromate ions on the cation exchangers is not an ordinary process: After passing the potassium dichromate solution through the columns, we found Cr(III) in the eluate, which suggests that in this case Cr(VI) is reduced at the interface also.

Then chromium is sorbed on the cation exchanger in the form of Cr(III). As a result, the Cr(VI) concentration in the eluate decreases, and Cr(III) is detected in the eluate.

It is seen from the sorption curves of Cr(VI) on the anion exchangers that, after passing the starting solution, the Cr(VI) concentration abruptly decreases, suggesting absorption of Cr(VI). Then the Cr concentration in the eluate gradually increases to reach that in the initial solution, suggesting the ion-exchange mechanism of sorption.

To characterize the sorption mechanism, we studied the ESR spectra of the air-dry samples of KU-2, AV-17, activated charcoal, and STRG. The occurrence of the signal in the ESR spectrum of KU-2 suggests the presence of paramagnetic Cr(III), which confirms that, in this case, Cr(VI) is reduced to Cr(III) through Cr(V) intermediate.

In the cases of activated charcoal and STRG (Figs. 1e, 1f), Cr is absorbed without changing its oxidation state.

CONCLUSION

Chromium is absorbed on ion exchangers and sorbents by both the classical mechanism and a mechanism involving a redox reaction, which can occur in both the resin phase and solution.

SORPTION AND ION-EXCHANGE PROCESSES

Mineral and Chemical Compositions and Structure–Sorption Properties of Bottom Sediments as the Basic Components of Enterosorbents and Application Materials

S. S. Stavitskaya, N. T. Kartel', N. N. Tsyba, M. F. Kovtun, and T. P. Petrenko

Institute of Sorption and Problems of Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received March 30, 2006; in final form, November 2006

Abstract—The mineral and chemical compositions, as well as some structure–sorption characteristics were determined for clay minerals selected for examination. The integrated coefficients of contamination of bottom sediments with each of the toxicant metals (Fe, Ni, Co, Cu, Zn, Pb, Mn) were calculated. The minerals examined presumably can be used in medicine as efficient application materials, cosmetic agents, and sorbents (enterosorbents).

DOI: 10.1134/S1070427207030081

The present environmental situation in many regions of Ukraine and other CIS countries is characterized by the occurrence of zones with enhanced contamination levels of toxic metals, in particular, radionuclides (RNs), which increases the number of environment-dependent diseases. Ever widening use in treatments and prevention of various diseases is found by sorption methods of detoxication [1–6], especially by the simplest method, enterosorption.

Enterosorbents are medical preparations of different structures, binding exo- and endogenic substances in the gastrointestinal tract (GIT) by adsorption, ion exchange, and complexing. The enterosorbents used either have a broad-action spectrum (combined enterosorbents) or exert selective action (selective enterosorbents), i.e., absorb toxicants, e.g., some RNs and heavy metals. In experts' opinion [6–14], combined enterosorbents are promising for solving the problem of body purification with simultaneous improvement of the basic biochemical parameters, i.e., normalization of the composition of the biological media.

Finding solutions to a wide range of problems of sorption therapy requires novel selective adsorption materials with polyfunctional ion-exchange sites. Such materials are prepared, e.g., from mechanical compositions made up of adsorbents principally differing in the nature, taken in strictly fixed proportions. For example, such compositions can include oxidized carbon [7, 8], a weakly acidic cation exchanger with a complexing function [15], and natural clay minerals exhibiting the properties of selective inorganic cation exchangers [9].

In our previous works [10, 11, 14] we showed that the properties of the initial components make a good combination in Ul'trasorb composite sorbent (earlier suggested for examination as a candidate medicinal substance of selective enterosorbents for treating diseases associated with accumulation of heavy metals and RNs in the body). This is evidenced by the corresponding distribution coefficients, which were estimated, e.g., at 30000 and over for radioactive cesium at the clay-to-carbon component ratio of 1 : 3.

Also, mention should be made of one of the developments of the Ukrainian sorption therapy, application sorbents, exhibiting unique properties in treatment of wounds and burns [6].

The underlying concept of this study is the use of mineral resources of the Black Sea (biologically active disperse minerals and other components of bottom sediments) as application materials, cosmetic agents, and enterosorbents for preparing medical formulations comprising a carbon component to treat GIT diseases and inflammatory processes in joints.

World practice of recent years suggests that the market of application medicinal materials, cosmetic agents, and enterosorbents based on natural biological complexes is steadily extending to include bottom sediments [16–20]. In this context, the use of raw materials of CIS countries for preparation of such

materials seems to be undoubtedly topical, promising, and environmentally attractive choice, as implementation of such a project can result in development of new, competitive, and efficient formulations based on inexpensive and readily available natural raw materials. This was the aim of our study.

The primary goal of the first stage was to select the objects for research and to examine the physicochemical, as well as the structure–sorption, properties of the preparations, making use of up-to-date methods of research.

The core material characterizing the bottom sediments from the northwest shelf of Crimea to the Caucasian shelf of Russia and Georgia was supplied by three expeditions organized in 2003–2005 with participation of staff members of the Research Institute of Geological Sciences, Ukraine. These samples were supplemented with those taken in different water bodies (lakes, limans of the Black Sea) and different regions of Ukraine. A total of 20 samples of silts of different origin and nature and bentonites taken at different depths, from 279 to 2026 m (Table 1), were examined. The bottom sediments from the Black Sea shelf are represented by clay–aleurite materials with quartz, feldspar, and other impurities. Out of eight samples of the core material, taken during the first expedition, we selected three samples: two samples of the Ukrainian origin, taken at station 24 from the Sevastopol beam and at station 31 from the town of Vilkovo beam, and, for comparison, a sample taken at station 34 from the Caucasian shelf (between Novorossiisk and Tuapse). Other materials were silts, bentonites differing in the appearance and color (pastelike, homogeneous, or having impurities, solid inclusions), differently behaving on drying as well: quickly or, on the contrary, slowly losing moisture at 100–120°C with a simultaneous change in color for some of the samples.

It is known that the pore structure characteristics allow predicting the performance of a sorbent under real conditions as part of a specific sorption technique. Therefore, we examined the structure–sorption characteristics of all the samples of the bottom sediments taken. Prior to measurements, the sorbents were dried in a desiccator at 100–120°C to constant weight and then thoroughly ground in an agate mortar. Based on the benzene vapor sorption, the sorption pore volume W_s, $cm^3\ g^{-1}$, was estimated by the desiccator method

* B is the moisture content of the sample; Δ, mass loss on calcination; A_{Mb}, Methylene Blue adsorption; and pH, pH of the water extract.

[21]; based on adsorption of Methylene Blue (MB) with the molecular weight of 319 amu, the pores of the samples were qualitatively analyzed [22]. Gas-chromatographic method of thermal desorption of argon [22] was applied to tentatively estimate the specific surface area of the bottom sediments S_{sp}, $m^2\ g^{-1}$, for Ar.

Using a NOVA 2200 E high-speed gas sorption analyzer, the isotherms of low-temperature (77 K) nitrogen sorption–desorption by the samples were measured; the specific surface area was calculated by the BET method [22]; the curves of differential ($dV/d\log r$) and integrated (V) distribution of the micropore volume with respect to the pore radii were obtained; the micropore volumes were determined by various calculation methods (Multi Point, BET Plot, BJH, DFT) at the chosen correlation coefficient of 0.999.

The mass losses on drying and calcination [22, 23] were determined for the preparation; pH of a water extract was measured; substances soluble in water [23] and mixtures of acids, HCl (1 : 1) and concentrated HNO_3 and H_2SO_4, were determined. Also, for some samples the amount of silicic acid $SiO_2 \cdot nH_2O$ was determined by the method of fusing the samples with Na_2CO_3 in platinum crucibles in a muffle furnace at 900°C [21, 23].

Chemical analysis of the solutions upon boiling the bottom sediments in water and in an acid mixture and upon melting and extraction of silicate was carried out by the atomic-adsorption method on a KAS-120.1 instrument (Table 2).

Table 2 presents the moisture content of the bottom sediments examined, the calcination loss, the amount of the samples soluble in water and in an acid mixture, pH of the water extracts, Methylene Blue adsorption (A_{MB}), S_{sp} estimated for argon, and the amount of silicic acid in some of the preparations examined. The sample nos. in Table 1 are identical to those in the tables and figures that follow.

Tables 3 and 4 present the chemical analysis data for the bottom sediments upon boiling in water and treating with an acid mixture, and Table 5, the calculated integrated coefficients of contamination against the reference (for each element mentioned in the MPC standards [17]). Table 6 gives a classification of the grounds for the Azov–Black Sea basin within Ukraine and the Sea of Azov. According to these data, the sediments examined belong to class A (naturally clean ground, reference); sample no. 1 was assigned to class II (moderately contaminated ground) only because of the content of Pb^{2+}.

Bazelyan et al. [24] and Berlinskii et al. [25] summarized the data on the content of heavy metal toxicants in the bottom sediments from the objects of dredging works in the Azov–Black Sea basin and

determined the levels of contamination with various microelements for the waters of ports in the western part of the Black Sea (Ust'-Dunaisk, Il'ichevsk, Odessa, Yuzhnyi, etc.) and in other regions: Kerch, Novorossiisk, Batumi, Anapa, Tuapse, and Sea of Azov ports (Mariupol, Taganrog). Strakhov [26] characterized the general features of distribution of elements over the surface layer area of the Black Sea, taking into account the migration forms of the elements in the river basins and the hydrodynamic regime of the surface oxygen zone of the water mass (Fe, Mn, Ni, Co, Cu, As).

Based on the concept postulating the existence of toxic concentration of elements, rather than of toxic elements proper [27], we calculated the contamination coefficients K_c [24]. The highest toxic concentrations were revealed for lead, nickel, copper, zinc, and, in some cases, for mercury. The highest contamination levels [24] for the bottom sediments were detected in the ports of Odessa, Nikolaev, and Kerch. For exam-

ple, the K_c parameters varied from 0.01 to 10 for zinc, from 0 to 3.7 for nickel, from 0.4 to 10.0 for copper, and from 0.2 to 7.6 for cobalt [24].

In the samples examined (Table 5), the amount of the nickel ions is of the same order as that reported in [24], and for the remaining toxicant metals, 1.5–3 times lower.

Of primary importance for correctly choosing the adsorbent for a specific practical application are the data on its pore structure. Above all, it is necessary to know whether the pore radius distribution corresponds to the molecular sizes of the specific sorbates and whether such a distribution provides sufficient penetration of these substances inside the sorbent granules. Depending on the size, the sorbent pores are typically divided into macro-, meso-, and micropores [9, 15, 28]. Most often, researchers deal with adsorbents of mixed structural types. This applies to clay minerals. Vermiculite is assigned to finely porous sorbents whose pore size varies during adsorption due to increase in the interplanar spacings, e.g., in adsorption of polar substances (methanol, water) [9]. Palygorskite is distinguished by the presence of finely porous zeolite channels in its structure.

Complete analysis of the pore structure of sorbents typically includes examinations using a set of physical and physicochemical methods, optical and electron microscopy, X-ray diffraction analysis, adsorption methods, and mercury porosimetry [22].

The use of microporous sorbents is expedient for removal from biological liquids of products with a low molecular weight, e.g., creatinine, aliphatic hydroxy acids, amino acids, uric acid, etc. Fairly uniformly porous sorbents of this kind allow solving to some extent the problem of selectivity of sorption, as for large molecules (hormones, vitamins, polypeptides) micropores are inaccessible, which prevents their absorption in appreciable amounts. The main characteristic of the micropores is their volume V_{mi} (Table 7).

The most widely used for pore structure examination is the structure–sorption method [29] based on analyzing the relationships in adsorption from vapor (gas) phase, derived experimentally in the form of adsorption isotherms, i.e., the plots of the amount of the absorbed sorbates vs. their relative pressure P/P_0 at a constant temperature.

Table 7 and Figs. 1, 2a, and 2b present the results of examination of the structure–sorption properties of the bottom sediments on a high-speed gas sorption analyzer based on the nitrogen sorption at 77 K. Figure 1 shows the obtained isotherms of nitrogen adsorption–desorption A as plots of A vs. P/P_s, and Figs. 2a and 2b, the plots of the pore volume V, $cm^3\ g^{-1}$, vs. the pore radius in the differential ($dV/d\log r$) and integrated (V) forms, calculated by the Multi-Point BET Plot and BJH Desorption methods for one of the samples. Table 7 presents the nitrogen

* A, nitrogen adsorption at 77 K.

adsorption at $P/P_s = 1$, obtained by these methods, as well as the specific surface area of the samples, the micropore surface area S_{mi}, the micropore volume V_{mi}, and the micropore radius r, determined from the pore radius distribution curves.

These data show that the samples chosen for examination are really microporous samples with a small pore radius varying from 4 to 70 Å, micropore volume of 1×10^{-3}–8×10^{-3} cm^3 g^{-1}, and the micropore surface area S_{mi} varying from 10 to 50 m^2 g^{-1}.

It should be noted that the medicinal effect of bottom sediments can be governed not only by their physicochemical parameters and chemical cleanliness but also by the complex effect exerted by all the components (biologically active components, minerals, and salts).

CONCLUSIONS

(1) Up-to-date methods were applied to examination of the physicochemical and structure–sorption

properties of bottom sediments of different origin. All the bottom sediments examined have a microporous structure with the pore radius varying from 4 to 70 Å and a specific surface area of 14–50 $m^2 g^{-1}$. Based on the contamination levels, the bottom sediments examined were assigned to class A (naturally clean ground).

(2) Analysis showed that the selected bottom sediments have the cleanliness required of enterosorbents.

Abstract—Redox-active sulfurized poly(methylene polysulfides) $-[CH_2S_y]_n-$ (y = 4–22) were prepared by deep sulfurization of poly(methylene di- and trisulfides) with elemental sulfur. The use of the substances obtained as an active cathode material of rechargeable lithium cells ensures their cycling with a specific discharge capacity of 418–550 mA h g^{-1}.

DOI: 10.1134/S1070427207030093

Sulfur-containing polymers exhibit high electrochemical activity and are promising materials for modern rechargeable chemical power sources [1–5]. Their electrochemical behavior is determined by the presence and number of redox-active S–S bonds in the structure of these polymers. It is well known that elemental sulfur can be inserted into S–S bonds of organic disulfides [6] and that this process is initiated by Lewis acids or bases.

Here we report on deep sulfurization of accessible poly(methylene di- and trisulfides) [7, 8] with elemental sulfur with the aim to prepare new redox-active sulfurized poly(methylene polysulfides).

EXPERIMENTAL

The starting poly(methylene di- and trisulfides) were prepared by procedures described previously [7, 8]. Their subsequent sulfurization was performed by heating with elemental sulfur at 125–135°C for 1.5 h. We examined the effect of a highly basic amine, diazabicyclooctane (dabco), of a cobalt salt, $CoCl_2 \cdot 6H_2O$, and of their combination on the sulfurization process and properties of the resulting poly(methylene polysulfides):

$$\left[-CH_2S_x-\right]_n \xrightarrow{S_8} \left[-CH_2S_y-\right]_n$$

x = 2, 3 nos. 1–8 y = 4–22

(y was determined by elemental analysis).

The polymers obtained (nos. 1–8) were washed with CS_2 to remove the soluble oligomers and unchanged sulfur and were vacuum-dried. The reaction conditions and characteristics of polymers are given in the table.

We found that, under the reaction conditions, elemental sulfur was actively inserted into the S–S bonds of the starting poly(methylene di- and trisulfides), which led to the formation of new polymers enriched in sulfur to 90–98%. The reaction performed without initiators yielded poly(methylene polysulfides) containing 92.10 and 95.48% S (nos. 1, 5). In the presence of dabco, the polymer yield increased by 2.9 (no. 2) and 4.3% (no. 6), and the sulfur content in the sample increased to 94.28 and 98.14%, respectively. Addition of the cobalt salt (both alone and in combination with dabco) led to a decrease in the sulfur content (sample nos. 3, 4, 7, 8; 90.06, 91.65, 94.04, and 93.34%, respectively).

The synthesized poly(methylene polysulfides) are insoluble light brown powders (nos. 1, 2, 4, 5, 6, 8) or viscous resins (nos. 3, 7). The wide melting interval of the samples is indicative of their wide molecular-mass distribution.

The IR spectra of the polymers (Specord IR-75 IFS 25 spectrometer, KBr pellets) contain absorption bands belonging to aliphatic CH_2 groups: 2922, 2855 (ν CH_2); 1511, 1457, 1361, 1176, 1027 cm^{-1} (δ CH_2); the band with a maximum at about 864 cm^{-1} is typical of the bending vibrations of aliphatic C–H groups [9], and the peaks at 776–705 cm^{-1} and narrow bands

Reaction conditions and characteristics of poly(methylene polysulfides). Reaction temperature 125–135°C, time 1.5 h

at 466–490 cm^{-1} correspond to the stretching vibrations of the C–S and S–S bonds, respectively [9, 10].

When studying the redox activity of poly(methylene polysulfides), we used thin-layer two-electrode disk cells with a lithium anode and an aluminum cathode (1.5 cm^2) onto which a composition of a polymer, carbon, and poly(ethylene oxide) (50 : 35 : 15 wt %) was applied. Porous polypropylene was used as separator, and 1 M $(CF_3SO_2)_2NLi$ in 1,2-dimethoxyethane, as supporting electrolyte. Cyclic voltammograms were recorded at a potential sweeping rate of 1 mV s^{-1} in the potential range 1.25–3.00 V (vs. Li/Li^+) using a PI-50-1.1 potentiostat and a PDA-1 *XY*-recorder. The cell cycling was performed at a current density of 0.25 mA cm^{-2} in the voltage range 1.25–3.00 V on a testing and measuring bench for chemical power sources.

The cyclic voltammograms of the poly(methylene polysulfides) under consideration (a typical pattern is shown in Fig. 1) are indicative of a multistep redox process with maxima at 2.30, 2.10, and 1.96 V at cathodic polarization and at 2.46 and 2.54 V at anodic polarization; such a pattern is characteristic of elemental sulfur and polysulfides [11–13] and confirms the presence of S–S bonds in the polymers prepared.

The first step of the cathodic process at a potential of 2.30 V yields soluble lithium polysulfides; in the course of further potential sweeping, at 2.10 and 1.96 V, they are reduced to lithium methanepolythiolates and lithium sulfide, respectively:

$$[-CH_2S_y-] \xrightarrow[n\text{Partial reduction}]{(Li^0)} \underset{nx + nx' + mx'' = y_n}{n(LiS_xCH_2S_{x'}Li) + mLi_2S_{x''}}$$

$$\xrightarrow[\text{Complete reduction}]{(Li^0)} \underset{2n + m = y_n}{n(LiSCH_2SLi) + mLi_2S}.$$

However, the products formed are oxidized under anodic polarization (at 2.46 and 2.54 V) incompletely. A part of lithium methanepolythiolates and sulfide do not participate in further electrochemical reactions, which is manifested as a decrease in the amplitudes of the cathodic and anodic maxima in the cyclic voltammograms. Such redox behavior is characteristic of organic compounds containing polysulfide blocks [4, 5, 11–13] and is apparently caused by homooxidation of sulfide and polysulfide ions with the formation of poly(methylene polysulfide) of somewhat different structure and molecular weight, along with polymeric sulfur:

$$n(LiS_xCH_2S_{x'}Li) + mLi_2S_{x''} \xrightarrow{\text{Oxidation}} \underset{ny' + y'' = y_n}{[-CH_2S_{y'}-]_n + S_{y''}} + Li^0.$$

Cathodes based on the synthesized poly(methylene polysulfides) were cycled in lithium cells with a higher discharge capacity *Q* compared to the cathodes

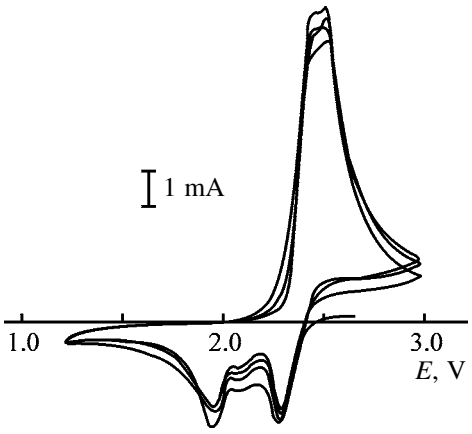

Fig. 1. Cyclic voltammogram of poly(methylene polysulfide) no. 6 (cycles 1–4). (*E*) Voltage (vs. Li/Li^+).

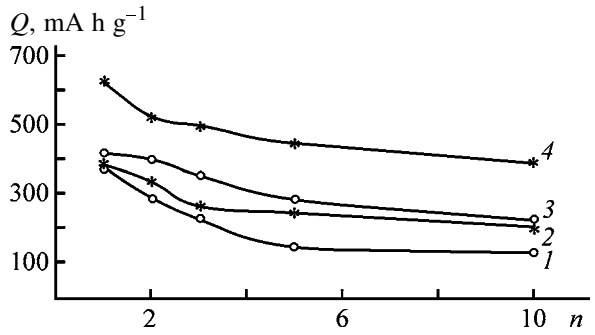

Fig. 2. Variation of the discharge capacity Q of cathodes based on (*1*) poly(methylene disulfide), (*2*) poly(methylene trisulfide), (*3*) poly(methylene polysulfide) no. 2, and (*4*) poly(methylene polysulfide) no. 6 in cycling in lithium cells. (n) Number of cycles.

based on the starting poly(methylene di- and trisulfides) (Fig. 2), which is indicative of a larger number of redox-active bonds in the structure of the polymers obtained. The specific discharge capacity correlates with the sulfur content in the samples.

CONCLUSION

High-sulfur poly(methylene polysulfides) (S content up to 98%) showing promise for the development of active cathode materials for modern lithium cells were prepared by deep sulfurization of poly(methylene di- and trisulfides).

Received March 24, 2006; in final form, November 2006

Abstract—Simple methods were suggested and conditions were found under which modified carbon materials with varied chemical nature of the surface and controllable catalytic activity in the model reaction of hydrogen peroxide decomposition can be produced from various raw materials. The pore structure parameters of the carbons synthesized were determined, the kinetics of the reaction under study on these carbons was analyzed, and the possibility of synthesis of carbon catalysts with high catalytic activity exceeding that of the known active carbons was demonstrated.

DOI: 10.1134/S107042720703010X

The increasing role of adsorption (ion-exchange) and catalytic processes in various fields of technology and medicine predetermines the topicality of a search for new materials (e.g., based on carbon sorbents) with improved physicochemical and service characteristics and catalytic properties. Indeed, activated carbons widely used in medicine and technology [1–5] possess, as demonstrated by numerous studies [3–15], a broad spectrum of catalytic action and accelerate many redox and acid–base reactions. Recently, a number of reports have appeared [6–11] in which the knowledge of carbon materials as catalysts was substantially extended and the causes of their catalytic behavior were elucidated. A study of the influence exerted by a number of factors on particular catalytic processes has more than once been the subject of analysis by various scientists, including the authors of this study [7–9].

The following basic factors governing the catalytic properties of carbons should be named [9]: presence of surface functional groups (–COOH, –OH, $=NH_2$, $–SO_3H$, etc.) and their relative numbers, presence of heteroatoms in surface formations (N, P, S) and of metal ions substituting hydrogen ions in surface groups, structure of the carbon matrix, electrical conductivity of carbon materials, and structural-sorption characteristics of carbons.

The surface modification of carbons by introduction of heteroatoms, e.g., nitrogen, phosphorus, or sulfur, into their structure opens up new opportunities for synthesis and use of effective carbon-based catalysts.

It has been shown [3, 6–10] that nitrogen-containing carbons, such as synthetic carbons of the SKN brand, possess clearly pronounced catalytic properties owing to the high perfection and long extension of their graphite lattice containing nitrogen atoms [7, 12–15]. These factors diminish the electron work function of the lattice and raise the electron-donor power of the carbon, and, consequently, enhance its activity in catalytic reactions of the electronic type, e.g., in the model reaction of H_2O_2 decomposition and oxidation of cumene, *o*-xylene, H_2S, SO_2, creatinine, and amino acids [3, 7–15].

However, the knowledge of the properties of carbon materials (including those oxidized) suffers from considerable gaps and ambiguities, which should be eliminated for development of both scientific foundations of synthesis of a new class of cation-exchange resins and catalysts on carbon matrices and reproducible technologies for their manufacture and further rational use for practical purposes. For example, we are not aware of any systematic studies concerned with the influence exerted by the extent of oxidation of carbon materials and by relative amounts of various types of surface acid groups (SAGs) on the catalytic properties of carbons in redox reactions, as it has been done for numerous protolytic properties [3, 8]. Methods for directed control over the content of SAGs in

oxidized carbons in order to create catalysts with prescribed capacity for acceleration of numerous industrially important reactions of the electronic type have not been developed, either.

In this study, we attempted to reveal a general pattern of the influence exerted by the extent of oxidation of carbons on their catalytic activity and a relationship between the total static ion-exchange capacity (SEC), which characterizes the total amount of SAGs, and the catalytic activity in the model reaction of H_2O_2 decomposition, and also to elucidate what are these relationships, if they do exist, for carbons of varied nature and origin.

EXPERIMENTAL

We suggested an improved procedure for modification of the carbon surface with nitrogen atoms and used a method for control over the SAG content of carbon by high-temperature (~700°C) vacuum treatment of the carbon surface to remove, when necessary, surface acid compounds whose presence impairs the catalytic activity to some extent. It should be noted that vacuum treatment of activated carbons, with determining the composition of the gases being released in various temperature intervals, was studied as long ago as 1947 in [16]. At the same time, we carried out a systematic study and applied this technique to a set of samples of the same origin, varied surface nature, and different kinds of modification.

For this purpose, we chose natural carbons produced from KAU fruit kernels and synthetic carbons prepared from vinylpyridine (SKN) and phenol–formaldehyde resins (FF and FFK, with various extents of oxidation). The surface of the chosen carbons was oxidized to various extents in the liquid phase of 25% HNO_3, with boiling on a water bath for varied time [3]. The SAG content was evaluated in relation to the origin of a carbon and extent of its oxidation by the conventional method of SAG titration with a 0.1 N aqueous solution of NaOH [3].

The vacuum treatment was performed in a quartz reactor at 750°C for 1 h after the optimal temperature was attained; the heating rate of a weighed portion of a catalyst (commonly 10 cm^3) was 20 deg min^{-1}. After the vacuum treatment, the sample was cooled to room temperature and placed in a vessel with a ground-glass stopper in a desiccator. The residual pressure varied from 13 Pa at the beginning of the process to 133 Pa by the time when T = 750°C was attained and was maintained at this level for 1 h.

Carbons containing nitrogen chemically bound to the graphite-like lattice are commonly prepared by various methods: calcination of starting carbons in the presence of ammonia, dicyan, nitrogen oxides, and ammonium salts or carbonization of nitrogen-rich compounds, as in synthesis of SKN [2, 3, 14, 15, 17]. To prepare nitrogen-containing carbons, we developed and suggested our own improved procedure using melamine. The oxidized carbon was treated with melamine solutions with addition of acetic acid of a certain concentration, dried, and thermally treated in a flow of an inert gas at a high temperature. To obtain a nitrogen-containing sorbent with a varied amount of the modifying additive (commonly 3 to 5%), the concentration of the impregnating solution, treatment time, and melamine : carbon ratio were varied.

We studied the structural-sorption characteristics of the samples obtained [18]: total volume of sorption pores for benzene, W_s ($cm^3\ g^{-1}$); sorption activity with respect to Methylene Blue, A_{MB} (mg g^{-1}); anion-exchange capacity with respect to a 0.1 N aqueous solution of HCl. The method of low-temperature (77 K) adsorption of nitrogen on a Quantochrome NOVA 2200 E high-speed gas sorption analyzer was employed to determine the following parameters: total specific surface area of the carbons, S_{sp} ($m^2\ g^{-1}$); volume V_{mi} ($cm^3\ g^{-1}$) and surface area S_{mi} ($m^2\ g^{-1}$) of micropores; the pore radius distribution curves (Fig. 1) were used to find micropore radii r (Å). The parameters obtained are listed in Table 1.

The catalytic effect of the carbons synthesized was studied for the example of a model reaction of H_2O_2 decomposition. We used hydrogen peroxide of chemically pure grade; the concentration of H_2O_2 solutions was determined by permanganatometric titration [19]. Kinetic measurements (Figs. 2–5) were made in a temperature-controlled cell (T = 20°C) with agitation, which eliminated the outer-diffusion hindrance. The volume of the H_2O_2 solution was 25 ml in each experiment, and the weighed portion of a catalyst of the same granulometric composition (average grain size 0.25–0.5 mm) was 0.25 g. The concentration was found as a function of time by sampling at regular intervals.

Table 1 illustrates certain structural-sorption properties of the samples studied. It can be seen that, as the degree of oxidation increases, S_{sp} of the sorbents becomes smaller, with S_{mi}, V_{mi}, and A_{MB} simultaneously decreasing. The vacuum treatment of the samples leads to an increase in their specific surface area (compare, e.g., sample nos. 3 and 4, 6 and 7, 18 and

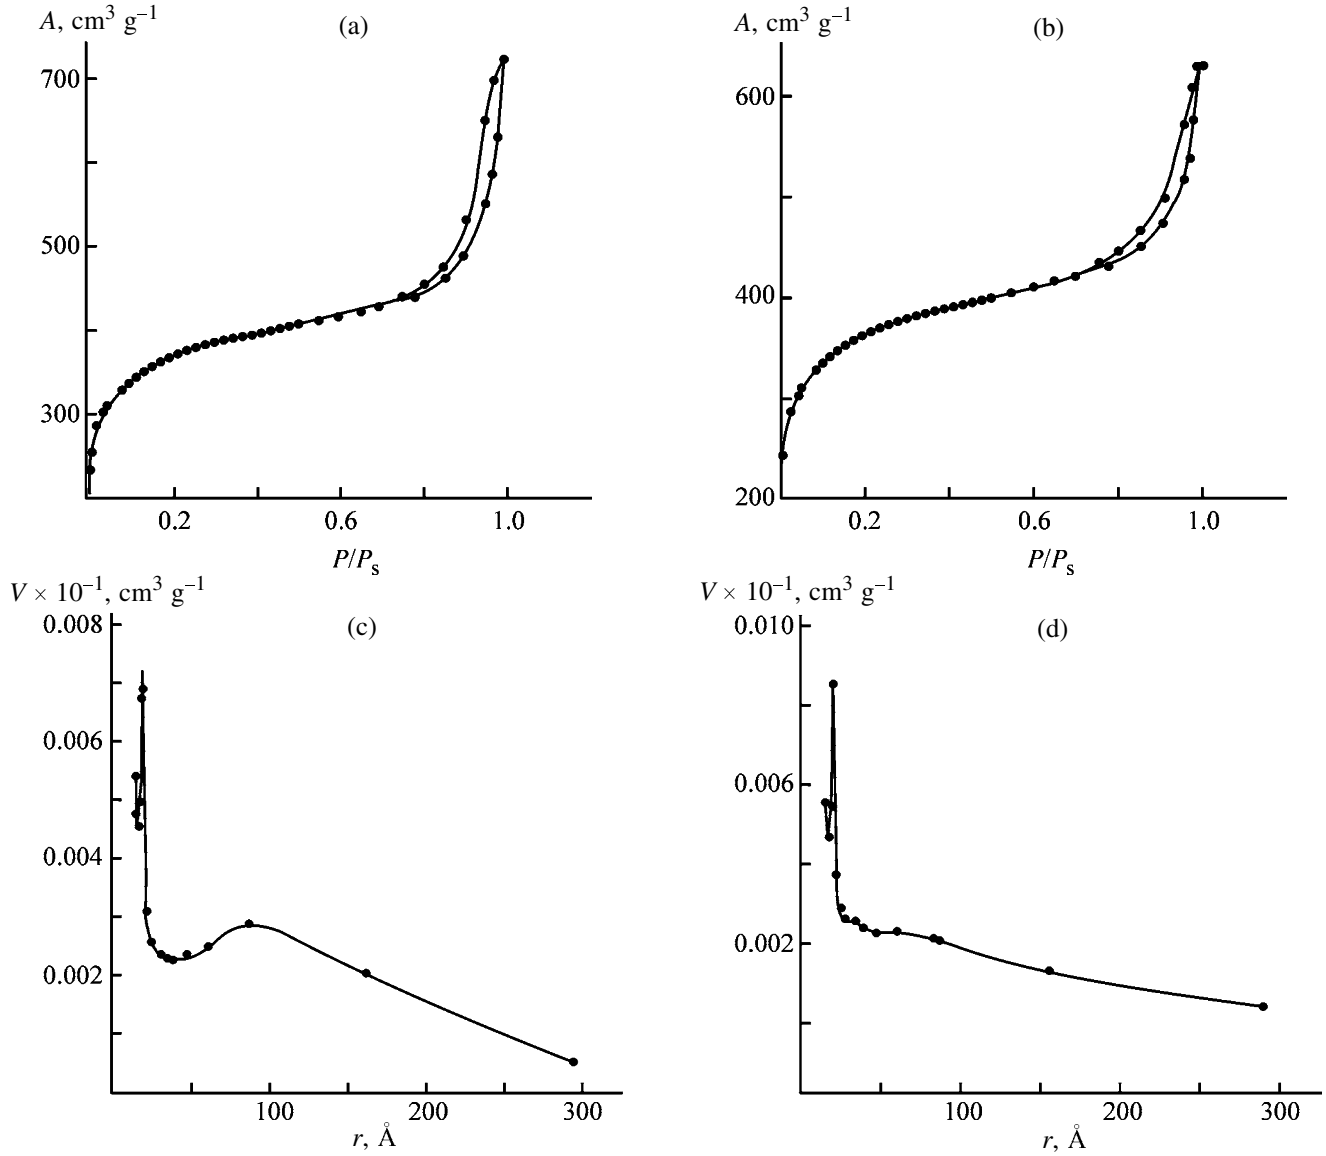

Fig. 1. (a, b) Isotherms of nitrogen sorption–desorption A and (c, d) curves of integral distribution of pore volume V with respect to pore radius r for various carbons. Carbon: (a, c) FF_{ox} (SEC = 1.72 mg-equiv g^{-1}), nitrogen-containing; (b, d) FF_{ox} (SEC = 1.72 mg-equiv g^{-1}), nitrogen-containing, vacuum-treated.

19). The sorption of N_2 from the gas phase is determined by V_{mi} and S_{sp}: 240–360 $cm^3\ g^{-1}$ for KAU carbons with smaller V_{mi} equal to 0.26–0.31 $cm^3\ g^{-1}$ and S_{sp} of 650–850 $m^2\ g^{-1}$ and a two- to threefold larger value (600–850 $cm^3\ g^{-1}$) for wider-porous carbons FF and SKN with V_{mi} of 0.49–0.63 $cm^3\ g^{-1}$ and S_{sp} of 1500–1690 $m^2\ g^{-1}$. These same carbons better sorbed Methylene Blue (260–300 mg g^{-1}; cf. A_{MB} of 80–118 mg g^{-1} for KAU carbon).

The study demonstrated that the catalytic activity of the samples synthesized is determined by the chemical nature of the carbon surface and, to a lesser extent, by the type of their pore structure (Figs. 2–5, Table 2), as, e.g., it was noted in [12, 20].

It has been found previously [3, 8, 12–15, 20–25] that the decomposition of H_2O_2 is substantially accelerated only in the presence of ordinary activated carbons positively charged in an aqueous solution. At the same time, oxidized carbons, which have a larger amount of SAGs on the surface and are negatively charged [3, 15], virtually do not catalyze this reaction.

The capacity for acceleration of the H_2O_2 decomposition increases with the number of basic groups (anion-exchange capacity), and H_2O_2 decomposes after exchange absorption of OOH^- ions, with OH^-

ions released into the solution [12, 20, 21]. The OOH^- anions in the surface layer have an increased oxidizing potential and can either undergo self-disintegration or oxidize a new H_2O_2 molecule to give oxygen and OH groups in the surface layer, with the result that the outer "plate" of the double layer of carbon takes on the original composition. The appearance of an excess of OH^- ions in the system is indicated [12, 20] by an increase in the pH value of the H_2O_2 solution in the course of H_2O_2 decomposition [12, 20], with the maximum pH shift observed on nitrogen-containing samples, and the minimum shift, on KAU carbon. In the course of several minutes, the H_2O_2 solution became alkaline (pH 8); on removing the carbon from

the H_2O_2 solution, the pH value instantaneously became 3.5–4.0. By contrast, the presence of oxidized samples led to acidification of the solution being decomposed.

The presence of basic nitrogen atoms, which change the charge of carbons and raise the capacitance of the electrical double layer and the anion-exchange capacity, strongly affects the catalytic properties of

carbon materials. The catalytic activity of oxidized carbons is affected by their highly developed surface to a lesser extent. For example, KAU sample nos. 3 and 4 (Table 2) possess about the same sorption pore volumes (W_s = 0.3–0.4 $cm^3\ g^{-1}$) and S_{sp} = 800–900 $m^2\ g^{-1}$ as carbon nos. 24 and 25 (SKN). However, the former (KAU) decompose 6–8% of H_2O_2 in 40 min, whereas the degree of decomposition on nitrogen-containing SKN with similar pore structure parameters is 68–76% (Table 2).

As can be seen in Figs. 2–5, H_2O_2 decomposes slowly in the presence of oxidized KAU, FF, and FFK carbons. As the extent of oxidation (SEC) of the carbons increases, the degree of decomposition decreases. At the same time, activated samples of the same carbons exhibit a pronounced catalytic effect (compare Figs. 2–5, curves *1* and *3*). Vacuum treatment of oxidized samples leads to an increase in their catalytic activity. As follows from Table 1, this occurs because vacuum treatment of the carbon surface changes its chemical nature: for example, the capacity for 0.1 N NaOH decreases virtually to zero (sample nos. 4, 7, 11, 15, 20, 23, 29, 31), i.e., the number of acid functional groups decelerating the catalysis decreases dramatically, and the degree of H_2O_2 decomposition on such modified samples grows, compared to their oxidized modifications.

Introduction of nitrogen atoms leads to an even more effective decomposition of H_2O_2 (Figs. 2–5, curves *5*), with the nitrogen-containing SKN carbons decomposing H_2O_2 approximately four times more actively than do activated KAU carbons. For example, H_2O_2 decomposed to 90–95% in 5–10 min on an activated SKN sample (Fig. 5, curve *1*) and on the same, but vacuum-treated carbon (curve *2*).

It should be noted that the catalytic activity of the carbons formed from phenol–formaldehyde resin is high, compared to KAU carbons. The FFK sample activated at a lower temperature (Fig. 4) is somewhat worse than the activated carbon of the FF brand in decomposition of H_2O_2. Under identical conditions, the nitrogen-containing carbons of the SKN type exhibited a considerably higher catalytic activity, compared to the KAU and FF carbons.

The presence of nitrogen atoms in the surface layer also imparts catalytic activity to oxidized SKN carbons: in contrast to KAU_{ox} and FF_{ox}, a considerable, although less pronounced than that on SKN-M, decomposition of H_2O_2 is observed in the presence of SKN-M_{ox} (Fig. 5, curves *3*). The procedures used in the study to control the catalytic activity of carbons: directed vacuum treatment and treatment with a nitrogen-containing reagent (melamine) by the new method, favored synthesis of carbon catalysts whose catalytic activity approached, or even exceeded, that of the known catalysts with high catalytic properties, activated carbons (anion exchangers).

The knowledge of the causes of the catalytic action of carbon materials should favor proper choice of carbon sorbents with prescribed properties and enable control not only over their sorption properties, but over their catalytic transformations as well. Taking into account the basic factors that affect the course of catalytic processes involving carbons makes it poss-

ible to modify these sorbents and thereby to determine the ways of varying and controlling the properties of carbon materials and obtaining technologically important materials with prescribed properties on the basis of these materials.

CONCLUSIONS

(1) Activated carbons of various origins, from synthetic and natural raw materials, were used to obtain their modifications oxidized to varied extent. The standard techniques were used to study some structural-sorption characteristics of the samples studied: specific surface area varying from 670 to 1800 $m^2 g^{-1}$, total volume of sorption pores, and size of micropores found in the carbon materials. The extent of oxidation varied from 0.2 to 3.0 mg-equiv g^{-1}.

(2) Simple methods were used to change the chemical nature of the surface of the samples synthesized: by raising or diminishing the number of surface acid groups via vacuum treatment of the surface and introduction of nitrogen atoms into the surface layer (3 to 5%).

(3) The possibility of controlling the catalytic activity of the carbon catalysts synthesized was shown for the example of the model reaction of the electronic type, decomposition of H_2O_2. The kinetic dependences obtained demonstrated that the catalytic effect of the carbons is not affected to any significant extent by pore structure parameters. At the same time, purposefully modified carbon materials can effectively decompose H_2O_2, with the degree of decomposition changing in a short time (5–10 min) from 6 to 95%.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Simulation of Suspension Separation by Two-Stage Pressure-Head Flotation in a Cylindrical Direct-Flow Hydrocyclone

Abstract—A mathematical model of separation of suspensions with a non-Newtonian dispersion medium by two-stage pressure-head flotation in a cylindrical direct-flow hydrocyclone was developed. A system of differential equations describing convective diffusion and motion of a particle–bubble complex was solved numerically. The concentration field was modeled and integral separation parameters were determined.

DOI: 10.1134/S1070427207030111

Pressure-head flotation is used in chemical industry for separation and purification of inhomogeneous liquid systems in the field of centrifugal forces. The necessity for achieving a high recovery of the solid phase in a number of chemical technologies predetermines use of two-stage flotation with additional introduction of a dispersed gas for these purposes. The apparatus that ensures the highest efficiency of this process is direct-flow cylindrical hydrocyclone in which the separation occurs in the film mode and the condition of linkage between a particle and a gas bubble is provided [1].

In [1, 2], a procedure was suggested for calculating, by solving the equation describing the radial motion of the particle–bubble system, the separation parameters of a hydrocyclone-flotator and the diameter of the cylindrical part of the apparatus at which prescribed separation parameters and minimal investment and energy expenditure are provided. The condition for a stable floating-up of the particle–bubble system was derived and the diameter of solid phase particles that can be removed at given operation mode parameters of the hydrocyclone was determined.

It was noted in [3, 4] that the number of probable collisions of solid particles and gas bubbles depends on the centrifugal acceleration; it was shown that the centrifugal field is a factor that makes larger the number of collisions between particles and bubbles. It was found that the prevalent mechanism of formation of flotation complexes in pressure-head flotation is that by collisions of solid particles and gas bubbles. The efficiency of pressure-head flotation, dependent on the number of collisions, is governed by the distance traveled by a solid particle in the liquid dispersion medium.

Kutepov et al. [5] came to a conclusion that the best way is to deliver air into the feeding pipe of a hydrocyclone, instead of using pressure-head flotation methods. As a result, the particle–bubble interaction can start already at the inlet of the hydrocyclone and the apparatus design can be significantly simplified. However, they disregarded the fact that the kinetic constant of flotation increases because of the formation of gas bubbles directly on solid particles in the case of pressure-head flotation. Therefore, it seems appropriate, in order to improve the kinetic characteristics of the pressure-head flotation process and markedly raise the recovery of solid particles, to use two-stage flotation with supply of the secondary through porous walls of the hydrocyclone, which combines the advantages of both methods.

The two-stage flotation occurs as follows (Fig. 1): a preliminarily aerated suspension is delivered at an elevated pressure (up to 0.8 MPa) into a cylindrical direct-flow hydrocyclone, tangentially along the generatrix, via the inlet pipe *1* mounted in the upper part of the hydrocyclone case. The suspension fed into the hydrocyclone flows down, forming a spinning film, along its walls, and has the circumferential (V_φ), axial (V_h), and radial (V_r) velocity components. As the pressure is lowered to the atmospheric value, a supersaturation of the dissolved gas is created and the

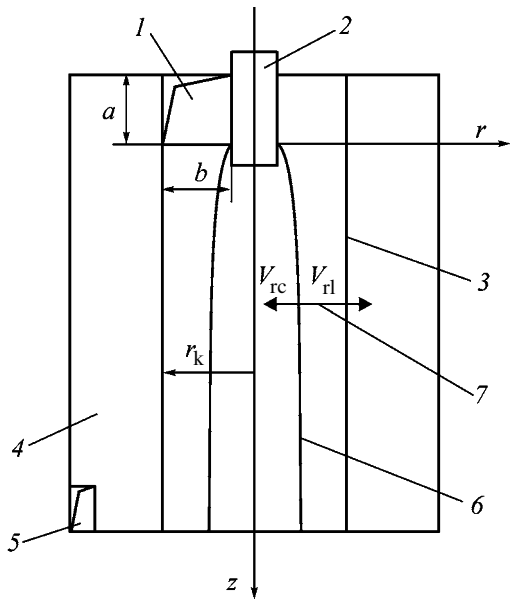

Fig. 1. Schematic of suspension separation by two-stage pressure-head flotation in a cylindrical hydrocyclone: (*1*) inlet pipe, (*2*) froth discharge pipe, (*3*) porous permeable wall of the hydrocyclone case, (*4*) gas supply collector, (*5*) pipe for gas delivery into the collector, (*6*) suspension film boundary, (*7*) particle–bubble complex.

suspension "boils up." Solid particles move under the action of the centrifugal force toward the wall of the hydrocyclone case, and gas bubbles driven by the buoyancy centripetal Archimedes force, in the opposite direction, toward the film surface. In the first stage of pressure-head flotation, flotation complexes are formed in collisions of solid particles with gas bubbles. These complexes carry the solid particles to the froth layer at the film surface, and this layer is removed via the froth discharge pipe *2*. Bubbles of the secondary gas are fed through the porous permeable wall *3* of the hydrocyclone case from the annular collector *4*. These bubbles, whose diameter exceeds by an order of magnitude that of gas bubbles formed in the suspension upon pressure drop, have a considerably higher velocity of floating-up to the film surface, compared with the complexes formed. In the second stage of flotation, secondary-gas bubbles collide with the floating-up complexes to form with them secondary complexes in which a particle is a bridge between gas bubbles [6]. These complexes rapidly move toward the film surface. The clarified suspension is removed from the apparatus via the bottom discharge pipe.

Owing to the high effective viscosity of non-Newtonian media, the flow in the cylindrical hydrocyclone occurs in the film mode [7], which provides a stable linkage in the particle–bubble complex because there is no steep increase in the circumferential velocity near the hydrocyclone axis. A mathematical model of the first stage of pressure-head flotation was considered in [8, 9].

The problem for the case of two-stage flotation is mathematically formulated under the following assumptions. Bubbles of the secondary gas delivered across the porous wall of the hydrocyclone case have a diameter an order of magnitude larger than that of gas bubbles formed in the first stage of pressure-head flotation. For this reason, the efficiency of collision of free solid particles with secondary-gas bubbles is low in accordance with the Sutherland formula [6] and can be neglected. In addition, the concentration of free solid particles rather rapidly decreases after the suspension enters the hydrocyclone. This occurs because of the formation of flotation complexes with gas bubbles formed in the first stage of flotation. Thus, it is reasonable to consider that secondary-gas bubbles, which float-up to the film surface at a higher velocity than complexes produced in the first stage, collide with the latter and remove them to the froth layer via formation of secondary complexes.

We assume that the solid phase of the suspension being separated, gas bubbles formed in the first stage of pressure-head flotation, particle–bubble complexes, and secondary-gas bubbles are all monodisperse. This will make it possible to achieve a prescribed recovery when simulating the separation by two-stage pressure-head flotation for the finest fraction of the solid phase.

For a film flow with a non-Newtonian dispersion medium having high effective viscosity, the flow mode is laminar and the mode of floating-up of gas bubbles and complexes is laminar, too [10].

The concentration field of solid particles bound into complexes in separation of suspensions with a non-Newtonian dispersion medium by two-stage pressure-head flotation in a cylindrical hydrocyclone is mathematically modeled using a differential equation describing convective diffusion in cylindrical coordinates. This equation can be written for solid particles and secondary-gas bubbles, with account of the inflow of particles, bound into complexes, via their formation in the first stage of pressure-head flotation and loss via formation of secondary complexes in the second stage, as follows:

$$\operatorname{div}(\bar{\mathbf{V}}_c c_{hc}) = j_{hc1} - j_{hc2},$$
$$\operatorname{div}(\bar{\mathbf{V}}_{g2} c_{g2}) = -j_{g2}, \quad (1)$$

where $\bar{\mathbf{V}}_c$ is the velocity vector of the complexes; $\bar{\mathbf{V}}_{g2}$,

velocity vector of secondary-gas bubbles; c_{hc}, volume fraction of solid particles bound into complexes ($m^3\ m^{-3}$); j_{hc1}, inflow of solid particles bound into complexes, formed in the first stage of flotation; j_{hc2}, loss of solid particles bound into complexes in the second stage of flotation; j_{g2}, loss of secondary-gas bubbles in the second stage of flotation.

The most widely occurring in the practice of hydrocyclone flotation is the case in which the volume fraction of secondary-gas bubbles in the suspension film markedly exceeds the volume fraction of solid particles bound into complexes, $c_{g2} > c_{hc}$, and it can be assumed that c_{g2} = const throughout the volume of the suspension film in the hydrocyclone. The volume fraction of gas bubbles formed in the suspension in the first stage of flotation also markedly exceeds the volume fraction of free solid particles, $c_{g1} > c_h$. In this case, the second equation in system (1) can be excluded and the system reduces to a single equation in which the loss of solid particles, bound into complexes, via flotation by secondary-gas bubbles, j_{hc2}, and their inflow from the first stage of flotation, j_{hc1}, have the form [6] similar to that in the kinetic equation of a first-order chemical reaction:

$$\bar{\mathbf{V}}_c \operatorname{grad} c_{hc} + c_{hc} \operatorname{div} \bar{\mathbf{V}}_c = A_1 c_h c_{g1} - A_2 c_{hc} c_{g2}, \quad (2)$$

where A_1 is the kinetic constant of the first stage of flotation (s^{-1}); A_2, kinetic constant of the second stage of flotation (s^{-1}); c_h, volume fraction of free solid particles ($m^3\ m^{-3}$); and c_{g1}, volume fraction of gas bubbles formed in the first stage of flotation ($m^3\ m^{-3}$).

We assume that complexes move in the axial direction without inertia, i.e., the axial velocities of the complexes and the dispersion medium are equal: $V_{zc} = V_{zl}$.

Because the radial velocities of the complexes and of the continuous flow of the dispersion medium are different, Eq. (2) takes, under the assumptions made, the following form:

$$V_{rc}(\partial c_{hc}/\partial r) + V_{zc}(\partial c_{hc}/\partial z) = -A_1 c_h c_g - c_{hc}\{A_2 c_{g2} + r^{-1}\partial[r(V_{rc} - V_{rl})]/\partial r\}, \quad (3)$$

where $V_{rc}(r, z)$ and $V_{zc}(r, z)$ are the radial and axial velocity components of a complex ($m\ s^{-1}$); $V_{rl}(r, z)$, radial velocity component of the dispersion medium ($m\ s^{-1}$); r and z, radial and axial coordinates (m).

Equation (3) was solved together with the motion equation of the particle–bubble complex.

We assume that the main mechanism by which secondary complexes are formed in the second stage of flotation, similarly to the case of single-stage pressure-head flotation, is collision of secondary-gas bubbles with complexes floating-up to the film surface. This mechanism is governed by dispersity characteristics and physical properties of phases.

Similarly to the assumptions made in [6], we believe that all collisions of secondary-gas bubbles with complexes are effective (produce secondary complexes) and the forming secondary complexes are not disintegrated in floating-up into the froth layer and do not fall down from this layer. With these assumptions, the stage of collision between secondary gas complexes and complexes predetermines the efficiency of two-stage pressure-head flotation under the conditions of a film flow of the suspension being separated in a cylindrical hydrocyclone. This is so because secondary-gas bubbles, which have an order of magnitude larger radius than bubbles formed in the first stage of pressure-head flotation, provide a considerably larger floating-up velocity of secondary complexes to the film surface. In the case of a single-stage pressure-head flotation, the rate-determining stage is that of transportation of complexes.

The kinetic constants of the first and second stages of flotation, A_1 and A_2, were found using a formula modified for the case of flotation in a field of centrifugal forces [11, 12]. This formula was derived on the basis of the fact that the probabilities of collision of solid particles with gas bubbles formed in the first stage of flotation and of secondary-gas bubbles with complexes are similar to the probabilities of molecule collisions in the molecular-kinetic theory of gases.

The inertia force acting on particle–bubble complexes and secondary-gas bubbles in the axial direction, gravity force, and buoyant Archimedes force were neglected by assuming that the axial velocities of the complexes and secondary-gas bubbles are equal to the axial velocity of the dispersion medium. This condition is well satisfied in practice because suspensions with a non-Newtonian dispersion medium having high effective viscosity are separated in hydrocyclones at large Froude numbers (separation factors). We assumed that complexes and secondary-gas bubbles move in the circumferential direction without inertia and their circumferential velocities are equal to the circumferential velocity of the dispersion medium.

When developing a model of the two-stage pressure-head flotation in a hydrocyclone, it is necessary to take into account the inertia forces acting on the particle–bubble complex in the radial direction. These

forces are important in the case of flotation of coarse particles in the field of centrifugal forces and at a significant difference in density between solid particles and the dispersion medium.

The radial velocity of the complex, V_{rc}, was found by solving a differential equation of motion, which has the following form, provided that the complex experiences the action of the centrifugal inertia force, buoyant centripetal Archimedes force, and resistance force in the radial direction:

$$V_{rc}(\partial V_{hc}/\partial r) + V_{zc}(\partial V_{rc}/\partial z) = V_{\varphi c}^2/r\left[1 - \frac{\rho(d_h^3/d_{g1}^2 + d_{g1})}{\rho_h d_h^3/d_{g1}^2 + \rho_g d_{g1}}\right] - \frac{3}{4}\frac{K_{fr}\rho(V_{rc} - V_{rl})\left|V_{rc} - V_{rl}\right|}{(\rho_h d_h^3/d_{g1}^2 + \rho_g d_{g1})\Phi(c_c)}, \quad (4)$$

where $V_{rc}(r, z)$ and $V_{zc}(r, z)$ are the radial and axial velocities of the particle–bubble complex (m s^{-1}); d_h, diameter of solid particles (m); d_{g1}, diameter of gas bubbles formed in the first stage of pressure-head flotation (m); K_{fr}, resistance coefficient for motion of the complex in the radial direction; and $\Phi(c_c)$, correction coefficient taking into account the hindrance to motion of complexes, found using the Brenner formula [2] in relation to the volume fraction c_c of complexes in the suspension.

Taking into account the orientation of the particle–bubble complex in its floating-up to the film surface, we took as the characteristic size d_c of the complex the diameter d_{g1} of gas bubbles formed in the suspension in the first stage of pressure-head flotation because d_{g1} markedly exceeds the diameter of solid particles. On making this assumption, the resistance force acting on a solid particle bound into a complex can be disregarded and the resistance coefficient K_{fr} in radial motion of a complex in the non-Newtonian liquid can be calculated for the characteristic size d_c of complex using an empirical formula from [13].

If the method of characteristics [14] is used, the system of partial differential equations (3), (4) reduces to an equivalent system of ordinary differential equations, which can be represented in the dimensionless form as

$$\begin{cases} dR/dZ = G_c/H_c, \\ dC_{hc}/dZ = -\dfrac{C_{hc}}{H_c}[d(G_c - G_l)/dR + (G_c - G_l)/R + F_{g2}] + C_h F_{gl}/H_c, \\ dG_c/dZ = \dfrac{\Theta_c^2}{H_c R}(1 - P) - \dfrac{3}{4}\dfrac{K_{fr}P(G_c - G_l)\left|G_c - C_l\right|}{(D_h^3/D_{g1}^2 + D_{g1})\Phi(c_c)}, \end{cases} \quad (5)$$

where $G_c(R,Z) = V_{rc}(r, z)/U_0$, $H_c(R,Z) = V_{zc}(r, z)/U_0$, $\Theta_c(R,Z) = V_{\varphi c}(r, z)/U_0$ are the dimensionless radial, axial, and circumferential velocities of the complex; $G_c(R,Z) = V_{rl}(r, z)/U_0$, dimensionless radial velocity of the dispersion medium; $F_{g1} = A_1 C_{g1} r_k/U_0$, dimensionless number characterizing the rate of the first stage of pressure-head flotation; $F_{g2} = A_2 C_{g2} r_k/U_0$, dimensionless number characterizing the rate of the second stage of pressure-head flotation; $C_h = c_h/c_{h0}$, dimensionless volume fraction of free solid particles; $C_{hc} = c_{hc}/c_{h0}$, dimensionless volume fraction of solid particles bound into complexes; $C_{g1} = c_{g1}/c_{h0}$, dimensionless fraction of gas bubbles formed in the suspension; $C_{g2} = c_{g2}/c_{h0}$, dimensionless volume fraction of bubbles of the gas fed through the porous wall of the hydrocyclone; $P = \rho(d_h^3/d_{g1}^2 + d_{g1})/[\rho_h(d_h^3/d_{g1}^2) + \rho_g d_{g1}]$, density parameter; $D_h = d_h/r_k$, dimensionless diameter of gas bubbles formed in the first stage of pressure-head flotation; $R = r/r_k$, $Z = z/r_k$, dimensionless radial and axial coordinates; r_k, radius of the hydrocyclone case (m); c_{h0}, initial volume fraction of free solid particles in the inlet pipe of the hydrocyclone (m^3 m^{-3}); $U_0 = q/(ab)$, average suspension velocity in the inlet pipe of the hydrocyclone (m s^{-1}); q, flow rate of the suspension (m^3 s^{-1}); and a, b, height and width of the inlet pipe of the hydrocyclone (m).

The boundary condition for the system of ordinary differential equations (5) has the form

$$Z = 0,\ 1 - B \le R \le 1,\ C_{hc0} = 0, \quad (6)$$

where $C_{hc0} = c_{hc0}/c_{h0}$ is the dimensionless volume fraction of solid particles bound into complexes in the inlet pipe of the hydrocyclone; c_{hc0}, volume fraction of solid particles bound into complexes in the pipe of the hydrocyclone (m^3 m^{-3}); and $B = b/r_k$, dimensionless width of the inlet pipe of the hydrocyclone.

The system of ordinary differential equations (5) with the boundary condition (6) was solved by the fourth-order Runge–Kutta method with fixed step. The simulation of the process of two-stage pressure-head flotation consisted in numerical solution of the system of differential equations (5) with the boundary condition (6), with approximation of the results obtained in modeling of the concentration field of free solid particles in the first stage of pressure-head flotation [8, 9] and of distributions of the velocities of the dispersion medium [15]. The simulation was performed for various values of the determining similarity criteria and for the rheological properties of the dispersion medium widely varying in the range corresponding to real rheological properties of media

separated in chemical industry and to operation modes of separating apparatus.

The flow of a non-Newtonian liquid in a hydrocyclone is characterized [7] by the centrifugal Froude number (separation factor) $\mathrm{Fr} = U_0^2/(g\,r_\mathrm{k})$, modified Reynolds number $\mathrm{Re}_n = (\rho_1 U_0^{2-n} r_k^n)/k$, and dimensionless flow rate $Q = q/(\pi r_\mathrm{k}^2 U_0) = (ab)/(\pi r_\mathrm{k}^2)$. The rheological properties of the liquid are described by the nonlinearity index n of the flow curve and the consistency factor k (Pa s^n).

To evaluate the influence exerted by the determining similarity numbers and rheological properties of the liquid on the efficiency of suspension separation by two-stage pressure-head flotation, it is necessary to use integral characteristics of the apparatus, the most important of which is the integral-average dimensionless volume fraction of solid particles that are bound into complexes and remain in the suspension in a given cross section of the film. This fraction is calculated by the formula

$$\bar{C} = \int_{1-\Delta(Z)}^{1} C_\mathrm{hc} H(R,Z)\,R\mathrm{d}R \Big/ \int_{1-B}^{1} C_{\mathrm{h}0} H_0(R,Z)\,\mathrm{d}R, \qquad (7)$$

where $\Delta(Z) = [\delta(z)]/r_\mathrm{k}$ is the dimensionless thickness of the suspension film and $\delta(z)$ is the suspension film thickness (m). To obtain operation characteristics of the hydrocyclone, the integral-average dimensionless volume fraction of solid particles bound into complexes was found in the outlet cross section of the apparatus. The results obtained in numerical simulation are presented in Figs. 2–5.

Figure 2 shows trajectories of complexes in the suspension film (Fug. 2a) and distributions of the dimensionless volume fraction of solid particles bound into complexes on the corresponding trajectories (Fig. 2b) for Fr = 73.4, $\mathrm{Re}_n = 4 \times 10^3$, $Q = 0.04$, and $n = 0.6$ in separation of a suspension with a pronounced anomaly of the non-Newtonian properties of the dispersion medium. Analysis of Fig. 2a shows that the trajectories originating at a certain distance from the wall emerge at the film surface under the action of the buoyant centripetal Archimedes wall, but trajectories 3 and 4 have portions in which a complex approaches the wall because of the radial velocity of the dispersion medium. The trajectories originating near the wall, where the centripetal Archimedes force is weak, come to the wall under the action of the radial velocity of the dispersion medium. Thus, instead of emerging to the froth layer, a part of solid

particles arrive at the wall of the hydrocyclone case, to form a deposit. Use of a two-stage flotation makes it possible to eliminate this undesirable phenomenon by reducing the volume fraction of solid particles bound into complexes on these trajectories to a negligible value and to accelerate the emergence of

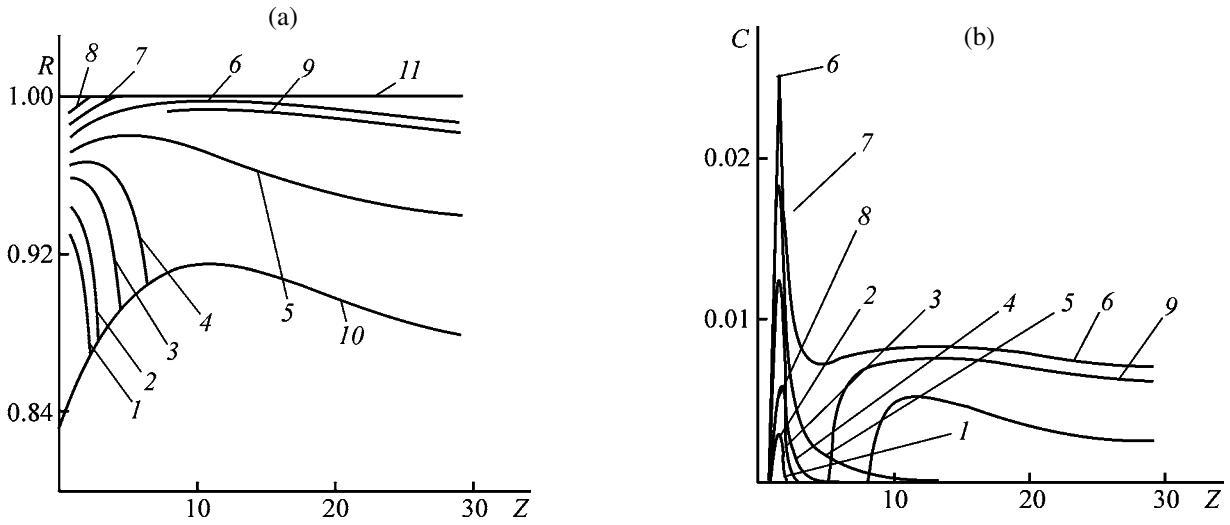

Fig. 3. (a) Trajectories of particle–bubble complexes and (b) distributions of the volume fraction of solid particles bound into complexes on the trajectories for Fr = 207 and the same values of the parameters as in Fig. 2. complexes being extracted by secondary-gas bubbles into the froth layer at the film surface.

As follows from Fig. 2b, the largest values of the volume fraction of solid particles bound into complexes are observed on trajectories located in the zone of high circumferential velocities of the dispersion medium, because of their considerable recovery in the first step of flotation [8, 9].

The volume fraction of solid particles bound into complexes on the trajectories first increases in the axial direction because of formation of complexes in the first stage of flotation and then decreases to negligible values owing to extraction of the complexes by secondary-gas bubbles. The integral-average residual dimensionless volume fraction of solid particles bound into complexes in the outlet cross section of the hydrocyclone at $Z = 30$ is $\bar{C} = 1.33 \times 10^{-4}$ for the given case. For the single-stage flotation at $C_{g2} = 0$, the same operation mode parameters of the hydrocyclone, and the same coordinate Z, $\bar{C}_0 = 6.52 \times 10^{-2}$.

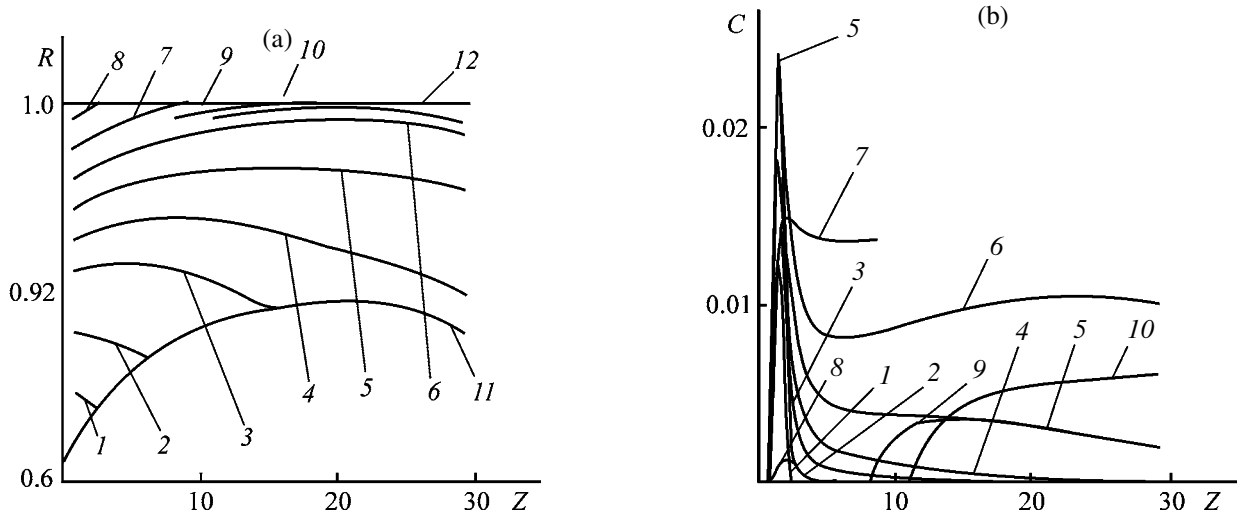

Fig. 5. (a) Trajectories of particle–bubble complexes and (b) distributions of the volume fraction of solid particles bound into complexes on the trajectories for $n = 1$ and the same values of the parameters as in Fig. 1. (*1–10*) (a) Trajectories of complexes and (b) distributions of the volume fraction of solid particles on the trajectories, (*11*) boundary of the suspension film, and (*12*) wall of the hydrocyclone case.

These values of C indicate that the two-stage pressure-head flotation is more efficient than the single-stage process.

Figure 3 shows trajectories of complexes (Fig. 3a) and distributions of the volume fraction of solid particles bound into complexes (Fig. 3b) for Fr = 207 and the same values of the parameters as in Fig. 2. Comparison of the data in Figs. 3 and 2 shows that the maximum values of the volume fraction of solid particles bound into complexes on the trajectories for Fr = 207 are considerably smaller than those for Fr = 73.4, whereas in the outlet cross section of the hydrocyclone, their volume fraction at Fr = 207 exceeds that at Fr = 73.4. This is due to the fact that the circumferential velocity of the dispersion medium, Θ_1, decreases in regions remote from the film surface because of a considerable increase in the suspension film thickness [7] and a decrease in the fullness of the radial distribution of the circumferential velocity of the dispersion medium at Fr = 207. Complexes are formed in the first stage of flotation at larger values of the axial coordinate Z and their extraction by secondary-gas bubbles decreases (kinetic constants of the first and second stages of flotation, A_1 and A_2, decrease). In addition, the decrease in the circumferential velocity of the dispersion medium, Θ_1, and the increase in the suspension film thickness result in that the emergence of complexes at the film surface becomes lower, which also leads to an increase in the residual volume fraction of solid particles bound into complexes in the outlet cross section of the film. In this case, $\bar{C} = 2.56 \times 10^{-4}$ and $\bar{C}_0 = 6.32 \times 10^{-1}$, in agreement with the results of the analysis we made.

Figure 4 shows trajectories of complexes (Fig. 4a) and distributions of the volume fraction of solid particles bound into complexes (Fig. 4b) for $\mathrm{Re}_n = 5 \times 10^2$ and the same values of the parameters as those in Fig. 2. Comparison of Figs. 4 and 2 shows that at $\mathrm{Re}_n = 5 \times 10^2$ the maximum volume fraction of solid particles bound into complexes on the trajectories decreases compared with the values at $\mathrm{Re}_n = 4 \times 10^3$, and their volume fraction in the outlet cross section of the hydrocyclone increases. This is due to a significant increase in the suspension film thickness [7], decrease in the fullness of the radial distribution of the circumferential velocity of the dispersion medium, and increase in the decay of the circumferential velocity of the dispersion medium, Θ_1, in the axial direction at $\mathrm{Re}_n = 5 \cdot 10^2$. The decrease in the circumferential velocity of the dispersion medium, Θ_1, results in that the kinetic constant of the first stage of pressure-head flotation, A_1, becomes smaller and complexes are formed at larger values of the axial component Z, the amount of complexes transferred to the froth layer on the film surface diminishes (see trajectories in Fig. 4a), and their extraction by secondary-gas bubbles falls down, which is due to a decrease in the kinetic constant of the second stage of flotation, A_2. $\bar{C} = 2.17 \times 10^{-3}$ and $\bar{C}_0 = 8.1 \times 10^{-1}$ at $Z = 30$, which points to a significant increase in the integral-average residual volume fraction of solid particles bound into complexes, compared with that at $\mathrm{Re}_n = 4 \times 10^3$.

Figure 5 shows trajectories of complexes (Fig. 4a)

and distributions of the volume fraction of solid particles bound into complexes (Fig. 4b) for $n = 1$ and the same values of the parameters as those in Fig. 2; this corresponds to separation in a hydrocyclone of a suspension with a Newtonian dispersion medium. Comparison of Figs. 5 and 2 shows that at $n = 1$ the maximum volume fraction of solid particles bound into complexes on the trajectories is significantly smaller than that at $n = 0.6$, whereas their volume fractions in the outlet cross section of the hydrocyclone considerably exceed the values at $n = 0.6$. This is due to a stronger decay of the circumferential velocity of the dispersion medium, Θ_1, in the axial direction at $n = 1$ [7], corresponding increase in the suspension film thickness, and decrease in the fullness of the radial distribution of the circumferential velocity of the dispersion medium, Θ_1. This results in that the kinetic constants of the first and second stages of pressure-head flotation decrease, complexes are formed at larger values of the axial coordinate Z, and the amounts of their extraction by secondary-gas bubbles and transfer to the froth layer on the film surface become smaller. In the case of separation of a suspension with a Newtonian dispersion medium ($n = 1$) at $Z = 30$, $\bar{C} = 1.97 \times 10^{-3}$ and $\bar{C}_0 = 6.33 \times 10^{-1}$. These values considerably exceed those for $n = 0.6$, which demonstrates that the separation of suspensions with a pronounced anomaly of the non-Newtonian properties of the dispersion medium by two-stage pressure-head flotation is markedly more efficient.

CONCLUSIONS

(1) A mathematical model of separation of suspensions with a non-Newtonian dispersion medium by two-stage pressure-head flotation in a cylindrical direct-flow hydrocyclone was developed. This model makes it possible to calculate the concentration field of solid particles and to find the average-integral residual volume fraction of solid particles in the suspension film.

(2) It was shown that the two-stage pressure-head flotation can markedly reduce the residual volume fraction of solid particles in the suspension film, compared with the single-stage process.

(3) The influence exerted by the determining similarity numbers and by the rheological properties of the dispersion medium on the separation parameters was analyzed and it was found that separation of suspensions with a pronounced anomaly of the non-Newtonian properties of the dispersion medium is more efficient and provides a smaller residual volume fraction of solid particles.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Promising Prospects for Using Partially Fluorinated Alcohols as O-Nucleophilic Reagents in Organofluoric Synthesis

Abstract—Perfluoroolefins react with isopropyl alcohol under the conditions of radical initiation to form partially fluorinated aliphatic alcohols. The reactions of these alcohols with hexafluoropropylene and compounds containing labile halogen atoms (in particular, with allyl bromide and epichlorohydrin) were studied.

DOI: 10.1134/S1070427207030123

Partially fluorinated primary alcohols of the type $H(CF_2CF_2)_nCH_2OH$ (n = 1–6), produced by the reaction of tetrafluoroethylene with methanol at elevated temperature and pressure in the presence of a peroxy initiator decomposing above 100°C [1–3], are widely used in organofluoric synthesis [4]. In particular, they are intermediates for the production of many fluorinated substances whose functionalization, occurring at the $CH_2OH^{\bullet}$ and CHF_2 groups, yields primarily partially fluorinated carboxylic [5–9] and alkanesulfinic [4] acids, as well as fluorinated glycol ethers [4]. At the same time, in the presence of bases fluorinated alcohols behave as active O-nucleophiles allowing preparation of a large set of ethers and esters [10]. The interest in the development of processes for the production of a definite alcohol considerably increased recently, when these alcohols proved to be efficient as materials for information-displaying media with the reproducing layer capable of reading the information with a laser, and also in production of high-performance surfactants and developers for photography [11].

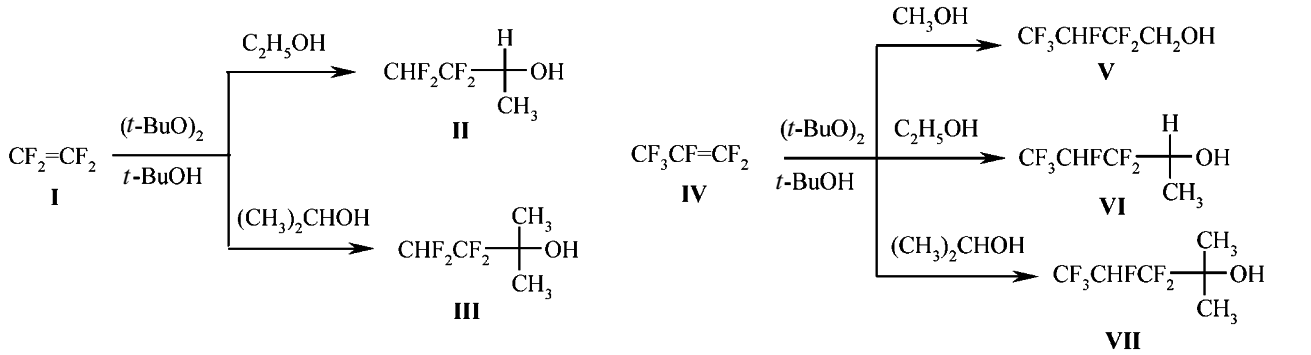
In the new patents, the procedure for preparing fluorinated alcohols is based on the main process, radical addition of methanol to tetrafluoroethylene, and the difference between the patents mainly consists in optimization of the process conditions with the aim to obtain the most demanded product, 2,2,3,3-tetrafluoropropyl alcohol [2]. The process proved to be more efficient in the presence of $CaCO_3$ [12–14]. When the reaction is performed at 60–65°C for 4 h, 2,2,3,3-tetrafluoropropyl alcohol is formed [13], whereas at 125°C and a pressure of 0.8 atm (6 h) the reaction gives a mixture of alcohols [13]. The best results were obtained at the tetrafluoroethylene : methanol ratio of 1 : 15 [14], when 2,2,3,3-tetrafluoropropyl alcohol was the only product. The possibilities of this method were somewhat extended by bringing into the reaction with methanol hexafluoropropylene and terminal perfluoroolefins $RCF{=}CF_2$ (R = C_1–C_4 perfluoroalkyl) in the presence of dialkyl peroxides [2, 11, 15]. A wider range of partially fluorinated alcohols thus became accessible. On the whole, there is growing interest in the development of processes for production of such alcohols; their accessibility will expand the prospects for their application.

Proceeding with studies on the synthesis of various partially fluorinated alcohols by reactions of available perfluoroolefins with aliphatic alcohols in the presence of peroxy initiators [16, 17], we examined in this work the possibility of performing this reaction with other perfluoroolefins and using the products obtained as O-nucleophilic agents in synthesis of promising intermediates.

Further development of the process suggested in [2] showed that the reactions of tetrafluoroethylene **I** and hexafluoropropylene **IV** with aliphatic alcohols in excess di-*tert*-butyl peroxide at 125°C and a pressure of 0.8 MPa smoothly yield partially fluorinated alcohols **II**, **III**, and **V**–**VII** by addition of aliphatic alcohols across the double bond (Scheme 1). We

showed previously [16] that alcohol **VI** occurs in the form of two stable diastereomers (in approximately 50 : 50 ratio) which can be separated on a capillary column; a GC–MS analysis gives two mass spectra. It is interesting that alcohol **VII** also occurs in two diastereomeric forms, but their ratio is 26.4 : 1. The target products should be isolated by direct distillation of the reaction mixtures:

Scheme 1.



Presumably, these reactions in the presence of di-*tert*-butyl peroxide occur via intermediate radicals generated from the alcohol by abstraction of the α-H atom with the peroxide, followed by the reaction of the resulting radical with perfluoroolefin. Various aliphatic alcohols (methanol, ethanol, isopropanol) can be sources of alkyl radicals.

Experimental syntheses of polyfluorinated telomeric alcohols showed that, to attain the maximal yield of the target products, it is necessary to keep within strictly definite limits the reaction time, temperature, and pressure, with the optimal parameters being different for each polyfluorinated alcohol. For example, the optimal reaction time is directly related to the activity of the starting aliphatic alcohol in telomerization with perfluoroolefins, which can be illustrated by a comparative diagram shown in Fig. 1.

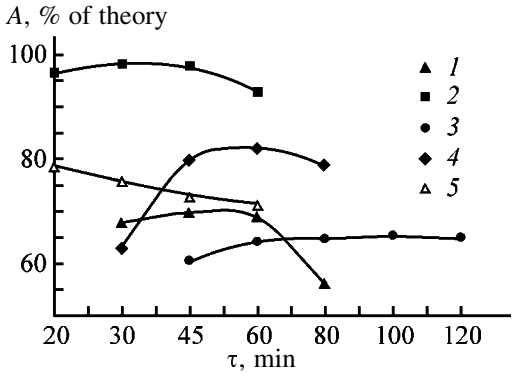


Fig. 1. Comparative diagram of the yields *A* of polyfluorinated telomeric alcohols vs. synthesis time τ: (*1*) 3,3,4,4-tetrafluorobutan-2-ol, (*2*) 3,3,4,4-tetrafluoro-2-methylbutan-2-ol, (*3*) 2,2,3,4,4,4-hexafluorobutan-1-ol, (*4*) 3,3,4,5,5,5-hexafluoropentan-2-ol, amd (*5*) 3,3,4,5,5,5-hexafluoro-2-methylpentan-2-ol; the same for Fig. 3.

This diagram shows that the optimal time of the synthesis of a polyfluorinated alcohol is the shorter, the higher the activity of the starting aliphatic alcohol (according to the radical telomerization theory, the activity of aliphatic alcohols decreases in the order isopropanol > ethanol > methanol) in telomerization with a perfluoroolefin. It should also be emphasized that the yield of a polyfluorinated alcohol derived from hexafluoropropylene is, as a rule (irrespective of the aliphatic alcohol used), lower (under the optimal conditions) than the yield of the corresponding telomer derived from tetrafluoroethylene. This may be due to the occurrence of side isomerization reactions in the course of the synthesis, in accordance with the above-described mechanism. At the same time, a decrease in the yield of the desired polyfluorinated alcohol with an increase in the synthesis time is due to the fact that the arising radical further reacts with tetrafluoroethylene (hexafluoropropylene forms exclusively monoaddition products), with the propagation of the polyfluorinated chain of the alkanol and formation of higher telomers. As a result, the reaction selectivity decreases and the amount of impurities increases. Simultaneously with the formation of higher telomers, decomposition of the initiator, di-*tert*-butyl peroxide, yields *tert*-butanol which actively reacts with the target polyfluorinated alcohol under the conditions existing at the end of the reaction (increased temperature and pressure, low pH), to form *tert*-butyl ether of the polyfluorinated alcohol. It should be noted, however, that too short reaction time also results in

increased content of impurities because of increased amount of unchanged aliphatic (starting) alcohol and initiator, especially at low temperatures and pressures of the synthesis. Thus, the amount of impurities formed in the synthesis depends on the conditions that are set or arise when the reaction time is made shorter or longer than the optimum, and also on the amount of the initiator participating in the synthesis. Figure 2 shows how the amount of impurities depends on the temperature and on the amount of the initiator taken for the synthesis.

Figure 2 shows that the optimal amount of the initiator participating in the process is 7–8 wt % relative to the starting aliphatic alcohol; in this case, the optimal temperature range is the broadest (135–150°C), and the yield of the desired polyfluorinated alcohol is reproducibly high provided that the synthesis time is wiithin the optimal range (Fig. 1). As the initiator amount is decreased below 7 wt %, the content of the desired perfluorinated alcohol in the reaction mixture decreases; this is due to an increase in the amount of unchanged aliphatic alcohols and di-*tert*-butyl peroxide, and if the temperature is increased to 145–150°C and the reaction time is made longer, the relative content of higher telomeric alcohols increases. When the initiator amount is higher (>9 wt %) than the optimal level, the increased content of impurities is due to decomposition of excess initiator and reaction of its decomposition products with polyfluorinated alcohols, and also to formation of higher telomers.

One more parameter significantly affecting the yield of polyfluorinated alcohols is the pressure produced by the perfluoroolefin in the reaction volume at optimal temperature and time of the synthesis. Within the framework of our method, with the aim to improve the synthesis safety and ensure control over the reaction rate, we fed the perfluoroolefin into the reaction volume in portions. As a fresh portion of perfluoroolefin is fed into the reactor, it starts to react with radicals of the aliphatic alcohol; as a result, the pressure in the reaction vessel decreases until the reaction is complete or until a new portion of the olefin is fed. Thus, pressure oscillations are always observed in the course of the synthesis (due to cyclic feeding of perfluoroolefin into the reaction mixture). The dependence of the yield of polyfluorinated alkanols on the mean synthesis pressure is shown in Fig. 3.

As seen from Fig. 3, the maximal yield of the desired polyfluorinated alcohols is attained in the range of mean working pressures from 9 to 11 atm, and for each polyfluorinated alcohol the optimal working pressure is specific for each combination of

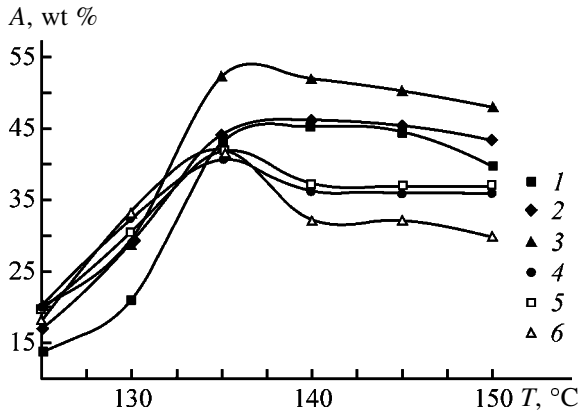

Fig. 2. Average statistical dependence of the content of polyfluorinated alcohols in the reaction mixture *A* on the synthesis temperature *T* and amount of initiator taken. Initiator amount, % relative to the starting alcohol: (*1*) 6, (*2*) 7, (*3*) 8, (*4*) 9, (*5*) 10, and (*6*) 12.

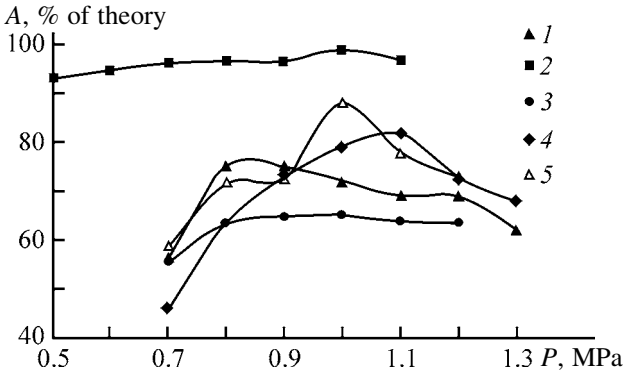

Fig. 3. Comparative diagram of the yield *A* of polyfluorinated alcohols vs. mean synthesis pressure *P*.

the starting aliphatic alcohol and perfluoroolefin, provided that the temperature and time of the synthesis and the amount of the peroxy initiator are within the optimal range. It should be noted that, if the working pressure exceeds the optimal level, the yield of polyfluorinated alcohols decreases as a result of formation of higher telomers (with tetrafluoroethylene) or of isomerization of the desired polyfluorinated alcohols under severe reaction conditions. This trend is due to an increase in the amount of perfluoroolefin dissolved in the liquid phase (i.e., occurring in the reaction zone) with an increase in the pressure. Excess perfluoroolefin will cause propagation (or branching) of the perfluorinated chain of the molecule (or radical) of polyfluorinated alcohol, especially at minimal saturation of the reaction mixture with free radicals of the peroxy initiator and starting aliphatic alcohol; just such conditions arise by the end of the reaction or at a long reaction time. At the same time, too low work-

Table 1. Optimal conditions of synthesis of polyfluorinated telomeric alcohols

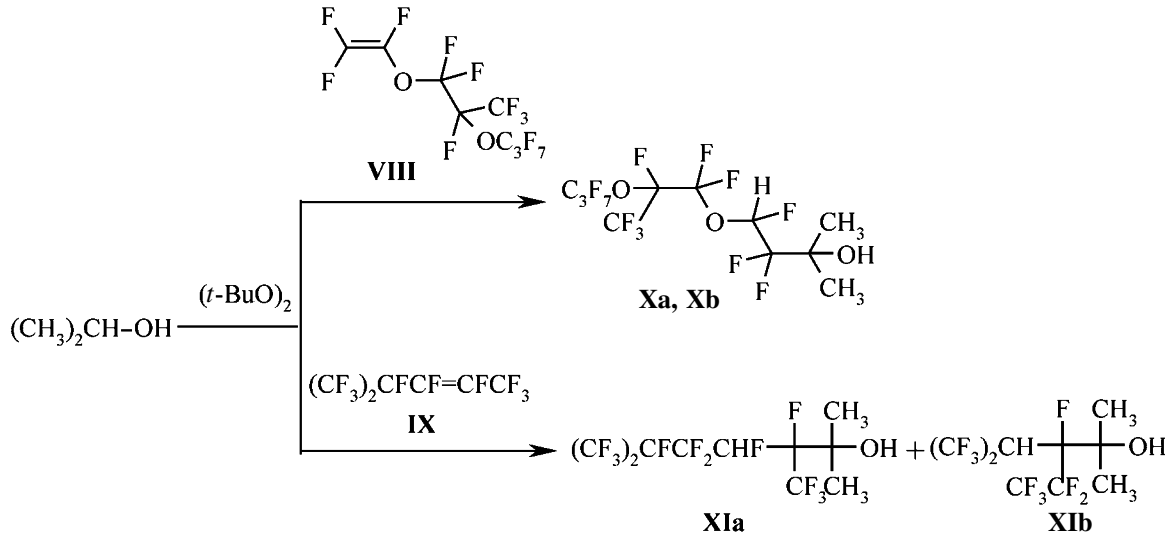
Alcohol	*t*, h	*T*, °C	*P*, atm	Amount of $(t\text{-BuO})_2$, %	Yield, %
II	60	140	9	8	Up to 75
III	30	140	10	7	Up to 97
V	10 0	140	10	8	Up to 66
VI	60	140	11	8	Up to 83
VII	20	140	10	7	Up to 88

ing pressures are also undesirable, because the content of the perfluoroolefin in the reaction zone in this case decreases; as a result, the decomposition products of the peroxy initiator are formed more actively, and the concentration of impurities capabale to react with the desired polyfluorinated alcohol increases.

Thus, to attain the maximal yield of a specific polyfluorinated telomeric alcohol, it is necessary to strictly keep the working pressure, temperature and time of the synthesis, and initiator amount in the optimal ranges. The optimal values of these parameters for each of the polyfluorinated alcohols obtained and the corresponding values of the average yield and main substance content are given in Table 1.

By the example of the reaction of isopropyl alcohol with perfluoroolefins **IV** and **VIII**, and also with internal perfluoroolefin **IX**, in excess $(t\text{-BuO})_2$ at 125°C and a pressure of 0.8 MPa, we demonstrated the principal possibility of preparing other partially fluorinated alcohols, in particular, **VII**, **X**, and **XI**. According to GC–MS analysis, alcohol **X** exists in the form of two stable diastereomers in a 1.65 : 1 ratio (Scheme 2). From perfluoroolefin **IX**, along with alcohol **XIa**, alcohol **XIb** is formed in a yield of up to 10%, which can be accounted for by isomerization of the starting perfluoroolefin into perfluoro-2-methyl-2-pentene and its reaction with isopropyl alcohol.

Scheme 2.



The structures of alcohols **VII**, **X**, and **XI** were confirmed by ^1H, ^{13}C, and ^{19}F NMR spectroscopy (Table 2), IR spectroscopy, and mass spectrometry. Despite the fact that all these alcohols contain the same $HCFCF_2$ fragment, the signals in the ^{19}F NMR spectrum show an *AB* pattern (Table 2). The position of the OH proton signal in the ^1H NMR spectrum depends on the solvent. For neat compound **VII**, the OH proton signal lies at 4.21 ppm, whereas for a 10% solution of **VII** in $CDCl_3$ it lies at 3.12 ppm. Similarly, for neat compound **XIa** the OH proton signal lies at 2.97 ppm, and for a 10% solution of **XIa** in $CDCl_3$, at 1.69 ppm. This is caused by differences in association of OH groups via intermolecular hydrogen bonds.

Introduction of fluorine atoms into the carbon chain of aliphatic alcohols decreases their nucleophilic activity. Nevertheless, telomeric alcohols $H(CF_2CF_2)_n \cdot CH_2OH$ [n = 1 (**XII**), 2 (**XIII**), 3 (**XIV**), 4 (**XV**)] in the presence of a catalytic amount of KOH react with hexafluoropropylene to form, though in a low yield,

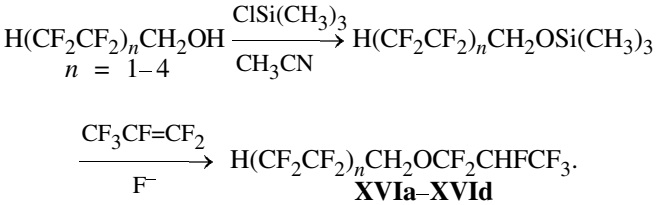
* The chemical shifts and coupling constants for this isomer (**XIb**) could not be determined because of its low content in the mixture.

partially fluorinated dialkyl ethers [18]. In the presence of equimolar amounts of bases, by-products are formed, apparently due to transformations of the starting hexafluoropropylene, occurring in this system.

To enhance the activity of O-nucleophiles, especially with a long carbon chain, it was suggested to use trimethylsilyl ethers of the corresponding telomeric alcohols, which are prepared from the alcohols by treatment with trimethylchlorosilane in the presence of an equimolar amount of triethylamine, or with bis(trimethylsilyl)amine [19, 20]. The subsequent reaction of these ethers with hexafluoropropylene, catalyzed by fluoride ion, yields the corresponding dialkyl ethers **XVI**–**XIX** (Scheme 3).

Scheme 3.

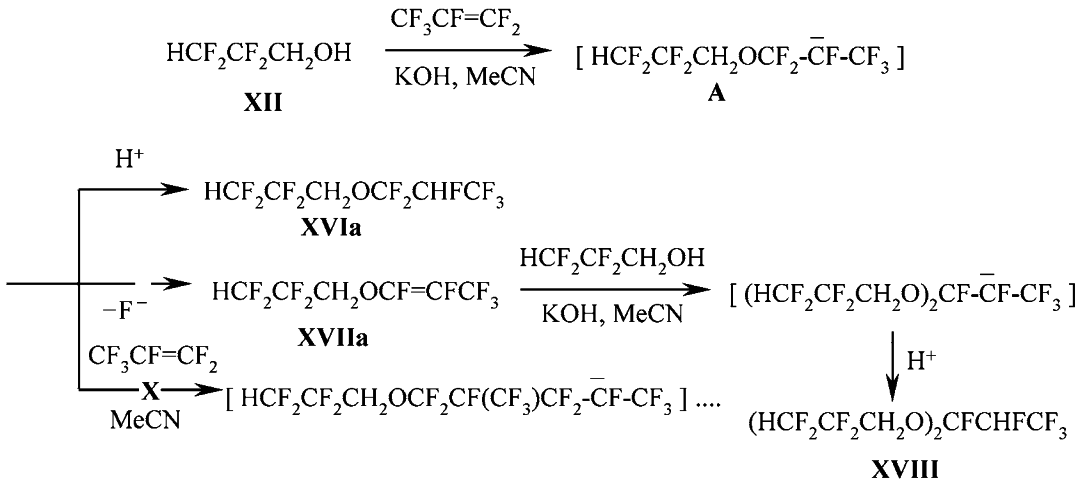


n = 1, **XVIa**; n = 2, **XVIb**; n = 3, **XVIc**; n = 4, **XVId**.

This route ensures appreciably higher yield of the target products because of lower contribution of degradation processes and controllable extent of polysubstitution.

An increase in the content of KOH relative to the telomeric alcohol leads to formation of high-molecular-weight by-products, apparently due to differences in the transformation pathways of intermediate carbanion **A**. The possible pathways of reaction of the alcohol $HCF_2CF_2CH_2OH$ with hexafluoropropylene are shown in Scheme 4.

Scheme 4.

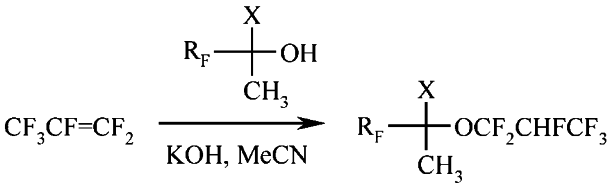


In one of these pathways, carbanion **A** reacts with a proton of the medium to give product **XVI**. Another pathway involves elimination of the fluoride ion with the formation of unsaturated ether **XVIIa**, which subsequently reacts with the O-nucleophilic agent to form by-product **XVIII**. Such compounds were not further studied, although they may be of practical interest as high-boiling liquids.

We found that ether **XVIa** under the action of solid KOH in acetonitrile undergoes cleavage to the starting alcohol **XII**, without formation of **XVIIa**. The pathway involving oligomerization with hexafluoropropylene under the action of fluoride ion is not realized under these conditions.

We believe that this approach has significant advantages and allows economically efficient preparation of diverse polyfluorinated dialkyl ethers. Indeed, the procedure for preparing partially fluorinated dialkyl ethers appeared to be fairly versatile (suitable not only for primary but also for secondary and tertiary alcohols). In particular, secondary alcohol **VI** and tertiary alcohols **VII** and **XI** react with hexafluoropropylene to form ethers **XIXa** and **XIXb** (Scheme 5).

Scheme 5.



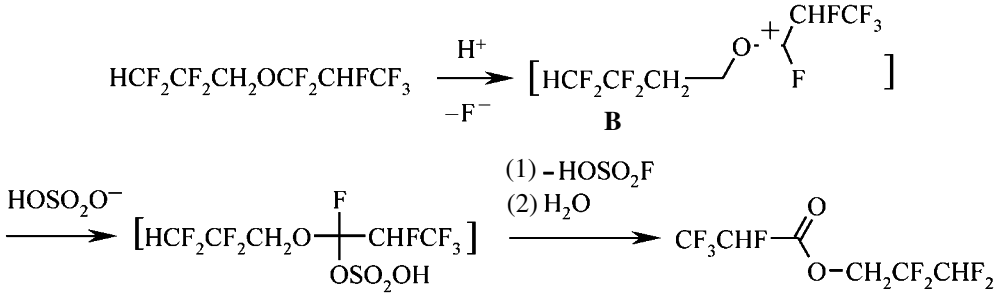
XIXa, XIXb

$R_F = CF_3CHFCF_2$, X = H (**XIXa**),
CF_3CHFCF_2, X = CH_3 (**XIXb**).

The partially fluorinated dialkyl ethers obtained can be of interest as intermediates for the synthesis of perfluorinated dialkyl ethers by direct additional fluorination with elemental fluorine and can be used as liquid

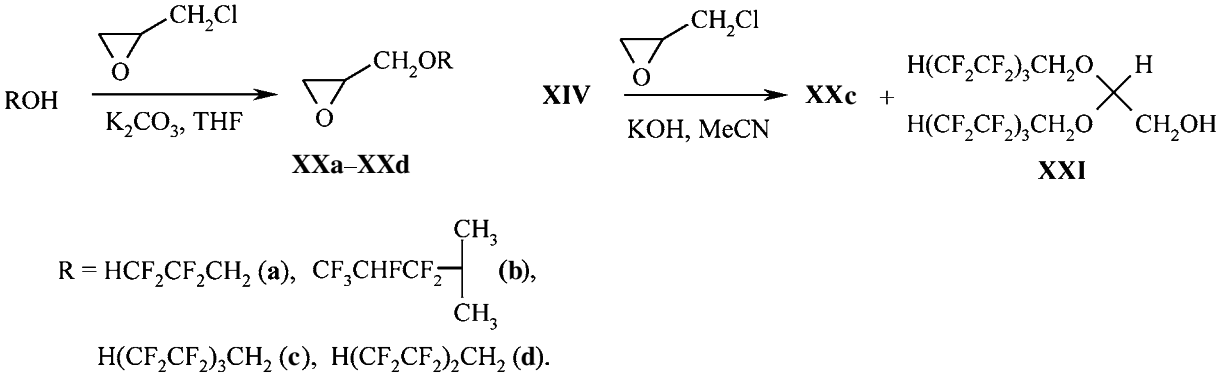
dielectrics for various purposes. Another area of their possible application can be preparation of partially fluorinated acrylates. It is known [16] that dialkyl ethers containing alkyl and CF_3CHFCF_2 groups at the oxygen atom readily transform into tetrafluoropropionic acid esters at room temperature in sulfuric acid solutions. On the contrary, ethers **XVIa**–**XVId** under these conditions are resistant to the action of concentrated H_2SO_4 and transform into propionic acid esters only upon prolonged heating [18]. Presumably, the limiting step of this reaction is the heterolysis of the C–F bond in the α-position relative to ether oxygen, with the generation of carbocation **B** whose subsequent reaction with the anion of the medium yields an intermediate transforming into propionic acid ester under the action of water (Scheme 6). Dehydrofluorination of the product formed can yield trifluoroacrylic acid ester.

Scheme 6.



In the reaction of polyfluorinated telomeric alcohols with epichlorohydrin, opening of the epoxy ring could be expected, although an example of preservation of the epoxy ring has been reported. It was shown [19, 20] that 2-fluoro-2,2-dinitroethyl alcohol in the presence of NaOH transforms into the corresponding epoxide. We found that the reaction of epichlorohydrin with telomeric alcohols **XII**–**XIV** in the presence of K_2CO_3 in acetonitrile gave the coresponding epoxides **XXa**–**XXd** (Scheme 7). However, their yield was low. A similar pattern was observed with alochols **V**–**VII** under the same conditions. The use of NaOH or KOH instead of K_2CO_3 increases the yield of products of the epoxy ring opening.

Scheme 7.



From the reaction of epichlorohydrin with alcohol **XIV**, we isolated the ring opening product **XXI** formed by attack of the O-anion $[H(CF_2CF_2)_3CH_2O^-]$ at the 2-position of the epoxy ring (Scheme 7).

Oxidation of perfluoroalkyl allyl ethers can be one of routes to polyfluorinated epoxides. It was shown previously [21] that telomeric alcohol **XII**, $HCF_2CF_2 \cdot CH_2OH$, reacts with allyl chloride in dimethylform-

amide in the presence of NaOH to form a partially fluorinated alkyl allyl ether. We further developed this approach and brought telomeric alcohols $H(CF_2CF_2)_n \cdot CH_2OH$ (n = 2–4) and the synthesized partially fluorinated alcohols into the reaction with allyl bromide in acetonitrile in the presence of KOH, to obtain polyfluoroalkyl allyl ethers **XXIIa**–**XXIIe** (Scheme 8).

Scheme 8.

$$ROH \xrightarrow[KOH,\ MeCN]{BrCH_2CH=CH_2} ROCH_2CH=CH_2,$$

XXIIa–**XXIIe**

R = $H(CF_2CF_2)_2CH_2$ (**a**), $CF_3CHFCF_2C(CH_3)_2$ (**b**), $H(CF_2CF_2)_3CH_2$ (**c**), $CHF_2CF_2C(CH_3)_2$ (**d**), $H(CF_2CF_2)_4CH_2$ (**e**).

The structure of the products obtained was confirmed by IR and ^1H, ^{13}C, and ^{19}F NMR spectroscopy (Table 2) and by mass spectrometry. The ^1H NMR spectra of the partially fluorinated compounds prepared contain proton signals of the $CH_2CH=CH_2$ and $CH_2=CHC(O)$ groups with the chemical shifts typical of such fragments. In the ^{19}F and ^{13}C NMR spectra, there are signals with the same chemical shifts and coupling constants from the F and C atoms of the CF_3CHFCF_2– and –$OCH_2CF_2CF_2$– groups; the CF_2 group in the CF_3CHFCF_2– fragment gives in the ^{19}F NMR spectrum an *AB* pattern with J_{FF} = 140–280 Hz. The fluorine signal of the CHF group (CF_3CHFCF_2–) is located in a higher field (from –40 to –49 ppm).

Thus, partially fluorinated aliphatic alcohols can be efficient O-nucleophilic reagents, which extends their possible applications for preparing various fluorinated materials.

EXPERIMENTAL

The ^1H, ^{13}C, and ^{19}F NMR spectra were recorded on a Bruker WP 400 SY spectrometer at operating frequencies of 400, 100, and 188 MHz, respectively [internal references HMDS, C_6F_6 (J_{CH} values were not measured), and $CDCl_3$]. The IR spectra (5% solutions in CCl_4) were recorded on a Specord M-80 spectrometer; GC–MS analysis was performed on a VG 707 OE device (ionizing electron energy 70 eV) and on a Hewlett–Packard G 1800 A GCD chromatograph with a mass-selective detector. In the latter case, we used a 30-m-long column 0.25 mm in diameter, coated with a 0.25-μm layer of HP-5 (5% diphenyl–95% dimethylsiloxane copolymer); carrier gas He, flow rate 1 ml min^{-1}, vaporizer temperature 280°C. The column temperature schedule was as follows: 50°C, 2 min; heating to 280°C, 10 deg min^{-1}; 280°C, 5 min. All the reactions were monitored by ^{19}F NMR. The reaction mixtures were analyzed with an LKhM 72 chromatograph (15% SE-30 on SKTF-803, QF-1, Chromosorb W, 4000 × 4-mm column). Compound **XVIa** was prepared as described in [20]. The NMR data are given in Table 2, and the analytical data and characteristics of the compounds, in Table 3.

The general procedure for preparing partially fluorinated alcohols was as follows. A reactor was charged with isopropyl alcohol and di-*tert*-butyl peroxide (3.5–15.4 wt % relative to the alcohol), sealed, and heated to 150°C in the presence of the polyfluorinated alcohol taken in an amount of 0.2–1.2 wt % relative to isopropyl alcohol, after which perfluoroolefin was fed at a pressure of 9–15 atm. The molar ratios were as follows: fluoroolefin : initiator (7.2–28.2) : 1, fluoroolefin : alcohol 1 : 15. The mixture was kept for 4 h, after which excess perfluoroolefin was removed and the mixture was distilled. After distillation of excess isopropyl alcohol, a base ($CaCO_3$) was added, and 99.9% pure partially fluorinated alcohol was distilled off. The characteristics of the alcohols obtained are given in Tables 2 and 3.

Reactions of hexafluoropropylene with partially fluorinated alcohols. To a suspension of 0.12 mol of KOH in 50 ml of acetonitrile, we added with stirring and cooling with cold water 0.1 mol of a partially fluorinated alcohol and then passed 0.1 mol of hexafluoropropylene with stirring and monitoring the reaction temperature. The solution volume increased. The mixture was poured into water, and the organic layer was separated, washed with water, dried over $MgSO_4$, and distilled. The results are given in Table 3.

Synthesis of α,α,β,ω-tetrahydroperfluoropropyl nonyl ether XVId. To a suspension of 7 g (0.12 mol) of KOH in 100 ml of acetonitrile at 20°C, we added dropwise with vigorous stirring 41.6 g (0.1 mol) of alcohol **XV**. The mixture was allowed to stand for 0.5 h, after which gaseous hexafluoropropylene (15 g, 0.1 mol) was passed at a rate allowing counting of separate bubbles. The reaction was exothermic; therefore, the mixture was cooled with ice-cold water. The gas was passed until the heat evolution ceased. The volume of the reaction mixture increased. After approximately 1.5 h, the mixture was poured into water, and the organic layer was separated, washed with water, dried over $MgSO_4$, and distilled; 40.2 g (69%) of **XVId** was obtained.

(2,2,3,3,4,4,5,5,6,6,7,7-Dodecafluoroheptyloxymethyl)oxirane XXc. IR spectrum (CCl_4, 5%), ν, cm^{-1}: 3064, 3002, 2928 (C–H), 1441 and 1250 (epoxy group), 1201 (C–O), 1169 and 1143 (C–F), 998 and 906 (epoxy group). Mass spectrum, *m*/*z* (I_{rel}, %): 368 $[M - HF]^+$ (15.29), 358 $[M - CH_2O]^+$ (2.55), 345 $[M - CHCH_2O]^+$ (54.01), 338 $[M - CF_2]^+$ (4.23), 245 $[CF_2CF(CF_2)CH_2]^+$ (16.75), 181 $[CF_2CF(CF_2)_3CH_2]^+$ (2.52), 151 $[HCF_2CF_2CF_2]^+$ (3.01), 131 $[CF_2CFCF_2]^+$ (13.94), 101 $[HCF_2CF_2]^+$ (9.72), 100 $[CF_2CF_2]^+$ (5.78), 87 $[CH_2OCH_2CHCH_2O]^+$ (2.84), 69 $[CF_3]^+$ (19.79), 57 $[CH_2CHCH_2O]^+$ (100), 51 $[CHF_2]^+$ (32.05).

The reactions of epichlorohydrin with the other partially fluorinated alcohols, yielding the corresponding oxiranes **XIIa**–**XIIc** (Tables 2, 3), were performed similarly.

Reactions of partially fluorinated alcohols with allyl bromide. To a suspension of 6.7 g (0.1 mol) of KOH in 50 ml of acetonitrile, we added with stirring and cooling with ice-cold water 23.2 g (0.1 mol) of alcohol **XIII**; the mixture was allowed to stand for 1 h at room temperature. Then 12.1 g (0.1 mol) of allyl bromide was added; the mixture was heated at 45°C for 4 h with stirring, after which it was poured into water. The organic layer was separated, washed with water, dried over $MgSO_4$, and distilled. 1,1,5-Trihydrooctafluoropentyl allyl ether **XXIIa** was obtained; yield 25.8 g (95%), bp 126–127°C (20 mm Hg). IR spectrum (CCl_4, 5%), ν, cm^{-1}: 3088, 3001, 2943, 2865 (C–H), 1673 (C=C), 1461 and 1402 (C–O), 1174 and 1134 (C–F), 935 and 898 (C–O). Mass spectrum, *m*/*z* (I_{rel}, %): 272 $[M]^+$ (29.33), 182 $[HCF_2CF_2 \cdot CF_2CF]^+$ (1.74), 131 $[HCF_2CF_2CH_2O]^+$ (6.14), 100 $[CF_2CF_2]^+$ (3.39), 71 $[CH_2OCH_2CHCH_2]^+$ (44.97), 69 $[CF_3]^+$ (13.76), 57 $[CH_2CHCH_2O]^+$ (12.19), 51 $[CHF_2]^+$ (24.78), 41 $[CH_2CH{=}CH_2]^+$ (100), 31 $[CH_2OH]^+$ (24.08).

The reactions of allyl bromide with the other partially fluorinated alcohols, yielding the corresponding ethers **XXIIb**–**XXIIe** (Tables 2, 3), were performed similarly.

CONCLUSIONS

(1) Partially fluorinated alcohols were prepared by reactions of perfluoroolefins with ethanol and isopropanol in the presence of di-*tert*-butyl peroxide. The reactions yield mixtures of thermodynamically stable diastereomers.

(2) The reactions of partially fluorinated alcohols with epichlorohydrin and allyl bromide in the presence of a base (K_2CO_3, KOH) give products of halogen replacement. With KOH, the products of epoxy ring opening are also formed in a low yield.

(3) The reaction of hexafluoropropylene with partially fluorinated alcohols in the presence of KOH yields dialkyl ethers and polysubstituted ethers, whereas with trimethylsilyl ethers of these alcohols the dialkyl ethers are formed without a base as the only products.

Abstract—The spectral characteristics of products formed in the reaction of an incompletely fluorinated impurity in perfluorodecalin, hexadecafluorobicyclo[4.4.0]dec-1(6)-ene, with amines in various solvents were studied. The reaction rates in various solvents were compared, and the distribution of the reaction products between perfluorodecalin and solvents was examined.

DOI: 10.1134/S1070427207030135

In perfluoroorganic compounds, all hydrogen atoms are replaced by fluorine atoms. Generally these compounds consist of carbon and fluorine atoms; they also can include other atoms, e.g., N, O, and S. The C–F bond energy is higher than the energy of the C–H and C–C bonds, which provides high thermal and chemical stability of perfluoroorganic compounds. As hydrogen atoms are replaced by fluorine atoms, e.g., in methane, the C–F bond becomes shorter and its energy increases. One more factor accounting for the stability of fluorocarbons is favorable ratio between the length of the C–C bond and the size of the F atom. The van der Waals radius of F is shorter than the C–C bond length; therefore, accumulation of F atoms in perfluoroorganic compounds does not lead to extension and weakening of C–C bonds as in perchlorocarbons. The fluorine atoms build up a dense shell reliably protecting the carbon chain from external effects and making it chemically inert; due to weak van der Waals interactions, perfluorocarbons are more volatile than common hydrocarbons [1, 2].

Thanks to unique chemical and physical properties, perfluoroorganic compounds are used as dielectrics, heat carriers, and inert materials, and also in medicine as perfusion fluids and components of blood substitutes [3–5].

Preparation of perfluorinated products by fluorination of the corresponding hydrocarbons is accompanied by formation of a large set of partially or fully fluorinated impurities. Perfluorinated impurities are analogs of the target products and have similar electrochemical and thermal characteristics, differing from the target products only in the lower viscosity and lower boiling point. When present in an amount of up to 5 wt %, these impurities do not noticeably impair the service characteristics of the target perfluoroorganic product. At the same time, partially fluorinated compounds, i.e., hydrogen-containing and unsaturated polyfluorinated impurities, even in minor amounts (below 10^{-3} wt %) impair the chemical and service properties of the perfluoroorganic products, imparting to them toxicity and corrosion activity and making worse the dielectric properties of the compositions [6].

A typical perfluoroorganic compound is perfluorodecalin (PFD), used in industry as a heat carrier and a dielectric, and also in medicine as a component of an artificial blood substitute and perfusion fluid [4, 5]. Production of PFD by fluorination of naphthalene and tetralin involves formation of a series of hydrogen-containing and unsaturated impurities (Table 1) [7, 8].

Partially fluorinated impurities with a high degree of substitution with fluorine atoms only slightly differ in physical properties from the fully fluorinated products; therefore, their separation from the target product is difficult. The main distinction of partially fluorinated compounds is their chemical activity. A characteristic reaction of partially fluorinated compounds is that with nucleophilic agents [1, 2]. The reactions of fluoroolefins and hydrogen-containing polyfluorinated compounds with amines yield amino derivatives, which essentially differ in the physicochemical properties from the starting fluoroolefins and target perflu-

Table 1. Partially fluorinated compounds formed by fluorination of naphthalene [7, 8]

Structural formula	Name
	PFDC, hexadecafluorobicyclo[4.4.0]dec-1(6)-ene
	PFHDC, 3*H*-pentadecafluorobicyclo-[4.4.0]dec-1(6)-ene
	3*H*-Heptadecafluorobicyclo[4.4.0]decane

orinated products. Conversion of partially fluorinated impurities into amino derivatives facilitates their separation from the target products. At the same time, the reaction of partially fluorinated impurities with amines can be used for estimating the degree of fluorination of a perfluoroorganic product and revealing partially fluorinated impurities.

In this study we examined the reactions of PFDC and PFHDC with amines.

It is known that solutions of products formed by reaction of diethylamine (DEA) with insufficiently pure PFD samples are red-brown [9]; however, no data on spectral characteristics of these colored compounds have been reported.

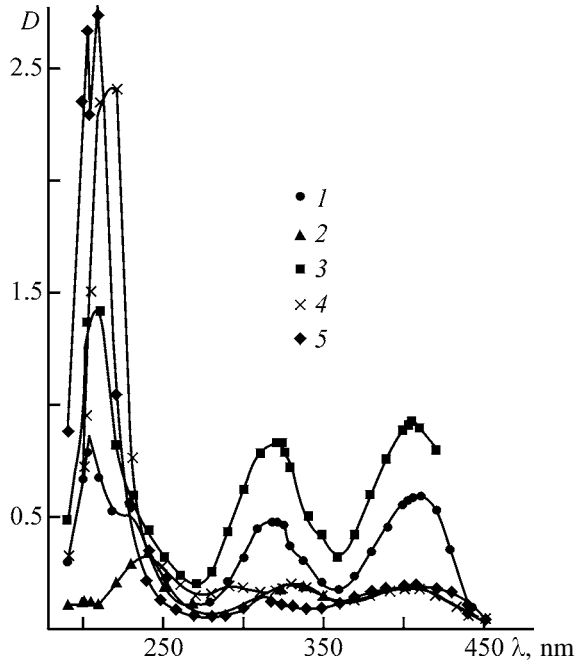

Fig. 1. Absorption spectra of products formed by reaction of PFDC (2.18×10^{-4} M) with DEA (2.19×10^{-3} M). (*D*) Optical density and (λ) wavelength; the same for Figs. 2 and 3. Solvent: (*1*) ethanol, (*2*) butanol, (*3*) acetonitrile, (*4*) 2-propanol, and (*5*) hexane.

EXPERIMENTAL

The UV/visible absorption spectra were recorded on an SF-46 spectrophotometer in the point-by-point mode with a step of 10 nm (near peaks, 2 nm) using 10-mm quartz cells. The ^{19}F NMR spectra were measured on a Bruker Spectrospin device (84.8 MHz, internal reference hexafluorobenzene).

Perfluorobicyclo[4.4.0]dec-1(6)-ene was isolated from crude PFD by two successive fractional distillations. The compound was chromatographically pure (stationary phase dibutyl phthalate). The ^{19}F NMR spectrum consisted of two singlets at 111.7 and 134.8 ppm, in agreement with published data [7].

3*H*-Heptadecafluorobicyclo[4.4.0]dec-1(6)-ene was isolated from crude PFD. According to the GLC analysis, the fraction in hand contained 39.8% 3*H*-heptadecafluorobicyclo[4.4.0]dec-1(6)-ene and 58.0% *trans*-perfluorodecalin. The ^{19}F NMR spectrum contained two characteristic high-field signals: a singlet at 187.7 ppm corresponding to the fluorine atom at the tertiary carbon atom in *trans*-perfluorodecalin and a broad signal at 214.2 ppm corresponding to the fluorine atom in the geminal position relative to the H atom. The ratio of the peak areas, 3 : 1, is equal to the ratio of the corresponding fluorine atoms, taking into account the relative content of both components.

The distribution ratios of the reaction products between PFD and the solvent were calculated as ratios of the optical densities of the solvent and PFD layers after performing the reaction for 30 min with continuous stirring and temperature control. The initial solutions were prepared by dissolution of PFDC and PFHDC in PFD and of DEA in appropriate organic solvent. The phase volume ratio was 1 : 1. As proved in [10], the optical densities of solutions are proportional to the concentrations of the reaction products. In calculations we took into account the hyperchromic effect observed in dissolution of reaction products in various solvents relative to hexane and PFD [11].

The spectra of products formed by the reaction of PFDC with diethylamine in various solvents have the following bands: λ_{max1} = 204–224, λ_{max2} = 310–322, and λ_{max3} = 401–408 nm (Fig. 1, Table 2).

The band at 204 nm is difficult to assign because of absorption of the starting compounds in this range. Amino derivatives prepared in different solvents have

Table 2. Characteristics of absorption bands of PFDC, DEA, and products of their reaction in different solvents

Solvent	Bands of starting compounds				Bands of reaction products		
	DEA		PFDC		λ_{max1}	λ_{max2}	λ_{max3}
	λ_{max}	ε_{max}*	λ_{max}	ε_{max}*

Acetonitrile	200		200		210	322	408

* (ε_{max}) Molar extinction coefficient.

similar absorption bands with a small relative shift depending on particular solvent.

The products of reactions of PFDC with primary (ethylenediamine) and tertiary (triethylamine) amines give two appreciably overlapping absorption bands (Fig. 2).

The absorption spectra of products formed by reactions of PFHDC with amines are similar (Fig. 2); therefore, the products presumably have similar structures. The absorption intensity of the products formed from PFHDC is higher than that of the products formed from PFDC.

The relative reaction rates in various solvents and the solvent parameters [12] are given in Table 3.

For reactions of fluoroolefins with amines, a mechanism with formation of an intermediate zwitterion was suggested [13, 14]:

$$>C=CF_2 + R_2NH \rightleftarrows >\bar{C}-CF_2\overset{+}{N}HR_2 \xrightarrow{-HF} >C=CFNR_2. \quad (1)$$

In the reaction of PFDC with diethylamine in 2-propanol, the formation of the zwitterion is presumably preceded by the formation of a π complex as a result of interaction of the nitrogen lone electron pair with the antibonding π* orbital of PFDC (*n*–π* state). This hypothesis is supported by the calculated activation energy, 34.2 kJ mol^{-1} [15], which is appreciably lower than the energies of formation of excited singlet and triplet states of perfluoroolefins (18 kcal mol^{-1}, or 75 kJ mol^{-1} [16]) but is in the range typical of *n*–π* and charge-transfer states (21–42 kJ mol^{-1} [17]). It can also be assumed that formation of the π complex from the starting reagents is reversible, but its transformation into the zwitterion is irreversible. The rearrangement of the π complex into the zwitterion should be very sensitive to the medium and to nucleophilic agents.

The observed (Table 3) increase in the reaction rate with an increase in the solvent polarity is consistent with the suggested mechanism. The abnormal, at first glance, results for dioxane are associated with the fact that the dioxane molecule consists of polar fragments but is symmetrical, which results in zero dipole mo-

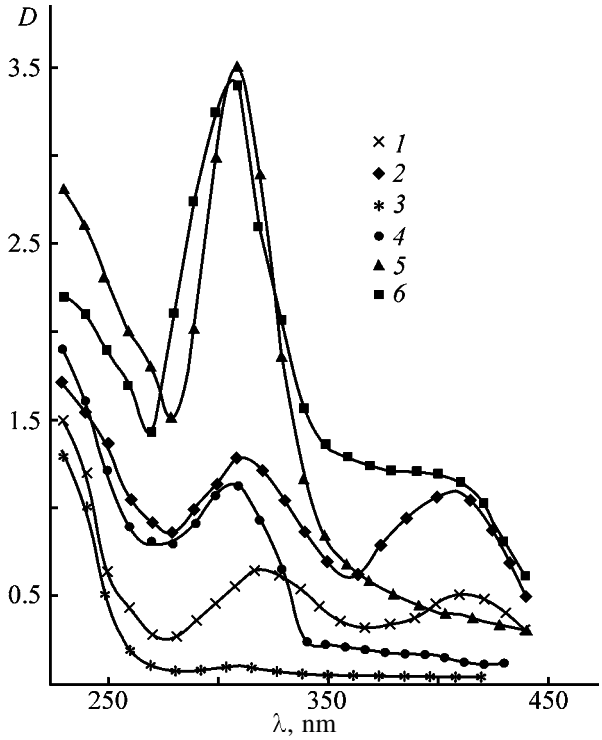

Fig. 2. Absorption spectra of products formed by reaction of PFDC and PFHDC with diethylamine (DEA), triethylamine (TEA), and ethylenediamine (EDA) (0.2 M solutions in ethanol): (*1*) PFDC + DEA, (*2*) PFHDC + DEA, (*3*) PFDC + TEA, (*4*) PFHDC + TEA, (*5*) PFDC + EDA, and (*6*) PFHDC + EDA.

Table 3. Solvent effect on the rate of product formation in the reaction of PFDC (0.002 M) with diethylamine (0.008 M) at room temperature

Solvent	Solvent parameters		Relative reaction rate* monitored at indicated λ_{max}, nm	
	μ, D	ε	310	406

Ethanol	6.80	3.0	24.3	54±5	100±10

ment and low dielectric permittivity. However, in this case the macroscopic characteristics of the solvent do not reflect in full measure its physicochemical properties associated with separate fragments of molecules.

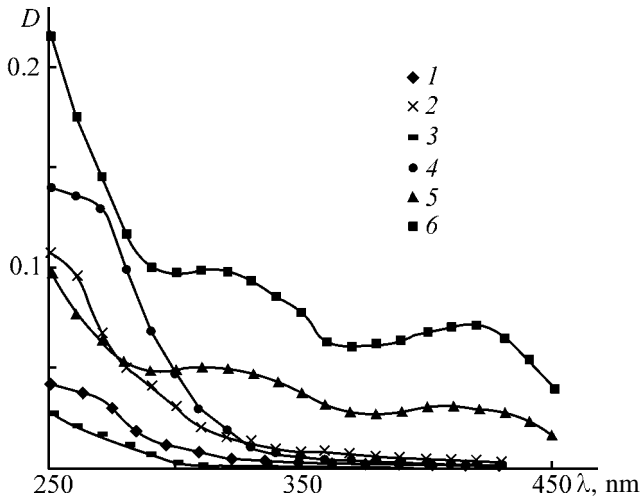

Fig. 3. Absorption spectra: (*1*, *2*) starting substances, (*3*, *4*) ethanol extracts, and (*5*, *6*) products of reaction of 0.2 M solution of diethylamine in ethanol with the samples. Crude PDF: (*1*, *3*) sample 1, (*2*, *4*) sample 2, (*5*) operation 42, and (*6*) operation 23.

The distribution ratios (ratios of equilibrium concentrations in the solvent and in the perfluoroorganic compound) of reaction products are important for assessing the suitability of the reaction for technological (purification to remove partially fluorinated compounds) and analytical purposes. The distribution ratios of the PFDC + diethylamine reaction products between various solvents and PFD are given in Table 4. These quantities were calculated from two absorption bands of the reaction products at 310 and 406 nm. Introduction of amino groups into the molecule of the initial polyfluorinated compound makes it more polar and thus enhances its affinity for polar solvents. At the same time, with an increase in the degree of substitution of fluorine atoms by amino groups, the proportion of hydrocarbon fragments in the molecule increases, and the compound becomes more soluble in less polar solvents. The combination of these two opposite trends gives a dependence with a maximum (point for 2-propanol).

Figure 3 shows the absorption spectra of ethanol extracts from treatment of process PFD samples with a diethylamine solution. These spectra are similar to those obtained for model compounds. This fact indi-

cates that the reactions of diethylamine with various partially fluorinated compounds (whose full identification is practically impossible) yields products structurally similar to those of the reaction of PFDC with diethylamine. This similarity opens prospects for the development, using this reaction, of procedures both for PFD purification and for integrated determination of partially fluorinated compounds in PFD in various steps of the production process.

CONCLUSION

The reaction of partially fluorinated hexadecafluorobicyclo[4.4.0]dec-1(16)-ene (an impurity in perfluorodecalin) with amines in various solvents is promising for purifying the target perfluoro compounds to remove partially fluorinated impurities and for evaluating the degree of fluorination of the target product.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A ^{19}F NMR Study of Products of Hexafluorobutadiene Sulfotrioxidation

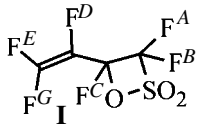
Abstract—The products of hexafluorobutadiene sulfotrioxidation were identified by ^{19}F NMR. The major products are hexafluoro-1-butene-3,4-β-sultone, hexafluoro-2-butene-1,4-sultone, hexafluoro-1-butene-3,4-pyrosultone, and hexafluoro-2-buten-1,4-diyl sulfate.

DOI: 10.1134/S1070427207030147

Hexafluorobutadiene, as fairly accessible perfluoro analog of divinyl, monomer of Lebedev's synthetic rubber, still attracts researchers' attention. However, it did not justify hopes in the field of fluoropolymer chemistry, since the fluorine electronegativity extended the conjugation of its double bonds, which precluded formation of *cis*-1,4 elastomer structures.

The variety of the reactions of fluoroolefins with sulfur trioxide resulting in formation of β-sultones in sulfotrioxidation or fluorosulfates in fluorosulfation attracted attention to the reaction of hexafluorobutadiene with sulfur trioxide.

From the evidence of ^{19}F NMR data (a Hitachi H60 spectrometer operating at 56.4 MHz), Knunyants et al. [1] assigned the structure of 4-(trifluorovinyl)-3,3,4-trifluoro-1-oxa-2-thiacyclobutane 2,2-dioxide (**I**), i.e., hexafluoro-1-butene-3,4-β-sultone, to the product:

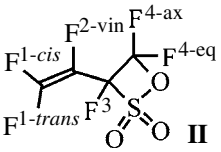


I

F^E: δ_F –88.7 ppm (d.d.d), J_{E-C} 5.6 Hz, J_{E-D} 38.6 Hz, J_{E-G} 49.5 Hz; F^D: δ_F –191.4 ppm (d.d.d.d), J_{D-B} 8.7 Hz, J_{D-C} 20.5 Hz, J_{D-E} 38.6 Hz, J_{D-G} 118.3 Hz; F^A: δ_F –94.5 ppm (d.d.d), J_{A-D} 1.8 Hz, J_{A-C} 7.8 Hz, J_{A-B} 163.5 Hz; F_G: δ_F –105.7 ppm (d.d.d.d), J_{G-D} 118.3 Hz, J_{G-E} 48.5 Hz, J_{G-C} 28.0 Hz, J_{G-B} 2.5 Hz; F^C: δ_F –123.5 ppm (d.d.d.d.d), J_{C-G} 28.0 Hz, J_{C-D} 20.5 Hz, J_{C-A} 7.8 Hz, J_{C-E} 5.6 Hz, J_{C-B} 3.1 Hz; F^B: δ_F –102.2 ppm (d.d.d.d), J_{B-A} 163.5 Hz, J_{B-D} 8.7 Hz, J_{B-C} 3.1 Hz, J_{B-G} 2.5 Hz.

However, actually the chemical shifts and spin–spin coupling constants disagree with the above structure. Signals of the F^A and F^B atoms of the CF_2 group neighboring to the SO_2 group have typically chemical shifts in the region of 115±5 ppm, while the F^C signal of the CF group neighboring to ester oxygen should lie at about 135 ppm. The geminal coupling constant in the four-membered ring commonly does not exceed 130 Hz, whereas the coupling constant equal to 163 Hz suggests that magnetically non-equivalent OCF_2 group is incorporated in the six-membered ring of pyrosultone.

In this study we examined the products formed in the reaction of hexafluorobutadiene with sulfur trioxide under various conditions and in various media. As the major sulfotrioxidation product (content in the mixture from 30 to 70 mol %) we identified hexafluoro-1-butadiene-β-sultone (**II**) from the following signals (^{19}F NMR spectra were recorded on a Bruker Spectrospin AM-500 spectrometer operating at 470.572 MHz against the background of hexafluorobenzene):

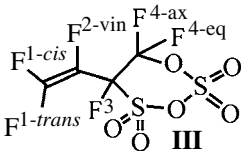


II

$F^{1\text{-}cis}$: δ_F –85.3±0.2 ppm (d.d.d), $J_{1\text{-}cis\text{-}3}$ 5.3±0.3 Hz,

$J_{1\text{-}cis\text{–}2\text{-vin}}$ 39.4 ± 0.6 Hz, $J_{1\text{-}cis\text{–}1\text{-}trans}$ 48.4 ± 0.4 Hz; $F^{2\text{-vin}}$: δ_F –188.5 ± 0.1 ppm (d.d.d), $J_{2\text{-vin}\text{–}3}$ 18.7 ± 0.3 Hz, $J_{2\text{-vin}\text{–}1\text{-}cis}$ 39.5 ± 0.3 Hz, $J_{2\text{-vin}\text{–}1\text{-}trans}$ 118.0 ± 0.2 Hz; $F^{4\text{-ax}}$: δ_F –76.3 ± 0.2 ppm (d.d.d), $J_{4\text{-ax}\text{–}3}$ 12.1 ± 0.4 Hz, $J_{4\text{-ax}\text{–}2\text{-vin}}$ 16.9 ± 0.5 Hz, $J_{4\text{-ax}\text{–}4\text{-eq}}$ 127.5 ± 0.5 Hz; $F^{1\text{-}trans}$: δ_F –102.5 ± 0.5 ppm (d.d.d.t), $J_{1\text{-}trans\text{–}2\text{-vin}}$ 118.0 ± 0.2 Hz, $J_{1\text{-}trans\text{–}1\text{-}cis}$ 48.4 ± 0.4 Hz, $J_{1\text{-}trans\text{–}3}$ 33.3 ± 0.3 Hz, $J_{1\text{-}trans\text{–}4\text{-eq}}$ 2.4 Hz; F^3: δ_F –115.0 ± 0.2 ppm (d.t.d.d), $J_{3\text{–}1\text{-}trans}$ 33.3 ± 0.3 Hz, $J_{3\text{–}2\text{-vin, }4\text{-ax}}$ 18.7 ± 0.3 Hz, $J_{3\text{–}1\text{-}trans}$ 10.3 ± 0.5 Hz, $J_{3\text{–}1\text{-}cis}$ 5.3 ± 0.3 Hz; $F^{4\text{-eq}}$: δ_F –88.5 ± 0.3 ppm (d.d.d), $J_{4\text{-eq}\text{–}4\text{-ax}}$ 127.5 ± 0.5 Hz, $J_{4\text{-eq}\text{–}4\text{-eq}}$ 10.7 ± 0.3 Hz, $J_{4\text{-eq}\text{–}1\text{-}trans}$ 2.5 Hz.

In the case of sulfotrioxidation of hexafluorobutadiene in the presence of an excess of sulfur trioxide, the structure of hexafluoro-1-butene-3,4-pyrosultone (**III**) was identified. This compound gives the following signals in the spectrum:

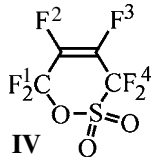


III

$F^{1\text{-}cis}$: δ_F –86.4 ppm (d.d.d), $J_{1\text{-}cis\text{–}3}$ 5.7 Hz, $J_{1\text{-}cis\text{–}2\text{-vin}}$ 40.0 Hz, $J_{1\text{-}cis\text{–}1\text{-}trans}$ 47.7 Hz: $F^{2\text{-vin}}$: δ_F –188.3 ± 0.1 ppm (d.d.d), $J_{2\text{-vin}\text{–}3}$ 19.1 Hz, $J_{2\text{-vin}\text{–}1\text{-}cis}$ 40.0 Hz, $J_{2\text{-vin}\text{–}1\text{-}trans}$ 118.0 Hz; $F^{4\text{-ax}}$: δ_F –92.9 ppm (d.d), $J_{4\text{-ax}\text{–}2\text{-vin}}$ 8.5 Hz, $J_{4\text{-ax}\text{–}4\text{-eq}}$ 163 Hz; $F^{1\text{-}trans}$: δ_F –103.6 ± 0.5 ppm (d.d.d), $J_{1\text{-}trans\text{–}1\text{-vin}}$ 118.2 Hz, $J_{1\text{-}trans\text{–}1\text{-}cis}$ 49.6 Hz, $J_{1\text{-}trans\text{–}3}$ 26.7 Hz; F^3: δ_F –120.7 ± 0.2 ppm (d.t.d), $J_{3\text{–}1\text{-}trans}$ 26.7 Hz, $J_{3\text{–}2\text{-vin, }4\text{-ax}}$ 21.0 Hz, $J_{3\text{–}1\text{-}cis}$ 3.8 Hz; $F^{4\text{-eq}}$: δ_F –103.3 ppm (d.d.d), $J_{4\text{-eq}\text{–}4\text{-ax}}$ 164 Hz, $J_{4\text{-eq}\text{–}3\text{-eq}}$ 28.6 Hz, $J_{4\text{-eq}\text{–}1\text{-}trans}$ 5.7 Hz.

It is evident that the signals in the ^{19}F NMR spectrum corresponding to this six-membered structure of pyrosultone do not noticeably differ from the signals of four-membered sultone **I** [1].

Among the reaction products we found a compound whose content varied from 15 to 25 mol % depending on the synthesis conditions. This compound was identified as a product of 1,4-addition of sulfur trioxide to hexafluorobutadiene with the formation of hexafluoro-2-butene-1,4-sultone (**IV**).

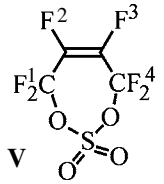


IV

F^1: δ_F –70.8 ppm (d.t), $J_{1\text{–}4}$ 9.6 Hz, $J_{1\text{–}2}$ 22.6 Hz; F^2: δ_F –143.6 ppm (t.m), $J_{2\text{–}3}$ 13.3 Hz, $J_{2\text{–}1}$ 22.6 Hz: F^3: δ_F –149.5 ppm (t.t), $J_{3\text{–}1}$ 9.6 Hz, $J_{3\text{–}4}$ 17.2 Hz; F^4: δ_F –104.6 ppm (t.t), $J_{4\text{–}3}$ 15.3 Hz, $J_{4\text{–}1}$ 9.6 Hz.

It should be emphasized that in [1] the chemical shifts were assigned incorrectly.

The ^{19}F NMR spectra always contained two signals at –68.0 and –140 ppm with the intensity ratio of 2 : 1 and the coupling constant corresponding to the $–OCF^1_2CF^2=$ fragment of structure **IV**. The content of this compound in the mixture varied from 1 to 15 mol %. These signals should be assigned to seven-membered hexafluoro-2-butene-1,4-diyl sulfate (**V**):



V

F^3: δ_F –140.2 ppm (t.t), $J_{3\text{–}4}$ 8.6 Hz, $J_{3\text{–}1}$ 22.6 Hz; F^4: δ_F –68.0 ppm (d.d), $J_{4\text{–}3}$ 8.6 Hz, $J_{4\text{–}2}$ 22.6 Hz.

Knunyants et al. [1] obtained this product by heating hexafluoro-2-butene-1,4-sultone. The mechanism of this conversion is not evident; on the other hand, this sulfate should be formed by elimination of sulfur dioxide with hexafluoro-2-butene-1,4-pyrosultone, which, contrary to sultone and 3,4-pyrosultone, has the same chemical shifts and coupling constants as hexafluoro-2-butene-1,4-sultone and cannot be distinguished by NMR.

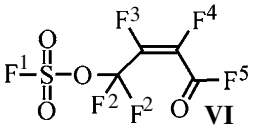
Among the products in the mixture we identified up to 5 mol % of perfluoro-4-fluorosulfatobut-2-enoyl fluorides **VI** and **VII**, formed by ring opening in **V**, in the form of isomers different in the chemical shifts and coupling constants of fluorine nuclei in *cis* and *trans* positions. These constants agree well with published data [2] for α,β-unsaturated acyl fluorides.

The ratio of intensities of the corresponding signals shows that the concentration of the *trans* species was higher than that of the *cis* species.

The mixtures contained up to 15% of perfluorinated polymer products, which were manifested in the ^{19}F NMR spectra as broad signals in the regions of –70 and –104 ppm.

We found that four- and six-membered sultone rings formed by sulfotrioxidation of hexafluorobutadiene are extremely stable and undergo only partial opening even on heating to 150–170°C in the presence of potassium fluoride or potassium hydrofluoride. This thermal treatment of the mixtures results

also in desulfotrioxidation of fluorosulfate groups in perfluoro-4-fluorosulfatobut-2-enoyl fluorides. After thermal treatment, the following compounds were identified in the mixture: (1) perfluoro-2-fluorosulfo-2-vinylacetyl fluoride (**VIII**) formed by the ring opening in hexafluoro-1-butene-3,4-sultone (**II**); (2) perfluoro-4-fluorosulfo-2-buteneoyl fluoride (**IX**) formed by the ring opening in hexafluoro-2-butene-1,4-sultone (**IV**); (3) perfluoro-*trans*-crotonoyl fluoride (**X**) formed by elimination of sulfur trioxide from perfluoro-4-fluorosulfato-*trans*-but-2-enoyl fluoride (**VII**); and (4) perfluoro-*cis*-crotonoyl fluoride (**XI**) formed by elimination of sulfur trioxide from perfluoro-4-fluorosulfato-*cis*-but-2-enoyl fluoride (**VI**):



VI

F^1: δ_F 49.8 ppm (t), J_{1-2} 8.3 Hz; F^2: δ_F –68.1 ppm (q), $J_{2-1;3;4;5}$ 8.3 Hz; F^3: δ_F –134.9 ppm (d.d.t), $J_{3\text{-}cis-2}$ 9.5 Hz, $J_{3\text{-}cis-5}$ 14.3 Hz, $J_{3\text{-}cis-4\text{-}cis}$ 25.0 Hz; F^4: δ_F –122.7 ppm (d.t.d), J_{4-2} 8.3 Hz, $J_{4\text{-}cis-5}$ 14.3 Hz, $J_{4\text{-}cis-3\text{-}cis}$ 25.3 Hz; F^5: δ_F 27.5 ppm (d.q), $J_{4\text{-}cis-5}$ 14.3 Hz, $J_{5-2;3\text{-}cis;4\text{-}cis}$ 8.3 Hz.

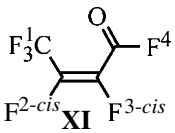
F^1: δ_F –71.5 ppm (t.d), J_{1-3} 7.6 Hz, $J_{1-2;4}$ 24.4 Hz; F^2: δ_F –150.7 ppm (d.q), $J_{2\text{-}trans-3}$ 138.0 Hz, J_{2-4} 22.9 Hz; F^3: δ_F –141.9 ppm (d.d.q), $J_{3\text{-}trans-1}$ 7.6 Hz, $J_{3\text{-}trans-2}$ 138.0 Hz, $J_{3\text{-}trans-4}$ 56.5 Hz; F^4: δ_F 28.2 ppm (d.q), $J_{4-3\text{-}trans}$ 56.0 Hz, J_{4-1} 22.9 Hz.



XI

F^1: δ_F –68.3 ppm (q), $J_{1-2;3;4}$ 10.2 Hz; F^2: δ_F –134.8 ppm (d.q), $J_{2\text{-}cis-4}$ 28.0 Hz, $J_{2\text{-}cis-1}$ 10.2 Hz; F^3: δ_F –123.7 ppm (q), $J_{3\text{-}cis-1;2;4}$ 12.7 Hz; F^4: δ_F 28.6 ppm (d.m), $J_{4-1;2;3}$ 10.2 Hz; $J_{4-2\text{-}cis}$ 25.4 Hz.

EXPERIMENTAL

The ^{19}F NMR spectra were recorded on a Bruker Spectrospin AM-500 spectrometer operating at 470.572 MHz in the pulse mode with the pulse delay of up to 5 s. Hexafluorobenzene as internal reference was added to the samples fuming in air. The samples were hermetically sealed and placed into the standard glass ampules 5 mm in diameter. Deuteroacetone whose signal was used for stabilization of the spectrometer was placed between ampule walls.

The composition of the mixtures was monitored by GLC using an LKhM-90 chromatograph equipped with a thermal conductivity detector on a column with d = 4 mm and l = 3 m (stationary phase 15 wt % SKTFT-50 on Silokhrom-2, 70°C, carrier gas helium).

In sulfotrioxidation of hexafluorobutadiene, 96 g of sulfur trioxide freshly distilled from oleum was charged into a 250-ml stainless-steel ampule, and

162 g of hexafluorodutadiene was fed into the ampule at room temperature. The ampule was hermetically sealed and heated at 80°C for 20 h. The resulting mixture contained virtually no sulfur trioxide, and the conversion of hexafluorobutadiene reached 90%. The raw material was distilled, and the resulting product contained approximately 70% of a fraction with bp 93–95°C. From the evidence of the ^{19}F NMR spectrum, this fraction contained three components: hexafluoro-1-butene-3,4-β-sultone, hexafluoro-2-butene-1,4-sultone, and hexafluoro-2-butene-1,4-diyl sulfate in 70 : 20 : 10 mol % ratio, respectively. The GLC analysis practically confirmed this result. The distillation bottoms amounted to 20% of the reaction mixture and were viscous polymeric tars. This product gave broad unresolved singlets in the NMR spectra, which did not allow its identification.

In the ^{19}F NMR spectrum of the reaction mixture we found the signals of fluorosulfate and carbonyl fluoride groups, whose intensities were proportional to those of difluoromethylene and fluoromethine groups in *cis* and *trans* structures of perfluoro-4-fluorosulfato-2-butenoyl fluorides whose content in the mixture reached 6%. The intensity of signals of the *trans* structure was approximately three times higher than that of the *cis* structure. The reaction mixture also contained polymeric products.

An attempt to reproduce the synthesis in the presence of sulfur dioxide, described in [1], led to a considerable decrease in the yield of the above sultones and sulfates. The ratio of these compounds in the mixture was 40 : 20 : 20 mol %, and the intensity of the polymer signals increased.

In sulfotrioxidation in the medium of 1,1,2-trifluorochloroethane, the conversion of hexafluorobutadiene did not exceed 65%; however, the yield of hexafluoro-2-butene-1,4-diyl sulfate noticeably decreased.

CONCLUSIONS

(1) In sulfotrioxidation of hexafluorobutadiene, the main process is 1,2-addition of sulfur trioxide yielding hexafluoro-1-butene-β-sultone and 3,4-pyrosultone.

(2) Sulfur trioxide also undergoes 1,4-addition yielding hexafluoro-2-butene-1,4-sultone. It is likely that elimination of sulfur dioxide from the related pyrosultone results in formation of hexafluoro-2-butene-1,4-diyl sulfate.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Surface-Active Properties of a Series of 1,1-Dimethyl-1-alkylhydrazinium Chlorides

Abstract—The surface-active properties of a series of 1,1-dimethyl-1-alkylhydrazinium chlorides with C_{10}–C_{18} in length were studied in comparison with Neonol AF 9-12 and Oksifos B surfactants. The limiting wetting angle, detergent and solubilization power, and foaming kinetics of these surfactants were studied in relation to the concentration of formation of monomolecular layer and type of the resulting micellar structures.

DOI: 10.1134/S1070427207030159

In contrast to highly toxic 1,1-dimethylhydrazine widely used as a component of liquid propellant, the use of its low-toxic 1-alkyl derivatives in various branches of industry seems promising [1–5].

1,1-Dimethyl-1-alkylhydrazinium chlorides (DMAHCs) are tertiary hydrazinium salts (THSs) and surfactants, which strongly decrease the surface tension at the water–air boundary [6]. However, the data on their surface-active properties are scarce and available only for a few compounds [6, 7]. In this study we examined the surface-active properties throughout the DMAHC homologous series.

EXPERIMENTAL

DMAHCs of the general formula $[R(CH_3)_2 \cdot NNH_2]Cl$ (where $R = C_nH_{2n+1}$; n = 10, 12, 14, 16, and 18 and mixture 12 + 14) were prepared by quaternization of 1,1-dimethylhydrazine with primary chloroalkanes using the known procedure [8] and purified by double or triple recrystallization from acetone. The content of the product in the samples, which was no less than 96%, was determined by the modified procedure given elsewhere [9].

The solubilization power was evaluated with respect to Sudan I oleophilic dye, which, being insoluble in water, is soluble in the hydrophobic part of micelles. The dye content was determined from the optical density of the solution recorded on an FEK-56M photocolorimeter (λ = 400 nm). Then, using the calibration curve, the content of the solubilized dye s in unit volume was calculated. The calibration curve was plotted using the solutions of Sudan I in benzene. The solubilization power of surfactants S was calculated as the ratio of s to the surfactant concentration:

$$S = s/c, \quad (1)$$

where c is the surfactant concentration in the solution (g l^{-1}) and s is the concentration of the solubilized dye (mg l^{-1}).

The detergent power with respect to M20 industrial oil and Tsiatim-221 lubricant was determined by the gravimetric method using St. 20 steel plates. A drop of the pollutant was deposited onto the plate, spread over its surface with a brush, and dried. Then, after drying, this procedure was repeated. After 1-day storage, the plates were weighed on an analytical balance with an accuracy of ±0.0002 g. The samples were immersed in the washing solution (40 ml) and stored in this solution with shaking for 3 and 30 min for the oil and lubricant, respectively. Then, the plates were carefully removed (holding at the edge), thoroughly washed with distilled water, and dried in air for a day. The dried plates were weighed. The detergent power (DP) (%) of the solutions in question was calculated from the following expression:

$$WP = (P_2 - P_3)/(P_2 - P_1) \times 100, \quad (2)$$

where P_1, P_2, and P_3 are the weights (g) of the plate before the experiment, with deposited model pollutant, and after treatment with the washing solution and distilled water, respectively.

The limiting wetting angle at the glass–DMAHC solution boundary and the kinetic stability of the foam were determined by the bubbling and shaking procedures, respectively [10].

The results given in this paper were averaged over three or four measurements, and the relative measurement error, as a rule, did not exceed 2–4%. The foam volume was normalized to 1 l of the disperse system. The experiments were performed at 20°C.

RESULTS AND DISCUSSION

The limiting wetting angles of DMAHC studied and of known surfactants of the other classes (anionic Oksifos B and nonionic Neonol AF 9-12) are listed in Table 1. All the compounds studied are the penetrating (wetting) agents, i.e., they hydrophilize the glass surface and decrease the limiting wetting angle at the glass–surfactant solution boundary (limiting wetting angle at the glass–water boundary 44°). As seen, Neonol AF 9-12 is the most active agent, except the concentration of 1 g l^{-1}, when the minimal wetting angle is observed for DMAHC with R = C_{12} and C_{14} (technical name ChGS-1214).

As seen from Table 1, the dependences of cos θ on the surfactant concentration are nonmonotonic for both individual compounds (DMAHC with R = C_{10}–C_{18}) and their mixtures (Neonol AF 9-12, Oksifos B, and DMAHC with C_{12} + C_{14}), which is probably due to the features of the surface layer structure and micelle formation with increasing surfactant concentration.

The isotherm of the limiting wetting angle of DMAHCs passes through a minimum at low surfactant concentrations (3–4 g l^{-1}). Similar minima for DMAHCs were found previously in the isotherms of the surface tension at concentrations smaller than the critical micellization concentration (CMC), which was attributed to the presence of impurities with higher surface activity as compared to DMAHCs [6]. The disappearance of this minimum with increasing surfactant concentration is probably due to the solubilization of the impurity with the micelles of the main surfactant, appearing upon attainment of CMC, which slightly increases the limiting wetting angle at high concentrations of the surfactant.

Study of foaming in the aqueous surfactant solutions showed that, for all the compounds studied, the kinetic dependences of changes in the foam volume are similar; first the foam volume sharply decreases and then it remains virtually constant (Fig. 1). As seen, the mixture of DMAHCs with C_{12} + C_{14} gives the highest foam column in the initial moment, but its stability is smaller as compared to Neonol AF 9-12 and Oksifos B.

Table 1. Limiting wetting angle θ at various concentrations of DMAHC $[R(CH_3)_2NNH_2]Cl$

R	θ, deg, at indicated concentration, g l^{-1}				
	1	2	3	4	5
$C_{10}H_{21}$	47	44	46	44	50
$C_{12}H_{25}$	41	43	45	41	36
$C_{16}H_{33}$	40	38	36	34	36
$C_{18}H_{37}$	38	41	36	39	38
C_{12-14}	33	34	39±2	44	40
Oksifos B	36	39	37	47	38
Neonol AF 9-12	36	32	35	37	28

In most cases, foams prepared at high surfactant concentration (c > 30 g l^{-1}) are unstable (Fig. 2). This is probably due to the fact that, with increasing concentration, the viscosity of the adsorption surfactant layers increases and they become heavier, which causes rapid foam degradation. The maximal lifetimes of the foam are listed in Table 2. The most stable foams are observed in the concentration range corresponding to the formation of the saturated adsorption layers [6].

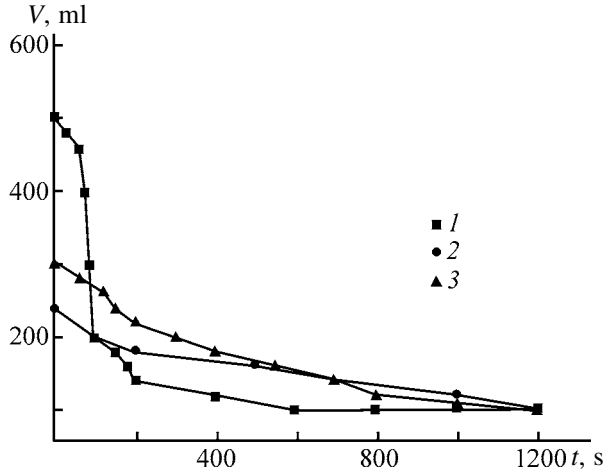

Fig. 1. Stability of foam obtained with different surfactants; surfactant concentration 5 g l^{-1}. (*V*) Foam volume and (*t*) time. (*1*) DMAHC with R = C_{12} + C_{14}, (*2*) Oksifos B, and (*3*) Neonol AF 9-12.

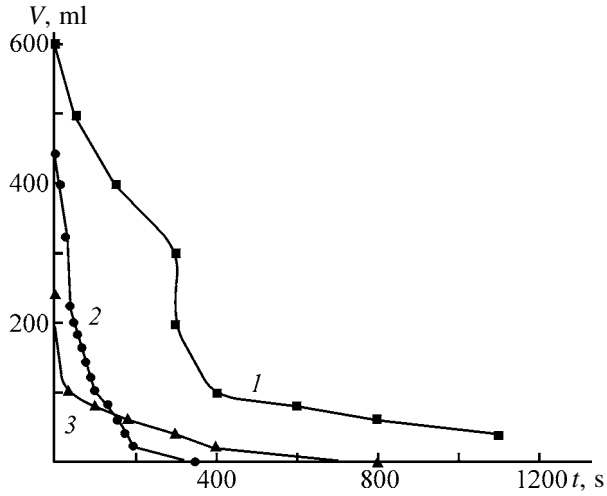

Fig. 2. Kinetics of changes in the foam volume V of an aqueous solution of DMAHC (R = $C_{12}H_{25}$) at various surfactant concentrations. (t) Time. Surfactant concentration, g l^{-1}: (*1*) 18, (*2*) 36, and (*3*) 9.

The data on the detergent power of the surfactant solutions with respect to industrial pollutants (Tsiatim-221 lubricant, M20 oil) are listed in Table 3. As seen, the detergent power of all the surfactants with respect to M20 oil is higher than that with respect to Tsiatim-221 lubricant, and the best results (98–99%) were obtained for DMAHCs with R = C_{18} (c = 0.12–0.25 g l^{-1}) and with R = C_{12} + C_{14} (c = 2 g l^{-1}, 92%). The detergent power of Neonol AF 9-12 and Oksifos B was lower and comprised 59 and 92%, respectively. As for Tsiatim-221 lubricant, the best result (94%) was obtained for DMAHC (R = C_{12} + C_{14}, c = 2 g l^{-1}), whereas Neonol AF 9-12 and Oksifos B were inefficient.

Table 2. Kinetic stability of the foam prepared from aqueous solution of DMAHC $[R(CH_3)_2NNH_2]Cl$

	10	1100
	1.25	1500

Our experimental results correlate with the surface-active properties of DMAHCs at the water–air boundary, and they are primarily determined by the surface tension and micelle formation.

Analysis of the detergent power (Table 3) along with data on the kinetic stability of foams (Figs. 1, 2) shows that the highest detergent power of all the surfactants studied corresponds to the surfactant concentration at which the maximal foam stability is observed.

Solubilization power is one of the most important surfactant characteristics. The data on the solubilization power with respect to Sudan I oleophilic dye are shown in Table 4. In the DMAHC homologous series, the solubilization power increases with increasing length of the hydrocarbon chain, which is due to the increase in the surface activity in accordance with the Traube–Duclaux rule [11]. The maximal solubilization power corresponds to the surfactant concentra-

tions close to CMC at which spherical micelles begin to transform into the micelles of more complex structure [6].

Colloidal electrolytes (including DMAHCs) are completely dissociated and do not aggregate up to concentrations close to CMC. In the narrow concentration range, the spherical particles are formed whose size and shape are constant at concentrations slightly higher than CMC. In this concentration range, solubilization only slightly affects the micelle size. In concentrated surfactant solutions ($c \gg$ CMC), spherical

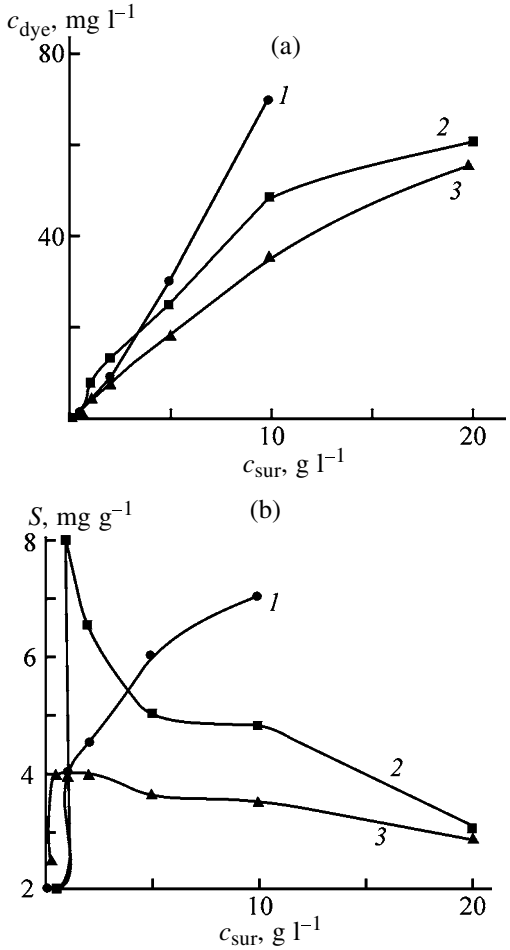

Fig. 3. (a) Concentration of solubilized dye c_{dye} and (b) solubilization power S as functions of the surfactant concentration c_{sur}. (*1*) DMAHC (R = C_{12} + C_{14}), (*2*) Neonol AF 9-12, and (*3*) Oksifos B.

micelles transform into thermodynamically more stable lamellar particles. This transformation increases the weight of the micellar nucleus, which increases the intramicellar solubility of the dye and the solubilization power of the surfactant solution. As a result, the colloidal structure of the solution sharply changes, which was confirmed visually.

The surfactant nature largely determines the solubilization mechanism. In the presence of ionic surfactants, an oleophilic dye containing polar groups penetrates into the surface layer of a micelle, where its molecules are arranged between the surfactant molecules (with parallel orientation) and their polar groups are turned to the aqueous phase. In this case, the dye molecules are dissolved either in the micelle core or in the hydrophilic micelle shell. In the case of nonionic surfactants, the localization of the dye is different: its molecules occur on the outer hydrophilic shell of the micelles.

These differences in the solubilization mechanism with surfactants of different nature give rise to certain features in the dependences of the solubilized dye concentration and solubilization power *S* on the surfactant concentration (Figs. 3a, 3b). For Neonol AF 9-12 and Oksifos B, the dependence of the concentration of the solubilized dye on the surfactant concentration tends to a constant value, whereas in the case of DMAHCs ($R = C_{12} + C_{14}$) this dependence is ascending. In the case of Neonol AF 9-12 and Oksifos, the concentration dependences of *S* on the surfactant concentration pass through the maxima, whereas for DMAHC ($R = C_{12} + C_{14}$) no peaks are observed.

Data on the aqueous solutions with 5–10 g l^{-1} concentrations of the surfactants studied show that the DMAHC with $R = C_{12} + C_{14}$ is the most effective solubilization agent, capable to dissolve the largest amounts of pollutants.

CONCLUSIONS

(1) The limiting wetting angle, detergent and solubilization power of a series of 1,1-dimethyl-1-alkylhydrazinium chlorides, Neonol AF 9-12, and Oksifos B surfactants, and their foaming kinetics are determined by the concentration of formation of monomolecular layer and type of the resulting micellar structures.

(2) The detergent and solubilization powers of a technical mixture of 1,1-dimethyl-1-alkylhydrazinium chlorides with $R = C_{12} + C_{14}$ are significantly higher than those of Neonol AF 9-12 and Oksifos B. Taking into account low toxicity of 1,1-dimethyl-1-alkylhydrazinium chlorides (hazard class 4), these surfactants can be used for preparing fireproof, low-concentrated, and environmentally mild aqueous-organic detergent formulations.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Additive Scheme for Estimating Properties of Solutions of Organic Compounds: Limiting Partial Molar Volumes of Alkanols in Water

D. V. Batov

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received October 9, 2006

Abstract—An additive scheme based on determination of the partial contributions of structural fragments proved to be applicable to analysis and prediction of the bulk and other properties of aqueous solutions of alkanols.

DOI: 10.1134/S1070427207030160

The additive-group contribution approach has been most thoroughly developed for estimating thermodynamic parameters of formation of molecules in the gas phase [1] and enthalpies of phase transitions [2]. As for condensed systems, the use of this approach is complicated by the need in taking into account different kinds of intermolecular interaction. Nevertheless, studies in this direction are being intensively performed [3–7].

Additive models are used generally to gain some thermodynamic and other information about systems for which no experimental data are available. Kizin et al. [8] noted that the additive-group contribution method combines sufficient accuracy and relative simplicity. It should be pointed out also that this method proved to be applicable to analysis of correlations between the physicochemical and thermodynamic properties of solutions, on the one hand, and the molecular structures of a solute and a solvent, on the other hand. Until recently, in terms of the additive-group contribution approach, the limiting partial molar volumes of organic compounds in solutions $\bar{V}_2^\infty$ were approximated generally by Eq. (1) [9, 10]:

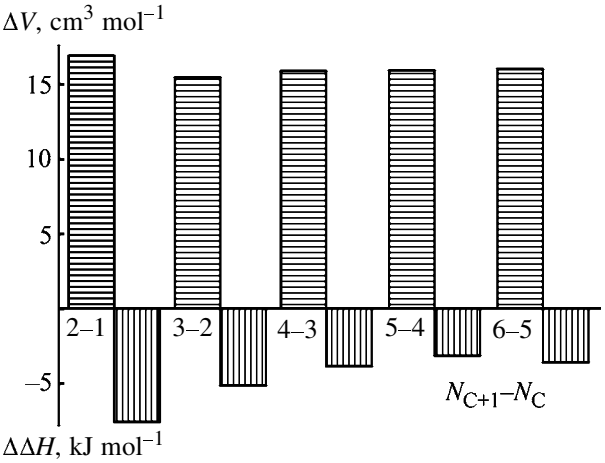
$$\bar{V}_2^\infty = a_v + b_v N_C, \quad (1)$$

where N_C is the number of the carbon atoms in the chain of the organic molecule, and coefficient b_v characterizes the contribution of the methylene group to $\bar{V}_2^\infty$.

Deviations of $\bar{V}_2^\infty$ from the value obtained using the simple additive scheme are considered as resulting from intergroup interactions in the molecule [11, 12].

The figure shows the increments of the limiting partial molar volume and enthalpy of hydration of *n*-alkanols, obtained using data taken from [13]. As seen, the properties of methanol and, in most cases, ethanol deviate significantly from the linear approximation [Eq. (1)] obtained for the homologs with $N_C \geq 3$.

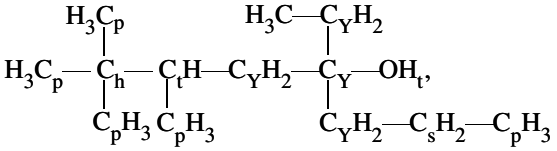
To provide the energetic and geometrical equivalence of allocated structural fragments in the additive models, these fragments should be selected taking into account their nearest surrounding. If this condition is not met, the resulting additive expansion includes some terms (absolute terms) having no clear physical sense, and properties of the first members of a homol-



Differences in the limiting partial molar volumes $\Delta V = [\bar{V}_2^\infty(N_{C+1}) - \bar{V}_2^\infty(N_C)]$ and enthalpies of hydration $\Delta\Delta H^0 = [\Delta_1 H^0(N_{C+1}) - \Delta_1 H^0(N_C)]$ in a series of *n*-alkanols. (N_C) Number of the carbon atoms of the hydrocarbon radical of the molecule.

ogous series and isomers deviate from the additive model.

To quantitatively describe the bulk properties of solutions, we used in this study the additive scheme that we proposed previously for the enthalpy characteristics of solutions [14, 15]. In this scheme, a compound is divided into structural elements in which some nuclei of atoms can belong to two or more structural fragments [16]. We selected the CH bond as such a structural element of hydrocarbon radicals. There are two reasons for this decision. First, more detailed specification (allocation of bonds, instead of radicals) makes it possible to include more substances into consideration without changing the number of structural elements. Secondly, no fractional values are used for the contributions of radicals (in [18], the fragment CH is set to be equivalent to the half of the methylene group). The summation of the partial bond contributions gives the contributions of the corresponding hydrocarbon radicals. According to the recommendations formulated in [16], the allocation of structural fragments is specified taking into account their nearest (first) surrounding. The basic scheme of allocation of structural fragments in the alkanol molecules with saturated hydrocarbon radicals is illustrated below with an example of 4-ethyl-6,7,7'-trimethyl-4-octanol:



where C_YH refers to the CH bonds in the hydrocarbon radical from the nearest surrounding of the functional group.

Taking into account the specific features of the hydration of organic nonelectrolyte molecules, we set the first surrounding of the functional group so as to include the CH bonds formed by two carbon atoms nearest to the functional group. Here C_sH, C_tH, and C_pH refer to the CH bonds formed by the carbon atoms distant from the functional group by at least two carbon atoms; C_h is the quaternary carbon atom; and OH_t is the functional group bound to the tertiary carbon atom. Correspondingly, in the *n*- and isoalkanol molecules, OH_p and OH_s groups are allocated.

Analysis of published data shows that, for monohydric alcohols, there is one of the most extended databases covering the bulk characteristics of aqueous solutions. Table 1 summarizes the types and numbers of the structural fragments allocated according to the above scheme in a series of monohydric alcohols and their limiting partial molar volumes in aqueous solutions at 298.15 K [18–22]. The theoretical $\bar{V}_2^\infty$ values were obtained using multiparametric Eq. (2):

$$\bar{V}_2^\infty = \bar{V}_2^\infty(Y_p) + \delta\bar{V}_2^\infty(Y_s) + \bar{V}_2^\infty(Y_t) + y\bar{V}_2^\infty(CH_Y) + p\bar{V}_2^\infty(CH_p) + s\bar{V}_2^\infty(CH_s) + t\bar{V}_2^\infty(CH_t), \quad (2)$$

where $\bar{V}_2^\infty$ is the limiting partial molar volume of the solute; $\bar{V}_2^\infty(Y_p)$, contribution of the polar OH group bound to the primary carbon atom; and $\delta\bar{V}_2^\infty(Y_s)$ and $\delta\bar{V}_2^\infty(Y_t)$ are the corrections introduced to take into account the differences between the bulk characteristics of the functional groups bound to the secondary and tertiary carbon atoms and those of the functional group bound to the primary carbon atom.

The contribution of the functional group bound to the secondary or tertiary carbon atom can be estimated by summing $\bar{V}_2^\infty(Y_p)$ and the corresponding correction term $\delta\bar{V}_2^\infty(Y_s)$ of $\delta\bar{V}_2^\infty(Y_t)$. The y, p, s, t; and $\bar{V}_2^\infty(C_YH)$, $\bar{V}_2^\infty(C_pH)$, $\bar{V}_2^\infty(C_sH)$, and $\bar{V}_2^\infty(C_tH)$ are the numbers and contributions of the allocated hydrocarbon fragments. If experimental data are available for the compounds containing the quaternary carbon atoms, the term $h\bar{V}_2^\infty(C_h)$ should be introduced in Eq. (2).

The calculated contributions of the allocated structural fragments to the limiting partial molar volumes of alkanols in water and the regression parameters are presented in Table 1. The $\bar{V}_2^\infty(Y_p)$ is determined as an absolute term in Eq. (2). The results show that the experimental data are well reproduced in the framework of the model proposed. The allocation of the CH bonds in the radicals directly bound to the functional group and in those separated from it by a carbon atom as structural fragments of the nearest surrounding of the heteroatom allows fairly fine differentiation of the compounds by the molecular structure. Previously we demonstrated in studying the enthalpy characteristics [14, 15] that such an allocation of the structural fragments is particularly efficient in analysis of the properties of aqueous solutions. The equality of the group contributions reflects the energy equivalence of the groups, suggesting their nearly same geometric configuration [16], which, in turn, suggests similar solvation surrounding of the groups.

The approach used in this study makes it possible to take into account the specific features of the structure and hydration of the two first members of the homologous series (all their CH bonds are energetically equivalent). Table 1 shows that Pr^{i}OH and Bu^{t}OH are structurally similar to methanol and ethanol. Struc-

tural similarity of solutions of water in MeOH and EtOH was also suggested in [23] on the basis of the bulk characteristics of the indicated systems. The phenomenon of a negative partial dilatability of water was observed in methanol and *tert*-butanol [24]. In the series MeOH, EtOH, Pr^{i}OH, and Bu^{t}OH, there was observed a monotonic change of such physicochemical characteristics as the density [23] and donor and acceptor numbers [25]. All these findings can be interpreted in terms of our additive scheme. It follows from Table 1 that, in the series MeOH, EtOH, Pr^{i}OH, and Bu^{t}OH, the number of unitypical C_YH fragments increases. Abrosimov and Ivanov [23] consider the indicated alkanols as homologs of methanol formed from it by successive substitution of the methyl protons by the methyl radicals. With an example of $\bar{V}_2^\infty$, it may be suggested that the contributions from OH_p, OH_s, and OH_t only slightly differ.

The results show that our additive scheme is quite sensitive to geometric isomerism. Thus, Table 1 shows that the group compositions of 2-pentanol and 2-hexanol significantly differ from those of 3-pentanol and 3-hexanol, and that the limiting partial molar volumes of the corresponding 2- and 3-alkanols also differ remarkably. At the same time, according to our scheme, the group composition of 3-heptanol is similar to that of 4-heptanol. Correspondingly, the experimental and calculated bulk characteristics of these compounds are practically equal (Table 1).

Data on the bulk properties illustrate high predictive ability of the additive method used. Let us restrict ourselves to the minimal basic dataset for the seven first compounds from Table 1, to calculate the contributions from the structural fragments and then estimate $\bar{V}_2^\infty$ for the other eleven compounds. We obtain good agreement between the calculated and experimental results (arithmetic mean error is within 0.43 cm^3 mol^{-1}).

Finally, let us examine the applicability of our ad-

Table 2. Group contributions to the molar volumes V_m, limiting partial molar heat capacities $\bar{C}_{p2}^{\infty}$, limiting activity coefficients γ_2^{∞} in aqueous solutions, and entropy of solution in water of alkanols $\Delta_s S^0$ at 298.15 K

Characteristics	OH_p	CH_Y	CH_s	CH_p	CH_t	OH_s	OH_t	se	Compound*

* Numbers of the compounds from Table 1, whose characteristics were used in regression analysis, are indicated; (Pe^iOH) 2-methyl-1-butanol, ($Pe^{neo}OH$) 2,2-dimethyl-1-propanol, and (Oc^nOH) 1-octanol; in all cases, the correlation factor was no less than 0.996.

ditive scheme to other thermodynamic characteristics of alkanols and their aqueous solutions. From the experimental data on the molar volumes [25], limiting partial molar heat capacities of alkanols in water [26–28], entropies of solution [26, 29], and limiting activity coefficients [26, 29, 30] at 298.15 K, we estimated the contributions of the allocated structural fragments to the indicated characteristics using Eq. (2) and data on the type and number of the structural elements of the alkanol molecules (Table 1). The results are summarized in Table 2. As seen, these thermodynamic characteristics can also be well approximated using our additive scheme. The approximation errors are well comparable with the experimental errors, which are as follows: V_m 0.1 $cm^3\ mol^{-1}$, $\bar{C}_{p2}^{\infty}$ 3–6 J mol^{-1} K^{-1}, and $\Delta_s S^0$ 1 J mol^{-1} K^{-1}.

CONCLUSIONS

(1) Analysis of the bulk and other properties of alkanols demonstrates the applicability of the additive scheme proposed. The contributions of structural fragments to the limiting partial molar volumes of alkanols in water at 298.15 K are estimated.

(2) The additive scheme allows taking into account specific features of the structure and hydration of the two first members of the homologous series, as well as the structural differences caused by the molecular isomerism. This scheme proved to be particularly efficient in describing properties of aqueous solutions of organic nonelectrolytes.

(3) The scheme of determination of the group contributions provides optimization of the experimental design aimed at further calculation of the corresponding characteristics in a homologous series or class of organic compounds.

Abstract—A method for modification of track membranes by immobilization of polymer complexes of colloid silver nanoparticles on the surface of microfiltration membranes was developed. The antimicrobial properties of track membranes modified with silver nanoparticles were tested on *E. coli*, *Ps. aeruginosa*, *St. aureus*, and *B. cereus*.

DOI: 10.1134/S1070427207030172

Microfiltration track membranes (TMs) are widely used in separation of virus-containing and colloid solutions and in final stages of drinking water treatment under household conditions [1–3]. When a membrane is brought in contact with an aqueous medium in the course of filtration, various components, with high and low molecular weight, are sorbed on its surface, as also do microbe cells to form a biological film [4–6]. This film is firmly fixed on the membrane surface, which leads to clogging of the filter and to contamination of drinking water with products formed by microorganisms.

Use of TM for drinking water treatment provides sterile working conditions. However, a currently topical issue is the improvement of the antiseptic properties of TM and cartridges based on these membranes in order to preclude overgrowth of the filtering surface of TM.

This study is devoted to immobilization of colloid silver on the surface of polyethylene terephthalate TMs.

EXPERIMENTAL

Polyethylene terephthalate (PET) TMs with a thickness of 10 nm, nominal pore size of 0.5 μm, and pore density of 5×10^7 cm^{-2} were used in the study, as well as PFM-800 membrane units manufactured by Plazmofil'tr Private Company (St. Petersburg). The following reagents were used: silver nitrate ($AgNO_3$), sodium thiocyanate (NaSCN), iron(III) perchlorate [$Fe(ClO_4)_3$], 96% ethanol manufactured by Vekton, and medicinal polyvinylpyrrolidone (PVP) with a molecular weight of 12600 [FS (Pharmacopoeia Item) 42-1194–98], manufactured by Novocherkassk Plant of Synthetic Products.

The track membranes were cleaned by the procedure described in [7]; the rest of the materials and reagents were used without any additional treatment.

A scanning electron microscopic (SEM) study of the surface of intact and modified TM samples was performed on a TESCAN Vega Plus TS 5135 MM (Czech Republic) electron microscope. For this purpose, a platinum layer of thickness 40–50 Å was preliminarily deposited on the TM samples by vacuum evaporation. The morphology of the membranes was studied by atomic-force microscopy (AFM) in the contact-force mode on a Digital Instruments Nanoscope-2 instrument (the United States).

The amount of silver immobilized on a track membrane was found using the modified Volhard method [8].

A silver-containing membrane sample was placed in a 50-ml glass vessel and poured over with a 10-ml portion of a 5% HNO_3 solution. The membrane was thermostated at 80°C on a water bath for 3–5 min, until the yellow coloration of the membrane disappeared. When the solution became transparent, the extraction was terminated and the hot extract was carefully discharged into a clean vessel. The hot extract was cooled in air to room temperature. A sample of volume V_s = 3 ml was taken for titration and 0.2 ml of an aqueous solution of $Fe(ClO_4)_3$, with a concen-

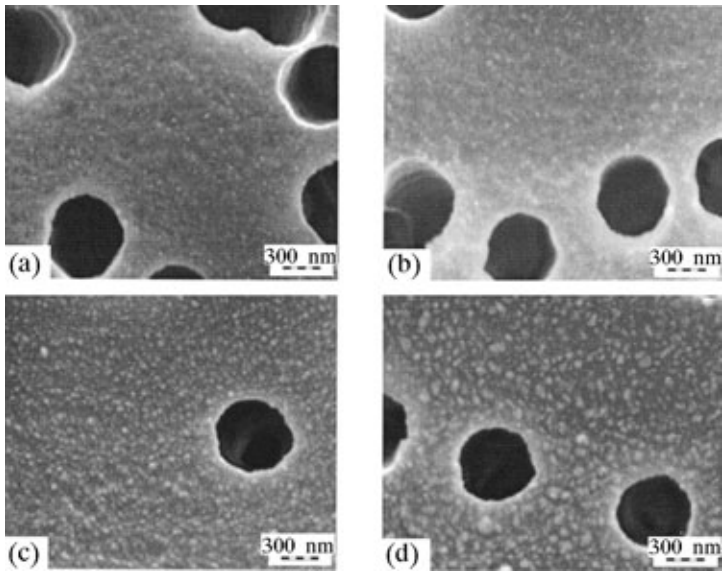

Fig. 1. SEM micrographs of the surface of track membranes with silver nanoparticles. Reaction time (min): (a) 15, (b) 60, (c) 120, and (d) 180.

tration of 0.56 M (0.2 mg ml^{-1}) (solution A), was added.

Solution A under study was gradually titrated with a NaSCN solution of concentration 8 mM (0.7 mg ml^{-1}) until the red coloration of $Fe(SCN)_3$ appeared, which indicates the end of titration. The volume of NaSCN, V_{NaSCN}, was measured and the amount of silver in the coating was calculated by the formula

$$m_{Ag} = \frac{V_{NaSCN} c_{NaSCN} V_{HNO_3}}{V_{sp}},$$

where V_{NaSCN} is the volume of the NaSCN solution consumed for sample titration (ml); c_{NaSCN}, concentration of the NaSCN solution (mg ml^{-1}); and V_{HNO_3}, volume of 5% nitric acid necessary for sample extraction (ml).

Highly dispersed colloid particles of silver were immobilized on the membrane surface by the chemical method of dispersion of this metal via reduction of silver ions to the molecular state in an aqueous–alcoholic medium in the presence of a water-soluble polymer (PVP), with subsequent deposition of silver nanoparticles onto the membrane surface [9, 10].

For this purpose, 0.15 g (0.9 mmol) of $AgNO_3$ and 29 g (2.3 mmol) of PVP were dissolved in a round-bottomed flask equipped with a reflux condenser and charged with 1 l of aqueous alcohol with an ethanol content of 70 wt %. After that, a membrane cut into fragments in the form of circles 4.5 cm in diameter was placed in the flask and the resulting solution was heated on a water bath with a reflux at 60–80°C. The process duration was set in the range from 10 to 120 min, depending on the amount of silver required for immobilization on the membrane. As the amount of silver on the membrane increased, its color changed from light yellow to dark brown. To find the optimal conditions of particle immobilization, the temperature and the relative and absolute concentrations of the reagents were varied. After silver immobilization on a membrane was complete, the sample was removed from the reaction mixture, successively washed with a 40% water–ethanol solution and distilled water, and dried between sheets of filter paper. The modified membranes were stored in a dry and dark place.

Figure 1 shows SEM micrographs of membranes with silver particles immobilized at a reaction mixture temperature of 80°C and varied process duration. The minimum size of clusters immobilized in 15 min (18 nm) is clearly seen in the micrographs.

Further course of the reaction leads to an increase in the particle size and number and to gradual saturation of the membrane surface with silver, as it is shown in Fig. 2. The saturation of the surface with silver is virtually complete in 120 min. Further, the mass of the already formed particles on the surface grows.

The AFM micrographs (Fig. 3) clearly demonstrate the regular spherical shape of colloid particles, whose average size is 70 nm. It should be noted that, under

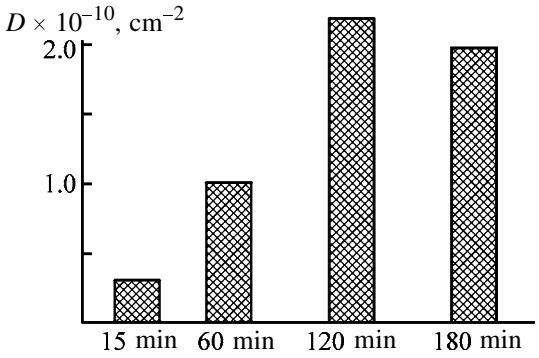

Fig. 2. Variation of the number density D of silver colloid particles per unit area of the track membrane with the duration of the immobilization process.

the optimal modification conditions (temperature and relative and absolute concentrations of the reagents), the shape and permeability of cylindrical pores of the membrane are preserved.

The rate of metal reduction in the presence of a water-soluble polymer is governed by numerous factors, the most important of which are the diffusion rate of ions of the metal and reducing agent into the polymer matrix, velocity of their motion within pores or polymer coils, rate of the chemical reduction itself, and, finally, the crystallization rate of the metal deposited. The size of the forming nanoparticles is also affected by the nature of the polymer [11].

To study the mechanism of formation and growth of colloid nanoparticles, temperature dependences of silver reduction in an aqueous–alcoholic solution in the presence of PVP was studied. Figure 4 shows curves that describe the kinetics of silver immobilization on a track membrane at 60, 70, and 80°C. It can be seen that the immobilization at 60 and 70°C is of about the same nature: the curves are S-shaped and consist of portions corresponding to the induction period I, acceleration period II, and deceleration period III.

The induction period is associated with the initial stages of the following concurrent processes: chemical reduction of silver in the solution bulk and sorption of metal cations on carboxy groups of the membrane, i.e., on hydrolyzed PET, with their subsequent reduction to metal and formation of stable particles of the new phase. Very small conversions correspond to this period.

The time in which nanoparticles are formed depends on numerous factors: relative and absolute concentrations of the reagents and presence of impurities.

At the end of the induction period, particle of size larger than 1 nm appear in the solution and on the membrane surface. These particles are formed via successive overgrowth of fine particles with metal atoms. After the completion of the induction period, metallic clusters-nuclei for the most part cease to form, i.e., further reduction occurs without any change in the number of particles, with their mass increasing.

At 80°C, the process is characterized by a smooth curve with a leveling-off portion, which has the form of the Langmuir isotherm. The rate of mass transfer at this temperature is an order of magnitude higher than that at 60°C. Presumably, the rate of particle formation in the bulk exceeds at this temperature that on the surface. Therefore, the induction period is weakly pronounced in the plot and the surface is rapidly saturated with the nanoparticles formed, i.e., particles that completed their growth are immobilized on the membrane surface. Data on the sorption rate in rela-

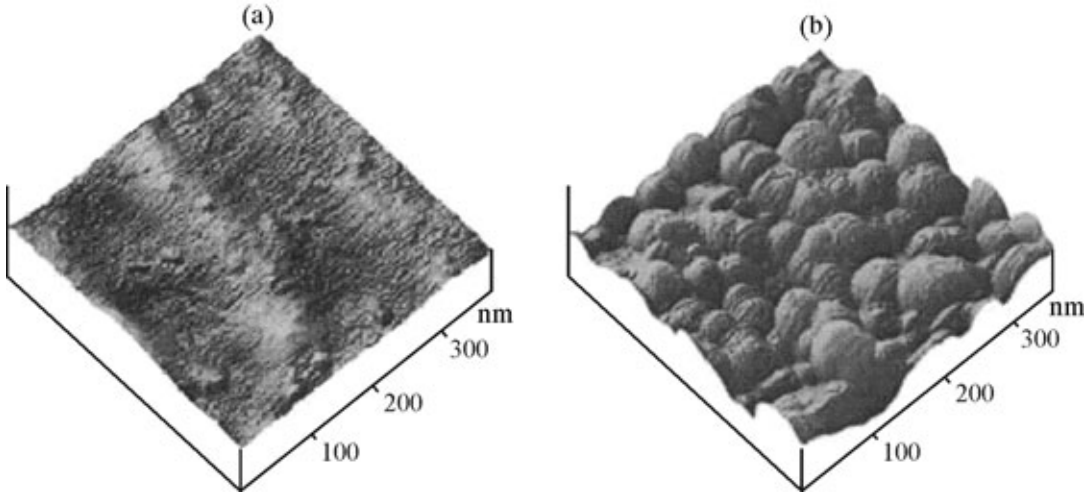

Fig. 3. AFM images of the membrane surface with immobilized silver. Membrane: (a) initial and (b) modified with silver.

tion to the temperature of the reaction mixture, which are calculated from the initial portion of the curve, are presented below:

Temperature, °C	60	70	80
Sorption rate, 10^2 μg cm^{-2} min^{-1}	0.4	1	4

Experiments on filtration of buffer solutions with modified membranes demonstrated that their hydrodynamic resistance remains virtually the same as that of control membranes. This indicates that the immobilization of nanoparticles does not change the effective diameter of pores in the membrane.

The bactericidal action of the membranes modified with silver nanoparticles was tested on model strains of microorganisms, recommended by the State Pharmacopoeia for tests of antimicrobial properties of medicinal preparations: *Escherichia coli*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Bacillus cereus*.

The modified membranes were placed in Petri dishes, each containing 15 ml of a solidified MPA nutritional medium. Suspensions with a concentration of 5×10^3 cells ml^{-1} were prepared from populations of 18–24-h-old cultures. A 0.1-ml portion of a suspension was applied to the membrane surface and evenly distributed over the entire surface. The inoculated Petri dishes were incubated at 37°C for 24 h. The results were recorded as presence or absence of colonies on the membrane (see table).

The experiments demonstrated that the concentration of immobilized silver on a membrane governs the growth of microorganisms. Silver in a concentration of 0.5 μg cm^{-2} suppresses only *E. coli*, whereas a threefold increase in the concentration of immobilized silver on the membrane results in that no colonies of microorganisms grow for all of the cultures studied.

Figure 5 shows photographs of growth of microbial cultures on membranes with different silver concentra-

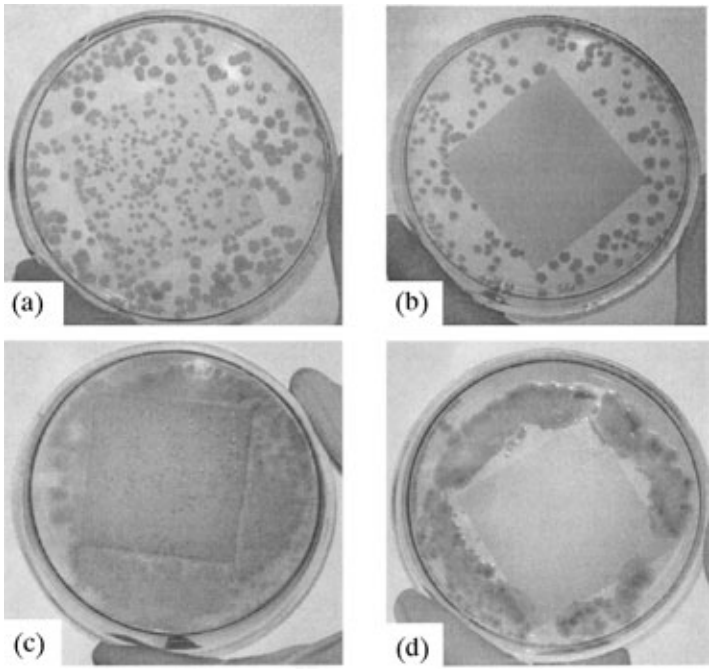

Fig. 5. Effect of the concentration of immobilized silver on the antimicrobial properties of modified track membranes. (a, b) Growth of a *St. aureus* culture on membranes with silver concentration of (a) 0.5 and (b) 1.4 μg cm^{-2}; (c, d) growth of *Ps. aeruginosa* culture on membranes with silver concentration of (c) 0.5 and (d) 1.4 μg cm^{-2}.

Antimicrobial effect of modified track membranes on test-strains of bacteria*

1.4	–	–	–	–

* (–) No growth of microorganism colonies. (+) Growth of microorganism colonies.

tions. The growth of staphylococcus and *B. cereus* colonies can be seen in the Petri dish with a membrane with a silver concentration equal to 0.5 μg cm^{-2}. It is also seen that staphylococcus colonies on the membrane are smaller than in the case of growth on agar, and colonies on the membrane with a higher silver concentration are absent.

Thus, imparting antimicrobial properties to a membrane makes wider the applicability of these materials in water treatment and in fine biotechnology of tissue cultures.

CONCLUSIONS

(1) A method for modification of track membranes by immobilization of colloid silver nanoparticles on the surface of microfiltration membranes was developed.

(2) The optimal conditions of immobilization of silver particles on the filtering surface of a membrane were determined.

(3) It was shown that track membranes modified with silver nanoparticles have an antimicrobial effect on *E. coli, Ps. aeruginosa, St. aureus*, and *B. cereus* microorganisms.

NANOTECHNOLOGIES AND NANOMATERIALS

Chemical Activation of Carbon Nanofibers and Nanotubes

Nguyen Chan Hung, I. V. Anoshkin, and E. G. Rakov

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received September 27, 2006

Abstract—Method of thermodynamic simulation was used to calculate the equilibrium parameters of reactions of graphite with anhydrous LiOH, NaOH, and KOH and with the alkalis in the presence of water vapor. The change in the specific surface area and mass loss were used to analyze the interaction of carbon nanofibers and multilayer carbon nanotubes produced by catalytic pyrolysis of CH_4 with the alkalis.

DOI: 10.1134/S1070427207030184

Threadlike carbon materials, nanofibers (NF) and nanotubes (NT), attract the attention of researchers and technologists owing to their dimensions and properties. They can serve as catalyst supports and electrocatalysts, electrodes of supercapacitors and lithium–ion power cells, and components of chemical sensors and composites [1, 2]. In many cases, the efficiency of use of such materials is determined by their specific surface area S_{sp}, which is comparatively small in the most readily available materials.

The value of S_{sp} of carbon materials can be raised (activation) in several ways: partial oxidation with air, water vapor, CO_2, molten alkalis, and some other reagents. Of these, alkalis are most frequently used to develop the surface and porosity. In particular, studies have been performed of the interaction with KOH of carbon NF [3–5] and multilayer carbon NT [6–9]. The S_{sp} of NF 50–500 nm in diameter has been raised from 13 to 212 $m^2 g^{-1}$ [3]. The action of KOH was the most effective (increase in S_{sp} from 24.5 to 360 $m^2 g^{-1}$) at a mass ratio KOH : NF = 7 : 1, but, simultaneously, the yield of activated NF decreased [5]. In the case of NT, a twofold increase in S_{sp} (to 1050 $m^2 g^{-1}$) was achieved at KOH : NT = 4 : 1, and even a 2.5-fold increase (to 1184 $m^2 g^{-1}$), at a 5 : 1 ratio [7]. Differences in the effect of KOH and NaOH on the NT morphology have been noted [8, 9].

However, the available published evidence is insufficient for determining the possibility and conditions of activation of materials produced by methods different from those used in the references cited, and, in particular, of carbon NT [10, 11] and multilayer carbon NT [12, 13]. Results of thermodynamic calculations have not been invoked previously when discussing the reaction mechanisms.

The aim of this study was to examine the activation of these materials.

EXPERIMENTAL

To activation were subjected three types of carbon NT and two samples of carbon NF. The NT-1 sample was an NT produced by pyrolysis of CH_4 in the presence of H_2 on a Co–Mo : MgO catalyst containing 6 mol % active components ($CoO : MoO_3$ = 1 : 5 mol/mol) at 970°C with recycling of the gas mixture. The product was washed with concentrated HCl to remove the catalyst support. Its ash content was $9.4 \pm 0.1\%$, and $S_{sp} = 221.7 \pm 2.4$ $m^2 g^{-1}$.

The NT-2 sample was produced by pyrolysis of CH_4 in the presence of hydrogen on a Co–Mo/MgO catalyst at 950°C by the procedure described in [12, 13]. It was also washed with concentrated HCl to remove the catalyst support and had the form of a mixture of thin multilayer carbon nanotubes 2 to 10 nm in diameter. The NT were annealed in air at 380°C for 30 min in order to remove admixtures of amorphous carbon. This was accompanied by an 8.15% mass loss. $S_{sp} = 358 \pm 2$ $m^2 g^{-1}$.

The NT-3 sample was produced by pyrolysis of CH_4 in the presence of hydrogen on a Co–Mo/MgO catalyst containing 3 mol % active components ($CoO : MoO_3 = 1 : 1$) at 900°C in a filtering bed. The sample was washed with concentrated HCl to remove the catalyst support. The ash content was 0.1%, and $S_{sp} = 694.8 \pm 4.0$ $m^2 g^{-1}$.

Both NF samples (NF-1 and NF-2) were produced by pyrolysis of CH_4 on a Ni/MgO catalyst [11]. Preliminary purification was done with a 10% HNO_3 solution. The NF diameter was 30–60 nm and length up to 2 μm. The NF-1 sample was preliminarily treated at 500°C in a flow of H_2 and had $S_{sp} = 82.8 \pm 0.4$ $m^2 g^{-1}$, and the NF-2 sample had $S_{sp} = 74.3 \pm 0.7$ $m^2 g^{-1}$. The loss of NF mass upon annealing in air at 410°C for 60 min was 6.6 wt %. According to the results of thermogravimetric measurements, the ash content of NF upon heating in air at 850°C for 30 min was 4.1 wt %.

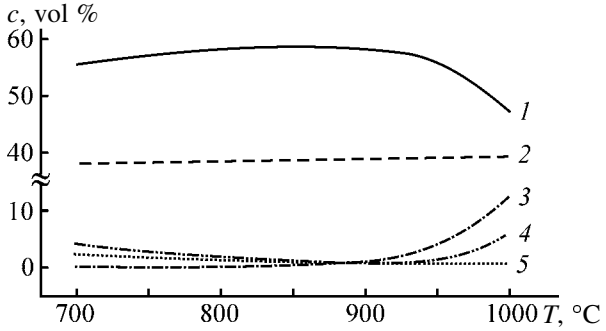

Fig. 1. Effect of temperature T on the equilibrium volume concentration c of gaseous components at a KOH : C mass ratio of 4 : 1. (*1*) H_2, (*2*) K (monatomic), (*3*) CO, (*4*) hydrocarbons, and (*5*) K (diatomic).

Carbon nanotubes and nanofibers were treated with molten KOH, NaOH, and NaOH–KOH mixtures at 800–850°C in a flow of dry Ar (flow rate 250 $cm^3 min^{-1}$) or in Ar saturated with H_2O vapor at 22°C (calculated flow rate about 100 $cm^3 min^{-1}$). Before being charged into the reactor, the starting NT and NF were ground in a mortar with a necessary amount of alkali until a paste of uniform gray color was formed. Part of NT and NF samples were subjected, prior to activation, to compaction at 280 MPa. The process was carried out in heated hermetic reactors of two types, vertical and horizontal, in which cylindrical nickel boats with, respectively, high and low rims were placed. The temperature was elevated at a rate of 10 or 20 deg min^{-1} to 850°C and maintained at this level for 60 or 90 min.

After performing the reaction, cooled products were treated with distilled water and 3 M HCl and filtered. The precipitate formed on the filter was three times washed with distilled water and dried at 110°C.

The specific surface area was determined with a Tristar 3000 instrument.

The reaction equilibria were calculated using the Astra software on the assumption that the thermodynamic parameters of carbon NF and NT coincide with those of graphite. It was presumed that this assumption does not strongly affect the results of calculations, even though it introduces a certain error. In addition, the database used for the calculations contains no evidence concerning characteristics of molten alkalis (melting points of LiOH, NaOH, and KOH are 473, 322, and 405°C, respectively), which affects the results obtained to a greater extent. However, disregarding the phase transitions in alkalis cannot strongly impair the calculation results, because their enthalpies of melting are low (4.8, 1.52, and 2.24 kcal mol^{-1}, respectively [14, 15]).

The calculations were performed in the temperature range 700–1000°C and alkali : carbon mass ratios of 1 : 1 to 6 : 1 at a total pressure of 101.3 kPa (1 atm). An example of the calculated results is presented in Tables 1 and 2.

It can be seen that the main solid products are graphite and K_2CO_3, with amount of graphite decreasing and that of the carbonate increasing as the KOH : C ratio grows. The yield of CO markedly increases at elevated temperatures.

The situation with other gaseous products is more complicated. As expected, the main gaseous components are hydrogen and potassium. Potassium is in the form of mono- and diatomic vapor, and hydrogen may

Table 3. Relationship between changes in mass and in S_{sp}

be present not only as molecular H_2, but as CH_4 as well (at low temperatures). At the same time, the concentration of the main component is weakly dependent on temperature (Fig. 1) and varies nearly linearly as the KOH : C ratio becomes larger. In particular, the fraction α of reacted C at various temperatures is, at the KOH : C mass ratio of 4 : 1 under equilibrium conditions, as follows:

T, °C	α, fraction units
700	0.313
750	0.295
800	0.297
850	0.294
900	0.295
950	0.307
1000	0.360

Introduction of even minor amounts of water vapor markedly changes the distribution of the reaction products (Fig. 2) and leads to an increase in the fraction α. As the H_2O : C ratio increases, the concentration of H_2 becomes lower and that of K vapor decreases. It would be the best to maintain the ratio at 0.65, in which case the concentration of H_2 is the highest, that of K vapor is already low, and that of CO is as yet low. However, it is not known how such a ratio can be maintained in a flow of gases.

The KOH : C mass ratio of 4 : 1 corresponds to a molar ratio of 6 : 7. Replacement of KOH with NaOH at the same molar ratio does not change α significantly, whereas replacement with LiOH at 950°C makes α significantly larger:

Reagent	KOH	NaOH	LiOH
α, fraction units	0.307	0.306	0.424

The effect of LiOH is the most pronounced at a LiOH : C molar ratio of 1 : 1 at 950°C, when α becomes as large as 0.495.

The principal result of the calculations is that the gasification of carbon materials with alkalis can be performed in a humid atmosphere with the minimum evolution of K vapor and CO.

Relationship between changes in mass and in the specific surface area. S_{sp} of solid cylinders subjected to chemical etching, with their radius R_{out} decreasing in this treatment, can be calculated on the assumption that the etching occurs uniformly over the entire surface and the substance density ρ remains unchanged. In this case, $S_{sp} = 2/R_{out}\rho$. Because $R_{out} = [m/(\pi l \rho)]^{0.5}$ (m is the cylinder mass), the equalities $R_{out} = \text{const}_1 m^{0.5}$ and $S_{sp} = \text{const}_2 m^{-0.5}$ will be valid at invariable cylinder length l and ρ. If, consequently, the initial mass m_0 and S_{sp}^0 of a sample composed of cylindrical particles are known, the behavior of $S_{sp} = S_{sp}^0(m_0/m)^{0.5}$ can be judged from variation of the mass in the course of etching.

In the case of a nonuniform etching and formation of local reaction zones (caverns), changes in mass must lead to a more pronounced increase in S_{sp} in accordance with the equation $S_{sp} = S_{sp}^0(m_0/m)^n$, where

$n > 0.5$. Published data can be used to find the experimentally observed value of n (Table 3). All the results refer to multilayer NT (MNT) with a number of layers not exceeding five.

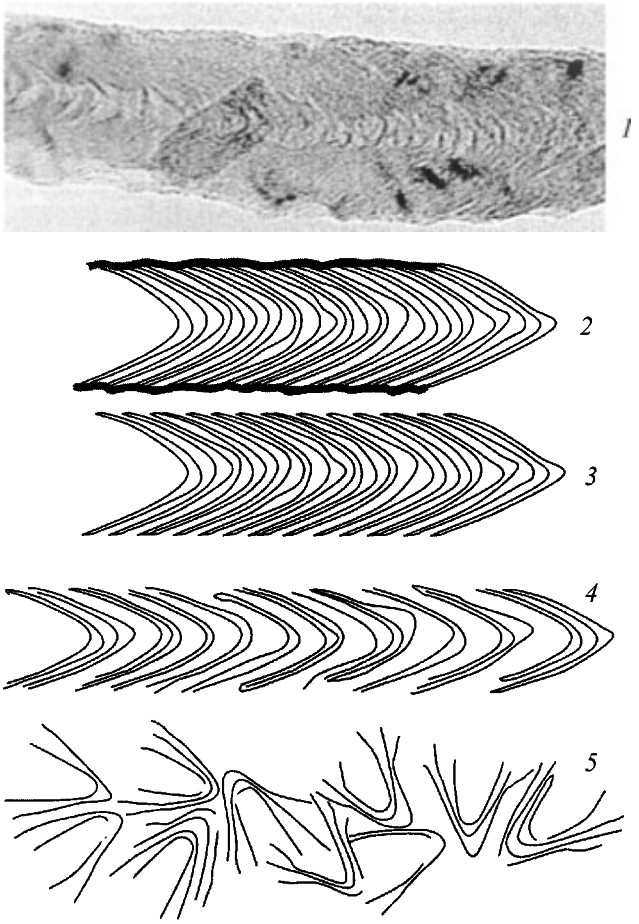

Fig. 3. Schematic of the successive surface development in interaction between carbon nanofibers. (*1*) Electron micrograph of a nanofiber and (*2–5*) successive stages of activation.

A certain pattern is observed: n markedly exceeds 0.5, i.e., the activation occurs with an increase in the contour surface area of particles. At a larger initial S_{sp}, the values of n are small.

The results obtained in the study are presented in Table 4. They, on the whole, agree with previously published data on the temperature and duration of activation and on the mass loss reached under closely similar conditions. As can be seen from the data presented, the behavior of NF and MNT in activation under similar conditions is not the same: the NF surface develops more intensively. For NF, n exceeds 0.5 in all cases and reaches values of 2.77. In the case of NT, all the three samples behave as if the gasification reaction involves only the outer layer of the tubes, because the value of n remains close to 0.5 even at a mass loss of about 50%.

The difference in behavior between NF and NT can be attributed to their different structures: in NF, graphene layers are arranged at angle to the axis (arborescent structure), which enables reagents to penetrate into the interlayer space, to make larger the reaction surface, and, presumably, in the end, to cut fibers into comparatively short fragments. The possibility of KOH intercalation into the interlayer space of NF was noted previously in [4]. The mechanism is schematically shown in Fig. 3.

At the same time, NT are characterized by a cylindrical arrangement of graphene layers and a considerably lower defect density, which predetermines localization of the reaction on the surface of the outer sheath. Here, the reaction occurs by another mechanism.

The difference between the data in Tables 3 and 4 may be due to the different diameters of NT used in

the present and earlier studies. If the way in which S_{sp} changes on removing one external layer is analyzed [16], it can be seen that, e.g., it changes by less than 100 $m^2 g^{-1}$ on passing from 20- to 10-layer NT and by 200–300 and 700–800 $m^2 g^{-1}$ on going from three-layer NT to two- and one-layer NT, respectively. The smaller the number of layers in NT, the faster should be the development of their surface in the course of activation. Another reason consists in the degree of ordering of NF and NT. This was clearly demonstrated in [9], where activation of NT with close initial S_{sp} (345, 330, and 326 $m^2 g^{-1}$), but different structures led to strongly different final S_{sp} (1670, 1220, and 868 $m^2 g^{-1}$).

Attempts to intensify the process by raising the mass ratio of alkalis to NT and by compaction of the samples studied failed, even though the same values of S_{sp} were obtained in the case of NF compaction at a somewhat higher yield. The addition of $AgNO_3$ in activation of NT-2 did not lead to any significant change in the mass loss. Changing the reactor configuration and boat shape did not produce any strongly different results, either. It seems that a more rational activation procedure is that using H_2O vapor in combination with alkalis. If the process is performed in dry Ar, noticeable amounts of metallic K are formed as a deposit on the inner wall of the gas-discharge pipe. Nothing of the kind occurred if water vapor was supplied.

The problem of efficiency of activation with mixtures of KOH with low-cost NaOH requires further analysis. The potassium vapor has a higher pressure, which favors its removal from the reaction zone. Sodium is less volatile than potassium, which may cause difficulties with removal of its vapor.

CONCLUSIONS

(1) The equilibrium yield of products formed in the reaction of alkalis with graphite was calculated. It was shown that the concentrations of the main gaseous components (H_2 and K) only slightly depend on temperature in the range 700–1000°C and linearly increase with the KOH : C ratio.

(2) It was demonstrated that introduction of H_2O vapor changes the equilibrium composition of the gaseous product, with the concentration of H_2 increasing and that of K vapor decreasing. At a H_2O : C mass ratio of 0.65, the concentrations of H_2 and K vapor reach the maximum and minimum values, respectively.

(3) The activation of two samples of carbon nanofibers and three samples of carbon nanotubes with KOH and its mixtures with NaOH in a flow of dry and humid Ar was studied on the basis of data on changes in mass and specific surface area. It was found that the specific surface area increases in activation of carbon nanofibers and nanotubes with alkalis in different ways: under identical conditions, nanofibers are activated more intensively. It was suggested that these dissimilarities are due to differences in the structure of nanofibers and nanotubes. Introduction of an $AgNO_3$ additive and compaction does not lead to any significant intensification of the process.

NANOTECHNOLOGIES AND NANOMATERIALS

Technology for Manufacture of Pure Fullerenes C_{60}, C_{70} and a Concentrate of Higher Fullerenes

Yu. S. Grushko, V. P. Sedov, and V. A. Shilin

Konstantinov Institute of Nuclear Physics, Russian Academy of Sciences, Gatchina, Leningrad oblast, Russia

Received September 28, 2006; in final form, December 2006

Abstract—An integrated technology for manufacture of fullerenes was developed. It includes the following stages: synthesis of a fullerene black, extraction of a mixture of fullerenes from the black, preliminary separation of the mixture into concentrates enriched in C_{60} and C_{70} fullerenes, and production of C_{60} and C_{70} fullerenes of purity exceeding 99.5 and 98.0 wt %, respectively, from the concentrates.

DOI: 10.1134/S1070427207030196

The development of nanotechnologies is a priority of the XXI century and, beginning in 2000, has been attracting considerable investment in all the developed countries of the world. In 2007, the Federal Target Program "Development of the Infrastructure of Nanotechnologies in the Russian Federation in 2007–2010" is brought in force in Russia. According to estimates, no less than 25% of current nanotechnological designs are, and will be, associated with use of fullerenes. However, despite the considerable progress in studies of fullerenes and development of technologies for their production, a number of problems have not been resolved, which hinders wide application of fullerene nanostructures. The major problem is high cost of production, separation, and purification of fullerenes.

Several methods for synthesis of fullerenes are presently known [1–10]. The most preferable of these are the electric-arc technique [9] and method of incomplete combustion of hydrocarbons (benzene, toluene, etc.) [6]. Other methods have been poorly studied and can be only used on a limited scale.

In both methods, the main synthesis product is the so-called fullerene-containing carbon black (FB). In addition to fullerenes, the black contains amorphous carbon and, in the case of incomplete combustion of hydrocarbons, also impurities of polycondensed aromatic hydrocarbons.

A characteristic distinction of fullerenes from other structures composed of pure carbon is their ability to dissolve in organic solvents. This enables recovery of fullerenes from FB by extraction with organic solvents [11–14].

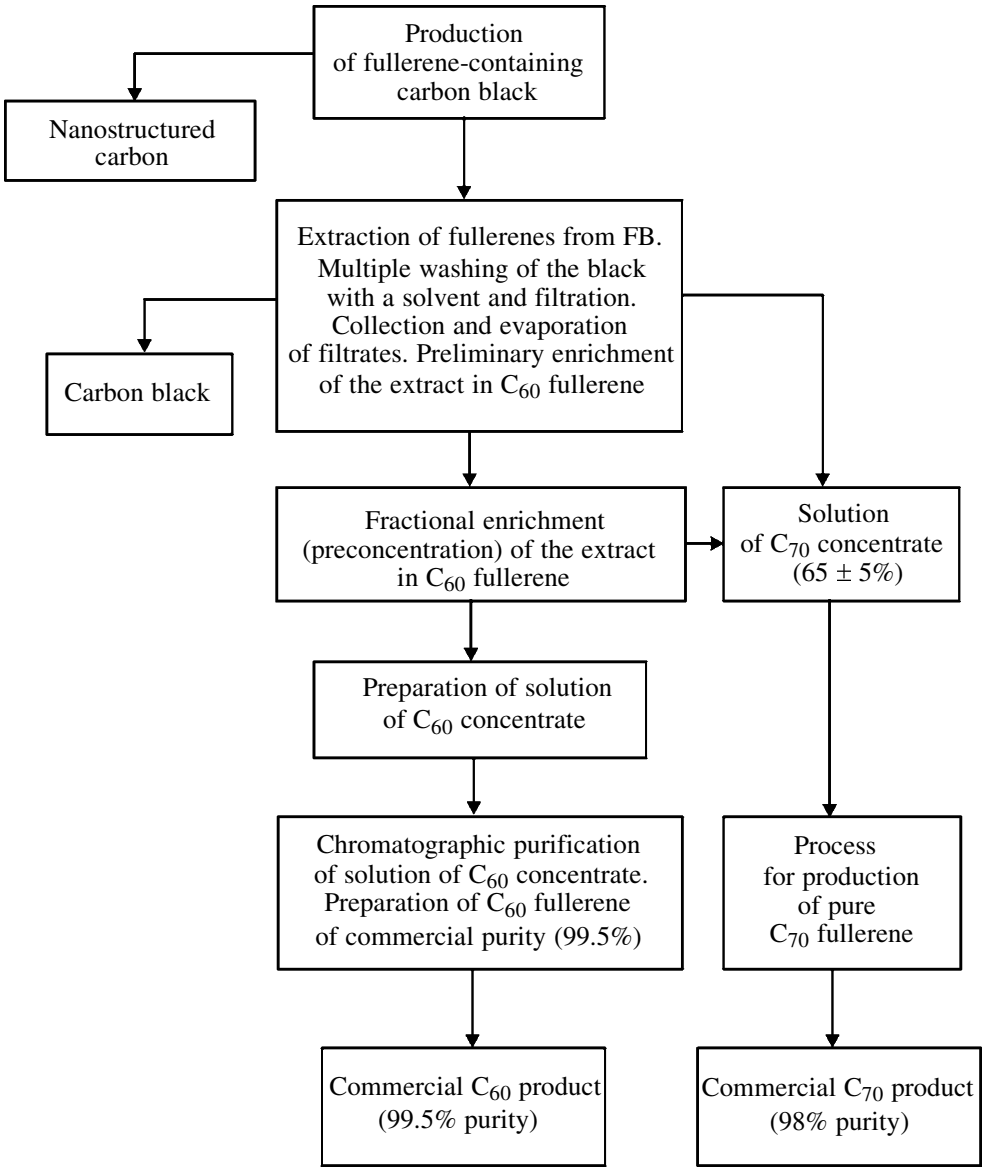
The integrated technology for manufacture of fullerenes, suggested in this paper, includes stages of FB synthesis, extraction of a mixture of fullerenes from the black, and subsequent separation and purification of the fullerenes (see scheme). This technology has been used for more than 10 years at the St. Petersburg Institute of Nuclear Physics for production of kilogram amounts of C_{60} of 99.5% purity (here and hereinafter, the composition of fullerenes is given in weight percents).

Manufacture of FB by electric-arc evaporation of graphite. The fullerene-containing carbon black produced by the electric-arc method, as a rule, contains a mixture of fullerenes with the following content of the main components (wt %): C_{60} 65–88, C_{70} 12–30, and $C_{n>70}$ 1–5. A specific feature of the electric-arc method is that it produces, together with a carbon black containing up to 20 wt % fullerenes, also so-called cathode deposits containing up to 40 wt % multilayer carbon nanotubes, which a valuable material for nanotechnologies.

The designs of electric-arc carbon-black generators (EACBGs), developed by now, provide, under certain conditions, a fullerene yield of up to 43 wt % [5]. However, the increase in the fullerene yield entails a decrease in the evaporation rate of graphite [15]. It has been noted [2] that, as the diameter of the electrodes being evaporated increases, the yield of fullerenes should necessarily decrease. This circumstance serves as a certain limitation in developments of a high-capacity EACBG design [5, 16–19].

Processing of FB with low content of fullerenes is unprofitable because of the increasing expenditure of

Integrated flowsheet for manufacture of fullerenes



electric power, solvents, and labor per gram of the final product. The experience of EACBG exploitation made it possible to find a balance between the content of fullerenes in a black and the output capacity that would be optimal from the profitability standpoint. The optimal output characteristics are provided both by limiting the diameter of a graphite rod being evaporated (as a rule, to 6–15 mm) and by choosing the rate of its evaporation. The generator designs used show the best performance with rods (electrodes) 6–8 mm in diameter. In prolonged operation modes, the average yield of fullerenes varies within 6–10% of the mass of the fullerene-containing carbon black, which, in turn, constitutes 35–50% of the mass of the evaporated graphite (the rest is the cathode deposit). The yield of the carbon black can be raised by reversing the polarity of the electrodes for "back" evaporation of the cathode deposit. However, the evaporation of the cathode deposit is slow because of its high electrical resistivity, which makes the gain in the output capacity insignificant.

The fullerene yield is markedly raised if water-cooled screens, coils, and other devices that shield fullerenes from the detrimental action of hard UV radiation of the arc are present in the evaporation chamber [5, 18]. The yield of fullerenes also depends on the purity of the graphite material. The best results were obtained with domestic raw materials on MPG-6

Table 1. Parameters of an extraction installation for extraction of fullerenes from electric-arc FB

Parameter	Value

Duration of extraction process (3 cycles), h	15–17

spectroscopic graphite rods of ultrapure 7-2 and 7-3 grades [TU (Technical Specifications) 48-4802-14–88].

An EACBG of basic design was used to process 225 kg of graphite rods (6 mm in diameter, 200 mm long). The capacity of the generator in terms of evaporation of graphite rods was, on the average, 100 g per hour. The mean fullerene content of FB was 6–8 wt %.

It was found in a prolonged exploitation of a working prototype of an electric-arc generator that maintaining the fullerene yield at a level not lower than 6 wt % in continuous operation requires that the helium atmosphere in the evaporation chamber should be renewed at regular intervals of time. This is necessary because impurities released from the graphite being evaporated (trace amounts of sorbed moisture, atmospheric oxygen, etc.) accumulate and suppress generation of fullerenes. A promising technical solution concerning the removal of FB from the electric-arc zone with a directed flow of inert gas (helium) and its collection in special containers proved to be poorly efficient for the given case because the system for helium recycling is bulky and complicated in use. A more practically feasible procedure is that with periodic renewal of the helium atmosphere in the evaporation chamber, correlated with maintenance stops.

Thus, the presently used electric-arc FB generators have limited output capacity, mainly determined by the evaporation parameters of the graphite material. The problem of raising the FB yield can be partly resolved by incorporating the electric-arc unit into a computer-controlled multiunit system [10]. This will markedly diminish loss of time for unit recharging.

Extraction of fullerenes from FB. Several methods are known for recovery of fullerenes from FB [11, 12, 14]. Their principal disadvantage consists in long duration of extraction and filtration and low degree of fullerene recovery (≤70 wt %). The solvents used in the process of fullerene recovery from carbon black should satisfy the following requirements: high solubility of fullerenes, as low boiling point as possible, low fire and explosion hazard, low toxicity, and low cost. Published data (e.g., [20, 21]) on the solubility of fullerenes in various solvents can be used to compose a list of solvents best suitable for large-scale extraction: toluene, *o*-xylene, *o*-dichlorobenzene, 1,2,4-trichlorobenzene, and 1,2,4-trimethylbenzene. Of these, *o*-xylene was chosen as satisfying the above requirements to the fullest extent. C_{60} and C_{70} fullerenes have a comparatively high solubility in *o*-xylene at 25°C: 8–10 and 15 g l^{-1}, respectively. Use of *o*-xylene instead of toluene, which frequently serves as an agent for extraction of fullerenes from carbon black, makes it possible to considerably reduce the volumes of the solutions being processed and thereby to minimize the dimensions of the basic process apparatus. The extraction installation developed in this study includes a mechanical stirrer with a filter, collectors for solutions and solvent, and a vacuum evaporator. The following parameters were found when using this installation: optimal mass of carbon black charged into the extractor, solvent/carbon black ratio, duration and number of repetitions of the extraction procedure, loss of the solvent via its capture by the carbon black, extraction efficiency, and residual content of fullerenes in the carbon black. The values of these parameters are listed in Table 1.

To accelerate the extraction process, the filtration was carried out under a nitrogen pressure of up to 5 kg cm^{-2}. A suspension of carbon black in the solvent was mechanically agitated at 2–3 revolutions per second. The material remaining on the filter is composed of a solid phase (carbon black, ~40 wt %) and a captured solvent (60 wt %), and, therefore, solvent regeneration requires that an additional operation, vacuum evaporation of the solvent from carbon black, should be performed.

As can be seen from Table 1, the extraction process is long and labor-consuming and involves a considerable irrecoverable loss of the solvent. The previously developed sublimation technique [22, 23] is devoid of the above-mentioned disadvantages. This method con-

sists in the following: A bulk finely dispersed carbon black is mixed in a certain proportion with a noninflammable mixture of solvents and agitated until free-flowing and no-dust-forming grains are formed (compaction). Then the resulting product is charged into a sublimation apparatus and fullerenes are sublimed at a temperature of 500–800°C and residual pressure of 0.1–1.0 Pa and condensed on a water-cooled removable collector. The conditions under which the sublimation occurs with an 88–90 wt % yield in 1–1.5 h were experimentally found. Experiments performed on larger FB samples demonstrated that a large-scale sublimation installation can be, in principle, developed.

A prompt analysis was made using spectrophotometry or microcolumn high-performance liquid chromatography (HPLC) on the C_{18} phase with a 60 : 40 acetonitrile–toluene mixture as eluent. Chromatography on this phase enables reliable observation of C_{60}, C_{70}, and their oxides, but, in this case, the peaks of the higher fullerenes are strongly broadened and their analysis is difficult. For analysis of high-purity fullerenes and higher fullerenes, we used chromatographic columns specially developed by Nacalai Tesque Inc. (Japan) for analysis and separation of fullerenes and metallofullerenes: analytical/semipreparative Cosmosil BuckyPrep 4.6×250 column and preparative Cosmosil BuckyPrep 10×250 column. The stationary phase of both of these columns is pyrenylpropyl silica gel. Standard analyses and separations use as the mobile phase (eluent) pure toluene. The sample volume and the eluent flow rate were 20 μl and 1 ml min^{-1} for the analytical column, and 4 ml and 4.7 ml min^{-1} in preparative separations. The peaks were recorded by absorption at a wavelength of 330 nm. The ratio of the molar extinctions of C_{70} and C_{60} at this wavelength is 0.76.

A single-stage analysis on the analytical column is sufficient for analysis of C_{60} with a 99.5%+ purity. In analysis of ultrapure (99.9%+) C_{60}, a weighed portion of the substance to be analyzed is preliminarily enriched with impurities on the preparative column. In this case, a fraction that follows C_{60} is taken. This fraction is concentrated to a certain volume and its aliquot is taken for analysis on the analytical column. The main impurities in pure C_{60} are monoxide $C_{60}O$ and C_{70}. On these columns, the retention time of fullerene oxides exceeds that for the corresponding unoxidized fullerenes, in contrast to the case of the C_{18} phase (octadecyl silica gel), on which the oxides are eluted earlier than the corresponding fullerenes with a 60 : 40 acetonitrile–toluene mixture as eluent. Under the above-mentioned analytical conditions, the peaks of C_{60} and C_{70} are well-resolved (the distance between the peaks is 11 times the width of the C_{60} line at half-maximum) and the relative content of impurities can be easily determined.

Enrichment of the extract by fractional concentration. At present, numerous technical solutions that enable production of pure fullerenes C_{60}, C_{70} and $C_{n>70}$ are known [24–26, 28–34]. These solutions are mostly based on the chromatographic method, which produces, in some cases, very pure solutions of C_{60} and C_{70} fullerenes of purity exceeding 99.5 and 98%, respectively. A disadvantage of the chromatographic method is its low output capacity in terms of the target component.

The previously revealed property of the anomalous temperature dependence of the solubility of C_{60} fullerene [20, 21, 24–28] served as a basis for a method of fullerene purification by fractional concentration [28]. The method of fractional crystallization [26, 27] can produce C_{60} fullerene of 99.5% purity; however, the process involves numerous stages and the yield of the target product is very low, only several percents [27]. In [26], a mixed solvent composed of toluene and 1,3-diphenylacetone was used. Three stages of crystallization yielded C_{60} of 99.5% purity, according to HPLC analysis. With this method, the total yield of pure C_{60} fullerene was 69% relative to the mass of the starting extract (at initial C_{60} content of the extract equal to 84%). The main disadvantages of this technique are as follows: large solvent volumes are used because of the low solubility of fullerenes in this solvent, toluene should be completely removed from the solvent after performing the procedure, high temperature (110°C) is necessary, duration of each stage is long, a difficultly available solvent component is used (1,3-diphenylacetone), and the mixed solvent is to be regenerated. Therefore, this technique should also be considered labor-consuming and poorly efficient despite the high yield of pure C_{60}.

The technique we suggest here employs, to obtain pure C_{60}, a kind of liquid chromatography, flash chromatography or flash filtration. This separation method can be used in those cases when the retention time of the components being separated differs by a factor of more than several tens. This method is devoid of the principal disadvantage of the classical chromatography, low output capacity, because it does not require a fixed one-time charging of a limited amount of the starting material. However, the service life of the sorbent in this technique is limited by its capacity for impurities being sorbed. Therefore, in order to make longer the working time of a column

Table 2. Main parameters of the FC process

FC stage	Time, h	Solvent : crystals, ml g^{-1}	Fraction composition, wt %				Mass of deposit, wt % relative to starting extract, for each stage
			deposit		filtrate		
			C_{60}	C_{70}	C_{60}	C_{70}	
First	1.5	10	87.0	13.0	31.4	68.6	79.5
Second	2.0	19	92.0	8.0	75.4	24.6	66.3
Third	3.0	15	96.7	3.3	84.6	15.4	60.8

without replacement of the sorbent, the content of the component being purified in the raw material should be as high as possible.

To obtain a concentrate of this kind, with a C_{60} content of up to 96%, a procedure for enrichment of the starting raw material for flash chromatography, fractional concentration (FC), was developed. The FC process is for the most part performed in three stages, the yield of the enriched product remains high, and the content of C_{60} fullerene in the concentrate is as high as $96 \pm 2\%$. The procedure consists in the following. A fullerene extract with a C_{60} content of 72–85% is dissolved in a certain amount of *o*-xylene heated to 80–85°C until a saturated solution is formed, this solution is filtered on a vacuum filter heated to the same temperature, and the separated crystals are dried under reduced pressure to constant mass. As a result, the crystals are enriched with C_{60} fullerene, and the filtrate, with C_{70} fullerene. The composition and yield of the enriched concentrate of C_{60} depends on the composition of the starting extract of fullerenes and solvent/crystals ratio. A decrease in the enrichment was observed on making longer the time for which the saturated fullerene solution is heated. In the multistage enrichment scheme, the decrease in enrichment becomes noticeable already in the third stage, with no enrichment occurring at a larger number of stages. Presumably, this is due to cross oligomerization of C_{60} and C_{70} under the action of temperature. It was found that the total time of all thermal treatments, including the duration of agitation and hot filtration, should not exceed 7 h. With account of this limitation, a process scheme of FC was developed. This scheme enables effective enrichment of extracts of virtually any composition in C_{60} fullerene, with a considerable yield of the final product. Table 2 lists the results of FC of C_{60} fullerene at the initial C_{60}/C_{70} ratio of 75/25.

It follows from the results presented that three stages of FC give in a 60% yield a concentrate of the following composition (wt %): $C_{60}O$ 2.2, C_{60} 94.9, C_{70} 2.9. This concentrate is a good half-product for production of pure C_{60} by flash-chromatographic purification.

The fractional enrichment procedure enables the following: (1) production of a concentrate with a C_{60} content sufficiently high for practical use in further flash-chromatographic purification; (2) removal of C_{70} from the starting extract in a smaller number of stages; (3) choice of the FC mode in which a first-stage solution with high C_{60} content, suitable for subsequent preparation of this fullerene, is formed; (4) determination of the conditions in which filtrate solutions of second and third stages have a composition close to that of the starting extract and the extract formed in the first stage of FC, respectively, which enables their use in the subsequent cycles of enrichment; (5) reduction of the volume of fractions with a low content of expensive C_{70}.

In continuous processing of fullerene extracts, the yield of the C_{60} concentrate is optimized and the loss of C_{70} is reduced to a minimum.

Production of pure C_{60} fullerene. Several methods for preparation of a pure C_{60} fullerene are known: chromatographic [29–36], fractional crystallization [26, 27], selective extraction [37, 38], and chemical techniques that use complexing agents, such as, e.g., 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) [39] or calixarenes [40], or those based on functionalization of the fullerene molecule (bromination [41] etc.). As already noted, the most efficient method for production of pure C_{60} is flash chromatography. The best, as regards the output capacity, stationary phase in purification of C_{60} fullerene by this method are activated carbons with a large specific surface area, e.g., of Darco (Fluka) or DCL GDC (Waterlink Sutcliffe Carbons) brands [42] or sorbents based on these carbons. Solvents of aliphatic or aromatic nature or mixtures of these, *o*-xylene in the given case, are commonly used as the mobile phase.

The use of a granulated activated carbon as a sorbent enabled application of a simple version of gravitational liquid chromatography. The choice of *o*-xylene for preparing the starting solution is due to the fact that *o*-xylene has been used previously for extraction and fractional concentration. An additional advantage of *o*-xylene over toluene frequently used for this purpose [37] is that, in this case, solutions with high concentration of fullerenes can be prepared; as a result, solutions with considerably smaller working volumes can be used and the duration of the chromatographic process can be made markedly shorter.

A saturated solution of a mixture of fullerenes in *o*-xylene, with a C_{60} content of about 96%, is continuously fed into the column, and the eluate contains C_{60}, in which no C_{70} or higher fullerenes are detected. The process of chromatographic purification is monitored by the concentration of C_{70} fullerene in the eluate. To obtain, e.g., C_{60} of 99.5% purity, the process is terminated when C_{70} appears at the outlet in a concentration exceeding 0.1 %. After C_{70} appears at the outlet, the supply of the feeding solution is terminated and pure solvent is fed into the column. The washing is performed to a C_{60} concentration in the eluate equal to 0.1–0.2 g l^{-1}. Further washing is inadvisable for practical reasons.

The mobile phase is supplied at a velocity of 0.2–0.8 ml min^{-1} cm^{-2} (preferably 0.4–0.5 ml min^{-1} cm^{-2}). If the process is carried out at a lower rate, the purity of the product obtained is improved, but the output capacity of the process decreases. An increased flow rate of the mobile phase not only impairs the quality of C_{60} obtained, but also leads to a decrease in the amount of the pure product obtained in a single cycle of use of the sorbent.

The yield of pure C_{60} is 72–78% relative to the amount of the concentrate charged, with 15–18% being the loss for irreversible sorption and up to 10% representing a material in which the content of C_{70} fullerene exceeds 0.5% (raw material for further recycling). The solvent is removed from the solution collected at the column outlet and crystals of pure C_{60} fullerene. Analysis shows that crystals of C_{60} fullerene, as a rule, contain, in addition to an insignificant impurity of C_{70} fullerene, that of the oxide $C_{60}O$ in an amount of up to 1.5–2.0% in some cases. Activated carbon has low selectivity with respect to this impurity, whose fraction increases in the course of chromatographic purification. This impurity can be removed in several ways. The most efficient way is vacuum treatment of the crystals obtained. This method can reduce the content of the oxide $C_{60}O$ to 0.05–0.1%. An advantage of the technology developed consists in that first portions of the eluate contain high-purity C_{60} fullerene (better than 99.9%). At a flow rate of the liquid phase exceeding 0.2 ml min^{-1} cm^{-2}, the fraction of such a product in the total output can be markedly raised, which improves the profitability of the production process.

With this technology used on a working equipment at St. Petersburg Institute of Nuclear Physics, Russian Academy of Sciences, the average rate of 99.5% C_{60} manufacture with double-shift work was 1–2 g h^{-1} (or 500–600 g per month). The developed flowsheet can be used without any significant change for manufacture of C_{60} fullerene in an amount exceeding 10 kg per month.

Manufacture of pure C_{70} fullerene. Flash chromatography on activated carbon cannot be used to separate C_{70} from C_{60} because C_{70} is sorbed on the carbon considerably more firmly than C_{60}. Therefore, it is advisable to use a combination of several methods for large-scale manufacture of pure C_{70} fullerene [43]. The technology we suggest includes the following sequence of procedures: enrichment of a mixture of C_{60}/C_{70} fullerenes with C_{70} fullerene by fractional concentration to a level of 85–92%; flash chromatographic purification of the concentrate obtained to remove the admixture of higher fullerenes on activated carbon; separation of trace amounts of C_{60} by fractional purification to obtain pure (98%) C_{70} fullerene.

The fractional concentration from *o*-xylene, which is an efficient and high-output-capacity technique for enrichment of C_{60}, has also been successfully used for enrichment of C_{70} fullerene [44].

The stage of fractional concentration in C_{70} fullerene is continuation of the first stage of fractional enrichment with C_{70} fullerene. The concentrate obtained in this stage (20–22% relative to the weight of the starting mixture of fullerenes) is a supersaturated solution (up to 26 g l^{-1}), from which crystals containing 85–92% C_{70} precipitate upon cooling. The yield of the crystals depends on temperature and duration of crystallization, and can be as high as 80% relative to the material contained in the filtrate at –24°C. The mother liquor contains 2–3 g l^{-1} of fullerenes and is enriched in C_{60} fullerene, compared with crystals.

Depending on the composition of the starting extract, the crystals obtained may contain admixtures of higher fullerenes in an amount of up to 4–5%. Such a high content of higher fullerenes makes their recovery feasible. This procedure can be effectively performed with 1,2,4-trichlorobenzene by multistage frac-

tional concentration. It was found experimentally that the content of higher fullerenes in C_{70} crystals can be reduced from 4–5 to 0.7–0.8% at room temperature in three to four stages. In this case, concentrates are obtained in all stages, which contain up to 10% higher fullerenes. The crystalline concentrate of C_{70} fullerene is further dissolved in *o*-xylene and subjected to chromatographic purification on activated carbon. The impurity of higher fullerenes is completely removed in this stage.

The process we suggest allows production of pure C_{70} fullerene in considerable amounts. For example, the concentrate of C_{70} fullerene, obtained in the first stage of fractional concentration from the starting mixture of fullerenes, contains less than 2% higher fullerenes, whereas a single cycle of two-stage crystallization can give C_{70} fullerene with the purity better than 98%. The total yield of pure C_{70} exceeds 100 g in a cycle (48 h) per 1000 g of the starting mixture of fullerenes [composition (%): C_{60}/C_{70} 75/25]. Presence of higher fullerenes in the starting extract in an amount exceeding 2% diminishes nearly twofold the yield of pure fullerene and makes nearly twice longer the purification of the C_{70} concentrate to remove impurities. Therefore, additional one or two stages of crystallization are necessary for obtaining C_{70} fullerene of 98% purity if more than 2% higher fullerenes is contained in the starting C_{70} concentrate.

The scheme suggested can be used to obtain, without any significant modification of the available inexpensive equipment, to produce up to 1 kg of C_{70} of commercial purity in a month. Because this method for production of C_{70} is a part of a unified flowsheet for synthesis of C_{60} and C_{70}, its use makes it possible to improve the output capacity in terms of pure C_{70} and reduce its cost severalfold, compared with the technique suggested in [40].

In 2003, Frontier Carbon Corp. declared that its annual output capacity of fullerenes by incomplete combustion of hydrocarbon raw materials was 40 t [45]. A plant constructed by this company could satisfy the whole world's demand for fullerenes, and their price would decrease severalfold. However, the authors are unaware of any offers by this company on the fullerene market. It would be expected that the raw mixture of fullerenes, produced by this technique, will be contaminated with polycondensed aromatic hydrocarbons. Isolation of pure fullerenes from a raw material of this kind is presently possible only with low-output-capacity and rather expensive chromatographic methods, and, consequently, the production cost of these fullerenes will long exceed that of fullerenes produced by the electric-arc technique.

CONCLUSIONS

(1) A semicommercial technology for manufacture of pure C_{60} and C_{70} fullerenes was developed.

(2) An apparatus for production of up to 1 kg of a fullerene-containing carbon black in 24 h was designed and fabricated.

(3) An apparatus for recovery of a mixture of fullerenes from a fullerene-containing carbon black, with a monthly processing capacity of up to 40 kg of carbon black, was designed and fabricated.

(4) An installation for chromatographic purification of C_{60} (to 99.5 or 99.9%), with a monthly output capacity of up to 500 g of 99.5% C_{60}, was designed and fabricated.

(5) The flowsheet developed can be used to produce up to 100 g of C_{70} (98%) in a month on the already existing equipment, provided that the content of higher fullerenes in the starting C_{70} concentrate is less than 2%. An additional special procedure for removal of higher fullerenes was developed for obtaining C_{70} fullerene of 98% purity from a concentrate with increased content of higher fullerenes.

Abstract—The solubility of fullerene C_{60} and a fullerene mixture [C_{60} (75%), C_{70} (24%), C_{76-80} (1%)] in linear alkanoic acids (C_2–C_9) was determined at 20°C. The solubilities of C_{60} and a fullerene mixture in carboxylic acids were examined in relation to the number of carbon atoms in the carboxylic acid.

DOI: 10.1134/S1070427207030202

Our preliminary study of the solubility of fullerenes were reported in [1]. In this study we examined the solubility of an individual fullerene C_{60} and a fullerene mixture [C_{60} (75%), C_{70} (24%), C_{76-80} (1%)] in linear carboxylic acids.

The development of techniques for efficient extractive separation and purification of fullerene mixtures to an extent suitable for their final chromatographic separation is an urgent problem [2, 3]. These processes are based on differences in the solubility of particular fullerenes (primarily C_{60} and C_{70}) in organic solvents.

However, published data on the solubility of fullerenes are scarce and contradictory. As a rule, these data refer to binary systems, for example, C_{60} or C_{70}–solvent. In these studies, aromatic (benzene, toluene, *o*-xylene, 1,2-dichlorobenzene) and nonaromatic (CCl_4, hexane) solvents were used [4–11]. Data on the solubility of binary fullerene mixtures in a certain solvent as well as on the solubility of a particular fullerene in solvent mixtures are lacking. The data on polythermal solubility of fullerenes in the ternary systems, such as C_{60}–C_{70}–solvent, which are necessary for choosing the optimal conditions for extractive separation of fullerenes, are also virtually lacking. An exception is a paper [2] in which the solubility diagrams of the ternary systems C_{60}–C_{70}–toluene at 25°C and C_{60}–C_{70}–*o*-xylene at 80°C were reported.

The only published paper on polythermal solubility of fullerenes in carboxylic acid homologs is [1]. In that study, the solubility of a multicomponent fullerene mixture enriched in C_{60} and C_{70} (C_{60} 38.8, C_{70} 33.0, C_{76-78} 5.6, C_{84} 8.6, C_{90} 2.6, and C_{96} 3.3%) and also the solubility of individual fullerenes C_{60} and C_{70} in higher isomerized carboxylic acids C_7–C_9 (HICAs) were studied within the temperature range 20–80°C. It was found that light fullerenes show relatively high solubility in HICAs, up to 0.5 g l^{-1}, and the solubility of C_{60} is lower than that of C_{70} by a factor of three. This difference in solubility allows preliminary separation of lighter fullerenes from the fullerene mixture before final chromatographic separation.

EXPERIMENTAL

In experiments we used fullerene C_{60} containing 99.9% main compound and about 0.1% C_{70} and a fullerene mixture [C_{70} 24, C_{60} 75, C_n (n > 70) 1%] produced by ILIP Private Company (St. Petersburg), *o*-xylene (analytically pure grade), and also *n*-alkanoic acids (C_2–C_9) (chemically pure grade).

The dependence of the solubility both the individual C_{60} and a fullerene mixture in carboxylic acids on the number of carbon atoms in them was studied by the isothermal saturation method at 20°C as follows. Large excess of fullerene was added to 10 ml of each carboxylic acid under consideration (homologous series from acetic acid to pelargonic acid), and the resulting suspension was shaken on a temperature-controlled shaker at 20 ± 0.05°C to attain the saturation. Dissolution of fullerenes in carboxylic acids is slow: the saturation is attained within 8–10 h. The saturated solutions were separated from the solid

phase by filtration through a Schott filter (porosity no. 16) and analyzed.

At each saturation step, an aliquot of a solution of C_{60} or the fullerene mixture in carboxylic acid was sampled, and after dilution with *o*-xylene, the optical densities at λ = 335.5 and 472.0 nm were measured on a Specord-32 spectrophotometer. The solutions of carboxylic acids in *o*-xylene of the same concentration were used as reference. This procedure was chosen because of problems with recovering fullerenes from high-boiling carboxylic acids.

The C_{60} and C_{70} concentrations in their *o*-xylene solutions were calculated by the following empirical equations reported in [12]:

$$c(C_{60}) = 13.10(D_{335} - 1.808D_{472}), \quad (1)$$

$$c(C_{70}) = 42.51(D_{472} - 0.0081D_{335}), \quad (2)$$

where D_{335} and D_{472} are the optical densities measured in a 1-cm cell; $c(C_{60})$ and $c(C_{70})$ are the fullerene concentrations (mg l^{-1}).

In these calculations, the presence of minor amounts of higher fullerenes (about 1 wt %) was neglected.

The electronic absorption spectra of solutions of C_{60} and the fullerene mixture in *n*-alkanoic acids (acetic to pelargonic) diluted with *o*-xylene (Fig. 1, 2) do not show solvatochromic effects typical of other binary solvents (acetonitrile–toluene, benzene–methanol, benzene–hexane, etc). The solvatochromic effect in fullerene spectra appears as a sharp change in the electronic spectra of fullerene due to its clusterization on minor variations in both the fullerene concentration and solvent composition [13–16]. Since solvatochromic effect is absent in solutions of fullerenes in the binary solvents carboxylic acid–aromatic solvent (*o*-xylene, benzene, toluene, *o*-dichlorobenzene, etc.), in these systems the concentration of particular fullerenes can be reliably determined spectrophotometrically by empirical equations (1) and (2).

Figure 3 shows the solubility of C_{60} and the fullerene mixture in carboxylic acids in relation to the number of carbon atoms in them. These dependences are nonmonotonic. With increasing number of carbon atoms, the solubility slightly increases from acetic to valeric acid, sharply increases to the maximum from valeric to enanthic acid, then sharply decreases from enanthic to caprylic acid, and finally sharply increases from caprylic to pelargonic acid.

Analysis of the published data on the solubility of

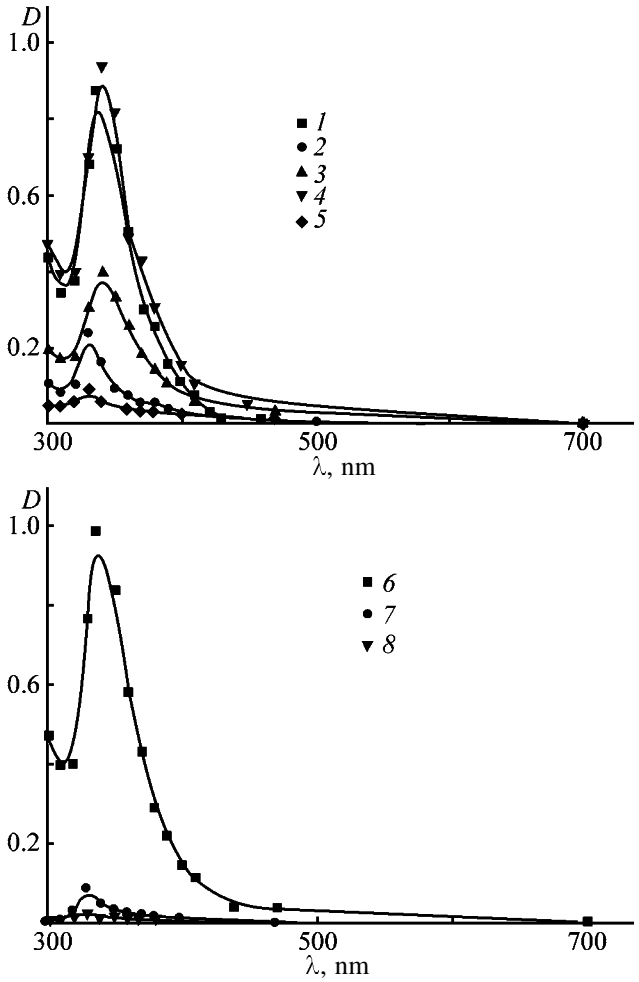

Fig. 1. Electronic spectra of solutions of C_{60} in carboxylic acid–*o*-xylene mixture. Test solution: solution of fullerene in carboxylic acid diluted with *o*-xylene in a volume ratio of 1 : 22. fullerenes in organic solvents [11, 16–18] shows that this characteristic does not correlate with main physicochemical parameters of solvents (refractive index, permittivity, molar volume, etc). However, it was found that high solubility of fullerenes is typical of solvents with a certain combination of physicochemical parameters: high refractive index, permittivity of about 4, large molecular volume V_m, the Hildebrand solubility parameter approaching 20 $(J\ cm^{-3})^{1/2}$, and moderate nucleophilicity [16, 18].

The nonmonotonic dependence of the solubility of fullerenes on the number of carbon atoms in carboxyl-

ic acid can be analyzed in terms of the Hildebrand theory of regular solutions. In this theoretical approach, the solubility is controlled by the solubility parameters of both the solute and solvent. The solubility parameter is determined by the equation [19]

$$\delta = [(\Delta H_{vap} - RT)/V]^{1/2}, \quad (3)$$

where ΔH_{vap} is the enthalpy of vaporization, J mol^{-1}; *T*, temperature, K; *V*, molar volume, mol cm^{-3}; and *R*, gas constant, J mol^{-1} K^{-1}.

The solubility parameter characterizes the energy of pair intermolecular interactions between identical components of solution: solvent–solvent and solute–solute [19]. In the Hildebrand theory, the solubility parameter δ is related to liquid components. Therefore, in calculation of δ of fullerene, its hypothetical state in the form of a supercooled liquid is used as the standard state and the enthalpy of sublimation is used instead of the enthalpy of vaporization [16].

The solubility of fullerenes under consideration in homologous series of carboxylic acids and the Hildebrand solubility parameters of these acids are listed in the table. These data show that, as a rule, the solubility of fullerenes is the higher, the smaller is the difference between the solubility parameters of fullerene and solvent. The maximal solubility of fullerene is reached at equality of the solubility parameters of the fullerene and solvent. Under these conditions, the solvent cohesion parameter also reaches a maximum.

The table shows that, in going from acetic to pelargonic acid, the solubility parameter of caprylic acid exhibits the large positive deviation from the general trend. We believe that this is the reason for the appearance of a minimum in the plot of solubility of fullerenes in carboxylic acids vs. the number of carbon atoms in them. An increase in solubility of C_{60} in going from acetic to enanthic acid correlates with a decrease in the carboxylic acid permittivity. In accordance with Semenchenko's rule [22], this means that the solubility of fullerenes increases with weakening of the carboxylic acid molecular field caused by growing inductive effect of hydrocarbon radicals. However, in going from caprylic to pelargonic acid, this rule does not hold. In this case, the increase in the permittivity of carboxylic acid is accompanied by a sharp increase in the solubility of fullerenes, which correlates with a decrease in the solubility parameter. Another factor is that the molar volume of pelargonic acid, compared to that of the other carboxylic acids, is closer to that of fullerene (429 cm^3 mol^{-1}).

The comparison of the relative content of C_{60} in the initial fullerene mixture (upper horizontal line in Fig. 4) and that in its saturated solutions in carboxylic acids shows that in all the systems the liquid phase is enriched in C_{70}. Thus, in dissolution of fullerene

mixture in carboxylic acids, the transfer of C_{70} into the liquid phase prevails. This phenomenon was previously found [1] in studies of the solubility of individual fullerenes and their mixtures enriched in higher fullerenes in a mixture of higher isomerized carboxylic acids HICAs.

The higher solubility of C_{70} as compared to C_{60} is caused by its less symmetrical structure and higher polarizability, equal to 8×10^{-23} and 6.4×10^{-23} cm^3 for C_{70} and C_{60}, respectively [22, 23]. The inductive and dispersion forces are mainly responsible for intermolecular interactions in the system carboxylic acid (polar molecules)–C_{70} (nonpolar molecules): $U(r) = U_{ind} + U_{disp}$. The dispersion forces arise from fast fluctuations of the electron density in molecules. These fluctuations induce the electrical moment in neighboring molecules and, as a result, cause molecular attraction. The appearance of inductive forces in contact of C_{70} with polar carboxylic acid molecules is caused by polarization of fullerene. From practical point of view, the most interesting is the fact that the difference in the solubility of particular fullerenes in carboxylic acids can be used for efficient separation of fullerene mixtures.

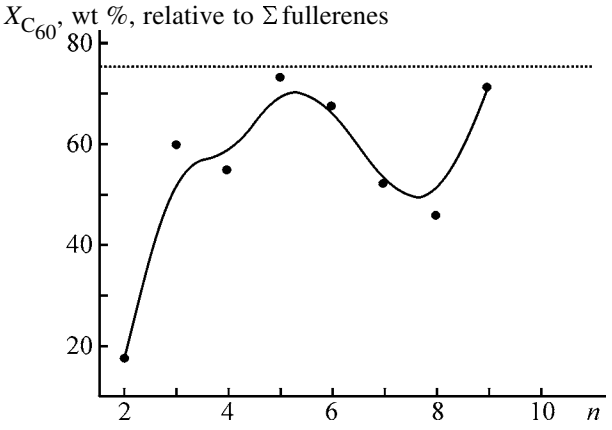

Fig. 4. Relative content of C_{60} in saturated solution of fullerene mixture in carboxylic acids as a function of the number of carbon atoms *n* in carboxylic acid.

CONCLUSIONS

(1) The variation in solubility of C_{60} and fullerene mixture (C_{60} 75, C_{70} 24, C_{76-90} 1%) in *n*-alkanoic acids (C_2–C_9) has a maximum for enanthic acid. In going from acetic to enanthic acid, the solubility increases from 6.8 to 256 mg l^{-1} for C_{60} and from 41 to 1207 mg l^{-1} for the fullerene mixture.

(2) In dissolution of fullerene mixture in carboxylic acids, the saturated solution is enriched in C_{70} as compared to the solid fullerene mixture, and this effect is maximal for acetic acid.

Abstract—The electret properties of low-density polyethylene with phosphorus-containing surface nanostructures were examined.

DOI: 10.1134/S1070427207030214

As known [1], when irradiated with charged particle (ion, electron) fluxes, polymer dielectrics accumulate a charge on their surface to form an electret state. The charged state of such materials, which are termed electrets, can be preserved for a fairly long time (years). This finds wide application in modern high technologies, in particular, in the development of electroacoustic transformers and sensors, as well as of nonlinear-optics components [2]. Of great practical importance for such systems is the stability of the electret state.

In our previous studies [3, 4] we showed that the stability of the electret charge in polytetrafluoroethylene (PTFE) films is substantially enhanced by chemical modification of the surface with phosphorus trichloride vapor. Therefore, it is of interest to examine the electret properties of other modified polyolefins, in particular, such commercially significant material as low-density polyethylene (LDPE). In this connection, we examined here the electret properties of LDPE as influenced by chemical modification of its surface with phosphorus trichloride vapor.

This study was underlain by the following concepts.

(1) The electret state in nonpolar polymers is determined not only by the charge capture sites in the bulk but also, to a significant extent, by the localized states on the surface [5].

(2) Surface modification of nonpolar polymers enables directed formation in such materials of surface deep energy wells acting as charge capture sites able of efficiently retaining the electret charge [3–5].

(3) An efficient way of polymer surface modification is the chemical nanotechnology based on the molecular layer deposition principles [6]. This technology enables incorporation of element-containing nanostructures into surface macromolecules in a controllable manner, thereby controlling the physicochemical, in particular, electret, properties of polymers [3, 4].

EXPERIMENTAL

Polymer films, $40 \times 20 \times 0.14$ mm in size, were chemically modified in a flow reactor by successive treatment of the substrate with PCl_3 and H_2O vapors by molecular layer deposition. For conditions of synthesis of phosphorus-containing structures on the polymer matrix surface, see [7].

The samples for electret measurements were prepared in the form of planar metal–polymer structures, whose basis was a 95-μm-thick St.3 steel substrate. A polymeric layer of the LDPE film, unmodified or modified with phosphorus trichloride, was fixed on the substrate surface by the thermal fitting method [5]. We used extrusion films of 10 203-003 brand polyethylene manufactured in Russia in accordance with GOST (State Standard) 16 337–70. This polymer has acceptable dielectric characteristics for producing corona electrets, namely, low values of dielectric permittivity (2.2 at a frequency of 1 MHz), dielectric dispersion, and dielectric loss tangent (2.7×10^{-4} at a frequency of 1 MHz).

Thermal fitting was carried out at 170°C for 60 s; it was followed by cooling in air to room temperature

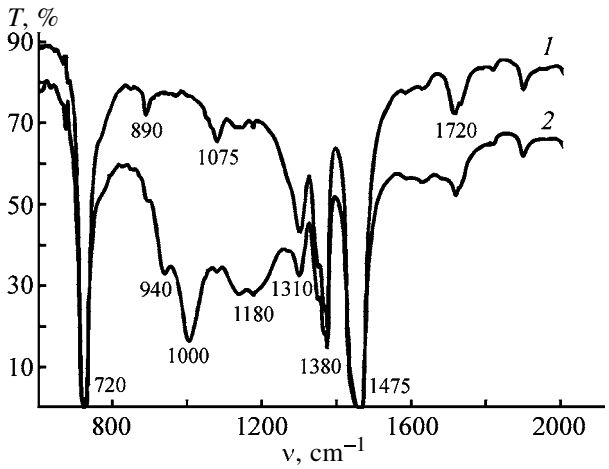

Fig. 1. IR spectra of low-density polyethylene films. (*T*) Transmission and (ν) wavenumber. Sample: (*1*) initial and (*2*) modified with PCl_3 vapor.

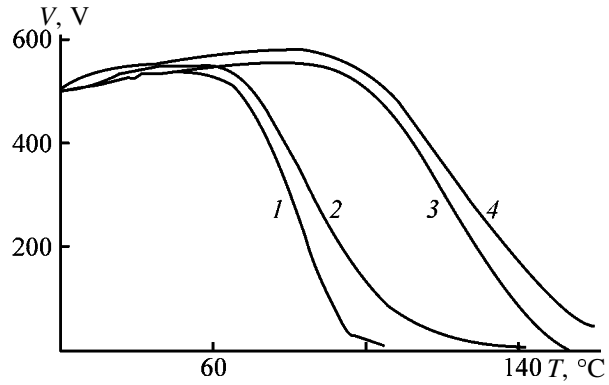

Fig. 2. Thermoinduced relaxation of the surface potential *V* of the (*1, 3*) positively and (*2, 4*) negatively charged electrets of LDPE. Sample: (*1, 2*) unmodified and (*3, 4*) modified; the same for Fig. 4.

over a period of about 2 min. The resulting samples exhibited fairly reliable adhesive contact between the polymer and the metal substrate. Because of shrinking, the average thickness of the polymeric layer of the LDPE–steel structures was 150 μm.

The electret state in LDPE–steel structures was formed by charging the samples in a corona discharge at room temperature for 30 s on a setup with control grid electrode [3]. The charging device allowed preparation of samples with identical preset initial surface potential V_0 of +500 and +1700 V for charging in a positive, and of –500 and –1700 V, for charging in a negative corona discharge. Thus, without taking into account the sign, the initial effective surface density of the homocharge of the electrets examined was 6.5×10^{-5} and 2.2×10^{-4} C m^{-2}, respectively.

The electret properties of the LDPE films were examined by the method of thermoinduced relaxation of the surface potential (TIRSP) [5] in the linear heating mode at a constant rate of 5.9 deg min^{-1}. The surface potential was measured by the contactless technique. To this end we used the method of dynamic capacitor in which the capacity between the measuring electrode and the charged surface of the electret was modulated using a rotating disk with holes [5].

The phosphorus concentration in the reaction products was determined by a standard technique [8]. The IR spectra[1] of the initial and modified samples were recorded on an FSM-1201 IR Fourier spectrometer (400–4000 cm^{-1} range, resolution 1 cm^{-1}, self-compensation interferometer). The IR examination and chemical analysis provided data on the composition and structure of the phosphorus-containing surface groups.

The examination of the films by atomic-force microscopy (AFM)[1] was carried out on a Solver P47 Pro (NT-MDT, Russia) scanning probe microscope in the tapping mode using a silicon cantilever in two scanning modes: topographic survey and phase contrast. The latter mode reveals the difference in the compositions of the sample surface sections from analysis of the changes in the phase shift of the amplitude–frequency characteristic (AFC) of the cantilever, due to adhesion interactions.

Chemical analysis of the samples showed that, under the actual conditions of synthesis, the total phosphorus concentration in the modified LDPE attains a maximum of ca. 0.4 wt %.

Figure 1 shows the IR transmission spectra of the films of the initial and modified polyethylene. The major changes of the spectral characteristics of the polymer upon treatment with PCl_3 vapor are observed within 400–2000 cm^{-1}. Introduction of phosphorus-containing structures into the material is responsible for appearance in the IR spectrum of absorption bands characteristic of phosphorus compounds at 1000 (stretching vibrations of the P–O bonds in the P–O–Alk groups) and 1140 and 1180 cm^{-1} (bending vibrations of the P=O bond) [9]. A decrease in the intensity of the bands at 890 and 1075 cm^{-1} (out-of-plane and in-plane bending vibrations of the C–H bonds in the –CH=CH_2 group, respectively) is due to replacement of the substituent in the polymer chain (appearance of phosphorus-containing groups) [10]. Vapor-phase hydrolysis of the modified films results in appearance of an absorption band near 940 cm^{-1}, associated with

[1] The physicochemical studies were carried out at Chemical Assembling of Nanomaterials, Center for Collective Use, St. Petersburg State Institute of Technology (Technical University).

the out-of-plane bending vibrations of the OH groups in phosphorus compounds.

Chemical analysis and spectroscopic examination suggest chemical grafting of phosphorus-containing groups at reactive centers of the polymer matrix. These include the hydrogen atoms at the tertiary carbon atoms and those in the α-position with respect to the double bonds, as well as unsaturated groups [11].

Figure 2 shows the data on thermoinduced relaxation of the surface potential of the modified and unmodified LDPE film. Analysis of these dependences suggests that treatment of the polyethylene surface with phosphorus trichloride vapor significantly enhances the thermal stability of the electret state. It should be noted that the shift of the TIESP curves to higher temperatures is virtually identical for the positively and negatively charged electrets, about 40°C (Fig. 2, curves *3, 4*).

We showed previously [3] that chemical modification of the PTFE film surface also enhances the thermal stability of the potential of the electret structures. However, we found that the surface potential relaxation depends on the sign of the charge. Only for electrets pretreated with PCl_3 vapor and charged positively this electrophysical parameter exhibits a significant (~80°C) increase. The effect of modification of the LDPE film surface, increasing the thermal stability of the electret state, is manifested for both positive and negative charges. This is evidently due to the structural transformations of the surface layer, which favor formation of additional sites of capture of the electret charge, at chemical modification of polymers of different chemical nature. An explanation to this phenomenon can be provided by AFM examination of the surface morphology of the initial and phosphorus-containing samples of the polymer materials.

Examination of the surface layer of polyethylene shows that the initial film is fairly uniform (Fig. 3a). Individual polymeric structures (up to 0.5 μm in size), partially and mutually fused, can be distinguished on its surface. However, the surface roughness of the initial polymer is insignificant, 16–20 nm. There are no profound relief defects and foreign inclusions affecting the adhesion interactions of polyethylene with the AFM probe (Fig. 3b).

Chemical modification of polyethylene with PCl_3 vapor (Fig. 3c) yields on the LDPE surface round "islet" structures 80–200 nm in diameter, in amount of 20–25 μm^{-2}. Scanning in the phase contrast mode reveals a sharp change in the AFC (θ) of the cantilever when crossing the boundary of such an islet (Fig. 3d). This suggests a difference in the structural and chemical properties of these "islets" from those of the surrounding polyethylene matrix [12]. The IR examination (Fig. 1) and chemical analysis show that treatment of the LDPE surface with PCl_3 vapor results in chemical grafting of the phosphorus-containing groups, which, apparently, can form the basis for such "islets." In view of their high hydrophilicity [13], it can be presumed that, due to adsorption of the water vapor, a hydrate shell is formed on the surface around the grafted structures. These topographic changes suggest formation of a larger number of new sites of the electret charge capture on the LDPE surface compared to PTFE.

Evidently, the efficiency of the electret charge capture on these structural traps will be governed by the ratio of the surface density of the incorporated

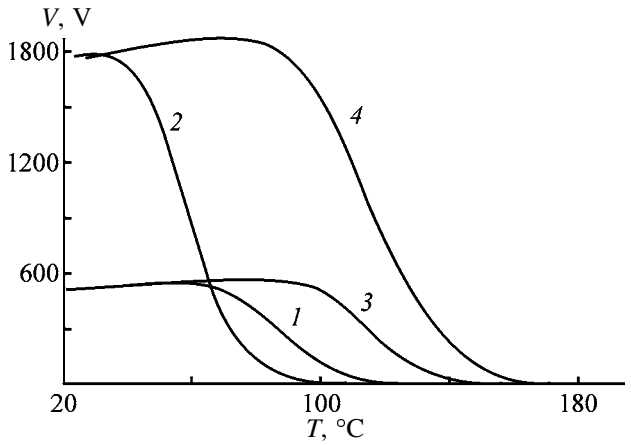

Fig. 4. Thermoinduced relaxation of the surface potential V of the electrets of LDPE, charged to the initial potential of (*1, 3*) 500 and (*2, 4*) 1700 V.

charge and the concentration of the nanostructures acting as electret charge capture sites. In our experiments, there are ca. 400 charges μm^{-2} at the charge density of 6.5×10^{-5} C m^{-2} (we believe that, at charging in a corona discharge, the charge carriers bear one elementary charge). Hence, one nanoformation retains no less than ten charge carriers. Presumably, the local electrostatic interaction of the electret charges in the vicinity of the nanoformation will substantially affect formation and relaxation of the electret state. For example, Coulomb repulsion decreases the probability of a charge capture by the trap belonging to the specific structure. Also, the local electric field of the captured charges decreases the energy depth of the corresponding traps [1, 2]. Therefore, it was of interest to examine the electret properties of LDPE at higher charge densities.

Figure 4 presents the data characterizing the electret properties of the modified (curves *3, 4*) and unmodified (curves *1, 2*) LDPE films charged in the corona discharge to the initial potential of 500 and 1700 V. In the case of the initial films, the "crossing" effect typical of electrets of polyethylene is observed [1, 2, 5]. This effect is manifested as a decrease in the stability of the electret state with increasing initial surface density of the electret charge. The curve of the potential drop of samples with a higher initial charge density during relaxation crosses the corresponding curve for samples with a lower initial charge density. This fact makes virtually impossible preparation of stable electrets from LDPE film with a high surface charge density.

A different situation is observed in the case of the LDPE films treated with phosphorus trichloride vapor. The plots in Fig. 4 (curves *3, 4*) show that there is no crossing effect and the samples charged to V_0 = 1700 V exhibit a high thermal stability of the charge. The shift of curve *4* to higher temperatures relative to curve *2* is about 55°C. Thus, chemical modification of the LDPE surface in phosphorus trichloride vapor significantly increases the electret charge and its stability. For example, in thermal stability of the charge the modified polyethylene surpasses such well-known electret materials as polyethylene terephthalate, polyvinyl chloride, and polyvinylidene fluoride [1, 2, 5].

CONCLUSIONS

(1) Chemical modification of low-density polyethylene with phosphorus trichloride vapor involves addition of phosphorus-containing groups to the reactive centers of the polymer via substitution reactions.

(2) Atomic-force microscopic and IR-spectroscopic examinations, as well as chemical analysis, revealed the differences in the morphology and chemical composition of the surface of the initial and modified polymers. The phosphorus-containing groups added to the reactive centers of polyethylene are responsible for formation on its surface of round nanoformations, 80–200 nm in diameter, whose surface concentration was estimated at 20–25 μm^{-2}.

(3) Chemical gas-phase modification substantially increases the electret charge and its stability in low-density polyethylene films. This effect is achieved via stabilization of the electret charge on the structural traps associated with the phosphorus-containing nanofomations arising on the polymer surface.

Abstract—The compatibility of fibroin with polyvinyl alcohol in blend films prepared from a common organic solvent, hexafluoroisopropanol, was studied by IR spectroscopy and DSC.

DOI: 10.1134/S1070427207030226

Moisture and oxygen permeability of fibroin membranes [1] and bacteriostatic properties of fibroin [2] make this polymer attractive for the development of biomedical materials, in particular, for contact lenses. However, films of fibroin regenerated from solutions are brittle. To improve the physicomechanical properties of films, fibroin should be modified by adding other polymers, e.g., in the step of dissolution. The following polymers are used today for producing contact lenses: polyacrylic acid derivatives, polyvinylpyrrolidone, and polyvinyl alcohol (PVA) [3, 4]; the latter is used as either a homopolymer [3, 5] or copolymer [6]. Polyvinyl alcohol has good film-forming properties; its films are elastic and strong. This fact, in combination with nontoxicity of polyvinyl alcohol, makes this polymer suitable for modification of fibroin in preparation of a material for contact lenses.

However, published data on the compatibility of fibroin with other polymers, both natural (cellulose [7, 8], chitosan [9, 10]) and synthetic (polyhydroxybutyrate [11], polyacrylamide [12]), show that micro- or macrophase segregation occurs in many blend films in a wide range of component ratios. The phase segregation makes the material nonuniform and complicates its use.

One of conditions for preparation of homogeneous polymer blends is the use of a common solvent for both components, which creates conditions for interaction of active groups of the macrochains in solution and then in the solid state. Silkworm fibroin is soluble in concentrated solutions of salts in water and nonaqueous solvents [13], in hexafluoroisopropanol [14], and in *N*-methylmorpholine *N*-oxide [15]; the choice of the solvent and conditions of dissolution and precipitation largely determine the supramolecular structure of the polymer [16, 17]. Fibroin/PVA blends prepared from 0.5–1.5% aqueous solutions of the components were studied in [18–21]. Tsukada et al. [18] used an aqueous solution of silk (so-called "liquid silk") directly from silkworm glands, and Tanaka, Suzuki, et al. [19– 21] used diluted aqueous solutions of fibroin in 9 M LiBr after dialysis. In both cases, the conformational state of fibroin in solutions and films was characterized as a random coil with a small content of macromolecules in the α-helical form. The phase segregation in the blends studied in [18–21] occurred in the entire range of component ratios. The IR and DSC data revealed no intermolecular interaction of components in the blends [18].

We studied the compatibility of fibroin with PVA and conditions for preparing their homogeneous blends from a common organic solvent, hexafluoroisopropanol (HFIP). Whereas dialyzed fibroin solutions are unstable (salt-free water is not a solvent for fibroin) and tend to gelation, HFIP allows preparation of solutions stable for a long time. In this solvent, fibroin has a structure of random coil and α-helix, with a certain fraction of macromolecules occurring in the β-folded form [16]. Polyvinyl alcohol is also soluble in HFIP [22]; thus, conditions are provided for preparing homogeneous blends stabilized by intermolecular interaction of the components. The regeneration is done by solvent evaporation; the films contain no traces of HFIP, and additional washing is unnecessary. As compared to aqueous solutions, commercial use of HFIP is less safe (LD_{50} 1040 mg kg^{-1}), and it becomes topical to develop a closed-loop process without emission of the solvent vapor into the environment.

EXPERIMENTAL

To prepare films, we used *Bombyx mori* silkworm fibroin in the form of short fibers, washed to remove impurities, PVA (molecular weight 31000–50000, degree of deacetylation 98–99%), and HFIP (1,1,1,-3,3,3-hexafluoro-2-propanol, Merck–Schuchardt, main substance content 99%, boiling point 58°C, density at 20°C 1.615–1.618 g cm^{-3}).

The dissolution of fibroin in HFIP was performed as described in [14]; PVA was dissolved in HFIP on heating to 30–40°C. The polymer concentrations in solutions were 4 wt %. The solutions were vacuum-filtered through a glass frit no. 1 and mixed in required proportions. The films were prepared by applying the solutions onto glass plates, with the subsequent solvent evaporation. The fibroin/PVA blend films prepared from HFIP solutions are optically transparent in the entire range of component ratios. The film thickness was 0.04–0.06 mm.

To compare the optical transparence, we also prepared fibroin/PVA blend films similarly to [19–21] from aqueous solutions with polymer concentrations of 4%. The films prepared from aqueous solutions are opaque; the most pronounced phase segregation, evaluated visually from the film turbidity, occurred at the polymer ratios from 70/30 to 30/70. The opacity of films prepared from aqueous solutions is associated with the thermodynamic instability of the dialyzed solution of fibroin, in which gelation starts within 2 days.

The IR absorption spectra were recorded on a Bruker IFS25 IR spectrometer. Thermal analysis of film samples was performed on a Mettler Toledo Star differential scanning calorimeter in the range from 25 to 500°C (heating rate 10 deg min^{-1}) in a nitrogen flow (flow rate 50 ml min^{-1}).

Figure 1 shows the DSC curves for films of fibroin, fibroin/PVA blends, and PVA, prepared from HFIP solutions. In the DSC curve of a fibroin film, there are endothermic effects caused by evaporation of bound water (maximum at 78°C) and devitrification of the amorphous part of the polymer (152°C), followed by a small exothermic effect due to transition to the β-crystalline modification [23–27]; a small endothermic peak at 246°C is associated with the molecular motion in α-crystals on heating [27]. The strong endothermic effect with a peak at 280°C is due to thermal degradation of the polymer. The DSC curve shows that fibroin exists in the films mainly in the amorphous form, with a certain amount of α-crystals. The DSC data give no evidence for the β-crystalline structure of fibroin in films.

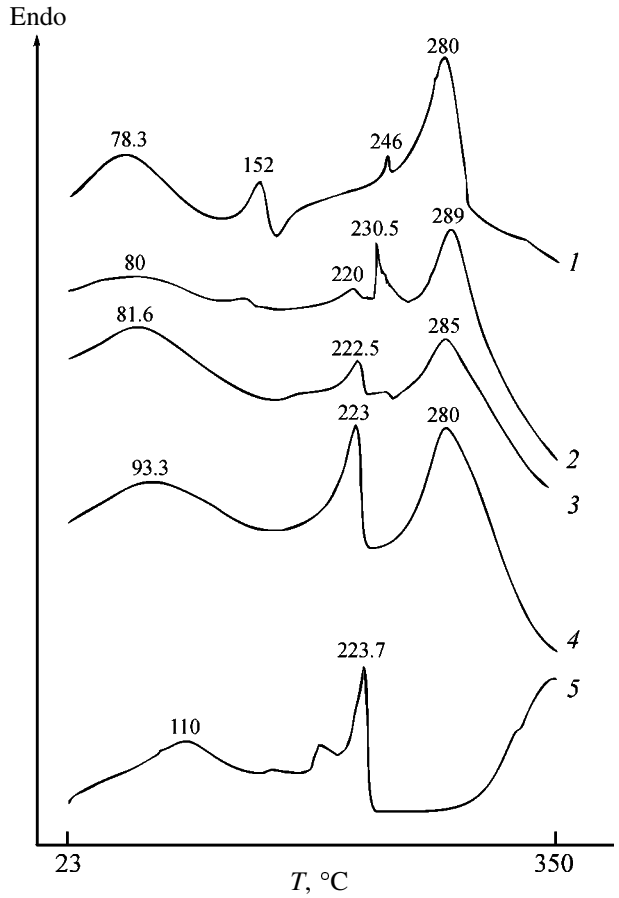

Fig. 1. DSC curves of fibroin/PVA blends prepared from solution in HFIP. Fibroin/PVA: (*1*) 100/0, (*2*) 80/20, (*3*) 60/40, (*4*) 20/80, and (*5*) 0/100. (*T*) Temperature.

In the DSC curve of polyvinyl alcohol, there are overlapping endothermic effects from evaporation of water and devitrification of the polymer, with a common peak at 110°C; melting of the crystalline parts starts at 223.7°C and is followed by gradual degradation of PVA [22].

Comparison of the phase transition temperatures in fibroin/PVA blend films with various component ratios reveals a gradual shift of the PVA melting point toward lower temperatures with an increase in the fibroin content. From the thermodynamic viewpoint, a decrease in the PVA melting point is due to exothermic interaction of the blend components [28–30].

Simultaneously, the enthalpy of melting ΔH_m per gram of PVA gradually decreases. Taking for ΔH_m^0 of fully crystalline PVA the value of 152 kJ g^{-1} [22], we estimated the degree of crystallinity of PVA in films as the ratio $(\Delta H_m/\Delta H_m^0) \times 100\%$. The experimental

Enthalpies of melting and degree of crystallinity of PVA in films of its blends with fibroin, prepared from HFIP solutions

Sample no.	Fibroin/PVA, wt %	ΔH_m of PVA, J g^{-1} PVA	Degree of crystallinity of PVA, %
1	100/0	–	–
2	80/20	16.5	10.8
3	60/40	50.8	33.4
4	40/60	52.8	34.7
5	0/100	61.0	40.1

values of ΔH_m of PVA and the calculated degrees of crystallinity are given in the table.

The state of fibroin also changes on blending with PVA. As a result of intermolecular interaction with the second component, the peak of fibroin degradation shifts toward higher temperatures. This trend is especially pronounced on adding 20% PVA: The peak of fibroin degradation shifted from 280 to 289°C (Fig. 1, curve *2*).

On adding 20% PVA, the endothermic peak of devitrification of the amorphous part of fibroin at about 152°C becomes considerably less pronounced (cf. curves *1* and *2*). This may be due to decreased content of the amorphous part of fibroin in the blend; the same conclusion follows from the IR spectra (see below). For the other blends (curves *3*, *4*), the devitrification peak merges with the peak of evaporation of bound water into a broad endothermic peak. On blending with PVA, the position of the endothermic peak of molecular motion in fibroin α-crystals changes, and its intensity increases. The shift toward lower temperatures (from 246 to 230.5°C) is caused by strong interaction with macromolecules of PVA occurring in the molten state at this temperature. An increase in the intensity is caused by an increase in the amount of fibroin macromolecules in this conformation (at 20% content of PVA in the blend). With a further increase in the PVA content, the peak becomes ill-defined (curve *3*) and then fully disappears (curve *4*).

The IR spectra of films of fibroin, PVA, and their blends are shown in Fig. 2. Structural studies of fibroin and other polypeptides show that the conformational state of a polypeptide can be judged from the positions in the spectra of the amide I (C=O), amide II (bound N–H, C–N), and amide III (C–N, bound N–H, CH_3–C) bands [23, 31, 32]. Since the amorphous coil and α-helix conformations are characterized by predominant formation of intramolecular hydrogen bonds, and the β-folded conformation, by an ordered system of intermolecular bonds, from the positions of the absorption bands we can reliably distinguish the β-structure of the polymer, for which the amide I and amide II frequencies are 20–40 cm^{-1} lower compared to the other conformations and the amide III frequency is, on the contrary, higher. However, IR spectroscopy does not allow the amorphous and α-helical structures to be unambiguously distinguished, and in this case the DSC data are additionally used.

The IR spectrum of a 100% fibroin film (curve *1*) suggests coexistence of different conformations of macromolecules in the film: a certain amount of β-crystals (weak shoulder of 1630 cm^{-1}, amide I; 1513 cm^{-1}, amide II; 1260 cm^{-1}, amide III) and the α-helical or random coil conformation (strong amide I, II, and III bands at 1650, 1536, and 1213 cm^{-1}, respectively).

The spectrum of a PVA film (curve *4*) in the frequency range shown in the figure has absorption bands at 1375, 1283, 1095, 892, and 839 cm^{-1}, characterizing the δ(CH–OH), ω(CH), γ(CO), γ(CH_2), and γ(C–C) vibrations, respectively [18]. The crystallization-sensitive band of PVA is observed at 1140 cm^{-1}. In the spectra of fibroin/PVA blends, the following changes in the position and intensity of absorption bands are observed. On adding 20% PVA to fibroin (curve *2*), the intensity of absorption bands at 1630 (a barely perceptible shoulder in curve *1* for 100% fibroin) and 1513 cm^{-1}, characteristic of the β-folded crystalline structure of fibroin, increases. This fact indicate that the presence of 20% flexible-chain PVA not only does not prevent but even favors β-folding of fibroin macrochians; due to strong macromolecular interactions of components, favorable steric conditions are provided for more ordered folding of fibroin macromolecules.

With a further increase in the PVA content in the blend, the absorption bands at 1630 and 1513 cm^{-1}, characteristic of the β-crystalline structure of fibroin, virtually disappear (curve *3*), i.e., at a high content of the second component the β-folded structure is absent from fibroin.

The crystallization-sensitive PVA band at 1140 cm^{-1} is barely visible at a PVA content in the blend of up to 20%, which confirms the conclusion made above from the DSC data that the degree of crystallinity of PVA decreases on blending with fibroin.

It can be concluded that, in HFIP solution, the conditions are favorable for the interaction between fibroin and PVA macromolecules, affecting the crys-

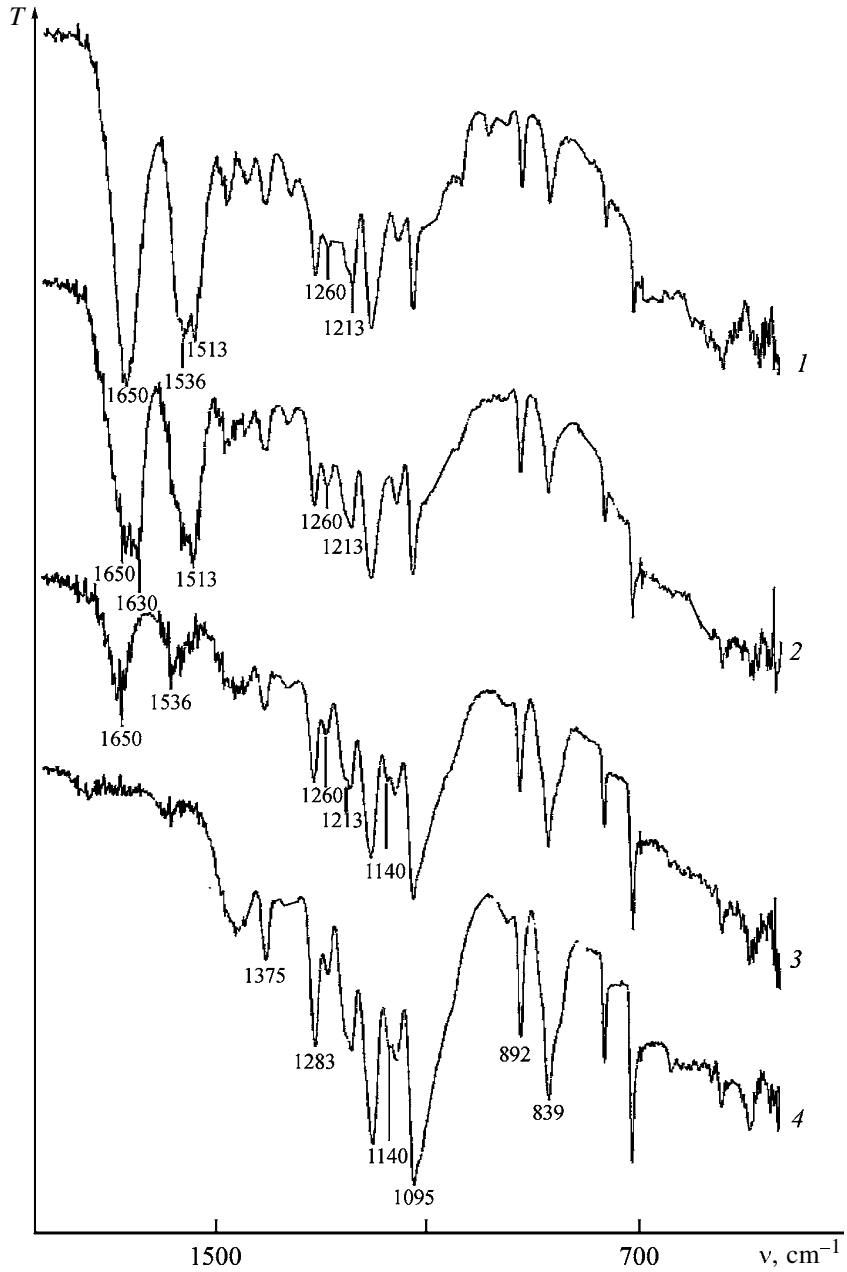

Fig. 2. IR absorption spectra of fibroin/PVA blend films prepared from HFIP solutions. (*T*) Transmission and (ν) wavenumber. Fibroin/PVA: (*1*) 100/0, (*2*) 80/20, (*3*) 20/80, and (*4*) 0/100.

tallization of the blend components; the most pronounced conformational changes are observed at 80/20 ratio of the components. In this blend, PVA is the least ordered, and fibroin is more ordered than in the 100% fibroin film. The content of both β-folded (according to IR spectra) and α-helical (according to DSC data) crystalline structures of fibroin increases. Apparently, the crystalline parts are stabilized by layers of flexible PVA chains owing to intermolecular interactions. Similarly, in natural silk a hydroxyl-containing polymer sericin interacts with fibroin, making silk fibers strong and elastic.

Microscopic examination of the blend films in a polarized light at ×200 magnification revealed that the fibroin/PVA 80/20 blend was homogeneous. Microscopic examination of the other films revealed phase segregation and formation of oval particles of size from 1–3 μm for the 20/80 blend to 4–7 μm for the 60/40–40/60 blends. In accordance with the character of phase segregation, more hydrophilic PVA tends to

form a continuous dispersion medium in which oval fibroin particles are distributed; the particle core is more crystalline, and the shell contacting with PVA is amorphous.

Addition of hydrophilic PVA to fibroin, on the one hand, allows the moisture content of the films to be increased from 8 to 11% in proportion with the PVA content, which is important for practical use. On the other hand, the PVA-containing films become more sensitive to water: They swell and, at a high PVA content, gradually become turbid; water competes with fibroin for the H-bonding with PVA, which can induce phase segregation. To enhance the resistance of intermolecular bonds in the blends to water without adding cross-linking agents, we examined the effect of heat treatment of the films at 70–80°C for 20 min. This treatment enhanced the moisture resistance of the films; the degree of swelling of the blends in water decreased by a factor of 1.5–3 depending on the PVA content. This effect is caused by the conformational transition of fibroin macromolecules upon heat treatment into the crystalline β-folded structure [10, 17], less accessible to the action of water.

CONCLUSIONS

(1) Films of fibroin/polyvinyl alcohol blends, prepared from solutions in hexafluoroisopropanol, are transparent in the entire range of component ratios, in contrast to the blend films prepared from aqueous solutions.

(2) In the films prepared from hexafluoroisopropanol, intermolecular interactions occur between fibroin and polyvinyl alcohol macromolecules, affecting the crystallinity and conformational state of the polymeric components.

(3) The strongest interaction between the components is observed at a fibroin/polyvinyl alcohol ratio of 80/20; in this case, the relative content of fibroin macromolecules in the crystalline modification is the highest.

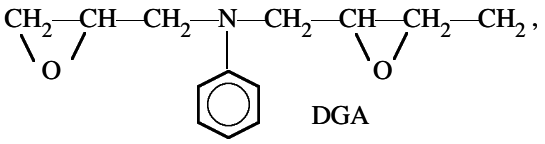
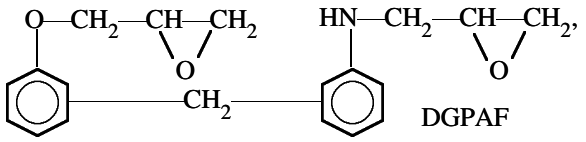
Abstract—Data on the synthesis of thermally and chemically stable ion exchangers based on glycidyl ethers of aromatic compounds and their derivatives with high exchange capacity are summarized. Optimal conditions of the synthesis of ion exchangers, their composition, structure, main physicochemical characteristics, and acid–base properties are determined. The complexing ability of the new polyelectrolytes and stability constants of complexes with transition metal ions are determined potentiometrically.

DOI: 10.1134/S1070427207030238

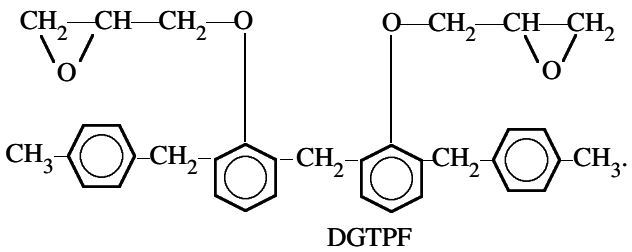
Introduction of aromatic amines and *N*-heterocyclic and phenolic compounds into epoxy polymers is one of ways to improve their physicochemical characteristics. To obtain thermally and chemically stable anion exchangers with high sorption ability, we studied formation of anion-exchange polymers by condensation of polyethylenepolyamine (PEPA) and polyethylenimine (PEI) with diglycidyl compounds: diglycidylaniline (DGA), diglycidyl phenol–aniline–formaldehyde (DGPAF) oligomer, and diglycidyl toluene–phenol–formaldehyde (DGTPF) oligomer of the following structures [1]:



DGA



DGPAF



DGTPF

The diglycidyl compounds synthesized are very reactive due to strained epoxy rings. The uniformity of functional groups and the presence of repeating aromatic rings enhance the thermal and chemical stability and improve the macronetwork structure, making the three-dimensional structure of the ion exchangers more regular.

As shown in [2, 3], polymeric amines are more nucleophilic than their low-molecular-weight analogs. Therefore, to synthesize ion exchangers with elevated sorption ability, we used soluble polyamines: PEPA and PEI.

EXPERIMENTAL

The epoxy compounds were condensed with amines in dimethylformamide at 80°C for 0.5 h. The resulting gel was cured in an oven at 80–100°C for 5 h.

To find the optimal conditions of the synthesis of anion exchangers, we studied the influence of the reactant ratio, amine composition, temperature, and reaction time on the properties of the resulting polymers [4]. It was found that the static exchange capacity (SEC) of the ion exchanger substantially depends on the amine composition and reactant ratio (Table 1). As seen, PEI is the most efficient aminating agent, which is caused by its high molecular weight and by high content of active groups in it. The increase in the amine concentration in the initial mixture from 0.5 to 2.5 wt parts (Table 1) increases the exchange capacity

Table 1. Influence of amine structure and reactant ratio on SEC_{HCl} (mg-equiv g^{-1}) and V_{sp} (ml g^{-1}) of ion exchangers (100°C, 5 h)

Anion exchanger based on	Reactant weight ratio

DGTPF : PEPA (100°C, 20 h)	Dissolves		6.5	4.9	6.9	5.6	7.0	7.0	Strongly swells	

of anion exchanger from 6.5 to 12.5 mg-equiv g^{-1} in the case of polycondensation of diglycidyl derivatives with PEI and from 6.0 to 11.0 mg-equiv g^{-1} in the case of polycondensation with PEPA, with simultaneous increase in their specific volume in the swollen state from 2.5 to 7.0 and from 3.0 to 7.0 ml g^{-1}, respectively. In practice, ion exchangers should have high exchange capacity and small swelling. For amination, the optimal reactant ratio for DGA, DGPAF, and DGTPF is 1.0 : 1.0 with PEPA and 1.0 : 2.0 with PEI. At a large excess of polyamine, insufficient amount of reactive epoxy groups hinders formation of network ion exchangers.

The IR spectra of the anion exchangers obtained contain no characteristic bands of epoxy groups (810–920, 1250, 3000–3010 cm^{-1}), which indicates that their chemical conversion was complete. At the same time, bands of N–H bending (1600–1670 cm^{-1}) and C–N stretching (1020–1220 cm^{-1}) vibrations of amino groups are observed (Fig. 1).

To outline the field of application of the new ion exchangers, we studied their acid–base properties, exchange capacity, selectivity of metal ion sorption, kinetic properties, swelling, and stability.

The sorption properties of the ion exchangers are determined by the concentration of functional groups in the polymer unit weight. The concentration of functional groups (SEC, mg-equiv g^{-1}) in the ion exchangers synthesized was determined chemically under static conditions and by potentiometric titration [5]. The potentiometric curves were recorded in concentrated solutions of a supporting electrolyte, because weakly and moderately basic anion exchangers contain only weakly dissociating functional groups.

The potentiometric titration curves are plotted in the pH–titrant amount (mg-equiv per gram of ion exchanger) coordinates (Fig. 2). Inflection in the titration curve corresponds to the concentration of functional groups in the ion exchanger. More precisely, the posi-

Table 2. Physicochemical characteristics of anion exchangers

Anion exchanger based on	SEC (potentiometric titration), mg-equiv g^{-1}	Specific volume, ml g^{-1}	pK_a	m
DGA : PEI = 1.0 : 1.0	8	3.6	7.8	2.0
DGPAF : PEI = 1.0 : 1.0	8	3.7	7.5	2.2
DGA : PEPA = 1.0 : 1.0	8	3.5	7.8	2.2
DGPAF : PEPA = 1.0 : 0.75	6	3.5	7.8	2.0

tion of the inflection is determined from the differential curve plotted in ΔpH–amount of working solution (mg-equiv per gram of ion exchanger) coordinates, where ΔpH is the pH change on addition of a definite amount (mg-equiv) of the working solution. The curve maximum corresponds to the equivalence point (Fig. 2).

To find the average constant of the acid–base dissociation of weakly basic groups of the anion exchanger, we used graphic solution of the Henderson–Hasselbach equation [5]

$$pH = pK_a + m\log[(1 - \alpha)/\alpha],$$

where pH is pH of the equilibrium solution; pK_a, negative logarithm of the acid–base dissociation constant of the polymer functional groups; m, empirical coefficient considering interunit interaction in the polymeric chain; and α, degree of protonation of the anion exchanger functional groups.

Typical straight lines of the graphic solution of this equation in the pH–log[(1 – α)/α] coordinates are shown in Fig. 3.

The coefficient m was determined as the slope of the above straight lines, and pK_a, as a segment cut off on the ordinate (Table 2).

Thus, our study confirms the polyfunctionality of the ion exchangers synthesized, determined by secondary and tertiary amine groups [6]. However, due to small difference in pK_a values of the functional groups, only one inflection is observed in the potentiometric titration curves. Therefore, only the total concentration of functional groups can be determined by potentiometric titration.

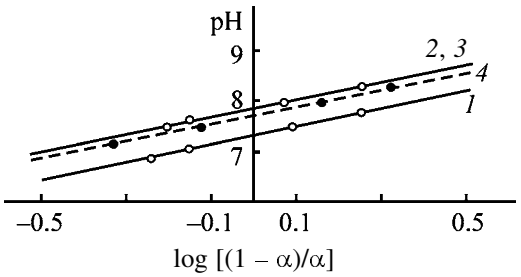

Fig. 3. pH of equilibrium solution as a function of log[(1 – α)/α] for anion exchangers (*1*) DGPAF : PEI, (*2*) DGA : PEI, (*3*) DGA : PEPA, and (*4*) DGPAF : PEPA.

The complex formation of the ion exchangers is characterized by the sorption of the metal ions on the polymer ligand groups due to donor–acceptor interaction, by the energy of the metal ion interaction with electron-donor atoms of the polymer ligand groups, and by the stability constant of the complex [5, 7, 8]. The role of nitrogen atoms of the ion exchanger, forming σ bonds with metal ion vacant orbitals, is determined by their lone electron pair on the sp^3 hybrid orbital.

To study the complexing properties of anion exchangers, we used solutions prepared from chemically pure grade copper, nickel and sodium nitrates. The composition and stability of the complexes formed were determined by potentiometric titration of anion exchangers in the absence and in the presence of the complexing metal ions by the method of separate weighed portions [5] at the ion exchanger content of 0.2 g per 50 ml of the solution (the ion exchanger was preliminarily dried to constant weight). To an ion exchanger sample we added a solution containing copper or nickel nitrate (0.025 M in 1 M $NaNO_3$, 10 ml), nitric acid (from 0 to 10 mg-equiv per gram of ion exchanger with the step of 0.5 mg-equiv g^{-1}), and 1 M sodium nitrate (added to the total volume of 50 ml). The ionic strength of the resulting solution was 1, and the experiment temperature, 20°C. After attaining the equilibrium (15 days), the pH of solutions was measured with a PB-11 pH meter (Sartorius), and the metal ion concentration was measured by atomic absorption spectroscopy.

In aqueous solutions, ionogenic groups of the nitrogen-containing anion exchangers exist in interdependent chemical forms:

$$\underset{\text{Free base}}{\geqslant N} + HOH \rightleftarrows \underset{\text{Hydrated form}}{\geqslant N\ldots HOH} \rightleftarrows \underset{\text{Protonated form}}{\geqslant NH^+} + OH^-,$$

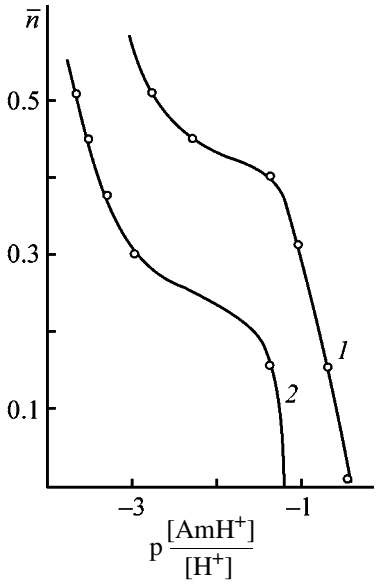

Fig. 4. Complexation of copper(II) with anion exchangers (*1*) DGPAFA : PEI and (*2*) DGA : PEI as a function of $p[AmH^+]/[H^+]$. ($\bar{n}$) Bjerrum formation function; the same for Fig. 5.

whose presence determines the possibility of ion exchange reactions

$$\geqslant NH^+OH^- + An^- \rightleftarrows \geqslant NH^+An^- + OH^- \qquad (1)$$

and complex formation with hydrated transition metal cations

$$n(\geqslant N\ldots HOH) + M(H_2O)_N \rightarrow M(\geqslant N)_n(H_2O)_{N-n} + 2nH_2O. \qquad (2)$$

Reactions (1) and (2) occur simultaneously and independently. The process direction as a whole is determined by the ratio of their equilibrium constants, experimental conditions, and first of all by the degree of protonation of anion exchanger amino groups.

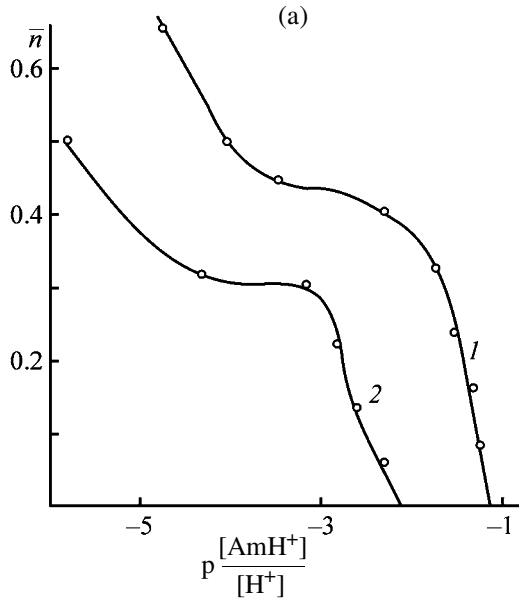
In the presence of metal ions, the total concentration of the amino groups in the system [Σ Am] consists of amino groups bound in the complex [Am_c], protonated anino groups [AmH^+], and free amino groups [Am]:

$$[\Sigma\,Am] = [Am_c] + [AmH^+] + [Am].$$

The concentration of protonated amino groups was determined in each point of the potentiometric titration curve:

$$[AmH^+] = NV/V_{tot} = 0.1V_{HNO_3}/50 \text{ ml (mg-equiv ml}^{-1}).$$

Using the equation $pH = pK_a + m\log[Am]/[AmH^+]$,



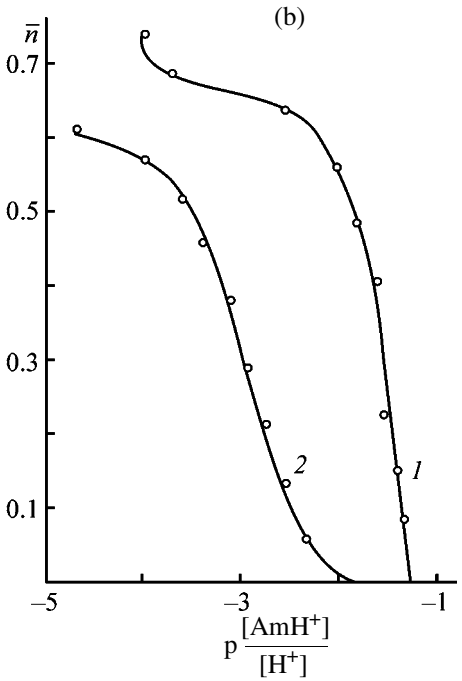


Fig. 5. Complexation of (*1*) copper(II) and (*2*) nickel (II) with anion exchangers (a) DGPAF : PEPA and (b) DGA : PEPA.

we calculated the concentration of free amino groups [Am] in the solution by the formula

$$p[Am] = (pK_a - pH)/m - \log[AmH^+].$$

The concentration of bound amino groups in the complex [Am_c] was determined as the difference between the total concentration of the amino groups in the system, SEC (mg-equiv ml^{-1}), and the sum

Table 3. Stability constants of copper(II) and nickel(II) complexes with anion exchangers

Complex, 0.025 M	$\log K_{st}$ with indicated anion exchangers			
	DGPAF : PEI = 1.0 : 1.0	DGA : PEI = 1.0 : 1.0	DGA : PEPA = 1.0 : 1.0	DGPAF : PEPA = 1.0 : 0.75
$Cu(NO_3)_2$	4.6	4.2	6.0	4.0
$Ni(NO_3)_2$	3.5	3.0	4.5	3.0

$[AmH^+]$ + [Am]:

$$[Am_c] = [\Sigma Am] - [AmH^+] - [Am].$$

The Bjerrum formation function (i.e., the amount of amino groups in the complex per metal ion) was calculated by the formula

$$\bar{n} = [Am_c]/c_M,$$

where c_M is the initial metal ion concentration in the solution (M).

The complex formation curves were plotted in $\bar{n}$ – $p[AmH^+]/[H^+]$ coordinates (Figs. 4, 5).

The shape of the curves of copper(II) and Ni(II) complex formation with anion exchangers at a cation concentration of 0.025 M corresponds to primary formation of 1.0 : 1.0 complexes, because $\bar{n}$ tends to 1. The composition of the complexes depends on the anion exchanger ionic composition and metal ion concentration in the solution [9–11]. The higher the concentration of hydrated coordination-active ionogenic groups and the lower the concentration of metal ions, the larger number of amino groups is coordinated to the metal ion.

The stability constants of copper(II) and Ni(II) complexes with the anion exchangers studied were determined by the Bjerrum–Gregor potentiometric method:

$$\log K_{st} = \log \beta_n + pK_a,$$

where β_n is the complexation step constant found from the complexation curves at half $\bar{n}$ values (in our case, $\bar{n} = 0.5$).

The most stable complexes are formed by the DGA : PEPA anion exchanger. The stability of the copper complex is higher than that of the nickel complex, which is probably caused by smaller ionic radius of copper. The stability of the complex with ionogenic groups of the same anion exchanger depends on particular metal, namely, on the charge and radius of the hydrated metal ion, its electronic state, and electronegativity.

CONCLUSIONS

(1) Polyfunctional ion exchangers were synthesized by condensation of glycidyl derivatives of aromatic compounds with polyamines. The influence of the type of the initial reagents and reaction conditions on formation of network polyelectrolytes was determined.

(2) The polymers synthesized are polyfunctional anion exchangers with pK_a 7.5–7.8 and high exchange capacity (up to 12.5 mg-equiv g^{-1}).

Abstract—The possibility of preparing epoxy–silica composites using *iso*-methyltetrahydrophthalic anhydride as curing agent was examined; the composition of the composites and conditions of their preparation were determined. The effect exerted by the concentration of precursors, tetraethoxysilane and epoxypropoxypropyltriethoxysilane, on the glass transition point, sol fraction yield, heat resistance, and adhesion properties of the hybrid materials obtained was studied.

DOI: 10.1134/S107042720703024X

The mechanical and thermal properties of polymeric materials are often improved by introducing an inorganic filler. The properties of such composites are determined by the properties of both physically mixed phases. In the past decades, numerous elastomers, thermoplastics, and linear or cross-linked polymers were modified with inorganic fillers formed in situ [1–4]. Such systems constitute a new class of composites, organic–inorganic hybrids. Inorganic particles in hybrid materials have usually nanometer size, so that the system is optically transparent. In such hybrids, the properties of inorganic and organic phases are combined, which allows preparation of materials with high levels of adhesion strength and resistance to heat, wear, scratching, and action of aggressive media; therefore, these materials are often used as protective and anticorrosion coatings.

The inorganic phase in hybrids is generated inside the forming polymer matrix using the sol–gel process: hydrolysis of alkoxy derivatives of Si, Ti, Al, and Zr followed by polycondensation of hydrolysis products and gelation of the system. The organic and inorganic components of the system can undergo polymerization (or polycondensation) both successively and simultaneously [5, 6]. The properties of the resulting composites largely depend on the interphase interaction determining their morphology; the compatibility of the organic and inorganic phases is often improved by adding compatibilizers: organic monomers or polymers modified with alkoxysilanol groups, e.g., 3-glycidyloxypropyltrimethoxysilane, aminopropyltrimethoxysilane, aminoethylaminopropyltriethoxysilane, etc. [7, 8]. In this case, hybrids with covalent bonding of the inorganic component with the polymer matrix can be prepared.

Epoxy–silica hybrids are among widely used organic–inorganic composites. The organic constituent of such systems is cured with polyamines, dicarboxylic acids, anhydrides, boron trifluoride, and tertiary amines. However, today the use of dicarboxylic acid anhydrides for preparing epoxy–silica nanocomposites is limited.

The goal of this study was to prepare epoxy–silica hybrid composites curable with *iso*-methyltetrahydrophthalic anhydride and to examine the effect of the silica component on the properties of the composites.

EXPERIMENTAL

To form the organic constituent of hybrid composites, we used a triepoxide based on 1,1-dimethylol-3-cyclohexene (UP-650T, MW = 360 g mol^{-1}, epoxy number EN = 37.4%), *iso*-methyltetrahydrophthalic anhydride (*iso*-MTHPA, acid number AN = 662 mg of KOH per gram), and a curing accelerator, 2,4,6-tris-(dimethylaminomethyl)phenol (UP-606/2). To obtain silicon oxide particles, we used tetraethoxysilane (TEOS, ρ = 0.9334 g cm^{-3}, n_D^{20} = 1.383) and epoxypropoxypropyltriethoxysilane (ES-1, ρ = 1.000 g cm^{-3}, n_D^{20} = 1.425).

Sol of colloidal particles of silicon oxide was pre-

Table 1. Influence of the composition of epoxy–silica composites on the gelation time and optical transmission coefficient

System	Content of epoxysilanes, wt %	Gelation time t_{gel} at 22±2°C, days	Optical transmission coefficient T_{540}, %
Uncured	0	23	97

	30	50	95
Cured	0	–	95
	10	–	93
	20	–	91
	30	–	90

pared by joint hydrolysis of TEOS and ES-1 (molar ratio 2 : 1) in the presence of 1 N aqueous HNO_3 and epoxy resin (molar ratio TEOS : H_2O = 1 : 2, ES-1 : H_2O = 1 : 2). The content of ethoxysilanes in the system was varied from 2 to 30 wt %. As solvent for performing the sol–gel process we used methyl ethyl ketone (35 vol % relative to the sol). After 24 h, water, solvent, and ehanol formed by hydrolysis of ethoxysilanes were removed in a vacuum at 25°C; then a stoichiometric amount of the curing agent (*iso*-MTHPA) and curing accelerator (UP-606/2, 0.3 wt % relative to the total amount of the anhydride and epoxy resin) were added. Film samples were prepared between glass plates coated with an antiadhesive (dimethyldichlorosilane). The film thickness was set with a 200-μm-thick fish line.

Photometric studies were performed with a KFK-3 photocolorimeter at λ = 540 nm. The DSC curves were taken on a DSM-2M device in the temperature range 70–240°C (heating rate 4 deg min^{-1}). The IR spectra of organic–inorganic composites were recorded on a Specord 75-IR spectrophotometer at room temperature using KBr windows. The wavelength range was 1400–400 cm^{-1}. The epoxy number of UP-650T resin was determined according to GOST (State Standard) 2087–92 by acid–base back-titration. The acid number of *iso*-MTHPA was determined by titration of a sample of the anhydride in acetone with 0.1 M NaOH [9].

The glass transition point of polymer samples was determined by a thermomechanical method with an automatic laboratory installation consisting of a TK-500 thermocryochamber, a BTP-78 programmable temperature regulator, an M-217 electronic measuring system, and an *XY* recording potentiometer. Measurements were performed with film samples (25 × 6 × 0.2 mm) at a constant tensile stress (2 MPa). The heating rate was 4 deg min^{-1}. The glass transition point was determined as the intersection point of the tangents to the flat and ascending portions of the curve.

The yield of the sol fraction of the polymers was determined from the weight loss of the film samples after extraction of low-molecular-weight products with methanol at 50°C for 3 days. To determine the adhesion strength, the compounds were applied onto aluminum foil and cured under the common conditions. The coating thickness was 20–30 μm. Adhesion to aluminum foil was evaluated by the lattice notch method in the five-point scale according to GOST 15 140–78 [10].

Thermogravimetric analysis was performed with an MOM Q-1500 D derivatograph (Hungary) in the dynamic mode in the temperature range 20–850°C. Finely divided film samples of the polymers (200 mg) were placed in ceramic crucibles. The heating rate was 10 deg min^{-1}. Aluminum oxide was used as reference. Measurements were performed in air. The device scale was 200 mg.

It is known that hydrolysis of ethoxysilanes at acid catalysis in the presence of UP-650T epoxy resin and an inert solvent is relatively fast [1] and is followed by polycondensation of the hydrolysis products. Under such conditions, nanosized silica particles with a defective structure are usually formed [12]. The preliminary tests showed that ethanol released in the course of hydrolysis of ethoxysilanes and HNO_3 present in the system do not cause opening of the epoxy ring to an appreciable extent. The epoxy number of UP-650T resin decreased by only 1.9% in 24 h after the start of the reaction. At the same time, the presence of ethanol causes unproductive consumption of the anhydride curing agent, namely, its transformation into the monoester. For a mixture of *iso*-MTHPA and ethanol in 1 : 1 molar ratio in methyl ethyl ketone, the degree of conversion (esterification) is 0.76 in 24 h. In the process, an S-shaped kinetic curve is observed, typical of autocatalytic reactions, which may be due to the catalytic effect of the carboxylic acid formed by opening of the anhydride ring [13].

The sols prepared by simultaneous mixing of all the components are stable in time, have uniform structure, and are optically transparent (Table 1). Table 1 shows that the gelation time is minimal for the composition containing no organosilicon precursors and increases with an increase in their content in the reaction mixture. This fact indicates that the sol–gel transition in the systems under consideration mainly oc-

curs via the reaction of epoxide with anhydride, which is slow at room temperature.

At a high concentration of ethoxysilanes in the starting mixture and hence high concentration of ethanol in the reaction zone, esterification can significantly distort the epoxide–anhydride stoichiometric ratio. Therefore, it becomes necessary to remove ethanol in a vacuum before adding anhydride. Water introduced into the system for the hydrolysis of ethoxysilanes is removed simultaneously, which prevents hydrolysis of the anhydride curing agent.

From the DSC data, we determined the temperature range of curing of the unfilled and filled compounds. The temperatures of the onset and end of the process and of the maximal rate of heat release are 75, 170, and 130°C, respectively, being essentially independent of the content of ethoxysilanes in the system. Based on these data, we chose the temperature and time conditions for preparing maximally cured epoxy polymers and epoxy–silica composites: 2 h at 130°C + 4 h at 160°C + 1 h at 180°C. Under these conditions, the limiting glass transition point of the film samples of the polymers is reached. Formation of the maximally cured polymers is also confirmed by the IR data, namely, by the disappearance of the absorption bands of the epoxy groups (910 and 840 cm^{-1}).

We studied how the concentration of ethoxysilanes added into the system affects the thermomechanical properties of the composites and found that the glass transition point decreased with an increase in the content of the silicon oxide constituent (Fig. 1). This results can be attributed to the fact that the condensation of hydrolyzed organosilicon precursors involves formation of –Si–O–Si– bonds with a low rotation barrier, which gives rise to a plasticization effect and causes a decrease in the glass transition point.

A decrease in the glass transition point can also be accounted for by formation of a structure with topological defects in the polymer matrix of the composite. Formation of topological defects is confirmed by the results of sol–gel analysis. We found that the content of low-molecular-weight compounds in the hybrid materials increases with an increase in the concentration of ethoxysilanes (Fig. 2). It is known that acid hydrolysis of ethoxysilanes in the presence of monosubstituted alkoxysilanes yields silica particles with a defective structure, containing organic substituents [12]. In the process, interpenetrating epoxy–silica polymer network can form, which can result in steric hindrance to formation of a three-dimensional epoxide structure; therefore, the glass transition point of the

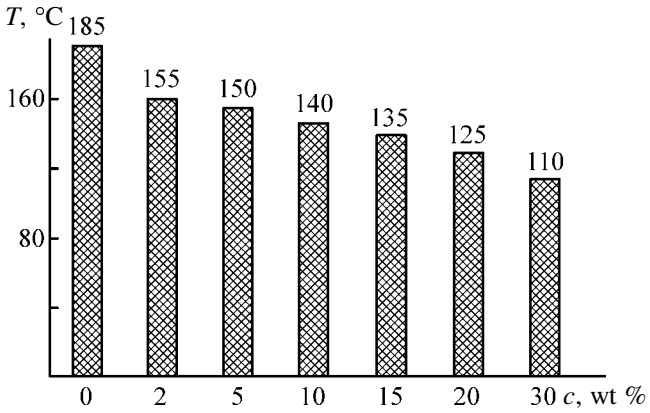

Fig. 1. Glass transition point T of epoxy polymers and epoxy–silica composites as a function of the content c of ethoxysilanes in the initial reaction mixture.

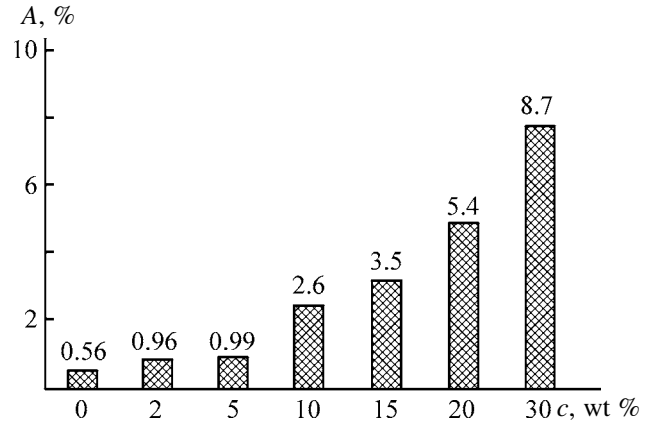

Fig. 2. Yield A of sol fraction from epoxy polymers and epoxy–silica composites as a function of the content c of ethoxysilanes in the initial reaction mixture.

composite should decrease. Similar phenomena are observed with classical interpenetrating polymer–polymer networks [14].

A decrease in the glass transition point is observed both when the anhydride is added after removing the volatiles in a vacuum and when all the components are mixed simultaneously (Fig. 3). In the latter case, as noted above, esterification of the anhydride with ethanol released from hydrolysis of ethoxysilanes occurs simultaneously with the formation of the sol. As a result, the overall stoichiometric ratio of the components is distorted, causing still stronger plasticization of the polymer matrix: the glass transition point decreases to 55°C. The esterification process in such a complex system is difficult to control, and attempts to reduce its effect on the thermomechanical properties of the polymers by introducing an additional amount of *iso*-MTHPA failed. Figure 3 shows that addition of the anhydride in amount fully compensat-

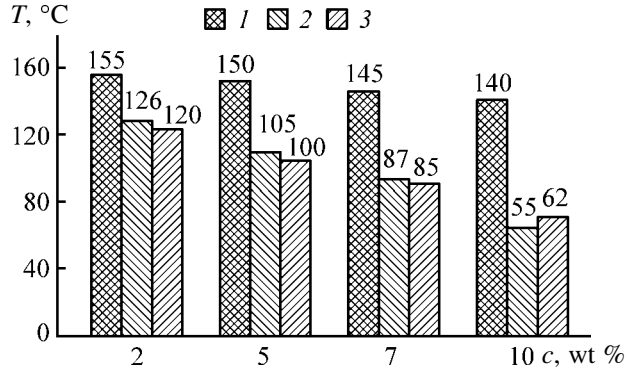

Fig. 3. Influence of conditions for preparation of epoxy–silica composites on their glass transition point T at various content c of ethoxysilanes in the initial reaction mixture: (*1*) vacuum treatment to remove volatiles, (*2*) no vacuum treatment, and (*3*) no vacuum treatment, with compensation of the anhydride loss in the reaction with alcohol.

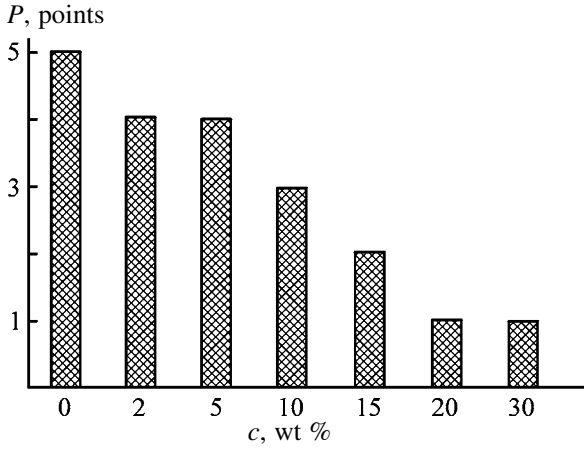

Fig. 4. Adhesion P of coatings based on epoxy–silica composites as a function of the concentration c of ethoxysilanes in the initial reaction mixture.

ing its theoretical loss in the reaction with the alcohol released by hydrolysis does not noticeably change the glass transition point of the product. In this case, the high plasticizing effect of ethoxysilanes is caused by formation of the monoester in the reaction of the anhydride with the alcohol (with a decrease in the density of the polymer network), in agreement with data of [15].

Unmodified thickly cross-linked epoxy polymers cured with anhydrides are very brittle and exhibit relatively low adhesion strength. Plasticization of the polymer matrix improves the adhesion characteristics of composite materials. Furthermore, it is known that epoxy–silica composites show increased affinity for aluminum surfaces compared to epoxy polymers because of interaction of hydroxy groups on the support surface with the inorganic constituent of the system [16, 17]. This interaction results in formation of the Si–O–Al bond on the coating | aluminum substrate interface. In the systems under consideration, with an increase in the content of the inorganic constituent, the capability to spread over the aluminum foil surface and the adhesion strength of the coatings increase (Fig. 4).

It is known that introduction of silica nanoparticles into epoxy polymers enhances their heat resistance [18]. For the systems under consideration, variation of the initial concentration of ethoxysilanes in the reaction mixture also strongly affects the heat resistance of the composites. As shown by thermogravimetric analysis (Fig. 5), the temperature of 5% weight loss of the epoxy–silica hybrids increases from 225 to 275°C with an increase in the content of TEOS and ES-1 from 0 to 10 wt %. The temperature of the maximal weight loss rate also increases (by 15°C). However, as the concentration of ethoxysilanes is increased further, the temperature of 5% weight loss decreases (to 175°C at 30 wt % content of TEOS and ES-1, Table 2). This significant decrease in the heat resistance may be due to the fact that, at high concentrations of ethoxysilanes in the initial reaction mixture, the three-dimensional network of the polymer matrix becomes looser and the content of low-molecular-weight compounds in the composites increases. This

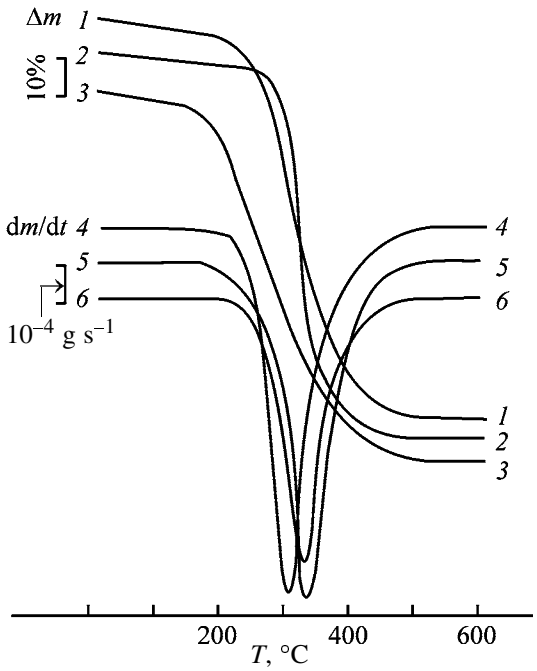

Fig. 5. (*1–3*) TG and (*4–6*) DTG curves of epoxy polymers and epoxy–silica composites. (Δm) Weight loss, (dm/dt) weight loss rate, and (T) temperature. Content of ethoxysilanes, wt %: (*1*, *4*) 0, (*2*, *5*) 10, and (*3*, *6*) 20.

30	175	320

explanation is well consistent with the above-given results of thermomechanical and sol–gel analysis.

CONCLUSIONS

(1) The use of *iso*-methyltetrahydrophthalic anhydride as a curing agent for UP-650T epoxy resin ensures preparation of uniform and transparent epoxy–silica composites (using sol–gel technology).

(2) As the concentrations of tetraethoxysilane and epoxypropoxypropyltriethoxysilane in the initial reaction mixture and, correspondingly, the content of the inorganic constituent in the composites are increased, the glass transition point of the composites decreases and their adhesion to aluminum substrates increases.

(3) Introduction into the system of up to 10 wt % tetraethoxysilane and epoxypropoxypropyltriethoxysilane appreciably enhances the heat resistance of the hybrid materials obtained. Further increase in the concentration of these ethoxysilanes to 30 wt % leads to a decrease in the heat resistance of the polymers.

Abstract—Bulk and viscous properties of solutions of dextrans of different molecular weights in formamide, water, and dimethyl sulfoxide were studied. The fractal dimension of the biopolymer was estimated from the hydrodynamic data.

DOI: 10.1134/S1070427207030251

Biopolymers, natural physiologically active compounds, attract considerable interest today. Since these compounds are biodegradable, they are widely used in medicine, microbiology, and pharmacy. Among these compound are dextrans. The colloidal osmotic and viscous properties of solutions of these polysaccharides allow their use as antishock blood substitutes. In addition, irregular structure and random branching of the polymer chains are the major factors responsible for high sorption capacity of these polysaccharides.

In this study we examined the influence of the solvent on the structural features and physicochemical properties of solutions of dextrans with different molecular weights.

EXPERIMENTAL

We studied dextrans with molecular weight of $(40–50) \times 10^3$ (Fluka AG, Buchs, Switzerland). The dextrans were dried in a vacuum at 313 K for 24 h. Formamide (FA) and dimethyl sulfoxide (DMSO) purified and dried by the standard procedure [1] and double-distilled water were used as the solvents. The water content of the solvents, determined by amperometric Fischer titration, was within 0.002%. The polymer solutions were prepared by weighing on a VLR-200 balance with an accuracy of $\pm 5 \times 10^{-5}$ g.

The bulk properties were estimated from the experimental density of the solutions by the procedure described in [2]. The density of the solutions was measured with a vibratory densimeter with an accuracy of $\pm 2 \times 10^{-6}$ g cm^{-3}, which allowed reliable calculation of the bulk properties of dextran (± 0.02 cm^3 mol^{-1}). The temperature was maintained with an accuracy of ± 0.002 K.

To decrease the calculation error, the partial and apparent molar volumes were calculated directly from the experimental results by the equations

$$V_2 = \frac{M_2}{\rho} - \frac{(1000 + mM_2)}{\rho^2}\frac{\partial\rho}{\partial m}, \quad (1)$$

$$V_\varphi = \frac{1000(\rho_0 - \rho)}{m\rho\rho_0} + \frac{M_2}{\rho}, \quad (2)$$

where V_2 is the partial molar volume of the solute, V_φ is the apparent molar volume of the solute, M_2 is the molecular weight of the solute, ρ is the density of the solution, ρ_0 is the density of the pure solvent, and m is the molar concentration of the solution.

The viscosity of the solution with the polymer concentration of 3–16 kg m^{-3} was measured on an Ubbelohde viscometer at 293–308 K. The root-mean-square error of these measurements was $\pm 0.5\%$. The reduced viscosity of all the examined dilute dextran solutions η_{sp}/c was a linear function of the polymer concentration (correlation coefficient $r = 0.95–0.98$). The Huggins constant was calculated by the equation [4]

$$\eta_{sp}/c = [\eta] + K_H c[\eta]^2, \quad (3)$$

where K_H is the Huggins constant characterizing the interaction between the segments of the polymer macromolecules and the solvent, and $[\eta]$ is the intrinsic viscosity.

The root-mean-square distance between the chain ends in polymer macromolecules $\langle\eta^2\rangle^{1/2}$ was calculated by the equation

$$[\eta] = \Phi\frac{\langle\eta^2\rangle^{3/2}}{M_2}, \quad (4)$$

where Φ is the Flory coefficient characterizing the deviation of the actual volume of macromolecules from the sphere volume and partial penetrability of a macromolecule globule for the solvent.

The concentration dependences of the density and partial and apparent molar volumes of dextrans of different molecular weights in FA are presented in Table 1. It is seen that the density and the bulk properties of the polymers in the solution increase with an increase in their molecular weight.

To understand structure formation in dilute polysaccharide solutions, we studied the concentration dependences of the partial molar volumes of the polymer of $M_2 = 110 \times 10^3$ in different solvents (Fig. 1). The bulk properties of dextran solutions in water and DMSO are reported in [7]. As seen from Fig. 1, the partial molar volumes of the macromolecules in dilute solutions ($c < 0.4$ wt %) increase with an increase in the solvent polarity. Solvation and hydration probably substantially affect the structure of the dextran solutions. In aqueous solutions, the volume of a macromolecular coil increases owing to its swelling and hydration and then decreases owing to formation of denser structures. The behavior of dextrans in nonaqueous solutions is different. Solvation of the macromolecules in DMSO and FA enhances their volume parameters. Intersection of $V_2 = f(c)$ curves at the concentration of 0.4 wt % (Fig. 1) is probably due to resolvation in liquid systems [8].

It is known that thermodynamic parameters of a solvent can be indirectly estimated form the results of viscometric measurements. The intrinsic viscosity, Huggins constants, and root-mean-square distance between the chain ends of dextran macromolecules in formamide are summarized in Table 2. The viscosity of dextrans of different molecular weights in FA is low. An increase in K_H and decrease in [η] and hydrodynamic size of the macromolecules with a decrease in the molecular weight of the polymer from 500×10^3 to 40×10^3 suggest structure formation even in dilute dextran solutions.

Let us compare the molecular properties of dextran solutions in formamide (Table 2) with viscosity of solutions of these polysaccharides in DMSO and water [7]. It is seen that the intrinsic viscosity and root-mean-square distance between the chain ends are maximal in DMSO and minimal in water. Apparently, coils of dextran molecules substantially swell in DMSO, which promotes dissolution of the polymer. These differences in the hydrodynamic parameters are probably due to different mechanism of solvation of

polymer macromolecules in FA, water, and DMSO, which, in turn, is caused by structural features of both the solvent and the dissolved macromolecules. It is known that water and formamide molecules can be bound by hydrogen bonds or dipole–dipole interactions to form associates or clusters.

Dimethyl sulfoxide is associated in the liquid phase to form clusters [9]. Since the lone electron pair of the oxygen atom of a DMSO molecule can interact with both polar (ionic compounds) and nonpolar molecules, dextran molecules are readily incorporated into the DMSO structure (the energy required for this process is lower than that for water) to form stable complexes with DMSO clusters. In this case, the size of a macromolecular coil increases and a developed intermolecular hydrogen bond network is formed. The increase in the intrinsic viscosity and root-mean-square distance between the chain ends can be due both to a decrease in the thermodynamic flexibility of a macromolecular coil and to formation of its unfolded conformation owing to formation of new polymer–DMSO intermolecular bonds.

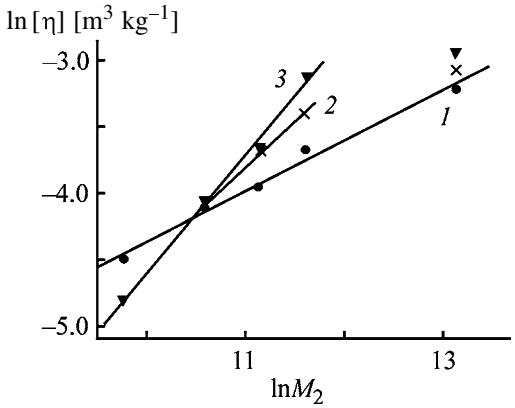

Fig. 2. Logarithm of the intrinsic viscosity [η] of dextran solutions in (*1*) water, (*2*) formamide, and (*3*) dimethyl sulfoxide at 298.15 K as a function of the logarithm of the molecular weight of dextrans M_2.

The fractal dimension [10] of the polymer in the examined solvents at different temperatures was estimated from the viscosity of solutions of dextrans with different molecular weights measured in [7] and in this study. Since the viscosity of polymer solutions is caused mainly by the factors determining the macromolecule volume in a solution, we constructed the $\ln[\eta]$–$\ln M_2$ dependences. These dependences for the dextran–water system are linear in the whole examined range of molecular weights (Fig. 2). In the case of the nonaqueous solvents, the dependence is linear at $M_2 < 110 \times 10^3$ and is not linear at higher molecular weights. The nonlinearity is probably caused by the influence of the solvent on the volume and shape of a dextran macromolecule in the solution.

The parameter α of the Mark–Kuhn–Houwink equation [5]

$$[\eta] = KM_2^{\alpha} \quad (5)$$

given in Table 3 characterizes the extent to which a macromolecule forms a coil. A decrease in parameter α for dextran macromolecules in going form aqueous to DMSO solutions suggests an increase in the penetrability of the macromolecular coil and hence higher solubility of the polymer in DMSO, which agrees well with the parameters of Flory–Huggins equation reported in [11].

It should be noted that, although dextran macromolecules are branched, they are characterized by internal order based on the scale invariance principle [10, 12] fundamental for polymer systems. This allows the scaling approach, including the concept of fractal objects, to be applied to dextrans.

The parameter α of the Mark–Kuhn–Houwink equation is related to the fractal dimension D_f by the equation [11]

$$D_f = \frac{3}{1 + \alpha}. \quad (6)$$

Hence, the fractal dimension can be determined

Table 3. Parameter α of Mark–Kuhn–Houwink equation and fractal dimension of dextrans in different solvents and at different temperatures

Solvent	T, K	α	D_f
DMSO	293.15	0.893	1.585
	298.15	0.970	1.523
	303.15	1.087	1.437

	308.15	0.363	2.201

from the slope of the experimental dependence $\ln[\eta] = f(\ln M_2)$ using Eq. (6). Fractal dimensions D_f of the dextrans in the examined solutions, given in Table 2, substantially differ from 3, which is typical for loose structures. It should be noted that fractal dimension D_f characterizes the structure of a polymer macromolecule in the solution rather than the initial polymer structure.

CONCLUSIONS

(1) The viscous and volume properties of solutions of dextrans with different molecular weights in different solvents were studied. The different behavior of dextrans is caused by different solvation mechanism of macromolecular chains.

(2) The fractal approach can be used to describe the dextran structure in the solutions.

CHEMISTRY OF FOSSIL FUEL

Improvement of Low-Temperature Properties of Diesel Fuels

S. G. Agaev, N. S. Yakovlev, and S. V. Gul'tyaev

Tyumen State University of Oil and Gas, Tyumen, Russia

Received December 21, 2005; in final form, October 2006

Abstract—Ways to improve low-temperature properties of summer diesel fuels by introduction of depressant additives and partial dewaxing of fuels in an electrostatic field are examined. Synthesis of amidopolyformaldehyde depressant additives for diesel fuels is described, and optimal synthesis conditions are determined.

DOI: 10.1134/S1070427207030263

The demand for winter grades of diesel fuels (DFs) is met to no more than 40%. Therefore, it is necessary to expand their production [1]. One of ways to prepare winter diesel fuels is urea dewaxing of oil fractions or their dewaxing on zeolites. Dewaxing results in removal from diesel fuels of not only relatively high-melting but also (which is undesirable) of relatively low-melting *n*-paraffins. This leads to reduction of diesel fuel resources and to a noticeable decrease in their cetane numbers.

In this study we consider two ways to improve low-temperature properties of diesel fuels with complete or partial preservation of paraffin hydrocarbons: use of depressant additives and partial dewaxing in an electric field.

Various low-molecular-weight and polymeric organic compounds were suggested to decrease the congelation point of diesel fuels [2]. At the same time, production of the best depressant additives (DAs), ethylene–vinyl acetate copolymers, has not been set up in Russia because of sophisticated technology. Polycondensation depressant additives [3–5] show high performance and their production process is simpler, but the required raw materials are not produced in Russia.

In this study we examined the possibility of preparing polycondensation amidopolyformaldehyde additives from the raw materials available in Russia. The depressant additives were prepared in two steps. The first step involved condensation of stearic acid (SA) with polyethylenepolyamines (PEPAs) to prepare acid amides. These amides were then brought into condensation with formaldehyde (FA) at the reactant molar ratio SA : PEPA : FA = (2.3–3.0) : 1.0 : (0.5–25). The condensation of SA–PEPA amides with FA presumably ensures higher molecular weight and better hydrophilic–lipophilic balance of the additives, which should enhance the depressant effect at the same consumption of the additives or to decrease the amount of the additives required to attain the same depressing effect.

We used technical-grade SA, PEPA, and Formalin. Stearic acid of T-18 brand met the requirements of GOST (State Standard) 6484–96 and had the following characteristics: molecular weight 284, congelation point 64.2°C, acid number 192.7 mg KOH/g, saponification number 195.1 mg KOH/g, iodine number 11.9 g I_2/100 g, and weight fraction of unsaponifiable substances 0.48%. Formalin met the requirements of GOST 1625–89 and contained 36.6 wt % FA and 7 wt % methanol; the content of acids (counting on formic acid) was 0.01 wt %. Polyethylenepolyamines met the requirements of TU (Technical Specifications) 2413-357-00203447–99: molecular weight 144; total nitrogen, 31 wt %; tertiary amino groups, 6.6 wt %; bottoms boiling above 200°C, 69.6 wt %; fraction distilled below 75°C/1.3 kPa, traces; fraction distilled at 75–200°C/1.3 kPa, 28.9%. To prepare SA–PEPA amides in the first step, we used technical-grade diethylbenzene as an azeotropic solvent (main substance content ≥99.8 wt %; isomeric composition, %: *para* ~30, *ortho* ≤ 3.8, and *meta* the rest). Diethylbenzene met the requirements of TU 2414-040-00203772–96. The other products used for preparing depressant additives, benzene and zinc oxide, were of reagent grade; their physicochemical properties agreed with reference data.

In the first step, by condensation of SA with PEPA we prepared amides with various degrees of substitution, which were then subjected to formaldehyde condensation. SA–PEPA amides were prepared by con-

densation in a 50% diethylbenzene solution at its boiling point, 183°C. Stearic acid and PEPA form an ammonium salt soluble in diethylbenzene. Therefore, the synthesis is performed under homogeneous conditions without mechanical stirring. The first step of the synthesis is performed with a Dean–Stark trap filled with diethylbenzene, until the distillation of water released in the process is complete. Then the solvent is completely distilled off, and the condensation is continued at a temperature gradually raised from 183 to 235°C, to obtain amides with the required acid number in the melt. The synthesis of amides is performed in the presence of 0.5 wt % ZnO as catalyst (relative to the sum of the reactants without solvent). The total synthesis time is determined from the final acid number of the amides, which does not exceed 20 mg KOH/g. The synthesis of SA amides takes approximately 6–10 h.

In the second step, a calculated amount of FA in the form of 37% aqueous solution (Formalin) and 50 wt % benzene (relative to the sum of the reactants) are added to the SA amide. The formaldehyde condensation is performed at the boiling point of benzene (80°C); water released in the reaction and present in Formalin is distilled off with a Dean–Stark trap. To prevent distortions of the reactant concentrations, the trap is initially filled with benzene. The synthesis is heterogeneous. The phase contact is provided by refluxing of the reaction mixture. To avoid overheating and violent boiling of the reaction mixture in the second step, water at its boiling point is used as a heat carrier in the reactor bath. The reaction time is counted from the onset of boiling of the reaction mixture and start of the solvent circulation through the Dean–Stark trap. Water is collected in the Dean–Stark trap within 0.5 h, and the total reaction time is 2 h. After the reaction completion, the solvent is distilled off in a vacuum. The additive is obtained as a neat substance. The molar ratios of the reactants in the synthesis of the additives are given in Table 1.

The performance of the depressant additives prepared was checked with summer diesel fuel from the Achinsk oil refinery. The DA content was 0.005–1.0 wt %. The diesel fuel used had the following characteristics: congelation point –10°C, cloud point –5°C, density at 20°C 835 kg m^{-3}, viscosity at 20°C 5 $mm^2 s^{-1}$, temperature of 50% distillation 277°C, aniline point 67.5°C, and content of hydrocarbons that formed the complex with urea 6.6 wt %. The latter compounds (*n*-alkanes) consist of the following fractions (wt %): $C_{12–15}$ 45.9, $C_{16–21}$ 48.3, and C_{22} 5.8. The congelation point of DF was determined according to GOST 20287–91 on introduction of depressant additives. The results are listed in Table 1. The congelation point of the diesel fuel containing SA–PEPA amides is given in Table 1 for comparison.

Table 1 shows that amidopolyformaldehyde depressant additives are more effective than SA–PEPA amides. Thus, the additional step of formaldehyde condensation is quite useful. The maximal depression of the congelation point of the diesel fuel at 0.05 wt % content of SA–PEPA amides (run nos. 1, 13) is 6–7°C, and at the same content of amidopolyformaldehyde DAs it reaches 12–16°C (run nos. 16, 7). At 0.5–1.0 wt % content of SA–PEPA amides, the maximal depression of the congelation point is 14–17°C, and at the same content of the suggested additives it reaches 22–23°C. The positive effect at a content of amidopolyformaldehyde additives within 0.1–1.0 wt % is attained in the entire range of molar ratios tested, SA : PEPA : FA = (2.3–3.0) : 1.0 : (0.5–25) [weight ratio (4.5–6.0) : 1.0 : (0.1–4.5)]. At 0.05 wt % content of amidopolyformaldehyde additives, the depressing effect is attained in a narrower range of component ratios: molar ratio SA : PEPA : FA = (2.3–3.0) : 1.0 : (0.5–15) [weight ratio (4.5–6.0) : 1.0 : (0.1–3)]. Apparently, additional step of the formaldehyde condensation increases the molecular weight of depressant additives and improves their hydrophilic–lipophilic balance.

For a series of amidopolyformaldehyde DAs prepared at the molar ratio SA : PEPA = 2.27 : 1.0, we determined the performance with respect to the cloud point of the diesel fuel. The cloud point of DF was determined according to GOST 5066–91 at a content of depressant additives from 0.005 to 1.0 wt %. We found (Table 2) that, at a high content (0.5–1.0 wt %), the additives appreciably increase the could point of DF, and only at a content of 0.01–0.05 wt % they meet the requirements to the cloud point of winter diesel fuels. The whole set of data on the congelation and cloud points allows us to recommend for use in winter DFs the additives prepared in run nos. 4–7 at their content of 0.1 wt %. The additive from run no. 7 can also be recommended at its content of 0.05 wt %.

Like many other additives, amidopolyformaldehyde depressant additives efficiently decrease the congelation point of diesel fuels. However, the depressant additives have a significant drawback: They do not decrease the cloud point of diesel fuels.

Partial dewaxing of oils and intermediates from straw oil production in an electrostatic field of high intensity is free of this drawback. This treatment en-

sures a decrease not only in the congelation point of petroleum products, but also in the cloud point [6–8], due to removal of the highest-melting fraction of solid hydrocarbons. Here we report the experimental data on partial dewaxing of summer diesel fuel from the Sibneft–Omsk Refinery Joint-Stock Company in an electrostatic field with the aim to prepare winter diesel fuel. The physicochemical parameters of the fuel used are given in Table 3.

Dewaxing of diesel fuel was performed in an electrostatic field in the presence of ester depressant additives; their characteristics are given in Table 4 [3–5, 9, 10]. Dewaxing of petroleum products is based on

*** Acid number for additives was determined without considering the solvent.

the effects of electrophoresis, double electrophoresis, dipolophoresis, and dielectrophoresis. The depressant additives were introduced into diesel fuel in amounts of 0.01–1.0 wt %. The mixture of the initial diesel oil and additive was heat-treated at 60–70°C until the additive completely dissolved.

Then the mixture was placed into a bronze cell for electrodewaxing. The cell was a system of coaxial electrodes. To prevent the electric breakdown, the cell bottom was made of a dielectric. The external diameter of the internal electrode was 15 mm, and the internal diameter of the external electrode, 30 mm; the height of both electrodes was 20 mm. The interelectrode spacing was 7.5 mm. The cell was placed in a temperature-controlled glass chamber equipped with a jacket through which kerosene was circulated as a cooling agent. The temperature-controlled cell had a glass lid. The glass chamber and lid had a hermetic grond-glass joint. Cold kerosene with a temperature no higher than –17 to –18°C was fed to the jacket from a Lauda E 100 low-temperature cryostat with a remote supply of the coolant. Double thermostating was used to prevent icing of the glass chamber. For this purpose, the glass chamber was placed into a Freon temperature-controlled air condenser with a temperature from –5 to –10°C. The cell with the petroleum product was cooled to a dewaxing temperature of –15°C. The required temperature inside the glass chamber was maintained with an accuracy of ±1°C and was monitored with a thermometer. The bronze cell was connected to a VS-20-10 rectifier. The additive imparted an electrokinetic potential to crystals of paraffin hydrocarbons formed at the dewaxing temperature. At an electric field intensity of 10000 V cm^{-1}, the paraffin hydrocarbons were separated from the petroleum products, forming a dense deposit on the electrodes, and the partially dewaxed diesel fuel remained in the interelectrode space. The electric treatment time was 60 min.

The efficiency of dewaxing of petroleum products was evaluated by the yield of the dewaxed diesel fuel, by a decrease in the congelation point of the dewaxed diesel fuel (congelation point depression) relative to that of the initial fuel without additive, and by a decrease in the cloud point of the dewaxed diesel fuel (cloud point depression) relative to that of the initial fuel without additive.

Data on the electrodewaxing of diesel fuel, given in Table 5, show that, in the presence of all depressant additives, the summer diesel fuel from the Sibneft–Omsk Refinery Joint-Stock Company is capable of dewaxing in an electric field. An exception is the DA-20EPU additive at its content in the initial DF of 0.5–1.0 wt %. The yield of dewaxed diesel fuel (DDF) as a function of the content of additives passes through a maximum. With an increase in the content of additives in DF, the DDF yield first increases and then, after reaching a maximum, starts to decrease. The latter trend is caused by adsorption saturation of the surface of paraffin crystals with the molecules of the additive and by passing of excess additive into the solution. In the process, the electrokinetic potential of paraffin particles decreases [11].

Table 5. Electrodewaxing of summer diesel fuel in the presence of depressant additives. Dewaxing temperature –15°C, mean electric field intensity 10 kV cm^{-1}, deposition time 1 h; time of cooling of the initial DF with the additive from room temperature to dewaxing temperature 60 min, time of electric treatment 60 min

* Temperature effect of dewaxing.
** (+ –) Deposition of paraffin on both electrodes.
*** Congelation point below the indicated value (is not attained with the available equipment).
**** No deposition of paraffin.

Dewaxing of the initial diesel fuel also occurs without additives. However, deposition of paraffin hydrocarbons occus on both electrodes (double electrophoresis effect). The yield of dewaxed DF is as low as 68.1 wt %. On adding DA-19/9PE and DA-20EPU additives, the paraffin crystals acquire stable positive and negative electrokinetic potential, respectively. The DA-65EPA additive also imparts a negative electrokinetic potential to crystals of paraffin hydrocarbons, but this potential is unstable and is readily lost; at a higher content of the additive, the paraffin crystals pass into the isoelectric state (double electrophoresis).

The DA-62 additive at its high content also imparts a positive electrokinetic potential to paraffin crystals. Irrespective of the existence of any kind of electrokinetic potential of paraffin crystals, introduction of additives increases the yield of the dewaxed diesel fuel. This is apparently due to a decrease in the congelation point of the initial diesel fuel in the presence of additives, i.e., to a decrease in their structural viscosity. Less viscous fuels are more readily separated into the solid and liquid phases in the electric field. The dewaxing of diesel fuel is particularly efficient when a stable electrokinetic potential is combined with the relatively strong depression of the congelation point on introducing a depressant additive. Such a pattern is observed with DA-19/9PE, DA-65EPA, and DA-20EPU additives. A decrease in the cloud point of the diesel fuel on introducing a depressant additive is undesirable for the dewaxing in an electric field. This negative effect is observed with DA-20EPU additive at its content of 0.5–1.0 wt %. In this case, the cloud point of DF decreases virtually to the level of the dewaxing temperature, and the process becomes inefficient because of the absence of the solid phase in the system.

Apparently, to characterize the dewaxing of diesel fuels, by analogy with low-temperature dewaxing of oils in selective solvents, it is appropriate to introduce

the parameter TED (temperature effect of dewaxing), namely, the difference between the dewaxing temperature and the attained cloud point of the dewaxed diesel fuel. With respect to this parameter, dewaxing of the initial diesel fuel is the most efficient in the presence of DA-19/9PE and DA-62. In this case, TED is close to zero, i.e., overcooling of the raw material is not required to attain the preset cloud point. Negative TED values are observed with diesel fuels containing DA-65EPA and DA-20EPU additives, because of relatively low cloud point of DF in the presence of these additives and unstable electrokinetic potential.

Our results show that the dewaxed diesel fuel prepared in the presence of DA-19/9PE additive (Table 5) meets requirements to DZp winter diesel fuel (TU 38.101 889–00) with respect to two parameters: cloud point (required –5°C, actually –15°C) and congelation point (required –25°C, actually –30°C). The limiting filterability temperature for DZp fuel should not exceed –15°C, and, most probably, the dewaxed diesel fuel with a cloud point of –15°C will meet this requirement also. The properties of the dewaxed fuels prepared in the presence of DA-62 additive (Table 5) are also close to those prescribed by the above TU. Only the congelation point slightly exceeds the prescribed level, but it can be readily brought to this level by additional introduction into the dewaxed diesel fuel of any of three effective additives: DA-19/9PE, DA-65EPA, or DA-20EPU. With respect to the combination of DDF yield and quality parameters, it can be recommended to take in dewaxing the DA-19/9PE additive in an amount of 0.1–1.0 wt %, or the DA-62 additive in an amount of 0.05–1.0 wt % with the subsequent introduction of, e.g., DA-19/9PE additive.

CONCLUSIONS

(1) The possibility of dewaxing of diesel fuels in a high-intensity electric field in the presence of depressant additives DA-19/9PE and DA-62 was examined. Under the optimal conditions, it is possible to prepare DZp winter diesel fuel meeting the requirements of TU 38.101 889–00 from summer diesel fuel produced by Sibneft–Omsk Refinery Joint-Stock Company.

(2) Among the suggested procedures for improving low-temperature properties of diesel fuel, the best is dewaxing of diesel fuel in an electric field. The thus treated fuel meets the requirements of TU 38.101 889–00) with respect to both congelation point and cloud point, although the process requires more sophisticated equipment compared to simple introduction of an additive.

Abstract—Polycrystalline samples of double barium borates of the composition $Ba_3R(BO_3)_3$, R = Ho, Yb, Sc, were synthesized by the method of solid-phase reactions. The temperature dependence of the electrical conductivity of the compounds obtained was studied at 200–500°C.

DOI: 10.1134/S1070427207030275

The development of modern fields of technology is impossible without directed synthesis and study of materials possessing a set of necessary physicochemical properties. To materials of this kind belong double borates of rare-earth elements of composition $Ba_3R(BO_3)_3$, whose specific structure results in that they show promise as nonlinear optical, ferroelectric, and pyroelectric materials. Crystals of barium ytterbium borate $Ba_3Yb(BO_3)_3$ have been grown and its crystal structure has been determined [1]. The compound crystallizes in the hexagonal crystal system (space group $P6_3cm$). The double borates $Ba_3R(BO_3)_3$, R = Ho, Yb, Sc, belong to the same structural type [2–4]. Their structure has the form of a 3D framework formed by networks of nine-vertex barium polyhedra that alternate in the (001) plane and are connected by six-vertex rare-earth polyhedra and BO_3 groups (Fig. 1).

A study of the temperature dependence of second optical harmonic generation (SHG) in the borates $Ba_3R(BO_3)_3$ for R = Y and Ho–Lu [5] demonstrated occurrence of reversible phase transitions to the state with axial symmetry. In the low-temperature phase,

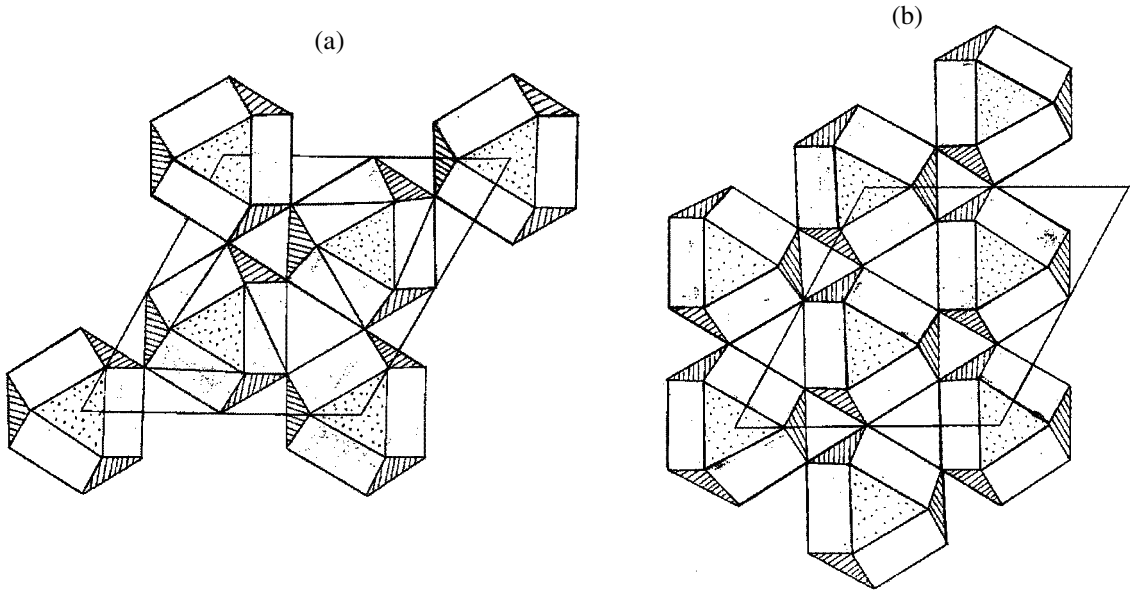

Fig. 1. Projection of the structure of $Ba_3Yb(BO_3)_4$ onto the (001) plane at a height of (a) 0.125 and (b) 0.250.

these compounds show optical nonlinearity, whose magnitude increases as the radius of a rare-earth element becomes smaller. A study by the SHG method makes it possible to relate the double borate $Ba_3Yb(BO_3)_3$ to new optical materials of B grade [6]. The pyroelectric coefficient measured on a single crystal of this compound [7], combined with the occurrence of a first-kind phase transition, indicates that it possesses ferroelectric properties.

The aim of this study was to synthesize and study the conductivity of the double borates $Ba_3R(BO_3)_3$, R = Ho, Yb, Sc.

The following compounds were used as starting reagents: barium carbonate of analytically pure grade; strontium carbonate of ultrapure grde; holmium, ytterbium, and scandium oxides with no less than 99.99% of the main component; and boric acid of chemically pure grade. Rare-earth oxides were preliminarily calcined at 850°C for 5–6 h, and the carbonates, at 400°C. Polycrystalline samples were synthesized by the method of solid-phase reactions in platinum crucibles in air at 600–1000°C. The attainment of equilibrium was monitored by measuring X-ray powder diffraction patterns on DRON-UM1 (CuK_α radiation) and Bruker D-8 Advance (CuK_α radiation, graphite monochromator, 2θ angles 10°–60°, 0.02° step mode) diffractometers.

The temperature dependences of the electrical conductivity σ, dielectric constant ε, and dielectric loss tanδ were studied by the polarization method of Vest and Tallan [8]. Dense ceramic samples in the form of pellets 10 mm in diameter and 1–1.5 mm thick were used for measurements. Electrodes were deposited by firing-in a platinum paste. The measurements were made with an E8-4 ac bridge at a frequency of 10^3 Hz, with an R-5025 capacitor box (determination accuracy ±5%). The dc current was recorded with an E6-13A teraohmmeter at a voltage set to 30–50 mV.

A phase analysis of samples annealed at 1000°C demonstrated that they do not contain the starting oxides of lanthanides and scandium, barium borates, and rare-earth borates. The X-ray diffraction patterns measured on a D-8 Advance diffractometer (Fig. 2) were identified using unit cell parameters of the $Ba_3Yb(BO_3)_3$ single crystal [1].

The temperature dependence of the electrical conductivity of $Ba_3R(BO_3)_3$ was studied in the range 200–500°C (Fig. 3). The experimental values of the activation energy of conductivity, E_a, and electrical conductivity σ for the double borates of this composition are listed in the table. An analysis of the electronic transport numbers t_e at various temperatures demonstrated that the samples have, in the temperature range under study, a mixed ionic-electronic conduction, with predominance of the electronic component. The result obtained is in agreement with the previously determined value of the electrical conductivity

of the $Ba_3Yb(BO_3)_3$ single crystal, 10^{-12} Ω mm^{-1}, measured with an R 4059 dc bridge [7].

CONCLUSIONS

(1) The method of solid-phase reactions was used to produce double borates $Ba_3R(BO_3)_3$, R = Ho, Yb, Sc from the starting oxides, barium carbonate, and boric acid.

(2) An X-ray phase analysis demonstrated that the compounds obtained are isostructural and crystallize in the hexagonal crystal system.

(3) A study of the temperature dependence of the electrical conductivity demonstrated that the double borates show a mixed ionic-electronic conduction, with predominance of the electronic component.

Received April 4, 2006; in final form, September 2006

Abstract—The kinetics of thermal decomposition of magnesite in a furnace in which the gaseous heat-transfer agent is replaced with a solid metallic heat-transfer element was studied.

DOI: 10.1134/S1070427207030287

Decarbonation processes are the most energy-consuming stage of thermal treatment in manufacture of technical products, such as lime, portland cement, caustic magnesite, and caustic dolomite. In the conventional firing technology, raw materials are decomposed in rotary kilns by the energy of flue gases. It has been suggested [1–4] to intensify the thermal decomposition of the material by using a liquid metallic heat-transfer agent, which provides a thermal-shock action on a material being fired. However, this solution involves a number of negative factors, the main of which are the complicated choice and high cost of the liquid metallic heat-transfer agent, intricate apparatus and stringent requirement to this equipment, contamination with the heat-transfer agent of the material being treated, and loss of the heat-transfer agent with a porous material.

All these factors preclude wide industrial use of liquid heat-transfer agents and require that alternative modes of heat treatment by thermal shock should be sought for. A possible solution is replacement of a liquid metallic heat-transfer agent with a solid one. Even though the coefficient of heat transfer from a solid metal to a material being processed is inferior to that in transfer of thermal energy from a molten metal to a solid substance, the former is still sufficiently high and markedly exceeds that for a gaseous heat-transfer agent. This is the principal factor responsible for the acceleration of solid-phase transformations. In addition, the possibility of using induction heating, which is known to provide the highest efficiency in conversion of electric energy into heat, counts in favor of the solid metallic heat-transfer agent. Finally, it is necessary to take into account the fact that replacement of a liquid metallic heat-transfer agent with a solid one shows promise of a less intricate equipment of the firing device.

In view of the aforesaid, it seems appropriate to study thermal decomposition of inorganic substances under conditions of a thermal shock produced when a material to be thermally treated is brought in contact with a solid metal heated to a prescribed temperature.

We consider the process of magnesite decomposition by thermal-shock calcination to magnesium oxide, whose application area includes such branches of chemical industry as technology of building materials, refractories, binders, and materials for electronics and electrical engineering, medicine, and cosmetology [5, 6].

We used magnesite of composition (wt %) SiO_2 1.5, CaO 0.49, MgO 46.14, R_2O_3 1.27, and calcination loss 50.60, from the Savinskoe deposit. The dependence of the degree of decomposition of magnesite on its residence time in the furnace and on the calcination temperature was studied. The starting magnesite was placed, in the form of 3–5-mm lumps, to produce a monolayer on the metallic heat-transfer agent heated to the temperature of the experiment and was kept there for a prescribed time. The temperature range 700–900°C was studied. In parallel, we performed thermal treatment with a gaseous heat-transfer agent, for which purpose a sample was placed in a heated muffle surface. For the calcined material, we evaluated the degree of conversion by measuring the calcination loss (900°C, 1 h).

Figure 1a shows kinetic curves of thermal decomposition of magnesite at various temperatures on a

Kinetic parameters and apparent activation energy at different temperatures and magnesite decomposition conditions

Heat-transfer agent	700°C		800°C		900°C		E, kJ mol^{-1}
	$K \times 10^3$	n	$K \times 10^3$	n	$K \times 10^3$	n	
Solid metallic	25.81	1.89	78.23	2.33	96.93	1.95	22.4
Gaseous	4.28	1.48	6.60	1.58	10.35	1.69	47.1

solid heat-transfer agent, and Fig. 1b, those for calcination by the conventional scheme with a gaseous heat-transfer agent. It can be seen that the decomposition in air and that in the installation with a solid metallic heat-transfer agent show a pronounced difference, which consists in that there is no induction period on the metallic heat-transfer agent. The times in which nearly 100% degree of decomposition is reached are also different. This time was 10 and 2.5 min for, respectively, the gaseous and metallic heat-transfer agents at 700°C, and 5 and 1 min at 900°C.

To find the kinetic parameter of magnesite decarbonation, we processed the experimental data with the use of the Erofeev equation [7]:

$$\alpha = 1 - \exp(-kt^n),$$

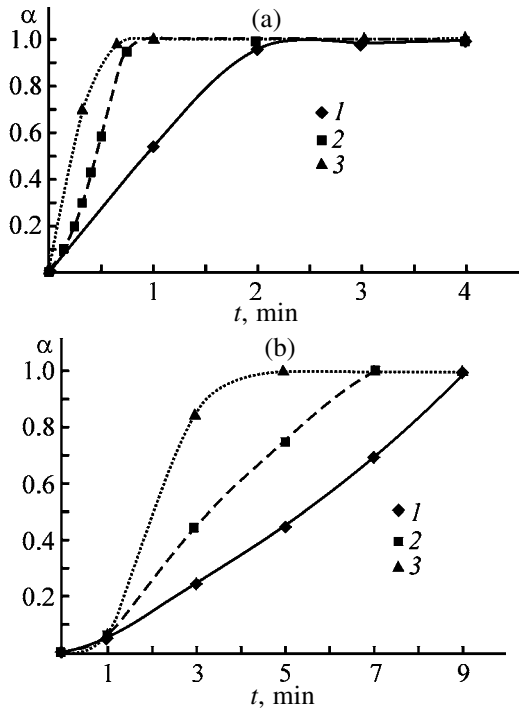

Fig. 1. Degree of magnesite decomposition, α, with (a) solid metallic heat-transfer agent and (b) gaseous heat-transfer agent vs. time t. Temperature, °C: (*1*) 700, (*2*) 800, and (*3*) 900.

where α is the degree of decomposition (fraction units); k, kinetic parameter of the reaction rate; n, parameter dependent on the reaction mechanism, nucleation rate, and nucleus configuration; and t, time elapsed from the beginning of the reaction (s).

Comparison of values of the kinetic parameter k for reactions carried out in different conditions is hindered by the necessity for taking into account the variation of both k and n. Sakovich [8] suggested to use the reduced reaction rate constant related to the constants k and n by $K = nk^{1/n}$, with K having the dimension of t^{-1}, which corresponds to the dimension of the rate constant of a monomolecular reaction. The table lists values of the kinetic parameter n, reduced rate constant K (s^{-1}), and apparent activation energy E found in terms of the Arrhenius equation.

The table shows that the reaction rate constant K is higher in calcination of magnesite with a solid metallic heat-transfer agent, compared with the conventional process. This is due to the acceleration of the heat supply to the material from the metallic heat-transfer agent. Simultaneously with an increase in K, we observe a rise in the parameter n, whose value provides information about nucleation processes [9, 10]. In the given case, we can assume that the rise in n is due to an increase in the nucleation rate because of the growing number of defects of the crystal structure, generated by abrupt heating (thermal shock).

Below are presented values of the specific surface area of magnesite calcined at 800°C with a solid metallic heat-transfer agent at different thermal treatment times:

Calcination time, s	15	40	90
Degree of $MgCO_3$ decomposition	0.15	0.70	1.00
Specific surface area, m^2 g^{-1}	10	30	95

The specific surface area increases with the exposure time, and thermal decomposition under thermal-shock conditions gives a product with a highly developed specific surface area, which is rather im-

portant for use of MgO as a component of binders and fillers.

The data obtained indicate that it is worthwhile to replace the gaseous heat-transfer agent with a solid metallic one and to develop furnace apparatus with a solid metallic heat-transfer agent for calcination of magnesite and other carbonates.

CONCLUSIONS

(1) It was found that the time of thermal decomposition of magnesite becomes considerably shorter (by a factor of 5–7) in the case of calcination in a furnace with a solid metallic heat-transfer agent, compared with thermal treatment in the gas phase.

(2) Kinetic parameters of $MgCO_3$ decomposition under the conditions studied were determined. It was found that the rate constant K varies from 25.8×10^{-3} to 96.9×10^{-3} s^{-1} and the activation energy is 22.4 kJ mol^{-1}.

(3) It was experimentally demonstrated that thermal decomposition of magnesite under thermal-shock conditions yields magnesium oxide with a highly developed specific surface area, up to 95 $m^2 g^{-1}$.

Abstract—Crystallization of an X-type zeolite from concentrated solutions of sodium aluminate (Al_2O_3 90–330 g l^{-1}) and silicate (SiO_2 110–180 g l^{-1}) was studied.

DOI: 10.1134/S1070427207030299

Methods for synthesis of powdered X-type zeolites, used to prepare adsorbents for dehydration and purification of various media, have been described in detail [1–6]. In these studies, X-type zeolites were synthesized by mixing solutions of sodium aluminate and silicate, with the concentrations of Al_2O_3 and SiO_2 equal to 70–90 and 80–110 g l^{-1}, respectively. An X-ray-amorphous colloid seed is added to the resulting silica–alumina hydrogel, and the reaction mixture is crystallized at low temperatures (<100°C) in the course of 12–16 h.

It was noted in [1] that an increase in the concentration of crystal-forming solutions should make higher the crystallization rate and dispersity of the forming zeolite crystals and improve its yield per unit reaction volume. However, crystallization of X-type zeolites from sodium aluminate and silicate solutions with concentrations exceeding those mentioned above has not been described in the literature.

This paper concerns crystallization of X-type zeolite from concentrated sodium aluminate and silicate solutions.

EXPERIMENTAL

Silica–alumina hydrogels were prepared by mixing in varied order calculated amounts of solutions of sodium aluminate, silicate, and hydroxide. Sodium aluminate solutions with a concentration of 90–330 g l^{-1} in terms of aluminum oxide and $NaOH/Al_2O_3$ molar ratio of 1.5–2.0 were used as raw materials for preparing silica–alumina hydrogels that can crystallize to give a highly dispersed NaX zeolite. Sodium silicate solutions with a concentration of 110–180 g l^{-1} in terms of silicon oxide and SiO_2/Na_2O molar ratio of 2.6–3.0 served as the silicate component.

The reaction mixtures from which the highly dispersed NaX zeolite was crystallized were prepared using 2.5–3.5 vol % X-ray amorphous colloid seeds preliminarily precipitated and aged (keeping at T = 20–35°C for 4–18 h). The chemical composition of the seeds corresponded to the formula $12.7Na_2O \cdot Al_2O_3 \cdot 12.0SiO_2 \cdot 220H_2O$. The NaX zeolite was crystallized from reaction mixtures of composition $(2.8–3.5)Na_2O \cdot Al_2O_3 \cdot (3.0–5.1)SiO_2 \cdot (75–170)H_2O$.

When studying how the order in which gel-forming solutions and the colloid seed are mixed affects the dispersion composition of the zeolite, the seed was introduced after all the solutions were combined (Table 1, sample nos. 1, 3, 5, 7, 9) or preliminarily, into the sodium silicate solution (Table 1, sample nos. 2, 4, 6, 8, 10). To obtain a chemically homogeneous silica–alumina hydrogel, the gel-forming solutions were mixed under continuous agitation of the reaction mass. The agitation was continued for 10–30 min after the solutions were discharged. The mixtures were crystallized at 98°C in the course of various intervals of time until a phase-pure X-type zeolite was obtained.

The samples synthesized were washed to remove impurities, dried at 150°C for 3 h, and then calcined at 540°C in air for 4 h. The chemical composition of the liquid and solid phases was determined by methods described in [7]. The phase composition of powder samples was determined by X-ray diffraction analysis on a Philips PW-1800 automated diffractometer. The X-ray diffraction patterns were identified using the known diffraction data [1].

* Composition of the silica–alumina hydrogel $3.0Na_2O \cdot Al_2O_3 \cdot 3.2SiO_2 \cdot N_{1-5}H_2O$; sample nos. 1 and 2, N_1 = 170; nos. 3 and 4, N_2 = 145; nos. 5 and 6, N_3 = 115; nos. 7 and 8, N_4 = 95; nos. 9 and 10, N_5 = 75.

** According to XPA data, the content of the X-type zeolite is close to 100% in all the samples.

The dispersion composition of the zeolites was determined by sedimentation analysis. The adsorption properties of the samples obtained were evaluated by the adsorption capacity for vapors of water and benzene [8].

Table 1 lists the results of syntheses, which show how the concentration of gel-forming solutions and the order of their mixing with the colloid seed affect the duration of crystallization, yield, and dispersion composition of the X-type zeolite.

The method of sedimentation analysis revealed that, irrespective of the way in which the seed is introduced into the reaction mixture, the size of separate crystals in the high-phase-purity X-type zeolites synthesized is 1–2 μm. At the same time, particles as large as 20–30 μm were found in some samples, which are presumably aggregations of crystals. The number and size of the aggregations formed on introducing the seed into the sodium silicate solution are considerably smaller (Table 1, sample nos. 2, 4, 6, 8, 10) than those obtained when the seed was introduced into the silica–alumina hydrogel formed on mixing the sodium aluminate and silicate solutions (Table 1, sample nos. 1, 3, 5, 7, 9). Presumably, if the seed is introduced in the second way, crystallization centers are uniformly distributed throughout the reaction mass and their aggregation is hindered.

It should be noted that, if concentrated sodium aluminate and silicate solutions (SiO_2 110–140 g l^{-1} and Al_2O_3 250–300 g l^{-1}) are used, the dilution leading to their possible partial decomposition can be eliminated. As a result, the prescribed chemical composition of the reaction mixture is preserved and appearance of foreign crystallization centers, coarsely dispersed particles of aluminum hydroxide, is ruled out. The yield of the crystalline phase of the X-type zeolite is close to 100%. The duration of crystallization is 2–10 h, depending on the concentration of crystal-forming components.

It was found that use of more concentrated solutions leads to inhomogeneity of the reaction mass because of the high viscosity of hydrogels. A mixture of zeolites, composed of faujasite, phillipsite, and hydrosodalite is formed in crystallization of reaction masses of this kind (Table 2).

It was found that, if the seed is introduced into the sodium silicate solution, the synthesis becomes shorter. Presumably, crystallization centers are uniformly distributed throughout the reaction mass, which favors rapid formation and growth of zeolite crystals. It should be noted that, under the synthesis conditions found in this study, the yield of zeolite is 1.6–2.1 times higher, and the duration of crystallization, 2–4 times shorter than those in synthesis with conventional solutions.

The figure presents experimental data on the influence exerted by dilution of a silica–alumina hydrogel of the same chemical composition and by the order of introduction of the X-ray amorphous colloid seed into reaction mixtures on the kinetics of crystallization of highly dispersed NaX zeolite. As the dilution increases, i.e., as the H_2O/Al_2O_3 molar ratio in

Table 2. Effect of the concentration of gel-forming solutions and crystallization conditions on the phase composition of the zeolite

Solution concentration, g l^{-1}		Crystallization time, h	Phase composition of the zeolite, wt %
sodium silicate, SiO_2	sodium aluminate, Al_2O_3

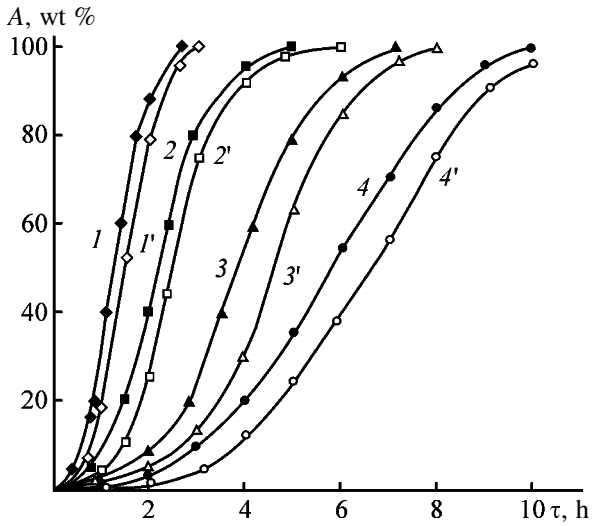
the reaction mixtures grows from 95 to 170, the synthesis duration of the zeolite increases from 2.5–3.0 to 10–12 h.

Introduction of a preliminarily prepared X-ray amorphous colloid seed of the composition $12.7Na_2O \cdot Al_2O_3 \cdot 12.0SiO_2 \cdot 220H_2O$ in an amount of 3.0 vol % into the sodium silicate solution prior to mixing of this solution with a sodium aluminate solution leads to rather strong acceleration of the zeolite crystallization (see figure, curves *1–4*). In parallel experiments with the conventional order of mixing of gel-forming solutions and seed introduction into the already formed silica–alumina hydrogel, synthesis of the X-type zeolite is complete 0.25–2.0 h later.



Effect of the concentration of silica-alumino hydrogel and order of seed introduction on the yield *A* of the crystalline phase of the X-type zeolite. Composition of the silica–alumina hydrogel $3.0Na_2O \cdot Al_2O_3 \cdot 3.2SiO_2 \cdot N_{1-4}H_2O$, where N_1 = 95, N_2 = 115, N_3 = 145, and N_4 = 170; T = 98°C. (τ) Crystallization duration. Seed introduction: (*1–4*) into sodium silicate solution; (*1'–4'*) into precipitated silica–alumina hydrogel.

CONCLUSIONS

(1) A method for synthesis of a high-phase-purity X-type zeolite was developed. This method is based on use of solutions of sodium aluminate, with concentrations of up to 300 g l^{-1} in terms of aluminum oxide, and sodium silicate, with concentrations of up to 140 g l^{-1} in terms of silicon oxide, and on introduction of an X-ray-amorphous seed of the composition $12.7Na_2O \cdot Al_2O_3 \cdot 12.0SiO_2 \cdot 220H_2O$ into the sodium silicate solution before its mixing with the sodium aluminate solution.

(2) Under the synthesis conditions found in the study, the dispersity of the zeolite and its yield per unit volume of the reaction mass increase by a factor of 1.6–2.1 and the crystallization time decreases by a factor of 2–4.

BRIEF COMMUNICATIONS

Calculation of Coefficients of the Temperature Dependence of Density of Inorganic Molecular Liquids

I. B. Sladkov and M. A. Shmakova

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received December 19, 2006

Abstract—A procedure is developed for estimating the temperature dependence of the liquid density on the basis of a minimum set of input data.

DOI: 10.1134/S1070427207030305

The majority of molecular compounds under normal conditions exist in the liquid state. While a quite extensive information on the liquid density is available for organic compounds [1], such data for inorganic molecular liquids are rather limited, especially as far as the temperature dependence of the liquid density is concerned. Here we report a theoretical method combining such advantages as the minimal set of input data and high reliability of the prediction of the liquid density at various temperatures.

Within the temperature range limited by the melting and boiling points, the density of molecular liquids is sufficiently well described by interpolation polynomial (1) [2]:

$$\rho = a - bT. \quad (1)$$

Let us demonstrate that, with lacking published data, parameters a and b of Eq. (1) can be estimated using the Mathias equation for the temperatures below the boiling point [2]:

$$\rho = 2\rho_{cr}(2 - T/T_{cr}), \quad (2)$$

where ρ_{cr} and T_{cr} are the critical density and critical temperature, respectively.

Equation (2) can be rearranged to the form of Eq. (3):

$$\rho = 4\rho_{cr} - (2\rho_{cr}/T_{cr})T. \quad (3)$$

Comparison of Eqs. (1) and (3) yields

$$a = 4\rho_{cr}, \quad b = 2\rho_{cr}/T_{cr}. \quad (4)$$

In this study, the calculation of the coefficients of Eq. (1) taking into account relations (4), followed by the estimation of the density, was performed by using three calculation procedures differing in the input data.

Procedure no. 1. Input data: experimental critical point parameters, temperature T_{cr} and volume V_{cr} ($cm^3\ mol^{-1}$) related to the critical density ($g\ cm^{-3}$) as $V_{cr} = M/\rho_{cr}$. Since the critical point parameters are not readily available, it is advisable to replace them by more accessible boiling point parameters. As a result, we obtain two more calculation procedures.

Procedure no. 2. Input data: T_{cr} and V_{cr} calculated from the boiling point parameters by the relationships including the determining criterion of the thermodynamic similarity ψ [2]:

$$T_{cr} = T_b + 0.89T_b^{0.2\psi + 0.92}, \quad (5)$$

$$V_{cr} = T_b(1.067\psi + 2.69), \quad (6)$$

$$\psi = 0.1\ln T_b - 0.122\ln V_b + 0.006, \quad (7)$$

where T_b is the boiling point (K) and V_b is the molar volume of the liquid at its boiling point ($cm^3\ mol^{-1}$).

Procedure no. 3. Input data: T_{cr} and V_{cr} calculated taking into account the determining criterion of the thermodynamic similarity f [3]:

$$T_{cr} = T_b/(0.667 - 0.055f^{0.5}), \quad (8)$$

$$V_{cr} = V_b(0.05f + 2.69), \quad (9)$$

$$V_b = (-6.2f + 31.2)\prod^{0.94}, \quad (10)$$

$$f = \ln T_b - 1.1\ln\prod - 4, \quad (11)$$

where $\prod$ is the parachor ($J^{1/4}\ cm^{5/2}\ mol^{-1}$) determined using the additive method [2].

Table 1. Error in calculating liquid density of $TiCl_4$ at various temperatures

T, K	ρ_{exp}, g cm^{-3} [2]	Error x, %, at indicated a, g cm^{-3}, and b, g K cm^{-3}, for different calculation procedures					
		a	$b \times 10^3$	a	$b \times 10^3$	a	$b \times 10^3$
		2.258	1.77	2.249	1.76	2.265	1.71
249	1.796	1.2		0.8		1.7	
281	1.746	0.9		0.5		1.4	
313	1.694	0.6		0.3		1.2

377	1.583	0.5		0.2		1.2	
	Mean:	0.8		0.4		1.3	

As seen, for the set of equations (8)–(11), the only input parameter is the boiling point.

We performed calculations for 50 substances with input data taken from [2]. Among them are hydrides B_2H_6, NH_3, and N_2H_4; fluorides PF_3, MoF_6, UF_6, PtF_6, PuF_6, and ReF_6; chlorides CCl_4, $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, BCl_3, PCl_3, $AsCl_3$, $BiCl_3$, $SbCl_3$, and HCl; bromides BBr_3, $SnBr_4$, $GeBr_4$, PBr_3, and $TiBr_4$; iodides BI_3, SiI_4, and SnI_4; mixed halides CCl_3F, CCl_2F_2, $CClF_3$, PCl_2F, $PClF_2$, $PBrF_2$, PBr_2F, $SiBr_2Cl_2$, and $SiBrCl_3$; hydrohalides $CHClF_2$, $SiHCl_3$, and $SiHBr_3$; oxyhalides PCl_3O, PBr_3O, SCl_2O, WCl_4O, VCl_3O, and ClO_3F; and oxides SO_2, RuO_4, and OsO_4. This set of substances includes variously polar compounds, among them such strongly polar compounds as SO_2, HCl, NH_3, etc.

Table 2. Error in calculating the liquid density from melting point to boiling point

Substance	Error Δ, %, with indicated calculation procedures		
	1	2	3
B_2H_6	0.9	2.0	3.2
NH_3	2.3	1.9	3.4
ReF_6	0.4	0.5	2.0
$TiCl_4$	0.8	0.4	1.3
$GeBr_4$	1.3	0.3	0.1
SiI_4	0.5	0.1	0.7
PCl_3O	0.7	0.3	2.5
WCl_4O	1.1	0.9	0.4
$SiBr_2Cl_2$	1.1	1.1	2.0
$SiHCl_3$	2.0	1.9	1.6
SO_2	0.1	0.7	0.6
RuO_4	0.3	0.8	1.7

For each compound, the density was estimated at five temperatures between melting and boiling points. For each temperature, the relative error of determination x (%) was determined as

$$\rho = 100\ (\rho^{calc} - \rho^{exp})/\rho^{exp}.$$

Then the relative error was averaged in the absolute values over the entire temperature range to obtain Δ (%). Data on x and δ are listed in Tables 1 and 2 for several compounds. The accuracy of different calculation procedures was characterized by the mean error σ:

$$\delta = \Sigma\Delta/N,$$

where N is the number of substances.

The resulting error σ, which is the average value over the whole set of 50 substances, is given in Table 3 for different calculation procedures.

Table 3 shows that, for any of the calculation procedures, the mean absolute error δ is within 2%. The lowest δ (0.8%) was obtained for calculation procedure no. 2, in which the critical parameters T_{cr} and V_{cr} were estimated by Eqs. (5)–(7). It should be pointed out that the accuracy of calculation procedure

Table 3. Comparison of different procedures for determination of the liquid density (accuracy and input data used)

Calculation procedure no.	Input data	Error δ, %
1	T_{cr}, V_{cr}	1.4
2	T_b, V_b	0.8
3	T_b	1.9

no. 2 appears to be even slightly better than that of procedure no. 1 employing the experimental critical parameters, which can be attributed to mutual compensation of the errors arising from estimating critical parameters from the boiling point parameters using the approximate relationships.

Calculation procedure no. 3, in which the critical parameters are estimated from the only experimental characteristic, the boiling point, also provides a quite satisfactory accuracy in predicting the liquid density (δ <2%). A significant advantage of this procedure is not only in that it employs the only input parameter, but also that it provides a prediction of the liquid density with absolutely lacking experimental data on the density of an investigated substance.

CONCLUSION

A method for estimating the temperature dependence of the liquid density of inorganic molecular compounds is developed, combining a satisfactory precision with the minimal set of easily accessible input data.

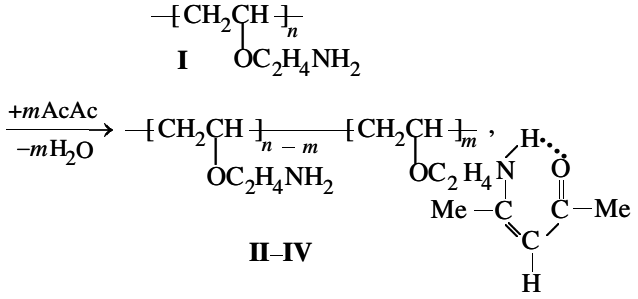
Abstract—Polyvinyloxyalkylamines with the content of modified units from 25 to 75% were synthesized by condensation of poly(monoethanolamine vinyl ether). Their suitability as modifying agents in dressing of copper–zinc sulfide ores was examined.

DOI: 10.1134/S1070427207030317

It is well known that the homopolymer and copolymers of monoethanolamine vinyl ether are efficient reagents for flotation of polymetallic ores [1]. Various low-molecular-weight enaminones are modifying agents in flotation of Pb–Zn and Pb–Cr–Zn ores [2, 3].

We expected that introduction of units containing enaminone fragments into the chain of poly(monoethanolamine vinyl ether) would enhance its flotation characteristics.

The compounds were synthesized by condensation of poly(monoethanolamine vinyl ether) (**I**) with various amounts of acetylacetone. Copolymers **II**–**IV** of monoethanolamine vinyl ether with (*Z*)-4-[2-(vinyloxy)ethyl]amino-3-penten-2-one with the content of the latter of approximately 25, 50, and 75%, respectively, were prepared. The yield of **II**–**IV** was 92–94%.



II–**IV**, n = 6–10; **II**, $m = 0.25n$; **III**, $m = 0.5n$; **IV**, $m = 0.75n$.

In the ^{1}H NMR spectrum of copolymer **III** (Bruker DPX-400 spectrometer operating at 400 MHz, solvent $CDCl_3$, 26°C, internal reference hexamethyldisiloxane), along with multiplets in the range 1.7–3.8 ppm belonging to the CH_2CH and NCH_2CH_2O groups, there are singlets with chemical shifts of 1.94, 1.98, 4.99, and 10.93 ppm assigned to protons of the enaminone fragment: $C{=}CCH_3$, $O{=}CCH_3$, C=CH, and NH, respectively. These signals (with the integral intensity corresponding to the theoretical intensity) suggest that the enaminone fragment exists in the form of only one of possible tautomers. A comparison of the chemical shifts of these protons with published data for the same protons in enaminones synthesized from acetylacetone and primary amines [4, 5] suggests that in the resulting compounds the enaminone fragment has the *cis,cis* configuration.

The flotation activity of **II**–**IV** was studied on the Cu–Zn ores of the Karabash pyrites deposit.

Under industrial conditions, the collective-selective scheme is used for the ore dressing. According to this scheme, first only copper and lead sulfides are recovered, with the depression of sphalerite and pyrite. Zinc sulfide is extracted from the tails. The resulting Cu–Pb concentrate is separated by flotation of copper minerals.

Copolymers **II**–**IV** were tested in a laboratory flotation machine of the mechanical type with a 1-l chamber.

An optimization of the conditions of flotation of

the copper–zinc–pyrite ore with copolymers **II**–**IV** showed that recovery of copper and zinc into the foamed product increases in comparison with the base run by 4.01 and 1.63%, respectively, for copolymer **II**; by 4.88 and 1.93%, respectively, for copolymer **III**; and by 4.19 and 1.72%, respectively, for copolymer **IV**. In all the cases, the expenditures of the copolymers were 4 g per ton of the ore. In addition, introduction of copolymers into the process allowed the expenditure of potassium butylxanthate to be decreased from 60 to 50 g per ton of the ore.

In selection of the collective copper–zinc concentrate, the recovery of copper and zinc by the base procedure was 57.78 and 27.40%, respectively. With the copolymers, the recovery of these minerals was 60.54 and 26.91 (copolymer **II**), 68.11 and 20.59 (copolymer **III**), and 69.65 and 17.15% (copolymer **IV**), respectively.

General procedure for synthesis of copolymers of monoethanolamine vinyl ether and (*Z*)-4-[2-vinyloxy)ethyl]amino-3-penten-2-one (II–IV). To a solution of poly(monoethanolamine vinyl ether) (**I**) (number-average molecular weight 710) in 100 ml of ethanol, acetylacetone was added at such a rate that the temperature of the reaction mixture did not exceed 30°C. After addition of the whole amount of acetylacetone, the reaction mixture was kept for 6 h at room temperature and poured into 900 ml of petroleum ether. The precipitated oil was separated and dried to constant weight at a pressure of 2 mm Hg and a temperature of 30°C.

Synthesis of copolymer II. From 69.7 g (0.8 mol) of poly(monoethanolamine vinyl ether) (**I**) and 20.0 g (0.2 mol) of acetylacetone, 81.1 g (94%) of copolymer **II** was obtained in the form of a light brown viscous resin.

Found (%): C 60.07, H 10.02, N 14.12.
$C_{42}H_{84}N_8O_{10}$.
Calculated (%): C 58.58, H 9.83, N 13.01.

IR spectrum (thin film), cm^{-1}: 1518, 1643 (N–C=C–C=O), 3000–3450 (NH, NH_2).

Synthesis of copolymer III. From 69.7 g (0.8 mol) of poly(monoethanolamine vinyl ether) (**I**) and 40.0 g (0.4 mol) of acetylacetone, 96.2 g (94%) of copolymer **III** was obtained in the form of a light brown viscous resin.

Found (%): C 61.87, H 9.96, N 11.31.
$C_{52}H_{96}N_8O_{12}$.
Calculated (%): C 61.91, H 9.44, N 10.93.

IR spectrum (thin film), cm^{-1}: 1527, 1645 (N–C=C–C=O), 3000–3450 (NH, NH_2).

Synthesis of copolymer IV. From 69.7 g (0.8 mol) of poly(monoethanolamine vinyl ether) (**I**) and 60.0 g (0.6 mol) of acetylacetone, 109.4 g (92%) of copolymer **IV** was obtained in the form of a light brown viscous resin.

Found (%): C 63.78, H 9.49, N 9.18.
$C_{62}H_{108}N_8O_{14}$.
Calculated (%): C 62.60, H 9.15, N 9.42.

IR spectrum (thin film), cm^{-1}: 1522, 1640 (N–C=C–C=O), 3000–3450 (NH, NH_2).

CONCLUSIONS

(1) Addition of a copolymer prepared by modification of poly(monoethanolamine vinyl ether) with acetylacetone in the stage of collective flotation of copper–zinc–pyrite ore in the amount of 4 g per ton of ore increases the recovery of copper and zinc into the foamed product in comparison with the base procedure by 4.01–4.88 and 1.63–1.93%, respectively.

(2) In selection of collective copper–zinc concentrate, the copolymers obtained increase the copper recovery in comparison with the base procedure by 2.76–11.87%.

Abstract—Synthesis of *N*-glycosylamines derived from *D*-glucose and *D*-galactose (glycoconjugates of aniline derivatives and of *d*-pseudoephedrine and cytisine alkaloids) was studied with the aim to develop new pharmaceuticals.

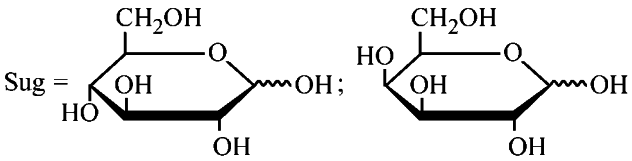
DOI: 10.1134/S1070427207030329

N-Glycosylamines find growing use for preparing natural glycopeptides, their analogs, and glycoconjugates used for various biological studies. *N*-Glycosylamines, the reaction products of carbohydrates with alkyl- and arylamines, attract attention of chemists, biochemists, and biologists. *N*-Glycosylamines can also be used for preparing new pharmaceuticals [2].

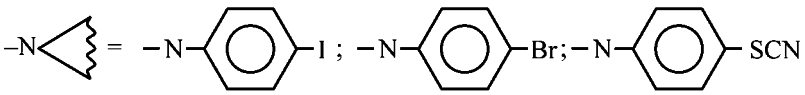
It is known than aniline is an antipyretic. However, it is too toxic to be used as a pharmaceutical. Introduction of various substituents into the benzene ring or the amino groups yields compounds with a wide range of pharmacological properties. Halogenation increases the lipophilicity of pharmaceuticals and facilitates their penetration through biomembranes [2]. For example, *p*-thiocyanatoaniline is a strong insecticide [3], and *p*-bromoaniline is a precursor for preparing Fenazepam, which is a tranquilizer with hypnotic and anticonvulsant effect [4].

N-Glycosylamines were prepared by condensation of *p*-substituted anilines and *D*-glucose (**1, 3, 5**) or *D*-galactose (**2, 4, 6**). Their biological activity was studied. The condensation was performed in an alcoholic solution on heating by the procedure described in [5]:

1–6



1, 3, 5 **2, 4, 6**



1, 2 **3, 4** **5, 6**

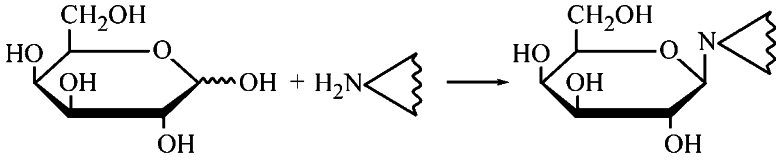
N-Glycosylamines **1**–**6** are white crystalline compounds readily soluble in water, ethanol, and DMF.

The presence of the band at 891 ± 7 cm^{-1} in the IR spectra of compounds **1**–**6** suggests the β-confor-

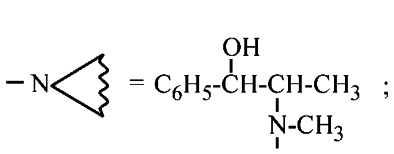
mation at the anomeric center. The bands in the range 1010–1090 cm^{-1} are assigned to the pyranose form of the glycoside residue. The bands in the range 2130–2160 cm^{-1} in the IR spectrum of compound **5** are due to the –S–C≡N group. The C–Hal and C–N stretching bands of compounds **1**–**4** are observed in the ranges 500–700 and 1280–1330 cm^{-1}, respectively.

New biologically active compounds can be prepared by functionalization of monosaccharide with phramacophore groups and physiologically active alkaloid fragments. In addition, it is known that introduction of carbohydrate residues into the structure of biologically active molecules increases their solubility in water, decreases their toxicity, and increases their target transport and penetrability into a cell.

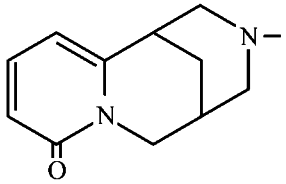
To prepare biologically active compounds and to increase the solubility and decrease the toxicity of alkaloid derivatives, we used commercial *D*-galactose as a substituent at the nitrogen atom. Condensation of *D*-galactose with an alkaloid, *d*-pseudoephedrine or cytisine, in a small volume of ethanol containing catalytic amounts of acetic acid yields *N*-galactosylamines **7** and **8**:



7, 8



7



8

Galactosylamines **7** and **8** are white crystalline compounds; their composition and structure were confirmed by elemental analysis and by ^1H NMR and IR spectroscopy. The absence of the band at 844 ± 8 cm^{-1} in the IR spectra of these compounds suggests their β-conformation. According to data of [6], absorption in the range 1120–1170 cm^{-1} is typical for cyclic sugars, and open-chain sugars do not absorb in this range. The strong band of the amide group (N–C=O) of the alkaloid at 1640–1650 cm^{-1} is present, along with bands of the carbohydrate fragment, in the IR spectrum of compound **8**.

The properties of compounds **1**–**8** are presented in the table.

The IR spectra of all the compounds presented in the table are characterized by strong stretching bands of the OH and NH groups in the range 3250–3400 cm^{-1}.

The ^1H NMR spectrum of compound **7** contains the signals of the protons of the alkaloid and carbohydrates moieties. The doublet of the CH_3–C group is observed at 1.14 ppm (J = 5.75 Hz), and the intense singlet of the *N*-methyl group, at 2.53 ppm. The signal of the methine proton of the CH–N group appears in the form of complex multiplet at 2.64–2.85 ppm. The doublet at 4.55 ppm is assigned to the methine proton of the CHO group (J = 3.5 Hz). The doublet of the anomeric proton H(1) of the carbohydrate residue is observed at 4.48 ppm (J = 9.2 Hz), which confirms the β-conformation of the reaction product.

EXPERIMENTAL

The ^1H NMR spectra of solutions in DMF–d_7 were recorded on a Varian XL-100 spectrometer operating at 100 MHz. The IR spectra of the samples in KBr pellets were recorded on an Avatar-320 spectrometer. Melting points were determined on a Boetius apparatus. The reaction course was monitored and the purity of the condensation products was determined by thin-layer chromatography on Sorbfil plates using isopropanol : benzene : ammonia = 10 : 5 : 2 system

Physicochemical constants and elemental analyses of the compounds

as the eluent. The chromatograms were developed with iodine vapor.

Glucosyl-*p*-iodoaniline (1). To a solution of glucose (0.02 mol) in ethanol (20 ml), *p*-iodoaniline (0.02 mol) was added. The mixture was stirred at 50–55°C for 4 h. Excess solvent was removed on a water bath. White crystals that precipitated on slight cooling were filtered off and washed with cold isopropanol. The product was recrystallized from an ethanol: isopropanol (5 : 1) mixture. Galactosyl-*p*-iodoaniline (**2**) was prepared similarly.

Glucosyl-*p*-bromoaniline (3). To a solution of glucose (0.02 mol) in ethanol (20 ml), *p*-bromoaniline (0.02 mol) was added with stirring. The mixture was stirred at 55–60°C for 5 h. Excess solvent was removed on a water bath. White crystals that precipitated on slight cooling were filtered off and washed with cold isopropanol. The product was recrystallized from ethanol. Galactosyl-*p*-bromoaniline was prepared similarly.

Glucosyl-*p*-thiocyanatoaniline (5). To a solution of glucose (0.01 mol) in ethanol (15 ml), *p*-thiocyanatoaniline (0.01 mol) was added. The mixture was stirred at 60–65°C for 6 h. Crystals that precipitated on cooling were filtered off and washed with cold isopropanol. The product was recrystallized from an ethanol : isopropanol (2 : 1) mixture. Galactosyl-*p*-thiocyanatoaniline (**6**) was prepared similarly.

Galactosyl-*d*-pseudoephedrine (7). To a solution of galactose (0.01 mol) in ethanol (15 ml), *d*-pseudoephedrine (0.01 mol) was added. The mixture was stirred at 55–60°C for 24 h in the presence of 1–2 drops of glacial acetic acid. White crystals that precipitated on cooling were washed with cold isopropanol and then with absolute ether. The product was recrystallized from isopropanol.

Galactosylcytisine (8). To a solution of galactose (0.01 mol) in ethanol (15 ml), cytisine (0.01 mol) was added. The mixture was stirred at 55–60°C for 24 h in the presence of 1–2 drops of glacial acetic acid. White crystals that precipitated on cooling were washed with absolute ether. The product was recrystallized from an isopropanol : benzene : ethanol (3 : 2 : 1) mixture.

CONCLUSIONS

(1) The carbohydrates were condensed with biologically active amines (*p*-iodoaniline, *p*-bromoaniline, and *p*-thiocyanatoaniline) and with alkaloids (*d*-pseudoephedrine and cytisine).

(2) The physicochemical constants, compositions, and structures of the condensation products were determined.

OBITUARIES

Konstantin Ivanovich Tikhonov (June 5, 1939–December 24, 2006)

DOI: 10.1134/S1070427207030330

On December 24, 2006, head of the Chair of Technology of Electrochemical Industries of St. Petersburg State Institute of Technology (Technical Univesity), doctor of chemical sciences, Professor Konstantin Ivanovich Tikhonov died of a severe illness at the age of 67. A prominent specialist in theoretical and applied electrochemistry, a man of great intellect and rare modesty untimely passed away.

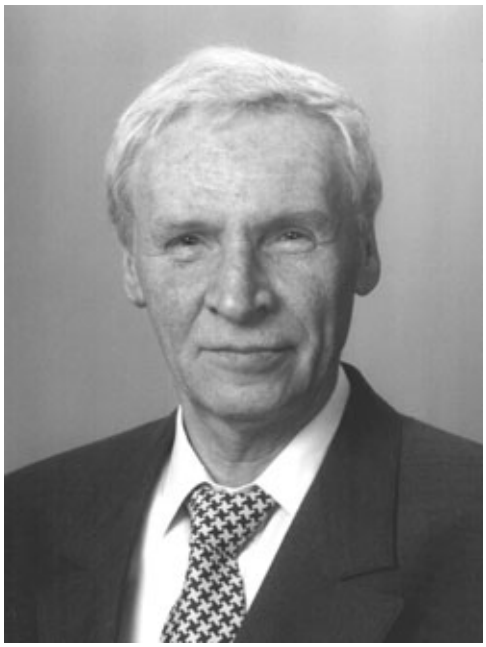
Konstantin Ivanovich Tikhonov was born in Leningrad into a workers' family. His father worked at Elektrosila plant. The life of Konstantin Ivanovich is typical of children born before the Great Patriotic War (World War II). His father took part, in ranks of the Red Army, in bloody battles at Oranienbaum bridgehead, and his mother, together with a small son, was evacuated with the plant to the town of Baranchi in the Urals.

After the war, the family returned to the war-ravaged Leningrad. In 1956, Tikhonov finished school and started to work as a metal craftsman at Elektrosila plant.

In 1957, Tikhonov entered Leningrad industrial technical college. He graduated from the college as a specialist in technology of electrochemical industries and worked as a technologist at one of defense plants of Leningrad. When serving in the army, Tikhonov took part in the construction of Plesetsk space launching site.

In 1963, Tikhonov entered the Leningrad Institute of Technology. Having graduated with brilliant success from this institute (chair of technology of electrochemical industries) and having completed his postgraduate education under the supervision of professors N.P. Fedot'ev and A.L. Rotinyan, Konstantin Ivanovich moved up in the ranks from assistant to head of the chair, which was headed by him from 1986 till the end of his life.

Professor Tikhonov was a prominent electrochemist. The principal works by Tikhonov were devoted to problems of electrochemical kinetics and development of theoretical foundations of technically important processes of electrochemical technology. He was the



first in the country to commence fundamental studies of the kinetics of electrochemical processes of charging–discharge of metals and nonmetallic compounds in aprotic solvents. The results obtained were directly relevant to design of lithium–ion chemical power cells and development of technologies for electrodeposition of metals, including aluminum, from organic solvents. Of considerable importance are Tikhonov's studies of the thermodynamics and kinetics of electrochemical reactions of cathodic reduction and anodic oxidation of solid nonmetallic compounds and metals as applied to the electrochemical behavior of electrodes in chemical power cells with an aprotic solvent.

It is this series of Tikhonov's works that made it possible to substantiate scientifically ways of development of new systems for chemical power cells with a negative alkali metal electrode and an aprotic solvent and principles of choice of active substances and electrolytes for these power cells. He also exhibited scientific interest in environmental problems of applied electrochemistry. His works of recent years were

concerned with specific features of lithium–ion secondary power cells.

He was an excellent lecturer who delivered lectures on basic theoretical disciplines of electrochemistry during many years. Twenty-five persons successfully prepared and defended candidate dissertations under his supervision. Many Tikhonov's former students and postgraduate students are successfully working in the field of electrochemistry or electrochemical technology at plants in Russia and abroad.

Tikhonov was the author of a number of books and brochures on theoretical and applied electrochemistry, the most important of which are *Teoreticheskaya elektrokhimiya* (Theoretical Electrochemistry), Leningrad: Khimiya, 1981, in co-authorship with Rotinyan and I.A. Shoshina and *Elektrokhimicheskie i khimicheskie pokrytiya* (Electrodeposited and Electroless Coatings), Leningrad: Khimiya, 1990, in co-authorship with S.Ya. Grilikhes. He published more than 200 papers and abstracts of papers and received 14 inventor's certificates.

He was an active participant of numerous scientific conferences in various cities of the country and abroad, chairman of the specialized scientific council of St. Petersburg Institute of Technology and member of specialized councils of St. Petersburg State University and Istochnik Research Institute of Batteries, Joint-Stock Company.

Konstantin Ivanovish did much for his coworkers and postgraduate students and gave up a considerable emotional power to them. His lecture courses on theoretical electrochemistry and methods of electrochemical studies are remembered by numerous graduates from the chair of electrochemistry.

Professor Tikhonov lived a brilliant creative life and was far from exhausting his scientific potential of an electrochemist. He was distinguished by a high professional level, creative initiative, scientific principles, and devotion to work. The memory of a prominent scientist and charming and kind man will be forever preserved in the hearts of his colleagues and disciples.

BOOK REVIEWS

Nemtsov, M.S., *Vospominaniya i razmyshleniya (zapiski khimika)* (Recollections and Reflection (Chemist's Memoirs))

St. Petersburg: GIPT, 2006, 96 pp.

DOI: 10.1134/S1070427207030342

One of the known Russian chemists of the XX century, Mark Semenovich Nemtsov (1900–1997), doctor of chemical sciences, professor, and Lenin Prize laureate (1967) wrote his recollections as far back as 1990. These memoirs, published only now on the initiative of a group of his co-workers from VNIIneftekhim Joint-Stock Company, are lively and interestingly written, have in full measure retained their topicality, and make a valuable contribution to the history of domestic chemical technology. The recollections of a scientist, who had lived a long life, reproduce the scientific, cultural, and political life of the country in the XX century. M.S. Nemtsov was actively involved in the development of four original processes successfully implemented in the industry. The author suffered from unsubstantiated repressions and worked for a number of years in detention, at a special laboratory of NKVD (Peoples' Commissariat of Internal Affairs). In his recollections, the coeval with the century pays a considerable attention to meetings with scientists and cultural workers, to presentation of the essence of scientific issues, and to moral and ethical problems encountered in scientific collectives.

The book comprises 28 brief essays, each containing scientist's recollections of events or meetings. In fact, the essays cover Nemtsov's life, from the time of his education at Petrograd commercial school till the end of perestroika in our country (1990). In 1917, the author graduated with a gold medal from the school and, after a break caused by the civil war, entered in 1921 the chemical faculty of the Petrograd Polytechnic Institute. It is noted that the curriculum at the institute was rather broad and based on profound study of the theoretical foundations of physics and chemistry. Among the lecturers were such known scientists as A.F. Ioffe, N.N. Semenov, N.S. Kurnakov, A.A. Baikov, and V.A. Kistyakovskii. Nemtsov very warmly recalls the consultant of his graduation work performed at the laboratory of Neftegaz plant, Prof. A.F. Dobryanskii, a talented scientist with broad interests.

Having successfully defended his graduation thesis in 1928, Nemtsov was assigned, with account of his inclination to research activities, to work at the laboratory of high pressures of the State Institute of Applied Chemistry, headed by Academician V.N. Ipat'ev (1867–1952). Already in 1929, the laboratory was transformed into the independent Institute of High Pressure, where Nemtsov worked till 1941. The author of the essays exceedingly highly appreciates V.N. Ipat'ev as a scientist and head of a large research team. Quite a number of later widely known young chemists worked at the Institute of High Pressure under Ipat'ev's supervision. These include A.A. Vvedenskii, B.N. Dolgov, V.V. Ipat'ev, B.L. Moldavskii, G.A. Razuvaev, and A.V. Frost.

At the beginning of July 1941, Nemtsov was arrested without any charges and sentenced to five years of imprisonment. Till March 1943 he was in prison at Andizhan, Uzbek SSR, and later was transferred to a special chemical laboratory of NKVD in Moscow. Till July 1946, the end of his imprisonment term, Nemtsov developed under laboratory conditions, together with P.G. Sergeev and R.Yu. Udris, disciples of Academician A.E. Chichibabin (1871–1945), a method for synthesis of phenol and acetone by acid decomposition of isopropylbenzene hydroperoxide (cumene method). All of these facts are described in sufficient detail in Nemtsov's recollections. In particular, a large essay is devoted to works and tragic fate of Udris (1899–1949), discoverer of the cumene method.

After being discharged, Nemtsov was sent to Leningrad, to the Lebedev Institute of Synthetic Rubber (VNIISK), to continue his studies of isoprene synthesis. Nemtsov and co-workers found the optimal conditions of isoprene synthesis from butylenes and formaldehyde via a stage of dimethyldioxane formation. This laid foundation of the industrial technology for manufacture of isoprene and isoprene rubber. For the development and industrial implementation of a method for synthesis of a rubber replacing natural caoutchouc, Nemtsov was awarded, in a group of

authors, a Lenin Prize. Nemtsov worked at VNIISK for nearly 17 years, till January 1963, when his laboratory was transferred to VNIIneftekhim institute.

A large essay presents Nemtsov's views concerning the state of the domestic science during the complete stagnation (zastoi) period. The author illustrates by quite a number of examples the degradation of the moral-ethical principles in scientific teams and among the supervising and administrative staff.

The supplement to *Vospominaniya i razmyshleniya* presents Nemtsov's letters to his wife, I.I. Nemtsova, exiled from Leningrad in March 1942 and an afterword written by T.M. Lesteva, one Nemtsov's coworkers, to 105th anniversary of the scientist's death.

The recollections and reflection by Mark Semenovich Nemtsov, a prominent scientist, are of interest for an exceedingly wide audience of readers and their publication is very timely.

BOOK REVIEWS

Kazanbaev, L.A., Kozlov, P.A., Kubasov, V.L., and Kolesnikov, A.V., *Gidrometallurgiya tsinka (ochistka rastvorov i elektroliz)* (Hydrometallurgy of Zinc (Solution Purification and Electrolysis))

Moscow: Ruda i Metally, 2006, 176 pp.

DOI: 10.1134/S1070427207030354

The metallurgy of zinc has been developing in the last decade under conditions of degrading quality of the raw materials being processed, growing cost of fuel and electric power, and increasing stringency of environmental requirements. The resulting rise in the production cost requires cardinal improvement of the technologies employed in the zinc subindustry. The book by L.A. Kazanbaev and co-authors discusses two key issues of the hydrometallurgy of zinc: purification of solutions formed in leaching of zinc-containing raw materials (fired zinc concentrates and other kinds of oxidized raw materials) and the theory and practice of solution electrolysis to give commercial zinc and various zinc-based alloys.

The brief introduction (pp. 3–19) presents general evidence concerning the physicochemical and mechanical properties of zinc, fields of its application, and composition of zinc concentrates processed at domestic and foreign plants, and gives the most characteristic results of solution purification to remove impurities prior to electrolysis. A considerable proportion of zinc (30 to 50% of the whole amount of the metal consumed) is expended for zinc-plating of iron. The consumption of zinc steadily grows and its application fields become wider.

The first part of the book (pp. 20–101) analyzes preparation of zinc-containing solutions for electrolysis: purification of the solutions to remove metallic and nonmetallic impurities. The classical flowsheet of this process envisages a stage-by-stage purification by hydrolytic, chemical, and cementation methods. The main attention is given by the authors to the cementation method for solution purification to primarily remove impurities of copper, cadmium, nickel, and cobalt. Zinc serves as a cementing metal. The authors present the theoretical foundations of the cementation purification technique and discuss the kinetics of cementation, sequence of impurity removal, effect of various factors on the cementation, the technology of cementation, and the apparatus used in the process.

The second part of the book (pp. 102–169) contains evidence on electrolysis of sulfate zinc-containing solutions after their purification. It describes cathodic and anodic processes and the effect of impurities of metal ions, chloride and fluoride anions, and organic substances on electrolysis parameters and quality of metallic zinc. The technology of electrolysis, equipment employed, remelting of cathodic zinc, and manufacture of zinc alloys are discussed in detail. All the descriptions of the technological part are mostly based on the experience of operation of Chelyabinsk zinc plant.

The introduction and two other parts of the book are provided with bibliographic lists. In some cases, references to publications could be more specific, with indication of the original works, rather than monographs devoted to metallurgy of zinc. The book by Kazanbaev and co-authors has a production-technological orientation. The way in which theoretical sections explaining the cementation (pp. 28–49) and electrolysis (pp. 103–115) processes are included in the book invites some critical remarks concerning the terminology used. The whole amount of the necessary electrochemical evidence could be presented in a simpler manner in a production-oriented book.

Similarly to other books published by Ruda i Metally Publishing House, the book by Kazanbaev and co-authors is distinguished by high polygraphic level. A success is the inclusion of color photographs forming a photo album of Chelyabinsk zinc plant. It only remains to wish that the publishing house should more widely recruit external referees and scientific editors.

REVIEWS

Solubility of CO_2 and H_2S in Alkanolamine-containing Aqueous Solutions

Yu. A. Anufrikov, G. L. Kuranov, and N. A. Smirnova

St. Petersburg State University, St. Petersburg, Russia

Received February 1, 2007

Abstract—Experimental studies of the solubility of carbon dioxide and hydrogen sulfide in aqueous solutions of alkanolamines, widely used industrial absorbents of acid gases, are reviewed. A comparative analysis of methods employed by various authors is made. The available published data on the solubility of CO_2 and H_2S in solutions of primary, secondary, and tertiary alkanolamines are analyzed. Fundamental aspects of the influence exerted by various additives on the phase behavior of systems constituted by an acid gas, alkanolamine, and water are considered.

DOI: 10.1134/S1070427207040015

Data on phase equilibria in aqueous systems containing alkanolamines and acid gases, such as hydrogen sulfide and carbon dioxide, are primarily required for solving problems associated with purification of industrial gas flows to remove the above-mentioned noxious components. These problems are topical for numerous technological processes. In particular, hydrogen sulfide frequently occurs as accompanying components in oil-and-gas fields. Carbon dioxide is formed as a by-product in many chemical industries. Absorption of these gases is important both economically and ecologically.

After the first patent [1] for use of an aqueous solution of triethanolamine as an absorbent was received, a large number of studies concerned with the solubility of acid gases in aqueous solutions of alkanolamines have been reported. These nitrogen-containing compounds are widely used for absorption of acid gases. Technological schemes of industrial installations for gas purification with alkanolamine solutions and specific features of their application were described in detail in a book by Kohl and Nielsen [2].

The effective absorption of acid gases by alkanolamine solutions is due to the capacity of amine molecules for protonation and chemical interaction with acid gases, which results in that molecular forms of gases are converted into the corresponding ionic forms. The conversion schemes are as follows form.

(1) Formation of hydrocarbonate and hydrosulfide ions:

$$CO_2 + H_2O + R^1R^2R^3N \rightleftarrows HCO_3^- + R^1R^2R^3NH^+,$$

$$H_2S + R^1R^2R^3N \rightleftarrows HS^- + R^1R^2R^3NH^+,$$

where at least one of the substituents R^1, R^2, R^3 is an alkanol radical ($-C_nH_{2n}OH$), whereas the others may be hydrogen atoms or methyl groups.

(2) Formation of carbamates (in the case of CO_2, also primary or secondary amines):

$$CO_2 + 2R^1R^2NH \rightleftarrows R^1R^2NCOO^- + R^1R^2NH_2^+.$$

To choose the optimal conditions of the absorption process, it is primarily necessary to have reliable experimental data on the solubility of acid gases in aqueous solutions of individual or mixed amines in a wide range of temperatures and pressures. Also required is information about the influence exerted on the solubility by various additives dealt with in purification of gas flows on industrial installations.

This review systematizes and analyzes the presently available relevant publications. The first to be considered in detail are experimental techniques used by various authors.

EXPERIMENTAL TECHNIQUES FOR STUDY OF THE SOLUBILITY OF ACID GASES

The list of experimentally determinable parameters providing full information about the liquid–vapor equilibrium in multicomponent systems includes the fol-

lowing: T and p, temperature and pressure, which are the same in both the coexisting phases in the thermodynamic equilibrium; x_i and y_i, mole fractions of the components in the liquid and vapor phases, respectively (i = 1, ..., k, where k is the number of components).

According to the rule of phases, only k variables can be independently varied. One of variables commonly fixed in experiments with the systems under study is temperature, whose constancy is provided by thermostating. What variables are additionally fixed depends on a particular experimental technique. This may be the empirical composition of the system (total amounts of component moles in both phases), composition of the liquid phase, and partial pressure of volatile components in the gas phase. Other parameters are determined in the course of an experiment after equilibrium between the liquid and vapor phases is attained. It is advisable to classify the methods by ways in which the parameters are set and equilibrium is attained.

The most widely employed techniques are the static and circulation methods, as well as the flow method.

Static method. Most of the available data on the solubility in the systems studied have been obtained by the static method [3–15]. The technique consists in that a thermostated system of a prescribed empirical composition is brought in thermodynamic equilibrium and the phase compositions and pressure are directly determined. The measurement procedure used in this method consists in the following. A known amount of an aqueous solution of an amine is placed in the cell, a required amount of carbon dioxide and (or) hydrogen sulfide is introduced, and the system is kept until equilibrium is established, after which values of the following thermodynamic parameters are recorded: equilibrium pressure and mole fractions of components in each of the coexisting phases.

Let us briefly describe specific features of various experimental installations, which make it possible to trace the development of the method from early publications to the present time.

In the study by Jones [3], a stainless steel cylinder placed in a thermostat served as a cell in which equilibrium was established. On one of its sides, the cylinder was equipped with a capillary with a valve for sampling the liquid phase. On its other side, it had a gage. A capillary for sampling the vapor phase was connected to the upper part of the cylinder. A similar cell design was used by Lawson and co-authors [5]. To agitate the contents of the cell, the installation was equipped with an attachment that rocked the cell during an experiment. In the later studies [7–9], the agitation was effected by a rabble placed within the cell and driven by a magnetic activator.

It should be noted that, in the case of H_2S, equilibrium is attained rather rapidly because an amine can be protonated without any solvent (water), with hydrogen sulfide molecules serving as a source of protons. At the same time, the amine cannot be protonated in the case of CO_2 without involvement of water and equilibrium is attained considerably more slowly in systems with CO_2. However, agitation is important in both cases, because it provides dissolution of fine gas bubbles, which could otherwise reside for a long time, e.g., at places where the capillaries are connected to the cell.

If a cell fully made of stainless steel is used, the data obtained in measurements at low pressures may be underestimated because of the adsorption of gases on metallic surfaces. The installation employed in [10] comprised a glass cylinder with stainless steel flanges. Use of this cell variety enables a convenient visual inspection of the state of a system under study and allows measurements at both elevated and low partial pressures of CO_2. Impeller rabbles served to agitate both the liquid and vapor phases, which favored a faster establishment of equilibrium.

In [11], a cell with a variable volume controlled with two pistons was used. The state of a system under study was observed through a sapphire window of the cell. The advantage of this design is in that the pressure within the cell can be varied by changing the cell volume, whereas in the designs described above, the pressure can be raised by introducing an additional amount of gas and lowering the pressure in the course of an experiment is impossible in principle.

The temperature was monitored in early experiments with mercury thermometers, with resistance thermometers widely used for this purpose in present-day studies. The pressure has been for the most part measured with electronic transducers having a rather high precision. In earlier studies, however, the pressure was measured with spring or mercury gages having poorer measurement accuracy.

Solvents are, as a rule, batched by the gravimetric method. In the automated static installation used in [12, 13], solvents were fed into a cell with calibrated piston batchers, which allowed accurate determination of the volume of a liquid placed in the cell. The recalculation in terms of mass is done using density data. The mass of the gas in the cell was found in

many studies by weighing the cylinder from which the gas was introduced, before and after an experiment. Some researchers use special-purpose batching devices of a known volume, with controlled pressure and temperature. The amount of a gas in the cell is calculated in this case using p–V–T data.

In many cases, the composition of the vapor phase was determined by gas chromatography [4, 8] or mass spectrometry [3, 5]. Occasionally, another method has been used to analyze the vapor for the content of H_2S: a vapor sample was absorbed with a 25% solution of methyldiethanolamine and the content of sulfide ions was found by potentiometric titration with a NH_4NO_3 solution with a salt concentration of 0.1 M. The concentration of H_2S in the liquid phase was determined in most cases by adding an excess amount of an acidified iodine solution, followed by back titration with a thiosulfate. In [11], small concentrations of H_2S in the vapor phase were determined using Methylene Blue. In this method, sulfide ions react with paraaminodimethylamine to give Methylene Blue and then the coloration intensity is quantitatively measured with a spectrophotometer calibrated against standard sulfide solutions.

Samples for determining the content of CO_2 in the liquid phase were commonly taken into a NaOH solution, with the gas thereby converted into nonvolatile ionic forms. Further, these forms were precipitated as barium carbonate, which was then titrated with a sulfuric acid solution. In [4], samples for analysis for the content of CO_2 were taken into a vessel containing a weighed amount of sulfuric acid. The CO_2 evolved was collected into a graduated burette for determining the volume of the gas. This method is rather simple in use, but fails to provide good accuracy. In [3], the concentration of CO_2 in the liquid was found by the Knorr method modified by Scott. The method consists in that a sample is acidified with sulfuric acid and then heated. The CO_2 evolved is washed out with nitrogen, dried, and passed through a tube packed with special Caroxite absorbent. The amount of the gas absorbed is found by weighing. If hydrogen sulfide is present, it is removed from the gas flow with an acidified solution of potassium permanganate. In [11], an $AgNO_3$ solution added in a minor excess was used to oxidize H_2S, instead of potassium permanganate. The content of the amine in solution was determined by titrating an aliquot of the liquid phase with sulfuric acid, with Methyl Red as indicator.

There exists an attractive variety of the static method, which does not require any analysis of equilibrium phases. This technique was used in [14, 15] in a study of methyldiethanolamine-containing aqueous solutions of CO_2 and H_2S in the pressure range 100–8000 kPa. These measurements were performed at Prof. Maurer's laboratory at the chair of technical thermodynamics of the University of Kaiserslautern. The initial state of the system in the measuring cell is an aqueous solution of an amine of prescribed composition. In the course of an experiment, a certain amount of a gas is introduced under pressure into the cell and additional portions of an aqueous amine solution are introduced until the system comes to a homogeneous state. After equilibrium is attained, the pressure in the cell is gradually lowered by taking small samples of the liquid until first bubbles of the gas phase appear. The pressure is recorded at this instant of time. In this case, the amount of the gas phase is very small, and, therefore, the composition of the saturated liquid coincides with the general composition of the mixture. The advantages of the method consist in that phase analysis can be avoided, the expenditure of reagents is small, and the measurement accuracy is high.

Circulation method. Another technique widely used for studying the solubility of gases is the circulation method [16–22]. In this method, the saturation of an amine solution with a gas is provided by a circulation pump serving to bubble the gas through the liquid phase. The experimental installation includes a measuring cell equipped with a system for vapor circulation, vapor tank, cell for gas batching, and pressure transducers [17]. A constant temperature is maintained with a thermostat. As in the static method, the amounts of each of the components of the system are fixed; the equilibrium pressure and phase compositions are determined in the course of an experiment. The difference is in that the vapor is circulated and an inert component, nitrogen, is present in the system. At the beginning of an experiment, a weighed amount of a solution of water and of an amine of prescribed composition are placed in the measuring cell. Nitrogen is introduced into the cell (for further control over CO_2 batching) and, after the temperature is equilibrated, the equilibrium pressure, constituted by water and amine vapor pressures and nitrogen pressure, is recorded. Then a portion of CO_2 is introduced into the cell by a special device. The amount of the gas introduced is determined from a change in the pressure in the batching vessel with the use of p–V–T data. The total pressure in the cell is measured and equilibrium is considered to be attained if the pressure remains constant during a long interval of time (say, 30 min). Commonly, this process takes 3–4 h. The equilibrium partial pressure of CO_2 is found as the difference of the total pressure and the equilibrium pressure recorded

before the introduction of CO_2. Further, a new portion of CO_2 is introduced into the cell. This experimental procedure is repeated several times for each solution until a sufficient body of data on the liquid–vapor equilibrium is obtained.

The specific feature of the circulation technique used in [18] is in that a constant gas concentration in the vapor phase serves as an indication that equilibrium is attained. To determine this concentration, small vapor samples were taken so that changes in the composition of the liquid were negligible. A vapor sample was cooled to 283 K in order to condense water and the amine, and the content of CO_2 was determined with an IR analyzer. After the system came to equilibrium (in 2–3 h), both liquid and vapor phases were sampled for analysis.

Flow method. In addition to the static and circulation methods, the flow method [23–26] is occasionally used to study the solubility of gases. The specificity of this technique is in that the partial pressure of the acid gas in the gas flow is set in the course of an experiment and the composition of the liquid solution through which the gas flow is passed changes until the solution comes to equilibrium with the gas. Thus, the quantities set in the experiment are temperature, number of moles of water and an amine in the solution, and partial pressure of the gas (for definiteness, this will be CO_2 in what follows). A typical description of an installation of this kind can be found in [25].

The installation comprised two stainless steel cylinders placed in the vertical position in a water thermostat. The first cylinder, a water saturator, served to feed a gas saturated with a water vapor into the cell. The second cylinder contained the alkanolamine solution under study. A stainless steel pipe was inserted into the upper part of each of the cylinders. A capillary via which a gas flow was passed through the solution ran from this pipe into the cylinder. The flow contained, in addition to an acid gas under study, an inert carrier-gas (helium), which was necessary for providing a sufficient rate of solution saturation and for controlling the concentration of CO_2 by varying the relative amounts of gaseous components delivered into the cell. An accurately calibrated flow regulator served to provide a stable flow of a gas mixture. In the course of an experiment, the content of CO_2 in the input gas flow could be gradually changed using the flow regulator. The gas flow at the cell outlet was cooled to 273 K to remove water, after which the concentration of CO_2 in the gas was determined with an IR analyzer. The analyzer was preliminarily calibrated against a CO_2–N_2 mixture of a known composition. The equality of compositions of the gas mixture at the cell input and output served as an indication that equilibrium was attained between the gas phase and the solution. After these compositions became equal, the partial pressure of CO_2 in the flow at the cell inlet was taken as the equilibrium partial pressure in the cell over the CO_2–amine–water solution. The content of CO_2 in the saturated solution was found analytically. In summary of the description of experimental methods used to study the solubility of gases, distinctive features of each of these methods should be noted. The static method is sufficiently accurate, but requires, in some variants, a considerable expenditure of reagents. The technique enables studies under widely varying conditions. However, it cannot always be used in measurements at low gas concentrations, which is due to a significant contribution from the adsorption of gases of the apparatus surface to the experimental error.

The flow method is simpler in use and involves a smaller expenditure of substances, but its applicability area is limited to low pressures, in contrast to the static method.

The circulation method enables measurements at low and medium pressures. In contrast to the flow method, it does not require a carrier-gas. Compared with the static method, the circulation technique is less accurate at elevated pressures. Nevertheless, each of the techniques has its own advantages in certain cases, and all of them find application in modern research.

EXPERIMENTAL DATA ON TE SOLUBILITY OF ACID GASES

In recent decades, a large body of experimental data on the solubility of acid gases in alkanolamine solutions has been accumulated. The most widely used in the industry are aqueous solutions containing individual amines: monoethanolamine (MEA), diethanolamine (DEA), methyldiethanolamine (MDEA), and "sterically hindered" amines, as well as amine solutions with various modifying additives.

Solutions of Individual Amines

Systems constituted by an acid gas, MEA, and H_2O. Aqueous solutions of monoethanolamine have long been the main absorption system for extraction of CO_2 and H_2S from natural gas. Nowadays, MEA solutions are replaced with more effective mixtures, but still remain preferable absorbents in the case when

gas flows with low content of acid gases are used and these gases are to be removed to the maximum possible extent.

The main advantages of MEA, which predetermine its still wide use, are the following: high reactivity, low cost, and low capacity for absorption of hydrocarbons.

The efficiency of this amine as an absorbent of acid gases is illustrated by Fig. 1, in which the solubility of CO_2 in an aqueous solution of monoethanolamine is compared with the solubility of the same gas in pure water. It can be seen that presence of the amine in the aqueous solution markedly changes the run of the solubility isotherm of the gas. In the case of pure water, the isotherm is a curve along which the pressure strongly increases as the CO_2 concentration grows, beginning at its zero concentration. In an aqueous solution of the amine, two portions can be distinguished in the solubility isotherms of acid gases. While the mole ratio of the gas and the amine remains markedly smaller than unity, the pressure increases only slightly with the gas concentration in the solution, because the amine is protonated and molecular forms of CO_2 are converted into ionic forms. As the equilibrium concentrations of the ionic forms in the solution are reached, the curve abruptly changes its run, because further increase in the gas concentration is not accompanied by chemical transformations. In this region, dissolution occurs via physical absorption.

As disadvantages of MEA should be mentioned the following: instability at elevated temperatures, which results in a corrosion activity with respect to the equipment, especially in the case of mixtures of CO_2 and H_2S; formation of stable carbamates, which leads to a gross energy expenditure in regeneration of the amine; high heat of the reaction with CO_2 and H_2S (30% higher, compared with DEA); comparatively high vapor pressure of MEA, which leads to a considerable loss of the amine via evaporation.

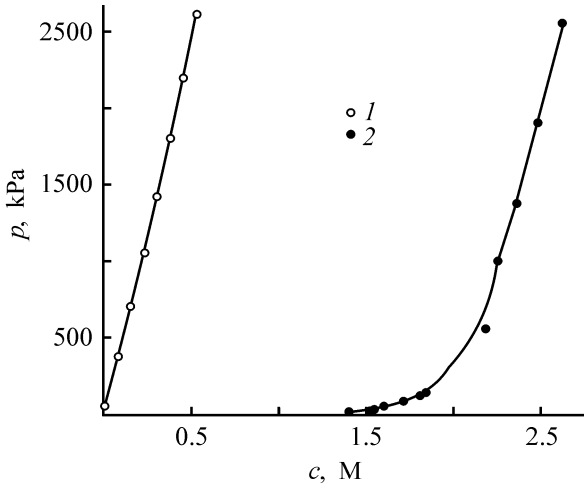

Fig. 1. Comparison of the solubilities of CO_2 in water and in an aqueous solution of MEA at T = 313 K. (c) CO_2 concentration and (p) pressure. (*1*) CO_2–H_2O [27] and (*2*) CO_2–MEA–H_2O [28] (c_{MEA} = 2.5 M).

Table 1 systematizes the available published data on the solubility of CO_2 and H_2S in aqueous solutions of MEA.

Systems constituted by an acid gas, DEA, and H_2O. Together with monoethanolamine, another representative of the same class of compounds, diethanolamine, is widely used in the industry. It retains all the advantages of MEA and, moreover, is thermally stable and, therefore, is not so aggressive with respect to the equipment. In addition, this secondary amine forms less stable carbamates. An additional important specific feature of DEA is its higher absorbing capacity, compared with monoethanolamine. As a disadvantage of DEA should be mentioned the need to use vacuum distillation in regeneration of spent solutions.

Published data on the solubility of acid gases in aqueous solutions of DEA are listed in Table 2.

Systems constituted by an acid gas, MDEA, and H_2O. Methyldiethanolamine found industrial use in the 1950s [47]. Despite the high coast, compared with MEA and DEA, and low rate of the reaction with CO_2, it has a number of specific features, which not only compensate for these disadvantages, but even make the process of gas treatment with MDEA economically more feasible than that with primary and secondary amines.

A most important specific feature of MDEA is its capacity for selective absorption of hydrogen sulfide from its mixture with carbon dioxide [48–50]. The selectivity of absorption is due in the given case to the kinetic factor, specifically, to the higher rate of the reaction of MDEA with H_2S. This is associated with specific features of the mechanism of chemical interaction, already mentioned above. It should be recalled that these two compounds can react directly, without involvement of solvent molecules. As for CO_2, its reaction with MDEA requires an aqueous medium as a source of protons for formation of hydrocarbonate ions.

Apart from the selectivity with respect to H_2S, MDEA has a number of additional advantages over MEA and DEA [48, 50]. This amine is a difficultly volatile compound, which makes it possible to avoid loss of the solvent via evaporation in processing of the gas flow. Use of this solvent is also economically justified in some cases for absorption of CO_2 [50], despite the unfavorable kinetic factor. The enthalpy of the reaction of acid gases with MDEA is sufficiently low [2], and, therefore the regeneration of the amine is considerably less energy-consuming than that in the case of MEA and DEA. The energy saving in re-

generation is also favored by the fact that the MDEA molecule has no hydrogen atoms directly bonded to nitrogen. Thus, the reaction with CO_2 yields no carbamates, whose decomposition requires additional energy expenditure in the case of primary and secondary amines. At the same time, the absorbing capacity of this amine exceeds that of MEA and DEA because of the very weak dissociation of the protonated form of MDEA.

Finally, the very high stability of the MDEA molecule should be noted. It does not decompose even upon strong heating, and, therefore, its corrosiveness with respect to the equipment is considerably lower than that of the other amines.

The available published experimental data on the solubility of acid gases in aqueous solutions of MDEA are summarized in Table 3.

These data were obtained in a wide range of temperatures and pressures. This is due to the practical demand for information about the phase behavior of the systems under consideration in various conditions. Gases are for the most part absorbed in industrial installations in the temperature range 313–333 K. Absorption at lower temperatures is unfeasible from the standpoint of the process kinetics. In addition, the chemical reaction of the gases with the amines is exothermic. Accordingly, there inevitably occurs heating by the heat of the reaction. The temperature range 373–413 K is also of interest for the industry. At these temperatures, amine solutions are regenerated via desorption. At higher temperatures the amines decompose, which leads to corrosion of the equipment. However, in the case of thermally stable amines, such as MDEA, desorption is also performed at temperatures higher than 413 K.

Of interest for development of various semiempirical models of industrial processes involving absorption–desorption of gases are data for other temperatures and, in particular, those for the temperature range 333–373 K. Therefore, there have been numerous reports on studies under these conditions.

The greatest body of experimental data on the solubility of acid gases in aqueous solutions of alkanolamines has been obtained by the research group of Prof. Mather [4, 16, 23, 24, 36, 52–54]. The solubility of CO_2 and H_2S in solutions of mono- and diethanolamine has been studied in detail by Lawson et al. [5]. Systematic data on the solubility of CO_2 and H_2S in aqueous solutions of MDEA under widely different conditions have been obtained in the framework of a joint scientific project of the authors of this review with the research group of Prof. Maurer (University of Kaiserslautern, Germany) [14, 15]. A large body of experimental data was also reported in [3, 6, 29].

Systems containing sterically hindered amines. A number of studies have been concerned with the solubility of acid gases in aqueous solutions of the so-called sterically hindered amines and, in particular, 2-amino-2-ethyl-1,3-prop-anediol (AEPD), triisopropanolamine (TIPA), and 2-amno-2-methyl-1-propanol (AMP). The interest in objects of this kind is due both to their high boiling point and to a low corrosion activity with respect to the equipment. Published data on the solubility of acid gases in solutions of sterically hindered amines are summarized in Table 4.

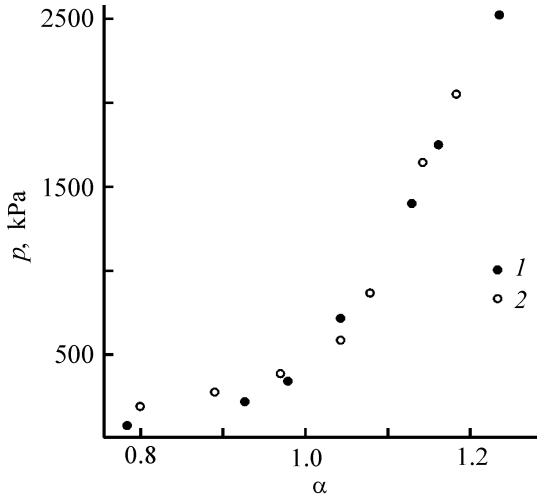

Fig. 2. Isotherms of CO_2 solubility in aqueous solutions of MDEA and TIPA at T = 313 K. (α) Ratio between the numbers of moles of the gas and the amine and (p) pressure; the same for Figs. 5, 6. (*1*) MDEA [14] (m = 2 mol kg^{-1} H_2O) and (*2*) TIPA [20] (m = 2.2 mol kg^{-1} H_2O).

The absorbing capacity of solutions of these amines is rather high. This is illustrated by Fig. 2, in which isotherms of CO_2 solubility in aqueous solutions of MDEA and TIPA are compared.

The data in Fig. 2 refer to a TIPA solution somewhat more concentrated than the MDEA solution. The coincidence of the isotherms under consideration means that the absorbing capacity of the TIPA solution is only slightly lower than that of the MDEA solution. A disadvantage of the sterically hindered amines is that carbamates are formed as in the case of extended primary and secondary amines. However, the carbamates formed with sterically hindered amines are considerably less stable than those formed by MEA and DEA and require a considerably smaller energy expenditure for their decomposition.

Use of Various Additives for Improving the Efficiency of Absorption of Acid Gases

A separate area of research is associated with analysis of the solubility of gases in aqueous solutions of amines in the presence of various compounds. These are the so-called modifying additives, whose role consists in minimizing the effect of factors unfavorable for absorption of gases. For example, it was already mentioned that, although MDEA has a number of advantages over other alkanolamines, its use for absorption of CO_2 is limited in some cases by the kinetic factor [28]. Therefore, it was suggested in 1985 to use aqueous solutions containing MDEA and a primary or secondary amine for treatment of gas flows [55]. The interaction of gases with MEA and DEA is faster than that with MDEA. At the same time, MDEA shows capacity for selective binding of H_2S and forms no stable carbamates (which is an important circumstance in regeneration of the amine). Thus, use of

a mixed solution makes it possible to simultaneously take advantage of the virtues of each of the amines. The solubility of CO_2 and H_2S in aqueous solutions of MDEA with MEA and DEA additives was studied in [56–58].

Addition of primary and secondary amines improves the interaction kinetics, but makes higher the corrosion activity of the solvent. Here, too, the choice of the solvent is aimed to raise the absorption rate without introduction of additional negative factors. Piperazine is frequently used as a modifying additive. A high efficiency of CO_2 absorption by the MDEA solution is achieved in the presence of piperazine. The effect of this compound is due, firstly, to its high capacity for protonation (one molecule of piperazine can add two protons). Secondly, piperazine can form three different carbamate ions with CO_2. Owing to this circumstance, its use in a mixture with MDEA for absorption of CO_2 is economically feasible. Addition of piperazine also has a positive effect in treatment of a mixture of carbon dioxide and hydrogen sulfide with an MDEA solution. In this case, piperazine improves the selectivity of hydrogen sulfide absorption.

The effect of piperazine on the solubility of CO_2 in aqueous solutions of MDEA was studied in [7, 59]. A systematic study of the solubility of the gas in the H_2S–MDEA–H_2O–piperazine system was carried out in [60].

One more way to improve the efficiency of absorption of acid gases is addition of "physical" solvents, i.e., compounds that do not react chemically with gas molecules, but can effectively absorb these molecules via physical absorption. The following positive factors are characteristic of absorbents of this kind: substantial increase in the solubility of the gases because of the larger contribution of the physical absorption and minimum energy expenditure for regeneration of the solvent.

One of the most widely used physical solvents is methanol. In [61], the effect of methanol on the solubility of CO_2 in an aqueous solution of MEA was studied. Henni and Mather [62] examined the effect of methanol on the solubility of CO_2 in an aqueous solution of MDEA and analyzed the solubility of the same gas in a nonaqueous solvent, MDEA–methanol, containing 50% of each of the components. A pronounced improvement of the solubility of CO_2 in the presence of methanol was observed.

Another widely used physical solvent is tetrahydrothiophene-1,1-dioxide (sulfolane). In [63], the solubility of carbon dioxide and hydrogen sulfide in a solution with a patented name Sulfinol, which contained 40 wt % diisopropanolamine (DIPA), 40 wt % sulfolane, and 20 wt % water, was studied. McGregor et al. [52] analyzed the effect of sulfolane on the solubility of CO_2 and H_2S in aqueous solutions of MDEA. In [64], the solubility of CO_2 in an aqueous solution of MDEA, simultaneously containing piperazine and sulfolane, was examined.

One more example of solutions of this kind is ethylene glycol. A study by Song [65] was devoted to analysis of the influence exerted by this additive on the solubility of CO_2 in an aqueous solution of monoethanolamine. It was found experimentally under what conditions addition of ethylene glycol improves the absorption capacity of the MEA solution to the greatest extent. The advantage of ethylene glycol also consists in that the selectivity of absorption of hydrogen sulfide from its mixture with carbon dioxide by an MDEA solution is improved. In this case, the selectivity is not due to the kinetic factor, as in to the case of the piperazine additive. Here, the positive property of ethylene glycol is manifested in that chemical binding of CO_2 by methyldiethanolamine is impossible without participation of water because of the lack of a sufficient number of protons. As for H_2S, it can react with MDEA even in a non-aqueous medium, because it is a source of protons by itself. A systematic study of the effect of ethylene glycol on the solubility of CO_2 and H_2S in aqueous solutions of MDEA was carried out in [66].

Compounds that Hinder Absorption of Acid Gases

The studies mentioned above were concerned with the effect of various compounds intentionally added to an absorbent solution to raise its absorption capacity on the solubility of gases. However, industrial processes include cases in which compounds are formed in an absorbent solution in treatment of gas flows.

An important particular case in which chemical compounds appear in the course of absorption of acid gases is formation of strong electrolytes. For example, the following process occurs in the aqueous solution of MDEA in the presence of sulfur trioxide in the gas flow:

$$SO_3 + H_2O + 2MDEA \rightarrow (MDEAH)_2SO_4$$

In the subsequent regeneration of the amine with an alkali, sodium sulfate is formed as a by-product:

$$(MDEAH)_2SO_4 + 2NaOH \rightarrow 2MDEA + 2H_2O + Na_2SO_4.$$

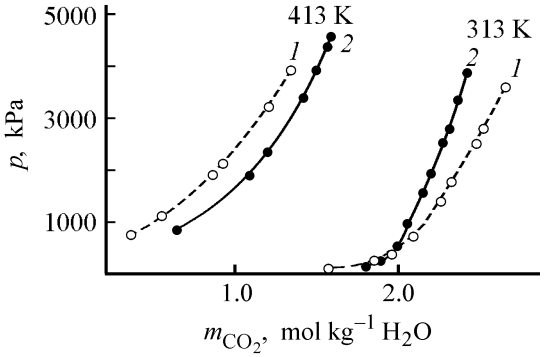

Fig. 3. Effect of sodium sulfate on the solubility of CO_2 in an aqueous solution of MDEA. (*m*) CO_2 concentration and (*p*) pressure. (*1*) CO_2–H_2O–MDEA [14] (m_{MDEA} = 2 mol kg^{-1} H_2O) and (*2*) CO_2–H_2O–MDEA–Na_2SO_4 [67] (m_{MDEA} = 2 mol kg^{-1} H_2O, m_{salt} = 1 mol kg^{-1} H_2O).

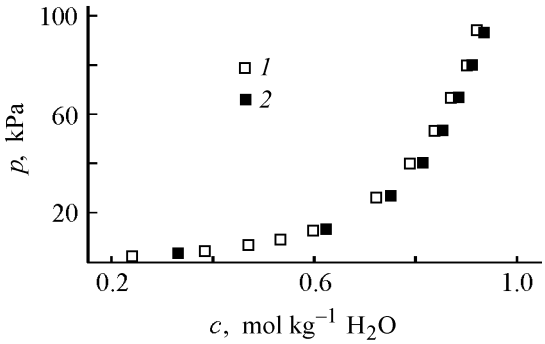

Fig. 4. Comparison of the data on the solubility of H_2S in an aqueous solution of MEA (c_{MEA} = 7 M) at T = 313 K, obtained by different authors. (*c*) H_2S concentration and (*p*) pressure. Data of: (*1*) [28] and (*2*) [29].

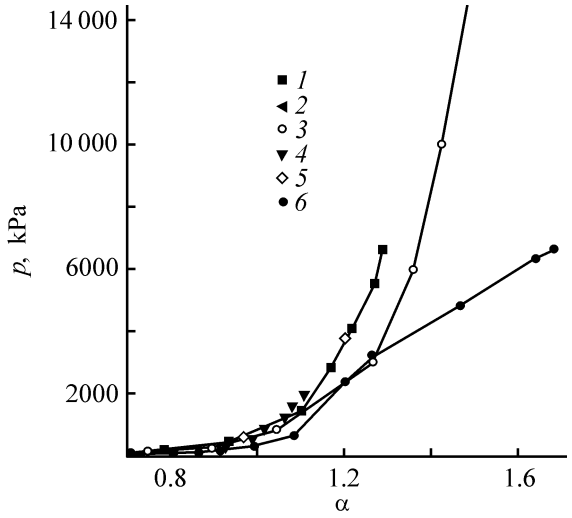

Fig. 5. Comparison of the data on the solubility of the gas in the CO_2–MDEA–H_2O system at T = 313 K, obtained by different authors. Data of: (*1*, *6*) [24], (*2*) [53], (*3*) [54], (*4*) [28], and (*5*) [52]. Amine concentration (mol kg^{-1} H_2O): (*1*) 8.02, (*2*) 4.50, (*3*, *4*) 3.60, and (*5*, *6*) 2.56.

Obtaining quantitative information about the effect of electrolytes on the solubility of gases in MDEA solutions is an important task, because these compounds strongly affect the solubility of acid gases in aqueous solutions of the amine. As demonstrated by the results of [67, 68], this influence is of a rather complicated nature, although electrolytes are not directly involved in chemical reactions. In some cases and, in particular, at elevated temperatures, it is impossible to predict a priori even qualitatively the effect of electrolytes on the solubility of gases in amine solutions.

For example, sodium sulfate commonly exerts a strong salting-out effect on gases, but at low CO_2 concentrations it, by contrast, improves the solubility of the gas (Fig. 3). This example of the seemingly unusual phase behavior of electrolyte-containing systems is not the only one.

A strong difference between the effects of sodium sulfate and methyldiethanolammonium on the solubility of CO_2 and H_2S in an aqueous solution of MDEA has been revealed [69]. The phenomena observed were interpreted with account of the ion sizes, different capacities for solvation, and ion association occurring in the solutions. Understanding of the effects observed furnishes an opportunity to prognosticate the phase behavior of the systems under study, which is important for optimization of industrial processes of absorption of CO_2 and H_2S.

RELIABILITY OF EXPERIMENTAL DATA ON THE SOLUBILITY OF ACID GASES

An important characteristic of any experimental data is their accuracy. For the systems under discussion, the experimental results obtained by different authors are well consistent in many cases. The reliability of data obtained even many decades ago is beyond any doubt and they are in a good agreement with the results of present-day studies. Figure 4 shows as an example the data of Shen [28] and Riegger [29] (obtained in 1992 and 1944, respectively) on the solubility of CO_2 in an aqueous solution of MEA.

The reliability of the data obtained is confirmed by use of modern precision techniques in the related measurements. For example, the solubility of gases in the systems CO_2–MEA–H_2O, CO_2/H_2S–DEA–H_2O, and CO_2/H_2S–MDEA–H_2O has been studied at a high experimental level [12–15, 60, 67, 68].

At the same time, quite a number of examples of strong discrepancies between data of different authors can be given. As can be seen in Fig. 5, a significant

difference is observed for the CO_2–MDEA–H_2O system between the data of Jou [24] and MacGregor [52] for the amine molality of 2.56. At the same time, isotherms reported by these authors and Shen [28] for solutions with different amine concentrations coincide. The solubility isotherm in plots of pressure against the ratio α between the numbers of moles of the gas and the amine should run the higher, the greater the content of the amine in a solution. However, the H_2S pressures obtained by Li and Shen [21] for a solution with a MDEA concentration of 3.56 mol kg^{-1} H_2O lie in Fig. 6 higher than the values obtained by Jou [24] for a MDEA concentration of 8.02 mol kg^{-1} H_2O.

To assess the reliability of published data on the solubility of gases in aqueous solutions of MDEA, it is necessary to subject these data to a thorough analysis. The assessment of the data quality is aided by comparison of results obtained by different authors. However, either there are no published data for comparison or the comparison is difficult because the data to be compared are obtained in different studies under dissimilar conditions.

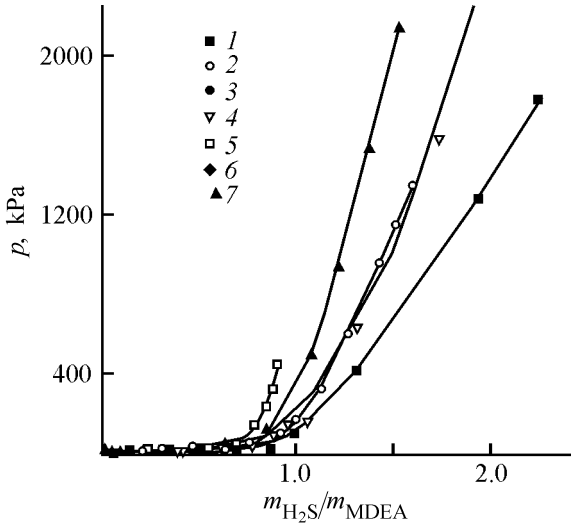

Fig. 6. Comparison of data on the solubility of the gas in the H_2S–MDEA–H_2O system at T = 313 K, obtained by different authors. Data of: (*1*, *3*, *7*) [24], (*2*) [37], (*4*) [52], (*5*) [21], and (*6*) [53]. Amine concentration (mol kg^{-1} H_2O): (*1*) 1.12, (*2*) 2.1 (T = 311 K), (*3*, *4*) 2.56, (*5*) 3.56, (*6*) 4.5, and (*7*) 8.02.

In addition, reports on studies of mixed amine solutions frequently present data that are rather detailed, but inconvenient for a thermodynamic analysis. For example, the solubility of CO_2 and H_2S in mixed solutions of AMP and DEA was studied in [22] at varied relative contents of the amines but constant total content of AMP and DEA, equal to 30 wt %. These data are undoubtedly useful for a particular industrial application, but it would be of real interest from the thermodynamic standpoint to have data obtained at a constant total number of moles of the amines in solution.

The verification of the accuracy of experimental data is well aided by thermodynamic models. However, the potentialities of these models are considerably higher. They enable correction of experimental data and prognostication of properties of systems under conditions for which there are no data. The important role of the models consists in that they relate the behavior of a system to molecular characteristics of its components and to contributions of physical and chemical interactions. The modeling of phase equilibria in aqueous systems containing alkanolamines and acid gases constitutes a separate research area in which a large number of studies have been carried out [70–73].

CONCLUSIONS

Effective and reliable methods for experimental studies of the solubility of acid gases have been developed. The choice of a particular technique is governed by specific conditions of a process being designed. There are sufficiently detailed published data on the solubility of gases in aqueous solutions of both individual amines and amines with additives improving the solubility. However, unreliable experimental results frequently occur, and attention should be given to the choice of a set of experimental data. As for the effect of additives that hinder the dissolution of acid gases, it has been studied in insufficient detail. For example, there are no data of the effect of additions of sodium sulfate and alkanolammonium in systems with primary, secondary, and sterically hindered amines. Information about the effect of other electrolytes cannot be found in the literature at all. Further studies are necessary in this area of research.

Abstract—Interaction of an oxide material with a melt of metals in the combustion mode was studied experimentally. The conditions in which processes of this kind can occur without any increase in the temperature of the environment are possible were analyzed.

DOI: 10.1134/S1070427207040027

Commonly, oxide materials brought in contact with liquid media, including molten metals, perform barrier functions and represent in this case a group of refractory materials [1–3]. Such an application of these materials imposes certain limitations on the nature of their interaction with liquids. Primarily, materials of this kind should, as a rule, provide an invariable chemical composition of the liquid in the course of their contact. In addition, the construction and functional characteristics of these materials should be preserved during an as long a period of time as possible. At the same time, the interest has increased in recent years in materials exhibiting a fundamentally different type of interaction with liquid media and, in particular, with high-temperature melts, which is due to their different functional purposes. Primarily, sacrificial materials should be distinguished in this regard.

The sacrificial materials are used in, e.g., production of inorganic nanotubes [4–7]. In this case, the primary goal of these materials is to create conditions for rolling of nanorolls after the sacrificial material is dissolved in the liquid phase.

Another example of sacrificial materials is constituted by materials for the passive safety system of nuclear reactors [8, 9]. The development of this class of functional materials was a consequence of the need to provide a significantly higher safety level for nuclear power engineering and the resulting design of new safety systems [10]. The sacrificial materials for the passive safety system of nuclear reactors should satisfy a large number of requirements, which are contradictory in some cases. It was shown in [11, 12] that a preferable mode of the interaction between a sacrificial material and a melt is the combustion of the material.

However, the combustion, as a rule, occurs with a strong exothermic effect [13, 14], which leads to a significant heating-up of the environment. In the case of interaction of a sacrificial material with a melt in the core of a nuclear reactor, this contradicts one of the basic fundamental requirements: the melt should be cooled in the course of its interaction with the material. Thus, combustion of a sacrificial material without heating of the melt with which it interacts would be preferable for providing the functionality of the material. Sacrificial materials with this type of interaction with a melt in the core of nuclear reactors have been developed [15–19]. At the same time, it should be noted that this type of combustion can find wider application than use only in safety systems in nuclear power engineering.

Of interest in accordance with the reasons mentioned above is a broader experimental study of processes of this kind, concerned with the interaction of oxide materials with melts of reducing agents having a composition different from that of the melt in the core of nuclear reactors.

EXPERIMENTAL

To study the interaction of an oxide material with a melt, a material based on aluminum and iron(III) oxides was synthesized. For this purpose, the starting components, alumina of G-OO brand [GOST (State Standard) 30558–98] containing no less than 99.5 wt % Al_2O_3 and iron(III) oxide [TU (Technical Specification) 14-15-228–90 with mod. 1] containing no less than 99.2 wt % Fe_2O_3, were mixed in a 40 : 60 wt % ratio, compacted under a pressure of 50 MPa, and calcined at a temperature of 1380°C for 2 h. The sintered material was crushed, ground to pass a sieve with a 0.063 mm mesh (GOST 6613–86), and again sintered at 1380°C. The resulting material had a total porosity of $23 \pm 2\%$.

The heat conductivity of the material, determined in conformity with GOST 12170–85, is approximated by the expression $\lambda(T) = (-16.12-2.119 \times 10^{-2}T)/(1-2.43 \times 10^{-2}T)$ W m^{-1} K^{-1} (interpolation range 500 K $\le T \le$ 1200 K).

The metal melt was prepared by induction melting in a cold crucible [20] on a Rasplav-3 installation. According to the results of an analysis, the melt contained (wt %): Fe 66.8, Cr 18.3, Ni 8.9, Zr 4.5, Ti 0.7, Mn 0.6, Cu 0.1, Mo 0.1, and impurities less than 0.1. It should be noted that the content of zirconium in the melt slightly varied in the course of the experiment because zirconium dioxide formed in oxidation of steel components by oxygen that passed into the melt with components of the oxide material interacting with the melt crystallized on cold members of the experimental setup.

Changes in the dimensions of samples upon their contact with the melt were determined in relation to the melt temperature and duration of contact between the material and the melt with an error not exceeding 0.1 mm.

The temperature was measured with a pyrometer both before the material was brought in contact with the melt and during the interaction, by a procedure described in [21]. Deviations from the average melt temperatures in the experiments varied between the runs, depending on the melt temperature and amount of aerosols released, which were the main sources of error in pyrometric measurements. However, these deviations did not exceed 100°C in all cases.

The microstructure and elemental composition in the interaction zone and separate phases in this region were studied by electron microscopy and microprobe analysis on an ABT-55 electron microscope (Japan) equipped with an Oxford Link AN10000/S85 X-ray fluorescence microanalyzer (Great Britain).

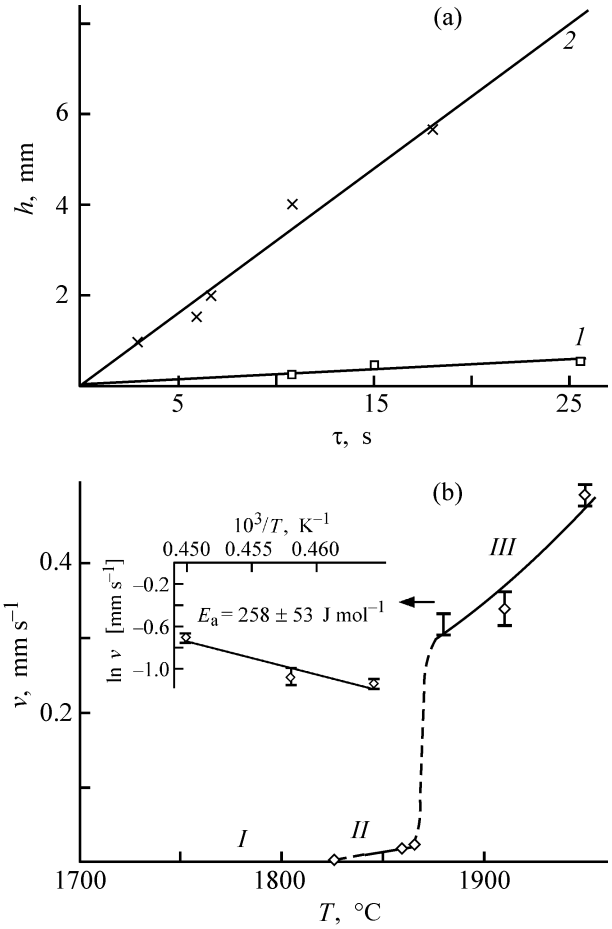

Fig. 1. (a) Distance h traveled by the front of interaction between the oxide material and the melt vs. the residence time τ of the material in the melt and (b) rate v of interaction of the oxide material vs. the melt temperature T. Melt temperature (°C): (*1*) 1865 and (*2*) 1880. (*I*, *II*, *III*) Temperature regions strongly differing in the rate of interaction between the melt and the material; the same for Figs. 2, 3.

Data on the motion of the front of interaction between the material based on aluminum and iron(III) oxides and the metal melt at different temperatures are presented in Fig. 1. The results obtained indicate that, in the entire temperature range studied, the motion velocity of the front is independent, within experimental error, of the time of interaction with the melt. Figure 1 shows as an example the corresponding kinetic data for two melt temperatures. Therefore, the results of the kinetic study can be represented in the case in question as a dependence of the rate of interaction between the metal melt and the oxide material on the melt temperature (Fig. 1b). The kinetic data in Fig. 1b make it possible to distinguish three temperature ranges differing in the nature of the process.

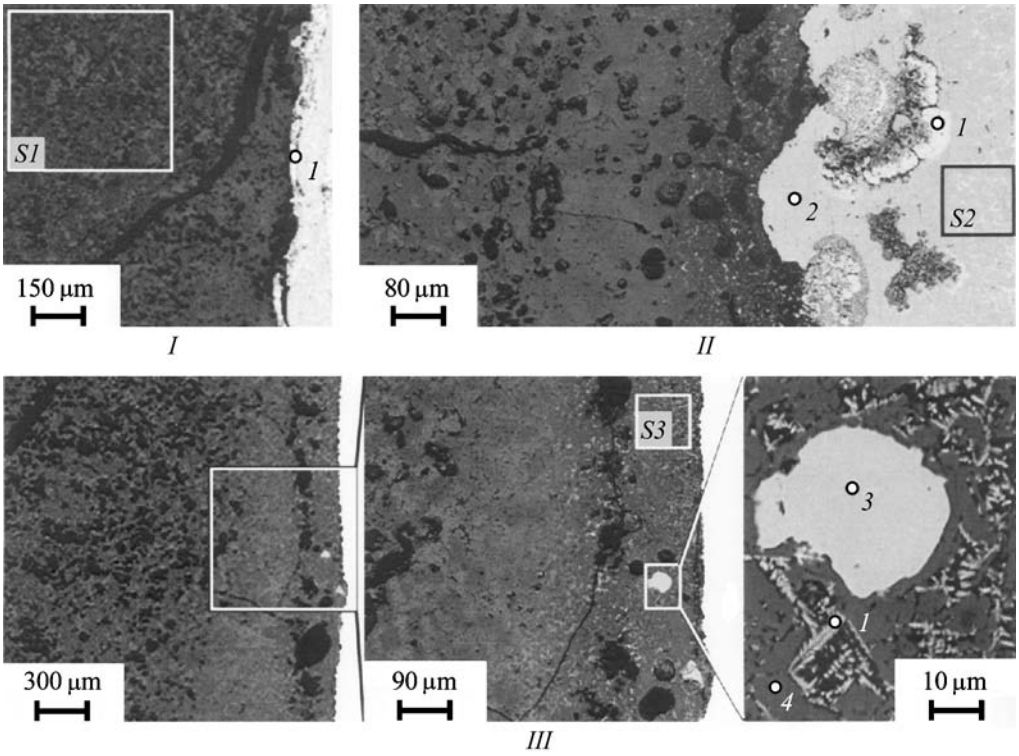

Fig. 2. Microstructure of the front of interaction between the oxide material and the metal melt (cooling from the interaction temperature in the quenching mode).

The first temperature region ($T < 1830$°C) is characterized by absence of any noticeable interaction between the material and the melt (Fig. 1b, region *I*). Presumably, this occurs because a ZrO_2 layer is formed at the interface between the oxide material and the melt, which is confirmed by electron microscopy and microanalysis (Fig. 2a, Table 1; region *I*). This layer is formed via oxidation of zirconium, the most active reducing agent contained in the metal melt, with a simultaneous full or partial reduction of the surface layer of iron(III) oxide and crystallization of the high-melting ZrO_2 at the interface between the sol-

Table 1. Chemical composition of the regions marked in Fig. 2

Region	Composition, wt %											
S1	Fe_2O_3* 61.5							Al_2O_3 38.5				
S2	Fe 67.7		Cr 17.1		Ni 10.3		Zr 4.4		Ti 0.3		Mn 0.2	
S3	Fe 20.0	Al 14.4		Cr 15.6		Zr 10.5		Ti 1.2		Mn 0.7		O** 37.6
1						ZrO_2 100						
2		Fe 74.2				Cr 17.5					Ni 8.2	
3		95.1				4.0					0.9	
4	Fe 17.8		Al 13.5		Cr 31.5		Ti 0.4		Mn 1.3			O** 35.6

* The content of the oxides is calculated using data on the cation ratio on the assumption that iron is in the oxidation state (+3).

** The content of oxygen is found from the mass balance.

id and liquid media. ZrO_2 forms rather high-temperature eutectics both with Al_2O_3 (1900°C) [22] and with Fe_3O_4 (1525°C) [23], the product of partial reduction of Fe_2O_3. Therefore, further interaction of the metal melt with the oxide material, which consists in transport of the oxidizing agent from the oxide material across the barrier layer of ZrO_2 and oxidation of melt components, limited during the time interval considered in the study (up to 27 s) solely by solid-phase processes, is rather slow [24], and just this is manifested in the kinetic curve (Fig. 1b, region *I*). This type of interaction between the material and the melt is confirmed by comparison of the microstructures of samples of the material after their interaction with the melt having temperatures of 1830°C, 1860°C, and more. In the first case, no zirconium dioxide is observed in the material beyond the zirconium dioxide layer formed at the interface between the solid and liquid media (Fig. 2a). At a higher temperature, a rather pronounced change in both the microstructure and composition can be observed at the interface between the sample and the melt (Figs. 2b, 2c; Table 1), which indicates that the liquid phase is present. At a temperature exceeding 1880°C, even metallic inclusions are observed in the material (Fig. 2c; Table 1, region *2*). According to the results of calculation by the software package GEMINI2 with the NUCLEA database of phase diagrams [25], there are no traces of the liquid phase beyond the ZrO_2 layer at a melt temperature of 1830°C exceeding the eutectic temperature in ZrO_2–Al_2O_3–Fe_3O_4(FeO) systems. This is presumably due to the low heat conductivity of both the porous ZrO_2 layer [26] and the material itself. What is more, the heat conductivity of the material decreases in the course of experiments because (i) microcracks are formed in the sample under the action of the temperature drop across the interface between the material and the melt (Fig. 2a) and (ii) the time of contact between the sample and the melt under the experimental conditions is short (27 s), which results in that the material has not enough time to be heated to the eutectic temperature.

In the temperature range 1830°C < T < 1880°C, a minor, but reliably recorded change in the size of a sample of the oxide material is observed upon its interaction with the metal melt (Fig. 1). The motion velocity of the interaction front is about 0.025 mm s^{-1} at a temperature of about 1879°C. A microstructure of the interaction interface, typical of this temperature interval, is shown in Fig. 2b. The type of microstructure of the sample suggests that, in interaction of the material with the metal melt, the boundary region of the oxide material melts and liquids flow into each other, with the process having exhibiting the behavior (Fig. 2b) typical of a slow flow of a less viscous liquid into a more viscous one (effect of "viscous fingers" [27]). Noteworthy is the configuration of the interface between melts based on oxides and those based on metals: drops of the liquids flowing into each other are separated from the main part by narrow necks, which hinders the transport of the reagents and removal of the reaction products and, consequently, restricts the motion velocity of the interaction front (Fig. 1, region *II*). That the existence of narrow necks at the contact between the drops and the main part of the liquid restricts the supply of reagents and the removal of the reaction products can be confirmed by comparison of the data on the composition of the drops and of the bulk of the liquid, connected to the drops via these necks. For example 4.4 wt % Zr is contained in the bulk of the metal melt (Fig. 2b, Table 1, region *S2*), whereas the content of zirconium in the drop itself is virtually zero (Fig. 2b; Table 1, region *2*). Conversely, the drop of molten oxides is enriched in the product of zirconium oxidation, zirconium dioxide (Fig. 2b; Table 1, region *1*), in contrast to the adjacent bulk of the oxides, in which white inclusions composed of zirconium dioxide are observed after crystallization.

It should be noted that, similarly to region *I*, the temperature region *II* under consideration is characterized by microcrack formation, but the microcracks are formed at a large distance from the contact boundary between the sample and the melt. In the case in question, the front of interaction between the material and the melt and the region in which cracks are formed, i.e., the region with a rather brittle behavior of the material, are separated by a zone whose microstructure indicates that the material is sintered on being placed in a high-temperature melt and by a zone in which, as follows from an analysis of its composition (Fig. 2b, Table 1), the solid and liquid phases coexist. The second zone contains oxidation products of certain components of the metal melt (primarily, ZrO_2 and a certain amount of Cr_2O_3).

The temperature region *III* (Fig. 1) is characterized by a constant and comparatively high motion velocity of the front of interaction between the oxide material and the metal melt, which is a distinctive feature of the combustion process [14, 28].

Analysis of the sample microstructure shows that the given case strongly differs from the interaction at lower temperatures, i.e., from the temperature regions *I* and *II* (Fig. 2). This is primarily manifested in that at the interaction front there are no barrier layers,

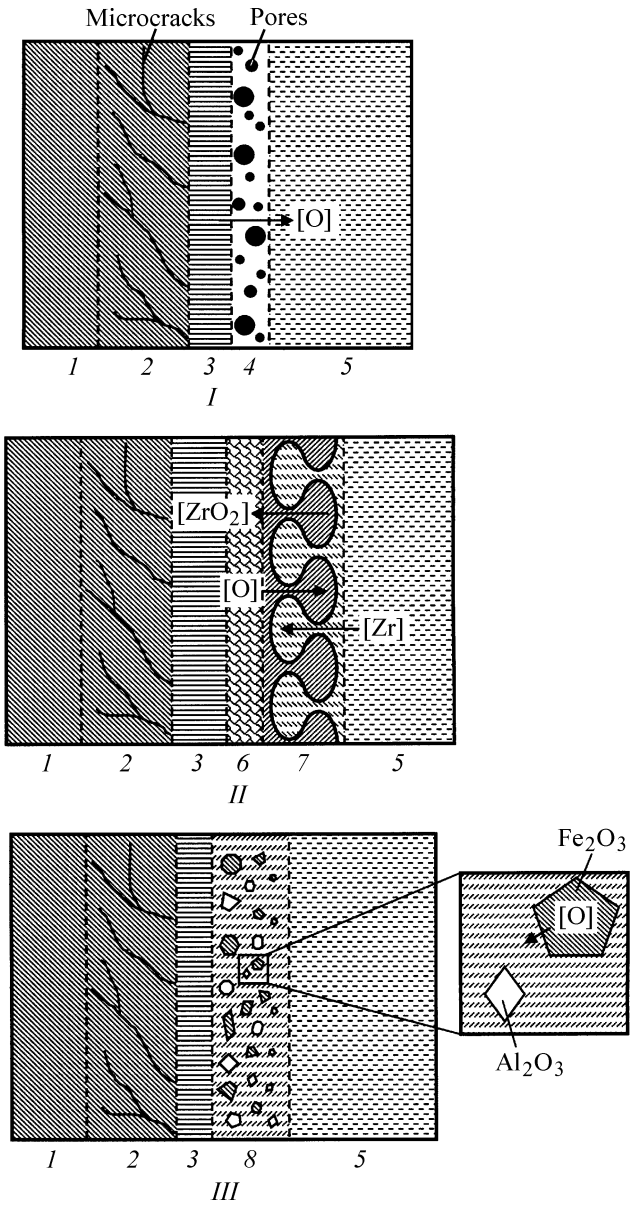

Fig. 3. Scheme of zones distinguished in the microstructure of the samples studied. (*1*) Oxide material without any indications of changes in the initial composition and microstructure; (*2*) zone of an oxide material with microcracks formed under the action of thermal stresses; (*3*) zone of sintering of the oxide material; (*4*) layer of porous ZrO_2; (*5*) metal melt; (*6*) layer of a material partly reacted with the melt components in the temperature range between the solidus and the liquidus of the system; (*7*) zone of mutual flowing-in of the melts of oxides and metals at the interaction front; and (*8*) reaction zone under the conditions of the liquid-phase combustion of the oxide material. The arrows show the motion direction of a component ([O], [ZrO_2], or [Zr]) that limits the interaction between the metal melt and the oxide material.

either solid, as in region *I* (Fig. 2a), or liquid-phase structures of the type of "viscous fingers" characteristic of the temperature region *II* (Fig. 2b). Another important difference is that a new zone appears in the sample near the contact boundary between the sample and the metal melt. This zone is separated from the rest of the material by a porous layer and contains inclusions of metal drops (Fig. 2c, Table 1). Analysis of the composition of this zone suggests that further reduction of Fe_2O_3 to give iron(II) oxide has occurred in this zone. This, in turn, made lower the eutectic temperature of the system [29] and led to a decrease in the viscosity of the oxide melt and, consequently, to an increase in the agitation rate of molten oxides and metals. Thus, there are virtually no significant kinetic hindrance to supply of reagents and removal of products from the interaction front via the liquid phase in the latter case. This, combined with the exothermic nature of the interaction between the melt and the material, creates conditions for the process to occur in the liquid-phase combustion mode [8, 11, 12]. A kinetic analysis of data on the temperature dependence of motion of the front of interaction between the material and the metal melt (Fig. 1b) demonstrated that the effective activation energy of the interaction process is $E_a = 258 \pm 53$ kJ mol^{-1}, i.e., is characteristic of most of the processes limited by diffusion in the solid phase [30]. In particular, the E_a value obtained coincides, within the experimental error, with $E_a = 259$ kJ mol^{-1}, the activation energy of oxygen diffusion in iron oxide [31]. Thus, in the case when there is virtually no diffusion hindrance to the supply of reagents and removal of reaction products in the liquid phase, the motion of the front of interaction between the metal melt and the oxide material is limited by the diffusion of the oxidizing agent (oxygen) in the solid phase (iron oxide) to the reaction zone.

The main processes occurring at the contact boundary between the material and the melt are shown schematically in Fig. 3 for the three temperature regions under consideration. Analysis of the results of the kinetic study, generalized in the form of the corresponding process schemes (Fig. 3), shows that, depending on the dynamic structure of the region of contact between the sample and the liquid phase, formed in the interaction between the material and the melt, widely diverse processes may restrict the motion velocity of the interaction front. This leads to the corresponding abrupt change in the interaction rate of the components.

The processes of oxidation of the main reducing agents, zirconium and chromium, in their interaction with iron oxide

$$2/3Fe_2O_3 + Zr = ZrO_2 + 4/3Fe, \quad (1)$$

$$1/2Fe_2O_3 + Cr = 1/2Cr_2O_3 + Fe, \quad (2)$$

are strongly exothermic with a change in enthalpy $\Delta H(1) = -520.99$ kJ mol^{-1} and $\Delta H(2) = -167.19$ kJ mol^{-1} (here and hereinafter the change in enthalpy is calculated using the IVTANTHERMO database of thermodynamic properties of substances [32]. In this context, it would be expected that the temperature in the system, including that in the melt, should considerably increase. However, the temperature of the metal melt near the oxide sample interacting with the melt remained, as shown by the experimental results, at the same level within the temperature measurement error. This can presumably be accounted for by compensation of the local rise in temperature in the zone of occurrence of redox reactions (1) and (2) by the endothermic effect associated with transfer of aluminum oxide into the melt and heating of the components of the material to the temperature of the metal melt. To analyze this possibility, calculations were carried out, whose results are listed in Table 2. For example, the change in the enthalpy of the system can be represented, with account of the redox reaction (ΔH_{redox}), heating of the components of the material (ΔH_h), and transfer of the components into the melt (ΔH_m), as

$$\Delta H = \Delta H_{redox} + \Delta H_h + \Delta H_m. \quad (3)$$

A calculation of the heat effects, carried out per mole of the metal melt interacting with the material on the assumption that the initial temperature of the material is 25°C and only zirconium contained in the melt is oxidized, gave a value $\Delta H(3) = 0.41$ kJ mol^{-1}. This means that, despite the large exothermic effect of reaction (1), a decrease in the melt temperature by 0.4% from the initial melt temperature would be expected in this case (Table 2). The experiment demonstrated that partial oxidation of chromium is observed together with the oxidation of zirconium (Fig. 2, Table 1). In this connection, the changes in the melt temperature because of the occurrence of oxidation reactions (1) and (2) were calculated. The calculation demonstrated that, although a rise in temperature would be expected because reaction (2) is exothermic, the total effect calculated by expression (3) with account of the heating of the material from 25°C must lead to a significant decrease in the melt temperature by 115.9°C (i.e., by about 6% relative to the initial temperature of the melt). Such a change in temperature is beyond the measurement error and it could be recorded experimentally. The fact that no changes in the melt temperature beyond the measurement error are observed in the experiment (Table 2) is presumably accounted for by only partial oxidation of chromium

Table 2. Change in the temperature of the metal melt in the liquid-phase combustion of oxide materials of various compositions

Composition of the material, wt %		Enthalpy of the reaction of zirconium oxidation by iron oxide, kJ mol^{-1}	Initial temperature of the material	Change in the melt temperature in the reaction zone

74.7	25.3		1900	191.6		

* The initial temperature of the melt was taken to be 1900°C in the calculations.

** The temperature of the melt was measured near the sample of the material, interacting with the melt. No changes in the melt temperature beyond the limits of the measurement error were observed.

in the course of interaction between the melt of metals and the oxide material (Fig. 2, Table 1).

Comparison of the calculated and experimental data shows that, with account of the above remarks, they coincide within the experimental error, which makes it possible to expect that the reliability of prognostication of changes in the temperature of the metal melt in liquid-phase combustion of oxide materials of various compositions, listed in Table 2, should be high.

Thus, the experimental data and the results of calculations show that the material based on aluminum and iron oxides interacts with a Fe–Cr–Ni–Zr melt in a certain temperature range in such a way that the kinetics of this process can be described in terms of the combustion theory [28], similarly to the interaction of the sacrificial material with a melt in the core of a nuclear reactor [8, 11, 12]. A specific feature of the process under consideration is that, despite the rather large exothermic effect of the reaction of oxidation of the melt components in their interaction with separate components of the oxide material, which is characteristic of combustion, the total heat effect of the interaction between the melt and the material is such that it does not lead to any significant increase in the melt temperature, or even makes this temperature lower. Consequently, combustion of substances without any increase in the temperature of the environment can be achieved not only in the interaction of sacrificial materials with a melt in the core of nuclear reactors, but includes a wider variety of chemical processes and can have a broader application field.

CONCLUSIONS

(1) Analysis of kinetic data and a study of the mechanism by which a zirconium-containing metal melt with a material based on aluminum and iron oxides shows that, beginning at a temperature of about 1800°C, the process occurs in a mode that can be described in terms of the combustion theory.

(2) Under certain conditions, the interaction between the oxide material and the metal melt containing active reducing agents can occur by the following scheme. The interaction of a part of components of the material and the melt, which occurs with an exothermic effect in the combustion mode, initiates a conjugated endothermic process, with the result that the total heat effect in the reaction zone may be close to zero or even lead to heat absorption.

Abstract—Behavior of the phase components of residues of carbonyl nickel synthesis in leaching with an iron(III) chloride solution was studied.

DOI: 10.1134/S1070427207040039

The development of hydrometallurgical processes as an alternative to pyrometallurgical processing of sulfide materials has given rise to technologies based on use of iron(III) chloride as a leaching agent [1–3]. The use of this reagent is advantageous in that no sulfur(IV) oxide is released in the process and leaching of high-complex materials can be carried out under normal pressure.

These advantages have favored the development of new kinds of processing of such materials as scrap metal, copper-nickel mattes, and complex nickel and copper sulfide concentrates. A significant progress has been achieved in application of chloride processes in the metallurgy of nickel; these techniques are employed at three plants processing copper-nickel and nickel converter matte and nickel-cobalt sulfide concentrate: Kristiansand (Norway), Sanouville (France), and Niihama (Japan) [1].

Hydrochloride processes developed by the following companies are known in the metallurgy of copper: Cuprus Metallurgical (Cymet), Duval (CLEAR), Minemet Recherche, Henkel, and US Mining Bureau. Also known are processes developed by MINTEK, Cominco, Cuprex, and Great Central Mines, which have passed the stage of large-scale laboratory and industrial tests [2, 3].

In addition to processing of the raw materials mentioned above, the feasibility of application of hydrochloride leaching directly to nickel ores and slags has been considered [4, 5].

In these reports are represented, with varied extent of understanding, mechanisms and decomposition rates of copper and nickel phase components of materials involved in processing. There is virtually no published evidence concerning the behavior of cobalt sulfides in hydrochloride leaching. At the same time, a low, compared with nickel, recovery of cobalt has been mentioned in a number of reports devoted to hydrochloride leaching of copper-nickel sulfide minerals [5–7]. The explanations given were undetailed and had a probabilistic nature.

In the context of the available published data, the possibility and specific features of leaching, with the above-mentioned solutions, of residues of carbonyl nickel synthesis (RCS) were studied. These residues are a sulfide product whose phase composition is represented by a complex multicomponent phase M_9S_8 (M = Co, Ni, Fe, Cu) including the nickel $Ni_{3.18}Fe_{3.36}Cu_{2.25}Co_{0.21}S_8$, cobalt $Co_{4.74}Fe_{2.06}Cu_{1.32} \times Ni_{0.84}S_8$, and copper $Cu_{7.13}Fe_{1.07}Ni_{0.48}Co_{0.35}S_8$ components and chalcosine Cu_2S [8, 9].

EXPERIMENTAL

Experiments were performed with RCS,* which were decarbonylated by keeping under a vacuum at the boiling point of nickel carbonyl (~45°C) and had the following composition (wt %): Ni 3.8, Co 14.0, Cu 33.0, Fe 4.4, S 18.9, and total platinum metals ~0.2. The specific surface area of RCS was 7.5 $m^2 g^{-1}$, which made it possible to exclude fine grinding of the material, the basic procedure providing a satisfactory recovery of valuable components.

* Supplied by Severonikel' combine, Kola Mining-and Smelting Co.

Laboratory studies of the leaching procedure were carried out in a 0.25-l thermostated three-necked vessel equipped with an impeller rabble and reflux. After the required temperature was reached, the starting material was charged into a vessel with an iron(III) chloride solution. All the experiments were performed in the temperature range 298–353 K. After the process was complete, the sludge formed was filtered and the chemical composition of the solid and liquid phases was determined. The weighed portion of RCS was 50 g in all the experiments.

Iron(III) and copper(II) sulfide solutions were prepared from reagents $FeCl_3 \cdot 6H_2O$ and $CuCl_2 \cdot 2H_2O$ of chemically pure grade. The chloride background was created by dissolution of the reactive $CoCl_2 \cdot 6H_2O$ of chemically pure grade, with this procedure guided by the composition of the starting material, in which copper(II) and cobalt(II) predominate.

The content of nickel, copper, cobalt, and iron was found by flame atomic-absorption spectrometry on an AAS-30 instrument (Carl Zeiss, Germany). The content of sulfate ions in solution was determined by a gravimetric method based on precipitation of SO_4^{2-} ions with barium chloride. An X-ray phase analysis was carried out on a DRON-2 diffractometer (Cu_{K_α} radiation). The specific surface area was measured with a Flow Sorb 2300 II analyzer.

The results of experiments on RCS leaching with iron(III) chloride solutions of various concentrations, presented in Fig. 1, indicate that the recovery of all the metals being monitored gradually increases with the concentration of iron(III) ions in the concentration range under study. The maximum recovery is achieved at a $FeCl_3$ concentration of 3.8 M (%): Cu 99.6, Fe 99.5, Ni 83.4, Co 27.3. According to X-ray phase analysis data, the phase composition of the resulting leaching residue is represented by two phases: elementary sulfur and thiospinel M_3S_4 (Fig. 2). The residue has the following elemental composition (wt %): Co 30.2, Ni 2.4, Cu 2.8, Fe 1.5, and S_{tot} 54.9, including S_{elem} 17.0.

As follows from the data obtained, virtually total decomposition of chalcosine and considerable decomposition of pentlandite occur in the course of RCS leaching, with cobalt compounds for the most part remaining in the leaching residue.

The dissolution of chalcosine in $FeCl_3$ solutions was studied in [10–12]. It was found that this process occurs by the inner-diffusion mechanism via formation of covelline and its decomposition to give elementary sulfur, which hinders penetration of the solvent to the surface of the mineral. The activation energy of the process depends on time and temperature and increases, in leaching for 30 min in the temperature range 333–423 K, from 15.3 to 16.9 kJ mol^{-1}.

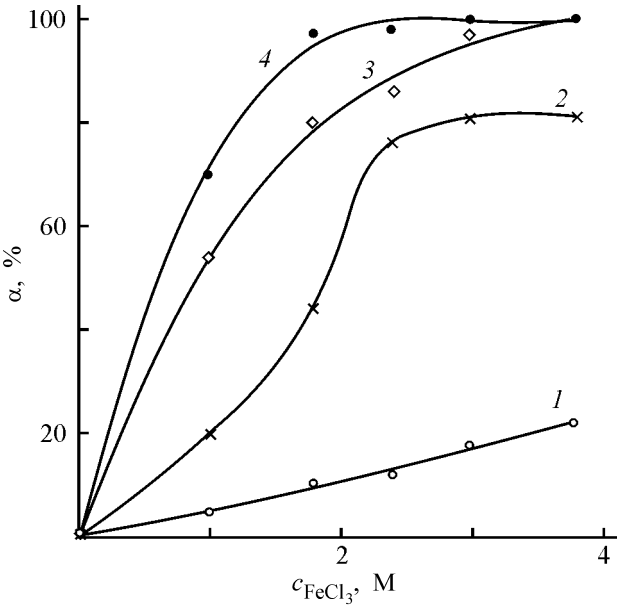

Fig. 1. Degree of recovery, α, of nonferrous metals and iron from RCS vs. $FeCl_3$ c_{FeCl_3}. T = 353 K, τ = 4 h, s : l = 1 : 5. Element being recovered: (*1*) cobalt, (*2*) nickel, (*3*) copper, and (*4*) iron; the same for Fig. 3.

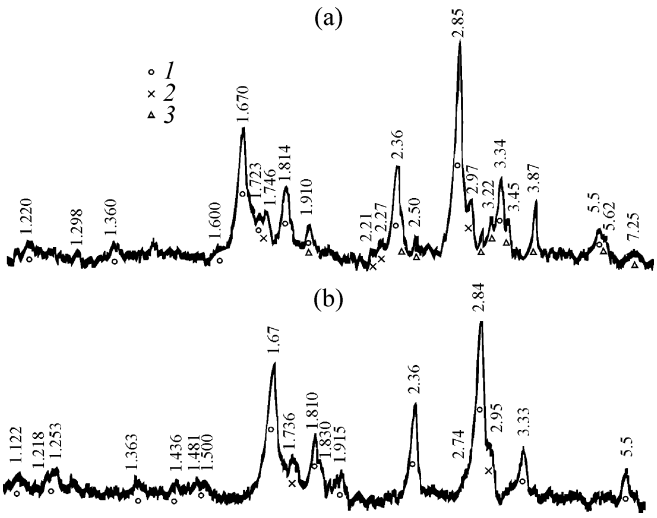

Fig. 2. X-ray diffraction pattern of an RCS leached with a 3.8 M solution of $FeCl_3$. (a) Without removal of sulfur and (b) after removal of sulfur. (*1*) M_3S_4, (*2*) M_9S_8, and (*3*) S.

Mineralogical and X-ray phase analyses revealed that, in leaching of chalcosine contained in RCS with a $FeCl_3$ solution, its complete recrystallization to give covelline CuS occurs in the first 10–15 min from

the beginning of leaching under optimal conditions and then CuS dissolves to give elementary sulfur in the course of 1 h. The high rate of chalcosine decomposition is apparently due to the large specific surface area of the starting material.

The interest manifested by the authors of [4, 5, 13–15] in a study of the decomposition of pentlandite $Ni_{4.5}Fe_{4.5}S_8$ with $FeCl_3$ solutions is associated with the question of whether or not it is advisable to apply hydrochloride leaching directly to nickel ores and complex nickel sulfide concentrates or slags, whose main nickel-containing mineral is pentlandite.

Mineralogical observations [16], data of X-ray photoelectron spectroscopy [13], and thermodynamic calculations [14] demonstrate that leaching-out of iron and nickel from pentlandite in an oxidizing medium yields intermediate compounds, such as violarite $FeNi_2S_4$ and bravoite $(Fe,Ni)S_2$, and phases containing sulfur in a higher oxidation state, e.g., orthorhombic sulfur or sulfate ions:

$$Fe_{4.5}Ni_{4.5}S_{8(s)} = FeNi_2S_{4(s)} + 3.5Fe^{2+}_{(aq)} + 2.5Ni^{2+}_{(aq)} + 4S. \quad (1)$$

However, a study of the decomposition of synthetic pentlandite in hydrochloric acid and $FeCl_3$ solutions [15] demonstrated that, under potentiostatic conditions in an acid medium close to that in leaching with iron(III) chloride (1 M HCl and 0.05 M $FeCl_3$) in the temperature range 293–353 K, pentlandite is oxidized directly to elementary sulfur without formation of any intermediate phases of metal sulfides:

$$Fe_{4.5}Ni_{4.5}S_{8(s)} = 4.5Fe^{2+}_{(aq)} + 4.5Ni^{2+}_{(aq)} + 8S_{(s)}. \quad (2)$$

The fact that no violarite is formed demonstrates that the system departs from equilibrium because of the slow solid-phase diffusion of metal atoms within the sulfur sublattice and the layer of forming sulfur is the factor limiting the reaction rate. The low rates of pentlandite dissolution in acid $FeCl_3$ solutions, obtained in the experiments, led the authors of this study to conclude that the most efficient way is the modern practice of pentlandite conversion into nickel matte, whose main phase is, as mentioned above, heazlewoodite Ni_3S_2. This is so because the dissolution of Ni_3S_2 in hydrochloric solutions of $CuCl_2$ and $FeCl_3$ occurs via formation of millerite NiS, which decomposes to give elementary sulfur at an acceptable rate and a low potential [17, 18].

The authors of [6, 19] found that the decomposition of pentlandite with a $FeCl_3$ solution (about 5 M Cl^-) can be accelerated by mechanical activation of the material, with the surface area of the material increased (to 7 $m^2\ g^{-1}$) and its reactivity enhanced by the deformation of its crystal lattice, caused by grinding. As a result, a 80% recovery of nickel is achieved and a conclusion is made that mechanical activation of the material may become an alternative to matte formation.

Thus, published data demonstrate that the decomposition of the nickel and cobalt components of the pentlandite-like phase of RCS can give a set of thiospinels: $FeNi_2S_4$, Ni_3S_4, $CoNi_2S_4$, $NiCo_2S_4$, Co_3S_4, whose individual identification by X-ray phase analysis is difficult in the case of their joint presence and varied content. Also, phases in leaching residues could not be identified on an MS-46 Cameca microprobe analyzer with a resolution of 0.2 μm because of the decrease in the size of grains of the starting material. The nature of dissolution of cobalt pentlandite under the conditions studied was unambiguously identified, specifically, the Co_3S_4 thiospinel was formed, and, therefore, it was necessary to explain the behavior of pentlandite. For this purpose, additional studies were carried out with natural pentlandite.

As a result, the nature of decomposition of natural pentlandite $Ni_{4.5}Fe_{4.5}S_8$ under conditions similar to those in RCS leaching with $FeCl_3$ solutions with a concentration of 3.8 M in the absence of hydrochloric acid and with 1 M HCl. In this case, an X-ray phase analysis of the residues formed in leaching of pentlandite (content of the main phase ~95%) identified two phases: starting pentlandite and elementary sulfur. The degree of decomposition of pentlandite was determined by the size of its particles. For example, the degree of decomposition of the –100…+50- and –50-mm fractions of the starting material in its leaching was 31.1 and 78.2%, respectively, in agreement with the results reported in [13]. An attempt of additional introduction of chalcosine (Cu_2S) in an amount corresponding to its content in RCS, or of $CuCl_2$ in an amount corresponding to its content in the solution formed in RCS leaching with a $FeCl_3$ solution led to similar results: no intermediate phases were formed. However, the rate and degree of decomposition of pentlandite markedly increases in this case. The synergetic effect of homogeneous catalysts based on halide salts of Cu(II) and Fe(III), whose occurrence is attributed by the authors to the formation of a heteronuclear complex $(CuClFe)Cl^{5-j}_{j-1} \cdot aq$, has been noted previously [20].

Analysis of the aforesaid suggests that leaching of pentlandite with $FeCl_3$ solutions under the condi-

tions studied occurs without formation of intermediate phases (in particular, violarite) and the reaction rate markedly increases as the surface area of the material increases and its crystal lattice is deformed.

The calculations performed demonstrated that the consumption of $FeCl_3$ at a concentration of 3.8 M and a s : l ratio of 1 : 4 in leaching of RCS of the composition specified corresponds to the stoichiometric consumption by the reactions

$$Cu_2S + 3FeCl_3 = CuCl + CuCl_2 + 3FeCl_2 + S, \quad (3)$$

$$M_9S_8 + 18FeCl_3 = 9MCl_2 + 18FeCl_2 + 8S, \quad (4)$$

$$M_9S_8 + 12FeCl_3 = M_3S_4 + 12FeCl_2 + 6MCl_2 + 4S, \quad (5)$$

where M = Ni, Co, Fe, Cu.

An analysis of published data [14, 15], results of additional experiments, and data furnished by chemical and X-ray phase analyses demonstrated that decomposition of the nickel component of the pentlandite-like phase occurs by reaction (4), and that of the cobalt component, by reaction (5).

Consequently, the composition of the phase formed in hydrochloric leaching under the optimal conditions corresponds to the formula Co_3S_4, with nickel, copper, and iron either present in the composition of undecomposed initial phases or contained in an insignificant amount in the thiospinel, isomorphically substituting cobalt.

The results obtained suggest that, in the case of hydrochloride processing of copper-nickel sulfide materials in whose composition cobalt is represented by its own sulfide compounds (e.g., cobalt pentlandite), cobalt remains in leaching products in the form of a Co_3S_4 compound, which is highly stable in chloride media [8].

It is known that presence of free hydrochloric acid in a $FeCl_3$ solution has a catalytic effect on the degree of decomposition of numerous materials [21]. Therefore, the behavior and degree of decomposition of the phase components of RCS at various concentrations of hydrochloric acid in the $FeCl_3$ solution was examined.

The results of these experiments (Fig. 3) demonstrated that, at an HCl concentration of 1–2 M and a $FeCl_3$ concentration lowered nearly twofold, the degree of copper and nickel recovery increases by 20 and 10%, respectively. In all probability, the process occurs with, first, the sulfides reacting with hydrochloric acid:

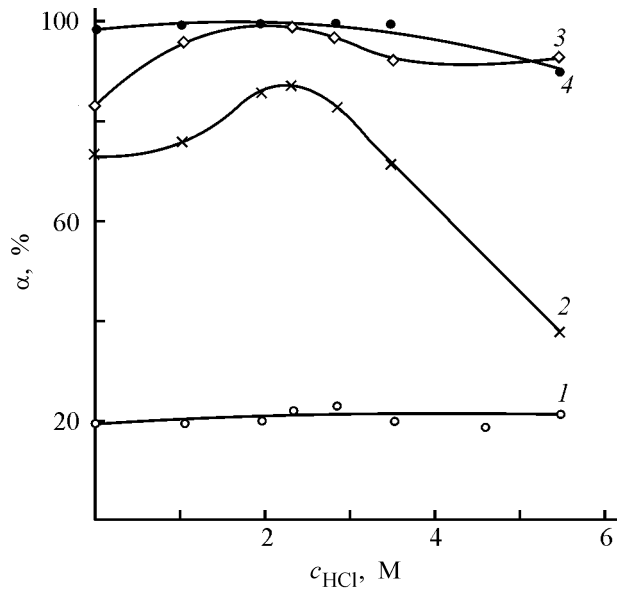

Fig. 3. Degree of recovery, α, of nonferrous metals and iron from RCS vs. the concentration of hydrochloric acid. c_{FeCl_3} = 2 M, T = 353 K, τ = 4 h, s : l = 1 : 5.

$$Cu_2S + 2HCl = 2CuCl + H_2S, \quad (6)$$

$$M_9S_8 + 18HCl = 9MCl_2 + 8H_2S + H_2, \quad (7)$$

$$M_9S_8 + 12HCl = 6MCl_2 + M_3S_4 + 4H_2S + 2H_2, \quad (8)$$

and then reaction with $FeCl_3$ proceeding in the solution bulk:

$$H_2S + 2FeCl_3 = 2FeCl_2 + S + 2HCl. \quad (9)$$

Reaction (9) proceeds to a rather full extent, because a chemical analysis demonstrated that the content of total sulfur in the reaction products is equal to its content in the starting material in the $FeCl_3$ and HCl concentration ranges studied.

Raising the HCl concentration to more than 2 M leads to a decrease in the degree of copper and nickel recovery into solution. This is apparently due to reverse precipitation of copper sulfide by the evolving hydrogen sulfide in the first case, and to formation of Ni_3S_4 and Co_3S_4 phases poorly soluble in chloride media, in the second case. This conclusion is confirmed by the X-ray diffraction pattern of the leaching residues obtained, which is identical to that shown in Fig. 2.

Thus, RCS leaching with a 2.0–2.3 M $FeCl_3$ solution in the presence of 1–2 M HCl at s : l = 1 : 4 and temperature of 80°C can provide in 4 h a degree of copper, nickel, and iron recovery into solution equal

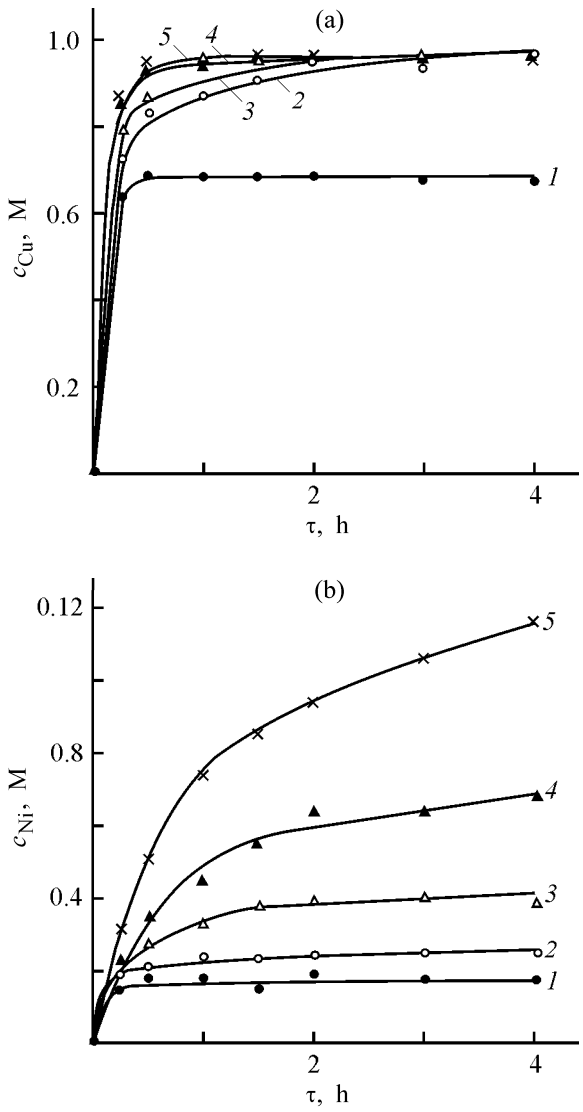

Fig. 4. Kinetic curves of (a) copper and (b) nickel leaching-out. c_{FeCl_3} = 2 M, c_{HCl} = 2 M, s : l = 1 : 5. (c_{Cu}, c_{Ni}) Concentration of an ion being leached-out and (τ) time. Temperature (K): (*1*) 298, (*2*) 323, (*3*) 333, (*4*) 343, and (*5*) 353.

to 99.6, 84.5, and 99.1%, respectively. Cobalt is concentrated in the solid phase in the form of Co_3S_4. As a result, solutions of the following composition are obtained (M): Cu 1.0, Ni 0.1, Fe 2.0, and Co 0.1.

The effect of temperature on the copper leaching in the temperature range 298–353 K at $FeCl_3$ and HCl concentrations of 2 M is illustrated by Fig. 4a. An increase in the degree of chalcosine dissolution is observed as the temperature is raised from 298 to 323 K. At above 323 K and copper concentration in solution of about 1 M, chalcosine virtually completely decomposes in 45–120 min.

An analysis of the experimental data demonstrated that, in the temperature range studied, the dependences obtained can be adequately described by the Erofeev–Kolmogorov equation, derived for describing the kinetics of topochemical processes:

$$\alpha = 1 - e^{-k\tau^n},$$

where α is the fraction of the reacted substance; τ, reaction time; and *k* and *n*, coefficients; coefficient *n* can serve as a criterion of departure of the leaching process from a first-order-reaction behavior.

The thus obtained value of coefficient *n* is 0.1–0.2 for chalcosine.

Raising the temperature in the range 298–353 at $FeCl_3$ and HCl concentrations of 2 M leads to an increase in the degree of pentlandite dissolution (Fig. 4b), with the value of *n*, obtained in analysis of the experimental data in terms of Erofeev–Kolmogorov equation, equal to 0.6.

Thus, it was found on the basis of the experimental data obtained that RCS can be leached with $FeCl_3$ solutions containing hydrochloric acid in two modes: the first, at a temperature of 60°C in the course of 1 h, with copper recovered into solution and the main part of nickel remaining in the solid residue; and the second, at a temperature of 80°C in the course of 4 h, with copper, nickel, and iron passing into solution in this case. Irrespective of the leaching conditions, 80% of nickel remains in the solid solution.

CONCLUSIONS

(1) It was found in a study of the behavior of phase components of residues of carbonyl nickel synthesis in leaching with $FeCl_3$ solutions that pentlandite decomposes without formation of intermediates, whereas cobalt pentlandite decomposes to give linnaeite Co_3S_4.

(2) It was shown that hydrochloric acid has a catalytic effect in the presence of $FeCl_3$ in decomposition of the phase components of the residues of carbonyl nickel synthesis.

(3) Conditions of selective leaching-out of copper, with nickel and cobalt remaining in the solid residue, were determined.

(4) It was found that the key influence on the degree of chalcosine decomposition is exerted by the concentration of the oxidizing agent, $FeCl_3$, whereas decomposition of pentlandite largely depends on temperature.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Application of the PC-SAFT Equation of State to Modeling of Solid–Liquid Equilibria in Systems with Organic Components Forming Chemical Compounds

Abstract—Equilibrium diagrams of liquid and solid phases were calculated by the equation of state, based on the perturbed-chain statistical associating fluid theory (PC-SAFT) for binary and ternary systems constituted by associating substances (water, alcohols, amines, phenol, bisphenol A, acetamide). Phase diagrams were considered for systems in which congruently and incongruently melting intermolecular compounds are formed and for a system with limited mutual solubility of the components in the liquid state. The results of prognostication of phase equilibria were illustrated by the example of a ternary system constituted by bisphenol A, phenol, and water, in which an adduct of bisphenol A and phenol is formed.

DOI: 10.1134/S1070427207040040

Data on the equilibrium between solid and liquid phases are rather important for analysis of crystallization, which is a method for separation and purification of various substances. Types of solid–liquid equilibrium phase diagrams in binary systems are widely diverse and include, in particular, solid–melt diagrams with limited mutual solubility of the components in the solid (liquid) state and formation of chemical compounds melting with or without decomposition. In the case of diagrams of the latter type, intermolecular compounds, frequently named adducts and hydrates (in aqueous systems) or solvates (in nonaqueous systems), can be formed. In the case of compound formation, liquidus curves corresponding to crystallization of compounds appear in the fusibility diagrams, in addition to the lines of crystallization of pure components. The main experimental technique for obtaining the diagrams mentioned above is differential scanning calorimetry.

In this study, the equation of state, suggested by Gross and Sadowski [1] on the basis of the perturbed-chain statistical associating fluid theory (PC-SAFT), was used to model the solid–liquid phase equilibrium in systems involving chemical compounds. This equation of state is a modification of the known molecular-statistical model SAFT (Statistical Associating Fluid Theory), which has been popular in engineering calculations recently. It is based on the results of the perturbation theory and a numerical experiment for a fluid formed by chains of solid spheres. The molecular model underlying the PC-SAFT takes into account the formation of chains of solid spheres, dispersion interaction described in terms of the Barker–Henderson perturbation theory [2], and association. It is assumed that there are contact areas on the molecule surface, which are capable of specific interactions with contact areas of other molecules. The PC-SAFT model is being intensively developed; in particular, its variants that take into account multipole interactions in description of polar components have been developed [3–5].

The PC-SAFT model has been successfully tested on various systems, including nonpolar, polar, and associating substances, as well as polymers and copolymers, in a wide range of conditions [1, 3–10].[1] The results obtained are rather promising for further development of this model. However, the consideration has been limited to only fluid phases (liquid–vapor, liquid–liquid, liquid–liquid–vapor). It was of interest to apply this equation to modeling of an equi-

[1] For the software package for calculation of phase equilibria in terms of various models, including SAFT and PC-SAFT, see http://www.tu-harburg.de/vt2/pe2000/HomePage.html.

librium between solid and liquid phases. The goals of the study were as follows: description of solid–liquid equilibria for a number of binary systems including associating components [water, alcohols, amines, phenol, bisphenol A (BPA), acetamide], which form stable and unstable chemical compounds of varied stoichiometry; description of liquid–liquid and solid–liquid equilibria for the water–phenol system; and prognostication of the fusibility diagram for the ternary mixture of BPA, phenol, and water, in which an adduct of BPA and phenol is formed. Systems in which the solid phase is a solid solution are beyond the scope of this study.

A detailed description of the PC-SAFT equation of state can be found in [1, 3, 6–8], and, therefore, only a brief consideration will be made here. According to the PC-SAFT model, the expression for the compressibility factor z can be written as

$$z = 1 + z^{hc} + z^{\text{disp}} + z^{\text{assoc}}, \quad (1)$$

where $z = PV/RT$; P, pressure; V, molar volume; R, universal gas constant; and T, temperature. The first term in the sum accounts for the contribution of the ideal gas ($z^{\text{id.gas}} = 1$), and the remaining three are related to contributions of chain formation, dispersion component, and association, respectively. Formulas for calculation of z^{hc} and z^{disp} were reported in [1], and the expression for z^{assoc} can be found in [11–13].

Description of ith pure associated substance requires five parameters: number m_i of segments forming the molecule-chain; segment diameter σ_i; segment interaction energy ε_i/k; effective association volume $k^{A_iB_i}$, and association energy $\varepsilon^{A_iB_i}/k$ (k is the Boltzmann constant). The last two parameters define the specific interaction between the contact areas A_i and B_i of ith component. When applying the model to mixtures, the Lorenz–Berthelot combination rules are used, with only a single fitting parameter of the binary interaction, k_{ij}, introduced to correct the dispersion component of interactions in the PC-SAFT equation:

$$\sigma_{ij} = \frac{1}{2}(\sigma_i + \sigma_j), \quad (2)$$

$$\varepsilon_{ij} = \sqrt{\varepsilon_i \varepsilon_j}(1 - k_{ij}). \quad (3)$$

To take into account the association between different-type molecules of ith and jth components, simple mixing rules suggested by Wolbach and Sandler [14] are introduced into the model without an additional fitting parameter:

$$\varepsilon^{A_iB_j} = \frac{1}{2}(\varepsilon^{A_iB_i} + \varepsilon^{A_jB_j}), \quad (4)$$

$$k^{A_iB_j} = \sqrt{k^{A_iB_i} k^{A_jB_j}} \left(\frac{\sqrt{\sigma_{ii}\sigma_{jj}}}{\frac{1}{2}(\sigma_{ii} + \sigma_{jj})} \right)^3. \quad (5)$$

Values of the parameters of the PC-SAFT equation of state for a number of pure associating components (water, alcohols) have been reported in the literature [6], and the lacking parameters for amines, phenol, BPA, and acetamide were determined in this study (Table 1). It was assumed that all molecules of associating components have two specific contact areas each.

Let us now pass to a thermodynamic description of the solid–liquid equilibrium for the case when the solid phase is a pure component, rather than a solid solution. The solubility of a solid in a solvent can be represented, in the case of low pressures and disregarded changes in specific heat, as the expression [15]:

$$x_i^{\text{L}} = \frac{\varphi_{0i}^{\text{L}}}{\varphi_i^{\text{L}}} \exp\left[-\frac{\Delta H_{0i}^{\text{m}}}{RT}\left(1 - \frac{T}{T_{0i}^{\text{m}}}\right)\right], \quad (6)$$

Table 2. Melting point and enthalpy of melting of pure substances

Substance	T_{0i}^{m}, K	ΔH_{0i}^{m}, J mol^{-1}

Octylamine	273.37	34740
Phenol	314.0	11510
Acetamide	353.5	15610
Bisphenol A	431.1	30100

where x_i^{L} is the mole fraction of *i*th component in the liquid phase (superscript L); ΔH_{0i}^{m} and T_{0i}^{m}, enthalpy of melting and melting point of pure *i*th component; and φ_{0i}^{L} and φ_i^{L}, fugacity coefficients of *i*th pure component and the same component in a mixture at prescribed temperature and pressure.

The values of the fugacity coefficients are calculated using the PC-SAFT equation of state [1]. Solving Eq. (6) for x_i^{L} at various temperatures, we finally obtain the crystallization line of the pure substance. The thermodynamic properties of the pure substances (H_{0i}^{m} and T_{0i}^{m}) considered in this study are listed in Table 2.

If a chemical compound $A_{\nu_A}B_{\nu_B}^{(S)}$ (S, superscript denoting the solid phase; ν_A and ν_B, stoichiometric coefficients) is formed in the system, then the crystallization curve of this compound can be calculated by considering the chemical reaction

$$\nu_A A^{(L)} + \nu_B B^{(L)} \rightleftarrows A_{\nu_A}B_{\nu_B}^{(S)}. \quad (7)$$

Taking the activity of the chemical compound in the solid phase to be unity, we can write for the equilibrium constant K_a

$$K_a = \Pi a_i^{\nu_i} = (x_A\gamma_A)^{-\nu_A}(x_B\gamma_B)^{-\nu_B}, \quad (8)$$

with the activity coefficients γ_i in the liquid phase expressed in terms of the ratio between the fugacity coefficients in solution and in *i*th pure liquid as

$$\gamma_i = \varphi_i/\varphi_{0i}. \quad (9)$$

We denote the enthalpy of melting and melting point of the compound by ΔH^{ref} and T^{ref}, respectively. If the compound fully dissociates in the liquid phase, the enthalpy of melting of the compound and the enthalpy of reaction (7) coincide. The temperature dependence of the constant of chemical equilibrium (8) is written as

$$\ln K_a = \ln K_a^{ref} + \frac{\Delta H^{ref}}{R}\left(\frac{1}{T^{ref}} - \frac{1}{T}\right). \quad (10)$$

Expression (10) is the integral form of the equation of the isobar of the chemical reaction. In a narrow temperature range, the enthalpy of reaction (7) can be considered constant and equal to ΔH^{ref}. The temperature T^{ref} may correspond to a congruent or an incongruent point in the fusibility diagram. Occasionally, there are no direct experimental data on values of ΔH^{ref}. Several methods for evaluating this quantity have been suggested in the literature.

(1) Method of weighted-average values of the entropies of melting of the starting compounds [16]; ΔH^{ref} is calculated by the formula

$$\Delta H^{ref} = T^{ref}\sum_i x_i \frac{\Delta H_{0i}^{m}}{T_{0i}^{m}}, \quad (11)$$

where x_i is the mole fraction of *i*th component in the compound.

(2) ΔH^{ref} and T^{ref} are found by extrapolation to the composition of the compound of the experimentally found concentration dependence of the heat (and temperature) of crystallization of the mixtures [17].

(3) The value of ΔH^{ref} is found by processing of experimental data (melting point–composition) on the assumption of an ideal mixture of monomers and the compound or with account of its nonideality; this value determines the temperature dependence of the association constant [18].

(4) The value of ΔH^{ref} serves as a fitting parameter in processing of experimental data on the crystallization of the compound; in this case, the activity coefficients are calculated using the equation of state [19].

(5) ΔH^{ref} is evaluated using the Schroder equation for ideal solutions [20].

The crystallization line of the chemical compound is calculated using Eqs. (8) and (10), which are solved by the iteration method for the mole fraction of the component in the range from the melting point of the compound (or incongruent point) to the eutectic point. The calculation procedure begins with finding K^{ref} at prescribed values of ΔH^{ref} and T^{ref} and molar composition of the chemical compound formed by reaction (7) [19]:

$$K_a^{ref} = \Pi a_i^{\nu_i} = [x_A\gamma_A(T^{ref}, x_A)]^{-\nu_A}[x_B\gamma_B(T^{ref}, x_B)]^{-\nu_B}. \quad (12)$$

Table 3. Melting points and enthalpies of melting of intermolecular compounds in the system under consideration

1 : 1, in ternary system (50 mol % water)	343.0	36870

Table 4. Binary interaction parameters evaluated for the systems under study

System	k_{ij}
Water–methanol	–0.18
Phenol–acetamide	–0.055
Hexylamine–*n*-octanol	–0.06
Octylamine–*n*-octanol	0.0
Phenol–bisphenol A	–0.01
Phenol–water	–0.018
Bisphenol A–water	–0.018

In a particular case in which an adduct of A and B of a stoichiometric composition is formed, $\nu_A = \nu_B = 1$ and $x_A = x_B = 0.5$. The activity coefficients $\gamma_A(T^{ref}, x_A)$ and $\gamma_B(T^{ref}, x_B)$ are calculated in terms of the PC-SAFT model. After finding K^{ref} from (12), Eqs. (8) and (10) are solved in the next stage of the calculation, at each running value of temperature, lower than T^{ref}, for the unknown quantity x_i^L. Repeating this procedure at other values of T, we can obtain the branch of the crystallization curve of the chemical compound, which intersects the lines corresponding to crystallization of pure components in the system. Table 3 lists the numerical values of T^{ref} and ΔH^{ref} for the chemical compounds formed in the systems under consideration. The optimal values of the binary-interaction parameter k_{ij}, used to describe the phase diagrams, are listed in Table 4.

Let us now discuss the results obtained. The results of modeling of the equilibrium between the solid phase and the liquid for the systems studied are illustrated by Figs. 1–6. Figure 1 shows the fusibility diagram for the methanol–water system in which alcohol monohydrate is formed (1 : 1 stoichiometry). This system shows noticeable negative deviations from the ideal behavior. We carefully checked the sensitivity of the calculation results to the chosen value of ΔH^{ref}, determined by various methods [16, 18, 19]. A testing of the PC-SAFT model demonstrated that the best agreement with the experimental data [18, 21] is provided by ΔH^{ref} equal to 8700 J mol^{-1}, found in [18] using the dimerization model for a nonideal water–methanol solution. The enthalpy of melting of the monohydrate, found using the method of average-weighted values of the entropies of melting of metha-

nol and water, is 3440 J mol^{-1}. At this value of ΔH^{ref} and in the case of a varied parameter k_{ij}, a satisfactory description of this system cannot be obtained. It is noteworthy that, at zero k_{ij}, the PC-SAFT equation of state predicts for the methanol–water mixture an incorrect type of the phase diagram (two crystallization branches of the pure components intersecting at the eutectic point). Figure 2 presents the results of correlation and prognostication in terms of the PC-SAFT model for the phenol–acetamide system, whose phase diagrams show crystallization curves of intermolecular compounds of stoichiometry 2 : 1 and 1 : 1; the crystallization curve of the 1 : 1 compound is very short. To evaluate ΔH^{ref} for both the compounds, we employed the method of weighted-average values of the entropy of melting of the starting substances [16]. The parameter k_{ij} was varied, but, unfortunately, the crystallization line of the 1 : 1 compound could not be described.

The phase diagram of the BPA–phenol system, in which an adduct of equimolar composition is formed, is shown in Fig. 3. The value of ΔH^{ref} of the incongruently melting compound was taken from [17]. This system shows nearly ideal behavior and the model rather well describes it for both zero and slightly negative values of the parameter k_{ij}. The solid–liquid equilibrium was calculated using the PC-SAFT equation of state for the amine–*n*-alkanol systems (Fig. 4), which are characterized by appearance of congruently melting compounds of 1 : 1 stoichiometry [22–24]; the enthalpies of melting of the adducts were determined in [20]. As demonstrated by Fig. 4a, the calculation correctly reproduces the general form of the diagram, but the calculated crystallization lines of the adduct somewhat differ from those obtained experimentally. This system exhibits strong negative deviations from the Raoult law. The results of prognostication by the PC-SAFT equation for the octylamine–octanol system (Fig. 4b), whose behavior is nearly ideal, coincide with the experimental data with good precision.

Recently, experimental data have been reported [25] on the solid–liquid equilibrium for the BPA–phenol–water ternary system in which an adduct of BPA and phenol is formed with a 1 : 1 stoichiometry. To prognosticate the phase diagram for this system, additional calculations of fusibility diagrams were performed for phenol–water and BPA–water binary subsystems.

As is known [26], the phase behavior of the phenol–water system is rather complex: the liquid solution stratifies and three-phase equilibria of different types appear. Figure 5 illustrates the phase diagram for this system under atmospheric pressure, with the solid–liquid, liquid–liquid, and liquid–vapor equilibria shown. It is noteworthy that the regions of coexistence of ice and the liquid phase (L_2) and of solid phenol

and liquid (L_2) are rather narrow and virtually invisible on the scale used in the figure. The PC-SAFT equation can reflect with an acceptable accuracy the full phase diagram of this system in a wide temperature range. Unfortunately, no experimental data on the solid–liquid equilibrium could be found in the literature, and, therefore, the fusibility diagram of this mixture was prognosticated (k_{ij} = 0). The predicted diagram was found to be similar to that for the phenol–water system.

Figure 6 shows the results of description of the phase diagram of the ternary system BPA–phenol–water for a constant mole fraction of water. The dependence of the melting point on composition was plotted for this system on the scale of a relative mole fraction of BPA (characterizing the composition of the BPA–water quasibinary mixture) at a prescribed content of water. The calculations for the ternary system used the same value of ΔH^{ref} as that for the BPA–phenol binary subsystem. T^{ref} were found by extrapolation from experimental data on the dependence of the melting point of the ternary mixture on its composition. The crystallization lines of the pure substances and adduct were prognosticated for the ternary aqueous-organic system for a zero value of the parameter k_{ij} for the BPA–water mixture; a calculation was also made with fitting of this parameter by using the data for the BPA–phenol–water system (k_{ij} = –0.018). The use of a corrected value of k_{ij} for the BPA–water binary subsystem made it possible to describe the experimental data with a good accuracy. As can be seen in Fig. 6, the crystallization curves in the ternary system shift to lower temperatures as the content of water increases.

CONCLUSIONS

(1) The PC-SAFT model describes, on the whole, successfully the solid–liquid equilibrium for binary and ternary systems (methanol–water, phenol–acetamide, bisphenol A–phenol, hexylamine–octanol, octylamine–octanol, and bisphenol A–phenol–water) in which intermolecular compounds are formed. Use of a single fitting parameter, that of the binary interaction, is sufficient for a satisfactory description of phase diagrams for all of the systems considered.

(2) The model reproduces with an acceptable accuracy the phase diagram of the phenol–water system at atmospheric pressure, in which various types of two- and three-phase equilibria are observed.

(3) The lines of crystallization lines of a chemical compound that completely dissociates in the liquid phase can be calculated using the method described in this study from data on the enthalpy of melting and the melting point of the compound.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Properties of Alkaloids Lappaconitine and Glaucine

Abstract—Calorimetric methods were used to study the enthalpy of solution of the alkaloids glaucine $C_{21}H_{25}NO_4$ and lappaconitine $C_{32}H_{44}N_2O_8$ in 96% ethanol and their heat capacity in the temperature ranges 173–298.15 and 173–423 K. Equations describing the dependences $\Delta H^{m}_{sol} \sim f(\sqrt{m})$ (m is molal concentration) and $C^{0}_{p} \sim f(\sqrt{T})$ for the compounds under study were derived. The enthalpies of combustion, melting, and formation of $C_{21}H_{25}NO_4$ and $C_{32}H_{44}N_2O_8$ were estimated by means of theoretical calculations.

DOI: 10.1134/S1070427207040052

Alkaloids belong to promising natural compounds owing to their biological activity. An interesting area of study of these compounds is analysis of their therodynamic properties to obtain new physicochemical constants necessary for standardization and certification of biologically active compounds and for directed synthesis of their derivatives possessing a high physiological activity.

This communication presents the results of experimental studies and calculations of the enthalpies of combustion, melting, and formation of the alkaloids glaucine and lappaconitine and of the temperature dependence of their heat capacity. In [1, 2], the thermodynamic properties of lappaconitine hydrochloride, which is an antiarrhythmic pharmacopoeic preparation Allapinine, and glaucine hydrobromide, basis of an antitussive preparation, were examined.

Lappaconitine (**I**) and glaucine (**II**) subjected to a calorimetric analysis were isolated from plants and accumulated in sufficient amounts at the laboratory of chemistry of alkaloids at Fitokhimiya NPTs AO (Karaganda) and had chromatographic purity:

298.15	0.4996 ± 0.0290	532 ± 29

The heat of solution of compounds **I** and **II** in 96% ethanol at three dilutions of 1 : 9000, 1 : 18000, and 1 : 36000 (moles of alkaloid per moles of ethanol) was experimentally studied on a DAK-1-1A isothermal automated differential calorimeter. The experimental procedure was described in detail in [3–6]. The operation of the instrument was tested by measuring the heat of solution of a three times recrystallized potassium chloride at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (moles of salt per moles of water). The average heat of KCl solution in water, equal to 17610 ± 333 J mol^{-1}, is in a good agreement with its recommended and reference values of 17577 ± 34 [7] and 17489 ± 371 J mol^{-1} [8].

Five parallel experiments were carried out at each dilution, and the results obtained were averaged. The experimental errors and the uniformities of their variances were calculated by methods of mathematical statistics with the use of Student's an Cochran's criteria [9]. The significance level of the criteria used was 5%. Results of the calorimetric measurements are listed in Table 1.

The experimentally obtained heats of solution of $C_{32}H_{44}N_2O_8$ and $C_{21}H_{25}NO_4$ in 96% ethanol at the dilutions specified were extrapolated to the infinite dilution, using the least-squares procedure. It was found on the basis of the relation $\Delta H^m_{sol} \sim f(\sqrt{m})$ [10] that the dependences of the enthalpies of solution of lappaconitine and glaucine on the molal concentration are described by the following equations (kJ mol^{-1}):

$$\Delta H^m_{sol}(C_{32}H_{44}N_2O_8) = 356.07 - 4845.92\sqrt{m}, \quad (1)$$

$$\Delta H^m_{sol}(C_{21}H_{25}NO_4) = 85.11 - 1302.28\sqrt{m}. \quad (2)$$

Equations (1) and (2) were used to calculate a fundamental thermochemical quantity, standard enthalpy of solution of these compounds in 96% ethanol at the infinite dilution, to be 356.07 ± 0.33 and 85.11 ± 1.53 kJ mol^{-1}, respectively.

The heat capacities of $C_{32}H_{44}N_2O_8$ and $C_{21}H_{25}NO_4$ were measured in the temperature ranges 173–423 and 173–298.15 K, respectively, at intervals of 25 K by the procedure described in [11], using an IT-s-400 calorimeter. The results obtained were averaged, subjected to mathematical processing, and used to calculate the molar heat capacity at each temperature. The instrument was calibrated by determining the heat capacity of α-Al_2O_3: the experimental value of $C^0_p(298.15)$ of α-Al_2O_3, equal to 76.0 J mol^{-1} K^{-1} was in a satisfactory agreement with the recommended value of 79.0 J mol^{-1} K^{-1} [12].

Table 2 lists experimental values of the specific and molar heat capacities of the compounds. The dependence $C^0_p \sim f(\sqrt{T})$ is plotted in the figure.

The curve describing the dependence $C^0_p \sim f(\sqrt{T})$ for lappaconitine in the temperature range 173–423 K shows sharp heat capacity peaks at 223 and 323 K. These effects are probably associated with structural

transformations of the molecule of this compound or with second order phase transitions. In this connection, for heat capacity equations related to different values of ΔT were derived for lappaconitine (J mol^{-1} K^{-1}):

$$C_{p1}^0 = -(3454 \pm 234) + (21886 \pm 1486) \times 10^{-3}T \quad (173\text{–}223\ \text{K}), \quad (3)$$

$$C_{p2}^0 = (3027 \pm 205) - (7179 \pm 487) \times 10^{-3}T \quad (223\text{–}298\ \text{K}), \quad (4)$$

$$C_{p3}^0 = -(3261 \pm 221) + (13924 \pm 945) \times 10^{-3}T \quad (298\text{–}323\ \text{K}), \quad (5)$$

$$C_{p3}^0 = -(9905 \pm 672) + (16226 \pm 1102) \times 10^{-3}T + (6156 \pm 418) \times 10^{5}T^{-2} \quad (323\text{–}423\ \text{K}). \quad (6)$$

The temperature dependence of the heat capacity of glaucine is monotonic in the temperature range under study and is described by the following equation (J mol^{-1} K^{-1}:

$$C_p^0 = (1642 \pm 101) - (2549 \pm 156) \times 10^{-3}T - (314.4 \pm 19.3) \times 10^{5}T^{-2}. \quad (7)$$

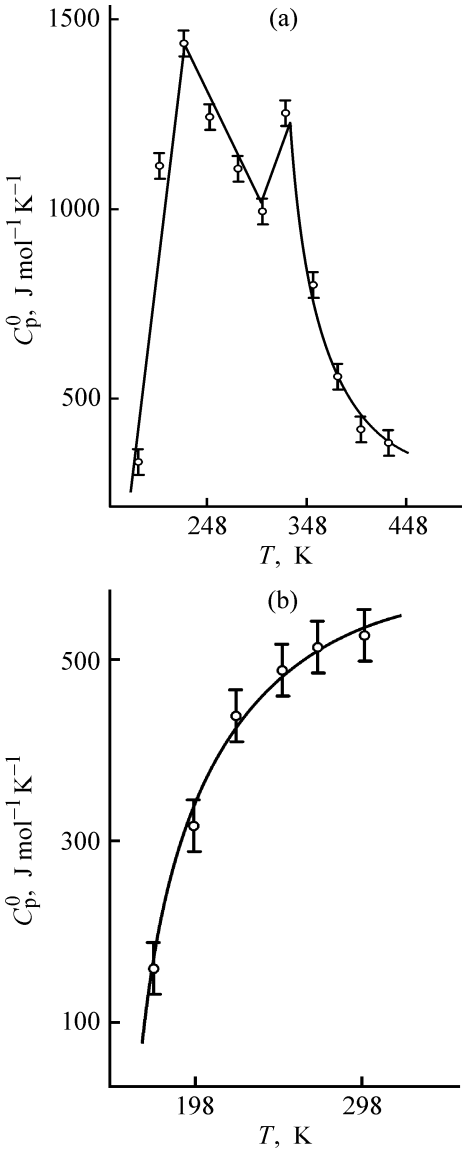
Further, the Karas and Frost equations [13] were used to estimate the standard enthalpy of combustion. The averaged values of the heats of combustion of $C_{32}H_{44}N_2O_8$ and $C_{21}H_{25}NO_4$, calculated by these two equations, are -18039 ± 708 and -11662 ± 382 kJ mol^{-1}, respectively. The Hess cycle for the reactions

$$C_{32}H_{44}N_2O_{8\,(l)} + 39O_{2\,(g)} = 32CO_{2\,(g)} + 22H_2O_{(l)} + N_{2\,(g)} - \Delta H_{comb}^0, \quad (8)$$

$$C_{21}H_{25}NO_{4\,(l)} + 50.5O_{2\,(g)} = 42CO_{2\,(g)} + 25H_2O_{(l)} + N_{2\,(g)} - \Delta H_{comb}^0, \quad (9)$$

was used to calculate the standard enthalpies of formation of the compounds in the liquid (molten) state to be -854.3 and -182.0 kJ mo^{-1}, respectively. The values of $\Delta_f H_{298.15}^0$ [$CO_{2\,(g)}$, $H_2O_{(l)}$], necessary for the calculation, were taken from [14].

In view of the fact that the compounds under study are in the crystalline state at the standard temperature (298.15 K), $\Delta_f H_{298.15}^0$ of their solid modification was calculated. For this purpose, ΔH_m of the compounds were evaluated using the empirical Gambill's equation



Heat capacity C_p^0 of (a) lappaconitine and (b) glaucine vs. temperature T.

[15] to be 766.7 and 110.5 kJ mol^{-1}, respectively. $\Delta_f H_s^0$ was calculated by the formula

$$\Delta_f H_{298.15\,(s)}^0 = \Delta_f H_{298.15\,(l)}^0 - \Delta H_m. \quad (10)$$

The standard enthalpies of formation of lappaconitine and glaucine in the crystalline state, calculated by substituting $\Delta_f H_{298.15\,(l)}^0$ and ΔH_m into (7), were -1621.0 and -293.5 kJ mol^{-1}, respectively.

CONCLUSIONS

(1) The heats of dissolution of natural alkaloids lappaconitine and glaucine in 96% ethanol were ex-

perimentally studied for the first time and the calorimetric data obtained were used to determine their standard enthalpies of solution in 96% ethanol at the infinite dilution.

(2) The temperature dependence of the heat capacity of $C_{32}H_{44}N_2O_8$ and $C_{21}H_{25}NO_4$ was studied in the temperature ranges 173–423 and 173–298.15 K, respectively. Sharp heat capacity peaks associated with second-order phase transitions were observed for lappaconitine at 223 and 323 K. Equations describing the temperature dependences of the heat capacity of the compounds were derived.

(3) The enthalpies of combustion, melting and formation of the compounds under study were estimated.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamics of Patina Formation

A. I. Demidov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received December 12, 2006

Abstract—Changes in the standard Gibbs energies in reactions that occur in the interaction of copper and copper oxides with oxygen, water, and impurities contained in atmospheric precipitations were calculated.

DOI: 10.1134/S1070427207040064

It is known [1] that copper and copper-based alloys (brass, bronzes) exhibit moderate stability under atmospheric conditions. The average depth of corrosion penetration is 0.1 to 1, 0.6 to 4, and 1 to 8 μm yr^{-1} in a rural, marine, and industrial atmosphere. After several years of exposure to an urban or coastal atmosphere, a dense layer of patina is formed on copper and copper alloys and this layer hinders further development of corrosion. The patina is mostly composed of basic copper sulfates, with minor amounts of basic copper chloride present in coastal regions and minor amounts of malachite (basic cupric carbonate) formed in some cases [2].

The present paper reports the results of a thermodynamic analysis of the interaction of copper and copper oxides with oxygen, water, and impurities contained in atmospheric precipitations. The change in the standard Gibbs energy in the reactions was calculated per mole of atoms of the starting substances [3, 4]. The calculations used published values of changes in the standard Gibbs energies [5, 6] (see table). The interaction of copper with oxygen at the standard temperature of 298.15 K can be described by the reactions

$$[2Cu + 1/2O_2 = Cu_2O]/3,$$
$$\Delta G^0_{298} = -50.2 \text{ kJ mol}^{-1}; \quad (1)$$

$$[Cu + 1/2O_2 = CuO]/2,$$
$$\Delta G^0_{298} = -64.7 \text{ kJ mol}^{-1}. \quad (2)$$

The smallest change in the standard Gibbs energy is observed for reaction (2).

Copper(II) oxide is reduced by copper to copper(I) oxide:

$$[CuO + Cu = Cu_2O]/3,$$
$$\Delta G^0_{298} = -7.03 \text{ kJ mol}^{-1}. \quad (3)$$

In turn, copper(I) oxide can react with oxygen:

$$[Cu_2O + 1/2O_2 = 2CuO]/4,$$
$$\Delta G^0_{298} = -27.1 \text{ kJ mol}^{-1}. \quad (4)$$

Thus, copper(II) oxide is the most stable compound in the system Cu–O. The exceedingly thin oxide film formed on copper in the atmosphere of oxygen at room temperature may be composed of a single CuO layer or of two layers: outer CuO layer and inner Cu_2O one. A noticeable interaction of copper with oxygen begins at temperatures of about 500 K [7].

Changes in the standard Gibbs energies of various substances and ions according to [5, 6]

Formula	ΔG^0_{298}, kJ mol^{-1}	Formula	ΔG^0_{298}, kJ mol^{-1}
Cu	0	$CuSO_{4(s)}$	–661.8
Cu^{2+}	65.6	$CuSO_4 \cdot H_2O_{(s)}$	–918.6
O_2	0	$CuSO_4 \cdot 3H_2O_{(s)}$	–1400.2
CuO	–129.4	$CuSO_4 \cdot 5H_2O_{(s)}$	–1879.9
Cu_2O	–150.5	O_2	0
H_2O	–237.2	$CuSO_4 \cdot 3Cu(OH)_2$	–1818.8
$Cu(OH)_2$	–359.4	Cl^-	–131.2
H^+	0	$CuCl_2 \cdot 3Cu(OH)_2$	–1340.3
$CuOH^+$	–134.7	$CO_{2(aq)}$	–386.2
$Cu(OH)_{2(aq)}$	–328.5	$CuCO_3 \cdot Cu(OH)_2$	–900.9
$[Cu(OH)_3]^-$	–501.7	HS^-	12.6
$[Cu(OH)_4]^{2-}$	–657.7	CuS	–53.6
SO_4^{2-}	–742.0	Cu_2S	–86.3

The reactions of copper(I) and (II) oxides with deoxygenated water, written per mole of atoms of the starting substances,

$$[Cu_2O + H_2O = Cu(OH)_{2(s)} + Cu]/6, \quad \Delta G^0_{298} = 4.72 \text{ kJ mol}^{-1}; \quad (5)$$

$$[CuO + H_2O = Cu(OH)_{2(s)}]/5, \quad \Delta G^0_{298} = 1.44 \text{ kJ mol}^{-1}; \quad (6)$$

are characterized by a small positive changes in the standard Gibbs energy and, consequently, by a small yield of the reaction products.

In oxygen saturated with water vapor, water is involved in oxidation of copper and copper(I) oxide:

$$[Cu + 1/2O_2 + H_2O = Cu(OH)_2]/5, \quad \Delta G^0_{298} = -24.4 \text{ kJ mol}^{-1}; \quad (7)$$

$$[Cu_2O + 1/2O_2 + 2H_2O = Cu(OH)_2]/10, \quad \Delta G^0_{298} = -9.39 \text{ kJ mol}^{-1}. \quad (8)$$

In turn, copper(II) hydroxide can be reduced by copper to copper(I) oxide:

$$[Cu(OH)_2 + Cu = Cu_2O + H_2O]/6, \quad \Delta G^0_{298} = -4.72 \text{ kJ mol}^{-1}. \quad (9)$$

Thus, a film composed of copper(I) oxide and copper(II) hydroxide can be formed on the surface of copper in the presence of water vapor.

Impurities in the atmosphere are one of the most important factors making higher the corrosion rate of metals. Sulfur dioxide SO_2 is directly formed in eruptions of volcanoes, combustion of coal or other kinds of fuel, or oxidation of H_2S in decomposition of organic substances [8]. The process of formation of sulfur trioxide SO_3 in photochemical oxidation of SO_2 can be schematically represented as

$$2SO_2 + O_2 + h\nu \rightarrow 2SO_3.$$

Then, sulfur trioxide is dissolved in drops of atmospheric moisture to give sulfuric acid:

$$SO_3 + H_2O \rightarrow H_2SO_4.$$

Sulfur dioxide can dissolve in drops of atmospheric moisture to give sulfurous acid

$$SO_2 + H_2O \rightarrow H_2SO_3.$$

In turn, sulfurous acid is oxidized by oxygen dissolved in water to H_2SO_4. Thus, the presence of sulfur dioxide in air leads to the formation of sulfuric acid in thin films of moisture on the metal surface and markedly accelerates the corrosion processes:

$$[Cu(OH)_2 + 2H^+ = Cu^{2+} + 2H_2O]/7, \quad \Delta G^0_{298} = -7.06 \text{ kJ mol}^{-1}, \ pH_{10}\ 4.33; \quad (10)$$

$$[CuO + 2H^+ = Cu^{2+} + 2H_2O]/4, \quad \Delta G^0_{298} = -10.6 \text{ kJ mol}^{-1}, \ pH_{11}\ 3.7; \quad (11)$$

$$[Cu_2O + 2H^+ = Cu^{2+} + Cu + H_2O]/5, \quad \Delta G^0_{298} = -4.22 \text{ kJ mol}^{-1}, \ pH_{12}\ 1.85. \quad (12)$$

When calculating the pH, we took the activities of copper compounds and ions of copper and water to be unity. The presented values of ΔG^0_{298} and pH indicate that reaction (10) predominantly occurs in dilute sulfuric acid solutions (2×10^{-5} N), and reactions (11) and (12), in more concentrated solutions.

Metal cations are hydrated in aqueous solutions, and, therefore, the copper(II) ion Cu^{2+} should be written as $Cu(H_2O)_4^{2+}$ in an aqueous solution [9]. The copper(II) ion $Cu(H_2O)_4^{2+}$ can undergo hydrolysis [10]. The hydrolysis of copper(II) ions occurs in stages by the scheme

$$Cu(H_2O)_4^{2+} + H_2O = Cu(H_2O)_3OH^+ + H_3O^+.$$

If water molecules bound to a copper(II) ion are dropped from this equation, we have

$$Cu^{2+} + H_2O = CuOH^+ + H^+, \quad K_{13} = 3.4 \times 10^{-7}, \ pH_{13}\ 6.47\ [11]. \quad (13)$$

The values of the constant K_{13} and Gibbs energies of formation of Cu^{2+} and H^+ ions and water were used to calculate the Gibbs energy of formation of the $CuOH^+$ ion (see table):

$$Cu(H_2O)_3OH^+ + H_2O = Cu(H_2O)_2OH_{2(aq)} + H_3O^+,$$

or, in reduced form,

$$CuOH^+ + H_2O = Cu(OH)_{2(aq)} + H^+, \quad K_{14} = 2.5 \times 10^{-8}, \ pH_{14}\ 7.60; \quad (14)$$

$$Cu(H_2O)_2(OH)_{2(aq)} + H_2O = Cu(H_2O)OH_3^- + H_3O^+;$$

or, in reduced form,

$$Cu(OH)_{2(aq)} + H_2O = [Cu(OH)_3]^- + H^+,$$
$$K_{15} = 6.3 \times 10^{-12},\ pH_{15}\ 11.2; \quad (15)$$

and

$$Cu(H_2O)(OH)_3^- + H_2O = [Cu(OH)_4]^{2-} + H_3O^+,$$

or, in reduced form,

$$[Cu(OH)_3]^- + H_2O = [Cu(OH)_4]^{2-} + H^+,$$
$$K_{16} = 6.3 \times 10^{-15},\ pH_{16}\ 14.2. \quad (16)$$

If hydrolysis of copper(II) ions is accompanied by formation of a copper(II) hydroxide precipitate:

$$Cu(H_2O)_4^{2+} + 2H_2O = Cu(OH)_{2(s)} + 2H_3O^+$$

or, in reduced form,

$$Cu^{2+} + 2H_2O = Cu(OH)_{2(s)} + 2H^+,$$
$$K_{17} = 2.2 \times 10^{-9}, \quad (17)$$

then the calculated theoretical value of pH_{17} is 4.33. According to the results of [12], copper(II) hydroxide is formed as a jelly-like blue precipitate in processing of cold solutions of copper(II) salts with alkali solutions at pH 5.0–5.5.

Copper ions (Cu^{2+}) contained in thin films of water on the metal surface can interact with sulfate ions to give the corresponding crystal hydrates:

$$[Cu^{2+} + SO_4^{2-} + H_2O = CuSO_4 \cdot H_2O_{(s)}]/9,$$
$$\Delta G^0_{298} = -0.56\ kJ\ mol^{-1}; \quad (18)$$

$$[Cu^{2+} + SO_4^{2-} + 3H_2O = CuSO_4 \cdot 3H_2O_{(s)}]/15,$$
$$\Delta G^0_{298} = -0.81\ kJ\ mol^{-1}; \quad (19)$$

$$[Cu^{2+} + SO_4^{2-} + 5H_2O = CuSO_4 \cdot 5H_2O_{(s)}]/21,$$
$$\Delta G^0_{298} = -0.83\ kJ\ mol^{-1}. \quad (20)$$

Summing reactions (10) and (18)–(20), we obtain

$$[Cu(OH)_2 + 2H^+ + SO_4^{2-} = CuSO_4 \cdot H_2O_{(s)} + H_2O]/12,$$
$$\Delta G^0_{298} = -4.53\ kJ\ mol^{-1}; \quad (21)$$

$$[Cu(OH)_2 + 2H^+ + SO_4^{2-} + H_2O = CuSO_4 \cdot 3H_2O]/15,$$
$$\Delta G^0_{298} = -4.11\ kJ\ mol^{-1}; \quad (22)$$

$$[Cu(OH)_2 + 2H^+ + SO_4^{2-} + 3H_2O = CuSO_4 \cdot 5H_2O]/21,$$
$$\Delta G^0_{298} = -3.19\ kJ\ mol^{-1}, \quad (23)$$

i.e., the interaction of copper(II) hydroxide with sulfuric acid on the metal surface can give copper(II) sulfate crystal hydrates. Taking into account reaction (21), we can suggest that brochantite is formed by the reaction

$$[4Cu(OH)_2 + 2H^+ + SO_4^{2-} = CuSO_4 \cdot 3Cu(OH)_2 + 2H_2O]/27,$$
$$\Delta G^0_{298} = -4.21\ kJ\ mol^{-1}. \quad (24)$$

An important role is played in the atmospheric corrosion of metals by salts contained in air. It is commonly believed that the influence of salts is an order of magnitude weaker than that of sulfur oxides [13]. Mear the sea coast, basic copper chloride $CuCl_2 \cdot 3Cu(OH)_2$ (atacamite) can also be formed on the copper surface:

$$[CuSO_4 \cdot 3Cu(OH)_2 + 2Cl^- = CuCl_2 \cdot 3Cu(OH)_2 + SO_4^{2-}]/23,$$
$$\Delta G^0_{298} = -0.05\ kJ\ mol^{-1}. \quad (25)$$

However, the content of copper sulfate exceeds that of the chloride even in the immediate vicinity of sea. For example, the patina formed on the Freedom statue is composed of 95% brochantite and 5% atacamite [14].

As mentioned above, minor amounts of malachite are present in some cases in the composition of patina:

$$[CuSO_4 \cdot 3Cu(OH)_2 + 2CO_{2(aq)} = 2CuCO_3 \cdot Cu(OH)_2 + 2H^+ + SO_4^{2-}]/27,\quad \Delta G^0_{298} = 1.76\ kJ\ mol^{-1}. \quad (26)$$

Thus, the presence of contaminations in the atmosphere plays an important part in the formation of green patina.

Modern sculptures and art articles made of copper and its alloys are virtually everywhere treated, to form patina, with aqueous solutions of ammonium hydrosulfide or potassium and sodium polysulfides [15]. Dark brown or black films are formed on the metal surface if concentrated solutions are used, and golden-brown, in the case of diluted solutions:

$$[Cu + 1/2O_2 + H^+ + HS^- = CuS + H_2O]/5,$$
$$\Delta G^0_{298} = -60.7\ kJ\ mol^{-1}; \quad (27)$$

$$[2Cu + 1/2O_2 + H^+ + HS^- = Cu_2S + H_2O]/6,$$
$$\Delta G^0_{298} = -56.0\ kJ\ mol^{-1}. \quad (28)$$

Upon prolonged exposure to open air, copper sulfides and the metal are oxidized to give brochantite:

$$[CuS + 3Cu + 7/2O_2 + 3H_2O = CuSO_4 \cdot 3Cu(OH)_2]/21,$$
