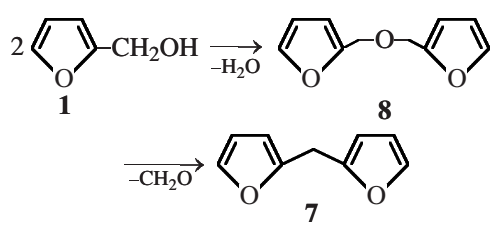
It should be noted that the well-known procedures for synthesis of **7**, which is a valuable odorant and a monomer for preparation of sensors for ion-selective chromatography, are rather complicated [10]. For example, one of the widely used procedures for synthesis of **7** is decarboxylation of bis(5-carboxyfuryl)methane in the presence of powdered copper [11]. The procedure for synthesis of **7**, based on reduction of difuryl ketone with sodium in ethanol [12, 13], is still more complicated. As can be seen, the procedure we suggested for synthesis of **7** is simpler and requires more available starting compounds as compared to the other well-known procedures.

As regards the mechanism of formation of **7**, according to [2], 2,2'-difurfuryl ether is formed in the first stage, and then it decomposes to give formaldehyde and 2,2'-difurylmethane, which is promoted by the rhodium catalyst $Rh(PPh_3)_3Cl$ whose ability to form a complex with CH_2O is well known [14]:



EXPERIMENTAL

The ^1H and ^{13}C NMR spectra of the compounds in $CDCl_3$ were recorded on a JEOL FX90Q spectrometer [90 MHz (^1H), 22.5 MHz (^{13}C)]; the chemical shifts δ (ppm) are given relative to TMS. The IR spectra were recorded on a UR-20 spectrophotometer in KBr pellets or in thin layer (film), and mass spectra, on a Finnigan MAT-112S chromatograph-mass spectrometer (EU, 70 eV). Chromatographic analysis was performed on a Chrom-5 device; 1.2 m × 3 mm column, stationary phase SE-30 (5%) on Chromaton N-AW-HMDS, heating from 50 to 250°C at a rate of 8 deg min^{-1}, carrier gas helium (47 ml min^{-1}). The hypochlorite concentration was determined by iodometric titration [15].

As the starting reactants we used commercially available alcohols: furfuryl alcohol, methanol, ethanol, propanol, and isopropanol, which were prepurified by distillation. Carbon tetrachloride was purified by the standard procedure.

Commercial iron acetylacetonate $Fe(acac)_3$ was recrystallized and dried in a vacuum desiccator before use; $Rh(PPh_3)_3Cl$ was synthesized by the procedure described previously and dried in a vacuum (20 h, 80°C) [16, 17].

The general procedure for synthesis of levulinic acid was as follows. A reactor (V = 100 ml) was charged with 0.1 mmol of $Fe(acac)_3$, 10 mmol of furfuryl alcohol, 40 mmol of aliphatic alcohol, and 20 mmol of CCl_4. The reaction was carried for 3.5–4 h at 70°C with continuous stirring. Then the reactor was cooled to room temperature and the reaction mixture was filtered through a silica gel bed (eluent hexane : ether = 1 : 1). The solvent was removed, and the residue was distilled.

The structure of the resulting compounds was confirmed by spectral data and also by comparison with authentic samples and reference data.

Methyl levulinate 2. Yield 98%, bp 76°C/10 mm Hg (bp 196°C [18]). ^1H NMR spectrum ($CDCl_3$; δ, ppm; J, Hz): 3.66 (3H, s, CH_3), 2.19 (3H, s, $COCH_3$), 2.56 (2H, t, CH_2, J 5.5), 2.70 (2H, t, CH_2, J 6.3), ^{13}C NMR (δ, ppm): 27.47 (C-2), 29.39 (CH_3), 37.65 (C-3), 51.37 (OCH_3), 173.03 (COO), 206.40 (CO). Mass spectrum, m/z (I_{rel}, %): 130 $[M]^+$ (10), 43 (96), 45 (7), 51 (1), 53 (3), 55 (57), 57 (38), 59 (40), 60 (4), 70 (2), 71 (32), 75 (6), 76 (1), 81 (4), 83 (1), 87 (25), 88 (45), 89 (3), 90 (0.5), 98 (44), 99 (100), 100 (10), 101 (2), 110 (0.5), 115 (98), 116 (6), 117 (2), 120 (0.5).

D_{10}-Methyl levulinate 6. Yield 40%. ^{13}C NMR ($CDCl_3$; δ, ppm): 27.09 (C-2, $^1J_{CD}$ 19.7 Hz), 37.15 (C-3, $^1J_{CD}$ 19.8 Hz), 29.00 (CH_3, $^1J_{CD}$ 19.1 Hz), 50.23 (OCH_3, $^1J_{CD}$ 19.3 Hz), 172.89 (COO), 206.40 (CH_3CO). Mass spectrum, m/z (I_{rel}, %): 140 $[M]^+$ (2), 44 (7), 45 (34), 46 (100), 57 (17), 61 (14), 62 (23), 76 (10), 77 (8), 92 (8), 93 (14), 95 (25), 96 (8), 102 (9), 103 (13), 104 (45), 105 (28), 106 (6), 119 (2), 120 (42), 121 (59), 122 (9), 129 (2), 130 (1), 138 (4), 139 (2), 140 (2).

Ethyl levulinate 3. Yield 95%, bp 73–74°C/6 mm Hg (bp 205–208 [18]). ^1H NMR spectrum ($CDCl_3$; δ, ppm; J, Hz): 1.25 (3H, t, CH_3, J 5.7), 2.17 (3H, s, $COCH_3$), 2.50 (2H, t, CH_2, J 5.5), 2.66 (2H, t, CH_2, J 6.3), 4.12 (2H, q, CH_2, J 6.1), ^{13}C NMR (δ, ppm): 28.32 (C-2), 36.95 (C-3), 29.52 (CH_3), 58.67 (OCH_2), 12.13 (CH_3), 171.52 (COO), 204.44 (CH_3CO). Mass spectrum, m/z (I_{rel}, %): 144 $[M]^+$ (5), 43 (100), 45 (7), 55 (8), 71 (10), 73 (15), 74 (20), 98 (13), 99 (80), 101 (24), 102 (22), 129 (30).

Isopropyl levulinate 4. Yield 85%, bp 86–87°C/10 mm Hg (bp 209–203 °C [18]). Mass spectrum, m/z (I_{rel}, %): 158 $[M]^+$ (0.3), 41 (12), 43 (93), 71 (8), 73 (7), 74 (29), 98 (5), 99 (100), 101 (19), 116 (13), 117 (15), 130 (3), 143 (7), 144 (0.2).

Propyl levulinate 5. Yield 80%, bp 95–96°C/10 mm Hg (bp 221–222°C [18]). ^1H NMR spectrum ($CDCl_3$; δ, ppm; J, Hz): 0.94 (3H, t, CH_3, J 5.2), 1.50–1.83 (2H, m, CH_2), 2.22 (3H, s, CH_3), 2.50–3.18 (4H, m, CH_2), 4.05 (2H, t, CH_2, J 5.5). ^{13}C NMR (δ, ppm): 29.59 (C-5, CH_3), 26.82 (C-2), 37.14 (C-3), 64.69 (OCH_2), 19.92 (CH_2), 8.59 (CH_3), 58.67 (OCH_2), 12.13 (CH_3), 170.68 (COO), 204.77 (CH_3CO). Mass spectrum, m/z (I_{rel}, %): 158 $[M]^+$ (0.3), 43 (99), 71 (12), 73 (14), 74 (21), 98 (18), 99 (100), 101 (31), 129 (39).

To synthesize difurylmethane, 0.1 mmol of Wilkinson complex $Rh(PPh_3)_3Cl$, 10 mmol of furfuryl alcohol, 40 mmol of water, and 20 mmol of CCl_4 were placed in a 100-ml reactor. The reaction mixture was heated with continuous stirring and kept for 6 h at 70°C. After cooling to room temperature, the reaction mixture was filtered through a silica gel

bed (eluent hexane : ester = 1 : 1), and the product was extracted with diethyl ether. The solvent was removed and the residue was distilled.

2,2'-Difurylmethane 7. Yield 80%, bp 88–89°C/10 mm Hg (bp 106–108°C/40 mm Hg, n_D 1.4865 [19]). ^{1}H NMR spectrum ($CDCl_3$, δ, ppm): 3.93 (2H, s, CH_2), 6.0–7.3 (6H, m, furyl). ^{13}C NMR spectrum ($CDCl_3$, δ, ppm): 150.52 (C-2, C-2'), 106.37 (C-3, C-3'), 107.21 (C-4, C-4'), 141.53 (C-5, C-5'). Mass spectrum, *m/z* (I_{rel}, %): 148 $[M]^+$ (87), 41 (2), 45 (3), 46 (4), 49 (1), 63 (8), 65 (19), 81 (12), 89 (6), 91 (100), 92 (14), 94 (15), 105 (3), 118 (2), 119 (20), 120 (29), 121 (4), 143 (7), 147 (15), 149 (10), 150 (1).

Difurfuryl ether 8. Yield 20 wt%, bp 100–101°C/2 mm Hg (bp 100–102°C/2 mm Hg [20]). ^{1}H NMR ($CDCl_3$, δ, ppm): 4.48 (4H, s, CH_2), 6.3–7.56 (6H, m, furyl). Mass spectrum, *m/z* (I_{rel}, %): 178 $[M]^+$ (6), 41 (6), 50 (2), 53 (22), 54 (6), 69 (6), 80 (3), 81 (100), 82 (50), 83 (4), 95 (7), 97 (11), 110 (5), 111 (1), 119 (0.5), 120 (0.5), 134 (0.5), 141 (0.2), 143 (7), 150 (0.5), 162 (1), 179 (1).

Oligomeric product. Yield 99%. Molecular weight *M* approximately 2144. Found (%): C 57.3, H 4.90, Cl 12.4. $(C_6H_8O_2)_x + (C_6H_9ClO_2)_y$, $x = 0.55$, $y = 0.45$. IR spectrum, cm^{-1}: 780, 1380, 1620, 1720.

CONCLUSIONS

(1) Synthesis of levulinic acid esters by the reaction of furfuryl alcohol with CCl_4 and alcohols under the action of $Fe(acac)_3$ and $Rh(PPh_3)_3Cl$ occurs with a high yield, 80–98%.

(2) In the reaction of furfuryl alcohol with a mixture of CCl_4 and water in the presence of Wilkinson complex $Rh(PPh_3)_3Cl$, 2,2'-difurylmethane is formed in 80% yield.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A New Approach to Synthesis of 2-Sulfonylamino-1,2,4-Triazolo[1,5-*a*]pyrimidines

V. M. Chernyshev, A. N. Sokolov, and V. A. Taranushich

Received January 22, 2007; in final form, April 2007

Abstract—A procedure for synthesis of 2-sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines by sulfonylation of 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines, followed by oxidation of intermediate 2-sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines, was suggested.

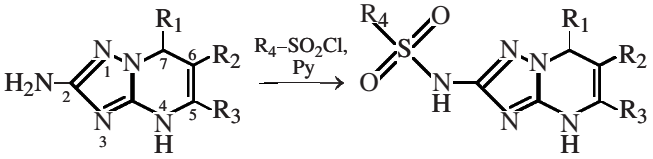
DOI: 10.1134/S1070427207100175

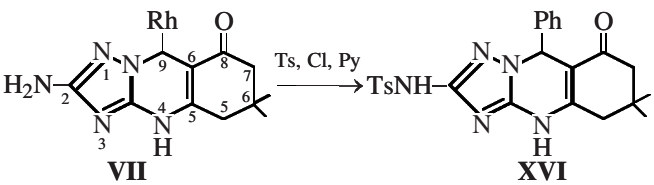
1,2,4-Triazolo[1,5-a]- and -[1,5-c]pyrimidines containing sulfonylamino group bonded to the triazole ring are of interest as new herbicides and plant growth regulators [1–7]. For example, 2-arylsulfonylamino-1,2,4-triazolo[1,5-a]pyrimidines has been suggested for weed removal from of wheat and soybean crops [4, 5], and 5,7-dimethoxy-2-(2-methoxy-4-trifluoromethylpyrid-3-yl)sulfonylamino-1,2,4-triazolo[1,5-*a*]-pyrimidine (Pyroxsulam^{R}) is intended for presprout protection of rice and corn crops [6, 7].

However, the existing procedures for synthesis of 2-sulfonylamino-1,2,4-triazolo[1,5-a]pyrimidines have certain drawbacks [4–7]. For example, cyclocondensation of 5-amino-3-sulfonylamono-1,2,4-triazoles with 1,3-dicarbonyl compounds can yield a mixture of isomers if unsymmetrically substituted dicarbonyl compounds are used. In addition, this procedure is limited by difficult synthesis of the initial compounds [8]. The procedures based on cyclization of *N*-hydroxy-*N*'-pyrimidinyl-*N*''-sulfonylguanidines by the Tisler reaction are multistage and require use of highly toxic chemicals [6, 7]. Sulfonylation of 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines usually proceeds with a low yield due to the low nucleophilicity of the amino group in these compounds [4–6]. A high yield of sulfonyl derivatives (92%) has been only reported for sulfonylation of 2-amino-5,7-dimethoxy-1,2,4-triazolo-[1,5-*a*]pyrimidine with 2,6-dichlorobenzenesulfonyl chloride [7]. However, acceptable yields of sulfonyl derivatives (55–75%) can be only obtained if sulfonylation of this substrate is catalyzed by sulfylimines [6]. Thus, a search for new routes to 2-sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines is an urgent task.

It can be assumed that the target 2-sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines can be synthesized by sulfonylation of more nucleophilic 2-amino-4,7-di-hydro-1,2,4-triazolo[1,5-*a*]pyrimidines, with subsequent oxidative heteroaromatization of intermediate 2-sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines. A similar approach has been used previously in synthesis of acetylamino-1,2,4-triazolo[1,5-*a*]pyrimidines [9].

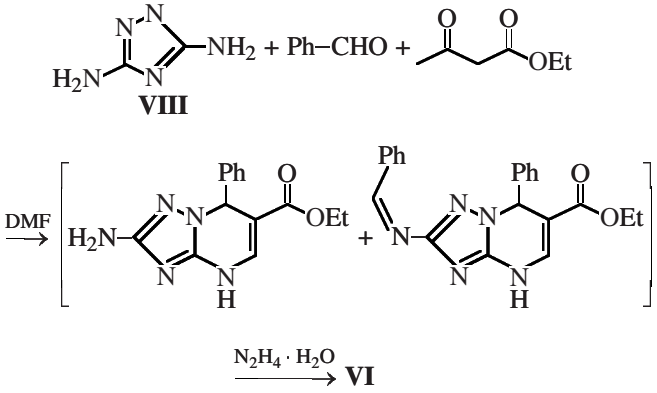
Here we studied the sulfonylation of 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines (**I**–**VI**) and of 2-amino-6,6-dimethyl-9-phenyl-6,7-dihydro-1,2,4-triazolo[5,1-b]quinazolin-8(4H, 5H, 9H)-one (**VII**) containing a dihydropyrimidine fragment with sulfonyl chlorides and the oxidative heteroaromatization of the resulting sulfonyl derivatives:





where R_1 Ph, R_2 H, R_3 Me (**I**, **X**, **XVII**); R_1, R_3 Ph, R_2 H (**II**, **XI**, **XVIII**); R_1 *p*-Me-C_6H_4, R_2 H, R_3 Ph (**III**, **XII**, **XIX**); R_1 Ph, R_2 H, R_3 *p*-Me-C_6H_4 (**IV**, **XIII**, **XX**); R_1 *p*-MeO-C_6H_4, R_2 H, R_3 Ph (**V**, **XIV**, **XXI**); R_1 Ph, R_2 COOEt, R_3 Me (**VI**, **XV**); R_4 *p*-Me-C_6H_4 (**X**, **XV**, **XVII**); R_4 *p*-Cl-C_6H_4 (**XI**, **XIV**, **XVIII**, **XXI**); Me (**XII**, **XIX**); Ph (**XIII**, **XX**).

The starting compounds **I**–**V** and 2-aminotriazoloquinazolinone **VII** were synthesized by condensation of 3,5-diamino-1,2,4-triazole **VIII** with unsaturated carbonyl compounds by the well-known procedures [10, 11], which are characterized by high regioselectivity and accessibility of the starting compounds and allow wide variation of substituents in the pyrimidine fragment [12–14]. 2-Amino-5-methyl-7-phenyl-6-ethoxycarbonyl-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidine **VI** was synthesized by three-component condensation of diamine (**VIII**) with benzaldehyde and acetoacetic ester:

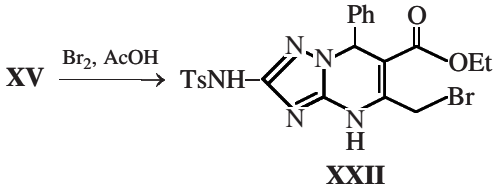


In the ^{1}H NMR spectrum of crude **VI**, there are signals of an impurity (its content is approximately 27%), which was assigned to azomethine **IX** (signals of aromatic protons in the range 7.5–7.9 ppm and of CH=N group, at 9.0 ppm). Compound **VI** was purified by refluxing in ethanol with hydrazine hydrate, followed by crystallization.

The reaction of **I**–**VII** with sulfonyl chlorides in dry refluxing pyridine gave 2-sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines **X**–**XV** and 6,6-dimethyl-2-tosylamino-9-phenyl-6,7-dihydro-1,2,4-triazolo[5,1-b]quinolin-8(4H,5H,9H)-one **XVI** in a yield of 60–89%. Thus, the lower electron-acceptor power of dihydropyrimidine fragment in **I**–**VII** makes these compounds more reactive in sulfonylation in comparison with aromatic 2-amino-1,2,4-triazolo[1,5-*a*]pyrimidines. Compounds **X**–**XVI** have not been described previously; their structure was confirmed by elemental analysis and data of mass spectrometry and ^{1}H NMR spectroscopy (see table).

Oxidation of **X**–**XIV** with *N*-bromosuccinimide in ethanol at 50–60°C or with bromine in acetic acid at 10–20°C resulted in the formation of 2-sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines (**XVII**)–(**XXI**) in a yield of 90–94%. Their structure was confirmed by elemental analysis and spectral data (see table).

Attempts to perform heteroaromatization of **XV** and **XVI** failed. In treatment of **XV** with bromine in acetic acid, the only reaction product was bromine derivative **XXII**:



The reaction of quinazolinone **XVI** with bromine or *N*-bromosuccinimide yielded an inseparatable mixture of bromination products and the starting compounds. In an attempt to perform heteroaromatization of **XV** and **XVI** by refluxing in an alcoholic solution of alkali in air, following the procedure described in [15], only the starting substances were recovered. Apparently, the resistance of **XV** and **XVI** to the action of oxidants is caused by their stabilization due to the electron-acceptor effect of the carbonyl group.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Varian Unity-300 spectrometer (300 MHz, DMSO-d_6, the internal reference TMS). The mass spectra were recorded on a Finnigan MAT Incos 50 device with direct sample inlet at ionizing electron energy of 70 eV. The elemental analysis was performed on a Perkin–Elmer 2400 analyzer. The melting points were determined by the capillary method on a PTP unit.

2-Amino-5-methyl-7-phenyl-6-ethoxycarbonyl-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidine VI. A mixture of 2 g (0.02 mol) of diamine (**VIII**), 2.12 g (0.02 mol) of benzaldehyde, 2.6 g (0.02 mol) of acetacetic ester, and 3 ml of DMF was refluxed for 30 min, then 10 ml of water was added and the mixture was cooled. The resulting precipitate was filtered off and mixed with 1 g (0.02 mole) of hydrazine hydrate, 1 ml of AcOH, and 5 ml of ethanol. The resulting mixture was refluxed for 30 min, cooled, and the precipitate of **VI** was filtered and crystallized from ethanol.

2-Sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines X–XV. To a mixture of 0.0044 mol of appropriate 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]-

Some physicochemical characteristics of **VI** and **X**–**XXII**

* The results of elemental analysis for C, H, and N agree with the calculated values to within ±0.34%; in the mass spectra of **VI**, **XX**–**XXI** there is a strong $[M]^+$ peak.

pyrimidine **I**–**VI** and 5 ml of dry pyridine, 0.0053 mol of the corresponding sulfonyl chloride was added with stirring. The reaction mixture was refluxed for 15–20 min, cooled, and diluted with 10 ml of water. The precipitate of **X**–**XV** was filtered and crystallized from a 1 : 3 DMF–ethanol mixture.

6,6-Dimethyl-2-tosylamino-9-phenyl-6,7-dihydro-1,2,4-triazolo[5,1-*b*]quinazolin-8(4H,5H)-one XVI was synthesized similarly to **X**–**XV** by tosylation of amine **VII**.

2-Sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines XVII–**XXI**. (a) To a stirred mixture of 0.0026 mol of dihydrotriazolopyrimidine **X**–**XIV** and 0.44 g (0.0052 mol) of sodium acetate in 10 ml of ethanol, 0.46 g (0.0026 mol) of *N*-bromosuccimidine was added in 0.1-g portions over of a period of 10 min at 50–60°C. Then the reaction mixture was refluxed for 15 min, diluted with 10 ml of water, and the precipitate of **XVII**–**XXI** was filtered off, washed with water (10 ml), and crystallized from a 1 : 3 DMF : ethanol mixture.

(b) To a stirred mixture of 0.0026 mole of dihydrotriazolopyrimidine **XIII**–**XIV** and 0.44 g (0.0052 mol) of sodium acetate in 2 ml of AcOH 0.42 g (0.0026 mol) of Br_2 was added dropwise over a period of 10 min. The reaction mixture was stirred for 30 min at 10–20°C and diluted with 10 ml of water, and the precipitate of **XX**–**XXI** was filtered off and crystallized from a 1 : 3 DMF-ethanol mixture.

5-Bromomethyl-2-tosylamino-7-phenyl-6-ethoxycarbonyl-1,2,4-triazolo[1,5-*a*]pyrimidine XXII. To a stirred mixture of 1.18 g (0.0026 mol) of dihydrotriazolopyrimidine **XV**, 0.44 g (0.0052) of sodium acetate, and 2 ml of AcOH, 0.42 g (0.0026 mol) of Br_2 was added dropwise over a period of 10 min. The reaction mixture was stirred for 30 min at 10–20°C and diluted with 10 ml of water; the precipitate of **XXII** was filtered off and crystallized from acetonitrile.

CONCLUSIONS

(1) Contrary to their aromatic analogs, 2-amino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines are more reactive toward sulfonyl chlorides and form 2-sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines in 60–89% yield.

(2) Oxidation of 2-sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines with bromine or *N*-bromosuccinimide gives 2-sulfonylamino-1,2,4-triazolo[1,5-*a*]pyrimidines and can serve as an efficient procedure for their synthesis (yield 90–94%).

(3) 2-Sulfonylamino-4,7-dihydro-1,2,4-triazolo[1,5-*a*]pyrimidines containing carbonyl group in position 6 as a substituent are resistant to heteroaromatization.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Enhancement of Catalyst Performance in Heck Reaction of Nonactivated Aryl Bromides in the Absence of Phosphine Ligands

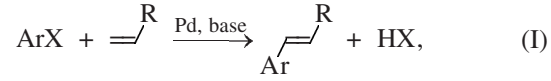
Abstract—Effective procedures for raising the yield of the Heck reaction, based on the reactants (bromobenzene, styrene), in the presence of the previously developed phosphine-free catalytic system ($PdCl_2$ + NaOOCH + NaOAc) were suggested.

DOI: 10.1134/S1070427207100187

The catalytic arylation of alkenes with aryl halides (I) [1, 2] has been extensively studied [3–7]:



$$ArX + \text{alkene} \xrightarrow{\text{Pd, base}} \text{Ar-alkene} + HX, \quad (I)$$

X = I, Br, Cl.

A special attention is paid to development of new catalytic systems that can activate more readily available, but less reactive aryl bromides and chlorides. Use of these catalytic systems will allow industrial application of the Heck reaction [5–7]. Insufficient catalytic activity in reaction (I) is mainly due to the low reactivity of nonactivated aryl bromides and chlorides in the final step of the catalytic cycle, oxidative addition to Pd(0) complexes. As a result, the catalyst is removed from the main catalytic cycle owing to the competing Pd(0) aggregation.

The catalytic systems free of any ligands and, in particular, of the commonly used phosphines are of particular practical interest. Homogeneous phosphine-free catalytic systems containing simple palladium salts [$Pd(OAc)_2$, $PdCl_2$] and capable of activating nonreactive aryl bromides were developed in 2003 [8–10]. The reaction is accelerated with as the catalyst amount decreases [8, 9]. Introduction of small amounts of NaOOCH reducing Pd(II) to catalytically active Pd(0) and of an excess of aryl halides preventing aggregation of Pd(0) enabled not only quantitative arylation of an alkene [10], but also a larger turnover number of the catalyst [7, 11], including reactions with aryl chlorides [7]. Clearly, the use of an excess aryl halide substantially restricts the practical applicability of this method. Hence we suggest simple ways to raise the yield of the valuable product based on aryl bromide, taken in excess, with the high catalytic performance of the system developed in our previous studies [10, 11] preserved.

EXPERIMENTAL

The reactions were performed in a temperature-controlled reaction vessel equipped with a magnetic stirrer under aerobic conditions. The solvent was dimethylformamide (DMF). The samples taken at regular intervals were analyzed on a HP-4890 gas–liquid chromatograph with using a flame-ionization detector and a 15-m HP-5 capillary column (Hewlett–Packard). Naphthalene was used as the internal reference. The analysis was performed under programmed heating from 100 to 250°C. The solvents and chemicals were purified by the conventional methods. The model reaction of styrene with bromobenzene was performed by the previously developed procedure [11]. PhBr (60 mmol), styrene (10 mmol), NaOAc (11.2 mmol), NaOOCH (1.8 mmol), and naphthalene (2 mmol, internal reference for GLC) were dissolved in DMF (10 ml) in the reaction vessel. Then, a freshly prepared solution of $Pd(PhCN)_2Cl_2$ (2.5×10^{-2} in 25 ml of DMF, 0.1 ml) was added. The reaction vessel was placed in an oil bath preheated to 140°C. The reaction mixture was stirred with a magnetic stirrer. After the reaction was complete, the liquid phase was distil-

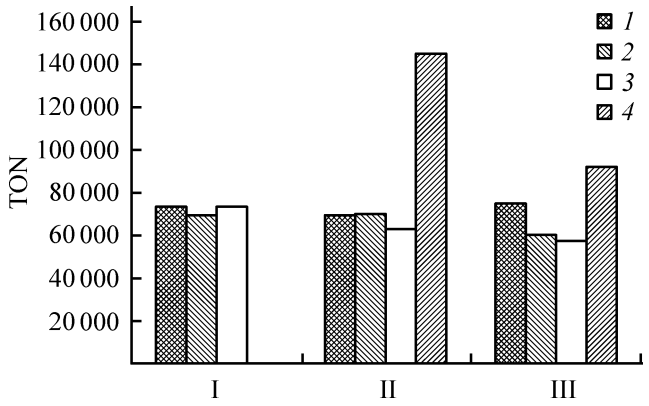


Fig. 1. Turnover number (TON) of the catalyst in successive cycles of reaction (II) with separation of liquid phase by (I) distillation and filtration through (II) glass filter and (III) aluminum oxide bed; the same for Fig. 2. In the fourth cycle, PhI was used instead of PhBr without addition of a fresh portion of the catalyst; the same for Fig. 2. (*1–4*) number of cycles; the same for Fig. 2.

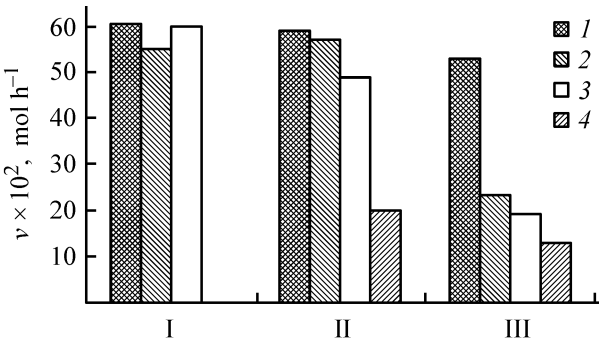

Fig. 2. Rate v of successive steps of reaction (II) with the use of different methods for separating the liquid phase.

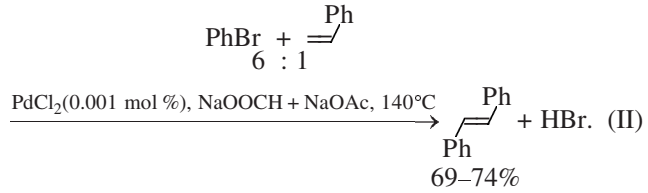
led off (34–45°C, 3–5 mm Hg), or filtered through a finely porous glass filter, or passed through an Al_2O_3 bed. The composition of the liquid phase was analyzed. Prior to the next experiment, the required amounts of bromobenzene and styrene and fresh portions of $PdCl_2$, NaOAc, and NaOOCH were added to the resulting solution. In experiments without additional introduction of $PdCl_2$, iodobenzene was added in the amount equimolar to styrene, instead of bromobenzene, to the separated solution.

The turnover number of the simplest catalytic system containing $PdCl_2$ and sodium formate, without inert atmosphere or any ligands, at the bromobenzene : styrene ratio of 6 : 1 and 140°C is 0.74×10^5 in 70 min. It should be noted that, when the turnover number is equal to, or higher than 10^5, the catalyst content of the product is 10 ppm or lower and there is no need to separate the catalyst even in the case of a medical application of the product [5]. Since there is no alternative to use of excess aryl bromide to reach a high turnover number of the catalyst in the phosphine-free Heck reaction, the only way to raise the yield of the target product, based on the arylating agent, is recycling of aryl bromide remaining in the reaction mixture:



The yield of diphenylethylene based on styrene in this reaction at a low catalyst content (0.001 mol %) ranged from 69 to 74%. The yield of this product based on bromobenzene was lower by ~12% owing to a sixfold excess of bromobenzene. At a 70% yield based on styrene, the concentration of the reaction products and the initial reactants did not change on further heating of the reaction mixture, which suggested complete deactivation of the catalyst. The simplest way to raise the yield based on the initial reagents is to distill-off the liquid phase of the reaction mixture and reuse it in new catalytic cycles.

The results of three successive reactions with intermediate distillation of the liquid phase and addition of free portions of reactants (including palladium chloride) are shown in Fig. 1. The turnover number was calculated as the ratio of the total amount of the reaction products formed in the catalytic step examined to the total palladium amount used in this and all preceding steps. As can be seen from Fig. 1, the turnover number of the catalyst in all steps is about the same. To estimate the catalytic activity, the average reaction rate prior to the reaction completion can be used.

As can be seen from Fig. 2, the reaction rate did not substantially change after separation of the liquid phase by distillation. The yield of the target product increases upon addition of unchanged styrene and bromobenzene to the reaction mixture. The total stilbene yield based on styrene in the first, second, and third cycles is 74, 83, and 89%, respectively. Since the whole amount recycled bromobenzene is converted to the reaction product in the second and third cycles, the relative change in the yield based on bromobenzene present in a sixfold excess in the reaction mixture was more significant. The stilbene yield based on bromobenzene in the first, second, and third cycles was 12, 21, and 29%, respectively. Thus, the yield based on bromobenzene increased in three successive catalytic cycles by a factor of 2.4. Our experimental results show that distillation of the liquid phase prevents accumulation of compounds poisoning the cata-

lyst in the reaction mixture. Hence, the stilbene yield based on the initial reactants can be raised by making larger the number of catalytic cycles.

We also examined other methods for involving the reactants in repeated reaction cycles without additional heating of the reaction mixture and use of a reduced pressure. It is generally known [6, 7, 12] that the catalyst deactivation in the Heck reaction with nonactived aryl halides is caused by aggregation of catalytically active dissolved palladium. We found [7, 11] that the deactivation of a catalyst under these conditions was an autocatalytic process presumably catalyzed by the solid phase of the catalysts formed in the course of the reaction. Thus, introduction of additional portions of the catalyst after its deactivation cannot substantially raise the conversion. In addition, we suggested that filtration of the reaction mixture and addition of a fresh portion of the catalyst could raise the conversion without distillation of liquid reaction products, owing to the separation of the solid phase of the catalyst. As can be seen from Fig. 1, cold filtration of the reaction mixture through a glass filter did give the acceptable results. The turnover number of the catalyst after the third cycle was 63000. In going from the first to the third cycle, the reaction decelerated by no more than 17 % (Fig. 2).

According to the mechanism of the Heck reaction, palladium can exist in solution in the form of molecular complexes and colloidal particles [6–8, 10–12], which cannot be separated by filtration. To determine palladium in the filtrate, the fourth reaction cycle was performed without addition of the catalyst, but in the presence of reactive iodobenzene, instead of bromobenzene. In this case, the high conversion of the initial reactants and the high stilbene yield unambiguously suggest the presence of palladium in the filtrate in the form ineffective in the reaction with bromobenzene.

A fresh catalyst portion added to the solution containing colloidal palladium can initiate fast autocatalytic growth and subsequent coagulation of palladium particles, which can decrease the catalytic activity in the experiments with filtration through a glass filter. To make palladium separation from the reaction mixture make complete, the solution was filtered through an aluminum oxide bed. As can be seen from Fig. 1, the turnover number of the catalysts in the second cycle of these experiments significantly decreased. This tendency was more pronounced for the reaction rate. The decrease in conversion and the deceleration of the reaction with iodobenzene in the test for dissolved palladium indicated that the palladium concentration

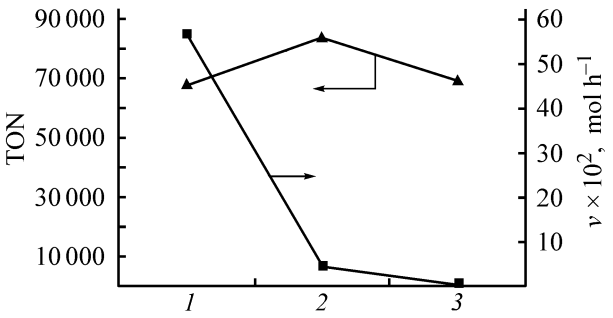


Fig. 3. TON of the catalyst and rate of reaction (II) catalyzed by (*1*) $PdCl_2$ and precipitate isolated after the first cycle of the reaction with (*2*) PhI and (*3*) PhBr.

in the solutions decreased, compared to the experiments with filtration through a finely porous glass filter. Thus, the presence of palladium in solution in experiments with filtration through a glass filter has a positive effect on the catalytic activity, whereas the decrease in the palladium concentration after filtration through an aluminum oxide bed impairs the catalyst performance.

We studied the catalytic activity of the precipitate isolated by filtration of the reaction mixture. The main components of the precipitate were NaBr and unchanged NaOAc. The precipitate was divided on the filter in two equal parts which were used as catalysts in the reactions with iodo- and bromobenzene without addition of fresh portions of the initial catalyst. As can be seen from Fig. 3, the turnover number of the catalyst in the reaction with iodobenzene slightly increases as compared to the first cycle, whereas the styrene conversion in the reaction with iodobenzene remains virtually the same. In both cases, the reaction is very slow. These experiments confirm that palladium irreversibly aggregates to form an agglomerate inert in arylation even with reactive aryl halides. As noted above, no appreciable conversion of the substrate is observed after introduction of a fresh portion of the catalyst without filtration of the reaction mixture. Thus, autocatalytic aggregation and deactivation of palladium in the Heck reaction are caused by palladium aggregates removed by filtration. These results are consistent with the mechanism of palladium deactivation in the phosphine-free catalytic systems [7, 8, 10–12]. In addition, the results of this study can be used to develop processes for indistrial arylation of alkenes, including continuous processes.

CONCLUSIONS

Methods were developed for raising the yield of the product based on the reactants with preservation of

high activity of the simplest phosphine-free catalytic systems in Heck reactions with nonactivated aryl bromides. Filtration of the reaction mixture, which, if necessary, can be supplemented with distillation of the liquid reaction components, allows repeated reaction cycles with preservation of a high turnover number of the catalyst and a high reaction rate.

Abstract—The catalytic activity of citric (H_4Citr) and malic (H_3Mal) acids, their coordination compounds with germanium(IV) $H_2[Ge(HCit)_2]$ and $H_2[Ge(Mal)_2]$, and germanium dioxide GeO_2 in polycondensation of maleic anhydride and ethylene glycol at various temperatures was studied (catalyst : ethylene glycol molar ratio 0.01 : 1). The process kinetics was evaluated and the time of its completion was determined. The copolymerization kinetics of some of the prepared oligoesters with triethylene glycol dimethacrylate was studied, and the copolymer properties were determined.

DOI: 10.1134/S1070427207100199

Polycondensation steadily attracts researcher's attention [1]. The problems of intensification of the condensation processes and, first of all, development and use of more effective catalysts are still topical. It is known that acids (including carboxylic acids) and their salts and a number of metal (magnesium, lead, thorium, uranium, etc.) [2] oxides are catalytically active in polycondensation of dicarboxylic acids with glycols. However, all these catalysts (even the most active) are toxic and deteriorate the physicochemical properties of the resulting oligoesters. It should be noted that in their presence, unsaturated polymeric resins (UPRs), should be synthesized from based dicarboxylic acid anhydrides and glycols at 180–200°C. No catalysts operate at lower temperatures. Thus, although UPRs are large-tonnage commercial products, there is no catalyst that would combine high activity with environmental safety and would allow resin preparation at lower temperatures.

In this regard, promise is shown by germanium complexes, which are successfully used as components of catalytic systems for preparing polymers based on styrene and other arylethylene monomers with high degree of syndiotacticity [3]. It is known that germanium compounds are effective polycondensation catalysts in synthesis of high-purity polyesters, polyethylene terephthalate, ethylene glycol, and bis-beta-hydroxyethyl terephthalates and in polymerization of α-olefins [4–6]. In this study, we examined the catalytic activity of new hydroxy acid complexes of germanium in polycondensation of maleic anhydride and ethylene glycol.

EXPERIMENTAL

Polyglycol maleinate (PGM) was prepared by polycondensation in a melt maleic anhydride and ethylene glycol (EG) of analytically pure grade [7]. This system was chosen as a model. The synthesis was carried out at 180°C until an acid number of about 45 was reached. The resulting oligomer was dried in a thermostat over calcined $CaCl_2$ at 200°C for 2 h.

The acid number was determined by titration of a sample taken directly from the reaction mixture and also found from the amount of water collected in a Dean-Stark trap.

Using a similar procedure [7], PGMs were prepared in the presence of several catalysts (catalyst : EG molar ratio 0.01 : 1) at 180 and 155°C. As catalysts we tested germanium dioxide GeO_2 (ultrapure grade), citric acid monohydrate $C_6H_8O_7 \cdot H_2O$ (H_4Cit) (chemically pure grade), malic acid $C_4H_7O_5$ (H_3Mal) (chemically pure grade), and complexes of germanium with these acids.

Complex dicitrato- and dismalatogermanic acids were prepared by the common procedure: Water (400 ml) was added to a mixture of GeO_2 (1.046 g, 0.01 mol) and H_4Citr (4.2 g, 0.02 mol) or H_3Mal (2.68 g, 0.02 mol). Then, the reaction mixture was boiled with

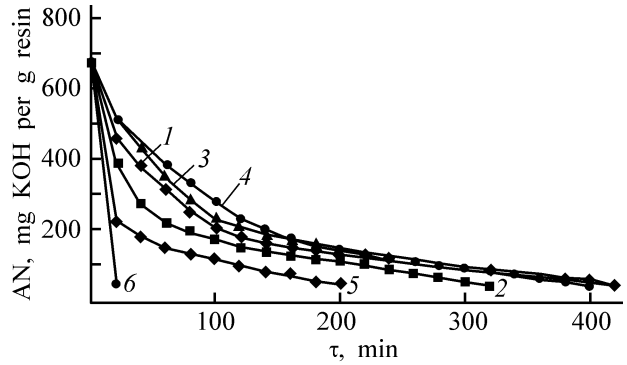

Fig. 1. Acid number AN of polyesters prepared at 180°C in the presence of a catalyst (1%) vs. the reaction time τ. (*1*) No catalyst, (*2*) GeO_2, (*3*) H_4Citr, (*4*) H_3Mal, (*5*) $H_2[Ge(HCitr)_2]$, and (*6*) $H_2[Ge(Mal)_2]$.

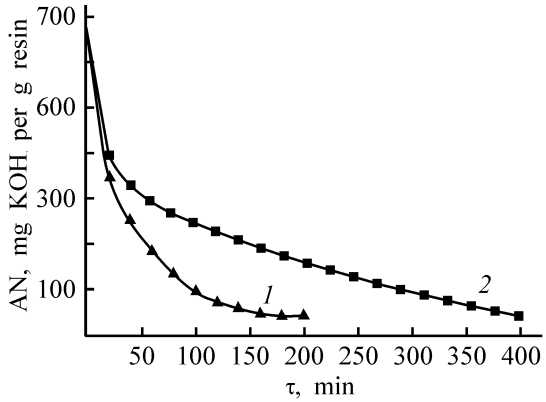

Fig. 2. Acid number AN of polyesters prepared at 155°C in the presence of a catalyst (1%) vs. the reaction time τ. (*1*) $H_2[Ge(Mal)_2]$ and (*2*) $H_2[Ge(HCitr)_2]$.

continuous stirring until the reactants completely dissolved and then was evaporated on a water bath until formation of white X-ray amorphous precipitates of Ge complexes (about 3 h). The resulting complexes were studied by chemical and X-ray diffraction analyses, thermogravimetry, and IR spectroscopy, and their formulas $H_2[Ge(HCit)_2]$ and $H_2[Ge(Mal)_2]$, were determined [8–10].

The effect of the procedure used to synthesize UPRs (with or without catalyst) on copolymerization was examined using 30% solutions of triethylene glycol methacrylate (TGM-3) in the UPRs prepared. The copolymerization constant was determined by dilatometry at 60°C, as using benzoyl peroxide (BP) initiator. The polymer densities were determined by hydrostatic weighing of standard bars ($120 \pm 2 \times 15 \pm 0.2 \times 10 \pm 0.2$ mm).

Kinetic characteristics of polycondensation of MA and EG in the presence of catalysts

Catalyst	$v_{pc} \times 10^3$, mol s^{-1} l^{-1}	Catalyst cycle	K_{pc}, $l\ s^{-1}\ mol^{-1}$	τ, min
Temperature 180°C				
–	2.3	–	0.3	420
GeO_2	4.1	1.8	0.7	330
H_4Citr	2.0	0.9	0.2	420
H_3Mal	2.0	0.9	0.3	400
$H_2[Ge(HCitr)_2]$	5.3	2.3	1.2	200
Temperature 155°C				
$H_2[Ge(HCitr)_2]$	3.7	1.6	0.6	200
$H_2[Ge(HCitr)_2]$	3.3	1.4	0.5	400

Analysis of experimental data shows that at 180°C citric and malic acids do not affect the polycondensation (Fig. 1, curves *1*, *3*, *4*), whereas germanium dioxide only slightly accelerates the process (Fig. 1, curve *2*). Complex germanium acids provide the highest reaction rate (Fig. 1, curves *5*, *6*). Moreover, the temperature of the process onset decreases in the presence of these acids and a significant fraction of the initial components is converted before the reaction temperature reaches 180°C. In the experiment with $H_2[Ge(Mal)_2]$, the reaction was so fast that only two points were obtained.

Therefore, complex germanium acid catalysts make it possible to perform polycondensation at lower temperatures and, thus, to diminish the energy consumption in synthesis of polyesters. Indeed, in the presence of these catalysts polycondensation was complete even at 155°C (Fig. 2) and $H_2[Ge(Mal)_2]$ strongly accelerated the process (Fig. 2, curve *1*).

Using data reported in [11], we calculated the rates of polycondensation in the initial stage at various temperatures and in the presence of various catalysts, determined the corresponding rate constants, and determined the catalyst cycle (see table).

From the experimental data at various temperatures, we calculated the activation energy of the process in the presence of complex catalysts $H_2[Ge(Mal)_2]$ (184.1 kJ mol^{-1}) and $H_2[Ge(HCitr)_2]$ (54.4 kJ mol^{-1}). The polycondensation is the second-order reaction, the activation energies are rather high, and the process is temperature-sensitive.

Based on published data for similar systems [12], we assumed that MA before esterification is protonated via dissociation of coordinated carboxy

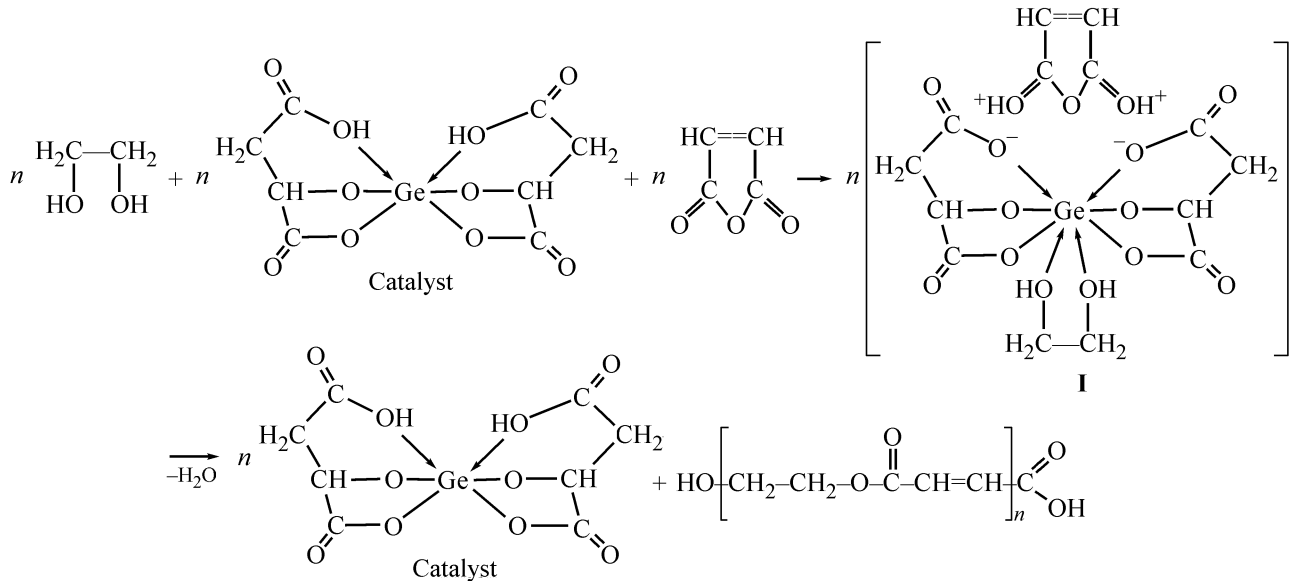

Fig. 3. Scheme of polycondensation of maleic anhydride with ethylene glycol in the presence of $H_2[Ge(Mal)_2]$.

groups of the complex germanic acid, in particular, $H_2[Ge(Mal)_2]$.

In the process, proton is attached to the carbonyl oxygen, making it more accessible to nucleophilic attack. Simultaneously EG is coordinated with germanium. Hence, intermediate **I** is formed in the first stage (Fig. 3), which accelerates the polycondensation. In the second stage, esterification with water removal and chain elongation occurs; simultaneously, the complex catalyst is regenerated.

Using the above scheme, we assumed that the catalytic activity of coordination compounds analyzed depends on the stability constant of the complex acid; the lower the stability, the higher the catalyst activity ($K_{y(H_2[Ge(HCitr)_2])}$ 100 and $K_{y(H_2[Ge(Mal)_2])}$ 4.13 [8, 9]).

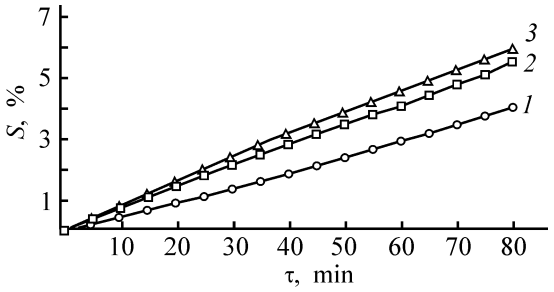

Fig. 4. Degree of S of UPR copolymerization with TMG-3 in the initial stages vs. time τ. BP concentration 0.02 M. (*1*) PGM, (*2*) PGM + 1% $H_2[Ge(HCitr)_2]$, and (*3*) PGM + 1% $H_2[Ge(Mal)_2]$. v_{cop}, mol l^{-1} s^{-1}: (*1*) 0.193, (*2*) 0.276, and (*3*) 0.285.

The copolymerization rate was determined as in [13]. It was found in a study of the copolymerization of UPRs (prepared by polycondensation in the absence of catalyst and in the presence of $H_2[Ge(Mal)_2]$ and $H_2[Ge(HCitr)_2]$) with TGM-3 (Fig. 4), the copolymerization rate is about the same in all the cases and independent of the presence of the catalyst. This fact additionally confirms that neither the metal nor the ligand are incorporated into the UPR molecule.

It was found that the physicomechanical properties of PGM copolymers with 30% TGM-3 cured in the presence of BP (1%) at 40°C and then heated at 80°C for 5 h, such as the hardness, impact resilience, electrical conductivity, and content of the gel fraction, are virtually independent of the catalyst. The properties of the copolymers were as follows: density 1.23–1.24 kg dm^{-3}, Brinell hardness 15–16 kgs mm^2, impact resilience 10–12 kJ m^{-2}, and electrical conductivity $(8–12) \times 10^{-9}$ Ω^{-1} m^{-1}.

CONCLUSIONS

(1) Complex dicitrato- and dimalatogermanic acids exhibit high catalytic acitivity in polycondensation of maleic anhydride and ethylene glycol.

(2) Complex catalysts lower the polycondensation temperature from 180 to 155°C; in addition, dimalatogermanic acid decreases the process time by a factor of 2.

(3) The mechanism of the catalytic reaction is

suggested. The less stable complex of germanium with malic acid is the most effective catalyst.

(4) The procedure for preparing unsaturated polymeric resins (with or without catalyst) noticeably affect neither the rate of their copolymerization with triethylene glycol methacrylate nor the physicomechanical properties of the resulting copolymers.

Abstract—Nontoxic water-soluble low-molecular-weight (MW 14 000–36 000 Da) copolymers of acrylamide with 2-acrylamido-2-methylpropanesulfonic acid, containing from 17.3 to 37.6 mol % sulfonate-containing monomeric units, were synthesized by heterophase radical polymerization in isopropanol or ethanol at 50°C with azobis(isobutyronitrile) as an initiator.

DOI: 10.1134/S1070427207100205

Copolymerization of acrylamide (AA) with sulfonate-containing monomers has been extensively studied [1–7]. Synthesis of copolymers of AA with 2-acrylamido-2-methylpropanesulfonic acid (AAMPSA) was reported by Hollander et al. [1], whose aim was to examine the possibility of using such copolymers in oil production, since the performance of polyacrylamide itself somewhat deteriorates with time because of the partial degradation and sorption on porous mineral surfaces. A study of the behavior of polyacrylamide and AA/AAMPSA copolymer with respect to the sorbing substrate (sodium kaolinite) revealed a slightly lower adsorption, and, therefore, higher performance of the copolymer containing 6.8 mol % AAMPSA. Synthesis of random copolymers of AA with AAMPSA sodium salt and sodium 2-sulfoethyl methacrylate [MW $(5–20) \times 10^5$ Da] was reported in [2]. These copolymers can be used in well boring and also as flocculants.

High-molecular-weight copolymers of AA with AAMPSA (or its sodium salt) are generally synthesized by copolymerization in water [1–4] or aqueous-organic solvents [5–7] in the presence of potassium persulfate as an initiator. At the same time, despite that low-molecular-weight AA–AAMPSA copolymers are of significant practical interest as polymeric carriers for cationic bioactive compounds (according to [8], polyacrylamide is nontoxic), they are little studied yet.

Therefore, we synthesized in this study low-molecular-weight AA–AAMPSA copolymers and characterized their physicochemical and toxicological properties.

The target copolymers were synthesized by heterophase radical copolymerization of AA with AAMPSA in isopropanol or ethanol in the presence of azobis(isobutyronitrile) (AIBN) as an initiator. Taking into account the high polymerization activity and tendency of AA to form cross-linked structures, we carried out the process at 50°C and AIBN concentration of 3.0 or 4.5 wt %. The composition of the products was controlled by varying the initial monomer ratio. The results are presented in Table 1. As can be seen, the yield of AA–AAMPSA copolymers exceeds 95% under the optimal conditions. At such a high conversion, the composition of the resulting copolymers appears to be close to that of the initial monomer mixture. In accordance with the general trends in radical copolymerization, the molecular weight of the resulting copolymers increased with the concentration of the monomers in the starting mixture $[M_1^0 + M_2^0]$

* (S) Sulfur content of the copolymer.

(Table 1, run nos. 1–3; 4 and 5; 6 and 7; and 8 and 9). Another way to control the molecular weight of the copolymers is to change the chemical nature of the solvent. Passing from ethanol to isopropanol as a common chain-transfer agent is accompanied by a decrease in the weight-average molecular weight $\overline{M}_w$ of the resulting copolymer.

We found it incorrect to determine the relative activities of AA and AAMPSA in copolymerization, because the process occurs under heterophase conditions, which affects the reaction kinetics. The occlusion of the macroradicals, resulting in a considerable decrease in the chain termination rate, causes an increase in the overall rate of the heterogeneous copolymerization in alcohols as compared to the homogeneous copolymerization in DMSO. Therefore, the material balance equation cannot be derived correctly in the case of heterophase copolymerization.

The composition of copolymers **I-1**–**I-9** (sulfonic group content) was determined by microanalysis for sulfur. The structure of the copolymers was confirmed by the IR spectra. Figure 1 shows the IR spectra of polyacrylamide (PAA) and AA–AAMPSA copolymer no. **I-8**. As for PAA, the IR spectrum of the copolymer shows an absorption band at 1650 cm^{-1}, corresponding to stretching vibrations of the carbonyl group, and bands at 1565 and 3356 cm^{-1}, corresponding to bending and stretching vibrations of NH, respectively. Unlike PAA, the spectrum of the polymer additionally contains characteristic absorption bands of the $-SO_3H$ groups at 1227, 1040, and 624 cm^{-1} (Fig. 2).

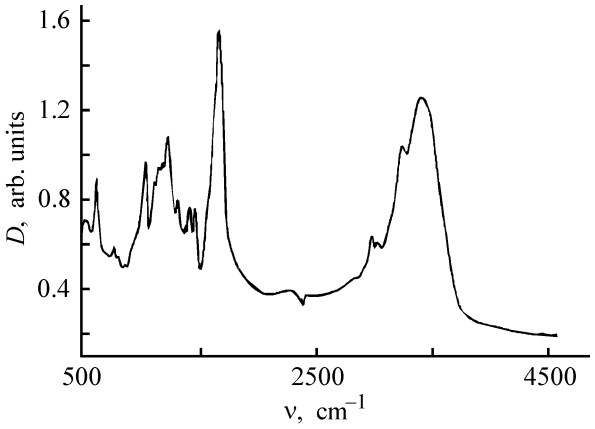

Fig. 1. IR spectrum of polyacrylamide in the range 400–4500 cm^{-1}. (D) Absorption and (ν) wavenumber; the same for Fig. 2.

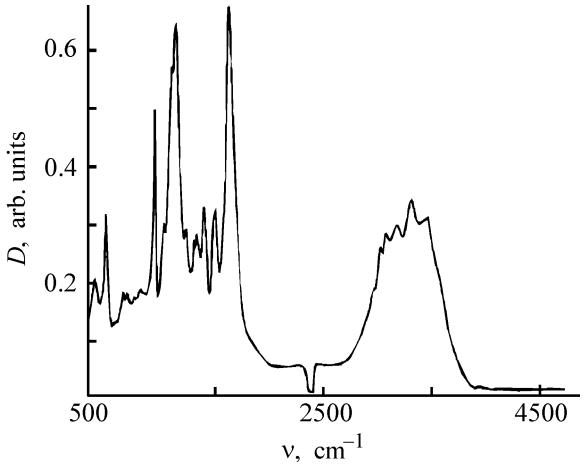

Fig. 2. IR spectrum of copolymer **I-8** in the range 400–4500 cm^{-1}.

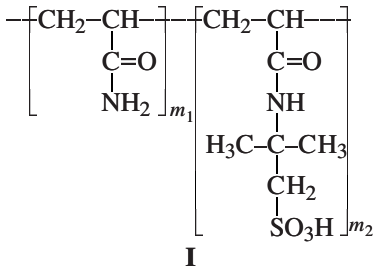
Data of IR spectroscopy and elemental and functional analyses suggest the following structure for copolymers **I**:



I

$m_1 + m_2 = 100$ mol %.

Copolymer nos. **I-1**–**I-9** are low-molecular-weight ($\bar{M}_w$ = 14000–37000 Da), containing 17.3 to 37.6 mol % $-SO_3H$ groups.

Copolymers **I** are strong polymeric acids, titratable with alkali solutions. Aqueous solutions of the copolymers are characterized by low pH, which decreases as the solution concentration increases (Fig. 3). At a fixed solution concentration, pH decreases with as the sulfonate group content of the copolymer grows (Fig. 4). Copolymers **I** are typical polyelectrolytes (polyanions), as demonstrated by the dependence of the reduced viscosity η_r of copolymer no. **I-2** on the NaCl concentration in solution (Fig. 5). The maximal η_r is observed in the absence of NaCl as a result of the strong repulsion between likely charged sulfonate groups of the copolymer. With increasing NaCl concentration, η_r decreases as a result of shielding of the sulfonate groups by the Na^+ counterions.

In run no. 10, AAMPSA homopolymer **II** was obtained in a yield of about 60% (Table 1). The sulfur content of the product is consistent with the theoretical value, and its molecular weight found from the diffusion and sedimentation data is 40000 Da.

It appeared significant to characterize the toxicity of the low-molecular-weight AA–AAMPSA copolymers obtained. The toxicity of copolymers **I**, homopolymer **II**, and such reference polymers as PAA, copolymer of AA with acrylic acid, and dextran sulfate was determined using the procedure described in [9]. As can be seen from Table 2, sulfonate-containing copolymer nos. **I-5** and **I-2** are less toxic than the copolymers of AA with acrylic acid of similar composition. Such a low toxicity of copolymer nos. **I-5** and **I-2** combined with the low molecular weight, solubility in water, and fairly high content of reactive sulfonate groups, makes these materials promising for use as polymeric carriers for lowmolecular-weight bioactive cationic compounds.

As is known [10], certain polyanions demonstrate antiviral activity by themselves. In this context, it appeared interesting to test the investigated sulfonate-containing polymers for antiviral activity. As a reference served dextran sulfate, which, according to

Table 2. Cytotoxicity of sulfonate-containing and reference polymers

Polymer	m_2, mol %	M, Da	IC50, mg ml^{-1}
AA–acrylic acid	20.2	33 000	11.8 ± 0.30
AA–AAMPSA	18.5	36 000	18.0 ± 5.5
AA–AAMPSA	22.8	28 000	16.3 ± 4.3
Poly-AAMPSA	100	40 000	10.2 ± 1.6
PAA	0	28 000	18.8 ± 1.3
Dextran sulfate	100	70 000	29.1 ± 6.1

published data [10], demonstrates antiviral properties. Copolymer nos. **I-2** and **I-5** demonstrated no antiviral activity. By contrast, AAMPSA homopolymer **II** and dextran sulfate exhibit a well-defined antiviral effect [with respect to human herpes simplex virus type 1 (HSV1)], even when taken in a relatively low concentration (100 μg ml^{-1}). The indicated compounds exhibited antiviral activity in vitro against *Vero* cell culture, which was well comparable with such well-known antiherpes drug as Zovirax. As for the antiviral action mechanism of certain sulfur-containing polyanions, it has been suggested that they suppress the adhesion of virus species and their penetration to target cells by blocking the receptors on the cell surface [9]. The occurrence of antiherpes activity in homopolymer **II** opens the door for its medical use, at least when locally administered.

EXPERIMENTAL

Acrylamide (from Germany) was recrystallized twice from ethyl acetate; mp 84.5°C.

Found, %: C 50.48, H 7.15.
Calculated, %: C 50.65, H 7.03.

2-Acrylamido-2-methylpropanesulfonic acid was purified as follows. A 50-g portion of AAMPSA and 290 ml of 90% acetic acid were charged into a 500-ml three-necked flask equipped with a stirrer, reflux condenser, and thermometer. The mixture was heated on a water bath at 80–85°C with stirring for 15 min. The stirrer was turned off, and the mixture was slowly cooled to 15°C. Then the stirrer was turned on, and 65 ml of acetic anhydride was added in portions. The mixture was cooled with an ice–salt mixture to 15°C. The precipitated sulfonic acid was separated on a Buchner funnel, washed with two 50-ml portions of glacial acetic acid, and squeezed on the funnel. Crude AAMPSA was multiply treated with acetone (ultrapure grade) to remove acetic acid, separated on a Buchner funnel, and vacuum-dried to constant weight. Yield 39.6 g (79.2%). Found: S 15.74%, SO_3H groups 39.20 wt %; mp 185°C. Calculated: S 15.46%, SO_3H groups 39.13 wt %.

The reference polymers, low-molecular-weight polyacrylamide and copolymer of AA with acrylic acid, were prepared by the procedure described in [11]. Dextran sulfate (from Austria) with MW 100 000 Da was used.

AIBN was thrice recrystallized from a chloroform/ethanol (1 : 5) mixture. The yield of purified AIBN was 76.2%; mp 103°C. Dehydrated 2-propanol and rectified ethanol were used without additional purification.

Procedure of heterophase copolymerization of AA with AAMPSA (with an example of run no. 2). AIBN (0.08820 g), AA (1.5 g), AAMPSA (1.46 g), and 75 ml of ethanol were charged into a 100-ml ampule. After purging with Ar for 15 min, the ampule was sealed, and the reaction mass was allowed to stand for 24 h at 50 ± 0.5°C. The copolymer was precipitated by adding acetone, and then multiply treated with acetone to completely remove the monomer. Finally, the copolymer was filtered off and dried. Yield 1.94 g (99.2%).The resulting product was further treated by dialysis with water for 3 days and separated by freeze drying. Elemental analysis gives 7.16% for the sulfur content, which corresponds to 22.8 mol % AAMPSA units in the copolymer; [η] = 0.32 dl g^{-1}, MW = 28 000 Da.

The IR spectra of copolymer no. **I-8** and polyacrylamide were recorded on a Bruker IFS spectrometer using KBr technique (3 mg of the sample per 600 mg of KBr).

The weight-average molecular weights $\overline{M}_w$ of copolymers with m_2 = 17.3–22.8 mol % were calculated by the relation used for polyacrylamide [12]:

$$[\eta]^{30}_{1\ N\ NaNO_3} = 3.73 \times 10^{-4}\ M_w^{0.66}.$$

The molecular weight of AAMPSA homopolymer was determined by the diffusion-sedimentation method [13].

Toxicologic tests in vitro. As a test method for characterization of the condition of fibroblasts in the strain we used the Resazurin reduction method [9]. The IC50 values for the polymers under study were estimated by linear regression relationships, using MS Excel 2003 software.

The antiviral activity of the sulfur-containing polymers was determined by the procedure described in [14] with respect to human herpes simplex virus type 1 (HSV1) from the virus strain collection of the Ivanovskii Research Institute of Virology. The virus was grown in the *Vero* cell culture.

CONCLUSION

Conditions of radical polymerization of acrylamide with 2-acrylamido-2-methylpropanesulfonic acid were optimized to allow preparation of low-cytotoxic water-soluble low-molecular-weight copolymers with high (up to 37.6 mol %) content of sulfonate-containing units.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A ^{1}H NMR Study of Radical Copolymerization of *N*-Vinylsuccinimide with *n*-Butyl Acrylate in Dimethyl Sulfoxide

Abstract—Kinetic features of radical copolymerization of *N*-vinylsuccinimide with *n*-butyl acrylate in dimethyl sulfoxide were studied by ^{1}H NMR spectroscopy. The dependences of the running concentrations of the monomers and of the "instant" and overall compositions of the copolymers on the reaction time were determined. The limiting conversions were established for correct analysis of the kinetic features of copolymerization at essentially different relative activities of the monomers. The copolymerization constants and the probability of alternation of the units in the copolymer chains were calculated.

DOI: 10.1134/S1070427207100217

Copolymers of *N*-vinylsuccinimide (VSI) and *n*-butyl acrylate (BA) have acquired importance in preparation of film materials for medical applications [1, 2]. Base hydrolysis of such copolymers involves opening of the succinimide ring to form *N*-vinylamidosuccinic acid (VASA) units containing a carboxy group at which low-molecular-weight physiologically active substances of basic nature can be added via formation of an ionic bond. The BA units act as an internal plasticizer.

Previously, we have studied the copolymerization of VSI with BA in dimethyl sulfoxide (DMSO) [3], acetic anhyride [4, 5], and pyridine [6]. The kinetic features of these reactions were examined by a combination of gravimetry (to estimate the conversion) with elemental analysis and IR spectroscopy (to determine the composition of the copolymer). Here, we employed a new technique for studying the copolymerization kinetics, which is based on monitoring the condition of the reaction mass by ^{1}H NMR spectroscopy at regular interval of time. For details of synthesis, see [3]. Samples were taken with a syringe via a rubber plug and immediately frozen. The ^{1}H NMR spectra were recorded in deuterated DMSO at 20°C, at a frequency of 400 MHz, with TMS as internal reference. This method for monitoring the copolymerization kinetics offers evident advantages.

(1) In examination of small amounts (tens of milligrams) of monomers, significant errors may originate from improperly performed additional operations (precipitation of the polymer; removal of residual monomers, initiator, and solvent; drying; and subsequent preparation for analysis of the copolymer composition). The results are strongly dependent on the thoroughness with which these manipulations are performed, which cannot be unified. The method that we suggest does not suffer from this drawback.

(2) Analysis of the spectra provides data on the running concentrations of both monomers. These data constitute a much more extensive body of information than those derived with the previously employed technique (elemental analysis or IR data provide information only about the overall composition of the coolymers obtained at different degrees of conversion). Using the running concentrations of the monomers, it is possible to determine the composition of individual fractions formed in a period between two successive measurements, in other words, to carry out a "virtual" fractionation of the copolymer, depending on its composition. It is especially important in the case of copolymerization of VSI, whose reactivity strongly differs from that of its comonomer, which result in that with copolymers nonuniform composition are formed. The extent of this nonuniformity should be taken into account when carrying out subsequent polymer-analogous transformations and immobilization of low-molecular-weight substances

(3) The new method can establish the limits within which the data on the conversion and composition

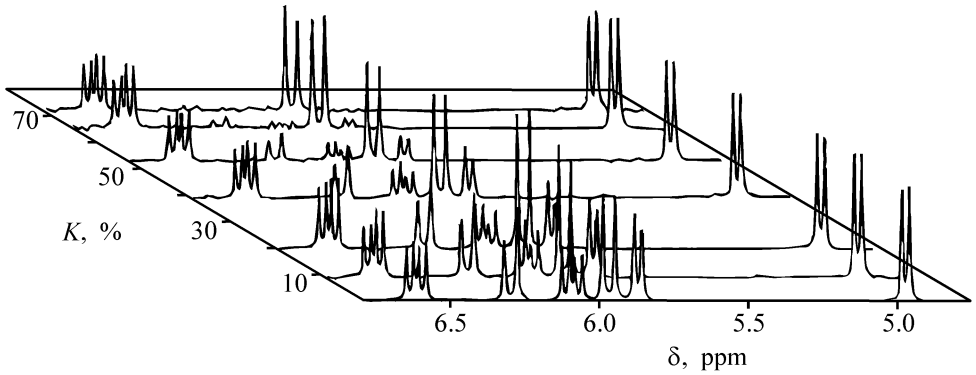

Fig. 1. Relative intensities of signals of the vinyl protons of VSI and BA vs. the conversion K in the ^{1}H NMR spectra of the VSI–BA copolymers. Content of VSI in the initial monomer mixture 50 mol %. (δ) Chemical shift.

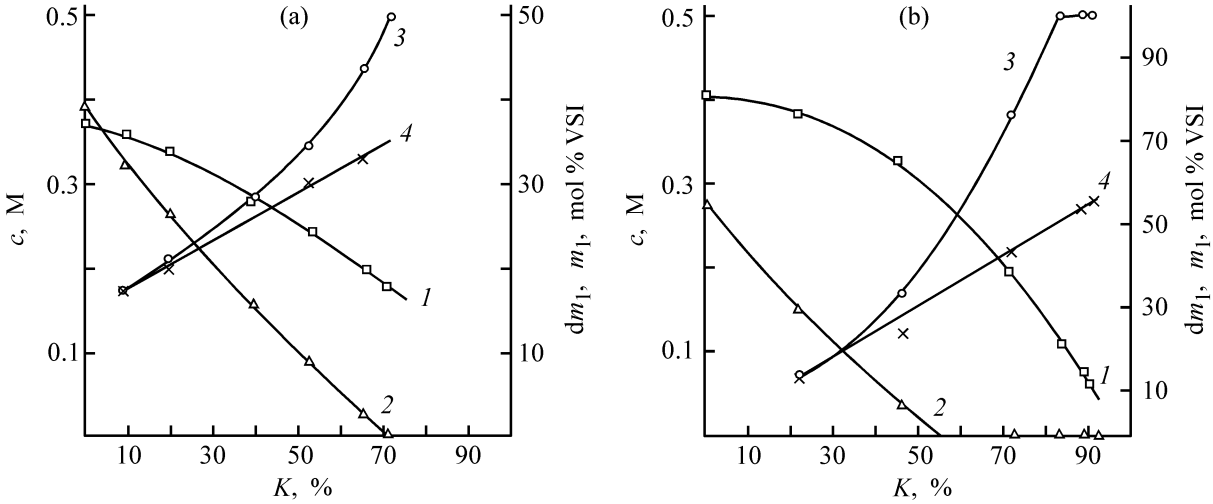

Fig. 2. (*1*, *2*) Concentration c of (*1*) VSI and (*2*) BA, (*3*) "instant" composition dm_1, and (*4*) empirical composition m_1 of the VSI–BA copolymers vs. the conversion K. Content of VSI in the initial monomer mixture, mol %: (a) 50 and (b) 60.

of the copolymers can be correctly used for calculation of the copolymerization constants. When the monomers differ substantially in relative activities, the overall composition at fairly high conversions may vary because of the homopolymerization of the unchanged less active monomer (after the more active monomer is completely spent). However, previous experiments did not answer the question as to whether this is really the case. In this situation, permanent monitoring of the concentrations of the monomers in the system can be helpful to avoid this error which is the more probable because of the use of new algorithms for calculational of copolymerization constants, based on the experimental data obtained at rather high conversions of up to 60%.

In this case the analysis of the composition of the reaction mixture is facilitated by the fact that the vinyl proton signals of the monomers that were used for calculations are clearly resolved in the spectra (Fig. 1). The following signals can be identified: for VSI, α-H appears as a doublet of doublets (6.63 ppm), and *cis*- and *trans*-β-H, as two doublets (5.96 and 4.99 ppm); α-H in butyl acrylate, as a doublet of doublets (6.11 ppm), and *cis*- and *trans*-β-H of BA, as two doublets (6.30 and 5.88 ppm). Figure 1 clearly demonstrates how the monomer ratio varies in the course of the reaction. In the beginning of the copolymerization reaction, the monomers are in the equimolar ratio; the intensities of the signals of their vinyl protons are equal. Because of the higher reactivity, BA is incorporated into the polymeric chain faster than VSI. This leads to depletion of the copolymer being formed in the VSI units relative to the running composition of the monoer mixture, which implies a faster expenditure of BA and a change of the concentration ratio of the monomers in favor of VSI. This is evident from the plots of the concentrations of the monomers and the composiion of the copolymer vs. the conversion (Fig. 2).

From the curves demonstrating how the concentrations of the monomers vary with the conversion

80	0.0931	0.2326	0.3371	1.28	1.69
90	0.2123	0.1047	0.3415	1.62	1.31

(Fig. 2) we can derive the conversion corresponding to the onset of homopolymerization of the less active VSI after BA is completely spent. For the initial composition of the monomer mixture VSI : BA = 50 : 50, this conversion is 71%, and for VSI : BA = 60 : 40, 56%. After these conversions are reached, the empirical composition of the copolymers changes in favor of VSI exclusively via formation of the homopolymer PVSI, and the results obtained in this stage of the process are unsuitable for analyzing the kinetic relationships in copolymerization.

These data were used for calculating the constants of copolymerization of VSI (M1) with BA (M2) by the specially developed routine according to technique from [7]. The constants were determined by modified methods of Ezrielev–Brokhina–Roskin (EBR) [8] and Kelen–Tüdös (KT) [9] (Table 1).

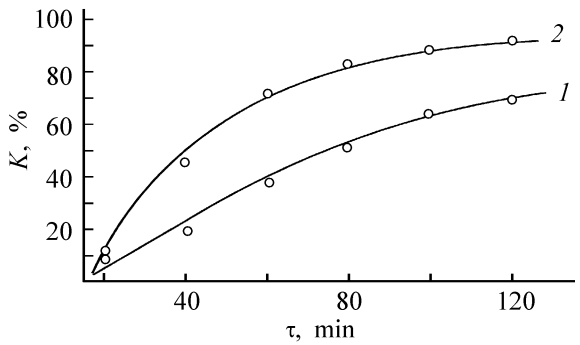

Fig. 3. Conversion of the monomers K vs. the reaction time τ. VSI content of the initial monomer mixture, mol %: (*1*) 50 and (*2*) 60.

Previously it has been shown by Lavrov and Krasil'nikova [7] and Ezrielev et al. [10] that the EBR method allows the most reliable determination of the copolymerization constants because the equations for the composition of the copolymer are symmetric with respect to r_1 and r_2. Therefore, just the values obtained by this method were used for calculating the effect of alternation of the units in the macromolecules of the copolymer [11], which is estimated by the probability of formation of various types of diads [M_1–M_1, M_1–M_2 (M_2–M_1), M_2–M_2] and by the statistical average length of blocks formed by units of each type in the polymer chains (Table 2).

Table 2 shows that formation of copolymers with alternating VSI and BA units (maximal values of f_{12} and f_{21}) is possible only in copolymerization of monomer mixtures containing VSI in a large excess (80–90 mol %). However, Fig. 2 suggests that, in this case, BA will be exhausted already at low conversions, and the subsequent process will consist in homopolymerization of VSI. Hence, a copolymer comparatively uniform in composition will be formed only in the initial stage of the reaction.

Copolymerization of VSI with BA is a homophase process; its pattern previously observed in [3] is confirmed by ^{1}H NMR in this study. The kinetic curves (Fig. 3) exhibit no gel effect; the reaction is

accelerated as the content of VSI in the initial monomer mixture is raised.

CONCLUSIONS

(1) ^{1}H NMR spectroscopy was applied for the first time to kinetic study of the radical copolymerization of *N*-vinylsuccinimide with *n*-butyl acrylate in dimethyl sulfoxide. This technique offers certain advantages over the previously used methods.

(2) An examination of the concentrations of the monomers and the "instant" and overall compositions of the *N*-vinylsuccinimide–*n*-butyl acrylate copolymers in the course of the reaction revealed the limiting conversions suitable for correct analysis of the kinetic relationships in copolymerization.

(3) Copolymerization constants were calculated with the use of a specially developed routine based on the Ezrielev–Brokhina–Roskin method, $r_{VSI} = 0.07$ and $r_{BA} = 2.76$, and Kelen–Tüdös method, $r_{VSI} = 0.07$ and $r_{BA} = 2.78$.

(4) It was shown that an *N*-vinylsuccinimide–*n*-butyl acrylate copolymer with a uniform composition can be obtained in dimethyl sulfoxide under the experimental conditions only at low conversions under a high excess of *N*-vinylsuccinimide in the initial monomer mixture (80–90 mol %).

Abstract—Activity of azanorbornenes: *N*-benzyl-2-azanorborn-5-ene, (2-azanorborn-5-en-2-yl)methyl acetate, and *N*-allyl-2-azanorborn-5-ene in radical homo- and copolymerization with vinyl monomers and sulfur dioxide was studied.

DOI: 10.1134/S1070427207100229

Polymers based on norbornenes have high elasticity and the ability to absorb mechanical energy [1–3]. Due to vibro- and sound-extinguishing properties, polynorbornenes are used in electronic, electrotechnical, motor-car, and packing industries [4, 5]. In addition, polynorbornenes are highly stable with respect to acids, alkali, fats, and oils, shows low shrinkage, and are environmentally harmless [5]. Polymerization with catalysts based on transition metals (metathesis catalysts), which allows preparation of polymers containing nonaromatic rings and double bonds in the backbone, is one of the main methods for synthesis of polynorbornenes. Spontaneous copolymerization of norbornene with sulfur dioxide by the radical mechanism at low temperatures (–40°C) to give alternating equimolar copolymers was reported in [6]. A search for novel polycyclenes and efficient methods of the synthesis of valuable macromolecular compounds from them is urgent because the polycyclene polymerization has high potential, but is poorly studied.

Heteroderivatives of norbornenes are of special interest. Much attention is focused on biologically active compounds in the series of azabicycloheptenes and heptanes [7–9]. In particular, derivatives of the above compounds demonstrate a highly selective activity with respect to various subspecies of nicotine and acetylcholine receptors and antagonists of muscarine receptors, used as an active ingredient of drugs for curing central nervous system [7], neurodegenerative and gastrointestine diseases [8], and in production of carbocyclic nucleosides used as antiviral preparations [9]. There are no data on radical polymerization of azanorbornenes (ANB). In this study, we examined the reactivity of *N*-benzyl-2-azanorborn-5-ene (BAN), (2-azanorborn-5-en-2-yl)methyl acetate (MAAN), and *N*-allyl-2-azanorborn-5-ene (AAN) in the radical copolymerization reactions and estimated the biological activity of the polymers synthesized.

EXPERIMENTAL

Azanorbornenes were prepared by the method described in [10]. The following fractions were used for polymerization: BAN, bp 99–102°C (66.6 Pa), n_D^{20} = 1.5489; MAAN bp 80–82°C (160.0 Pa), n_D^{20} = 1.4830; and AAN, bp 51–53°C (133.3 Pa), n_D^{20} = 1.4880. The chemical shifts and multiplicities of ^1H ^{13}C NMR signals are listed in Table 1.

Acrylonitrile (AN), methyl methacrylate (MMA), maleic anhydride (MA), styrene (ST), vinyl acetate (VA), azobis(isobutyronitrile) (AIBN), and benzoyl peroxide (BP) used for synthesis of copolymers, and also the solvents dimethyl sulfoxide (DMSO), methanol, and acetone had characteristics corresponding to reference data after purification by the standard methods. Sulfur dioxide was dried by passing through concentrated H_2SO_4 and freshly calcined $CaCl_2$.

The homo- and co-polymerization of azanorbornenes with vinyl monomers was performed in the bulk and in solution in the presence of AIBN (or BP) in

ampules in a vacuum, and copolymerization with SO_2, in a glass reactor [11]. The polymers obtained were purified by twofold reprecipitation from a solution in DMSO into a precipitant (acetone) and dried in a vacuum to constant weight at 50°C. The compositions of the polymers were calculated from the data of elemental analysis. The NMR spectra were recorded on a Bruker AM-300 spectrometer with a working frequency of 75.5 MHz (^{13}C). The spectra were recorded in the broad-band proton-decoupling mode and in the JMOD mode. DMSO-d_6 was used as solvent, and tetramethylsilane, as internal reference.

In the presence of radical initiators (AIBN, BP), ANBs are not noticeably involved in the homopolymerization. In particular, the yield of homopolymers in 10 h at 80°C does not exceed 0.5 wt % in the presence of 2.5 wt % AIBN. In copolymerization with vinyl monomers, ANBs are more active. The reaction conditions and results obtained are listed in Table 2. The copolymers formed (^{13}C NMR data) have a random distribution of comonomeric units in the macrochain. The data obtained show that ANB copolymerization with methyl methacrylate and styrene proceeds at higher rates. With respect to incorporation

into the polymeric chain, ANBs are more active in copolymerization with vinyl acetate and maleic anhydride. In particular, the BAN content in the macrochain is about 70 mol % in copolymerization with VA at equimolar ratio of monomers in the initial mixture. In copolymerization with vinyl monomers, the copolymerization rates decrease with increasing ANB fraction in the reaction medium (Table 2).

In copolymerization with sulfur dioxide possessing a high electron-acceptor power, ANBs are substantially more active. This reaction proceeds at high rates to give alternating copolymers (data of spectral and elemental analysis) of equimolar composition, irrespective of the monomer ratio in the starting mixture, medium (in the bulk, in solvent), initiator (AIBN, BP), reaction temperature (60–90°C), and degree of conversion. The constancy of the copolymer composition at various monomer ratios in the reaction medium and known data on copolymerization of other unsaturated compounds with SO_2 [6, 13] suggest that the copolymerization proceeds through formation of donor–acceptor [ANB$\cdots$$SO_2$] complexes, which was confirmed by NMR studies.

Mixing of ANB with SO_2 gives black adducts. Comparison of ^{13}C NMR spectra of BAN, AAN, and products of their reaction with SO_2 (Table 3) shows substantial downfield shifts of signals of C_5 and C_6 atoms of the bicycle double bond. In particular, in the spectrum of BAN product with SO_2 (structure **II**), the C_5 and C_6 signals of bicycle double C bond are shifted downfield with respect to the monomer (structure **I**) by +12.76 and +25.98 ppm, respectively. The C_7 bridging atom in the reaction product is also noticeably (+9.77 ppm) deshielded. In addition, upfield shifts (–9.96 to –9.32 ppm) of signals of C_3 and C_8 atoms bonded with the nitrogen atom are observed. The above signal shifts indicate that the nitrogen atom, having a lone electron pair, is also involved in the complexation.

Similar shifts of the signals of the above carbon atoms are observed in the ^{13}C NMR spectra of the product of AAN reaction with SO_2. In the spectrum of the product (structure **IV**), the signals of the C_{10} atom in the double bond of the allyl group are shifted downfield, and those of C_9 atom, upfield by +5.16 and –6.32 ppm, respectively, as compared to the AAN spectrum (structure **III**). The shift and broadening of the signals of thedouble bonds of the allyl group in the AAN adduct show that these bonds are also involved in complexation. However, the signal shifts indicate that the double bond of norbornene ring makes the largest contribution to the formation of AAN complex with SO_2. The shifts of the signals of the corresponding carbon atoms in MAAN adducts with SO_2 are smaller (structures **V** and **VI**), which is probably due to redistribution of the electron density, with the acetate group involved.

The reaction conditions have no effect on the polymer composition, but strongly affect the reaction rate and copolymer yield. A study of the kinetic features of ANB copolymerization with SO_2 showed that dependences of the reaction rates on the ratio

of monomers pass through a maximum at their equimolar ratio (this is shown by the example of MAAN, Fig. 1). Both positive and negative deviations from the equimolar ratio lead to a decrease in the reaction rate, caused by a decrease in the concentration of the reactive complex in the system.

It is known that alternating copolymerization has pronounced specific features in comparison with random distribution [14], such as spontaneous initiation and insensitivity to the action of the majority of inhibitors. These features are manifested in copolymerization of ANB with SO_2. Copolymerization proceeds in the absence of initiators and also upon addition of inhibitors (diphenylpicrylhydrazyl or nitroxyl radical). However, the copolymerization rates in all the systems studied increase in the presence of the initiator. In particular, in BAN copolymerization with SO_2 in methanol at 75°C and 3.2 M concentration of monomers, the reaction rates in the absence of the initiator and at AIBN content of about 1 wt % are 0.5 and 0.9% per min, respectively. The reaction order with respect to initiator at AAD content within the range 0.55×10^{-1}–1.00×10^{-1} M is 0.45.

The solvent strongly affects ABN co-polymerization with SO_2. In DMSO, copolymerization of all ABNs proceeds at a substantially (approximately three times) higher rate as compared to methanol, which is probably due to different stabilities of the reaction complex in the above media.

As temperature is elevated, the reaction rate in the systems studied increases. The total activation energies of copolymerization of BAN and AAN with SO_2 in methanol, calculated from the Arrhenius equation within the 70–90°C range, are 76.4 and 79.6 ± 2.0 kJ mol^{-1}, respectively (Fig. 2). It is known [15] that the activation energy of alternating copolymerization is frequently lower than that for the majority of reactions of free-radical polymerization, whose apparent activation energy usually lies within the range 84–96 kJ mol^{-1}.

In the NMR spectra of the products of ANB reaction with SO_2 in the presence of initiator at 60–90°C, the signals of the C atoms of the double bond in the norbornene ring are absent. The products obtained contain up to 75% copolymers and about 15% exo- and endostereoisomeric dimers. The double bond of the AAN allyl group is not involved in copolymerization with SO_2, both at their equimolar ratio and at a twofold excess of SO_2.

Copolymers of ANBs with SO_2, which are black powders, are soluble in DMSO and methanol (in

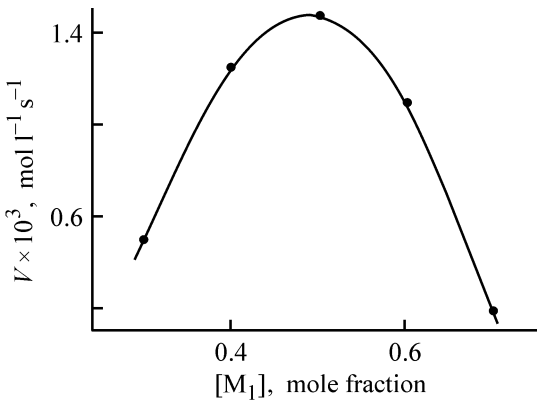

Fig. 1. Dependence of the initial rate V of MAAN (M_1) copolymerization with SO_2 (M_2) on the composition of the initial monomer mixture (mole fraction). $[M_1 + M_2] = 3.50$, $[AIBN] = 3.05 \times 10^{-2}$ M, $M_1 : M_2 = 1 : 1$, $T = 80$°C.

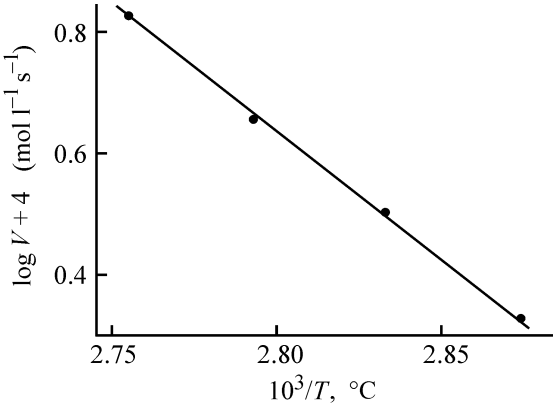

Fig. 2. Dependence of the initial rate V of MAAN (M_1) copolymerization with SO_2 (M_2) in methanol on temperature T. $[M_1 + M_2] = 3.15$, $[AIBN] = 5.47 \times 10^{-2}$ M, $M_1 : M_2 = 1 : 1$.

the initial steps of conversion) and insoluble in other commonly used solvents (acetone, methyl ethyl ketone, benzene, tetrahydrofuran, ethyl acetate, chlorinated hydrocarbons, etc.). The solubility of BAN copolymers with vinyl monomers depends of the nature of the second comonomer (Table 2).

Toxicological tests showed that copolymers of azanorbornenes with sulfur dioxide belong to hazard class 4 and can be used in medicine.

CONCLUSIONS

(1) Azanorbornenes, *N*-benzyl-2-azanorborn-5-ene, (2-azanorborn-5-en-2-yl)methyl acetate, and *N*-allyl-2-azanorborn-5-ene do not homopolymerize in the presence of radical initiators and are involved in copolymerization with vinyl monomers at low rates to give copolymers with a random distribution of comono-

meric units in the macromolecule and with a fairly high content of norbornene units in the macrochain. The copolymerization rate decreases as the azanorbornene fraction in the initial mixture becomes larger.

(2) Azanorbornenes demonstrate high activity in copolymerization with sulfur dioxide. Copolymerization proceeds at the double bond of the norbornene ring via formation of a donor–acceptor complex, to give alternating copolymers with equimolar composition, irrespective of the monomer ratio in the initial mixture and reaction conditions.

Abstract—The initiating ability of *N*-hydroxyphthalimide in polymerization of methyl methacrylate and acrylonitrile was examined. For the polymerization of methyl methacrylate, the initial polymerization rates and activation energies were determined, and the dependences of the polymerization rates on the initiator and monomer concentrations were evaluated. An initiation mechanism was suggested.

DOI: 10.1134/S1070427207100230

In recent years, much attention has been received by *N*-hydroxyphthalimide (HPI), a catalyst for oxidation of organic substrates by molecular oxygen at C–H bonds, with a view to preparation of valuable oxygen-containing products [1]. In such processes, HPI acts as a radical catalyst of the chain propagation stage in which the *N*-oxyl radical of phthalimide, formed from the HPI molecule, exhibits high selectivity in abstraction of a hydrogen atom [2]. An examination of how it influences the oxidation of unsaturated compounds showed that *N*-hydroxyphthalimide is also efficient in initiation of radical polymerization of methyl methacrylate (MMA) and acrylonitrile (AN), i.e., it can enter into addition reactions at double bonds. Sato et al. [3] also mentioned the initiating effect of HPI in polymerization of vinyl compounds.

We examine here the kinetic relationships in *N*-hydroxyphthalimide-initiated radical-chain polymerization.

EXPERIMENTAL

N-Hydroxyphthalimide available from Fluka was used without additional purification. Benzoyl peroxide (BP) and azobis(isobutyronitrile) (AIBN) were recrystallized twice from ethanol. Acetonitrile was purified by the standard technique [4]. Methyl methacrylate was thrice washed with 10–15% aqueous alkali solution to exhaustively remove the inhibitor. Then it was thrice washed with distilled water, dried over anhydrous calcium chloride, and distilled in a nitrogen atmosphere at reduced pressure to isolate the (22 ± 0.2)°C/25 mm Hg fraction. We used freshly distilled methyl methacrylate.

Acrylonitrile was washed successively with dilute sulfuric acid, a 5% Na_2CO_3 solution, and water, whereupon it was dried over molecular sieves and distilled in a nitrogen stream.

The polymerization kinetics for methyl methacrylate and acrylonitrile was examined dilatometrically. The monomer content of the reaction mixture was 25 vol %. Polymerization of MMA and AN in the presence of HPI, BP, and AIBN was carried out in an acetonitrile solution at 339 K. The concentrations of AIBN and BP were 5×10^{-3} and 1×10^{-2}, respectively, and that of HPI, 1×10^{-3}–1×10^{-2} M.

The polymerization rates were estimated from the slope of the kinetic curve in the initial stage of the reaction (up to 5% conversion of the monomer), when it is virtually linear.

The table lists the initial rates of polymerization in acetonitrile for methyl methacrylate and acrylonitrile in the presence of BP, AIBN, and HPI, as well as of PB–HPI and AIBN–HPI systems.

It is seen that addition of *N*-hydroxyphthalimide to the monomer containing initiator (BP or AIBN) accelerates the polymerization of MMA. Importantly, HPI can by itself initiate the polymerization in the absence of classical initiators in the system. It should be noted that, under the actual conditions,

Rates of radical polymerization of MMA and AN in acetonitrile in the presence of initiating systems

Monomer	[HPI] × 10^{-3}	[BP] × 10^{-3}	[AIBN] × 10^{-3}	W_{pol}, mol l^{-1} s^{-1}
	M			
MMA	5.0			4.21 ± 0.04
		1.0		8.1 ± 0.1
			5.0	9.8 ± 0.1
	5.0	1.0		11.00 ± 0.02
	5.0		5.0	11.6 ± 0.1
AN	5.0			9.13 ± 0.03
	5.0		5.0	26.3 ± 0.04

MMA and AN do not polymerize without addition of initiators or HPI.

N-Hydroxyphthalimide is a very efficient radical catalyst in chain reactions of oxidation of organic compounds by molecular oxygen [5]. In the polymerization reactions (see table) it can act as initiator. Under steady-state conditions, the rate of initiated radical polymerization in the presence of two initiators is described by the equation

$$W_{0\Sigma} = k_p(k_t)^{-1/2}[RH](f_{HPI}k_d[In_1] + f_{AIBN}k_d[In_2])^{1/2} = (W_{0In_1}^2 + W_{0In_2}^2)^{1/2},$$

where k_d is the rate constant of decomposition of the initiator, In; f, initiation efficiency; k_p, chain propagation rate constant; and k_t, chain termination rate constant.

The experimental dependences of the polymerization rate on the concentrations of the initiators in reactions initiated by individual initiators and their mixture are consistent with the equation above. After substituting in it the polymerization rate of MMA in the presence of AIBN only (9.8×10^{-5} mol l^{-1} s^{-1}) or HPI (4.21×10^{-5} mol l^{-1} s^{-1}), we obtain the calculated rate of oxidation under the combined action of these initiators of 10.7×10^{-5} mol l^{-1} s^{-1} against the experimental $W_{0\Sigma} = 11.6 \times 10^{-5}$ mol l^{-1} s^{-1}. Similar results were obtained for benzoyl peroxide–*N*-hydroxyphthalimide mixtures. Thus, HPI acts in polymerization reactions as a typical initiator.

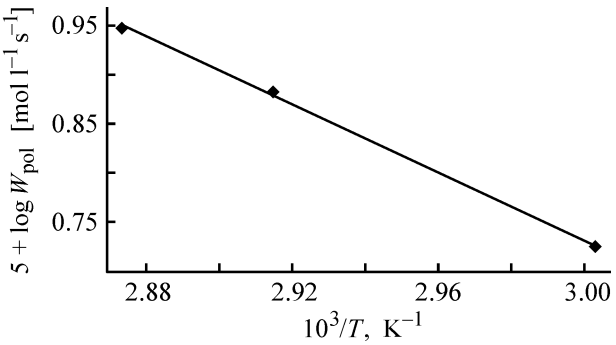

Fig. 1. Temperature dependence of the polymerization rate W_{pol} in the Arrhenius coordinates. Solvent acetonitrile, [MMA] = 2.24 M, and [HPI] = 0.005 M.

To elucidate the specific features of initiation with *N*-hydroxyphthalimide, we studied the kinetics of the MMA polymerization in the presence of this initiator.

Figure 1 shows the temperature dependence of the rate of *N*-hydroxyphthalimide-initiated polymerization of MMA. The activation energy of MMA polymerization is 32 ± 4 kJ mol^{-1} (Fig. 1); the activation energy of MMA polymerization initiated by AIBN was estimated at 84.3 ± 4 kJ mol^{-1}. These data suggest that the activation energy of the initiation reaction involving *N*-hydroxyphthalimide is much lower than that of the AIBN decomposition into radicals.

The activation energy of radical-chain polymerization can be represented as

$$E_a = 1/2E_{in} + E_p = E_t,$$

where E_{in} is the activation energy of initiation (in the case of AIBN, this is the activation energy of decomposition of the initiator); E_p, activation energy of chain propagation; and E_t, activation energy of chain termination.

Considering that the activation energy of AIBN decomposition is 125.4 kJ mol^{-1} [6]

$$E_{a.\,AIBN} - E_{a.\,HPI} = 1/2(E_{in.\,AIBN} + E_{in.\,HPI}),$$

$$E_{in.\,HPI} = 125.4 - 2(84.3 - 32) = 20.8 \text{ kJ mol}^{-1}.$$

we obtain 20.8 kJ mol^{-1} for the activation energy of initiation by *N*-hydroxyphthalimide, which cor-

responds to a bimolecular reaction. According to [7], the activation energy of monomolecular decomposition of the initiator molecules, accompanied by cleavage of covalent bonds, is within 115–130 kJ mol^{-1}.

We also found that, at a constant monomer concentration of 2.24 mol g^{-1}, the polymerization rate is proportional to the square root of the initiator concentration (Fig. 2). This suggests that, in the initiation stage, the reaction kinetics is described by the first-order equation with respect to *N*-hydroxyphthalimide concentration, since the radical-chain polymerization of MMA involves bimolecular termination of the poly(methyl methacrylate) radicals [8].

Figure 3 shows the plot of the polymerization rate vs. the monomer concentration. It is seen that the polymerization rate linearly varies with the methyl methacrylate concentration to power 3/2.

The IR spectrum of poly(methyl methacrylate) yielded by polymerization in the presence of *N*-hydroxyphthalimide is identical to that of the polymer obtained by thermal polymerization of methyl methacrylate. This supports the radical-chain mechanism of the polymerization.

These experimental dependences can be described by the following scheme:

$$M + HPI \rightarrow 2r_i^{\cdot}, \ k_i; \quad (1)$$

$$r_i^{\cdot} + M \rightarrow M^{\cdot}, \ k_p; \quad (2)$$

$$M^{\cdot} + M \rightarrow n_i M^{\cdot}, \ k_p; \quad (3)$$

$$n_i M^{\cdot} + n_j M^{\cdot} \rightarrow P, \ k_t, \quad (4)$$

where k_i, k_p, and k_t are the rate constants of the reactions of chain initiation, propagation, and termination, respectively; and M, methyl methacrylate monomer.

Under steady-state conditions and with long chains, the rate of *N*-hydroxyphthalimide-initiated polymerization of methyl methacrylate by reaction (1) is described by the equation

$$W_{pol} = k_p k_i^{1/2} (2k_t)^{-1/2} [M]^{3/2} [In]^{1/2}. \quad (5)$$

The initiation mechanism, i.e., the mechanism of reaction (1), still remains to be elucidated. In polymerization of vinyl compounds in the absence of oxygen and other initiation sources, chain initiation proceeds at a very low rate. Under the actual conditions, dissociation of the C–H, C–C, and C=C bonds into radicals is excluded (the strength of these bonds is within 260–500 kJ mol^{-1} [9]); the same is true for dissociation of the N–O and O–H bonds. More probable is formation of radicals from bi- and trimolecular reactions. As is known [3], polar vinyl monomers are able at temperatures below 100°C of complexing with organic compounds via hydrogen bonding or via π bonds. For example, the hydroperoxide and monomer molecules form an ROOH···M complex, which further yields radicals by the reaction ROOH + ⟩C=C⟨. This reaction is more competitive than the ROOH → RO· + ·OH reaction in the initiation stage.

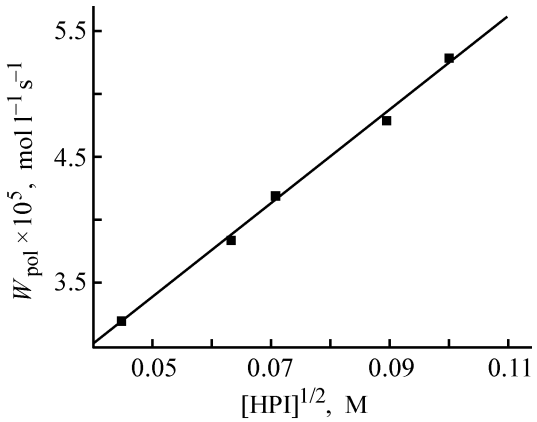

Fig. 2. Rate of MMA polymerization W_{pol} vs. initiator concentration [HPI]. Solvent acetonitrile, T = 339 K, and [MMA] = 2.24 M.

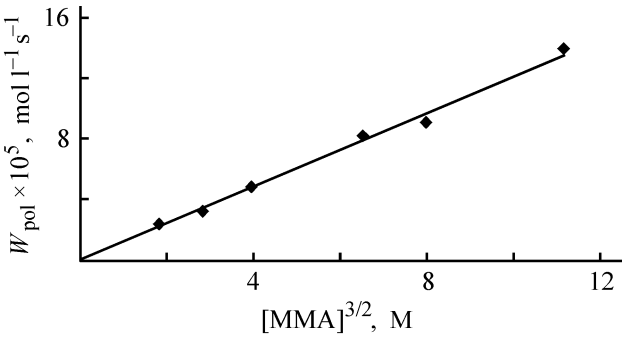

Fig. 3. Rate of polymerization of MMA W_{pol} vs. monomer concentration [MMA]. Solvent acetonitrile, T = 339 K, and [HPI] = 0.005 M.

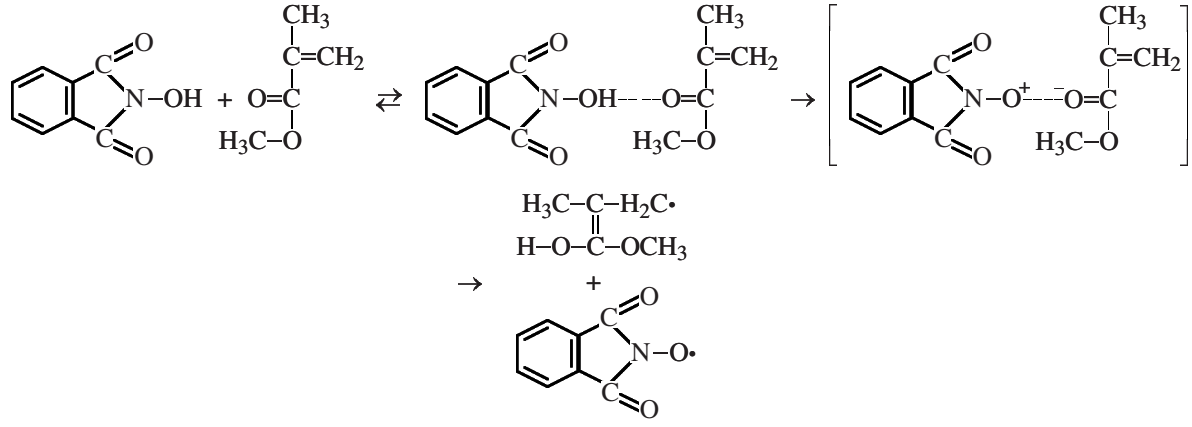
Our experimental data suggest that *N*-hydroxyphthalimide is involved in the initiation stage. The following mechanism of radical formation in the methyl methacrylate polymerization in the presence of HPI can be presumed. In the first stage, *N*-hydroxyphthalimide and the monomer molecules form a complex, which further decomposes into radicals. In this case, two pathways of complexing are possible. The first pathway is via hydrogen bonding between the hydrogen of the hydroxy group in HPI and oxygen

of the carbonyl group in the methyl methacrylate molecule. Next, phthalimide-*N*-oxyl radical yielded by decomposition of the complex initiates polymerization:



A similar mechanism has been suggested by Saito et al. [3] for the methyl methacrylate polymerization in the presence of *N*-hydroxysuccinimide. The second pathway of complexing involves the double bond of the monomer, similar to initiation by hydroperoxides. However, there are no experimental data to decide unambiguously between the first and second pathways of complexing in the initiation reaction.

The mechanism we suggested explains the experimentally established order of the polymerization reaction with respect to the monomer, namely, 3/2. At high MMA concentrations, the initiator is completely complexed with the monomer, and the polymerization rate is no longer dependent on the monomer concentration.

CONCLUSION

N-Hydroxyphthalimide efficiently initiates radical-chain polymerization of vinyl monomers in the bimolecular reaction of *N*-hydroxyphthalimide with the monomer. The low activation energy of this initiation reaction makes it promising for radical-chain polymerization reactions at temperatures lower than those for classical initiators.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Kinetics of Thermal Oxidative Degradation of a Compound Based on a Polyester Resin and Dimethylethylphenylammonium Iodide

N. I. Polezhaeva and A. A. Nefedov

Siberian State University of Technology, Krasnoyarsk, Russia

Received October 30, 2006; in final form, January 2007

Abstract—The kinetics of thermal oxidative degradation of a compound based on a polyester resin and dimethylethylphenylammonium iodide was studied. The rate constants of thermal decomposition were determined. The degradation of the compound was studied by dynamic thermogravimetric analysis.

DOI: 10.1134/S1070427207100242

To develop various formulations of low-temperature solder creams, taking into account specific conditions of their application, it is necessary to know how materials used as an organic binder behave at working temperatures of solder cream fusion. In particular, the rate of their decomposition at working temperatures should be evaluated [1].

This paper reports on a further study of the developed formulations of low-temperature noncorrosive solder creams based on a polyester resin modified with rosin and on quaternary ammonium salts [2, 3].

EXPERIMENTAL

The parameters of thermal oxidative degradation of dimethylethylphenylammonium iodide (DMEPAI) and a compound based on a polyester resin and DMEPAI were determined by dynamic thermogravimetric analysis [4]. To determine more accurately the temperature at which the samples start to degrade, we recorded the DTG and DTA curves along with the TG curve (Figs. 1a, 1b). Measurements were performed with an MOM Q-1000 derivatograph (Hun-

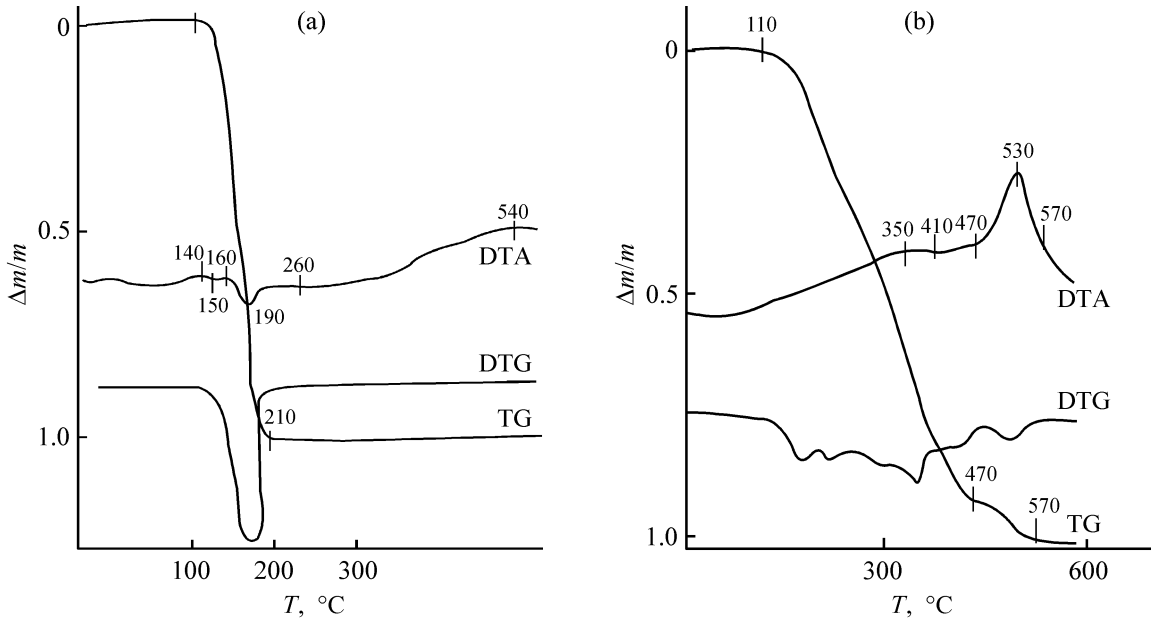

Fig. 1. Thermograms of (a) dimethylethylphenylammonium iodide and (b) compound based on a polyester resin and dimethylethylphenylammonium iodide. ($\Delta m/m$) Relative weight loss and (T) temperature.

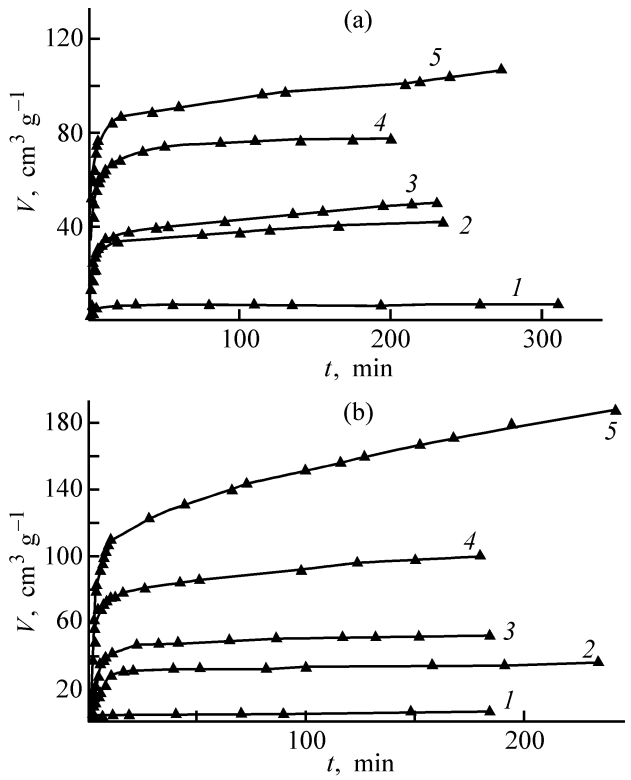

Fig. 2. Manometric curves of gas evolution from samples (a) 1 and (b) 2 at temperatures of up to 300°C. (V) Volume of the released gas and (t) time; the same for Figs. 3 and 4. Temperature, °C: (*1*) 100, (*2*) 150, (*3*) 180, (*4*) 250, and (*5*) 300.

gary) in the programmed-heating mode. Samples (0.05 g) were heated in a platinum crucible in air at a rate of 10 deg min^{-1}. The sensitivity parameters were as follows: balance, 100 mg; DTA, 1/3; and DTG, 1/10.

When heated in air, DMEPAI decomposes in the temperature range 140–200°C (Fig. 1a).

The compound, when heated in air, degrades in three steps in the temperature range 110–570°C (Fig. 1b). The first step (110–190°C) involves the weight loss due to removal of the residual solvent, free reaction water, alcohol, and unsaponifiable substances boiling in this temperature range. The second step (220–410°C) involves simultaneously occurring endothermic decomposition of DMEPAI and exothermic oxidation of a part of the released products [3, 5]. The third step is characterized by a complex exothermic effect with characteristic temperatures of 470 (onset of the exothermic peak in the DTA curve due to the onset of oxidation) and 530°C. The strong peak at 530°C corresponds to oxidation of gaseous products formed by thermal degradation of the polyster resin [2, 5].

The kinetics of thermal degradation under static conditions was studied by the manometric method using a glass Bourdon zero gage (hereinafter, manometer) at a residual pressure in the reaction volume of 10^{-1}–10^{-2} mm Hg in the temperature range 100–300°C. The temperature in the thermostat was maintained with an accuracy of ±(0.2–0.5)°C. The scheme of the installation and the experimental procedure were described in [6, 7].

To make the data comparable, the results of the manometric study of thermal degradation were converted to the normal volume of gaseous products per gram of the starting substance:

$$V_t = (T_0 V_r P_t)/(T P_0 m),$$

where V_r is the volume of the reaction space of the manometer (cm^3); P_t, pressure of decomposition products at time t (mm Hg); V_t, volume of gaseous decomposition products at time t (cm^3); T_0, temperature under normal conditions (273.15 K); T, experimental temperature (K); m, sample weight; and P_0, pressure under normal conditions (760 mm Hg).

Using experimental data, we plotted the time dependence of the volume of the released gases (per gram of starting substance). The character of the thermal degradation can be judged from the shape of the smoothed kinetic curve. When a substance degrades by a first-order rate law, the dependence $V_i = f(t_i)$ is described by a curve that levels-off (actually observed in our experiments). In this case, the rate constant of thermal degradation is calculated by the formula

$$k = (1/t)\ln[V_\infty/(V_\infty - V_t)],$$

where V_∞ is the total volume of gaseous decomposition products under normal conditions per gram of the starting substance (cm^3). The volume V_∞ was taken from the experimental manometric curves. It is specific too each temperature, because, as temperature increases, more and more components become volatile.

Because the working fusion temperature of low-temperature solder creams varies in the range 120–350°C, depending on composition, manometric studies of samples 1 and 2 were performed at 100, 120, 150, 180, 250, and 300°C [8].

Manometric studies of the polyester resin (sample 1) and its compound with DMEPAI (sample 2) showed that these substances are stable up to approximately 250°C (Figs. 2a, 2b). The gas evolution observed in the experiments was due to removal of the re-

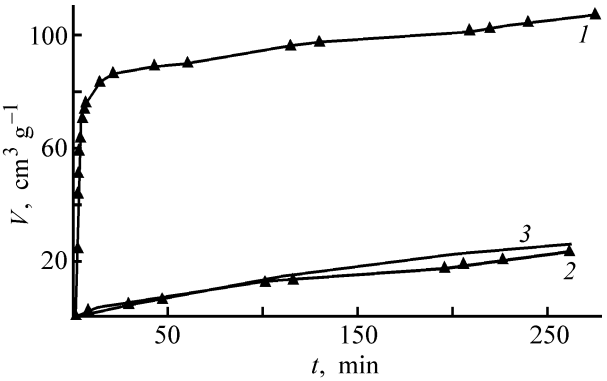

Fig. 3. Manometric curves of gas evolution from sample 1 at 300°C: (*1*) experimental curve, (*2*) curve after subtracting the volume of the initially released gases, and (*3*) fitting by a first-order rate equation.

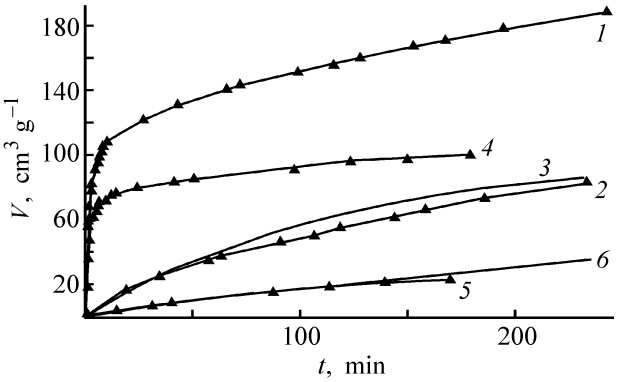

Fig. 4. Manometric curves of gas evolution from sample 2 at (*1–3*) 300 and (*4–6*) 250°C: (*1*, *4*) experimental curves, (*2*, *5*) after subtracting the volume of the initially released gases, and (*3*, *6*) fitting by first-order rate equations.

sidual solvent, free water, alcohol, and unsaponifiable substances. The initial gas evolution was up to 80 ml per gram of the sample (depending on temperature).

The thermal degradation of samples 1 and 2 starts at approximately 250°C. The initial portion of the manometric curve corresponds to removal of the solvent from the sample, and this is followed by degradation proper (Figs. 3, 4). Thermal degradation of the samples is described by first-order rate equations. The rate constant of thermal degradation (s^{-1}) of sample 1 is 6.9×10^{-5} at 300°C, and that of sample 2, 3.5×10^{-5} at 250 and 1.4×10^{-4} at 300°C, i.e., the substances are fairly heat-resistant. The higher resistance of sample 1, compared to sample 2, to thermal oxidative degradation may be due to acid catalysis of the degradation of the polyester resin by DMEPAI producing an acidic medium as a result of hydrolysis.

The results of the manometric studies are consistent with the data furnished by dynamic thermogravimetric analysis: Samples start to lose weight at approximately 100°C.

CONCLUSION

Thermal analysis of the polyester resin and its compound with dimethylethylphenylammonium iodide under isothermal and dynamic conditions shows that these substances are resistant to thermal oxidative degradation at temperatures of fusion of low-temperature solder creams.

Abstract—The effect of the content and structural features of residual lignin on the ordering of supramolecular structures in sulfate birch and aspen cellulose was studied by Fourier IR spectroscopy.

DOI: 10.1134/S1070427207100254

One of the advantages of molecular spectroscopy is the possibility of performing an integrated analysis of the main characteristics of lignocellulose materials. Among elements of the carbohydrate component, this nondestructive method can distinguish molecularly ordered (CI_{ord}) and molecularly disordered (CI_{dis}) regions of natural cellulose CI, and also structural regions of cellulose II (CII_{dis}) present in samples of wood origin. The simultaneously recorded IR spectra of the lignin component furnish information not only on the residual lignin content of fibers, but also on the relative amounts of lignin fragments in surface and bulk regions of fibers and on the relative content in lignin of aromatic structures of guaiacyl and syringyl type. The spectral data also allow estimation of the relative content of strongly bound water and of functional (carbonyl, carboxy) groups formed in lignin, depending on the procedure of lignin recovery from wood.

It has been shown previously [1, 2] that, in samples of sulfate softwood pulp containing less than 4% residual lignin, variations of the optical parameters of CI_{ord}, CI_{dis}, CII_{ord}, and CII_{dis} and the optical densities of residual lignin bands at 1600 and 1510 cm^{-1} closely correlate with each other and with the strength characteristics of cellulose fibers ($r = 0.80–0.90$).

The relative intensities of the lignin bands at 1600 and 1510 cm^{-1} are equal for birch and aspen wood. As the residual lignin content the intensity of the band at 1510 cm^{-1} of sulfate birch and aspen pulp becomes lower, by 20–30% [3], whereas in the pulp from the alkaline process this trend is not observed [4].

In this study, we examined by Fourier IR spectroscopy how the residual lignin content of sulfate birch and aspen cellulose affects the relative content of ordered and disordered supramolecular structures of cellulose.

EXPERIMENTAL

Pulping experiments were performed with manually prepared birch (*Betula pubesceus*) and aspen (*Populus tremula*) chips of length 25–30, width 20–25, and thickness 2–3 mm. The lignin content determined by the sulfuric acid method was 20.0% in birch wood and 20.4% in aspen wood; the cellulose content determined by the nitric acid–alcohol method was 45.6 and 50.6%, respectively.

Kraft pulpings were performed with white liquor (30% sulfidity, Na_2O amount 17% relative to aromatic structures of wood) with the same temperature schedule (uniform heating to 170°C over a period of 120 min, cooking at 170°C for 60 min) in a group of six autoclaves. Sulfate–ethanol and alkaline–ethanol pulpings were performed in the same mode in a liquor containing 50 vol % ethanol. After the pulping was complete, the pulp was squeezed, washed on the filter with hot water, and dried in air; then the yield and residual lignin content were determined. All the analyses were performed by the standard procedures [5].

To record the Fourier IR absorption spectra, pulp fiber samples were compacted in thin pellets 13 mm

Table 1. Yield and residual lignin content of cellulose samples

Sample no.	Characteristics of cellulose samples	Cellulose yield, %	Lignin content of cellulose, %	Amount of removed lignin, %
1	From kraft pulping of birch:			
	without additives	47.2	2.7	93.4
2	after extraction with methylene chloride	47.2	2.7	93.4
3	from pulping with addition of 3% DTO	45.7	1.80	95.9
4	From kraft pulping of aspen:			
	without additives	51.6	0.95	97.6
5	after extraction with methylene chloride	51.6	0.95	97.6
6	from pulping with addition of 3% DTO	51.7	1.0	97.5
7	From kraft pulping of 50 : 50 birch–aspen blend			
	without additives	52.0	1.80	95.3
8	after extraction with methylene chloride	52.0	1.80	95.3
9	from pulping with addition of 3% DTO	50.9	1.40	96.4
10	From sulfate–ethanol pulping of 50 : 50 birch–aspen blend	54.4	1.68	95.4
11	From alkaline–ethanol pulping of 50 : 50 birch–aspen blend	52.3	1.68	95.6

in diameter, weighing 2–4 mg, in a mold without adding KBr. Spectra were measured on an IFS-25 Fourier IR spectrometer (Bruker). Prior to measurements, samples were purged with air in the cell compartment of the device for 5 h to reduce the intensity of adsorption bands associated with atmospheric moisture and moisture adsorbed on the fiber surface. By so doing, the quality of the spectra was improved.

Addition of distilled tall oil (DTO) in the course of pulping allows the residual lignin content of hardwood cellulose to be decreased, with a simultaneous increase in the cellulose yield [6]. The specific effect of DTO additions on the residual lignin content and yield of cellulose in kraft pulping of birch and aspen wood may be caused by structural features of natural cellulose or by its changes in the course of pulping.

The characteristics of cellulose samples obtained by kraft pulping of birch (nos. 1–3) and aspen (nos. 4–6) wood and of a blend of birch and aspen chips (nos. 7–9), and also by sulfate–ethanol (no. 10) and alkaline–ethanol (no. 11) pulping of a 50 : 50 blend of birch and aspen chips are listed in Table 1.

Addition of 3% DTO (relative to aromatic structures of wood) in the course of pulping decreases the residual lignin content of birch cellulose but does not affect that of aspen cellulose. This additive somewhat decreases the cellulose yield in kraft pulping of birch wood and of birch–aspen blend. The highest cellulose yield is attained after sulfate–ethanol and alkaline–ethanol pulping of the blended chips.

The IR spectra of cellulose samples in the range 4000–400 cm^{-1} are shown in Fig. 1. The strong broad

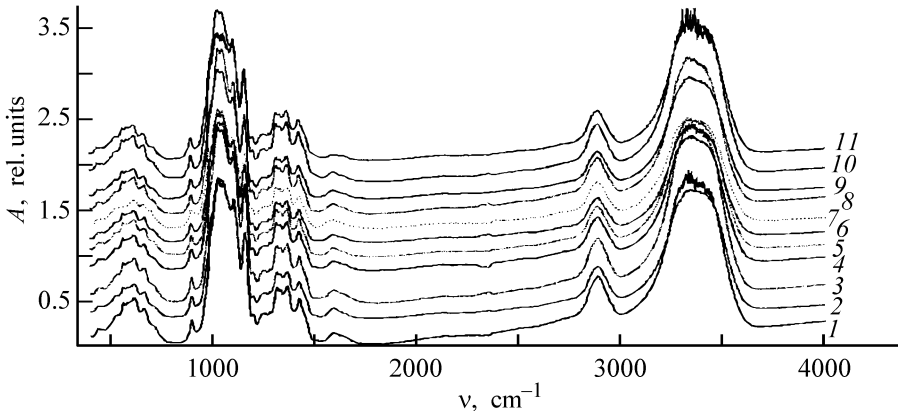

Fig. 1. Experimental IR absorption spectra of cellulose samples in the range 4000–400 cm^{-1}. (*A*) Absorption and (ν) wavenumber; the same for Fig. 2. *Figures at curves* are sample nos. in Table 1; the same for Fig. 2.

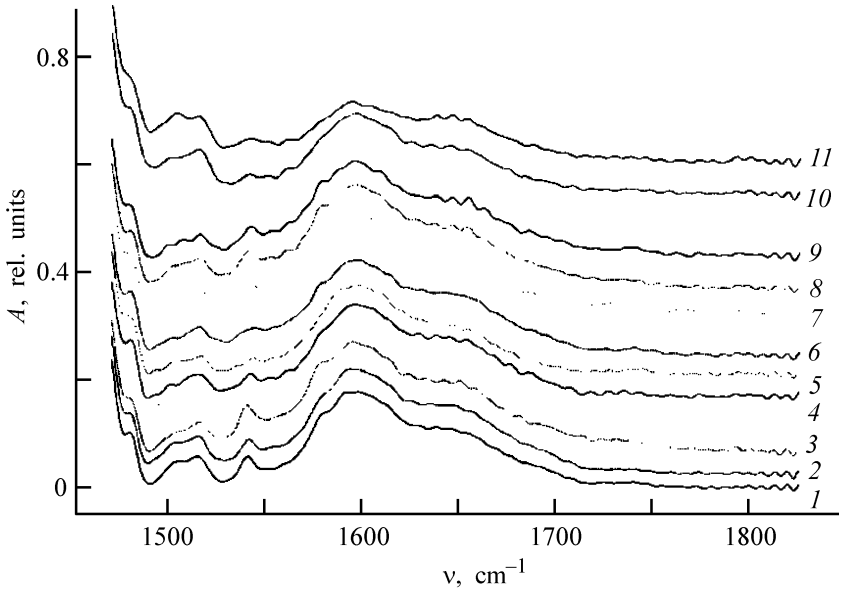

Fig. 2. Mathematically processed spectra of cellulose samples in the range 1450–1800 cm^{-1}.

absorption band at 3600–3000 cm^{-1} belongs to stretching vibrations of hydroxy groups involved in hydrogen bonding, and the band at about 2900 cm^{-1}, to stretching vibrations of the CH and CH_2 groups. For more detailed analysis of the experimental spectral curves, we used the method of Fourier self-deconvolution (Fig. 2) allowing improvement of their resolution and fairly accurate calculation of the intensities of some characteristic bands in the range 1450–1800 cm^{-1}.

The main components of the fibrous semifinished product absorb in this range. Along with complex bands of stretching vibrations of aromatic rings of residual lignin, peaked at 1600, 1540, 1515, 1510, and 1502 cm^{-1}, the spectrum also contains in this range an absorption band of strongly bound water at about 1650 cm^{-1} and a weak band of C=O stretching vibrations at 1740 cm^{-1}, belonging to the carbohydrate and lignin components. The relative intensities of the absorption bands at 1600 and 1510 cm^{-1} are listed in Table 2.

An accurate analysis showed that the latter band is a superposition of two bands peaked at 1515 and 1502 cm^{-1}, and their intensity ratio allows estimation of the relative content of rings of the guaiacyl (G) and syringyl (S) types in macromolecules of residual lignin of each sample. Also listed in Table 2 are the relative intensities of the absorption bands of bound water at 1650 cm^{-1} and quantitative data on the relative content of the main supramolecular structures of the carbohydrate component, determined by computer processing of the Fourier IR spectra.

In contrast to chemical analysis, the spectroscopic data show that addition of DTO decreases the residual lignin content of not only birch, but also aspen cellulose; the DTO addition appreciably alters the intensity of the bands at 1600 and 1510 cm^{-1}.

The results of our study show that the structural state of residual lignin can change in the process. For example, the relative content of guaiacyl- and syringyl-type rings in residual lignin macromolecules depends not only on the sample origin, but also on the delignification procedure. For example, the relative content of guaiacyl-type aromatic structures in residual lignin after kraft pulping of birch wood is somewhat lower, compared to aspen wood. It can be seen that macromolecules of residual lignin after sulfate–ethanol pulping contain a two times larger amount guaiacyl-type structures, compared to lignin after alkaline–ethanol pulping.

Table 2 shows that the modification–phase composition of the cellulose matrix varied insignificantly in the series of the examined samples. No appreciable effect of the pulping procedure on the cellulose structure was revealed. The level of crystallinity of aspen cellulose samples was somewhat higher than that of birch cellulose.

The content of strongly bound water does not significantly correlate with the lignin content of the cellulose and mainly depends on the sample pretreatment procedure. For example, the content of such water was somewhat lower in samples of birch and aspen deresined cellulose, which is apparently caused by their certain dehydration in the course of extraction.

A decrease in the intensity of the C=O band of carbonyl and carboxy groups, observed in cellulose samples after their extraction with methylene chloride, shows that a certain contribution to the intensity of the band at 1740 cm^{-1} is made by carbonyl and carboxy groups of resinous substances.

CONCLUSIONS

(1) The Fourier IR data show that addition of distilled tall oil makes lower the residual lignin content of both birch and aspen cellulose. Changes in the relative content of guaiacyl rings in residual lignin macromolecules and in the lignin content do not correlate with changes in the ordering of supramolecular structures.

(2) In the series of birch, aspen, and mixed cellulose samples prepared under similar conditions of kraft pulping with and without addition of distilled tall oil, the modification–phase composition of cellulose does not change, because it is determined by similar (and stronger) effects of white liquor, time, and temperature on the cellulose structure.

(3) The ratio of the ordered and disordered supramolecular structures in birch and aspen cellulose in the course of kraft pulping is not affected by tall oil addition either. The ordering of the supramolecular structures of cellulose is determined by the main parameters of kraft pulping.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Chlorinated Polymers Based on Low-Molecular-Weight 1,2-Polybutadiene

Abstract—Chlorinated polymeric products were synthesized from 1,2-polybutadiene by introduction of chlorine atoms into macromolecules at carbon–carbon double bonds.

DOI: 10.1134/S1070427207100266

Chlorinated polymers are widely used in production of materials having good mechanical and dielectric characteristics and resistant to acids, oils, and gasoline [1–3]. Among the general methods for synthesis of chlorinated polymers is chemical modification by introduction of chlorine atoms into macromolecules at reactive bonds of finished polymers. 1,2-Polybutadiene (1,2-PB) is a convenient polymer for chemical modification. The presence of the vinyl fragments in the side chains of the macromolecules enables addition of chlorine at unsaturated >C=C< bonds to give various chlorinated polymeric products.

In this study, we examined the functionalization of 1,2-PB by introduction of chlorine atoms at the unsaturated double bonds of the polydiene and properties of the resulting polymeric products.

For modification we used low-molecular-weight 1,2-PB (number-average molecular weight 8350; polydispersity 1.98) containing at least 70% 1,2-units, with 1,4-units the rest.

The microstructure of the initial and modified 1,2-PB was examined by ^{1}H NMR (Tesla BS-467 device) and ^{13}C NMR (Bruker AM-300). Infrared spectra were recorded on a Specord 75-IR spectrometer.

The dropping point of the test polymer, T_d, was recorded as a temperature at which the first drop of the polymer melt fell upon heating [4].

The viscosity of polymer solutions in chloroform was measured with an Ubbelohde viscometer at 25 ± 0.1°C. The intrinsic viscosity [η] was estimated by double extrapolation of the ratios η_{sp}/c and $\ln \eta_{rel}/c$ to $c \to 0$, where c is the solution concentration (g dl^{-1}) and η_{sp} and η_{rel} are the specific and relative viscosities [5].

The functionalization of 1,2-PB was carried out by addition of chlorine at carbon–carbon double bonds of the 1,2-PB macromolecules. Chlorine derivatives were synthesized at 10–20°C by bubbling chlorine gas through a solution of 1,2-PB in an organic solvent ($CHCl_3$ or CCl_4). After the completion of the synthesis, the reaction mixture was purged with nitrogen and treated with aqueous sodium hydrocarbonate. Finally, the polymer was precipitated from the organic phase by adding ethanol, separated from the solvent, and vacuum-dried.

The weight fraction of chlorine in the resulting polymeric products was determined by the Schoeniger combustion method [6]. The degree of functionalization of the polymer, α (%), was calculated as

$$\alpha = [w(\mathrm{Cl})/56.8] \times 100,$$

where w(Cl) is the actual chlorine content of the chlorinated polymer (wt %); 56.8, chlorine content (wt %) of the polymer estimated for the case of 100% functionalization at double bonds (this corresponds to addition of two chlorine atoms at the >C=C< bond of the polydiene in each monomeric unit of the macromolecule).

Properties of the adhesive composites used for fabrication adhesive PVC tapes, containing additives of the chlorinated 1,2-PBs, were characterized by (1) adhesion A to steel, by which is meant the detachment

(stripping) force related to 1 cm of the tape width; and (2) exfoliation time t_e [7]. The adhesion A of the adhesive PVC tape to steel was determined by uniform stripping at a peel angle of 180° to the steel surface for a length of 50–100 mm. The adhesion was calculated as

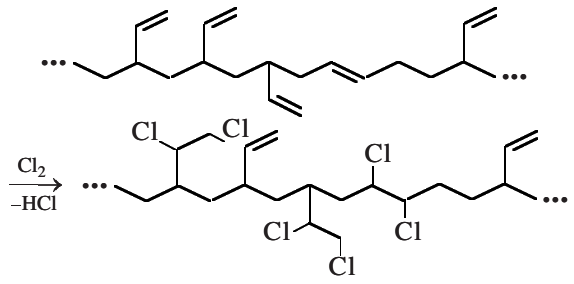
$$A = F/B,$$

where F is the peelling force (N) and B, width of the tape to be peeled (cm).

The exfoliation time t_e was determined for the adhesive tape by measuring the time of exfoliation of the tape folded up in half (adhesive layer inside) under a 100-g load. We synthesized chlorinated derivatives of 1,2-PB with a chlorine content of 5 to 56 wt %. The yield of the modified polymer was 87–95% (see table). The resulting products were characterized by IR and NMR spectra. The IR spectra of the chlorinated products show the bands characteristic of the ≡C–Cl bond in the range 710–770 cm^{-1}. In the ^1H NMR spectra there are signals (multiplets) of the $–CH_2Cl$ (3.6 ppm) and >CHCl groups (4.0 ppm). The ^{13}C NMR spectra of the modified polymer show the signals corresponding to $–CH_2Cl$ (62.6 ppm) and >CHCl groups (45.3 ppm). At the same time, the intensity of the signals of the olefinic carbon atoms at 115–143 ppm decreases upon chlorination. In the spectra of the chlorinated derivatives of 1,2-PM with a chlorine content above 30 wt %, the characteristic bands are broadened,, which is due to superposition of signals of different chlorine-containing structures formed in functionalization of the 1,2-polydiene.

Our results reveal that chlorine is quite readily added to the carbon–carbon double bonds of low-molecular-weight 1,2-PB, so it is possible to virtually totally chlorinate the olefinic bonds in both the backbone and side chains of the polydiene macromolecules. As a result, we synthesized polymeric products with a chlorine content of up to 56 wt %, which corresponds to degrees of functionalization of up to 99%.

Based on the IR and NMR data, we can suggest the following scheme for describing the chlorination of low-molecular-weight 1,2-PB:



Intrinsic viscosity [η] and dropping point T_d of the modified polymer, as influenced by the degree of chlorination of 1,2-polybutadiene

Cl content in 1,2-PB, wt %	Degree of chlorination, %	[η],* dl g^{-1}	T_d, °C
0	0	0.34	54
5.2	9.2	0.29	60
16.3	28.7	0.26	67
23.7	41.7	0.23	73
35.4	62.3	0.21	80
42.4	74.6	0.18	84
50.3	88.6	0.13	127
56.4	99.3	0.11	Does not flow

* Temperature 25 ± 0.1°C; solvent chloroform.

The rheological study showed that solutions of chlorinated 1,2-PB in chloroform have a remarkably lower viscosity than those of the initial polymer (see table). As the degree of functionalization increases, the intrinsic viscosity [η] of 1,2-PB decreases, which can be attributed to changes in the thermodynamic affinity of the polymer for chloroform [8].

Among the parameters characterizing the flowability of polymeric products is the dropping point T_d. Our results show that T_d noticeably increases with the degree of chlorination of 1,2-PB (see table). Introduction of the polar chlorine atoms into the macromolecule strengthens the intermolecular interaction between the polymer chains and, as a result, raises T_d. This is confirmed by the fact that, at room temperature, samples of modified 1,2-PB with a chlorine content <25 wt % are viscous resinous compounds, while the polymers containing 30–56 wt % Cl are thermoplastic solids. It should be noted that modified 1,2-PB containing >56 wt % Cl does not flow under heating, which can be attributed not only to higher glass-transition point and T_d after chlorination, but also to degradation (primarily dehydrochlorination) of the chlorinated polydiene at elevated temperatures. The degradation is accompanied by cross-linking, which hinders the transition of the polymer into the viscous-flow state.

Introduction of the chlorine atoms into macromolecules generally improves the adhesion properties of polymeric products [9]. We examined the effect of chlorinated 1,2-PB with various Cl contents on the adhesive characteristics of the commercial adhesive composite intended for fabrication of an adhe-

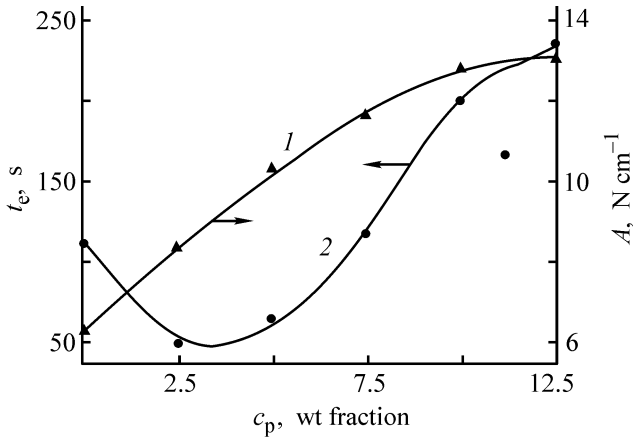


Fig. 1. (*1*) Adhesion to metal A and (*2*) exfoliation time t_e of an adhesive PVC tape as functions of the chlorinated 1,2-PB content c_p of the adhesive composite. Chlorine content of the modified polydiene 48 wt %.

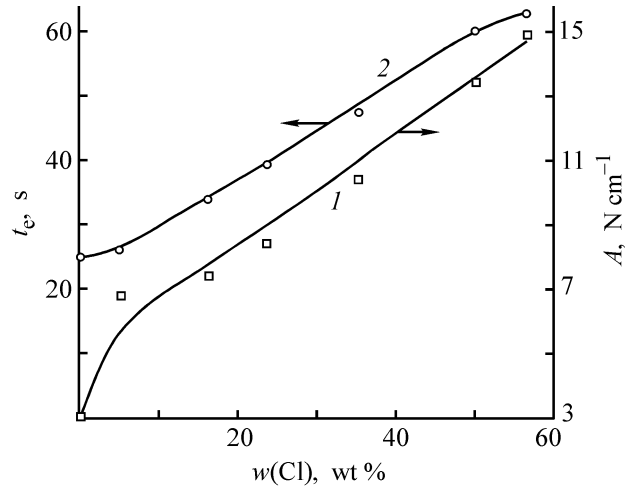

Fig. 2. (*1*) Adhesion to metal A and (*2*) exfoliation time t_e of an adhesive PVC tape with an adhesive composite modified with chlorinated 1,2-PB as functions of the chlorine content w(Cl) of chlorinated 1,2-PB. Chlorinated polymer content of the adhesive composite 5 wt %.

sive PVC tape for insulation of gas and oil pipelines. The adhesive composite includes perchlorovinyl resin (chlorinated PVC with a Cl content of 63 wt %), plasticizer [mixture of di(2-ethylhexyl) phthalate, di(2-ethylhexyl) sebacate, and KhP-470 chloroparaffin], adhesive agent (rosin), and filler (mixture of natural zeolite and calcium oxide). Into this composite, chlorinated 1,2-PB was additionally introduced in an amount of 2.5 to 12.5 wt %. The adhesive composite was applied to plasticized PVC film, and the adhesion A of the resulting adhesive tape to steel was determined.

Figure 1 shows that introduction of even a small amount (2.5 wt %) of chlorinated 1,2-PB [w(Cl) = 48 wt %] into the adhesive composite remarkably increases the adhesion of the PVC tape to the metal (Fig. 1, curve *1*). The adhesion steadily increases with the content of the chlorinated polydiene to at least 12.5 wt %. It should be noted that, by contrast, introduction of unmodified 1,2-PB into the adhesive composite leads to a decrease in A from 6 to 3 N cm^{-1}.

We also studied the effect of the degree of chlorination of 1,2-PB on the adhesion characteristics of the adhesive composite. The adhesion of the adhesive PVC film to steel considerably increases with the chlorine content of modified 1,2-PB (at fixed content of chlorinated 1,2-PB in the adhesive composite) (Fig. 2, curve *1*). The highest adhesion (A = 16.3 N cm^{-1}) was observed with modified 1,2-PB containing 56 wt % Cl, i.e., with 1,2-PB virtually totally chlorinated at double bonds (Fig. 2). Thus, addition of chlorinated low-molecular-weight 1,2-PB with high chlorine content may be recommended in production of adhesive PVC tape to improve the adhesion of the composite to metal.

Another significant parameter of adhesive composites for adhesive PVC films is the exfoliation time t_e characterizing the stickiness of the film [7]. This parameter quantifies the cohesion strength of the adhesive composite, because defoliation of adhesive PVC tape proceeds primarily across the adhesive layer.

The dependence of t_e on the content of chlorinated polydiene [w(Cl) = 48 wt %] in the adhesive composite passes through a minimum corresponding to a polymer content of the adhesive layer of about 3.0 wt % (Fig. 1, curve *2*). The exfoliation time of adhesive PVC film increases as the content of chlorinated 1,2-PB in the adhesive composite is raised further, and at the content >7.5 wt %, it starts to exceed t_e of the unmodified adhesive composite.

As the degree of chlorination of 1,2-PB increases (to a chlorine content of the polymer of at least 56 wt %), the stickiness of the adhesive layer grows (Fig. 2, curve *2*). This is evidently caused by an increase in the polarity of the chlorine-containing polydiene, which, in turn, makes hifher the energy of intermolecular interaction and, consequently, the cohesion strength of the adhesive composite.

CONCLUSIONS

(1) Chlorination of a 1,2-polydiene strongly changes the physicochemical characteristics of the polymer,

as the solution viscosity, dropping point, and adhesion properties.

(2) Chlorinated 1,2-polybutadiene can be recommended as an adhesion additive to adhesion mixtures based on chlorinated PVC to be used in production of variously purposed adhesive PVC films.

Abstract—Preparation of an electrically conducting heat-resistant composite from nickel powder (conducting component) and plasticized or unplasticized polymethylphenylsiloxane (binding matrix) was studied. The optimal preparation conditions and component ratio were determined. The phase composition, thermal resistance, and electrical conductivity of a coating based on this composite were studied in relation to the preparation temperature.

DOI: 10.1134/S1070427207100278

Composites based on organisilicon polymers and metal powders are widely used as conducting materials. These composites can be used for preparing flat heating elements [1]. The advantages of application of these materials as conducting coatings in heating elements are heat resistance, available raw materials, and simple preparation procedures. The electrical conductivity of a coating based on a polymer–metal system is provided by the electrical contact between particles of the conducting phase (metal). The electrical conductivity substantially depends both on the properties of the polymeric matrix, and type of the conducting particles and on the phase composition of the metal surface [2].

In this study, we examined the composite based on a nickel powder (conducting component) and plasticized or unplasticized polymethylphenylsiloxane (PMPS) (binding matrix). Nickel has a high electrical conductivity resistance to oxidation in air, and is, therefore, used in conducting composites to substitute silver.

The main requirement to materials used in heating elements is preservation of their conductivity at preparation and operation temperatures. The conductivity can decrease owing to structural rearrangements of the polymeric matrix on heating (as a consequence of local degradation of the conducting network) and to metal oxidation.

The aim of this study was to determine the influence of the composition and preparation temperature of PMPS/Ni composites on their electrical resistance and phase composition of the metal and to assess the possibility of preparing a film heating element.

The phase composition of nickel was determined in the course of heat treatment by the voltammetric procedure using a carbon-paste electroactive electrode (CPEE). The influence of the preparation temperature on the polymeric matrix was studied by IR spectroscopy.

EXPERIMENTAL

Model samples of conducting coatings were prepared from the following components: PNK-1L5 nickel as conducting powder (100–200 μm particles of almost spherical shape), 40% solution of PMPS in xylene, and 40% solution of plasticized PMPS (PlPMPS) of empirical formula $[C_6H_5Si_{1.5}]_m[C_6H_5Si(OH)_3]_{n-m} \cdot [(CH_3)_2SiO]_n \times 0.037$ in xylene. A pentaphthalic oligomer was used as the plasticizer.

A mixture of nickel powder and a polymer solution taken in different ratios (see table) was thoroughly mixed in a porcelain mortar for 5–10 min. Coatings were prepared by the following procedure. The mixture was cast onto glass supports and kept at room temperate to remove oxygen introduced in mixing. Then the samples were heated at different temperatures (up to 300°C). The electrical conductivity of the samples prepared at each temperature was measured, and their electrochemical behavior was studied.

To study the phase composition of nickel in the composite by voltammetry, a working CPEE was prepared from milled sample, carbon powder, and organic binder (paraffin) mixed in a 2 : 10 : 10 weight ratio. A saturated silver chloride electrode was used as an auxiliary electrode. The supporting electrolyte was 0.1 M KNO_3 in the 0.001 M HNO_3. Cyclovoltammograms (CV) were recorded on a PU-1 polarograph in differential mode of potential sweeping at a rate of 30 mV s^{-1} in the range from –0.2 to –1.4 V (cathodic current measurements) and from –1.4 to 0.8 V (anodic current measurements) [3–5].

The electrical resistance of the samples was measured with an F-400 ohmmeter. The current–voltage [$I(U)$] curves were measured on a unit consisting of a B5-43 DC source and an F4313 ammeter. A voltage of 0 to 10 V was applied to the sample. X-ray phase analysis was performed on a DRON-UM-1 diffractometer (ν = 4 deg min^{-1}, Co_{K_α}). The IR spectra were recorded on a Nicolet 5700 Spectrometer[1].

The temperature dependence of the resistance of the composites is shown in Fig. 1. The dependence passes through a maximum at 180°C. The increase in the resistivity of the composite in the first heating step is due to removal of the solvent and decrease in the mobility of macromolecules. On heating above 180°C, the resistivity decreases because of the densification of the composite structure and formation of a through-conducting network of nickel particles. The resistance of the composites containing plasticizer is, as a rule, higher than that of the composites with unplasticized polymer.

As the plasticizer content increases, the composite dries nonuniformly on heating, so that bubbles and cracks appear. As determined by CV, nickel in the composites with a high plasticizer content is oxidized significantly faster.

Nickel powder contained in the composite also changes during heat treatment. As determined by X-ray phase analysis, appreciable amounts of nickel oxide are formed only on heating above 300°C in air [6, 7]. However, nickel oxides were detected in the PlPMPS composite heated to only 100°C.

The influence of the composition and preparation temperature of the composites on their phase composition is seen from the CVs of the samples heated at 40, 100, and 150°C (Fig. 2). The increase in the current, observed when the content of the polymer binder decreases, is caused by the higher nickel content on the sample surface (Fig. 2b). However, the shapes of cyclovoltammograms of the samples treated at different temperatures and having different compositions are similar. The rise in the oxidation current (lower curves), observed as the heat treatment temperature is elevated, is due to an increase in the fraction of "accessible" nickel after removal of the solvent from the system. The cathodic current curve shows that the overvoltage of the electrolyte discharge typical of metals decreases along with an insignificant increase in the nickel oxide fraction. Therefore, nickel in mainly in the metallic form up to 150°C.

Composition of the composites

Sample no.	Nickel	PlPMPS	PMPS
	wt %		
1	35.0	65.0	0
2	34.8	48.5	16.7
3	34.6	32.1	33.2
4	51.9	48.1	0
5	51.7	36.0	12.4
6	51.4	23.9	24.7
7	68.3	31.7	0
8	68.1	23.7	8.2
9	67.9	15.8	16.3
10	87.8	12.2	0

The peaks on the cathodic curve suggest the presence of nickel oxide. Therefore, we used the reduction current peaks as an analytical signal to estimate

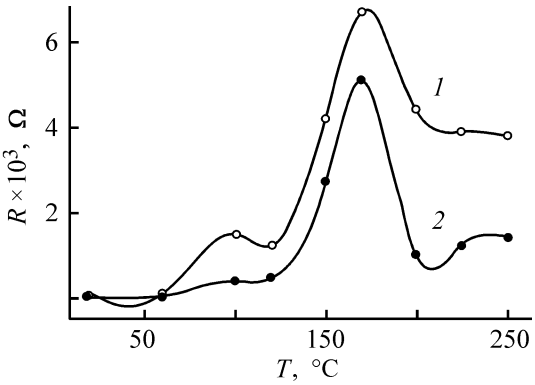

Fig. 1. Resistance of sample nos. (*1*) 4 and (*2*) 10 vs. temperature.

the influence of the type of the polymer binder on the phase composition of nickel (Fig. 3). As can be seen from Fig. 3, the fraction of nickel oxide in the composite increases with the content of plasticized polymer.

Undoubtedly, the presence of OH groups in plasticizer molecules accelerates nickel oxidation. However, the chemical reaction of nickel particles with functional groups of the plasticizer is not the main reason. If this were the case, low-temperature oxidation would be faster since the mobility of accessible groups in the semiliquid composite is higher. The oxidation of nickel in the composite with a high plasticizer content is probably due to the fact that the spatial structure of PlPMPS differs from that of the unplasticized polymer. The OH groups of the plasticizer form strong hydrogen bonds with terminal OH groups of the polymer. This is clearly seen from the IR spectrum of the polymer (Fig. 4). The band at 2200 cm^{-1} is due to formation of strong intermolecular bonds. The intensity of this band in the spectrum of PlPMPS is significantly higher (Fig. 4, curve *1*) than that of PMPS (Fig. 4, curve *2*). In addition, a high water content of the polymer matrix is caused by the presence of the plasticizer. Water molecules are also

bound by hydrogen bonds to the functional groups of the polymer and plasticizer. The absorption in the range from 3200 to 3800 cm^{-1} is assigned to OH groups of the polymer, plasticizer, and water molecules. This band in the spectrum of PlPMPS is substantially broader owing to a higher content of bound OH groups.

The presence of the plasticizer and water molecules in the composite prevents cross-linking upon heating and, as consequence, the structure of the plasticized polymer is more porous. Nickel is oxidized in these systems by air penetrating into the pores.

It should be noted that introduction of the plasticizer in the system simplifies mixing of the polymer solution with the filler. As a result, the structure of these composites is more uniform. Hence, composites with minimal amount of the plasticizer should be used to prepare heating elements.

Fragments of $I(U)$ curves of sample no. 10 containing PlPMPS and prepared at different temperatures are shown in Fig. 5. These curves were constructed by measuring the current passing through a sample at a definite applied voltage. The curves consist of two linear portions at 0–(0.5–0.8) and (0.8–1)–10 V. The slope dI/dU corresponding to 1/R, of the first portion of the curve is smaller by a factor of approximately 2 than that of the second portion, which suggests a decrease in the resistance of the sample. At the same time, as the heat treatment temperature is raised, the slope decreases and the resistance accordingly increases. The voltage corresponding to the discontinuity in the curve increases with the heat treatment temperature.

To understand these results, it should be taken into account that the so-called "contact resistance" appearing when a charge carrier passes across the interface between two metal particles is the major factor determining the electrical conductivity [2]. Therefore, the state of the surface of metal particles plays in this case the critical role. It is known that the surface of metallic nickel exposed to air is coated with a 1–3 nm film consisting of oxide, hydroxide, and carbonate phases [8]. This film does not noticeably prevent transfer of electrons between particles. In this case, electrons can pass either directly between particles or via the tunneling effect. Hence, we suggest that the increase in the resistance with the heat treatment temperature is mainly due to growth of the surface film via oxidation of nickel by atmospheric oxygen. This is also consistent with an increase in the oxidation current observed on the voltammograms as the heat treatment temperature is raised. At a certain voltage (calculated field strength is 10^5–10^6 V m^{-1}) corresponding to the break in the $I(U)$ curve, electric break-down of the film is observed and the resistance decreases.

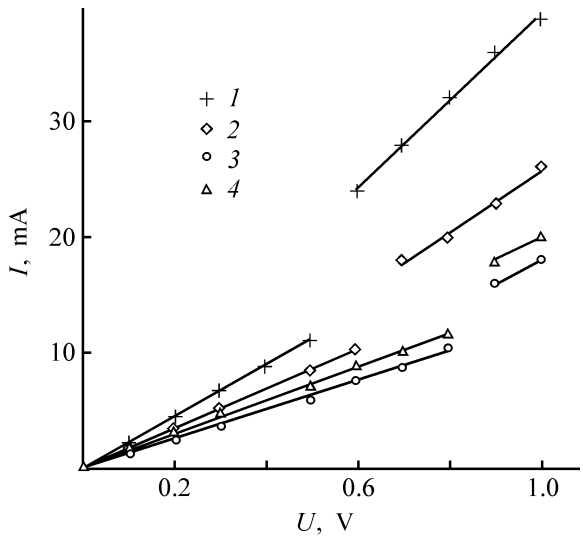

Fig. 5. $I(U)$ curves of sample no. 10 prepared at (*1*) 100, (*2*) 120, (*3*) 170, and (*4*) 250°C. (*I*) Current and (*U*) voltage.

CONCLUSIONS

(1) Introduction of the plasticizer into the polymethylphenylsiloxane–nickel composites promotes nickel oxidation.

(2) The recommended content of the filler in the matrix is no less than 50 wt%. The optimal preparation temperature of the composite is 200°C. The working eration temperature of the composites should not be higher than 300°C.

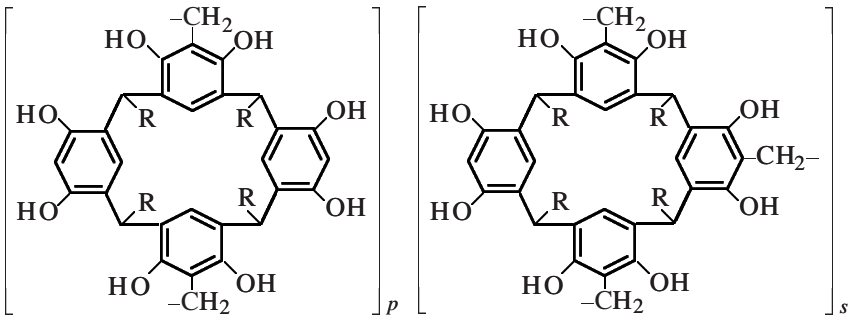
Abstract—Rates of cation exchange H^+–Li^+, H^+–Na^+, H^+–Ag^+, and H^+–Cu^{2+} on the sulfonic network polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene were studied, and the cation interdiffusion coefficients were estimated.

DOI: 10.1134/S107042720710028X

There is a steadily growing interest in calixarenes (macrocyclic polyphenols). The structure of *cis*-calix[4]resorcinolarenes (hydrophobic lower rim of benzene rings forming a cup-shaped structure and hydrophilic upper rim of hydroxy groups) makes them convenient matrices in design of molecular ensembles and supramolecules [1]. The progress in the calixarene chemistry is associated with functionalization which favors development of new types of highly organized reactive structures. Functionalized calixarenes show promise as new complexing agents, stabilizers for polymers, and extractants [2].

Immobilization of calixarenes in the polymer phase allows practical implementation of their unique properties. It is known that, in the polymer phase, immobilized calix[4]resorcinolarenes form supramolecular ensembles involving cations of alkali [3, 4] and transition [5, 6] metals and ammonium [7]. Previously, we have reported on synthesis and characterization of a network polymer based on *cis*-tetraphenylcalix[4]-resorcinolarene [3, 4]. This polymer, being a weakly acidic cation exchanger, can recover metal cations from alkaline solutions. The ion exchange rate in this polymer is controlled by slow diffusion of a substance in the polymer phase: the half-conversion time is longer than 500 s in sorption of cations from aqueous solutions [8].

Functionalization of immobilized calixarenes through introduction of the carboxy [5], furyl(hydroxy)methyl [3], or phosphoric acid [6] groups improves the cationic selectivity of the polymers. Previously [9, 10], we have synthesized a new sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene. Thanks to the presence of the SO_3H groups dissociating with liberation of protons, this polymer is a strongly acidic sulfonic cation exchanger with enhanced performance as compared to the known calixarene-based cation exchangers. In particular, the sulfonic polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene behaves as a cation exchanger over a wide pH range [10]. The monomeric unit of the network sulfonic polymer contains (tetrasulfonatophenyl)calix[4]resorcinolarene cross-linked with the neighboring macrocycles via methylene groups:



where R = Ph-SO_3H.

Compared to the existing *cis*-calixarene-based cation exchangers, the sulfonic polymer exhibits higher ion-exchange capacity [10]. In contrast to the commercial sulfonic cation exchangers, the monomeric unit of the sulfonic polymer has a highly organized 3*D* structure. According to the model views, the sulfur atoms of the sulfo groups of the monomeric unit are are situated vertices of a parallelogram with sides of 5 and 5.5 Å. As a result, the sulfonic polymer exhibits high selectivity with respect to polyvalent cations, and it can be used for separation of binary and multicomponent electrolyte mixtures [11].

The kinetics of ion exchange in the sulfonic polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene has not been studied yet. The highly organized 3*D* structure of the polymers generally causes a decrease in the interdiffusion rate of cations in the polymer phase. Therefore, a study of the kinetics of ion exchange on the new sulfonic polymer is theoretically and practically important.

In this study, we examined the kinetics of H^+–Cat^{z+} exchange on the sulfonic polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene from neutral solutions by the reaction:

$$\overline{R\text{–}SO_3H} + \frac{1}{z}Cat^{z+} = \frac{1}{z}\overline{R\text{–}SO_3Cat} + H^+, \qquad (1)$$

where the overscore designates the polymer phase, and $Cat^{z+} = Li^+$, Na^+, Ag^+, and Cu^{2+}.

EXPERIMENTAL

The polymer under study was prepared by sulfonation of the network polymer synthesized by resol polycondensation of *cis*-tetraphenylcalix[4]resorcinolarene with formaldehyde, as described in [3, 4]. The resulting product was obtained in the form of spherical granules 0.01–0.05 cm in diameter. The sulfur content of the polymer was determined according to [12] to be 7.8% (it has been shown previously [10] that the sulfo groups are situated in the lower (tetraphenyl) rim of the polymer). The size of the spherical granules was determined using an IMTs 100×50A microscope. The size distribution of the granules corresponded to the normal (Gaussian) distribution. The mean particle size was calculated as the arithmetic mean of the size of 1000 spherical granules to be $(1.02 \pm 0.53) \times 10^{-2}$ cm.

Interdiffusion coefficients $D_{H^+–Cat^{z+}}$ in network sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene

Cation to be sorbed	$D_{H^+–Cat^{z+}} \times 10^7$, $cm^2\ s^{-1}$
Li^+	2.08 ± 0.08
Na^+	2.09 ± 0.35
Ag^+	1.91 ± 0.25
Cu^{2+}	1.99 ± 0.13

The dynamic ion-exchange capacity of the polymer (for sulfo groups) was determined in a column by passing 0.05 M NaCl through a bed of the polymer in the H form until saturation. The exchange capacity was related to 1 g of the polymer in the H form, dried at 105°C to constant weight. The resulting value is 2.25 mg-equiv g^{-1}.

The swellability was determined gravimetrically after separation of the sample in the H form from the equilibrium solution (isopiestic conditions) [13]. The moisture content was found to be 40 mol H_2O per 1 g-equiv of the exchange capacity of the polymer.

The sorption kinetics was studied at 298°C in the dynamic mode by the thin-layer method [14] from an infinite volume of solutions: 0.05 M LiCl, 0.1 and 0.01 M NaCl, 0.05 and 0.01 M $AgNO_3$, and 0.025 and 0.015 M $CuCl_2$. The degree of sorption was calculated as

$$F = g_t/g, \qquad (2)$$

where g_t is the current sorption of cations, and g, limiting sorption by the sulfo groups.

The interdiffusion coefficients for the pairs H^+–Li^+, H^+–Na^+, H^+–Ag^+, and H^+–Cu^{2+} were calculated by Eq. (3) [15]:

$$F = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\exp\left(-\frac{Dn^2\pi^2 t}{r^2}\right), \qquad (3)$$

where r is the mean grain radius (cm); D, interdiffusion coefficient of cations in the polymer ($cm^2\ s^{-1}$); and t, time (s).

The kinetic curves of the sorption F plotted against $t^{0.5}$ are shown in Fig. 1.

The F-vs.-$t^{0.5}$ curves are linear ($r > 0.99$ at $F < 0.6$) and cross the origin (Fig. 1), suggesting that the interaction of the sulfonic polymer in the H form with aqueous LiCl, NaCl, $AgNO_3$, and $CuCl_2$ is controlled by diffusion of a substance in the polymer, being independent of the solution concentration [16]. Experimental data on the exchange of the protons of the SO_3H groups of the network sulfonic polymer with the metal cations are described by Eq. (3) over the entire range of the degrees of sorption, suggesting the gel kinetics of ion exchange [13].

The table lists the mean interdiffusion coefficients $D_{H^+–Cat^{z+}}$, calculated by Eq. (3) at a confi-

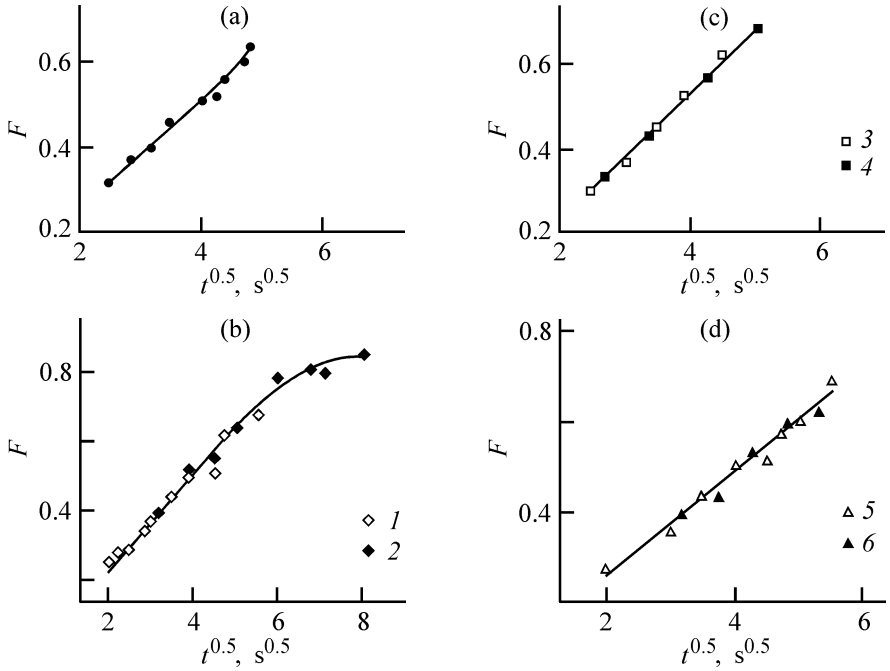


Fig. 1. Kinetic curves of sorption of metal cations on the sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene in the H form from aqueous electrolyte solutions. (F) Degree of sorption and (t) time. Solutions (M): (a) LiCl 0.05; (b) NaCl: (*1*) 0.1 and (*2*) 0.01; (c) $AgNO_3$: (*3*) 0.05 and (*4*) 0.01; and (d) $CuCl_2$: (*5*) 0.025 and (*6*) 0.015.

dence level $p = 0.9$ from experimental data for the pairs H^+–Li^+, H^+–Na^+, H^+–Ag^+, and H^+–Cu^{2+}, in the sulfonic polymer. The interdiffusion coefficients are in the range $(1.9–2.1) \times 10^{-7}$ $cm^2\ s^{-1}$. Similar values are typical of commercial sulfonic cation exchangers, e.g., 1.1×10^{-7} $cm^2\ s^{-1}$ for Dowex 50×16 [17].

Figure 1 shows that the half-conversion time for all the cation pairs in the polymer under study is 16 ± 0.5 s, which is considerably shorter than that in the initial polymer (>500 s). Therefore, the ion exchange rate in the sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene is considerably higher.

CONCLUSIONS

(1) The rate of ion exchange H^+–Cat^{z+} from aqueous solutions in a new sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene is controlled by the gel kinetics, i.e., by the interdiffusion of cations in the polymer phase. The interdiffusion coefficients of protons and metal cations in the polymer phase are in the range $(1.9–2.1) \times 10^{-7}$ $cm^2\ s^{-1}$.

(2) Sulfonic polymer based on *cis*-tetraphenylcalix[4]resorcinolarene exhibits better kinetic characteristics of ion exchange than its nonsulfonated analog.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Chemical Degradation of Elastic Foamed Polyurethanes under the Action of Thiodiglycol

E. I. Galeeva and I. N. Bakirova

Kazan State University of Technology, Kazan, Tatarstan, Russia

Received February 26, 2007

Abstract—Alcoholysis of elastic block foamed polyurethane under the action of thiodiglycol and its mixture with Laprol 3603 polyether was studied. The structure and physicochemical properties of alcoholysis products were determined.

DOI: 10.1134/S1070427207100291

Polyurethanes (PUs) are the most valuable and widely produced commercial polymers; their consumption increases by 4–5% annually [1]. The most demanded polyurethane-based materials are elastic block foamed polyurethanes (EFPUs). Thanks to a combination of low density, high air permeability, high concussion resistance, good heat and moisture exchange, physiological inertness, and feasibility of processing, these materials are widely used in production of soft furniture parts and bedding, in automobile production, textile industry, and other fields. Today the share of these materials in the total amount of PUs produced in the world is about 35% [2]. This rapid growth of the production and consumption inevitably involves the formation of waste whose utilization is an urgent problem.

Chemical degradation by alcoholysis seems to be the best way to utilize the EFPU waste. A number of hydroxyl-containing systems suitable for chemical cleavage of PUs have been reported. However, no data have been published on the use of organoelement polyols for this purpose. At the same time, it would be possible to prepare with such agents compounds containing atoms of S, P, and some other elements. Such products may be of interest for production of polymeric compounds with a set of special properties.

The goal of this study was to develop a procedure for chemical degradation of elastic block foamed polyurethanes under the action of thiodiglycol (TDG) and to prepare a thiourethane compound from the transformation product.

EXPERIMENTAL

As substrates we chose block EFPU samples, and as degradation agent (DA), TDG containing a sulfur atom along with two hydroxy groups and a mixture of DG with Laprol 3603 (L 3603) polyether. Laprol 3603 was added to decrease the concentration of OH groups in the degradation product. The EFPU : DA ratio was chosen empirically, so as to ensure reprocessing of the largest amount of waste and to minimize the DA consumption.

Alcoholysis was performed in a flask equipped with a stirrer, in the temperature range 180–200°C, by continuous supply of milled waste into DA at a stirring rate of 300 rpm. The time of addition of the EFPU crumb to the degradation agent was considered the start of degradation. Alcoholysis products were taken for analysis since the system homogenization.

The total content of hydroxy and amino grops, $c_{OH + NH_2}$, in alcoholysis products was determined by acetylation [GOST (State Standard) 25261–82).

The dynamic viscosity $\eta_{50°C}$ (Pa s) of alcoholysis products was determined with a Hoeppler rheoviscometer at 50 ± 0.1°C.

The chemical structures of DA and alcoholysis products were studied by IR spectroscopy with a Perkin–Elmer 16 spectrometer. Samples were prepared as thin liquid films between KBr plates.

The physicomechanical tests of the sealants were performed in accordance with the following standards: nominal tensile strength, relative elongation, and elongation set, with GOST 21751–76; adhesion

strength to metal at exfoliation, with GOST 21981–76; and degree of swelling, with GOST 421–59.

The process parameter allowing monitoring of the degradation and use of the alcoholysis product as a secondary raw material is the total content of terminal hydroxy and amino groups. Figure 1 shows that, in the initial period of degradation, the c_{OH+NH_2} values show strong scatter because of the insufficient uniformity of the system, due to the presence of unchanged EFPU. This time interval is shown in Fig. 1 by dashed lines. With the progress of the degradation, the c_{OH+NH_2} values get stabilized at a level of 22.2 wt % for the EFPU + TDG system and 11.4 wt % for the EFPU + TDG + L 3603 system. Further treatment leads to a decrease in the content of OH and NH_2 groups via secondary cross-linking:

$$\sim R'\text{–}OH + HO\text{–}R''\text{–}OH + HO\text{–}R'''\sim \rightarrow \sim R'\text{–}O\text{–}R'\text{–}O\text{–}R'''\sim + 2H_2O, \quad (1)$$

where R', R'', and R''' are polyol fragments.

Elevating the temperature has virtually no effect on the equilibrium values but makes shorter the time required to attain them (Fig. 2).

The alcoholysis kinetics, monitored by the dynamic viscosity, is shown in Fig. 3. Initially the dynamic viscosity monotonically decreases owing to the progress of degradation and decrease in the molecular weight of the alcoholysis products. Then the viscosity gets stabilized, indicating that the system approaches the equilibrium state. However, longer heating leads to an increase in the viscosity of the degradation products, coinciding in time with a decrease in c_{OH+NH_2} (Fig. 2). It should be noted that an increase in the heat treatment temperature leads to a decrease in the absolute viscosity.

The chemical structure of alcoholysis products was studied by IR spectroscopy. The IR spectra of alcoholysis products of the EFPU + TDG + L 3603 system (Fig. 4) contain absorption bands characteristic of TDG and Laprol 3603: stretching vibrations of associated OH group (3360–3340 cm^{-1}), band of the ether

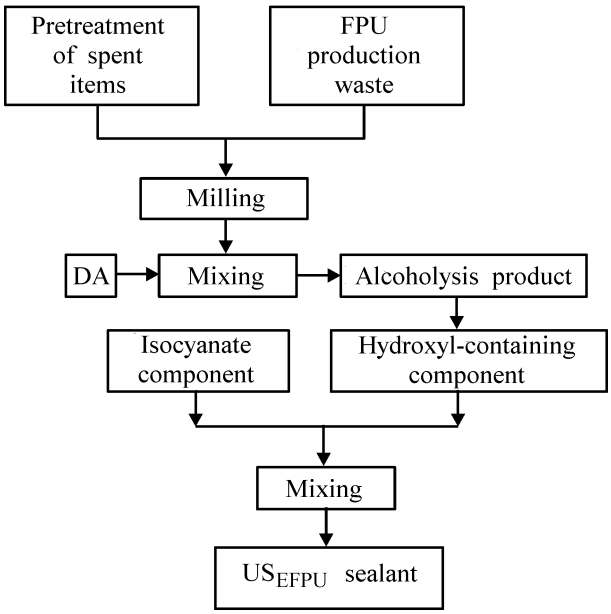
C–O–C bond (about 1074 cm^{-1}), and a group of bands in the range 800–600 cm^{-1}, characteristic of the C–S bond. In the spectra of the reclaimed raw material, new peaks appear, assignable to vibrations of the aromatic fragment (1636–1600 cm^{-1}) and urethane group (1718 cm^{-1}, C=O stretching; 1540 cm^{-1}, NH bending). Interpretation of the amino group is complicated by the fact that its absorption range, 3500–3390 cm^{-1}, overlaps with the range of stretching vibration bands of associated OH groups; however, the presence of amino groups is quite probable [3].

Thus, analysis of the IR spectra of these groups shows that the degradation products are compounds with terminal hydroxy and amino groups, containing sulfide, urethane, and ether bonds in the backbone, which allows these compounds to be used in synthesis of thiourethane hermetic compounds as a hydroxyl-containing component. These polymers are prepared by the flowsheet shown in the scheme and ensuring chemical recycling of EFPU waste.

According to this scheme, the sealant is prepared by the reaction of an isocyanate component with the hydroxyl-containing component in 1 : 1 ratio.

The main service and physicomechanical properties of the thus prepared US_{EFPU} sealant are listed in the table in comparison with commercial compounds based on thiokols (U-30M, UT-30MES-5) and with Forsazh poly(ether–urethane) [4, 5]. It can be seen that the use of the reclaimed polymeric polyol allows preparation of a thiourethane sealant well competitive in its main properties with commercially produced thiokol vulcanizates and cured poly(ether–urethane) compounds.



Scheme.

CONCLUSIONS

(1) A procedure was developed for chemical degradation of elastic block foamed polyurethanes under the action of thiodiglycol and its mixture with Laprol 3603 polyether.

(2) The degradation products are compounds with terminal hydroxy and amino groups, containing sulfide, urethane, and ether bonds in the backbone.

(3) Based on the reclaim obtained, a thiourethane sealing compound was developed, well competing in the main properties with commercial sealants.

Abstract—Sulfo esters of cellulose, dextran, starch, and amylopectin with a degree of substitution equal to 0.1–1.1 were prepared in the system constituted by sodium pyrosulfate and dimethyl sulfoxide. The intrinsic viscosity of aqueous solutions of sulfo polysaccharides was determined, and their anticoagulant activity was evaluated.

DOI: 10.1134/S1070427207100308

Polysaccharide derivatives with ionic groups are of interest as polymeric carriers for immobilization of enzymes and drugs. Among these derivatives, particular attention is attracted by sulfo esters exhibiting anticoagulant and antithrombotic activity [1, 2]. A combination of the intrinsic biological effect of a sulfated polysaccharide with the activity of an immobilized drug opens up prospects for development of a combined pharmaceutical preventing and curing a wider spectrum of complications of cardiovascular and other diseases.

This study continues our research on sulfation of polysaccharides. It is concerned with synthesis of water-soluble sulfo esters of starch, amylopectin, dextran, and cellulose in the sodium pyrosulfate–dimethyl sulfoxide (DMSO) system. The choice of this system was governed by its availability and suitability for medical applications, as sodium pyrosulfate $Na_2S_2O_7$ used as sulfating agent is nontoxic and DMSO is considerably less harmful than pyridine or dimethylformamide.

EXPERIMENTAL

As starting materials we used prehydrolyzed potato starch, amylopectin [TU (Technical Specification) 6-09-10-391–75], cellulose in the form of FN-15 chromatographic paper, and dextran with a molecular weight of 4×10^4.

Cellulose was hydrolyzed in refluxing 2 N HNO_3 (2 l of HNO_3 solution per 100 g of chromatographic paper) for 20–30 min to obtain a powder-like mass. The resulting microcrystalline cellulose (MCC) was washed with distilled water to neutral reaction of the wash water and was dried at room temperature to the air-dry state. The molecular weight of the MCC obtained was about 3×10^4.

The acid and enzymatic hydrolyses of starch and amylopectin were performed in accordance with [3]. A 20% suspension of polysaccharides in a 0.1 N sulfuric acid solution was prepared and kept for 6 h at 328 K with continuous stirring. Hydrolyzed starch and amylopectin were precipitated with acetone, washed with the water–acetone mixture (volume ratio 1 : 1), filtered, and dried at room temperature to the air-dry state.

For enzymatic hydrolysis of starch and amylopectin, we used pancreatin [3]. To 200 ml of a 14% polysaccharide paster, heated to 333 K, we gradually added with stirring 20 ml of a 1% pancreatin solution. The precipitation, washing, and drying of the hydrolyzed products were performed as described above for acid hydrolysis.

The sulfation of polysaccharides (PSs) in the $Na_2S_2O_7$–DMSO system was performed in accordance with [4]: 1–5 g of a polysaccharide dried to constant weight was placed in a flask with a ground-glass stopper, sodium pyrosulfate and dimethyl sulfoxide (pure grade) were added in succession with stirring, and the mixture was heated for the required time (no less than 6 h) on an oil bath at a definite temperature. After the lapse of the required time, the mixture was neutralized with a saturated sodium carbonate solution

* Composition of the sulfating mixture, g g^{-1}: AP : $Na_2S_2O_7$: DMSO = 1.0 : 3.0 : 3.0; ST : $Na_2S_2O_7$: DMSO = 1.0 : 3.0 : 2.5; MCC : $Na_2S_2O_7$: :DMSO = 1.0 : 3.0 : 5.0; the same for Table 2.

to pH 8–10. After that, the sulfo esters were demineralized by dialysis on cellophane membranes until the qualitative reaction for sulfate ions in wash waters was negative. The solubility of polysaccharide sulfo esters was determined gravimetrically [5]. The purified solutions were freeze-dried. The sulfur content of polysaccharide sulfates was determined by potentiometric titration [6]. Prior to the analysis, the Na salt of the sulfo esters was converted to the H form by passing the solutions through a column packed with a KU-2 × 12 cation-exchange resin.

The sulfo esters synthesized were studied by IR spectroscopy with a Varian 3100 FT-IR spectrophotometer. Samples were prepared as KBr pellets.

The intrinsic viscosity of sulfo polysaccharides was measured in 0.5 N aqueous NaCl at 310 K in an Ubbelohde viscometer with a capillary diameter of 0.54 mm [7].

The effect of polysaccharide sulfo esters on the coagulation activity of plasma was evaluated by the change in the thrombin time [8].

The sulfation of polysaccharides with sodium pyrosulfate can be schematically described by the equation

$$R\text{–}OH + Na_2S_2O_7 \rightarrow R\text{–}OSO_3H + Na_2SO_4.$$

The process is accompanied by the side reaction

$$Na_2S_2O_7 + H_2O \rightarrow 2NaHSO_4,$$

i.e., the sulfating agent decomposes in the presence of water in PS or in the solvent, and the efficiency of its utilization in the target reaction with PS decreases. The simultaneous occurrence of the two concurrent reactions limits the degree of substitution (DS) of the sulfo derivatives. Their composition can be controlled by varying the reaction conditions.

As can be seen from Table 1, the polysaccharides studied differ considerably in the reactivity in sulfation with sodium pyrosulfate in DMSO. The initial cellulose and starch do not undergo modification in this system. At the same time, sulfation of amylopectin and dextran yields sulfo esters with a fairly high degree of substitution. To enhance the reactivity, the polysaccharides (cellulose, starch, amylopectin) were subjected to acid and enzymatic (starch, amylopectin) hydrolyses. As can be seen from Table 1, acid hydrolysis raises the reactivity of cellulose in sulfation, does not affect the reactivity of starch, and lowers the reactivity of amylopectin. The enzymatic hydrolysis considerably raises the reactivity of starch, and only slightly, that of amylopectin.

These features of the behavior of the polysaccharides are apparently caused by features of their structure (number and strength of hydrogen bonds, degree of polymerization). The acid hydrolysis of cellulose not only lowers the degree of polymerization, but also leads to cleavage of crystallites [9], thus making the cellulose structure more accessible to the sulfating agent.

The acid hydrolysis of starch and amylopectin also lowers the degree of polymerization, but is accompanied by accumulation of the linear component, which favors [3] an increase in the number of hydrogen bonds between the macromolecules, preventing the sulfation.

By contrast, the enzymatically hydrolyzed starch and amylopectin are sulfated considerably more readily, which may be due to weakening of intermolecular interactions. Indeed, it is known that, under the action

of the enzyme, polysaccharides are selectively hydrolyzed across α-1,4-glucoside bonds, and the degree of branching remains essentially unchanged. The process yields macromolecules of a critically small size, which cannot form ordered regions (crystallites) of the polysaccharides.

The sulfur content of the sulfo esters is a function of the composition of the sulfating mixture (Figs. 1, 2) and reaches a maximum at the weight ratios PS : $Na_2S_2O_7$: DMSO = 1.0 : (2.5–3.5) : (2.5–5.0), depending on a particular PS. The sulfo esters formed at the optimal component ratios not only have the highest DS, but are also more uniform in the composition, as suggested by their complete solubility in water. A decrease in the solvent amount relative to the optimum and further increase in the sodium pyrosulfate amount lead to worse swelling of PS in DMSO, which impairs the sulfation efficiency. At the same time, a decrease in the sodium pyrosulfate amount and an increase in the liquid to solid ratio lead to a decrease in the content of sulfo groups in the product in accordance with the law of mass action.

The trend in variation of the optimal liquid-to-solid ratio ensuring the highest DS along the series of PSs, seen from Fig. 2, is primarily determined by the degree of branching of the macromolecules, rather than by their size. An increase in the degree of branching of macromolecules in going from cellulose to dextran and amylopectin favors swelling and even dissolution of PS in DMSO, with the subsequent formation of more homogeneous partially substituted sulfo esters even at a low solvent content.

Table 2 shows that an increase in the temperature (except in the case of cellulose) and time of sulfation do not lead to an increase in DS of the sulfo esters. Similar results have been obtained in experiments on sulfation of PSs with other agents [1]. However, to obtain the most homogeneous partially substituted PS esters, it is advisable to perform sulfation in the $Na_2S_2O_7$–DMSO system at 333 K for no less than 5–6 h. Under these conditions, the PS swelling in the solvent is the strongest, and more homogeneous products are obtained. An increase in the homogeneity of PS sulfo esters with increasing time and temperature of the reaction can be judged from the fact that the turbidity of the sulfo ester solutions, caused by the presence of finely dispersed unsubstituted or low-substituted fractions, becomes weaker or even disappears at all.

The compositions of dextran, cellulose, starch, and amylopectin samples treated with the $Na_2S_2O_7$–DMSO system were monitored by IR spectroscopy (Fig. 3). It is known [2, 10] that the most significant changes in the absorption pattern upon introduction

* For dextran, the starting mixture had the following composition, g g^{-1}: D : Na_2S_2O7 : DMSO = 1.0 : 2.5 : 4.0.

** Sulfation experiments were performed with enzymatically hydrolyzed starch.

Table 3. Influence of sulfation conditions on some characteristics of polysaccharide sulfo esters*

Polysaccharide	Sulfating system	DS_{SO_3H}	S, %	Yield, %		[η], dl g^{-1}	Activity, units mg^{-1}
				insoluble fraction	water-soluble sulfo ester		
Amylopectin	$Na_2S_2O_7$–DMSO	0.6	8.6	0	90	0.09	3
Dextran		0.6	8.6	0	76	0.14	4
Starch		0.8	10.5	0	53	0.05	9
MCC		0.7	9.6	0	96	0.02	<2
Amylopectin	SO_3–DMF	0.9	11.0	0	91	0.08	<2
Dextran		0.03	0.80	0	69	0.14	0
Starch		0.8	10.5	36	40	0.08	4
MCC		1.1	13.1	0	92	0.01	2

* Prior to sulfation, starch was pretreated with the enzyme. For the composition of the sulfating mixture $Na_2S_2O_7$–DMSO and the time and temperature of the treatment, see notes to Tables 1 and 2. Sulfation with the SO_3–DMF complex [1] was performed at 293 K in the course of 24 h.

of sulfo groups into a polysaccharide are observed in the range 800–820 (C–O–S) and about 1240 cm^{-1} (S=O). Figure 3 shows the IR spectra of the initial and modified dextran. The appearance of strong absorption bands at 800 and 1240 cm^{-1} is consistent with the analytical data and indicative of the formation of polysaccharide sulfo esters.

Thus, sulfo esters with a fairly high degree of substitution and uniform composition can be prepared by treatment with sodium pyrosulfate in dimethyl sulfoxide. The dependences of the degree of substitution and the extent of homogeneity on the PS reactivity, PS : $Na_2S_2O_7$: DMSO weight ratio, and the temperature and time of the treatment were evaluated.

The results of a comparative in vitro evaluation of the anticoagulant activity of sulfo polysaccharides prepared with the $Na_2S_2O_7$–DMSO and SO_3–DMF systems are presented in Table 3. It can be seen that

the biological activity depends not only on the degree of substitution and structure of the polysaccharide, but also on the sulfating agent used. Sulfo polysaccharides prepared with the $Na_2S_2O_7$–DMSO system are more active anticoagulants than those prepared with the SO_3–DMF system, which may be due to the better homogeneity of the former substances.

CONCLUSIONS

(1) A comparative study of the reactivity of dextran, cellulose, starch, and amylopectin in sulfation with sodium pyrosulfate in the presence of dimethyl sulfoxide was made. The degree of substitution of the polysaccharides is primarily determined by the mixture composition and the procedure for polymer pretreatment prior to the reaction.

(2) With increasing temperature (from 298 to 333 K) and time (from 0.5 to 6 h) of the sulfation, more homogeneous sulfo polysaccharides fully soluble in water are obtained.

(3) Aqueous solutions of polysaccharide sulfo esters (degree of substitution 0.6–1.1) have the intrinsic viscosity in the range 0.01–0.14 dl g^{-1} and exhibit anticoagulant activity.

Abstract—Graft copolymers of *N*-vinylcaprolactam on chitosan were prepared by the radical mechanism with potassium persulfate as initiator. The process characteristics were examined, and sorption of water vapor with the copolymers prepared was studied.

DOI: 10.1134/S107042720710031X

Chitosan (CS) shows much promise thanks to such valuable properties as biocompatibility, biogedradability, nontoxicity, etc. The development of chitosan compounds with synthetic polymers and, in particular, synthesis of graft and block copolymers based on two polymers differing in molecular structure and nature is of interest. The graft copolymerization of a number of monomers, including vinyl acetate and *N*-vinylpyrrolidone, on CS was studied by Nud'ga et al. [1, 2]. Here we report for the first time on graft radical copolymerization of *N*-vinylcaprolactam (VC) on CS in the presence of potassium persulfate (PPS). The influence of the synthesis conditions on the copolymer composition and moisture absorption is examined.

EXPERIMENTAL

Experiments were performed with crab CS. The molecular weight M = 750000 (±5%) was determined from the intrinsic viscosity of the initial CS, measured at 25°C in 0.25 M CH_3COOH + 0.25 M CH_3COONa buffer [3]. The degree of deacetylation was 63%. *N*-Vinylcaprolactam was purified by vacuum distillation. For synthesis under homogeneous conditions, we found an appropriate solvent: a mixture of water, acetic acid, and isopropyl alcohol (IPA), with 20% IPA content. Syntheses were performed in a flask equipped with a stirrer in a nitrogen stream, or in sealed glass ampules. In the latter case, the reaction mixture was purged with nitrogen for 15 min, after which the ampules were sealed. The synthesis temperature was 60°C. To isolate the synthesized copolymers, the mixture was poured into a Petri dish, and the solvent was allowed to evaporate at room temperature. To separate the homopolymer and unchanged VC monomer, the product was extracted with benzene, after which it was vacuum-dried to constant weight. The completeness of extraction was checked by adding a sample of the benzene extract to diethyl ether, which is a precipitant for PVC. If the extract contained PVC, the mixture became turbid. The nitrogen content of the copolymer was determined by the Dumas method. The IR spectra of the VC–CS copolymers were recorded on a Specord 75-IR spectrometer in the range 400–3800 cm^{-1}. Samples were prepared as KBr pellets. Sorption of water vapor by the copolymers was studied with a high-vacuum sorption installation with mercury seals and a MacBain quartz spring balance in the humidity range 0–100% at 25±0.5°C. Prior to measurements, the polymers and water were degassed at a residual pressure of 0.013 Pa to constant weight. The solvent was fed in successively increasing portions. The total relative error of the equilibrium amount of water sorbed by 1 g of the polymer did not exceed 3%, and the relative fixed error in measuring the vapor pressure, 0.1%.

The results of analysis of the copolymers for nitrogen are listed in the table. As can be seen, the weight

Copolymer composition at various concentrations of reaction mixture components (initial CS weight 0.25 and 0.1 g, IPS concentration 20%, synthesis time 5 h, total nitrogen content of the initial CS 7.45%)

* Initial CS weight 0.12 g.

and total nitrogen content of the reaction product increase relative to the initial CS, which is one of the evidences in favor of the formation of the VC–CS copolymer. The copolymer composition was evaluated from the nitrogen content. Separation of VC homopolymer from the copolymer inevitably involves a certain loss of the copolymer in the course of extraction and decanting. Therefore, data on the weight gain and nitrogen content are not fully consistent, and the weight gain can be used only for confirming the fact of copolymer formation on the qualitative level.

We examined the synthesized copolymers by IR spectroscopy (Fig. 1). The spectrum of CS has a broad strong band peaked at 3450–3460 cm^{-1}, associated with stretching vibrations of –OH and –NH groups involved in hydrogen bonding. The band observed at 2940 cm^{-1} characterizes stretching vibrations of CH and CH_2 groups. A broad amide I absorption band of chitin units (1620 cm^{-1}) obscures the amide II absorption band at 1550 cm^{-1}. There are also several absorption bands in the ranges 1300–1450 and 1000–1260 cm^{-1}, mainly associated with CH, CO, and COC bending vibrations.

The PVC spectrum contains at 3450 cm^{-1} a strong absorption band of OH groups involved in hydrogen bonding; this band apparently originates from sorbed moisture. The stretching vibration bands of CH and CH_2 groups are observed at 2945 and 2875 cm^{-1}, and the C=O stretching vibration band, at 1620 cm^{-1}. The CH_2 bending vibration band is observed at 1400–1500 cm^{-1}. The range 1250–1350 cm^{-1} corresponds to bending vibrations of C–C and R–C=O bonds. The C–N bond gives absorption at 1225 and 1180 cm^{-1}. The band at 1140 cm^{-1} belongs to C–C stretching vibrations; that at 955 cm^{-1}, to CH bending vibrations; and that at 830 cm^{-1}, to CH_2 bending vibrations.

In the spectrum of the copolymer, the bands of hydroxy and amino groups of CS are shifted to lower frequencies, and a very strong and broad band at 1620 cm^{-1} is due to stretching vibrations of carbonyl groups of VC. The CS absorption band at 1000–1260 cm^{-1} is preserved but overlaps with the bands of VC units.

We monitored the variation of the reaction mixture viscosity in the course of the synthesis. For this purpose, the synthesis was performed in a VPZh-2 viscometer with a capillary diameter of 1.75 mm

in a nitrogen atmosphere (Fig. 2). In all the cases, the viscosity of the reaction mixture decreased in the initial period after starting the synthesis. This fact suggests that the reaction of CS with PPS is accompanied by a decrease in the molecular weight of CS, presumably caused by cleavage of glycoside bonds in the macromolecules with PPS. Therefore, one of the possible mechanisms of copolymerization is growth of VC chains on active radicals generated by cleavage of glycoside bonds [2].

We studied the sorption of water vapor with the synthesized copolymers. Variation of the copolymer composition has virtually no effect on the sorption of water vapor. At the same time, the moisture absorption is strongly affected by the initiator concentration at which the copolymers were prepared. At high initiator concentrations, the resulting copolymers have a relatively dense 3*D* structure with low capacity for water absorption (Fig. 3). At decreased initiator concentrations, loosely cross-linked copolymers with higher water absorption are formed. With a further decrease in the initiator concentration, the copolymers become soluble.

It is known that PVC is a polymer with a lower critical temperature of solution. For VC–CS graft copolymers, this effect can be controlled by varying the copolymer composition and the size and distribution of comonomer blocks. This can be useful for various applications, e.g., in medicine, biology, and biotechnology.

Block and graft copolymers are also of interest from the viewpoint of the development of composite materials based on two polymers differing in molecular structure and nature. Of large interest is also the development of nanocomposite materials based on CS with synthetic polymers. Such materials can be used in food, cosmetic, and pharmacological industries, and also as carriers of drugs and biologically active substances. The presence in these composites of a block copolymer whose blocks exhibit affinity for each component of the material can favor formation and stabilization of the nanostructural organization.

CONCLUSIONS

(1) Graft radical copolymerization of vinylcaprolactam on chitosan in the presence of an initiator, potassium persulfate, was performed.

(2) Higher water absorption is observed with the copolymers synthesized at low initiator concentrations.

Abstract—Structural properties of the initial and reprecipitated chitin and chitosan samples in dry and wet states were studied.

DOI: 10.1134/S1070427207100321

Base hydrolysis of chitin (CTN) and chitosan (CSN) is one of the main procedures for deacetylation of these natural polysaccharides [1].

The kinetics of deacetylation of chitin and chitosan was analyzed in [2–4]. It was found that complete deacetylation of chitin and chitosan cannot be attained in a single-stage treatment of these polysaccharides with concentrated alkali. Several explanations were suggested for the decrease in the rate of chitin deacetylation in the alkaline solutions.

This paper is devoted to elucidation of the mechanism of chitin deacetylation on the basis of published data and our experimental results.

EXPERIMENTAL

Chitin and chitosan were prepared in laboratory by the known procedure [5] from shell-containing wastes from king crab processing.

Chitin and chitosan were deacetylated in a 50% NaOH solution at 100°C. Samples with various degrees of deacetylation were prepared from chitin and chitosan by repeated treatments with 50% NaOH solution at 100°C.

Prior to reprecipitation from NaOH, chitin was dissolved in alkali by the procedure described elsewhere [6]. A suspension of chitin (3 g) in a 40% aqueous solution of sodium hydroxide (75 g) was stored for 3 h at 25°C under reduced pressure. The resulting alkaline chitin was mixed with crushed ice (225 g) at approximately 0°C. The resulting chitin solution with a 10% alkali concentration was filtered through a Schott filter in a vacuum. Then, chitin was precipitated by gradual neutralization of this solution with HCl to pH 6.5. The precipitate was separated by centrifugation, and a part of the wet reprecipitated chitin was dried at 60°C.

Reprecipitation of chitin from acid solutions was performed as follows. Chitin (10 g) was mixed with cold concentrated HCl (200 ml), and the resulting mixture was stored for a day with intermittent stirring. Then, the chitin solution was filtered through a Schott filter in a vacuum. The resulting solution was diluted with cold distilled water (3 l) under stirring. The resulting suspension was kept until the precipitation was complete, and then the chitin precipitate was separated by centrifugatoin. The precipitate was washed with distilled water to pH 6.5, and a part of the resulting reprecipitated wet chitin was dried at 60°C.

Chitosan was precipitated from an acid solution. For this purpose, chitosan (2 g) was mixed with a 0.1 M HCl solution (200 ml), and the resulting mixture was kept for 18 h until the chitosan completely dissolved. The resulting solution was filtered through a Schott filter under reduced pressure and then was neutralized with stirring to pH 7.5 with a 0.5 M NaOH solution. The chitosan precipitate was separated by centrifugation and washed with distilled water. A part of the wet chitosan was dried at 60°C.

The degree of chitosan deacetylation was determined by potentiometric titration of the chitosan so-

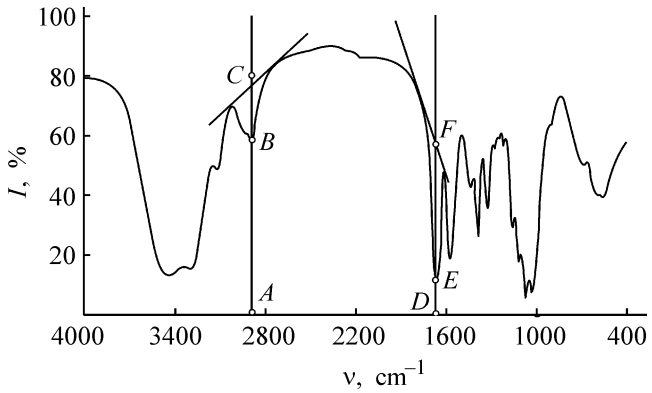

Fig. 1. IR absorption spectrum of a chitin sample. (*I*) Transmission and (ν) wavenumber. *Lines and points* illustrate the graphical processing of the data for DD calculation.

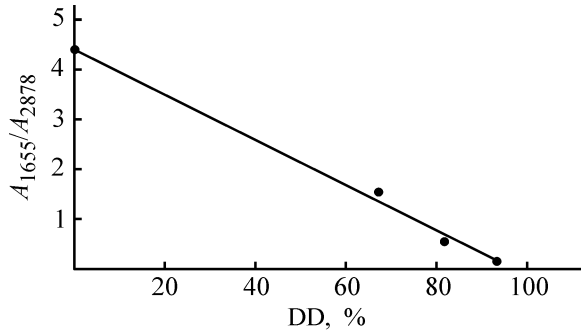

Fig. 2. Absorption of chitin in the IR spectra vs. the degree of deacetylation DD. (A_{1655}/A_{2878}) Ratio of the optical densities of the bands at 1655 and 2878 cm^{-1}.

lution with a 0.1 M HCl solution. The solution pH was measured on an Anion 4151 pH-meter (Infraspak-Analit Research and Production Enterprise, Russia). The absolute error in determining the degree of deacetylation was ±0.5%. The chitosan sample (0.2 g) weighed with an accuracy of ±0.0001g was dissolved in a 0.1 M HCl solution (20 ml), and the resulting solution was titrated with a 0.1 M NaOH solution with the resulting potentiometric titration curve plotted, pH = $f(V_{NaOH})$. Then, the points of the maxima of the first derivative, which correspond to the equivalence points in titration equivalence of excess HCl (V_1) and amino groups (V_2), were determined.

The degree of deacetylation DD (%) was calculated using the following expression:

$$DD = \frac{203.2}{42.0 + \dfrac{1000m}{c_{NaOH}(V_2 - V_1)}} \times 100,$$

where m is the content of chitosan in the sample, g; c_{NaOH}, concentration of the NaOH solution, M; $V_2 - V_1$, volume of the NaOH solution consumed in titration of the amino groups, cm^3; 203.2, molecular weight of the acetylated monomeric unit of the polysaccharide; 42.0, difference between the molecular weights of the acetylated and deacetylated monomeric units; 1000, factor of conversion of milliliters to liters; and 100, factor of conversion of DD to percents.

The degree of deacetylation of chitin and chitosan was also determined by IR spectroscopy [7, 8].

The IR spectra were recorded on an IR-420 Shimadzu spectrophotometer (Japan) in the 4000–400 cm^{-1} range using KBr pellets. The pellets were prepared using samples ground in a TI-100 mill (C.M.T. Co, Japan) for 10 min and dried to constant weight at 100°C. KBr was recrystallized from an aqueous solution and calcined at 600°C. The purity of KBr was checked by IR spectroscopy. The weight ratio of the sample and KBr in the pellet was 1 : 49. To prepare a pellet with diameter and thickness of 13 and 0.42 mm, respectively, the resulting mixture (120 mg) was compacted at a 650-kg cm^{-2} pressure for 1 min at room temperature on an SSP-1 hand press (Shimadzu, Japan).

The procedure for DD determination was improved for its use in a wide DD range. Using the samples with DD varying from 0 to 98%, we found that the IR absorption band at 2878 cm^{-1} is the most appropriate for measurements. This absorption band corresponds to the stretching vibrations of the C–H bond [8], and its optical density obeys Beer's law in the entire DD range studied. The bending vibrations of the amino group (amide I) are observed at 1655 cm^{-1}. The graphical processing of the IR spectrum is illustrated in Fig. 1.

The optical density was calculated as follows:

$$A_{2878} = \log(AC/AB),$$

$$A_{1655} = \log(DF/DE).$$

The degree of deacetylation was calculated from the calibration dependence obtained for samples with the known DD (Fig. 2). The resulting regression equation can be represented as

$$A_{1655}/A_{2878} = -0.04529DD + 4.4214,\ r^2 = 0.9946,$$

where r is the linear-regression coefficient.

The degree of crystallinity of the samples was determined by the known procedures [10, 11].

The structural properties of chitin and chitosan samples were studied at the Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials (Kola Scientific Center, Russian Academy of Sciences) on a DRON-2 diffractom-

eter (Burevestnik Research and Production Association; Cu_{K_α}, Ni filter, 24 kV, 10 mA) in the range $2\theta = 6°–36°$. The X-ray diffraction (XRD) patterns were recorded from the initial wet samples and samples suspended in mineral oil deposited on sapphire supports. The reflections were identified using JCPDS tables [12] and published data [13].

The XRD patterns were mathematically processed using the Graph Digitizer Ver. 1.9 (Nick's Production), PeakFit Ver. 4.12 (SeaSolve Software Inc.), and Microsoft Excel 2002 program packages.

Kurita et al. [2] attributed the features of deacetylation to the crystal structure of natural chitin.

It is known that chitin is formed in nature in various crystal modifications. In most cases, it has a highly ordered structure, named α-chitin, which is typical of the majority of crustacea and insects [14].

Other modifications, such as β- and γ-chitin, are also known [15]; they differ in the mutual orientation of adjacent chitin macromolecules. Chitosan is also characterized by high crystallinity, but its structure differs from that of α-chitin [11].

As shown in [1, 4, 11], strong intermolecular hydrogen bonds should affect the rate of chemical reactions of the functional groups of macromolecules involved in formation of the crystal structure.

The degree of crystallinity, χ_{cr}, is frequently determined from the ratio of the integral intensity of the peak of the crystalline regions in the diffraction pattern to the total integral peak [10, 11].

To calculate the intensity of the peak originating from the crystalline regions in the samples, the total area under the diffraction curve S_{tot} and the area of the amorphous component S_{am} were determined graphically.

The degree of crystallinity, χ_{cr}, was calculated by the following expression:

$$\chi_{cr} = \frac{S_{tot} - S_{am}}{S_{tot}} \times 100,$$

where S_{tot} is the total area under the diffraction curve in the angle range $2\theta = 6°–36°$, and S_{am}, the area of the amorphous component in the same range.

The degrees of crystallinity evaluated by the above procedure are listed in the table.

It should be noted that the XRD patterns exhibit a series of peaks typical of the crystal structure of α-chitin, described in [12, 13].

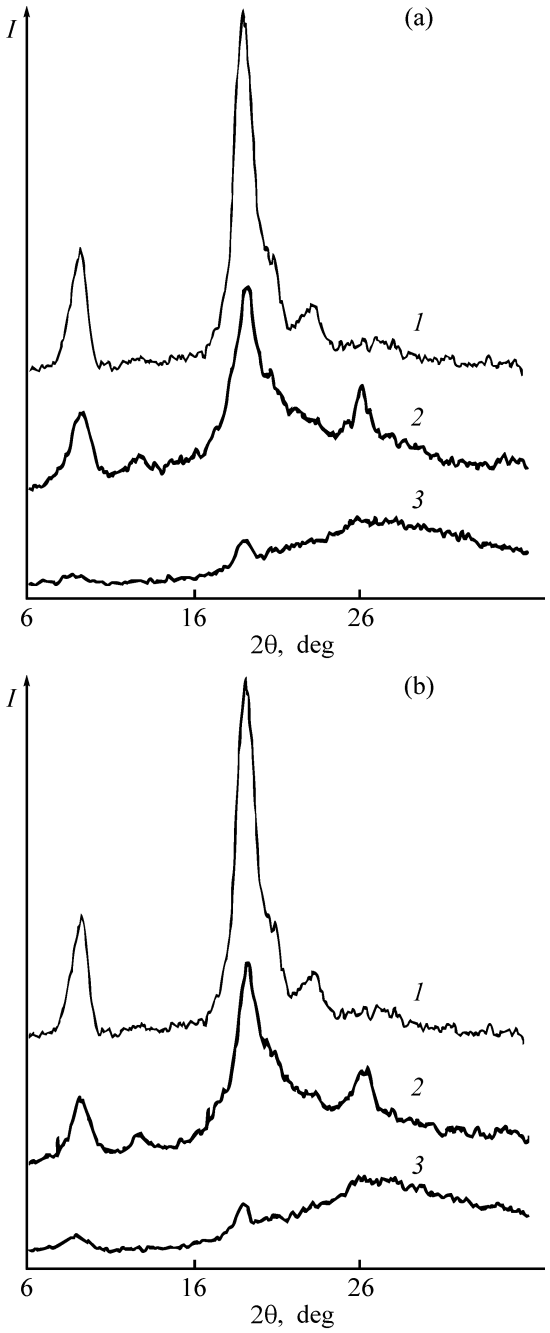

Fig. 3. XRD patterns of (*1*) initial chitin and (*2*) dry and (*3*) wet chitin reprecipitated from solutions of (a) NaOH and (b) HCl. (*I*) Peak intensity and (2θ) diffraction angle; the same for Fig. 4.

The results listed in the table show that reprecipitation virtually completely restores the crystal structures of chitin and chitosan. The diffraction peaks of the restored structures of the chitin samples recrystallized from solutions of NaOH (Fig. 3a) and HCl (Fig. 3b) are broader as compared to the initial chitin, but their positions in the XRD patterns are similar.

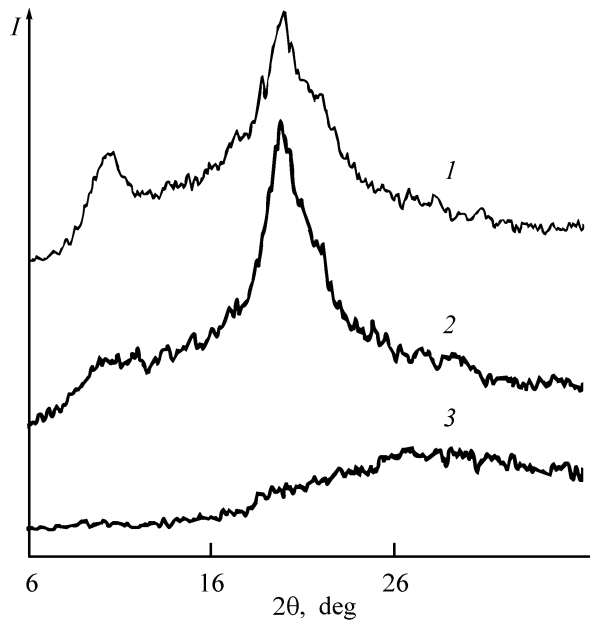

Fig. 4. XRD patterns of (*1*) initial chitosan and (*2*) dry and (*3*) wet chitosan reprecipitated from HCl solutions.

To compare the crystal structures of the chitin samples reprecipitated from acid and alkali, their XRD patterns were normalized as in [16]. It was found that dry chitin samples reprecipitated from NaOH and HCl exhibit similar XRD patterns, which suggests similarity of their structures.

Our results agree with experimental data reported in [2, 16].

It is assumed [2] that, in the course of recrystallization, the α-chitin structure is restored only partly, simultaneously with the formation of other crystal forms and amorphization.

Degree of crystallinity, χ_{cr}, of chitin and chitosan samples

Sample	χ_{cr}, %
Initial dry chitin	61.1
Chitin reprecipitated from NaOH, dry:	
from NaOH, dry	55.5
from HCl, dry	60.7
from NaOH, wet	8.8
from HCl, wet	8.5
Initial dry chitosan, DD 82%	35.8
Chitosan reprecipitated:	
from HCl, DD 82%, dry	37.5
from HCl, DD 82%, wet	3.8

As for chitosan samples, their crystal structure was also restored during reprecipitation (Fig. 4), with certain differences from the initial chitin structure. Two main peaks in the XRD pattern of chitosan are shifted as compared to α-chitin. In the XRD patterns of chitin with DD less than 71%, two peaks at 2θ 9.2° and 19.1° are observed. In the case of chitosan with DD 95%, these two peaks are shifted to 2θ 11.2° and 20.1°–20.4°, respectively. These experimental data do not contradict those reported in [2, 11, 16–18].

Partial restoration of the α-chitin structure after recrystallization and drying of the samples of α- and β-chitin was also confirmed by NMR, IR, and Raman spectroscopy [19].

On the whole, the above data suggest that the crystal structure of chitin and chitosan is restored after recrystallization of the initial sample from alkali and acid and their drying (see table).

The XRD patters of the wet chitin and chitosan samples show that they are virtually amorphous (Figs. 3 and 4, curves *3*).

It should be noted that the weak peaks observed in the XRD patterns of the wet recrystallized chitin (Figs. 3a, 3b) are absent in the XRD patterns of the wet recrystallized chitosan (Fig. 4).

It has been suggested previously [2, 20] that deacetylation of crystalline chitin proceeds more slowly than that of the amorphous compound.

Ottoy et al. [21] studied the DD distribution of various fractions of partly deacetylated chitosan exhibiting different solubilities in acid. Their experimental results suggest that deacetylation proceeds by the diffusion mechanism in which the deacetylation rate is controlled by the rate of alkali diffusion into the solid particles, rather than by the ratio of the crystalline and amorphous regions in the polysaccharide structure.

Chang et al. [22] showed that the deacetylation rate depends on the alkali concentration: as the NaOH concentration increases, the reaction rate constant becomes higher. Chang et al. suggested that the rate of heterogeneous deacetylation can be controlled by both the chemical reaction and the diffusion of the reactant and reaction products in the polysaccharide particle.

Thus, our experimental results and published data suggest that the kinetics of deacetylation of dry reprecipitated chitin and chitosan should be similar to that of the initial samples, whereas the rate of deacetylation of the wet recrystallized samples should be higher. However, our experimental kinetic de-

pendences of deacetylation do not fit in the model analyzing the effect of the degree of crystallinity of chitin on the degree of its deacetylation.

It is known that, as DD increases, the crystallinity of chitin decreases and, when DD reaches 90–95%, a new crystal structure typical of chitosan starts to form [2, 17]. In this case, the rate and degree of chitin deacetylation should increase with the initial DD owing to the rise in the content of amorphous regions. Previously, Novikov et al. have shown [23] that the rate of deacetylation of chitin and chitosan are independent of the initial degree of deacetylation of the corresponding polysaccharide. The shapes of the kinetic curves for chitin and chitosan with various initial DD (up to 95%) were similar [23, 24].

Yaghobi and Mirzadeh [25] explained the increase in the degree of deacetylation in the course of repeated alkaline treatments as follows. They suggested that the initial structure of chitin hinders penetration of NaOH molecules to all the polysaccharide molecules. When the alkaline treatment is performed continuously, the rate of deacetylation decreases at DD 75%. The authors assume that water-washing of chitin or partly deacetylated chitin after the first stage of deacetylation is of particular importance. Washing changes the chitin morphology, causing its swelling, and makes chitin macromolecules more accessible to NaOH molecules. At the same time, the authors attribute the decrease in the rate of continuous deacetylation to a decrease in the concentration of NaOH molecules from 50 to 43%, i.e., to a concentration at which, as they believe, deacetylation is terminated.

However, this explanation contradicts the experimental data. Novikov et al. have shown [26] that the NaOH concentration decreases insignificantly (from 50 to 49.4%). If the decrease in the rate of deacetylation were due to a decrease in the alkali concentration below some limit, then its increase would accelerate deacetylation. However, the rate of deacetylation does not increase in the presence of excess NaOH [26]. Probably, the deacetylation rate is determined by formation of solvated structures owing to interaction of polysaccharide macromolecules and low-molecular-weight electrolyte with the solvent.

For example, Percot et al. [27] suggested formation of NaOH hydrates, which are less active in chitin deacetylation than nonhydrated alkali molecules.

Previously, we suggested in [23, 24, 28] that OH^- complexes with chitin are formed and showed that deacetylation can be described by two parallel reactions of pseudo-first order: (1) deacetylation and (2) formation of chitin complex with hydroxide ions.

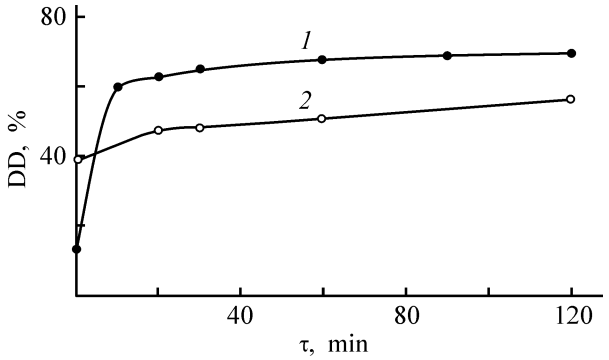

Fig. 5. Kinetic curves of deacetylation of (*1*) dry chitin and (*2*) wet chitin reprecipitated from 50% NaOH solution at 100°C. (DD) Degree of deacetylation and (τ) time.

Figure 5 shows the kinetic dependences of deacetylation of dry chitin (curve *1*) and wet chitin reprecipitated from NaOH solution (curve *2*). As can be seen, the rate of deacetylation of wet reprecipitated chitin (χ_{cr} 4.0%) is lower than that of the dry sample (χ_{cr} 59.0%). This fact suggests solvation (hydration) of polysaccharide molecules in NaOH solution. The water dipoles are located in a certain order near the acetamide and glycoside bonds of the chitin macromolecules. In accordance with the mechanism of deacetylation in the alkaline medium [29], hydrolysis of the acetamide bonds starts with a nucleophilic attack of the carbonyl carbon atom of the acetamide group by OH^- ions. The hydrate shell probably hinders this nucleophilic attack, causing a decrease in the deacetylation rate.

The above results suggest that the influence exerted by the degree of crystallinity of the samples studied on the deacetylation rate is significantly weaker than that exerted by the hydrate shell probably formed around the polysaccharide macromolecules, which hinders nucleophilic attack of the hydroxide ions and decreases the deacetylation rate.

CONCLUSIONS

(1) The IR spectrophotometric procedure for evaluating the degree of deacetylation of chitin and chitosan samples was improved.

(2) The possibility of formation of a hydrate shell around the macromolecules and its effect on the deacetylation rate were suggested.

(3) The influence exerted by the degree of crystallinity of the samples on the deacetylation rate is

weaker thanthat exerted by the hydrate shell formed around the polysaccharide macromolecules. This shell hinders nucleophilic attack of the hydroxide ions and decreases the deacetylation rate.

Abstract—Specific features of the distribution of high-molecular-weight normal alkylbenzenes in crude oils from the Nepa–Botuoba anteclise were studied by chromatography–mass spectrometry. The possible biochemical precursors and mechanisms of formation of normal alkylbenzenes with an odd number of carbon atoms in the molecule were determined.

DOI: 10.1134/S1070427207100333

Among precambrian crude oils of the Siberian platform, two independent families are distinguished. The first family is localized within the Baikit anteclise, and the second family fills traps of the Katanga saddle and Nepa–Botuoba anteclise. The main geochemical criteria for this classification are the results of studying the distribution of biomarker molecules, mainly of tricyclic cheilanthanes, tetracyclic steranes, and pentacyclic hopanes.

The GC–MS analysis[1] of aromatic hydrocarbons (ACs) in crude oil samples from the Nepa–Botuoba oil-and-gas-bearing region revealed the presence of a homologous series of alkylbenzenes with linear hydrocarbon substituents. Such substances have not been found previously in oils from this region.

The composition and distribution of alkylbenzenes C_{11}–C_{30} in oils, organic matter (OM) of rocks, and coals were examined in detail in numerous studies [1–12].

It was found that the content of high-boiling alkylbenzenes varies from 20 to 45 wt %. These hydrocarbons form several homologous series of different structures and can contain two or three methyl groups and one long linear or branched chain with up to 20 or even more carbon atoms. Among such compounds are *n*-alkylbenzenes, 1,2-, 1,3-, and 1,4-methylalkylbenzenes, 1,3- and 1,4-ethylalkylbenzenes, and C_{20} and C_{27} hydrocarbons with alkyl chains of the isoprenoid structure. The concentration of alkylbenzenes decreases with an increase in the molecular weight, and the concentration of *p*-substituted methylalkylbenzenes is considerably lower than that of the other disubstituted isomers.

Aromatic hydrocarbons are not synthesized by living organisms, but are formed from organic substances present in them by biochemical and thermochemical transformations. The aromatic structures found in nature are associated with lignins, pigments, and essential oils [1, 13, 14].

Unsaturated fatty acids of lipid components of the living matter are believed to be a biochemical source of high-molecular-weight alkylbenzenes with a linear chain. Presumably, the homologous series of *n*-alkylbenzenes is formed by dehydrative cyclization of these acids on natural catalysts, followed by degradation, addition of free radicals, and decarboxylation. The process follows the scheme acid–lactone–ketone–hydrocarbons [1, 6, 7]. The formation of alkylbenzenes and extension of the alkyl substituent can

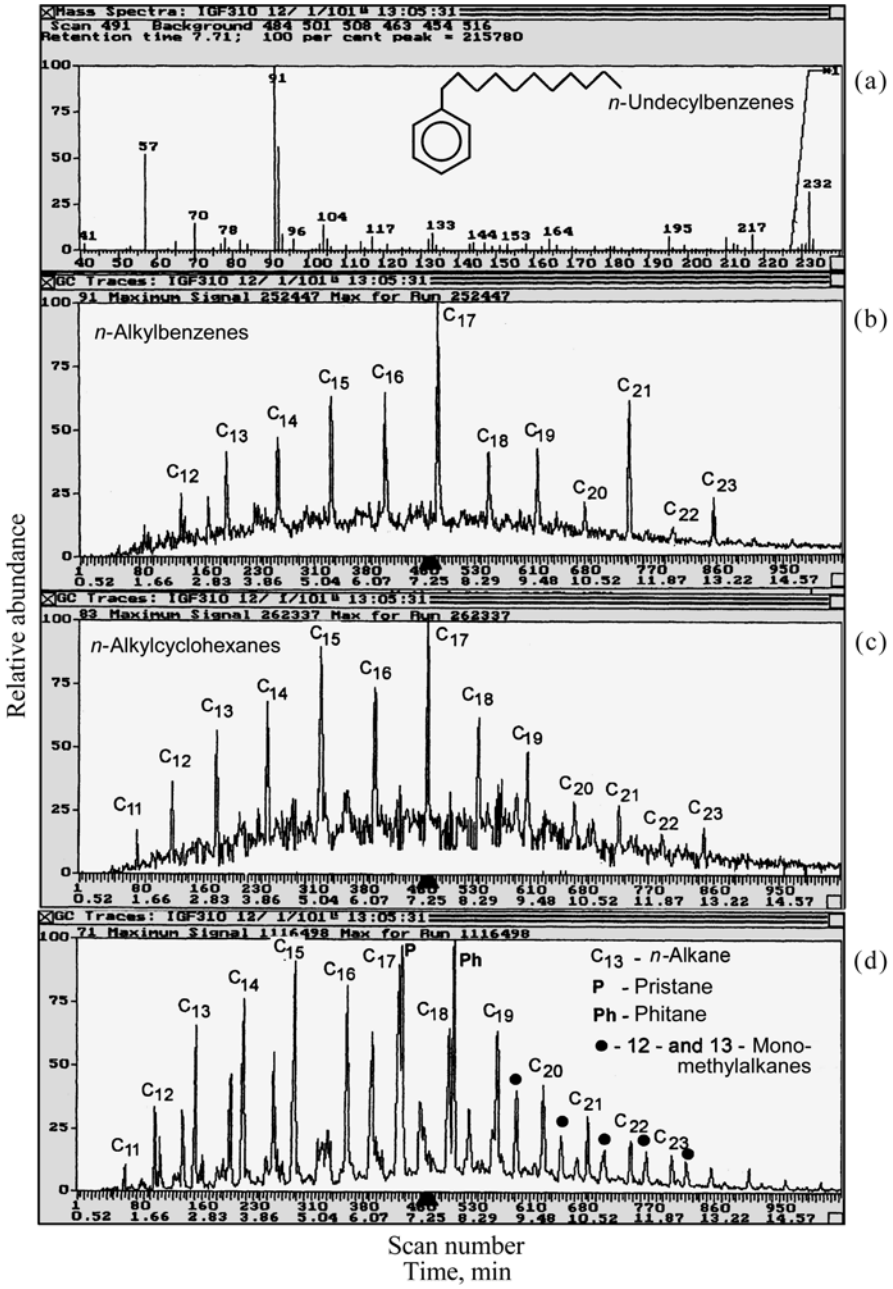

Fig. 1. (a) Mass spectrum of *n*-undecylbenzene and mass fragmentograms, recorded at *m*/*z* (b) 91 (*n*-alkylbenzenes), (c) 83 (*n*-alkylcyclohexanes), and (d) 71 (*n*-alkanes), of oils from the Talakan deposit.

occur under the conditions of catagenetic transformations of OM and oils.

Thus, analysis of the available data gives a fairly definite pattern of the composition and structure of monoaromatic petroleum hydrocarbons, their biological precursors, pathways of their transformations into petroleum hydrocarbons, and also transformations in deposits. Nevertheless, some problems related to their formation remain poorly understood.

In this paper, based on published and newly obtained data, we present our views on the formation of monoaromatic hydrocarbons (in particular, alkylbenzenes with linear alkyl chains) in the Earth's interior. The choice of *n*-alkylbenzenes was governed by the fact that they have no analogs in the living nature and hence their formation should reflect, to a certain extent, the pathways of transformation of bioorganic matter in the Earth's interior.

EXPERIMENTAL

Studies were performed with Vend-Cambrian crude oils from the Middle Botuoba, Irelyakh, and Talakan oil fields.

Crude oils from the Nepa–Botuoba oil-and-gas-bearing region are characterized by a broad range of physicochemical parameters: density 0.821–0.907 g cm^{-3}; paraffin content from trace amounts to 4.4%; sulfur content 0.1–2.0; naphtha yield 7–38%. The oils mainly differ in the methane composition (41–73% methane–naphthene hydrocarbons). Except Talakan oil, other oils have increased content of asphalt and resin substances: resin up to 43% and asphaltenes up to 11%.

Saturated and aromatic hydrocarbons of crude oils were analyzed by gas chromatorgaphy–mass spectrometry with a Q-mass-910-Autosystem quadrupole system (Perkin–Elmer). The chromatograph was equipped with a quartz capillary column (diameter 0.25 mm, length 90 m) coated with PE-5. The carrier gas was helium, flow rate 1 ml min^{-1}. The vaporizer temperature was 320°C. The column was heated from 40 to 300°C at a rate of 6 deg min^{-1}. The ionizing electron energy was 70 eV. Scanning of chromatograms at characteristic fragment peaks, *m*/*z* 71, 83, and 91, allowed identification of the homologous series of *n*-alkanes, *n*-alkylcyclohexanes, and *n*-alkylbenzenes in the crude oil samples.

The compounds were identified by comparing the individual mass spectra with those included in the library of the system and with published data [15].

The mass fragmentograms recorded at *m*/*z* 71, 83, and 91 are identical for all the three oil samples. For the subsequent discussion, we chose as an example the crude oil from the Talakan oil field.

As can seen be from Fig. 1 and the table, *n*-alkylbenzenes are mainly represented by the homologous series from $C_{12}H_{18}$ to $C_{23}H_{40}$, i.e., the linear alkyl substituent contains from 6 to 17 C atoms. Low-molecular-weight homologs prevail: $\Sigma(C_{12}–C_{16})$ 44.5, $\Sigma(C_{17}–C_{20})$ 37.9%. The relative content of high-molecular-weight homologs is 17.6%. The molecular-weight distribution of *n*-alkylbenzenes is bimodal with peaks at C_{17} and C_{21}. Among C_{17}–C_{23} *n*-alkylbenzenes, homologs with the odd number of C atoms prevail ($K_{odd/even}$ 1.90).

n-Alkanes are represented by the homologous series from C_{11} to C_{27}. The peaks of the *n*-alkane distribution are at C_{15} and C_{17}; the odd/even ratio is 1.11. The distribution of individual *n*-alkanes in the range C_{12}–C_{17} is similar to that of *n*-alkylbenzenes, but for higher-molecular-weight homologs the pattern is essentially different. Along with *n*-alkanes, we identified 12- and 13-monomethylalkanes, which are a "calling card" of a sort of East-Siberian crude oils.

Composition of *n*-alkylbenzenes, alkylcyclohexanes, and *n*-alkanes in crude oil from the Talakan deposit

Hydrocarbon	Relative content, %		
	n-alkylbenzenes	alkylcyclohexanes	*n*-alkanes
C_{11}		3.24	1.58
C_{12}	4.58	5.95	5.18
C_{13}	8.50	9.73	9.91
C_{14}	8.50	10.81	11.26
C_{15}	11.76	14.59	13.51
C_{16}	11.11	11.89	11.71
C_{17}	20.26	16.76	13.06
C_{18}	6.54	9.73	9.01
C_{19}	7.84	7.03	8.11
C_{20}	3.27	3.24	5.41
C_{21}	12.42	3.24	3.60
C_{22}	1.31	1.62	2.25
C_{23}	3.92	2.16	1.80
C_{24}	–	–	1.35
C_{25}	–	–	1.13
C_{26}	–	–	0.68
C_{27}	–	–	0.45
ΣC_{11}–C_{16}	44.45	56.21	53.15
ΣC_{17}–C_{20}	37.90	36.76	35.59
ΣC_{21}–C_{25}	17.65	7.02	10.13
ΣC_{26}–C_{27}	0.00	0.00	1.13
Maximum	C_{15}, C_{21}	C_{15}, C_{17}	C_{15}, C_{17}
$K_{odd/even}$	1.90	1.27	1.11

n-Alkylcyclohexanes are represented by the homologous series C_{11}–C_{23}. Low-molecular homologs prevail. The relative content (%) is as follows: C_{11}–C_{13} 56.2, C_{17}–C_{20} 36.8, and C_{21}–C_{23} 7.0. The peaks of the *n*-alkylcyclohexane distribution are observed at C_{15} and C_{17}. The odd/even ratio is 1.27. The distribution patterns of alkylcyclohexanes and *n*-alkanes are similar.

The differences in the ranges of the homologous series of *n*-alkylbenzenes and *n*-alkylcyclohexanes, compared to *n*-alkanes, can be attributed to specific features of oil catagenesis, which led to degradation of longer alkyl substituents, and the prevalence of low-molecular-weight homologs in the considered groups of petroleum compounds demonstrates the plankton–algal character of the initial organic matter.

As noted above, only the distribution of *n*-alkylbenzenes has a peak in the high-molecular-weight

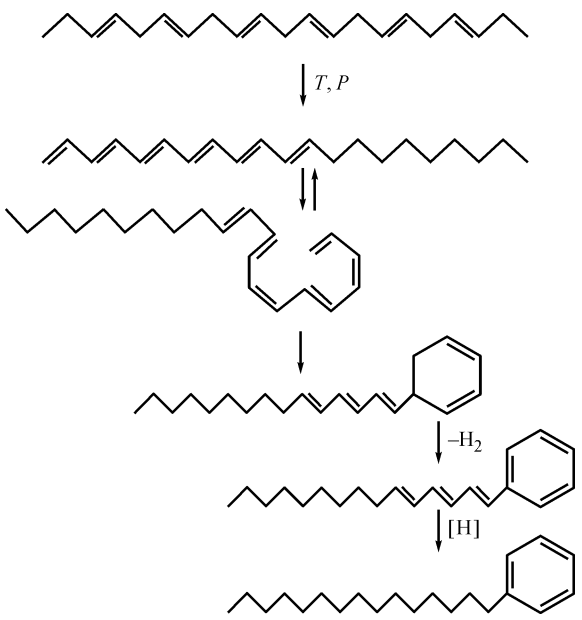

Fig. 2. Possible scheme of formation of *n*-pentadecylbenzene from polyene $C_{21}H_{32}$.

region, at C_{21}, and shows a pronounced prevalence of odd molecules over even molecules. Ostroukhov [16] attributed the prevalence of *n*-alkylbenzene C_{21} in oils to involvement of a definite organic compound of the composition C_{21} in the formation of this hydrocarbon.

The increased content of odd *n*-alkylbenzenes in the high-molecular-weight region may be due to a high content of odd linear polyenes C_{15}–C_{21} with one to six double bonds in marine plants [14]. The prevalence of the C_{21} hydrocarbon is attributable to the fact that some species of plankton algae contain only one hydrocarbon, polyene $C_{21}H_{32}$ with six double bonds: heneicosa-3,6,9,12,15,18-hexaene [17]. The suggested scheme of *n*-pentadecylbenzene formation from this hexaene is shown in Fig. 2. The other odd homologs are formed by cyclization and aromatization of other olefins.

The sequence of transformations leading to high-molecular-weight odd *n*-alkylbenzenes presumably consists of four steps.

The first step is isomerization of heneicosa-3,6,9,12,15,18-hexaene into conjugated thermodynamically stable heneicosa-1,3,5,7,9,11-hexaene. It is known that various conjugated polyenes are capable of concerted cyclization under the influence of light or heating. This reaction results in that a double bond disappears and the other double bonds are shifted, with the formation of a new single bond between two reactive ends of the conjugated system. Reactions of this type or reverse processes in which a cyclic product transforms into an acyclic polyene are termed electrocyclic reactions. As these reactions are reversible, their direction (direct or reverse) is governed by thermodynamic factors [18–25].

The second step is cyclization of the conjugated polyene to cyclohexadiene with an unsaturated hydrocarbon substituent.

The third step is dehydrogenation of the cyclohexadiene ring to benzene ring. The transformation product is 1-phenylpentadeca-1,3,5-triene.

The fourth step is reduction of the unsaturated substituent. Since ripening of the fossil organic matter had occurred under reducing conditions, hydrogenation of the unsaturated radical yielded *n*-pentadecylbenzene.

CONCLUSIONS

(1) A homologous series of *n*-alkylbenzenes with clearly pronounced prevalence of odd homologs in the range C_{17}–C_{23} was identified in crude oils from the main industrial oil fields of the Nepa–Botuoba anteclise.

(2) A possible model of the formation of an odd C_{21} *n*-alkylbenzene, *n*-pentadecylbenzene, from a polyene, heneicosa-3,6,9,12,15,18-hexaene (compound present in marine plankton algae), was suggested.

(3) The identified homologous series of *n*-alkylbenzenes, along with the known geochemical features of crude oils from this area, suggest that the genetic sources of the hydrocarbon fluids are similar or common.

Received May 30, 2007

Abstract—Effect of the duration of mechanochemical synthesis (0.5–3 h) and amounts of hydrogen peroxide (0.1–0.5 g g^{-1} raw material) and ammonia (0.25–0.5 g g^{-1} raw material) on the content of nitrogen and humic and fulvic acids in products of oxidative ammonolysis of peat by the mechanochemical method was studied. The functional composition of fixed nitrogen was analyzed. Agrochemical tests of the preparations obtained as nitrogen-containing fertilizers were performed.

DOI: 10.1134/S1070427207100345

The agrochemical value of peat is largely determined by its organic component (humic and fulvic acids) and by its nitrogen content. However, the poor accessibility of the organic substance results in that the source peat only weakly manifests fertilizer properties. The organic component of peat can be activated with aqueous ammonia, which extracts humic substances as water-soluble ammonium humates [1].

A known method for production of a nitrogen-containing organic fertilizer, ammonified peat, consists in treating peat having certain moisture content with aqueous ammonia. The main disadvantages of the known method for peat ammonification are its long duration, which leads to loss of ammonia, and low content of fixed nitrogen in the ammonified peat [1].

Previously, a method has been developed for obtaining a plant-growth stimulant from peat by its treatment with hydrogen peroxide in aqueous ammonium in an autoclave at a hydromodulus of 9.5 : 1, ammonia content of 20–50%, and hydrogen peroxide content of 20–30% (both relative to absolutely dry peat mass) at 120°C for 4 h. This method has important technological disadvantages: high process temperature (120°C), duration of up to 4 h, and multistage nature [2].

A new mechanochemical technique has been suggested for production of nitrogen-containing organic fertilizers by oxidation of peat with hydrogen peroxide in an aqueous-ammonia medium to give humin-containing derivatives in quantitative yield [3].

The aim of the present study was to examine the effect of preparation conditions on the composition of products formed in oxyammonolysis of peat by the mechanochemical method.

EXPERIMENTAL

Raised-bog fuscum peat from the Vasyuganskoe deposit in Tomsk oblast was used as a raw material. It had the following parameters (%): degree of decomposition 10, ash content 2.6, and moisture content 60; and contained (%): total nitrogen 2.2, humic acids 13.8, and fulvic acids 18.5.

The mechanochemical synthesis of products of peat oxidation with hydrogen peroxide in an aqueous-ammonia medium was carried out in a vibration mill.

As shown by the results of the experiments performed (Table 1), the content of humic and fulvic

Table 1. Effect of the duration of mechanochemical vibration grinding on the composition of ammonified peat (moisture content of peat 60%, mass of absolutely dry peat 5.0 g, amount of hydrogen peroxide 0.1 g g^{-1} absolutely dry peat, amount of ammonia 0.25 g g^{-1} absolutely dry peat)

* g g^{-1} absolutely dry peat.

acids in peat steadily increases as the duration of vibration grinding of peat in the presence of ammonia and an oxidizing agent (hydrogen peroxide) is made longer. The increase in the content of fixed nitrogen by a factor of 2.5 after 3 h of mechanochemical synthesis indicates that the organic substance of peat undergoes oxidative ammonolysis.

Raising the amount of hydrogen peroxide per gram of absolutely dry peat from 0.1 to 0.4 g leads to a steady rise in the amount of fixed nitrogen and humic and fulvic acids in the ammonified products obtained (Table 2). Further increase in the amount of the oxidizing agent to 0.6 g g^{-1} peat does not raise to any significant extent the content of fixed nitrogen and humic substances.

It can be seen from Table 3 that the amount of ammonia also affects the composition of nitrogen-containing fertilizers produced from peat. As can be seen from these data, raising the amount of ammonia by a factor of 2 leads to an increase in the content of fixed nitrogen by a factor of 1.4 and to a steady rise in the content of humic and fulvic acids in ammonified peat. It should be noted that, in all cases of mechanochemical oxidation (Tables 1–3), the content of fulvic acids increases to a greater extent than does that of humic acids, i.e., humic acids are converted into fulvic acids in oxidation.

The functional forms of fixed nitrogen were determined in the product of oxidative ammonolysis of peat, which contained (%): total nitrogen 5.3, humic acids 18.7, fulvic acids 31.1.

The content of ammonium nitrogen was determined after extraction of a weighed portion of ammonified peat with a 1 N KCl solution [4], and that of fixed nitrogen, by differentiated sulfuric acid hydrolysis with sulfuric acid solutions, with the concentration of these solutions raised from 0.5 to 5 N, by methods described in [5] and the content of residual nitrogen in hydrolyzed samples analyzed.

It was found that the products formed in oxyammonolysis of peat contain (%): ammonium nitrogen 24, amide nitrogen 15, ammine nitrogen 15, and heterocyclic nitrogen 43 of its total amount.

A product containing 5.3% fixed nitrogen was tested as a nitrogen-containing humic fertilizer for peas of Sakharnyi brand. It was shown that nitrogen-containing peat derivatives stimulate growth of peat plants by 26–34%, with the total biomass raised by 50–65%, and the chlorophyll content of the plants, by 66–120%.

CONCLUSIONS

(1) A method for synthesis of nitrogen-containing humic fertilizers from peat by its oxidative ammonolysis with hydrogen peroxide in an aqueous-ammonia medium by mechanochemical treatment was developed and products containing up to 5.3% organically fixed nitrogen and up to 23.2 and 31.1% humic and fulvic acids, respectively, were obtained.

(2) It was found that the products formed in oxyammonolysis of peat contain (%): ammonium nitrogen 24, amide nitrogen 18, ammine nitrogen 15, and heterocyclic nitrogen 43 of its total amount.

(3) It was shown that the products obtained exhibit high biological activity and can be used as nitrogen-containing humic fertilizers that improve the productivity of cereals by 26–34%.

Abstract—Dissolution of gadolinium, europium, neodymium, dysprosium, and samarium oxides to give nitrates of these metals was studied in a system constituted by tributyl phosphate (30 vol %), tetrachloroethylene (70 vol %), and NO_2. The activation energy of anhydrous dissolution of gadolinium oxide was calculated. The effect of water on the conversion efficiency of gadolinium oxide into nitrate was examined.

DOI: 10.1134/S1070427207100357

It is known that solvometallurgical methods for processing of ores and secondary raw materials [1] make it possible to intensify dissolution processes, improve the selectivity of the processing techniques, and substantially diminish, or even completely abandon use of water in technological processes [2].

Development of the solvometallurgical technologies for processing of mineral resources requires a study of the fundamental aspects of interaction between dissolved materials and nonaqueous systems. The authors of [3] studied the oxidative dissolution of rare-earth elements in tributyl phosphate (TBP). In [4], chlorination of yttrium oxide in the system constituted by dimethylformamide (DMFA) and Cl_2 was analyzed, with the kinetic properties of the interaction disregarded.

This study is concerned with the nonaqueous low-temperature nitration of gadolinium, europium, neodymium, dysprosium, and samarium oxides in the system constituted by TBP, tetrachloroethylene (TCE), and nitrogen dioxide.

EXPERIMENTAL

We used TBP of chemically pure grade, prepared by the method described in [5]. Tetrachloroethylene was purified by distillation [5].

The dissolution was studied in a temperature-controlled reactor (stirring rate 800–900 rpm). It was confirmed by preliminary experiments that these conditions correspond to the kinetic dissolution mode. Powders of gadolinium, europium, neodymium, dysprosium, and samarium oxides were prepared by calcination of their hydroxides under identical conditions at 800°C [6]. Gadolinium oxide used in the experiments had cubic structure.

Visible-range spectra of the organic solutions prepared were recorded on a Shimadzu UV-3000 instrument.

We studied the dissolution of gadolinium, europium, neodymium, dysprosium, and samarium oxides in the system constituted by tributyl phosphate (30 vol %), TCE (70 vol %), and NO_2 (1.5 M) at 40°C. The results of the experiments are shown in Fig. 1. The conversion of rare-earth element oxides proceeds without an induction period, with its rates in

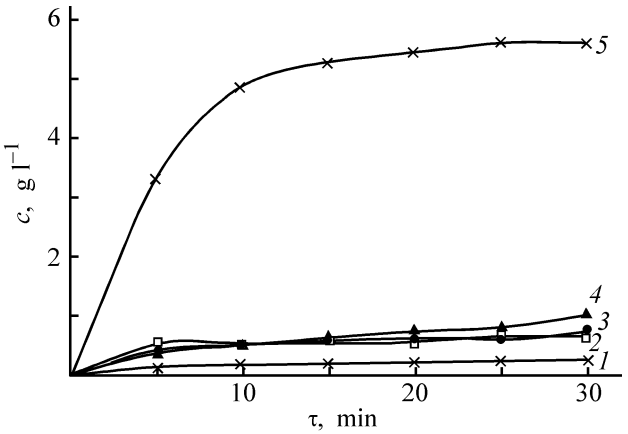

Fig. 1. Dissolution of REE oxides in the system TBP (30 vol %)–TCE (70 vol %)–NO_2 (1.5 M) at T = 40°C. (c) Concentration and (τ) time; the same for Figs. 2–4. REE: (*1*) Eu, (*2*) Sm, (*3*) Dy, (*4*) Nd, (*5*) Gd.

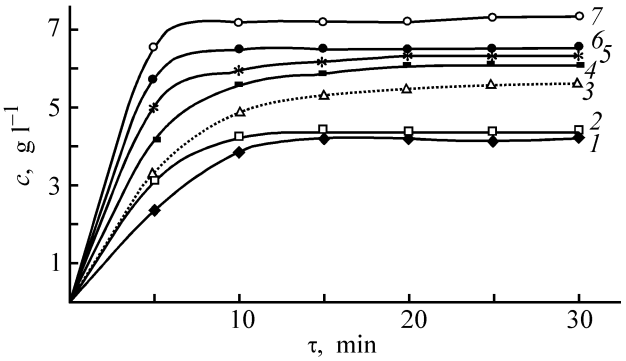

Fig. 2. Dissolution of Gd_2O_3 in the system TBP (30 vol %)–TCE (70 vol %)–NO_2 at different concentrations of NO_2 at T = 40°C. NO_2 concentration (M): (*1*) 0.5, (*2*) 1, (*3*) 1.5, (*4*) 2, (*5*) 2.5, (*6*) 3, and (*7*) 3.5.

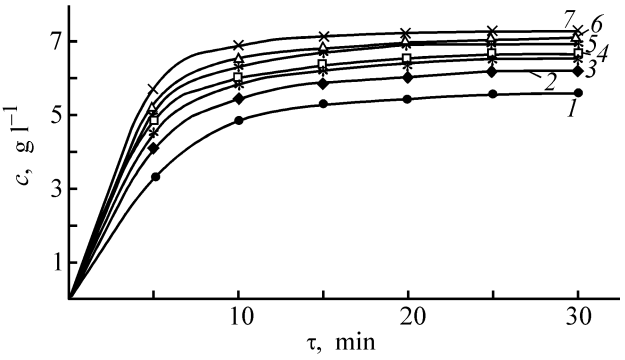

Fig. 4. Dissolution of Gd_2O_3 in the system TBP (30 vol %)–TCE (70 vol %)–NO_2 (1.5 M) with addition of small amounts of water at T = 40°C. H_2O content (vol %): (*1*) 0, (*2*) 0.3, (*3*) 2.5, (*4*) 0.5, (*5*) 2, (*6*) 0.76, and (*7*) 1.

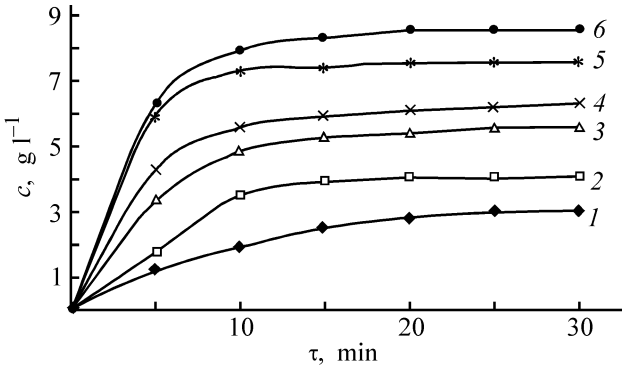

Fig. 3. Dissolution of Gd_2O_3 in the system TBP (30 vol %)–TCE (70 vol %)–NO_2 (1.5 M) at different temperatures. T (°C): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 60, and (*6*) 70.

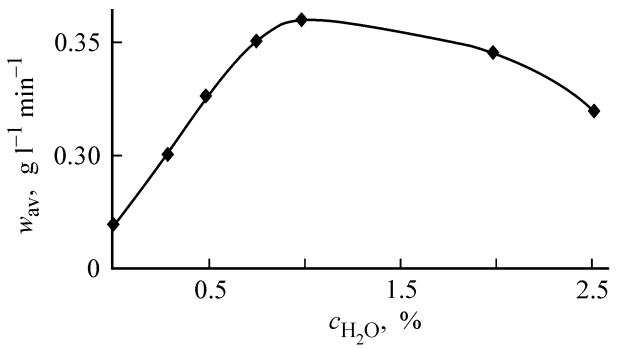

Fig. 5. Average gadolinium dissolution rates w_{av} at different contents of water c_{H_2O} in the course of 20 min.

the initial period increasing in the order Eu < Nd < Dy < Sm < Gd. In the spectrum, the characteristic absorption bands of Nd were observed at 422, 512, 526, 584, 678, 736, 743, 800, and 870 nm, which shows that the rare-earth metal is present in solution as Nd(III) [7]. The bands characteristic of the following elements in the following states were observed: Dy(III) at 449 nm [6], Sm(III) at 464 and 477 nm [8], and Eu(III) at 390 nm [6]. Thus, it was established that, upon nonaqueous low-temperature nitration of oxides of rare-earth elements (REE), they pass into the organic solution in the trivalent state.

The dissolution kinetics of gadolinium oxide in the system composed of TBP (30 vol %), TCE (70 vol %), and NO_2 was studied in relation to the oxidant concentration. The results of the experiments are shown in Fig. 2. The data obtained indicate that the dissolution rate increases with the NO_2 concentration in the solution. A calculation of the initial dissolution rates and processing of the experimental data by Microsoft Excel 97 software demonstrated that the conditional reaction order and the rate constant are n = 0.6 and K = 713.35 mg mol^{-1} min^{-1}, respectively.

The results obtained when studying the temperature dependence of the kinetics of gadolinium oxide dissolution in the range 20–70°C are presented in Fig. 3. The data obtained show that the dissolution rate increases with temperature. A calculation of the initial dissolution rates and processing of the experimental data by Microsoft Excel 97 software showed that the activation energy of the system is E_a = 30.6 kJ mol^{-1} and the constant $K = 7.515 \times 10^7$ mg l^{-1} min^{-1}.

It has been reported that water strongly affects the rate of interaction between metals and certain nonaqueous dissolving systems [9, 10].

We studied the dissolution kinetics of gadolinium oxide in the system constituted by TBP (30 vol %), TCE (70 vol %), and NO_2 (1.5 M), to which water was added. The results of the experiments are shown in Fig. 4. The data obtained were used to calculate the average dissolution rates of gadolinium oxide (Fig. 5).

As can be seen from Fig. 5, the given dependence has an extremum. It is known that nitrogen dioxide reacts with water to give nitric and nitrous acids. To study processes of anhydrous low-temperature dissolution, we used REE oxides, i.e., already oxidized substances. Thus, the oxidation process proper does not occur in the system, and, consequently, water must affect the conversion process only by making higher the acidity of the system. When the content of water is raised to more than 1.5 vol %, the whole amount of nitrogen dioxide is already reacted with water, and, further, the solution is diluted, i.e., the acidity of the system decreases.

CONCLUSIONS

(1) The results obtained in a study of the dissolution of gadolinium, europium, neodymium, dysprosium, and samarium oxides in the system composed of tributyl phosphate (30 vol %), tetrachloroethylene (70 vol %), and NO_2 with the formation of their nitrates demonstrate that gadolinium oxide is dissolved under the kinetic control and the activation energy of dissolution in this system is 30.6 kJ mol^{-1}.

(2) The relative reaction order with respect to NO_2 for the reaction of gadolinium oxide conversion is 0.6.

(3) The dissolution rate of gadolinium oxide is at a maximum at a water content of 1.0–2.0 vol %.

Abstract—The effect of the structure and molecular weight of fluorocarboxylic acids on their dissociation constants in acetonitrile and its mixtures with water and methanol was studied.

DOI: 10.1134/S1070427207100369

It is known that, owing to the strong electron-acceptor properties of the trifluoromethyl radical, trifluoroacetic acid has a dissociation constant of 5.9×10^{-1} in water [1] and virtually does not differ from strong acids, such as hydrochloric acid. Its homologues, perfluorocarboxylic acids, are also rather strong acids. As, however, the length of the carbon chain increases, micelle formation leads to a decrease in the degree of ionization [2].

Electrochemical syntheses with anodic dimerization and cross-anodic combination of various fluorocarboxylic acids in acetonitrile mixed with water and methanol are of practical importance for preparation of new organofluoric compounds possessing various useful properties [3]. The specific role played by acetonitrile in electrolytic media, which primarily determines the efficiency of these processes, makes necessary a study of the electrochemical characteristics of fluorinated carboxylic acids in its mixtures with protonating electrolytes in order to choose the electrolysis conditions and prognosticate the results of electrosyntheses.

EXPERIMENTAL

The dissociation constants of fluorocarboxylic acids were determined by potentiometric titration [4] with a pH-673M millivoltmeter, using a glass working electrode and the standard calomel electrode. The solutions were agitated with a magnetic stirrer.

The dissociation constants of the acids were measured in individual solvents (acetonitrile, water, and methanol) and in their mixtures with relative solvent concentrations commonly used in electrochemical syntheses [3].

Depending on a medium, the following solutions were used as titrants: 0.1 M KOH for acetonitrile, 0.1M aqueous solution of NaOH for water and its mixtures with acetonitrile, and 0.1 M solution of sodium methylate in methanol for methanol and its mixture with acetonitrile.

The solvents were purified by the known procedures [5].

Titration was applied to 0.2 M solutions of the following polyfluorocarboxylic acids of reagent grade or those synthesized and purified by rectification: CF_3CF_2COOH (**I**) pentafluoropropionic acid; $CF_2ClCFClCOOH$ (**II**) 1,2-dichloroperfluoropropionic acid prepared by the method [6]; $CF_3CF_2CF_2COOH$ (**III**) heptafluoromaleic acid; $CF_3CF_2CF_2OCF(CF_3)$-COOH (**IV**) perfluoro-3-oxo-2-methylhexanoic acid; $CF_3OCF_2CF_2CF_2OCF(CF_3)COOH$ (**V**) perfluoro-3,7-dioxo-2-methyloctanoic acid [prepared by condensation of $CF_3OCF_2CF_2COF$ with hexafluoropropene oxide and subsequent hydrolysis of acylfluoride $CF_3OCF_2CF_2CF_2OCF(CF_3)COF$]; $CF_3CF_2CF_2OCF$-$(CF_3)CF_2OCF(CF_3)$C OOH (**VI**) perfluoro-3,6-dioxo-2,5-dimethylnonanoic acid; $F(CF_2CF_2O)CF_2COOH$ (**VII**) perfluoro-3,6,9,12-tetraoxotetradecenoic acid prepared by hydrolysis of the tetrafluoroethene oxide pentamer.

The equivalence point pH_{eq} was determined by differentiating the titration curve. The determination accuracy was ±2%.

The negative logarithm of the dissociation constant, pK_{HA}, was calculated by the equation [4]:

$$pK_{HA} = 2pH_{eq} - pK_{H_2O} + \log c_{HA} = 2pH_{eq} - 13.3010.$$

Calculated dissociation constants of polyfluorocarboxylic acids in various solvents

Acid	$K_{HA} \times 10^2$							
	CH_3CN	H_2O	CH_3OH	CH_3CN–H_2O, vol % CH_3CN				CH_3CN–CH_3OH, 10 vol % CH_3CN
				90	50	40	30	
CF_3CF_2COOH (**I**)	3.66	2.50	1.58	3.55	–	–	–	1.12
$CF_2ClCFClCOOH$ (**II**)	3.12	3.98	1.26	3.16	–	–	–	1.07
$CF_3CF_2CF_2COOH$ (**III**)	1.80	1.58	–	1.25	–	–	–	–
$CF_3CF_2CF_2OCFCOOH$ (**IV**) $\quad\quad\quad

pendant trifluoromethyl groups, also gives no way of observing this dependence.

CONCLUSIONS

(1) It was shown that the dissociation constants of fluorocarboxylic acids are lower by at least an order of magnitude than the dissociation constant of trifluoroacetic acid. Therefore, the above compounds cannot be classed with strong acids.

(2) In water and acetonitrile, the dissociation constants of fluorocarboxylic acids of various structures and molecular weights differ only slightly, although their dielectric constants are strongly different.

Abstract—Extraction of Cu(II) with *N*,*N*-diethylbenzohydrazide and the effect of ammonium salts on this process were studied. The composition and structure of the complex being extracted was analyzed.

DOI: 10.1134/S1070427207100370

The exists a rather wide assortment of compounds that can be used for extraction of copper(II) from various media [1]. However, the extractive agents employed in industry have a number of disadvantages that limit their applicability and stimulate a search for new, more effective reagents. A promising class of compounds for Cu(II) extraction is constituted by hydrazides suggested for recovery of CuII) from acid solutions [2]. There have been no reports devoted to Cu(II) extraction with *N*,*N*-dialkyl derivatives of hydrazides. Meanwhile, introduction of two alkyl radicals into the hydrazide group can markedly change the extractive properties of the compounds obtained. This study is concerned with Cu(II) extraction with *N*,*N*-diethylbenzohydrazide (DEBH), $PhCONHN(Et)_2$.

EXPERIMENTAL

DEBH was synthesized as follows. Benzohydrazide [13.6 g (0.1 mol)] was dissolved in 100 ml of isopropanol, 19 ml (0.25 mol) of ethyl bromide was added, and a solution of 11.2 (0.2 mol) of KOH in 80 ml of isopropanol was introduced dropwise. The reaction mixture was heated to neutral reaction (2–3 h), filtered, and evaporated. To the residue was added 50 mol of chloroform and the mixture was filtered and evaporated. The residue was recrystallized from a 2 : 1 mixture of hexane and *n*-xylene. Yield 11.2 g (58%); mp = 121.5–123.0°C; R_f = 0.50 (*m*-xylene : BuOH = 2 : 1). IR spectrum, ν (cm^{-1}): 1572 (amide II); 1639, 1652 (amide I); 3195 (N–H). ^1H NMR spectrum, δ (ppm; *J*, Hz): 1.09 (t, 6H, Me, *J* = 6.9), 2.81 (q, 4H, CH_2, *J* = 6.9), 6.60 (s, 1H, NH), 7.3–7.5 (m, 3H, Ph), 7.69 (d, 2H, Ph, *J* = 7.2).

IR spectra were recorded on a Bruker JFS 66/S Fourier spectrometer in Vaseline oil, and ^1H NMR spectra on a MERCURY plus 300 spectrometer (300 MHz) in $CDCl_3$, with HMDS as internal standard. The pH values were measured with an I-160 M ion-meter with glass and silver chloride electrodes. UV spectra and the optical densities were measured with an SF-26 spectrophotometer. SILUFOL plates served as the chromatographic material. $CuSO_4$, $NiCl_2$, $CoCl_2$, and $K_2Cr_2O_7$ of analytically pure and chemically pure grades were used. The content of elements in standard solutions and in the aqueous phase was determined using the following methods: Co(II), Ni(II), and Cu(II) by complexonometry [3–5]; small amounts of copper(II), by the extractive-photometric technique with sodium diethyldithiocarbamate [6]; and Cr(VI), photometrically with diphenylcarbazide [7].

The solubility of the reagent, found gravimetrically, is 10.5 g l^{-1} in *m*-xylene and 1.6 g l^{-1} in hexane.

Figure 1 shows UV spectra of DEBH solutions in various media. It can be seen that, depending on pH, the reagent exists in different forms. The acid–base

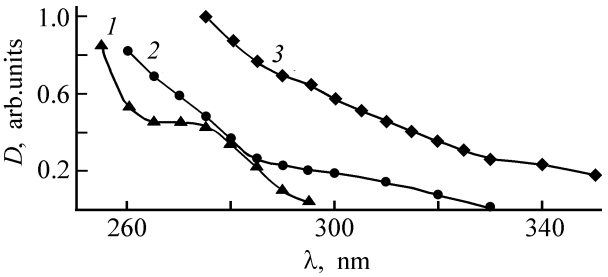

Fig. 1. UV spectra of DEBH solutions in various media. (*D*) Optical density and (λ) wavelength. *l* = 1 cm, H_2O : EtOH = 10 : 1, $c_{DEBH} = 4.9 \times 10^{-4}$ M. (*1*) pH 0.85, (*2*) pH 4.82, and (*3*) 7.3 M NaOH.

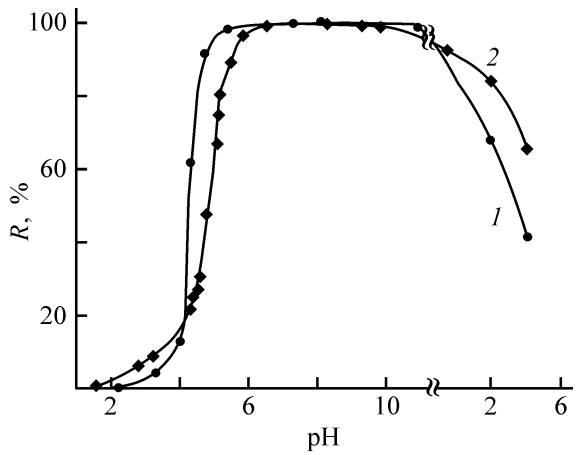

Fig. 2. Degree of copper(II) extraction, R, vs. the pH value of the aqueous phase. $V_{org} : V_{aq} = 1 : 10$, $c_{Cu(II)} = 0.001$ M, $\tau = 3$ min. 0.05 M DEBH solution: (*1*) in *m*-xylene and (*2*) in *i*-AmOH.

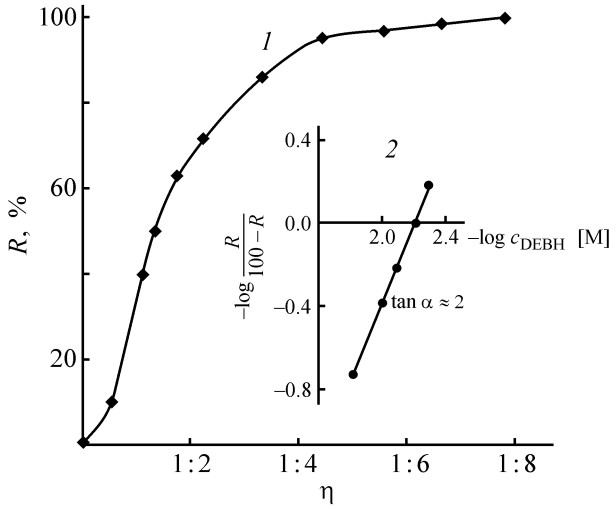

Fig. 3. Determination of the composition of the Cu(II) complex with DEBH. $c_{DEBH} = 0.05$ M, $c_{Cu(II)} = 0.004$ M, pH 9.0–10.5 (ammonia buffer solution), $I = 0.2$ (KCl). (R) Degree of Cu(II) extraction from solution and (h) [Cu(II)] : [DEBH] molar ratio. (*1*) Saturation curve and (*2*) processing of this curve by the equilibrium shift method.

equilibria in its solutions can be expressed in the general form as follows:

$$H_2L^+ \underset{-H^+}{\overset{pK_{a_1}}{\rightleftharpoons}} HL \underset{-H^+}{\overset{pK_{a_2}}{\rightleftharpoons}} L^-,$$

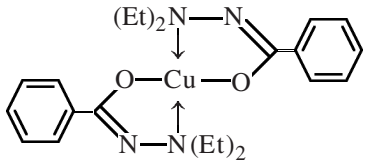
where HL is the DEBH molecule.

The pK_a values were determined spectrophotometrically in 10 : 1 H_2O : EtOH at $l = 1$ cm and $c_{DEBH} = 4.9 \times 10^{-4}$ M for pK_{a_1} at $\lambda = 260$ nm and $I = 0.1$ ($NaNO_3$) and for pK_{a_2} at λ 280 nm: $pK_{a_1} = 3.24 \pm 0.02$ ($n = 5$, $P = 0.95$) and $pK_{a_2} = 14.94 \pm 0.03$ ($n = 6$, $P = 0.95$) (at c_{NaOH} the Hammett function was used).

The extraction of Cu(II), Co(II), Ni(II), and Cr(VI) with a DEBH solution in *m*-xylene was studied. Co(II), Ni(II), and Cr(VI) ions are extracted from neither acid nor ammonium medium. The Cu(II) compound is extracted as a red complex; the dependence of the degree of extraction, R, on pH is shown in Fig. 2 (curve *1*). It can be seen that Cu(II) starts to be extracted at pH > 3; at pH 3.0–5.4, the degree of recovery steeply increases from 4 to 98% and then remains constant up to $c_{NH_3} = 1$ M. As the NH_3 concentration is raised further, to 4 M, R gradually decreases to 41%, which is presumably due to a competing formation of ammoniates.

The composition of the copper(II) complex was determined by the method of molar ratios. The curve obtained in an ammonia buffer solution had no pronounced inflections (Fig. 3). The method of the equilibrium shift revealed the formation of an extractable complex with a ratio [Cu(II)] : [DEBH] = 1 : 2.

When an extract of the complex, colored red brown, is passed through a KU-2-8 cation-exchange resin in the Na^+ form, the coloration of the extract is preserved, which indicates that the complex is not charged. This is only possible in the case when the complex contains hydrazide in a deprotonated form. The structure of the complex can reflected by the formula



Because the deprotonated form of DEBH starts to be formed at pH > 13, which is not the case under the extraction conditions, it can be concluded that a reagent molecule already incorporated into the complex undergoes deprotonation.

By analogy with dimethylhydrazides [8], *N*,*N*-diethylbenzohydrazide forms a complex of the cation type with copper(II), with a blue-green coloration and $[Cu^{2+}]$: [DEBH] ratio of 1 : 2. The extraction of this complex was studied using a solution of DEBH in isoamyl alcohol. The curve obtained for the dependence of R on pH (Fig. 2, curve *2*) was found to be close to that obtained with the solution of the reagent in xylene. The extract was also red. This indicates that only an uncharged complex of the $[Cu(L–H)_2]$ type is extracted in both cases.

On shaking the blue-green solution of a charged complex of the cation type in isoamyl alcohol with

Effect of ammonium salts on the extraction of copper(II) from an ammonia solution [$c_{Cu(II)}$ = 0.005 M, V_{org} : V_{aq} = 1 : 2, c_{DEBH} = 0.05 M (*n*-xylene)]

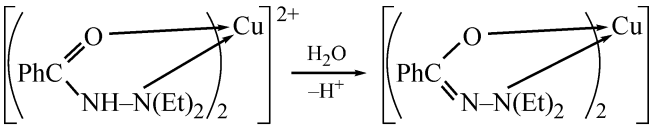
water, the coloration of the organic layer changes to red, which points to a transition of this complex to the neutral [Cu(L–H)$_2$]. The transition process can be represented as:



Industrial ammonia solutions of Cu(II) commonly contain ammonium salts, which can suppress the extraction. The results obtained in Cu(I) extraction from a solution containing 0.1 M NH_3 and varied amounts of $(NH_4)_2SO_4$ and NH_4Cl are listed in the table. It can be seen that presence of ammonium sulfate and chloride in amounts of up to 1 M has virtually no effect on the recovery of copper(II).

CONCLUSIONS

(1) *N*,*N*-Diethylbenzohydrazide effectively recovers Cu(II) from ammonia solutions with NH_3 concentrations of up to 1 M.

(2) Replacing *m*-xylene with isoamyl alcohol has virtually no effect on the dependence of the degree of Cu(II) recovery on pH. In both cases, the Cu(L–H)$_2$ complex is extracted.

(3) Presence of NH_4Cl and $(NH_4)_2SO_4$ in concentrations of up to 1 M has little effect on the degree of Cu(II) recovery.

Received December 19, 2006; in final form, April 2007

Abstract—Apparent molar volume, enthalpy of activation, and Gibbs energy of viscous flow of aqueous copper sulfate solutions were calculated from experimental data. The concentration dependences of the above parameters were analyzed from the standpoint of structural transformations.

DOI: 10.1134/S1070427207100382

A solution is a complex equilibrium chemical system formed by a solvent, dissolved substance (solute), and products of their interaction. One of the most structurally sensitive properties of the solutions, which characterizes the internal friction of a liquid, is viscosity. As a rule, determining the viscosity under atmospheric pressure is rather simple. More severe difficulties arise when experimental data are discussed in order to identify structural changes in solution, associated with the component concentrations and temperature. There exist several approaches to interpretation of viscosity data as applied to structural transformations in electrolytes [1–3]. One of these is based on the Eyring theory [4], which allows calculation of activation characteristics of the viscous flow of dilute [3] and concentrated electrolyte solutions [5]. In the present study, this approach was used to analyze the viscous flow of aqueous copper sulfate solutions. The given salt is the main component of electrolytes used for plating of copper and its alloys.

EXPERIMENTAL

The solutions were prepared by gravimetric method from twice-distilled water and recrystallized reagents of chemically pure grade. Measurements were made in the temperature range 20–50°C. The kinematic viscosity was determined with a VPZh-4 viscometer with a capillary diameter of 0.56 mm [GOST (State Standard) 10028–81], and the density, by the pycnometric method. The measurement error was 0.2–0.4%. A calculation of the Cochran criterion [6] confirmed the reproducibility of the results.

The interaction of copper ions with water dipoles makes hydrogen bonds in the solvent structure weaker and, at higher concentrations, even leads to rupture of these bonds to give a hydrated ion $[Cu(H_2O)_n]^{2+}$. According to the data of [7], the Cu^{2+} ion in aqueous solution has a distorted octahedral environment of H_2O molecules. As shown in [8], the nearest environment of the Cu^{2+} ion is less ordered in copper sulfate solutions, compared with solutions containing other oxygen-containing anions. This phenomenon is accounted for by the effect of the sulfate ion, which competes with water molecules for the place in the first hydrate shell of the cation. It is known that SO_4^{2-} anions can occupy voids without any pronounced distortion of the water structure, with two water molecules in the lattice replaced by two oxygen atoms of the anionic tetrahedron, and two its other oxygen atoms occupy two adjacent voids. Being strongly hydrated, sulfate ions form with water molecules short hydrogen bonds and SO_4^{2-}–H_2O associates may appear in solutions containing these ions via transfer of a water molecule into a void [9].

The bulk properties of the solutions under study can be interpreted in terms of the approach suggested by Onori [10]. In this case, the solution is considered in the approximation of an ideal mixture of hydrated ions and molecules of "free" water, and the apparent molar volume V is determined by the relation

$$\Phi_V = (V - X_1V_1)/X_2, \quad (1)$$

where V is the average molar volume of the solution,

$$V = (X_1M_1 + X_2M_2)/\rho; \quad (2)$$

Gibbs energies of viscous flow, ΔG_η^*, of aqueous solutions of $CuSO_4$

T, °C	ΔG_η^*, kJ mol^{-1}, at indicated solution concentration, M

X_1, X_2, M_1, and M_2, mole fractions and molecular weights of the solvent and dissolved substance; ρ, solution density (g cm^{-3}); and V_1, volume of 1 mol of free water molecules, which can be calculated by the formula

$$V_1 = (1 - x)/V_s. \quad (3)$$

Here x is the mole fraction of water molecules in voids, and V_s is the molar volume of the skeleton.

The apparent molar volume of the ions grows with their concentration because of the decrease in the amount of water subjected to electrostriction and ceases to increase when no free water molecules remain in the solution outside the coordination sphere of the cations. Departure from linearity of the Φ_V–$c^{1/2}$ dependence for the solutions studied (see figure) may indicate that full hydration limit is reached. As is known [11], the molar volume of pure water increases with temperature. For copper sulfate solutions, the apparent molar volume Φ_V also increases as the temperature is raised from 20 to 50°C. This is probably due to deformation and rupture of hydrogen bonds in the solvent structure and to simultaneous binding of free water molecules into hydrated complexes.

Because water is an associated liquid, the viscous flow of aqueous solutions is accompanied by a structural deformation that involves energy expenditure [12]. The energy expenditure for the process of viscous flow can be estimated using the Eyring theory [4]. In terms of this theory, the Gibbs energy of the solutions studied was calculated by the formula

$$\Delta G_\eta^* = RT \ln \frac{\nu \overline{M}}{h N_A}, \quad (4)$$

where R is the universal gas constant; T, absolute temperature; η, kinematic viscosity (cm^2 s^{-1}); $\overline{M}$, average molecular weight ($\overline{M} = \Sigma M_i N_i$, M_i and N_i are molecular weights and mole fractions of the solution components); h, Planck constant; and N_A, Avogadro number.

Apparently, the change in the free Gibbs energy of viscous flow is due to the transformations occurring in the solution: destabilization of the structure is accompanied by a decrease in ΔG_η^*, whereas in the case of structuring, ΔG_η^* increases (see table).

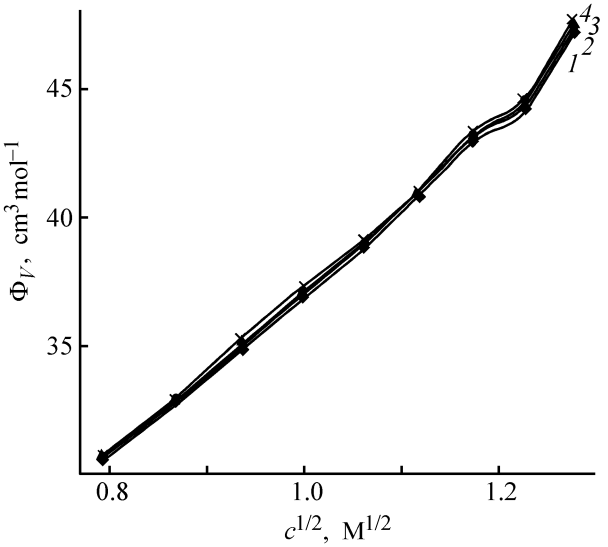
The following equation [4]

$$\Delta H_\eta = R \frac{d \ln \nu}{d(1/T)} \quad (5)$$

was used to calculate the enthalpy of activation of the viscous flow, ΔH_η^*, for the solutions studied at t = 20–50°C:

c, M	0.63	0.75	0.88	1.00	1.13	1.25	1.38	1.50	1.63
ΔH_η^*, kJ mol^{-1}	4.7	4.6	4.5	7.6	6.9	5.4	6.2	5.7	5.5

The values of ΔH_η^* for the $CuSO_4$ solutions are lower than the enthalpies of activation of the viscous flow of water (ΔH_η^* of water is 16.26 kJ mol^{-1} [3]). This confirms that transition from one equilibrium



Φ_V–$c^{1/2}$ dependence for an aqueous $CuSO_4$ solution. (Φ_V) apparent molar volume and (c) concentration. Temperature, °C: (*1*) 20, (*2*) 30, (*3*) 40, and (*4*) 50.

to another is facilitated, and, consequently, the solution structure is disordered. The increase in ΔH_{η}^{*} on reaching $CuSO_4$ concentrations of 1.00 and 1.38 M is probably due to redistribution of water molecules in the hydrate spheres of the cations and anions and to formation of more stable hydrate complexes. Further decrease in the potential barrier with increasing viscosity can be understood on the assumption that a new polyionic structure consisting of hydrated ions and water molecules is formed in concentrated solutions. However, the forming structure is less stable than the water skeleton.

CONCLUSION

The manner in which in the activation characteristics of the viscous flow and the apparent molar volume of $CuSO_4$ aqueous solutions change with increasing concentration and temperature indicates that there occur complex structural transformations accompanied by destruction of the solvent structure, hydration of ions, and formation of a new polyionic structure in concentrated solutions.

OBITUARY

Georgii Gerogievich Furin (1939–2007)

DOI: 10.1134/S1070427207100394

On March 8, 2007, at the age of 69 passed away Georgii Georgievich Furin, a prominent Russia's fluoroorganic chemist, doctor of chemical science, professor. Georgii Georgievich was born on February 27, 1939, in Novorossiisk. Having early become an orphan (his father, G.I. Furin, was killed in action in December 1941, when defending Sevastopol), Georgii Georgievich got used to work already in his childhood; during years of education at Dnepropetrovsk University (1957–1962), he worked as loader, fireman, typography worker, and teacher of chemistry. Having graduated from the university in 1962, Georgii Georgievich became a staff member of Novosibirsk Institute of Organic Chemistry, where he worked during his whole life and made his way up from a senior laboratory assistant to deputy director for research activities. Georgii Georgievich was an exceedingly erudite chemist, closely acquainted with almost the entire body of chemical literature (he was the author of numerous articles in encyclopedias published by Springer, Guben-Weill, Harwood, and Elsevier publishing houses). G.G. Furin was an excellent experimenter-synthesist and a brilliant analyst.

The main area of Georgii Georgievich's scientific activities was study of fluorine-containing heterocyclic compounds; here, he was rightly considered a world-renown authority. G.G. Furin was the author of more than 400 papers, 30 reviews, and 8 monographs and holder of 40 patents. Georgii Georgievich was an excellent and attentive pedagogue. His pupils include 3 doctors and 9 candidates of science in Russia and 3 doctors of science in the Republic of Korea. Georgii Georgievich took care of his pupils during his whole life by helping in their employment, research, publication of papers and books, and, occasionally, financial problems. He was a member of scientific-technical councils at numerous chemical plants in our country and took part in the organization

of shops for manufacture of quite a number of fluoroorganic compounds.

Georgii Georgievich was a cultured person and a tactful, courteous and well-wishing, interesting and witty interlocutor, and a hospitable host. He was an honest man of principle who deeply loved his Motherland.

Respectful memory of Georgii Georgievich Furin will be forever preserved in hearts of all those who was acquainted with this excellent person.

BOOK REVIEWS

Fundamental'nye problemy preobrazovaniya energii v litievykh elektrokhimicheskikh sistemakh: Materialy IX Mezhdunarodnoi konferentsii (Fundamental Problems of Energy Conversion in Lithium Electrochemical Systems: Proc. IX Int. Conf.), Kolosnitsyn, V.S., Ed.,

Ufa: Reaktiv, 2006, 330 pp.

DOI: 10.1134/S1070427207100400

The proceedings of the International Conference on lithium power cells, held in Ufa on August 14–18, 2006, are published. The conference organizers included the Scientific Council for Electrochemistry (Section "General problems of chemical power cells") of the Russian Academy of Sciences, Academy of Sciences of Bashkortostan, Russian Foundation for Basic Research, and other institutions. The Proceedings volume reflects the results obtained in recent years in studies concerned with fundamental problems of energy conversion in lithium electrochemical systems. Particular attention is given to synthesis and properties of new materials for negative and positive electrodes of lithium power cells, mechanism of the processes occurring at the lithium electrode, thermodynamics of lithium intercalation into, and deintercalation from various electrode materials, and electrolyte properties.

The materials published in the collection of papers are grouped in six sections in accordance with the subjects covered. The first section (pp. 3–56, 20 papers) is devoted to the behavior, properties, and fabrication of the negative electrode in various lithium power cells. Problems associated with the behavior and cycling of metallic lithium in electrolytes based on aprotic organic solvents, behavior of the carbon electrode in charging of a lithium-ion battery, use of various brands of natural graphite and of modified oxide graphite as anode materials, and intercalation of lithium into various anodes are considered.

The second section (pp. 57–130, 27 papers) discusses a wide variety of issues associated with the behavior and choice of cathode materials for lithium power cells. Quite a number of papers consider synthesis of the $LiCoO_2$ compound and specific features of its use as a cathode material in lithium-ion batteries. Also discussed are cathode materials based on manganese compounds and more complex spinel formulations. One of the papers suggests that redox polymers with high content of sulfur should be used as an active cathode component for the lithium-sulfur battery. The possibility is discussed of employing natural pyrite FeS_2 and a thin-layer electrolytic FeS_2 composite as a cathode material for film-like lithium batteries.

The third section of the collection of works (pp. 131–221, 25 papers) presents new data on electrolyte systems. It should be noted that, despite the certain progress and extensive research in the field of polymeric electrolytes, solutions of lithium salts in aprotic media have been mostly used as liquid electrolytes in manufacture of lithium and lithium-ion batteries so far. On the whole, this circumstance is reflected in the subject field of the papers presented at the conference, which are mostly devoted to analysis and improvement of aprotic electrolytes. In particular, it is suggested to add polysulfides of various compositions to the electrolyte to improve the cycling capacity of batteries. The potentialities of polymeric gel-electrolytes in lithium and lithium-ion power cells are considered and the possibility of obtaining a solid polymeric electrolyte is discussed. An issue that remains topical is a search for various inorganic solid phases with high lithium-cationic conductivity.

The fourth section (pp. 222–255, 11 papers) contains evidence about the history of development and the modern state of manufacture of lithium-ion batteries. The lithium-ion technology can produce lithium-ion batteries with high specific energy and power, long service life, wide range of working temperatures, and high reliability. These advantages enable development of lithium-ion batteries for a wide range of purposes, including defense, space, and civilian applications. The positive electrode of industrially manufactured lithium-ion batteries is commonly fabricated

from lithium-intercalated cobalt oxide $LiCoO_2$, and the negative electrode, from various carbon materials, mostly graphite. The possibility of replacing graphite with thin-film hydrogenated silicon is considered. The choice of electrode materials and active paste formulations for a lithium-ion battery with increased capacity is discussed.

The fifth section of the collection of works (pp. 256–308, 11 papers) is devoted to lithium power cells. The problem of development of lithium–sulfur batteries with aprotic electrolytes, which has been attracting attention during many years, is discussed in detail. The theoretical specific energy of the Li–S system is 2600 W h kg^{-1}. This circumstance gives reason to believe that batteries with a specific energy as high as 500–700 W h kg^{-1} can be developed. The real specific energy of prototype lithium–sulfur batteries being developed by a number of companies is substantially lower, 250–350 W h kg^{-1}. Mechanisms of the possible corrosion processes in chemical power cells with a lithium anode are considered.

The small sixth section (pp. 309–318, 5 papers) discusses new devices and apparatus for studies of chemical power cells. These include an automated potentiostat-galvanostat, a stand and software for tests of chemical power cells in the prolonged-cycling and low-current mode, and a multifunctional automated stand for studies of electrode materials and power cell.

Analysis of the evidence presented in the collection of works suggests that lithium electrochemical systems are being most intensively studied in Russia at the following institutions: Istochnik Research Battery Institute (St. Petersburg); Siberian State Technological University (Krasnoyarsk); Frumkin Institute of Physical Chemistry and Electrochemistry (Moscow); Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences; Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences (Yekaterinburg); Favorskii Institute of Chemistry, Siberian Division, Russian Academy of Sciences (Irkutsk); Nikolaev Institute of Inorganic Chemistry, Siberian Division, Russian Academy of Sciences (Novosibirsk); and Chernyshevsky State University (Saratov).

BOOK REVIEWS

Vakarin, S.V., *Orientirovannyi rost vol'framovykh bronz pri elektrolize rasplavov* (Oriented Growth of Tungsten Bronzes in Electrolysis of Melts),

Yekaterinburg: Ural. Otd. Ross. Akad. Nauk, 2005, 109 pp.

DOI: 10.1134/S1070427207100412

At the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, pupils of Academician A.N.Baraboshkin (1925–1995) continue systematic studies initiated by him in the field of the electrocrystallization of metals and various complex compounds from molten electrolytes. The research in this area, distinguished by original problem formulation and novelty, has already yielded theoretically and practically important results. The monograph by S.V.Vakarin is concerned with the oriented growth of crystals of tungsten bronzes in electrocrystallization from molten electrolytes. The book comprises an introduction, four chapters, conclusion, and bibliographic list.

The brief introduction (pp. 3, 4) notes advantages of the electrolytic method for growth of tungsten bronze crystals over other techniques. The aim is to find conditions under which crystals with a certain shape and spatial orientation can be obtained. The first chapter (pp. 5–36) analyzes some general evidence available in the scientific literature. It discusses the mechanism of crystal growth in various media under various conditions, morphological stability of crystals, and theory of formation of a preferential orientation of crystals. A separate section of the chapter is devoted to oxide tungsten bronzes, their nature, their synthesis by electrolysis of melts, and growth of single crystals.

The second chapter (pp. 37–46) includes description of methods for study of the oriented growth of single crystals directly in the course of electrolysis. The third chapter (pp. 47–89) considers the relationship between the growth rates of single crystals of bronzes with tetragonal and hexagonal structure and the overvoltage. The experiments performed with Baraboshkin's participation by the author of the monograph were aimed to measure the growth rates of crystals in different directions, analyze their faceting and the morphology of the crystal faces, and determine the chemical composition of the crystals and their lattice constants. Melts of the system K_2OWO_4–Na_2WO_4–WO_3 (700°C) served as the electrolyte in a study of the growth of single crystals of an oxide bronze with a tetragonal structure; single crystals of the oxide bronze with a hexagonal structure were obtained in electrolysis of a melt of the system K_2WO_4–Li_2WO_4–WO_3 (700°C).

The experimental results are illustrated by a large number of photographs. The author makes a comparative characterization of the morphological features of metals and oxide bronzes.

The small fourth chapter (pp. 90–98) discusses certain aspects of crystal structure formation. The conclusion (pp. 99, 100) summarizes the main concepts considered in the monograph. It is, in particular, noted that conclusions concerning the crystal growth types, made for oxide tungsten bronzes, can be extended to other substances. The bibliographic list (pp. 101–107) contains references to 148 domestic and foreign publications, with a prominent place occupied by works of Baraboshkin and co-workers, including the author of the monograph. As already noted, tungsten bronzes can be regarded as a model object in high-temperature studies of the electrocrystallization process.

The monograph by Vakarin may be of interest for a wide audience of specialists studying the crystallization process. The Institute of High-Temperature Electrochemistry (Ural Division, Russian Academy of Sciences), which celebrates its 50th foundation anniversary in 2007, is the only Russia's specialized institution engaged in broadscope studies of promising systems and processes associated with electrochemistry of molten and solid electrolytes. The research conducted at this institute is distinguished by a high experimental and theoretical level. The monograph is well written and accurately published, and makes quite a favorable impression.

BOOK REVIEWS

Tarantseva, K.R. and Pakhomov, V.S., *Pittingovaya korroziya nerzhaveyushchikh stalei: Teoriya i praktika zashchity* (Pitting Corrosion of Stainless Steels: Theory and Practice of Corrosion Protection),

Penza: Penz. Gos. Tekhnol. Akad., 2006, 134 pp.

DOI: 10.1134/S1070427207100424

As is known, pitting corrosion is one of the most dangerous and widely occurring types of local corrosion-induced disintegration of passivatable metals and alloys in media containing activator ions. A major contribution to studies of the pitting corrosion was made by Ya.M. Kolotyrkin (1910–1995), academician of the Russian Academy of Sciences, and his coworkers. It has been established that both pure metals (iron, zinc, aluminum, magnesium, nickel, cobalt chromium, titanium) and various alloys, including those in the amorphous state, may suffer from pitting corrosion. The set of anions, both causing the corrosion process and acting as inhibitors, has been outlined.

The small monograph by K.R. Tarantseva and V.S. Pakhomov presents modern concepts concerning the mechanism of pitting formation in stainless steels and considers factors affecting the resistance of steels to this kind of corrosion. Methods used to study the pitting corrosion, prognosticate pitting, and protect metals from pitting corrosion are discussed. The book comprises an introduction, five chapters, and bibliographic list including 455 references to publications by domestic and foreign authors.

The brief introduction (pp. 3, 4) notes that a number of issues in the theory of pitting corrosion and protection from this kind of corrosion require an additional analysis and there remains an important problem of prognostication of this kind of corrosion. The first chapter (pp. 5–12) discusses the mechanism of pitting corrosion of stainless steels. It shown that the following is necessary for this kind of corrosion to occur: a metal should be in the passive state; the amount of activator ions should exceed the critical concentration; and an oxidizing agent or external polarization, which shift the corrosion potential, should be present. Reasons for local disintegration of the passive film are discussed in detail and it is noted that the adsorption-electrochemical theory provides the presently most substantiated explanation of the passivity phenomenon.

The second chapter (pp. 13–34) considers factors that affect the pitting corrosion of steels. To these belong the composition of stainless steels, solution composition, temperature and heat-transfer conditions, and motion of the medium. The authors systematized the fundamentally important results obtained in studies of the pitting corrosion, including those carried out in the last 10–15 years. It is noted, in particular, that carbon, sulfur, and phosphorus adversely affect the resistance of steels to pitting corrosion. The low content of carbon in ferrite steels and their single-phase structure predetermine their high pitting resistance.

The third chapter (pp. 35–64) is devoted to methods for studying, modeling, and controlling the pitting corrosion. The fourth chapter (pp. 65–81) discusses the possibility of prognostication of the pitting corrosion. The final, fifth chapter (82–107) contains evidence about the principal ways of protection from this kind of corrosion. Of special interest is that section of this chapter in which practical recommendations for choice of pitting-resistant steels are given. The authors composed an algorithm for obtaining the necessary information when choosing corrosion-resistant materials in the stage of article design.

The monograph by Tarantseva and Pakhomov is well written, presents an analysis of a vast material, and is accessible to an exceedingly wide audience of specialists engaged in studies of corrosion processes and to engineers and technical workers of design bureaus and research institutes. The book may be of use for students and postgraduate students specialized in the field of corrosion and metal protection.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Quantum Synthesis

All that exists is composed of comparatively not numerous "pure" individual substances and unimaginably enormous number of their extremely complex mixtures, substances of variable composition. When molecules, or individual substances, were discovered, chemistry naturally made them key objects of study and the XIX century became the century of its development. However, it was found in the XX century that most of substances are solid supramolecular substances that are not described by chemical laws, although these laws are based on the atomic-molecular theory whose reliability is beyond any doubt. Meanwhile, the physicochemical analysis was developed, which made it possible to determine the dependence of properties of a substance on its composition. And this was sufficient for the development of a technology for processing of solid substances into all kinds of materials. Because of this circumstance the chemical science accepted that, together with compounds of invariable composition, molecular compounds, there also exist individual solid compounds of variable composition, nonstoichiometric compounds. Despite that individual solid compounds were synthesized at the beginning of the second half of the XX century [1], it is still commonly believed that formation of stoichiometric solid compounds is prohibited by the nature.

One can readily imagine the huge loss inflicted on technologies by the necessity to "purify" starting substances to remove "impurities," or, in effect, to separate the solid solutions that surround us into components, i.e., chemical individuals. Also suffers the solid-state chemistry, which deprived itself of objects of study and degraded to an accessory of physics. The consequences are evident from the monograph [2], whose authors reported that "however, we are only beginning to understand the principles to be used in design and manufacture of nanostructures and nanodevices." And the reason is the lack of skill to synthesize "isolated nanostructures."

At the same time, studies of synthesis of solid chemical individuals, polyatomic compounds, demonstrated that their formation is exceedingly unlikely. To obtain these compounds, it is necessary to raise the probability of their formation to 100%; in other words, to collect and generalize the whole body of information about the nature of a compound and, primarily, to use it in the same way as genetic information is used in biosynthesis [3].

First of all, it was necessary to find out how an individual solid is built and what it is from the chemical standpoint. In the first half of the XX century, this problem was solved at the Lensovet Technological Institute in Leningrad. According to the "core theory" developed at this institute [4], the structure of a solid includes 0D, 1D, 2D, 3D, or coordination core composed of atoms bonded by covalent bonds. The surface of the core is constituted by functional groups. In contrast to the commonly accepted physical model, which only reflects the periodicity of the crystal structure, the core model reveals the atomic structure of a solid. A single glance at this model was sufficient for understanding that, by connecting all the peripheral atoms by functional groups, one can obtain a solid that is nothing other than a supramolecule of a stoichiometric solid compound, a polyatomic chemical individual.

Polyatomic individuals, including quantum bodies (nanostructures), have been synthesized as a result of the discovery of irreversible chemisorption, epitaxial method of atomically precise batching of reagents. Using this method, the surface of a solid with known area was treated with an excess of an adsorbate during a time required for 100% coverage of the substrate surface with a monolayer of the adsorbate. With one monolayer after another batched-out and bound together by chemical bonds, a number of simple, e.g., carbon-containing, substances have been synthesized by the above-mentioned molecular layering method,

and series of individual solids, by the chemical assembly technique. Apparently, these syntheses are controllable irreversible processes. At the same time, these are processes of batching-out of atomic portions (quanta) of a substance, i.e., quantum synthesis processes, and those of 3D writing with chemical symbols and the resulting materialization of information. Thus, it can be stated that, similarly to biosynthesis, synthesis of chemical individuals is based on production and materialization of information in quantum processes programmed to form solids in a stationary discrete nonequilibrium state, quanta of solid substances or solid bodies up to approximately 100 nm in size.

Similarly to biosynthesis, quantum synthesis occurs in an open system, with genetic information, energy, and reagents (and the related structural information) fed into the system; synthesis products and the information contained in these products extracted; and excess reagents, invaluable products, and degraded, low-temperature energy removed.

This process is initiated and controlled, similarly to biosynthesis, by the genetic information, which is "written" not in the DNA structure, but in the dynamic structure of flows of starting substances and, in part, in the structure of these substances themselves, but primarily in the program of synthesis, developed by its designers.

This synthesis is, similarly to biosynthesis, a process of transcription, translation, and production of information, although more primitive. Its additional characteristic feature is localization, isolation of the synthesis process from the ambient medium, which, however, does not preclude interaction with this medium. This suggested that, similarly to biosynthesis, quantum synthesis of polyatomic individuals is only possible in irreversible processes based on the same principles, including those of transcription and translation of the genetic information delivered by the corresponding mother structure (substrate, matrix).

Unfortunately, this remained unnoticed by nearly everyone. Meanwhile, as can be seen from what follows, all efforts of a large number of researchers struggling to solve the problem of synthesis of nanostructures, as well as the general problem of the nature of solid matter, have been in vain. However important the problems of modern chemistry may be, they fall far into the background now. In the light of the great discoveries of the XX century, there appeared an absurd, at first glance, concept of our world as a very rapidly expanding flow of waves, constituted by wave packets, which generates space and time in its motion. A wave packet is a quantum of mass–energy and action of certain value, which exchanges photons, quanta (quantity of action) of minimum value, with other packets. There is no way to know where a wave packet, i.e., an object, is situated at a given instant of time. However, the Schrödinger function ψ can be used to calculate the probability of its localization, and this can be found with 100% reliability by taking the square, ψ^2.

From this standpoint, atoms, molecules, and small bodies are nothing other than quantum particles, and chemistry is quantum chemistry obeying quantum probability laws.

Elements of quantum technology. Seeing no real reasons for accepting the impossibility of existence of solids of invariable composition, I started in mid-XX century, together with a group of co-workers, students, and postgraduate students, to study the problem of synthesis of polyatomic individuals, without realization of the opening-up prospects. It was found that the problem of synthesis of individuals consists in structuring of an appropriate substance in a certain stationary nonequilibrium discrete state, "quenching" of this substance in this state, and stabilization via modification. Thus, the individuals can be synthesized using any suitable irreversible process. This is demonstrated in the present paper for the example of flame quantum synthesis of benzene derivatives and nanodispersed activated carbon in combustion of methane.

In 1974, the Presidium of the Academy of Sciences of the USSR considered the report [5, 6] that solid substances of invariable composition, allegedly nonexistent according to modern concepts, were synthesized by molecular layering and chemical assembly. In that communication, we reported that this technique consists in multiple stages of alternating irreversible chemisorption of monolayers of the same or different compositions on a substrate prepared in an appropriate way and each stage is continued until 100% coverage of the substrate area. It was stated that the "chemical assembly method" can be used to obtain metastable modifications of solid substances. Their number is huge because it is due to the number of possible energy states constituting a whole band. Such a band lies between the formation energies E_{min} and E_{max} of a solid substance. To each discrete state of this energy spectrum corresponds a single chemical individual, a member of a homologous series of nanostructures, and to the continuum of degenerate states, the whole set of ordinary macroscopic solid bodies of the given composition. Thus, that communication

considered synthesis of chemical individuals for the first time as quantum synthesis, which can "synthesize materials, physical devices, and, in perspective, biological tissues and organs" [6].

Later, a number of syntheses of nanostructures and quantum devices were performed: e.g., chalcogenide superlattices, system of quantum wells. Also, diamond-like films, carbon nanostructures, and nanostructures of many other types were synthesized [6].

By the end of the XX century, it was found [7, 8] that, like biosynthesis, chemical assembly consists in replication, production, and materialization of information, its implementation in the structure of reaction products. Also, synthesis of individual chemical and biological products is only possible via batching of reagents on the atomic level. Thus, it was demonstrated that synthesis of chemical individuals is, in fact, quantum chemical synthesis. It was also found that chemical assembly is not the only possible method of quantum chemical synthesis. For example, the long-known, but used only by special branches of technology, chain chemical processes are true quantum processes, conversion of chemical energy, quantum after quantum, into heat and mechanical energy. And there is nothing that could prevent their reorganization on the basis of the principles underlying the chemical assembly technique into processes of quantum synthesis. Indeed, it is not so important that nanostructures are dwarfs among the known chemical structures. It is more important that they are, similarly to atoms, quanta of matter and obey laws of quantum theory and chemistry of highly organized substances [9]. Quantum processes play an important part not only in the microcosmos, they universally occur in nature in those cases when chemical and biological conversions of substance proceed. For example, they enable such oxidation processes as combustion and life. It is also essential that the corresponding individuals are formed in both cases. However, in the course of combustion, polyatomic individuals are converted into those with small number of atoms and their chemical energy degrades into heat, whereas in biosynthesis, by contrast, comparatively low-atomic individuals are converted into polyatomic and ultrapolyatomic ones and the chemical energy of the former is nearly entirely expended for creation of the structure of biosynthesis products. As shown in [10], chain reactions occur via relay transfer of electrons from starting substances to final products with a nearly 100% probability. The chemical energy is virtually not dissipated at all in these reactions. Synthesis proceeds at an exceedingly high rate, with release of the minimum amount of heat and by-products, being only slightly exceeded in efficiency by biosynthesis.

From combustion to quantum flame synthesis. Combustion was the first chemical process mastered by the humankind. Its heat and light enabled humans to survive and build first civilizations, and its working power, to approach the modern state of development. At present, the advances in knowledge open up prospects for use of the fire not only as the most accessible environmentally safe source of energy, but also as the most efficient generator of organic and inorganic products. And not only as a versatile chemical generator, but as a most potent source of information.

As a rule, ordinary chemical syntheses are comparatively slow probabilistic processes occurring near the equilibrium state. Their efficiency is low. To raise the rate of these processes, syntheses are performed at elevated temperatures. For example, technical-grade carbon, e.g., carbon black, is commonly synthesized at 1000–1300°C. The yield of the target product in this process commonly does not exceed 3–4%. Carbon black is obtained in a somewhat higher yield by combustion of a fuel, e.g. methane, in a narrow channel at a deficiency of oxygen. As carbon black is accumulated, it is discharged.

The flame freely burning in air, diffusion flame, is a self-organizing stationary process of oxidative degradation of a fuel to give the simplest inorganic compounds, H_2O and CO_2, as products. The combustion rate and, consequently, flame temperature are determined by the rates of oxygen supply and combustion product removal. At a deficiency of oxygen, as, e.g., in the above-mentioned synthesis of carbon black, an inseparable mixture of products of oxidative condensation of the fuel is formed in the flame, with the components of this mixture, such as individual polyatomic, including supramolecular, solid compounds condensed immediately after formation.

The flame combustion is known to be an instantaneously occurring multistage chain process of oxidation. Its products of a given composition, formed in a stage of this process, are instantaneously converted into products of another composition in the subsequent stage. In the case of an excess of oxygen, increasingly oxidized substances instantaneously appear from one stage to another. At the same time, at a deficiency of oxygen, the excess part of the fuel reacts with intermediates to give mixtures of highly condensed products, such as soot and carbon black.

It was shown in [11] how this exceedingly rapid process can be interrupted at one of stages so that

the product formed in this stage is preserved. Generalizing the data obtained in studies of chain processes, beginning with publications by N.N. Semenov and his school, Azatyan noted [12]: "branched-chain ignition, in contrast to the thermal ignition, is caused by avalanche multiplication of active intermediates, free atoms, radicals, and, occasionally, even excited species, in their fast reactions with starting reagents and with each other" and pointed to the efficiency of control over chain combustion by inhibitors. However, what is particularly important, he called attention to the fact that the chemical energy in branched-chain combustion is nearly totally accumulated as chemical energy of unpaired spins, rather than converted into heat and dissipated. This energy of free valences is "transferred by the relay mechanism to the newly formed atoms and radicals and is even expended for their multiplication." "Chain branching is a dominant factor" that determines the specific pattern of the given process.

It should, however, be noted that, from the standpoint of our theory of structural organization, the chain branching itself is controlled, as well as the entire combustion process, by genetic information introduced into it by the synthesis program. The oxidation processes occurring in living bodies, translating information and solar energy to molecules, feed the living world in the planet with these factors. At the same time, combustion processes devour that part of the living substance which cannot be eaten by living bodies themselves. Oxidation in cells is a complex process of electron transfer via chemical interaction of polyatomic complementary structures, programmed by the genetic (parental) information. Combustion is a process of instantaneous direct, "relay" transfer of electrons from one radical (free atom) to another. Both these processes, oxidation in a cell and combustion in a flame, are localized. However, combustion is a process of virtually instantaneous degradation of all reagents, with dissipation of most part of their chemical energy and synthesis of the simplest products at the expense of its remaining amount. At the same time, oxidation in cells is a process of successive conversions of nearly the whole oxidation energy into work of synthesis of highly organized products. Having analyzed the oxidation process from this standpoint, we decided to form a kind of a dynamic cell from the flame, in order to imitate biosynthesis by creating, based on such a modified combustion process, a new productive technology for synthesis of organic and inorganic products.

Combustion of gaseous substances is commonly initiated by a spark or a flame from any source. Free atoms and molecules flying from this auxiliary flame into the gas collide with gas molecules and enter into chain reactions, in which uncountable new radicals are vigorously formed, and the chain process encompasses the whole volume of the given gas and flame flares up. If the fuel and oxygen are replenished and delivered in such amounts that the heat expenditure is balanced by its inflow, with the combustion products continuously removed, and only CO_2 and H_2O are formed. However, the combustion process can also be directed to synthesis of an aliphatic or aromatic derivative, e.g., benzene, the intermediate product of the given process. According to the theory of structural organization, it is necessary to impart to the flame a certain shape and structure and to establish a synthesis mode in which products in a prescribed stationary nonequilibrium (e.g., discrete) state, i.e., nanostructures, can be obtained by instantaneously interrupting the process in an appropriate stage of the chain process.

Because chain processes occur at a great rate, an exceedingly large amount of products is formed in comparatively small flame volumes. And this makes unnecessary use of large-capacity reactors, pipes, and apparatus for gas-phase synthesis.

Construction of a compact flame. The spontaneous flame is a dynamic dissipative structure set by the genetic information inflowing from the outside. It can have a very peculiar shape, but this shape always provides the maximum dissipation of the combustion energy. Using the flame as a generator of certain intermediate combustion products, rather than a source of heat, we are, naturally, not interested in transformation of the chemical energy into heat and in dissipation of the latter. By contrast, our task is to use the maximum amount of the chemical energy released in the given process for formation of chemical bonds constituting the structure of the desired target product and to minimize the decomposition they experience when leaving the flame. For this purpose, we impart to the flame the form of a "dynamic cell," in which, as in cells of living bodies, degradation of reagent molecules precedes synthesis from their fragments of some programmed highly organized compounds.

As shown in the figure, the flame grows, in a literal sense, from flows of the oxidizing agent ($\downarrow\downarrow$) and fuel ($\uparrow\uparrow\uparrow$).

This flame was created by forming counterflows of reagents. Entering from two sides into the flame through the vapor–gas shell *3* heated to a temperature of about 350°C, counterflows of Cl_2 and CH_4 molecules are heated within the high-temperature zone *2* to

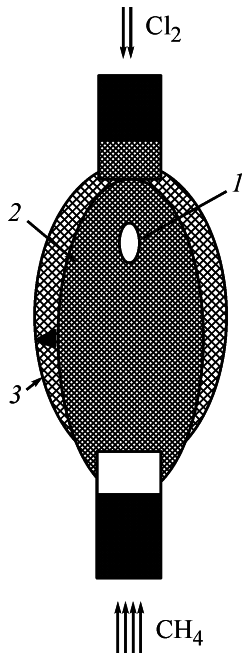
a temperature of dissociation, whose products, the corresponding atoms and radicals, enter into chain reactions. The heat of these reactions, released at the flame core, raises in this mode the combustion temperature in zone *1* to a certain value of about 10^3°C at which the given chemical system is in the equilibrium state. In the process, a plasma of clusters, corresponding "preproducts", is formed in zone *1*.

When flying into zone *2*, clusters react with each other and with products formed by dissociation of fuel and oxidant molecules, which move in the opposite direction, and lose most part of their excess energy on the periphery of this zone. Thus, when arriving into zone *3*, the clusters are in the stationary nonequilibrium discrete state and become target products upon "quenching." Because the flame lies at the axis of the reaction vessel whose walls are washed from the inside by water, the quenching of the reaction products occurs automatically: some are quenched when flying across shell *3* and others, upon collision with the surface of water flowing down over reactor walls.

Apparently, this method can be used to obtain from the flame of, e.g., methane any aliphatic or aromatic derivatives. Each of these derivatives is formed in its own synthesis mode, specifically, in the mode in which its clusters are in zone *1* in a prescribed "starting" state, i.e., in the next to last stage of the corresponding chain process. If we wish to obtain, e.g., hexachlorobenzene, we take chlorine as oxidizing agent and experimentally find the combustion mode in which this polychloride is formed. What is this mode? This is combustion, under other appropriate conditions, at a certain flow rate ratio of the fuel and chlorine, i.e., at the ratio for which the temperature in zone *1* of the flame reaches the above-mentioned maximum value. In this case, heat exchange occurs in shell *3* and "preliminary" structures of the target products, which are more complex and have higher energy content than those formed in the high-temperature mode, are formed in plasma *1*, and less complex, in zone *3* or outside this zone.

The principal specific feature of this synthesis consists in that it is quantum synthesis occurring via chain reactions localized in the dynamic cell, which is constituted by a flame formed in an appropriate way, and in that it is controlled by the natural or artificial genetic information coming from parents.

In a well-organized flame, the chemical energy of the fuel and oxidant is nearly completely converted into a higher-potential energy, as it also occurs in living cells, but without any enzymes, cofactors, or other intermediaries, and the amount of information



Schematic of the flame formed as a "dynamic cell." (*1*) Cluster plasma zone, (*2*) heat exchange and thermal dissociation zone, and (*3*) shell.

contained in them becomes many times larger and more valuable. In the process, both the energy and information are embodied in the structure of the synthesis products and thereby determine the level of the structural organization of the target products.

Being a branched-chain process, the quantum flame synthesis occurs via instantaneous transfer of electrons from donors to acceptors, i.e., by the quantum-chemical mechanism, without any significant dissipation of energy. Nearly the whole chemical energy of the reagents and the information they contain is converted into a high-potential energy of highly organized final products, rather than into heat or energy of bonding and structural information of CO_2, H_2O, and other simplest structures. The excess amount of the chemical energy is expended in the course of heat exchange for dissociation of molecules of the starting substances.

The fact that the flame is separated into temperature zones *1–3*, in which occurs effective heat exchange between products and reagents, the combustion products can lower, in the given synthesis mode, their energy state to a level prescribed by the program. In this flame, any desired target product can be, in principle, formed from the plasma of clusters-nuclei of intermediate products of oxidative condensation. Because virtually any, and not only organic, substance

can be burnt in a flow of an appropriate oxidizing agent, the flame quantum synthesis is a versatile synthesis technique, which is no less efficient than biosynthesis, but is considerably faster.

Pathway to life. The aforesaid leads to a working hypothesis according to which the pathway of evolution to the origination of life passed via flame, i.e., started from localization of a very tenacious, "energetically favorable" branched-chain process of oxidative condensation. However, because of its rapidity and excessive aggressiveness, this process did not become the process of life, but instead devoured its excessive and obsolete creatures and was subjected to evolutionary transformation. The genetic information programming the combustion process and incoming with heat fluxes from outer sources was substantially supplemented and, in the course of time, embodied in stationary structures of solid products. Chain reactions were replaced with a sequence of quantum reactions, along which the huge oxidation energy gradually, as over a staircase steps, descended to a moderate level and executed on its way a work of organism structuring. This gave rise to biosynthesis, the most perfect accomplishment of the evolution. In this way, the process of oxidative condensation formed a basis of two life phenomena: combustion, or complete destruction of a substance in a flame, and breathing and structuring of a substance in a living body. The flame quantum synthesis is a kind of symbiosis of these two phenomena, which is favorably distinguished from the known industrial processes by the very high utilization level of the energy of a fuel, exceedingly high rate, and full isolation from the ambient medium.

The atmosphere is not overheated and nothing is discharged into the environment except water. In this context, we can prognosticate with a quite substantiated confidence a transition from the existing technology to the quantum flame technology and, therefore, to the course of evolution, with all the resulting favorable consequences. As a prototype of the quantum flame technology can serve the process considered in what follows.

Synthesis of nanodispersed activated carbon. A study of the flame process of oxidative condensation of methane under the action of oxygen and chlorine [11, 13] demonstrated that a considerable part of methane burns in an oxygen flame in any combustion modes to give CO_2 and H_2O. At the same time, a chlorine process utilizes, in a certain range of conditions, the whole amount of methane carbon to give polyatomic aliphatic or aromatic chlorides, derivatives of benzene, naphthalene, anthracene, and hydrocarbons with numerous benzene rings. There also exists a combustion mode in which a predominantly nanodispersed carbon is formed. Having established these facts, we found the combustion parameters at which valuable products are formed and developed a synthesis program that makes it possible to pass from one combustion mode to another. This program contains a genetic information which directs the combustion process to disintegration of the structures of the starting products and formation of certain target products from these structural elements. Thus, the flame turns from a disintegrator of chemical products into a versatile generator of chemical compounds, and it is nearly as efficient as biosynthesis. The process of flame synthesis is localized (but not isolated from the medium) in the flame, where optimal conditions are created, as in living cells, for synthesis of individuals and premature contact with the medium of their not quite formed structures is precluded. Because chain processes occur at a very high rate, an exceedingly large amount of products is formed in a comparatively small volume of the flame. In many cases, e.g., in methane conversion, this makes unnecessary use of large-volume reactors, pipes, and apparatus for gas-phase synthesis.

At present, having accomplished under the author's supervision R&D work at Tekhnolog Special Design Office, State Unitary Enterprise in 2004–2005, the Scientific school of chemistry of highly organized substances, Aerotekhkosmos Private Company, and Nanomaterialy Limited Liability Company prepare to putting into operation a semicommercial model installation for flame synthesis of nanodispersed activated carbon and other individual products of conversion of natural gas in its combustion, e.g., hexachlorobenzene, which can be readily converted in a similar process into benzene. According to calculations, a finite set of large stationary and small mobile installations of this kind could provide the world with all that is necessary, at least until a demographic equilibrium is attained. Now, the task is, for the most part, to organize industrial implementation of this technology.

Theory. When trying to comprehend the knowledge accumulated by mid-XX century, I.R. Prigogine, one of the leading researchers of our time, outlined a scientific picture of the World, from which it can be seen that we live in a world of unique accidental events and irreversible processes, in a world in which all kinds of dissipative structures are accidentally formed under certain conditions far from equilibrium, among which "precursors" of life had once appeared. It is known from the thermodynamics of irreversible processes that the disorder governing a sys-

tem in equilibrium gives way to order relatively far from equilibrium: the system passes into a stationary discrete nonequilibrium state and takes on one of the wide variety of its possible structures. Which one? According to Prigogine [5], this occurs by chance. In what follows, we demonstrate that individual structures are formed under the action of an order factor, information, rather than by chance. For example, structures appear in the course of biosynthesis under the action of the genetic, parental information.

According to the quantum theory, there is neither a phenomenon, nor an event whose probability cannot be calculated. And if the square of the corresponding wave function, $\psi^2 = 1$, an event, e.g., formation of an individual solid compound, is not only possible, but undoubtedly occurs in nature.

At the end of the XX century, we found that, as expected, the probability of any event can, in principle, be raised in some way to 100% via expenditure of a certain amount of energy. What are the possible ways? As shown in [5, 6], these are synthesis procedures in the course of which a sufficiently large amount of information is produced. It was also suggested in these communications that the information and structure are inseparable: information is "inscribed" in the structure. Extending this working hypothesis, we take that substance consists of inseparable entities: mass, energy, and information. Bringing, in accordance with Prigogine's theory, a given system of interacting substances to the stationary state, we introduce into it, together with a flow of energy, a certain amount of information, specifically, that equal to the difference $(I - S_{min})$, where S_{min} is the minimum entropy corresponding to the stationary state of this system. The point is that, as is known, the sum $I + S = 1$.

If, however, this is so, then any chemical system, e.g., a system of interacting gases, say a reducing gas and an oxidizing gas, can be brought in an appropriate way to a stationary state in which individual products corresponding to the composition of the system are formed in it via a redox reaction. As shown above, the experiment confirms this working hypothesis.

CONCLUSION

The twentieth century was a century of great discoveries, which made clear that matter consists of exceedingly small quanta, "packets" of waves with a certain frequency, carrying mass and energy. Each of such clusters of mass–energy produces on all the other quanta an action proportional to a quantity on the order of 10^{-33} erg s, which changes to a certain extent their structure and causes an adequate counter effect (sets their program, i.e., programs their further existence). Our working hypothesis was the suggestion that substance is a mass intimately related not only to mass, but also to action and, consequently, to space and time. If it had no action, the quantity having dimension of energy multiplied by time, substance would be devoid of motion and its particles, quanta, could not interact by exchanging mass, energy, and action. Observing an action, we obtain information, a physical quantity of dimension nat J^{-1}. The quantum of action, Planck constant h, is a quantity on the order of 10^{-33}. The smallest quantum of matter, its elementary particles, has the same order of magnitude.

Constructing chemical processes as reproduction of natural processes, such as combustion (chain process) and biosynthesis (transcription, translation, and at the same time production and embodiment of information), we learned to create fast chemical synthesis processes.

ACKNOWLEDGMENTS

The author notes, with deep sincere gratitude, that he is fully obliged to his younger colleagues, many of whose names are mentioned in the book [14], and thanks foundation of Russian State for the financial support of the School.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Fundamental Aspects of Silicon Nitride Synthesis by Combustion of an Iron–Silicon Alloy in Nitrogen

L. N. Chukhlomina

Tomsk Scientific Center, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received January 12, 2007

Abstract—Synthesis of silicon nitride by reaction of a Fe–Si alloy with nitrogen gas in the mode of self-propagating high-temperature synthesis was studied.

DOI: 10.1134/S107042720711002X

Possessing a set of unique service properties (high mechanical strength, crack resistance, corrosion resistance in aggressive media, heat resistance), silicon nitride finds wide use in modern technology. The main industrial methods for synthesis of silicon nitride are furnace and plasmochemical syntheses. These methods are highly energy intensive and employ expensive equipment, which reflects on the production cost of silicon nitride powders obtained in these ways.

At present, silicon nitride is produced by the method of self-propagating high-temperature synthesis (SHS), which provides high output capacity at minimum energy expenditure. The SHS method for synthesis of silicon nitride is based on the reaction of silicon with nitrogen gas [1–3]. Alloys of a nitride-forming element with iron can serve as raw materials for synthesis of nitrides, instead of high-cost element powders [4, 5]. Iron and concomitant impurities contained in raw materials can be removed by acid enrichment.

In this study we examined the fundamental aspects of silicon nitride synthesis in combustion of a Fe–Si alloy in nitrogen gas and the acid enrichment of SHS products.

EXPERIMENTAL

We used as raw material the dust fraction of the Fe–Si alloy, formed in considerable amounts in crushing of industrial ferrosilicium. The material under study had the form of a polydispersed powder with a particle size less than 160 μm and silicon content of 82.0 wt %. According to the results of X-ray phase analysis (XPA), ferrosilicium is a two-phase material composed of silicon and high-temperature lebeauite ($FeSi_2$). The ferrosilicium powder was charged into cylindrical tube 50 mm in diameter, made of a metallic grid. Prior to synthesis, the starting ferrosilicium was dried in a vacuum oven at 150–200°C to remove moisture and volatile impurities. Samples were burnt in a constant-pressure installation in the atmosphere of gaseous nitrogen [GOST (State Standard) 9203–74] with a nitrogen content of 99.996 vol %. The nitrogen pressure was varied in the range 1–10 MPa. The samples were ignited using a powder-like igniting mixture, with a tungsten coil through which electric current was passed. After the combustion front passed, a sample was kept in the atmosphere of nitrogen to complete cooling; then, the pressure was relieved and the SHS product was removed from the installation for further studies. The XPA was performed on a DRON-2 diffractometer with Co radiation. The phase composition was evaluated using the standard calibration-curve method [6]. The calibration plot was constructed using artificial calibration mixtures with a known content of α- and β-Si_3N_4.

The content of nitrogen taken up in the course of combustion was preliminarily determined from the gain in mass, and more precisely, on a TN-114 (LECO) instrument by the standard procedure employing the hot-extraction method based on reductive fusion of samples being analyzed in the atmosphere of a chemically pure inert gas. The chemical composition of quenched combustion products was studied by X-ray fluorescence microanalysis (XRFMA) on a CAMEBAX-MICROBEAM instrument. The morphology of the starting and synthesized powders was examined with a JEM100CXII electron microscope with an ASID-4D scanning attachment (JEOL, Japan). The combustion temperature was measured with

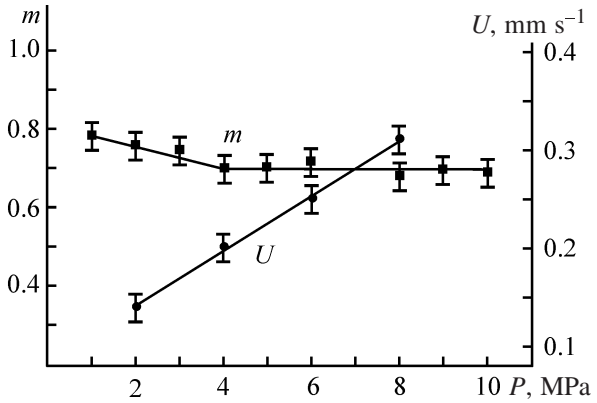

Fig. 1. Degree of nitriding, *m*, and the combustion velocity *U* of ferrosilicium vs. the nitrogen pressure *P*.

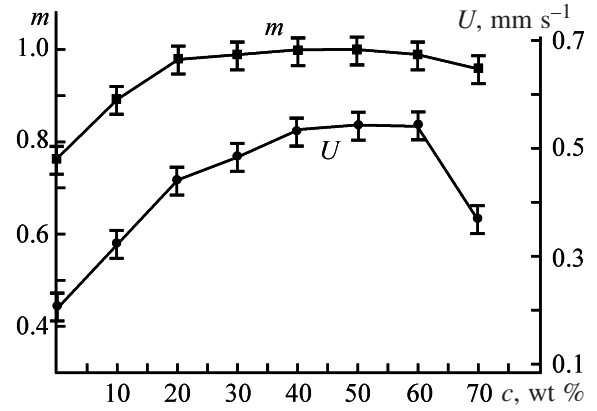

Fig. 2. Degree of nitriding, *m*, and the combustion velocity *U* of ferrosilicium vs. the dilution *c* of the starting alloy with ferrosilicium preliminarily nitrided at $P = 4$ MPa.

tungsten–rhenium thermocouples (VR5-VR20) 100 μm in diameter, introduced into samples to a depth of 10–15 mm.

The acid enrichment of the SHS products was performed in a special installation equipped with a thermostat and a stirrer. A weighed portion of a nitrided ferroalloy was placed into a reaction vessel with an acid and kept there for a certain time at a constant temperature under vigorous stirring. After a prescribed time elapsed, the content of iron and silicon that passed into solution was monitored. For this purpose, the undissolved precipitate was separated from the solution by filtration and the filtrate was subjected to chemical analysis. The residue that remained on the filter was washed, dried, and subjected to chemical analysis and XPA.

It was found experimentally that combustion of ferrosilicium in nitrogen occurs in the self-oscillating, rather than stationary mode. A burnt sample is composed of alternating layers with different colors. According to the results of chemical analysis, the light band is enriched in silicon nitride, and the dark band, in silicon and iron silicides. The presence of the components of the starting alloy (silicon and iron disilicide) in the combustion products points to the low degree of its nitriding. The degree of nitriding, *m*, was determined as the ratio of the amount of nitrogen taken up by a sample in the course of combustion to the amount of nitrogen necessary for complete conversion of silicon to silicon nitride. Characteristically, the degree of nitriding is smaller than unity in the entire pressure range studied (Fig. 1). The degree of nitriding equal to unity corresponds to formation in the course of combustion of a product composed of only silicon nitride and iron.

The pressure dependence of the combustion velocity of ferrosilicium is typical of silicon combustion in nitrogen [1]. As the pressure increases, the filtration rate in the reaction zone becomes higher, which accelerates the reaction at the interface between the condensed phase and the gas.

A study of the effect of synthesis parameters, such as the relative density of a sample, its diameter, particle size of the starting alloy, on the degree of nitriding demonstrated that the maximum degree of nitriding and stationary propagation mode of the combustion front cannot be achieved by varying these parameters.

An effective way to raise the degree of conversion is dilution of the starting stock with various additives.

To raise the degree of nitriding, the starting ferrosilicium was diluted with preliminarily nitrided ferrosilicium with the degree of nitriding equal to 0.76. The dependence in Fig. 2 shows that the degree of nitriding increases with the amount of an additive (the amount of nitrogen introduced with the additive was taken into account when calculating the degree of nitriding). Upon introduction of the additive in an amount of 40–60 wt %, the degree of nitriding becomes unity. Upon a 70% dilution, it somewhat decreases, and in the case of further dilution, the system becomes incombustible. The combustion velocity also increases from 0.2 to 0.5 mm s^{-1} upon introduction of nitrided ferrosilicium into the system.

A study of the microstructure of the starting alloy and quenched (by rapid discharge of nitrogen) samples demonstrated the following. In the case of combustion of undiluted ferrosilicium, a region is formed before the combustion front, characterized by the presence of molten particles, their coagulation, and formation of reaction cells whose size is several times the initial size of ferrosilicium particles (Fig. 3).

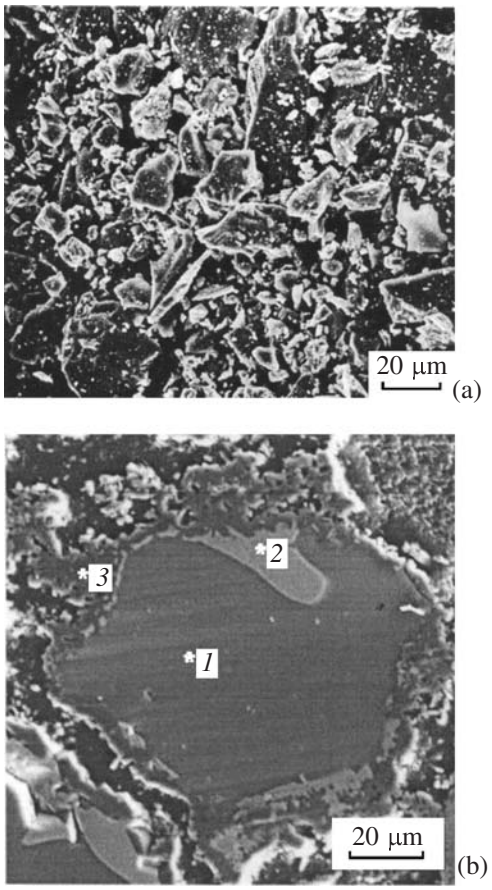

Fig. 3. Microscopic structure of (a) starting ferrosilicium and (b) quenched burnt sample. (*1*) Si, (*2*) $FeSi_2$, and (*3*) Si_3N_4.

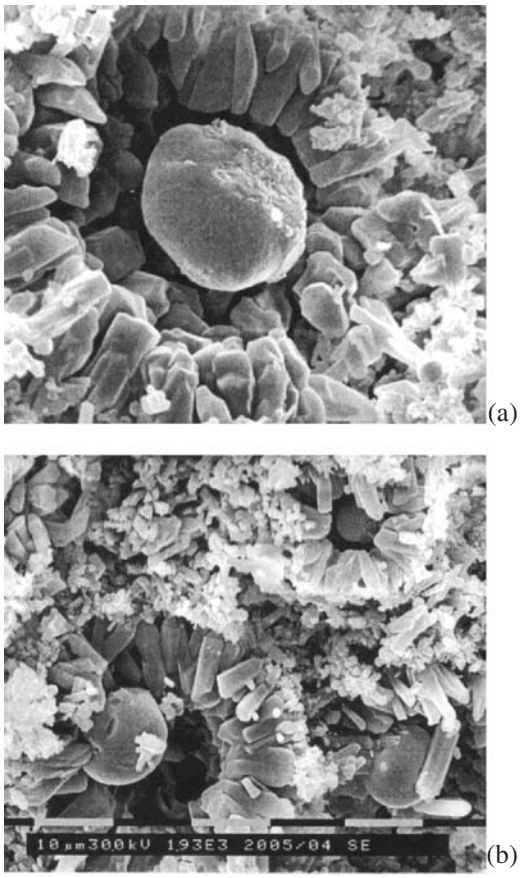

Fig. 4. Microscopic structure of quenched sample of nitrided ferrosilicium. Stock composition, %: ferrosilicium 40, nitrided ferrosilicium 60; P = 4 MPa. Magnification: (a) 1500 and (b) 1930.

Dilution with nitrided ferrosilicium precludes coagulation before the combustion front and favors preservation of the initial size of particles of the starting alloy, which leads to an increase in the combustion velocity and degree of conversion (Fig. 2, curve *2*).

Figure 4 shows microstructures of quenched samples burnt with addition of 60 wt % nitrided ferrosilicium to the starting alloy. The use of diluted samples made it possible to monitor the nitriding of separate ferrosilicium particles and formation of silicon nitride crystals. The microstructures shown are characterized by the presence of a spherical particle from which extend as rays columnar crystals, so that the structure resembles a "flower." An XRFMA of the spherical particle demonstrated that it is composed of silicon and iron, and the "petals of the flower" are crystals of silicon nitride. The "flowers" have different outer diameters, which is due to the polydispersity of the starting ferrosilicium. The results of electron-microscopic studies and XRFMA suggest the following growth mechanism of silicon nitride crystals.

In the course of SHS synthesis, when the combustion temperature exceeds the temperature at which the liquid phase appears (1206°C), particles of the starting ferrosilicium melt to give separate drops. The growth of silicon nitride crystals begins directly from the melt surface, at the place where particles of silicon nitride, "diluent," contact with the surface layer of the melt. In this case, silicon nitride particles serve as seed. As crystals grow and silicon evaporates from the melt, the diameter of a molten particle steadily decreases. In the growth process, silicon nitride crystals slowly extend from the melt until the entire amount of silicon in the melt is exhausted.

As additives were used ammonium halides and magnesium fluoride. Introduction of 1–10 wt % ammonium chloride and(or) fluoride results in that the maximum degree of nitriding is reached. Gasifiable additives intensify the synthesis of silicon nitride via formation of intermediates, such as silicon tetrachloride, tetrafluoride, and diimide. According to the data of [3], amorphous silicon nitride is formed in the

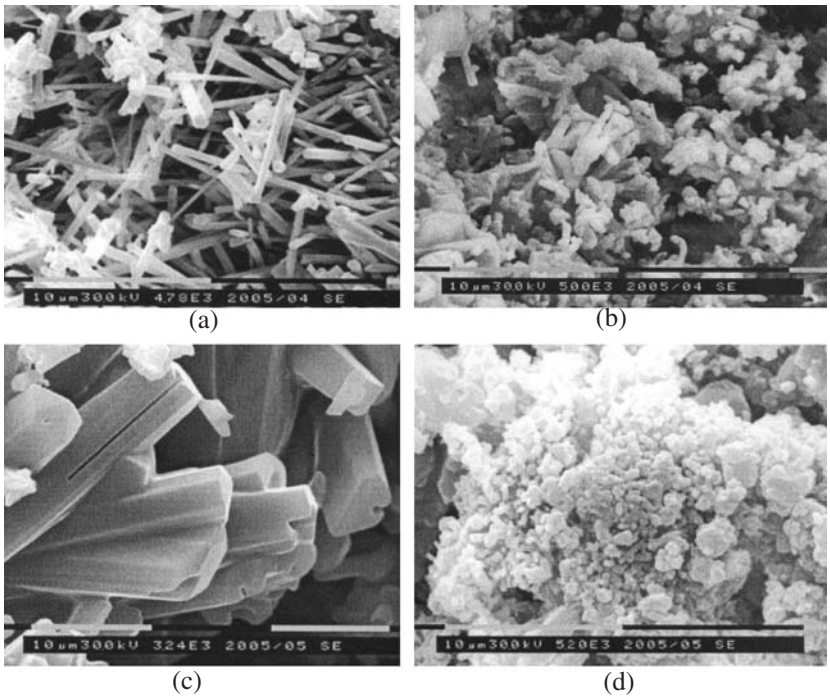

Fig. 5. Morphology of particles of silicon nitride formed in combustion of ferrosilicium in nitrogen in the presence of (a) magnesium fluoride and (b, d) ammonium chloride and (c) upon dilution with preliminarily nitrided ferrosilicium. Magnification: (a) 4780, (b) 5000, (c) 3240, and (d) 5200.

presence of ammonium salts even at 100°C, and it crystallizes at 1200°C to give α-Si_3N_4. Thus, the sample already contains synthesized silicon nitride before the onset of melting of the eutectic $FeSi_2$–Si (1206°C). The high-melting silicon nitride hinders coagulation of particles of the starting ferrosilicium, so that their initial size is preserved. Introduction of ammonium salts promotes reactions mostly in the gas phase, which, in the end, diminishes the filtration hindrance and raises the degree of nitriding.

Introduction of 1 wt % MgF_2 into the starting stock extends the ferrosilicium combustion range to 0.4 MPa (the minimum pressure at which combustion is observed without MgF_2 is 1 MPa). The activation of the nitriding process in this case is due to the high chemical activity of fluorides of alkaline-earth metals, which leads to removal of the oxide film from the surface of reacting particles.

Silicon nitride has two crystalline modifications: α- and β-Si_3N_4. Both modifications have hexagonal crystal lattices with unit cell parameters (nm) a = 0.776, c = 0.5662 and a = 0.7603, c = 0.2907, respectively [7].

According to the results of XPA, the products formed in the reaction of ferrosilicium with nitrogen are, as a rule, of predominantly the β-modification, with a minor amount (up to 20%) of α-Si_3N_4. Along with the main phases, the sample also contained silicon, iron, and iron silicides $FeSi_2$, FeSi, Fe_5Si_3, and Fe_3Si, whose presence indicates that the nitriding is incomplete.

Upon dilution of the starting alloy with preliminarily nitrided ferrosilicium, the combustion products always contained only the high-temperature β-modification. This occurred because the addition of the high-melting component eliminated the effect of coagulation hindrance to the reaction, the processes of nitrogen filtration to the reaction zone were improved, and, as a result, high synthesis temperatures were reached. The maximum temperature in the reaction zone was 2100°C, and the monotropic α → β transition occurs at substantially lower temperatures (1450–1500°C).

Magnesium fluoride intensifies nitriding of iron silicides, which ends in formation of silicon nitride and liberation of iron. The results of XPA of the combustion products indicate that β-Si_3N_4 is mostly formed (95%) in the presence of magnesium fluoride.

The introduction of ammonium chloride (1–10 wt %) into the starting ferrosilicium made it possible to obtain combustion products with various relative contents of α- and β-modifications of silicon

nitride. By varying the ratio between the initial nitrogen pressure and amount of ammonium chloride, one can obtain nitrided ferrosilicium both with 100% β-Si_3N_4 and with increased content of α-Si_3N_4 (up to 80 wt %).

Electron-microscopic studies of the morphology of silicon nitride particles demonstrated that their shape and size depend on the synthesis conditions. Upon dilution of the starting ferrosilicium with preliminarily nitrided ferrosilicium, coarse lamellar crystals of regular shape are formed (Fig. 5c). Upon introduction of ammonium chloride, the temperature and velocity of combustion become lower, which leads to a decrease in the particle size. In this case, silicon nitride particles are isometric shapeless formations (Figs. 5b, 5d). Introduction of magnesium fluorides into the starting ferrosilicium leads to the formation of whisker-like crystals of silicon nitride (Fig. 5a). Our study of the SHS process resulted in that a combustion product having the form of a formulation composed of silicon nitride and iron was obtained. It is known that iron well dissolves in mineral acids, whereas silicon nitride is, by contrast, stable in these acids. Therefore, we studied how iron passes into solutions of hydrochloric, sulfuric, and nitric acids. The dependences we obtained, which describe the accumulation of iron in acid solutions in the course of time, show that the rate at which iron passes into solution is virtually independent of the nature of an acid, with about 70 wt % of iron passing during the first 15 min. Further studies of the process of acid enrichment were carried out in hydrochloric acid solutions.

Using the data obtained, we found the optimal parameters of acid enrichment and produced pilot batches of silicon nitride powders. The residual content of iron in silicon nitride is 0.01–0.1 wt %, depending on the dispersity of the product formed in SHS synthesis.

CONCLUSIONS

(1) The combustion of the silicon–iron alloy in nitrogen occurs in the nonstationary mode. The combustion product is multiphase, heterogeneous, with low degree of nitriding (0.76). The maximum degree of nitriding (1.0) is achieved by introduction of nitrided ferrosilicium, ammonium halides, or magnesium fluoride into the starting ferrosilicium.

(2) Before the combustion front, the starting particles melt and coagulate to form reaction cells whose size is several times that of the starting particles. This makes smaller the reaction surface area, hinders filtration of nitrogen toward the reaction zone, and reflects on the kinetic characteristics of the process and on the degree of nitriding of synthesis products.

(3) Synthesis of silicon nitride with increased (up to 80 wt %) content of the low-temperature α-modification of silicon nitride is only possible in the presence of ammonium chloride. If other additives are used, β-Si_3N_4 predominates (>95 wt %) in the synthesis product.

(4) Acid enrichment of products formed in ferrosilicium combustion in nitrogen yielded silicon nitride with a residual iron content of less than 0.1 wt %.

Abstract—Complex formation of zinc(II) with citric acid in acidic medium was studied by pH-potentiometric titration at various metal to acid ratios. The speciation diagrams of the complexes in relation to pH were plotted, and the stability constants of the complexes were determined. Precursors of the synthesis of metal oxide materials were prepared at two reactant ratios. A scheme of the precursor thermal decomposition based on data of derivatography and IR spectroscopy was suggested, and the compositions of compounds formed during decomposition were determined.

DOI: 10.1134/S1070427207110031

Transition metal oxides and materials based on them attract researchers' interest for a long time due to a wide set of possibilities of their use as cathode masses for chemical power sources, catalysts and photocatalysts, highly selective sorbents, semiconductors, and magnetic materials [1–7]. Previously these materials were usually prepared by sintering of oxides or thermal decomposition of hydroxides or metal salts (nitrates, acetates, carbonates, oxalates). In the case of poorly soluble salts, their precipitation or coprecipitation preceded thermal decomposition.

A new step in the development of the synthesis of oxide materials is connected with the use of polybasic hydroxy carboxylic acids. Concentrated solutions containing metal salts and the above acids tend to form sols and then gels (or glasses). This procedure differs from traditional sol–gel methods in that the agent forming the polymeric matrix is polybasic hydroxy carboxylic acid and not hydrated silicon, titanium, zirconium, etc. species tending to form H-bond network, which significantly extends the range of objects that can be involved in the process. Precursors containing metal salts and excess acid are formed when the major fraction of water is removed from gels (glasses). Their further thermal treatment gives homogeneous oxide materials.

In [8], we suggested an optimized method for preparing oxide materials, which was tested with zinc, nickel, copper, manganese, and cerium salts. Many of the materials obtained showed high activity in catalytic oxidation of CO [9] and of volatile organic compounds: paraffin and aromatic hydrocarbons [10], alcohols, ethers, and esters [11].

Complex compounds are formed in the solution when the initial metal salts are mixed with the acid. Their composition and stability determine the composition of the precursor, pathway of its thermal decomposition, and parameters of the oxide material formed (crystal dimensions, specific surface area, porosity, etc.). These questions have not been adequately discussed in the literature [12].

In this study, with the Zn^{2+}–citric acid ($C_6H_8O_7$) system as example, we examined complex formation in solution at various pH values and metal to acid ratios, determined the compositions of complexes formed in solution, prepared the precursors, and analyzed pathways of their decomposition. Zinc was chosen because it does not undergo redox transformations which could complicate the precursor decomposition. In addition, zinc oxide has been actively studied recently for various applications [13, 14].

EXPERIMENTAL

All chemicals used were of chemically pure grade and were used without additional purification. The metal and acid concentrations were determined by complexometric and acid–base titration [15, 16].

The pH-potentiometric titration was performed on an I-160M device. The results were treated with CLINP 2.1 software for stability constant calculations [17]. The thermal decomposition of precursors was studied on a Q-1500D derivatograph. The composition of precursors and decomposition products was studied by IR spectroscopy on a Specord M-80 spectrophotometer within the 4000–400 cm^{-1} range using KBr pellets.

The metal ion to acid ratio in solutions was 1 : 1, 1 : 2, and 1 : 4, and the concentrations were varied within the 2.5×10^{-4}–1.0×10^{-3} M range. Low concentrations were taken to avoid introduction of additional chemicals for supporting the ionic strength, i.e., to ensure the conditions most similar to those of the actual synthesis.

The lower position of the titration curves of the mixtures with respect to those of citric acid suggests complex formation in the system (Fig. 1a). Similarity of the curves in the acid region shows that only acid carboxy groups participate in the process. This is confirmed by the curve inflection at addition of 3 equiv of alkali. In the alkaline region, the titration curves substantially diverge, probably due to formation of zinc(II) hydroxo complexes.

Based on these facts and data of [18–22], we can suggest that in the acid region at low concentrations 1 : 1 citrate complexes of zinc(II) are formed, and with increasing pH the degree of ligand deprotonation changes. The scheme of complex formation can be presented as follows:

$$M^{i+} + H_nL \rightarrow [MH_{n-m}L^{i-m}] + mH^+, \quad (1)$$

where $n = 4$ for citric acid.

The equilibrium constant of reaction (1) is

$$K = \frac{[MH_{n-m}L^{i-m}][H^+]^m}{[M^{i+}][H_nL]} = \frac{[MH_{n-m}L^{i-m}]}{[M^{i+}][H_{n-m}L^{m-}]}$$

$$= \frac{[H^+]^m[H_{n-m}L^{m-}]}{[M^{i+}][H_nL]} = \beta_i K_m, \quad (2)$$

where β_i is the stability (formation) constant of the protonated complex; K_m, total constant of acid ionization in step m, $K_m = k_1k_2k_3...k_m$, and k_i, ionization step constants.

The ionization constants of citric acid calculated from data obtained in this study ($pK_1 = 3.110 \pm 0.016$, $pK_2 = 4.450 \pm 0.015$, and $pK_3 = 5.810 \pm 0.017$) well coincide with the reference data [23–25].

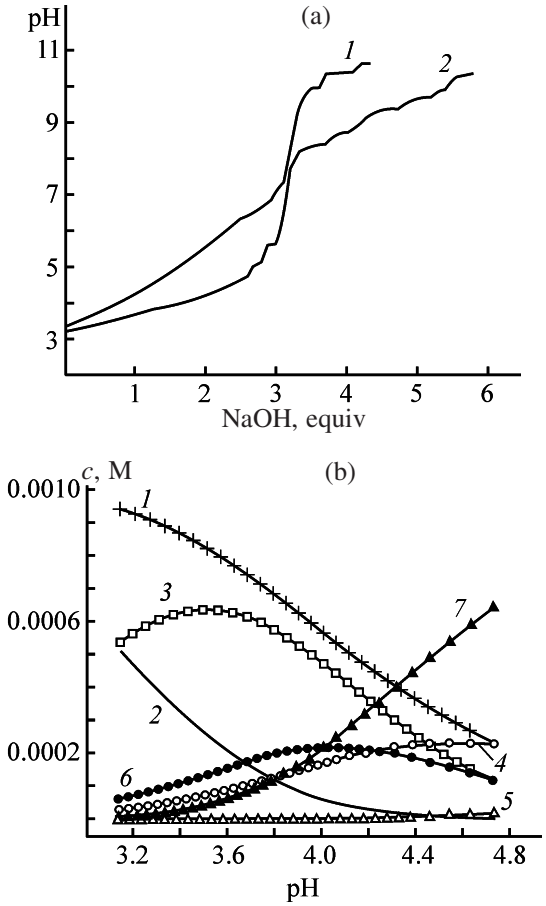

Fig. 1. (a) pH-potentiometric titration curves of (*1*) citric acid and (*2*) $Zn(NO_3)_2$–citric acid system; (b) speciation diagram of citric acid and metal citrate complexes in the system $Zn(NO_3)_2$–citric acid (H_4L)–NaOH at the molar ratio $Zn : H_4L$ 1 : 1. $c_a = 1 \times 10^{-3}$, $c_m = 1 \times 10^{-3}$ M; (*c*) concentration of components. (b) (*1*) Zn^{2+}, (*2*) H_4L, (*3*) H_3L^-, (*4*) H_2L^{2-}, (*5*) HL^{3-}, (*6*) ZnH_2L^0, and (*7*) $ZnHL^-$.

The calculated compositions of the complexes and their stability constants are listed in the table. From these data, the speciation diagrams of the acid and complexes in relation to pH at various component ratios were obtained. For example, in Fig. 1b, the diagram for system $Zn(NO_3)_2$–$C_6H_8O_7$ (H_4L)–NaOH is presented at equimolar ratio of the components.

At pH 3, zinc(II) exists in the solution almost entirely (95%) in the unbound state, irrespective of the citric acid concentration. With increasing pH, the acid dissociates (initially, at pH 3, half of the acid is dissociated), and two complexes with the metal ion to ligand ratio of 1 : 1 but with different degrees of the ligand protonation are formed.

At a metal ion to acid molar ratio of 1 : 1 and pH 4, 20% of zinc(II) ions are bound in ZnH_2L (**I**) and

Comparison of stability constants of zinc complexes with citric acid (H_4L), determined in this study, with published data

Molar ratio $Zn(NO_3)_2 : H_4L$	pK_i			
	this study		published data	
	MH_2L^0	MHL^-	MH_2L^0	MHL^-
1 : 1	3.35 ± 0.04	5.15 ± 0.015	2.42 [19], 2.98 [21]	4.36 [18], 4.83 [20], 4.98 [19, 21]
1 : 2	3.34 ± 0.08	4.6 ± 0.05		

20%, in the complex ZnHL (**II**). It follows from the speciation diagram that the second complex is more stable: at pH 4.5–4.75 65% of the initial metal exists in this form. The stability constants also show higher stability of complex **II** (see table).

The increase in the acid content of the solution does not change the composition of the complexes but increases their yield. The maximal amount of each complex at the acid excess is formed in more alkaline region than at the equimolar ratio. For example, at pH 4, 20% of metal ions (maximum) are bound in the complex at the metal ion to acid ratio of 1 : 1, whereas at the ratio of 1 : 2 their fraction is 36%. It should also be noted that, in spite of acid excess, 1 : 2 complexes in the systems studied are not formed, or their stability is low.

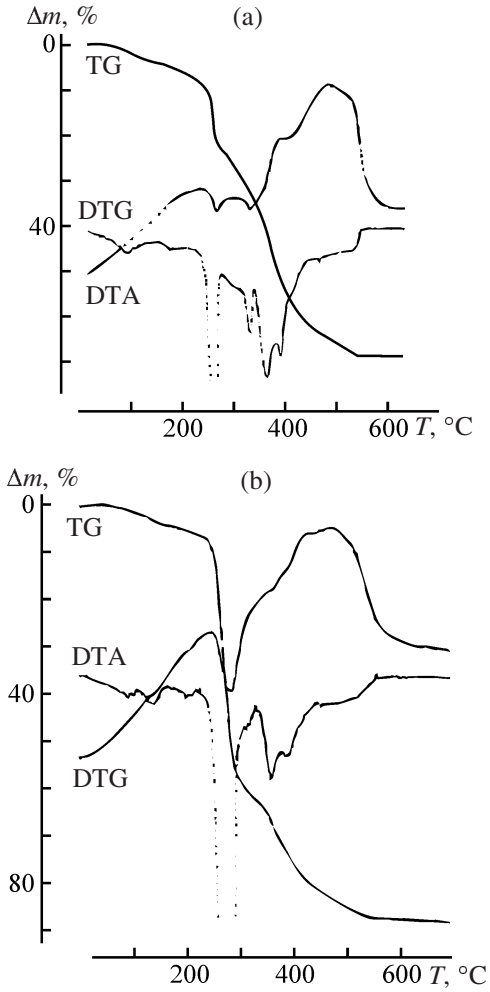

Fig. 2. DTA, DTG, and TG curves for the system $Zn(NO_3)_2$–citric acid. (Δm) Weight loss and (T) temperature. Molar ratio of components: (a) 1 : 1 and (b) 1 : 2; the same for Fig. 3.

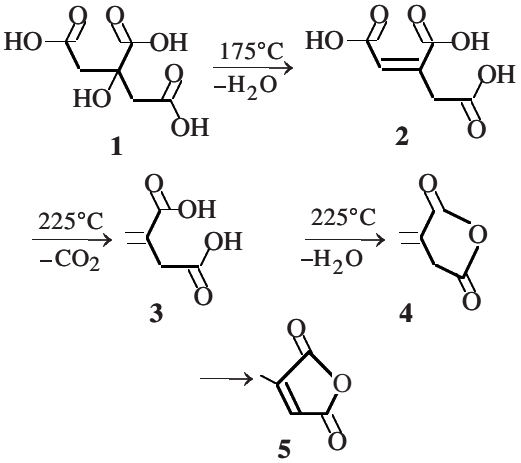
To understand the structure of the precursors, they were studied by IR spectroscopy and derivatography. The samples were synthesized as in [8]. The concentrations of zinc nitrate and citric acid solutions were from 0.25 to 1 M, and the metal ion to acid ratios were 1 : 1 and 1 : 2. After mixing the components, keeping to attain the equilibrium, and removing water, a polymeric resin was obtained. The measurement of light scattering showed the absence of the Tyndall cone, which indicates that the samples obtained are glasses rather than gels. Drying of these glasses in an oven at 110–120°C leads to substantial (by a factor of up to 15) increase in the volume with formation of a porous product. In so doing, nitrogen oxides and physically bound water were removed.

The derivatogram of the precursor with the metal ion to acid ratio of 1 : 1 is shown in Fig. 2a. After water removal (~100°C), a strong endothermic effect accompanied by 20% weight loss was observed. Then, three small endothermic effects at 330, 360, and 400°C (weight loss 32, 43, and 51%, respectively) were observed against a background of an exothermic effect at 300–520°C. The process completes at 550°C; the total weight loss of 68.4% corresponds to the formation of ZnO.

The derivatogram of the precursor with the metal ion to acid ratio of 1 : 2 is characterized by similar effects, but with larger weight losses (figures in parentheses, %): 260 (33), 360 (66), and 390 (73). The process is complete at 550°C (87%); the calculated weight loss corresponding to the oxide formation is 82%.

The thermal decomposition products were studied by IR spectroscopy. It is known [26] that the thermal decomposition of citric acid (**1**) follows the scheme



Initially, with removal of water molecule, aconitic acid (**2**) is formed. Then, CO_2 molecule is eliminated, and itaconic acid (**3**) is formed. On further heating, a mixture of two isomeric anhydrides [itaconic (**4**) and citraconic (**5**)] is evaporated. Presumably, a similar scheme should be realized in the thermal decomposition of metal citrates [26].

The most characteristic bands in the IR spectrum of citric acid are listed in [26]. The C–O bond of the α-hydroxy group gives a double band at 1075 cm^{-1}. Vibrations of the C=O bond in carboxy groups lie at 1700–1750 cm^{-1}. The O–H bonds of carboxy and α-hydoxy groups give a broad band at 3300–3100 cm^{-1} and a band at 3490 cm^{-1}. During gradual heating of citric acid, the following changes occur in the IR spectra. At 140°C, the band of the α-hydroxy group disappears as a result of dehydration of citric acid and formation of aconitic acid. At 160°C, the ν(C=O) bands characteristic for itaconic anhydride appear at 1780 and 1850 cm^{-1}. The appearance of a double band at 895, 1005 cm^{-1} is an additional evidence of the anhydride formation. At 180°C, citraconic anhydride is formed; in its IR spectrum, the above double band is shifted toward lower frequencies (to 700 and 980 cm^{-1}). Citraconic anhydride completely disappears at 210°C.

Deprotonation of citric acid and its coordination with *d*-metals are accompanied by the following changes in the IR spectrum [27, 28]. The strong ν(C=O) bands at 1700 cm^{-1} in the spectra of carboxylic acids are absent in the spectra of their salts. Instead of them, bands at 1300–1400 and 1550–1610 cm^{-1} assigned to symmetric and asymmetric stretching vibrations of ionized COO^- groups appear. If the compounds studied contain at least one undissociated –COOH group, the band at 1700 cm^{-1} is preserved.

If hydroxy groups do not participate in the complex formation, bands in the region of 3450 cm^{-1} (OH^- stretching vibrations) should be observed in the spectra. On detachment of protons from all hydroxy groups, these bands disappear. If undissociated hydroxy groups participate in the complex formation, low-frequency shift of ν(OH) should be observed [27].

The IR spectra of the 1 : 1 and 1 : 2 precursors and products of their thermal decomposition are shown in Fig. 3. As can be seen, the spectra of the initial compounds have certain differences. The spectra of the 1 : 1 precursor, recorded without heat treatment and after heating to temperatures of up to 120°C, contain the bands at 1410–1600 cm^{-1} assigned to coordinated carboxy groups, ν_s(C=O) and ν_{as}(C=O), but the band at 1700 cm^{-1} is also observed. This fact indicates that one carboxy group does not participate in the complex formation. The doublet at 1075 cm^{-1} corresponding to vibrations of α-hydroxy group of citric acid is preserved, i.e., this group does not participate in the complex formation either. Presumably, in this case the compound ZnH_2L is formed, in the which zinc ion is bound with two carboxy groups through oxygen atom.

The spectrum of the 1 : 2 precursor, recorded without heat treatment and after heating to temperatures of up to 120°C, in addition to the band of coordinated carboxy groups (1410–1600 cm^{-1}) and free carboxy group (1700 cm^{-1}), contained the double band of changed shape (1050–1110 cm^{-1}), which suggests participation of the α-hydroxy group in the complex formation. In this case, most likely, the zinc ion acts as a bridge between two acid molecules in the compound $Zn(H_3L)_2$.

For the further study of the decomposition of the 1 : 1 precursor, we compared the IR spectra of products of its thermal decomposition with the published data [26] and spectra of products of citric acid decomposition. Formation of zinc aconitate and itaconate was not observed, probably because of low stability of these compounds. The compound formed at 250°C, in accordance with the measured weight loss, is most likely zinc citraconate. Its further decomposition proceeds within the 300–350°C temperature range and is accompanied by evolution of CO_2 and H_2O (20 and 10% weight loss, respectively). The IR spectrum of the residue obtained contains a band at 450 cm^{-1} corresponding to vibrations of the Zn–O bond and weak

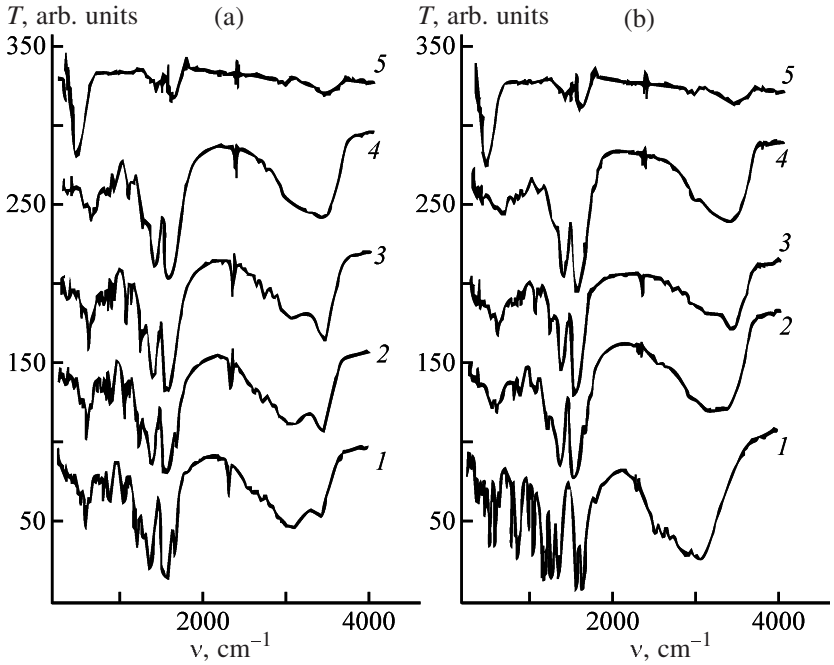


Fig. 3. IR spectra of precursors and products of their decomposition at various temperatures for the system $Zn(NO_3)_2$–citric acid. (*T*) Transmittance and (ν) wavenumber. Temperature of thermal decomposition, °C: (*1*) 120, (*2*) 220, (*3*) 250, (*4*) 300, and (*5*) 350. Zn : citric acid ratio: (a) 1 : 1 and (b) 1 : 2.

bands at 1360 and 1600 cm^{-1}, indicative of the presence of residual organic compounds. Their removal is complete after prolonged heat treatment of the residue at 700°C.

After heating to 250°C, the IR spectra of 1 : 1 and 1 : 2 precursors become identical (Fig. 3). Hence, the compound $Zn(H_3L)_2$ is unstable and decomposes to citric acid and ZnH_2L. This is confirmed by the presence in the spectrum of the 1 : 2 compound heat-treated at 220°C of two weak bands at 1770 and 1845 cm^{-1} (formation of cyclic anhydrides from free citric acid).

CONCLUSIONS

(1) In the $Zn(NO_3)_2$–citric acid (H_4L)–NaOH system, irrespective of the acid amount, complexes with the metal ion to ligand ratio of 1 : 1 with different degrees of ligand protonation, ZnH_2L (**I**) and ZnHL (**II**), are formed. At the metal ion to acid ratio of 1 : 1, the contents of **I** and **II** are equal. With increasing acid content of the solution, the yields of **I** and **II** increase; compound **II** is more stable than **I**.

(2) According to data of derivatography and IR spectroscopy, depending of the initial ratio of the components, the citrate precursors for preparing zinc oxide have different compositions and can contain the complexes ZnH_2L and $Zn(H_3L)_2$. On heating to 250°C, the second complex loses a citric acid molecule and transforms into the first complex. The subsequent decomposition pathways of both precursors are the same and are complete with the formation of zinc oxide at 350°C.

Received March 29, 2007

Abstract—New complex plasticizing additives for mortars based on Portland cement, increasing the mobility of the cement paste and improving some technological properties of the resulting materials, were prepared.

DOI: 10.1134/S1070427207110043

Wide use of various chemical modifying agents of various functional purpose is a typical feature of modern building technology. For example, corresponding plasticizers are widely used to provide the required properties of concretes and building mortars for the monolithic, composite, and composite-monolithic building constructions. These additives control the rheological properties of the cement paste, improve its mobility and placeability, and provide retention of its consistence, which, in turn, decreases the water consumption of mortars and enhances the strength parameters of the resulting objects [1]. Plasticizing additives optimize the setting time of the cement paste, providing transportation of the quality cement paste to the destination point and shorter time in which the formwork of concrete structures can be stripped [2].

Both domestic plasticizers of naphthalenesulfonic type (S-3, Russia), which have certain disadvantages, and new imported plasticizers (as a rule, polycarboxysilicate superplasticizers, such as Stachement-2000, Sika Visco Crete, Socolan [3]) are widely used in the monolithic building. Such additives decrease the water content by 35–40% and strongly increase the concrete strength [4]. Therefore, search for new types of domestic plasticizers and their adaptation to the cements produced in Belarus are urgent problems.

This study concerns preparation of new complex plasticizers, their addition to mortars based on the Portland cement, and properties of materials and mortars based on them.

EXPERIMENTAL

The complex plasticizers were prepared by mixing of an unsaturated fatty acid or its sodium salt with a modified tertiary amine in a wide range of the weight ratios. The process was carried out in a high-speed stirrer or ultrasonic dispersant (UZDN-1U, 15 kHz) providing high dispersity, uniformity, and stability of the resulting emulsions.

The complex additives (CAs) contain a hydrophilic microfoaming water-soluble component, namely, modified tertiary amine (MTA) and other components whose hydrophilic–lipophilic balance was varied in a wide range (from 1 to 18): unsaturated fatty acid (CA-1), a salt of fatty acid (CA-2), and the reaction product of the acid and alkanolamine (CA-3). We tested various procedures for preparing complex additives: addition of hydrophobic component (unsaturated fatty acid) into an organic solvent with subsequent mixing with a water-soluble component, mixing of acid with modified tertiary amine in the presence of emulsifier (CA-1), and mixing of the reaction product of the acid and alkanolamine with MTA (CA-3). The above procedures provide after mixing the formation of CAs exhibiting superadditive plasticizing effect, because, as was found, none of the individual components used in these systems provides effective thinning effect even at its high content in the mortar.

The complex plasticizers were added into the mortars in amounts from 0.5 to 0.8 wt %. The experiments were carried out using cement–sand blends based on domestic additive-free cement [M500 DO brand, GOST (State Standard) 10178–85, Belarus Cement Plant, Kostyukovichi, Belarus]. This cement is characterized by elevated content of aluminate component with high specific surface area. Before preparation of the cement–sand blends (cement : sand = 1 : 1.5), the sand was dried to constant weight and sieved; 0.16–2.00-mm fractions were used. The additives were introduced either directly at tempering of

the cement–sand mixture or into the hydrated mixture in certain time after mixing of the cement with water.

The mobility of the freshly prepared cement paste and changes in the mobility with time measured in 30-min intervals (time parameter of the mobility retention) were determined from the immersion of a minicone (100 mm in diameter, 60 mm high, GOST 10181.1).

From the mortar we prepared cubic samples ($2 \times 2 \times 2$ cm), which were hardened under the standard conditions (20–22°C, 80–90% humidity) and subjected to strength tests in accordance with GOST 10180.

Addition of the given plasticizers decreases the water consumption of the system and simultaneously increases the hydrophobicity of the pore walls, thus decreasing their water absorption capacity. Using the samples stored under the standard humidity conditions for 28 days, we determined their water absorption capacity and frost resistance grade in accordance with GOST 12730.3 and GOSTs 10060.1 and 10060.2, respectively.

The plasticizers prepared were identified by IR spectroscopy. The IR spectra of the initial components (unsaturated fatty acid, product of its reaction with alkanolamine) and of their mixtures with modified tertiary amine were recorded using silicon supports on a UR-20 spectrophotometer in the 650–4000 cm^{-1} range.

The crystalline products of hardening of the Portland cement mortars were identified by X-ray diffraction analysis on a DRF-2.0 diffractometer (CuK_α radiation).

The value and sign of the electrokinetic potential (ζ potential) of the electrical double layer on the surface of the cement articles were determined by electrophoresis on a Dzeta-90 apparatus (measurement range 5–80 mV, error 5%, resolution in the light background 3–50 μm, sample volume 5–50 ml).

The interaction of the hydrophobic and hydrophilic components of the complex additives was monitored by the IR spectra of fatty acid, product of its reaction with alkanolamine, and mixtures with modified tertiary amine. Unsaturated fatty acid was characterized by the stretching vibrations of the carbonyl group at 1711 cm^{-1}. New peak at 1550 cm^{-1} appears in the spectra of its mixtures with MTA (Fig. 1a). Simultaneously the intensity of the stretching vibrations of the carbonyl group decreases, which suggests interaction of the initial components to form a new compound with an ionic bond. The vibrations typical for modified tertiary amine at 967 cm^{-1} are observed in both individual compound and its mixture with acid. Their interaction is initiated by water and proceeds more actively in aqueous MTA solutions.

acid and MTA, the intensity of the carbonyl group at 1711 cm^{-1} decreases to a still greater extent than in the above-described system, simultaneously the intensity of the peak at 1560 cm^{-1} strongly increases, suggesting formation of the reaction product of the fatty acid and alkanolamine; tertiary amine interacts with this product.

The use of single-component additives for improving placeability of cement paste is hindered by the fact that most of them exhibit plasticizing power only at definite conditions of the concrete preparation, i.e., fixed conditions of mixing and preset content of cement in the mortar. As shown in [5], any attempt to attain strong plasticizing effect by mixing of organic surfactants of two types is not very promising. However, as shown in [1], the use in a complex additive of both hydrophilic and hydrophobic components differing in the surface tension provides intense air-entraining effect, which positively affects plasticizing of the cement paste. Therefore, the mobility and time parameter of the mobility retention of the building solutions are the functions not only of the plasticizer content but also of the time and intensity of mixing of the mortars.

The curves of the mobility loss by the mortars containing one of the additives prepared (CA-1) are shown in Fig. 2; the mortars were mixed on a mechanical stirrer at a rate of 60 rpm for 5 and 15 min (Fig. 2, curves *1, 2*) and 90 rpm for 5 min (Fig. 2, curve *3*). At relatively slow mixing of the building mortars (Fig. 2, curve *1*), the mobility of the mixtures is lower compared to mixing at higher rates (Fig. 2, curve *3*), which may be due to elevated air entrainment of the cement paste. The data on the density of the resulting materials measured by hydrostatic weighing confirms significant effect of air entrainment in the later case. With increasing mixing time to 15 min (Fig. 2, curve *2*), the mobility of the mixtures increases as compared to the above modes; simultaneously the air entrainment increases, the concrete density decreases, and the time parameter of the mobility retention also increases.

As shown in [6], floccules (coarse aggregates containing water) are formed in cement after addition of water. The effect of common plasticizers (deflocculating agents) is due to sorption of their molecules on the surface of cement particles and newly formed aggregates. These additives, being adsorbed, should provide formation of similar electrical charge on the particle surface and thus stabilize dispersions owing to the repulsion forces (electrostatic factor). Similar deflocculating effect can be caused by air inclusions which mechanically separate the cement particles and thus hinder their mutual approach to the distance of electrostatic attraction (structural-mechanical factor). To determine what factor provides the decisive effect on the plasticization of the mortars, we measured the electrokinetic potentials of the electrical double layer at the cement particle surface (ζ potential) in the absence of hydrophobic plasticizing additives and in their presence.

In the absence of plasticizers, the ζ potential of the particles of given concrete is negative (–9 mV) and after treatment of the cement surface with CA-1 the absolute value of the ζ potential increases (–11.3 mV). After treatment of the cement with CA-2, the ζ potential decreases to –7.7 mV. With increasing content of hydrophobic component in the complex additive CA-2, the negative value of the ζ potential decreases, and the electrical double layer undergoes recharging to +2.8 mV. Despite the above differences in the ζ potential, the plasticizing effects of these additives is similar, i.e., the effect of the electrokinetic potential on the mobility of the cement systems is not decisive. Hence, air inclusions presumably exert a stronger effect on the mobility of the mortars upon addition of the plasticizers. Moreover, unsaturated fatty acid present in the additive smoothes microroughness between the particles, decreases the internal friction, and forms a hydrophobic lubricating film on the cement particles plasticizing the cement paste.

The experiments with plasticizing additives introduced into preliminarily hydrated cements (postponed addition) were also performed. It was found that addition of chemical modifying agents in the preinduction period of the concrete hardening improves strength properties of the hardened materials; however, in this case the plasticizing effect decreases. These additives

Composition of the complex additives and properties of the resulting materials

Additive	Content, %		Decrease in water consumption, %	Time parameter of mobility retention	Compression strength after storage for 28 days, MPa	Water absorption, wt %	Frost resistance grade
	MTA in additive	additive in mortar					
CA-1	15	0.5	20	2.5	55	3.2	F 400

Reference	–	–	–	1.0	50	5.5	F 300

also cause intensive thinning of the mortars with increasing mixing time.

We assumed that addition of the given hydrophobic-plasticizing agents into the mortars is accompanied by sorption of the oriented asymmetrically polar molecules on the hydrophilic surface of the cement particles, which is accompanied by a slight change in the ζ potential. The polar groups of diphilic molecules are bound with the cement particle surface, whereas the hydrophobic hydrocarbon radicals are oriented outwards. These radicals exhibit water-repellent properties, and polar sections of the adsorbed molecules can form water-insoluble salts of fatty acid with calcium and, thus, the hydrophobic section of the molecule is fixed of the solid surface, providing micromudding effect.

In accordance with Khigerovich's theory [7], sorption occurs not on the whole cement surface but only on its active centers, blocking them. Probably, plasticizer components form not continuous but cellular films on the cement surface, so that the cement can participate in hydration upon addition of water. Our complex plasticizing mixture also affects the morphology of the crystallization nuclei and growing crystals. Sorption hinders the crystal growth, and the structure of the concrete monolith becomes more disperse and poorly crystalline, which is confirmed by the data of XRD analysis: the content of calcium hydroxide decreases simultaneously with decreasing degree of crystallinity of the newly formed compounds, i.e., additives cause adsorption modification of the products of cement hydration.

The above results are confirmed by the kinetic data on the increase in the strength of the resulting materials (Fig. 3). Owing to the formation of adsorption layers on the cement surface, the mortars are characterized by slow strength increase as compared to those containing other polycarboxylate plasticizers (Fig. 3, curve *1*). However, owing to the growth of new formations and adsorption binding of the hydrophobic-plasticizing additives by their surfaces, the adsorption layers are broken, which causes an increase in the strength parameters of the resulting materials in the final stage of concrete hardening (28 days) (Fig. 3, curves *2, 3*).

With increasing content of the complex additive in the mortar over 0.8%, the mobility of the cement paste strongly increases and the time parameter of the mobility retention increases by a factor of 3.0–3.5. This is due to extremely small penetration of water through the layers of hydrophobic-plasticizing additive and causes noticeable deceleration of the cement hydration in the induction and accelerated periods of hardening. At a high content of the additive, the effect of air entrainment increases, which decreases the strength properties of the hardened materials, especially in earlier stages of hardening. As a rule, the strength of the materials even in the final stages of hardening is significantly lower than the strength of

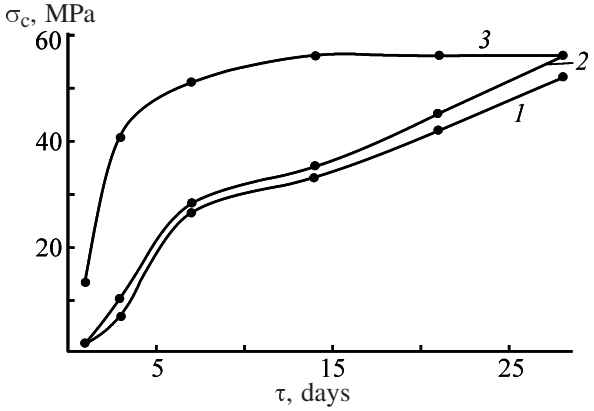

Fig. 3. Compression strength σ_c of hardened materials as a function of the hardening time τ. CA-3, %: (*1*) 0.8 and (*2*) 0.5; (*3*) 0.3% polycarboxylate plasticizer.

the material without additives, which hinders preparation of highly mobile mixtures and materials with satisfactory strength properties. The properties of materials prepared using hydrophobic-plasticizing additives CA-1, CA-2, and CA-3 are given in the table.

As seen from the experimental results, complex plasticizing additives improve some functional characteristics of the resulting materials, namely, decrease the water consumption of the cement paste, increase the time parameter of the mobility retention, decrease the water absorption, and improve the frost resistance of the hardened materials.

CONCLUSIONS

(1) New complex plasticizers containing unsaturated fatty acid and its salts or esters with modified tertiary amine increase the mobility and time parameter of the mobility retention of the cement mortars.

(2) New complex plasticizers containing components that differ in the hydrophilic–lipophilic balance and surface tension, when added to cement mortars, provide air entrainment, which positively affects the plasticization of the cement paste.

(3) Plasticizers added to Portland cements decrease the water consumption of the system, increase the hydrophobic properties of the pore walls, decrease the water sorption of the materials, and enhance their frost resistance.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Influence of Fluoroelement Acids on Extraction of Group IV–VI Element Fluorides

V. G. Maiorov, A. I. Nikolaev, V. K. Kopkov, and O. P. Adkina

Abstract—Effect of titanium(IV) and silicon(IV) on extraction of Ti(IV), Nb(IV), Ta(V), and W(VI) with octanol and tributyl phosphate from fluoride solutions was studied.

DOI: 10.1134/S1070427207110055

The diversity of stable compounds of various elements recovered from fluoride solutions suggests the diversity of complexes formed in these media [1]. However, only some of them are well extracted as fluoride complexes. This is attributed to the fact that in fluoride systems metal ions are characterized by maximal coordination numbers and form fluoride complexes with a high negative charge. For example, Fe(III) forms the complex $FeCl_4^-$ in chloride solutions and FeF_6^{3-} in fluoride solutions. It is known that, the higher the charge of an ion, the worse it is extracted [2, 3].

In industry, fluoride systems are used most widely for extraction, separation, and purification of Ta(V) and Nb(V) [4, 5]. Usually, tantalite–columbite concentrates are used as the initial raw material. However, because of limited resources of rich niobium–tantalum raw material, growing attention is focused on recovery of tantalum and niobium from solutions in which the content of impurities substantially (by an order of magnitude) exceeds the content of the target metals. Such solutions are obtained by hydrometallurgical processing of unconventional mineral raw materials and artificial rare-metal concentrates. For example, Ti(IV), Si(IV), and Fe(III) in titanoniobates, Si(IV) and Zr(IV) in eudialyte, or Sn(IV) in tin dross are the major macroimpurities.

The efficiency of the extraction treatment of niobium–tantalum solutions with a high content of impurities is largely determined by the chemical state of metal ions in the fluoride solutions. The Ta(V) and Nb(V) ions are extracted from fluoride solutions as complex fluorometallic acids $HTa(Nb)F_6$. Published data [2–5] show that many extrinsic elements, similarly to Ta(V) and Nb(V), can form fluoroelement acids of types H_xMF_y, $H_xMO_zF_y$, etc. As a rule, these compounds are strong acids and readily dissociate, which increases the hydrogen ion concentration (i.e., solution acidity) and hence increases the Ta(V) and Nb(V) extraction. Using ^{19}F NMR, we found that Ti(IV) forms complex acids $HTiF_5 \cdot H_2O$ and H_2TiF_6 in 2 : 1 ratio. The compound H_2SiF_6 is stable in aqueous solution and behaves as a strong dibasic acid (stronger than sulfuric acid) [6]. The series of the stability of Group IV–VI element fluoride complexes is presented in [7]: $[ZrF_6]^{2-} \geq [MoO_2F_4]^{2-} \geq [HfF_6]^{2-} \geq [TiF_6]^{2-} > [VOF_4]^{2-} > [GeF_6]^{2-} > [SiF_6]^{2-} > [MoO_2F_3]^-$.

All the above facts provide a basis for the development of an extraction technology with the recovery of Ta(V) and Nb(V) from solutions containing only HF, without addition of other mineral acids (usually H_2SO_4 and less commonly HCl). The solution of this problem facilitates utilization of spent solutions with regeneration of HF.

Here we report preliminary data on the influence of fluorotitanic and fluorosilicic acids and (for comparison) H_2SO_4 on the Mo(VI) and W(VI) extraction. We also present some results from our previous papers [8–10] concerning the effect of the above acids on Ti(IV), Nb(V) and Ta(V) recovery.

Tributyl phosphate (TBP) and 1-octanol (OCL) were used as extractants. The chemicals were of analytically pure or chemically pure grade, and TBP and OCL were of pure grade. Extraction was performed at volume ratios $V_o : V_w$ equal to 1 : 1 for TBP and 2 : 1 for less basic OCL. To determine the

Mo(VI) or W(VI) concentrations in extracts, they were back-extracted with 4 M HF at $V_o : V_w = 1 : 2$, with subsequent colorimetric determination of Mo(VI) and W(VI) in the backwash. The extraction time was 30 min. The initial aqueous solutions for extraction were prepared from concentrated fluoride solutions containing (M): (1) 5.76 Mo(VI), 19.6 F^-; (2) 2.38 W(VI), 21.6 F^-; (3) 7.02 Ti(IV), 35.6 F^-; and (4) 4.75 Si(IV), 28.5 F^-. The other features of handling aggressive fluoride solutions and of analytical monitoring are described in [8].

The data on the influence of Ti(IV), Si(IV), and H_2SO_4 on the distribution of metal ions studied are listed in the table; HF_{fr} is the calculated HF content over the amount required for formation of the complexes H_2TiOF_4, H_2SiF_6, $HMoO_2F_3$, and $H_2WO_2F_4$ (in accordance with data of [3, 5, 7, 11], these complexes are dominating in the systems studied). Introduction of fluorotitanic and fluorosilicic acids sharply increases the Mo(VI) and W(VI) extraction. With respect to the influence of the acids considered on the Mo(VI) recovery, these acids can be ranked as follows: $H_2SiF_6 > H_2SO_4 > H_2TiOF_4 >> HF$. For the recovery of W(VI), the order is as follows: $H_2SiF_6 > H_2TiOF_4 > H_2SO_4 >> HF$. Under the conditions studied, Mo(VI) is extracted substantially better than W(VI). Probably, this is caused by the fact that Mo(VI) is predominantly recovered in the form of monobasic acid $HMoO_2F_3$, and W(VI), as worse extracted dibasic acid $H_2WO_2F_4$.

For the system with Ti(IV), the replacement of H_2SO_4 by H_2SiF_6 also substantially increases the Ti(IV) recovery. In extraction from the 0.5 M HF + 4 M Si(IV) solution, with $V_o : V_w = 2 : 1$ for TBP and 4 : 1 for OCL, the Ti(IV) recovery in one step of the extraction reaches 80% and more [10].

The effect of complex fluoroelement acids on the extraction decreases in the order $H_2SiF_6 > H_2TiOF_4 \geq H_2SO_4$ for Nb(V) and $H_2TiOF_4 \geq H_2SiF_6 \geq H_2SO_4$ for Ta(V). We also studied the influence exerted on the extraction by other elements capable to form fluoroelement acids: Al(III), Zr(IV), Sn(IV), and Fe(III). We found that Fe(III) affects the Nb(V) extraction more weakly than does Ti(IV). The influence of these elements on the Ta(V) recovery is close to the effect of Ti(IV), except Sn(IV) exerting a weaker effect. Coextraction of fluoroelement acids as macroimpurities with Nb(V) and Ta(V) at low $V_o : V_w$ is relatively small, and Nb(V) and Ta(V) can be readily separated from them by washing of the corresponding extracts.

It should be noted that fluosilicic acid affects the extraction of Ti(IV), Nb(V), Ta(V), Mo(VI), and W(VI) particularly strongly. For example, the recovery of Mo(VI) in extraction with TBP in the system with H_2SiF_6 in one step is more than 80%, which provides in the countercurrent extraction mode practically complete Mo(VI) extraction with separation from W(VI). In the presence of H_2SiF_6 at $V_o : V_w = 2 : 1$, the efficient recovery of Ti(IV) is also possible. At the same time, the complete Ti(IV) recovery from H_2SO_4 solutions is problematic under the conditions studied.

The data on extraction with OCL are also of interest. In the system with H_2SiF_6 in extraction from

2 M Si(IV), OCL is a weaker extractant than TBP, despite the fact that in some cases extraction with OCL is performed at large $V_o : V_w$ ratios (see table). However, at a Si(IV) content close to 4 M, the OCL extraction ability approaches that of TBP at similar $V_o : V_w$ ratios. We can expect that the same effect will also be observed for Mo(VI) and W(VI). This shows that the influence of fluoroelement acids (which generate H^+ ions) on the phase distribution of the metal ions studied depends not only on particular fluoroelement acid, but also on the organic extractant. The latter effect should be taken into the account when studying the influence of fluoroelement acids on extraction.

It should be noted that the use of OCL for extraction from acid fluoride solutions is preferable as compared to TBP, since TBP is hydrolyzed on contact with aqueous acid solutions [5]. In [12], we evaluated the extraction power of extractants by the degree of HF recovery depending on time of their contact with a solution of 4.25 M HF + 5 M H_2SO_4. In extraction with OCL, the HF recovery decreased in 160 days insignificantly, from 36 to 29%, whereas TBP completely decomposed in 70 days (a homogeneous solution was formed).

The results of our studies are of interest for the recovery of Ta(V) and Nb(V) from aqueous solutions of fluoroelement acids derived from macroimpurities, without addition of other mineral acids except HF. The implementation of this approach is urgent in connection with the observed tendency toward increased processing of lean niobium–tantalum raw materials with a high content of the impurities. From spent solutions [after Ta(V) and Nb(V) recovery], HF can be regenerated by dialysis or pyrolysis [13]. In so doing, so-called extrinsic elements in some cases can be obtained as marketable products, e.g., titanium (in one of procedures of loparite processing) in the form of titanium dioxide [13]. All the above-said provides a basis for the development of low-waste technology of processing of lean niobium–tantalum raw materials.

However, at a high content of impurities and hence at a high solution acidity, their extraction also increases. As a result, a strong competition arises between fluoroelement acids of Ta(V), Nb(V), and macroimpurities for the organic phase, which can deteriorate the separation and purification of Ta(V) and Nb(V). In this connection, further systematic study of the mutual influence of components in these complex extraction systems, including the influence of the extractant, is topical.

CONCLUSIONS

(1) Fluorotitanic and fluorosilicic acids affect the extraction of Group IV–VI element fluorides, Ti(IV), Nb(IV), Ta(IV), Mo(VI), and W(VI) to the same extent as does H_2SO_4, or even more strongly.

(2) Mutual influence of all metal ions capable to form fluoride complexes, which can dissociate by the acid type, should be taken into the consideration to efficiently use fluoride extraction systems.

Received April 19, 2007

Abstract—The effect exerted by the concentration of salts (NaCl, Na_2SO_4, and $NaNO_3$) on the ozone solubility in aqueous solution at 20, 30, and 40°C was studied. The solubility coefficients of ozone were calculated. The Henry constants and the Sechenov coefficients were determined.

DOI: 10.1134/S1070427207110067

The fields of ozone application have expanded considerably recently. Ozone is used for disinfection of drinking water and for oxidative decomposition of organic and inorganic impurities present in process waste and wastewater. At radiochemical and nuclear power plants, ozone is used, in particular, to decompose organic compounds in treatment of liquid radioactive waste containing high concentrations of dissolved salts (nitrates, chlorides, sulfates, and others) [1]. In the development of the optimal process conditions, the ozone solubility as a function of the salt concentration is an important parameter. The above parameter makes it possible to estimate the concentration of ozone in working solutions and predict the efficiency of oxidative processes and the rate of ozone removal from the reaction zone.

The effect of additives to the electrolyte on the solubility of ozone in aqueous solution was considered in [2–5]. These experiments were performed at a low concentration of salts under conditions minimizing the decomposition of dissolved ozone (in particular, at low pH).

This study is aimed to determine the ozone solubility in neutral aqueous solutions of certain salts in a wide range of concentrations typical of industrial processes.

EXPERIMENTAL

The objects of study were aqueous solutions of Na_2SO_4, NaCl, and $NaNO_3$ (all chemical purity grade). The concentrations of the salts were varied from 0.35 to 3.5 M. The solutions used had pH ~6.

The ozonation was performed in a temperature-controlled cell at 20, 30, and 40°C. The ozone was obtained in a Trinity ozonizer equipped with a capillary discharge chamber ensuring formation of the ozone–oxygen mixture (OOM) containing as much as 180 mg l^{-1} of ozone. The ozone–oxygen mixture passed through the solution being tested at a given temperature until a steady-state concentration of O_3 in the liquid phase was attained. The ozone concentration in the solution was continuously monitored by its absorption spectrum (λ_{max} = 258 nm and ε = 2900 l mol^{-1} cm^{-1} [6]), which allowed the time of attainment of the limiting solubility (about 10 min) to be established correctly. It was found by the special experiments that in the examined temperature range the position and shape of the absorption band of ozone in aqueous salt solutions remain constant.

It is known that the solubility of a gas depends on its concentration in the gas phase (Henry's law). As noted in [7], the Henry's law is fulfilled in a wide range of ozone concentrations. Therefore, the composition of the OOM was maintained constant. The concentration of O_3 in the OOM was 166 mg l^{-1}.

To estimate the O_3 solubility in the solution, we calculated a dimensionless parameter, the solubility coefficient α defined as a ratio of the O_3 concentration in the liquid to its concentration in the gas:

$$\alpha = c_l/c_g.$$

The data on the O_3 solubility in the solutions studied are listed in Tables 1–3 and Fig. 1. The coefficients α of the O_3 solubility in pure water, obtained by different authors at 293 K and a pressure of 0.1 MPa, lie within 0.23–0.41 [2, 4, 8, 9]. In our experiments α was equal to 0.3.

The data presented show that the ozone solubility

decreases as the concentration of the salts in the solution and the temperature increase. The data for Na_2SO_4, NaCl, and $NaNO_3$ solutions are compared in Fig. 1. As seen, for $NaNO_3$, variations of the O_3 solubility with the molal concentration of the salt are the least pronounced. The Henry constant H was calculated as

$$H = P_{O_3}/M_{O_3},$$

where P_{O_3} is the partial pressure of ozone in the gas and M_{O_3}, molar concentration of ozone in the solution.

For water, $H_0 = 7.5 \times 10^3$ MPa cm^3 mol^{-1}, in good agreement with the value obtained by other authors [2, 4, 8] at 20°C. The Henry constant increases as the

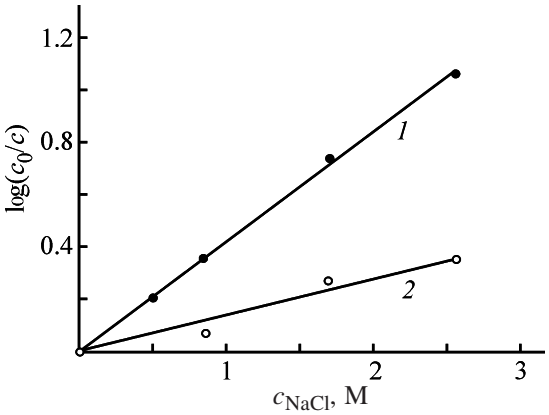

Fig. 2. $\log(c_0/c)$ for ozone vs. c_{NaCl} at 20°C. (*1*) Without acidification and (*2*) pH 2. Calculated K_s: (*1*) 0.4174 and (*2*) 0.1389.

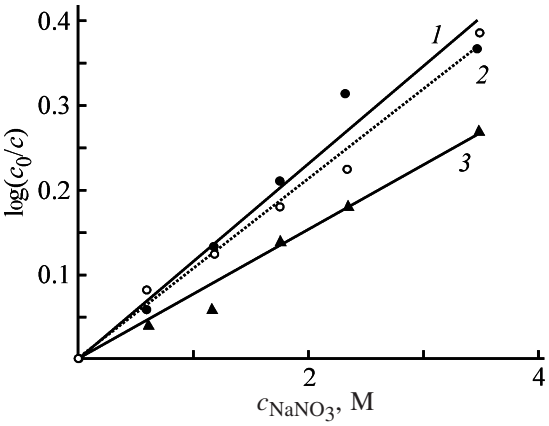

Fig. 3. $\log(c_0/c)$ for ozone vs. c_{NaNO_3}. Temperature, °C: (*1*) 20, (*2*) 30, and (*3*) 40. Calculated K_s: (*1*) 0.114, (*2*) 0.1051, and (*3*) 0.0756.

electrolyte concentration in the solution increases. For salt solutions at 20°C, the calculated H values are close to those obtained in [2]. Also, there is good agreement with the values measured for Na_2SO_4 solutions at 30°C in [3].

The effect of electrolyte concentration on the solubility of gases is described by the Sechenov equation [10]:

$$\log(c_0/c) = K_s c_s,$$

where c_0 is the solubility of the gas in pure water and c, its solubility in the salt solution; c_s is the salt concentration; and K_s is the salting-out coefficient or the Sechenov constant, a quantity characteristic of a given salt.

Thus, the Sechenov coefficients can be used for estimation of the solubility of a gas, and O_3 in particular, in aqueous solutions of electrolytes. As known [11], K_s depends on both the nature of the electrolyte and the temperature and pressure. Appreciable dependence of K_s on the electrolyte concentration is also possible in most cases [11]. It is rather important for practical purposes to establish the boundaries of applicability of this relationship.

The dependence of the ozone solubility in a solution on the NaCl concentration at 20°C is plotted in Fig. 2 in the coordinates of the Sechenov equation. As can be seen, the $\log(c_0/c)$ vs. c_s dependence is linear over the entire range of the salt concentrations studied. The K_s values for NaCl solutions in a wide range of the concentrations ranging from 0.5 to 2.56 M (see also Table 1) are approximately the same (0.42). The experimental procedure used here was checked in experiments on the dependences of ozone solubility for NaCl solutions acidified to pH 2.

It was found that the data obtained are in good agreement with the results of [2] for the same solutions. It is seen from Fig. 1 and Table 1 that the solubility coefficient α increases, whereas the Henry constant decreases on passing from neutral to acidic NaCl solution. In this case, the Sechenov equation is also well fulfilled over the entire range of the salt concentrations studied (Table 1). The K_s parameter decreases to 0.14.

It was also established for Na_2SO_4 solutions (Table 2) that the Sechenov equation is well fulfilled for two temperatures, 20 and 30°C, with K_s slightly decreasing with increasing temperature. As noted in [11], the Sechenov coefficients can noticeably depend on the electrolyte concentration at the concentrations of more than 0.5–1 m (molality) and decrease with increasing concentration at relatively high concentrations of the electrolyte. In our case, however, the Sechenov constants were virtually constant. According to the data of [2], the Sechenov equation may be fulfilled up to 1.5 M and only for KCl its fulfillment to 1.0 M may be expected.

No systematic studies was performed on the O_3 solubility in $NaNO_3$ solutions. The data of Table 3 demonstrate the change in the solubility coefficients of O_3, Henry constants, and Sechenov coefficients at the temperatures increased from 20 to 40°C at a salt concentration of up to 3.5 M. The values obtained may be useful when estimation of the ozone solubility in $NaNO_3$ solutions is necessary for technology. This electrolyte is the main salt formed when wastewater from nuclear power plants is concentrated by evaporation for the subsequent storage.

Raising the solution temperature from 20 to 40°C affects only slightly the salting-out coefficient, with K_s tending to slightly decrease. It should be noted that, for $NaNO_3$ solutions, the Sechenov equation is also fulfilled reasonably well. The $\log(c_0/c)$ vs. c_s dependence is satisfactorily fitted by a straight line with an average K_s value (Fig. 3). The plots for three temperatures and the K_s values calculated from the plots, averaged over the whole region of the salt concentrations, are presented in Fig. 3. The calculated values of H and K_s can be compared with the data of [2] for $Ca(NO_3)_2$ ($K_s = 0.182$ l mol^{-1}).

Thus, to estimate the ozone solubility in process solutions and wastewater, one should take into account the dependence of the salting-out coefficient K_s on the nature of the electrolytes contained in them and the effect of ambient temperature.

CONCLUSIONS

(1) Data on the ozone solubility in aqueous solutions of salts agree satisfactorily with the empirical model of salting-out of gases.

(2) The salting-out coefficient K_s for NaCl solutions at concentrations of 0.5–2.6 M is constant (about 0.42 at 20°C). For Na_2SO_4 solutions K_s is 0.48 (at 20°C), and for $NaNO_3$ K_s ~0.11 and remains constant up to 3.5 M. The coefficients decrease slightly with increasing temperature.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Liquid-Phase Ozonation of Fusainized Components of SS Coal

S. A. Semenova and Yu. F. Patrakov

Institute of Coal and Coal-Tar Chemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received April 19, 1007

Abstract—Stepwise ozonation of leaning fusainized components of fossil coal of SS grade in acetic acid was studied. The dynamics of accumulation of oxygen-containing groups in the course of ozonation was examined, and the main pathways of the reaction of ozone with structural fragments of the coal substance were revealed.

DOI: 10.1134/S1070427207110079

Ozone is a powerful oxidant of the majority of organic compounds, which is due to low energy of detachment of an O atom from an O_3 molecule and high electron affinity of the ozone molecule [1]. Thanks to the reactivity of ozone toward hydrocarbons of various classes [2], ozonation finds wide use in coal chemistry in studies of structural features of solid fossil fuels and their processing productes (shales [3, 4], lignites [5, 6], coal tar [7, 8], humic acids [9], etc.). For example, analysis of the ozonation products of oil shale showed that kerogen has predominantly alicyclic structure [4]. Ozonation of polyfunctional humic acids [9] converts macromolecular substances forming their basis into low-molecular-weight water-soluble products. It is suggested [7, 8] to use ozonation of neutral oxygen-containing fractions and asphaltenes of coal tar for preparing aliphatic and aromatic dicarboxylic acids.

Previously [10–12] we considered the effect of ozonation in the gas phase and in chloroform on the organic matter of vitrinite components of coal with various degrees of metamorphism. We found that coals with the medium degree of metamorphism are the most reactive toward ozone, irrespective of the reaction medium (gas or liquid). In the liquid phase, the ozonation rate increased [12] with an increase in the ozone concentration in the solvent [1]. We also found that, in low-metamorphized coals, ozone primarily reacts with alkyl substituents of benzene rings by the radical mechanism, and with increasing degree of metamorphization the contribution of electrophilic addition of ozone across π bonds of condensed aromatic structures increases [10].

One of the problems of coal-mining industry is accumulation of large volumes of low-grade coal slacks enriched in mineral substances and in leaning petrographic components of the inertinite group. This problem is particularly acute for enterprises of the Prokop'evsk–Kiselevsk deposit where the coal mainly consists of fusainolites with the total content of leaning components as high as 50–70% [13]. At the same time, coal slacks depleted of baking compounds can be considered as raw materials for preparing organic oxygen-containing products by ozone treatment.

The goal of this study was to reveal specific features of liquid-phase ozonation of fusainized components of SS grade coal of the Kuznetsk coal fields and to examine the composition and properties of products soluble in acetic acid.

EXPERIMENTAL

As investigation object we used fusain petrographic coal lithotype (95–97 wt % content of microcomponent of inertinite group) recovered from SS coal slack (Ziminka mine, Prokop'evsk–Kiselevsk deposit, Kuznetsk coal fields). The recovery procedure was based on individual visual signs of the lithotype with additional fractionation of the recovered fusain varieties with respect to density under static conditions in the CCl_4–C_6H_6 mixture. The sample characteristics (%) are as follows: ash content A^d 10.0, moisture content W^a 1.3, reflection index of vitrinite $R_{0.r}$ 1.06; elemental composition, %: C 88.1, H 4.6, N + S 2.5, and O 4.8.

Ozonation was performed at 20°C in a temperature-controlled rotating reactor providing intense mixing of the reaction mixture, with continuous supply of an ozone–oxygen mixture (1.5 vol % ozone). As solvent we used glacial acetic acid (75 ml) in which the ozonation products are the most soluble. The coal sample (fraction 0–0.063 mm) was 2 g. After the process

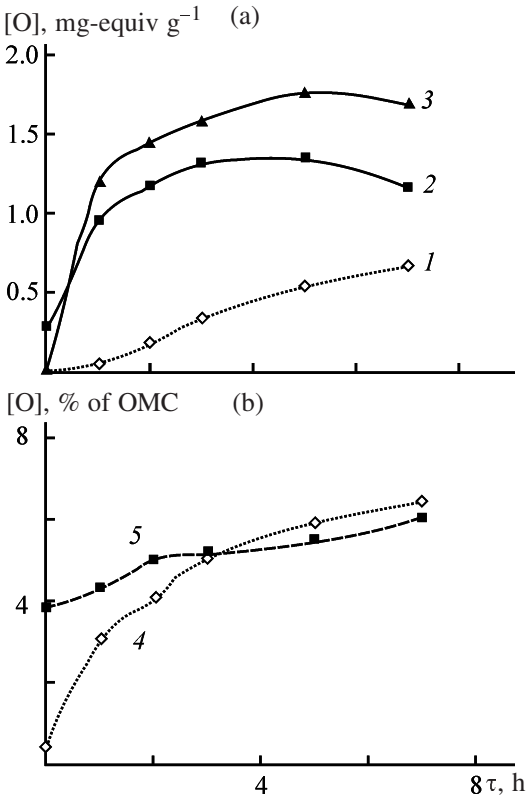

Fig. 1. (a) Amounts of (*1*) carboxy, (*2*) phenolic, and (*3*) carbonyl groups, and (b) oxygen content in (*4*) active and (*5*) inactive forms, as functions of ozonation time τ.

completion, the coal was filtered off and the solvent was distilled off from the soluble products. The distillation residue was treated with 100 ml of distilled water, heated for 2 h on a water bath, and separated into water-soluble (WS) and water-insoluble (WI) products.

The samples were examined by elemental and chemical functional analysis, IR spectroscopy, thermal gravimetric analysis, and mass spectrometry.

The oxygen content in the "active" form was calculated by summation of its amounts in the form of phenolic, carbonyl, and carboxy groups, and in the "inactive" form, as the difference. The content of carbonyl groups was determined by the reaction with hydroxylamine hydrochloride; content of carboxy groups, by the acetate method; and total content of carboxy and hydroxy groups, by ion exchange with sodium hydroxide.

The IR diffuse reflection spectra were recorded on a Tensor-27 spectrometer (Bruker). Thermal analysis was performed with an STA 409 thermal analyzer (Netzsch); the sample (10–20 mg) was heated in a helium atmosphere to 500°C at a rate of 10 deg min^{-1}. The mass spectra of thermal degradation products were recorded on an Acolos mass-spectrometric unit, with ionization by electron impact (70 eV). Analysis by gas chromatography–mass spectrometry (GC–MS) was performed with a 19091S-433 device (Agilent) using an HP-5MS capillary column (5% diphenyl–95% dimethylsiloxane), 30 m × 0.25 mm × 0.25 μm; carrier gas helium. Prior to chromatographic analysis, the products were methylated with diazomethane in diethyl ether.

Ozonation of fusain in acetic acid leads to a considerable increase in the content of active oxygen-containing groups (Fig. 1). The carboxy, phenolic, and carbonyl groups are accumulated in the largest amount in the organic matter of coal (OMC) in 5 h of ozonation, after which their content varies insignificantly. The oxygen content in the inactive form (Fig. 1) and the O/C ratio (Fig. 2) monotonically increase throughout the process. A decrease in the rate of accumulation of active oxygen with an increase in the ozonation time may be due to saturation of the reaction surface of coal particles with oxidation products. In the process, the formation of products soluble in acetic acid decelerates also (Fig. 3).

Table 1. Characteristics of initial and residual coal and of ozonation products

Sample	Yield,* % based on OMC	Elemental composition, % based on OMC			Atomic ratio	
		C	H	O + N + S	H/C	O/C
Initial coal	100.0	88.1	4.6	7.3	0.62	0.04
Water-soluble products	75.0	48.8	4.2	47.0	1.03	0.72
Water-insoluble products	16.0	61.0	3.4	35.6	0.67	0.44
Residual coal	18.1	76.5	3.4	20.2	0.53	0.18

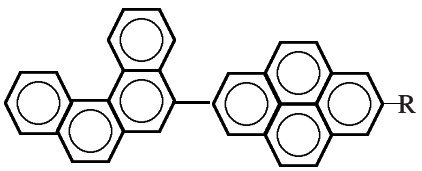
* Based on the initial (before ozonation) organic matter of coal.

Table 2. Results of functional and IR spectral analyses

Sample	Functional composition, mg-equiv g^{-1}			Oxygen in indicated groups, % based on OMC		IR parameters	
	–COOH	–OH	>C=O	active	inactive	A_{2920}/A_{1610}	A_{1690}/A_{3400}
Initial coal	–	0.28	–	0.50	3.81	–	–
Water-soluble products	8.36	1.50	4.24	32.54	14.46	0.22	1.38
Water-insoluble products	4.70	2.71	4.00	22.56	13.04	0.14	1.94
Residual coal	0.77	7.89	1.02	15.90	2.28	–	–

Therefore, we restricted the ozonation time to 5 h. To avoid further degradation of soluble products with ozone, in the subsequent experiments we performed ozonation in the stepwise mode, with intermittent removal of the soluble products from the reaction zone and washing of unchanged coal with fresh acetic acid. As a result of prolonged ozonation (12 cycles), the yield of soluble products exceeded 90% based on OMC. Among them, low-molecular-weight WS substances accounted for 75 wt % (Table 1).

The higher reactivity of fusain compared to vitrinite coals [11] is apparently due to specific structural features of this lithotype. Despite the common opinion that fusain exhibits higher aromaticity [14, 15], it is unlikely that its polynuclear fragments are highly condensed. The average statistical structural unit of this lithotype can be conventionally illustrated by the scheme



where R is an aryl, heteroatomic (O, N, S), or short-chain alkyl (–CH_2–) bridge between fragmentary units of OMC.

The dependence of the structure of fusains on metamorphic transformations of OMC [14–16] is weak, which is apparently responsible for the fact that the reaction with ozone is essentially independent of the degree of coal metamorphism.

Thus, whereas all the main reactions of ozone with organic matter of vitrinite coals of high degree of metamorphism can occur only in the peripheral region of condensed polyaromatic blocks of OMC [11], in the structure of fusains, according to the hypothetical model, there are considerably more sites for ozone attack. At the same time, the lack in fusain organic matter of a shell of peripheral alkyl and active oxygen-containing groups (Table 2) characteristic of low-metamorphized vitrinite coals may also be favorable for ozonation. As the most promising raw materials for preparing benzenecarboxylic acids are artificially carbonized coal formations with the smallest crystallite size (pyrolysis products of peat, lignite, wastes from hydrolysis and woodworking industry) [17], fusain can be considered as a natural material with the favorable structure of the carbon framework.

As the limiting factor of the process is the diffusion of an oxidant molecule to the reactive surface of coal, it is also necessary to take into account the specific features of the texture of this lithotype. For example, in contrast to other petrographic components, fusain

is characterized by the maximal total porosity, and coarse pores with the diameter of about 10^{-4} cm, formed in the course of thermal oxidative coal formation processes, account for 99% of the total pore volume [18, 19]. Thus, relatively large amount of macropores can also stimulate the ozonation owing to free diffusion of ozone into the interpore space of coal.

Based on the features of molecular and supramolecular structure of fusainized coal components [14–16, 18, 19], reactivity of ozone [2], and the occurring changes in the functional composition of OMC upon ozonation, the following pathways of the reaction of ozone with fusain organic matter can be outlined: (1) degradation of benzene ring via formation of ozonides and cleavage of interfragmentary alkyl links, leading to an increase in the amount of carboxy and carbonyl groups in OMC; (2) reaction of ozone with polyaromatic structures of OMC without ring cleavage, leading to an increase in the amount of phenolic groups; and (3) oxidation of anthracene-type fragments to anthraquinone and of ether links to carbonyl groups.

Presumably, π bonds of aromatic fragments undergo oxidative degradation first, with opening of condensed rings. This results in a decrease in the degree of aromaticity and in a certain increase in the H/C ratio (Fig. 2). In the next step, apparently, heteroatomic and "bridging" alkyl fragments of OMC are involved in the oxidation, with partial removal of hydrogen atoms from them into the gaseous or liquid medium; as a result, the H/C ratio returns to the level characteristic of the initial sample.

Analysis of the fusain ozonation products showed that the water-soluble substances are characterized by higher atomic ratios H/C and O/C (Table 1). This fact indicates that relatively low-molecular-weight oxygen-containing compounds prevail in their composition. The prevailing functional groups in WS and WI ozonation products are carboxy groups (Table 2). Whereas in the initial coal sample inactive oxygen (ether, heterocyclic [14]) prevailed, in ozonation products active oxygen-containing groups were predominant.

In the IR spectra of the WS and WI fractions (Fig. 4), the strongest bands belong to oxygen-containing groups [20]: 3100–3500 cm^{-1}, vibrations of OH groups of phenols and carboxylic acids, involved in hydrogen bonding; 2500–2700 cm^{-1}, stretching vibrations of OH groups involved in stronger intramolecular bonds (acid dimers). A strong ill-resolved peak at 1630–1780 cm^{-1} corresponds to vibrations of C=O groups in aromatic and aliphatic acids and in ketones. In the range 1100–1300 cm^{-1}, a broad strong band

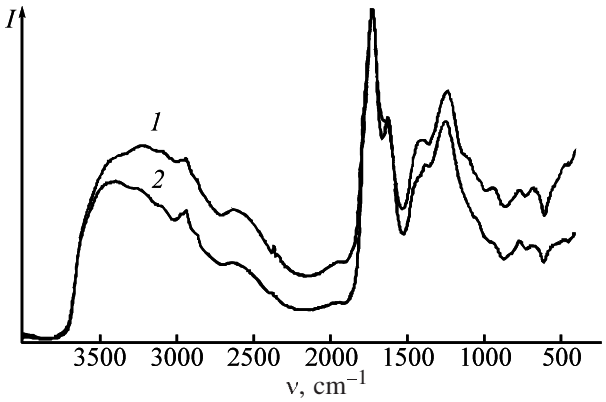


Fig. 4. IR spectra of (*1*) WS and (*2*) WI products of fusain ozonation. (*I*) Intensity and (ν) wavenumber.

with a maximum at 1260 cm^{-1} characterizes stretching vibrations of C–O groups of ethers, esters and phenols. The bands of all the O-containing groups are stronger in the spectra of water-soluble products. The intensities of the absorption bands of aliphatic CH_n (2920, 2850, 1440, 1380 cm^{-1}), aromatic C=C, and aromatic C–H (3040, 1600, 690–870 cm^{-1}) groups in the IR spectra of WS and WI substances differ insignificantly. More information can be gained from the ratios of the intensities of the absorption bands of aromatic C=C (1610 cm^{-1}), aliphatic CH_n (2920 cm^{-1}), carbonyl (1690 cm^{-1}), and phenolic and carboxyl OH groups (3400 cm^{-1}). For example, the parameter A_{2920}/A_{1610} (Table 2) correlates with the H/C atomic ratio (Table 1) and is lower for water-insoluble substances. The values of A_{1690}/A_{3400} are consistent with the results of functional analysis (Table 2), suggesting relatively higher content of acidic groups in WS products.

As thermal decomposition pathways of organic substances are largely determined by the content and chemical forms of oxygen in them, the results of thermal gravimetric analysis also bear certain information about the features of ozonation products. The shape of the temperature dependences of the weight loss rate indicates that oxygen-containing groups in the isolated products differ in the thermal stability (Fig. 5). The WS products in which the content of carboxy groups is the highest (Table 2) decompose in one step at low temperatures with a maximum at 152°C (weight loss rate 4.1 deg min^{-1}). The major volatile products of thermolysis of WS substances in the low-temperature range are water vapor (release of H_2O gives rise to peaks with *m*/*z* 17 and 18) and carbon oxides (*m*/*z* 28, 44) (Fig. 6a). Also detected are fragments of oxygen-containing (*m*/*z* 30, 46, 62), alkyl (*m*/*z* 14, 15, 38, 82), cyclic unsaturated (*m*/*z* 54, 80), and aromatic (*m*/*z* 76, 78, 92) hydrocarbons [20].

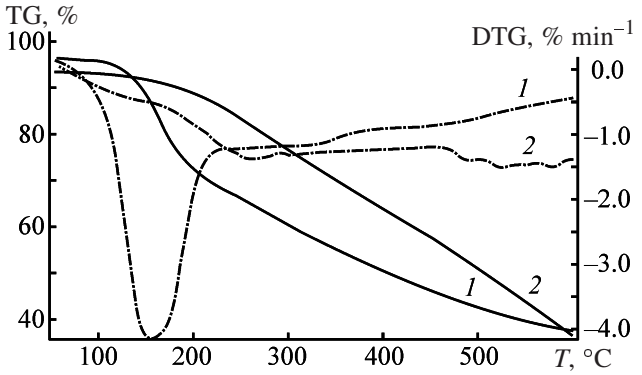

Fig. 5. TG and DTG curves for (*1*) WS and (*2*) WI products of coal ozonation. (*T*) Temperature.

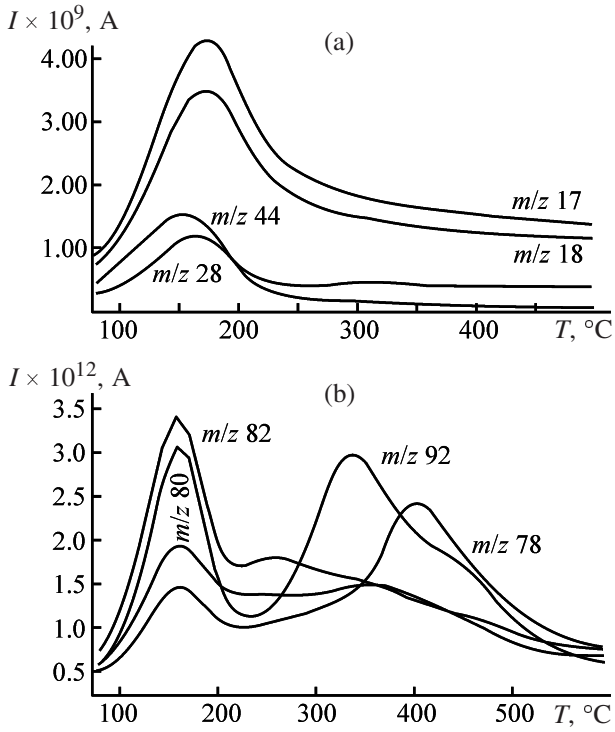

Fig. 6. Mass-spectroscopic patterns of release of (a) H_2O (*m*/*z* 17, 18) and CO_2 (*m*/*z* 28, 44), and (b) alkyl (*m*/*z* 82), unsaturtated (*m*/*z* 80), and aromatic (*m*/*z* 78, 92) volatile products of thermal degradation of WS compounds. (*I*) Ion current and (*T*) temperature.

The ion currents of the latter fragments increase with temperature (Fig. 6b).

The WI products, on the contrary, are characterized by a weak (1.4 deg min^{-1}) DTG peak, smeared over the whole temperature interval, which suggests the macromolecular polyfunctional structure of the WI compounds with close intervals of thermal decomposition of the components.

A GC–MS analysis of WS products of fusain ozonation revealed no aliphatic compounds. Phthalic acid (60.3%) and its isomers (19.5%) account for approximately 80% of aromatic compounds. Benzenetricarboxylic (trimellitic) and benzenetetracarboxylic (pyromellitic) acids account for 10.2 and 7.8% of the products, respectively, i.e., the major fraction of ozonation products of fusainized coal substance is a concentrate of benzenecarboxylic acids of relatively uniform composition. The content of oxy, hydroxy, and nitrogen-containing derivatives of aromatic compounds in water-soluble ozonation products is low.

From water-insoluble products esterified with diazomethane, we isolated an ether-soluble fraction containing esters of benzenedicarboxylic acids (43.5%) and higher linear aliphatic monocarboxylic acids (56.5%). The presence of palmitic (31.7%) and stearic (24.8%) acids in WI products suggests participation of natural fats in the genesis of fusainized coal [21].

CONCLUSIONS

(1) Experiments on stepwise ozonation of fusainized components of SS coal revealed the possibility of conversion of its organic matter into products soluble in acetic acid. The major components of the products obtained are low-molecular-weight water-soluble compounds: a concentrate of benzenecarboxylic acids with the prevalence of dicarboxylic acids.

(2) Thanks to high oxidation rate and to low cost and ready availability of reagents, ozonation of fusainized coal slacks can be considered as a route to valuable aromatic acids, alternative to classical oxidation of aromatic hydrocarbons.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Catalytic Decomposition of H_2O_2 in Hydrophilic Solvents: The Kinetic Aspect

A. P. Pokutsa, A. B. Zaborovskii, and D. S. Maksim

Abstract—Decomposition of hydrogen peroxide in organic hydrophilic solvents, catalyzed by cobalt(II) palmitate [$Co(palm)_2$], was studied by the method of inhibitors.

DOI: 10.1134/S1070427207110080

Physicochemical characteristics of the medium affect the kinetics of homogeneous reactions, among them redox reactions, accelerating or inhibiting their elementary steps [1, 2]. Despite relatively low sensitivity of these processes to the solvent, variation of the rates of individual pathways can noticeably affect the yield of target products. Because the processes in hand, as a rule, involve the radical pathway of transformation, by which, in particular, the initiation reaction occurs, it is of interest and important to study this elementary stage. The most common initiators are peroxy compounds. It is commonly believed that the decomposition of peroxy compounds (including hydrogen peroxide) in solutions proceeds by two parallel pathways, molecular and induced [3]. The role of the solvent in these reactions is governed by its solvation characteristics [4] affecting molecular decomposition, and the induced decomposition is mainly governed by self-association of the solvent (cohesion energy density) [5]. An increase in the cohesion energy density accelerates the process, presumably due to strengthening of the effect of "cage" formed by solvent–solvent and solvent–peroxide hydrogen bonds [6], which results in decreased energy barrier of the reaction and increased rate of induced decomposition [7].

This work continues the study of catalytic decomposition of hydrogen peroxide in hydrophilic solvents [8]. The choice of H_2O_2 as a subject of the study is caused by the fact that its use as an oxidant of many organic substrates is promising from environmental, technological, and economical viewpoints. The kinetic data were obtained using the method of inhibitors as one of the most approved, accessible, and informative methods of studying radical reactions.

The decomposition of hydrogen peroxide was studied at 35°C in a temperature-controlled 25-ml glass cell with stirring by a Teflon-covered magnetic stirrer. The kinetics of H_2O_2 consumption in the solvents was studied by titration of the samples (1 ml), withdrawn from the reaction mixture, with a $KMnO_4$ solution. The electronic absorption spectra of the solutions placed in a quartz cell 1 cm thick were recorded on an SF-20 double-beam spectrophotometer. Quinone (InH) was synthesized from hydroquinone by the procedure described in [9] and purified by double recrystallization from ethanol. The solvents of analytically pure grade were purified by standard procedures and distilled just before experiments. Their characteristics are presented in [5, 7]. Cobalt(II) palmitate (Aldrich) was used without additional purification.

The experimental rates of pseudo-first-order decomposition of H_2O_2 catalyzed by Co^{2+} indicate that the solvent significantly affects this process (Fig. 1a, Table 1). In the solvents containing hydroxy groups (alcohols), the decomposition rate is very high ($W \sim 20 \times 10^{-5}$ mol s^{-1}), and within approximately 30 min after the beginning of the reaction the H_2O_2 concentration is close to zero. At the same time, in water and acetic acid the decomposition rate is significantly lower. The reaction rate in electron-donor dioxane and especially in morpholine is still lower. This experimental fact correlates well with the dependence of the decomposition rate of peroxides on the effect of specific (ability to form donor–acceptor complex) and nonspecific (electrostatic) solvation with the solvent [10]. Hence, the solvents containing hydroxy groups (alcohols) and, in a lesser extent, acids and water are favorable for decomposition of H_2O_2, whereas

electron-donor solvents (morpholine and dioxane) stabilize H_2O_2.

The presence of an inhibitor (quinone) significantly affects the pattern observed for the noninhibited process (Table 1). As known, in free-radical processes, species with free valence can induce decomposition of compounds with weakened O–O bond. Inhibitors of free radicals hinder this pathway of conversion of peroxy compounds [11], and thus it is possible to estimate quantitatively the contribution of individual decomposition pathways (molecular and induced) to the overall rate of hydrogen peroxide consumption. It was established experimentally (Fig. 1b) that an increase in the quinone concentration above 0.01 M does not further affect the rate of H_2O_2 consumption. Hence, it can be assumed that, at this concentration of the inhibitor, the decomposition of peroxide in the examined solvents proceeds by the molecular pathway.

The decomposition rate in solvents more prone to self-association is more sensitive to the presence of InH than in solvents containing no hydroxy groups (Table 1). For example, in alcohols and acetic acid the contribution of induced decomposition was approximately 90%. The next in this characteristic are acetonitrile and tetrahydrofuran (approximately 80%), and then go water, morpholine, and dioxane (40–70%). The special position of water in this series is apparently caused by a combination of electrochemical characteristics that distinguish water from alcohols and organic acids.

As follows from Table 1, the highest ratio of the overall rates of H_2O_2 decomposition in the examined solvents is approximately 16 ($W_{i\text{-PrOH}}/W_{\text{dioxane}}$). For molecular decomposition, this ratio is 3.6, and for induced decomposition, approximately 33. Hence, under the conditions studied, the medium affects the induced pathway of peroxide decomposition by almost an order of magnitude more significantly than the molecular pathway, which agrees with the published data [5].

With the aim of additional elucidation of the solvent effect on the conversion of Co^{2+} into Co^{3+}, we recorded the electronic absorption spectra of Co(II) palmitate solutions before and after their treatment with H_2O_2. The positions of absorption maxima corresponding to Co^{2+} and Co^{3+} (Table 2), similar to the rate of their transformations upon addition of hydrogen peroxide, depend on the physicochemical properties of the solvent. For example, in solvents capable of formation of strong hydrogen bonds (alcohols),

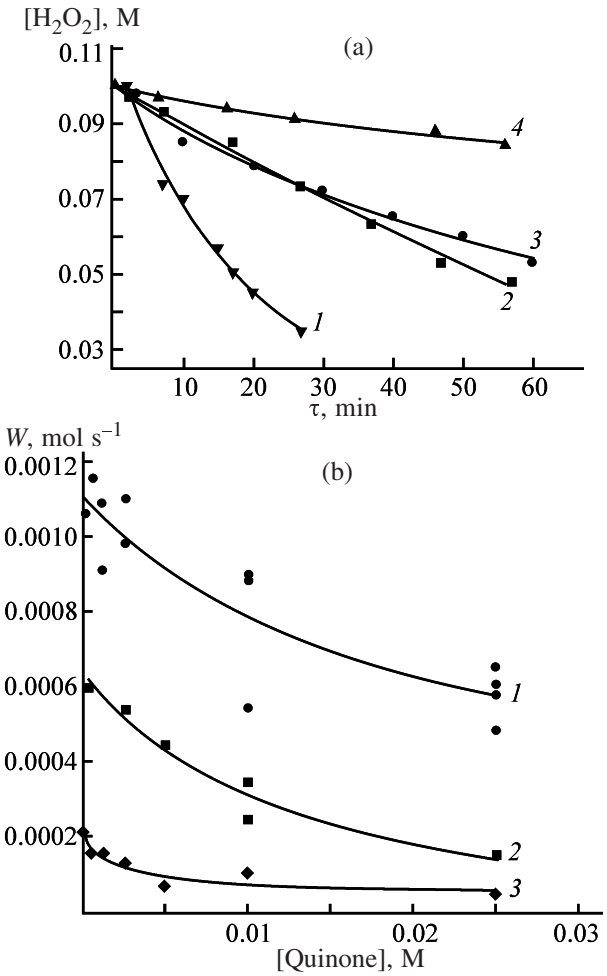

Fig. 1. (a) Kinetic curves of H_2O_2 decomposition catalyzed by $Co(palm)_2$ in solvents at 35°C and (b) rate of H_2O_2 consumption W in acetic acid as a function of quinone additions. THF	18.0	3.5	14.5	81

Table 2. Absorption maxima of Co^{2+} and Co^{3+} ions in various solvents, 20°C

Solvent	λ_{max}, nm	
	Co^{2+}	Co^{3+}
i-PrOH	490	605
HOAc	545	610
H_2O	530	610
Dioxane	520	610
Morpholine	550	570
MeCN	510	610
THF	525	610

the absorption maximum of Co^{2+} and Co^{3+} is observed at 490 and 605 nm, respectively (Fig. 2a, Table 2). The rate of transformation of Co^{2+} into Co^{3+} after addition of H_2O_2 in these solvents and also in MeCN is essentially diffusion-controlled. It is of interest that in acetic acid and in water, capable of formation of hydrogen bonds [7, 12] similarly to alcohols, a bathochromic shift of the absorption maxima of Co^{2+} is observed (Table 2). This may be due to the difference in the pK_a values of the two latter solvents.

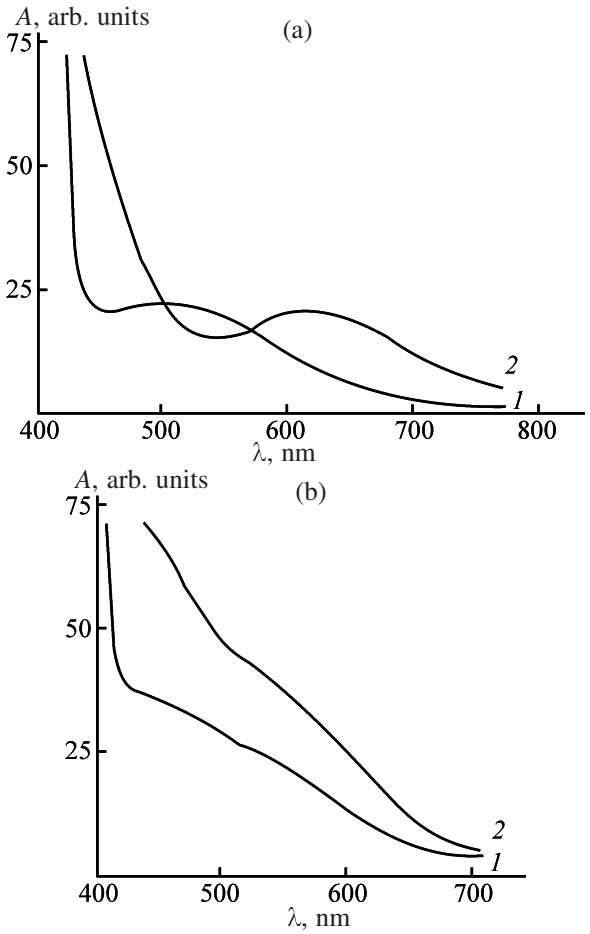

Fig. 2. Electronic absorption spectra of (a) $Co(palm)_2$ solution and (b) the same solution in the presence of 0.02 M of quinone (*1*) before and (*2*) after addition of H_2O_2. Solvent isopropanol, 20°C, $[Co^{2+}]_0 = 1 \times 10^{-3}$ M, $[H_2O_2]_0 = 5 \times 10^{-2}$ M.

In electron-donor solvents: morpholine, dioxane, and acetonitrile, the spectrum of Co^{2+} changes under the action of H_2O_2 within a short time (1 min). However, there is a discrepancy between the rate of formation of oxidized cobalt species and the rate of decomposition of hydrogen peroxide in these solvents. This fact is attributable to oxidation of the reduced Co^{2+} species in electron-donor solvents predominantly with $OH^{\bullet}$ radicals.

The absorption maxima of Co(II) in morpholine (550 nm), THF (525 nm), dioxane (520 nm), and acetone (510 nm) are shifted bathochromically in comparison with alcohols (Table 2). The absorption maximum of Co^{3+} in acetonitrile, THF, and dioxane (610 nm) coincides with that in the solvents capable of formation of hydrogen bonds (Table 2). As regards the electronic spectrum of Co^{3+} in morpholine, its absorption maximum (570 nm) is close to that of Co^{2+} (550 nm) in this solvent. This significant hypsochromic shift of the absorption for the more polar Co^{3+} ions in comparison with the other solvents is apparently caused by stronger electron-donor power and lower polarity of morpholine compared to MeCN [13].

Addition of hydrogen peroxide to a $Co(palm)_2$ solution in isopropanol containing 0.1 M quinone does not result in formation of oxidized cobalt species: The absorption peak corresponding to Co^{3+} is absent (Fig. 2b). The spectrum did not change in 1 h after mixing this solution with H_2O_2.

Thus, it was confirmed that the induced decomposition of hydrogen hydroxide makes a decisive contribution to the overall rate of hydrogen peroxide consumption and valence transformations of the catalyst in the solvents characterized by a high cohesion energy density and significant specific solvation. The influence of physicochemical characteristics of solvents on the rate of hydrogen peroxide decomposition is complicated and ambiguous. To a first approximation, we can assume that the decomposition rate is proportional to the solvent polarity (dielectric constant) and its electrophilicity (ability to be donor of hydrogen bonds). This fact suggests the combined contribution of several factors to the mechanism of hydrogen peroxide decomposition, as in the decomposition of per acids [14].

CONCLUSION

Physicochemical characteristics of solvents affect both the decomposition rate of hydrogen peroxide and formation of oxidized forms of the catalyst by affecting the ratio of the molecular and induced pathways of H_2O_2 decomposition.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Formation of Ionic Associates by Phenol Red and Their Interaction with Ionic Surfactants in Aqueous Solutions

S. A. Shapovalov

Karazin Kharkov National University, Kharkov, Ukraine

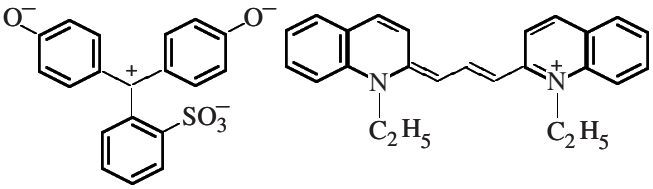
Received January 16, 2007; in final form, June 2007

Abstract—Formation of associates between single- or double-charged anions of sulfophthalein dye Phenol Red and single-charged cations of cyanines in aqueous solutions was considered. The association constants were estimated from the spectral data. Geometric and energy characteristics of the associates were calculated. The suitability of the associates formed by Phenol Red for quantitative determination of cationic surfactants in aqueous solutions was examined.

DOI: 10.1134/S1070427207110092

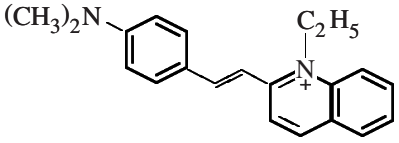
Interaction of dye ions with organic counterions can substantially modify the optical properties of solutions because of formation of ionic associates [1]. Of special interest is association in aqueous solutions, since water is a medium in which protolytic and aggregated forms of dyes exhibit unique spectral-luminescent properties. Since recently, the focus of attention has been on association of ionic forms of sulfophthalein dyes [2], above all, of Phenol Red (PR). Under certain conditions, the dye associate can act as analytical reagent, color marker, and biological probe, which is essential for solving a number of applied problems. For example, Liu et al. [3] developed a highly sensitive method for detection of vitamin B_1, underlain by formation of an associate between the vitamin and PR. Phenol Red was successfully applied in the development of new pH sensors for cells and biological tissues [4] and of promising technologies for monitoring of the chemical composition of biological systems (e.g., determination of the acidity of cellular liquid [5] and monitoring of the liquid exchange via mucous membranes [6] and skin [7]).

We reported earlier [8] that the properties of PR associates can underlie development of new methods for analysis of surfactants in aqueous solutions. The associates prove to be more "sensitive" to the content of ionic surfactants than are dye ions proper. The reason is that, in associate + surfactant systems [1, 5, 9], spectral changes occur at much lower surfactant concentrations than in dye + surfactant systems [10]. Importantly, solving such practical problems implies elucidation of both the spectral properties of dyes and the equilibrium characteristics of the association processes. In this connection, we considered here in more detail the properties of single- and double-charged PR ions and the specific features of their association with cations of cyanine dyes, Pinacyanol (PNC) and Quinaldine Red (QR), as well as interaction of the associates of PR with ionic surfactants:



PR^{2-} anion

PNC^+ cation



QR^+ cation

Owing to their physicochemical properties, many cyanines tend to form associates [1, 11]. Among them, PNC and QR cations proved to be suitable counterions for examination of the properties of ionic associates formed by dyes from different classes [1, 12, 13], in particular, sulfophthaleins [14].

EXPERIMENTAL

The procedures for spectral measurements and analysis of data obtained are basically identical to those in [9, 12, 15]. We used sodium salt of PR and chloride salts of PNC and QR. The degree of purity of

Table 1. Spectral and protolytic characteristics of dyes

Characteristic*	Ion			
	PR^- [18]	PR^{2-} [18]	PNC^+ [19]	QR^+

	Molecule			
	PR		PNC	QR
pK_{a1}	1.03 [20]		3.5 [21]	2.63 [18]
pK_{a2}	8.00 [18]		–	–

* The parameters λ_{max} were determined accurately to within 1 nm, and ε_{max}, to within 500 $l\,mol^{-1}\,cm^{-1}$.

the dyes was monitored spectrophotometrically using the known molar extinction coefficients ε_{max} of the protolytic forms at the absorption band maxima. The surfactants, anionic sodium dodecyl sulfate (SDDS) and cationic cetylpyridinium bromide (CPB), contained 98 ± 1% main substance. All other chemicals were of analytically pure grade; pH of medium was created by buffer solutions and monitored potentiometrically with a glass electrode. The absorption spectra were measured on Hitachi-U3210 and SF-46 spectrophotometers at room temperature.[1]

The equilibrium of PR in a solution can be represented by the scheme of stepwise dissociation of the tribasic acid

$$H_3An^+ \rightleftarrows H_2An^0 \rightleftarrows HAn^- \rightleftarrows An^{2-}.$$

The PR cation and molecule in aqueous media are weakly colored (the H_3An^+ species are manifested in anhydrous acetonitrile [16, 17]). By contrast, the anionic species HAn^- and An^{2-} have a high light absorption intensity (Table 1, ε_{max}), which facilitates spectral examination of ionic association at low concentrations of the species ($\geq 1 \times 10^{-6}$ M). The absorption bands of PR^- and PR^{2-} are well resolved. Owing to sufficient difference in the pK_{a1} and pK_{a2}, it is possible to achieve virtually absolute domination of the target anion in a solution. The cyanines examined exist as cation (Ct^+) over a wide pH range. Only in strongly acidic media Ct^+ is protonated into HCt^{2+}, and in alkaline media, carbinol CtOH is formed. Both processes result in decolorization of the solution.

[1] The spectral measurements were carried out with participation of Ya. Svishcheva and M. L'vovskaya.

There exist two essential prerequisites to examination of association: First, the basic light absorption law should be obeyed, and, second, the acidity of the medium should be maintained at the level providing the occurrence in solution of those ionic forms of dyes that form associates. We found that a satisfactory linear dependence of the optical density on the dye concentration (Bouguer–Beer law) is observed at PR concentrations within 1×10^{-6}–9×10^{-5} and QR concentrations of 1×10^{-6}–1×10^{-4} M. The linear regression equations (for three series of independent determinations with 8–9 concentrations in each series) have the form

$$PR^-: A_{430} = -0.0124_{(0.0083)} + 24345.6_{(277.51)}c_{PR},$$
$$R = 0.9981_{(0.018)},$$
$$PR^{2-}: A_{558} = 0.00944_{(0.0151)} + 675527.8_{(322.0)}c_{PR},$$
$$R = 0.9999_{(0.0054)},$$
$$QR^+: A_{528} = -0.0379_{(0.015)} + 33747.9_{(324.48)}c_{QR},$$
$$R = 0.9996_{(0.033)},$$

where A_{430} is the optical density at 430 nm (23250 cm^{-1}), A_{558}, at 558 nm (17920 cm^{-1}), and A_{528}, at 528 nm (18940 cm^{-1}); figures in parentheses are the rms deviations of the corresponding parameters; c, initial molar concentration of the dye; and R, correlation coefficient.

Since the absolute term of the regressions is close to zero, we took $A_i \approx kc$. To estimate the association constants, we created the PNC concentration of 5×10^{-7}–5×10^{-6} M, since higher concentrations favor undesirable self-association [15].

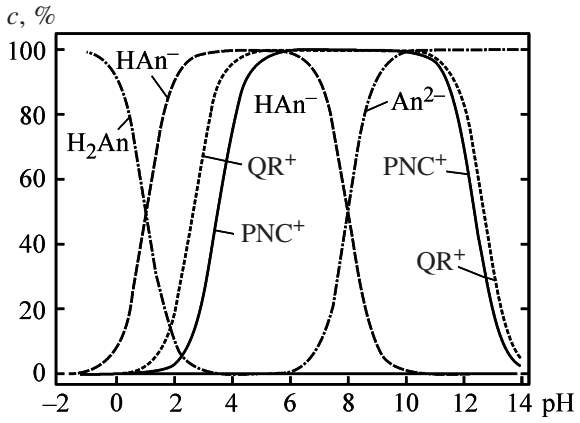

Fig. 1. Ranges of existence of protolytic forms of PR (H_2An, molecule; HAn^-, single-charged anion; and An^{2-}, double-charged anion) and single-charged cations of Pinacyanol (PNC^+) and Quinaldine Red (QR^+) in an aqueous solution. (*c*) Concentration, %.

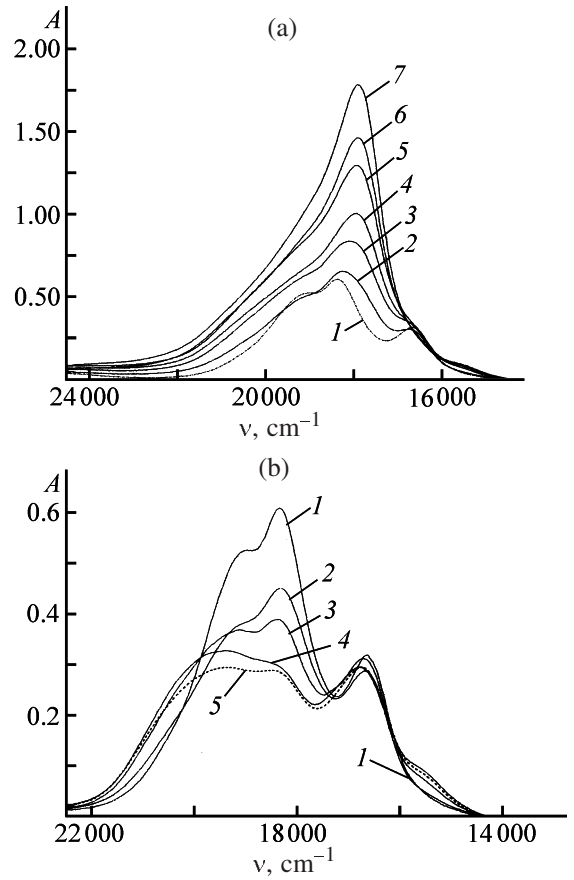

Fig. 2. Absorption spectra for the PNC + PR system. Reference solution: (a) water and (b) PR in indicated concentration. Absorption layer thickness 0.20 cm, pH 9.2, c_{PNC} 4.86×10^{-5} M. (*A*) Optical density and (ν) wavenumber; the same for Fig. 5. c_{PR}, M: (*1*) 0, (*2*) 2.5×10^{-5}, (*3*) 5.0×10^{-5}, (*4*) 7.5×10^{-5}, (*5*) 1.00×10^{-4}, (*6*) 1.25×10^{-4}, and (*7*) 1.50×10^{-4}.

To elucidate the optimal association conditions, we calculated (Fig. 1) the proportions of the species examined, taking into account the above-listed protolytic processes (Table 1, pK_a), occurring in aqueous solutions. Figure 1 suggests, in particular, that it is appropriate to observe interaction of QR^+ ions with HAn^- at pH 4.5–5.5, and that of PNC^+ with An^{2-}, at pH close to 10.

A characteristic feature of association of PR is a substantial decrease in absorption intensity, clearly observed upon adding ever growing amounts of one ion to the other ion whose content remains unchanged. For PNC^+ having a more developed vibronic structure (Table 1, α-, β-, and γ-bands), these changes are more distinct, but they are also observed in the case of QR^+. Analysis of the electronic spectra reveals nonadditivity of the optical density. The optical density of a mixture of dyes is systematically lower than the sum of the optical densities of individual dyes in the mixture. This fact is not always evident, especially when the absorption bands of the interacting dyes are located close to each other. In this case, changes of the optical density in individual portions of the spectrum can be "veiled" by absorption of one of the dyes, occurring in excess with respect to the counterion (Fig. 2a) (an excess is required for exhaustive association). Nevertheless, these changes can be revealed when a dye, rather than water, is used as the reference solution (Fig. 2b).

Analysis of the stoichiometric composition of the associates [2, 9, 12] showed that interaction of PR with cyanines can be represented by the scheme

$$Ct^+ + HAn^- \rightleftarrows Ct^+ \cdot HAn^-$$

$$2Ct^+ + An^{2-} \rightleftarrows (Ct^+)_2 \cdot An^{2-}.$$

The stability of these compounds is estimated from the equilibrium association constant K^t_{as} (thermodynamic parameter), determined from the mass action law. The K^t_{as} values obtained (by analogy with [15]) for associates of PR with PNC and QR differ from each other; the associates formed by PNC are more stable. For example, $\log K^t_{as}$ was estimated at 5.83 ± 0.10 for $PNC^+ \cdot PR^-$ and 11.81 ± 0.10 for $(PNC^+)_2 \cdot PR^{2-}$, and for $QR^+ \cdot PR^-$ and $(QR^+)_2 \cdot PR^{2-}$, at 5.13 ± 0.09 and 8.64 ± 0.09, respectively. One of the reasons for the difference in the stability of the associates is an increase in the proportion of hydrophobic interactions in the PNC-containing associates. The hydrophobic contribution from the quinolyl moiety in the PNC molecule exceeds that from the *N,N*-dimethylaniline moiety in the QR molecule. Also, association

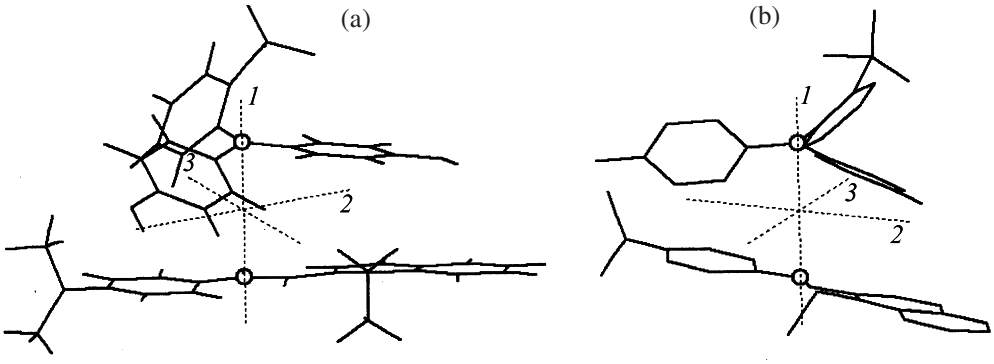

Fig. 3. Mutual location of the counterions in the $QR^+ \cdot PR^-$ associate (PR is on the top; projections (a) and (b) differ in the rotation about axis 1 by approximately 110°; the solvent molecules, as well as the hydrogen atoms, are not shown in projection (b)).

is enhanced by dispersion interactions prominent in developed π-electron systems [22, 23]. Because of specific structural features of PNC^+ and QR^+, they are more characteristic for the former.

Figure 3 shows the structure of the $QR^+ \cdot PR^-$ associate [from here on, calculations follow the MOPAC 2000 procedure [24, 25]: spatial optimization by AM1 method; convergence gradient for two consecutive iterations no larger than 1 kJ mol^{-1}; distance separating the marked atoms along axis *1*, 4.0 Å; and the dimension of the QR^+ cation (bottom) along axis *2*, approximately 13 Å]. The PNC + and QR^+ cations are planar (because of sp^3 hybridization, only ethyl groups in PNC^+ and QR^+ and the dimethylamino group of QR^+ are out of the chromophore plane). By contrast to cyanines, the PR anions have the benzene rings arranged like propeller blades, symmetrically about the central carbon atom. Therefore, the PR anions can be represented as spheres (radius of the sphere centered at the carbon atom marked in Fig. 3 is 5.6 Å; central angles with the carbon atom as apex, 119°–124°). However, despite the essentially different geometries, the counterions appreciably interact, as revealed not only by spectral measurements.

We carried out model calculation of the energies of the interacting species and the resulting associates (MOPAC 2000 procedure, vacuum as medium). Figure 4 presents the energy characteristics of interaction of PR^- with QR^+ (from here on, the dimensionality for all energy parameters is kJ mol^{-1}).

The initial states of QR^+ and PR^- are characterized by total energies of 65.2 and 274.2, respectively (Table 2; from here on, calculations are accurate to within 1.5 kJ mol^{-1}), and their algebraic sum, 339.4 (Fig. 4, energy level *1*), exceeds the energy of the associate, 276.7 (level *2*). Thus, the energy gain (ΔE) for the $QR^+ \cdot PR^-$ associate is 339.4 – 276.7 = 62.7 kJ mol^{-1}. It should be noted that ΔE for the interaction between PNC^+ and PR^- was estimated at 72.6, which exceeds that for the $QR^+ \cdot PR^-$ associate. The situation with the associates of the PR^{2-} anion is similar: ΔE = 149.1 [$(PNC^+)_2 \cdot PR^{2-}$ associate] and 122.5 [$(QR^+)_2 \cdot PR^{2-}$ associate]. For associates of PNC^+, ΔE systematically exceeds that of QR^+. This difference is due to stronger interaction with PR

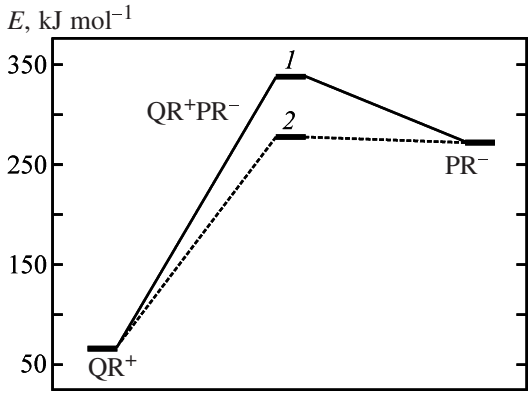

Fig. 4. Energy levels of the QR^+ and PR^- ions and of the $PNC^+ \cdot PR^-$ associate. (*E*) Energy: (*1*) sum of the total energies of PNC^+ and PR^- and (*2*) total energy of the associate.

Table 2. Energy characteristics of the interacting ions and associates*

Cation, Ct^+ (energy, kJ mol^{-1})	PR anions and associates (energy, kJ mol^{-1})	
	HAn^- (274.2)	An^{2-} (271.7)
QR^+ (65.2)	339.4**/276.7	402.1/279.6
PNC^+ (140.8)	415.0/342.4	553.3/404.2

* The data for the associates correspond to specific stoichiometric compositions, $Ct^+ HAn^-$ and $(Ct^+)_2 \cdot An^{2-}$.

** Numerator is the algebraic sum of total energies of the ions, and denominator, total energy of the associate.

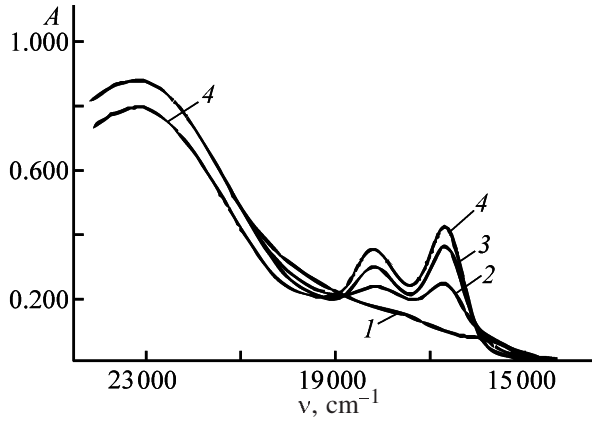

Fig. 5. Spectral changes in the PNC + PR system upon addition of CPB. Reference solution water; absorption layer thickness 1.00 cm; pH 4.6; $c_{PNC} = 4.9 \times 10^{-6}$, $c_{PR} = 7.1 \times 10^{-5}$ M; the same for Fig. 6. c_{CPB}, M: (*1*) 0, (*2*) 3.0×10^{-5}, (*3*) 6.0×10^{-5}, and (*4*) 8.0×10^{-5}.

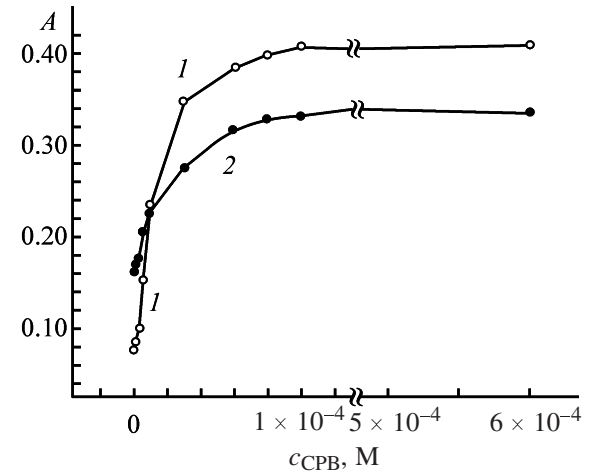

Fig. 6. Optical density of the solution vs. CPB concentration. λ, nm: (*1*) 600 and (*2*) 550.

anions for PNC^+ cation compared to the QR^+ cation because of van der Waals interactions (semiempirical calculations cannot take into account the hydrophobic interactions). The results presented agree with the calculated energy characteristics and association constants.

Addition of CPB or SDDS to the $Ct^+ \cdot HAn^-$ and $(Ct^+)_2 \cdot An^{2-}$ associates causes changes in the spectra of aqueous solutions, suggesting decomposition of the associates (Fig. 5; $PNC^+ \cdot PR^-$ associate as an example). In all cases, the shapes of the bands of each dye are restored in the absorption spectra [in Fig. 5, the short-wave absorption band with $\nu_{max} = 23\,250$–$22\,990$ cm^{-1} (430–435 nm) corresponds to the single-charged PR anion (with increasing content of the surfactant, the band slightly shifts), and bands with $\nu_{max} = 18\,180$ cm^{-1} (550 nm) and $\nu_{max} = 16\,660$ cm^{-1} (600 nm), to PNC]. Analysis of the experimental data suggests that, at low concentrations of the surfactants, the associate interacts with the dodecyl sulfate (DDS^-) anion or cetyl pyridinium bromide (CPB^+) cation according to the schemes

$$Ct^+ \cdot PR^- + DDS^- \rightleftarrows Ct^+ \cdot DDS^- + PR^-,$$

$$Ct^+ \cdot PR^- + CP^+ \rightleftarrows Ct^+ + CP^+ \cdot PR^-.$$

Thus, the corresponding ion of the surfactant exerts a competing effect on the ions of the dyes forming the associate.

Decomposition of the cyanine associates of PR upon addition of a surfactant is similar to that of the associate of the tetrabutylammonium cation with oxyxanthene dye tetrabromophenylfluorone which was examined earlier [26]. However, in our case, decomposition of the associates formed by PR is not evident. In view of its practical importance, we examined this aspect in more detail for the PNC + PR system and found that, under certain conditions, the parameter *A* at a fixed wavelength linearly increases with increasing content of CPB in the solution (Fig. 6, CPB concentration from 2×10^{-6} to 2×10^{-5} M). These changes are more profound for the long-wave band of PNC (curve *1*), since it has the highest absorption intensity. For the dye concentrations indicated in Fig. 6 and at 600 nm (16 660 cm^{-1}), *A* varies with the CPB content c_{CPB}, M, as $A_{600} = (0.032 \pm 0.010) + (2.31 \pm 0.09) \times 10^4 c_{CPB}$ (CPB concentration range 3×10^{-6}–2×10^{-5} M). Similar dependences can underlie the development of quantitative spectrophotometric and test methods for determination of cationic surfactants in solution. An advantage offered by such methods is that they combine a very high sensitivity (at a level of 1×10^{-6} M) and high contrast of the color reaction, provided by the presence in the solution of two dyes whose absorption bands are well separated in the spectrum (Table 1; cf. the λ_{max} values for the single-charged PR anion and PNC cation). The latter fact is of principal importance for the development of semiquantitative (test) methods for determination of surfactants, based on visual indication of the analytical signal.

CONCLUSIONS

(1) Interaction of single- (HAn^-) and double-charged (An^{2-}) anions of sulfophthalein dye Phenol Red with cations (Ct^+) of Pinacyanol or Quinaldine Red in an aqueous solution results in formation of

ionic associates with the stoichiometric composition $Ct^+ \cdot HAn^-$ and $(Ct^+)_2 \cdot An^{2-}$.

(2) The reasons for the decomposition of $Ct^+ \cdot HAn^-$ and $(Ct^+)_2 \cdot An^{2-}$ associates upon addition of cationic and anionic surfactants in low concentrations is the competing action of the surfactant ions on the ions forming the associate.

(3) The properties of the associates of Phenol Red, in particular, of $PNC^+ \cdot PR^-$, can be utilized in the development of new quantitative and test methods for the determination of the content of cationic surfactants (e.g., cetylpyridinium bromide) in aqueous solutions at concentrations $\geq 10^{-6}$–10^{-5} M. It was suggested that the quantitative determination be underlain by the direct proportionality between the optical density of the solution and the content of the cationic surfactant in it.

Abstract—Formation of the adsorption layer at the solution–air interface is characterized by data on the surface tension in alkaline solutions of kraft lignins extracted from deresined spruce and birch wood. The effects of the lignin nature and solution concentration on intermolecular interaction in the surface layer are studied.

DOI: 10.1134/S1070427207110109

Many technologies for processing plant materials are based on heterogeneous reactions resulting in dissolution of lignin. Particularly, the removal of lignin from wood cell walls is one of the basic processes in cellulose production. The presence of a hydrophobic group and a lot of polar functional groups makes the lignin macromolecule diphilic. This, in turn, causes surface activity in lignin derivatives, which should be taken into account in pulping, regeneration of cooking liquor, and production of secondary products.

Surfactant properties of lignin derivatives obtained in sulfite delignification of spruce wood were studied in detail [1, 2]. However, sulfate lignins have not been studied from this standpoint. The kraft pulping allows production of cellulose not only from spruce wood, but also from other soft- and hardwood species. It is known that soft- and hardwood lignins differ from each other in their topological structure, molecular-weight distribution, hydrophilic–oleophilic properties, etc. [3–5].

In this study we examined the interfacial adsorption in aqueous alkaline solutions of lignins obtained from spruce and birch wood by sulfate delignification.

It should be taken into account that, generally, the solution obtained after alkaline delignification, in addition to lignin, contains also extractive substances, and that the major part of these substances (resin and fatty acids) in alkaline solutions form sodium salts exhibiting high surface activity. In the presence of such substances, it appears impossible to obtain reliable information on the surfactant properties of lignin itself. Therefore, to eliminate the effect of extractive substances on the surfactant properties of kraft lignins, lignin samples were prepared from wood preliminarily deresined by successive treatment with petroleum ether and 20% NaOH. Spruce and birch wood pulping was carried out using the standard procedure. The solution after delignification was concentrated by vacuum evaporation like that in the actual process, to remove volatiles. Lignin was precipitated from the solution by acidification to pH 2 with heating (80–85°C). The resulting flaky precipitate was settled, separated by decantation, and dried with water to neutral reaction. The spruce and birch lignin samples were different in the molecular weight (MW 9700 and 2800), elemental composition (C : H : O 63.1 : 5.8 : 31.1 and 66.0 : 7.8 : 26.2), and hydrophilic–oleophilic ratio (HOR 21.8 and 29.6, respectively).

Surfactant properties of kraft lignins were characterized by the surface tension of their solutions, measured by the Wilhelmy method. The lignin concentration was varied by successive dilution with 0.01 N NaOH of the initial lignin solution after neutralization with 1 N NaOH.

The specific feature of the formation of the interfacial adsorption layer in solutions of high-molecular-weight surfactants is that this process is kinetically controlled [6, 7]. It was demonstrated previously that, in lignosulfonate solutions, the adsorption equilibrium is established in 5–20 h.

Analysis of the $\sigma = f(\tau)$ curves (Fig. 1) revealed that, in the case of spruce lignin, the surface tension is decreased most rapidly in the first 10 min (initial portions of the curves). At low solution concentration (<1.5 g l^{-1}), the surface tension depression is in the range 1×10^{-3}–10×10^{-3} J m^{-2}. At higher concentra-

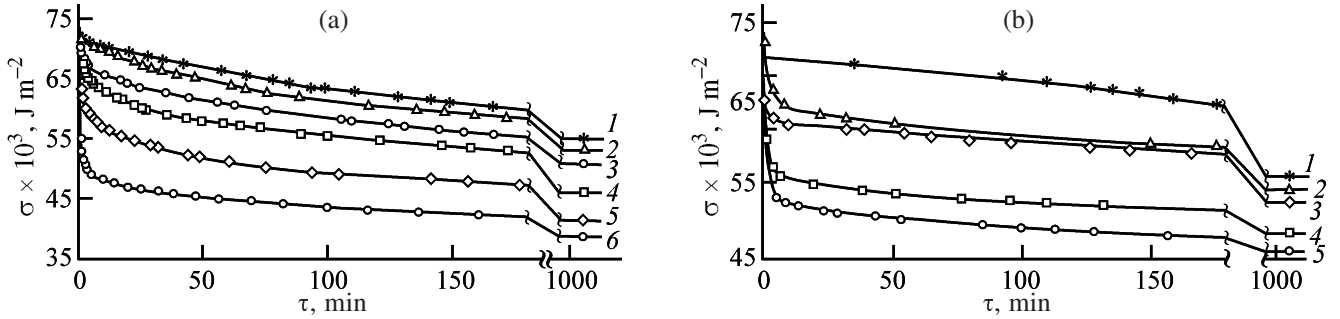

Fig. 1. Surface tension σ in alkaline solutions of (a) spruce and (b) birch lignins as a function of the time τ. Solution concentration, g l^{-1}: (a) (*1*) 0.044, (*2*) 0.22, (*3*) 0.52, (*4*) 1.54, (*5*) 7.70, and (*6*) 17.5; (b): (*1*) 0.02, (*2*) 0.17, (*3*) 0.56, (*4*) 1.4, and (*5*) 5.6.

tions (7–17.5 g l^{-1}), the decrease in the surface tension in the same time is more remarkable [(15–25) × 10^{-3} J m^{-2}]. In the next 10 min, as the adsorption layer is filled, the diffusion rate of the lignin macromolecules to the surface layer decreases, and the surface tension of the solution decreases to a lesser extent [$\Delta\sigma$ = (0.5–1.5) × 10^{-3} J m^{-2}]. In highly concentrated solutions, the adsorption equilibrium is established much more rapidly than in dilute solutions (Fig. 2a). In this case, with increasing solution concentration, the time required for the surface tension to acquire an equilibrium value increases from 4 to 20 h.

Similar trends were observed in the birch lignin solutions (Fig. 1b) with the difference that, in this case, the adsorption equilibrium is established more rapidly (Fig. 2a, curve *2*) because of the lower molecular weight and, therefore, higher mobility of the macromolecules. The lower the solution concentration, the more pronounced is the difference in the surface tension depression in the first 10 min after the beginning of the formation of the adsorption layer between the birch and spruce lignin solutions.

According to the recent data [8], native hardwood lignins are regularly branched star-like polymers with a tetrafunctional branching point, while native spruce lignin represents a randomly branched polymer. These structural features of the lignin macromolecules could affect their interfacial adsorption from aqueous alkaline solutions.

It was demonstrated in [7] that classical adsorption equations, derived for ideal processes, are inapplicable to the adsorption kinetics of high-molecular-weight surfactants. Therefore, we used modified equation (1) [2, 9] to describe the experimental curves $\sigma = f(\tau)$.

$$\sigma_\tau = (\sigma_0 - \sigma_{eq})\exp(-k_c\tau)^n + \sigma_{eq}, \qquad (1)$$

where σ_0 is the surface tension of the solvent; σ_τ and σ_{eq} are the current and equilibrium (static) surface tensions of the solution, respectively; k_c, rate constant of ideal adsorption; and n, exponent reflecting particle interaction in the adsorption layer, i.e., deviation of the system from ideality.

The difference $\sigma_0 - \sigma_{eq}$ is equivalent to the surface pressure π. For computation convenience sake, k_c^n can be expressed in terms of the rate constant of nonideal adsorption β.

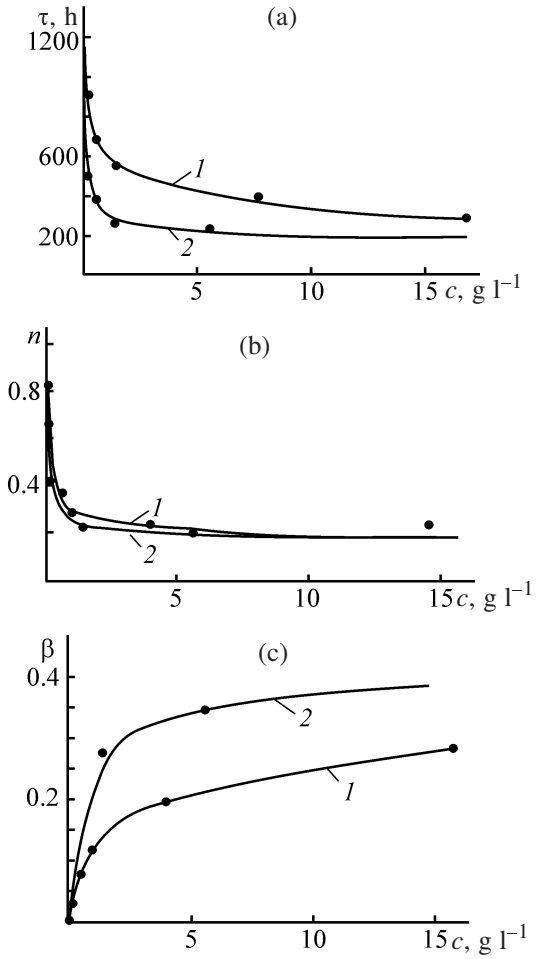

Fig. 2. (a) Time of establishment of equilibrium τ, (b) activity coefficient n, and (c) coefficient β as functions of the concentration c of (*1*) spruce and (*2*) birch lignins in solutions.

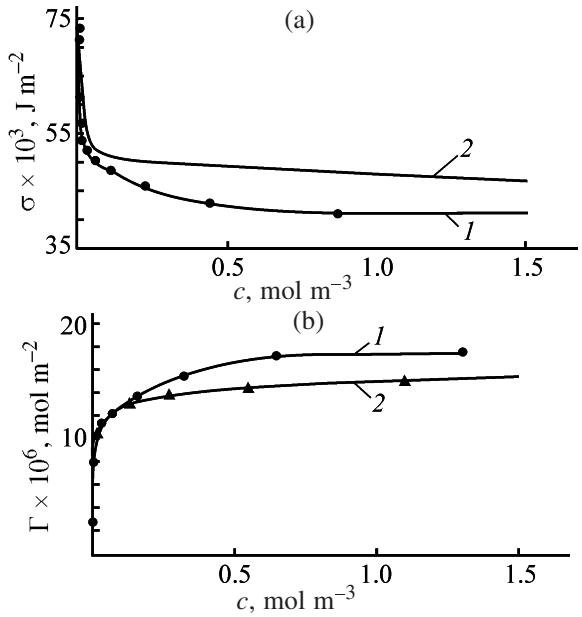

Fig. 3. (a) Surface tension σ and (b) adsorption Γ as functions of the concentration c of (*1*) spruce and (*2*) birch lignins in solutions.

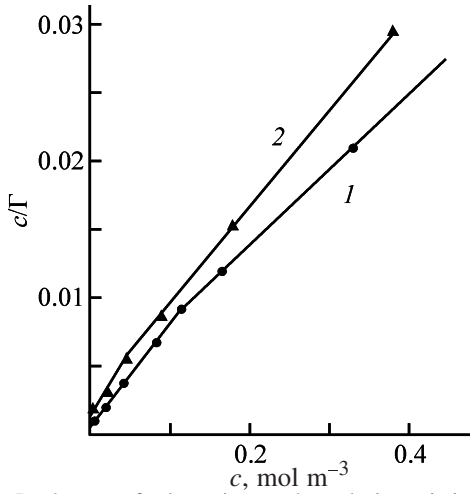

Fig. 4. Isotherms of adsorption at the solution–air interface in the Langmuir equation coordinates $c/\Gamma = f(c)$: (*1*) spruce and (*2*) birch lignins.

Theoretically, $n = 1$ corresponds to ideal adsorption layer (low degree of filling), i.e., Eq. (1) passes to a kinetic equation of the Langmuir type:

$$\sigma_\tau = (\sigma_0 - \sigma_{eq})\exp(-k_c\tau) + \sigma_{eq}. \quad (2)$$

In solutions of spruce and birch kraft lignins, n varies from 0.8 to 0.2, depending on the solution concentration (Fig. 2b), suggesting that intermolecular interaction in the adsorption layer increases with increasing degree of filling.

The time of establishment of the adsorption equilibrium is controlled by β. The higher β, the higher the rate of formation of the adsorption layer. It is seen from Fig. 2c that coefficient β increases with increasing solution concentration. This coefficient is slightly lower for spruce lignin than for birch lignin because of the lower mobility of the macromolecules (higher molecular weight).

The isotherms of the surface tension (Fig. 3a) and adsorption (Fig. 3b) of aqueous alkaline solutions of kraft lignins are classical curves typical of surfactants. For spruce lignin solution, the maximal surface tension depression, equivalent to the equilibrium surface pressure, is 30×10^{-3} J m^{-2}, which is well comparable with that of the solutions of such high-molecular-weight surfactants as lignosulfonates. For birch lignin, this value is slightly lower (25×10^{-3} J m^{-2}), suggesting higher surface activity of this more hydrophobic and higher-molecular-weight lignin. The surface activity of spruce and birch kraft lignins is 3100 and 830 J m mol^{-1}, respectively. For spruce lignin, saturation of the adsorption layer is observed at concentrations of 0.6–0.8 mol m^{-3} (6–8 g l^{-1}) (Fig. 3a), and for birch lignin, at lower concentrations [0.2–0.4 mol m^{-3} (0.7–1.4 g l^{-1})].

Analysis of the Langmuir isotherms $c/\Gamma = f(c)$ (Fig. 4) reveals that the interfacial adsorption of the lignin macromolecules from solutions corresponds to the model of monomolecular filling of the surface layer not in the entire concentration range, which is reflected in the deviation of the isotherms $c/\Gamma = f(c)$ from linearity by virtue of decreasing energy of interaction of the macromolecules with the gas phase, as a result of structural rearrangement in the surface layer. In the spruce lignin solution, the break in the isotherm is observed at a solution concentration of about 0.1 mol m^{-3} (1 g l^{-1}). For birch lignin, whose molecular weight is three times lower than that of spruce lignin, the isotherm deviates from linearity at higher solution concentration [0.64 mol m^{-3} (1.8 g l^{-1})]. As a result of changing adsorption mode, in the spruce lignin solution, the equilibrium adsorption constant K_{eq} decreases by an order of magnitude from 250 to 22. In the birch lignin solution, the rearrangement of the surface layer structure is accompanied by proportional decrease in K_{eq}, but at lower absolute values (from 71 to 7).

Another significant parameter characterizing the filling mechanism of adsorption layers is the area occupied by a macromolecule in the surface layer. We determined the areas occupied by molecules in an unfilled (S_m) and saturated (S_0) monomolecular layer using the Adamson procedure [6].

According to our estimates, the area occupied by

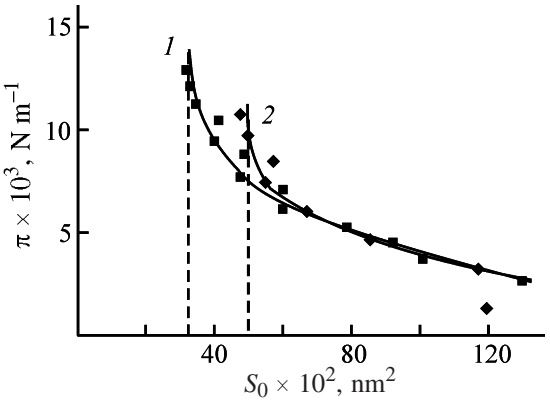

Fig. 5. Correlation between the surface area S_0 occupied by the lignin molecule at the solution–air interface (monomolecular filling) and a function of the surface pressure π: (*1*) spruce and (*2*) birch lignins.

spruce lignin molecules in the saturated monolayer (Fig. 5) is 49×10^{-2} nm^2. The birch lignin molecules occupy a smaller area (34×10^{-2} nm^2). These values are well comparable with those previously reported for lignosulfonates under condition of suppressed polyelectrolytic effect [2]. Finally, despite differences in the molecular weight and functional composition between spruce and birch lignosulfonates and kraft lignins, these compounds demonstrate similar trends in the surfactant properties and mechanisms of formation of adsorption layers at the solution–air interface.

CONCLUSIONS

(1) Kraft lignins can decrease the free energy at the solution–air interface, which allows considering them as surfactants.

(2) The time of establishment of the equilibrium at the solution–air interface in kraft lignin solutions is controlled by the solution concentration, ranging from 3 to 20 h, which should be taken into account in surface tension measurements. This time is longer in solutions of spruce lignin with higher molecular weight as compared to birch lignin.

(3) Formation of the adsorption layer in solutions of spruce and birch kraft lignins proceeds by the mechanism similar to that in lignosulfonate solutions, being controlled by the structure and functional composition of macromolecules.

Abstract—Hydrated nanosize oxides of the system TiO_2–Fe_2O_3–Al_2O_3–H_2O were tested as sorbents for recovery of phosphate and arsenate ions from aqueous solutions in a wide range of pH values. The optimal compositions of the sorbents were found, their ion-exchange functions were studied, and limiting sorption capacities were determined.

DOI: 10.1134/S1070427207110110

Recently, researchers' attention has been focused on a search for efficient, nontoxic, and inexpensive sorbents for water treatment to remove phosphorus and arsenic [1]. These include hydrated oxides of Group II–IV metals having high affinity for phosphates, arsenates, and arsenites. In particular, the following sorption activity series have been established [2]: $Mg(OH)_2 < Zn(OH)_2 < Cu(OH)_2 < Co(OH)_2 < Ni(OH)_2 < Al(OH)_3 < Cr(OH)_3 < Fe(OH)_3$; $MnO_2 < Nb_2O_5 < ZrO_2 < TiO_2$. Moreover, it has been noted that the sorption of arsenates by soils correlates with their content of aluminum and iron oxides [3].

Because hydrated aluminum, iron, and titanium oxides are the most promising as absorbents of phosphates and arsenic, the sorption properties of their natural and synthetic varieties have been extensively studied [2, 4–11]. These substances retain high selectivity at low concentrations of the elements being absorbed (0.3–300 mg l^{-1}) and high concentrations of the salt background. They show an ion-exchange function toward phosphates, arsenates, and arsenites. Therefore, they can be repeatedly used, which makes them attractive for treatment of not only wastewater, but also drinking and mineral water.

An efficient method for control over the sorption-selective properties of inorganic ion exchangers is synthesis of mixed or modified sorbents [12, 13]. In addition, the cost of the thus obtained ion exchangers can be lowered by using intermediates and process waste from chemical and metallurgical industries as raw materials.

The aim of this study was to examine the sorption characteristics of new composite materials of the composition $TiO_2 \cdot xFe_2O_3 \cdot yAl_2O_3 \cdot zH_2O$, synthesized from a titanyl sulfate solution produced in the process cycle of breakdown of the ilmenite concentrate at Sumykhimprom Open Joint-Stock Company.

EXPERIMENTAL

A 3.184 M process solution of $TiOSO_4$ with iron and sulfate ion concentrations of 0.57 and 5.79 M, respectively, served as a titanium-containing raw material for synthesis of sorbents. The solution was diluted with water to a titanium concentration of 1 M and, when necessary, enriched with aluminum chloride. To this solution we added with vigorous stirring an equivalent, for complete precipitation of hydroxides, amount of a 3 M NH_4OH solution. The resulting gel was poured onto a filter paper and dried in air at room temperature to complete solidification. Further, it was washed for a long time with distilled water to remove sulfates, chlorides, and ammonium ions, with the presence of SO_4^{2-} and Cl^- ions in the filtrates monitored using qualitative reactions with barium and silver ions. Then it was dried in air at room temperature, ground, and sieved to select the 0.25–0.5-mm fraction.

The ion-exchange capacity and chemical resistance of the sorbents, as well as the sorption of phosphate and arsenate ions, were studied by the static method. To 20 ml of a solution we added 200 mg of a sorbent,

the system was equilibrated under shaking for 4 h, the precipitate formed after 72 h of sedimentation was filtered off, and the measurements were made. The pH-potentiometric studies were carried out on an I-160M device with NaOH and HNO_3 solutions, and a 0.1 M sodium nitrate as supporting electrolyte. Solutions of $Na_2HPO_4 \cdot 2H_2O$ and $Na_2HAsO_4 \cdot 7H_2O$ were used in sorption studies. When necessary, these solutions were acidified with phosphoric or hydrochloric acid. The sorption capacities A (mmol g^{-1}) were calculated by the formula

$$A = 10^{-3}(c_0 - c_{eq})V/m,$$

where c_0 and c_{eq} are the sorbate concentrations in the starting solution and equilibrium solution after sorption (mM); V, solution volume (ml); and m, sorbent mass (g).

All the analyses (iron as *o*-phenanthroline complex and aluminum as aluminon, phosphate as vanadium phosphomolybdate, and arsenate as molybdate complexes) were performed by photocolorimetry on a KFK-2 photocolorimeter. The maximum relative error of the A values presented does not exceed 15%. The sorbent density was found by pycnometry (with water as pycnometric liquid). The specific surface area of the sorbents and the pore radius distribution were determined with a Quantachrom NOVA 2200e instrument by the method of nitrogen and argon adsorption–desorption. IR spectra were obtained on a Specord M-80 spectrophotometer. Samples for the spectral range 4000–400 cm^{-1} were prepared as KBr pellets with a 1.9-mg portion of a substance under study, and those for the far-IR range (>200 cm^{-1}), as pellets with CsI and a 0.45-g portion of a substance.

An increase in the aluminum oxide content of the sorbents positively affects their absorbing capacity for phosphates and arsenates in both alkaline and acid media (Tables 1, 2). The sorption in the acid medium is accompanied by alkalization of a solution, and that in the alkaline medium, by its acidification. It can be seen that the values of A in the acid medium exceed those in the alkaline medium.

It is known that transition of substances to the nanosize state occurs when the size of their particles becomes 100 nm and less [14]. A calculation in accordance with [15] shows that crushing of particles of titanium, iron, and aluminum oxides to a size of 100 nm yields specific surface areas not exceeding 15 $m^2\ g^{-1}$. The oxides obtained in this study have specific surface areas exceeding 400 $m^2\ g^{-1}$. As the content of aluminum oxide increases, the specific surface area of the sorbents grows.

On the basis of these data, the sorbent with Ti : Fe : Al = 1 : 0.18 : 0.67 was chosen for a detailed study. It has a density of 1.901 g cm^{-3} and a porous structure with a minimum pore radius of about 18 Å, i.e., it is a mesoporous material (Fig. 1a). The main weight loss (40.1%) upon heating occurs at 200°C. The total weight loss is 42.3% (800°C). This corresponds to sorbent compositions $TiO_2 \cdot 0.09Fe_2O_3 \cdot 0.34Al_2O_3 \cdot 5.22H_2O$ (**1**) and $Ti(OH)_4 \cdot 0.18FeO(OH) \cdot 0.67AlO(OH) \cdot 2.79H_2O$ (**2**).

Table 2. Static sorption capacity of composites of the system TiO_2–Fe_2O_3–Al_2O_3–H_2O for the arsenate ion (c_0 = 50 mM)

Ti : Fe : Al ratio	pH_{in}	pH_{eq}	A, mmol g^{-1}
1 : 0.18 : 0.25	8.7	7.9	4.2
	2.8	4.0	4.4
1 : 0.18 : 0.67	8.7	8.4	4.2
	2.8	4.5	4.4

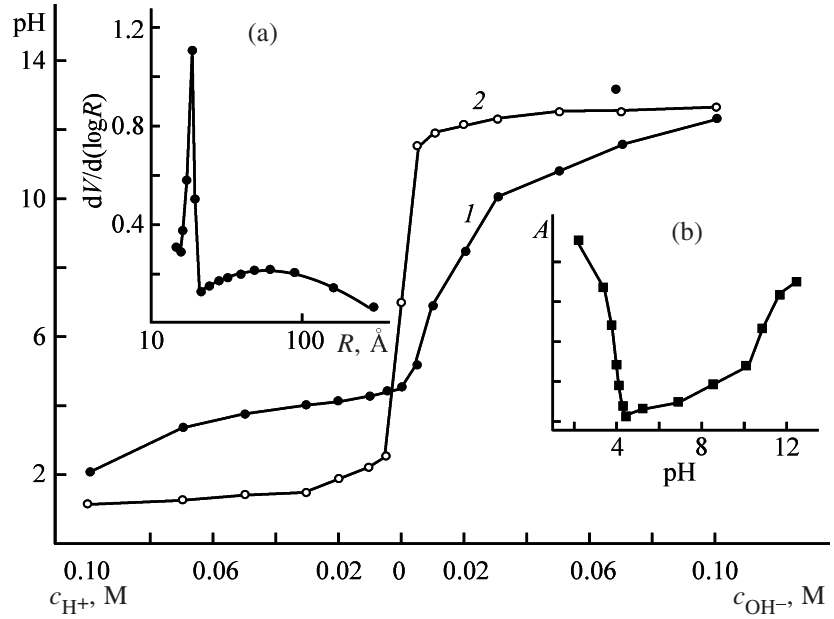

Fig. 1. (a) Pore distribution with respect to radii R for a sorbent of composition $Ti(OH)_4 \cdot 0.18FeO(OH) \cdot 0.67AlO(OH) \cdot 2.79H_2O$; variation of the pH of HNO_3 and NaOH solutions, with 0.1 N $NaNO_3$ as supporting electrolyte, (*1*) with and (*2*) without a sorbent; and (b) sorption capacity A vs. pH. [dV/d(log R)] Pore radius distribution, (c_{H^+}) concentration of H^+, and (c_{OH^-}) concentration of OH^-.

The results of a potentiometric titration suggest that the substance obtained is a typical ampholyte (Fig. 1b). Its ion-exchange capacity in acid and alkaline media is virtually the same, 7–9 mmol g^{-1} of exchangeable protons (Fig. 1c) or more than one third of OH groups contained in compound **2** (1.55–2 out of 4.85). The pH value of the sorbent suspension in distilled water (sorbent to water mass ratio 1 : 40) is 4.69. The sorbent shows a high hydrolytic stability in the entire pH range studied. Only in strongly acidic media (pH < 1.7), iron and aluminum start to be leached-out from the sorbent (0.0035 and 2.07%, respectively).

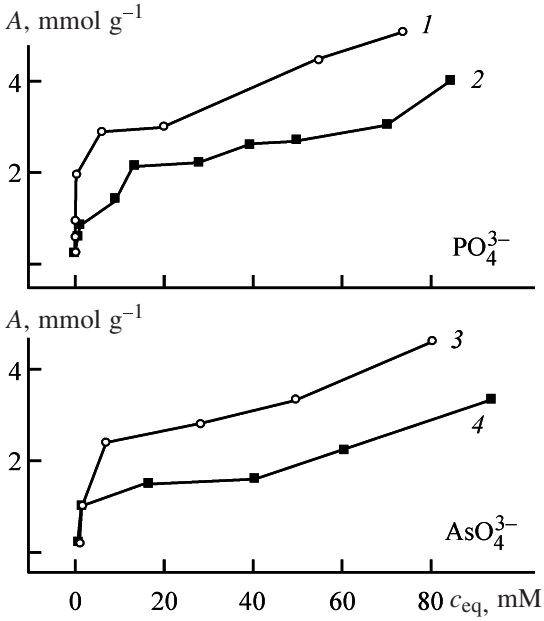

Fig. 2. Isotherms of sorption of phosphate and arsenate ions by a sorbent of composition $Ti(OH)_4 \cdot 0.18FeO(OH) \cdot 0.67AlO(OH) \cdot 2.79H_2O$. ($A$) Sorption capacity and (c_{eq}) sorbate concentration in the equilibrium solution after sorption. pH: (*1*) 2.2–3.4, (*2*) 8.2–9.0, (*3*) 2.5–3.6, and (*4*) 8.2–9.3.

Isotherms of sorption of phosphate and arsenate ions by the material under study from solutions with the maximum initial concentration of these ions equal to 125 mM are shown in Fig. 2. Depending on the pH of the medium, the maximum sorption capacities are 4.0–5.1 mmol g^{-1} for phosphate ions and 3.3–4.6 mmol g^{-1} for arsenate ions; in the concentration range 0.05–0.5 mM, phosphate ions are completely recovered from solutions. This circumstance places the material obtained among the best of the known sorbents for phosphate and arsenate ions [1]. Noteworthy is the fact that the sorption isotherms do not level-off. Presumably, this behavior is specific to materials with sorption centers of more than one type [13].

The understanding of the sorption process can be strongly aided by IR spectroscopy. For example, analysis of IR spectra in the range of vibrations of P–O bonds suggests that phosphate ions sorbed on oxides of iron [4, 10], titanium [8], and aluminum [7]

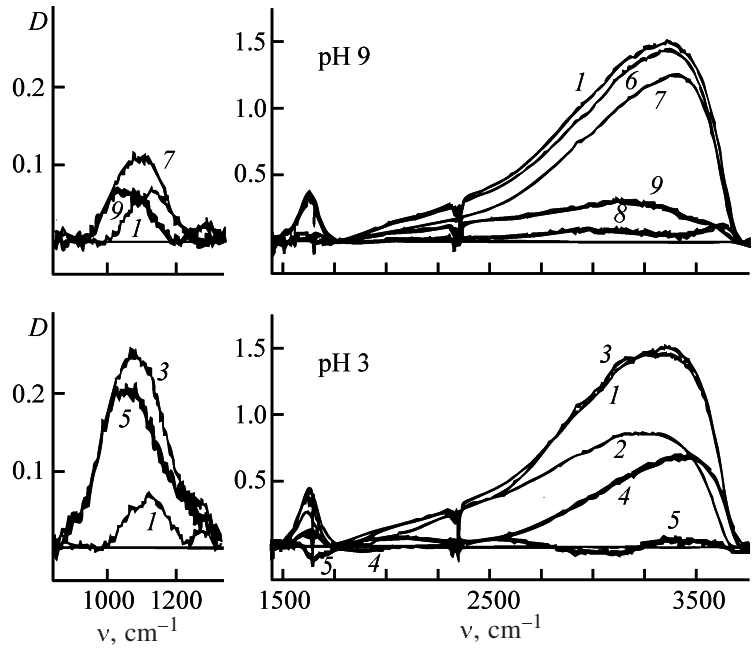

Fig. 3. IR absorption spectra of a sorbent of composition $Ti(OH)_4 \cdot 0.18FeO(OH) \cdot 0.67AlO(OH) \cdot 2.79H_2O$ (*1*) before sorption, (*2*) after treatment with an acid, (*3*) after sorption of the phosphate ion from an acid solution, (*6*) after treatment with an alkali, and (*7*) after sorption of the phosphate ion from an alkaline solution. (*D*) Optical density and (ν) wavenumber. Difference of the spectra: (*4*) 1 and 2, (*5*) 1 and 3, (*8*) 1 and 3, and (*9*) 1 and 7.

are bound to the surface in the mono- and bidentate fashion. As is known, in accordance with the dissociation equilibrium, phosphate ions are predominantly in the doubly charged form (HPO_4^{2-} content 97–98%) at pH ~9 and are singly charged (about 99% $H_2PO_4^-$) in an acid medium (pH ~3) [16]. Nevertheless, the spectra indicate that HPO_4^{2-} ions are present on the sorbent surface in acid media, and PO_4^{3-} ions, in alkaline media.

The data in Fig. 3 are consistent with these statements. The bands corresponding to the ν_3 vibration (F_2) of the PO_4^{3-} ion sorbed from acid (curve *5*) and alkaline solutions (curve *9*) are split, which shows that its symmetry is lowered via protonation and(or) coordination to the sorbent surface.

These conclusions can be refined by comparing the spectra in the range of stretching (ν_{OH}) and bending (δ_{OH}) vibration of the O–H bonds of the sorbent and water present on its surface before sorption, after treatment with an acid (alkali), and after sorption. The acid treatment leads to a substantial decrease in the absorption in the ν_3 and δ_{OH} ranges (curve *4*), which points to neutralization of OH groups of the sorbent and a considerable decease in the amount of surface water. In acid solutions, the absorption in the δ_{OH} range decreases after sorption of phosphate ions, whereas that in the ν_{OH} range remains virtually unchanged (curve *5*). This means that new OH groups appear on the surface through sorption of $H_2PO_4^-$ or HPO_4^{2-} ions (ν_{OH} bands of hydrophosphates have low intensity [17]). The alkaline treatment leads to a slight decrease in the absorption in the ν_{OH} and δ_{OH} range (curve *8*), which possibly indicates that the protons of OH groups are replaced with sodium ions. The sorption of the phosphate in alkaline solutions results in a considerably stronger decrease in the absorption in the ν_{OH} and δ_{OH} range (curve *9*) because of the substitution of OH groups of the sorbent by PO_4^{3-} ions containing no protons.

CONCLUSIONS

(1) Among hydrated oxides of the system TiO_2–Fe_2O_3–Al_2O_3–H_2O, the best absorbing capacity for phosphate and arsenate ions is exhibited by nanosize mesoporous ampholyte of the composition $Ti(OH)_4 \cdot 0.18FeO(OH) \cdot 0.67AlO(OH) \cdot 2.79H_2O$, which contains about 9 mmol g^{-1} of exchangeable protons.

(2) Depending on the pH of the medium, the maximum sorption capacities of the sorbents with the optimal composition are 4.0–5.1 mmol g^{-1} for phosphate ions and 3.3–4.6 mmol g^{-1} for arsenate ions, with complete recovery of phosphate ions from solutions in the concentration range 0.05–0.5 mM.

(3) Phosphates are sorbed on the sorbents under study as $H_2PO_4^-$ or HPO_4^{2-} ions from acidic solutions

and as PO_4^{3-} ions with lowered symmetry alkaline solutions.

Abstract—Synthesis conditions of HNa forms (with the residual content of Na_2O not exceeding 0.2 wt %) of high-silica (SiO_2/Al_2O_3 = 5.6–6.0) faujasites were found.

DOI: 10.1134/S1070427207110122

HNa forms of synthetic faujasites (zeolites of X and Y types) with different degrees of exchange of Na^+ cations for H^+ (α_{Na}) exhibit catalytic activity in acid–base reactions [1]. For example, the zeolite of the Y type with $\alpha_{Na} \geq 90\%$ is used as an active component of modern catalysts for cracking of hydrocarbons [2, 3]. The HNa forms of faujasites are most frequently synthesized by substitution of Na^+ cations with NH_4^+, with the subsequent thermal decomposition of NH_4Na forms in the temperature range 220–600°C [4–7]. The ion exchange of Na^+ for NH_4^+ in faujasites with the ratio $SiO_2/Al_2O_3 \leq 5$ was described in [4–11].

It was shown [6] that, upon a single ion-exchange treatment, the value of α_{Na} for the $Y_{0.5}$ zeolite (the subscript shows the silica ratio of the zeolite) does not exceed 65% and can be raised to 95% only upon nine successive treatments in a 0.1 M NH_4NO_3 solution. Raising the concentration of the ion-exchange solution of NH_4Cl from 1.0 to 1.5 M when performing five successive ion-exchange treatments [8] results in that α_{Na} increases from 73.1 to 93.0% and from 70.1 to 90.3% for $X_{2.53}$ and $Y_{4.25}$ zeolites, respectively.

It is known that, the higher the silica ratio, the lower the ion-exchange capacity of a faujasite. This is due to the lower charge of the crystalline skeleton of the zeolite. For Na^+ cations localized within small voids of the crystal lattice of faujasite to migrate into large voids, it is necessary to calcine the zeolite at 450–540°C between ion-exchange runs. However, a thermal treatment of this kind may lead to partial amorphization of the crystalline skeleton of the zeolite [6]. The thermal and high-temperature steam stability of the crystal structure of a zeolite are determined by its silica ratio, nature of the exchange cation, and presence of defects in the crystal structure. It has been found that the higher the silica ratio of a faujasite, the higher its thermal stability [4]. This ratio is commonly raised by special treatments. These treatments lead to partial dealumination of the crystal lattice of the faujasite, which may give rise to lattice defects [6, 12–16]. A method has been suggested for direct synthesis of high-silica zeolites of the Y type [17, 18]. This method yields faujasites in the sodium form, with a silica ratio of 5.6–7.2. The pattern of the deep exchange of Na^+ for NH_4^+ in these faujasites has not been described in the literature.

The aim of this study was to develop a technique for synthesis of HNa form of faujasites of this kind, with α_{Na} exceeding 98%, by ion exchange of Na^+ for NH_4^+ with intermediate thermal treatment and to examine the effect of the exchange conditions on the crystal structure of the zeolite.

EXPERIMENTAL

The study was performed with samples of $NaY_{5.6}$ and $NaY_{6.0}$ zeolites synthesized by the procedure described in [17, 18]. For comparison, industrial $NaY_{5.1}$ and $NaX_{2.5}$ zeolites manufactured by Salavatnefteorgsintez Open Joint-Stock Company were subjected to decationation. The ion exchange was carried out in a batch isothermal reactor, with vigorous agitation of a suspension of a powdered faujasite in an aqueous solution of NH_4NO_3. The use of highly dispersed zeolite samples and vigorous agitation minimized diffusion hindrance to exchange. The cation exchange at high temperatures was carried out in a stainless steel autoclave. Weighed portions of 20 g were used in all the experiments. The chemical composition of the starting zeolites is listed in Table 1.

Table 1. Chemical composition of zeolites with different silica ratios

Zeolite	Content, wt %		
	Na_2O	SiO_2	Al_2O_3
$NaX_{2.5}$	21.7	46.6	31.7
$NaY_{5.1}$	12.0	64.6	22.7
$NaY_{5.6}$	11.4	66.9	21.3
$NaY_{6.0}$	10.9	68.2	20.6

Table 2. Effect of temperature on α_{Na} in synthetic faujasites. G = 1.5, τ = 120 min

T, °C	α_{Na}, %			
	$X_{2.5}$	$Y_{5.1}$	$Y_{5.6}$	$Y_{6.0}$
20	60	52	50	50
40	65	56	55	55
70	75	65	65	65
180	78	70	65	65

The following parameters were varied in the course of the experiments: exchange temperature (T = 20–180°C), molar ratio between NH_4^+ cations in a solution to Na^+ in a zeolite (G = 0.25–20), pH of the medium (5.5–8.0), and exchange duration (τ = 0.4–1200 h). In some of the experiments, the exchange was performed with ultrasonic treatment (UT) of a zeolite suspension (frequency 22 kHz, power 30 W, temperature 45–70°C, duration 0.4–1 h).

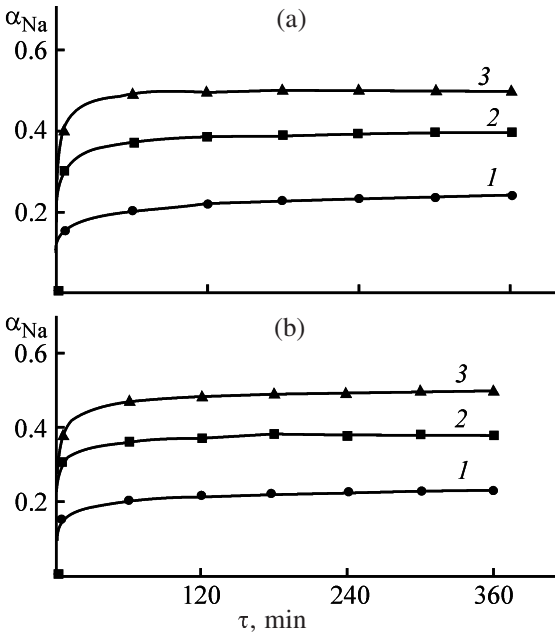

Fig. 1. Kinetic curves of ion exchange of Na^+ for NH_4^+ in powder-like NaY zeolites with various silica ratios M at 20°C. (α) Degree of ion exchange and (τ) time. M: (a) 5.1 and (b) 6.0. G: (*1*) 0.25, (*2*) 0.62, and (*3*) 1.5.

The exchange kinetics was studied by monitoring the variation of the chemical composition of the liquid and solid phases by flame photometry [19]. The phase composition of the zeolites was found by X-ray phase analysis (XPA) on a Philips PW 1800 automated diffractometer by the Debye–Scherrer (powder) method. The measurement conditions were as follows: $\theta/2\theta$ scanning; holder rotation at 1 rps; anode material, copper; scanning range 5°–55°/2θ; scanning step 0.05°; exposure in a step, 2 s; anode voltage and current, 40 kV and 30 mA, respectively. The X-ray diffraction patterns were identified using the known diffraction data [10].

The limiting adsorption capacity of the faujasites for water vapor was determined at 20°C and P/P_s = 0.5 by the desiccator method [20].

Figure 1 shows dependences of α_{Na} in samples of Y zeolites with different silica ratios on the duration of exchange at 20°C. It can be seen that the variation rate of α_{Na} is at a maximum in the first 15 min. During this period of time, the exchange of Na^+ in the zeolite for NH_4^+ from solution occurs at the highest rate, these concentrations rapidly decrease and, simultaneously, the concentrations of NH_4^+ in the zeolite and Na^+ in solution increase. After the initial period, the exchange rate markedly decreases and α_{Na} tends to a certain maximum value characteristic of specific exchange conditions (T, G, pH). This trend in variation of the concentrations of Na^+ and NH_4^+ indicates that the exchange reaction is reversible. Therefore, it is necessary to change the exchange conditions in order to raise α_{Na}.

It was found that, on raising G from 0.25 (deficiency of NH_4^+ cations) to 1.5 (excess of NH_4^+ cations), the degree of Na^+ exchange for NH_4^+ increases from 20 to 52% (Fig. 1, curves *1–3*). At the same time, raising G further, to 20, has no noticeable effect on α_{Na}. All other exchange conditions being the same, an increase in temperature from 45 to 180°C (Table 2) leads to an only slight rise in the degree of exchange, α_{Na}. In exchange of Na^+ for cations of rare-earth elements (REE) in Y zeolite, elevating the process temperature to 180°C leads to virtually complete replacement of Na^+ with REE cations [11]. However, raising the temperature from 70 to 80°C in exchange of Na^+ for NH_4^+ does not noticeably change α_{Na} (Table 2).

The authors of [6, 8] could raise α_{Na} in exchange of Na^+ for NH_4^+ in synthetic faujasite samples

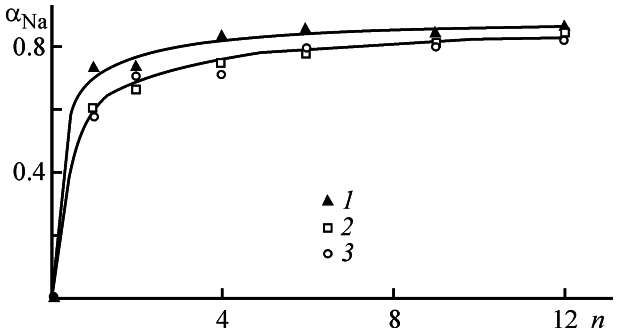

Fig. 2. Degree of ion exchange, α_{Na}, vs. the number n of treatments performed. G = 1.5, T = 70°C, τ = 120 min. (*1*) NaX (M = 2.5), (*2*) NaY (M = 5.1), and (*3*) NaY (M = 6.0).

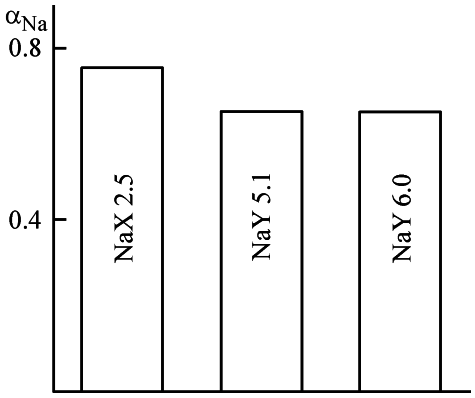

Fig. 3. Degree of ion exchange, α_{Na}, in faujasites after 1200 h of treatment. T = 20°C, G = 1.5.

by carrying out several exchanges and making these exchanges longer. Similar approaches were used in this study. For this purpose, the exchange solution containing Na^+ and NH_4^+ cations was discharged after a constant α_{Na} was reached and a repeated exchange was performed with the same amount of a NH_4NO_3 solution. It was found that even after 12 exchanges (Fig. 2) and total exchange duration of 50 days (Fig. 3), α_{Na} cannot be substantially raised. An ultrasonic treatment of a faujasite suspension in the exchange solution does not lead to any noticeable increase in α_{Na}, either (Table 3).

Thus, it was found that, under the conditions of Na^+ exchange for NH_4^+ in samples of synthetic faujasites with different silica ratios, α_{Na} can be raised only to values not exceeding 78 and 65% for X and Y zeolites, respectively. This is due to the fact that part of Na^+ cations (16 per unit cell), contained in hexagonal prisms, sodalite cells of the crystal lattice of faujasites, are difficultly accessible to exchange. The diameter of inlet windows leading to these cations is 2.5 Å and, consequently, they are inaccessible to NH_4^+ ions whose diameter is 2.86 Å [6]. In addition, as the zeolite silica ratio increases, repulsion between ammonium cations localized in the zeolite structure and present in the ion-exchange solutions becomes stronger, which hinders further migration of NH_4^+. A thermal treatment after an ion exchange is accompanied by thermal decomposition of the introduced NH_4^+ ions and migration of Na^+ cations from small into large voids, i.e., to places accessible to exchange. This allows Na^+ cations to enter into exchange in subsequent treatment of the zeolite with a NH_4NO_3 solution [6, 8], and, therefore, the experimental samples were subjected, before a repeated exchange, to thermal treatment at 540°C for 4 h, as described in [3]. The results obtained are listed in Table 4.

A triple ion exchange with two intermediate calcinations yielded HNa forms of faujasites with α_{Na} not lower than 98.0%. A study of the phase composition of the faujasite samples obtained demonstrated that, as α_{Na} increases from 74 to 99% for $X_{2.5}$ zeolite, there occurs partial amorphization from 15 to 70% of the crystalline skeleton. As α_{Na} increases from 65 to 99% for $Y_{5.1}$ zeolite, the degree of amorphization increases from 6 to 60%. The crystal structure of high-silica $Y_{5.6}$ and $Y_{6.0}$ zeolites is stable and does not disintegrate even when α_{Na} increases from 65 to 98% (Table 4). The results obtained using the XPA method were later confirmed by adsorption measurements (Table 4).

CONCLUSIONS

(1) On varying temperature, concentration ratio of the exchange cations in the zeolite and in solution, and duration of ion-exchange treatments, the replacement of Na^+ with NH_4^+ in zeolites of the Y type with a silica ratio of 5.1–6.0 is possible to an extent not exceeding 70%.

(2) To obtain HNa forms of faujasites with a residual content of Na_2O not exceeding 0.1 wt %, it is necessary to perform a triple ion exchange of Na^+ for NH_4^+ with two intermediate thermal treatments at 540°C for 4 h.

(3) Ion exchange with an intermediate thermal treatment at 540°C leads to partial amorphization of faujasites with a silica ratio of 5.1 and lower, which increases to 70% for $X_{2.5}$ zeolite and 60% for $Y_{5.1}$. In zeolites of the Y type with a silica ratio of 5.6 and more, the crystalline skeleton does not disintegrate.

Abstract—Adsorption-structural and chemisorption properties of carbonate tripolites were studied in relation to their chemical and mineral composition and conditions of sorption of heavy and nonferrous metal ions. Prospects for application of carbonate tripolites as chemisorbents were considered.

DOI: 10.1134/S1070427207110134

The innovation policy of the state in the field of rational nature management is aimed to involve new, presently unused local types of mineral resources into material production. The most promising in this regard are carbonate-siliceous and siliceous deposits of the Coniacian stage of the Cretaceous system, tripolite and opoka, which widely occur in the eastern part of Mogilev oblast. These siliceous rock with sand-clayey or carbonate clayey admixtures are valuable raw materials whose main application area is manufacture of cement. In addition, they are used as binders, abrasives, filtering materials, and sorbents [1].

Studies of specific features of the mineral composition and physicochemical properties of carbonate tripolites from the Stal'noe deposit (Republic of Belarus), carried out at the Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, and Belarussian Geological Exploration Research Institute, Republican Unitary Enterprise, indicate that there are serious prospects for use of carbonate tripolites as adsorption raw materials. Carbonate tripolites have favorable sanitary-hygienic parameters and exhibit high biological activity; they contain no toxic impurities. The polycomponent phase composition of the rock is represented by a finely dispersed mixture of amorphous silica, zeolite, montmorillonite clay, and calcium carbonate, with each of the mineral components having individual sorption properties.

This paper summarizes the results of studies of the chemisorption capacity of carbonate tripolites for ions of heavy and nonferrous metals Pb(II), Cr(III), Cu(II), Zn(II), and Fe(III) and considers prospects for use of carbonate tripolites.

EXPERIMENTAL

As demonstrated by the results of detailed surveys, the tripolite resources of the Stal'noe deposit are characterized by rather strong variability of the composition of the main rock-forming components (Table 1).

On the basis of statistical processing of data on the chemical composition of 60 group samples taken from wells rather uniformly distributed over the deposit area, four representative laboratory samples of tripolite were prepared. These samples reflect the main types (classes) of ores of the deposit, their chemical composition is represented in Table 2.

The mineral composition of tripolites was determined by quantitative X-ray phase analysis (XPA) on a DRF-2 diffractometer (CuK_α radiation), and the

chemical composition, by X-ray fluorescence analysis on an SRF instrument. An analysis for carbon was made on a CHN analyzer.

The adsorption-structural parameters of the samples were calculated from adsorption isotherms of benzene and carbon tetrachloride, measured in a vacuum adsorption installation with a McBain–Bakr spring balance at 20°C.

The chemisorption properties of tripolites with varied content of $CaCO_3$ for Pb(II), Cr(III), Cu(II), Zn(II), and Fe(III) ions were determined under static conditions at 15–20°C from 0.001–0.1 N nitrate solutions. The sorbent (0.2 g, 0.09–0.25-mm fraction) was poured over with 25 ml of a metal salt solution, and the mixture was kept for 24 h with intermittent agitation. Then, the solution was separated from the solid phase. In the filtered solution, the residual content of metal ions being adsorbed was determined by complexometric titration or atomic-absorption spectroscopy (AAS-3 spectrometer). In order to obtain information about the mechanism of absorption of metal ions by tripolites, the solid phase was subjected to XPA after the sorption.

The X-ray diffraction patterns of the tripolites under study, obtained from various wells at the Stal'noe deposit, are qualitatively identical and show the same reflections, with only the relative intensities of peaks varying in accordance with quantitative changes in the mineral composition of a rock being studied. A typical X-ray diffraction pattern of a carbonate tripolite is shown in Fig. 1.

Table 2. Chemical composition of carbonate tripolite samples from the Stal'noe deposit

Sample no.	Content of indicated oxides, %				
	$SiO_{2(tot)}$	CaO	Al_2O_3	$Fe_2O_3 + FeO$	CO_2
1	44.60	24.22	7.02	2.32	15.65
2	49.12	21.72	6.81	2.18	18.74
3	57.40	17.93	6.10	1.91	16.31
4	73.66	9.55	5.29	1.78	5.48

As can be seen in Fig. 1, the phase composition of the tripolites is represented by four basic rock-forming minerals: opal–cristobalite, clinoptilolite, montmorillonite, and calcite, and the aleurite material, by quartz, chlorite, and mica.

The adsorption-structural parameters of tripolites directly depend on their mineralogical and chemical composition.

The total content of SiO_2 is the main parameter reflecting and determining the quality of natural adsorbent raw materials. The amount of SiO_2 in tripolites is determined by the total contribution of weakly crystallized free silica of opal–cristobalite, X-ray amorphous biogenic silica, silica of a finely dispersed material (quartz, feldspar, mica, clay), and silica of zeolites.

The adsorption isotherms of benzene and carbon tetrachloride by tripolites with varied content of silica and calcite are shown in Fig. 2, and the specific surface areas S_{sp} and limiting sorption volumes V_s of the samples under study are listed in Table 3.

All the adsorption isotherms are S-shaped and show capillary-condensation hysteresis, which indicates that the tripolites are structurally inhomogeneous. Under pressures close to saturation, the sorption branches of the isotherms steeply ascend, whence follows that the main amount of the adsorbate is absorbed in intermediate pores. The higher the SiO_2

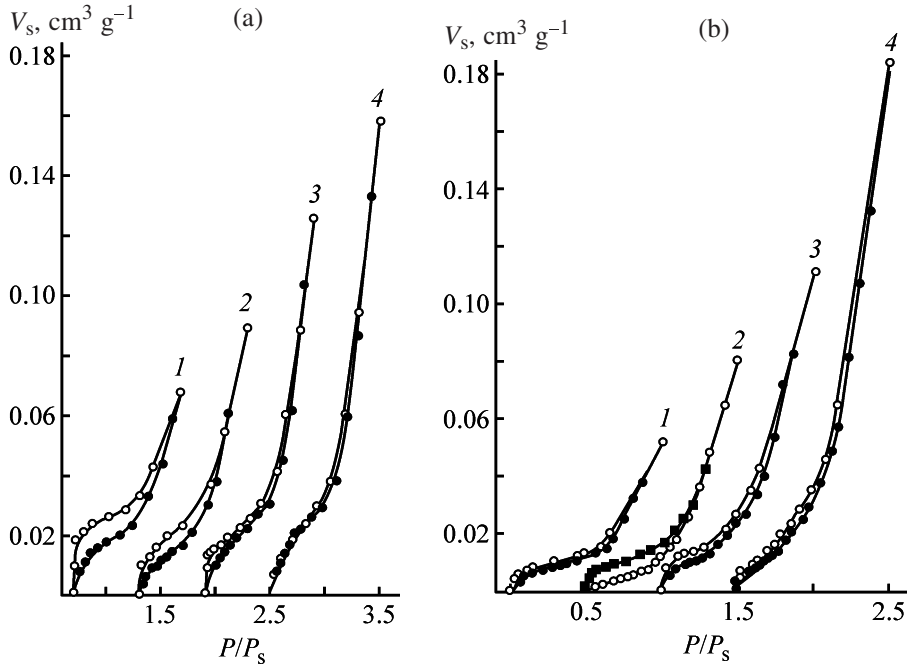

Fig. 2. Adsorption isotherms of (a) benzene and (b) carbon tetrachloride vapors by tripolites with varied silica content. (V_s) Limiting sorption volume and (P/P_s) relative pressure. Silica content, wt %: (*1*) 1, (*2*) 2, (*3*) 3, and (*4*) 4.

content of a tripolite, the larger its adsorption-structural parameters: specific surface area and limiting sorption pore volume.

As the carbonate component of the samples increases, the adsorption-structural parameters of the tripolites become worse, and the carbonate tripolites are markedly inferior to "pure" tripolites and opokas as porous sorbents. However, it has been shown [2–5] that carbonate tripolites show a substantial chemisorption capacity for ions of heavy and nonferrous metals, with the chemisorption capacity of a rock the higher, the larger the $CaCO_3$ content of the tripolite.

Figure 3 shows absorption curves of Pb(II), Cr(III), Cu(II), Zn(II), and Fe(III) ions by tripolites with varied content of calcium carbonate. The maximum absorption of lead ions for tripolites containing 37 and 43% $CaCO_3$ is 5.5 and 9.01 mg-equiv g^{-1}, respectively; for the sample containing no $CaCO_3$, this value does not exceed 1 mg-equiv g^{-1}.

A study of chemisorption products by XPA and chemical analysis demonstrated that absorption of ions of heavy and nonferrous metals is accompanied by formation of amorphous or crystalline carbonates, hydroxo carbonates, and, only in some cases, metal hydroxides.

The absorption of metal ions by carbonate-containing tripolites can be represented as a set of main reactions occurring in the system constituted by $CaCO_{3(cryst)}$ and a $M(NO_3)_n$ solution.

(1) Reactions at the surface of a solid calcium carbonate to give less soluble M(II) carbonates:

$$CaCO_{3(cryst)} + M^{n+} \longrightarrow MCO_{3(s)} + Ca^{2+}.$$

(2) Formation at the surface or nearby of poorly soluble hydroxo carbonates and hydroxides of polycharged metals:

$$CaCO_{3(cryst)} + M^{n+} + HOH \rightarrow [M(OH)_{n(s)}$$
$$\text{and/or } M_x(CO_3)_y(OH)_{z(s)}] + Ca^{2+} + H^+,$$

where n is the degree of M oxidation, $nx = 2y + z$.

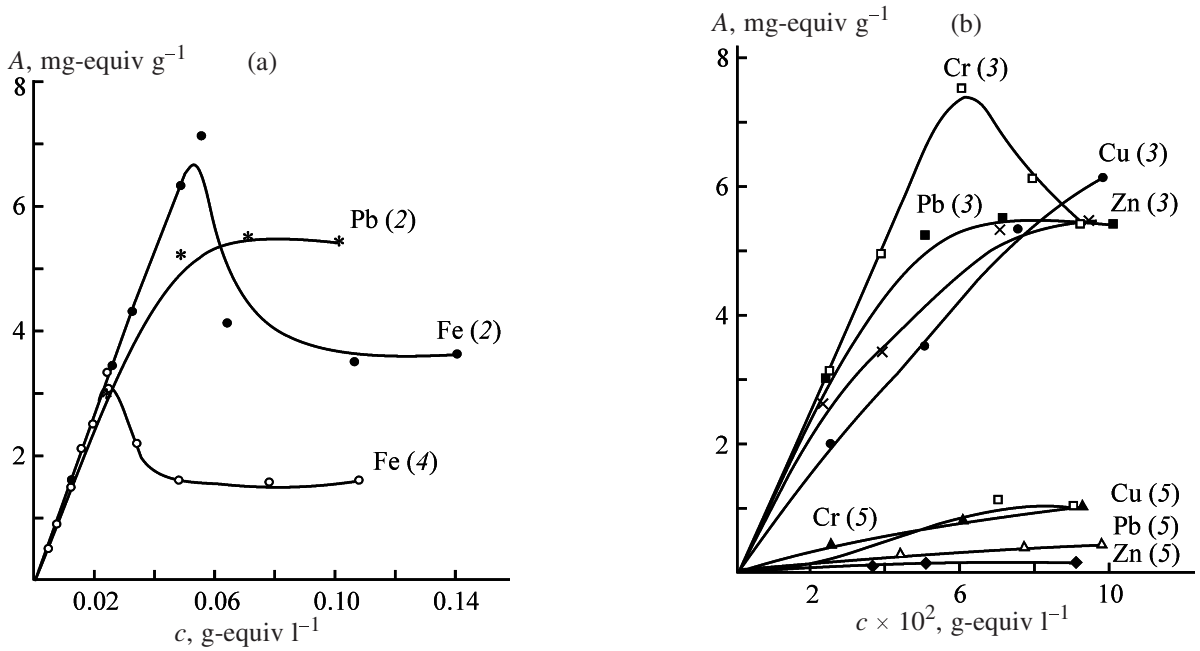

Fig. 3. Curves of absorption A of Pb(II), Cr(III), Cu(II), Zn(II), and Fe(III) ions by natural carbonate-containing tripolites. (c) Initial concentration of $M(NO_3)_n$ solutions. $CaCO_3$ content of tripolite sample, wt %: (*2*) 43, (*3*) 37, (*4*) 13, and (*5*) 0.

Depending on the conditions, the chemisorption process can occur by different mechanism to give different products. The anomalous shape of the chemisorption curves in Fig. 3 indicates that the chemical processes occurring in the system change.

Analysis of the previously obtained results [2–5] suggests that the most complete removal of metal ions from solutions can be only achieved in those case when the equilibrium solution has pH values necessary for complete precipitation of multiply charged metal ions in the form of carbonates, hydroxo carbonates, or hydroxides.

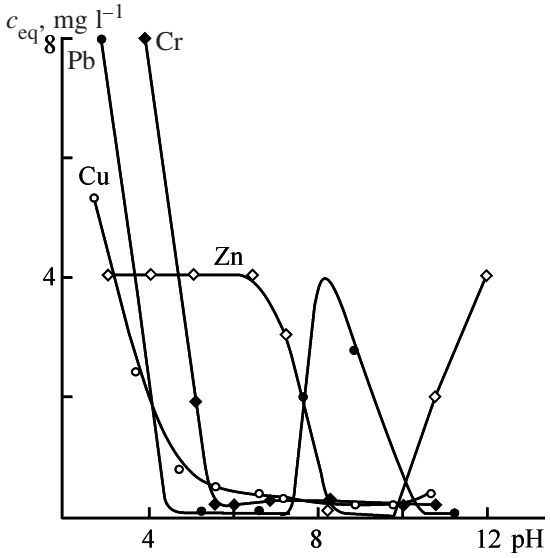

Fig. 4. Equilibrium concentration of Pb(II), Cu(II), Zn(II) and Cr(III) in solution after absorption c_{eq} as a function of equilibrium pH.

The maximum recovery of copper, chromium, and zinc ions is observed at pH 7–10, >5.5, and 8.5–9.5, respectively. At these pH values, the equilibrium concentration (concentration after sorption) of Cu^{2+}, Zn^{2+}, and Cr^{3+} ions does not exceed 0.2–0.3 mg l^{-1}. The dependence of the equilibrium concentration of metal ions on the solution pH is shown in Fig. 4.

It can be seen that the $c_{eq}^{M^{n+}}$–pH curve has for lead ions, in contrast to other ions, two minima, at pH 5–7 and pH > 10.5. The existence of two minima in the $c_{eq}^{Pb^{2+}}$–pH dependence indicates that, in absorption of Pb^{2+} ions by tripolite, compounds (or their modifications) with different solubilities are formed at different pH values.

As demonstrated by the XPA results, the forming products are X-ray amorphous substances in the pH range 7.0–10.5, i.e., near the peak in the $c_{eq}^{Pb^{2+}}$–pH curve. At pH > 10.5, the X-ray diffraction pattern shows that crystalline products are formed: a mixture of cerussite and lead(II) hydroxo carbonate of the composition $Pb_3(OH)_2(CO_3)_2$. Amorphous substances are, as a rule, more soluble than crystalline substances.

According to the XPA data, zinc ions are absorbed

by tripolite from solution as $Zn_2(OH)_2CO_3$ up to pH ~7, whereas at pH > 7, the amorphous phase, $Zn(OH)_2$, is formed.

After sorption of Cu^{2+}, the X-ray diffraction pattern of carbonate tripolite starts to show reflections of copper hydroxo nitrate of composition $Cu_2(OH)_3NO_3$. Its formation in interaction of calcium carbonate with Cu^{2+} ions indicates that the interaction of metal ions with solid carbonates is governed not only by the nature of a cation, its concentration, and solution pH, but also by the nature of anions present in solution.

A particular place among ions of nonferrous metals is occupied by iron(III). Underground natural sources of drinking and technical water contain admixtures of mineral substances, of which iron(III) is the most widely occurring. Its presence in water gives rise to problems in operation of various kinds of equipment for housing, public utilities, and industries, and, therefore, preliminary measures should be taken for its removal in conformity with the existing regulations. As can be seen from the data obtained, carbonate tripolites can be successfully used for these purposes. However, as shown by the study, the degree of purification to remove iron(III) approaches 100% only in those cases when the pH of a solution after its contact with tripolite exceeds 7 [4].

The absorption efficiency of multiply charged metal ions from aqueous solutions by natural carbonate-containing tripolites is determined by acid–base equilibria in the system under consideration and, in particular, by the equilibrium pH value. This value is, in turn, a function of the pH of the starting solution and of the ratio between the tripolite mass and the solution volume, i.e., bath ratio M.

To find the relationship between these parameters, acid–base equilibria were studied in the tripolite–water system under static conditions in a wide range of pH values and s : l ratios. In doing so, the experimental procedure was similar to that in a study of the absorption of metal ions, with the only difference that the weighed portion of a sample was poured over by distilled water with different pH values adjusted with HNO_3 or NaOH solutions, rather than by a solution of a metal salt. The results obtained are shown in Fig. 5 as a set of pH_{eq}–$1/M$ curves for solutions with different pH_0 values.

A mathematical processing of a set of five equations determining the pH_{eq}–$1/M$ dependence at different pH values, described in detail in [4], revealed a relationship between pH_{eq}, pH_0, and bath ratio M = s : l, which has the form of a linear equation

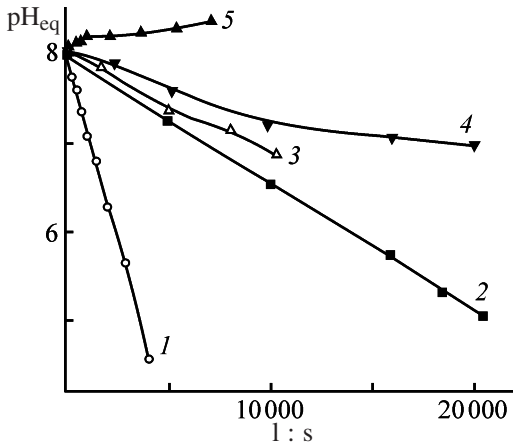

Fig. 5. pH of the equilibrium solution vs. the l : s ratio. (pH_{eq}) Equilibrium value in the solution after absorption and (l : s) ratio between the tripolite mass and volume of the starting aqueous solution. pH of the starting solution: (*1*) 2.6, (*2*) 3.5, (*3*) 4.6, (*4*) 6.5, and (*5*) 7.5.

$$pH_{eq} = 7.98 - (31.372 - 4.1627\,pH_0) \times 10^{-5}M. \quad (1)$$

This linear dependence is observed for solutions with pH_0 in the range 3.5–7.5 and can be used for rapid evaluation of the efficiency of carbonate-containing materials in purification of real solutions. For example, at a 1-kg weighed portion of tripolite and a prescribed pH_0 value of 6, the solution volume V_l (l) that can be neutralized to pH 7 can be readily found using the equation

$$V_{eq} = \frac{(31.37 - 4.16\,pH_0) \times 10^{-5}T}{7.98 - pH_{eq}} = 6.5 \times 10^5. \quad (2)$$

At present, dilute solutions of nonferrous metal ions are concentrated using nonselective and selective ion-exchange materials. In the former case, all ions present in a solution are absorbed, and in the latter, only the group of nonferrous metal ions. The nature of selectivity in chemisorption processes is quite different. In contrast to ion-exchange materials, selective chemisorbents can be used not only for group concentration of nonferrous metal ions, but also for their separation. Poorly soluble carbonates of bivalent metals and, in particular, alkaline-earth metals show chemisorption activity toward ions of heavy and nonferrous metals, because, in the process, compounds less soluble than the starting compounds are formed. The efficiency of chemisorption depends on a number of factors, the main of which is ΔSP, difference of the solubility products (SP) of the starting sorbent and the compound formed in chemisorption.

Table 4. Results of determination of the concentration and pH of $Fe(NO_3)_3$–$Ni(NO_3)_2$ solutions before and after sorption

A sorbent suitable for absorption of certain ions from the mixture can be chosen using the solubility series of carbonates of doubly and triply charged metals.

A possible promising area is application of chemisorption processes for selective recovery of nonferrous metal ions from two- and multicomponent solutions.

Previous studies [5] confirmed that natural carbonates can be used as selective sorbents for recovery of iron(III) ions from binary solutions containing Fe(III)–Ni(II). Two-component (Fe^{3+}–Ni^{2+}) dilute aqueous solutions are formed in processing of worked-out nickel–iron battery electrodes [6] and in processing of electrolytic baths for nickel-plating of iron articles.

The solubility products of $CaCO_3$ and $NiCO_3$ are virtually equal (4.8×10^{-9} and 6.6×10^{-9}, respectively). The SP of iron hydroxide, which is formed, according to published data, in contact of Fe(III) ions with calcium carbonate, is many orders of magnitude lower. Thus, calcium carbonate should selectively absorb iron(III) ions from a two-component Fe^{3+}–Ni^{2+} solution. The experimental data obtained confirmed this assumption.

Table 4 lists the concentrations of iron(III) and nickel(II) ions in two-component Fe^{3+}–Ni^{2+} solutions before and after sorption and pH values of the starting and equilibrium solutions. It also lists the following parameters calculated from the solution concentrations before and after sorption: amounts of absorbed ions and those released into solution (mg-equiv g^{-1}) and degrees of recovery of iron(III) ions from solutions with various concentrations (%).

In the case of two-component solutions with initial iron(III) concentrations exceeding 240 mg l^{-1}, the solutions obtained after sorption contain small amounts of iron, 0.5–0.9 mg l^{-1}.

In three-component and more complex systems, the course of chemisorption processes will be primarily determined by the ratio between the sorbent mass and solution volume. It is quite apparent that the chemisorption technique can be used for successive selective recovery of ions forming the least soluble compound from more complex, multicomponent mixtures. In doing so, the weighed portion of a sorbent should be calculated with account of the amount of ions of the metal forming the least soluble compound with the precipitating anion.

With account of the fact that chemical reactions proceed rather efficiently in concentrated solutions, the chemisorption techniques can be used for successive recovery of ions from relatively concentrated solutions and for processing of an electroplating waste.

Practical implementations of chemisorption techniques for selective absorption of metal ions may be widely diverse. In addition to the cases described above, the "reverse selectivity" mode is possible. The solubility products of carbonates, basic carbo-

nates, and hydroxides of virtually all heavy and nonferrous metals, except nickel, are substantially lower than that of calcium carbonate.

Thus, carbonate materials can be used to purify nickel solutions to remove admixtures of other metals, under both static and dynamic conditions. It is interesting to note that, according to experimental data, calcium carbonate does not adsorb from solutions cobalt ions, either, although reference values of SP for cobalt carbonate and hydroxide are several orders of magnitude lower than the SP of calcium carbonate. Apparently, the conditions in this heterogeneous system (pH, concentration, ratio between masses of the sorbent and the solution, temperature, etc.) are unfavorable for formation of these compounds. For example, a strong absorption of cobalt ions in the form of hydroxide in contact with shell rock was observed in [7] only at elevated temperatures.

CONCLUSIONS

(1) Tripolites from the Stal'noe deposit are a natural composite whose sorption properties are determined by the relative contents of the principal rock-forming phases: opal–cristobalite (silica) and calcite (calcium carbonate).

(2) The limiting sorption volume and specific surface area vary similarly to the content of silica in tripolite.

(3) The adsorption-structural parameters of tripolites become worse as the content of calcite in the mineral increases; however, this improves the chemisorption properties of tripolites.

(4) Carbonate tripolites containing 20–30% calcite and more are highly efficient sorbents for ions of heavy and nonferrous metals. They show promise for solution of a number of technological and environmental problems: treatment of technical and drinking water, processing of electroplating wastes, selective recovery and concentration of nonferrous metals, and deironing of water.

Abstract—The effect exerted by current density, cathode material (platinum, palladium, nickel, silver, copper, and cadmium), and temperature on the rate of the reduction of sodium thiosulfate was studied.

DOI: 10.1134/S1070427207110146

Previous studies [1–5] of the cathodic reduction of anions showed that the reduction rate is determined by the zero-charge potential. The reduction starts at potentials corresponding to positive charges on the metal surface, then the current reaches limiting value, and at potentials close to the zero-charge potential it starts to decrease. After passing a minimum, the current increases again with increasing negative potential. Since the cathode surface acquires a negative charge with increasing negative potential, the anions are repelled from the cathode and the current increase is due to the reduction of hydrogen ions. In this case, the reaction rate is limited by the concentration of hydrogen ions and by the overvoltage of hydrogen evolution. Presumably, in the region of hydrogen evolution the thiosulfate anions may be reduced on the cathode. It was shown that pure silver, a mixture of silver with silver sulfide, or pure silver sulfide is formed on the cathode, depending on current density [6]. In this case, as seen from Fig. 1, the amount of silver sulfide and, consequently, sulfide anions is directly proportional to the cathodic current density. At less negative potentials, the reduction rate of the thiosulfate ions is determined by the zero-charge potential and is low [7].

In the region of the potentials of hydrogen evolution, the thiosulfate ions are reduced with atomic hydrogen. In this case, the reaction rate is determined by the surface concentration of atomic hydrogen on the cathode. The hydrogen concentration depends on both the overvoltage of hydrogen evolution and the current density [8–10]. Increasing the current and using the cathodes with a large overvoltage of hydrogen evolution results in the increase in the concentration of atomic hydrogen.

The dependence of the reduction rate of thiosulfate ions on the current density and cathode material can be predicted from the above results. For example, platinum and palladium have a low overvoltage of hydrogen evolution, and nickel, silver, copper, and cadmium, higher overvoltage. The higher the overvoltage, the higher the concentration of atomic hydrogen on the cathode surface [8]. Therefore, it was of interest to study the rate of reduction of thiosulfate ions to sulfide ions on metals with various potentials of hydrogen evolution as a function of current density.

Reduction of thiosulfate ions with atomic hydrogen can be proved using an electrochemical cell equipped with a membrane cathode made of a thin palladium foil. The polarization of the cathode membrane causes atomic hydrogen to evolve on its back side. The amount of the evolved hydrogen on the surface is de-

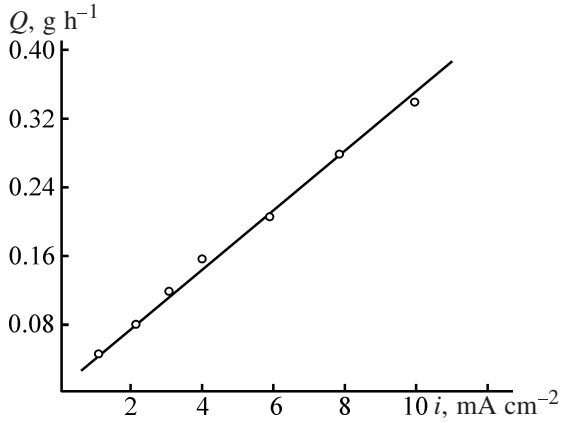

Fig. 1. Effect of current density i on the rate of silver sulfide deposition on the cathode Q. Electrolyte: 0.5 g l^{-1} silver and 0.5 M sodium thiosulfate; stainless steel cathode (11 cm^2).

termined by the recombination or electrochemical desorption of hydrogen atoms to form the molecules [11]. As established in [12, 13], the rate of diffusion of atomic hydrogen through a palladium cathode membrane is inversely proportional to the membrane thickness, i.e., the thinner the membrane, the higher the diffusion rate. Therefore, this study is concerned with the effect exerted by the current density on the amount of sulfide ions obtained by reduction of thiosulfate ions with atomic hydrogen on a membrane cathode 80 μm thick.

The effect of the cathode material on the rate of reduction of thiosulfate ions was studied in a U-shaped glass cell. The cathode and anode compartments of the cell were separated with a glass filter no. 1. The volume of the cathode space was 60 cm^3. Cathodes 3×4 cm in size were made of a thin sheet of different metals, and their nonworking side was insulated with epoxy resin. Reduction of thiosulfate ions with atomic hydrogen was studied in a rectangular Plexiglas cell. The cathode and anode compartments of the cell were separated with a membrane made of a tightened Khlorin fabric, and its diffusion space was separated from the cathode compartment with a palladium membrane, with no electric and liquid contact between the cathode and diffusion spaces. The thickness of the membrane was 80 μm and its area, 10 cm^2. In each of three compartments, the electrolyte volume was 40 cm^3. A 0.5 M solution of sodium thiosulfate was poured into the diffusion space in all experiments. In the course of the experiments, the palladium membrane deformed owing to absorption of atomic hydrogen. Therefore, it was annealed at 800°C for 1 h and then cooled in a muffle furnace to room temperature. After that, it was flattened between two thin nickel sheets, mounted between the cathode and diffusion spaces, and fixed there with bolts. Hermetic gaskets made of acid-resistant rubber were arranged on each side of the palladium membrane. As anode we used platinum. A 0.5 M sodium hydroxide solution was poured into all the three compartments and the electrolysis was performed at a current density of 20 mA cm^{-2} for 1 h until saturation of the palladium cathode with atomic hydrogen. In the process, hydrogen in the form of bubbles started to evolve on the opposite side of the palladium cathode after 30–35 min. Experiments were performed with chemically pure grade chemicals. Prior to the experiment, cathodes were polished, degreased with Vienna lime, and washed in distilled water. The amount of sulfide and sulfite ions formed in the solutions in the course of the experiments was determined titrimetrically [14].

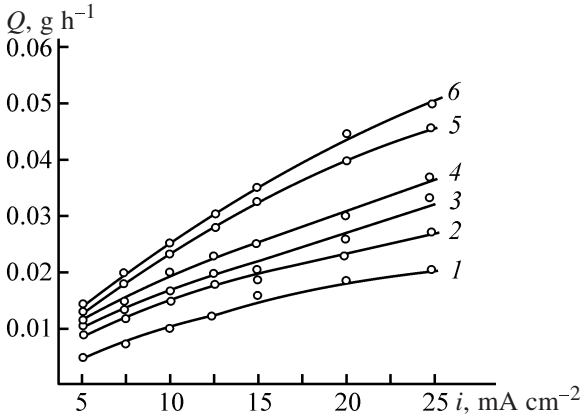

Fig. 2. Effect of cathode material and current density i on the rate of generation of sulfide ions Q in the cathode space. Catholyte: 0.5 M solution of sodium thiosulfate, volume 60 cm^3, cathode area 8 cm^2. Cathode material: (*1*) Pt, (*2*) Pd, (*3*) Ni, (*4*) Ag, (*5*) Cu, and (*6*) Cd.

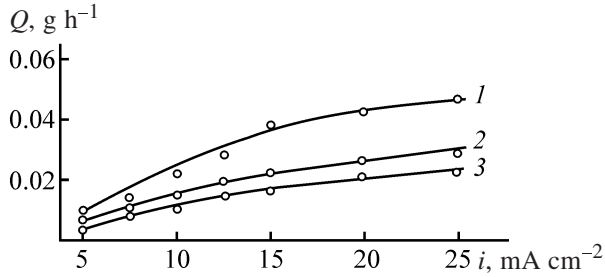

Fig. 3. Effect of current density i and temperature on the rate of generation of sulfide ions Q in the cathode space. Cathode material cadmium; catholyte: 0.5 M solution of sodium thiosulfate. Temperature, °C: (*1*) 20, (*2*) 50, and (*3*) 75.

The study performed showed that, for all the cathodes studied, the reduction rate of the thiosulfate ions increases by a factor of 5 on passing from platinum to cadmium cathode and with increasing current density, i.e., it increases with the overvoltage of hydrogen evolution (Fig. 2). The overvoltage of hydrogen evolution decreases with increasing temperature [11]. As a result, the rate of recombination of atomic hydrogen into the molecule increases, whereas the reduction rate of the thiosulfate ions decreases (Fig. 3, curves *1–3*).

We also studied the reduction of thiosulfate ions with atomic hydrogen in the diffusion compartment of the electrochemical cell. When cathodic current is applied to the polarization side of the cathode membrane and the potential is shifted to the negative side, the evolution of hydrogen occurs initially only on the polarization side and then, after 0.5 h, hydrogen in the form of bubbles evolves on the diffusion side. The results obtained in reduction of thiosulfate ions

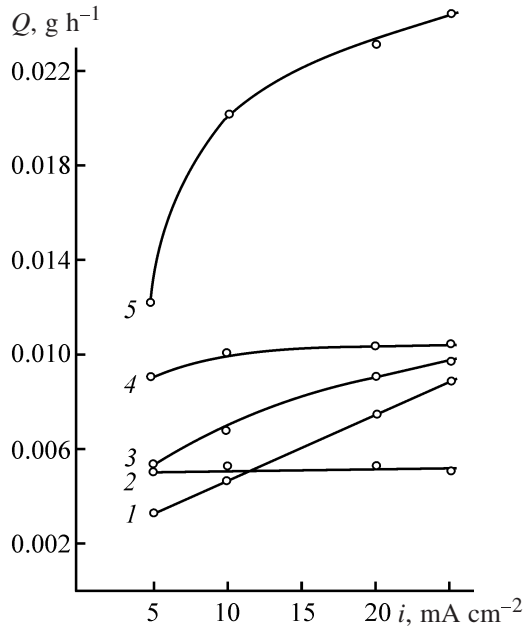

Fig. 4. Effect of cathodic current density i on the rate of generation of sulfide ions Q in the (*1–3*) diffusion space and (*4, 5*) catholyte. Electrolyte: (*1*) 0.5 M solution of sodium hydroxide; (*2*) 0.5 M solution of sodium thiosulfate; (*3, 4*) 0.5 M solution of sodium hydroxide + 1 g l^{-1} sodium thiosulfate; and (*5*) 0.5 M solution of sodium thiosulfate.

with atomic hydrogen in the diffusion compartment are presented in Fig. 4. In the presence of pure sodium hydroxide in the cathode compartment, the amount of sulfide ions in the diffusion space (curve *1*) increases with increasing current on the cathode side of the membrane. This is because the amount of atomic hydrogen on the cathode surface increases with the cathodic current density [8] and the rate of diffusion through the palladium membrane toward the diffusion compartment of the cell increases. When 1 g l^{-1} of sodium thiosulfate, which is reduced on the cathode to the sulfide ion and increases the overvoltage of hydrogen evolution [11], is introduced into the cathode space, the concentration of atomic hydrogen on the surface of the cathode membrane increases. The increase in the amount of atomic hydrogen on the cathode increases the rate of its diffusion through the cathode membrane toward the diffusion space, with the rate of the reduction of thiosulfate ions to sulfide ions increasing (curve *3*). If a 0.5 M sodium thiosulfate solution is used in the cathode space, then the rate of its reduction to sulfide ions sharply increases (curve *5*), thus decreasing the amount of atomic hydrogen on the cathode. In the process, the rate of diffusion of atomic hydrogen through the membrane cathode toward the diffusion space decreases, thus decreasing the reduction rate of the thiosulfate ions (curve *2*).

The analysis of the electrolysis products in the cathode and diffusion compartments showed that, along with sulfide ions, the sulfite ions in equimolar amount are also present in the solution. Reduction of thiosulfate ions with atomic hydrogen proceeds in the near-cathode layer, and the process rate is determined by the concentration of atomic hydrogen rather than by the electrode potential, i.e., the reduction proceeds by the chemical mechanism. The standard potential of the reaction $H = H^+ + e$ is –2.106 V [15], which confirms the high reductive ability of atomic hydrogen. The reduction of thiosulfate ions is described by the equation

$$S_2O_3^{2-} + H + OH^- = S^{2-} + SO_3^{2-} + H_2O. \quad (1)$$

At electrode potentials not exceeding the potential of hydrogen evolution, the thiosulfate ions are reduced to sulfide and sulfite ions by the equation [16]

$$S_2O_3^{2-} + 2e = S^{2-} + SO_3^{2-}. \quad (2)$$

In this case, the reduction rate of the thiosulfate ions, as established in [7], is determined by the zero-charge potential.

Our study allowed us to establish the following mechanism of the reduction of thiosulfate ions on the cathode. At cathode potentials not exceeding the potential of hydrogen evolution, the reduction rate of the thiosulfate ions is determined by the zero-charge potential. At electrode potentials closer to the potentials of hydrogen evolution, a part of hydrogen atoms reduces the thiosulfate ions to sulfide and sulfite ions owing to the retardation of the recombination of hydrogen atoms into the molecules. In this case, the reduction rate is determined by the cathode material, i.e., by the overvoltage of hydrogen evolution or by the amount of atomic hydrogen on the cathode surface.

Our results allow us to suggest the conditions of the electrochemical neutralization of spent fixing solutions of sodium thiosulfate [17]. On storage, the above solutions absorb oxygen and undergo chemical transformations resulting in the formation of toxic compounds with unpleasant odor. Upon electrolysis of sodium thiosulfate solutions containing iron sulfate, the final products of the electrolysis are an insoluble iron sulfide deposit and sodium sulfite in a solution, i.e., less toxic products are formed.

CONCLUSIONS

(1) The study of the effect exerted by the current density, cathode material (platinum, palladium, nickel, silver, copper, and cadmium), and temperature on the rate of the reduction of thiosulfate ions showed that the process rate increases with the overvoltage of hydrogen evolution on the metals and decreases with increasing temperature of the solution. The electrolysis proceeds with the formation of equivalent amounts of sulfide and sulfite ions.

(2) The reduction of thiosulfate ions with atomic hydrogen diffusing through a palladium membrane cathode is determined by the rate of hydrogen diffusion. The amount of atomic hydrogen is determined by the current density on the membrane cathode and by the overvoltage of hydrogen evolution.

(3) The mechanism of the reduction of the thiosulfate ions on the cathode was determined.

Abstract—Electrolysis of a WC–Ni pseudoalloy in aqueous sulfuric acid solutions was studied. A flowsheet for production of ammonium paratungstate and nickel(II) sulfate is suggested, in which the process solutions are recycled. The principal electrolysis parameters are presented.

DOI: 10.1134/S1070427207110158

Tungsten is a high-melting metal whose natural resources are close to exhaustion. Therefore, secondary tungsten becomes the principal source of this metal and its compounds. One of the most promising, in technological, energetic, and environmental regards, methods for processing of secondary tungsten is electrolysis of aqueous solutions [1–6]. The variety of products of the electrochemical transformation depends on the form of tungsten in secondary raw materials and on the electrolyte composition. For example, tungsten is anodically oxidized in alkaline and alkaline–ammonia electrolytes to the tungstate ion WO_4^{2-} from alloys, including those containing tungsten carbide (WC) [1, 2]. In acid electrolytes, WC–Co is converted to the oxide WO_3 [1, 3–5]. Tungsten carbides are contained in hard alloys widely used to fabricate special tools, drills, and military equipment. Therefore, integrated processing of worked-out and obsolete articles of this kind is a topical area of the electrochemistry of tungsten.

This study proceeds with an integrated analysis of the utilization of secondary tungsten with the use of electrochemical processes [7, 8] and is aimed to develop process aspects of electrolysis of a poorly studied WC–Ni system in order to obtain commercial products, ammonium paratungstate and nickel(II) sulfate.

EXPERIMENTAL

Cores of armor-piercing shells 18 and 30 mm in diameter and 70 mm high, fabricated from a WC–Ni alloy of compositions (wt %): W 86.4, C 5.8, Ni 7.2, were used in the study.

The electrolysis was performed in a laboratory electrolyzer of capacity 5 dm^3, schematically shown in Fig. 1. A 1 M H_2SO_4 solution served as the starting electrolyte. The cores were placed in a titanium basket *1*. During the electrolysis, the basket was shaken every 15 min with a vibrator *2*, and the electrolyte (H_2SO_4 + $NiSO_4$) was filtered at regular intervals. After the electrolysis was terminated, the cores were cleaned to completely remove tungsten oxides and

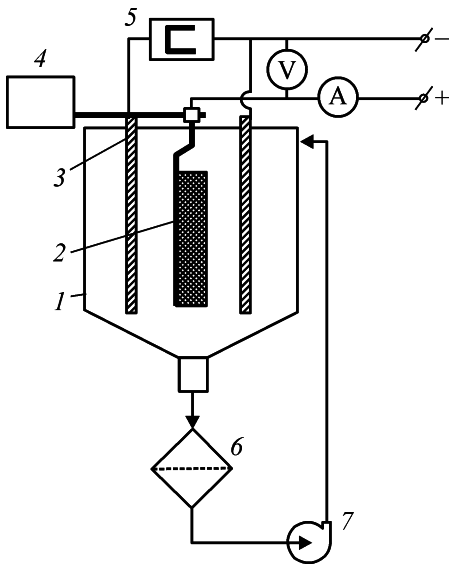

Fig. 1. Schematic of the laboratory installation. (*1*) Titanium basket, (*2*) vibrator, (*3*) aluminum cathodes, (*4*) electrolyzer case, (*5*) coulometer, (*6*) filter, and (*7*) pump.

weighed. The loss of mass by the cores and the mass gain of the coulometer cathodes were used to calculate the anode current efficiency CE_a. The precipitate of tungsten oxides was washed with water, centrifuged, and dissolved using ammonia water or gaseous ammonia. The ammonium tungstate solution formed was filtered and evaporated on a water bath. After cooling, the resulting crystals of ammonium paratungstate $(NH_4)_{10}[H_2W_{12}O_{42}]\cdot 4H_2O$ (APT) were filtered off, washed with water, and thermally analyzed for the content of tungsten(VI) oxide. To study the surface morphology of the samples, electrolysis was performed at E = const with a PI-50-1.1 potentiostat and a silver chloride reference electrode. The morphology of the core samples was examined with a REMMA-102-02 scanning electron microscope (SEM),[1] with the outward appearance of the surface with tungsten oxides photographed using a digital camera.

The anodic behavior of the WC–Co [3] and WC–Ni [8] systems in acid solutions is characterized by selective dissolution of the binder, cobalt or nickel, respectively, with the subsequent conversion of the carbide to WO_3 and CO_2.

$$Ni \rightarrow Ni^{2+} + 2e, \quad (1)$$

$$WC + 5H_2O \rightarrow WO_3 + CO_2 + 10H^+ + 10e. \quad (2)$$

The potential of nickel oxidation by reaction (1) is 0.5–0.7 V lower than the conversion potential of tungsten carbide by reaction (2) [8]. Therefore, anodic dissolution of the nickel binder is the leading stage of electrolysis of the WC–Ni system, causing a change in the surface profile (Fig. 2). It becomes more developed, which intensifies the conversion of tungsten carbide.

The occurrence of anodic reaction (2) favors formation of a film composed of hydrated stoichiometric oxide WO_3 and hydrated nonstoichiometric oxides WO_x (including the "tungsten blue" $WO_{2.8}$). Its growth is accompanied by cracking (Fig. 3) and periodic detachment of the conversion deposit from the substrate. This behavior is accounted for by the very large Pilling–Bedworth ratio (3.45 for the W–WO_3 system), which is defined as the ratio V_{WO_3}/V_W, where V_{WO_3} and V_W are the molar volumes of tungsten(VI) oxide and metallic tungsten, respectively [9].

Under the conditions of electrolysis with a bulk anode, i.e., with baskets, spontaneous removal of

the forming deposit of tungsten oxides becomes more complicated. As a result, the core surface is blocked, which leads to a decrease in the anode currents. It was found on the laboratory electrolyzer (Fig. 1) that periodic shaking of the basket in solution circulation favors removal of the anode deposit from the core surface into the electrolyte bulk and restoration of the anode currents to their initial values.

Principal parameters of electrochemical processing of the WC–Ni system in 1.0 M H_2SO_4

U, V	i_r,* A dm^{-2}	CE_a, %
3.5	5	103.00
4.0	6	104.58
4.5	7.6	105.00
5.0	9	102.25
6.0	13	105.35

* i_r is the reduced current density (ratio between the current strength and cross-sectional area of the bulk anode).

As shown by the study, tungsten carbide is completely converted into the oxide in prolonged electrolysis. Thus, all WC particles are provided with an electric contact until their complete anodic conversion. This is due to the structure of the cores, because a strongly branched nickel skeleton is formed in the course of compaction of a powder formulation composed of tungsten carbide and nickel (Fig. 4). With account of the comparatively high nickel content (7–10 wt %) of the WC–Ni system, it, in fact, envelops each tungsten carbide particle and thereby acts as a rigid current lead.

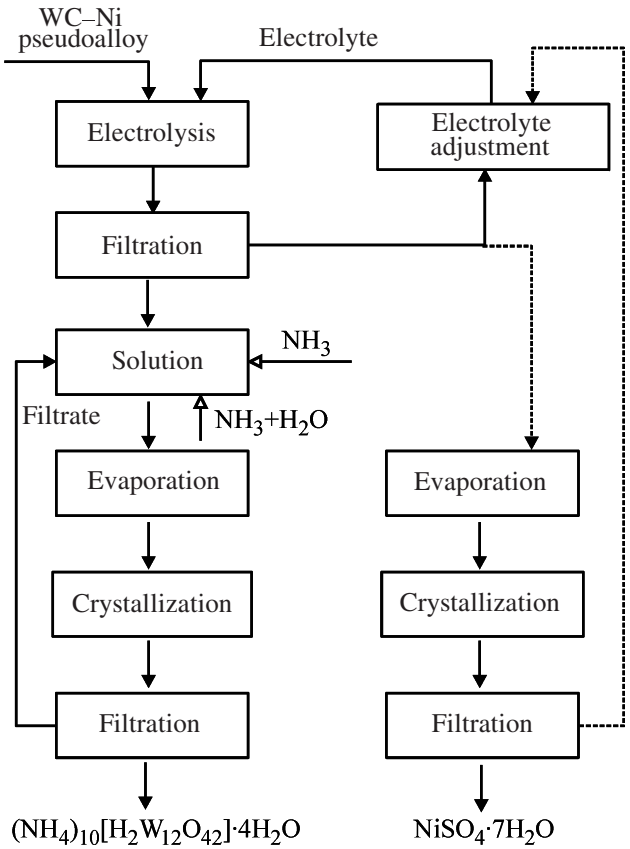
The main part of the deposit formed in the course of electrolysis is composed of the oxide WO_3 and nonstoichiometric oxides ("tungsten blue") embedded in this deposit. This is due to the fact that the conversion occurs with a stage-by-stage formation of oxides. For example, lower tungsten oxides are converted into higher oxides in the direction away from the metal surface and into the oxide WO_3 at the interface between the solid phase and the electrolyte [10]. In detachment of the conversion product from the anode surface, especially under vibration conditions, incompletely oxidized oxides are incorporated into the deposit. Therefore, the current efficiency in terms of tungsten(VI) oxide exceeds 100% (see table).

The reduced current density reaches values (see table) that are acceptable to industrial processing of cores by electrolysis. As the voltage is raised, the current density i_r increases to 15 A dm^{-2} and more. However, under these conditions, not only the specific electric power expenditure increases, but also the electrolyte is rapidly heated and hydrogen vigorously evolves at the cathode. The first, energetic, factor can affect the production cost, whereas the last two complicate the electrolysis technology. Therefore, the optimal current density can be only found on an industrial electrolyzer.

One of the most frequently used tungsten compounds is ammonium paratungstate, which, taken in large amounts, can serve as a raw material for manufacture of a tungsten powder [1]. Therefore, it is electrochemically appropriate to process alloys of the system WC–Ni into APT.

On the basis of the experimental data obtained, a flowsheet for processing of secondary alloys of the system WC–Ni was suggested for the example of cores of armor-piercing shells. The flowsheet comprises three principal stages: electrolysis, synthesis of

Flowsheet for electrochemical processing of the WC–Ni pseudoalloy in sulfuric acid solutions



ammonium paratungstate, and recovery of nickel(II) sulfate. The central stage of the process is electrolysis, whereas the remaining stages are typical processes of chemical technology.

The electrolysis yields a suspension from which tungsten oxides are recovered by filtration. After being washed, the tungsten oxides are delivered in the form of slurry to dissolution with gaseous ammonia. The solid residue (~0.5 wt %) is mostly composed of graphite not oxidized by reaction (2). The solution formed is evaporated to remove the excess amount of ammonia and convert ammonium tungstate into poorly soluble ammonium paratungstate.

The solution filtered off after the electrolysis is delivered, as nickel sulfate is accumulated, to recovery of the salt in the form of a crystal hydrate. The electrolyte is adjusted with sulfuric acid in an amount equivalent to the recovered product, $NiSO_4 \cdot 7H_2O$.

Thus, the suggested technique for processing of an alloy of the system WC–Ni, which provides the environmental safety of the process, can yield two commercial products, ammonium paratungstate and nickel sulfate crystal hydrate. The products are of pure grade. Their purity is improved, i.e., their conditioning is carried out, by the known methods.

CONCLUSIONS

(1) Anodic treatment of a WC–Ni pseudoalloy in sulfuric acid solutions causes nickel dissolution and tungsten conversion into the oxide WO_3 at a specific electric energy expenditure of 4.0–7.5 kW h kg^{-1} of the starting product.

(2) Shaking and circulation of the electrolyte enable use of bulk anodes and electrolysis at current densities of 5–13 A dm^{-2}.

(3) The degree of electrochemical conversion of tungsten into oxide and of nickel dissolution reaches 100%, which enables processing of a WC–Ni pseudoalloy to give pure commercial products, ammonium paratungstate and nickel sulfate. The technique provides full recycling of process solutions and environmental safety of the processes performed.

Abstract—Electrodeposition of the Co–Cu system in pores of anodic aluminum oxide was studied.

DOI: 10.1134/S107042720711016X

The electrodeposition of metals and semiconductors in pores of various membranes is an urgent problem of the past decade, which is stimulated by the demand for nanosized regular structures in various scientific and technical areas. The above membranes can be obtained by different methods. One of them is bombardment in a cyclotron of polymeric, mostly polycarbonate, film with high-energy heavy ions [1, 2]. These membranes have a nonequilibrium and random pore distribution. A porous layer of oxide formed on the surface of aluminum and its alloys by anodizing in aqueous solutions of di- and tribasic acids is essentially free of this drawback. The pore distribution in an anodic oxide layer is reasonably uniform, and manufacture of porous membranes of a cellular structure with a porosity from 10^9 to 10^{11} pores per 1 cm^2 is fairly facile. The pore diameter in such membranes varies from several to 300 nm, and their thickness can reach 250 μm [3–6].

Nonetheless, studies concerning the direct electrodeposition of metals in pores of anodic aluminum oxide are relatively few. We have in view only dc electrodeposition, because the processes of ac deposition are used for a long time. Among classic studies of the deposition of silver and copper in pores of anodic oxide are those by Gileadi et al. [7, 8]. They showed that contact with a support is realized owing to "invasion" of a barrier part of anodic oxide. The same conclusion was made in studying the behavior of anodic oxide in an acid electrolyte of tin salts in [9]. In addition, the optical properties of a gold deposit and the magnetic properties of ferroelectric metals deposited in pores of anodic oxide were studied in [10, 11] and [12, 13], respectively. Also, studies are available on the filling of pores of anodic aluminum oxide with nanoparticles of zinc and antimony oxides and sulfides [14, 15]. The comparatively small number of studies concerning processes that occur upon direct filling of anodic oxide with metallic nanoneedles is apparently caused by difficultes arising from a breakdown of a semiconductor barrier layer on the pore bottom under the conditions of dc electrolysis.

As shown previously [16], a two-stage chemical treatment of anodized aluminum ensures virtually complete removal of the barrier layer formed at the pore bottom of anodic oxide film. The first stage involves treatment with a 0.08 M solution of phosphoric acid, and the second, with a fluoroborate immersion solution, which is commonly used for pretreating the surface of aluminum and its alloys prior to electroplating [17]. The two-stage treatment results in the formation of a porous membrane on the aluminum surface. With the above membrane, the electrodeposition of metals in pores using dc current can be performed.

This study is concerned with the deposition of the Co–Cu system. We used differences in the deposition of copper and cobalt to reveal certain details of the electrodeposition of the above metals in a limited space inside pores and the specific features of diffusion of the discharging metals. This study is necessary to understand the conditions at which various metallic nanosystems, including multilayer magnetic systems, are formed in pores of anodic aluminum oxide and polycarbonate membranes.

EXPERIMENTAL

We used in the study aluminum (ultrapure and ADOM grades) and AMg-2 alloy [18]. Prior to anodizing, their surfaces were etched in a 1 M solution of

sodium hydroxide at a solution temperature of 40°C for 2 min, washed with distilled water, treated in a 1 : 1 solution of nitric acid at 20°C for 30 s, and washed again with distilled water. Aluminum was anodized in a 0.045 M solution of oxalic acid at a voltage of 90 V and a solution temperature of 15°C for 80 min, and then the voltage was lowered stepwise by 10 V every 5 min. The anodizing process was terminated on reaching a voltage of 0.1 V. Then the electrodes were treated with 0.08 M phosphoric acid at 20°C. The duration of the treatment is indicated below in the text. After washing with distilled water, a barrier layer of anodic oxide was formed by etching in a fluoroborate immersion solution containing (M) $Ni(BF_4)_2$ 0.87, NH_4BF_4 0.38 (pH 4±1), and $Zn(BF_4)_2$ 0.17 [17].

Cobalt needles and layered needles of cobalt and copper (Co–Cu system) were deposited from a solution containing (M) $CoSO_4$ 0.5, $CuSO_4$ 0.01, and H_3BO_3 0.65. The electrodeposition was carried out by alternation of two potentiostatic pulses. Copper was deposited during the first pulse (0 to –0.6 V, 20 s) and cobalt, during the second pulse (–0.9 to –1.1 V, 2 s). The current values during the pulses were recorded wiht a computer using appropriate programs and devices. The potentials are given relative to a silver chloride electrode (EVL-1M3-100).

The atomic force microimages of the surface of anodized aluminum were obtained on an Explorer TM atomic force microscope. We also used in the study a Model XL 30 scanning (Philips) and PEM-100 transmission electron microscopes.

The electrolyte chosen for the electrodeposition of a multilayer Co–Cu system had a high concentration of Co^{2+} ions and a low concentration of Cu^{2+} ions. Layers of pure copper and the cobalt layers with only minor amount of copper impurity can be obtained from the above electrolyte by varying the deposition potential. The deposition of multilayer systems should be performed in the potentiostatic mode to maintain the composition of the single layers constant. The voltammetric study showed that the copper deposition occurs at the potentials from 0 to –0.6 V employed at the limiting current, and the cobalt deposition, at the potentials from –0.9 V to –1.1 V on the ascending branch of the polarization curve. Hence, variation of the potential in the above intervals does not noticeably affect the current of the copper deposition, but affects considerably the current of the copper deposition. These features of the electrodeposition of copper and cobalt were taken into account in studying the different polarizations in pores of anodic oxide and

Fig. 1. Time of treatment of anodized surface in 0.08 M phosphoric acid, h: (*1*) 0, (*2*) 0.5, (*3*) 1, (*4*) 2, and (*5*) 5; subsequent treatment in an immersion solution for 10 min; the same for Fig. 3.

on metallic electrodes. Therefore, it was reasonable to calculate for copper and cobalt the ratios of the deposition currents in pores of anodic aluminum oxide and on a copper electrode $j_{Cu(Al)}/j_{Cu(Cu)}$ and $j_{Co(Al)}/j_{Co(Cu)}$.

Apparently, the efficiency of the pretreatment of anodized aluminum for electrodeposition of metals in pores of the oxide can be evaluated to a certain extent from the current ratios. For example, the relative increase or decrease in the total pore area of the oxide where the metal electrodeposition can occur can be estimated in relation to the brand of aluminum and probably to the method of pretreatment of its surface. It should be emphasized that, in the given case, the true active pore area cannot be determined because of differences in the diffusion processes occurring in pores of aluminum oxide and on a metallic electrode, which, in turn, determines the differences in the current densities.

The study showed that the $j_{Cu(Al)}/j_{Cu(Cu)}$ and $j_{Co(Al)}/j_{Co(Cu)}$ ratios depend on the purity of the applied aluminum, which determines the size of pores in anodic oxide. The lowest values of the $j_{Cu(Al)}/j_{Cu(Cu)}$ and $j_{Co(Al)}/j_{Co(Cu)}$ ratios are observed on ultrapure grade aluminum (Fig. 1), in which the total pore area is small (Fig. 2). For aluminum of lower purity the ratios increase (Figs. 3, 4). This may be accounted for by accumulation of lattice defects in the bulk of the metal and on its surface with increasing impurity concentration in aluminum. In the defective zones, the anodizing process is faster and the anodic oxide film has a more branched structure. As compared to aluminum, the intermetallic Al–Mg compounds on aluminum alloys with magnesium are anodized more readi-

ly and are dissolved in anodizing electrolytes many times faster [19, 20]. Therefore, the total pore area should be larger on the surface of anodized aluminum alloys or on the surface of aluminum with higher concentration of impurities. Moreover, the $j_{Cu(Al)}/j_{Cu(Cu)}$ and $j_{Co(Al)}/j_{Co(Cu)}$ ratios for each type of aluminum are different (Figs. 1, 3, 4). In the initial stages of the deposition of a multilayer Co–Cu system, the $j_{Co(Al)}/j_{Co(Cu)}$ ratios are considerably lower than the corresponding $j_{Cu(Al)}/j_{Cu(Cu)}$ values. With increasing the number of pulses, the current ratios approach each other (Figs 1, 3, 4). However, the $j_{Co(Al)}/j_{Co(Cu)}$ values rarely, if ever, reach the $j_{Cu(Al)}/j_{Cu(Cu)}$ values. Apparently, the $j_{Co(Al)}/j_{Co(Cu)}$ ratios are also affected by the conditions of the pretreatment of the anodized aluminum surface, because the increase in the $j_{Co(Al)}/j_{Co(Cu)}$ ratios upon cobalt deposition can also be due to the specific shape of pores of anodic aluminum oxide. Presumably, after the appropriate procedure such as, e.g., treatment in an immersion solution, pores, and their tops in particular, become to a certain extent funnel or conic in shape. This suggestion is satisfactorily illustrated by the atomic force topographic images of the surface of the anodized aluminum after the treatment in an immersion solution (Fig. 5a). The above suggestion is also consistent with the shape of acicular cobalt formations separated from the pores after treating the anodic aluminum oxide in a 1.25 M sodium hydroxide solution (Fig. 5b). This causes the surface area on which the Co–Cu system is deposited to increase also with increasing number of pulses, i.e., the electrolysis conditions become nearly identical to those on a metallic, e.g., copper electrode.

In the limiting case, as shown previously [16], the electrolytic deposition of metals gets out from a pore

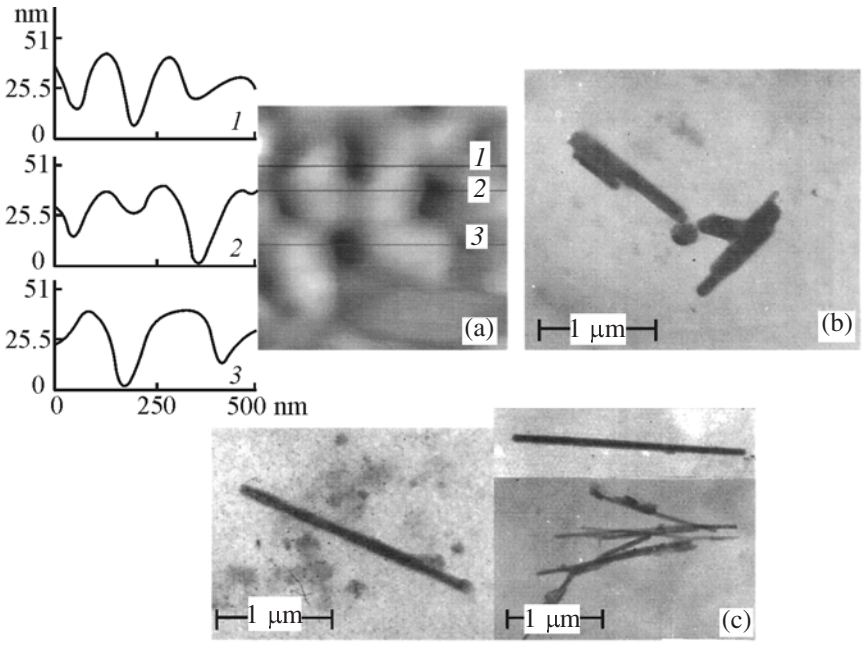

Fig. 5. (a) Atomic force image (scan area 500 × 500 nm) and roughness of the anodized surface of ADOM aluminum after treatment in immersion solution for 10 min and (b, c) acicular cobalt formations separated from pores of anodic aluminum oxide (ADOM brand). Time of treatment in 0.08 M phosphoric acid, h: (a, c) 5 and (b) 3.

space onto the aluminum surface to form a so-called "cap." At the same time, attention should be drawn to the fact that the $j_{Cu(Al)}/j_{Cu(Cu)}$ ratio is independent of the number of pulses, which is, in all probability, due to the fact that the copper deposition at the potentials employed occurs at the limiting current. However, the fact that the $j_{Co(Al)}/j_{Co(Cu)}$ ratios are lower than the $j_{Cu(Al)}/j_{Cu(Cu)}$ ratios suggests that the electrodeposition of metals in pores is hindered. The additional studies showed that the $j_{Co(Al)}/j_{Co(Cu)}$ values can be made closer to the $j_{Cu(Al)}/j_{Cu(Cu)}$ ratios by increasing the cathodic polarization in the course of cobalt electrodeposition to –50 mV. Presumably, at the very beginning of the electrodeposition the polarization increase is due to the retardation of cobalt deposition owing to passivation. This is assisted by the well-known physicochemical properties of aluminum and its oxide [20, 21]. Then, apparently, an increase in the concentration polarization caused by the specific features of metal deposition in pores is predominant. Owing to the small diameter of the pores and a comparatively large spacing between them, some of pores start acting as microelectrodes, described previously in [22, 23].

The behavior of microelectrodes can be accounted for by the features of diffusion of the ions involved in the reactions in the oxide pores and in the solution near the electrode surface. One of such features is an appreciable decrease in the concentration restrictions. Under these conditions, the overall concentration gradient and the thickness of the diffusion layer are equal to the thickness of the anodic oxide layer (approximately 5–6 μm in the given case). The thickness of the diffusion layer in electrodeposition of metals on metallic electrodes can reach 500 μm in an electrolyte without stirring and up to 10 μm in a stirred electrolyte [24]. Hence, the current density in pores should be higher than on the surface of a metallic electrode. This is due to the increased concentration polarization. The above suggestion is confirmed by a simple calculation based on size, and, consequently,

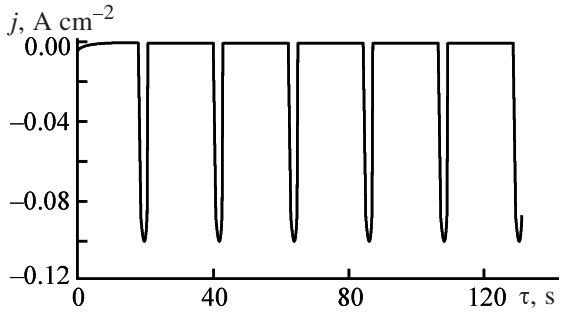

Fig. 6. Current density j of the pulsed deposition of the Co–Cu system vs. time τ, obtained on a copper electrode. Pulse duration, s: Cu 20 and Co 2. Potential amplitude, V: Cu –0.4 and Co –1.1.

mass of acicular cobalt deposits (Fig. 5c). According to the above calculation, the current density in pores is $(1.5–2.3) \times 10^{-1}$ A cm^{-2}, i.e., twice larger on the average than the current of the cobalt deposition on a copper electrode in both pulse and continuous modes at a potential of –1.1 V (1×10^{-1} A cm^2) (Fig. 6).

CONCLUSIONS

(1) The current densities of the electrodeposition of metals in pores of anodic aluminum oxide are no less than twice higher than in the case when the electrodeposition occurs on a copper electrode at the same potential. This is apparently due to the fact that the anodized aluminum behaves in the process like a combination of microelectrodes. The most acceptable method for determining current densities in pores of anodic aluminum oxide involves calculations based on size, and, consequently, mass of acicular metallic deposits.

(2) For copper and cobalt, the ratios of deposition currents in pores of anodic aluminum oxide and on a copper electrode ($j_{Cu(Al)}/j_{Cu(Cu)}$ and $j_{Co(Al)}/j_{Co(Cu)}$) show the relative increase or decrease in the total pore area of the oxide depending on aluminum purity and, in part, on the conditions of pretreatment of the anodized aluminum surface.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Membrane Extraction and Electrodeposition of Silver(I) in Systems with Di(2-ethylhexyl) Hydrogen Phosphate

T. Zh. Sadyrbaeva

Institute of Inorganic Chemistry, Riga Technical University, Salaspils, Latvia

Received March 23, 2007

Abstract—Extraction of silver(I) from nitric acid solution by electrodialysis with liquid membranes containing di(2-ethylhexyl) hydrogen phosphate with addition of tri-*n*-octylamine in 1,2-dichloroethane is studied. The effects of the composition of aqueous solutions and liquid membranes as well as of the basic parameters of electrodialysis on the Ag(I) transport and electrodeposition rates are examined, and the process conditions are optimized.

DOI: 10.1134/S1070427207110171

Acid organophosphorus reagents are widely used for extraction of metal cations from neutral and weakly acidic solutions [1]. Particularly, di(2-ethylhexyl) hydrogen phosphate (HDEHP) was used as a cation exchanger for Ag(I) in systems with emulsion and impregnated liquid membranes [2–4]. In these cases, membrane extraction proceeds by the mechanism of countercurrent transport of Ag(I) and hydrogen ions:

$$Ag^{+}_{(w)} + HR_{(o)} \rightarrow AgR_{(o)} + H^{+}_{(w)}, \quad (1)$$

where HR = HDEHP; and (w) and (o) stand for the aqueous and organic phases, respectively.

Back extraction of Ag(I) is performed with highly acidic solutions, since the driving force of the process is the pH gradient between the feeding and receiving solutions.

On applying an electric field to the membrane extraction system, the transport of metal cations occurs in the same direction as that of hydrogen ions. In this case, the transport of ions across the liquid membrane is intensified, and back extraction of metals into dilute mineral acids becomes possible [5]. Previously, we reported on recovery of copper(II) from sulfuric acid solutions [6] by electrodialysis with HDEHP-based liquid membranes, and also on separation of Cu(II) and platinum metals in their recovery from hydrochloric acid solutions [7, 8]. It was shown that, after introduction of a tri-*n*-octylamine (TOA) additive to increase the conductivity, liquid membranes containing crude HDEHP provide efficient recovery and thorough separation of copper(II) from palladium(II) and platinum(IV).

Silver is widely used in various branches of industry, as a corrosion inhibitor, antifriction additive, as a material improving the conductivity and reflectance, and also in manufacturing surgical armaments and for decorative finishing. In silver plating, highly toxic cyanide-containing electrolytes are generally used [9]. To replace them, a number of cyanide-free electrolytes (iodide-, thiocyanate-, sulfite-, and pyrophosphate-based) are developed [10]. However, they are not widely used, and, therefore, developments in silver electroplating are of a significant practical interest.

In this study, we examined recovery of Ag(1) by galvanostatic electrodialysis with crude HDEHP-based liquid membranes modified with TOA. Also the silver electroplating conditions from the receiving solution were optimized.

EXPERIMENTAL

The transport of Ag(I) was studied using an assembled fluoroplastic cell with a liquid membrane confined between vertical cellophane films. Silver electroplating was examined using a four-compartment cell with a cathode placed in the receiving solution:

(+) Pt, HNO_3	$AgNO_3$ HNO_3	HDEHP TOA	$HClO_4$, Pt (–)
	MK 1	2	

In a series of experiments, we also used a five-compartment cell with a separate cathodic chamber:

(+) Pt, anodic solution	$AgNO_3$ HNO_3	HDEHP TOA	Receiving solution	Receiving solution, Pt (–)
	1		2	

A dc current was passed across flat platinum electrodes in the galvanostatic mode. The volume of the liquid membrane was 2 cm^3, its thickness, 0.2 cm, and the phase contact area, 7.1 cm^2. The cellophane films confining the liquid membrane were preliminarily soaked in water. The electrode compartments 17 cm^3 in volume were separated from the feeding and receiving solution chambers (both 13 cm^3 in volume) with solid MK-40 cation-exchange or MA-40 anion-exchange membranes. Generally, 0.1 M HNO_3 was used as an anodic electrolyte and 0.05 M $HClO_4$, as a cathodic electrolyte in the four-compartment cell (or 0.1 M HNO_3 in the five-compartment cell).

As liquid membranes, we used 1,2-dichloroethane solutions of crude HDEHP (about 63% main product) with addition of TOA (pure grade). Generally, we used 20 vol % HDEHP containing 0.1 M TOA. The feeding solution was prepared by dissolving $AgNO_3$ (analytically pure grade) in 0.01 M HNO_3. The initial Ag(I) concentration was generally 0.01 M. The Ag(I) concentration in the aqueous solutions was determined spectrophotometrically with rubeanic acid [11]. The optical density was measured on an SF-46 spectrophotometer.

In organic solutions, HDEHP forms an ion pair with TOA, i.e., a binary extractant [12]:

$$Oct_3N + HR \rightleftarrows Oct_3NH^+R^-, \quad (2)$$

where Oct_3N = TOA and HR = HDEHP.

Silver(I) is extracted into the organic phase via the cation-exchange mechanism:

$$Ag^+_{(w)} + NO^-_{3(w)} + Oct_3NHR_{(o)} \rightleftarrows AgR_{(o)} + Oct_3NHNO_{3(o)}, \quad (3)$$

where (w) and (o) stand for the aqueous and organic phases, respectively.

In a polar solvent, the extracted complex dissociates [13]:

$$AgR \rightleftarrows Ag^+ + R^-. \quad (4)$$

The Ag(I) ions are transferred by diffusion to the feeding solution/liquid membrane phase boundary (boundary 1) and interact with the carrier. Under the electric field, the resulting complex is transported across the organic layer, to be decomposed at the liquid membrane/receiving solution phase boundary (boundary 2) by the reaction reverse to (3). The carrier molecules diffuse back to boundary 1, which is driven by the concentration gradient. The hydrogen ions are transferred across the liquid membrane in the same direction as Ag(I). The X^- anions from the receiving solution are transferred across the liquid membrane in the opposite direction, interacting with the amine salt via the anion-exchange mechanism, and passing to the feeding solution:

$$H^+_{(w)} + NO^-_{3(w)} + R_3N_{(o)} \rightleftarrows R_3NHNO_{3(o)}, \quad (5)$$

$$X^-_{(w)} + R_3NHNO_{3(o)} \rightleftarrows R_3NHX_{(o)} + NO^-_{3(w)}, \quad (6)$$

where $X^- = ClO^-_4$, OH^-, or NO^-_3.

In the preliminary electrodialysis experiments, the transport of Ag(I) was studied using a five-compartment cell with a separated cathodic solution. It was demonstrated that applying electrical field induces Ag(I) transfer across the liquid membrane to the receiving nitric acid or ammonia solution, but the process is commonly accompanied by precipitation in the aqueous solutions or on the cellophane film at boundary 2 (Table 1). In the case of nitric acid solutions, a precipitate is formed in the receiving solution, and when dilute ammonia solutions were used, white precipitates were formed at the liquid membrane/receiving solution phase boundary. Electrodialysis is strongly affected by the nature of the solid ion-exchange membranes confining the electrode compartments. With the MA membrane in the anodic chamber and ammonia receiving solution, precipitates are formed in the initial Ag(I) solution and on the membrane surface, and the length of electrodialysis decreases because of desalting of the initial solution and abrupt increase of the potential. When the anode compartment is confined with the MK membrane, a precipitate is formed on the cellophane film at the liquid membrane/receiving solution phase boundary. With the cation-exchange (MK) membranes in both electrode compartments, the Ag(I) ions are transferred across the receiving solution and solid membrane to the cathodic solution, to be deposited on the platinum cathode. This explains the observed decrease in the Ag(I) concentration in the receiving solution with increasing current density (Table 1). In the further experiments, the transmembrane transport followed by silver electrodeposition was studied in a four-compart-

Table 1. Influence of the electrodialysis conditions on Ag(I) recovery into the liquid membrane E and into the receiving solution R (five-compartment cell; c_{HDEHP} = 20 vol %, c_{TOA} = 0.1 M, and c_{Ag} = 0.01 M)

ment cell with the only cation-exchange membrane MK-40 in the anode compartment.

As a cathodic solution for silver electroplating, we used ammonia, nitric acid, and perchloric acid solutions. The composition of the receiving solution has a considerable effect on the adhesion of the resulting silver deposits to the platinum cathode (Table 2). In the case of ammonia solutions, the resulting loose Ag precipitates demonstrate poor adhesion to the electrode. In the course of electrodialysis, white precipitates are formed on the cellophane film confining the ammonia solution. In the case of nitric acid receiving solution, we also observed partial peeling of the deposited metal from the cathode. It was found that the densest finely crystalline silver deposits, demonstrating good adhesion to the electrode, are separated from perchloric acid solutions. A decrease in the $HClO_4$ concentration to 0.05 M increases the Ag(I) recovery, and further decrease results in silver precipitation from the receiving solution (Table 2). Therefore, the effects of the basic parameters of membrane extraction on the Ag(I) transport and electrodeposition rates were examined at an $HClO_4$ concentration of 0.05 M.

An increase in the current density results in proportional increase in the Ag(I) recovery and electrodeposition over the current density range 0–8 MA cm^{-2} (Fig. 1). Further increase in the current density has no effect on the Ag(I) transport rate, and at i = 12 mA cm^{-2}, silver precipitation occurs in the receiving solution. In 1 h of electrodialysis at i = 10 mA cm^{-2}, about 90% of Ag(I) is extracted from the initial solution with c_{Ag} = 0.01 M into the liquid

Table 2. Influence of the receiving solution composition on Ag(I) recovery into liquid membrane E and into receiving solution R (four-compartment cell; i = 6.4 mA cm^{-2}; τ = 60 min; c_{HDEHP} = 20 vol % and c_{TOA} = 0.1 M)

membrane; about 50% of silver passes to the receiving solution; and about 35% of silver is deposited on the cathode. The current efficiency of Ag(I) in the transmembrane transport, estimated from the liquid membrane surface area, is below 10% under the experimental conditions. With supporting electrolyte taken in excess, the current across the liquid membrane is passed by essentially hydrogen ions from the initial solution and perchlorate ions from the receiving solution.

The kinetic dependences of Ag(I) transport and electrodeposition in the galvanostatic electrodialysis mode at various current densities are presented in Fig. 2. At a high current density (i = 10 mA cm^{-1}), Ag(I) is practically totally recovered from the initial solution in 1.5 h. The Ag(I) recovery into the receiving solution reaches about 50% in 1–1.5 h, depending on the current density. It should be pointed out that, at low current density, the recovery of Ag(I) into the receiving solution is late by about 30 min, and, correspondingly, the electrodeposition starts later than at i = 10 mA cm^{-2}. The length of electrodialysis is confined by the precipitation from the receiving solution and then from the initial solution, which starts 1.5–2 h after the beginning of the process.

With increasing Ag(I) concentration from 0.01 to 0.1 M, the Ag(I) flux across the liquid membrane and the cathodic deposit weight increase, but the recovery and electrodeposition efficiencies decrease (Fig. 3a). The current efficiency with respect to Ag(I) slightly increases with increasing starting Ag(I) concentration, remaining, however, rather low (about 7%). Within the experimental Ag concentration range, the current across the membrane is passed by essentially supporting electrolyte ions.

Increasing nitric acid concentration in the initial solution from 5×10^{-3} to 1×10^{-1} M considerably decreases the rates of transmembrane transport and electrodeposition of Ag(I) (Fig. 3b), which is caused by the decrease in the extracting power of HDEHP with increasing acidity of the aqueous phase [14]. The optimal HNO_3 concentration in the initial Ag(I) solution is 5×10^{-3} M. At this concentration and at a moderate current density, in 1 h of electrodialysis, the Ag(I) recovery from the initial solution is 90%, back extraction into the receiving $HClO_4$ solution is 60%, and about 40% of Ag(I) is deposited on the cathode.

With increasing $HClO_4$ concentration in the receiving solution from 0.05 to 1.0 M, the Ag(I) recovery and electrodeposition efficiencies decrease (Fig. 4). Such an effect of pH of the cathodic solution is typical of the electrodialysis transport, in contrast to the traditional membrane extraction with HDEHP, which requires high acidity of the stripping solution. An increase in the $HClO_4$ concentration results in increas-

Table 3. Influence of the composition of the liquid membrane on the Ag(I) recovery into the liquid membrane E and receiving solution R, electrodeposition efficiency m, and flux J (i = 5.7 mA cm^{-2}; receiving solution 0.05 M $HClO_4$; τ = 60 min)

ing flux of the ClO_4^- anions across the liquid membrane, which, in turn, decreases the current efficiency with respect to Ag(I).

Table 3 illustrates the influence of the HDEHP and TOA concentrations in the liquid membrane on the rates of Ag(I) transport and electrodeposition. An increase in the carrier concentration from 10 to 40 vol % at a fixed amine content increases the recovery of Ag(I) into the organic phase, only slightly influencing the transmembrane transport rate. The observed slight decrease in the Ag(I) recovery and electrodeposition efficiencies in the system with 40 vol % HDEHP can be attributed to an increase in the viscosity of the organic phase.

Solutions of crude HDEHP demonstrate low conductivity because of the presence of large amount of strongly associated monoalkylphosphoric acid [1]. To employ these solutions in electrodialysis with liquid membranes, it is necessary to use additives enhancing the conductivity. It was demonstrated that changing TOA concentration in the liquid membrane from 0.05 to 0.3 M slightly decreases the Ag(I) recovery into the organic phase and receiving solution (Table 3), which is probably due to an increase in the ClO_4^- flux with increasing concentration of the anion-exchange carrier.

An increase in the TOA concentration in the liquid membrane results in increasing conductivity and decreasing potential in the system. On the contrary, an increase in the carrier (HDEHP) concentration decreases the conductivity of liquid membranes (Fig. 5). In the course of electrodialysis, generally, the potential gradually decreases as a result of increasing total concentration of ions in the liquid membrane upon HDEHP extraction of Ag(I) and amine extraction of acids, and also because of accumulation of water in the organic phase. With increasing $HClO_4$ concentra-

tion in the receiving solution, the conductivity of the membrane system considerably increases (Fig. 6). In some cases, after 50–55 min of electrodialysis, an abrupt drop of the potential was observed, which can be attributed to the transfer of water to the organic phase (so-called electrical breakdown) (Fig. 6, curves *3, 4*). Water is transferred into the liquid membrane as a component of the ionic hydration–solvation shells and also via electroosmotic transport [15]. The observed increase in the potential in the system with the lowest $HClO_4$ concentration (curve *1*) is probably due to desalting of the receiving solution as a result of the transfer of the perchlorate ions across the liquid membrane into the feeding solution and also of the cathodic reduction of the hydrogen ions.

CONCLUSIONS

(1) In galvanostatic electrodialysis, liquid membranes containing crude HDEHP and TOA additive in 1,2-dichloroethane provide Ag(I) transport from nitric acid solutions into dilute ammonia, perchloric acid, and nitric acid solutions.

(2) The densest Ag(I) deposits with the highest adhesion to the electrode were obtained in electrodeposition from perchloric acid solutions. The optimal $HClO_4$ concentration in the receiving solution is 0.05 M.

(3) The Ag(I) transmembrane transport and electrodeposition rates increase with increasing current density, electrodialysis duration, and starting metal concentration in the initial solution. The HDEHP concentration in the organic phase only slightly influences the transport of Ag(I).

(4) An increase in the nitric acid concentration in the initial solution and in the perchloric acid concentration in the receiving solution, and also in the TOA concentration in the liquid membrane has a negative effect on the Ag(I) recovery and electrodeposition rates.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Heterophase Nitration of *o*-Nitrotoluene with Sulfuric–Nitric Acid Mixtures of Low Nitrating Activity in Gas-Containing Emulsions

A. V. Artemov, E. A. Veretennikov, and I. V. Tselinskii

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received July 12, 2007

Abstract—Heterophase nitration of *o*-nitrotoluene, in which an increase in the contribution of the reaction in the boundary adsorption monolayer under conditions of surface aeration leads to a higher yield of 2,4-dinitrotoluene and larger 2,4-/2,6-dinitrotoluene isomer ratio, was studied.

DOI: 10.1134/S1070427207110183

It is known that, in a two-phase reaction system formed in nitration of aromatic hydrocarbons with mixtures of sulfuric and nitric acids, nitration commonly occurs in a rather narrow region of the acid phase, adjacent to the phase boundary. At least two zones in which the nitration reaction occurs can be distinguished in this region: (i) bulk of the acid phase and (ii) boundary adsorption monolayer adjacent to the phase boundary on the acid phase side, in which the reaction proceeds between adsorbed molecules of the nitrating agent (nitronium cation) and an aromatic compound [1]. The kinetics and mechanisms of these reactions are different [1, 2].

The overall reaction rate v_n can be written as a sum of the nitration rate in the bulk (bulk nitration), v_{bl} (mol s^{-1}), and the rate of boundary nitration, related to the volume taking into account the adsorption monolayer thickness, v_{bn} (mol s^{-1}):

$$v_n = v_{bl} + v_{bn}. \quad (1)$$

Despite the attempts made [1], rigorous evaluation of the contribution of the boundary reaction to the overall rate and regioselectivity of the process has been impossible so far. As evidence that the reaction occurs just in the boundary region can serve the change in the isomeric composition of products formed in nitration of toluene and its *o*-nitro derivative (*o*-NT), compared with nitration in the bulk of the acid phase, because the reaction occurs with spatially oriented molecules of the aromatic hydrocarbon (Fig. 1) [1–3].

The nitration of *o*-NT in the boundary layer can occur when the rate of the chemical reaction in the boundary layer is comparable with, or higher than, the rate of *o*-NT diffusion across the phase boundary into the boundary layer of the acid phase. If this condition is satisfied, the reaction zone can contract to the thickness of the boundary layer.

EXPERIMENTAL

o-NT was nitrated with sulfuric–nitric acid mixtures of low nitrating activity (nitrating activity factor Φ = 70%) at 1-, 2.5-, 5-, and 10-fold molar excess of nitric acid in a 30 cm^3 glass reactor equipped with a thermostating jacket, four-blade turbine stirrer, vertical deflecting partitions, and thermocouple for measuring the reaction mass temperature.

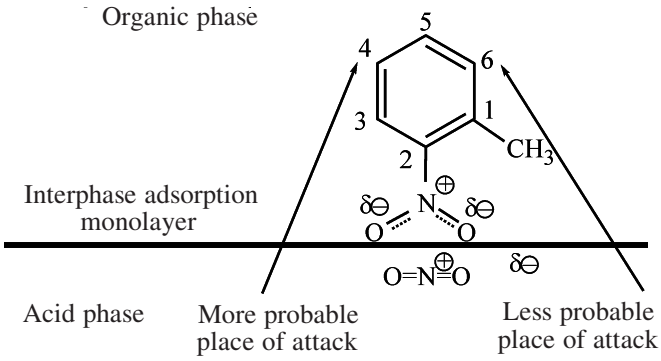

Fig. 1. Orientation of *o*-NT molecules at the phase boundary [1].

* Averaged gas contents are given for the acid mixtures used (as shown by the study, Γ varies only slightly within the composition range of the acid mixtures).

The deflecting partitions were mounted at a 90° angle with respect to each other in order to prevent formation of a whirlpool and projected by 5 mm over the reaction mixture to raise the air content of the foamed acid mixture. The agitation intensity was varied in the range 700–5000 rpm.

Nitric and sulfuric acids of pure grade were used in the experiments. The concentrations of the acid mixtures were determined by titration to within 0.02%. The acid mixtures were prepared by successive mixing of concentrated acids at 0°C with double-distilled water to reach a prescribed concentration. *o*-NT of chromatographic purity was used. The compositions of the acid mixtures used are listed in Table 1.

As the molar concentration of HNO_3 decreases in the series of acids in Table 1 (and, simultaneously, the molar concentration of water increases), the equilibrium concentration of the nitronium ion falls (1.0, and 0.3, and 0.1 mol % for mixture nos. 1, 2, 3, respectively [4]).

The isomeric composition of products and the yield of dinitrotoluenes (DNT) were determined on a Laboratorni Pristroje liquid chromatograph with an LCD 2563 UV double-beam detector at a wavelength of 254 nm. A 250 × 46-mm DuPont chromatographic column with a ZorbaxR Sil direct stationary phase with particle size of 5 μm was used. Eluent, 400 : 8 : 2 mixture of *n*-hexane, dichloromethane, and 2-propanol; elution rate, 0.4 ml min^{-1}; relative error in the yield of nitrotoluene and DNT isomers, ±0.2%.

In nitration of *o*-nitrotoluene, a calculated amount of this compound was introduced with a syringe into a reactor charged with an acid mixture, under agitation at a prescribed reaction temperature. After the lapse of the prescribed time, the agitation was switched off and the reaction mixture was poured into a fivefold amount of cold water (10–15°C). The nitro products were twice extracted with chloroform, with 6 ml of the solvent taken per gram of toluene subjected to nitration. Combined extracts were washed with an equal amount of water, the solvent was removed, and the nitro products were analyzed for the content of mono- and dinitro derivatives.

The gas content of the acid mixture was found from the increase in the volume of an agitated acid mixture with respect to that without agitation. The acid mixture was poured into the reactor to the lower overflow level of the apparatus. The temperature was raised to a prescribed level by supply of a heat-carrying agent into the apparatus jacket, and the reaction mixture was kept without agitation for 10 min. The volume of the acid mixture remaining in the apparatus (V_1) accounted for the thermal-expansion loss of the acid mixture. Similarly was measured the volume of the acid mixture remaining in the reactor after agitation for 5 min (V_2).

The gas content of the acid mixture at fixed parameters, Γ (vol %), was calculated by the formula

$$\Gamma = \frac{V_1 - V_2}{V_1} \times 100. \quad (2)$$

The values obtained for the gas content of the acid mixture at different temperatures are listed in Table 2.

The aim of this study was to examine the effect of *o*-NT nitration parameters on the isomeric composition of DNT.

The boundary mechanism in *o*-NT nitration includes the following stages [1]: (1) *o*-NT diffusion from the bulk of the dispersed organic phase toward the phase boundary, (2) diffusion of nitronium ions from the bulk of the acid phase to the phase boundary, (3) adsorption of nitronium ions and *o*-NT at the

phase boundary, (4) reaction between adsorbed nitronium ions and *o*-NT at the phase boundary, and (5) desorption of the product (dinitrotoluene) and its removal from the phase boundary.

Toluene is nitrated by sulfuric–nitric acid mixtures to mononitrotoluene in the diffusion mode at all the agitation modes studied. By contrast, the contribution of the kinetic component (chemical reaction proper) in nitrotoluene nitration to the overall process rate increases because of the decrease in the substrate reactivity [2, 5], whereas in *o*-NT nitration with sulfuric–nitric acid mixtures of low nitrating activity, this contribution may be even more significant.

Stages 1 and 2 cannot be rate-determining, because the acid mixtures used in mononitrotoluene nitration in this study have low nitrating activity. The adsorption/desorption stages (stages 3 and 5) involve small-size molecules [2] and are expected to be very fast. Consequently, it can be assumed that stage 4, i.e., the chemical reaction, can be rate-determining stage.

If the model [1] of heterogeneous nitrobenzene nitration is used, the overall nitration rate v_n (mol s^{-1}) can be expressed by the equation

$$v_n = -dm_n/dt = v_{bl} + v_{bn}, \quad (3)$$

where m_n is the nitric acid content of the system (mol %);

$$v_n = k'_{bl}[ArNO_2]_a^{sol}[NO_2^+]_a V_a + k'_{bn} S[ArNO_2]_{bn}^{sol}[NO_2^+]_{bn}, \quad (4)$$

where k'_{bl} and k'_{bn} are second-order rate constants for the bulk (m^3 mol^{-1} s^{-1}) and boundary (m s^{-1}) types of nitration, respectively; V_a, volume of the acid phase (m^3); $[ArNO_2]_a^{sol}$, concentration of *o*-NT dissolved in the acid mixture (mol m^{-3}); $[NO_2^+]_a$, concentration of nitronium cations in the mineral phase (mol m^{-3}); S, surface area of the phase boundary (m^2); $[ArNO_2]_{bn}^{sol}$ and $[NO_2^+]_{bn}$, boundary concentrations of *o*-NT and nitronium cations, respectively (mol m^{-2}).

It is important that hydrated protons in the acid phase compete with nitronium cations for the adsorption sites at the phase boundary. Consequently, the concentration of NO_2^+ ions at the phase boundary will depend on the ratio between the concentrations of NO_2^+ and protons in the bulk of the acid phase. This ratio increases with the sulfuric acid concentration. This fact was confirmed in [1], where the effective rate constant k_{bn} of the boundary reaction increased with the H_2SO_4 concentration.

It is known that, at a stirrer rotation rate exceeding a certain value, agitation is accompanied by spontaneous capture of air from the surface of a liquid being agitated (surface aeration) and gas bubbles are dispersed in the bulk of the reaction mass to give a gas-containing emulsion [6]. Under these conditions, the air content of the reaction mass increased from 0 to 65% (Table 2) as the agitation intensity was raised within the limits specified above.

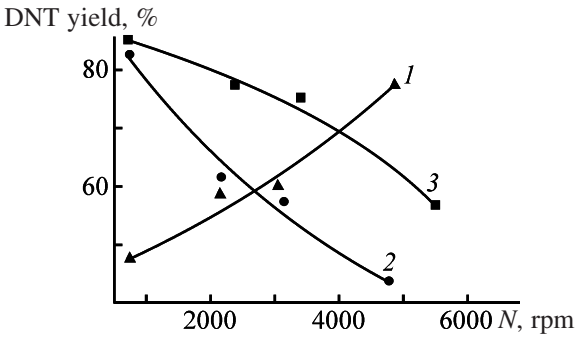

Fig. 2. DNT yield vs. the agitation intensity N in *o*-NT nitration with sulfuric–nitric acid mixtures (Φ = 70). (*1*) 7.2% HNO_3, 30.0% H_2SO_4, 62.8% H_2O, *o*-NT : HNO_3 = 1 : 10; (*2*) 15.5% HNO_3, 30.0% H_2SO_4, 54.5% H_2O, *o*-NT : HNO_3 = 1 : 10; (*3*) 22.3% HNO_3, 30.0% H_2SO_4, 47.7% H_2O, *o*-NT : HNO_3 = 1 : 5. T, °C: (*1*) 50 and (*2, 3*) 25. τ, min: (*1, 2*) 60 and (*3*) 30.

A study of the *o*-NT nitration yielded results that have not been obtained previously in analysis of the nitration macrokinetics of aromatic nitro compounds. First, raising the stirrer rotation rate, and accordingly the gas content of the reaction mass, in acid mixtures containing 22.3 and 15.5 mol % HNO_3 leads to a decrease, rather than an increase, in the nitration rate of *o*-NT (Fig. 2, Table 3, run nos. 1–8). For example, the yield of DNT in 30 min in *o*-NT nitration with a mixture containing 22.3 mol % HNO_3 is 85% at 700 rpm and 57.7% at 5000 rpm. Second, raising the agitation intensity changes the isomeric composition of the forming DNT: the content of 2,4-DNT grows, with the 2,4-/2,6-DNT ratio increasing to 2.50–2.68, compared with that obtained (1.85 [7]) under the standard nitration conditions (sulfuric–nitric acid mixture; Φ = 80.2; excess of nitric acid over the theoretical value 20%; zero or low gas content).

The experimental data obtained contradict the assumption that increase in the phase boundary area should lead to a higher formation rate of dinitrotoluene (because of the increase in the overall rate of the chemical reaction and mass-exchange processes). Consequently, the observed decrease in the overall nitration rate is due only to the gas content of the reaction mass, because it is known that an increase in the gas content of the reaction mass leads to a decrease in its density and viscosity and, accordingly, to

17	700	–	52.8	65.40	34.60	1.89	95	60

lower rates of mass transfer between the immiscible phases [6]. Thus, the nitration rate in the bulk of the acid phase, governed by mass-transfer processes, will decrease, which will make larger the contribution of the boundary reaction to the overall process rate.

The mass-transfer processes between phases are presumably also decelerated because, at high agitation intensity, the interaction between drops of the dispersed organic phase is largely suppressed and drops behave as solid spheres within which the mass transfer is hindered [8].

At a slow stirrer rotation rate (700–1500 rpm) and insignificant gas content (0–15 vol %), the contribution of the reaction in the boundary zone to the overall rate is presumably low as compared with the reaction in the bulk of the acid phase. Under these conditions, the highest dinitrotoluene yields are observed (Fig. 2, Table 3; run nos. 4, 8). However, the contribution of the boundary reaction increases as the gas content grows and rate of mass-exchange processes decreases, with the nitration rate in the bulk of the acid phase accordingly becoming lower.

As an additional evidence in favor of the possibility of the reaction in the boundary layer can serve the isomeric composition of the forming dinitrotoluene, which is distinguished by high content of 2,4-DNT (Table 3, run nos. 1–8).

By contrast, raising the stirrer rotation rate in *o*-NT nitration with weaker acid mixtures from 700 to 5000 rpm leads to an increase in the nitration rate, rather than to its decrease, and makes larger the DNT yield despite the higher gas content of the reaction mass (Fig. 2, Table 3, run nos. 9–17). For example, the yield of DNT in nitration with a mixture containing 7.2 mol % HNO_3 for 60 min is 48.6% at 700 rpm and 77.7% at 5000 rpm. In the given case, in which the rate of the chemical reaction is substantially lower than the diffusion rate, the reaction zone shifts, as the agitation intensity increases, from the surface layer into the bulk of the acid phase, and just there the reaction between the dissolved *o*-NT and the nitrating agent occurs. However, the decrease in the rate of mass-exchange processes in gas-containing systems results in that the overall reaction rate is mostly affected under the conditions specified by diffusion of

the reacting components into the reaction zone.

As evidence in favor of the occurrence of the reaction under kinetic control in the bulk of the acid phase in *o*-NT nitration with acid mixtures containing 7.2 and 3.5 mol % nitric acid can serve the isomeric composition of the forming dinitrotoluene: the content of 2,4-DNT decreases as the agitation intensity is raised from 700 to 5000 rpm and the 2,4-/2,6-DNT ratio is smaller (1.89–2.16) than that in nitration with mixtures containing 22.3 and 15.5 mol % HNO_3.

Further studies were concerned with the effect of temperature, agitation intensity, and composition of the sulfuric–nitric acid nitrating mixture (with the excess of nitric acid reduced to 1- and 2.5-fold) on the relative contributions of the kinetic and diffusion components of the *o*-NT nitration process on the overall process rate at different gas contents of the reaction mixture. The decrease in the *o*-NT/HNO_3 molar ratio made it possible to diminish the expenditure of the acids to bring the process closer to preparative conditions.

The dependence of the 2,4-/2,6-DNT ratio on the nitric acid content of the acid mixture passes through a maximum at 22.3 mol % HNO_3 at any of the agitation intensities studied (Table 4, Fig. 3).

* Reaction time 60 min.

and 3.5 mol % nitric acid can serve the isomeric composition of the forming dinitrotoluene: the content of 2,4-DNT decreases as the agitation intensity is raised from 700 to 5000 rpm and the 2,4-/2,6-DNT ratio is smaller (1.89–2.16) than that in nitration with mixtures containing 22.3 and 15.5 mol % HNO_3.

Further studies were concerned with the effect of temperature, agitation intensity, and composition of the sulfuric–nitric acid nitrating mixture (with the excess of nitric acid reduced to 1- and 2.5-fold) on the relative contributions of the kinetic and diffusion components of the *o*-NT nitration process to the overall process rate at different gas contents of the reaction mixture. The decrease in the *o*-NT/HNO_3 molar ratio made it possible to diminish the expenditure of the acids to bring the process closer to preparative conditions.

The dependence of the 2,4-/2,6-DNT ratio on the nitric acid content of the acid mixture passes through a maximum at 22.3 mol % HNO_3 at any of the agitation intensities studied (Table 4, Fig. 3).

It is known that raising the concentration of nitric acid in the acid mixture at the expense of the H_2O content in heterogeneous nitration leads both to an increase in the solubility of aromatic compounds in the bulk of the acid phase [9] and to a rise in the activity of the nitronium cation [4]. Presumably, as the content of nitric acid is raised from 7.2 to 22.3%, the contribution from the rise in the activity of the nitronium cation prevails over that of the increase in the solubility of *o*-NT in the acid mixture, which leads to contraction of the reaction zone, larger contribution of the reaction in the boundary layer, and increase in the 2,4-/2,6-DNT ratio from 1.96 to 2.19.

Possibly, further increase in the HNO_3 content of the acid mixture causes the rise in the substrate solubility and in the equilibrium concentration of *o*-NT in the bulk of the mineral phase, which can lead to a larger contribution of the reaction in the bulk of the acid phase, which is a function of the reactant concentrations, to the overall process rate [1].

The experimental data obtained confirm the assumption that underlies this study: specifically, that raising the molar concentration of HNO_3 in the nitrating mixture at a constant molar content of H_2SO_4 leads to an increase in the nitration rate and decrease in the 2,4-/2,6-DNT ratio. This indicates that the contribution of the kinetic component to the overall process rate becomes more pronounced. This fact was additionally confirmed in a study of how the reaction

rate and isomeric composition of DNT depend on the agitation intensity (Table 4; run nos. 1–4, 5–8, etc.). The increase in the 2,4-/2,6-DNT ratio from 1.80 to 2.03 on raising the stirrer rotation rate from 700 to 5000 rpm (Table 3) confirms the increasing contribution of the nitration in the boundary region and is well consistent with the previously obtained data [1].

The noticeable increase in the contribution of *o*-NT in the boundary layer in the entire range of compositions of acid mixtures studied at an agitation intensity of 5000 rpm can be further confirmed by the effect of temperature on the yield and relative contents of isomers in the forming DNT. It would be expected that, as the reaction temperature is raised, the solubility of *o*-NT in the mineral phase should increase and the interaction between drops should be enhanced, with their size increasing and the rate of mass-exchange within drops becoming slower [8]. Consequently, the contribution of the boundary reaction in the adsorption layer to the overall kinetic component of the process will decrease.

In the range of acid mixtures studied, the content of 2,4-DNT falls as the nitration temperature is raised. For example, the 2,4-/2,6-DNT isomer ratio in nitration with an acid mixture containing 15.5 mol % HNO_3 falls from 2.21 to 1.80 as temperature is elevated from 25 to 75°C (Table 5, run nos. 13–15). This dependence is observed at 5000 rpm, i.e., under high gas content conditions (Table 5).

At the same time, a slight increase in the total yield in 60 min of the reaction was observed at nitric acid contents in the range 22.3–31.1 mol % as temperature was elevated (e.g., from 61.2 to 67.5% on raising the temperature by 25°C) (Table 5, run nos. 4 and 6). An insignificant increase in the reaction rate is observed when the rate-determining stage of nitration is diffusion of components into the reaction zone at a high rate of the chemical reaction itself. This behavior can be understood if the temperature coefficients of the rates of the chemical reaction and diffusion are compared. For example, raising the temperature by 10°C leads to a 3–4-fold increase in the rate constant of the chemical reaction of nitration, whereas the diffusion rate of aromatic compounds increases by only a factor of 1.1–1.5 [7]. In nitration with a weaker acid mixture containing 15.5 mol % HNO_3, the increase in the product yield with temperature is more pronounced (Table 5, run nos. 13–15), which indicates that the contribution of the chemical reaction stage to the overall process rate increases.

CONCLUSIONS

(1) The heterophase nitration of *o*-nitrotoluene can be performed with weak sulfuric–nitric acid mixtures of various compositions and a nitrating activity factor Φ equal to 70.

(2) Raising the gas content of the reaction mixture by high-intensity agitation (>2000 rpm) results in that the contribution of the reaction in boundary adsorption monolayer to the overall process rate increases, the yield of 2,4-dinitrotoluene grows, and the 2,4-/2,6-DNT isomer ratio becomes larger.

(3) The rise in the contribution of nitration in the bulk of the acid phase as a result of a decrease in the reaction temperature and an increase in the molar concentration of nitric acid in the acid mixture is accompanied by an increase in the yield of 2,6-dinitrotoluene.

(4) The deceleration of the mass exchange between phases, observed as the gas content of the reaction mass increases, occurs because, at high agitation intensity, the interaction between drops of the dispersed organic phase is largely suppressed and the drops behave as solid spheres within which mass exchange is hindered.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Composition of Reaction Mixtures Formed by Ethanolamine Detoxication of Yperite

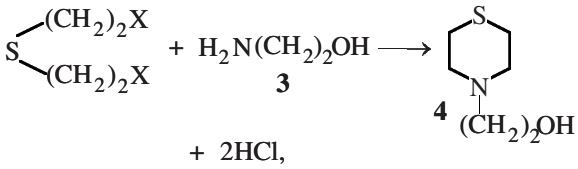
Abstract—The reaction mixture from detoxication of technical-grade yperite with monoethanolamine was fractionated, and its composition was determined. The structures of the free thiomorpholine bases formed in the process were determined by gas chromatography–mass spectrometry.

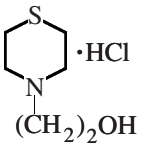
DOI: 10.1134/S1070427207110195

In accordance with the Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on Their Destruction, various war gases, in particular, yperite **1**, accumulated in Russia, are subjected to detoxication. The detoxication is based on the reaction with ethanolamine **3** with the formation of 2-(thiomorpholin-4-yl)ethanol **4**, similar to the reaction described as early as 1934 for the bromine analog of yperite **2** [1–5]:



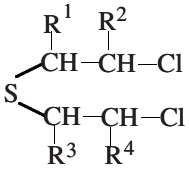
where X = Cl (**1**), Br (**2**).

The released hydrogen chloride is absorbed by a base: excess **3** [1], sodium carbonate [2], or reaction product **4** [3–5]. The reaction of pure yperite **1** with **3** can yield either free compound **4** or its hydrochloride **5** depending on the amount of the bases taken:

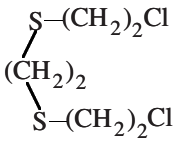


5

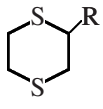
Technical-grade yperite intended for use as a war gas is a mixture of substances. Its composition depends on the synthesis procedure, purity of the starting compounds, and storage conditions. According to published data [6], technical-grade yperite contains as impurities homologs **6**–**10**, 1,2-bis(2-chloroethylthio)-ethane (sesquiyperite) **11**, small amounts of 1,4-dithiane **12** and 2-methyl-1,4-dithiane **13**, and other polysulfurous compounds:



1, **6**–**10**



11



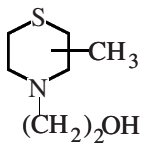
12, **13**

where $R^1 = R^2 = R^3 = R^4 = H$ (**1**); $R^1 = CH_3$, $R^2 = R^3 = R^4 = H$ (**6**); $R^1 = R^3 = R^4 = H$, $R^2 = CH_3$ (**7**); $R^1 = R^3 = CH_3$, $R^2 = R^4 = H$ (**8**); $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$ (**9**); $R^1 = R^3 = H$, $R^2 = R^4 = CH_3$ (**10**); R = H (**12**); R = CH_3 (**13**).

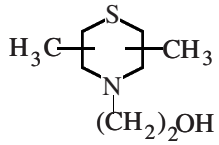
The presence of homologs **6**–**10** in technical-grade yperite may be due to the presence of a propylene impurity in ethylene taken for the synthesis of yperite [6]. In detoxication of technical-grade yperite, the products of reaction with base **3** will be rather diverse, and the composition of the reaction mixture will depend on the composition of technical-grade yperite. This can be readily seen from comparison of data of [6–8].

According to the process sheet accepted in Russia, 2.4–2.6 mol of ethanolamine **3** as aqueous solution is taken per mole of technical-grade yperite. Therefore, the reaction mixture is alkaline (pH 9–10). In such a medium, the corresponding free bases should be inevitably present along with the hydrochlorides described in the literature [3, 9]. Among such bases are compound **4**, methyl derivatives of 2-(thiomorpholin-4-yl)ethanol **14**–**21**, 6-thia-3,9-diazaundecane-1,11-diol

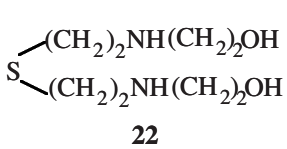
22, 6,9-dithia-3,12-diazatetradecane-1,14-diol **23**, and their derivatives:



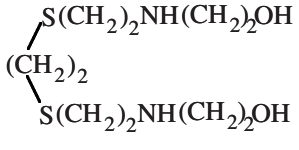
14, **15**



16–**21**



22



23

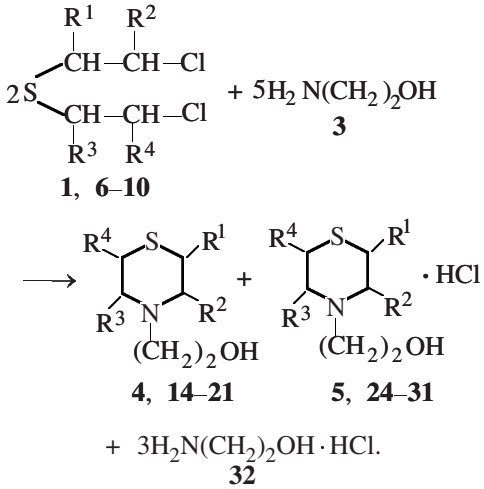
The formation of free base **4** by the reaction of **1** with aqueous ethanolamine **3** was described in [4].

The presence of free bases in the reaction mixture was proved by extraction of an aqueous solution of the reaction mixture with hexane, ether, or chloroform, followed by analysis by gas chromatography–mass spectrometry (GC–MS). The analysis revealed the presence of 1,4-dithiane **12**, 2-methyl-1,4-dithiane **13**, 2-(thiomorpholin-4-yl)ethanol **4**, isomeric 2-(2-methylthiomorpholin-4-yl)ethanol **14** and 2-(3-methylthiomorpholin-4-yl)ethanol **15**, and six isomeric (including *cis* and *trans* isomers) dimethyl derivatives of 2-(thiomorpholin-4-yl)ethanol **16**–**21**. Compounds **4** and **12** were identified by comparison of their mass spectra with those from the MAINLIB NIST library.

Compounds **4**, **12**, **13**, and their methyl derivatives **14**–**21** were detected by GC–MS in gases released from bitumen–salt masses incorporating products of yperite detoxication by its reaction with base **3** [8]. The positions of methyl groups were not indicated.

The structures of amino alcohols **14** and **15** (without assignment within this pair) and of six isomeric dimethyl derivatives **16**–**21** (each of which can exist as *cis* and *trans* isomers) were determined by comparison of their mass spectra with that of base **4**. The *m*/*z* values for the molecular ions (162 for **14** and **15**, 176 for six isomers **16**–**21**) correspond to their molecular weights, and the number of the observed isomers agrees with that expected theoretically. The strongest peaks in the mass spectra, *m*/*z* 130 (100) and 131 (100) for two monomethyl derivatives **14** and **15**, and 144 (100) for six dimethyl derivatives **16**–**21**, correlate with the strongest peak in the mass spectrum of **4**, *m*/*z* 116 (100), differing from the latter peak by the weight of one and two CH_2 groups, respectively. The structure of cyclic disulfide **13** was determined by comparison of its mass spectrum with that of 1,4-dithiane **12**. The GC–MS data for reaction mixtures are given in the table. The presence of hydrochlorides was proved by alkali treatment of the solution after the extraction of free bases, followed by extraction of the released bases with chloroform. Compounds **12** and **13** were absent in the extract, and the qualitative composition of the bases (compounds **4**, **14**–**21**) repeated the composition of the mixture of bases in extracts from the initial aqueous solution of the reaction mixture.

Thus, within the framework of the accepted process for detoxication of technical-grade yperite, the formation of thiomorpholine derivatives can be described by the following scheme:



1, **6**–**10** **3** **4**, **14**–**21** **5**, **24**–**31**

32

where $R^1 = R^2 = R^3 = R^4 = H$ (**1**, **4**, **5**); $R^1 = CH_3$, $R^2 = R^3 = R^4 = H$ (**6**, **14**, **24**); $R^1 = R^3 = R^4 = H$, $R^2 = CH_3$ (**7**, **15**, **25**); $R^1 = R^3 = CH_3$, $R^2 = R^4 = H$ (**8**, **16**, **17**, **26**, **27**); $R^1 = R^4 = CH_3$, $R^2 = R^3 = H$ (**9**, **18**, **19**, **28**, **29**); $R^1 = R^3 = H$, $R^2 = R^4 = CH_3$ (**10**, **20**, **21**, **30**, **31**).[1]

Open-chain free bases of types **22** and **23**, as well as their derivatives, were not studied.

EXPERIMENTAL

The reaction mixture was taken from a plant for elimination of chemical weapons near Gornyi urban village, Saratov oblast, Russia.

Gas–liquid chromatography (GLC) was performed on a Kristall-2000 M device equipped with a CP-

[1] There are no data in the literature on the stereoisomerism of **6**–**10**. Therefore, their isomerism is assumed but is not considered in detail. We did not assign the peaks of two isomeric methyl derivatives of 2-(thiomorpholin-4-yl)ethanol to particular compound **14** or **15**. Six peaks of dimethyl derivatives of 2-(thiomorpholin-4-yl)ethanol were not assigned to particular isomers either.

Results of GC–MS analysis of reaction mixture components: 1,4-dithianes and 2-(thiomorpholin-4-yl)ethanols

* The *m/z* values and intensities for the molecular peaks are printed bold, and those for the strongest peaks of the given compound are printed italic.

WAX-58 (FFAP) capillary column (length 30 m, inside diameter 0.32 mm, thickness of liquid phase coating 0.25 μm) and a flame ionization detector. The carrier gas was helium (flow rate 1.0 ml min^{-1}). The vaporizer and detector temperatures were 280 and 300°C, respectively. The temperature was elevated from 80 to 160°C at a rate of 8 deg min^{-1}.

The GC–MS studies were performed with a Saturn 2200 gas chromatograph–mass spectrometer (Varian) equipped with an ion trap detector and a CP-SIL 8CB LOW BLEED/MS capillary column (length 30 m, inside diameter 0.25 mm, thickness of liquid phase 0.25 μm). The flow rate of the carrier gas (helium) was 0.9 ml min^{-1}. Experiments were performed with a typical sample of the reaction mixtrue obtained by detoxication of technical-grade yperite with 80% aqueous ethanolamine.

The compounds that do not exhibit basic properties, dithianes **12** and **13**, were studied as follows: 15.11 g of the reaction mixture and 25 ml of distilled water were shaken up in a 250-ml Erlenmeyer flask for 5 min. The resulting dark brown solution of the reaction mixture with a small amount of undissolved fine black particles had pH 9–10 according to universal test-paper. The mixture was acidified with ~20% HCl to pH 1–2 and extracted with three portions of ether (20, 10, and 10 ml). The combined extracts were analyzed by GLC. Dithiane **12** was eluted first (identification with an authentic sample). Its structure and the structure of its homolog **13** were confirmed by GC–MS. The ratio of the GLC peak areas of **12** and **13** was 2.2 : 1.

The quantitative determination of the sum of dithianes **12** and **13** was performed as follows: Combined light yellow ether extracts were dried over anhydrous sodium sulfate, and the ether extract was carefully decanted from the desiccant to a preliminarily weighed 250-ml flat-bottom flask. The solvent was evaporated, and the remaining oil gradually crystallized to form light yellow needle-like crystals. The weight of the neutral fraction thus obtained (mixture of dithianes **12** and **13**) was 0.30 g.

To confirm the structure of substances present in the reaction mixture, we examined by GC–MS the *n*-hexane extract from the reaction mixture diluted by a factor of 2 with distilled water. The extract (1 μl)

was introduced into the injector of the gas chromatograph–mass spectrometer. The injector temperature was 250°C. The temperature schedule of the column was as follows: 100°C, 3 min; heating to 150°C, 10 deg min^{-1}; 150°C, 3 min; heating to 250°C, 5 deg min^{-1}; 250°C, up to the end of the run. The total analysis time was 30 min. The ion trap was not switched on in the first 10 min, and then the analysis was performed in the El Auto mode. As a result, we identified dithianes **12** and **13**.

To examine the components present in the reaction mixture in the form of hydrochlorides, the reaction mixture was diluted with a fivefold volume of distilled water, filtered through silica gel, and repeatedly extracted with chloroform. The chloroform extracts were discarded, and the aqueous solution was alkalized with 20% aqueous NaOH to pH 11–12 and again extracted with chloroform to recover components that were initially present in the reaction mixture as hydrochlorides. A 1-μl portion of the extract was introduced into the GC–MS injector. The injector temperature was 250°C. The temperature schedule of the column was as follows: heating from 50 to 250°C at a rate of 15 deg min^{-1}. The total analysis time was 20 min. The ion trap was not switched on in the first 5 min, and then the analysis was performed in the El Auto mode. Among bases **4**, **14**, and **15**, 2-(thiomorpholin-4-yl)ethanol **4** was eluted first, which was followed by elution of **14** and **15** (the order of their elution was not determined). The ratio of the areas of the three peaks (in the order of their elution) was 6 : 2.3 : 1. Six isomeric dimethyl-2-(thiomorpholin-4-yl)ethanols **16**–**21** were also detected in small amounts.

We determined the weight fractions of basic products formed by the reaction of yperite with ethanolamine and present in the reaction mixture in the form of both hydrochlorides and free bases.

For the quantitative determination of components present in the reaction mixture in the form of free bases and tars, the reaction mixture (23.92 g) was placed in a flask and diluted with 120 ml of distilled water. The contents were shaken up for 5 min. By so doing, we obtained a dark brown aqueous solution of the reaction mixture with a small amount of undissolved fine black tarry particles. The solution pH was 9–10 by the universal test-paper.

A wool filter was placed in a tip of a chemical funnel, after which the funnel was charged with 25 g of silica gel. The aqueous solution of the reaction mixture was filtered through this filtering unit to separate tars and fine particles. The filtrate was a transparent yellow-brown solution, which became turbid within several hours.

The silica gel with the deposited tars was dried for 24 h at 45–50°C. The weight of the tars was estimated from the difference between the weights of the initial silica gel and silica gel with the deposited tars; it was 1.59 g.

From the aqueous solution of the reaction mixture, we recovered by extraction with chloroform (nine 15-ml portions) both neutral substances (1,4-dithiane, 2-methyl-1,4-dithiane, unidentified polysulfides) and basic compounds [mixture of homologs of 2-(thiomorpholin-4-yl)ethanol and 6-thia-3,9-diazaundecane-1,11-diol] in the form of free bases. In so doing, ethanol did not pass into the chloroform phase, which was confirmed by TLC (Silufol plate, eluent acetone).

When the extraction was performed in a separating funnel, three layers formed. The upper layer was an aqueous solution of the reaction mixture; the lower layer was the chloroform extract; and the middle layer was a stable emulsion consisting of the aqueous reaction mixture and chloroform. In each extraction run, only the chloroform extract was taken. The chloroform extracts were combined.

After the extraction completion, the remaining emulsion and reaction mixture were left to settle for 2 days. The chloroform extract thus obtained was separated and combined with the other chloroform extracts.

The chloroform and aqueous solutions were filtered prior to the next extraction runs, and an additional 0.74 g of tars insoluble in water and chloroform was obtained. Thus, the total content of tars in the given portion of the reaction mixture was 2.33 g. After the chloroform evaporation, a mixture of neutral and basic (in the form of free bases) substances was obtained (total amount 2.87 g).

It was shown above that 1,4-dithianes were present in the reaction mixture in an amount of 2.0%. Thus, in the given portion of the reaction mixture (23.92 g) the weight of basic compounds present in the form of free bases was 2.39 g. The remaining aqueous solution of the reaction mixture was used for further recovery of basic compounds present in the reaction mixture as hydrochlorides.

For quantitative determination of basic components present in the reaction mixture as hydrochlorides, an aqueous solution of the reaction mixture after the recovery of free bases and 1,4-dithianes was alkalized with 10% aqueous NaOH to pH 11–12, which was

followed by repeated extraction with chloroform (eight 10-ml portions). A transparent light yellow extract was obtained; after the solvent evaporation, 1.74 g of basic compounds was recovered.

The total content of water, ethanolamine, and other unidentified water-soluble organic compounds that were not recovered by extraction was determined as the difference between the initial weight of the reaction mixture and total weight of all the recovered components. For the given reaction mixture sample, it amounted to 16.98 g.

CONCLUSIONS

(1) The major components of the reaction mixture obtained by detoxication of yperite with ethanolamine are mixtures of free bases, 2-(thiomorpholin-4-yl)ethanols and the corresponding salts (hydrochlorides). The ratio between the bases and their salts is 1.37 : 1. 1,4-Dithianes are detected as minor impurities.

(2) A fractionation procedure was developed, allowing separation of free 2-(thiomorpholin-4-yl)ethanols, their salts, and 1,4-dithianes.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Activity and Stability of Ni/Al_2O_3 Catalysts in Carbon Dioxide Conversion of Methane as Influenced by Alkali Metal Oxide Additives (K_2O, Na_2O, Li_2O)

Abstract—Properties of Ni/Al_2O_3 composites supported by synthetic cordierite ceramic block matrices of honeycomb structure in carbon dioxide conversion of methane in the presence of alkali metal oxides (K_2O, Na_2O, Li_2O) were studied in comparison with those of GIAP-18 granulated catalyst.

DOI: 10.1134/S1070427207110201

Production processes of ammonia, alcohols, and other compounds are based on oxidative conversion of methane into synthesis gas. Only steam and steam–air conversion is used in modern industry. Carbon dioxide conversion of methane (CDCM) attracts growing researchers' attention. This reaction can be used for processing greenhouse and flue gases [1] and for preparing synthesis gas in production of dimethyl ether (high-performance additive to gasoline) [2]. In addition, activation of fairly inert molecules of CH_4 and CO_2 is of great scientific interest.

Highly active and cheap nickel-containing catalysts (NiO/Al_2O_3, NiO/ZrO_2) are most frequently used in oxidative conversion of methane. High positive enthalpy of the reaction $CH_4 + CO_2 \rightleftarrows 2CO + 2H_2$ ($\Delta H^0 = +247$ kJ mol^{-1}) and deactivation of all the known catalysts owing to their carbonization [3] complicate industrial implementation of CDCM. Nickel-containing catalysts are fairly active in CDCM, but they are rapidly deactivated owing to formation of elemental carbon on their surface.

These are several approaches to solve the problem of carbonization of CDCM catalysts. One of them is adjustment of the structural properties of catalysts. The operation stability of the catalysts in CDCM increases with a decrease in the particle size of metallic nickel [1, 4]. The catalysts containing 10–20-nm nickel particles have the highest stability [4]. This is due to the fact that the nanocomposite catalysts provide the required balance between the rates of degradation of CH_4 on metallic nickel and of dissociation of CO_2 at the metal–oxide interface [5]. In this connection, NiO/Al_2O_3 composites can be promising catalysts for CDCM. Preparation of the catalysts from these components involves formation of spinel $NiAl_2O_4$ during the heat treatment and reduction of spinel to form finely divided metallic nickel stabilized in the Al_2O_3 matrix. The other way to improve the catalyst stability in CDCM is to enhance the surface basicity, which is usually accomplished by introducing alkali and alkaline-earth metal oxides as promoters [6].

Thermodynamics of oxidative conversion of methane (steam, carbon dioxide) requires high temperatures to reach high methane conversion. This reaction is controlled, as a rule, by diffusion. Catalytic oxidation of methane penetrates into a catalyst granule to a depth of no larger than 0.25 mm. Therefore, ceramic block matrices with honeycomb structure and small wall thickness show promise as the catalyst supports. We expect that these catalysts will not only increase the process productivity but also decrease carbonization of the internal surface of the catalyst owing to facilitation of oxidant diffusion into the reaction zone.

The aim of this study was to examine the influence of alkali metal oxides (K_2O, Na_2O, Li_2O) on the activity and operation stability in CDCM of Ni/Al_2O_3 catalysts supported by ceramic block matrices of honeycomb structure.

Ceramic block matrices of honeycomb structure made from synthetic cordierite ($2Al_2O_3 \cdot 2MgO \cdot$

Table 1. Activity and performance of the catalysts in CDCM. Concentrations of CH_4 and CO_2 are 5.5 and 7.0%, respectively

Sample no.	Catalyst, %	Temperature of 80% conversion, °C	Performance	
			$A \times 10^6$, mol s^{-1} g_{cat}^{-1-1}	$B \times 10^6$, mol s^{-1} g_{NiO}^{-1}
1	GIAP-18	485	12.96	1.62
2	(8.2NiO + 11.2Al_2O_3)/cordierite	480	38.3	4.8
3	(3.8NiO + 11.2Al_2O_3)/cordierite	492	30.0	7.8
4	(1.0NiO + 2.0Al_2O_3)/cordierite	533	27.6	27.6

$5SiO_2$)[1] were used as supports. The cell size was 1.0 × 1.0 mm, and the wall thickness was 0.2 mm. The support is stable up to 1250°C.

The catalysts were prepared by impregnation of block matrices with a solution of nickel and aluminum nitrates, followed by calcination in a muffle furnace at 600°C for 3 h in air. The salt ratio in the solution provided the required composition of the catalysts. To modify Ni/Al_2O_3 catalysts with alkali metal oxides (K_2O, Na_2O, Li_2O), the samples were impregnated with aqueous solutions of the corresponding alkali metal carbonates, dried, and calcined.

To determine the catalytic activity, a cylindrical 0.25-g fragment 7 mm in diameter and 12 mm long was cut from a sample of the block catalyst. The catalyst fragment was placed in a flow reactor so as to prevent breakthrough of the gaseous reaction mixture without contacting the catalyst. Comparative study of GIAP-18 catalyst was performed with a 1.0-g weighed portion of the 1–2-mm fraction. Prior to the experiment, the catalyst was reduced in the reactor with 2% H_2 in He at 700°C for 2 h. Then, the sample was cooled to the temperature of CDCM in a flow of the reducing gas mixture. To determine the catalytic activity, the methane conversion at different temperatures was measured. The flow rate of the gas mixture was 100 ml min^{-1}. The space velocity of the reaction mixture in the experiment with block catalysts and GIAP-18 was 6000 and 3000 h^{-1}, respectively. We used a mixture of He with 5.5 vol % CH_4 and 7.0 vol % CO_2. The composition of the reaction mixture was analyzed chromatographically with a thermal conductivity detector.

The strength of the Ni–O bond in the catalysts was determined by temperature-programmed hydrogen reduction (TPHR). The experiments were performed on a flow unit with chromatographic determination of hydrogen consumed for reduction of the catalyst. The unit was heated from 20 to 850°C at a rate of 10 deg min^{-1}. The reaction products (water vapor) were collected at –50°C in a trap packed with 5 Å molecular sieves. A mixture of 10% hydrogen with argon was used as the reducing agent.

The activity and performance of the block catalysts with different compositions and honeycomb structure (samples nos. 2–4) are presented in Table 1 in comparison with those of GIAP-18 catalyst (sample no. 1). It is seen that the activities of granulated (sample no. 1) and block (sample no. 2) catalyst with similar content of the reactive component (8% NiO) are similar. However, the performance of the block catalyst per unit weight of the catalyst is higher than that of granulated GIAP-18 catalyst by a factor of approximately 4. The difference in performance of the granulated and block catalyst per unit weight of nickel oxide is still higher. This is due to the fact that the wall thickness of a block in the catalysts with honeycomb structure is commensurable with the depth of the working layer. As a result, the performance of the reactive component in the catalytic reaction increases.

To estimate the operation stability of the catalyst in CDCM, the $x = f(T)$ dependences are successively measured for the sample catalyst sample. The temperature dependence of the methane conversion $x = f(T)$ in the presence of (1.0%NiO + 2.0%Al_2O_3)/cordierite catalyst repeatedly measured after keeping the sample at each temperature to the constant conversion are shown in Fig. 1. It is seen that the methane conversion is incomplete in the second experiment (curve *2*). The conversion decreases on heating above 700°C. The strongest decrease in the methane conversion is observed in the third experiment (curve *3*), and then the catalyst is deactivated owing to carbonization. Some decrease in the reaction onset temperature in the third experiment may be due to reduction of the catalyst with the reaction gas mixture.

[1] The ceramic block supports were developed and prepared at Frantsevich Institute of Materials Science Problems, National Academy of Science of Ukraine.

Coke can be formed on the catalyst by the following reactions [3]:

$$CH_4 = C + 2H_2, \quad \Delta H^0 = +74.8 \text{ kJ mol}^{-1}, \quad (1)$$

$$2CO = C + CO_2, \quad \Delta H^0 = -172.5 \text{ kJ mol}^{-1}. \quad (2)$$

The reaction enthalpy shows that an increase in the temperature is favorable for reaction (1) and a decrease in the temperature, for reaction (2). The most pronounced decrease in the catalytic activity is observed at high temperatures (Fig. 2). Hence, the most probable pathway of catalyst carbonization is reaction (1).

The mechanism of CDCM on the nickel catalyst can be described by the following steps [3, 7]:

$$CH_4 + Z \rightleftarrows \{CH_x\}\text{–}Z + (4 - x)H_{ads} \rightleftarrows ZC + 2H_2, \quad (3)$$

$$CO_2 + Z \rightleftarrows Z\text{–}O + CO, \quad (4)$$

$$Z\text{–}C + Z\text{–}O \rightleftarrows Z\text{–}CO + Z, \quad (5)$$

$$Z\text{–}CO \rightleftarrows Z + CO, \quad (6)$$

where Z is an active center of the catalyst.

Activation of methane and its dissociation to form molecular hydrogen and carbon occur on the acid centers of the catalyst surface. The rate-determining step is oxidation of carbon with surface oxygen [reaction (5)].

High surface acidity accelerates methane activation [reaction (3)] but promotes coke accumulation, thus deactivating the catalyst. Carbonization of the catalyst can be decreased by adjustment of the acid–base properties of the catalyst surface. However, this can slightly decrease the catalytic activity. The activity of the Ni/Al_2O_3 catalyst is maximal in the first reaction steps. The nickel catalysts on base supports Ni/MgO, Ni/CaO, Ni/MnO, and Ni/ZrO_2 show higher performances than does Ni/Al_2O_3, and these catalysts are stable to carbonization [8].

The temperature dependences of methane conversion in the presence of the catalysts modified with alkali metal oxides are shown in Fig. 2. The most active is the catalyst modified with K_2O (curve *1*), and the least active is the catalyst containing Li_2O (curve *3*). In addition, the latter catalyst is characterized by unstable operation. At high temperature providing high methane conversion, the activity of this catalyst decreases with time. This is probably due to the fact that lithium oxide exerts a corroding effect on the majority of metals at high temperatures [9].

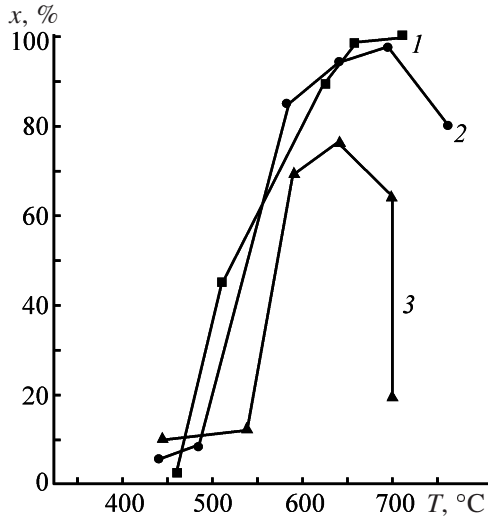

Fig. 1. Variation of the activity of (1.0% NiO + 2.0% Al_2O_3)/cordierite catalyst in repeated experiments on CDCM. (*x*) Conversion and (*T*) temperature; the same for Figs. 2 and 3. (*1–3*) Run nos.

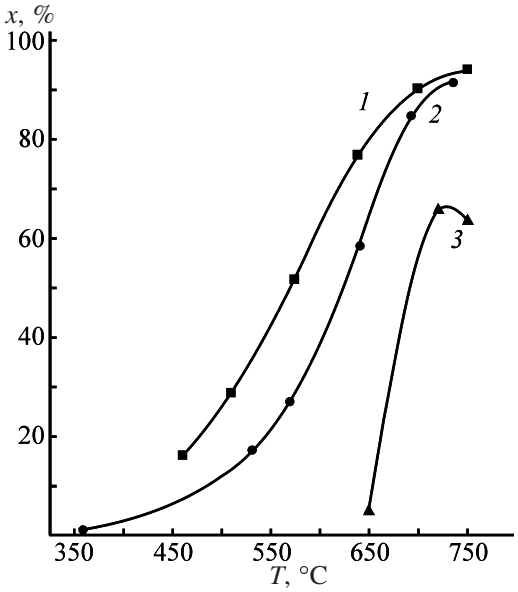

Fig. 2. Temperature dependence of methane conversion in the presence of catalysts with alkali additives: (*1*) 1.0% NiO + 2.0% Al_2O_3 + 0.6% K_2O, (*2*) 1.0% NiO + 2.0% Al_2O_3 + 0.9% Na_2O, and (*3*) 1.0% NiO + 2.0% Al_2O_3 + 0.7% Li_2O.

It reacts with metallic nickel to form nickel oxide inert in CDCM [10]. The catalytic activity slightly decreases with increasing potassium oxide content from 0 to 1.3% (Fig. 3), which can be caused by formation of inactive alkali metal aluminates. In this case, however, the operation stability of the catalyst increases.

Thus, alkali metal oxides (K_2O, Na_2O) decrease carbonization of the nickel–aluminum catalyst in

Table 2. Influence of CO_2 concentration on CDCM at 700°C and CH_4 concentration of 5.5 vol %

Catalyst, %	Methane conversion, %, at indicated CO_2/CH_4 ratio			
	1.3	1.6	1.8	2.2
1.0NiO + 2.0Al_2O_3 + 0.6K_2O	98	90	85	78
1.0NiO + 2.0Al_2O_3 + 1.3K_2O	95	88	77	63

CDCM, thus increasing their operation stability. The activity of nickel–aluminum catalyst significantly decreases after its modification with lithium oxide.

To prevent carbonization of a catalyst in steam conversion of methane, excess oxidizing agent (H_2O) is introduced into the reaction mixture [11]. Usually, the H_2O/CH_4 ratio is 2.0–2.5. We studied the influence of the CO_2 concentration on CDCM. In these experiments we used the catalysts modified with potassium oxide (1.0% NiO + 2.0% Al_2O_3 + 1.3% K_2O and 1.0% NiO + 2.0% Al_2O_3 + 0.6% K_2O), which show stable operation in this reaction. The methane conversion at 700°C with increasing CO_2/CH_4 ratio from 1.3 to 2.0 was measured. The results are summarized in Table 2.

As seen from Table 2, the methane conversion decreases with increasing CO_2 concentration. The negative effect of the oxidizing agent increases with increasing the K_2O content of the catalyst from 0.6 to 1.3%. This is probably caused by reaction of CO_2 with K_2O to form low-active surface carbonates [12]. This data confirm the assumption that reverse Boudoir reaction of CO_2 with carbon [13] is not the main pathway of CDCM in the presence of the catalysts in question.

The activity of oxide catalysts in redox reactions can be estimated from the oxygen–catalyst bond energy, which, in turn, can be estimated form the reduction onset temperature and peak temperatures in the TPHR curves. The TPHR curves of unmodified nickel–aluminum catalyst (curve *1*) and the catalyst modified with alkali metals (curves *2–4*) are shown in Fig. 4. It can be seen that the reduction rate of the catalysts with hydrogen decreases in the following order: NiO + Al_2O_3 > NiO + Al_2O_3 + Na_2O > NiO + Al_2O_3 + K_2O > NiO + Al_2O_3 + Li_2O. The activity of these catalysts in CDCM varies similarly (Fig. 2).

The results of these experiments agree with the above mechanism of CDCM. According to this scheme, the surface carbon formed by dissociation of adsorbed methane is oxidized with oxygen of

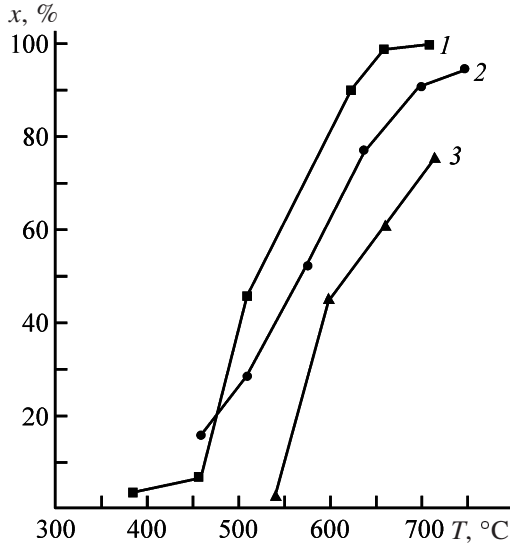

Fig. 3. Conversion of methane in CDCM on (*1*) 1.0% NiO + 2.0% Al_2O_3, (*2*) 1.0% NiO + 2.0% Al_2O_3 + 0.6% K_2O, and (*3*) 1.0% NiO + 2.0% Al_2O_3 + 1.3% K_2O.

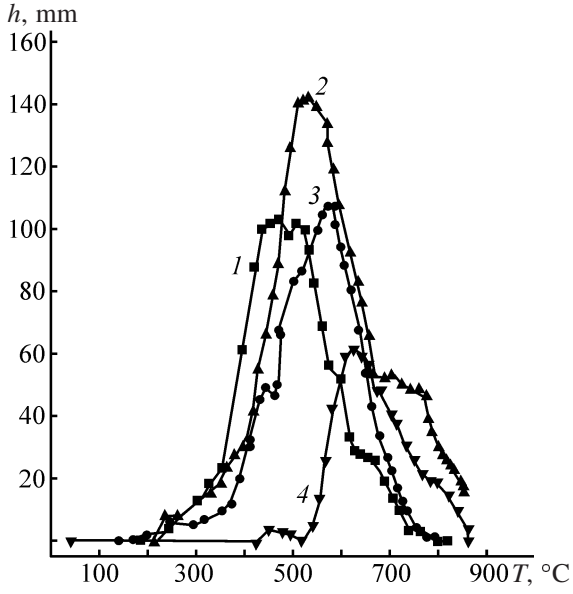

Fig. 4. TPHR curves of (*1*) 1.0% NiO + 2.0% Al_2O_3, (*2*) 1.0% NiO + 2.0% Al_2O_3 + 0.6% K_2O, (*3*) 1.0% NiO + 2.0% Al_2O_3 + 0.9% Na_2O, and (*4*) 1.0% NiO + 2.0% Al_2O_3 + 0.7% Li_2O. (*h*) Peak height and (*T*) temperature.

the catalyst surface. The surface oxygen formed by partial reoxidation of the reactive component rapidly reacts with surface carbon. This process not only accelerates the methane decomposition, but also decelerates the reaction $CO_2 + Ni–C \rightarrow 2CO + Ni$, which, as suggested in [13], can be the rate-determining step of CDCM. The promoting effect of an alkali metal is caused by formation of finely divided nickel particles which cannot be detected by X-ray diffraction [6, 14, 15].

In addition, alkali metals decrease the acidity of the catalyst surface, thus suppressing methane dissociation to form coke. The presence of potassium additive in the catalyst decreases not only the carbonization but also the methane conversion.

CONCLUSIONS

(1) Ni/Al_2O_3 composites supported by synthetic cordierite ceramic block matrices of honeycomb structure are effective catalysts of carbon dioxide conversion of methane. The performance of these catalysts is significantly higher than that of conventional granulated catalysts. The use of structured catalysts with thin walls eliminates the diffusion problems in carbon dioxide conversion of methane, thus decreasing coke formation.

(2) Introduction of alkali metal oxides increases the operation stability of the catalysts by controlling the acid–base properties of the catalyst surface. The decrease in the carbonization of the surface of the catalysts modified with alkali metal oxides improves the stability of the catalyst operation.

(3) Alkali metal oxide additives slightly decrease the catalytic activity owing to alteration of the crystal structure of nickel and formation of thermodynamically stable and low-reactive alkali metal aluminates. As a result, the strength of the nickel–oxygen bond increases, which is manifested in deceleration of the reduction of nickel–aluminum catalysts modified with alkali metals.

Abstract—Single-stage plasma-arc synthesis of metallo-endofullerenes of the types $C_{60}Pd$, $C_{60}Ni$, and $C_{60}Cr$, whose content in a mixture of extracted fullerenes was 0.05 to 0.15 wt %, was performed. The effect of introduction of these metals into the reaction plasma on the total yield of fullerenes and on the fraction composition of the fullerene mixture was studied. The fullerene mixtures were analyzed by mass spectrometry and liquid chromatography.

DOI: 10.1134/S1070427207110213

As is known [1], endofullerenes is the commonly accepted name for derivatives of light (C_{60}, C_{70}) or heavy (C_n, $n \geq 72$) fullerenes with one or several noncarbon atoms (X) incorporated within the hollow skeleton of fullerenes. To our knowledge, stable endofullerenes based on the so-called ultralight fullerenes or "subfullerenes" (C_n, $n \leq 58$) have not been described, although part of these can have a hollow structure (C_{36}–C_{58}). The role of a heteroatom X can be played both by atoms of metals: alkali, alkaline-earth, transition, heavy, lanthanide, and actinide (X = Li, Na, K, Cs, Ca, Mg, Hf, Ti, Zr, Y, Sc, La, Ce, Sm, Gd, Tb, U, Pu, and some others) [2, 3], and by atoms of some nonmetals and, primarily, noble gases (X = He, Ne, Ar, Kr, Xe, N), as well as by some diatomic molecules (X = CO, CN) [1, 4]. Typically, a single heteroatom is incorporated in fullerenes (C_nX compounds), although endofullerenes have been described with two (C_nX_2 compounds) and even three heteroatoms (C_nX_3), which may be identical ($C_{60}La_2$ [2]) or different ($C_{60}Cs_2Rb$ [5]).

The main methods for synthesis of metallo-endofullerenes are the same as those for ordinary fullerenes [1]: namely, laser evaporation of graphite in the atmosphere of inert gases, resistive and high-frequency heating of graphite in an inert gas, evaporation of graphite in focused solar light, burning of graphite electrodes in an electric arc in an inert gas (plasma-arc method), evaporation of graphite microparticles in a thermal plasma under atmospheric pressure, combustion of hydrocarbons in a laminar of volume flame [6–13]. The basic issue is the way in which metal ions (or atoms) are introduced into the carbon-containing reaction plasma generated in synthesis of "ordinary" fullerenes.

Several methods have been described in the literature: impregnation of graphite articles (rods, discs) with solutions of well-soluble salts of the type $LaCl_3$ [1, 2] in laser or flame-arc synthesis of fullerenes; introduction of high-purity metal compounds, commonly oxides, directly into the material of a graphite rod (anode) being evaporated, by compaction followed by preliminary annealing, e.g., of La_2O_3, in plasma-arc synthesis of a lanthanum-endofullerene $C_{60}La$ [14]; implantation of metal ions (e.g., Li^+) into the carbon plasma or, vice versa, implantation of fullerene ions (e.g., C_{60}^-) into a metal-containing plasma [3]; also possible is synthesis of endofullerenes by direct introduction of some heteroatoms [He, Ne, Ar, Kr, Xe, N (N_2)] into already synthesized fullerene voids from the gas phase at comparatively high temperatures (600–1000°C) and pressures (100–1000 atm) [4].

Metallo-endofullerenes can be used as high-tem-

perature superconductors [5, 15–17], ferromagnetic materials [18], heterogeneous catalysts in organic synthesis and, in particular, in (de)hydrogenation [19], medicine, pharmacology, etc.

The aim of this study was to develop a simple technologically convenient single-stage method for synthesis of metallo-endofullerenes and an analytical method for their identification.

Metallo-endofullerenes were synthesized by the plasma-arc method [12] on an installation described in [13]. The electrode being evaporated, anode, had the form of a rod (ultrapure graphite, 99.999 wt % carbon) 12 mm in diameter. An orifice 1 mm in diameter was drilled in the electrode and a metallic wire of the same diameter was pressed into this orifice. The wire was composed of individual metals: Ni, Cr, Pd (99 wt %), or Nichrome alloy (with 40 wt % Cr). No metals were introduced into the cathode (12-mm graphite rod). The synthesis was performed in the atmosphere of ultrapure He (99.9995 vol %) at a pressure of about 300 mm Hg.

This synthesis method proved suitable only for sufficiently high-melting metals with melting points not lower than 1400°C. With lower-melting metals (e.g., Cu), microdrops of metals spattered and metal ions were not delivered in sufficient amounts to the plasma reaction zone, with the result that metallo-endofullerenes were not formed in noticeable amounts.

Samples were prepared for analysis as follows: the carbon black accumulated in the carbon-black receiver and in the reaction chamber after synthesis was collected and sieved on a sieve with a 40-μm mesh; the ordinary fullerenes and metallo-endofullerenes formed were extracted with *o*-xylene (analytically pure grade) at room temperature under vigorous stirring (magnetic stirrer) in the course of 60 min. The phase ratio in the extraction was 1 mg of carbon black per 1 ml of *o*-xylene (the solvent was taken in manyfold excess).

The solution of fullerenes was allowed to settle for 30 min and then twice filtered through a blue-band paper filter. The filtrate was evaporated to a humid paste on a rotary evaporator at 80±5°C. The paste was evaporated to constant weight in a vacuum oven for 150 min at 220–230°C and a residual pressure of 0.01–0.1 mm Hg (dynamic vacuum).

The expected forms of fullerenes in the resulting mixtures are the following: light (C_{60}, C_{70}) and heavy fullerenes (C_n, $n \geq 72$); subfullerenes (C_n, $n \leq 58$); fullerene oxides, the so-called epoxites (C_nO_m) formed because of the presence of oxygen or water vapor admixtures (the most probable is formation of monoxides of light fullerenes: $C_{60}O$ and, possibly, $C_{70}O$); metallo-endofullerenes C_nX_m (in this case, too, formation of mono derivatives of light fullerenes, $C_{60}X$ and, possibly, C_{70}, is the most probable).

Fullerene mixtures are commonly analyzed by the following methods: spectrophotometry (for proximate analysis), high-resolution liquid chromatography, mass spectrometry, and liquid chromatogeaphy–mass spectrometry (the latter technique is a combination of the second and third methods).

The spectrophotometric analysis [20] is suitable only for rough determination of the composition of a fullerene mixture in terms of light fullerenes and approximate estimation of the total content of fullerenes in the mixture and, therefore, cannot be used for our purposes.

Liquid chromatography was used in the mode described in [21]: Lumachrom chromatograph (manufactured by Lumex Co., St. Petersburg), with UV detection at a wavelength λ = 254 nm. A characteristic example of the chromatograms obtained is shown in Fig. 1. As can be seen from the chromatogram, all the fullerene groups mentioned above can be qualitatively identified. However, two groups of subfullerenes, "C_{60} companions," and the group C_{62}–C_{84}, "C_{70} companions," are eluted as two broad unresolved peaks. Even after a 10-fold increase in the device sensitivity, two well-resolved peaks of heavy fullerenes of the C_{76}–C_{84} group were followed by difficultly identifiable and poorly resolved broad peaks of mixed origin, associated with heavier fullerene groups C_{86}–C_{116} and, possibly, with some metallo-endofullerenes of uncertain composition. Thus, this method is equally unsuitable for precise quantitative determination of the fullerene composition of the mixtures obtained (including metallo-endofullerenes).

A mass-spectrometric method was developed for analysis of fullerene mixtures. This method enables quantitative determination of the concentrations of all the fullerene components of interest. For this purpose, we dissolved fullerene mixtures without a residue in *o*-xylene (analytically pure grade), with a solution containing 0.1 mg of a sum of fullerenes per 1 ml of solution. Then, a 1-ml sample of this solution was taken and transferred to a quartz cell. After that, the solvent was evaporated at 100°C, with the fullerenes (about 100 μg) forming in the process a thin yellowish film on the quartz surface. The mass-spectrometric analysis was made on an MKh-1320 instrument at a pressure of 10^{-7} mm Hg, sublimation temperature of

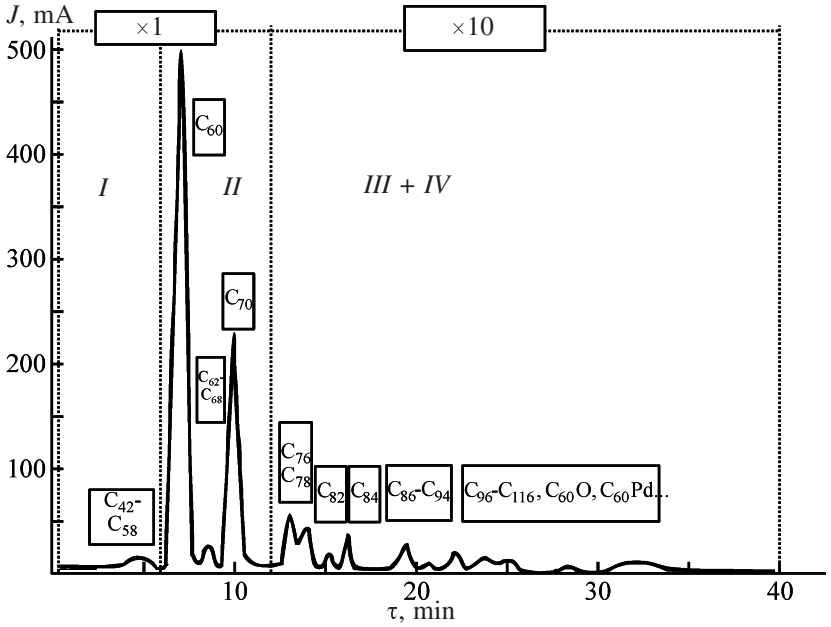

Fig. 1. Chromatogram of a fullerene extract containing subfullerenes, light and heavy fullerenes, monoxides of light fullerenes, and PdC_{60}. (*J*) Current strength and (τ) elution time. (*I*) Subfluuerenes, (*II*) light fullerenes, (*III*) heavy fullerenes, and (*IV*) fullerene derivatives; the same for Fig. 3.

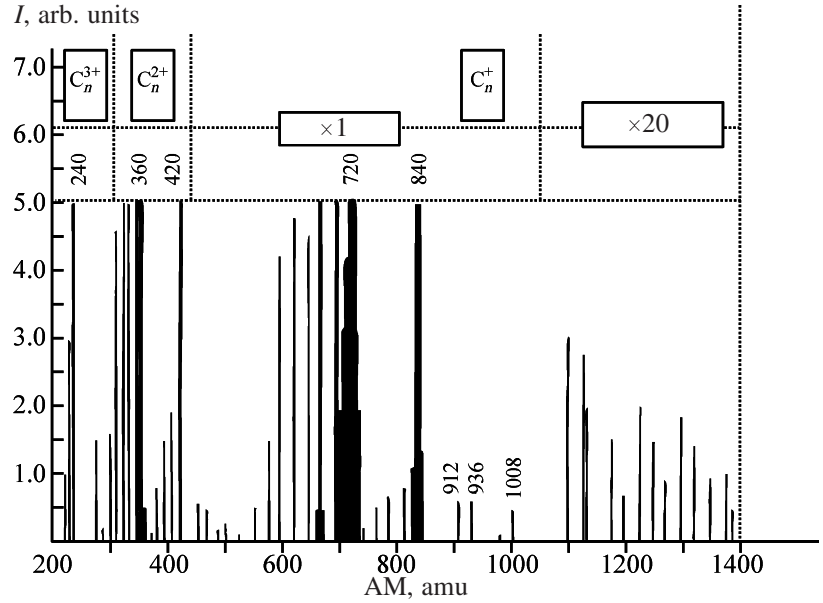

Fig. 2. Mass spectrogram of a fullerene extract containing subfullerenes, light and heavy fullerenes, monoxides of light fullerenes, and PdC_{60}. (*I*) Ion current and (AM) atomic mass.

250–480°C, and ionization by electron impact (ionization energy 10–100 eV). In the course of the analysis, all the fullerene components were nearly completely evaporated from the surface of the quartz cell (analysis for the residual content of fullerenes on the cell of the KU brand was made spectrophotometrically by the light absorption at a wavelength λ = 335.67 nm, common to the absorption by light fullerenes [20]).

As a result, we obtained mass spectra whose typical shape is schematically shown in Fig. 2 (chromatogram of a Pd-containing fullerene extract). Figures 3a–3c show the same mass spectrograms on the more convenient semilog scale. Similar mass spectrograms were obtained for fullerene extracts containing individual Ni and Cr. However, these spectra exhibited no specific features, compared with those in Fig. 3c, and, therefore, are not presented here.

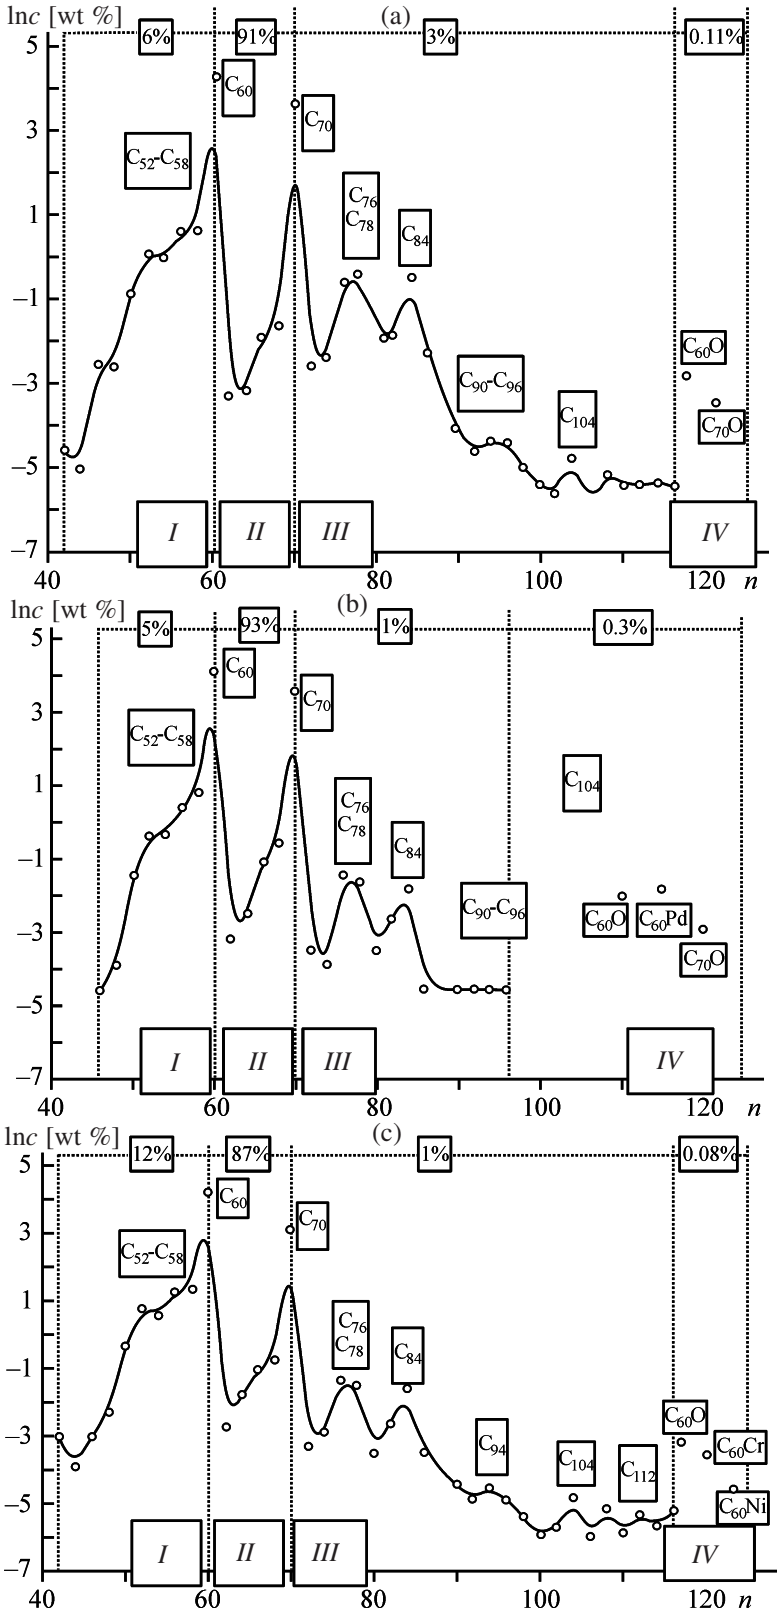

Fig. 3. Mass spectrograms of fullerene extracts containing (a) subfullerenes, light and heavy fullerenes, and monoxides $C_{60}O$ ($C_{70}O$), (b) PdC_{60}, and (c) NiC_{60} + CrC_{60}. (*c*) Content of a fullerene in the mixture and (*n*) number of carbon atoms in C_n fullerene. (a) Standard nonmetallized extract from a mixture of fullerenes for comparison, (b) Pd-containing fullerene extract, and (c) (Ni + Cr)-containing fullerene extract.

Figure 2 shows sets of peaks corresponding to different extents of nondestructive ionization of fullerenes, which increase in the series $C_n^{3+} \rightarrow C_n^{2+} \rightarrow C_n^+$ (in Fig. 3, these intensities corresponding to a single fullerene form are summed up).

When recording the mass spectrogram shown in Fig. 2, we raised the instrument sensitivity by a factor of 20, beginning with fullerene atomic masses exceeding 1050 amu.

It can be seen from Figs. 2 and 3 that this analytical technique enabled quantitative determination of the concentrations of all forms of fullerenes, including fullerene derivatives: metallo-endofullerenes and epoxides.

The results obtained in extraction and mass-spectrometric measurements demonstrate the following: (i) the total content of all the fullerene components contained in the fullerene black is virtually independent of whether or not metallic phases are present in the anode and equal to 12 ± 1 wt % (typical value for the installation described in [13]); (ii) the ratio of the main fullerene components, light fullerenes C_{60} and C_{70}, is also nearly insensitive to presence of metallic phases and equal to about 2.5/1.0; (iii) the content of metallo-endofullerenes of the types $C_{60}Pd$, $C_{60}Ni$, and $C_{60}Cr$ in a mixture of extracted fullerenes is in the range from 0.05 wt % (for $C_{60}Pd$ and $C_{60}Ni$, irrespective of whether Ni or Cr are introduced into the anode, or both these metals simultaneously) to 0.15 wt % (for $C_{60}Pd$); (iv) upon introduction of Ni and/or Cr, the content of subfullerenes in the fullerene black substantially increases; and (v) no metallo-endofullerenes are found in the fullerene black upon introduction of a lower-melting metal (Cu) into the anode.

In the context of discussion of the results obtained, we note some additional fundamental issues.

(1) The paper describes syntheses of just endo forms of light-fullerene derivatives, i.e., metal atoms are situated in these compounds within the carbon skeleton of fullerenes. It is clear that direct mass-spectrometric measurements cannot answer the question as to what form, endo or exo (with a metal atom outside the fullerene carbon skeleton), of metallofullerenes is formed in a synthesis. Although we did not carry out additional labor-consuming spectral studies capable of tackling with this issue in a direct experimental way, the answer seems to be quite obvious because, on the one hand, no metallo-exofullerene of the type $C_{60}Me_n$ or $C_{70}Me_n$ has been synthesized so far (whereas the tens of metallo-endofullerenes have been synthesized and identified) and, on the other hand, even rough quantum-mechanical calculations demonstrate that, just for metallofullerenes, formation of endo forms is strongly preferential, compared with exo forms.

(2) Despite that the content of the synthesized metallo-endofullerenes in the samples obtained is comparatively low, up to 0.15 wt % in the sum of fullerene products, their preparative recovery even in comparatively large amounts (grams) is not difficult because (according to the results of a preliminary study) the solubility of metallo-endofullerenes in some heterocyclic compounds, e.g., pyridine, markedly exceeds that of their nonmetallized analogues, C_{60} and C_{70}, which, in turn, are considerably better soluble in ordinary aromatic solvents, e.g., *o*-xylene. Thus, rather pure materials (<90 wt %) can be produced in a rather simple way by the method of recrystallization recovery of metallo-endofullerenes at a comparatively low recovery loss. Micro- and milligram amounts of metallo-endofullerenes can, naturally, be extracted by liquid chromatography.

(3) The output capacity of the method we develop can be improved (or, in other words, the fraction of metallo-endofullerenes in the sum of fullerene products can be made larger), with its operation principle [12, 13] preserved, by raising, based on general considerations, the mass fraction of metals in the metal–carbon–helium plasma in the zone of preferential formation of metallo-endofullerenes (1500–4000 K). A probably good solution in this case would be removal of heat from metals in the reactor plasma by heavier molecules of inert gases (with He possibly replaced with Ne or Ar). However, in addition to the expected rise in the fraction of metallo-endofullerenes in the sum of fullerenes, such a replacement might lead to a simultaneous decrease in the total content of fullerenes in the fullerene black, so that such a technological modification would require a rather prolonged optimization.

CONCLUSIONS

A comparatively simple and low-cost direct single-stage plasma-arc method for synthesis of metallo-endofullerenes and a proximate technique for their identification in the fullerene black were developed.

The synthesis was performed for the example of metallo-endo derivatives of light fullerenes, C_{60} and C_{70}, with Ni, Cr, and Pd used as metals.

ACKNOWLEDGMENTS

The study was supported by the Federal Target Research Program "Research and Development in Priority Areas of Science and Technology" for 2002–2006 (State contract no. 02.467.11.7005 of May 23, 2005).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermochemical Reactions of Flax Lignocarbohydrate Complexes and Their Cyanoethylated Derivatives

Abstract—A thermochemical study of short flax fibers and boon and of their cyanoethylated derivatives was made with the aim to examine the possibility of preparing carbonized materials.

DOI: 10.1134/S1070427207110225

The development of technologies for production of carbon materials by industrial processing of cheap plant wastes whose volumes are very large is a topical problem. This problem is closely associated with utilization of wastes from production of linen articles and with the development of a wasteless technology of flax processing. The studies pursued today concern utilization of wastes from production of flax fibers [lignocarbohydrate complex including short flax fibers (SFFs) and ligneous part of flax stems (boon)] as cellulose raw materials to replace cotton linter and wood cellulose.

It is known that various cellulose derivatives [1–4], carbon adsorbents [5, 6], and building materials [7] can be prepared from SFFs and boon [1–4]. Gribanov and Sazanov [8, 9] showed that nitrogen atoms play an important role in formation of structures of carbon materials in the course of carbonization of heteropolymers. This phenomenon was also noted in studies of carbonization of some cellulose ethers and esters [10, 11] and of cocarbonization of polyacrylonitrile with chitin and chitosan [12, 13].

In this study we examined thermochemical reactions of lignocarbohydrate complexes of SFFs and boon and of their cyanoethylated derivatives (CEFFs, CEB) with the aim to assess prospects for carbonization of these products.

EXPERIMENTAL

As starting materials we used SFFs (degree of polymerization of cellulose 3350) and boon (degree of polymerization of cellulose 2600). The degree of polymerization of cellulose in the starting samples was determined according to [14]. The cellulose materials used in the study were examined by the methods described in [15–17] to determine the chemical composition (see table). To prepare cellulose ethers, SFFs and boon were purified to remove waxes, fats, and resins by treatment with an alcohol–benzene (1 : 1 by volume) mixture in a Soxhlet apparatus, and pectins were removed by treatment with an aqueous solution of ammonium citrate. Boon was finely divided in a knife mill. Cyanoethyl ethers of cellulose were prepared as follows:

$$C_6H_7O_2(OH)_3 + xCH_2{=}CH{-}CN \xrightarrow{NaOH} C_6H_7O_2(OCH_2{-}CH_2CN)_x(OH)_{3-x}.$$

Prior to cyanoethylation, SFFs and boon were allowed to swell in an excess of a mixture of 7% aqueous NaOH and dimethyl sulfoxide (volume ratio 1.5 : 1) at 20°C for 2 h. After sqeezing to triple initial weight, the cellulose material was treated with excess

Chemical composition of flax fibers and boon used

Component	Content, wt %	
	boon	fibers

acrylonitrile at 20°C for 24 h. After the reaction completion, excess NaOH was neutralized with an aqueous solution of acetic acid, after which excess acrylonitrile was removed by extraction with ethanol. The washed samples were dried at room temperature. The nitrogen content of the samples was determined by the Kjeldahl method. It amounted to 12 wt % in flax fibers and 10.9 wt % in boon. It should be noted that, in contrast to cyanoethylated flax fibers, samples of chemically modified boon retain a certain fraction of lignin. This fact is confirmed by the presence of the lignin absorption band at 1512 cm^{-1} [4] in the IR spectra of the initial and cyanoethylated boon.

Thermal analysis of samples (50 mg) was performed on a C derivatograph (MOM) in air under conditions of dynamic heating (10 deg min^{-1}).

Thermal analysis shows (Figs. 1, 2) that SFFs and boon, as well as their cyanoethylated derivatives, degrade on heating to 800°C in three steps. The temperature limits of these steps are close for all the samples; nevertheless, there are certain specific features. For example, for SFFs, the weight loss due to removal of residual volatiles (solvents, washing, etc.), observed on heating to 152°C, is about 5%, whereas for boon it is about 8% of the initial weight. The second step of degradation of SFFs and boon, with a major weight loss (48–55%), starts at 220–223°C and involves thermal oxidative degradation of cellulose macromolecules. In this step, a certain difference is observed between SFFs and boon, attibutable to the presence of residual lignin in boon. Thus, before the onset of carbonization (third step), SFFs lose about 65% of their weight, and the weight loss of boon is approximately 10% smaller. Carbonization occurs in the typical mode of uniform weight loss starting from 360–370°C and is complete at 800°C when the residue fully burns out. In this step, there are no sharp changes in the weight loss rate; however, thermal effects with maxima at 355, 382°C for SFFs and 385, 389°C for boon (Fig. 1b, curves *1*, *2*) should be noted. These effects can be assigned to the formation of oriented phases in the initial step of carbonization of both samples.

Thus, SFFs and boon are promising raw materials for preparing carbon materials with carbon residues

exceeding those of cotton cellulose. This is seen from comparison of data on carbonization of these natural compounds under the conditions of dynamic heating to temperatures in the range from 400 to 800°C. The carbon residues of cotton linter at 400, 500, 600, 700, and 800°C, according to [28], are 20, 17, 8.5, 1.5, and 0%, respectively, whereas for SFFs and boon (in parentheses) the carbon residues are 30 (37), 24 (29), 16 (18), 8 (11), and 2% (2), respectively.

As for cyanoethylated samples of SFFs and boon (Fig. 2), their behavior is essentially similar to that of the initial samples. The effect of cyanoethyl groups is noticeable in the first step of thermal degradation: The initial weight loss tends to zero, apparently because the samples are more hydrophobic. The weight loss in the second step of thermal degradation increases by 12–18 wt % compared to SFFs and boon. This fact is apparently associated with loosening of the structure of the starting compounds due to introduction of bulky cyanoethyl substituents and to a decrease in the relative content of hydroxy groups responsible for intermolecular bonds in SFFs and boon. The above-noted differences in the thermal stability, caused by significant amount of lignin in the boon, are also preserved in the cyanoethylated samples, which is clearly seen from the carbonization parameters (third step, from 322 to 800°C, Fig. 2a, curve *2*). The role of nitrogen atoms in the formation of carbonized structures via cyanoethylation of SFFs and boon cannot be unambiguously interpreted on the basis of only one series of thermal measurements. For example, no effect of nitrogen can be noticed from the parameters of thermal stability derived from TG curves at a constant heating rate (Fig. 2a). However, in the third step of degradation, internal changes in the carbonization products can be revealed from the shape of the DTA curves (Fig. 2b). The above-noted exo- and endothermic effects associated with probable formation of partially ordered structures shifted toward higher temperatures by approximately 100°C. The exothermic peaks with maxima at 491 and 472°C (curves *1*, *2*) can be characterized as effects of crystallization, similar to those noted in [11] for samples of cyanoethyl cellulose and its blends with polyacrylonitrile. Apparently, the participation of nitrile groups in carbonization of SFFs and boon provides the conditions for the formation of intermediate nitrogen-containing cyclic compounds giving rise to exo- and endothermic effects in the DTA curves. It should also be noted that increased heat resistance of CEB compared to CEFFs, observed also for the corresponding noncyanoethylated samples (Fig. 1a) and attributed to the presence of lignin in boon, gives grounds to consider thermochemical reactions of lignin and its blends with polyacrylonitrile (PAN) by analogy with [10–12]. The assumption that lignin (LG) enhances the heat resistance of boon is confirmed by the thermograms of LG and LG + PAN (Figs. 1 and 2, curves *3*). The results of these measurements show that, starting from 300°C and up to 800°C, the thermal degradation of LG is accompanied by smaller weight loss compared to SFFs and boon. Introduction of 25% polyacrylonitrile into an LG sample by blending the powdered components did not noticeably affect the course of thermal degradation of lignin. Hence, for the nitrile nitrogen to act as initiator of thermochemical synthesis of a new carbonizate derived from LG, the conditions of heat treatment should be changed essentially, in accordance with principles of cocarbonization [19].

CONCLUSIONS

(1) Carbonized products of flax processing: short flax fibers, flax, and ligneous part of stems (boon), are promising carbon materials for preparing sorbents.

(2) The presence of residual lignin in flax enhances the heat resistance of carbonization products and increases the carbon residue.

(2) The nitrogen atoms of nitrile groups of cyanoethylated derivatives of flax and boon affect the formation of carbonized residues.

Abstract—Radical copolymerization of methyl methacrylate and methacrylamide was studied. For polymer films prepared from acetic acid solutions, the heat resistance and thermomechanical behavior were evaluated, and adhesion to silicate glass was determined.

DOI: 10.1134/S1070427207110237

Much attention is given today to the development and improvement of optical information technologies, because their capabilities with respect to the information transfer rate and information content and to the performance of separate components are significantly higher as compared to microelectronics [1]. Among the materials for recording and treatment of optical information, exhibiting high optical transparency in the visible region and relative stability of the recorded information in a wide temperature range, various polymers, e.g. polymethyl methacrylate (PMMA), are of particular importance [2–4]. However, low thermal and adhesion properties hindering their use in optical recorders operating in contact with silicate glass at elevated temperatures are the main disadvantages of the materials based on PMMA.

Modification of PMMA by copolymerization of methyl methacrylate (MMA) with polar monomers, yielding polymers with a higher softening point [5, 6], is one of solutions of this problem. Methacrylamide (MAA) [5] and acrylic acid [6] were studied as such polar monomers. Kuo et al. [5] examined in detail the composition of the copolymerization products of MMA and MAA and the dependence of the glass transition point (DSC data) on the content of methacrylamide units in the copolymer. However, there are no data on changes in the other thermal properties of PMMA on passing to the copolymerization products of MMA and MAA and on the adhesion properties of the resulting copolymers.

In this study we examined the heat resistance and the thermomechanical and adhesion properties of the products of MMA and MAA copolymerization.

EXPERIMENTAL

The radical copolymerization of MMA and MAA was performed in a 40% solution of the monomer mixture in acetone at 57°C for 5 h in the presence of 2,2'-azobis(isobutyronitrile) (AIBN) initiator taken in an amount of 0.2% with respect to the monomer weight. The MAA : MMA molar ratio was varied from 1 : 4 to 3 : 2, i.e., the mole fraction of MAA in the monomer mixture α was varied from 0.2 to 0.6.

The synthesis was carried out in a three-necked flask equipped with a mechanical stirrer with a hydraulic lock and a reflux condenser. A weighed portion of MAA was dissolved in acetone at 40°C with continuous stirring, and then freshly distilled MMA was added. The mixture was heated to 55°C, and the required amount of the initiator was added. The reaction began in 10–15 min, which was confirmed by formation of a precipitate after addition of an aliquot of the reaction mixture into ethanol. Simultaneously, the viscosity of the reaction mixture increased. After heating for 5 h, the reaction mixture was cooled and the reaction products were reprecipitated from acetone with water and additionally washed with acetone.

The homopolymerization of MMA and MAA was also performed in a 40% monomer solution in acetone

at 57°C using AIBN initiator (0.2% with respect to the monomer weight), the synthesis time was 5 h. PMMA was soluble in acetone, and it was separated by precipitation with water. Polymethacrylamide (PMAA) precipitated from the acetone solution in the course of the synthesis, and the residual monomer was washed out with acetone.

The compositions of the resulting samples were determined by IR spectroscopy. As analytical bands for the products of copolymerization of MMA and MAA we chose strong absorption bands at 1730 and 1650 cm^{-1}, belonging to the vibration of the carbonyl group in the ester and amide side functional groups. The calibration dependences of the optical densities of the absorption bands at 1730 and 1650 cm^{-1} on the mole fraction of the MAA units were plotted using the IR data for the mixtures of MMA and MAA homopolymers. The content MAA units in copolymer β was expressed in mole fractions.

The heat resistance and the glass transition and flow points of the copolymerization products of MAA and MMA were studied by the methods of combined thermal and thermomechanical analysis. The combined thermal analysis was performed on an MOM OD-103 derivatograph (Hungary) in air at a heating rate of 5 deg min^{-1} using 100-mg samples. The thermomechanical analysis was carried out on a UIP-70 apparatus (TsKB UP, USSR Academy of Sciences) in air at the same heating rate; the pressure applied to the sample was 0.59 MPa. The glass transition and flow points were evaluated using the dependences of the relative yield-point strain ε (%) on temperature T (°C).

The polymer samples for thermal and thermomechanical tests were prepared from 6% acetic acid solutions. These solutions were cast onto glass or polypropylene plates and dried at 90°C to remove the solvent. The completeness of solvent removal from the films (~50 μm thick) was controlled by the absence in the IR spectrum of the absorption band in the 1690–1700 cm^{-1} region typical for the vibrations of the carbonyl group in the carboxy group of acetic acid. The spectra of the PMMA films prepared from acetic acid solutions and water are identical. This suggests that, owing to high volatility, acetic acid completely evaporated from the films upon drying and did not affect the results of thermal analysis. The adhesion properties were evaluated from the strength of their adhesion to silicate glass support.

Along with radical copolymerization of MMA and MAA, homopolymerization of these monomers could also take place. Since polymerization occurs in an acetone solution of the monomers and among three possible products (namely, copolymer of MAA and MAA, MMA homopolymer, and MAA homopolymer) only two compounds are soluble in acetone, the resulting product can contain not only the copolymer but also MMA homopolymer. The monomers were completely removed by precipitation of the product from acetone solution with water, followed by washing with acetone, because MAA and MMA are readily soluble in water and acetone, respectively. The yield of the polymerization products was higher than 80%, and the MMA : MAA molar ratio depended on the mole fraction of MAA in the initial monomer mixture. For example, α 0.3 corresponded to β 0.35, and α 0.4, 0.5, and 0.6, to β 0.65, 0.67, and 0.78, respectively. At a low content of MAA in the monomer mixture (α 0.2), the composition of the monomer mixture coincided with the copolymer composition. At a higher content of MAA in the monomer mixture, the product was enriched in MAA units.

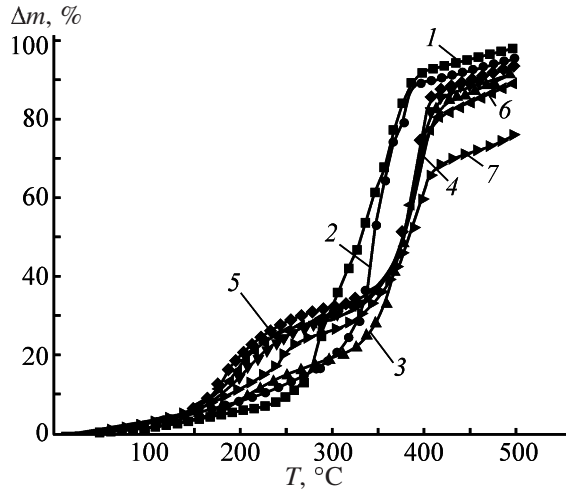

Fig. 1. Weight loss Δm of (*1*) PMMA, (*2–6*) products of MMA and MAA copolymerization, and (*7*) PMAA as a function of temperature T. β: (*2*) 0.2, (*3*) 0.35, (*4*) 0.65, (*5*) 0.67, and (*6*) 0.78.

Casting of the solutions of the copolymerization products of MAA and MMA onto supports led to the formation of optically transparent films, except the sample with β 0.78 when an opaque milk-white film was obtained.

The results of thermal analysis of the products of MAA and MMA copolymerization are illustrated in Fig. 1. In the 20–170°C range, the weight loss Δm for all the samples is similar. In the 170–270°C range corresponding to intensive degradation of the samples, Δm of the copolymerization products with β 0.65–0.78 (Fig. 1, curves *4–6*) is higher than that of the homopolymers (Fig. 1, curves *1* and *7*); Δm for co-

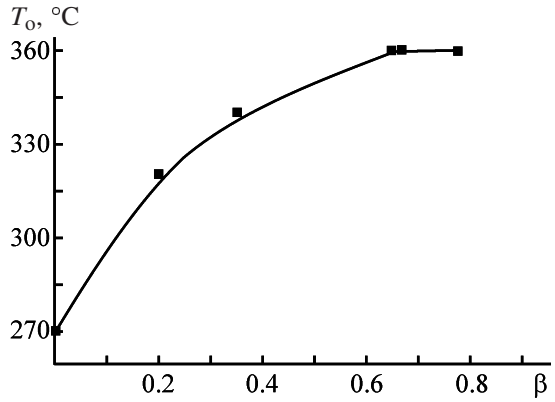

Fig. 2. Onset temperature T_o of intensive degradation of the products of MMA and MAA copolymerization as a function of the content of MAA units β.

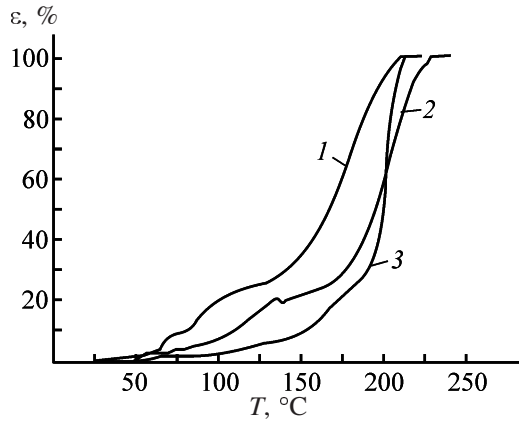

Fig. 3. Relative yield-point strain of (*1*) PMMA and (*2, 3*) products of MMA and MAA copolymerization as a function of temperature *T*. β: (*2*) 0.2 and (*3*) 0.78.

polymers with β 0.2–0.35 is intermediate between the weight losses of PMMA and PMAA, i.e., the heat resistance of PMMA in the given temperature range is higher. However, at temperatures higher than 300°C, Δm for copolymerization products is smaller than that for PMAA, which indicates that their thermal stability increases as compared to PMMA, and the smallest weight loss is observed for PMAA. Probably, thermal oxidative stability depends on both the composition of the products of MAA and MMA copolymerization and on the experimental temperature. With increasing β from 0.2 to 0.78, the onset temperature of intensive degradation T_d of the copolymerization products increases from 320 to 360°C (Fig. 2). Probably, in the initial stage of degradation the MMA–MAA copolymer exhibits higher thermal stability compared to PMAA and PMMA. The thermomechanical curves of the initial PMMA and products of MMA and MAA copolymerization are shown in Fig. 3. As can be seen, the thermomechanical curve for PMMA is typical for amorphous polymer, and we can determine the temperature ranges corresponding to glassy, hyperelastic, and viscous-flow states. The transition points from glassy to hyperelastic state (glass transition point T_g) and from hyperelastic to viscous-flow state (flow point T_f) for PMMA are 63 and 155°C, respectively. The thermomechanical curve for the copolymer with β 0.2 is principally similar to that of PMMA except higher glass transition and flow points (T_g 82°C, T_f 183°C). For both samples, the deformations corresponding to the hyperelastic state are similar. With increasing β to 0.78, the glass transition and flow points increase to 150 and 193°C, respectively. Owing to small difference between T_g and T_f, the region of hyperelastic state is poorly pronounced.

Thus, copolymerization of MMA and MAA yields the products with higher softening temperatures as compared to PMMA. Copolymerization increases not only the glass transition point (as shown previously [5]), but also the flow point. Moreover, on passing from PMMA to the products of MMA and MAA copolymerization, the adhesion of the polymer film to the glass support increased according to qualitative estimates.

CONCLUSIONS

(1) Copolymerization of methyl methacrylate and methacrylamide increases the glass transition and flow points and the heat resistance of the polymer and enhances its adhesion to silicate glass supports.

(2) The effect of increase in the glass transition and flow points and in the heat resistance on passing from polymethyl methacrylate to the copolymerization products of methyl methacrylate and methacrylamide increases with increasing content of methacrylamide units in the polymer, but at a high content of these units (β 0.78) the film losses its transparency.

(3) The films prepared from the copolymerization products of methyl methacrylate and methacrylamide at $\beta < 0.78$ show promise as a polymer support for design of optical recorders operating in contact with silicate glass at elevated temperatures.

Abstract—The kinetics of polycondensation of allyl bromide, epichlorohydrin oligomer, and polyethylenimine was studied. The rate constants and activation energies were determined.

DOI: 10.1134/S1070427207110249

The kinetic parameters and relationships of chemical reactions are the main quantitative characteristics necessary for providing a basis for efficient control of chemical processes [1]. In studying kinetic characteristics of practically all reactions, one of the most important experimental problems is determination of how the concentrations of the reaction participants vary in time. A very promising and convenient method for studying kinetics and mechanism of chemical reactions, among them polymerization and polycondensation in solutions, is classic polarography, in which the error in determination of the monomer concentration is 2–3 rel %.

Previously [2] we developed procedures of synthesis of anion exchangers based on allyl bromide, epichlorohydrin oligomer, and polyethylenimine, and studied their main physicochemical characteristics [2].

Here we report on a polarographic study of the kinetics of polycondensation of the above compounds.

EXPERIMENTAL

Dimethylformamide (DMF) of pure grade was dried over calcium hydride and distilled at 44–45°C/15 mm Hg; n_D^{20} 1.4300 (bp 153°C/1013 hPa [3]).

Epichlorohydrin (ECH) of chemically pure grade was dried over calcium hydride and distilled; the fraction boiling at 115–116°C/918 kPa was collected; n_D^{20} 1.4380 (bp 161.1°C; n_D^{20} 1.4381).

Epichlorohydrin oligomer (ECHO) was synthesized in the presence of the M-14 catalyst, activated aluminosilicate ($H^+ + Al^{3+}$), taken in an amount of 1% of the monomer weight. The reaction mixture was heated for 2 h at 30–50°C and for 5–6 h at 60–80°C with stirring at a constant rate and then cooled. The reaction product was dissolved in benzene, precipitated with water–ethanol mixture (2 : 1), and filtered off. The resulting viscous brown product was dried at room temperature in a vacuum to constant weight.

Allyl bromide (AB) was of chemically pure grade, n_D^{20} 1.4690 (bp 71.3°C/1013 hPa).

Polyethylenimine (PEI) (MW 1×10^4) was used in the form of 50% aqueous solution. The content of titratable nitrogen in anhydrous sample was 29.3%.

Polycondensation of ECHO with AB and PEI in a weight ratio of 1 : 1 : 1 was performed in DMF at 40–70°C for 4 h. Samples were withdrawn from the reaction mixture at certain intervals and diluted with a large excess of DMF to completely stop the reaction. Then, the content of the monomer, allyl bromide, in the samples was determined polarographically.

The polarographic study was performed in a temperature-controlled cell at 25 ± 0.2°C on a PU-1 polarograph with a capillary characteristic at an open circuit $m^{2/3}t^{1/6} = 4.38$ mg$^{2/3}$ s$^{-1/2}$. Saturated calomel electrode was used as a reference electrode. Oxygen was removed from the solution by argon bubbling for 5 min. The polarography was performed using an 0.02 M solution of $(C_2H_5)_4NI$ in 50% DMF as a supporting electrolyte.

It should be noted that, among three reactants (AB, ECHO, and PEI), only allyl bromide is polarographic-

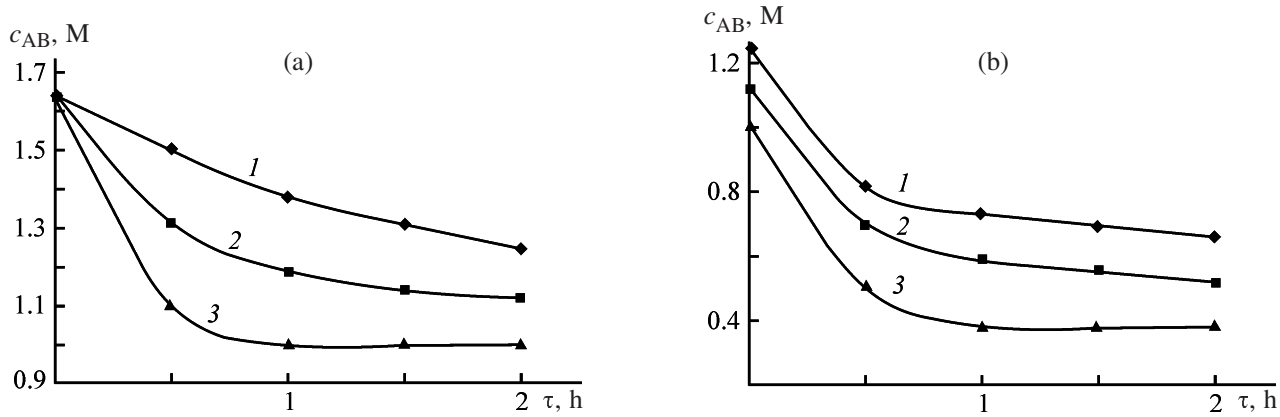

Fig. 1. Kinetic curves of allyl bromide consumption in the reaction of (a) AB with ECHO and (b) AB, ECHO, and PEI. (c_{AB}) Concentration of allyl bromide and (τ) time. Temperature, °C: (*1*) 43, (*2*) 50, and (*3*) 57.

ally active. It is reduced on a mercury dropping electrode with 0.05 M $(C_2H_5)_4NI$ in 90% DMF as a supporting electrolyte at $E_{1/2}$ = –1.82 V; therefore, the reaction order was determined only with respect to AB.

The rate constants were evaluated by the first-order reaction equation [1]:

$$k = 2.303\frac{\log h_1 - \log h_2}{t_1 - t_2},$$

where h_1 is the wave height at time t_1 and h_2, the wave height at time t_2.

The activation energy was found graphically from the Arrhenius plot.

The polarographic analysis of the reaction mixture for the content of allyl bromide, performed at certain intervals, showed that allyl bromide is consumed both in the first and in the second stages. The kinetic curves of AB consumption, obtained for the reaction of AB with ECHO, are presented in Fig. 1a. Two hours after the start of the reaction, PEI was added to the reaction mixture and the process was continued at the same temperature for an additional 2 h. The kinetic curves of AB consumption in the second stage are presented in Fig. 1b.

To determine the reaction order of the first stage, i.e., the reaction of AB with OEBH, we used the integral method [4]. For this purpose, we plotted the dependence of $\ln(c/c_0)$ on time, where c_0 is the initial concentration of AB and c is the current concentration. The resulting linear dependence passing through the origin of the coordinates suggests the first reaction order (Fig. 2a).

The plot of $\log k$ vs. $1/T$ for the reaction of AB with ECHO shows (Fig. 3a) that the points fall on a straight line, following the Arrhenius equation. The apparent activation energy of the reaction of AB with ECHO, evaluated from the Arrhenius plot, is 108.35 kJ mol^{-1} (see table).

Previously [5] polycondensation of AB, diglycidyl resorcinol ether (DGRE), and polyethylenepolyamine (PEPA: MW 265; n_D^{20} 1.4546, total nitrogen content 22%, content of titratable nitrogen 19.1%) was studied and the activation energy of the reaction of AB with DGRE was found to be 32.15 kJ mol^{-1}. Comparing the results obtained with published data [5], we can

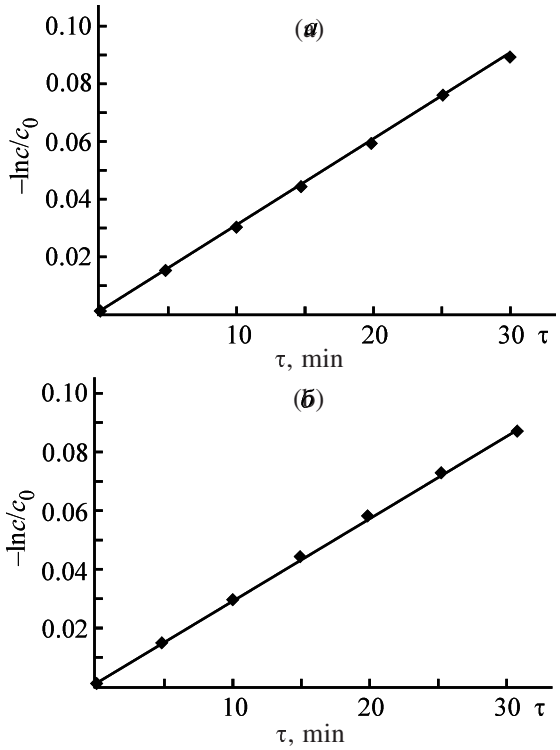

Fig. 2. $\ln(c/c_0)$ as a function of the reaction time τ. Reaction of (a) AB with ECHO and (b) AB, ECHO, and PEI.

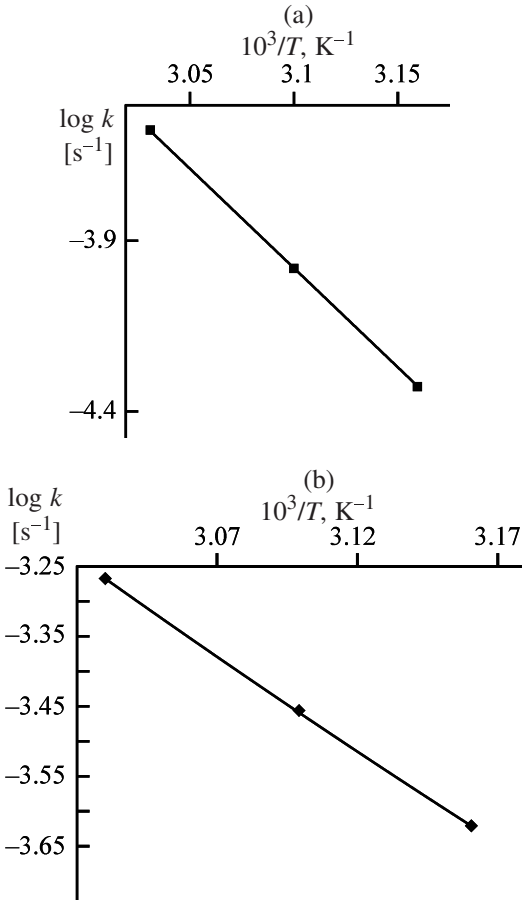

Fig. 3. Rate constant k of the reaction of (a) AB with ECHO and (b) AB, ECHO, and PEI as a function of temperature T in the Arrhenius coordinates.

conclude that ECHO is significantly less active in the reaction with AB than DGRE, which reacts with AB at room temperature. This is apparently caused by the oligomeric nature of ECHO. It was also shown [6] that the reaction of AB with DGRE is a first-order reaction with respect to allyl bromide. Thus, the results obtained in this study are in good agreement with published data.

Kinetic characteristics of the reaction of AB with ECHO and of AB, ECHO, and PEI

T, K	$k \times 10^5$, s^{-1}	E_a, kJ mol^{-1}
	AB–ECHO	
316	4.76	108.35
323	11.73	
330	27.18	
	AB–ECHO–PEI	
316	24.01	45.02
323	32.81	
330	53.25	

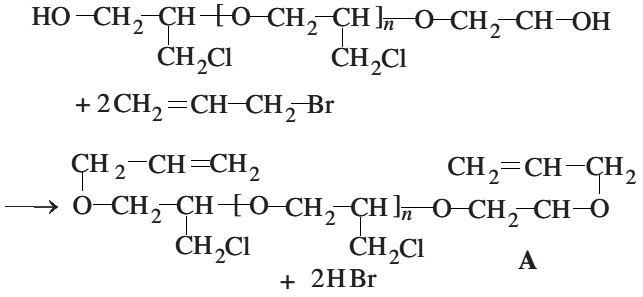
Figure 2b shows that the second stage of the reaction of AB, ECHO, and PI in the initial period is also the first-order reaction with respect to allyl bromide concentration. The rate constants of polycondensation of AB, ECHO, and PEI, evaluated from the first-order kinetic equation, and the apparent activation energy found from the Arrhenius plot (Fig. 3b) are presented in the table.

It is seen that the second stage of the process is significantly faster than the first stage. The similar relationship was also found for the polycondensation of AB, DGRE, and PEPA [7]. This is not in conflict with published data [4], where it was noted that in multistage reactions one of the stages is usually significantly slower than the other stages.

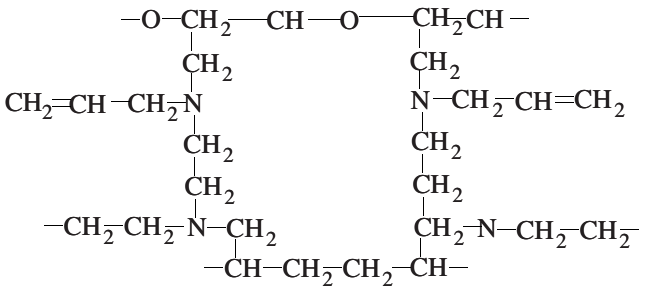
A conductometric study of the kinetics of the reaction of ECH oligomers and some di- and polyamines in DMF at various temperatures [5] showed that the apparent activation energy of amination of ECH oligomer with polyethylenimine is 24.24 kJ mol^{-1}. As seen from our data, addition of the third component, AB, into the system hampers the reaction and for the reaction of AB with ECHO and PEI a higher energy is required.

A study of polycondensation of AB, DGRE, and PEPA [8] showed that in the first stage the reaction between AB and DGRE involves opening of the epoxy ring of the ether and the cleavage of the C–Br bond in allyl bromide. In the second stage, on adding PEPA into the reaction mixture, a cross-linked anion exchanger is formed owing both to rupture of the C–Br bond in the intermediate and of the N–H bond in the amino group, and to cleavage of the double bond of the allyl group.

The first stage of the reaction between AB and ECHO apparently involves the reaction of terminal OH groups of ECHO and AB with the release of HBr and, which is less likely, the opening of a small amount of residual epoxy groups, similar to the reaction between AB and DGRE:



In the second stage, after addition of PEI into the reaction mixture, an anion exchanger of the following structure is formed via abstraction of proton of PEI amino group with chlorine atoms of the product of the first reaction stage (**A**) and, simultaneously, via attack of NH groups by allyl bromide with elimination of HBr, and also, apparently, via cleavage of the double bond of the allyl group:



CONCLUSIONS

(1) A kinetic study of polycondensation of allyl bromide, epichlorohydrin oligomer, and polyethylenimine showed that the process occurs in two stages, each of which is a first-order reaction with respect to the concentration of allyl bromide.

(2) The activation energies show that the reaction of allyl bromide with epichlorohydrin oligomer proceeds at a lower rate than the second stage.

Abstract—Turbidimetry and gel-permeation chromatography were applied to examine the composition of the polymer–colloid complexes of polyethylenimine with aluminum hydroxychloride. The size-distribution characteristics of the macromolecules of the polymer–colloid complexes were determined by photon correlation spectroscopy.

DOI: 10.1134/S1070427207110250

Polyelectrolytes belong to reactive polymers; they enter, in particular, into reactions in which their ionic groups interact with inorganic colloid particles, yielding in aqueous solutions polymer–colloid complexes (PCCs) [1, 2].

The chemistry and physical chemistry of these complexes attracts ever increasing interest because of the widening scope of their application as high-performance flocculants, structure-formation agents, and stabilizers of colloid dispersions. Previously [3] we demonstrated that PCCs based on polyethylenimine (PEI) and aluminum hydroxychloride (AHC) exhibit high performance characteristics in separation of model and real oil- and fat-containing dispersions. A specific feature of such PCCs is high reactivity in acid media, associated with the conformational behavior of the macromolecules. The relationships in formation and physicochemical properties of PCCs are examined inadequately.

We examined here the composition and size-distribution characteristics of PCCs of PEI with AHC.

EXPERIMENTAL

We used AHC prepared by the procedure from [4] (Al^{3+} content 12.8 wt %, atomic ratio Cl^-/Al^{3+} = 0.48, pH 4.5, ρ = 1330 kg m^{-3}, dry residue 46.5 wt %) and PEI with the molecular weight of 30000–40000, available from Serva, the United States. Polycomplexes were prepared by mixing an aqueous solution of PEI (1 wt %) with an aqueous solution of AHC at room temperature; the molar ratio of the reactants, calculated for Al^{3+} : PEI unit, varied from 0.25 to 4. Prior to measurements, the solutions were kept for 1 day.

The viscosity of PEI and PCCs was measured on an Ubbelohde viscometer (Cannon, d_{cap} = 0.25 mm) at 30 ± 0.1°C; pH of solutions was adjusted within 3.5–6.0 using a pH-300 pH-meter (HANNA Instruments, the United States) with an HI 1131 glass electrode.

The optical density was determined on a Specol-10 (PGH Radio Fernsehen Elektro Marienbery) spectrophotometer at λ = 460 nm in a cell with a layer thickness of 5 cm. The PCCs were precipitated from aqueous solutions by adding sodium sulfate available from Reakhim. The precipitated PCCs were separated from water with a Hermle-Z200A (Hermle Labortechnik GmbH) centrifuge at a rotation rate of 5000 rpm and the centrifugation time of 10 min. The precipitates were dried to constant weight in a desiccator at 110°C.

The gel-permeation chromatographic analysis was carried out in a KNAUER (Advanced Scientific Instruments) chromatographic system. The column was packed with PolySep-SEC 1000 (Phenomenex) gel with the fractionation range of 1000–100000 for dextrans.

The PCC particle size was determined by photon correlation spectroscopy with a He–Ne laser (λ = 633 nm, 15 mW) as the light source; the temperature in the measurement cell was maintained accurately to within 0.1°C. The autocorrelation functions (ACFs) of fluctuations of the scattered light intensity were meas-

ured using a FotoCor-SP 288-channel correlator with a logarithmic time scale extending from 2.5×10^{-8} to 6800 s. The signal accumulation time was 600 s. The ACFs were analyzed using the DynaLS program by the regularization method (to obtain the size distribution of the scattered particles).

Prior to measurements, all the solutions were filtered through Millipore membrane filters (pore diameter 0.8 μm) directly into the measurement cell to remove dust.

In [5] we showed that PEI can occur in three states: totally charged (pH < 3.4), partially charged (3.4 < pH < 9.8), and totally uncharged (pH > 9.8). Evidently, under these conditions, the complexing ability of PEI with respect to AHC can be manifested in different ways. However, Pilipenko et al. [6] showed that, at pH > 6, AHC is hydrolyzed and forms an insoluble precipitate $Al(OH)_3$, and in this pH range PEI can be complexed with these aluminum hydroxide partciles rather than with aluminum polycations. Hence, examination of the complexing between AHC and PEI at pH > 6 seems unreasonable.

We examined how the specific viscosity of a mixture of aqueous solutions of PEI and AHC with the molar ratio Al^{3+} : PEI unit = 1 : 1 is influenced by pH of the medium and compared this dependence with that for an aqueous solution of PEI (Fig. 1). It is seen that, at pH < 3.5, the mixture of the components and PEI have virtually identical viscosities. The reason is that, at low pH values, AHC is depolymerized, and aluminum occurs in aqueous solutions as hydrated Al^{3+} ions [6]. Thus, we further examined complexing at pH 4.5, at which the PEI macromolecules assume the most extended conformation.

In this contest, the composition of PCCs, i.e., the number of particles bound to one polymer macromolecule, is one of the essential issues.

We carried out a turbidimetric study of the aqueous solutions of PCCs with different compositions under varied ionic strength of solution (Fig. 2). At the molar ratios Al^{3+} : PEI unit under 1.25, salting-out of the complexes was observed only at high ionic strengths of the solution, exceeding fourfold those at which individual AHC is precipitated. A probable reason is that the number of hydrophobic units of the PEI macromolecules bound to different AHC particles is insignificant, i.e., the particles are uniformly distributed among the PEI macromolecules. When the molar ratio Al^{3+} : PEI unit increases beyond 1.25 and the AHC concentration grows, the tubridimetric curves are shifted to lower ionic strengths. This effect

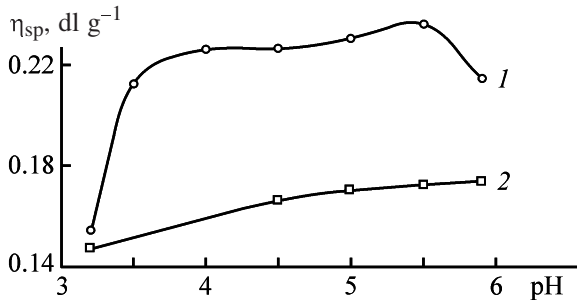

Fig. 1. Specific viscosity η_{sp} of (*1*) PEI and (*2*) PEI–AHC mixture with the molar ratio Al^{3+} : PEI unit = 1 : 1 vs. pH of the aqueous solution. PEI concentration 0.5 g dl^{-1}, T = 30°C.

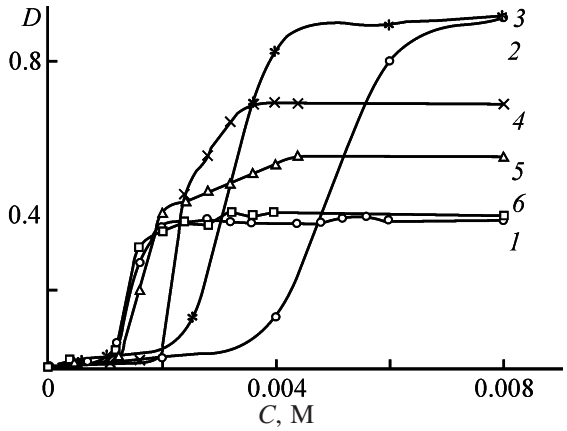

Fig. 2. Optical density D of aqueous solutions of PCCs with different compositions vs. the ionic strength of solution C, created by sodium sulfate. Al^{3+} concentration 0.02 g dl^{-1}, T = 30°C. Molar ratio Al^{3+} : PEI unit: (*1*) 0, (*2*) 1.25, (*3*) 2, (*4*) 3, (*5*) 4, and (*6*) 10.

is not associated with an increase in the ionic strength of solution due to increase in the AHC concentration, since AHS is a weak electrolyte. A probable reason is an increase in the number of the hydrophobic PEI units, bound to several different AHC particles, with increasing PCC content.

The precipitates formed during PCC salting-out with sodium sulfate were analyzed for the nitrogen content by elemental analysis (see table).

Our data suggest that the nitrogen content of the PCCs increases with increasing molar ratio Al^{3+} : PEI unit in the initial mixture and attains a maximum at the ratio of 1.25. This suggests an increase in the number of PEI macromolecules complexed with AHC particles. With a further increase in the ratio of the reactants, the content of nitrogen in the precipitate decreases, since the latter contains both complexed AHC and AHC unbound to the macromolecules of the polymer as the AHC amount is increased. This fact

Aluminum content of aqueous solutions of PCCs and nitrogen content of the precipitate in relation to the molar ratio of the reactants. c(PEI) = 0.5 g dl^{-1}, c(Na_2SO_4) = 1 M

Molar ratio Al^{3+} : PEI unit in initial mixture	Al^{3+} content of initial mixture, g	Nitrogen content of PCC, wt %
0.25	0.02	6.60
0.50	0.04	6.85
0.75	0.06	8.06
1.25	0.10	9.13
1.50	0.12	6.60
2.00	0.16	5.96
3.00	0.24	3.90
4.00	0.32	3.65

suggests that, at the molar ratios of interest, PEI is exhaustively complexed.

To elucidate how complexation is influenced by the molar ratio of the reactants, we used gel-permeation chromatography. This method provides information about the molecular-weight distribution of the particles of the PCC formed. We found that the chromatograms of individual AHC (Fig. 3) are characterized by unimodal distribution at Al^{3+} concentrations under 0.3 g dl^{-1}. With increasing aluminum concentration, the distribution becomes bimodal, with the second mode corresponding to particles with a higher molecular weight. This fact, combined with the results reported by Radchenko et al. [7] and Zakharchenko et al. [8], suggests that aqueous solutions of AHC consist to 95% of small particles, and large particles are present only in insignificant amounts; their number increases only at high AHC concentrations. Also, we showed (Fig. 4) that, when the molar ratio of reactants (Al^{3+} : PEI unit) is increased to 1.25, the gel chromatogram contains one well-defined maximum with the retention time corresponding to individual AHC and a less-defined maximum with the retention time of PEI. This suggests that, above all, a complex with small AHC particles is formed in which the number of the polymer macromolecules corresponds to that of the PCC particles. With further increase in the molar ratio, the retention time of the PCC particles decreases; the maximum in the chromatogram becomes well-defined and is enhanced, which suggests increases in the molecular weight of the PCC particles and in their concentration.

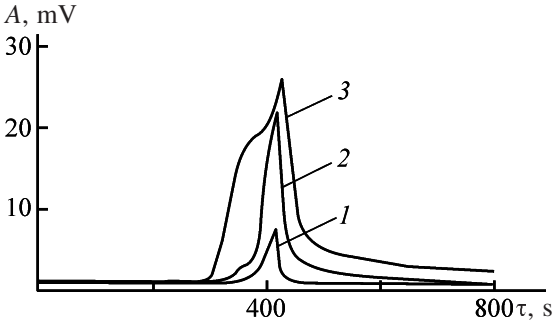

Fig. 3. Gel chromatograms of aqueous solutions of AHC (T = 30°C). Al^{3+} concentration, g dl^{-1}: (*1*) 0.08, (*2*) 0.31, and (*3*) 0.94. (*A*) Signal intensity and (τ) elution time; the same for Fig. 4.

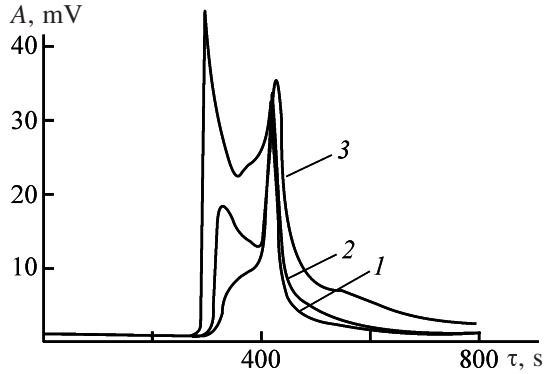

Fig. 4. Gel chromatograms of aqueous solutions of PCCs. Molar ratio of reactants (Al^{3+} : PEI unit): (*1*) 0.25, (*2*) 1.25, and (*3*) 3.00. PEI concentration 0.5 g dl^{-1}, T = 30°C.

To determine the size-distribution characteristics of PCCs, these complexes were examined in detail by photon correlation spectroscopy. We found that, with increasing molar ratio of the reactants, the correlation time increases. This suggests interaction of the polymer macromolecules with aluminum polycations and formation of strongly associated particles of the complex. To determine the hydrodynamic radii of the particles, we calculated the size distributions reconstructed from the corresponding ACFs (Fig. 5). We showed that, for individual components, the presence of particles 10 nm in size (for PEI) and 2 and 40 nm in size (for AHC) is typical. A mixture of these components with the molar ratio under 1.25 is characterized by three peaks in the histogram, which suggests complexation of PEI both with "small" and "large" AHC particles; also, the system contains free polymer macromolecules. Up to the molar ratio of the components of 1.25, an increase in the AHC concentration is responsible for an increase in the relative intensity of the peak corresponding to large particles, which suggests their significant contribution to the light scattering. We showed in [3] that, at the molar ratio Al^{3+} : PEI unit of 1.25, all the PEI macromolecules are complexed, and a PCC with this composition is characterized by the largest number of bonds between the reactants. Further increase in the molar ratio is accompanied by disappearance of the mode corresponding to free PEI, and a new peak appears which

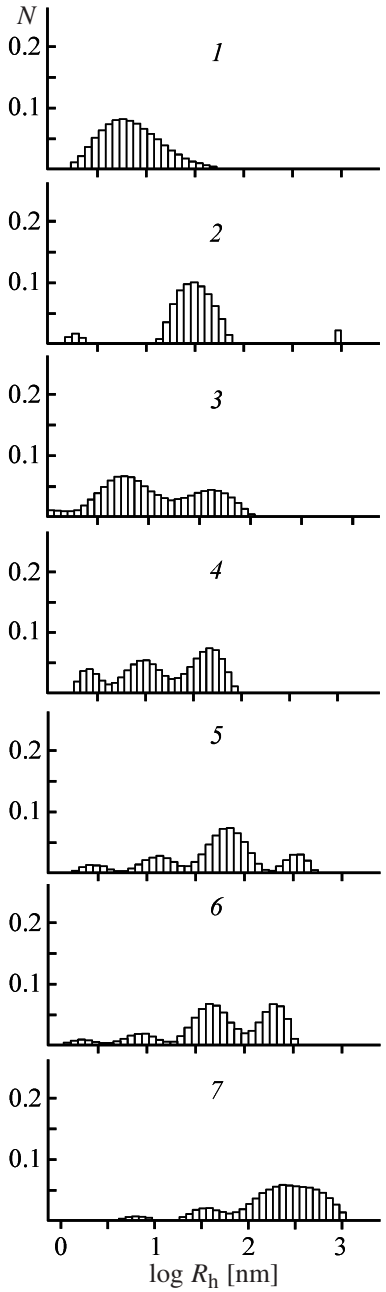

Fig. 5. Particle-size distribution for (*1*) unbound PEI, (*2*) unbound AHC, and (*3*–*7*) PEI–AHC complexes at molar ratios Al^{3+} : PEI unit of (*3*) 0.50, (*4*) 1.25, (*5*) 2.00, (*6*) 3.00, and (*7*) 4.00. Scattering angle 90°, T = 30°C. (*N*) Reduced light scattering intensity, and (R_h) hydrodynamic radius of the particle.

corresponds to strongly associated PCC particles with the size of 100–300 nm. This is accompanied by a smooth growth of the total intensity of the scattered light. The latter fact suggests that, throughout the examined range of the mixture compositions, an increase in the average molecular weight of the light-scattering particles is associated with formation of a complex comprising at least one PEI macromolecule and several AHC particles, both small and large.

CONCLUSIONS

(1) In aqueous solutions, polyethylenimine macromolecules and aluminum hydroxychloride particles form a polymer–colloid complex whose composition varies in the range of the molar ratios of reactants, Al^{3+} : polyethylenimine unit, of 1.25–4.

(2) At molar ratios of the components under 1.25, the system contains two types of particles of the complex, formed with small (2 nm) and large (40 nm) aluminum hydroxychloride particles occurring in the system.

(3) Further increase in the Al^{3+} : polyethylenimine unit ratio results in formation of associated particles of the polymer–colloid complex, whose size differs from that of the initial particles by approximately an order of magnitude.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure and Properties of Polymeric Ethyne–Hexacarbonyldicobalt π Complexes

V. M. Misin, N. N. Glagolev, and M. V. Misin

Emanuel' Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia

Received March 16, 2007

Abstract—A polymeric ethyne–hexacarbonyldicobalt π complex was prepared by the reaction of poly-*p*-diethynylbenzene with $Co_2(CO)_8$. The conformations in which the polymer chains can exist and the conformations in which the –C≡CH and –Ph– groups can form π complexes with $Co_2(CO)_8$ were revealed by analysis of Stuart–Briegleb molecular models. The IR spectra of the polymeric complexes were analyzed, and their thermal degradation in air was examined.

Interest in polymers containing metal atoms π-coordinated to organic macromolecules is due to the possibility of preparing catalytically active systems based on such polymers. Catalytic systems in which a transition metal is π-coordinated to a polymeric support acting as a macroligand are well known [1]. Of particular interest are π complexes with polyconjugated polymers, because of their specific physicochemical, electrophysical, and catalytic properties. In particular, some of these complexes are organometallic ferromagnetics, i.e., materials absorbing or scattering electromagnetic fields. Sergeev et al. [2] prepared π-arene–tricarbonylmetal complexes derived from carbonyls of molybdenum, chromium, vanadium, and various polyphenylenes. At the same time, numerous π-acetylene–hexacarbonyldicobalt complexes with various mono- and disubstituted acetylenes as ligands are known [3].

Therefore, it seemed interesting to synthesize π complexes of metal carbonyls with polysubstituted polymers containing ethynyl groups –C≡CH.

Previously [4] we described preparation and molecular structure of poly-*p*-diethynylbenzene (PDEB), a polyconjugated polyene polymer containing ethynyl groups in pendant chains, $–[HC{=}C(p\text{-}C_6H_4{–}C{\equiv}CH)]_n–$ [4]. The polymer was prepared by selective polymerization of *p*-diethynylbenzene HC≡C–(*p*-C_6H_4)–C≡CH via one of the –C≡CH groups in the presence of an anionic initiator. The use of such polymers opens prospects for preparing diverse complexes whose structure will be preset by both the polymeric chain and the complexing metal fragment. By properly choosing the type and amount of the complexing metal species, it may be possible to prepare in a polymeric matrix both small organometallic fragments and relatively lengthy metal clusters.

This study deals with the synthesis of π-acetylene complexes with a metal carbonyl, based on PDEB. As metal carbonyl we took octacarbonyldicobalt, $Co_2(CO)_8$.

EXPERIMENTAL

The starting PDEB is an X-ray amorphous brown polymer soluble in aromatic and polar solvents. To prepare polymeric complexes, we used polymers with a number-average molecular weight of 3500, containing 0.62 ethynyl group per monomeric unit of the macromolecule [4].

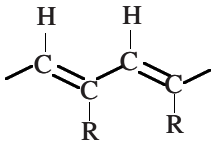
Ethyne–hexacarbonyldicobalt π complex with PDEB (PDEBC). A reactor preliminarily purged with argon was charged with 0.3 g of PDEB in 30 ml of benzene, and a solution of 0.19 g of $Co_2(CO)_8$ in 6 ml of benzene was added dropwise. The reaction was performed at room temperature until the CO evolution ceased. The presence of unchanged $Co_2(CO)_8$ was monitored by TLC on Silufol, eluent hexane. After 3 h, the solution was filtered and the product was precipitated into hexane at the solvent : precipitant ratio of 1 : 10. Yield of PDEBC 0.31 g (68%).

The IR spectra were recorded on a UR-20 spectrophotometer from KBr pellets (1%) or from 5% benzene solutions. The ESR spectra were taken on an

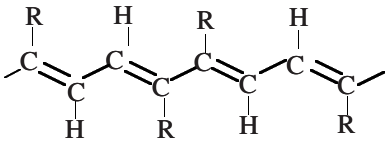
EPR-20 spectrometer (Institute of Chemical Physics, Russian Academy of Sciences; HF modulation, 100 kHz, HI_{max} = 0.6 G). The TGA/DTA curves in air were recorded with an OD-2 derivatograph (MOM, Hungary, continuous heating at a rate of 5 deg min^{-1}).

The molecular weights and molecular-weight distributions of polymers were determined with a GPC-200 liquid gel permeation chromatograph (Waters) using Styrogel columns. The solvent, THF, was fed at a rate of 1 ml min^{-1}; temperature 25°C.

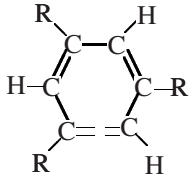
It seemed necessary first to consider the intramolecular structure of the initial poly-*p*-diethynylbenzene with the aim to examine he possibility of formation of metal π complexes with one or several unsaturated groups of the polymer: –C=C– bonds in the polyene chain, *p*-phenylene groups $–C_6H_4–$, and ethynyl groups –C≡CH. To this end, using Stuart–Briegleb molecular models, we considered four different conformations of the poly-*p*-diethynylbenzene chains: *trans-S-cis*, *cis-S-trans*, *cis-S-cis*, and *trans-S-trans*. In so doing, we took into account two possible modes of coupling of unsymmetrical monomer R–C≡C–H (R = $HC≡C–C_6H_4–$): head-to-tail or head-to-head:

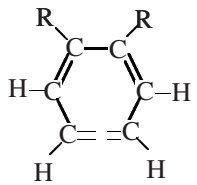


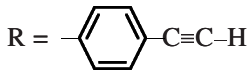
trans-S-trans-Form, "heat-to-tail"



trans-S-trans-Form, "heat-to-head"

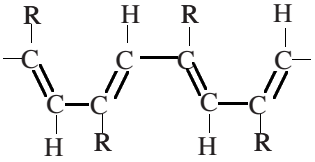




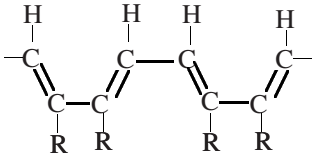


cis-S-cis-Form, "heat-to-tail"

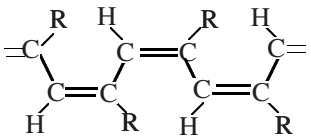
cis-S-cis-Form, "heat-to-head"



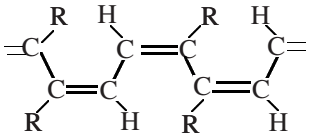
trans-S-cis-Form, "heat-to-tail"



trans-S-cis-Form, "heat-to-head"



cis-S-trans-Form, "heat-to-tail"



cis-S-trans-Form, "heat-to-head"

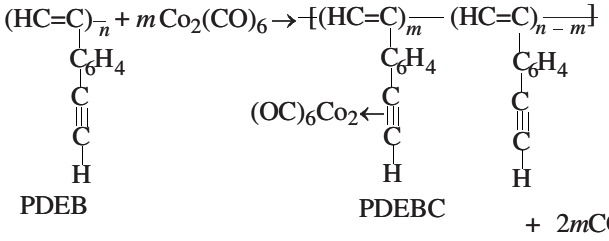
In earlier papers [5], we admitted the possibility of existence of all these coupling modes in chains of substituted polyacetylenes. However, we found that only assembling of no less than six to eight units could give an adequate estimate of steric hindrance in one or another conformation. If only three units are assembled, any of the eight possible conformations is possible.

We found that the poly-*p*-diethynylbenzene molecule cannot exist because of steric hindrance in the following three forms: *trans-S-cis*, head-to-head; *cis-S-trans*, head-to-tail; and *cis-S-trans*, head-to-head.

For all the other five forms, we considered the possibility of formation of metal π complexes with both –C≡CH and $–C_6H_4–$ groups. We found that π complexes of cobalt carbonyl with the –C≡CH group can be formed with four out of five forms (except *trans-S-trans*, head-to-tail).

The complexation of $Co_2(CO)_8$ with Ph groups is possible in only two forms: in the linear *trans-S-cis*, head-to-tail structure and helicoidal *cis-S-cis*, head-to-head structure. The complexation with –C=C– units of the polyene chain is possible in none of the conformations.

However, as will be shown below, under the reaction conditions the π electrons of the phenyl ring did not react with $Co_2(CO)_8$. Cobalt carbonyl reacted only with the π electrons of the –C≡CH triple bond:



PDEB PDEBC

The reaction yielded ethyne–hexacarboyldicobalt π complex in which the –C≡CH bond of the acetylenic ligand is perpendicular to, and noncoplanar with the Co–Co axis [3].

The PDEBC samples prepared were brown powders insoluble in organic solvents. It should be emphasized that the complex, as a rule, lost the solubility

Composition of polymeric complexes

only after precipitation. At the maximal $Co_2(CO)_8$: –C≡CH ratio, 1 : 1 (see table), the insoluble product formed directly in the course of the synthesis. It was shown previously that, under the mild conditions used in our experiments (room temperature), the –C≡C– bond in disubstituted acetylenic monomers is not opened, and the corresponding macromolecules are not formed [6]. Therefore, the loss of the solubility in the course of complexation with the polymer cannot be attributed to the cross-linking of the macromolecules via the same –C≡CH bonds in PDEB units. More likely, the insolubility of the product is due to more complex physicochemical factors preventing the penetration of solvent molecules between macromolecules of the polymeric complex in the course of its attempted repeated dissolution.

To determine the extent of transformation of the –C≡CH group, we performed the elemental analysis of the complexes. The results are given in the table. It can be seen that $Co_2(CO)_8$ reacts with the triple bond of PDEB within the reaction time virtually quantitatively.

The formation of the fragments $\overset{C}{\underset{C}{\|\|}}{\rightarrow}Co_2(CO)_6$ is confirmed by IR spectroscopy (Fig. 1). The IR spectrum of a benzene solution of the polymeric complex [the reaction mixture containing no $Co_2(CO)_8$ according to TLC] contains, along with bands of the starting polymer, also four characteristic strong bands of CO stretching vibrations in the range 2100–2000 cm^{-1} [7]. Preservation of these bands after the isolation of the polymeric complexes from the solution shows that the complexes do not decompose in the course of precipitation. According to [7], the stretching band of a coordinated monosubstituted triple bond –C≡CH is observed at 1550 cm^{-1}. Unfortunately, this band cannot be recorded, because it is obscured by strong stretching vibration bands of PDEB benzene rings. In the range 480–550 cm^{-1}, there are a number of bands corresponding to bending vibrations of carbonyl groups and stretching vibrations of Co–C bonds.

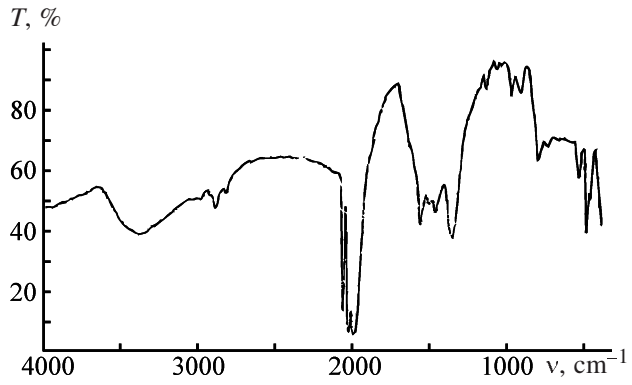

Fig. 1. IR spectrum of the π complex of hexacarbonyldicobalt with poly-*p*-diethynylbenzene. (*T*) Transmission and (ν) wavenumber.

In addition, in the IR spectra of complexes with a low content of $\overset{C}{\underset{C}{\|\|}}{\rightarrow}Co_2(CO)_6$ fragments (PDEBC-1), there is a well-defined band at 3300 cm^{-1}, corresponding to ≡C–H stretching vibrations in unchanged ethynyl groups –C≡CH [8]. This band decreases in intensity with an increase in the content of the above fragments in the polymeric complexes, and in PDEBC-4 it is lacking at all. Simultaneously, in the IR spectra of the complexes with a high content of $\overset{C}{\underset{C}{\|\|}}{\rightarrow}Co_2(CO)_6$ fragments (PDEBC-3, -4), the band at 2100 cm^{-1}, characteristic of stretching vibrations of the monosubstituted triple bond RC≡CH in PDEB, disappears. No changes in the bands characteristic of aromatic groups were observed in the spectra, suggesting the absence of complexation between the phenyl groups and cobalt carbonyls.

The polymeric complexes prepared were studied by TGA/DTA (Fig. 2). The TG curves show that the thermal oxidative stability of polymeric complexes PDEBC is considerably lower than that of the starting PDEB polymers. In the DTA curves of the polymeric complexes, there are exothermic peaks at 120 and

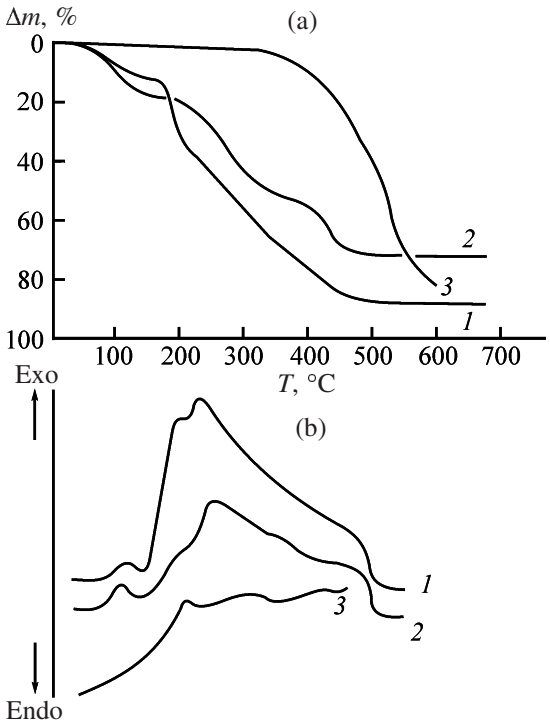

Fig. 2. Thermal oxidative degradation of polymeric π complexes. (Δ*m*) Weight loss and (*T*) temperature. (a) TGA and (b) DTA. (*1*) PDEBC-1, (*2*) PDEBC-4, and (*3*) partially cross-linked PDEB (thermolysis in a vacuum, 100°C, 6 h).

205°C. The former peak, corresponding to significant weight loss, is attributable to elimination of two CO groups from the $\begin{matrix}C\\ \|\\ C\end{matrix}\!\!\rightarrow Co_2(CO)_6$ fragments. This assumption is confirmed by the fact that the weight loss at 120°C, according to TGA data (8% for PDEBC-1 and 12% for PDEBC-4), is approximately equal to the weight fraction of two CO groups in the polymeric complex, calculated from the analytical data (7.37% for PDEBC-1 and 11.67% for PDEBC-4). The exothermic peak at 205°C corresponds to opening of the –C≡CH triple bond. A peak in this region was also observed in DTA studies of partially cross-linked PDEB [4] and polydiphenylacetylene [6].

The polymers studied, as well as their complexes with cobalt carbonyl, exhibit paramagnetism. The concentration of paramagnetic species in the starting polymer is about 10^{17} spins g^{-1}, and it does not noticeably change upon formation of the polymeric complex. Then the polymeric complexes obtained were subjected to additional treatment with the aim to obtain the corresponding ferromagnetic material. As a result, the first laboratory samples of a new radio-absorbing material with improved properties was obtained. The material decreased the Q-factor in an ESR spectrometer waveguide ($\lambda = 3 \pm 1.2$ cm) by $(5–13) \pm 10\%$ dB mg^{-1}, instead of 0.6–0.8 for ferrite-containing materials taken for comparison. Thus, we prepared a substance ensuring by a factor of 2.3 lower material consumption (down to 2.8 kg m^{-2}).

CONCLUSIONS

(1) π-Acetylenic complexes of poly-*p*-diethynylbenzene with octacarbonyldicobalt, $Co_2(CO)_8$, were prepared.

(2) The formation of π complexes of cobalt carbonyl with the –C≡CH group of the side substituent of the polymer is possible in four types of intramolecular conformations. No complexation of cobalt carbonyl with phenyl rings or polyene chain is observed.

(3) Samples of a radio-absorbing material were prepared from the synthesized complexes.

Abstract—The kinetic features of functionalization of natural polysacharide, pectin, by liquid-phase oxidation were studied.

DOI: 10.1134/S1070427207110274

Water-soluble oligomers of natural polysaccharides (chitosan, arabinogalactan, and pectin) are promising environmentally clean raw materials for preparing prolonged-action pharmaceuticals and additives for food and cosmetic industry [1–3]. It is interesting to examine the possibility of preparing pharmaceuticals from modified (additionally functinalized) low-molecular-weight natural polymers (oligomers) in which the polymeric carrier is a transporter of the pharmaceutical through cell membranes. It is known that natural polysaccharide pectin is a radioprotector and detoxicant [4]. Combination of these properties with therapeutic action of a pharmaceutical in the form of a pectin complex results in effective positive effect on an organism. Pectin can be readily functionalized by oxidation in an aqueous solution. Preparation of a water-soluble oxidized polysaccharide using nontoxic and readily separable oxidizing agents is an urgent problem. To determine the optimal preparation conditions of the oxidation product with required properties, the kinetic features of oxidation of the biopolymer in an aqueous solution should be studied.

EXPERIMENTAL

We used citrus pectin with molecular weight of 132000 ([η] = 2.4 dl g^{-1}, 25°C). Hydrogen peroxide (H_2O_2), iron(II) sulfate, ethylenediaminetetraacetic acid disodium salt (Na_2EDTA), and potassium iodide were of chemically pure grade; crystalline iodine was of pure grade. An ozone–oxygen mixture was prepared with the aid of an ozonizer of the known design [5]. We used freshly prepared double-distilled water as the solvent. Oxidation of aqueous pectin solutions was performed in a glass temperature-controlled bubbling reactor. Samples of the reaction mixture were taken at regular intervals. The total concentration of the carboxy groups was determined by titration with NaOH.

A chemiluminescence unit consisted of a lightproof chamber in which a glass temperature-controlled reactor equipped with a reflux condenser, a stirrer, and a syringe for injection of reactants was placed. The experiments were performed by the following procedure. An aqueous solution with a known pectin concentration was placed in the reactor and the reactor was controlled thermostatically for 15 min. Hydrogen peroxide was then rapidly injected with the syringe, or an ozone–oxygen mixture was bubbled with stirring. A change in the chemiluminescence intensity measured in arbitrary units proportional to the signal height was recorded. The UV spectra of 0.2% aqueous solution were recorded on a Specord M-40 spectrophotometer.

Pectins are macromolecular compounds whose chemical structure is close to that of hemicelluloses (colloidal polysaccharides) or plant glucopolysaccharides. Pectins are composed of *D*-galacturonic acid residues bound by α-(1→4)-glycoside bonds into a straight-chain macromolecule of polygalacturonic (pectic) acid [6]. No thermal degradation and oxidation of pectin are observed in an aqueous solution at 50–80°C. Under these conditions, pectin is not oxidized even when air is bubbled through the solution. The content of carboxy groups of pectin increases after addition of H_2O_2 to an aqueous pectin (P) solution or bubbling of an ozone–oxygen mixture through the solution (Fig. 1).

Since accumulation of carboxy groups in the examined reaction systems decelerates with time (Fig. 1), we used the initial rate of accumulation of carboxy groups V_{COOH} as the quantitative parameter of the process.

Previously we showed [7, 8] that oxidation of natural polysaccharide arabinogalactan and poly(vinyl alcohol) in an aqueous solution, initiated by hydrogen peroxide or an ozone–oxygen mixture, was a radical reaction. To determine the oxidation mechanism in the system in question, we determined the initial rate of accumulation of carboxy groups in the presence of phenol (Fig. 2).

Phenol is a conventional inhibitor of radical-chain oxidation of organic compounds [9]. As seen from Fig. 2, phenol inhibits pectin oxidation, which suggests the radical mechanism of polysaccharide oxidation.

Variable-valence metal cations (M^{n+}) catalyze radical decomposition of hydrogen peroxide [10]:

$$H_2O_2 + M^{n+} \rightarrow HO^- + HO^\bullet + M^{(n+1)+}, \qquad (1)$$

and hence this reaction may initiate radical processes. Therefore, variable-valence metal salts should catalyze pectin oxidation with hydrogen peroxide, which is the case.

The dependence of the initial rate of accumulation of carboxy groups on the concentration of iron(II) sulfate at $T = 70°C$, $[P]_0 = 0.2$ wt %, $[H_2O_2]_0 = 1$ M is presented below.

$[FeSO_4] \times 10^4$, M	$V_{COOH} \times 10^4$, mol l^{-1} min^{-1}
0	0.76
1	1.35
3	2.94
5	4.61
7	5.84
10	8.88

It is seen that the rate of initiation by reaction (1) increases with increasing content of Fe^{2+} ions in the solution. As a result, accumulation of carboxy groups accelerates. Trace amounts of variable-valence metal ions can be introduced into the reaction mixture with distilled water which was not subjected to special treatment to remove M^{n+} impurities [11]. Therefore, pectin oxidation can be weakly initiated in P + H_2O_2 + O_2 + H_2O system by reaction (1) even in the absence of $FeSO_4$.

To confirm the radical mechanism of pectin oxidation, we added disodium salt of ethylenediaminetetra-

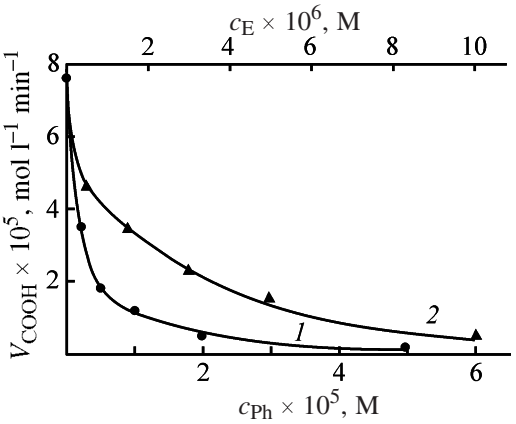

Fig. 2. Initial rate of accumulation of carboxy groups V_{COOH} as a function of the initial concentration of (*1*) phenol c_{ph} and (*2*) Na_2EDTA c_E at 70°C. $[P]_0 = 0.2$ wt %, $[H_2O_2]_0 = 1$ M.

acetic acid. It is known that Na_2EDTA is a strong complexing agent forming complexes with variable-valence metal cations [12, 13]. These complexes do not catalyze decomposition of hydrogen peroxide by reaction (1) [14]. Introduction of Na_2EDTA into the system decreases the concentration of free variable-valence metal cations and decreases the rate of initiation by reaction (1), thus decreasing V_{COOH} (Fig. 2).

Oxidation of pectin in aqueous solutions at 70°C with hydrogen peroxide or with an ozone–oxygen mixture bubbled through the solution is accompanied by chemiluminescence (CL) in the visible range. It is known [15] that CL is observed, as a rule, in systems in which species having a free valence are generated. For example, in the absence of an initiator in the P + O_2 + H_2O system, no free radicals are formed and CL

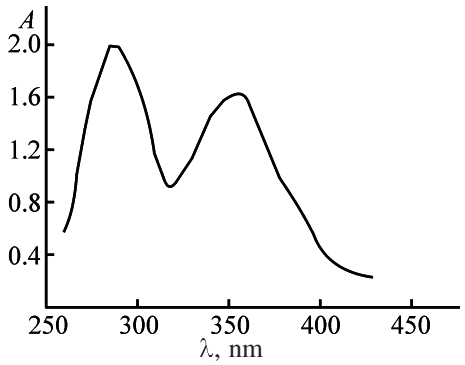

Fig. 3. UV spectrum of a solution of mixture I at 25°C. $[P]_0$ = 0.2 wt %, $[I_2]_0 = 10^{-4}$ M, $[KI]_0 = 6\times10^{-4}$ M. (*A*) Optical density and (λ) wavelength.

is not observed. CL signals in P + O_3 + O_2 + H_2O and P + H_2O_2 + O_2 + H_2O systems are observed in the first reaction steps (~30–200°C), with CL intensity decreasing exponentially. It should be noted that CL in the examined systems can be due to oxidation of not only pectin but also readily oxidizable impurities [16] present in the polysaccharide in trace amounts.

A great attention is paid to the study of different biologically active additives prepared from food fibers. Biologically active compounds can be readily prepared by treatment of pectin with molecular iodine [17]. These compounds are probably formed by electron donor–acceptor interactions of pectin functional groups and I_3^- formed in an aqueous solution of I_2 + KI mixture. We studied how oxidative functionalization of the biopolymer affects the bonding in these complexes.

The electronic absorption spectrum of an aqueous solution of a mixture containing 10^{-4} M I_2 and 6×10^{-4} M KI has two bands at 285 and 355 nm (Fig. 3), typical for I_3^- anion [18]. These bands are absent in the spectrum of an aqueous solution of pectin.

These bands are also present in the spectrum of a P + I_2 + KI mixture (I) with commensurable concentrations of the components. The intensities of these bands increase by a factor of approximately 1.3–1.6, which suggests formation of pectin complexes with triiodide ions. Formation of this complex is also confirmed by a change in the color of the solution from dark brown to intense yellow [19]. The intensity of these bands increases to a lesser extent after complexation of oxidized pectin with I_3^-. Probably, functional groups of pectin responsible for complexation of I_3^- are oxidized.

CONCLUSIONS

(1) Oxidation of pectin with molecular oxygen in an aqueous solution in the presence of hydrogen peroxide or ozone occurs by the radical mechanism.

(2) Variable-valence metal ions initiate radical oxidation in the presence of H_2O_2. Phenol and Na_2EDTA inhibit peroxide oxidation of the biopolymer.

ACKNOWLEDGMENTS

This study was partially financially supported by the state scientific and technical program of Bashkortostan Republic "New Materials, Chemical Technologies for Industry, Medicine, and Agriculture on the Basis of Petrochemical, Mineral, and Recyclable Raw Materials of Bashkortostan Republic" for the year 2007.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Chemically Active Polymeric Fibers Bearing Sulfo and Carboxy Groups

Yu. V. Bondar' and S. W. Lee

Institute of Environmental Geochemistry, Kiev, Ukraine
Yeungnam University, Yeungnam, Korea

Received May 2, 2007

Abstract—A chemically active material bearing two types of acid groups, strongly acidic sulfo groups and weakly acidic carboxy groups, was prepared by radiation-induced graft copolymerization of two kinds of monomers, acrylic acid and sodium styrenesulfonate, onto polypropylene fibers. The main parameters affecting the graft copolymerization are considered.

DOI: 10.1134/S1070427207110286

The development and improvement of chemical procedures for the synthesis of functional polymeric materials participating as active components in various chemical processes is of large scientific and applied interest. The majority of developments in this field concern preparation of functional polymers in the granulated form for the use in traditional ion-exchange processes. However, synthesis of chemically active polymeric materials in the form of fibers would substantially expand possible applications of functional polymers. This is due to the fact that fibers have a developed surface and show high kinetic and adsorption parameters; they can be readily molded into articles of any size and shape; they show high performance when used in closed-loop processes.

Passing from traditional functional polymers to their new physical forms (fibrous and bulk-porous) requires new approaches to the synthesis and modification of polymers. One of such modern methods is radiation-induced polymerization. This method allows grafting of a nano- or microchain of a monomer with a desired functional group onto the surface of an inert polymeric matrix, ensuring control over the length and density of the grafted chains. The method can be used for modification of the surface, bulk, or a local section of a material or ready article [1–3]. The method is environmentally clean and economical, and it is widely used for preparing chemically active polymeric materials (based on diverse polymeric matrices) for industry, medicine, biotechnology, and environmental protection [2–9].

The range of vinyl monomers with functional groups, used in radiation-chemical technologies, is narrow. Grafting of a monomeric precursor followed by polymer-analogous transformations, or copolymerization of several monomers with different functional groups expands the possibilities for the synthesis of functional polymeric materials.

From the practical viewpoint, it is extremely interesting to prepare chemically active polymeric fibers with sulfo groups. The common route to such materials is sulfonation of grafted polystyrene chains [10–12].

Direct introduction of sulfo groups by radiation-induced graft polymerization with sodium styrenesulfonate as vinyl monomer failed [13]. Only postradiation copolymerization of acrylic acid (AA) and sodium styrenesulfonate (SSS) onto the surface of a polyethylene film led to a positive result: A cation-exchange membrane with an ion-exchange capacity of 25 mg-equiv g^{-1} was obtained. However, in that paper the specific features of radiation-induced copolymerization of two monomers were not considered, and the content of sulfo groups in the synthesized cation exchanger was not reported. Therefore, a study of the radiation-induced copolymerization of two monomers and evaluation of the ion-exchange properties of the product remains a topical problem.

EXPERIMENTAL

As a polymeric base for performing radiation-induced graft copolymerization of a mixture of monomers, acrylic acid (CH_2=CHCOOH, Junsei Chemical Co. Ltd) and sodium styrenesulfonate [CH_2=CHC_6H_4·

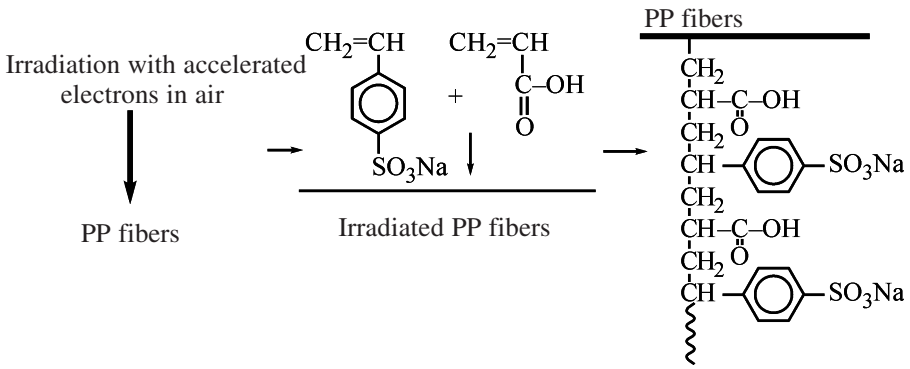

Fig. 1. Scheme of the experiment on copolymerization of acrylic acid and sodium styrenesulfonate monomers on the surface of polypropylene fibers.

SO_3Na, Tokyo Kasei Kogyo Co. Ltd (Japan)], we used a nonwoven material of polypropylene (PP) fibers with a density of 120 g m^{-2} and degree of crystallinity of 65% (Toray-Saehan Co. Ltd, Korea). Irradiation was performed on an ELV-04 accelerator by accelerated electrons (1 MeV) in air (preirradiation procedure). After the irradiation, the sample was stored in a desiccator at room temperature, and the copolymerization was performed within 1–5 days after the irradiation.

The preliminarily weighed irradiated sample was placed in a flask containing an aqueous solution of monomers [0.1 mol (20.6 g) of SSS + 0.1 mol (7.2 g) of AA in 100 ml of H_2O] and Mohr's salt [$(NH_4)_2 \cdot Fe(SO_4)_2 \cdot 6H_2O$, Merck, Germany]; the solution was saturated with nitrogen, the flask was tightly stoppered and thermostated at 50°C, and the graft copolymerization was performed with continuous stirring.

After the reaction completion, the product was thoroughly washed in a Soxhlet apparatus for 12 h with water and methanol to remove the adsorbed homopolymers and unchanged monomers, dried in a vacuum oven at 50°C to constant weight, and weighed.

The degree of graft copolymerization of the two monomers, Q_{gr} (%), was calculated from the results of gravimetric analysis, namely, from the weight gain after the reaction:

$$Q_{gr} = \frac{m_{gr} - m_0}{m_0} \times 100,$$

where m_0 and m_{gr} are the sample weights before and after grafting, respectively.

The functional groups were detected with a Perkin–Elmer Golden Gate Single Reflection ATR System IR spectrophotometer.

The total exchange capacity of the product, E_{ex} (mg-equiv g^{-1}), reflecting the total number of acid groups introduced into the PP material, was calculated from the results of back-titration [14]. The content of sulfo groups was estimated from the results of static sorption of Cu(II) and Co(II) ions from acidic solutions of their salts.

The amount of metal ions adsorbed on unit weight of dry modified fibers, S_M (mmol g^{-1}), was calculated by the formula

$$S_M = \frac{c_0 - c}{m} V,$$

where c_0 and c are the concentrations of metal ions in the solution (mmol mg^{-1}) before and after adsorption, respectively; V, volume of the solution being analyzed (ml); and m, weight of the modified sample (g).

The concentration of M(II) ions in aqueous solution was measured on a UNICAM 989 atomic absorption spectrometer (the United Kingdom).

The scheme of the experiment is shown in Fig. 1.

This paper deals with the effect of various process parameters on the copolymerization of SSS and AA monomers on polypropylene fibers as support. Three sets of parameters related to the irradiation, graft copolymerization proper, and nature of the support affect the degree of radiation grafting. We examined the effect exerted by the main parameters: absorbed dose, temperature, reaction time, and inhibitor concentration.

In the course of irradiation of a polymeric matrix with accelerated electrons in the presence of atmospheric oxygen, the major products formed on its surface and in the bulk are hydroperoxides, which are stable at ambient temperature but decompose on heat-

Influence of the Mohr's salt content on the degree of graft copolymerization of SSS and AA monomers

Mohr's salt content	Degree of grafting, %	
	SSS + AA monomer mixture	7% AA
0	18.6	57.7
5×10^{-5}		61.7
10^{-4}	29.3	113.0
5×10^{-4}	86.5	150.4
10^{-3}	110.0	164.6
5×10^{-3}	82.2	108.3
10^{-2}	79.7	101.4
10^{-1}	19.9	34

ing above 60°C with the generation of macroradicals ($PPO^{\bullet}$) and hydroxyl radicals ($^{\bullet}OH$). In the macroradicals, there is a site for monomer (M) grafting, and hydroxyl radicals can initiate the homopolymerization of the monomers. The reaction mechanism is discussed in numerous papers (see, e.g., [15]) and can be presented as follows:

$$PP \xrightarrow{\text{Irradiation}} PPH^{\bullet} \xrightarrow{O_2} PP\text{–}OOH \xrightarrow{\text{Heating}} PPO^{\bullet} + {}^{\bullet}OH,$$

$$M + {}^{\bullet}OH \rightarrow {}^{\bullet}M\text{–}OH \xrightarrow{n\text{M}} {}^{\bullet}M\text{–}(M)_n\text{–}OH,$$

$$PPO^{\bullet} + M \rightarrow PPO\text{–}M^{\bullet} \xrightarrow{k\text{M}} PPO\text{–}(M)_k\text{–}M^{\bullet},$$

$$PPO^{\bullet} + {}^{\bullet}M\text{–}(M)_n\text{–}OH \longrightarrow PPO\text{–}M\text{–}(M)_n\text{–}OH,$$

$$PPO\text{–}(M)_k\text{–}M^{\bullet} + {}^{\bullet}OH \longrightarrow PPO\text{–}(M)_k\text{–}M\text{–}OH,$$

$$PPO\text{–}(M)_k\text{–}M^{\bullet} + {}^{\bullet}M\text{–}(M)_n\text{–}OH \longrightarrow PPO\text{–}(M)_{k+n+2}\text{–}OH.$$

The homopolymerization can be suppressed by adding transition metal salts [16, 17]:

$$^{\bullet}OH + Fe^{2+} \longrightarrow OH^{-} + Fe^{3+}.$$

If the grafting is performed at temperatures lower than 60°C, the degree of radiation grafting can also be increased by adding transition metal salts, as in their presence hydroperoxides decompose more efficiently:

$$PP\text{–}OOH + Fe^{2+} \longrightarrow PPO^{\bullet} + OH^{-} + Fe^{3+}.$$

At the same time, an excess of such salts can deactivate the system and lead to a decrease in the degree of polymerization:

$$PPO^{\bullet} + Fe^{2+} \longrightarrow PPO^{-} + Fe^{3+}.$$

The influence of the content of Fe^{2+} ions (Mohr's salt) on the degree of graft copolymerization of SSS and AA onto irradiated (absorbed dose 70.5 kGy) samples of PP fibers, performed at 50°C for 12 h, is illustrated by the table. It can be seen that, on adding Fe(II) ions into the reaction medium, the degree of grafting increases and reaches a maximum on adding 10^{-3} wt % Mohr's salt.

We examined how the degree of graft copolymerization of SSS and AA from aqueous solution of these monomers onto PP fibers depends on the absorbed dose (Fig. 2).

In contrast to Chen et al. [16], who reported on a linear increase in the degree of radiation-induced grafting of AA onto a polypropylene material with an increase in the absorbed dose to 120 kGy, we obtained a more complex dependence of the degree of radiation-induced graft copolymerization of the two monomers on the absorbed dose. Figure 2 shows that the degree of radiation-induced graft copolymerization first slowly increases with an increase in the absorbed dose to 40.3 kGy and then rapidly increases with a further increase in the absorbed dose to 70.5 kGy.

To reveal the specific features of graft copolymerization of SSS and AA monomers, we examined the copolymerization kinetics at 50°C and analyzed the IR spectra of the corresponding samples. The kinetic curve shown in Fig. 3 consists of several portions (0–9, 9–12, 12–33 h), apparently reflecting the stepwise course of the copolymerization at this temperature. In the first step of the process (0–9 h), smooth ascent of the kinetic curve suggets slow development of the copolymerization; in the second step (9–12 h), the copolymerization rate sharply increases, and in the third step (12–30 h) it increases more slowly, reaching saturation in 28–32 h.

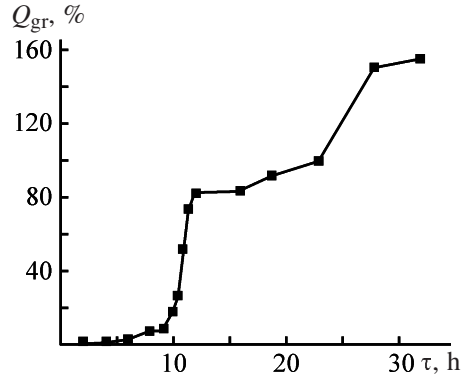

Fig. 3. Degree of graft copolymerization of SSS and AA, Q_{gr}, as a function of the copolymerization time τ.

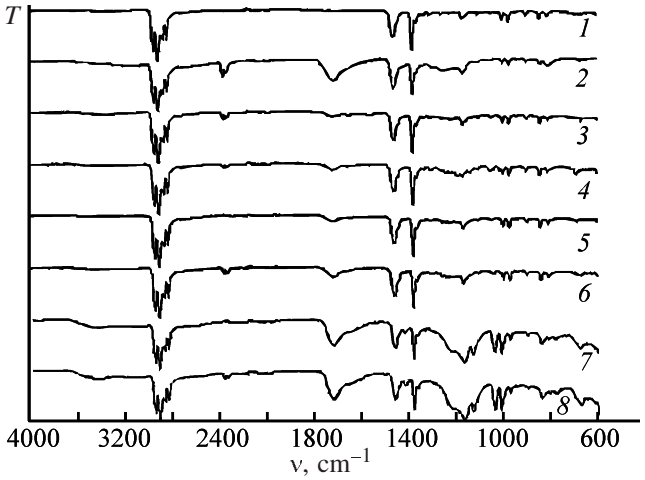

Fig. 4. IR spectra of (*1*) initial PP fiber, (*2*) PP fiber with grafted polyacrylic acid (Q_{gr} = 95%), and (*3*–*8*) PP fibers modified with SSS + AA, with different degrees of grafting. (*T*) Absorption and (ν) wavenumber. Q_{gr}, %: (*3*) 2.9, (*4*) 7.7, (*5*) 8.8, (*6*) 17.8, (*7*) 73.0, and (*8*) 98.6.

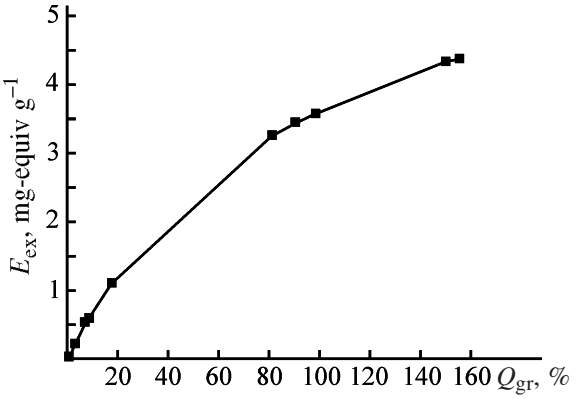

Fig. 5. Total exchange capacity E_{ex} of chemically active PP fibers as a function of Q_{gr}.

Figure 4 shows the IR spectra of the initial unmodified PP fibers, PP fibers with grafted polyacrylic acid chains (Q_{gr} = 95%), and samples of PP fibers with different degrees of graft copolymerization.

In the IR spectra *3*–*6* of the samples corresponding to the first step of the copolymerization (Q_{gr} 2.9, 7.3, 8.6, and 17.8%, respectively), there is an absorption band at 1715 cm^{-1}, assigned to the C=O vibrations in acrylic acid. The intensity of this band grows with an increase in the degree of grafting. The characteristic absorption bands of the sulfonate group (1150, 1030, 670 cm^{-1}) appear in the IR spectra in the second and third steps of the copolymerization (spectra *7* and *8*, Q_{gr} 73.0 and 98.6%, respectively). Their intensity, like that of the above-noted absorption band of acrylic acid, grows with an increase in the degree of polymerization.

Comparison of the kinetic curve of the copolymerization of SSS and AA monomers with the IR spectra of the corresponding samples shows that the copolymerization of the monomers starts with grafting of acrylic acid monomers (in the first step), and sodium styrenesulfonate monomers are incorporated in the propagating chains in the subsequent steps.

This can also be confirmed by the results of a blank grafting experiment in which the irradiated fiber samples were placed for 9–12 h in a nitrogen-saturated aqueous solution containing 10^{-2} wt % Mohr's salt and heated to 50°C, after which AA was added and the mixture was kept at 50°C for an additional 5–9 h. The absence of characteristic absorption bands of AA in the IR spectra of the resulting samples indicated that, under these conditions, virtually all the active centers capable to initiate the graft copolymerization were deactivated. Thus, we can conclude with confidence that SSS monomers are incorporated in the propagating polyacrylic acid chains, rather than grafted directly to PP fibers.

By the radiation-induced copolymerization of sodium styrenesulfonate and acrylic acid monomers, we prepared chemically active PP fibers bearing two types of functional groups: strongly acidic sulfo groups and weakly acidic carboxy groups. As the synthesized fibers can be considered as a bifunctional adsorbent (cation exchanger), it is very interesting to evaluate its ion-exchange parameters. For several samples, we determined by back-titration the total exchange capacity reflecting the actual number of acid groups. Figure 5 shows the dependence of the total exchange capacity of the samples on the degree of graft copolymerization of SSS + AA.

The maximal total exchange capacity (acid groups), 4.37 mg-equiv g^{-1}, was obtained for the sample with 155% degree of grafting.

To single out the contribution of sulfo groups to the total exchange capacity, we performed a series of

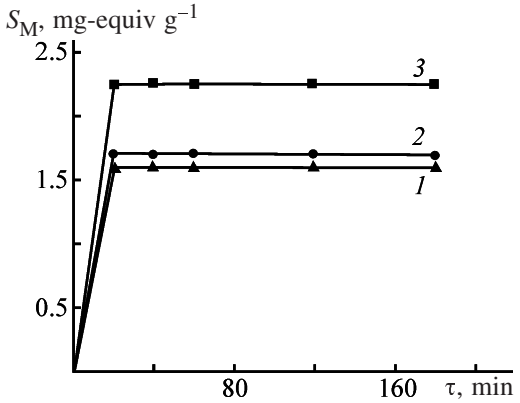

Fig. 6. Adsorption S_M of Cu(II) and Co(II) ions acidic solutions of their salts (pH 4) with the synthesized PP fibers as a function of time τ. Curve nos. are sample nos.

experiments on the adsorption of Cu(II) and Co(II) ions from acidic solutions of their salts (pH 4). As in acidic solutions (at pH < 5) the carboxy groups of AA are only weakly ionized and do not take part in the ion exchange to a noticeable extent, the sorption occurs only via strongly ionized sulfo groups.

Three synthesized samples in the H^+ form with the total exchange capacity of 3.2 (sample 1), 3.4 (sample 2), and 4.3 mg-equiv g^{-1} (sample 3) were chosen for the experiments.

The kinetic curves of adsorption of Cu(II) and Co(II) ions with the synthesized PP fibers from acidic solutions of their salts are given in Fig. 6.

It can be seen that the equilibrium adsorption values (1.55, 1.68, 2.55 mg-equiv g^{-1}) are almost two times lower than the total exchange capacities of the samples. This fact suggests that chemically active PP fibers synthesized by radiation-induced graft copolymerization of SSS and AA monomers contain groups of a strong acid (sulfonate groups). In the examined samples, the amount of these groups is large and comparable with the amount of carboxy groups.

CONCLUSIONS

(1) A chemically active polymeric material bearing two types of acidic groups, strongly acidic sulfonate and weakly acidic carboxy groups, was prepared by radiation-induced graft copolymerization of two types of monomers, acrylic acid and sodium styrenesulfonate, onto polypropylene fibers.

(2) The main parameters affecting the graft copolymerization are the absorbed dose, reaction temperature and time, and inhibitor concentration.

(3) The kinetics of the copolymerization of acrylic acid monomers and sodium styrenesulfonate at 50°C was studied. The copolymerization starts with the grafting of acrylic acid monomers, and sodium styrenesulfonate monomers are subsequently incorporated in propagating monomer chains.

Abstract—Conditions for modification of cellulose under laboratory and industrial conditions with A-1 and A-2 fire retardants as P,N-containing modifiers were examined with the aim to prepare difficultly inflammable materials. The degrees of crystallinity of the products, crystallite size, and features of their thermal decomposition in air in the range 20–500°C were examined.

DOI: 10.1134/S1070427207110298

Wide use of cellulose-containing materials in private life gives rise to permanent fire hazard in case of violation of fire safety requirements. Therefore, the amount of goods produced in fire-safe modifications in developed countries is doubled every year. In CIS contries, fireproof cellulose-containing materials for domestic purposes virtually are not produced, whereas the demand of offices, hotels, boarding schools, hostels, and transport for these materials steadily grows. Studies on preparation of phosphorus-containing cellulose esters made it possible to formulate the requirements to esterifying fire-retardant agents for cellulose and to technologies for production of phosphorus-containing materials of decreased combustibility.

The goal of this study was to develop the conditions for treatment of fabrics with P,N-containing fire retardants and to examine the properties of the resulting materials.

EXPERIMENTAL

In our study we used P,N-containing fire retardants (A-1 and A-2) differing in the anionic form of the phosphates taken for the modification [1, 2]. Treatment of fabrics differing in the thickness and density (markings 134, 142, 1672, 3154) was performed both under laboratory conditions and in pad equipment of a textile finishing shop; heat treatment was performed both an an SNOL laboratory oven (130–170°C) and in a Textima-140 tenter drier (175–200°C) at a fabric feeding rate of 6 m min^{-1}. After the heat treatment, the samples were washed in a bath (bath ratio 15) with water under laboratory conditions or in an Eliteks-4580 dye-rolling machine to negative reaction for phosphorus in wash waters [3]. The phosphorus content of fabrics heat-treated in different chambers of the Textima-140 apparatus is given in Table 1.

The wash waters from laboratory samples heat-treated at 130–170°C were subjected to chromatographic analysis for the content of condensed phosphates. The results are given in Table 2.

The composition of the ester groups of cellulose phosphates prepared at different temperatures was determined by their enzymatic hydrolysis followed by evaluation of the degree of condensation of phos-

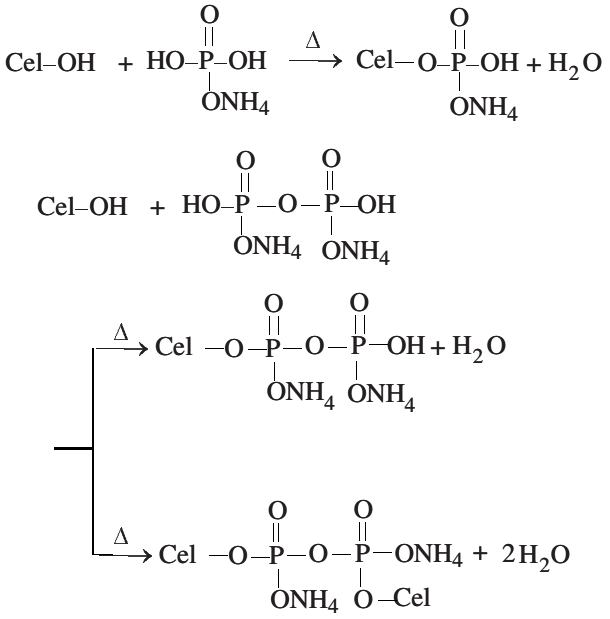
A-2	20	27.4	32.3	40.2	53.0	67.0

phates after their chromatographic separation [4]. The results are given in Table 3.

The above data show that the ester groups of the samples prepared by treatment of the fabric with A-1 fire retardant mainly consist of orthophosphoric acid residues. Treatment of the fabric with A-2 fire retardant yields an ester containing up to 48 wt % phosphates with the degree of condensation $n \geq 2$ (mainly pyrophosphate) [5]. Presumably, in the course of treatment with A-1 and A-2 fire retardants, acidic salts of orthophosphoric acid react with cellulose by the scheme shown below.

Scheme of reaction of acidic salts with cellulose



The structural changes occurring in cellulose crystallites upon phosphorylation were monitored by X-ray phase analysis. The X-ray diffraction patterns of the samples were taken with a URS-50M device (copper cathode, Ni-filtered CuK_α radiation, λ 1.5405 Å) using the POWDER X program. As seen from the diffraction patterns (Figs. 1a, 1b), the crystalline cell

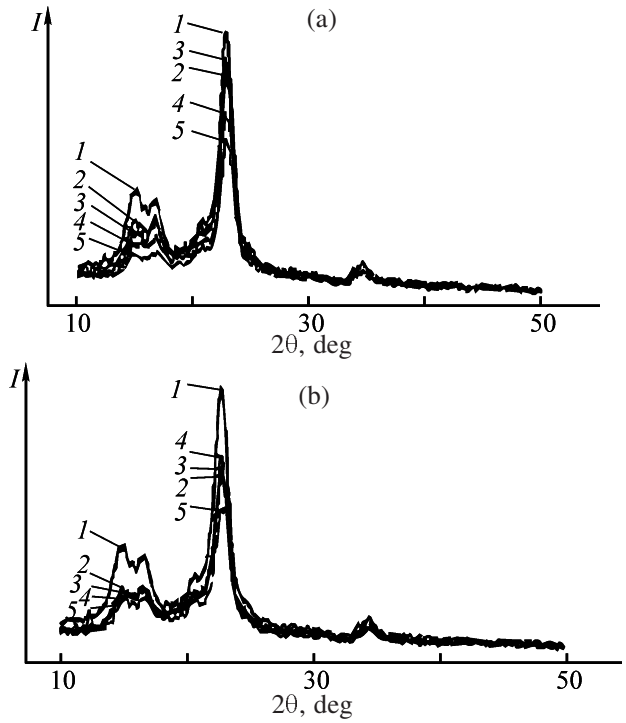


Fig. 1. X-ray diffraction patterns of celluloses modified with (a) A-1 and (b) A-2 fire retardants. (*I*) Intensity and (2θ) Bragg angle. (*1*) Initial cellulose; phosphorus content, wt %: (a) (*2*) 2.0, (*3*) 3.2, (*4*) 4.2, and (*5*) 5.1; (b) (*2*) 2.2, (*3*) 3.8, (*4*) 4.9, and (*5*) 5.9.

of cellulose does not undergo significant structural changes, as indicated by preservation of the (101), (10$\bar{1}$), and (002) reflections at 2θ 14.5°, 16.5°, and 22.3°, respectively.

The degree of crystallinity and composition of the modified fabrics were calculated according to [6]. The crystallite size was estimated by the Scherrer formula [7, 8]. The structural chaarcteristics of cellulose phosphates differing in the phosphorus content are given in Table 4.

As seen from Tables 1 and 4, the phosphorus content of fabrics increases with an increase in the temperature of treatment with A-1 and A-2 fire retardants. The degree of crystallinity of the samples tends to decrease, which is apparently due to the occurring amorphization of cellulose and to increasing defectiveness of the crystallites as a result of distortion of the chain arrangement in the polymer, which leads to a decrease in the crystallite size. The strength characteristics of cellulose phosphates prepared under the industrial conditions are given in Table 5.

Upon treatment with fire retardants, washing, and drying, the strength of the modified fabrics (markings 742, 1672, 3154) somewhat decreases (by 7–40%) but

Table 3. Composition of ester groups of cellulose phosphates in relation to the fire retardants used and to the temperature and time of the heat treatment

remains sufficient and still meets the standard requirements to these kinds of fabrics.

The heat resistance of the fabrics on heating in air was evaluated with an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1}. The results obtained are given in Table 6. We found that the modified cellulose materials started to degrade at temperatures 60–90°C lower compared to the temperature of the major degradation of the unmodified cellulose. The degradation rate reached a maximum at 180–200°C for the fabrics treated with A-1 and at 200–215°C for those treated with A-2. It should be noted that the degradation rate of the modified cellulose decreased in the low-temperature step from 1.25 to 1.0, and in the major degradation step, from 15.5 to 10.0 mg min^{-1}. The degradation intensity for the modified fabrics was also appreciably lower (2.0 against 3.1 mg deg^{-1}). In the course of thermal degradation of the modified fabrics, the amount of evaporated phosphorus-containing volatiles decreases. The yield of the condensed residue (CR) at 500°C is 13 wt % for the initial fabric, 22–32 wt % for the fabric treated with A-1, and 28–40 wt % for the fabric treated with A-2. Exothermic effects in the DTA curves in thermal decomposition of phosphorus-containing cellulose are 30–40% weaker than those observed with the initial cellulose.

The efficiency of fire protection of the fabrics, characterized by the combustibility coefficient K, is plotted in Fig. 2 vs. phosphorus content. The combus-

tibility coefficient was determined by the formula $K = S_{test}/S_{inc} - 1$, where S_{test} is the area enclosed by the temperature curve of the release of gaseous combustion products and the straight line drawn through the initial temperature point and the temperature point after testing for 20 min; S_{inc} is the analogous quantity for an asbestos cement plate taken as incombustible reference. If $K > 2.5$, the material is combustible; if $K < 1$, it is difficultly combustible; and if $1 \le K \le 2.5$, it is combustible but difficultly inflammable.

The results obtained show that the fire protection efficiency for cellulose polyphosphates containing 2.1 wt % phosphorus ($K = 1$) virtually coincides with that determined for cellulose orthophosphate containing 5.0 wt % phosphorus. Thus, the fire protection efficiency depends not only on the phosphorus content, growing with its increase, but also on the anionic organization of the phosphorus chain in the ester.

The fire protection tests were performed by the procedure described in [9], from the length of the carbonized section of the specimens (in accordance with the standard, the limit is 150 mm for difficultly inflammable fabrics).

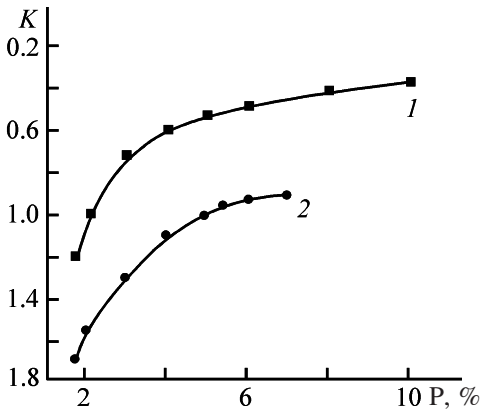

Fig. 2. Combustibility coefficient K of phosphorus-containing materials as a function of phosphorus content. Cellulose modified with (*1*) A-2 and (*2*) A-1.

The results of the fire protection tests show that treatment of cellulose materials with any of the two fire retardants ensures preparation of a flame-retarded (difficultly inflammable) fabric whose combustion or smoldering do not continue after withdrawing the specimen from the flame. For the modified fabrics, the length of the carbonized section of the fabric varied from 90–111 mm depending on the phosphorus content and the fire retardant used, which meets the requirements to fire-retarded fabrics.

It should be noted that the flame-resistant properties of the phosphorus-containing fabrics obtained is preserved to high extent after launderings, which is a very valuable property. For example, the combustibility coefficient of the tested samples treated with A-1 and A-2 did not increase after ten alkaline launderings under the conditions described in [10].

We also examined the possibility of preparing fire-protected blend fabrics (cotton or viscose 30–86%, polyester 14–70%) of density 254–293 g cm^{-2} (markings 5S 35KV, 6S 35KV, 7S 12KV, 7S 44KV, 6S 15KV, 6S 21KV), produced by the MOGOTEKS Open Joint-Stock Company. We found that, after modification with A-2 fire retardant, the mixed fabrics containing no less than 50 wt % cellulose fibers (cotton or viscose) exhibit high flame resistance, are stable in laundrings, and only slightly (by up to 10%) lose the mechanical strength.

CONCLUSIONS

(1) The conditions for the synthesis of cellulose phosphates involving modifiers based on ortho- and polyphosphates were optimized. The resulting prod-

ucts contain 2–5.9 wt % phosphorus. The polymer modification leads to a decrease in the degree of crystallinity and crystallite size.

(2) The dehydration of modified cellulose in the temperature range 20–500°C in air starts at 90–130°C lower temperature compared to the initial polymer, and the rate of degradation of the carbohydrate moiety decreases considerably.

(3) The phosphorus-containing fabrics modified with A-1 and A-2 fire retardants are difficutly inflammable fabrics. The fire protection efficiency is preserved after alkaline launderings. The fire-retarded fabrics can be produced at finishing shops of weaving-mills, and their strength is sufficient for use as clothes.

(4) Fabrics of decreased combustibility can be produced from 100% cotton fabric or cotton (viscose)–polyester blend fabrics containing no less than 50 wt % cotton or viscose.

Abstract—Mechanical and sorption properties of starch-, PVA-, and peat-based composites for fabricating planting containers are studied.

DOI: 10.1134/S1070427207110304

Because of their lightness, good mechanical properties, and low cost, polymeric materials are widely used in agriculture. Diverse polypropylene, polyethylene, or polystyrene containers are used in hothouse and lawn-and-garden farming for plant seeding, prickling-out, and growing. However, in contrast to other materials, synthetic polymers are not biodegradable under natural conditions [1, 2]. Recycling of plastics is cost expensive, and the essential part of plastic wastes is fired or dumped, thus deteriorating the environmental situation [3, 4]. The problem of utilization of plastic wastes may be eliminated, if using containers fabricated from biodegradable materials, such as peat- or cellulose-based composites.

It is known [5, 6] that biodegradable polymers combine good mechanical properties of synthetic polymers with easy biodegradability of natural polymers. Among such materials are hydroxy carboxylic acid based polymers, polyvinyl alcohol (PVA), commercial polymers (polyethylene and polypropylene) functionalized to make them biodegradable, and also composites of the indicated polymers with biodegradable additives [7, 8]. However, the cost of these materials is much higher as compared to large-tonnage commercial synthetic polymers, thus reducing the potentiality of their agricultural applications.

Composite materials based on renewable natural polymers (starch, cellulose, proteins) with various additives are used in agriculture [9–12], most well-known among them are starch-based composites [13]. Presently, the primary issue is the problem of compatibility of components, which is critical not only for performance characteristics of the resulting materials, but also from the technological standpoint.

In this study, we examined mechanical and sorption properties of polymeric composite materials based on starch, PVA, and peat.

EXPERIMENTAL

For fabrication of biodegradable composites we used potato starch (Lach-Ner, Czech Republic), polyvinyl alcohol Mowiol 23-88 (Kuraray Specialities Europe), glycerol (Barta a Cihlar, Czech Republic), and peat pots (Floryn, Poland).

Test samples were prepared as follows. A solution containing starch and PVA (see table for the solution composition) was stirred at 80°C for 60 min until gelation, and glycerol (4%) was added. From the resulting mixture, films were formed (10-ml portions were cast into Petri dishes 10 cm in diameter and dried at 40°C). Peat-based composites were prepared by impregnation of plates cut from peat pots in the resulting mixture at 80°C for 5 min, followed by dry-

6	0	10

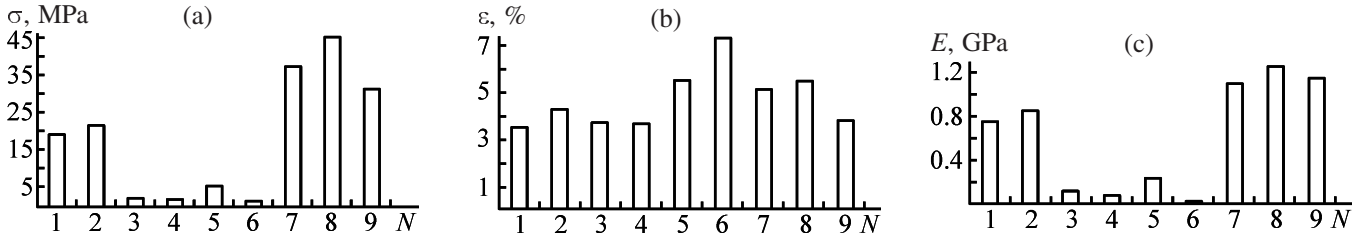

Fig. 1. Mechanical characteristics of films: (σ) tensile strength, (ε) elongation, and (*E*) Young modulus. (*N*) Sample no.; (7, 8) polypropylene and (9) polystyrene films.

ing at 40°C. As a result, we obtained samples whose total starch and PVA content was as follows (% of the dry weight): sample no. 1, 43; nos. 2–4, 30; no. 5, 26; and no. 6, 18.

Mechanical characteristics of the films were tested with a device specially designed for uniaxial microtension tests [14]. From the experimental dependences of the mechanical stress on the elongation $\alpha = f(\varepsilon)$, we determined the Young modulus, tensile strength, and elongation under maximal load.

The moisture absorption was determined gravimetrically after keeping the sample in a desiccator at 100% relative humidity and 20°C. The vapor permeability was determined as follows. The film was tightly fixed on the top of a beaker filled with water and allowed to stand in a desiccator at 0% relative humidity and 20°C. After a certain time, the sample was weighed, and the vapor permeability VP (g m^{-2} day^{-1}) was estimated. pH of the samples was measured on an IQ140 pH meter with a CER711 electrode.

The principal criteria in selecting materials for fabricating planting pots are sufficient mechanical strength and high moisture retention and vapor permeability.

Figure 1 shows the experimental mechanical characteristics of the starch and PVA. For comparison, data for commercial polypropylene (sample nos. 7, 8) and polystyrene (sample no. 9) films, used for fabricating planting pots, are presented. Among the biodegradable films studied, starch and starch–PVA (8 : 2) films exhibited the highest strength. However, their strength is about half that of the synthetic polymer films. The highest relative elongation at maximal load was shown by PVA and PVA–starch (8 : 2) films. The Young modulus, characterizing the resistance of the films to tensile stress, was estimated at a 2% strain of the samples. The highest Young modulus was obtained for the synthetic films and for starch and starch–PVA (8 : 2) films.

Data on the water absorption of the films and composites are shown in Fig. 2. The sorption capacity of the samples depends on their composition. As can be seen, the water absorption is different for the polymers (Fig. 2a) and their composites with peat (Fig. 2b). The water absorption of straight peat plates (sample no. 0) is much lower than in the polymer-containing composites.

Data on the vapor permeability of the composites after 20-day testing are presented in Fig. 3. The high-

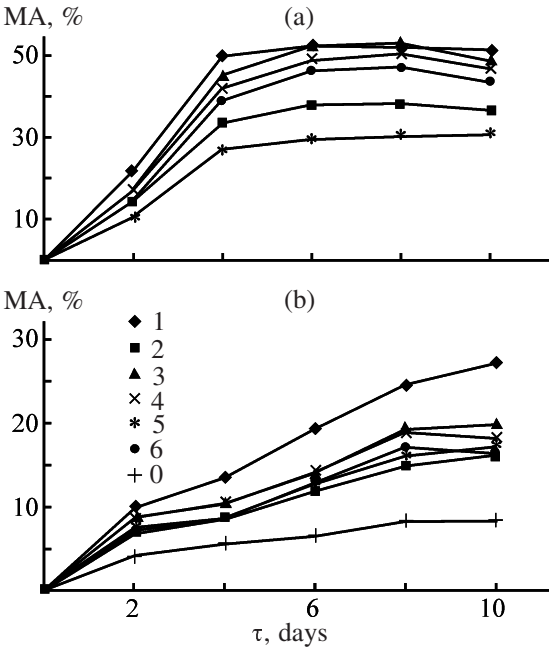

Fig. 2. Moisture absorption MA of (a) films and (b) composites as a function of the time τ. (1–6) Sample no.

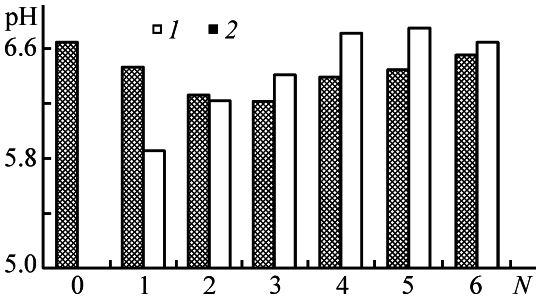

Fig. 4. pH in (*1*) films and (*2*) composites.

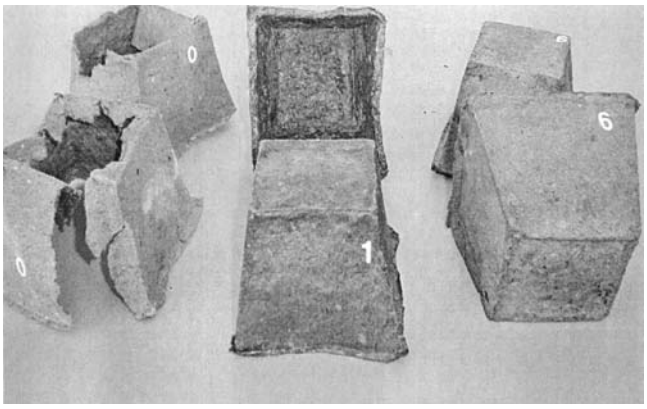

Fig. 5. Appearance of the spent planting pots: (0) peat, (1) starch + peat, and (6) PVA + peat.

est water permeability was observed in peat plates (sample no. 0). Addition of polymers decreases this parameter.

In plant growing, among the most significant parameters is pH of the soil. The most favorable is pH 6–7. In contrast to the inert polypropylene or polyethylene, the materials of biodegradable planting pots are components of the nutrition medium, participating also in ion-exchange processes. Therefore, a material for fabricating planting pots should not significantly disturb the soil nutrition system and pH. Figure 4 shows that, with increasing PVA content, pH of the films increases. Modification of the peat plates with the polymer solution only slightly changes pH.

The changes in the mechanical characteristics in the containers after use for a month under the natural conditions were evaluated visually. The used containers after washing and drying are shown in Fig. 5. As can be seen, the peat pots are totally destroyed, while starch–peat and PVA–peat pots could be reused.

CONCLUSION

Biodegradable polymeric composites, based on starch, polyvinyl alcohol, and peat, are suitable materials for fabricating planting pots. They exhibit better (compared to peat pots) mechanical properties: higher moisture absorption and lower vapor permeability, which is needed to keep steady moisture–temperature regime in the soil.

Abstract—A linear correlation between the permittivity of a composite dielectric based on polyvinyl alcohol cyanate and the content of active surface sites in its filler (dispersed barium titanate) was established. This correlation, in combination with a thermodynamic model of composite dielectrics, allows estimation of their permittivity from the surface characteristics of the filler.

DOI: 10.1134/S1070427207110316

Electrophysical characteristics of functional composites containing micro- and nanodispersed fillers are controlled by the energy of the interfacial interactions between the composite components, which depends on the filler dispersity and the kind of filler functional groups. Therefore, to elucidate how the chemical or physical modification of fillers affects the composite permittivity, the surface features of fillers should be taken into account. In the thermodynamic model of the composite dielectrics developed in [1, 2], the local and cooperative filler–polymer interactions were evaluated taking into account the polymer–filler interface structure [3]. This model allowed estimation of the physicochemical features of vulcanized siloxane rubber filled with titanium dioxide of different crystalline modifications and brands [2]. With this model, the dielectric properties of polyvinyl alcohol cyanate (PVAC) filled with modified barium titanate were also analyzed on the basis of characteristics of active sites on the filler surface, determined from the sorption of Hammett indicators [4–7]. In these experiments, along with the initial barium titanate, its samples modified by hydration and thermal treatment were also examined. This modification was found to change the particle size, specific surface area, and chemical composition of barium titanate particles. In this study, dispersed barium titanate was modified without thermal treatment or chemical impact. For this purpose, the initial barium titanate was irradiated with accelerated electrons [8] ensuring selective modification of its surface layer without changes in the specific surface area and chemical composition [9].

Since the filler permittivity ε exceeds that of the polymer by two orders of magnitude, the composite dielectric features are mainly determined by changes in the polymer characteristic at the polymer–filler interface, caused by interactions between functional groups of the filler and polymer. Taking into account that a solution is an equilibrium multicomponent system, the surface layers of filler particles uniformly distributed over the polymer bulk can be considered as their solution in the polymer [10]. It was shown [2] that, in accordance with the thermodynamic theory of curved surfaces [11], the change in the free energy of polymer molecules arranged on the surface of monodispersed filler ΔG_k is proportional to the specific surface area of filler S_s squared and the surface energy at the polymer–filler interface σ_s^0, which depends on the character of the polymer–filler interactions. ΔG_k is also dependent on the shape of distribution of the potential field of the filler in the bulk of the polymer. In the case of the exponential distribution,

$$\Delta G_k = \frac{8R_m c_f \sigma_s^0}{2R^2 k R_m} = \frac{4c_f \sigma_s^0}{R^2 k} = \text{const}\frac{\sigma_s^0 S_s^2}{k}, \quad (1)$$

where k is the exponent index.

This thermodynamic model allows evaluation of the critical size and surface energy of filler particles at which ΔG_k starts to noticeably affect the composite characteristics [4]. The correlations between physicochemical and electrophysical characteristics of polymeric composites, on the one hand, and the surface features of the natural mineral fillers [12] and luminophores [13], on the other hand, were established. However, the experimental measurement of the surface energy σ_s^0 is rather difficult. Therefore, to estimate the filler–polymer interaction, instead of σ_s^0 we determined the concentration of sorption sites on the filler surface q_{pK_a} capable of binding the polar functional groups of the polymer. It is evident that the filler–polymer interface interaction is dependent on the active site concentration. Therefore, with a knowledge of this concentration, the permittivity of composite dielectrics can be estimated from analysis of the ε–$S_s^2 q_{pK_a}$ correlation.

In this study the factors influencing the permittivity of polymeric dielectric composites were analyzed, and the possibility of estimating the permittivity of composite dielectrics based on their thermodynamic model was demonstrated. The problems under consideration were examined by the example of a dielectric composite based on polyvinyl alcohol cyanate (PVAC) containing large amount of polar functional groups. Dispersed $BaTiO_3$ modified by irradiation with accelerated electrons was used as filler.

EXPERIMENTAL

Dispersed barium titanate [TU (Technical Specification) 027.800.FGO] with an average particle size of 5.4 μm and the permittivity of 1600 was used as filler. The specific surface of barium titanate was determined by low-temperature adsorption of air. The electron-beam treatment of $BaTiO_3$ was carried out on an RTE-V transformer-resonance electron accelerator [9] (electron beam energy 900 keV, current 1 μA, absorbed dose from 25 to 200 kGy). To prevent air access, a thin layer of $BaTiO_3$ powder to be irradiated was placed into a polyethylene container. The absorbed dose was monitored by the optical density of standard dosimetric films CDP-F2 based on polycarbonate containing a phenazine dye.

The surface concentrations of active centers in the initial and modified barium titanate were determined by sorption of the acid–base Hammett indicators with pK_a from –5 to 14 [6–8, 12, 13]. The optical densities of solutions of the indicators before and after sorption were recorded on an SF-46 spectrophotometer (LOMO) in the 200–640 nm range. The content of particular sorption centers q_{pK_a} was assumed to be equal to the amount of sorbed indicator with a certain pK_a. The changes in the filler surface state caused by its modification are manifested either as the changes in q_{pK_a} or as the shift of pK_a of the indicator adsorbed on a certain sorption site. The acidity function of the filler surface was determined by the formula $H_0 = \Sigma pK_a q_{pK_a} / \Sigma q_{pK_a}$, where Σq_{pK_a} is the total amount of the sorption sites of all the kinds.

The indicators with the lowest (as a rule, negative) pK_a are selectively adsorbed on the sorption sites of Lewis base type containing unshared electron pairs. The water molecules fixed on these sites dissociate to liberate the hydroxide anions. With increasing pK_a of indicators, they start to be selectively adsorbed on sites of the Brønsted acid type (pK_a 0–7). These water molecules dissociate to liberate protons. The active surface sites of the Brønsted base type (the surface hydroxide anions capable of dissociation) have pK_a in the range 7–14. The sorption sites of the Lewis acid type (atoms with free orbitals) binding the hydroxide anions have $pK_a > 14$. The sorption of water molecules on these sites is accompanied by liberation of protons.

In preparing film polymeric composites based on PVAC, both the initial and modified barium titanate powders were used as fillers [14]. The PVAC samples were prepared at the Plastpolimer Joint-Stock Company (Laboratory of Polyvinyl Acetate Polymers and Vibration-Absorbing Materials). Dielectric film composites 30–35 μm thick, based on the initial and modified barium titanate, were prepared by the screen printing technique. The initial paste-like reaction mixture was prepared by dispersing a barium titanate powder in a solution of PVAC in dimethylformamide–ethylene glycol monomethyl ether mixture. The optimal concentration of barium titanate in these films was found to be 40%. At higher filler content, the physicomechanical characteristics of films became worse and their permittivity decreased. The composite film permittivity was measured on an R5010 ac bridge in accordance with GOST (State Standard) 6433.4–71.

Figure 1 shows the distribution of the sorption sites of different kinds for the initial and irradiated barium titanate. It can be seen that the initial barium titanate surface is enriched in the sorption sites of the Lewis base type (pK_a –4.4 and –0.3). These sites are apparently the Ba–O groups formed during thermal treatment of barium titanate in the course of its synthesis. The Brønsted acid sorption sites can be as-

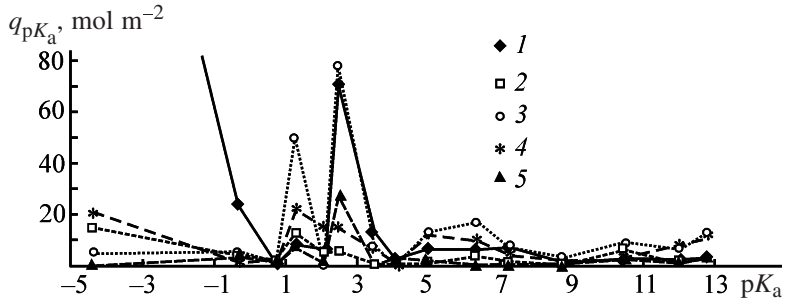

Fig. 1. Distribution of active sites of different kinds on the surface of (*1*) initial $BaTiO_3$ and (*2–5*) $BaTiO_3$ irradiated with accelerated electrons. (q_{pK_a}) Active site content and (pK_a) negative logarithm of the indicator ionization constant. Absorbed dose, kGy: (*2*) 100, (*3*) 25, (*4*) 200, and (*5*) 50.

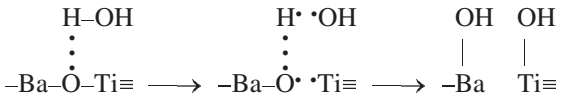
signed to the Ti–OH groups formed by the hydrolytic sorption of water [7].

After irradiation of barium titanate to the absorbed dose of 25 kGy, the Lewis base sorption sites virtually completely disappear. At the same time, the content of Brønsted acid (pK_a 1.3–6.4) and base (pK_a 8.2–12.8) sorption sites increases. We believe that these changes in the distribution of the surface sorption sites are caused by hydroxylation of barium titanate surface by the reaction of the lattice oxygen atoms with H and OH radicals formed in radiolytic decomposition of adsorbed water by the scheme



Since the barium cation charge is smaller than that of Ti^{4+} and its size is larger, the Ba–O bonds in Ba–OH groups are weakened and the formation of the Brønsted base sorption sites prevails. Therefore, for example, after electron-beam treatment of barium titanate to an absorbed dose of 25 kGy, the surface acidity function H_0 changed from –1.6 to 3.9, and the total concentration of the active sites decreased from 410 to 215 μmol m^{-2}.

With increasing absorbed dose to 50 kGy, the content of all kinds of active sites decreases. This effect was assigned to dehydroxylation of barium titanate surface caused by the radiation heating [9]. With a further increase in the absorbed dose to 100–200 kGy, the active site content increases again, which is apparently due to formation of radiation defects (deterioration of barium titanate surface structure, rupture of surface metal–oxygen bonds followed by partial surface hydroxylation). At the same time, the irradiation does not affect the particle size and their specific surface area.

The table shows that, as the absorbed dose changes, the amount of the particular active sites and their total content change differently. In particular, the permittivity of composites based on irradiated $BaTiO_3$ well correlates (linear correlation factor of 0.99) with the content of the Brønsted base sites only.

This correlation and also the fact that both the permittivity and the content of the Brønsted base active sites depend on absorbed dose similarly (Fig. 2) indicate that the permittivity of the composite is controlled by the interfacial interactions between $BaTiO_3$ particles and the polymer. With increasing content of the Brønsted surface sites (after irradiation to the absorbed dose of 25 kGy), the surface interactions of $BaTiO_3$ with the functional groups of the polymer (nitrile, hydroxy) are enhanced, and the macromolecules and supramolecular structures transform into the ordered state. As a result, the free energy of the system decreases, whereas the permittivity increases. On the contrary, with decreasing concentration of the Brønsted base sites (after irradiation to the absorbed dose of 50 kGy), the polymer–filler interactions weaken, and, as a result, the permittivity decreases.

Since the irradiation of barium titanate with accelerated electrons causes insignificant changes in the specific surface area, the knowledge of content of the Brønsted sorption sites determined by the indicator technique is sufficient for predicting the permittivity of polymeric dielectric composites based on barium titanate treated with accelerated electrons. However, along with this case, it was of interest to examine whether the thermodynamic model is applicable to predicting the permittivity of polymeric composites based on barium titanate modified by other techniques (chemical treatment, thermal treatment).

Figure 3 shows that, in accordance with Eq. (1), the experimental permittivity of composites based on the initial barium titanate and that modified by various techniques linearly depends on the term $S_s^2 \Sigma q_{pK(BB)}$,

Linear correlation factors between the permittivity of polymeric composites and content of sorption sites of different types on the surface of irradiated $BaTiO_3$

q_{pK_a}, μmol m^{-2}	Type of sorption center	Absorbed dose, kGy					Correlation factor ε–q_{pK_a}
		0	25	50	100	200	
$q_{-5–0}$	Lewis base	280	10	3	18	22	–0.23
$q_{0–7.5}$	Brønsted base	121	175	43	32	88	0.77
$q_{7.5–13}$	Brønsted acid	10	31	6	12	25	0.99
$\sum_{-5}^{13} q_{pK_a}$	–	410	215	51	62	134	0.19

where $\Sigma q_{pK(BB)}$ is the total content of the Brønsted base sites. Composite samples corresponding to curves *3* and *4* were modified by keeping barium titanate in water and calcining it in air, respectively [5].

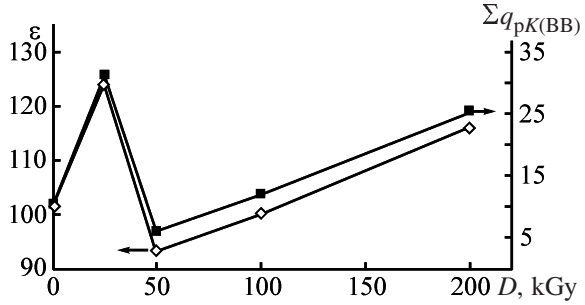


Fig. 2. Dependence of the permittivity of the composite dielectric ε and content of the Brønsted base sites $\Sigma q_{pK(BB)}$ on the absorbed dose *D* in barium titanate irradiated with accelerated electrons.

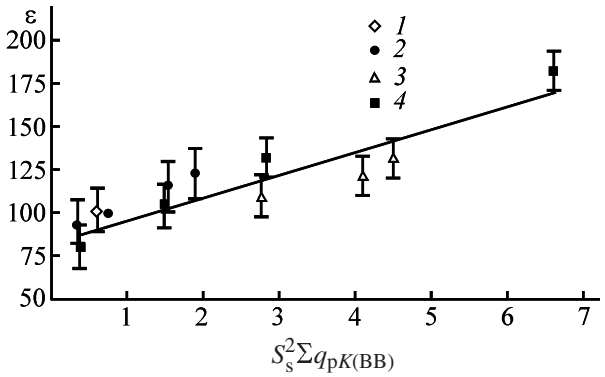

Fig. 3. Plot of the composite permittivity ε vs. the term of the thermodynamic model $S_s^2\Sigma q_{pK(BB)}$ characterizing both the content of the Brønsted base sites and the particle size of modified barium titanate. $\varepsilon = 13.4S_s^2\Sigma q_{pK(BB)} + 81.4$; $R = 0.92$. Barium titanate: (*1*) initial, (*2*) irradiated with accelerated electrons, (*3*) treated by hydration, and (*4*) thermally treated.

The ε–$S_s^2\Sigma q_{pK(BB)}$ correlation curve given in Fig. 3 shows that, although the averaged correlation factor is equal to 0.92, the separate groups of samples modified by identical techniques are characterized by the correlation factor close to unity. We believe that this difference is caused by the fact that the set of indicators used in our experiments is insufficient to determine all the active sites present on the modified $BaTiO_3$ surface. Apparently, more detailed evaluation of the distribution of the active surface sites by thermal desorption or potentiometric techniques [1] may allow more accurate estimation of the permittivity of composites based on modified fillers.

It should be noted that our results are consistent with the qualitative correlations between donor–acceptor characteristics of the filler surface and features of suspensions and polymeric composites reported in [15–17]. It was found [18] that PVA adsorption on Aerosil involves its nondissociated acid–base centers.

Thus, the concentration of sorption sites on the surface of a filler, determined by an indicator technique, allows quantitative estimation of the permittivity of polymeric film composites using their thermodynamic model taking into account both the chemical and geometric factors influencing the interfacial polymer–filler interactions.

CONCLUSIONS

(1) The model based on the thermodynamics of curved surfaces can be used for predicting the permittivity of film composites based on polyvinyl alcohol cyanate and modified $BaTiO_3$ as filler.

(2) The permittivity of polymeric composites based on polyvinyl alcohol cyanate and dispersed ferroelectric $BaTiO_3$ as filler is controlled by interactions between the polar functional groups of the polymer

and the Brønsted base surface sites of $BaTiO_3$ particles.

(3) The changes in composition of the active surface sites of dispersed $BaTiO_3$ irradiated with accelerated electrons correlate with the absorbed dose. The irradiation of $BaTiO_3$ with accelerated electrons under optimal conditions allows the permittivity of composite dielectrics to be increased owing to an increase in the concentration of the Brønsted base surface sites.

Abstract—The physicomechanical, viscoelastic, and rheological characteristics of syndiotactic 1,2-polybutadiene were studied and compared with those of the analogs produced in other countries.

DOI: 10.1134/S1070427207110328

Thermoelastoplastics, i.e., polymers combining the elasticity of vulcanized rubbers with the capability to pass into the viscous-flow state at elevated temperatures and to be processed like thermoplastic polymers, find growing use today. Among such thermoelastoplastics is syndiotactic 1,2-polybutadiene (1,2-SPB) prepared by stereospecific polymerization of butadiene in solution [1–4].

In this study we examined the physicomechanical, viscoelastic, and rheological properties of 1,2-SPB prepared by polymerization of 1,3-butadiene in the presence of a cobalt catalytic system [4]. As references we used syndiotactic polydienes of the JSR RB-820 and JSR RB-830 brands (Japan Synthetic Rubber Co.).

EXPERIMENTAL

Polymer samples for physicomechanical tests were prepared by pressing (150°C, 11 MPa, 10 min). The ultimate strength and relative elongation at break were determined according to GOST (State Standard) 270–75, and the Shore hardness, according to GOST 263–75. The brittle point was determined according to GOST 7912–74. The glass transition and melting points of the polymers were determined on a thermomechanical installation at a load of 9 kg mm^{-2} and heating rate of 3 deg min^{-1}. The molecular weight of the polymeric products was determined with a Waters Breeze gel permeation chromatograph using high-resolution columns (effective range of molecular weights $500-4\times10^6$) packed with divinylbenzene gel. The content of 1,2-polymerization units was determined by IR spectroscopy. The spectra were recorded with a Specord M-82 spectrophotometer. The viscoelastic properties of the polymers at shear were measured with an RPA-200 device (Alpha Technologies) at a frequency of 1 Hz and strain amplitude of 10% (~0.7°) in the temperature range 40–180°C. The rheological properties of polymers were studied by capillary viscometry with an IIRT device in the temperature range 120–180°C at a load of 11.8–158.9 N (capillary length 8 mm, diameter 2.09 mm).

We used syndiotactic 1,2-polydiene samples SPB-1, SPB-2, and SPB-3 and polymers of the JSR RB series, differing in the molecular weight, polydispersity, degree of crystallinity, and syndiotacticity (Table 1), and also polydiene of SKD-SR brand, which is amorphous atactic 1,2-polybutadiene (M_n = 76×10^3, 71.8% 1,2-units).

The experimental results show that the synthesized polymeric products are similar to JSR RB polymers in the molecular weight ($M_w\times10^{-3}$ = 115–128) and microstructure (content of 1,2-units 86–89%, Table 1). SPB-1 and SPB-2 are simlar in the degree of crystallinity to JSR RB-820, and SPB-3, to JSR RB-830. As for the physicomechanical parameters, 1,2-polydienes SPB-1 and SPB-3 are the most similar to the Japanese analogs (Table 2). It should be noted that the density and hardness of the synthesized syndiotactic 1,2-polybutadienes are somewhat lower than those of the JSR polymers (Table 2).

Figures 1 and 2 show the temperature dependences of the elastic modulus G' and mechanical loss modulus G'' for the synthesized 1,2-polydienes. As seen

Table 1. Characteristics of syndiotactic 1,2-polybutadiene

from Fig. 1, the elastic modulus of syndiotactic polydiene G' (curves *1–4*) quantitatively characterizing the resistance of the polymer to the development of elastic strain varies with temperature more strongly than does G' of the atactic polymer, for which the dependence $\log G' = f(T)$ is approximately linear. For syndiotactic 1,2-polydiene, in the temperature range 40–100°C, a correlation is observed between the elastic modulus and degree of crystallinity of the polymer: An increase in the degree of crystallinity is accompanied by an increase in the elastic modulus G' of the polymer (Table 1, Fig. 1). For the syndiotactic polymer samples with different initial degrees of crystallinity, the G' values at temperatures exceeding 100°C differ insignificantly (Fig. 1). Apparently, variations of G' in the range 40–100°C are mainly determined by elastic deformation of the crystalline phase, and at higher temperatures, exceeding the melting point of the crystalline phase, they are determined by rheological properties of the polymer melt.

The temperature dependences of the mechanical loss modulus G'' of 1,2-polydiene, characterizing the amount of energy scattered in unit time in the course of dynamic deformation of the polymer, have characteristic inflections (Fig. 2) corresponding to significant changes in G'': at 75°C for SPB-2, at 90°C for SPB-1, at 110°C for SPB-3, and at 115°C for JSR RB-830 (curves *1–4*). These temperatures are close to the melting points of the polymers, found from the ther-

momechanical curves (Table 2). The characteristic changes of G'' are apparently associated with the destruction (melting) of the crystalline phase and transition of the polymer into the viscous-flow state.

A different pattern is observed with atactic 1,2-polydiene. In the $\log G'' = f(T)$ plot for SKD-SR, there are no bends characteristic of syndiotactic polydienes (Fig. 2, curve *5*). Also, atactic SKD-SR is characterized by higher values of G' and G'' in the range 110–180°C, compared to syndiotactic 1,2-polydiene (Figs. 1, 2). The experimental results show that atactic 1,2-polydiene preserves the hyperelastic properties in the above temperature range and therefore cannot be processed by converting it into the viscous-flow state, in contrast to thermoplastic syndiotactic 1,2-polydienes.

Analysis of the thermomechanical properties of 1,2-SPB revealed two glass transition points: in the ranges from –12 to –18°C (T_1) and from 33 to 47°C (T_2) (Table 2). The presence of two glass transition points of 1,2-SPB is apparently due to the existence in 1,2-polydiene of two phases. Namely, the macromolecules of the thermoelastoplastic contain, along with syndiotactic 1,2-structures forming ordered crystalline regions [5], also sequences of units formed by 1,4-polymerization of the monomer (10–15% content), which are highly flexible and form an amorhous phase. Fragments consisting of 1,4-polymerization units apparently act as flexible links between macrochain blocks consisting of syndiotactic 1,2-polymerization units.

The rheological characteristics of polydiene melts were studied in the temperature range 120–180°C at a load of 11.8–158.9 N. The flow of the polymers was evaluated by the melt flow index (MFI).

We found that melts of SPB-2 characterized by relatively low number-average molecular weight and broad molecular-weight distribution (Table 1) show higher flowability compared to the other analogs (Fig. 3). At the same time, the flowability of JSR RB-820 changes with temperature more strongly than that of SPB-1, although SPB-1 has a somewhat lower molecular weight.

From the experimental MFI values, we determined according to [6, 7] the parameters of the viscous flow of the polymers: shear rate $\dot{\gamma}$, shear stress τ, and effective viscosity of the polymer melt η_{eff}.

The log–log plot of the shear stress τ of polymer melts vs. shear rate $\dot{\gamma}$ in the examined range of $\dot{\gamma}$ and τ is linear (Fig. 4). For SPB-1, SPB-2, and SPB-3, the flow index n [8, 9] found from the slope of the experimental straight lines $\log\tau = f(\log\dot{\gamma})$ (Fig. 4) is essentially the same, 0.7 ± 0.03 (in the temperature range 120–180°C).

As seen from the plot of $\log\lambda_{eff} = f(\log\tau)$ (Fig. 5), the effective viscosity η_{eff} of the SPB-2 melt, under equal other conditions, is appreciably lower than that of the SPB-1 and SPB-3 melts, which should be attributed to differences in the molecular characteristics of these polymers.

The $\log\eta_{eff}$–$1/T$ dependences obtained at different temperatures for the examined 1,2-polydienes are linear (Fig. 6). The apparent activation energy of viscous flow E_a for SPB-1, SPB-2, and SPB-3, calculated from this dependence, is 53 ± 1 kJ mol^{-1}, and the load applied does not appreciably affect E_a. For JSR RB-820 polymer, E_a is similar (58 ± 1 kJ mol^{-1}). As the activation energy of viscous flow is almost independent of the molecular weight of the polymer and is mainly determined by the size of the polymer chain segment [8], the experimental results suggest

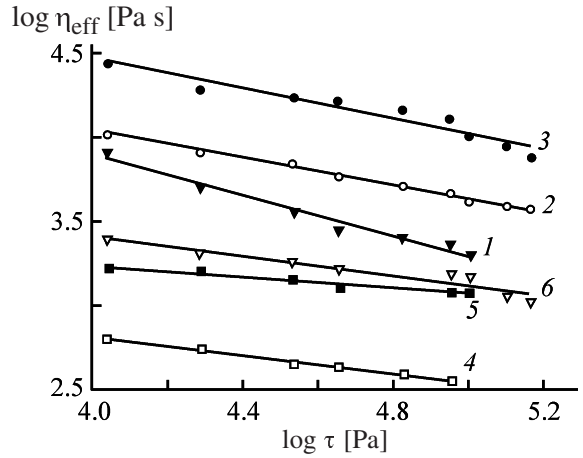

Fig. 5. Effective viscosity η_{eff} of melts of (*1*, *4*) SPB-2, (*2*, *5*) SPB-1, and (*3*, *6*) SPB-3 as a function of the shear stress τ (log–log plots).

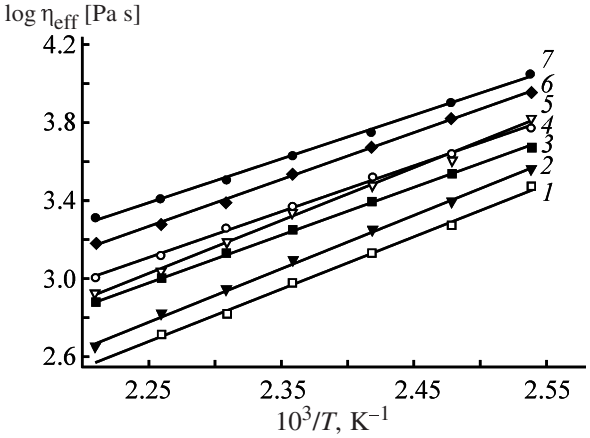

Fig. 6. Effective viscosity η_{eff} of polymer melts as a function of reciprocal temperature. Polymer: (*1*, *2*) SPB-2, (*3*, *4*) SPB-1, (*5*) JSR RB-820, and (*6*, *7*) SPB-3. Load, N: (*2*, *4*, *5*, *7*) 49 and (*1*, *3*, *6*) 98.

similar molecular structures of the 1,2-polydienes under consideration.

It should be noted that the activation energies of viscous flow E_a obtained for the polydiene thermoelastoplastics are appreciably lower than E_a of a commercial thermoelastoplastic, divinyl–styrene block copolymer (77–118 kJ mol^{-1}) [5]. Hence, 1,2-SPB melts can be processed at lower temperatures and loads than divinyl–styrene thermoelastoplastics.

CONCLUSIONS

(1) The synthesized syndiotactic 1,2-polybutadienes are similar to JSR RB commercial polymers in the molecular, physicomechanical, and rheological parameters. The viscoelastic properties of syndiotactic 1,2-polybutadiene are mainly determined by the degree of crystallinity of the polymer, and the rheological properties, by the molecular characteristics of 1,2-polydiene.

(2) By controlling the molecular characteristics and degree of crystallinity of syndiotactic 1,2-polybutadienes in the synthesis step, it is possible to prepare 1,2-polybutadienes with variable properties.

(3) The manifestation of thermoelastoplastic properties by syndiotactic 1,2-polybutadiene is due to the two-phase character of its structure, namely, to the presence in the polymer of a rigid crystalline phase formed by 1,2-polymerization units and an amorphous phase formed by 1,4-polymerization units.

(4) Syndiotactic 1,2-polybutadiene exhibits good physicomechanical properties and is of interest for the production of materials requiring a balance of properties of an elastomer and a thermoplastic polymer (packaging and electric-insulation materials, shoe sole parts, blow articles, etc.). This substance can also be used as a polymeric modifier for improving the processing conditions and properties of composites based on thermoplastics and elastomers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Viscosity of Concentrated Solutions of Polystyrene and Poly(Vinyl Acetate) (Empirical Equations)

A. A. Grishchuk and Ya. I. Estrin

Institute of Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received January 16, 2007; in final form, June 2007

Abstract—The viscosity of solutions of polystyrene with M_w from 2.8×10^4 to 7.8×10^5 in toluene and of poly(vinyl acetate) with M_w from 2×10^4 to 1.4×10^5 in butyl acetate at 30–80°C is measured. The dependence of the activation energy of the viscous flow of the solutions on the molecular weight of the polymers and solution concentration is examined. This dependence is approximated by a cubic polynomial for polystyrene solutions and by a quadratic polynomial for poly(vinyl acetate) solutions. The dependences of the solution viscosity on the concentration, molecular weight, and temperature are approximated by exponential equations in which the exponents are sums of polynomials. The coefficients of the polynomials are determined.

DOI: 10.1134/S107042720711033X

Many polymers, in particular, polystyrene, are produced in batch reactors with stirrers, in which the polymerization is performed in the bulk to high conversions of the monomer. An advantage of such technology is that the afterpolymerization performed in continuous reactors at high temperatures yields a ready polymer, with no need in special recovery procedures required for polymerization in solutions or emulsions (suspensions) and no contamination of the polymer with auxiliary substances used in dispersion polymerization. At the same time, in bulk polymerization, the temperature is considerably more difficult to control than in polymerization in solutions or dispersions. One of the major factors complicating the temperature control is inevitable increase in the viscosity of the reaction mixture by several orders of magnitude with the progress of bulk polymerization, making the heat exchange considerably less efficient.

Usually the dependence of the coefficient of heat transfer to the inner wall of the reactor on the liquid viscosity is described by criterial equations of the form [1]

$$\mathrm{Nu} = C\mathrm{Re}_c^{a1}\mathrm{Pr}^{a2}(\mu/\mu_w)^{a3}\Gamma_1^{a4}\Gamma_2^{a5}..., \quad (1)$$

where $\mathrm{Nu} = \alpha D/\lambda$; D is the apparatus diameter; α, heat transfer coefficient, λ, thermal conductivity of the liquid; $\mathrm{Re}_c = nd^2\rho/\mu$, centrifugal Reynolds criterion; n and d, rotation frequency and diameter of the stirrer; $\mathrm{Pr} = \mu c\rho/\lambda$; c, heat capacity; Γ_1, Γ_2, etc., geometric simplexes determined by the sizes and shapes of system elements.

The ratio of the liquid viscosity in the bulk to that at the wall temperature, μ/μ_w, takes into account the effect exerted by the heat flow direction on the heat transfer coefficient. According to experimental data, $a2 \approx 0.33$ and $a3 \approx 0.14$. The quantity $a1$ can vary from 0.4 to 0.92 depending on the stirring mode; at the turbulent mode, $a1 \approx 0.67$. The quantity C depends on the type and number of stirrer blades, presence of reflecting partitions, interval of Reynolds numbers, and other parameters. According to [1], C varies from 0.35 to 0.76. If we assume all the quantities except viscosity to be constant and take $(\mu/\mu_w)^{a6} \sim 1$, then for the dependence of α on viscosity we obtain

$$\alpha = C_1/\mu^b, \quad (2)$$

where b can vary from 0.07 to 0.6.

At a turbulent mode, b should be approximately equal to 0.34. This means that, when the viscosity varies from the value characteristic of the monomer (<1 cP) to the value of several hundreds of poises, characteristic of concentrated polymer solutions, i.e., by more than five orders of magnitude, α can decrease by a factor of more than 100 (provided that the turbulent mode will be preserved; otherwise the heat transfer intensity will decrease to a considerably greater extent).

Apparently, variation of the intensity of heat transfer by several orders of magnitude will inevitably affect the thermal conditions in the reactor. Such conditions were considered in [2] for the initiated radical and "living" anionic polymerization of styrene. In both cases, a transition to the high-temperature mode of reaction completion is possible, when already after 50% conversion of the monomer the reaction mixture temperature decreases by several tens of degrees as compared to the temperature of the heat carrier in the reactor jacket.

With an increase in the viscosity of the reaction mixture, the power consumption for stirring increases considerably, giving rise to an additional heat source which noticeably affects the temperature conditions. However, the calculations made in [2, 3] were based on the dependences of the polymer solution viscosity on the concentration C and molecular weight M, taken from the literature:

$$\mu(C) = AC^a, \quad \mu(M) = BM^b, \tag{3}$$

where $a \sim 4.8–5$, $b \sim 3.4–3.5$ [4].

Equations (3) are quite suitable for qualitative consideration, but are a very rough approximation for quantitative simulation of the reactor. Available specific data on the dependences of the viscosity of concentrated polymer solutions on the concentration, M, and temperature, covering wide ranges of these parameters, are few. In most cases, such studies are aimed to refine one or another model of the theory of viscosity of polymer solutions and/or melts and to compare the expressions obtained with the experimental data. For example, Pogrebnyak and Toryanik [5] substantiate an equation of type (3) on the basis of the theory of viscosity of polymer melts. For the dependences of the viscosity of aqueous poly(ethylene oxide) solutions on M, the calculated viscosities reasonably agree with the experimental data up to $M \sim 10^5$ and solution concentration of 40%; however, the concentration dependence of the viscosity is not analyzed in detail. Some parameters of the equations are fitted to attain agreement with the experiment.

The concentration dependences of the viscosity of concentrated solutions of some polymers (e.g., polystyrene, vinyl acetate) are described by Irzhak et al. [6]. They showed that analytical description of these dependences, based on the model of compressible coils, is possible only up to concentrations not exceeding 20–30 wt % (for polyisobutylene, up to 50%). Exceptions are solutions of polydimethylsiloxane in siloxane pentamer, for which the model is valid up to 100% concentration in a wide range of M. The dependences of the viscosity on the concentration and M are well described by equations of type (3), with the parameters a and b equal to 8 and ~4.5, respectively. It should be noted that the numerical values of the main parameters in the equation for this model are chosen empirically, on the basis of the "best linearization" criterion. Deviations from this equation are also observed for dilute solutions.

In recent Sadeghi's paper [7], the modified nonrandom factor model (NRF) is compared with the measurement results for poly(ethylene oxide) solutions with M from 192 to 6000 at 25–55°C in several solvents over a wide concentration range, up to the neat polymer melt. In the latter case, the dependence of the viscosity on M is described by an equation of type (3) with $b \approx 6$.

Wang et al. [8] described a model of a reactor for styrene polymerization in the bulk, using the nonlinear adaptive control of the temperature conditions of the process taking into account the influence exerted on the heat exchange intensity by the viscosity of the reaction mixture. However, in that paper, the equation used for the dependence of the viscosity on the conversion (polymer concentration), M, and temperature gave the viscosity values that differed from the experimental data by several orders of magnitude.

Thus, data available in the literature are rather contradictory, and for polystyrene and poly(vinyl acetate) they are apprently insufficient for constructing an adequate thermal model of a reactor for bulk polymerization.

In this connection, it seemed appropriate to measure experimentally the dependences of the viscosity of polymer solutions on the concentration, M, and temperature in as wide ranges of these parameters as possible and to describe these dependences by an approximating function suitable for computer models of reactors. The goal of this study was to obtain such dependences for solutions of polystyrene and poly(vinyl acetate) (PVA).

EXPERIMENTAL

The viscosity of dilute solutions was measured with a glass capillary Ubbelohde viscometer with suspended level. For solutions with intermediate viscosities (up to 10^3 P), we used a Höppler falling-ball rheoviscometer, and for more viscous solutions, a Höppler consistometer (VEB MLW Prüfgeräte-Werk Medingen). For each solutions, measurements were performed at temperatures from 30 to 60°C (for some

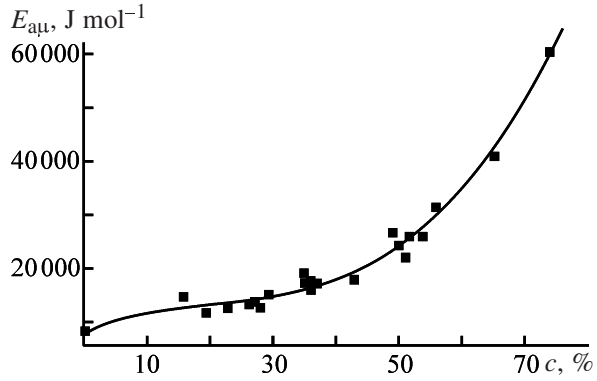

Fig. 2. Activation energy of viscous flow $E_{a\mu}$ of solutions of polystyrene ($M = 2.8 \times 10^4$–7.8×10^5) in toluene as a function of solution concentration c.

solutions, up to 80°C). For polystyrenes, the range of M (M_w) was 28×10^3–780×10^3; the concentration range, 0–56 wt %; and the temperature range, 30–80°C (for the lowest-molecular-weight sample, the maximal concentration was 74 wt %). For PVA, the range of M_w was 2×10^4–1.4×10^5; the concentration range, 0–50 wt %; and the temperature range, 30–70°C.

Because for viscous solutions the measurements take a long time, to avoid changes in the solution concentration in the course of measurements due to uncontrollable polymerization of the monomer, we used toluene as a solvent for polystyrene and butyl acetate as a solvent for poly(vinyl acetate), as these solvents are similar to the corresponding monomers in the thermodynamic, viscometric, and thermophysical parameters. The choice of butyl acetate instead of ethyl acetate, a closer analog of vinyl acetate, is governed by the high volatility of ethyl acetate, which also leads to appreciable changes in the solution concentration at elevated temperatures.

Concentrated solutions of polystyrenes that were prepared by radical polymerization and have the polydispersity index exceeding 2 behave as non-Newtonian fluids. Figure 1 shows the plot of the stress vs. shear rate for one of the solutions. These dependences are well approximated by second-order polynomials. Therefore, in these cases we used as a viscometric characteristic of solutions the maximal Newtonian viscosity obtained by extrapolation of the derivatives of the polynomials to zero shear rate (μ_0).

Solutions with the concentration less than 20% behave as Newtonian fluids, as also do solutions of polystyrene with $M = 3 \times 10^5$ and narrow MWD (polydispersity index 1.2) up to ~40% concentration; in what follows, this sample is denoted as ND.

Figure 2 shows the concentration dependence of the effective activation energy of viscous flow $E_{a\mu}$ found from the Arrhenius dependences of the viscosity. We found that $E_{a\mu}$ is essentially independent of M of polystyrene but strongly depends on the solution concentration at a polymer content exceeding 30%. The dependence obtained is satisfactorily described by a third-degree polynomial

$$E_{a\mu} = 8280 + 458c - 15.55c^2 + 0.255c^3, \qquad (4)$$

where $E_{a\mu}$ is the activation energy (J mol^{-1}) of the viscous flow of the polystyrene solution in toluene, and c is the solution concentration (wt %).

The point for the zero concentration corresponds to $E_{a\mu}$ for toluene [9]. The rms deviation is 1.6 kJ mol^{-1}.

Figure 3 shows the semilog plots of the viscosity of polystyrene solutions in toluene vs. concentration at 30°C. Similar dependences were obtained at other temperatures. It can be seen that all the dependences are well fitted by third-order polynomials:

$$\ln \mu_0 = -5.26 + B_1c + B_2c^2 + B_3c^3. \qquad (5)$$

(with the viscosity measured in P, and concentration, in wt %).

The dependences of the coefficients B_1, B_2, and B_3 of Eq. (5) on M are shown in Fig. 4. For B_1, the dependence is well described by a linear function. The dependences for B_2 and B_3 can also be approximated by linear functions, but the scatter is larger than for B_1. It is noteworthy that the coefficients B_2 and N_3 for

the sample with a narrow MWD do not fit in the linear dependences for the other polymers with a broad MWD. Apparently, the coefficients B_2 and B_3 depend on the MWD width considerably more strongly than does B_1 and reflect the influence exerted on the solution viscosity by the polymer polydispersity.

Hence follows that the dependences of the viscosity of polystyrene solutions on M are exponential rather than power, and the concentration dependences of the viscosity cannot be described by simple equations at all. Apparently, power equations of type (3) can be used in relatively narrow ranges of variation of the parameters, and the exponents will depend on the interval of M chosen and on the kind of the polymer.

Summing up the dependences obtained, we can write the following empirical equation for calculating the viscosity of polystyrene solutions:

$$\ln\mu_0 = -5.26 + (6.51\times10^{-2} + 1.326\times10^{-6}M)c + (1.52\times10^{-3} - 3.497\times10^{-8}M)c^2 - (4.309\times10^{-6} - 3.022\times10^{-10}M)c^3 + (8280 + 458c - 15.55c^2 + 0.255c^3)(1/T - 0.0033)/8.31, \quad (6)$$

where μ_0 is the viscosity at zero shear rate (P); M, weight-average M of polystyrene (M_w); c, solution concentration (wt %): and T, temperature (K).

The viscosities calculated using Eq. (6) in most cases closely coincide with the experimental data. Noticeable deviations (the calculated values exceed the experimental values) are observed only with the lowest-molecular-weight sample ($M_w = 2.8\times10^4$, deviations by up to an order of magnitude) and with concentrated (>30%) solutions of the highest-molecular-weight sample ($M_w = 7.8\times10^5$; deviations by a factor of 3–4, which corresponds to the error in calculation of the heat transfer coefficient by a factor of no more than 1.4–1.5). It should be noted, however, that both these samples have the polydispersity index exceeding 3.5, in contrast to the other samples whose polydispersity index is 2.2–2.7. Apparently, it would be more correct to use for the approximations the viscosity-average values of M, which may significantly differ from M_w in the case of a broad MWD. However, when simulating polymerization processes, it is possible to calculate and use in further calculations only the statistical moments of MWD (M_n, M_w, M_z, etc.). Consideration of the effect of MWD on the viscosity characteristics of solutions would apparently allow refinement of the model.

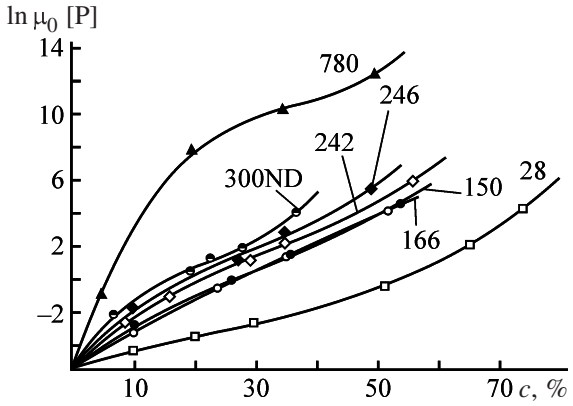

Fig. 3. Viscosity μ_0 of solutions of polystyrene in toluene at 30°C as a function of solution concentration c. Figures at curves are the values of $M_w\times10^{-3}$; points: experimental data; solid lines: approximation by cubic polynomials. Curve denoted by 300ND corresponds to a sample with a narrow MWD ($M_w/M_n = 1.2$); the polydispersity indices for the other samples range from 2.2 to 2.6.

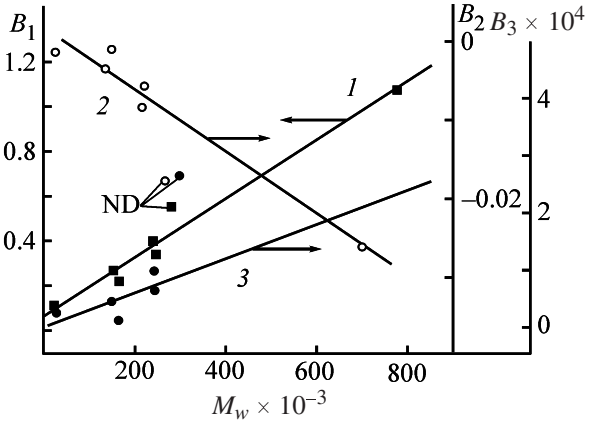

Fig. 4. Coefficients of Eq. (5): (*1*) B_1, (*2*) B_2, and (*3*) B_3, as functions of M of polystyrene. Points denoted by ND refer to the sample with a narrow MWD. These points were not taken into account when constructing linear approximations for B_2 and B_3.

Similar measurements showed that solutions of PVA in butyl acetate (ranges: concentration 0–50 wt %, M 2×10^4–1.4×10^5, M_w/M_n 3.1–5.6), in contrast to polystyrene solutions, behave as Newtonian fluids. The concentration dependences of the viscosity are well described by an exponential function in which the exponent, in turn, is a function of M and concentration. The concentration dependence of the logarithm of viscosity is well approximated by second-order polynomials (Fig. 5).

The activation energy of viscous flow $E_{a\mu}$ of PVA solutions in the temperature range 30–70°C, similarly to polystyrene solutions, increases with the concentration, and this dependence is well described by a sec-

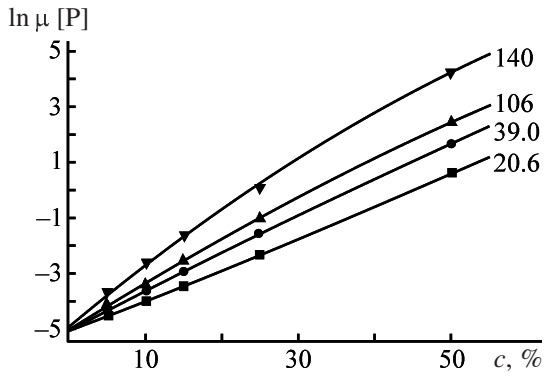

Fig. 5. Viscosity μ of solutions of poly(vinyl acetate) in butyl acetate at 30°C as a function of concentration *c*. Points: measured values; solid lines: approximation by second-order polynomials. Figures at curves denote the values of $M_w \times 10^{-3}$ of PVA samples.

ond-order polynomial. In the above-indicated ranges of parameters, the viscosity of PVA solutions can be calculated from the following equation:

$$\ln \mu = -5.0 + (0.0916 + 9.015 \times 10^{-7}M)c + (2.93 \times 10^{-4} - 7.949 \times 10^{-9}M)c^2 + (7910 + 410c + 1.65c^2)(1/T - 0.0033)/8.31, \quad (7)$$

where μ is the viscosity (P); *M*, weight-average molecular weight of poly(vinyl acetate); *c*, solution concentration (wt %); and *T*, temperature (K).

Empirical equations (6) and (7) can be actually applied only to the parameter intervals that were used in the approximations, with only short extrapolations admissible. However, these intervals, especially for polystyrene, correspond to those realized most frequently in batch polymerization reactors [10]. Therefore, when simulating reactors, these equations can provide considerably higher level of adequacy of the models compared to equations of type (3) and thus can enhance the reliability of predicting the thermal modes of polymerization.

CONCLUSIONS

(1) The dependences of the viscosity of concentrated solutions of polymers on *M* and concentration in the case of polystyrene and poly(vinyl acetate) are more complex than simple power functions. These dependences are described considerably more accurately by exponential functions whose exponents, in turn, are complex functions of both the solution concentration and the molecular weight of the polymer.

(2) The features of the molecular-weight distribution of polymers also make certain contribution to these dependences. Simpler dependences obtained with poly(vinyl acetate) are most likely due to the fact that the measurements were performed in a relatively narrow range of *M* and were restricted to relatively low solution viscosities (≤50 P). Extension of the ranges of *M* and concentration in the case of poly(vinyl acetate) may make it necessary to use approximating polynomials of the order higher than 2.

(3) The activation energy of the viscous flow dramatically increases at solution concentrations exceeding 40% but is essentially independent of *M* of the polymers.

ANNIVERSARIES

Sergei Stepanovich Ivanchev (to His 75th Birthday)

DOI: 10.1134/S1070427207110341

On December 1, 2007, Sergei Stepanovich Ivanchev, Deputy Editor-in-Chief of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry), corresponding member of the Russian Academy of Sciences, professor, doctor of chemical science, Honored scientist and technologist of the Russian Federation, director of the St. Petersburg Branch of Boreskov Institute of Catalysis (Siberian Division, Russian Academy of Sciences), is 75.

S.S. Ivanchev was born in Mukachevo, Transcarpathia. In 1954, he graduated with excellence from the chemical faculty of Uzhgorod State University, and in 1957, finished his postgraduate education at the Chair of Physical Chemistry at Franko State University, Lvov. He early started his working life, combining education at the university with work as teacher of physics in an evening school. Having finished his postgraduate education, he remained as a lecturer at the Chair of Physical Chemistry, and, after his supervisor was transferred to Odessa, worked at the newly organized Chair of Physical Chemistry of Polymers at Mechnikov State University in Odessa as assistant professor, professor, and dean of the chemical faculty.

Since 1970, the development of Ivanchev as a scientist and researcher continued in Leningrad, where he was invited to head the research laboratory created at Plastpolimer Okhta Research and Production Association (ORPA). Soon the laboratory became a research department and Sergei Stepanovich was appointed, first, deputy director, and then, director of the Research Institute of Polymerization Plastics at the Association. In 1981, he became the first deputy director of Plastpolimer ORPA. In this position, he exhibited capacity for research organization in the whole subbranch of polymerization plastics, became engaged in the development and implementation of new technological solutions and in creation of the pilot experimental facilities of the subbranch at the Tomsk Petrochemical Combine being constructed. He supervised and coordinated research work in COMECON countries in the field of polymerization plastics as head of the corresponding Scientific Council and member of the Scientific Council at the Ministry of Chemical Industries.

As a scientist, Ivanchev made a major contribution to solution of a number of basic problems of polymer syntheses. He scientifically substantiated and implemented pathways for synthesis of new classes of polyfunctional components used in manufacture of reactive oligomers, polymers, block-grafted oligomers, and filled polymer formulations. He suggested and confirmed the polymerization–recombination mechanism of macromolecule formation in the case when polyfunctional initiators are used. He made an important contribution to the improvement of the technology of emulsion polymerization and development of technologies for production of latexes with hollow particles and vibration-absorbing polymeric coatings for ship-building industry. In the past decade, he has been actively engaged in the development of new catalytic systems for polymerization and polymeric membrane systems for various purposes, including polymeric proton-conducting membranes for fuel cells.

In view of the change of the situation in the field of polymerization plastics and liquidation of the Ministry of Chemical Industries, Ivanchev, already a corresponding member of the Russian Academy of Sciences, went to work in the Academy and organized the St. Petersburg Branch of the Boreskov Institute of Catalysis and has been successfully heading the branch ever since.

Ivanchev is the author and co-author of more than 600 publications, including 4 monographs, more than 40 reviews, and more than 250 patents and inventor's certificates in Russia, the United States, Germany, Japan, and France. He is the founder of an acknowledged scientific school in the field of synthesis and modification of polymers, represented by 9 doctors of science and more than 40 candidates of science.

Ivanchev was a member of the Expert council of the Higher Attestation Commission for three decades and a member of the Editorial Board of *Vysokomolekulyarnye Soedineniya* (Macromolecular Compounds) journal for more than two decades. At present, he is a member of the Editorial Board of *Uspekhi Khimii* (Russian Chemical Reviews) journal and Deputy Editor-in-Chief of *Zhurnal Prikladnoi Khimii*.

Professor Ivanchev is a laureate of the Award of the Council of Ministers of the USSR (1989), laureate of the Academician Kargin Prize of the Russian Academy of Sciences (1993), Honorary Chemist of the Russian Federation (1995). He was awarded Tsiolkovsky gold medal (2002) and Academician Zhukov gold medal (2004). He is Honored Engineer of St. Petersburg (2002), Honorary Doctor of the Belyi Institute of Mechanics of Metal–Polymer Systems (National Academy of Sciences of Belarus) (2005), and bearer of the gold sign of the Mendeleev Russian Chemical Society (2006).

Sergei Stepanovich is full of creative energy and optimism and continues active work.

Friends, co-workers, Editorial board and editorial staff of *Zhurnal Prikladnoi Khimii.*

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

To Centennial Anniversary of the First Mendeleev Congress on General and Applied Chemistry

DOI: 10.1134/S1070427207110353

In January 1907, the Russian Physicochemical Society (RFKhO), Russia's science, and the world's scientific community suffered severe losses. On January 20, 1907 (hear and hereinafter dates are given in Julian calendar), died Honorary chair of the Department of chemistry of RFKhO, Honored Professor Dmitrii Ivanovich Mendeleev (1834–1907). On January 23, 1907, deceased president of RFKhO, one of its founders, Honored Professor Nikolai Aleksandrovich Menshutkin (1842–1907).

Already on February 1, 1907, was held, in commemoration of the scientists, joint meeting of the departments of physics and chemistry of RFKhO. After detailed information about the funeral was provided, a decision was made to hold, in commemoration of D.I. Mendeleev, a memorial meeting during the Christmas vacations of 1907. It was decided to hold a special meeting in commemoration of N.A. Menshutkin by agreement with the Council of the Polytechnic Institute [1]. In conformity with these decisions, the question of organizing the Mendeleev Congress on General and Applied Chemistry was considered on May 3, 1907, at a meeting of the Council of the Department of Chemistry of RFKhO [2]. It was decided to hold the Congress in St. Petersburg on December 20–30, 1907. It was recommended to have three types of meetings at the Congress:

(1) Memorial meetings devoted directly to Mendeleev (biography, scientific works, and recollections of the scientist).

(2) Joint meetings devoted to general issues of interest for all the participants.

(3) Meetings in separate specialties.

The statute of the Congress read that the Mendeleev Congress on General and Applied Chemistry is aimed to promote advances in chemistry and its applications in Russia, on the one hand, and understanding between those dealing with chemistry. All persons interested in the advances in chemistry in Russia can be participants of the Congress. The Congress is held by the Russian Physicochemical Society affiliated with the Imperial St. Petersburg University and is under the authority of the Minister for Public Education. The program of the Congress includes problems of general chemistry, all branches of chemical technology, and applications of chemistry in other fields. Particular attention is to be given to the following topics:

Dmitrii Ivanovich Mendeleev.

(1) General chemistry (inorganic, organic, analytical, physical).

(2) Methods for technical analysis.

(3) Fuels, oil.

(4) Chemistry of metallurgical processes. Metallography.

(5) Electrometallurgy. Applied electrochemistry.

(6) Glass. Ceramics. Cements.

(7) Biological chemistry. Hygiene. Pharmaceutical chemistry. Forensic chemistry. Chemistry of nutrients.

(8) Agronomic chemistry.

On its meeting on May 8, 1907, the Department of physics of RFKhO supported the suggestion to convene the Mendeleev Congress on General and Applied Chemistry [2]. The final name of the Congress was as follows: "Mendeleev Congress on General and Applied Chemistry, held by the Russian Physicochemical Society." The Congress was held in St. Petersburg on schedule, on December 20–30, 1907.

The oldest Russian chemist, N.N. Beketov (1827–1911), was elected the chair of the first Mendeleev Congress. Because of the death of F.F. Beilstein (1838–1906), Beketov was at that time the only chemist among full members of the Imperial St. Petersburg Academy of Sciences. Known scientists, chemists and physicists representing various regions of Russia, were elected deputy chairpersons: F.M. Flavinskii (Kazan), N.E. Zhukovskii (Moscow), P.N. Lebedev (Moscow), P.I. Walden (Riga), I.A. Kablukov (Moscow), S.N. Reformatskii (Kiev), and D.N. Pryanishnikov (Moscow). Among the foreign participants was elected S. Arrhenius, director of the Nobel Institute in Stockholm, 1903 Nobel Prize laureate, foreign corresponding member of St. Petersburg Academy of Sciences.

Participants of the Congress headed its special departments. This work was done by St. Petersburg scientists representing various higher-school institutions of the city, who supervised the following departments of the Congress: N.S. Kurnakov, Department of Chemistry of Metallurgical Processes and Metallography; A.A. Krakau, Department of Electrometallurgy and Applied Electrochemistry; A.A. Baikov, Department of Cements; A.M. Sokolov, Department of Glass, Ceramics, and Technology of Mineral Substances; S.A. Przhibytek, Department of Pharmaceutical Chemistry, Forensic Chemistry, and Chemistry of Nutrients; V.I. Palladin and S.S. Salazkin, Department of Biological Chemistry; G.V. Khlopin, Department of Hygiene; P.S. Kossovich, Department of Agronomic Chemistry; and O.D. Khvol'son, Department of Physics.

Prior to the opening of the Congress, a memorial board was opened on the building of the Central Board of Weights and Measures, where Mendeleev had worked beginning in 1892. The first memorial meeting devoted to Mendeleev was commenced on December 20, 1907, at 2 p.m. in the central building of the University. V.E. Tishchenko, one of the oldest members of RFKhO and Mendeleev's and Butlerov's disciple, delivered a report "D.I. Mendeleev: Brief Biography." The final part of a rather detailed report noted that the scientific achievements of Mendeleev were acknowledged and highly appreciated not only in Russia, but also in a large number of other countries. The scientist had been elected honorary member of all Russian universities and many other higher-school institutions of Russia, a corresponding member of the Imperial Academy of Sciences, and honorary member of the Russian Physicochemical Society and many other Russian scientific societies. Mendeleev had a *honoris causa* degree from Edinburgh, Oxford, Cambridge, Göttingen, and Princeton universities and was a member of the Royal Society (Great Britain) and of quite a number of academies of France, Germany, Italy, and other countries. He was recipient of most honored scientific awards, including Davy and Faraday medals.

A brief report "Importance of D.I. Mendeleev's Periodic System" was delivered by Academician Beketov. The report "General Review of D.I. Mendeleev's Scientific Activities" was presented by a young scientist, lecturer of St. Petersburg Technological Institute, V.Ya. Kurbatov.

At the second (December 26, 1907) and final third (December 30, 1907) memorial meeting of the Congress, devoted to Mendeleev, 14 more reports were presented, in which the achievements of the great Russian scientist in widely diverse areas of science, technology, and public life were analyzed. In addition to works in chemistry and physics, Mendeleev's studies in aeronautics, manufacture of explosives, and oil industry were discussed. Separate reports were devoted to scientist's works on industrial-economical, educational, and metrological issues.

In addition to the reports presented at three memorial meetings devoted to Mendeleev, 147 reports were made at meetings of Departments (sections) of Chemistry, Physics, Agrochemistry, Biology, Hygiene and at joint meetings of the Departments of Chemistry and Physics. These reports included:

68 at the Department of Chemistry;

13 reports at the Department of Physics;

23 reports at the Department of Agrochemistry;

13 reports at the Department of Biology;

Title page of the Proceedings of the first Mendeleev Congress on General and Applied Chemistry. Printed: Proceedings of the first Mendeleev Congress on General and Applied Chemistry, which took place in St. Petersburg, December 30–30, 1907. Published by the Administrative Committee of the Congress, edited by Congress secretary V.I. Tishchenko. St. Petersburg: M.P. Frolova's Typolithography, Galernaya 6, 1909.

4 reports at the Department of Hygiene.

Twenty-six reports were presented at joint meetings of the Departments of Chemistry and Physics. Detailed information on the reports made at meetings of the Departments and their work can be found in Proceedings of the first Mendeleev Congress on General and Applied Chemistry [3], with brief evidence included in the collection of works [4].

The Congress attracted considerable interest of a wide audience of specialists and students. The Congress gathered 1008 delegates from 80 cities of Russia. The full list of delegates, with places of their work and positions occupied, can be found in the proceedings of the Congress [3].

The Congress approved the statute of periodically convened Mendeleev Congresses on General and Applied Chemistry.

The congresses were originally organized by the Russian Physicochemical Society, and later, by the Academy of Sciences of the USSR. The second Mendeleev Congress on General and Applied Chemistry was held also in St. Petersburg on December 21–28, 1911. During the Congress, Mendeleev's study-museum, organized by the Russian Physicochemical Society at the building of St. Petersburg University and situated there until now, was opened for visitors.

BOOK REVIEWS

Kozin, L.F. and Volkov, S.V., *Sovremennaya energetika i ekologiya. Problemy i perspektivy* (Modern Power Engineering and Ecology: Problems and Prospects)

Kiev: Naukova Dumka, 2006, 773 pp.

DOI: 10.1134/S1070427207110365

The monograph devoted to topical problems of modern power engineering was written by known Ukrainian chemists, staff members of the Vernadsky Institute of General and Inorganic Chemistry (National Academy of Sciences of Ukraine), Prof. L.F. Kozin and Academician S.V. Volkov (academician of the National Academy of Sciences of Ukraine). In the monograph, the extent to which leading countries in the world are provided with energy carriers is analyzed and prospects for use of renewable power sources and development of hydrogen energetics are discussed. The book comprises an introduction, nine chapters, conclusion, bibliographic list, and subject index.

In the introduction (pp. 5–10), the authors note that their purpose is to familiarize the reader with the state of modern problems of power engineering in the world and in Ukraine, with particular attention given to hydrogen energetics and renewable power sources. Chapter 1, entitled "Energy, Technological Progress, Hydrogen, and Ecology" (pp. 11–32), analyzes the general world's energetic and environmental problems and their interrelationship. Special attention is paid to the situation with power resources in Ukraine. At present, 47–50% of the consumed electric power is provided in this country by nuclear power plants, whereas the resources of oil and natural gas are exceedingly scarce.

Chapter 2 (pp. 33–66) discusses the consumption scale of various kinds of energy carriers in industrially developed and developing countries. The energy balance takes into account the consumption of basic kinds of organic fuel: coal, oil, and natural gas, as well as the contribution of renewable energy sources and nuclear power plants. Chapter 3 (pp. 67–127) discusses the world's resources of combustible fossil fuels (coal, oil, natural gas) and their distribution over regions and countries. A separate section of the chapter is devoted to hypotheses of the origin of the hydrocarbon fuel on the Earth; in particular, the authors substantiate their own approach to this problem. The final part of the chapter analyzes the relationship between the most important parameters characterizing the standard of living in a country (energy consumption per capita, gross domestic product, life duration, population, etc.).

Chapter 4 (pp. 128–209) is devoted to nuclear power engineering, its origination, development, and prospects. The basic evidence concerning the present-day state of nuclear power engineering is summarized in the first section of the chapter. The authors cover a wide variety of problems, which necessarily leads to brevity of presentation and separate disputable issues. The small second, third, and fourth sections deal with promising designs: possibility of developing high-temperature liquid-salt reactors, prospects for combination of nuclear and hydrogen energetics, and controlled fusion. The final, fifth section of Chapter 4 considers the environmental safety of the nuclear power engineering, based on two aspects: safe operation of nuclear power plants and reliable disposal of nuclear waste. The authors analyze in detail the reasons for the largest technological disaster of the late XX century, accident at the fourth unit of Chernobyl nuclear power plant. The whole contents of the nuclear reactor was melted and discharged by explosion into the environment.

Chapter 5 (pp. 210–252) discusses power production in the United States, Germany, Russia, and Ukraine. The energy balance of Ukraine is considered in most detail. As already noted, in this balance, 47.75% of power is produced by nuclear power plants; 45.66%, by thermal power plants and other hydrocarbon fuel consumers; 6.53%, by hydroelectric power plants; and 0.66%, by other renewable energy sources. According to the data presented by the authors, in the last 25 years, the electric power production in Ukraine was at a maximum (298.4 billion kW h^{-1}) in 1990 and

at a minimum in 2000 (171.4 billion kW h^{-1}).

Chapters 6 (pp. 253–438) and 7 (pp. 439–533) are devoted to production of hydrogen and prospects for development of hydrogen energetics. The authors consider in detail the basic technological parameters of ten most promising methods for hydrogen production, which include both already existing techniques and those possible in the future. Prospects for use of hydrogen as an environmentally clean and unique energy carrier in industry, vehicles, and energy conversion (fuel cells of various deigns) are discussed in detail. Special attention is given to problems associated with hydrogen storage and transportation.

In Chapter 8 (pp. 534–662), the authors consider global environmental problems that alarm the modern society: the so-called greenhouse effect, its causes and the related illusory climatic changes, "ozone holes," and "acid rains." The book substantiates the standpoint according to which the human technological activities do not exert, for the time being, any detrimental influence on the thickness of the ozone layer over our planet. It is also emphasized that the greenhouse gases (CO_2, CH_4, H_2O, etc.) produced by human activities cannot affect the climatic changes.

Chapter 9 (pp. 663–703) prognosticates the components of the world's energy balance in the XXI century and third millennium. The main concepts the authors elaborate upon are summarized in the brief conclusion presented in Russian (pp. 704–710) and English (pp. 711–717). The bibliographic list at the end of the book (pp. 718–760) is compiled separately for each of the chapters and contains 1068 references in all. The book is provided with a subject index (pp. 761–769). The table of contents is given in Russian and English. The polygraphic design of the book deserves a high appreciation.

On the whole, the book analyzes a vast and diverse material, with an important contribution to the problems discussed made by many years' research by the authors themselves. Although the book has an official status of a monograph, the numerous publicistic digressions do not arouse any discord and are interesting and justified. Kozin and Volkov have written a book of interest and use and discussed a wide variety of problems affecting the development of modern civilization. Thanks to the understandable manner of presentation, the book can attract the attention of an extremely wide audience of readers.

BOOK REVIEWS

Davenport, W.G., Jones, D.M., King, M.J., and Partelpoeg, E.H., *Flash Smelting: Analysis, Control, and Optimization*

Warrendale: TMS, 2001

Translated under the title *Vzveshennaya plavka: kontrol', analiz i optimizatsiya,* Starykh, R.V., Ed.

Moscow: MISIS, 2006, 400 pp.

DOI: 10.1134/S1070427207110377

At present, flash smelting is widely used in manufacture of copper and nickel all over the world. The book by W.G. Davenport and co-authors presents in chronological order modern achievements and understanding of the process of flash smelting. The descriptive and mathematical sections of the book reflect the level of industrial use of smelting as of 2000. Microsoft Excel software was used in mathematical calculations.

The book comprises twenty-three chapters and a supplement. The first three chapters (pp. 5–14, 15–59, 60–76) present general evidence about furnaces for flash smelting and their purpose and discusses in detail the smelting processes used by Outokumpu and INKO companies. The flash smelting is mostly used to produce matte with high copper content from a fine flotation Cu–Fe–S concentrate. Further, the matte is subjected to conversion to give raw copper. The flash smelting is the most important process in recovery of copper from sulfide ores.

Chapter 4 (pp. 78–94) considers the basic equations describing the mass and heat balances for a steady-state flash smelting process. In the following several brief chapters, from 5 to 14 inclusive (pp. 95–175), the mass-and-heat balance equations are applied to analysis of various particular processes: flash smelting of compound concentrates, effect of nitrogen on the smelting process, production of mattes with prescribed composition (65% Cu) in autogenous smelting of concentrates, and other processes are discussed. Chapter 15 (pp. 176–191) pays main attention to the expenditure of technical oxygen and fuel in smelting of pure $CuFeS_2$. Chapter 16 (pp. 192–202) discusses the behavior of moisture in flash smelting. Various issues of the smelting technology are discussed in Chapters 17 to 21 (pp. 203–312). Chapter 22 (pp. 313–333) is devoted to methods for control over flash smelting furnaces; Chapter 23 (pp. 334–353) presents results of optimization calculations. Reference data, thermodynamic parameters, and results of process calculations are summarized in the supplement (pp. 354–385).

Each chapter of the book ends with a brief conclusion and problems to be solved without assistance. Most of chapters include lists of recommended literature. The book by Davenport and co-authors has original structure, contains a vast body of technological evidence, and can be of use for research and design-office workers and senior students specialized in metallurgy of heavy nonferrous metals.

BOOK REVIEWS

Boiko, V.I., Vlasov, V.A., Zherin, I.I., Maslov, A.A., and Shamanin, I.V., *Torii v yadernom toplivnom tsikle* (Thorium in a Nuclear Fuel Cycle)

Moscow: Ruda i Metally, 2006, 360 pp.

DOI: 10.1134/S1070427207110389

The book generalizes and systematizes the results of studies concerned with the place of thorium in the nuclear fuel cycle, carried out at Tomsk Polytechnic Institute and at a number of other leading Russian and foreign scientific centers. It discusses the chemical properties of thorium and its most important compounds, describes the technology of production of thorium compounds and the metal for nuclear power engineering, and considers nuclear and physical properties of thorium and its compounds. The monograph compares the advantages and disadvantages of the uranium–plutonium and thorium–uranium nuclear fuel cycles.

The book comprises a foreword, ten chapters, and conclusion. Bibliographic lists with references to domestic and foreign publications are contained at the end of each chapter. Chapter 1 (pp. 6–15) presents brief evidence about basic stages of nuclear fuel cycles, materials used, and methods for uranium fuel enrichment. Chapters 2 (pp. 16–33), 3 (pp. 34–48), 4 (pp. 49–97) and 5 (pp. 99–118) contain data on the occurrence of thorium in nature, chemical properties of thorium and its compounds, processing technology of thorium-containing ores, production of the main thorium compounds (thorium dioxide, tetrafluoride, and tetrachloride), production of metallic thorium by thermal reduction and electrolysis, iodide refining, and production of a compact metal.

Chapter 6 (pp. 119–163) considers nuclear, physical, and thermal properties of thorium, its alloys, and ceramic compounds of thorium. Chapter 7 (pp. 164–209) includes general evidence about operation of a nuclear power installation. Chapter 8 (pp. 210–251) compares the nuclear and physical properties of the thorium and uranium cycles.

Chapter 9 (pp. 252–314) summarizes the experience gained in use of ex-warhead plutonium in nuclear power installations and discusses the possibility of organizing the thorium–plutonium nuclear cycle. The problem discussed is associated with the release of warhead plutonium in nuclear warfare reduction. Chapter 10 (pp. 315–353) is devoted to processing of irradiated nuclear fuel in various kinds of cycles. The brief conclusion emphasizes that thorium actually remains undemanded by the world's technological practice, although its use has certain positive aspects.

The book is of indubitable interest for specialists engaged in design and research work in the field of nuclear technologies and may be of use in training of masters and postgraduate students specialized in certain scientific areas.

Abstract—The necessity of using sulfur-containig fertilizers in agricultural production is evidenced. By neutralizaation with gaseous ammonia of a mixture of extractive phosphoric and sulfuric acids the ammonium sulfatophosphates are produced, containing nitrogen, phosphorus and sulfur in various ratio. The regimes for producing them are described and material flows in the industrial manufacturing are given.

DOI: 10.1134/S1070427207110390

Our target was development of technology for production of a complex fertilizer containing sulfur, besides nitrogen and phosphorus. D.N. Pryanisnikov has pointed that sulfur as an element for feeding plants occupy position in the same row as nitrogen, phosphorus and potassium [1]. However, till the recent years this element attracted little attention. In part this is explained by the fact that with the development of industry a great amount of sulfur attained the fields providing enough feeding of plants at that level of development of agiculture. But since recently in many countries, including Uzbekistan, the content of sulfur was found deficient.

Sulfur is supplied to the soil from atmosphere with rainfalls and from mineral fertilizers. Amount of sulfur in the atmosphere becomes lower because industrial plants are equipped with apparatus for trapping sulfur dioxide from exhaust gases. Production of sulfur-containing fertilizers (ordinary superphosphate and ammonium sulfate) is insufficient. In 2004, the plants of Uzbekistan have produced 157.7 thousands tons of nitrogen as carbamide, 509.6 thousands tons as ammonium nitrate and only 27.8 thousands tons as ammonium sulfate; phosphorus has produced as 108.6 thousands tons of P_2O_5 in ammophos (ammonium phosphate) and 24 thousands tons only as ordinary superphosphate.

The importance of sulfur for agriculture was considered in [2–6]. Sulfur is a component of aminoacids cystine and methionine, it is importatn for the protein metabolism and oxidation-reduction processes. Sulfur shows positive effect on the formation of chlorophyll, promotes formation of nodules at the roots of legumes and of rhizobiums responsible for binding atmospheric nitrogen. Deficiency of sulfur in plants destroys metabolism and synthesis of protein and causes chlorosis leading to decrease in productivity and quality of plant production [2]. At growing cotton plant, sulfur shows positive effect of the process of growing, yield, technological properties of cotton fiber and the quality of seeds for sowing, at low dozes of fertilizers in particular. It promotes increase in effect of nitrogen fertilizers and increases mobility of soil phosphates. Yield of cotton plant increases in the range from 2.1 to 16.3%, the oil content in the seeds up to 3.8%. Optimal norm for sulfur content in the soil is 20 to 40 kg per hectare [5].

The total content of sulfur in the layer form 0 to 20 cm of Uzbekistan's gray desert soil is 300 [5], while power black soil contains 1506 kg per hectare, turfy-podzilic soil contains 756 kg per hectare [7]. The main part of sulfur (up to 90%) constitutes organic substance of a soil. Humus contains sulfur and nitrogen in a certain ratio, commonly N : S = (8–12) : 1. Acessibility of organic sulfur in a great extent is defined by the rate of its transformation into sulfate form. The process of sulfur mineralization proceeds slowly. Its intensity is affected by the composition and activity of the soil microflora, humidity and temperature.

Many of farm cultures consume as much sulfur as phosphorus or even more. The S : P consuming ratio more than unity is characteristic for lucerne, cabbage, onion, weat, barely, sunflower and rape. The most

demanding toward sulfur as an element of food are the plants form the families of Cruciferae, Legumes and Hemorocallis. Cramineaes require less sulfur. Much sulfur consuming from soil is characteristic of cabbage, sugar beet, turnip, onion and lucerne; clower and cotton plant also consume much enough sulfur; potato, cereals and food grains are less demanding toward this element. The sulfur consuming can be estimated from the following data:

Yield, centner per hectare	Culture	Sulfur consuming, kg per hectare
26–38	Cereals	5–15
60	Corn	8–10
170–250	Potato	11–12
520–540	Table beet	14–15
250–350	Cabbage	30–60
150–350	Onion	18–22
200–300	Turnip	25–55
50–100	Lucerne	20–30
40–100	Clower	15–30
40–100	Cereal herbs	8–15
350–400	Sweet beet	31–35
24	Cotton plant	36–51

The sulfur consuming from soil depends directly from the plant yield. Therefore additional placement it to the soil is particularly important for the countries with highly productive agriculture [4].

A diagnostic index of the sulfur demand of cotton plant is the N : S ratio in its leafs. The optimal N : S ratio showing sufficient providing the cotton plant with sulfur is 20 : 1 in the initial phase and 15.0–13.5 : 1 in the further phases of its growing [5].

We suggest that the best way of making sulfur-containing complex fertilizer is ammonization of a mixture of phosphoric and sulfuric acids. This method is protected by several patents [8–10]. According to the patent [8] to the neutralized by ammonia mixture of the acids should be added KCl and carbamide. The acids should me mixed in a proportion providing P_2O_5 : SO_3 ratio (0.5–0.9): 1, and the pulp after ammonization the ratio (N + SO_3) : P_2O_5 should fall to the range (1.6–1.9): 1. In the patent [9], sulfuric acid amount is 0.2–0.5 ton per 1 ton of P_2O_5, ammonium for neutralization should be added in amount sufficient for achieving in the final product the molar ratio NH_3 : H_3PO_4 = 1 : 1.5 and the obtained phosphate pulp should be mixed with KCl or K_2SO_4 and then passed to granulation and drying. By the patent [10], the method for producing sulfoammophos includes neutralization of phosphoric and sulfuric acids with ammonia for obtaining phosphoric–sulfuric acid pulp with pH 4.6–5.8, the phosphoric acid should preliminary be neutralized with ammonia maintaining it in the zone of neutralization, pH 6.2–9, in the presence of magnesium salts in amount 7–28% MgO relatively to content of P_2O_5 in the phosphoric acid.

Publication [11] is denoted to production of fertilizers containing phosphates and ammonium sulfate. It claims that increase in amount of ammonium sulfate in the solution of ammonium phosphate leads to increase in total solubility of the salts with simultaneous decrease in content of ammonium phosphates in such solutions, viscosity of the saturated sulfate–phosphate solutions falls and pressure of ammonium over these solution diminishes. Varying the ratio of ammonium sulfate and ammonium phosphates in solution allows controlling over their contents in the produced salt.

We also obtained a preliminary patent on the method of producing ammonium sulfatophosphate [12], that defines technology realized on the facility of ammofos production in Almalyk enterprise "Ammofos". The raw material is:

– extractive phosphoric acid produced by the dehydrat method from the thermoconcentrate of the phosphorites of Central Kyzylkum, containing 21.5% or more P_2O_5 and 3.0 g/100 cm^3 or less SO_3;

– Sulfuric acid with weight fraction of H_2SO_4 monohydrate 92.5% or higher;

– Crude liquid ammonia with weight fraction of NH_3 99.6% or higher;

– Acidic effluences with density 1.1–1.15 g cm^{-3}.

The essence of technology consists in mixing acids, their neutralization with ammonia, granulation and drying of the pulp in the presence of returning product in a drum type granulator – dryer, classifying the product and cooling. The ratio of acids at mixing is defined by the required composition of the product. Neutralization of the acid mixture is carried out by introducing gaseous ammonia at 80–100°C to pH 4.2–4.5. At the higher temperature ammonia is evolved to gas phase, at lower temperature the salts can crystallize from the saturated solution. The acidic effluents consist of the absorbing liquid (a weak solution of ammonium sulfatophosphate) formed after absorption of vapor–air mixture from the saturator where the neutralization is carried out, BGS and the dust from the sanitary equipment returning to the saturator for neutralization. Temperature of the gas flow at the inlet of the BGS apparatus is 500–800°C, at the outlet 100–120°C.

Regimes for producing ammonium sulfatophosphate of six sorts are developed. According to the Technical Requirments TSh 6-12-96 they should satisfy the following conditions:

Condition	Norm for sort A		Norm for sort B		Norm for sort C	
	high quality	first quality	high quality	first quality	high quality	first quality
1. Weight fraction of general phosphates,%	23±1	20 ±1	17±1	15±1	7±1	4±1
2. P_2O_5 hydrogen / P_2O_5 total, %	50	50	50	50	50	50
3. Weight fraction of general nitrogen, %	15±1	16±1	17±1	18±1	18±1	19±1
4. Weight fraction of water, less than, %	2.0	2.0	2.0	2.0	2.0	2.0
5. Content of granules with size:						
1–4 mm, no less than, %	80	80	80	80	80	80
more than 6 mm, %	-	-	-	-		
6. Strength of granules, kg/cm^2	30	30	30	30	30	30
7. Friability, %	100	100	100	100	100	100

Note: Contents of sulfur in these products is: Sort A high quality 12%, first quality 13.2%; Sort B high quality 15.3%, first quality 16.8%; Sort C high quality 21.0%, first quality 21.6%.

In 2006 was produced 14,600 ton of ammonium sulfatophosphate recalculated on the 100% P_2O_5 .

Figure shows the scheme of material flows at the production of ammonium sulfatophosphate of A sort.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Application of Polymerized Bottoms from Styrene Rectification to Producing Polybutadiene

O. N. Filimonova, N. S. Nikulina, S. S. Nikulin, and V. A. Sedykh

Voronezh State Forestry Engineering Academy, Voronezh, Russia

Received February 28, 2007

Abstract—Polymeric materials are obtained by high-temperature copolymerization of bottoms from styrene rectification with maleic acid, which can be used for preparation of antioxidant solutions for further adding at the polybutadiene processing before passing the latter to the step of isolation.

DOI: 10.1134/S1070427207110407

Vinylaromatic hydrocarbons are the most widespread monomers for producing plymeric materials of wide application. However, their production is accompanied by the formation and accumulation of great amount of wastes (about 20-25 kg per one ton of commercial styrene), basically the bottoms forming at the isolation and purification of the main product [1]. The bottoms are composed of many various organic compounds including styrene, which cannot be isolated completely at the current industrial technology. The composition of bottoms at the styrene rectification (styrene bottoms) in a great extent is defined by the method of styrene producing, the used inhibitors and technological features of the processing. Depending on the conditions of its isolation, the styrene content in styrene bottoms can vary from 10 to 50 %, the content of polystyrene can fall to the range from 15 to 70% [2]. A problem for effective using the styrene bottoms consists in the fact that its qualitative and quantitative composition varies in a wide range. Despite this fact, research works on their processing and application are in progress. A series of work has been published in this respect [3–5]. The proposed method of styrene bottoms processing are mainly directed to the obtaining on their base of polymer materials, and this has been applied in commercial scale. The polymers based on the styrene bottoms were widely used at manufacturing of painting materials. In some publications [6, 7] was shown performance of application the polymeric materials from styrene bottoms for impregnating compositions for protection and improving commercial quality of wooden materials and for similar purposes. Nevertheless, up to now the prospecting research on processing and application of styrene bottoms are continued. Exploring the most progressive methods for processing the sturene bottoms are important in scientific and applied sense because this could decrease loses of valuable hydrocarbon raw material, obtain materials with a complex of new properties and improve ecological situation. Development of new technologies and processes of recovering based on secondary products still remains an important industrial challenge toward increase productivity of technological processes and economical consumption of chemical raw materials.

The aim of this work is producing low molecular weight polymeric material from the styrene bottoms for the further consideration of its application in polybutadiene manufacturing.

The low molecular weight polymeric material from styrene bottoms can be introduced into polybutadiene resin by the following methods:

- Direct mixing of solution of polybutadiene with a solution of low molecular weight polymeric material based on the styrene bottoms;

- Dissolving in the obtained low molecular weight polymeric material of antioxidants before its passing to the mixing with polybutadiene solution;

- Dissolving antioxidants in the low molecular weight polymeric material followed by emulsifying the obtained polymer-antioxidant mixture in water phase containing surfactants and mixing this emulsion with the polybutadiene solution.

The two last methods are preferable because adding the polymeric material from styrene bottoms to the polybutadiene allows rather complete consuming the expensive raw material.

For isolation of the rubber from solution we used method of aqueous degassing. The water removing was achieved by drying in a drier at 80–85°C. Further the polybutadiene thus obtained was used for preparation of rubber mixtures and vulcanized products.

In the present work we studied synthesis of polymers based on the styrene bottoms from the join production of styrene and propylene oxide, containing, by the data of chromatography, the following compounds, %: styrene 28.08, acetophenone 35.45, methylphenylcarbinol 10.96, ethylbenzene 0.96, α-methylstyrene 1.65, diphenyldiethyl ether 4.49, benzaldehyde 1.58, not identified components 3.93, heavy residue 12.9.

To the styrene bottoms was added maleic acid in amount up to 5.0 %. Use of maleic acid in this process gives rise to solving the problem of its application, because maleic acid is a by-product which did not find quality application [8].

The following procedure was used for the synthesis:

To a reactor equipped with a stirring unity were loaded styrene bottoms and added precalculated amounts of maleic acid and hydroperoxide. The reactor was hermetically closed and the reaction mixture was heated at 110, 130 and 150±2°C and kept a given time at continuous stirring. The process was monitored by periodical taking samples from the reactor and distilling from them off the unreacted compounds.

Experimental data on the influence of temperature and the process duration on the yield of polymeric materials from the styrene bottoms are shown in Table 1.

The study showed that polymerization of styrene and other unsaturated compounds composing the styrene bottoms requires elevated temperature and long process duration. Additional introducing pinane or ethylbenzene hydroperoxides (5% calculated on unsaturated, the process duration 50 h) to the reaction mixture showed that their absence in the reaction mixture does not affect significantly the yield of polymeric materials based on styrene bottoms (Table 2). Study of application in the process of hydroperoxides, the ethylbenzene hydroperoxide in particular, was stipulated by the fact that this compound is formed intermediately and hence its formation in this step of the process is not excluded.

Table 1. Effect of process duration and reaction mixture temperature on the yield of polymeric materials based on styrene bottoms and maleic acid

Process temperature, °C	Yield of polymeric materials (wt.%) at the process duration, h:					
	3	6	9	16	30	50
110	38.8	42.6	52.7	58.3	61.2	67.9
130	43.9	47.1	55.1	66.6	75.4	84.7
150	48.3	53.6	59.2	69.8	77.3	86.5

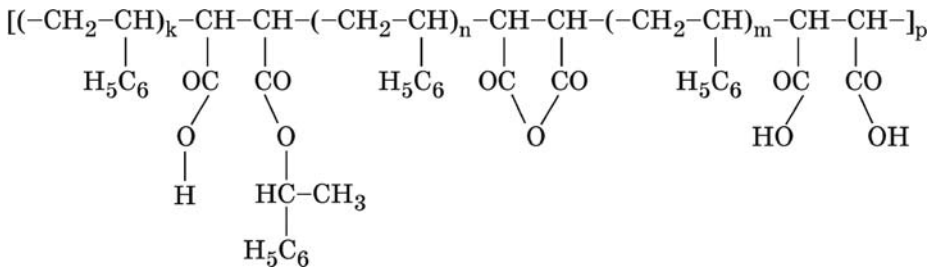
$$C_6H_5–CH_2–CH_3 + O_2 \rightarrow C_6H_5–\underset{\displaystyle OOH}{\underset{|}{CH}}–CH_3$$

Therefore consideration of a possibility of its application in the same technological process is reasonable. This would allow solving the problem of application the side product of the manufacturing and increase yield on polymeric materials from styrene bottoms. However, as our study showed, adding more hydroperoxides during the process do not increases yield. On the other hand, this results in the increase of content of low molecular weight fraction due to decomposition of the initiator and probably owing to destruction and oxidation processes under action of peroxide.

Mathematical treatment of experimental results gave equations reflecting the effect of the polymerization processes duration (x, h) on the yield of polymeric materials based on styrene bottoms (Y, %) at various temperatures (110, 130 and 150°C).

$$Y_{110} = 36.78 + 1.439x - 1.671 \times 10^{-2}x^2$$
$$Y_{130} = 38.49 + 1.897x - 1.968 \times 10^{-2}x^2$$
$$Y_{150} = 44.55 + 1.690x - 1.725 \times 10^{-2}x^2$$

It is significant to note that the process of producing polymeric material based on styrene bottoms in this case includes various processes and joins polymerization, dehydration of methylphenylcarbinol, reaction with maleic acid and others, leading not only to polymeric material but also to ethers and esters. The esters (ethers) formed can play the role of plasticizer in the polymeric material based on styrene bottoms. The esters (ethers) should be compatible with the polymer composition based on the styrene bottoms, containing many polar functional groups in the chain. Presence of such components in the reaction products poits to formation of rather complex multicomponent system possessing a complex of new versatile properties. Structure of the obtained polymeric material can be represented as follows:



In some publications [9–11] has been shown a possibility of application low molecular weight copolymers from the wastes and side products of petroleum chemistry for making rubber mixtures. Adding the polymeric materials from side products of petroleum technology to butadiene resin, which is characterized by low plasticity, allows to increase the plasticity and decrease viscosity of the resin. By their action such additives approaches to the plasticizer PN-6.

An important aspect is the method of introducing the polymeric material to the rubber and estimation of its effect on the properties of the obtained resin, resin mixtures and vulcanized rubber. Introducing the of low molecular weight polymeric materials based on wastes and side products of petroleum chemistry to the resin by means of rolling in the process of producing rubber mixtures does not provide fast and homogenous distribution of the material in the rubber matrix bulk. The most prospective is using a solution of the polymeric material in toluene for preparation of solution of an antioxidant followed by adding it to the solution of polybutadiene before degassing the latter. Even more prospective is preliminary emulsification of the obtained toluene solution of the styrene bottoms polymer and antioxidant before passing the mixture to mixing with polybutadiene solution. The polymeric material based on styrene bottoms possess many active oxygen-containing functional groups enhancing its affinity to aqueous phase, and this should provide formation of stable emulsion practically without adding surfactants. However, emulsification requires use of water phase which contains alkali. The latter reacts with anhydride and carbonyl functional groups to form salts which provide formation of stable emulsion.

Table 2. Effect of hydroperoxide nature and process temperature on the yield of plymeric materials based on styrene bottoms

Hydroperoxide	Yield of polymeric material (wt %) at the temperature, °C :		
	110	130	150
Pinane hydroperoxide	68.4	85.2	87.2
Ethylbenzene hydroperoxide	68.2	84.9	78.1

Table 3. Properties of butadiene rubber, rubber mixtures and vulcanizates

Characteristics	Content of styrene bottoms copolymer in the polybutadiene, wt%				Oil PN-6, 5.0 wt%	Check sample

Aging coefficient (100°C, 72 h) :						
- by strength	0.42	0.44	0.50	0.49	0.35	0.42
- by relative elongation	0.54	0.55	0.59	0.57	0.49	0.52

Note: Vulcanization temperature 143 °C, vulcanization duration 40 min, agidol-2 content 0.6 wt%

The molecular mass of the polymeric materials from styrene bottoms determined by the method of viscosimetry falls to the range 20000 to 30000.

To the obtained from styrene bottoms polymeric material was added additional toluene to decrease its viscosity and for obtaining solution with the concentration 40–60 wt.%. Then was added an antioxidant (agidol-1, agidol-2, BTC-150, BC-30 or other) used at the polybutadiene producing. The polybutadiene with polymeric material from styrene bottoms and antioxidant emulsified in the aqueous solution containing 2.0 % of sodium hydroxide was then isolated from the solution by means of aqueous degassing and dried in a dryer at 80–85°C. From the obtained samples of polybutadiene the rubber mixtures were prepared alongside the common prescriptions and vulcanized. The resins and vulcanizates obtained were examined by commonly used methods. The results obtained are shown in Table 3.

Consideration of the obtained results shows that introducing the polymeric material based on styrene bottoms to polybutadiene provides mild plasticizing action and leads to small decrease in elastic-strength characteristics of the vulcanizates. This is seen particularly when content of the polymeric material from styrene bottoms in the polybutadiene is enhanced. Estimation of the effect of PN-6 oil on the polybutadiene properties in comparison with the effect of the synthesized polymeric material shows advantage of the latter expressed as lesser decrease in strength characteristics of vulcanizates. This can be explained by strengthening of polymer matrix by polystyrene fragments which are known to possess higher physico-mechanical properties than polydienes.

It should also be noted that adding antioxidant together with polymeric material provides less loses of the former in the process of degassing (isolation of rubber from solution)consisting in removing not polymerized monomers and solvent from the polymerizate. This can result from the fact that at the preparation of solution the phenol or amine type antioxidant can form hydrogen bonds with the molecules of polymeric material based on the styrene bottoms. As a result, occurs decrease in the loses of the antioxidant in the step of degassing. Probably a "depo" of antioxidant is formed which provides more rational use of the latter, decrease in loses and admitting greater protecting properties of the commodity. The possibility of formation of antioxidant's "depo" has been shown in [12]. This should enhance the rubber and based on it vulcanizates quality.

CONCLUSIONS

1. By copolymerization of styrene bottoms with maleic acid can be obtained polymeric materials.

2. Additional introducing of radical initiators does not lead to increase in the polymeric material yield.

3. A solution of the synthesized polymeric material can be used in the polybutadiene technology for preparation of antioxidant solution or emulsion.

4. It is reasonable to provide content of the polymeric material in the polybutadiene matrix on the level below 3.0 wt.%.

5. The polymeric material based on the styrene bottoms shows milder plasticizing effect on the properties of the forming rubber than the PN-6 oil.

6. Introducing the antioxidant together with the polymeric material based on styrene bottoms allows to enhance stability of vulcanizates toward thermo-oxidative aging.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Technology for Producing Adsorbents from Petroleum Residues

Yu. V. Pokonova

St. Petersburg State Technological Institute (Technical University)

Received February 28, 2007

Abstract—Advantage of use residue from thermal cracking and products of its condensation as components of the mixture for manufacturing mechanically rigid (93%) granulated and ground carbon sorbents with extended volume of micropores (up to 0.27 cm^3/cm^3), showing enhanced sorption activity (E is up to 25.6 kJ mol^{-1}) and high ability of separation various gas mixtures is demonstrated. As a carrier for medicine preparations these adsorbents show higher performance as compared with industrial samples. Solutions of the cracking residue can be used for impregnation of worked out zeolites for petroleum technology and for production of organomineral adsorbents with high adsorption capacity on extraction mercury from sewages.

DOI: 10.1134/S1070427207110419

Currently in Russia is mined and treated up to 80% of petroleum with high an extra high content of sulfur which also contain up to 20% of petroleum residues which, as our study showed [1–4], are appropriate as raw material for obtaining many practically important products with higher exploitation properties as compared with the analogs produced by industry. Profound treatment of petroleum for enhance yield of light petroleum products and improving their quality is achieved by means of secondary thermal technological processes. This results in formation of cracking residues. Taking into account low cost of these residues, great enough resources of this raw material and high exploitation properties of the products based on them, use of the cracking residues can be considered as reasonable practically and economically. The prospective products that can be used as binders and as components of mixtures at producing adsorbents are the multifunctional compounds in the cracking residues. Their molecules consist of condensed aromatic structures with some of heterocycles and alkyl substituents. The cracking residues contain very reactive double bonds capable of entering to polymerization reactions for three-dimensional structuring. Therefore the cracking residues are cross-linking (structuring) agents like divinylbenzene, butadiene and glycol dimethacrylates.

In the present publication we summarize the methods for application cracking residues as components of a mixture for obtaining carbon adsorbents for organo-mineral adsorbents.

1. APPLICATION OF CRACKING RESIDUES AS COMPONENTS OF MIXTURES

As a raw material for the investigation we used residue of thermal cracking with the following characteristics: density kg/m^3, coking capacity 39.4%; temperature of softening by ring and ball 82°C, iodine number 93; content, wt%: asphaltenes 34.5; carbenes and carboids 6.6; sulfur 2.3. Sludge at benzene purification contained, wt%: tar-asphaltene substances 34, sulfuric acid 26. Also was used coil dust from Kuznetsk field (the mine Central) of the following composition, wt%: volatile substances 13.7; ash 8.1; carbon 90.2, hydrogen 3.9.

Adsorption and selectivity properties were estimated from the values of specific capacity on low-boiling gases. The conditions of developing chromatographic analysis were taken as follows: column height 1 m, internal diameter 4 mm, temperature of column 28, 110 and 160°C; carrier gas helium (rate 41 ± 0.1 ml/min), the adsorbate doze volume 1.0 cm^3; the sample loaded to the column 12 cm^3; adsorbent particle size 0.25–0.5 mm.

The cracking residue being not modified can not be used directly as a component of mixture due to its low softening temperature: in the beginning of the process it can be melted out from the mixture. On the other side, owing to its high reactivity it can react with aldehydes, and the polycondensates thus obtained can be used directly (after carbonization and activation) or can be included into the mixture composition. An example of

such polycondensate is furanoformolyte which has been obtained from cracking residue, technical furfurol and acidic sludge. Inclusion of the latter allows to use its asphaltene tars as additional source of raw material and sulfuric acid as a catalyst [5]. At mixing occurs vigorous exothermic reaction and appears a frothed block with low mechanical strength and therefore easily crumbling. The reaction is completed in 15–20 min, and then the block should be kept in a thermostat at 100°C for 2 h for solidification, then it is ground and used in composition of the mixture for producing adsorbents by industrial scheme. For producing the polycondensate (furanoformolyte) the ratio of the components cracking residue : furfural : acidic sludge equals 33 : 25 : 42, and the mixture for the adsorbents consists of, respectively, 39 : 39 : 22 wt% of coal dust, furanoformolyte and wood tar. The adsorbents produced alongside the industrial scheme [6–7] (Table 1) show high C:H ratio, that is, they are highly condensed, contain low ash, contain 10-fold more oxygen and twofold more sulfur than industrial carbon AR-3 (recuperation carbon) providing high polarity of surface. The performed investigations (Table 1) attest presence of molecular size pores in the adsorbents with less than 10% combustion loss; they sorb methane, carbon dioxide and xenon better than industrial adsorbents.

The high content of heteroatoms that provide surface polarity give rise to ability of intensive sorption of polar gases. Thus, ratio of retained volumes of xenon and methane (that differ by polarity almost by 21.5 times at approximately equal sizes) is 1.8 times higher for the cracking residues as compared with AG-2 gas carbon. Hence, these adsorbents can be used for fine purification of hardly sorbed and polar gases.

A possibility to change properties of adsorbent is using the cracking residues copolycondensates of different nature. For this purpose can be used the compounds with reactivity similar to that of the cracking residues, in part, schist phenols and tars. By industrial technology the copolycondensates with the schist tars and phenols (Table 2) are produced with the high mechanical strength and can be used as ground adsorbents [8]. For this purpose the copolycondensate prils were exposed to thermo-oxidation (180°C) and carbonization in rotating drum oven in two steps (450 and 800°C) under the CO_2 atmosphere and activated with steam at 820°C. As seen from the data in Table 3 the difference in recipe and in content of gel fraction affect the carbonizates properties. The highest yield of carbon residue is found in the case of copolycondensate 1 and the product was the most dense and rigid. Arter two steps of carbonization it has

the lowest volume of pores. The most extended volume of pores on benzene (0.28 cm^3/cm^3) has the carbonizate from the product 2 (Table 3), containing maximal gel fraction and schist phenols content.

The values of total volume of pores of the carbonizates with low combustion loss (Table 3) on various pycnometric liquids point to presence in the adsorbents of the properties of molecular sieves. The maximum strength inherent in the adsorbent 1 obtained from the copolycondensate with the lowest content of gel fraction (76%), that is, with the lowest cross-linking.

Earlier was shown [9] that the adsorbents by their sorption and retaining capability toward γ-globulin can be recommended as a base for hemo-sorbents. Characteristics of the above described adsorbents show that they also can be used for this purpose. To confirm this viewpoint the ground adsorbent 2 containing minimum ash was treated by 6N solution of HC1 followed by washing with diluted 0.5N solution of HC1 to iron for reducing ash content. Then the ground adsorbent was heated under vacuum and washed in a column with 2.6% NaC1 solution. After 10 times washing with equilibrium with the adsorbent 2.5% solution of sodium chloride it was examined on mechanical strength. The loss due to mechanical damaging was 5–6%. For estimation efficiency of application the ground adsorbent as a carrier for medicine preparations it was saturated

with caffeine – sodium benzoate. Through a column with the adsorbent was passed a solution of caffeine – sodium benzoate (concentration 40 g/l) with the rate 1.3 ml/min. Adsorption was conducted till complete saturation of the adsorbent, then with the same rate the column was washed with 0.85% NaC1 solution [5]. Then was measured the amount of sodium benzoate retained in the sorbent after washing. The adsorption ability on caffeine–sodium benzoate was determined under isothermal conditions at keeping for 7 days, change in concentration was measured spectrphotometrically. For estimation we calculated selectivity factor ($K_{selectivity}$), characterizing partition coefficient for caffeine–sodium benzoate between the adsorbent and solution (Table 5): $K_{selectivity} = \alpha/C_{equilibrium}$, α is the adsorbent capacity on the caffeine – sodium benzoate at equilibrium concentration.

These data show that retaining ability of the adsorbent on caffeine – sodium benzoate is satisfactorily in comparison with the carbons applied for extraction compounds from solutions: it is lower compared with SKT but higher than BAU shows.

2. APPLICATION OF CRACKING RESIDUE AS IMPREGNATOR

In the oil refinement technology are used zeolites, mostly for deparaffinization. The zeiolites extract

paraffines from petroleum fractions and then desorbed with ammonia, calcinated and passed for recirculation. Zeolite can work for 4–5 years and then should be renewed. They are the side products of oil refinement appearing in multitons amounts. But they can be utilized for producing practically important products, inpart, organomineral adsorbents. In this publication we propose a technplogy fro impregnation the used zeolites with a solution of cracking residue in furfural. The binder is prepared by the following procedure: crude furfural is mixed with cracking residue and sludge, then sludge is added to the mixture in portions.The mixture is used for impregnation of zeolite in an installation consisting of column 30 cm height and 10 cm diameter with porous glass membrane at bottom. To the column bottom is attached a receiver for collection of unused impregnating mixture and a cock on side wall below the glass membrane, attached through throttle bottle to vacuum pipe. The column is filled by half with worked out zeolite and impregnator is passed through it. After coplete impregnation, when the liquid is passed the zeolite layer, the column is sealed and evacuated for 15 min. Then fresh portion of impregnant is loaded and operation is continued till the impregnant is no more consumed and is passed through the zeolite layer almost without delay. The impregned zeolite is left in the column to formation of three-dimensional polycondensate, then is unloaded into flat metallic pan, covered with metallic sheet and left for 24 h in air to complete solidification. Then stick particles are separated in a shaker. The impregnated zeolites are carbonized in a rotating oven at 800 ± 10°C under carbon dioxide and activated in the same oven at 82010°C with steam to combustion loss 30–35%. The obtained organo-mineral zeolite was used for extraction mercury from waste water of the following composition: pH 8.12, content of sulfate ion 480 mg/l, chloride ion 124.1 mg/l, mercury as nitrate 1.24 mg/l.

The adsorption ability on mercury was measured by atomic absorption spectroscopy on a Perkin-Elmer instrument, model 503. Kinetic characteristics were determined by the method of constant concentrations of the targeted component and salt composition (with change of solution under static conditions). Sorption capacity of the impregnated zeolite at combustion loss 30–33% was 15.8–16.6 mg/g at 120 h sorption. Under the same condition the sorption capacity of KAD-iodine was 5.6–6 mg/l.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

On the Synthesis of Glass and Glass-Crystalline Black-Blue Facing on Thin Ceramic

A. V. Zaichuk, V. V. Koleda, and Ya. I. Belyi

Ukrainian State Chemical Technological University, Dnepropetrovsk, Ukraine

Received June 28, 2007

Abstract—By x-ray phase analysis the optimal temperature is established for the spinel formation in the oxide system Co_2O_3–Fe_2O_3 at the producing ceramic black-blue pigment and the phases playing the role of basic chromophores. The synthesized pigments provide the glass facing with black-blue color and strong flashing (up to 86%) and with semi-dull fine crystalline facture based on the developed unfritted glaze characterized by strong and stable color in a wide range of roasting temperature.

DOI: 10.1134/S1070427207110420

The consumers' demand of ceramic products, those of everyday use in particular, is defined in much by their appearance which in turn depends on the color and quality of glaze facing. Producing the exclusive strong drinks induces necessity in development of special ceramic bottles with high aesthetic and decorative characteristics. Therewith significant is the process of glazing, that is, formation on surface of glass layer either flashing or of semi-dull fine-crystalline facture. Developing research in this direction is very actual. Therefore the purpose of this work is development of compositions and investigation of pigment-containing black-blue glaze covers.

The blue and black pigments, as is known [1], should be synthesized as a rule at high temperature (up to 1300°C), predominantly from the cobalt, iron, manganese and chromium oxides.

Earlier investigations [2] showed that it is reasonable to use two-component oxide system CoO–Fe_2O_3 for the synthesis of black ceramic pigments, in part, for high melting unfritted glazes. The basic chromophores in this system providing formation of required color of glass layer are cobalt ferrite ($CoFe_2O_4$) and free cobalt oxide.

Taking above into account, at the synthesis of such pigments we studied the compositions that include cobalt and iron oxides with Co_2O_3/Fe_2O_3 ratio in the range from 1.40 to 2.38. Their thermal treatment initially was carried out in laboratory roasting furnace at maximal temperature 1000°C with isothermal 1 h exposure.

From the data of x-ray phase analysis (Fig. 1) follows that the experimental pigments besides cobalt ferrite also contain cobalt oxide, the latter in much bigger amount than necessary for stoichiometric spinel $CoFe_2O_4$. At higher values of Co_2O_3/Fe_2O_3 ratio the intensity of diffraction maxima corresponding to cobalt oxide (Co_3O_4, d = 2.43; 2.86; 1.43) increases considerably. The phase composition of the pigment also includes gematite (α-Fe_2O_3), appearing due to incomplete spinel formation.

The studied pigments were ground in a ball mill to the particle size 5–10 m and were added in amount up to 8 wt. fraction above 100 wt % into unfritted transpaent glaze containing pegmatite, sand, chalk, kaolin and microvollastonite. The obtained dross with 38% moisture was applied by pulverization on the ceramic samples that after drying were roasted at maximum temperature 1200°C for 2 h. Properties of the glazes obtained are listed in the table.

The data obtained show that including the synthesized by us ceramic pigmets into the mixture for producing unfritted transparent glaze allows obtaining after roasting the glass layer of strong black-blue color, as seen visually and as follows from spectral wavelength of the cover which is related to purple region (575–579 nm), as well as from low values of color purity (1–2%) and CDR (coefficient of diffuse reflection) in the range 3.20–3.69% inherent in black color. The most intense black-blue color has the glaze containing pigment n-8 with maximum Co_2O_3/Fe_2O_3 rate. The CDR of such glass coating material is minimal, being equal to 3.20%, and flash is 87%.

Formation of cobalt ferrite at the thermal treatment of the pigment mixture leads to black colorization of glaze cover. Appearance of blue color is stipulated by

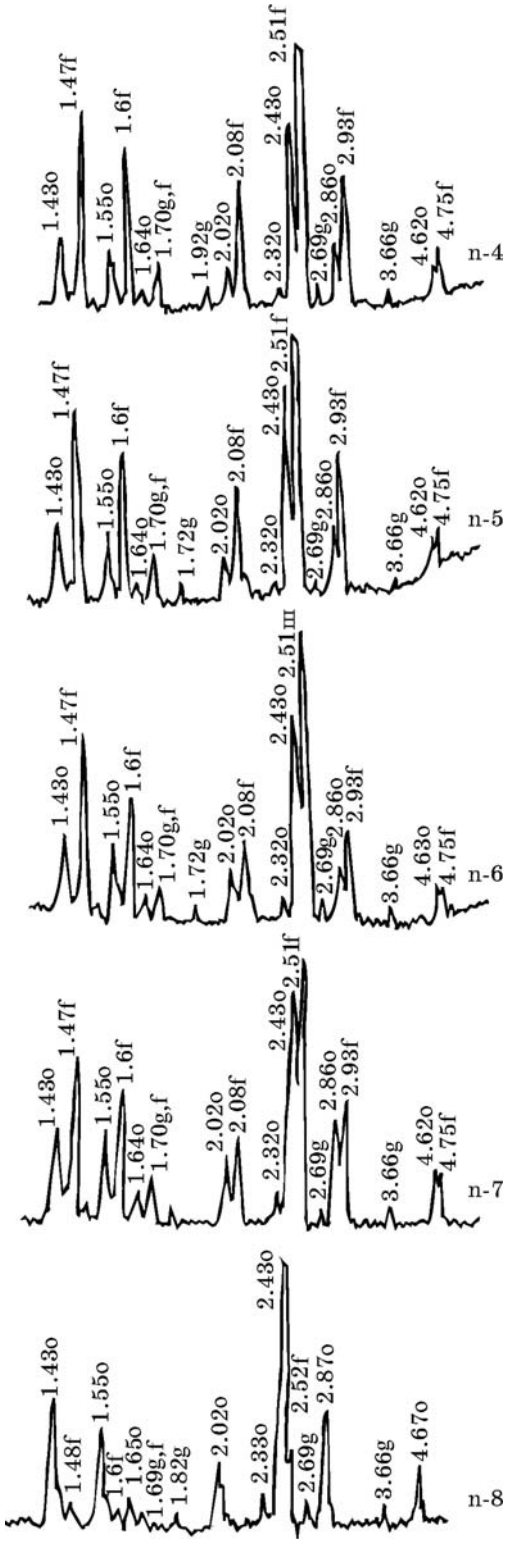

Fig. 1. Difractograms of experimental ceramic pigments synthesized at 1000°C (numbers correspond to the table): (f) cobalt ferrite ($CoFe_2O_4$); (g) gematite (α-Fe_2O_3); (o) cobalt oxide (Co_3O_4).

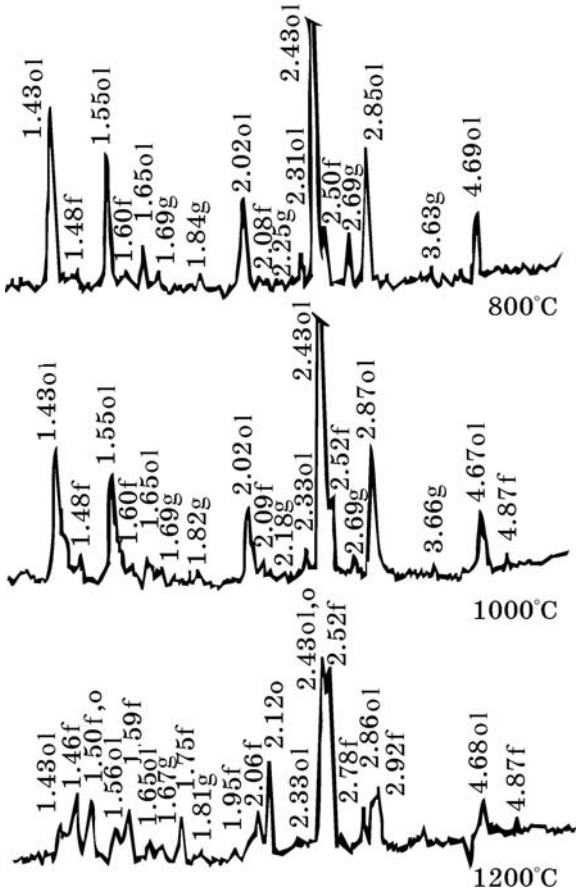

Fig. 2. X-ray diagrams of experimental ceramic pigment n–8 synthesized at various temperatures: (f) cobalt ferrite ($CoFe_2O_4$); (g) gematit (α-Fe_2O_3); (o1) cobalt oxide Co_3O_4; (o) cobalt oxide CoO.

the presence in the glass layer of tetracoordinated ions of bivalent cobalt arising due to dissolution in the glaze melt of the not bound into spinel cobalt oxide in the composition of experimental pigment mixture. As showed investigations, increase in the fraction of Co_3O_4 in the pigment leads to increase in the fraction of blue color in the resulting glass layer.

Thus, at roasting the studied not fritted glaze its color appears via two mechanisms: pigmental – by formation of cobalt ferrite, and ionic, due to dissolving cobalt oxide in melted glaze and formation in the glass coating of stable complexes consisting of tetracoordinated Co^{2+} ions.

A disadvantage of experimental pigment-containing glaze covers is appearance on the surface so-called "metallization" due probably to the incomplete proceeding of the processes of phase formation in the studied pigment mixtures roasted at 1000°C.

Characteristics of glaze coverings roasted at 1200°C

Rate Co_2O_3/Fe_2O_3 in pigment mixtures	Number of pigment				
	n–4	n–5	n–6	n–7	n–8
	1.40	1.59	1.81	2.07	2.38
Properties of glaze coverings					
Color (visual estimation)	Black with blue background		Black, tinged with blue	Black-blue	Saturated black-blue
Color tint, nm	577	575	575	575	579
Color purity, %	2	2	2	2	1
CMR*, %	80	82	86	86	87
CDR**, %	3.69	3.59	3.40	3.35	3.20

* Coefficient of mirror reflection.
** Coefficient of diffuse reflection.

For elucidating optimal temperature of the synthesis of pigment n-8 whose composition provides best color characteristics, its initial mixture was roasted in the temperature range from 800 to 1200°C.

As seen from x-ray diagrams (Fig. 2), the phase composition of pigment n–8 powder obtained at 800–1200°C consists mainly of cobalt oxide Co_3O_4 and includes cobalt ferrite ($CoFe_2O_4$) and gematite (b-Fe_2O_3).

Phase composition of the pigment n-8 synthesized at 800°C is characterized by high content of Co_3O_4 (d = 2.43; 2.86; 1.43) and α-Fe_2O_3 (d = 2.69; 1.84; 1.69), as confirmed by intensity of diffraction maxima, and this fact points to incomplete spinel formation.

Roasting at 1000°C also not allows complete binding iron oxide at spinel formation, as confirmed by the presence of low intensity peaks characteristic of gematit (Fig. 2b). The maximum possible formation of spinel in the pigment appears at roasting temperature 1200°C, as seen from high intensity of main diffraction maxima (d = 2.52; 1.50; 1.46) related to cobalt ferrite. Intensity of the peaks inherent in cobalt oxide and b-Fe_2O_3, on the contrary, falls down. Besides, partial transfer of Co_3O_4 into CoO (d = 2.43; 2.12; 1.50) is noted, Fig. 2c.

At higher temperature the synthesis of these pigments leads to less "metallization" of glaze cover, and roasting of the ceramic pigment at 1200°C results in its complete absence. This fact says in favor of the statement that this temperature provides the most complete interaction of components of pigment mixture, cobalt and iron oxides, promoting decrease in content of free cobalt oxide and not bound iron oxide in the composition of the synthesized pigments providing their rather high stability toward aggressive glaze melt. The glass cover formed in this case are characterized by saturated black-blue color which is confirmed by the low CDR value and color purity, 3.05% and 1% respectively, and by high flashing, 86%.

Using these developed pigment-containing glaze covers we investigated ways for achieving lusterless surface. We proceeded from the fact that known methods of synthesis the covers with low dull are differ principally from each other by the mechanism of the process of their preparation. Our method consists in the adding to the glaze composition of mineral or synthetic material providing function of high-melting filler. This method is the simplest and most economical one.

Therefore for producing glass black-blue covers with semi-dull fine crystalline structure with high decoration characteristics of the fine ceramic goods in the process of their exploitation, we studied introducing into ground mixture of not fritted pigment-containing glaze of high disperse fire resistant fillers as alumosilicate chamotte (ShK-38) and crude alumina (G-00) in amounts 8–14 and 1–4 wt. fraction respectively.

Dependence of optical and color characteristics of glass cover on the content of experimental additives in the composition of not fritted glaze is shown in Fig. 3.

From the graphic plots follows that increase in amount of alumosilicate chamotte in the composition of experimental pigment-containing glaze from 8 to 14 wt.

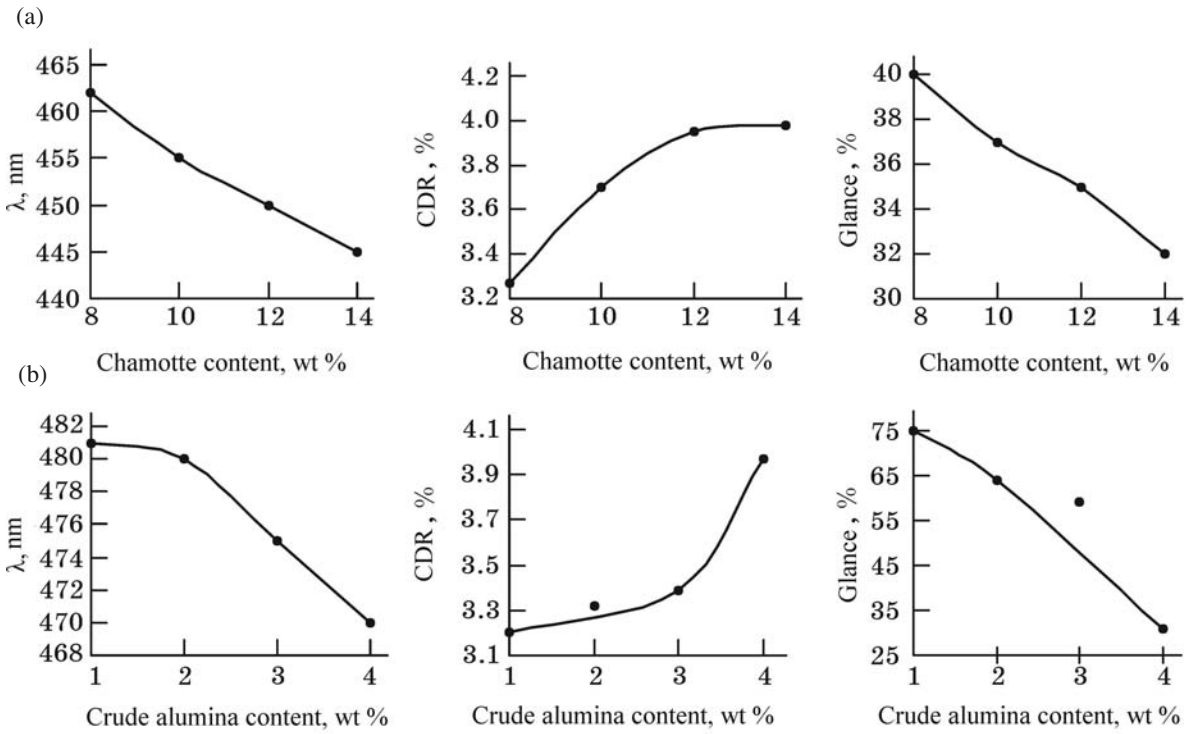

Fig. 3. Effect of flame resistant fillers on optical and color characteristics of experimental glaze covers. (a) Chamotte, (b) crude alumina.

fraction leads to stepwise decrease in flashing of glass cover to 32%. Simultaneously was registered certain decrease in strength of black-blue color, as seen from increase in CDR from 3.27 to 3.98% and by shift of wavelength value from 462 nm to shorter wavelengths in blue part of spectrum, 445 nm.

Increase in the composition of experimental glaze of crude alumina up to 4 wt. fraction results in formation in the process of roasting of semi-dull surface with reduce in flashing from 75 to 31%. However, simultaneously grows CDR, from 3.20 to 3.97%, due to decrease in saturation with black-blue color. The main wavelength of glaze cover falls to the range 470–481 nm.

The characteristics of the glass cover prepared by roasting at 1200°C shows that shamotte and crude alumina being homogenously distributed in the glaze melt practically are not dissolved in it within this temperature range and remains as fine disperse particles thus providing micro-heterogeneity of the system and at cooling of the ceramic product glass layer is formed with fine crystalline inclusions differ by refraction index from the bulk glass mass. Finally this leads to appearance of unusual decorative effect of semi-dull surface. Optimal concentration of the flame resistant additives for obtaining semi-dull glaze covers is: chamotte 8–10 wt. fraction, crude alumina 3 wt. fractions [3].

Thus, as a result of performed investigations we synthesized ceramic pigments based on the iron-cobalt oxide system at the temperature 1200°C, which provide formation of glass cover on fine ceramic goods with saturated black-blue color with either high (up to 87%), or low (37–59%) flashing, formation temperature is 1180–1220°C, using not fritted glazes not containing deficient and very expensive raw material (barium carbonate, zinc oxide and talk). The developed glazes are successfully used in technological processes at "Dneprokeramika" enterprise (town Pologi, Zaporozh'e area) for external covering ceramic bottles used for exclusive alcohol beverages.

Abstract—Grinding of ordinary phosphorite powder of Central Kyzylkum with urea nitrate and ammonium carbonate salt to the particles size less than 0.16 mm is shown leading to significant increase in content of consumable by plants form of P_2O_5 in the products.

DOI: 10.1134/S1070427207110432

In 21 century the world food problem increased sharply owing to higher growing of population as compared with the increase in production of food and due to decrease in such basic resources as arable land, fresh water basin and energy sources necessary for agricultural production [1]. The population growing on the planet can be judged form the following data. To the beginning of 20-th century the whole population was 1.62 billion. In the following 60 years the population increased twice and in the next 25 years it triplicated. In 2000 the world community consisted of 6.1 billion of inhabitants. According to calculations, at the current rate of growing population to the year 2050 the planet will have 8.9 to 10 billion people. At the same time the land area under food grains fall from 0.24 to 0.12 hectare per capita. By calculations, to 2050 it will be contracted to 0.08 hectare per capita.

The processes of arable land contracting per capita stipulate the necessity of wide application of industrial technology in agriculture. The second half of 20th century becomes "era of chemization" due to wide application of mineral fertilizers and pesticides. The world consumption of mineral fertilizers within 40 years period (1951–1990) increased ten-fold, from 14 million to 140 million ton. Many countries were able to solve the food problem in part due to chemization. A bright sample is China: in 10 years of reformation of agriculture (1975–1984) at the practically the same area of arable land consumption of mineral fertilizers increased from 6 to 19 million ton on active component, that is, 3.2-fold. This led to increase in grain production to 365 million ton providing absolute increase 120 million ton.

In 21-th century the exclusively important factors for solving world food problem become chemization and irrigation. In Uzbekistan there is 25 736 000 hectare of agricultural land, but 3 730 000 hectare is irrigated [2]. But the irrigated land gives 97 % of all agricultural production of the Republic. Due to insufficient water resources, Uzbekistan has no possibility of significant extension of the area of irrigated arable land. Therefore priority belongs here to the problem of chemization of agricultural production.

Demand of nitrogen, phosphorus and potassium fertilizers in the Republic is 761 820 ton of nitrogen, 518 270 ton of P_2O_5 and 278 120 ton of K_2O as 100% active substance. The industry produces 740,000 ton of nitrogen and 137,000 ton of P_2O_5. Potassium fertilizers 25,000 ton of K_2O purchased from Russia. While providing agriculture with nitrogen fertilizers is more or less satisfactory, the problem with phosphorus and potassium is hard. The Republic Government makes all possible for improving this situation. It was decided to built Dekhkanbad plant of potassium fertilizers based on Tyubegatan birthplace of potassium salts in Kashkadarine region, to increase facility of Kyzylkum phosphorite mill, on reconstruction of Almalyk "Ammofos" and of "Samarkandkimye" join stocks. Despite, the plants producing phosphorus-containing

fertilizers exert problems. The plant of Republic began treatment of local raw material, the phosphorite of Central Kyzylkum. This ore is poor in respect of phosphorus, contains much carbonates and chlorine and is difficultly enriching. In the world such raw material is used for production of ordinary superphosphate. Such low quality product is manufactured by Kokand plant, it contains 11% of P_2O_5 and 1.5% of N. To produce high quality phosphorus-containing fertilizer from such ore enrichment is requiring. The multistep enrichment is carried out in Kyzylkum mill, it includes grinding, dry enrichment giving ordinary phosphorite powder, washing out of chlorine and roasting for removing CO_2. In fourth quarter of 2006 in this plant were brought into use the facility for producing 400 000 ton/year of washed and roasted phosphorus concentrate containing up to 30% of P_2O_5, 200 000 ton/year of washed and dried phosporus concentrate (18–19% P_2O_5) and 200 000 ton/year of ordinary phosphorite powder (16-18% P_2O_5).

Washed and roasted phosphorite concentrate will be used in Almalyk "Ammofos" for producing concentrated phosphorus-containing fertilizers: ammophos, superphos and ammonium sulfate-phosphate. From washed and dried phosphorite concentrate in Kokand plant will be produced ordinary ammonized superphosphate and from the ordinary phosphorite powder in Samarkamd plant will be produced nitrocalcium phosphate [3]. In summary, industry will produce in the year 2010 169 000 ton of 100% P_2O_5, but this amount is still far from agriculture demand of phosphorus fertilizers.

Enriching the Central Kyzylkum phosphorites in Kyzylkum phosphorite mill leads to formation of wastes in a great amount. At the dry enriching at producing ordinary phosphorite powder the dust fraction (18–19% P_2O_5) and mineralized mass (12–14% P_2O_5) are pushed aside. At the washing out chlorine the 30% of P_2O_5 in the ore is washing off with washing water into sludge receiver. The P_2O_5 content in the phosphorite from dried sludge is 8–10%. These wastes in our opinion form a reserve for increasing production of phosphorus-containing fertilizers. But acid methods are not acceptable for their treatment. For these materials would be appropriate so-called mechanochemical activation: transfer of not plant feeding form of P_2O_5 in the raw material into acceptable form by mechanical treatmet in the presence of certain chemical reagents [4–6].

We studied mechanochemical activation of various sorts of Central Kyzylkum phosphorites with ammonium nitrate and sulfate [7–10]. Both ammonium nitrate and ammonium sulfate increased sharply the content of acceptable form of P_2O_5 in the phosphate raw material after mechanical activation. The product of phosphorite mechanochemical activation has one defect: it has dust-like form not convenient for introducing into soil. However, this defect can be overcame, because the product can be easily granulated by pressing [11].

In this work we used for mechanochemical activation the ordinary phosphorite powder of Central Kyzylkum with the composition (wt %): P_2O_{5total} 18.33; relative content of $P_2O_{5acceptable}$ with Trilon B 12.1; CaO 47.48; CO_2 15.20, in a mixture with ammonium carbonates produced by Chirichik join stock company "Elektro-khimpribor" and urea nitrate of "pure" grade. The ammonium carbonates contained 23.12% N and showed pH 8.19 (10% water solution). The urea nitrate contained 33.97% N, its 10% solution showed pH 0.81. The mixtures were prepared with different nitrogen – phosphorus ratio. The ammonium carbonate salts are also interesting as they themselves are effective nitrogen fertilizers and simultaneously they capable to convert hardly soluble soil phosphates into the form acceptable by plants [12, 13]. As to ammonium nitrate, it attracts attention of Indian scientists as a reagent promoting mechanochemical activation of phosphate raw material [14–16].

The grinding was carried out using laboratory porcelain stamp to the particle size below 0.16 mm. Grinding of phosphorite powder only resulted in increase of relative content of $P_2O_{5acceptable}$ with Trilon B to 23.8%, that is, twice. Analysis of the products of the fertilizer grinding was conducted alongside the known procedures [17]. The acceptable form of P_2O_5 was determined with Trilon B. The experimental results are listed in Tables 1 and 2.

As seen from Table 1, the ammonium carbonate salts promote activation of phosphate raw material. The relative content of P_2O_5 acceptable form in the product varies from 56.97% at the N:P_2O_5 ratio in the mixture 1 : 0.75, to 80.39% at N: P_2O_5 = 1 : 0.15. The higher amount of ammonium carbonate salts n the mixture, the higher value of relative content of acceptable form of P_2O_5. The products with even this ratio of acceptable P_2O_5 form to its overall content are prospective nitrogen-phosphorus fertilizers. They include nitrogen in a varied amount in the range of 11.54 to 18.71%, and P_2O_{5total} from 3.11 to 9.25%. By composition they are advantageous over simple ammonized superphosphate. At the activation of the mixture, in the product appears also the water-soluble

form of P_2O_5 (0.16–0.20 absolute %), attesting the fact that the solid phase reaction between the phosphorite and ammonium carbonate salts leads to formation of either $Ca(H_2PO_4)_2$, or $NH_4H_2PO_4$. A disadvantage of the process is nitrogen loss into gas phase. At grinding the mixture is heated, and thermally instable ammonium carbonates partially decompose with escape nitrogen into gas phase. In our case the nitrogen loss falls to the range 4.57 to 8.05%. The loss value was determined from the mixture weight loss at the grinding and from the nitrogen content in the initial mixture and the product.

Table 2 shows results of mechanochemical activation of phosphorite powder with urea nitrate. Changing N: P_2O_5 ratio in the mixture from 1 : 0.3 to 1 : 1 leads to appearance of acceptable P_2O_5 in amount 98.62 to 45.43% of total P_2O_5. Presence in the product of water-suluble form of CaO in a significant amount shows that the solid phase reaction of phosphorite powder with urea nitrate first of all results in decomposition of carbonates with formation of calcium nitrate. This conclusion is attested also by the data on the changes in the degree of decarbonization of the mixture. Simultaneously proceeds partial decomposition of mineral phosphate with formation of acceptable and water-soluble forms of P_2O_5. At the N : P_2O_5 ratio in the initial mixtureequal to 1 : 0.5 we obtain the fertilizer containing (wt. %): N_{total} 17.03; P_2O_{5total} 9.43; $P_2O_{5acceptable}$ 6.40; $P_2O_{5water\text{-}soluble}$ 0.70; CaO_{total} 25.34; $CaO_{acceptable}$ 19.42; $CaO_{water\text{-}soluble}$ 10.73, the content of acceptable form of P_2O_5 is 67.87% of the total one. By its composition, this is a good nitrogen-phosphorus fertilizer. But high content of calcium nitrate leads to high hygroscopicity and necessity of conditioning.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Technology of Magnesium Hexafluorosilicate Production

O. E. Khotyanovich and M. I. Kuz'menkov

Belarussian State Technical University, Minsk, Belarus

Received July 11, 2007

Abstract—Systematic study of parameters of the techological process for producing crystalline magnesium hexafluorosilicate from hexafluorosilic acid and caustic magnesite: reagents concentrations and ratio, temperature of the synthesis and evaporation, order of pouring the reagents (caustic magnesite suspension and hexafluorosilic acid), intensity of the solution stiring at its crystallization. Optimal values providing maximal yield of the targeted product are elucidated.

DOI: 10.1134/S1070427207110444

Currently in the Republic Belarus' increased demand on the magnesium hexafluorosilicate, the main component for producing the impregnating compositions for the increase endurance limit of concrete and ferroconcrete constructions. However, in the countries of former Soviet Union including Republic Belarus' this product did not produce on the industrial scale. The current demand is covered by import from USA, Germany, Italy and other countries.

Reviewing published sources and patent data showed that in distinct to other fluorine-containing salts the bivalent metal hexafluorosilicates, those of magnesium, calcium and zinc in particular, are the poorly studied compounds. Publications [1–8] are not complete and often contradict one another, up to now there is no general opinion concerning optimal technological parameters for producing the bivalent metal hexafluorosilicates. Therefore the aim of this research is development of technological process for producing magnesium hexafluorosilicate from crude raw material.

In this study we used hexafluorosilic acid of the company "Gomel' Chemical Plant", the side product of the production of extractive phosphoric acid. The authors [1–5] have used for the synthesis of magnesium hexafluorosilicate the hexafluorosilic acid of 8–15 wt % concentration; the solution obtained then should be evaporated for isolation of $MgSiF_6 \cdot 6H_2O$. In this sense, it would be preferable to use concentrated acid (up to 33 wt % H_2SiF_6) [6], to obtain in the process of the synthesis a suspension of magnesium hexafluorosilicate in its saturated solution. However, in the "Gomel' Chemical Plant" at the producing extractive phosphoric acid, in the process of absorption of fluorine gases with water is formed hexafluorosilic acid with concentration 12–14 wt%. It is technologically difficult to increase its concentration, because it would lead to sharp increase in aggressive action on the material of evaporating unit. Therefore in the study we used hexafluorosilic acid of 14% concentartion. As a neutralizing agent was used caustic magnesit PMK-75 (State standard GOST 1216-87) with the composition, wt%: MgO 75–80, CaO 2.5–3.0, SiO_2 2.0–2.5.

For the development of the magnesium hexafluorosilicate regime of synthesis the following technological parameters were varied: concentration of each reagent and their ratio, temperature of the synthesis and evaporation of solution, order of pouring the reagent, caustic magnesite and solution of hexafluorosilic acid, intensity of stirring the solution in the process of crystallization.

For the synthesis of magnesium hexafluorosilicate we used a three-neck flask placed into a thermostate unit, to provide stability of chosen temperature. The following order of operations was applied: To the reaction vessel was loaded given precalculated amount of hexafluorosilc acid taken with excess against stoichometry. At the permanent stirring to the acid was poured caustic magnesit in one portion. The suspension obtained was filtered and the filtrate was evaporated on a water bath. The crystalline product obtained was dried in a drier to constant weight.

For identification of the targeted product were applied chemical method (complexometry) and X-ray phase analysis (difractometer DRON-3 with CuK illumination) and IR spectroscopy (SPECORD-751R).

In the first step we studied effect of the order of pouring the initial reagent on the yield of magnesium hexafruorosilicate. The synthesis temperature was maintained at 50°C, hexafluorosilic acid concentration 14 wt%, its excess 2 wt% over stoiciometry. The magnesit suspension concentration was varied. This reagent was loaded to the reactor in one portion. The results obtained are shown in Table 1. As seen, at the same other parameters of the synthesis the order of pouring when hexafluorosilic acid is added to the suspension of caustic magnesit in the most cases leads to decrease in the yield of $MgSiF_6 \cdot 6H_2O$. This obviously is connected with two-step formation of magnesium hexafluorosilicate: In the initial step the solution is oversaturated with Mg^{2+} ions relatively to SiF_6^{2-} resulted in formation of magnesium fluoride [9]. In the further process the solution is oversaturated with SiF_6^{2-} ions leading to dissolution of magnesium fluoride and formation of magnesium hexafluorosilicate. However, up to 4% of magnesium fluoride remains in the precipitate, which leads to decrease in the yield of crystalline magnesium hexafluorosilicate and its contamination with the products of the synthesis. At the alternative order of pouring, the magnesium hexafluorosilicate is formed in one step alongside the reaction:

$$MgO + H_2SiF_6 = MgSiF_6 + H_2O \quad (1)$$

Reverse order of pouring reagents, namely, adding of caustic magnesit suspension to the solution of the acid restrict its homogenous dozing. Therefore further research on the regime of synthesis of magnesium hexafluorosilicate was carried out at mixing initial components by adding caustic magnesit as a powder to the solution of hexafluorosilic acid, to provide maximum yield of the targeted product and simplify the technological process by excluding the step of preparation of water suspension of caustic magnesit.

The next step of research was denoted to the problem of effect of the reagents ratio on the yield of the final product. For this purpose was varied the hexafluorosilic acid excess relatively to stochiometric amount from 0 to 14 wt%.

The dependence of magnesium hexafluorosilicate yield on the excess of hexafluorosilic acid over stoichiometry is shown in Table 2

It is seen that increase in the acid excess to 7–10 wt% leads to increase in the yield. This can be explained by decrease of magnesium hexafluorosilicate solubility in the $MgSiF_6 \cdot H_2SiF_6 \cdot H_2O$ system at the increase of free hexafluorosilic acid content in the mother liqueur [6] affecting positively the yield of $MgSiF_6 \cdot 6H_2O$.

Excess of hexafluorosilic acid over 10 wt% does not affect significantly the magnesium hexafluorosilicate yield. On the basis of the data obtained on the influence of reaction product yield on the ratio of the components we conclude that hexafluorosilic acid excess should be applied, because this leads, all other conditions are the same, to more complete proceeding of the reaction and practical absence of amorphous silicon oxide in the crystalline reaction product.

Table 1. Effect of the order of pouring reagents on the yield of magnesium hexafluorosilicate

7	93.2	97.9	90.0	87.5
10	93.1	98.1	90.4	87.0
14	93.7	98.0	90.4	88.1

X-ray diffraction analysis of a sample obtained with optimal regime showed that the main phase consists of magnesium hexafluorosilicate, which contains as admixed phase calcium hexafluorosilicate. IR spectrum contans the bands characteristic of both $MgSiF_6 \cdot 6H_2O$ and $CaSiF_6 \cdot 2H_2O$. These obtained experimental data well conform to the published ones [10]. According to chemical analysis the product obtained has a composition, wt%: $MgSiF_6 \cdot 6H_2O$ 96–98, $CaSiF_6 \cdot 2H_2O$ 2.0–2.5, other is admixture of amorphous silica. The content of main product obtained experimentally well conform to the calculated value.

At the study of the effect of temperature on the yield of magnesium hexafluorosilicate crystals we varied the temperature in the range from 20 to 70°C. At the temperature above 70°C the synthesis was not performed due to beginning of hydrolysis of magnesium hexafluorosilicate leading to formation of magnesium fluoride and silic acid [1, 2].

As seen from thr data in Table 2, increase in temperature of reaction mixture to 30-40°C while all other parameters remain unchanged leads to increase in nagnesium hexafluorosilicate yield, while at further increase in temperature occurs the yield falls down. The temperature factor in the range is known important at the synthesis of well soluble substances because rate of formation is proportional to $e^{-1/T}$, while the rate of formation of poorly soluble substances is proportional to e^{-T} [11]. From the x-ray diffraction data of the sample obtained at 30°C is seen that the main phase is magnesium hexafluorosilicate, and the admixed phase is calcium hexafluorosilicate.

At further increase in temperature to 50°C and over despite the decrease in viscosity and diminished deceleration at the penetration of acid into the magnesit particles the yield of magnesium hexafluorosilicate falls. It is explainable by hydrolytic decomposition of magnesium hexafluorosilicate at the temperature above 50°C with formation of amorphous silicon oxide and magnesium fluoride, the latter is registered by x-ray diffraction. Besides, the SiF_6^{2-} ions existing in the solution are also unstable and inclined to hydrolysis alongside the reaction equation: $SiF_6^{2-} + 2H_2O \rightarrow SiO_2 + 4H^+ + 6F^-$. Our experimental data correlate with data in [10].

Thus, the optimal temperature for the synthesis of magnesium mhexafluorosilicate falls to the range 30–40°C, which provides maximum yield of the product (up to 98 wt%), all other conditions are the same.

In respect of isolation crystalline magnesium hehafluorosilicate from its solution, we studied effect of the crystallization temperature on the yield. The magnesium hexafluorosilicate solubility changes by ~10% only when the slution temperature is varied in the range from 0°C to 60°C, therefore crystallization under cooling in this case is not effective. Therefore oversaturation in the system was created by partial removing the solvent by evaporqation.

As noted above, at the temperature over 50°C magnesium hexafluorosilicate exerts hydrolytic decomposition, therefore for its isolation in crystalline form the process of evaporation was carried out at the lower temperature. While studying the effect of evaporation temperature on the yield of magnesium hexafluorosoilicate crystals the temperature was varied in the range from 20°C to 50°C (see Fig. 1).

As seen, increase in the temperature affords crystalline magnesium hexafluorosilicate in higher yield. It can be assumed that at higher temperature the rate of formation of the crystal nuclei grows not only due to diminishing of their critical size but also because the ions are less hydrated and their joining into the nucleus is easier. Besides, at the elevated temperature falls the surface tension on the board between the solution and forming

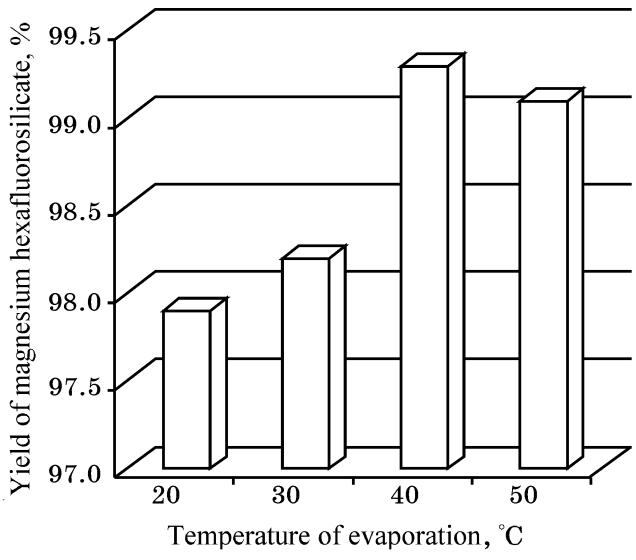

Fig. 1. Dependence of the yield of crystalline magnesium hexafluorosilicate on the temperature of evaporation of its solution.

Table 3. Dependence of magnesium hexafluorosilicate crystals size on the excess over stoichiomettry of water and evaporation temperature

Excess of hexafluorosilicate acid over stoichiomettry, wt%	Size of the crystals $MgSiF_6 \cdot 6H_2O$ at evaporation temperature, °C			
	20	30	40	50
5	2.4	2.4	2.3	1.9
7	2.5	2.6	2.5	1.9
10	3.8	3.8	3.6	2.1
14	3.7	3.8	3.7	2.2

nucleus and hence degreases the work function of their formation 11].

In the process of the experiment was found that not only the yield, but also the size of the $MgSiF_6 \cdot 6H_2O$ crystals grows with increase in the temperature (Table 3).

Obviously crystallization in the region of higher temperatures promotes increase in the size of crystals of the targeted product. This fact can probably be explained by decrease in the hydration of ions thus making much easier their transfer from the structurized in a certain degree laminar layer of the solution on the crystal surface to the crystal lattice, thus promoting faster grow of the crystals. A certain role probably plays also decrease in the solution viscosity, thus diffusion of the substance to the growing crystal edges accelerates.

As seen from Table 3, the crystal size depends substantially on the presence in the solution of hexafluorosilic acid excess. Studying the effect of silic acid excess in the system on the size of depositing crystals of magnesium hexafluorosilicate we found that decrease in the hexafluorosilic acid concentration leads to decrease in the average size of the crystals $MgSiF_6 \cdot 6H_2O$. This can be explained as follows. On one side, the magnesium hexafluorosilicate hexahydrate solubility falls with increase in hexafluorosilic acid content in the solution, that is, the solution becomes oversaturated by SiF_6^{2-} ions relatively to the ions of Mg^{2+}. Thus, when oversaturation of the solution increases, also increases concentration of submicro nuclei and becomes easier their joining together. On the other hand, the rate of appearance of the nuclei also grows, but not all them form further a crystal. Some of them join together or combine with a macrocrystal accelerating grow of the latter. By this

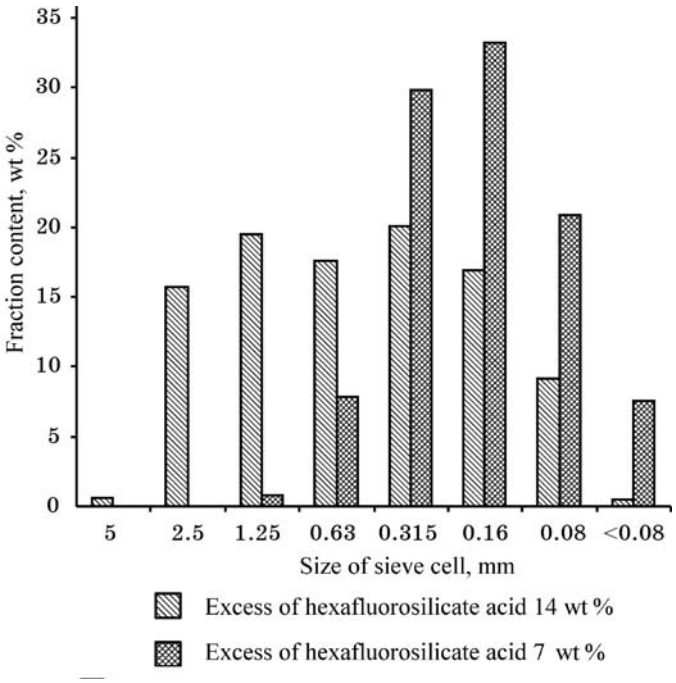

Fig. 2. Size distribution of magnesium hexafluorosilicate particles.

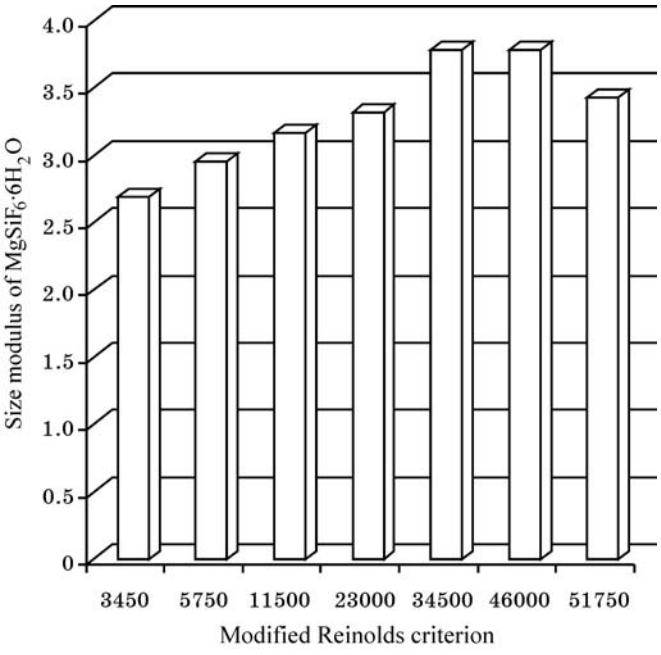

Fig. 3. Influence of hydrodynamic situation in the reaction vessel on the size modulus of $MgSiF_6 \cdot 6H_2O$ crystals.

reason, the higher oversaturating due to higher evaporation temperature and presence of hexafluorosilic acid excess, the less a number of appearing nuclei that then form separate crystals. The increase in crystal size with increase in oversaturation in a system at the sedimentation of soluble salt has been noted in literature [11, 12].

At the applied oversaturations while other synthesis parameters remains the same (synthesis temperature 30–40°C, hexafluorosilic acid concentration 14 %, excess of hexafluorosilic acid over stoichiometry 10 %, evaporation temperature 40°C) the magnesium hexafluorosilicate crystals precipitate with the size modulus in the range 3.6 to 3.8.

The precipitates obtained are polydisperse ones, due to non-simultaneous formation of critical nuclei and difference in the rate of grow of small and large particles [13]. Fig. 2 shows a histogram of distribution of magnesium hexafluorosilicate particles by the size.

As seen from the histogram, crystalline magnesium hexafluorosilicate consists of the particles with the size within a certain range of dispersion. Decrease in the excess of hexafluorosilic acid in the system leads to narrowing of this range and shifting it to the side of formation of the finely divided crystalline product.

Among the many factors affecting the rate of crystals growing in the mother liqueur, a significant one is intensity of supplying of the "building material" to the growing crystal edges. The growing of crystals is known depending in a great extent on the concentration fluctuations appearing in the process of stirring or sometimes due to changes in density in the reaction process or due to changes in temperature due to the exothermic reaction. Direction and intensity of the concentration fluctuations affect the rate of the crystal growing. Therefore it is significant to study effect of the intensity of stirring at the evaporation the magnesium hexafluorosilicate on its crystallochemical parameters..

For the description of the stirring process we used the modified Reynolds criterion (Re_M) [14, 15]. In the investigation we varied rotation frequency of the propeller-type agitator in the range from 30 rpm (Re_M = 3450) to 450 rpm (Re_M = 51750). Diminishing in the rotation frequency below 30 rpm (Re_M < 3450) leads to restrictions in stirring the crystalline magnesium hexafluorosilicate suspension in its saturated solution and the process is not homogenous.

Influence of hydrodynamic situation in the reaction vessel on the size of the formed crystals of magnesium hexafluorosilicate is shown in Fig. 3. It is seen that increase in modified Reynolds criterion from 3450 (rotation frequency 30 rpm) to 34500 (rotation frequency 300 rpm), all other conditions of the synthesis and evaporation are the same, leads to increase in average size of $MgSiF_6 \cdot 6H_2O$ crystals. But further increase in the rotation rate either leads to some decrease in the average size, or does not affect the crystals size.

Thus, from the data obtained we can conclude that increase in the intensity of stirring of the solution at its evaporation to a certain value (Re_M = 34500) makes easier access of "building material" to the face of growing crystal and the rate of the crystal growing increases resulting in the increase of its average sizes. However, at the increase in the modified Reynolds criterion above this value the rate of dissolving of surface layers of the growing crystal becomes higher than the positive effect of acceleration of diffuse supply of the substance and the rate of crystal growing falls [11]. Besides, there is an opinion [12] that under such conditions of crystallization can occur acceleration in the growing of big crystals and deceleration in the growing of the crystals of small size. This all leads to decrease in the average size of the magnesium hexafluorosilicate crystals at the increase in modified Reynolds criterion over 34500. Therefore we accept this intensity of stirring the solution at its evaporation as the optimal.

On the basis of this research we optimized regime of the sybthesis of magnesium hexafluorosilicate from caustic magnesit and hexafluorosilic acid. We established that the optimal parameters are: hexafluorosilic acid concentration 14 wt%, excess of hexafluorosilic acid over stoichoiometric amount is 7–10 wt%; temperature of the synthesis 35–45°C; temperature of evaporation 40–50°C [16].

These optimized conditions of the synthesis are taken as a basis for the technology of industrial scale producing magnesium hexafluorosilicate hexahydrate (Fig. 4).

The developed technological regime of the synthesis of magnesium hecxafluorosilicate allowed to produce this material with the quality some as imported analogs. Experimental bathes produced in the plant "Gomel' Chemical Plant" showed a possibility of organization of industrial producing of magnesium hexafluorosilicate.

Abstract—Composition of nitrogen-phosphoric fertilizers produced by introduction into ammonium nitrate melt of ordinary phosphorite powder, dust fraction and mineralized mass of Central Kyzylkum phosphorites in the amount necessary for providing final product with 0.5 to 5% of P_2O_5 is described.

DOI: 10.1134/S1070427207110456

Currently in various countries in the world is produced and circulated ammonium nitrate in a huge amount (ca. 33 000 000 ton in 2002) for covering agriculture demand. A significant part of world production (6 400 000 ton) is used as low cost and safe raw material for producing industrial explosives at the places of their application instead of expensive and dangerous for application explosives produced in plants [1]. The most powerful facilities for producing ammonium nitrate belong to USA and Russia, the world fraction of each country is estimated slightly over 13% (in USA these facilities include carbamide – ammonium nitrate solutions and other ammonium nitrate solutions 60%, products of industrial use 28%; in Russia these facilities include mainly granulated product for agriculture) [2]. In Uzbekistan three plants produce ammonium nitrate for agriculture, their total product is above one million ton per year.

Ammonium nitrate has two significant disadvantages: deterioration in storage and explosion risk [3, 4]. While one can avoid aggregation by means of various additives, the problem of explosion risk does not surmount completely. To avoid caking, sulfate, sulfate-phosphate or sulfato-phosphato-borate additives as well as caustic magnesite and other compounds are used [5]. Caustic magnesite is found the best one. Since 1949, "Elektrokhimprom" company in Chirik and since 1952 "Azot" corporation in Severodinetsk have produced caking-resistant ammonium nitrate by mixing with the product of apatite decomposition (RAP) with nitric acid as an additive introduced in the amount providing 0.7–1.6% P_2O_5 in the ammonium nitrate [6]. But to the end of 70th this additive was refused owing to depositing insoluble components in the heat exchange units and clogging granulators. The plants turned to use a technology with caustic magnesite. Nevertheless, adding RAP in amount much larger than necessary to avoid caking seems to be prospective also for diminishing explosiveness of ammonium nitrate. However, hopefully the problem of ammonium nitrate explosion risk can be resolved using phosphorus-containing additives. In publications [7–9] was described technology for producing complex nitrogen-phosphate fertilizer containing 32.3% of N and 5.2% of P_2O_5 by introducing to the ammonium nitrate melt of liquid complex fertilizer containing 11% of N and 37% of P_2O_5, based on the superphosphoric acid. This additive increased initial temperature of the ammonium nitrate decomposition by 22–24°C, reduced rate of its thermal decomposition, increased strength of granules, decreased the product porosity, increased resistance of the product to repeated phase transformations and, that is the most important, decreased its ability to detonation. The "Cherepovets Azot" plant applied this technology in 2002 to produce 1000 ton per a day, in a great extent owing to the fact that required liquid fertilizer was produced at a neighboring plant. The plant technologists noted that explosiveness of the product is less than that of pure

Table1. Material composition of phosphate raw material

Raw material	Content of components, wt%							$P_2O_{5\ acceptable}/\ P_2O_{5total}$
	P_2O_5	CaO	Al_2O_3	Fe_2O_3	MgO	F	CO_2	
Ordinary phosphorite powder	17.20	46.22	1.24	1.05	1.75	2.00	16.00	18.49

ammonium nitrate, but mixing of ammonium nitrate and liquid complex fertilizer solutions is accompanied by formation of precipitates causing troubles in the steps of evaporation and granulation [9].

The authors' certificates [10, 11] also propose methods of producing complex fertilizers by introduction of superphosphoric acid into ammonium nitrate melt, in [10] with additional loading apatite.

The Russian plants "Azot" in Kemerovo, join stock company "Kirovo-Chepetskii Khimkombinat," join stock company "Minudobreniya" in town Rossosh and Novgorod join stock company "Akron" decided to produce stabilized ammonium nitrate by adding phosphorus-containing materials. The first enterprises that realized in 2001 industrial producing the nitrogen-phosphorus fertilizer based on ammonium nitrate used as the phosphorus-containing raw material the extraxtion phosphoric acid or ammonium dihydrogen phosphate solution produced from this acid [12–14]. The problem that appeared were: (1) strong corrosion on the liquid – gas interphase board due to fluorine containing in the phosphoric acid, (2) Sedimintation of Fe, Al, Mg and Ca salts on the equipment walls leading even to sealing. The system productivity felt down more than twice as compared with the work on pure ammonium nitrate.

In 2003 started industrial producing the nitrogen phosphorus fertilizers (32% of N and 6% of P_2O_5) with the preliminary purified nitro-phosphoric acid extract from the azofoska production [15, 16]. This led to the same problems as at the use of extraction phosphoric acid.

Therefore searching for appropriate phosphorus-containing material for stabilization of ammonium nitrate is continued. In the Kirovo-Chepetsk chemical mill was proposed to load mixed extraction phosphoric and sulfuric acids into the nitric acid prior to ammonizarion [17]. But at evaporation of the solution formed and granulation here also will be occurring the equipment stoppage.

We decided to produce stabilized ammonium nitrate by introducing phosphate raw material from Central Kyzylkum, namely, ordinary phosphorite powder, dust fraction and mineralized mass, either. The two latter materials are side products at producing the phosphorite powder by dry enrichment of phosphorite ore. Of course, granulation of ammonium nitrate should be carried out in a drum-type granulator-drier or in plate or drum granulator, as proposed, e.g., in the patent [18], rather than in a tower granulator. The initial raw material composition is shown in Table 1.

The ordinary powder contains fluoroapatite $Ca_5F(PO_4)_3$ 40.6% and calcium carbonate $CaCO_3$ 36.4%. The dust fraction contains these components,respectively, 43.9 and 33.70%, mineralized mass 34.70 and 29.2%.

The aim of this work is studying composition of the products obtained at introducing phosphate raw material from Central Kyzylkum into the ammonium nitrate melt. The ammonium nitrate produced at Chirik join stock company "Elektrokhimprom" was melted in a metallic cup heated by electric heater. To the melt obtained was introduced phosphate raw material in amount corresponding to the final product P_2O_5 content 0.5 to 5%. At 180°C the mixture was stirred for 30 min. Cooled product was grinded and analyzed alongside the known procedures [19]. The acceptable forms of P_2O_5 and CaO were determined from solubility of the product in citric acid. The loss to gas phase was measured by weighting

the cup with the initial mixture and with the final product. The results are listed in Tables 3 – 5.

From the tables is seen that the ammonium nitrate melt activates phosphate raw material, that is, transfers the non-acceptable form of P_2O_5 into the form acceptable by plants. The product containing 5% P_2O_5 from ordibary phosphorite powder contains 25.24% of N and 88.29% of acceptable form of P_2O_5 to the total P_2O_5. The product from dust fraction with 5% of P_2O_5 contains 26.01% of N and 88.20% of acceptable P_2O_5 to the total one. The values for the product containing 5% of P_2O_5 from mineralized mass are: 23.94% of N and55.75% acceptable P_2O_5 to total P_2O_5. More phosphate raw material is introduced, less content of acceptable forms of P_2O_5 and CaO and less phosphorite decarbonization. Presence in the product of water-soluble form of CaO and loss to gas phase indicate that at 180°C occurs reaction between ammonium nitrate and calcium carbonate in the phosphate raw material leading to formation of calcium nitrate:

$$2NH_4NO_3 + CaO \rightarrow Ca(NO_3)_2 + 2NH_3 + H_2O$$

Thus, introduction of phosphate raw material into nitrate ammonium melt allows obtaining effective nitrogenphosphorus fertilizers.

MODELLING AND CALCULATION OF TECHNOLOGICAL PROCESSES

Modelling a Flow of a Highly Viscous Liquid with the Boundary Layer of Low Viscosity in an Extruder

Abstract—Features of the flow of a highly viscous liquid in an extruder with boundary layer of low viscosity liquid at the cylinder wall and at the endless screw surface are considered. The liquid flow is modeled under conditions of isothermal simple shift using cylindrical model of a screw canal. The profiles of rates for the stream of a highly viscous liquid with the ring boundary layer of low-viscous liquid at the cylinder wall and at screw in the both presence and absence of a counter pressure are calculated. Consideration of computer calculations shows that increase in the flow rate is possible when the counter pressure tends to zero and the low-viscous liquid forms a ring boundary layer at the cylinder wall.

DOI: 10.1134/S1070427207110468

A great amount of polymeric materials in the industry is treated by the method of extrusion. Intensity of this method can be increased by different ways, one is creation of a lubricant layer between the processed material and the canal wall.

A construction of extruder is known where the screw wall is porous or perforated, and through the holes to it surface is supplied a gas or low-viscous liquid [1]. Another variant is also possible, with the lubricant layer near the wall of cylindrical case.

In this work we consider features of the flow of a highly viscous liquid in an extruder with a low-viscous boundary layer at the cylinder wall and on a screw surface. A physical model of such flow is shown in Fig. 1. It is represented by a cylindrical canal with the radius R and length l, containing inside a rod with the radius $R_1<R$ moving symmetrically relative the axis with angular rate ω and rate along the axis u. The main stream of highly viscous liquid μ_1 moves in the ring gap $R–R_2$, the stream of low-viscous liquid μ moves in a ring layer $R_2 –R_1$ near the rod wall.

The differential equation in the tensions for axial moving along the z axis is represented by [2, 3]:

$$-\frac{\partial p}{\partial z}+\frac{1}{r}\frac{\partial\left(r\,\tau_{rz}\right)}{\partial z}=0 \qquad (1)$$

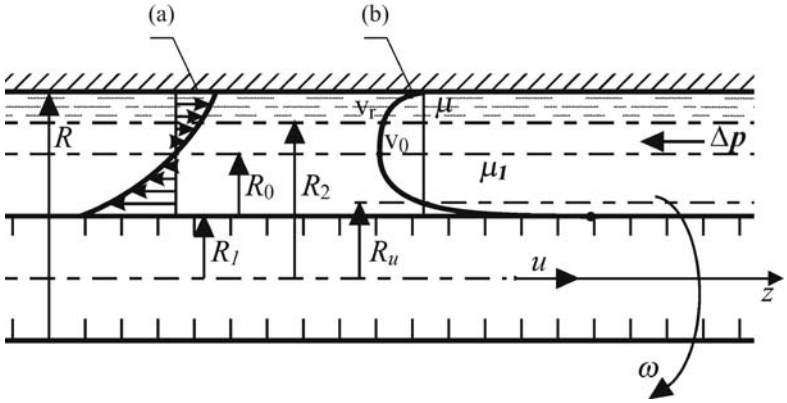

Fig. 1. Scheme of moving liquid with low-viscous boundary layer near vthe wall: (a) epure of tangent tensions, (b) profile of rates (R_2 is ring board of two liquids, R_0 is a radius coreesponding to the maximal rate, $\tau=0$; R_u is a board where the flow rate changes sign from plus to minus).

Let $\Delta p/\Delta z = \Delta p/l$: pressure increases along the axis, because the screw works like a pump, then:

$$\tau_{rz} = \frac{\Delta p}{2l} r + \frac{c_1}{r} \tag{2}$$

For the highly viscous liquid moving in the ring gap ($R_2 - R_1$):

$$\tau_{rz} = \mu_1 \frac{dv_z}{dr} \tag{3}$$

Join solving the equations (2) and (3) leads to the expression:

$$v_1 = -\frac{\Delta p}{2l\mu_1} r^2 + \frac{c_1}{\mu_1} \ln r + c_2 \tag{4}$$

At a $r = R_1$, v_1 = boundary conditions u we obtain:

$$v_1 = u + \frac{\Delta p}{4l\mu_1}\left(r^2 - R_1^2\right) + \frac{c_1}{\mu_1} \ln \frac{r}{R_1} \qquad R_1 \le r \le R_2 \tag{5}$$

Similarly, for low-viscous liquid moving in the ring gap ($R–R_2$):

$$\tau_{rz} = \mu \frac{dv_z}{dr} \tag{6}$$

$$v = \frac{\Delta p}{4l\mu} r^2 + \frac{c_3 \ln r}{\mu} + c_4 \tag{7}$$

Accounting for the boundary conditions $r = R$, $v = 0$, the expression is transformed into:

$$v = -\frac{\Delta p}{4l\mu}\left(R^2 - r^2\right) + \frac{c_3}{\mu} \ln \frac{r}{R} \qquad R_2 \le r \le R \tag{8}$$

The integration constants c_1 and c_3 are found from the equality of tangent tensions and rates at $r=R_2$:

$$c = c_1 = c_3 = -\frac{u + \frac{\Delta p}{4l}\left(\frac{R^2 - R_2^2}{\mu} + \frac{R_2^2 - R_1^2}{\mu_1}\right)}{\frac{1}{\mu} \ln \frac{R}{R_2} + \frac{1}{\mu_1} \ln \frac{R_2}{R_1}} \tag{9}$$

Finally we obtain formulas for calculation of rate profile for both the liquids:

$$\begin{cases} v_1 = u + \dfrac{\Delta p}{4l\mu_1}\left(r^2 - R_1^2\right) + \dfrac{c}{\mu_1} \ln \dfrac{r}{R_1}; \quad R_1 \le r \le R_2 \\ v = -\dfrac{\Delta p}{4l\mu}\left(R^2 - r^2\right) + \dfrac{c}{\mu} \ln \dfrac{r}{R}; \quad R_2 \le r \le R \end{cases} \tag{10}$$

Integrating equations for elementary flows

$$\begin{cases} q_1 = 2\pi \int_{R_1}^{R_2} v_1 r dr \\ q = 2\pi \int_{R_2}^{R} v r dr \end{cases} \tag{11}$$

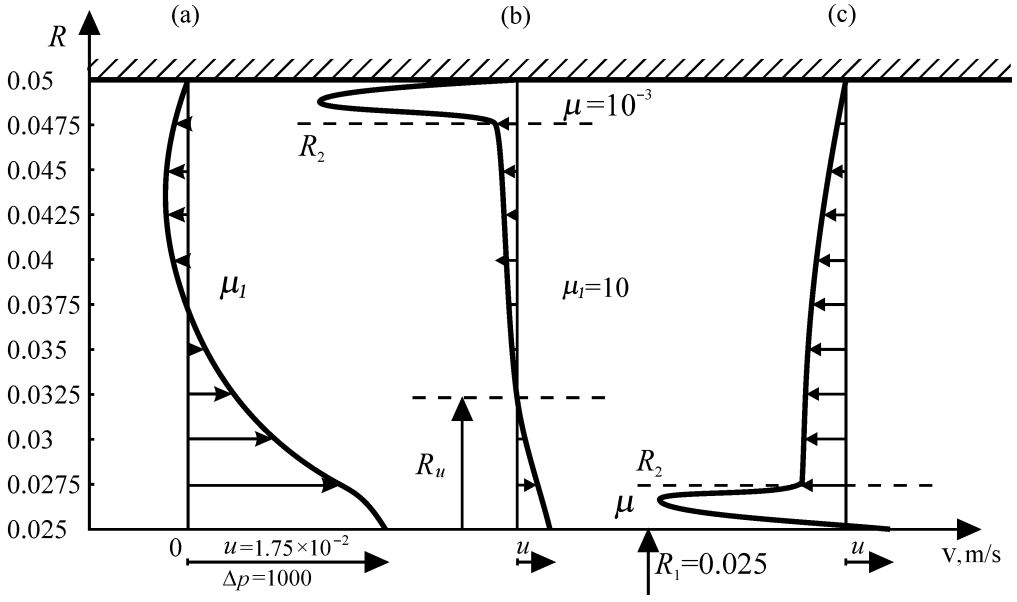

Fig. 2. Dependence of model profiles of the flow rate of highly viscous liquid μ_1 = 10 Pa sec in a screw extruder at $\Delta p/l$ = 1000 Pa m^{-1}, R_1 = 0.025 m, R = 0.05 m: (a) Flow of highly viscous liquid only, (b) Flow in the case of boundary ring layer of low-viscous liquid (water) μ=10^{-3} Pa sec at the cylinder wall, δ = 0.0025 m; (c) Flow with boundary ring layer of low-viscous liquid at the screw, $\ddot{a}$ = 0.0025 m.

we obtain:

$$\begin{cases} q_1 = \pi\left\{u\left(R_2^2 - R_1^2\right) + \dfrac{\Delta p}{8l\mu_1}\left(R_2^2 - R_1^2\right)^2 + \dfrac{c}{\mu_1}\left[R_2^2 \ln\dfrac{R_2}{R_1} - \dfrac{\left(R_2^2 - R_1^2\right)}{2}\right]\right\} \\ q = \pi\left\{-\dfrac{\Delta p}{8l\mu}\left(R^2 - R_2^2\right)^2 + \dfrac{c}{\mu}\left[R_2^2 \ln\dfrac{R}{R_2} - \dfrac{\left(R^2 - R_2^2\right)}{2}\right]\right\} \end{cases} \quad (12)$$

Fig. 2 shows rate profiles according to equations of the system (10) accounting for the integration constant (9). As seen from the figure, at $u = 1.75 \times 10^{-2}$ m s^{-1} and $\Delta p/l$ = 1000 Pa m^{-1} at the geometric sizes R_1 = 0.025 m, R = 0.05 m and viscosity μ_1 = 10 Pa sec and $\mu = 10^{-3}$ Pa sec (water) at the boundary layer of low-viscous liquid near the cylinder wall (Fig. 2b) with thickness 0.0025 m or at the screw with the same thickness (Fig. 2c) there is no gain in flow rate of the main stream of the highly viscous liquid (Fig. 2a) as compared with ordinary working endless screw when it flows over all the section.

Analysis of the results obtained using cokputer calculations shows that such a gain is possible in the case when counter pressure is near the zero and low-viscous liquid forms ring shape boundary layer near the cylinder wall (Fig. 3b).

For this case when $\Delta p/l = 0$ (no counter pressure, all energy of the screw dissipates) we obtain at R_2 = 0.0475 m: q=6.5 × 10^{-6} m^3 s^{-1} c; q_1=8.9 × 10^{-5} m^3 s^{-1} (Fig. 3b).

When R_2=R, when the bounder layer of low-viscous liquid (water) near the cylinder wall is absent $R_2 = R$ = 0.05 m; R_1=0.025 m; $q = 0$; $q_1 = 4 \times 10^{-5}$ m^3 s^{-1}, that is,

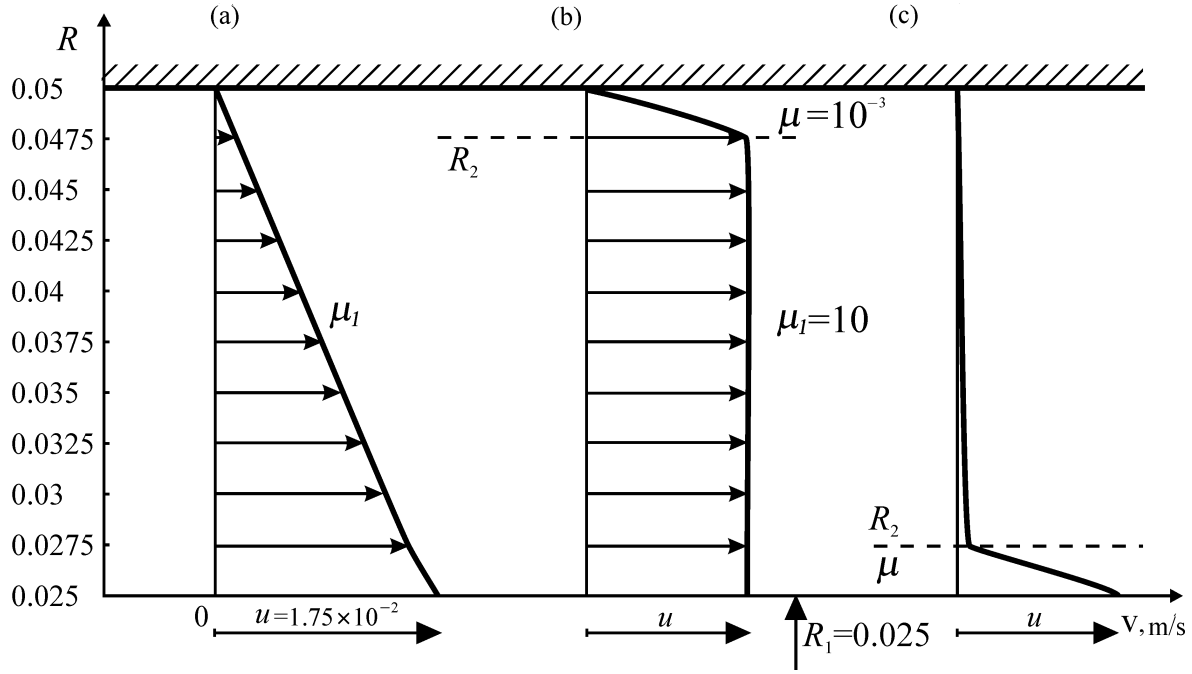

Fig. 3. Dependence of the model rate profile of a highly viscous liquid μ_1 = 10 Pa sec in an endless screw extruder at $\Delta p/l$ = 0 Pa m^{-1} R_1 = 0.025 m, R = 0.05 m: (a) Flow of highly viscous liquid only, (b) Flow in the case of boundary ring layer of low-viscous liquid (water) $\mu = 10^{-3}$ Pa sec at the cylinder wall, δ = 0.0025 m; (c) Flow with boundary ring layer of low-viscous liquid at the screw, δ = 0.0025 m.

if the flow rate of low-viscous liquid (water) at the cylinder wall equals 7.3 % of the main stream of highly viscous liquid, the flow rate of the latter ecreases by 2.22 times (Fig. 3a). When the ring boundary layer of low-viscous liquid is near the screw, the flow rate of the main stream of highly viscous liquid falls, $q_1 = 3.5 \times 10^{-6}$ m^3 s^{-1} (Fig. 3b).

Thus, it is reasonable to feed the low-viscous liquid as ring boundary shape to the cylinder wall and when there is no counter pressure.

INDUSTRIAL ECOLOGY

Investigation of Adsorption Purification of the Effluences Containing Heavy Metal Ions

D. Yu. Morozov, M. V. Shulaev, I. A. Khramova, and L. I. Khabibullina

Kazan State Ubiversity, Kazan, Russia

Received April 24, 2007

Abstract—Kinetics of adsorption purification of effluences containing heavy metal ions and adsorption of the metal ions under dynamic conditions using various adsorbents, including the products from industrial wastes are studied.

DOI: 10.1134/S107042720711047X

We investigated and considered adsorption characteristics of various adsorbents at the adsorption of the ions Cr(VI), Mn(VII), Fe(II), Cd(II), Cu(II) and Zn(II). As the adsorbents, we used granulated active carbon SKT-3, the zeolite-containing rock diatomite from he birth place in Ul'yanovsk region and precipiates which could form at local coagulation purification of effluences at producing polysulfide resins (thiocols) with 30% iron(III) chloride and aluminum chloride solutions, the iron-containing precipitate (ICP) and aluminum-containing precipitate (ACP), respectively. The precipitates are solid disperse materials with hydrogen sulfide odor.

The results of studying kinetics of adsorption of the ions Cd(II), Zn(II), Cu(II), Cr(VI), Mn(VII) and Fe(II) are shown in Figs. 1–6 and table 1.

Consideration of the data obtained leads to conclusion that in the initial step all the curves are similar: for the

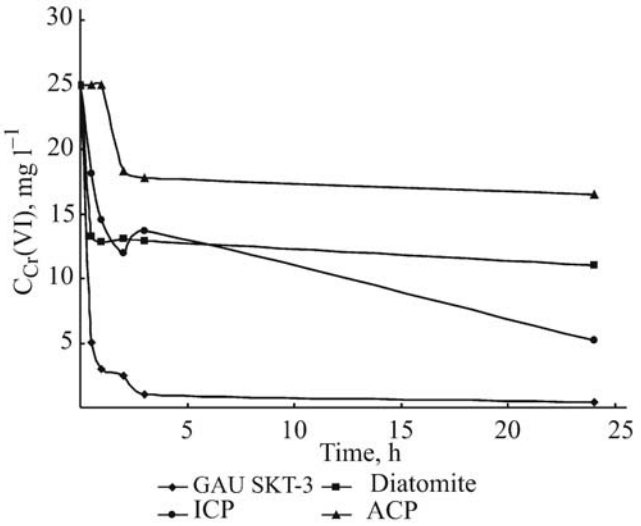

Fig. 1. Kinetic curves of adsorption Cr(VI) ions.

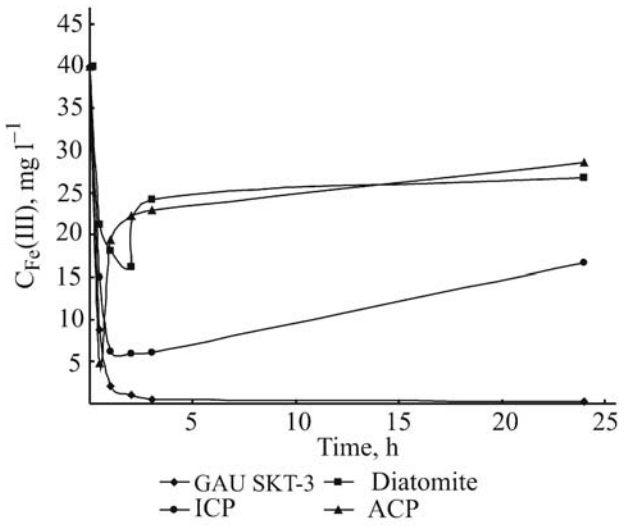

Fig. 2. Kinetic curves of adsorption Fe(III) ions.

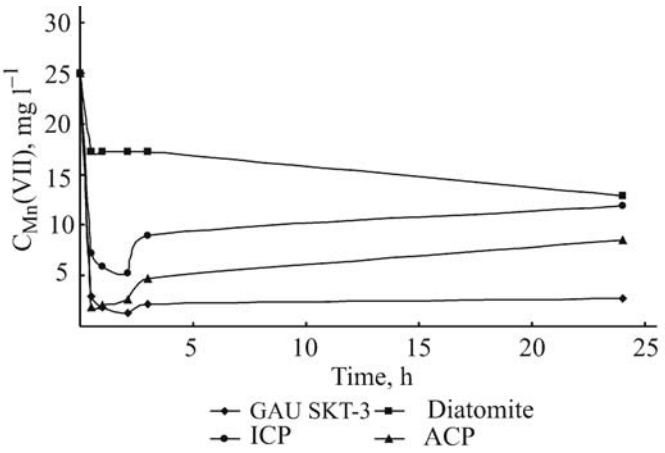

Fig. 3. Kinetic curves of adsorption Mn(VII) ions.

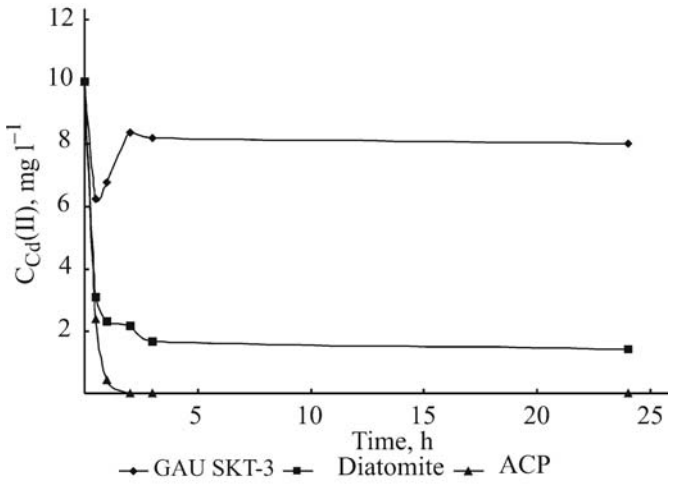

Fig. 4. Kinetic curves of adsorption Cd(II) ions.

first 1 to 2 h of each experiment the concentration of heavy metal ions in the model effluences falls down sharply. Then the curves run differently, and we could select 5 main types of the kinetic curves by the mode of changes of the heavy metal ion concentration during experiment:

(1) After sharp fall in the initial period, the system is stabilized and concentration of heavy metal ion remains practically unchanged during whole experiment. Thus, static adsorption equilibrium is achieved. The such type curve is characteristic of Zn(II) ion adsorption with all the studied adsorbents, ions Fe(II) and Cr(VI) with granulated active carbon SKT-3, ions Cd(II), Cu(II) and Cr(VI) with ACP and Cd(II) ions with diatomite.

(2) Sharp fall of heavy metal ion concentration in the initial step of experiment is replaced by stepwise decrease up to the end of experiment. Here adsorption equilibrium is not achieved. Such curve reflects adsorption of Mn(VII) ions on diatomite.

(3) Sharp fall of heavy metal ion concentration in the initial step of experiment is replaced by stepwise growing concentration. Equilibrium in the system is also not achieved. The curve of such type occurs for Fe(II) ions adsorption on iron-containing precipitate (ICP).

(4) After sharp fall occurs fast growing in concentration of heavy metal ion at 1 to 3 h after the experiment beginning, and then concentration decreases smoothly up to the end. Such variantions can be explained by different adsorption affinity of various heavy metal ions toward asorbent, leading to substitution of one ion by another during the experiment. This leads to

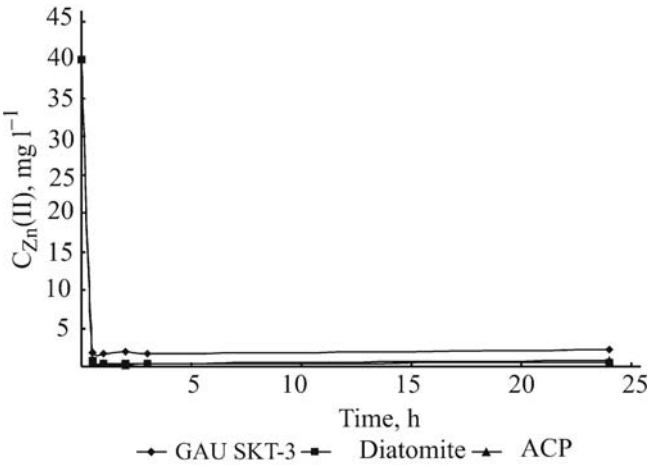

Fig. 5. Kinetic curves of adsorption Zn(II) ions.

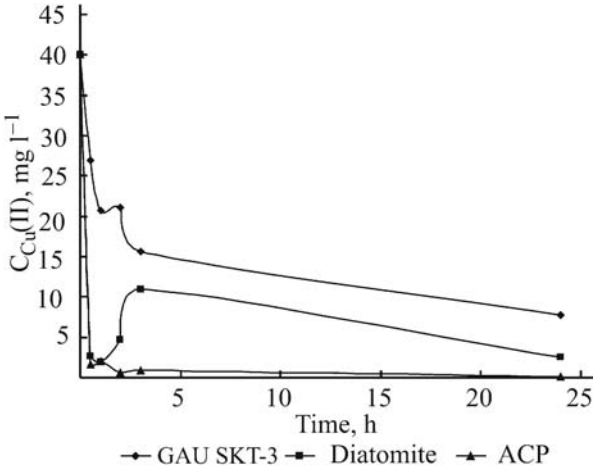

Fig. 6. Kinetic curves of adsorption Cu(II) ions.

Table 1. Kinetics of adsorption of heavy metal ions from solution

Adsorbents	Heavy metal ions								
	Cr(VI)			Mn(VII)			Fe(II)		
	Initial concentration, mg/ml	Final concentration, mg/ml	Purification, %	Initial concentration, mg/ml	Final concentration, mg/ml	Purification, %	Initial concentration, mg/ml	Final concentration, mg/ml	Purification, %
Granulated active carbon SKT-3	25	0.440	98.24	25	2.753	88.99	40	0.168	99.58
Diatomite	25	11.035	55.86	25	12.820	48.72	40	26.9	32.75
Iron-containing precipitate	25	5.215	79.14	25	11.863	52.55	40	13.336	66.66
Granulated active carbon SKT-3	10	8.003	19.97	40	2.260	94.35	40	7.756	80.61
Diatomite	10	1.439	85.61	40	0.492	98.77	40	2.584	93.54
Aluminum-containing precipitate	10	-	99.99	40	0.752	98.12	40	0.068	99.83
Aluminum-containing precipitate	25	16.458	34.17	25	8.550	65.80	40	28.5	28.75

appearance of concentration gradient between phases resulting in change of concentrations of the heavy metal ions in a model effluence, that is, no equilibrium ocurs in the system. Such kinetic curve is characteristic of adsorption Cr(VI) ions with iron-containing ptecipitate (ICP) and Cu(II) ions on the active carbon and diatomite.

(5) After sharp changes in the heavy ion concentrations during the first 3 h of the experiment, the concentration grows stepwise till the experiment end. Such curve type reflects adsorption of Mn(VII) ions with granulated active carbon SKT-3, ACP and ICP, of Fe(II) ions on diatomite and ACP and of Cd(II) ions with carbon.

The data obtained show that the most effective adsorbents are activated carbon, aluminum-containing precipitate (ACP) and diatomite. The iron-containing precipitate (ICP) shows stable satisfactory results.

PROCESSES AND DEVICES OF CHEMICAL MANUFACTURES

Parameters of Heterogenic Liquid Phase Process and Temperature Profile in a Displacement-Type Reactor

A. V. Zheranin

Biisk Technological Institute (Filial) of Polzunov Altai State Technical University, Biisk, Russia

Received January 23, 2007

Abstract—The results are presented of mathematical modeling the processes of heat and mass transfer in a displacement-type reactor.

DOI: 10.1134/S1070427207110481

Our earlier calculations [1] showed a possibility of application a displacement-type reactor [2] for the carrying out exothermic heterogenic liquid phase process complicated by heat and mass transfer due to extended heat transferring surface of specific configuration with rational mutual location of heat transferring elements (Fig. 1). In the calculations was presumed that the disperse phase drops are parting (fusing) instantly and their size (diameter) is changed and following homogenous distribution of parent component and reaction product over the drop volume proceeds instantly.

However, actual distribution of parent component and reaction product over the volume of a newly forming disperse phase drop in the beginning of sections n2, n3, n4 at the top of canal and n3, n2, n1 at its bottom (Fig. 1) is not homogenous and is close to that occurring in the bulk of drops in the end of preceding section. The sections are defined in correspondence with the accepted in [1] scheme of moving (and parting) the drops of disperse phase in the continuous medium flow along the canal changing with its height. Therefore now let us define the parameters of heterogenic liquid phase processwith fast chemical transformation on the interphase surface [3] and the temperature profile in th canals of the reactor [2] taking into account the non-homogenous distribution of parent component and reaction product in the bulk of newly forming disperse phase drops. We will use the model in [4] and accept the same as in [1] scheme of moving (and parting) the disperse phase drops in the flow of continuous medium along the canal changing with its height. For all five variants of the reactor construction (see the table) the accept changing of canal along height like in [1], alongside the formula: $h_i = aR_i^{-b}$. The disperse phase and continuous medium are feeding into the canal in the amounts 0.35 and 1.3 kg/s, respectively.

Distribution of weight fractions of the initial component C(r, t) and reaction product Cm(r, t) over the volume of a newly forming drop of dispersion phase in the beginning of the sections n2, n3, n4 in top part and n3, n2, n1 in the bottom part of the canal initially is taken the same as in the bulk of the parent drops at the end of preceding section. For example, distribution of weight fraction C(r, t) of the parent component is shown in Fig. 4. Then we define the extent of conversion SP_n of the parent component in the bulk of newly forming drops at the beginning of the sections n2, n3, n4 in top part and n3, n2, n1 in the bottom part of the canal (at the initial moment of passing these sections).

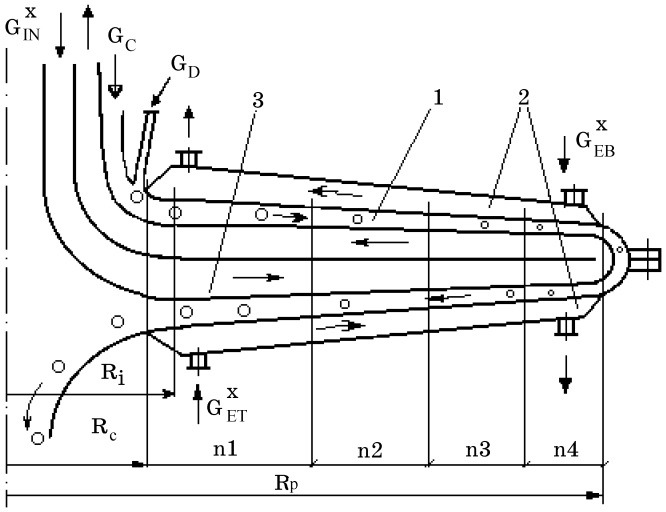

Fig. 1. Scheme of a displacement-type reactor. (1) canal with medium (disperse G_D and continuous G_C phases); (2) external top and bottom canals with cooling agent (G_{ET}^{X}, G_{EB}^{X}); (3) internal canal with cooling agent (G_{IN}^{X}).

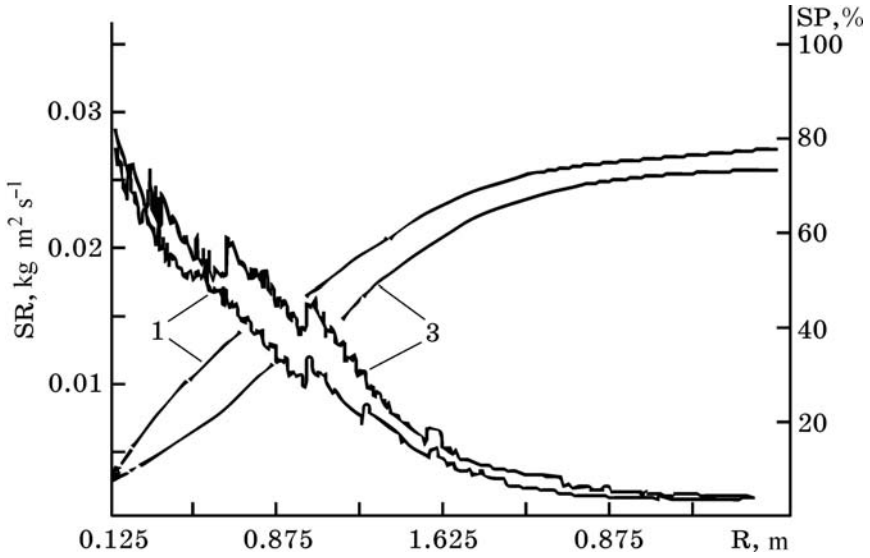

Fig. 2. Change in the process rate SR and extent of conversion SP along the canal for the variants 1 and 3 of reactor construction.

The extent of conversion SP_n we calculate using the formula: $SP_n=((TL-TLj)/TL)\times100\%$, where TL is a quantity of initial component in one parent drop of disperse phase that did not enter to the reaction in the time period when it was located in a preceding section, per one newly formed drop; TLj s a quantity of the parent component in one newly forming drop of disperse phase that did not enter to the reaction in the period of location the disperse phase drops in the beginning of next section.

Then we begin correction of distribution of weight fractions C(*r, t*) and Cm(*r, t*) continuing it till the extent of conversion SP_n approaches zero. The correction is needed because the quantity of initial component in two newly forming drops (from one parent), which did not enter to the reaction, should necessarily be equal to the same quantity in one parent drop in the end of preceding section.

The extent of conversion SP*(t)* (Fig. 2) of initial component during its time of location of the disperse phase drops in the reactor we calculate, same as in [1], alongside the formula: $SP(t) = SP = ((\rho_T V_T - T(t)dh)/(\rho_T V_T))\times100\%$, where ρ_T and V_T are respectively density and volume of the "parent" drop of disperse phase, *dh = 1, 2, 4, 8* is the number of "new" drops forming from one "parent" drop in the sections, respectively, n1, n2, n3 and n4, *T(t)* is the quantity of parent component in a drop in each actual time moment of location the disperse phase in the reactor. The smoothness of the curves *SP(t)* = SP = *f(R)* in Fig. 2 obviously better corresponds to real character in varying of extent of conversion SP*(t)* of the parent component in time (SP is change along the canal) than their step-like form obtained in [1] where inhomo-genity of distribution of the parent component and reaction product over the volume of a newly forming drop was not taken into account.

Systematic small fluctuations (Fig. 2) of the process rate *SR* defined in the model of [4] as a mass flow [3] of parent component to the drop surface are stipulated, like in [1], by the variations in the coefficients of mutual molecular diffusion of the parent component, D(*r, t*), and the reaction product, Dm(*r, t*). The diffusion coefficients were varied in each step of realization of the differential schemes [4] for providing balance of mass flows of the diffusing components. More significant splashes on the curves SR=*f(R)* are stipulated by the significant changes in the gradient of mass fraction of the initial component near the interphase surface. This is connected with parting (fusing) of the drops and redistribution of the fraction of parent component and the reaction product over their volumes.

The temperature profile in the reaction canals we determine by solving, similarly to [1], the boundary Cauchy problem for each of four sections n1, n2, n3, n4 in the top and bottom parts of the reactor. Solving this problem allowed to find the temperature profiles of medium and cooling agent for all five variants (see the table) of the reactor construction (e.g., see Fig. 3) and to find required cool consumption (cooling agent flow rate) and cooling agent temperature at the canals inlet.

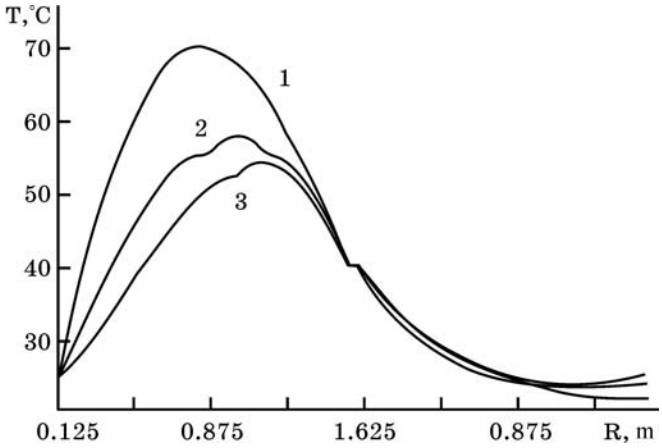

Fig. 3. Variation in the medium temperature T along the canal for the reactor construction variants 1, 2 and 3.

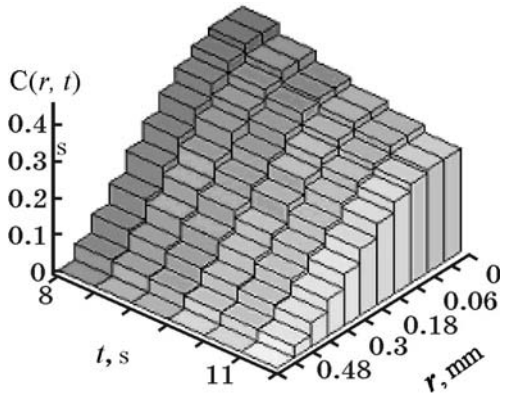

Fig. 4. Distribution of weight fraction C(*r, t*) of the parent component along the radius r of a drop of disperse phase in time t for the 4th section n4 of the canal bottom part for the variant 3 of the reactor construction.

The results obtained in turn confirm:

– capability of application reactor [2] for carrying out the process of exothermic heterogenic liquid phase process complicated by heat and mass transfer at the enough high extent of conversion of the parent component at the values (see note under the table) of the coefficient of mutual molecular diffusion inherent [5] in organic not viscous binary mixtures;

Parameters		Number of the variant of construction

Abstract—The work showed a phenomenon of influence of seismic and resonance shock waves on the long-range order in a liquid. On examples of damage of ion pair solvated clusters in aqueous solutions of NaCl (3.5 wt%), HCl (2 wt%), $AgNO_3$ (1.7 wt%) and molecular bunches (clusters) in distilled water placed to laboratory chemical reactor far distant from the epicenters of earthquakes the relations between incoming shock and seismic waves and instability of cluster and supracluster long range organization (molecular bunches assocoates) in a liquid is demonstrated. Understanding of risks for chemical industry both in respect of quality and chemical processes instability, and in respect of loose control over chemical technology is considered. Examples of changes in internal organization of solutions in the period of strong hurricane in Europe at February 17, 2007, strong earthquake in Japan at March 25, 2007 and a series of earthquakes at April 4 to 9, 2007 are given and the phenomenon is explained. The risks for chemical industry and the chances of practical using the phenomenon are considered. The clusters in liquids show different responses to the processes in the disaster epicenter, and their responses can be used for understanding chemical processes in Earth crust and in the centers of hurricanes and for strategy of disposing and protecting chemical facilities.

DOI: 10.1134/S1070427207110493

INTRODUCTION

For long time was noted that natural disasters influence state of health of animals, which even have been used by people in the regions of frequent earthquakes for advance informing about their forthcoming. At the moment there is no clear understanding of reasons for these effects. It is only clear that behavior of animals and forthcoming earthquake are connected.

Japan seismologists found that prior to an earthquake, liquids exert sharp changes in their properties. For example, viscosity of olive oil grows anomalously [1]. The authors do not explain these phenomena, but intuitively point to certain interconnection between natural disaster and structure of liquid. Another group of Japanese investigators [2] describes anomalous effects in the properties of water in the area of forthcoming earthquakes. These effects could not be omitted by specialists on chemical technology and safety of chemical plants.

Let us attempt to find sources of this interconnection basing on the known low-energy changes in structure of liquids described by us earlier [3, 4]. The aim of this work is finding a connection between long-range order in a liquid and natural disasters.

MATERIALS AND METHODS

As the objects of investigation were taken: distilled water, agarose hydrogel (0.7 wt. %), solutions of salts and acid [NaCl (3.5 wt%), HCl (2 wt%), $AgNO_3$ (1.7 wt. %)]. The experimental procedure has been described in details in [3–6]. The works on the study of long-range order in liquids in the North part of Germany were carried out in the period from February to May 2007. Comparison of the data on the long-range order in liquids and natural disasters is made using the principle of "coincidence" in the time of events in the cell of measurements (53.08° north latitude and 12.75° east

longitude) and time of a disaster that has not been predicted to the moment (except the hurricane at February 17, 2007 over North Sea and territory of Germany). All event times are by Greenwich.

RESULTS AND DISCUSSION

Study of long-range order in the agarose hydrogel commonly used for modeling biological matrices showed effects of instability of long-range structure appearing as a sharp increase in average value of f parameter that characterizes interaction of clusters with environment [3, 4] (Fig. 1).

Average scattering of f parameter thus reflects "nervousness" of the system of supracluster structure in the hydrogel long-range order. The agarose hyrogel contains up to 99.3 wt.% of water, therefore increase in the cluster vibrations can be with a great probability assigned to strengthening in oscillation of water clusters. The water clusters, as is known, affect conformations of biomolecules [7], hence, influence direction and rate of certain biochemical processes in living organisms and, further, affect their biological reactions, that is, behavior. Thus we can trace indirect influence of the impact of the earthquake seismic waves on the organism biomatrix and fix connection between behavior of people and animals and natural disasters. Damage of long-range order in cluster structure of water in a biomatrix can influence health state of the operators in chemical plants and this can introduce the factor of human risks, which should be taken into account.

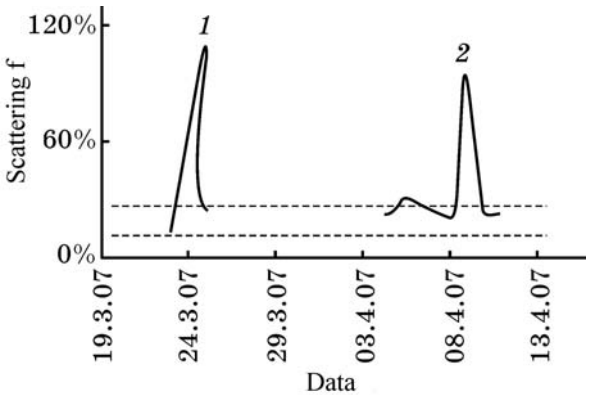

Fig. 1.

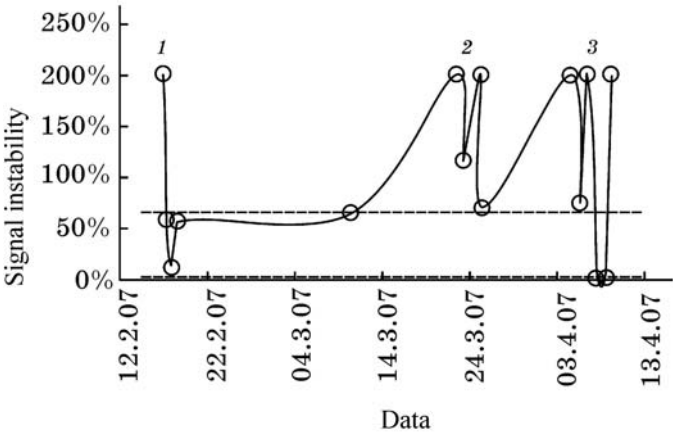

Fig. 2.

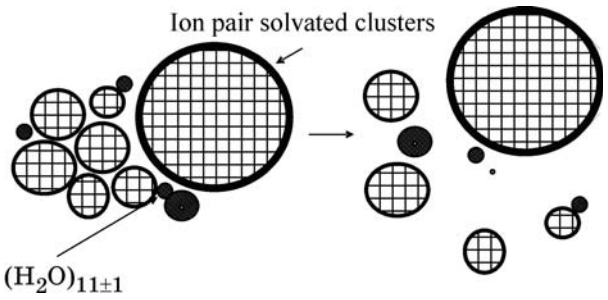
It should be noted that in the period of April 4 to 9, 2007 occurred many earthquakes, and we succeeded to register events shown in Fig. 1, proceeding from the time of achieving cells of flicker noise spectrometer (FNS) in Germany by seismic waves (4-7 km/sec) and the time of experiment carrying out. At other events the time of registering FN spectra and that of coming earthquake shock wave did not coincide. We found that coming shock wave activates FNS sensor differently and strongly depends on the chemical composition of liquid. In some liquids the long-range order reaction on the shock wave impact can continue for several hours and is selective in respect of mode of the molecular bunch. On the other hand, chemical processes in the earthquake epicenter can be understood by means of analysis of this selectivity which reflects resonance interaction of such oscillators in the measuring cell and in the earthquake epicenter. Therefore for chemical plants working in continuous regime can be used the possibility of monitoring events in the Earth interior for understanding the whole wide spectrum of chemical processes of earthquake.

Fig. 2 shows variations in average value of f parameter for ion pair solvated clusters of NaCl and water in 3.5 wt. % solution modeling sea water. From the figure is seen that these NaCl clusters response to damage of long-range order in sea water. Therewith, it is not significant whether this is a damage due to hurricane (1) or due to compression in the epicenter of a earthquake in ocean (2, 3). The long-range damage in the salt solution can be represented by the scheme (I):



Such a scheme assumes dispersing the salt ion pair solvated cluster nanosuspension under the action of shock wave of the earthquake or resonance wave from the ion pair solvated cluster damaged due to hurricane in the North Sea. This process is not stable one, and the system quickly returns into the state close to the initial even in a few hours. However, for some of large NaCl ion pair solvated clusters the process of achieving equilibrium of its interaction with environment can get a few days. We found that integral characteristics of solutions, including such as average molecular weight of all clusters ($M_{FNS}= m \cdot |f|$) "fill" appearance of earthquake in two-three days, as probably a result of strong pressure in the earthquake zone prior to the collapse and the sea water long-range order damage in the zone of epicenter.

Understanding the Scheme I of developing the process of disintegration of ion pair solvated clusters in salt solutions should be taken into account in chemical technology, because this can lead to sharp increase in the rate of chemical reaction and distortion of stability of chemical plants. On the other hand, one can expect that architecture of displacement of chemical reactors with forced dissolving and forced stirring near the reactors of fine synthesis can lead, according to the Scheme I, to induced or continuous action on the long-range order in the reactor for the synthesis, or on psychological stability of staff.

Some difference occurs in the response of hydrochloric acid solution to the natural disasters. Fig. 3 presents change in average molecular weight of clusters in 0.6 M HCl solution. As seen from the figure, increase in M_{FNS} at approaching earthquake in ocean can be registered even in a few days (shown by arrows). Thus, the integral characteristics of long-range order can be used to predict earthquakes. According to view of Japanese seismologists [1] that in the region of earthquake in Japan Sea occurs dehydration of mineral pores under the action of very high pressure of moving layers, we can assume that such dehydration affects strongly the structure of solvated ion pairs in sea water due to forced shift of equilibrium to the side of formation of HCl ion pair solvated clusters with the size less than the size of solvated clusters of NaCl ion pair [5, 8, 9].

$$NaCl{\cdot}aq + H_2O \rightarrow HCl{\cdot}aq + NaOH{\cdot}aq$$

Thus, principally appears a possibility of obtaining distant information on the chemical processes in the zone of earthquake and on their influence on technological processes with solutions.

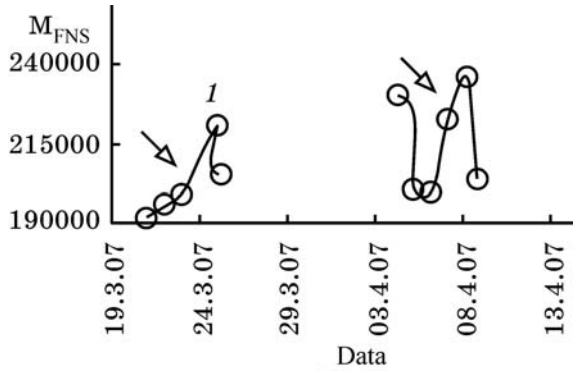


Fig. 3.

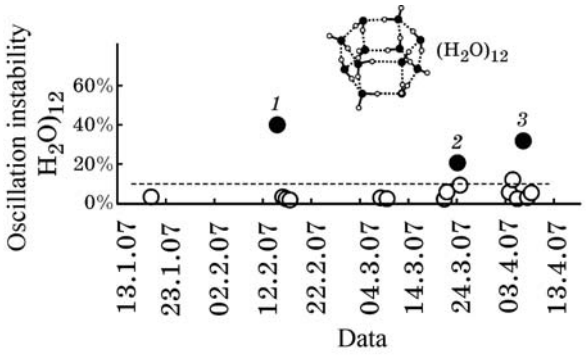

Fig. 4.

Fig. 4 presents dynamics of variations in instability of *f* signal of water cluster $(H_2O)_{12}$ [10] in 0.1N $AgNO_3$ solution. This cluster also is found to be distant sensitive toward weak energy streams of oscillation of its analogs in sea water affected by hurricane or earthquake. In the series of earthquakes in the period April 4 to 9, 2007, it showed selectivity in respect of shock waves attaining the place of measuring. Hence, seismic waves are the superpositions of a series of waves, and the clusters response actively to those defined by signals from their damaged analogs in the epicenter of hurricane or earthquake. For chemical technology this means a necessity to select technology and equipment appropriate for the zone of frequent natural disasters.

CONCLUSION

Liquids are unique natural sensors of energetically weak processes in nature. Natural disasters affect distantly long-range order in liquid. Changes in long-range order in a liquid under the influence of seismic waves or resonance fields of oscillation of molecular bunches (clusters) can result in destabilization of technological process and even lead to failure. These

changes can be used for early information on forthcoming disasters by continuous monitoring of structure of the liquids applied in technological processes. Risks of chemical processes due to this phenomenon lie in the quality of products, stability of technological processes and in the area of human factor: fatigue and overstrain. In our opinion the situation can be improved by means of inclusion to technology of the systems for monitoring distant influence on the long-range order in liquids and distribution of early information.

Abstract—Due to obsolescence of basic technological equipment of fan-type cooling towers in the enterprises of chemical complex built in 1980 and earlier the actual problem is their reconstruction using new technological solutions and developments aimed at the increase in efficiency of the process of evaporation cooling.

DOI: 10.1134/S107042720711050X

Due to obsolescence of basic technological equipment of fan-type cooling towers in the enterprises of chemical complex built in 1980 and earlier the actual problem is their reconstruction using new technological solutions and developments aimed at the increase efficiency of the process of evaporation cooling.

In [1] has been proposed a regular polymer packing constructed of four-blade helicoid elements turbulizing gas and liquid flow. The blades were stacked in horizontal rows turned by right angle in neighboring rows. Further development of this approach was shown in [2] publishing the results of examination of modernized constructions of helicoid-structural packing of PN-2D type made of polymer material.

Construction of helicoid-structural packing with varied geometry of stacking the individual blades in a block allows to recommend such packing for providing a given profile of the air flow rate along the transverse section of trickling space of cooling tower [3]. Programming the profile of rates in a cooling tower using the proposed prospective construction consisting of horizontal helicoids is performed keeping unchanged block height only by varying geometry of stacking and distance between the helicoid blades. This results in changing living section and hence in hydraulic resistance of the packing blocks [3]. The packing PN-2D allows varying the stacking pitch in the range from 1 to 3 diameters of the helicoid.

General view of the packing of PN-2D type with different modes of stacking geometry is shown in Fig. 1. The following modes of stacking geometry are possible:

- PN-2D kd – unstaggered (corridor) stacking,
- PN-2D ch – staggered (chess type) stacking,
- PN-2D kk – slant canal.

In this work we present results of air-thermal examination of helicoid-structural packing PN-2D with a predetermined stacking geometry of elements in a block.

The experiments were carried out under identical conditions, on the installations in the Vedeneev Research Institute of Hydraulic Engineering and Moscow State University of Engineering Ecology according to the procedure described in [4].

Plots in Figs. 2–4 show experimental data on the dependence of degree of cooling water in cooling tower, Δt, on the value of specific liquid rate, q_L, obtained on

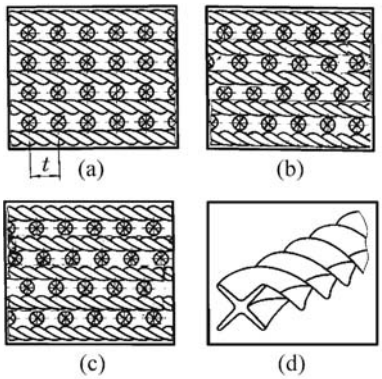

Fig. 1. General view of blocks of PN-2D packing with different modes of stacking of its elements, the helicoids: (a) PN-2D kd – unstaggered (corridor) stacking, (b) PN-2D ch – staggered (chess type) stacking, (c) PN-2D kk – slant canal, (d) general view of separate packing element.

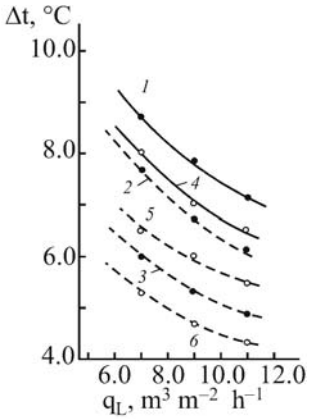

Fig. 2. Effect of the mode of stacking helicoids PN-2D ch and PN-2D kd on the character of the plot $\Delta t = f(q_L)$ at $X_t = 2$, block height H = 0.86 m, W_o = Var (*1, 3*) packing PN-2D ch, W_o = 2.0 m/s; PN-2D kd, W_o = 2.0 m/s; (*2, 4*) packing PN-2D ch, W_o = 1.5 m/s; PN-2D kd, W_o = 1.5 m/s; (*3, 6*) packing PN-2D ch, W_o = 1.0 m/s; PN-2D kd, W_o = 1.0 m/s.

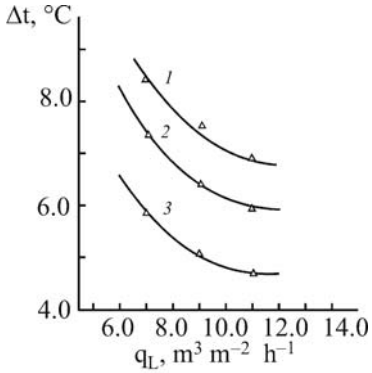

Fig. 3. Plot $\Delta t = f(q_L)$ for the mode of packing geometry PN-2D kk at varied air flow rate W_o: (*1*) W_o = 2.0 m/s; (*2*) W_o = 1.5 m/s; (*3*) W_o =1.0 m/s.

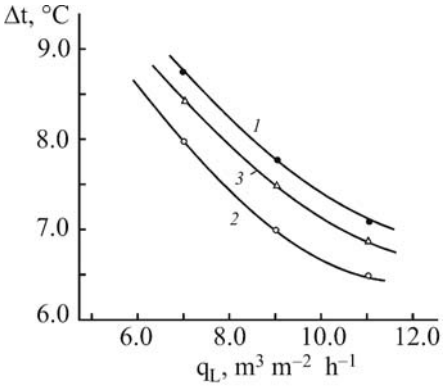

Fig. 4. Plot $\Delta t = f(q_L)$ at W_o = 2.0 m/s. (*1*) packing PN-2D ch, (*2*) packing PN-2D kd; (*3*) packing PN-2D kk.

the installation at various geometry of stacking helicoids in the packing. As seen, in the studied range of liquid rate (q_L from 0 to 12.0 m^3 m^{-2} h^{-1}) and gas rate (W_0 from 0 to 2.5 m/sec, the air flow rate calculated on the full section of empty tower), increase in amount of cooled water the cooling degree Δt regularly falls. This is seen particularly at increase in q_L from 6.0 to 10.0 m^3 m^{-2} h^{-1}.

The experimental data for the process of evaporation cooling in cooling tower are given as a dependence of evaporation number K_{vap} on the relative air consuming λ [4]:

$$K_{vap} = A\,\lambda^m, \quad (1)$$

where A and m are coefficients, $\lambda = q_G/q_L$, (q_G and q_L are specific gas and liquid consuming values, respectively).

Dependence of the A coefficients as A/H plots against geometry parameter X_t for the packing of PN-2D kd type is shown in Fig. 5.

The X_t parameter equals:

$$X_t = \frac{t}{d}, \quad (2)$$

where d is external diameter of a helicoid, mm; t is distance between central axes of neighboring helicoids, mm (see Fig. 1).

The hydraulic resistance coefficient of the packing, ξ, was calculated according to the known Weisbach formula, which in mixed units system (MKGCS-SI) looks as [4]:

$$\xi = \frac{\Delta P 2g}{\gamma_{air} W_o^2}, \quad (3)$$

where ΔP is pressure loss (difference in the air pressure) in the packing [kg m^{-2}] or [mm Hg]; γ_{air} is air

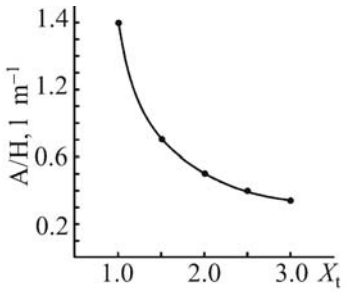

Fig. 5. Dependence of A/H simplex on the geometry parameter X_t from the experiments with spryer block PN-2D

Table 1. Values of A and ξ coefficients for the packing differ by geometry

Packing type	PN-2D kd	PN-2D ch	PN-2D kk
A_0=A/H [1/m]	0.65	0.67	0.665
Hydraulic resistance coefficient ξ	25	26	25.2

Table 2. Characteristics of PN-2D kd packing

Geometry parameter X_t	2
Porosity, ε, m^3/m^3	0.907
Equivalent diameter, d_{eq}, m	0.052
Specific surface, S, m^2/m^3	70

specific gravity [kg/m^{-3}]; g is acceleration by gravity pull [m s^{-2}]; W_o is average air flow rate calculated on the full section of empty tower [m s^{-1}].

The values of obtained A and ξ values for PN-2D packing with different stacking geometry are listed in Table 1. Here X_t = 2.

The values of hydraulic resistance ξ of the blocks of examined packing at the block height H = 0.86 m in Table 1 are given at liquid flow rate q_L = 10 m^3 m^{-2} h^{-1} and air flow rate W_o = 1.5 m/s.

Geometry characteristics of the most widely used packing PN-2D kd are shown in Table 2. The principal chatracteristics of PN-2D type packing are considered in [2].

From the data in Table 1 is seen that the value of hydraulic resistance coefficient ξ for the blocks of PN-2D kk packing is practically the same as for PN-2D kd. Among the studied three modes of packing the PN-2D kk is the most prospective because it provides higher efficiency at the lower hydraulic resistance.

Abstract—The experience in running mineral oils in hydraulic system allows us to conclude that basically their properties obey requirements: they provide reliability and durability of work of a hydraulic transmission, but have unavoidable disadvantage: flammability.

DOI: 10.1134/S1070427207110511

Modern hydraulic transmissions as a rule contain many actuating mechanisms with many connectors and oil seals. The working fluid exerts a pressure tenths and hundreds over atmospheric one. Even minor disturbance in the system tightness can lead to spraying the oil, formation of aerosols (oil fogs) prone to inflammation or even explosion due to presence of hot surfaces or from electric spark and other sources of ignition. World practice knows many cases of conflagration caused by such sources.

In the last decade in the world practice found wide application the working fluids with diminished flammability. A series of fluids differ by their chemical nature and not equal from the viewpoint of fire resistance, toxicity, performance, cost and other characteristics was developed.

According to international classification, the flame resistant liquids for hydraulic systems fall to four classes:

HFA – aqueous emulsions of "oil in water" type consisting of 97–98 % of water and 2–3 % of mineral oil with additives. Low viscosity (2–4 mm^2/sec at 50°C), not high enough lubricant properties and low stability restrict their application in the hydrosystems designed for working on mineral oil.

HFC – inverted emulsions of "water in oil" type containing 40 % of oil and 60 % of water and additives (the most important additive is emulsifier which allows comprising smallest particles of water by oil). By lubricant properties these fluids are second to mineral oils, with low stability and disposed to separation, but rather inexpensive.

HFC – water–glycol liquids containing 30–50% of water, 45–60% and polymer tickening agent, together with antirust, antiwear, fireproofing and other additives. Such fluids are compatible with practically all classes of metallic construction materials, plastics, the materials based on gum, are nontoxic, possess good lubricant properties, are stable and can be used in the hydraulic systems designed for mineral oil without significant construction improvement. They can be used at moderate power regimes, at the temperature up to 60°C. Their disadvantage is evaporation of water, especialy at elevated temperature and in not enough hermetic systems.

HFD – synthetic fluids not containing water. They comprise organic silicon, chlorine and fluorine compounds and the compounds based on phosphoric esters.

The fluids of HFD class are expensive, toxic, not compatible with oil seals based on nitrile gums that commonly are used in the hydrosystems on petroleum oils, but they possess high lubricant characteristics and can be used at rigid regimes of strength and work temperature.

The most widespread in world practice are fire safe and ecologically safe water–glycol fluids of HFC class.

In the Russian scientific center "Applied Chemistry" during 30 years period has been developed a big set of flame safe working fluids of water–glycol class with viscosity form 1 to 40 mm^2/sec at 50°C [1–8]. Some of them are shown in Table 1.

For determination the name of water–glycol fluid appropriate for application in a certain hydraulic transmission should be considered its physico-chemical, antiwear, antirust and other properties in comparison with mineral oil recommended for the same hydraulic transmission [9].

The physico-chemical properties of fluids are listed in Table 2.

Table 1. Physico-chemical characteristics of fire safe working fluids

Fluid	Specific temperature cal g^{-1} deg^{-1}	Heat conductivity kcal m^{-1} g^{-1} deg^{-1}
Promhydrol	0.71–0.75	0.305
oil	0.45–0.50	0.139

An important property of working fluid is its viscosity. For the correct operations of the hydraulic transmission is providing required viscosity-temperature characteristics of working fluid.

Viscosity defines the possibility of formation of liquid layer on the surfaces of rubbing pair and the rate of flow, heating of liquid and parameters of work for all mechanisms.

For effective operations of a hydraulic system the fluid viscosity should fall to a certain range responding to the types of used mechanisms.

Viscosity of a liquid varies with its temperature. Fig. 1 shows comparison of dependence of viscosity on the temperature for water–glycol fluids PGV, Promhydrol P-2OM1, Promhydrol P-2OM3 and VLP-10, and the mineral oils in hydraulic transmissions.

The plots shows that by viscosity-temperature characteristics in the temperature range from +50 to +10°C to the mineral oil IGP-18 best fits the fluid Promhydrol P-2OM1, and in the range from +10 to "10°C the fluid Promhydrol P-2OM3; to mineral oil Tp-22 and VNIINP-403 corresponds fluid Promhydrol P-2OM3, to transformer oil and to spindle oil AU the best corresponds by these characteristics the fluid PGV; to the mineral oil VMG3 which is recommended for use in winter period best fits by viscosity-tmperature characteristics the fluid VLP-10.

Study of baric dependence of viscosity and density of water–glycol fluids showed their low compressibility. The data for Promhydrol are shown in Fig. 2.

By their toxic properties the water–glycol fluids relate to low hazard or moderate hazard substances (III-IU class according to the classification GOST 12.I.007-76).

Ecological safety at the exploitation of water–glycol fluids is provided by their property of fast biochemical degradation at the accidental spilling or at purification of sewages in regional biochemical stations. For example, the fluid Promhydrol P-2OM3 áhas the following biochemical charatcteistics: (a) Chemical absorption of oxygen (CAO) 1.09 mg/mg, (b) Biochemical absorption of oxygen BAO_5 0.69, BAO_{20} 0.99 mg/mg.

Thus, biochemical index BAO_{20}/CAO is enough high, being equal to 0.90. This characterizes the product as appropriate for biological decomposition.

At the same time, stability of water–glycol fluids

toward biological damage in the process of exploitation is provided by special additives.

A doubtless advantage of water–glycol fluids at their exploitation from the viewpoint of industrial culture and requirements on technological safety is their easy washing off from surface at the occasional pouring.

Fire resistance of water–glycol fluids is stipulated by the presence of water in them. Testing the water–glycol fluids on several characteristics that are recommended by Russian Institute of Fire Guard (VNIIPO) showed their high fire resistance. At spraying under high pressure (up to 25 MPa) on the flame of acetylene burner the water–glycol liquids, in distinct to mineral oil, are inflammable, do not burn and do not propagate flame along the spray stream.

In distinct to mineral oil that shows high electric resistance, that is, are insulators for electric current, the water–glycol fluids are conductors. Their specific resistance at 20°C is $(3–6) \times 10^5$ Ohm m. The dielectric permeability at the frequency 500 kHz is ca. 49.0, hence they are unsatisfactory dielectrics.

Such fluids can not be used in the systems with immersed to liquid electroelements with unprotected contacts.

By their thermophysical characteristics, the water–glycol fluids are much advantageous over mineral oil and provide effective heat transfer from the friction nodes making the regime of exploitation much milder. The comparative characteristics for the fluid Promhydrol and oil are shown in Table 3.

A significant requirement to the fluids for hydraulic systems is their ability to liberate air without frothing. Strong frothing leads to lose of the fluid and can cause damage of elements of the hydraulic system.

Practically, liquids always contain some dissolved air, more at higher pressure. The presence of air at constant pressure is commonly imperceptible. However, reducing in pressure leads to liberating dissolved air, and this probably results in fuming.

Due to higher density of water–glycol fluids as compared with oil, their ability to deaeration is lower and gas liberation proceeds slower.

The acceptable frothing of water–glycol fluids is defined by the standard GOST 25821-83: it should be below 100 ml. Antifrothing property of water–glycol fluids is provided by introducing antifrothing additives to their compositions.

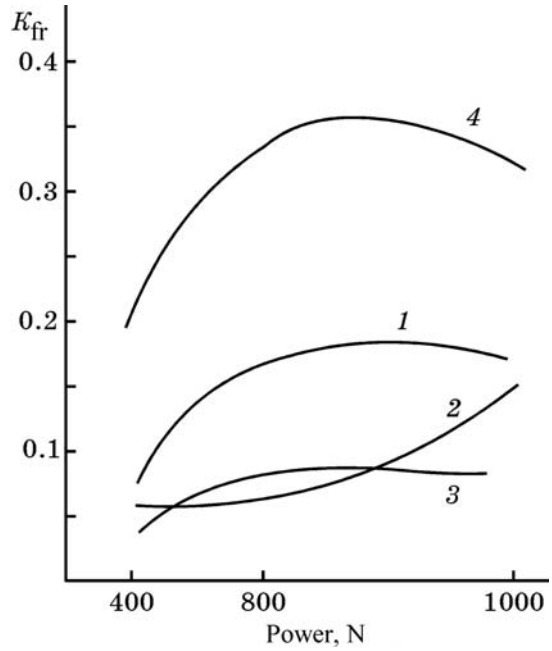

Fig. 3. Dependence of friction coefficient onn the strength at the examination on an IST-MT/5 friction machine (*1*) Promhydrol P-2OM1; (*2*) Promhydrol P-2OM3; (*3*) PGV; (*4*) Oil IGP-18;

The working fluid in a hydraulic system should possess high lubricant property, which is characterized by a scope of antiscuff, antiwear and antifriction factors.

This property defines intensity of wearing the friction nodes and reliability of the hydraulic transmission as a whole.

The standard method for estimation antiwear property is examination of the hydraulic fluid on a 4-balls friction machine (GOST 9490-75) which contain friction node as a pyramid of four bearing balls. Three balls in the base of the pyramid are fixed in the cup with the tested liquid and are unmovable; the upper

ball is fixed in a rotating spindle. The bottom balls are held up to the top one with a given power. The lubricant property of the fluid is characterized by:

- Scuff index (I_s) defines effect of the fluid on the wearing of the rubbing surfaces;

- Critical pressure (P_c), kg is the power just before sharp increase the wearing spot on the balls;

- Welding pressure (P_w), kg is the power leading to welding of the balls.

The higher I_s, P_c and P_w values, the better antiwear property. The results of examination are listed in Table 4.

The table shows that by all antiscuff characteristics the water–glycol fluids have better characteristics than the mineral oil IGP-18.

At the estimation of lubricating ability of working fluids and prognosis of their working capacity is significant the dependence of friction coefficient on the power and temperature which characterize antifriction property of the fluid.

Examination of dependence of friction coefficient on the force was performed on an ITS-MT/5 machine with top boll rotating at the constant rate. Axial pressing was varied stepwise within 1000 Newton.

The friction coefficients for the water–glycol fluids in the force range from 400 to 1000 N is by 2.5–3 times lower than for the mineral oil IGP-18 (Fig.3).

The dependence of friction coefficient on temperature was exaqmined by thermal method according to GOST 17604-72 on a 4-boll machine KT-2. The method is based on an external heationg of samples and surrounding layer of a lubricant at the constant pressing in the contact of friction, with low rate of sliding, to avoid heating due to friction and appearing of liquid-type lubricating. The examination was carried out in the temperature range 20 to 200°C, the

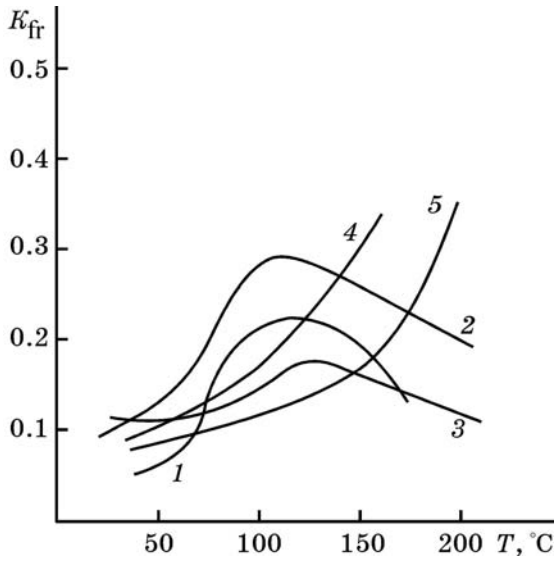

Fig. 4. Dependence of friction coefficient on the temperature of working fluids. (*1*) Promhydrol P-2OM1; (*2*) Promhydrol P-2OM3; (*3*) PGV; (*4*) Oil IGP-18; (*5*) Transformer oil.

sliding rate was 0.2 mm s^{-1} , pressing 110 N, which provides contact pressure 0.21 MPa.

The friction coefficients of water–glycol fluids and mineral oil IGP-18 in the temperature range from 20 to 120°C are comparable by value, however, at the temperature above 120°C those of the former show tendency to decrease when temperature grows (Fig. 4).

The working fluid should be compatible with the material of hydrosystem. This means that metal, cover and various construction materials contacting or under certain conditions could contact with the fluid should be mutually inert.

Our study showed that the water–glycol fluids owing to antirust additives show high antirust properties toward basic classes of construction materials (Table 5).

From Table 5 follows that the corrosion rate of construction materials in the fluid Promhydrol P-2OM-3 is comparable with that in mineral oil IGP-18.

A very important property is chemical resistance of gum and other non-metallic laying, thickening and covering materials. As a rule, gum swelling should not exceed 3%. The results of examination of thickening materials are listed in Table 6.

Among the examined nonmetallic materials in the Promhydrol P-2OM3 fluid the unstable ones are fiber and asbestos, and they are not recommended for use. Paronit is moderately stable material.

The results of examination of gum of various types on the swelling in the fluid Promhydrol P-2OM3 are listed in Table 7.

To conclusion, we note that in the RSC "Applied Chemistry" is accumulated prolonged experience on continuous expluatation of water-glycol fluids in hydraulic systems including the system of screw, axial-plunger, plate, gear and other types of pump.

Abstract—Abstract—X-ray phase analysis, thermogravimetry, IR spectroscopy, and chemical analysis were used to study bismuth(III) precipitation from nitrate solutions upon addition of aqueous solutions of hydrobromic acid or ammonium bromide, and from bismuth-containing hydrobromic acid solutions. The conditions in which bismuth(III) oxobromide of BiOBr composition is formed were determined and the possibility of obtaining a high-purity product was assessed.

DOI: 10.1134/S1070427207120017

Bismuth oxobromide is used in veterinary medicine [1], in technology for manufacture of piezo-, pyro-, and ferroelectric materials, and in physical development of silver-containing photographic materials [2, 3]. This compound is obtained by dissolving bismuth oxide of reagent-grade purity in hydrobromic acid, with the subsequent dilution of the resulting solution with hot water [4, 5]. A method is known for preparation of bismuth oxobromide, in which a mannitol-containing aqueous solution of bismuth nitrate is reacted with an alkali metal bromide at pH 5.0–5.2 in the presence of a buffer mixture based on urotropin and hydrobromic acid [6].

Bismuth compounds are commonly synthesized from a metal of Vi1 brand (mass fraction of Bi ≥98%) by dissolution of its grains in 9 M nitric acid, followed by hydrolytic purification of bismuth to remove impurity metals at pH 1.5–2.0 [7]. A disadvantage of this method is in that toxic nitrogen oxides are released into the gas phase in the stage of preparation of bismuth nitrate solutions, because the dissolution process occurs in accordance with the equation

$$Bi + 6HNO_3 = Bi(NO_3)_3 + 3NO_2\uparrow + 3H_2O. \quad (1)$$

It has been shown [8] that preliminary oxidation of metallic bismuth with atmospheric oxygen to give a technical-grade oxide makes it possible to reduce the expenditure of nitric acid by a factor of 2 and to eliminate release of nitrogen oxides into the atmosphere in the stage of preparation of bismuth nitrate solutions. This is so because the dissolution process is described in this case by the equation

$$Bi_2O_3 + 6HNO_3 = 2Bi(NO_3)_3 + 3H_2O. \quad (2)$$

Hydrobromic acid well dissolves bismuth oxide, as also does nitric acid, and the dissolution reaction has the form

$$Bi_2O_3 + 6HBr = 2BiBr_3 + 3H_2O. \quad (3)$$

It is of practical interest in this context to study synthesis of bismuth(III) oxobromide directly from solutions produced by dissolution of technical-grade bismuth oxide in nitric or hydrobromic acid.

This communication reports on a study of the influence exerted by the concentration of bromide ions and the process temperature on the purity and degree of bismuth(III) oxobromide precipitation from nitrate and bromide solutions. The metal was oxidized in a stainless steel reactor equipped with a screw for melt agitation. A single batch charged into the oxidation reactor was 150–160 kg. The metal was melted at a temperature of 350°C and bismuth oxide from the preceding stage of oxidation of metallic bismuth was introduced in an amount of 20% into the melt under agitation. The temperature was raised to 600°C and the powder was agitated for 6 h. The technical-grade oxide contained 88.4% bismuth.

Hydrolytic processing of technical-grade bismuth oxide I to give oxobromides II–IV

Product	Content, %					
	Pb	Cu	Ag	Fe	Zn	Cd
I	1.08	8.7×10^{-3}	5.0×10^{-2}	5.6×10^{-3}	5.8×10^{-4}	27×10^{-3}
II	6.2×10^{-2}	7.5×10^{-4}	3.0×10^{-3}	1.0×10^{-3}	2.0×10^{-5}	5.0×10^{-5}
III	0.22	7.8×10^{-4}	9.0×10^{-3}	5.2×10^{-4}	1.2×10^{-5}	3.6×10^{-5}
IV	4.8×10^{-5}	1.0×10^{-6}	2.0×10^{-6}	$<1.0 \times 10^{-4}$	1.0×10^{-5}	5.0×10^{-6}

Its composition (I) in terms of impurity metals is presented in the table.

A bismuth(III) nitrate solution containing 380 and 110 g l^{-1} of Bi(III) and free nitric acid, respectively, was prepared by dissolving technical-grade oxide in 6 M nitric acid. The composition corresponded to that of solutions commonly used in the technology of bismuth compounds. A bismuth(III) bromide solution containing 385 g l^{-1} of bismuth and 70 g l^{-1} of free hydrobromic acid was obtained by dissolving technical-grade bismuth(III) oxide in 7 M hydrobromic acid. The volume ratio between the starting and final bismuth-containing solutions was 1 : 10. Upon addition of hydrobromic acid or an ammonium bromide solution to the bismuth nitrate solution, it was adjusted by addition of distilled water.

The bismuth-containing bromide solution was processed by its dilution with distilled water (1 : 9). This was done in glass vessels with the use of stirrers. The mixture was agitated for 20 min. After settling for 0.5 h, the precipitate was filtered off with the use of a vacuum, washed on the filter with distilled water, and dried in air. An X-ray phase analysis (XPA) of the precipitation products was made on a DRON-3 diffractometer with Cu_{K_α} radiation, counter rotation rate of 0.5 deg min^{-1}, and I = 4000. Curves of differential thermal analysis (DTA) and thermogravimetry (TG) were measured for the samples under study on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1}. Electron microscopic images of the products were obtained using a JSMT-20 scanning electron microscope with a resolution of 200 Å. The specific surface area of the samples obtained was measured by the chromatographic method of thermal desorption of argon. Macroscopic amounts of bismuth(III) in the liquid and solid phases were determined by titration with a solution of Complexon III, with Xylenol Orange as indicator, and microscopic amounts, by photocolorimetry in the presence of KI. The concentrations of metals (Pb, Ag, Cu, Fe, Zn) were determined by the atomic-absorption method on a Saturn 2M spectrophotometer. The precipitation products were preliminarily dissolved in nitric acid (1 : 1). The concentration of nitrate ions was found by voltammetry on a renewable copper electrode [9], and that of bromide ions, on a silver electrode, after being transferred to solution by preliminary treatment with a sodium hydroxide solution (2 M) at 70–90°C.

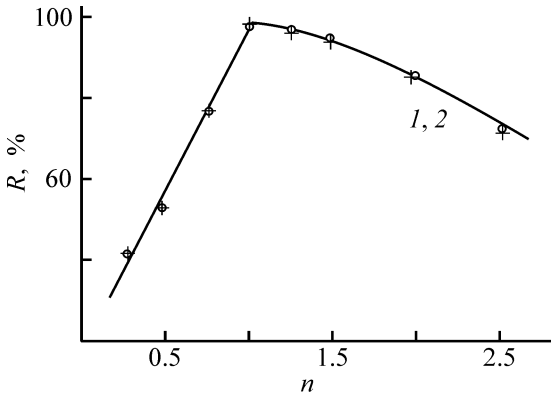

Fig. 1. Degree R of bismuth(III) precipitation from a nitrate solution vs. the molar ratio n between bromide ions and bismuth(III) in the system. Process temperature (°C): (*1*) 22 and (*2*) 90.

The study of the hydrolytic processing of bismuth-containing bromide solutions demonstrated that, upon their dilution with distilled water (1 : 9), the degree of bismuth(III) recovery into oxobromide at 25 and 65°C is 97.9 and 96.5%, respectively. In precipitation of bismuth(III) from nitrate solutions by addition of a hydrobromic acid solution, the dependence of the degree R of metal precipitation on the molar ratio n between bromide ions and bismuth in solution passes through a maximum at 1.0–1.1 (Fig. 1). In this case, the degree of bismuth(III) precipitation is 99.4%. The decrease in the degree of bismuth(III) precipitation at $n > 1$ is due to the formation of bromide complexes of the type $BiBr_x^{3-x}$ in solution [11], which hinders bismuth precipitation in the form of oxobromide. It can also be seen in Fig. 1 that raising the process temperature has virtually no effect on

the degree of bismuth(III) recovery into a precipitate. It should be noted that solutions of both hydrobromic acid and ammonium bromide can be used for quantitative precipitation of bismuth(III). With ammonium bromide used as a donor of bromide ions, the degree of bismuth recovery into the precipitate somewhat increases to become 99.6% at $n = 1.0$.

Bismuth oxobromide has clearly pronounced diffraction peaks at d 8.10, 4.05, 3.52, 2.82, 2.77, 1.96, and 1.61 Å (Fig. 2) [12]. It follows from the results of X-ray studies that, in bismuth precipitation from nitrate solutions to which bromide ions were added, the positions of these peaks remain virtually unchanged, irrespective of the nature of the solutions used (Fig. 2, curve *1*). This confirms that bismuth precipitates from these solutions as the oxobromide BiOBr in the pH range under study (0–3). X-ray studies also demonstrate that bismuth(III) precipitation from bromide solutions upon addition of water to these solutions depends both on the process temperature and on the order in which reagents are introduced. At a process temperature of 22°C and addition of a bismuth bromide solution to water, the X-ray pattern of the product corresponds to bismuth oxobromide (Fig. 2, curve *2*). If, however, water is added to a bismuth bromide solution (Fig. 2, curve *3*) or the process is performed at an elevated temperature (90°C) (Fig. 2, curve *4*), an additional reflection appears in the X-ray diffraction patterns at $d = 6.32$ Å. As a result of washing of these products with water, this reflection disappears. An analysis demonstrated that the washing solution contains hydrogen ions and bromide ions. This indicates that, in bismuth precipitation from bromide solutions (ratio between bromide ions and bismuth equal to 3.8), the product can capture hydrobromic acid, which can be removed in the stage of product washing with water.

DTA and TG data for bismuth oxobromide samples obtained by processing of nitrate solutions (Fig. 3a) indicate that the product is stable in a wide temperature range. On heating of bismuth oxobromide, the loss of mass begins at temperatures higher than 600°C, which is due to sublimation of bismuth in the form of bromide to give oxobromides with a Bi : Br molar ratio exceeding unity [13]. In the case of samples obtained by bismuth precipitation from bromide solutions (Fig. 3b), the loss of mass begins at 250°C and is complete at 300°C. In this case, the loss of mass is 6.3% for a product obtained upon addition of water to a bismuth-containing solution at a process temperature of 22°C and 2.7% in the case of a reverse order of addition of the reagents. When synthesis is performed at 90°C, the loss of mass by the product upon

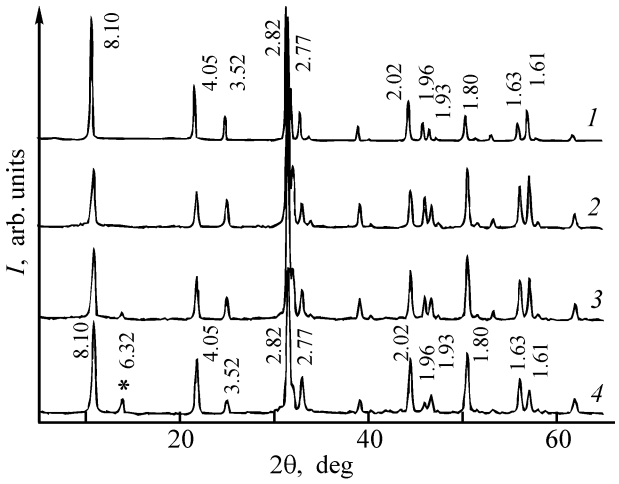

Fig. 2. X-ray diffraction patterns of bismuth oxobromides obtained by precipitation from (*1*) nitrate solutions and (*2*–*4*) bromide solutions, with (*2*, *4*) a bismuth solution added to water and (*3*) water added to a bismuth solution. (*I*) Intensity and (2θ) Bragg angle. Temperature (°C): (*1*) 65, (*2*) 22, and (*4*) 90.

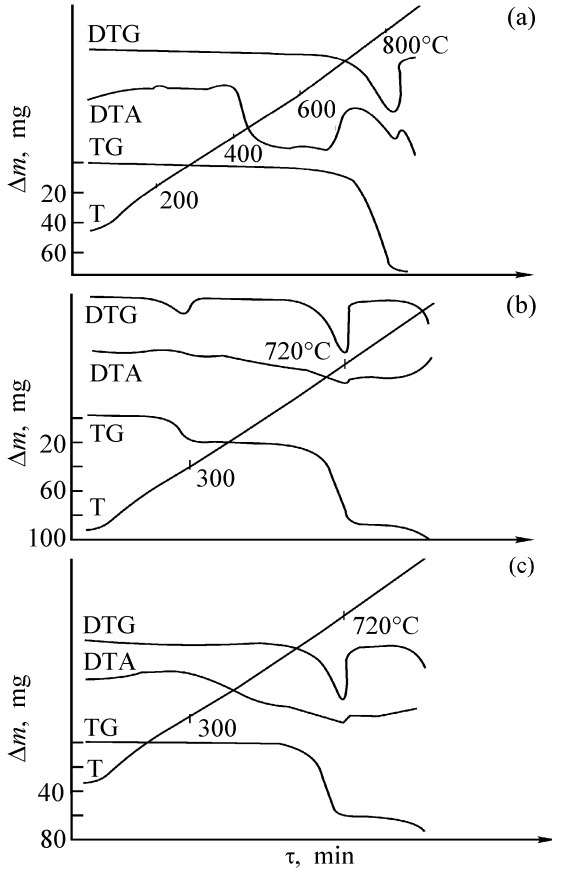

Fig. 3. Thermograms of bismuth oxobromides obtained by precipitation from (a) nitrate and (b) bromide solutions and (c) of bismuth oxobromide formed by thermal treatment of the product at 300°C. Sample mass 300 mg. (Δm) Loss of mass and (τ) time.

calcination is 6.7% in both cases. A chemical analysis of a product calcined at 300°C and kept in air for 10 days demonstrated that this product is pure bismuth oxobromide (its thermogram is shown in Fig. 3c). It should be noted here that the product obtained from bromide solutions has a yellowish tint, which disappears upon washing with water or calcination at 300°C.

Analysis of IR absorption spectra of bismuth oxobromides obtained by precipitation from both nitrate and bromide solutions, and of the same oxobromides calcined at 300°C, shows that all these spectra contain in the spectral range under study (400–4000 cm^{-1}) only a single band associated with symmetric stretching vibrations of the Bi–O bond (510 cm^{-1}) of the A_{2u} type.

According to the results of electron-microscopic studies of hydrolysis products, bismuth oxobromide produced by precipitation from nitrate and bromide solutions has in all cases, irrespective of the order in which reagents are poured-in, the form of aggregates composed of thin-lamellar oval microcrystals with a size of 0.3–3 μm in the basal plane and a thickness of about 0.1 μm. On washing with water, the morphology of the initial microcrystals remains virtually unchanged. The specific surface areas of bismuth(III) oxobromides obtained at 22 and 65°C from nitrate solutions are 1.7 and 1.3 $m^2 g^{-1}$, respectively, and of those formed at 22 and 90°C from bromide solutions, 1.9 and 1.2 $m^2 g^{-1}$. The order of introduction of the reagents has virtually no effect on the specific surface area of the product. In the case of washing with water of a bismuth oxobromide having a specific surface area of 1.2 $m^2 g^{-1}$, it increases to 3.0 $m^2 g^{-1}$, and upon calcination at 300°C, decreases to 1.0 $m^2 g^{-1}$. A product with a specific surface area of 23 $m^2 g^{-1}$ was obtained by bismuth precipitation from dilute [20 $g l^{-1}$ Bi(III)] bromide solutions.

In order to synthesize bismuth(III) oxobromide of increased purity, the possibility of its purification to remove basic impurity metals in precipitation from bromide media was assessed. A processing of bismuth-containing bromide solutions diluted with water (1 : 9) at a process temperature of 65°C, with the subsequent washing of the precipitate with water at 65 ± 5°C and drying of the product at 100°C, yielded bismuth(III) oxobromide whose composition (II) is listed in the table. The results of an analysis of the product obtained indicate that processing of bismuth-containing bromide solutions does not involve effective purification of bismuth to remove lead, silver, and iron. In this context, the possibility of obtaining bismuth oxobromide from nitrate solutions commonly used in synthesis of bismuth compounds was analyzed. Precipitation of bismuth(III) from nitrate solutions in the form of an oxobromide at a molar ratio between bromide ions and bismuth equal to 1.05, as well as its precipitation from bromide solutions, fails to provide effective purification of bismuth to remove lead and silver [see table, composition (III)].

Precipitation of bismuth from nitrate solution in the form of a compound of composition $[Bi_6O_5(OH)_3](NO_3)_5 \cdot 3H_2O$ enables its effective purification to remove impurity metals. This process is used to synthesize special-purity bismuth(III) oxide [14]. Therefore, in order to obtain high-purity bismuth oxobromide, it is advisable to preliminarily purify bismuth nitrate solutions to remove associated metals by precipitation of bismuth in the form of an oxo hydroxonitrate, followed by its dissolution in nitric acid.

In view of the aforesaid, the variant of bismuth oxobromide synthesis by precipitation from nitrate solutions was chosen for larger-scale tests. An additional advantage of this process is that it yields solutions more concentrated in terms of bismuth in the stage of dissolution of the technical-grade oxide and enables use of stainless steel apparatus employed in synthesis of other bismuth compounds. Metallic bismuth of the Vi1 brand was used in the tests.

High-purity bismuth(III) oxobromide was synthesized by its precipitation from a bismuth nitrate solution upon addition of a hydrobromic acid solution at a molar ratio between bromide ions and bismuth equal to 1.05 and a process temperature of 65°C. The precipitate was twice washed with distilled water at 65°C and dried at 100°C. The tests yielded bismuth(III) oxobromide containing (%) 68.54 bismuth, 26.21 bromide ions, and less than 1×10^{-3} nitrate ions. The contents of impurity metals in product (IV) are listed in the table. The degree of bismuth recovery from the technical-grade oxide into oxobromide is 90.3%.

CONCLUSIONS

(1) Bismuth(III) is virtually completely precipitated as an oxobromide of composition BiOBr from bromide solutions upon their dilution with water and from nitrate solutions upon addition of bromide ions.

(2) The product obtained in processing of bromide solutions may contain hydrobromic acid, which is removed by washing of the product with water or its calcination at 300°C.

(3) To obtain high-purity bismuth oxobromide from technical-grade products, it is necessary to preliminarily purify bismuth to remove associated metals by its precipitation from nitrate solutions in the form of a compound of composition $[Bi_6O_5(OH)_3](NO_3)_5 \cdot 3H_2O$.

Abstract—Leaching of vanadium(IV, V) with water and a NaOH solution from ash produced in black oil combustion was studied.

DOI: 10.1134/S1070427207120029

The world production and consumption of vanadium has been steadily growing, especially in recent years. Vanadium is one of the most promising alloying elements. Vanadium has acquired particular importance as an element that can considerably improve, even when present in low concentrations (0.03–0.15%), the physicochemical, technological, and service characteristics of steels. For example, introduction of vanadium in amounts of hundredths to tenths of a percent (0.06–0.12%) into steels of various brands raises their hardness by 15–30%. These properties of vanadium and its low cost in comparison with other alloying metals, such as tungsten, molybdenum, and niobium, make it the most preferable additive in manufacture of low-alloy steels, the extent of whose industrial application has become an important indication of advances in technology. There is steadily growing demand for low-alloy steels for industrial and civil engineering, construction of natural gas and oil pipelines, and automotive industry. Vanadium and its compounds are also widely used in many other industries.

Vanadium is widely abundant in nature. Its content in the earth crust is higher than of, e.g., copper, zinc, and lead. At the same time, vanadium is a considerably more scattered element and industrial deposits of vanadium ores proper are scarce. Therefore, recovery of compounds with this element from various half-products, such as, e.g., ashes formed in black oil combustion, is a topical issue. The vanadium content of high-sulfur oils is as high as 300 g per ton, and that of ash, up to 10–20 wt % V_2O_5. The extraction of vanadium is also necessitated by ecological regulations, because vanadium compounds are highly toxic. The maximum permissible concentration (MPC) of V_2O_5 in air is 0.0001 mg l^{-1} [1–8].

This communication reports on a study of recovery of vanadium compounds from ash formed in black oil combustion (Kirov Heat and Power Plant, Apatity, Murmansk oblast). The ash was ground in a ball mill and sieved, with the <0.2-mm fraction used in the experiments (yield of this fraction, 76%). The ash composition is listed in Table 1. The results of X-ray

*** After additional treatment with a 150-g l^{-1} solution of Na_2CO_3 (s : l = 1 : 10, temperature 100°C), the total degree of extraction was 83.7%.

**** After calcination of the residue at 800°C and second leaching with a 100-g l^{-1} NaOH solution (s : l = 1 : 5, 50°C) the total degree of extraction was 94.2%.

phase and other physicochemical analyses tentatively suggest that the ash contains Fe(II) and Fe(III) hydroxides, Fe(II) and Fe(III) sulfates, $VOSO_4$, and V(III)-iron and Ni(II)-iron spinels. Preliminary experiments demonstrated that, upon treatment of ash with water and acid and alkaline solutions, a major part of vanadium compounds easily pass into the liquid phase. This shows that vanadium is present in ash mainly as V(IV) and V(V), and only partly, as V(III). V(IV) compounds are more stable in acid solutions, and V(V) compounds, in alkaline solutions. Vanadium(III) is present in the ash in form of spinels, which are known to be difficult to decompose. Therefore, to make the overall recovery of vanadium compounds higher, the ash was subjected to oxidative calcination in some experiments, as in the case of processing of vanadium slag, in order to convert V(III) to V(IV) and V(V) [1–4, 9].

Tables 2 and 3 present results obtained in recovery of vanadium(IV, V) from the ash. The weighed portion was 10 g. Leaching was performed under agitation. The precipitate formed upon treatment with the reagent was filtered and washed with water, and the wash water was combined with the main filtrate. The ash was calcined for 8 h, with NaCl and $NaNO_3$ preliminarily added in amounts of 25 and 2%, respectively, relative to the mass of the product. Vanadium was determined by atomic emission spectroscopy with inductively coupled plasma.

Because of the hydrolysis of iron sulfates, water treatment of ash results (Table 2) in a decrease in the pH of the liquid phase to approximately 2 (at s : l = 1 : 3), i.e., leaching is, in fact, performed with a dilute H_2SO_4 solution. With the leaching time τ raised from 12 to 20 h (run nos. 1 and 2), the degree of vanadium(IV, V) recovery increases to 87.6%. However, iron sulfates pass into the liquid phase together with vanadium(IV, V), which is indicated by the small mass of the precipitate formed upon the treatment of the ash with water.

Raising the solid-to-liquid ratio (run no. 3) makes lower the degree of V(IV, V) recovery. A possible reason is that an increase in water expenditure diminishes the solution acidity, and, as consequence, impairs leaching of vanadium compounds. This is con-

firmed by the results of run no. 4, in which the degree of the V(IV, V) recovery from the ash by treatment with a H_2SO_4 solution (200 g l^{-1}) was 89.6%. It can be tentatively concluded that acid leaching provides a 90% transfer of vanadium into the liquid phase. Presumably, more complete recovery is only possible upon introduction of a stage of oxidative calcination.

The leaching of ash with alkaline solutions was studied in more detail (Table 3), because, in this case, transfer of Fe(II) and Fe(III) to the liquid phase is impossible. At the same time, the degree of V(IV, V) recovery in the case of leaching with NaOH solution at s : l = 1 : 5 and room temperature was only 38.7% (run no. 1). Intensification of the leaching by raising the process temperature (Table 3, run no. 2), making longer the treatment time (run no. 3), or introducing a calcination stage and making larger the solid-to-liquid ratio and elevating temperature (run no. 4) essentially improved the transfer of V(IV, V) to the solution. An even better recovery of vanadium compounds was achieved in a two-stage leaching (Table 3, run no. 5) and a two-stage treatment with an intermediate calcination (run no. 6), with the total degree of V(IV, V) transfer to the liquid phase as high as 83.7 and 94.2%, respectively. However, the alkali leaching of ash is, on the whole, less efficient than acid leaching, and acceptable results were only obtained by introducing additional procedures, which makes the technology more expensive.

Other modes of ash treatment with joint use of calcination, acid leaching, and alkali leaching were also tested in the study. In successive leaching with a solution of 100 g l^{-1} HCl (s : l = 1 : 10), calcination at 800°C, and leaching with a NaOH solution (100 g l^{-1}, s : l = 1 : 10), the total degree of recovery was 97.2%. In the case of a preliminary calcination at 900°C, followed by leaching, first, with a NaOH solution (100 g l^{-1}, s : l = 1 : 5, 50°C) and then, with a H_2SO_4 solution (75 g l^{-1}, s : l = 1 : 5), the total degree of V(IV, V) transfer into solution was as high as 99.25%. In these experiments, the V(IV, V) recovery is close to 100%; however, the mass of the residue obtained after the joint treatment is small, which shows that V(IV, V) and Fe(II, III) are not separated. Moreover, these modes are labor consuming and expensive.

Analysis of the experimental data leads to a tentative conclusion that the leaching conditions in which V(IV, V) virtually completely passes into the solution and Fe(II, III) remains in the solid phase have not been found so far. The optimal leaching conditions are as follows: (1) treatment with water and (2) double leaching with alkaline solutions.

Naturally, leaching with water is attractive because of its simplicity. The solution obtained in this mode contained about 20 g l^{-1} V_2O_5. With this solution, two ways to separate V(IV, V) from Fe(II, III) were tested. The first of these consisted in hydrolysis and precipitation of NH_4VO_3 by addition of a NH_4Cl solution [1, 2, 9]. In the course of the hydrolysis (pH 1–2, 80–90°C, 2 h), separation was not achieved because the above components precipitated in nearly equal amounts.

In the second variant, Fe(II, III) hydroxides were preliminarily recovered from solution by neutralization with a NaOH solution to pH ~9, after which NH_4VO_3 was precipitated by addition of a NH_4Cl solution (270 g l^{-1}). To raise the degree of extraction, the precipitate of Fe(II, III) hydroxides was treated with a NaOH solution and NH_4VO_3 was also precipitated from the liquid phase after filtration. The NH_4VO_3 precipitate was washed with a NH_4Cl solution (20 g l^{-1}) and calcined at 500°C to obtain V_2O_5. The total direct yield of V_2O_5 from the ash into the final product was about 50%. An emission spectral analysis of V_2O_5 revealed the following impurities (wt %): 0.1–0.3 Al, 0.03–0.1 Si, 0.01–0.03 Fe, and ~0.01 Ni. With account of the possible recycling, the yield of V_2O_5 can be raised to 75% and higher.

A promising avenue of research is direct use of ash as an alloying additive in steel melting. In this case, it is unnecessary to separate V(IV, V) and Fe(II, III). The mass of ash decreases two-fold upon calcination at 900°C, with the content of carbon and, especially, sulfur sharply decreasing (Table 1). It is known that high-quality steels should contain less than 0.01% phosphorus and sulfur [5, 6, 8]. In widely used steels, the content of vanadium does not exceed 0.2%. The calcined ash contains 18.9% V_2O_5 or 10.6% V (Table 1), which exceeds that in steels by approximately a factor of 50. Accordingly, in the case when calcined ash is used as an alloying additive, the content of P and S introduced into the steels with the ash will be considerably lower than the value specified above (0.01%). The presence of nickel in ash is also a positive factor.

CONCLUSIONS

(1) It was found that, under the optimal conditions, the degree of vanadium(IV, V) recovery into solution is 87.6% in the case of leaching with water, 83.7% in two-stage leaching with alkaline solutions, and more than 97% in the case of joint use of calcination, acid leaching, and alkaline leaching.

(2) It was demonstrated that calcined ash containing 19 wt % V_2O_5 can be used as an alloying additive to steels.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Study of Chromium(VI) Reduction in the Presence of Metal Salt Additives

I. V. Goshu, Yu. V. Tsarev, and V. V. Kostrov

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received May 10, 2006; in final form July, 2007

Abstract—Reduction of Cr(VI) to Cr(III) in a model wastewater in the presence of copper, iron, and nickel nitrates, sulfates, and chlorides was studied. The effect of the process temperature on the final pH values of the solutions was examined.

DOI: 10.1134/S1070427207120030

Chromium is a hazardous impurity in the environment, with the form Cr(VI) being the most toxic. To prevent discharge of this form of chromium into the environment, it is necessary to reduce Cr(VI) to Cr(III) and to remove it from wastewater. Beukes and co-workers studied reduction of Cr(VI) with sulfites in wastewater [1]. The experiments were carried out in an aqueous solution of $Na_2Cr_2O_7 \cdot 2H_2O$ at various pH values and contact durations. It was shown that the rate of Cr(VI) reaction with sulfites strongly depends on the pH of the reaction mixture. As pH increases from 2.0 to 5.0, the rate of Cr(VI) reduction decreases. This process is in many respects analogous to Cr(VI) reduction in neutral aqueous media by Fe(II) ions; however, Fe(II) is effective in a wider pH range.

The catalytic analytical methods used to determine components in redox reactions and the mechanism of catalytic action were considered in [2]. This mechanism consists in that the oxidized form of the catalyst vigorously reacts with a reducing agent, and the resulting product is rapidly oxidized under the action of the oxidizing agent. The reaction of Fe^{3+} ions with thiosulfate, which is catalyzed only by copper(II) ions, was considered as an example.

According to the data of Smirnov and co-workers [3], metal-organosiloxanes containing a transition metal (including copper) that is used in traditional catalysts, can be chosen for homogeneous catalysis. It was shown that the activity of copper-containing compounds is rather high.

The reduction of iron(III) to iron(II) with sodium sulfite was studied in [4]. It was found that the maximum yield of iron(II) is observed in the pH range 2.8–3.0, with the yield of iron(II) decreasing as pH increases.

It was of interest to study the Cr(VI) reduction in aqueous solutions containing copper, iron, and nickel nitrates additives. The reason why these additives are used is due to the necessity for acceleration of the process of Cr(VI) reduction, because it is rather slow in neutral media [1].

The aim of this study was to examine the effect of the process temperature T and duration τ on the Cr(VI) reduction to Cr(III) in the presence of $Cu(NO_3)_2$, $Fe(NO_3)_3$, and $Ni(NO_3)_2$ additives.

EXPERIMENTAL

We carried out experiments were carried out with a model wastewater solution based on chromic anhydride (CrO_3) with a Cr(VI) concentration of 100 mg l^{-1}. A 5% Na_2SO_3 solution was used as a reducing agent. The reduction was carried out in the presence of 10% aqueous solutions of $Cu(NO_3)_2$, $Fe(NO_3)_3$, and $Ni(NO_3)_2$ introduced into 100 ml of the model solution in amounts of 2 mg.

The content of Cr(VI) in the presence of Cr(III) in the model wastewater was determined by photometry [1].

The technique used in the kinetic experiments was described in [5]. The duration of the Cr(VI) reduction process was 60 min.

Previously, it has been found that the degree of Cr(VI) reduction in the model chromic acid solution

under study exceeds that in solutions of its salts [5]. It was noted that the higher degrees of Cr(VI) reduction are due to lower pH values of the reaction medium. Because the rate of chromium(VI) reduction in a neutral medium is extremely low, the reduction was accelerated with metal salts as catalysts: aqueous solutions of copper(II), iron(III), nickel(II), and sodium nitrates, and also solutions of copper and sodium sulfates and chlorides. Based on the data on the redox power of the substances present in the model solution, we made a thermodynamic analysis of the possibility of occurrence of various redox reactions. The standard reduction potentials of the systems under study [6, 7] are listed in the table.

Based on the results of the thermodynamic analysis and on the fundamental concepts of the theory of homogeneous catalysis [2, 7], we suggested a mechanism of the chromium(VI) reduction involving copper, iron, and nitrate ions.

Let us consider the reaction of Cr(VI) reduction

$$2H_2CrO_4 + 3SO_3^{2-} + H_2O \xrightarrow{[Cat]} 2Cr(OH)_3\downarrow + 3SO_4^{2-}. \quad (1)$$

Based on the data in the table and using the "Z" rule for determining the pathways of redox processes, we can assume that the following reactions can occur in the presence of copper(II) ions:

$$SO_4^{2-} + H_2O + 2e \rightarrow SO_3^{2-} + 2OH^-, \; E^0 = -0.93 \text{ V};$$

$$Cu^{2+} + e \rightarrow Cu^+, \qquad E^0 = +0.153 \text{ V};$$

$$2Cu^{2+} + SO_3^{2-} + 2OH^- \rightarrow 2Cu^+ + SO_4^{2-} + H_2O; \quad (2)$$

$$Cu^{2+} + e \rightarrow Cu^+, \qquad E^0 = +0.153 \text{ V};$$

$$CrO_4^{2-} + 8H^+ + 3e \rightarrow Cr^{3+} + 4H_2O, \; E^0 = 1.477 \text{ V};$$

$$3Cu^+ + CrO_4^{2-} + 8H^+ \rightarrow 3Cu^{2+} + Cr^{3+} + 4H_2O. \quad (3)$$

The difference of the standard potentials for reactions (2) and (3), $\Delta E^0 > 0$, is positive and, consequently, $G_p^0 > 0$, which points to a high thermodynamic probability of their occurrence. Based on the properties of Cu^{2+} ions in solution [2, 3], we can assume that the mechanism of the Cr(VI) reaction

Standard potentials of a number of redox systems present in the model solution

Reaction	E^0, V
$SO_4^{2-} + H_2O + 2e \rightarrow SO_3^{2-} + 2OH^-$	–0.93
$Cu^{2+} + e \rightarrow Cu^+$	+0.153
$CrO_4^{2-} + 8H^+ + 3e \rightarrow Cr^{3+} + 4H_2O$	+1.477
$NO^{3-} + 3H^+ + 2e \rightarrow HNO_2 + H_2O$	+0.94
$Fe^{3+} + e \rightarrow Fe^{2+}$	+0.771

with sodium sulfite is described by Eqs. (2) and (3). We estimated in a similar way the effect of iron(III) nitrate and confirmed the possibility of involvement of iron(III) ions in the reduction of Cr(VI) by sodium sulfite. It would be expected that nickel(II) nitrate can affect the Cr(IV) reduction only at temperatures exceeding 200°C.

The temperature dependences of the final pH value and of the degree of chromium(VI) reduction in the presence of various metal salt additives are shown in Figs. 1 and 2. It was shown in [5] that the solution pH changes because of the nonbuffer nature of the model solution under study. The temperature dependence of pH of the model wastewater solution after the reduction of chromium(VI) to chromium(III) in this wastewater at a $Na_2SO_3 : H_2CrO_4$ ratio of 3 : 1 is shown in Fig. 1. It is seen that the final pH values of the model wastewater differ from the initial values. For example, the initial pH value of the model wastewater is 5.3–5.5. In the course of the reduction of chromium(VI) to chromium(III) upon addition of

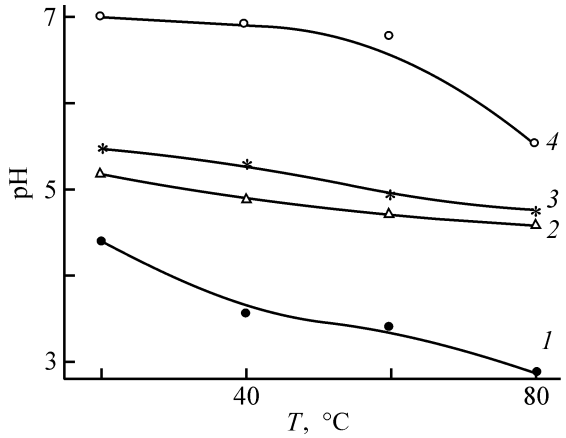

Fig. 1. Final pH value vs. temperature T of the model solution in the presence of various salts. $H_2CrO_4 : Na_2SO_4$ = 1 : 3; the same for Fig. 2. Additive: (*1*) $Fe(NO_3)_3$, (*2*) $Ni(NO_3)_2$, (*3*) $Cu(NO_3)_2$, and (*4*) none.

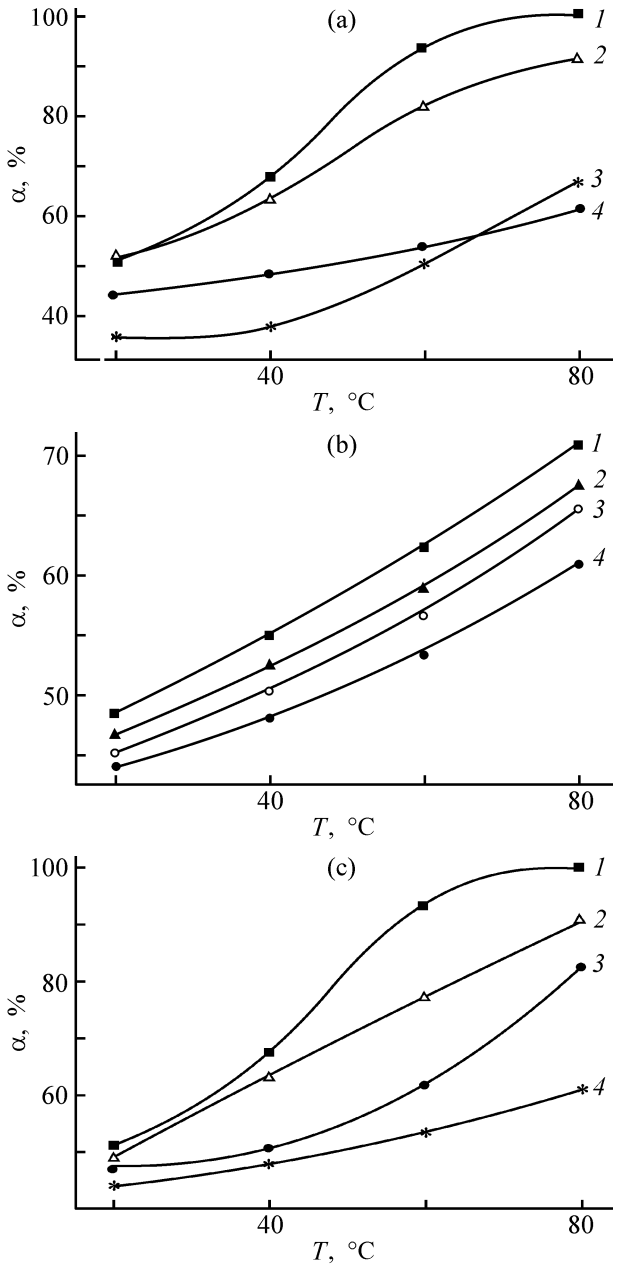

Fig. 2. Degree α of Cr(VI) reduction vs. temperature *T* in model solutions (*1*–*3*) containing various additives and (*4*) free of additives. Addition: (a) (*1*) $Cu(NO_3)_2$, (*2*) $Fe(NO_3)_2$, (*3*) $Ni(NO_3)_2$; (b) (*1*) $NaNO_3$, (*2*) NaCl, (*3*) Na_2SO_4; (c) (*1*) $Cr(NO_3)_2$, (*2*) $CuCl_2$, (*3*) $CuSO_4$.

Na_2SO_3, the final pH value of the model solution increases. The system constituted by sodium sulfite and chromic acid free of metal nitrates is characterized by higher final pH values (up to 6.5–7.0). This is due to the presence of an excess amount of sodium sulfite in the solution, which favors an increase in the solution pH. Thus, the degree of chromium(VI) reduction correlates with the change in pH during the reduction, which may be due to the completeness of sodium sulfite consumption in the course of the reaction.

For the systems constituted by sodium sulfite and chromic acid with copper and nickel nitrate additives, the pH values virtually do not vary with the reduction temperature, whereas for the system with iron nitrate, pH decreases from 4.5 to 3.0. Similarly to the case of the system without metal nitrate additives, the final value of the solution pH is determined by the degree of chromium reduction and, hence, by the completeness of sodium sulfite consumption in the reduction reaction.

The temperature dependence of the degree α (%) of chromium(VI) reduction in the presence of Cu^{2+}, Fe^{3+}, and Ni^{2+} cations and nitrate anions at H_2CrO_4 : Na_2SO_3 = 1 : 3 is shown in Fig. 2. It is seen that addition of metal nitrates raises the degree of chromium(VI) reduction to 95–99% for Cu(II) and 82–90% for Fe(III) at 60–80°C. The only exception is the system with nickel nitrate, for which the degree of chromium reduction (30%) at 20–40°C is even somewhat lower than that for the system without an additive.

Such a behavior of the system constituted by chromic acid, sodium sulfite, and nickel nitrate results from the fact that the reaction of sodium sulfite with chromium(VI) is rather slow because of the high pH value of the solution. At 60–80°C, the degree of reduction increases to 60%, which can be attributed to involvement of nitrate ions. This is confirmed by the experimental data in Fig. 2b, which demonstrate the effect of anions (nitrate, chloride, and sulfate) on the chromium(VI) reduction. It was found that higher degrees of chromium(VI) reduction are observed in model solutions containing nitrate ions.

Because nickel has a stable oxidation state +2, its ions are not involved in the chromium(VI) reduction, which is confirmed by experimental data (Fig. 2a).

Under the experimental conditions, the temperature of the model aqueous solution of chromium(VI) did not exceed 80°C, and, therefore, formation of high positive oxidation states of nickel is unlikely [8].

At the same time, nickel ions can inhibit the chromium(VI) reduction via formation of nickel chromates by the scheme [8, 9]:

$$[Ni(H_2O)_6]^{2+} \rightarrow Ni^{2+} + 6H_2O, \quad (4)$$

$$Ni^{2+} + CrO_4^{2-} \rightarrow NiCrO_4. \quad (5)$$

The efficiency of the influence exerted by cations on the degree of Cr(VI) reduction to Cr(III) in

the systems under consideration decreases in the order $Cu^{2+} > Fe^{3+} > Ni^{2+}$.

To evaluate the contributions of anions and cations to the reduction process, we measured the temperature dependences of the degree α of chromium reduction in the presence of NO_3^-, Cl^-, and SO_4^{2-} anions and copper(II) and sodium cations at $H_2CrO_4 : Na_2SO_3 = 1 : 3$. The experimental results obtained are presented in Figs. 2b and 2c.

It can be seen from Fig. 2b that nitrate ions make the greatest contribution to the increase (by 5–12%) in the degree of chromium(VI) reduction. The effect of sulfate and chloride ions is considerably less pronounced. The effect of anions on the degree of Cr(VI) reduction to Cr(III) in the systems under consideration can be described by the series $NO^{3-} > Cl^- > SO_4^{2-}$.

The temperature dependence of the degree of chromium reduction in the presence of NO_3^-, Cl^-, and SO_4^{2-} anions and copper cations at $H_2CrO_4 : Na_2SO_3 = 1 : 3$ is shown in Fig. 2c. The system with a copper(II) nitrate additive is characterized by a high degree of reduction. The degree of Cr(VI) reduction upon addition of $Cu(NO_3)_2$ and $Fe(NO_3)_3$ is 60% in the temperature range 20–40°C and as high as 99.7% at temperatures of up to 80°C. Because the contribution of anions to the chromium(VI) reduction does not exceed 5–12%, we can conclude that, for the salts under study, Cu^{2+} and Fe^{3+} cations make the main contribution to the increase in the degree of chromium(VI) reduction. In the case of nickel(II) nitrate, the experimental data suggest that the increase in the degree of chromium(VI) reduction is caused by the presence of nitrate ions.

CONCLUSIONS

(1) The reduction of chromium(VI) by sodium sulfite in the presence of $Cu(NO_3)_2$, $Fe(NO_3)_3$, and $Ni(NO_3)_2$ solution additives was studied in model solutions of chromic acid with pH ~7. A thermodynamic analysis of the reactions that can proceed in the model solution was made, and a mechanism of the process of chromium(VI) reduction by sodium sulfite, with copper(II) and iron(III) ions involved, was suggested.

(2) Is was shown that the final values of the solution pH characterize the completeness of chromium(VI) reduction by sodium sulfite.

(3) It was found that Cu^{2+} and Fe^{3+} ions make the greatest contribution to the increase in the degree of chromium(VI) reduction, whereas nickel ions do not affect the chromium(VI) reduction. The effect of the anions under study on the degree of reduction is insignificant and the strongest in the presence of nitrate ions.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extractable Oxo Complexes of Vanadium(V) with Di(2-ethylhexyl) Hydrogen Phosphate

L. D. Kurbatova and D. I. Kurbatov

Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received January 31, 2007

Abstract—Extraction of vanadium(V) with di(2-ethylhexyl) hydrogen phosphate from 1.0–8.0 M aqueous sulfuric acid solutions was studied. The optimal conditions for the extraction were found. The composition of the extractable complex was determined, and the reaction equation for the extraction of V(V) was established. The extraction constant was determined.

DOI: 10.1134/S1070427207120042

It is known that di(2-ethylhexyl) hydrogen phosphate (HDEHP) is an efficient extractant for V(IV). It has also been reported [1] that HDEHP poorly extracts V(V) present in solutions in the form of dioxocations VO_2^+. At the same time, it was shown earlier that HDEHP effectively extracts V(V) from weakly acidic solutions. In this study, we examined extraction of V(V) with HDEHP from moderately concentrated aqueous sulfuric acid.

EXPERIMENTAL

Before use, di(2-ethylhexyl) hydrogen phosphate was purified to remove mono(2-ethylhexyl) dihydrogen phosphate [3]. The extraction of V(V) with HDEHP was studied at 25.0 ± 0.5°C by multistage contact of neat HDEHP with a solution of V(V) in aqueous sulfuric acid for 4 min. The V(V)-containing solutions were prepared by dissolving potassium metavanadate in aqueous sulfuric acid (chemically pure grade). The V(V) concentration was determined by the atomic-absorption method. The electronic absorption spectra of both the solutions of V(V) in aqueous sulfuric acid and V(V)–HDEHP extracts were recorded in the range 13000–30000 cm^{-1} in a 1-cm quartz cell (Specord UV-VIS spectrophotometer). The IR spectra of V(V)–HDEHP extracts (thin layer between KRS-6 plates) were recorded in the range 400–4000 cm^{-1} on a Specord 75 IR spectrometer.

In this study we examined the extraction of V(V) from both straight moderately concentrated aqueous sulfuric acid solutions ($c_{H_2SO_4}$ = 1.0–8.0 M) and those containing cationic and anionic additives. We found that the extraction of V(V) with HDEHP starts at a sulfuric acid concentration higher than 5.0 M, when extractable ionic species of V(V) are formed. The electronic absorption spectra of a solution of V(V) in aqueous sulfuric acid of concentration 1.0–3.0 M contains the absorption bands at 48000, 44000, and 36000 cm^{-1}, which belong to mononuclear complexes of V(V) with the dioxocationic VO_2^+ coordination center [4]. An increase in the sulfuric acid concentration over 5 M results in that the optical density grows and the shape of the spectrum noticeably changes. These spectroscopic effects suggest that a new kind of extractable ionic V(V) species is formed under these conditions.

To identify ionic species of V(V) extracted with HDEHP, the IR and electronic absorption spectra of V(V)–HDEHP extracts were examined. It can be seen from Fig. 1 that, in going from HDEHP–H_2SO_4

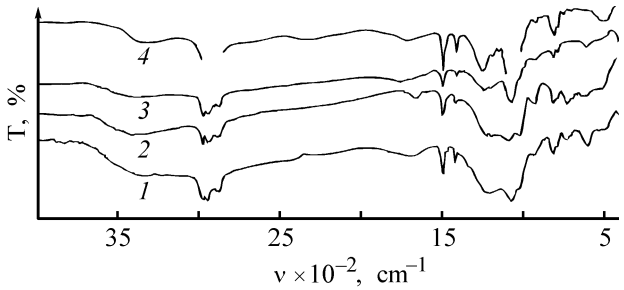

Fig. 1. IR spectra of HDEHP–H_2SO_4 and HDEHP–V(V) extracts. (T) Transmission and (ν) wavenumber. (*1*) HDEHP–V(V) extract (c_V^{init} = 0.1053 M), (*2*) HDEHP-V(V) extract after compensation of HDEHP absorption, (*3*) HDEHP–H_2SO_4 extract, and (*4*) HDEHP.

extract to HDEHP–V(V) extract, the component (1680 cm^{-1}) of the absorption band of P–OH groups shifts to 1630 cm^{-1}.

Two other components of the absorption bands ν_{P-OH} of HDEHP (2260, 2660 cm^{-1}) are lacking in the IR spectrum of the V(V)–HDEHP extract. This fact suggests that V(V) is extracted by the ion-exchange mechanism involving coordination of the P–OH groups with V(V) [5]. The IR spectrum of the V(V)–HDEHP extract also contains absorption bands at 1170 and 1050 cm^{-1}, assigned to ν_s(POO) and ν_{as}(POO) vibrations, respectively [5]. The low-frequency shift of the absorption bands of the ν_{as}(POO) vibrations in the spectrum of the HDEHP–V(V) extract, compared to that of the HDEHP–H_2SO_4 extract, shows that the POO groups are also coordinated with V(V) [6]. This IR spectrum also contains a doublet band (980–990 cm^{-1}) against the background of absorption bands of HDEHP and sulfate anions. The compensation of the absorption of HDEHP in the IR spectrum of the V(V)–HDEHP extract reveals an absorption band of medium intensity at 985 cm^{-1}. By analogy with [7], this absorption band can be assigned to ν_1 vibrations of the dimeric oxovanadium(V) cation. We found no absorption band at 750 cm^{-1}, apparently because it is obscured by the stronger absorption band of HDEHP. These spectroscopic data show that HDEHP extracts V(V) from 8 M aqueous sulfuric acid in the form of a complex of HDEHP with dimeric oxovanadium(V) cation by the cation-exchange mechanism.

It has been reported previously [8] that V(V) is extracted with HDEHP from 12 M aqueous sulfuric acid by the cation-exchange mechanism. Under these conditions, dimeric oxovanadium(V) hydrosulfate cations are extracted. We found that the electronic absorption spectra of extracts of V(V) from 8 and 12 M H_2SO_4 are identical. In both cases, the electronic spectra of V(V)–HDEHP extracts contain the absorption band at 25 000–26 000 cm^{-1}. Thus, the composition of the V(V)–HDEHP extractable complex remains unchanged upon dilution of sulfuric acid.

Sulfate anions and water molecules present in the V(V)–HDEHP extractable complexes formed in extraction of V(V) from 12 M and 8 M aqueous sulfuric acid are manifested as the absorption bands at 660 (sh), 580, and 3400 cm^{-1} [9]. To determine the composition of V(V)–HDEHP extractable complexes formed in extraction of vanadium from moderately concentrated solutions of sulfuric acid, the interaction between V(V) and HDEHP was examined. Using the molar ratio technique, we found

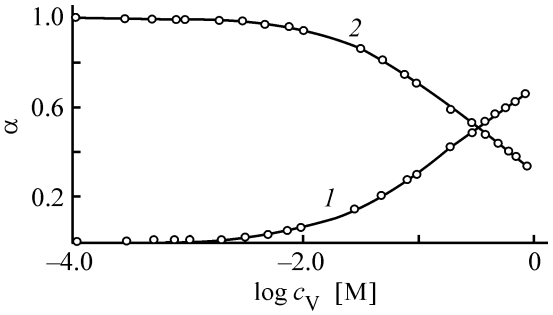

Fig. 2. Speciation of V(V) in 8 M aqueous H_2SO_4 vs. V(V) concentration. (α) Degree of formation of V(V) species and (c_V) V(V) concentration. (*1*) VO_2^+ and (*2*) $V_2O_3^{4+}$.

that the V(V) to HDEHP molar ratio in the extractable complex is 1 : 2 and its stoichiometry can be expressed by the formula $V_2O_3 \cdot (H_2O)_{6-n} \cdot (HSO_4)_n \cdot (HR_2)_2^{(2-n)+}$. The extraction of V(V) with dimeric HDEHP from 8 M aqueous sulfuric acid can be described by the equation of the following heterogeneous reaction:

$$V_2O_3 \cdot (H_2O)_{8-n} \cdot (HSO_4)_n^{(4-n)+} + 2H_2R_2 \rightleftarrows V_2O_3 \cdot (H_2O)_{6-n} \cdot (HSO_4)_n \cdot (HR_2)_2^{(2-n)+} + 2H_3O^+.$$

The extraction constant of V(V) with HDEHP was determined taking into account the data on V(V) polymerization reported in [10]. Figure 2 shows the distribution of V(V) species (VO_2^+ and $V_2O_3^{4+}$) in 8 M aqueous H_2SO_4 vs. the V(V) concentration.

The V(V) speciation in aqueous sulfuric acid was calculated using the dimerization constant of V(V) in 8 M H_2SO_4, reported in [7]. Figure 2 shows that a solution of V(V) in 8 M H_2SO_4 is an equilibrium mixture of its monomeric and dimeric species. At low V(V) concentrations ($c_V < 1 \times 10^{-3}$ M), the monomeric V(V) dioxocations prevail. A noticeable amount of dimeric species appears only at $c_V > 5 \times 10^{-3}$ M. Taking into account that the extractable species of V(V) is dimeric V(V) oxocation, the constant of extraction of V(V) with HDEHP was determined using V(V) solutions in moderately concentrated H_2SO_4, with the V(V) concentration ranging from 6×10^{-3} to 1.4×10^{-2} M. The equilibrium concentration of dimeric oxovanadium(V) cations was calculated taking into account the dimerization of V(V) in aqueous sulfuric acid [10]. We found that, at sulfuric acid concentration of 8.0 M and $\alpha = 0.95$, the extraction constant of V(V) $K = (3.47 \pm 0.02) \times 10^{-1}$.

CONCLUSIONS

(1) Di(2-ethylhexyl) hydrogen phosphate extracts V(V) within a wide range of sulfuric acid concentrations (5.0–12.0 M).

(2) V(V) is extracted with HDEHP by the cation-exchange mechanism in the form of mixed-ligand extractable complexes of dimeric oxovanadium cations with hydrosulfate and alkyl phosphate anions.

Abstract—Activity dynamics of an AO-MK-2 aluminum oxide catalyst in conversion of hydrogen sulfide and carbonyl sulfide during four years of service in an industrial Claus reactor was analyzed. The rate constants of the Claus reaction were determined and changes in the active surface area of the catalyst were examined.

DOI: 10.1134/S1070427207120054

The efficiency of manufacture of elementary sulfur by the Claus method primarily depends on the activity of the catalysts used [1], which necessitates their current diagnostics and prognostication of their remaining life.

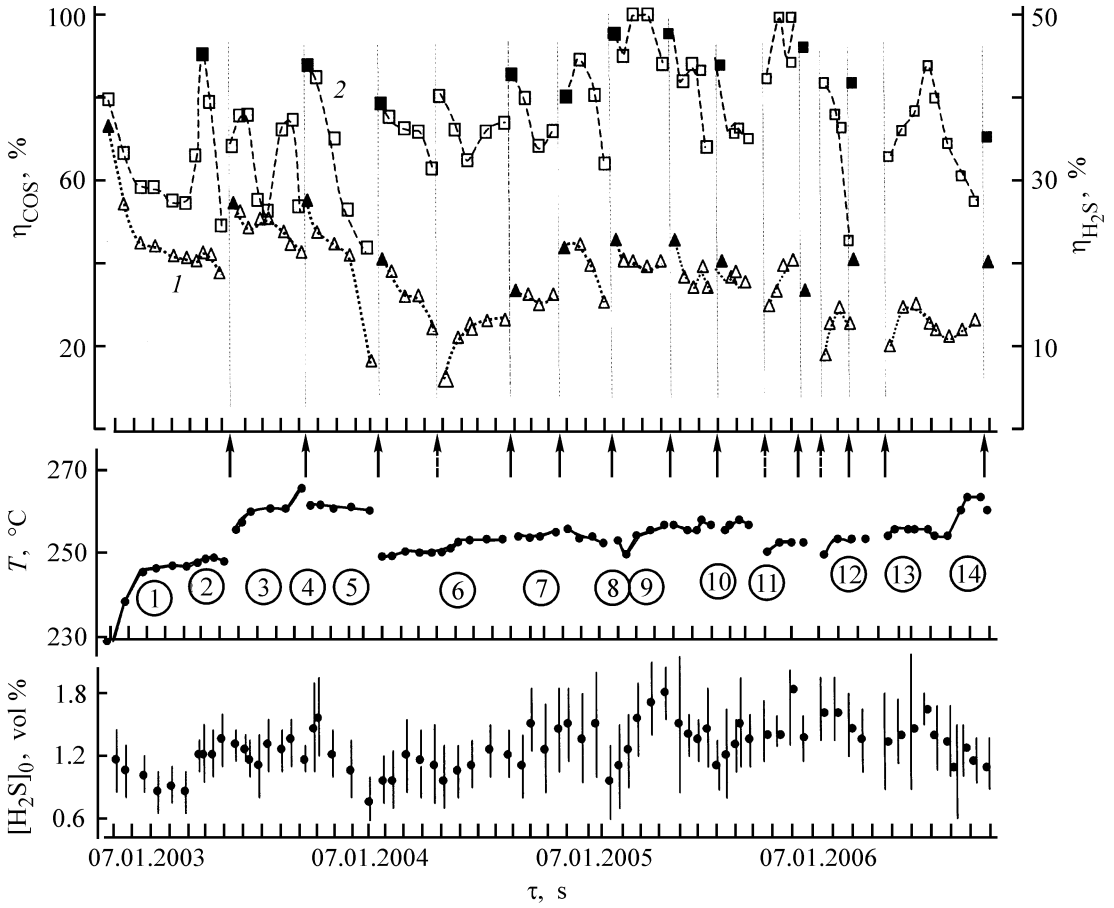
The known methods for laboratory monitoring with accelerated catalyst aging procedures [2, 3] fail to reproduce industrial conditions and, therefore, are inadequate to real working conditions. Catalyst sampling from an industrial reactor, followed by standard testing, requires regular shutdowns of the reactor, which is, apparently, not always possible under the conditions of an operating plant.

A widely used way to monitor the current activity of a catalyst is to examine industrial reactors in the on-line mode, which is, however, not quite versatile. For example, a criterion of equilibration of an effluent gas, developed for a gas-processing plant [4], is virtually inapplicable in the case when the source of an acid gas and its oxidation mode are unstable. This situation is typical of Claus installations that process gases of, e.g., by-product coking origin [5], with low content (<8 vol %) of hydrogen sulfide. This predetermines the topicality of a current diagnostics of catalysts for the Claus process, irrespective of the composition of a gas being processed.

In this communication, we present a procedure for catalyst diagnostics and results of an analysis of how the activity of an AO-NKZ-2 catalyst (original name AO-MK-2 [5, 6]) varied during four years of operation in a Claus reactor in the line for desulfurization of the coke gas at a by-product coke shop (BCP) of Magnitogorsk metallurgical combine (MMC) at a temperature of 230–260°C and volume load W = 2000 h^{-1}. A specific feature of the acid gas being processed is the considerable variability of the concentration at its low value: the content of hydrogen sulfide is 6–8 vol % at the inlet of the Claus furnace and ≤1.5 vol % at the inlet of catalytic units. In addition to the chromatographically determinable gas components (concentrations of N_2, O_2, H_2, CH_4, CO_2, CO, H_2S, COS, and SO_2 are determined in dried samples), the gas being processed contains 10–30 g m^{-3} of elementary sulfur and about 120 g m^{-3} of H_2O.

The activity of the AO-NKZ-2 catalyst in the passive-experiment mode in operation of a technological Claus line at MMC was evaluated by the degrees of conversion of the main sulfur-containing components (H_2S, COS, and SO_2), found by the commonly accepted technique [5] in the Claus reactor unit being tested.

Taking into account that the conversion of the sulfur-containing components depends on composition, we determined the catalyst activity at a ratio between the initial concentrations of components in the gas equal to $\gamma \equiv ([H_2S]_0 + [COS]_0)/([SO_2]_0 \approx 2$, which corresponds to the stoichiometry of the target reac-



Variation of the observable conversion η of (*1*) carbonyl sulfide and (*2*) hydrogen sulfide on an AO-NK3-2 catalyst at $W = 2200\ h^{-1}$ and $T = 253 \pm 13°C$ during the period from 04.02.2003 to 03.25.2007. For explanations, see text. *The arrows* show instants of catalyst regeneration, and *black points*, values of conversion on a fresh (regenerated) catalyst; *digits in circles* are the numbers of events being analyzed.

tions of the Claus conversion, (1) and (2), and hydrolysis (3):

$$2H_2S + SO_2 = 2H_2O + 3/nS_n; \quad (1)$$

$$2COS + SO_2 = 2CO_2 + 3/nS_n, \quad n = 1–8; \quad (2)$$

$$COS + H_2O = H_2S + CO_2. \quad (3)$$

Quantitatively, the catalyst activity in the kinetic equation describing the hydrogen sulfide consumption on a aluminum oxide catalyst

$$-d[H_2S]/dt = k[H_2S][SO_2]^{0.5} \quad (4)$$

was estimated with account of the process factors, taking into account the definition of the rate constant k [7]

$$k = (1 - c^{1/2}/c_0^{1/2})/(\tau c^{1/2}) = (c_0^{1/2}/c^{1/2} - 1)/(\tau c_0^{1/2}), \quad (5)$$

from the initial ($c_0 \equiv [H_2S]_0$) and final ($c \equiv [H_2S]$) hydrogen sulfide concentrations reached during a contact time τ at stoichiometric initial concentrations of the reagents, $[H_2S]_0 = 2[SO_2]_0 = 2c_0$.

Independent laboratory tests were performed in a flow-through quartz reactor with a fixed catalyst bed. A catalyst of the 6–8-mm fraction was tested at 255°C on model gas mixtures containing (vol %): 1–7 H_2S, 0.5–3.5 SO_2, 30 H_2O, and He the rest. The flow rate of the dry gas mixture was 10 $l\ h^{-1}$ at a volumetric flow rate (for the working conditions) of about 3500 h^{-1}.

The specific surface area and content of sulfates in a catalyst sample taken from the Claus reactor were determined by the methods described in [3].

The activity dynamics of a catalyst in its operation in a Claus reactor at MMC during the period from 04.02.2003 to 03.25.2007 is shown in the figure.

* Volume of pores in the range 17–3000 Å.

The upper part of the figure presents average conversions of hydrogen sulfide (η_{H_2S}) and carbon oxysulfide (η_{COS}). The lower panels show the corresponding variations of the principal conversion factors: average temperature of the catalyst bed and initial concentration of hydrogen sulfide at the inlet of the Claus reactor, $[H_2S]_0$. The vertical portions correspond to variance of the average hydrogen sulfide concentrations $[H_2S]_0$ in the corresponding intervals of time.

The arrows on the time scale show "instants" of catalyst regeneration: 11.13–14.2003, 03.17–18.2004, 07.22.2004, 02.25–26.2005, 05.20–21.2005, 08.10–11.2005, 11.12–13.2005, 02.02–03.2006, 06.09–10.2006, 08.20–21.2006, and 03.21.2007, which consisted in raising the catalyst bed temperature to 280–300°C without changes in the inlet-gas composition (we used the built-in bypass of the exhaust-heat boiler of the Claus furnace). Dashed lines shows cases of restarting the Claus line after shutdowns (idle periods): 10.22–26.2004, 03.25–04.24.2006, 06.27–07.09.2006, and 09.04–10.11.2006, when the catalyst was heated to working temperatures after line shutdown with flue gas (α ~1.07) in the absence of hydrogen sulfide.

The activity parameters of the AO-NKZ-2 catalyst in a Claus reactor at BCP MMC [hydrogen sulfide conversion and rate constant of the reaction, calculated by Eq. (5)] in relation to the process parameters are listed for the period of time from 04.02.2003 to 03.25.2007 in Table 1.

The texture parameters of the AO-NKZ-2 aluminum oxide catalyst in the initial state and after tree years of operation and the content of surface sulfates are listed in Table 2.

Analysis of the data presented in the figure shows the following specific features of the conversion dynamics of hydrogen sulfide and carbonyl sulfide.

Dynamics of hydrogen sulfide conversion. Even minor (within 3–5°C) temperature increments (these events are indicated on the time scale by digits) in the course of operation are accompanied by a considerable increase in the observable hydrogen sulfide conversion. This effect is manifested to the greatest extent at the leading edge of the temperature rise at average catalytic bed temperatures of 245–250°C (events 1, 2, 6, 7). A monotonic lowering of the catalyst bed temperature is accompanied by a fast and strong decrease in the hydrogen sulfide conversion (period from 03.19.2004 to 07.20.2004, event 5). Regeneration of the catalyst in a flow of the reaction mixture at 280–300°C and treatment of the catalyst with oxygen-containing flue gases (α ~1.07) at temperatures equal to, or lower than 250°C leads to a virtually full restoration of the hydrogen sulfide conversion.

Thus, the deactivation of the catalyst in the Claus reaction is reversible and the activity of the AO-NKZ-2 catalyst in hydrogen sulfide conversion is virtually preserved during four years of operation. Therefore, it can be assumed that the main reason for the catalyst deactivation in the Claus reaction (1) is closure (blocking) of the active surface because of sulfur deposition in pores of the catalyst. Evaporation of sulfur upon each rise in temperature and(or) during an idle run opens the active surface, with the catalyst thereby regenerated.

The rate constants of the Claus reaction (1), calculated by Eq. (5) for the corresponding conversions $\eta^0_{H_2S}$ during the post-regeneration periods (Table 1), show that the rate of irreversible aging of the AO-NK3-2 catalyst in hydrogen sulfide conversion does not exceed 3–5% per year, which provides its service life of no less than 7–10 years.

Dynamics of carbonyl sulfide conversion. The data presented in the figure demonstrate that the conversion of carbonyl sulfide irreversibly decreases by 50% from the initial value two months after the beginning of operation (40 and 73%, respectively). Treatment of the catalyst with oxygen-containing flue gases (α ~1.07) leads to a sharp decrease in COS conversion (to ≤20%) (see figure, events 6, 11, 12, and 13). Subsequent delivery of a flow of a technological gas containing H_2S results in that η_{COS} starts to grow immediately after the reactor startup. This means that, in contrast to the case of the Claus reaction, the catalyst deactivation is reversible only partly in reactions (2) and (3) of carbonyl sulfide conversion, and the sulfation of the catalyst surface under the action of a dry weakly oxidizing gas mixture results in strong, but reversible deactivation of the catalyst. It can be assumed that the irreversible deactivation of the AO-NK3-2 aluminum oxide catalyst in carbonyl sulfide conversion is primarily due to loss of the active surface via hydrothermal aging. The specific surface area S_{BET} of the catalyst in its sample taken on 04.03.2006 during a shutdown of the Claus line from the upper (back) part of the catalyst bed after its complete cooling was 148 $m^2 g^{-1}$ at an initial surface area of a fresh AO-NKZ-2 catalyst equal to about 270 $m^2 g^{-1}$ (Table 2). To this decrease in the active surface area of the catalyst in three years of operation corresponds a relative decrease in the conversion η^0_{COS}.

As shown previously [8, 9], the sharp decrease in the specific surface area of the catalyst occurs already during first hours of its operation. The results obtained in an industrial examination, presented here, suggest the specific surface area of the AO-NKZ-2 catalyst also occurs during first two months of operation, which leads to a rapid fall of the carbonyl sulfide conversion.

Conversion of organosulfur compounds under the working conditions (temperature 240–260°C, volumetric flow rate ~2000 h^{-1}) is virtually fully governed by the hydrolysis reaction [10]. Hydrolysis of COS under typical industrial conditions (volumetric flow rate ~1000 h^{-1}) on an aluminum oxide catalyst rater completely occurs at temperatures exceeding 330°C [11]. In the conditions of AO-NKZ-2 catalyst operation in the MMC reactor, the Claus reaction (1) occurs under the diffusion control, when the decrease in the specific surface area is compensated for by an increase in the pore size, and the slower reaction (3) of carbonyl sulfide hydrolysis proceeds under the kinetic control, with the activity of the catalyst directly proportional to its specific surface area. In other words, η_{COS} depends on the specific surface area of the catalyst to a greater extent than η_{H_2S} does. Because the AO-NKZ-2 catalyst has a considerable reserve of a surface area for the Claus reaction [3], hydrothermal aging should not noticeably limit the H_2S conversion.

One more factor affecting both the reversible and irreversible deactivation of the catalyst in the reaction of COS conversion is the sulfation of the catalyst. It is known that the hydrolysis reaction is more sensitive to the content of sulfates on the catalyst surface than the Claus reaction [12].

A study of a catalyst sample taken on 04.03.2006 demonstrated that the amount of sulfates present on the catalyst surface is 1.1 wt % (Table 2) and should

not exert any significant influence on the hydrogen sulfide conversion [12].

The comparative independence of the activity of the catalyst in the Claus reaction (1) from sulfation of its active surface can be understood in terms of the mechanism of the Claus reaction, suggested in [8]. Sulfur is formed on the catalyst surface via formation of thiosalts (thiosulfate, polythionates), and the sulfate is a by-product of the reaction. This means that, even when the H_2S/SO_2 molar ratio is nearly stoichiometric and the gas mixture contains no oxygen, a stationary concentration of oxygen sulfurous salts adsorbed on both Lewis and Brønsted basic centers is present at the catalyst surface in the reaction medium. These centers are responsible, as shown in [13], for the catalyst activity in the hydrolysis reaction, and their blocking results in that the hydrolysis rate decreases not only on Al_2O_3, but on TiO_2 and ZrO_2 as well.

The industrial experiment we performed demonstrated that, with the H_2S/SO_2 molar ratio maintained close to stoichiometry and no oxygen present in the gas mixture, the activity of the aluminum oxide catalyst in the Claus reaction weakly depends of the sulfation of the catalyst, which directly determines its activity in hydrolysis of organosulfur compounds. It can be assumed that (i) the differences revealed are typical of catalysts used in processing of sulfur-containing gases and (ii) individual selection of catalysts is necessary for hydrolysis of organosulfur compounds (the catalysts should be sulfation-resistant) and Claus conversion of hydrogen sulfide (the best for this purpose are comparatively low-cost aluminum oxide catalysts). Therefore, it is advisable to use different types of catalysts in preliminary stages of hydrolysis of sulfur-containing compounds and in low-temperature Claus conversion in installations for sulfur recovery.

The differences between the aging rates of the AO-NKZ-2 aluminum oxide catalyst in conversion of carbonyl sulfide and hydrogen sulfide mean that the frequently used determination of the activity of Claus catalysts in hydrolysis of sulfur-containing compounds (carbon disulfide [2]) for monitoring the operation of catalysts for the Claus process is incorrect.

CONCLUSION

A study of how the activity of the AO-NKZ-2 (AO-MK-2) aluminum oxide catalyst varies in the course of four years of operation in a Claus reactor of the line for purification of the coke oven gas at Magnitogorsk metallurgical combine at an average temperature of 245–260°C and a volumetric flow rate of about 2000 h^{-1} revealed fundamental differences in the conversion dynamics of hydrogen sulfide and carbonyl sulfide. It was shown that it is advisable to use specialized catalysts in the stages of hydrolysis of organosulfur compounds and low-temperature Claus conversion.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Stability in the System Constituted by Ammonium Nitrate, Potassium Dichromate, and Alkaline-Earth Metal Nitrates

Abstract—Methods for modification of ammonium nitrate as an oxidizing agent for ecologically safe solid propellants were sought for and the influence exerted on phase transitions in ammonium nitrate by three-component inorganic additives in which a synergic effect lowering the transition energy is manifested was determined.

DOI: 10.1134/S1070427207120066

A promising approach that can be employed to make lower the cost of solid propellants and diminish the amount of chlorine-containing discharges is to use ammonium nitrate (AN) as an oxidizing agent partly or completely replacing ammonium perchlorate (APC). The cost of ammonium nitrate is an order of magnitude lower and it forms no ecologically dangerous products in combustion. The most important difficulties associated with the development of AN-based fuels consist in that AN undergoes polymorphic transformations at working temperatures of the fuel, which are accompanied by an increase in volume, and its combustion velocity is low.

The existing technical solution [1] based on cocrystallization of AN with a binary additive (ammonium nitrate + calcium nitrate) eliminates only the phase stability problem. Additional use of catalysts making higher the thermal decomposition rate and combustion velocity in a phase-stabilizing additive to AN will allow an integrated solution of the problem of its suitability as an oxidizing agent for ecologically safe solid propellants.

EXPERIMENTAL

One of the most effective and readily available compounds, potassium dichromate (PDC), was used as a catalyst. It was introduced into a binary additive composed of potassium nitrate (PN) and nitrates of alkaline-earth metals, such as magnesium nitrate (MN), calcium nitrate (CN) and strontium nitrate (SN). In some systems, potassium nitrate was replaced with potassium perchlorate. The total content of the additive in modified AN was 4%.

Experiments were carried out using Scheffe's design [2], which makes it possible to evaluate nonlinear effects in binary and ternary additive mixtures. The experiments were replicated and their results were used to construct polynomial models whose adequacy was estimated by Fisher's criterion. The models were constructed with exclusion of nonsignificant (according to Student's criterion) coefficients, followed by recalculation [3], which yielded adequate models with the smallest number of terms.

The additives were introduced into AN by isothermal crystallization from aqueous solutions. The solid phase was additionally dried and subjected to differential-thermal analysis (DTA). After the drying, all procedures were performed in a chamber with a relative air humidity not exceeding 50%.

The DTA of a powder of the <400-μm fraction was made in the temperature range from –50°C to the melting point. The weight of a sample for analysis was about 0.1 g, and the heating rate, 3 deg min^{-1}. DTA curves were recorded in the coordinates of the sample temperature and the temperature difference between a sample and the reference. The phase transition energy (J g^{-1}) was evaluated by the area under the corresponding peaks in the DTA diagram, with the use of a calibration plot.

The experiments demonstrated that the V → IV phase transition in AN is not manifested in the whole range of additive compositions studied. The dependences of the energy of the IV → III phase transition in AN on the composition of the ternary additives: (i) potassium nitrate, potassium dichromate, and magnesium nitrate, J_{Mg}; (ii) potassium nitrate, potassium dichromate, and calcium nitrate, J_{Ca}; and (iii) potassium nitrate, potassium dichromate, and strontium nitrate, J_{Sr}; are described by the equations

$$J_{Mg} = 6.3c_{MN} + 20.5c_{PN} + 14.8c_{PDC} - 37.3c_{MN}c_{PN} - 25.4c_{MN}c_{PDC} - 178.7c_{MN}c_{PN}c_{PDC}, \quad (1)$$

$$J_{Ca} = 10.0c_{CN} + 20.9c_{PN} + 15.0c_{PDC} - 38.0c_{CN}c_{PN} - 26.7c_{CN}c_{PDC} - 196.9c_{CN}c_{PN}c_{PDC}, \quad (2)$$

$$J_{Sr} = 15.9c_{SN} + 21.4c_{PN} + 15.3c_{PDC} - 18.9c_{SN}c_{PN} - 34.0c_{SN}c_{PDC} + 688.6c_{SN}c_{PN}c_{PDC}, \quad (3)$$

where c_{MN}, c_{CN}, c_{SN}, c_{PN}, and c_{PDC} are the mass fractions of, respectively, magnesium, calcium, strontium, and potassium nitrates and potassium dichromate.

The general form of Eqs. (1)–(3) demonstrates that the energy of the phase transition in AN is constituted by parts associated both with the effect of individual components (equation terms containing the mass fraction of only a single component) and with that of their binary mixtures (equation terms named binary interaction terms, which contain a product of the mass fractions of two components) and ternary mixtures (equation terms named ternary interaction terms, which contain a product of the mass fractions of three components).

As follows from an analysis of the coefficients at those terms in Eqs. (1)–(3) which contain only individual components, introduction of alkaline-earth metal nitrates improves the phase stability of AN, because these coefficients are smaller than the energy of the IV → III phase transition in AN (19.8 J g^{-1}, according to reference data [4]). Introduction of potassium nitrate in the amount studied has virtually no effect on the transition energy, whereas potassium dichromate has a phase-stabilizing power close to that of strontium nitrate. The coefficients at the terms of the individual components increase in the order: magnesium nitrate, calcium nitrate, strontium nitrate,

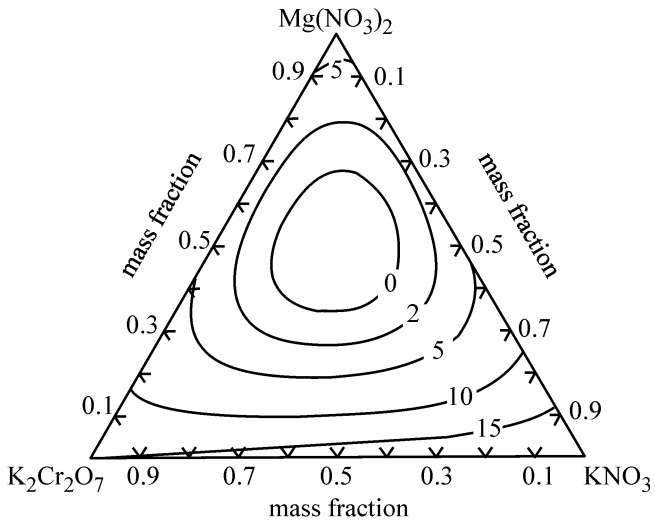

Fig. 1. Diagram relating the composition to the energy of the IV → III phase transition in ammonium nitrate for the additive KNO_3–$K_2Cr_2O_7$–$Mg(NO_3)_2$. *Curves*, lines of equal phase transition energies; the same for Figs. 2–5.

which corresponds to a decrease in the phase-stabilizing power in the same order.

The negative sign of the coefficients at all binary interaction terms in Eqs. (1)–(3) indicates that there is a synergic effect making lower the phase transition energy in the presence of binary mixtures of alkaline-earth metal nitrates with potassium nitrate or potassium dichromate. The absence of the interaction term $c_{PN}c_{PDC}$ in Eqs. (1)–(3) demonstrates that the mixture of potassium nitrate and potassium dichromate virtually does not make any additional contribution to *J*.

The ternary additives containing magnesium and calcium nitrates [Eqs. (1) and (2)] cause a decrease in the phase transition energy (negative sign of the corresponding ternary interaction term), and that with strontium nitrate [Eq. (3)] makes *J* larger.

If the absolute values of the coefficients at the binary-interaction terms in Eqs. (1)–(3) are considered, it can be seen that virtually the same contributions to the overall estimate of *J* come from the binary additives (magnesium nitrate + potassium nitrate) and (calcium nitrate + potassium nitrate), whereas the binary additive composed of potassium and strontium nitrates has a considerably weaker effect. If potassium nitrate is replaced with potassium dichromate, the binary additive containing strontium nitrate as the second component improves the phase stability of AN to a considerably greater extent, compared with other nitrates of alkaline-earth metals.

The graphical interpretation of Eqs. (1)–(3) is shown in Figs. 1–3.

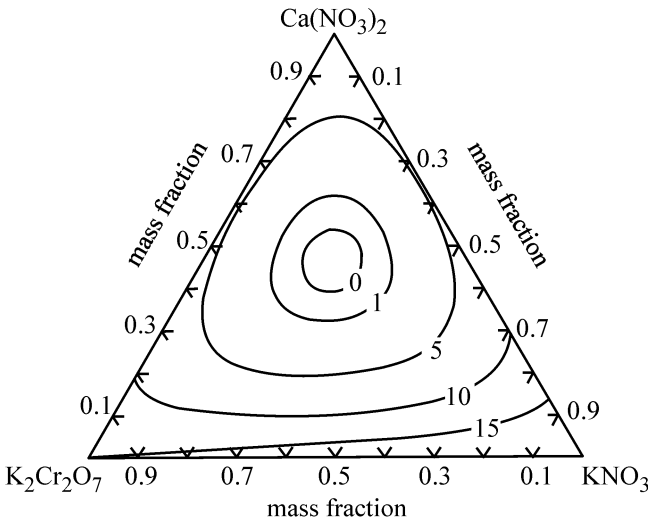

Fig. 2. Diagram relating the composition to the energy of the IV → III phase transition in ammonium nitrate for the additive KNO_3–$K_2Cr_2O_7$–$Ca(NO_3)_2$.

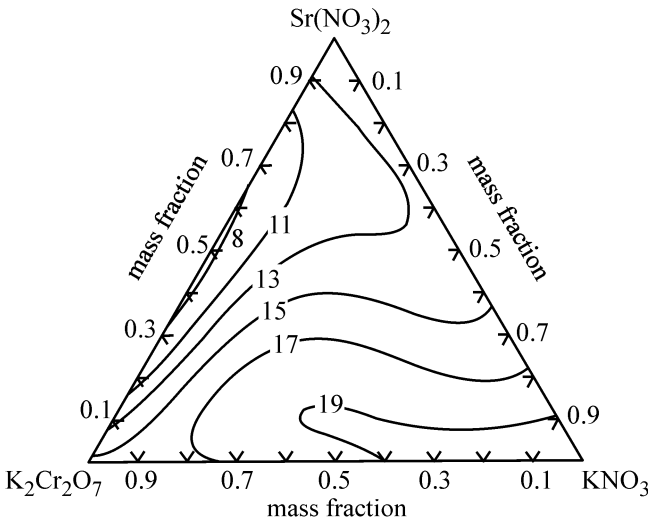

Fig. 3. Diagram relating the composition to the energy of the IV → III phase transition in ammonium nitrate for the additive KNO_3–$K_2Cr_2O_7$–$Sr(NO_3)_2$.

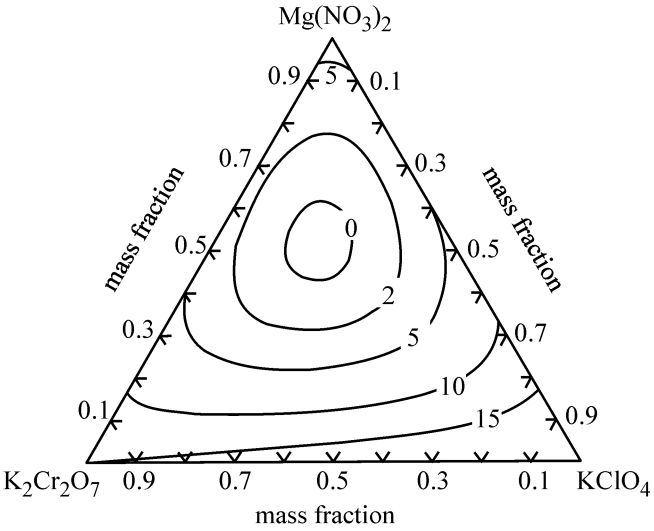

Fig. 4. Diagram relating the composition to the energy of the IV → III phase transition in ammonium nitrate for the additive $KClO_4$–$K_2Cr_2O_7$–$Mg(NO_3)_2$.

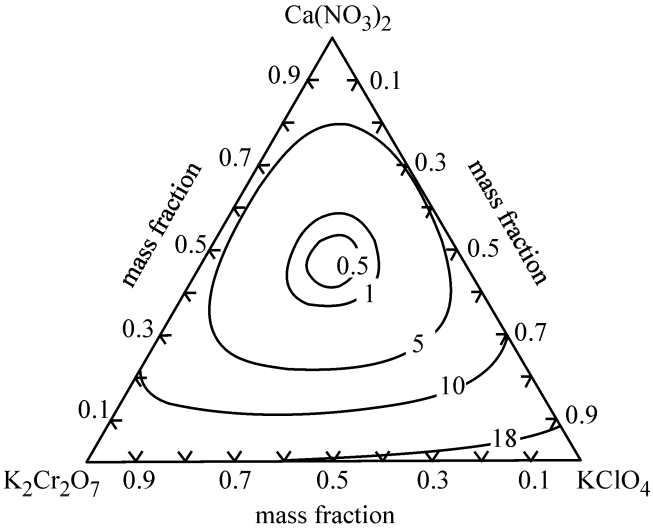

Fig. 5. Diagram relating the composition to the energy of the IV → III phase transition in ammonium nitrate for the additive $KClO_4$–$K_2Cr_2O_7$–$Ca(NO_3)_2$.

For the ternary additives containing magnesium and calcium nitrates (Figs. 1, 2), there are ranges of minimum energies of the phase transition in AN (zero energies according to the models), which lie within the composition–property diagram.

Comparison of the diagrams in Figs. 1 and 2 shows that the region of minimum phase transition energies becomes narrower for the additive containing calcium nitrate at the invariable position of this region in the diagram. Replacement of magnesium and calcium nitrates with strontium nitrate leads to a substantial general deterioration of the phase stability and to a shift of the region of minimum energies to the tie line between the components of the binary additive composed of strontium nitrate and potassium dichromate (Fig. 3). This is accounted for by the large positive value of the coefficient at the ternary-interaction term in Eq. (3), which, in turn, may result from appearance in the ternary mixture of an intermolecular complex formed because of the substantial increase in the radius of the strontium ion, compared with the magnesium ion.

Also, a ternary additive containing potassium perchlorate (PPC) instead of potassium nitrate was stud-

ied. The dependences of the energy of the IV → III phase transition in AN on the composition of the ternary additives: (i) potassium perchlorate, potassium dichromate, and magnesium nitrate, J_{Mg}; and (ii) potassium perchlorate, potassium dichromate, and calcium nitrate, J_{Ca}; are described by the equations

$$J_{Mg} = 6.3c_{MN} + 22.1c_{PPC} + 15.0c_{PDC} - 31.8c_{MN}c_{PPC} - 26.8c_{MN}c_{PDC} - 170.4c_{MN}c_{PPC}c_{PDC}, \quad (4)$$

$$J_{Ca} = 10.2c_{CN} + 21.9c_{PPC} + 15.2c_{PDC} - 40.7c_{CN}c_{PPC} - 25.4c_{CN}c_{PDC} - 186.2c_{CN}c_{PPC}c_{PDC}. \quad (5)$$

Diagrams relating the composition to the energy of the phase transition in ammonium nitrate, plotted using Eqs. (1)–(3), are shown in Figs. 4, 5. It can be seen that the replacement of potassium nitrate with potassium perchlorate has virtually no effect on the position of the region of minimum phase transition energies, but makes somewhat smaller its diameter for the additive containing magnesium nitrate and lowers the minimum depth (according to the model, the energy does not reach the zero value) for calcium nitrate. The experiments demonstrated that an increase in the total content of the ternary additive KNO_3–$K_2Cr_2O_7$–$Mg(NO_3)_2$ to 5% makes the region of zero phase transition energies substantially broader.

Thus, introduction of additives containing potassium, calcium, and magnesium nitrates, potassium perchlorate, and potassium dichromate into ammonium nitrate yields phase-stabilized ammonium nitrate with an increased thermal decomposition rate, which can be used as an oxidizing agent for ecologically safe solid propellants.

CONCLUSIONS

(1) Under the conditions of a differential-thermal analysis, ternary additives (potassium nitrate + potassium dichromate + magnesium nitrate and potassium nitrate + potassium dichromate + calcium nitrate) to ammonium nitrate suppress the V → IV phase transition and lead to a synergic decrease in the energy of the IV → III phase transition in ammonium nitrate to values smaller than the experimental error.

(2) Replacement of magnesium and calcium nitrates with strontium nitrate gives rise to an antagonism, which markedly impairs the phase stability of ammonium nitrate.

(3) Replacement of potassium nitrate in a ternary additive with potassium perchlorate does not change fundamentally the pattern of interactions in the system, but somewhat diminishes the range of zero transition energies.

(4) Additional introduction of a potassium dichromate additive does not impair the phase stability of ammonium nitrate and, as a result, an oxidizing agent for solid propellants with a substantially higher thermal decomposition rate can be obtained.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Limiting Activity Coefficients of Hydrocarbons in Phenol

E. A. Maiorov and Yu. G. Dobryakov

St. Petersburg State University, St. Petersburg, Russia

Received August 10, 2007

Abstract—Temperature dependence of the limiting activity coefficients of saturated (*n*-hexane, *n*-heptane, *n*-octane, and cyclohexane) and aromatic (benzene, toluene, ethylbenzene, *o*-xylene) hydrocarbons in phenol was studied in the temperature range 308–348 K by the headspace analysis method.

DOI: 10.1134/S1070427207120078

Among the thermodynamic characteristics of solutions, to be known in development of processes for substance separation and impurity extraction, are the limiting activity coefficients γ^{∞} of solutes. Values of γ^{∞} for various substances in the same solvent furnish information about the solvent selectivity toward this series of substances and enables evaluation of the extraction properties of the solvent [1]. Finally, values of γ^{∞} are related to parameters of the correlation equations widely used at present for description and calculation of liquid–vapor equilibria in binary and multicomponent systems, which makes it possible to calculate and prognosticate liquid–vapor equilibria at any concentration of the components of the system [2].

Studies of phenol-containing systems are initiated by the practical and theoretical interest in strongly associated solutions in which the effect of hydrogen bonds is manifested and, as a result, deviations of solution properties from the ideal behavior are observed. It is difficult to describe systems of this kind in terms of the existing models, because reliable experimental data necessary for estimating the base energy parameters of the interaction are occasionally lacking.

Huge amounts of phenols are necessary for production of lacquers, synthetic resins, and plastics, for development of a number of new types of polymeric materials, synthetic rubber, pesticides, and surfactants, and for preparation of plastifiers, drugs, and many other products [3]. The amounts of consumption of phenols are significant and steadily grow every year. Nevertheless, published data on the properties of dilute solutions with phenol as a solvent are comparatively scarce. The limiting activity coefficients in systems of this kind have been mainly investigated by the dynamic method of gas–liquid chromatography (on the basis of the retention time) [1, 4], with significant discrepancies between experimental data obtained by different authors.

The aim of this study was to apply the static vapor-phase analysis as an alternative experimental method for determining γ^{∞} at low temperatures and to measure the limiting distribution and activity coefficients of a number of organic substances in phenol in order to refine and supplement the available published data. Hydrocarbons of various homologous series: alkanes (*n*-hexane, *n*-heptane, *n*-octane, and cyclohexane) and arenes (benzene, toluene, ethylbenzene, and *o*-xylene), were chosen as solutes.

EXPERIMENTAL

The limiting activity coefficients of hydrocarbons in phenol were determined experimentally by the headspace analysis, with the vapor phase calibrated against an exterior standard [5, 6], using a Perkin Elmer Multifract F-45 Headspace analyzer. This method is well suitable for measurements in systems with a volatile dissolved component. The chromatograms were obtained and interpreted using a Multichrom hardware-and-software complex of version 1.47. The chromatographic analysis was carried out on a 300 × 0.3 mm steel column with an SE-30 (20%) packing on 60–80 mesh celite. The analysis conditions were as follows: column temperature 100–180°C, carrier-gas flow rate 20 ml min^{-1}, flow divider 1 : 20. Gas samples were taken automatically from glass vials with solutions under study by a pneumatically operated Headspace injector equipped with an internal liquid ther-

Ethylbenzene	16.0195	3279.47	–59.95	300–450
o-Xylene	16.1156	3395.57	–59.46	305–445

mostat and additional heater for the upper space to avoid condensation of substance vapors on the vial covers. The purity of all the reagents was checked by the chromatographic method; in case of unsatisfactory results, the substances were rectified on a rotary rectifying column with an efficiency of 20 theoretical plates. Phenol (purchased from Merck), with the main product content of no less than 99.5%, was not subjected to additional purification because it contained no admixtures that could hinder determination of a dissolved component.

Equal amounts (3 ml) of liquid phenol (mp 41°C) were poured into 22.3-ml glass vials of the same type with an automatic dispenser. The solvent mass was determined by weighing on an electronic analytical balance (Ohaus Explorer, USA) to within 0.1 mg. Then, the second component was introduced in an amount of 1 to 5 μl with a microsyringe into each vial with phenol. A series of solutions with mole fractions x_2 of the solute in the range 0.0002–0.001 was prepared. The same volumes of the second component were introduced into empty vials to prepare reference samples. The vials were hermetically sealed and thermostated for 1 h, after which the vapor phase was automatically sampled and analyzed by chromatography. At least three parallel samples were prepared for each concentration.

We assumed in calculations that the partial pressure and the number of moles of the second component in the gas phase are proportional to the area of its chromatographic peak. As a result of an experiment, we directly determined the distribution coefficient of a solute (index 2) between a vapor and a liquid by the relation

$$K_2^{l-v} = \frac{c_2^l}{c_2^v} = 1 + \frac{V^0}{V^l}\left(\frac{S_2^0}{S_2} - 1\right). \quad (1)$$

Here, K_2^{l-v} is the distribution coefficient of component 2 between the liquid and vapor phases; c_2^l and c_2^v, molar concentrations of component 2 in the liquid and vapor phases, respectively; S_2^0 and S_2, areas of the peaks corresponding to component 2 in a reference vial and over the solution; V^0 and V^l, total volumes of a vial and the volume of the liquid in it.

To determine the limiting distribution coefficient K_2^∞, we extrapolated the data obtained for a series of solutions to zero concentration and then calculated the limiting activity coefficient γ_2^∞ by the formula

$$\gamma_2^\infty = \frac{\rho_l RT}{p_2^0 K_2^\infty M_l}. \quad (2)$$

Here, p_2^0 is the vapor pressure of pure component 2 at the temperature of experiment, T; ρ_l and M_l, density (g cm^{-3}) and molecular weight (94.13 g mol^{-1}) of the solvent; R, universal gas constant; and T, thermodynamic temperature (K).

Formula (2) was derived on the assumption of an ideal vapor phase, which is fully justified at low pressures and temperatures.

The phenol density ρ_l (g ml^{-1}) at the experimental temperatures was calculated using the relation obtained on the basis of the reference data [7] on the molar volume of phenol at various temperatures:

$$\rho = \frac{94.13}{7.63 \times 10^{-5}T^2 + 2.40 \times 10^{-2}T + 73.9}, \quad (3)$$

where T is temperature (K).

In the temperature range under study, polynomial (3) better reproduces the experimental dependence of phenol density on temperature than the Francis equation [7]. The vapor pressures of the pure solutes, p_2^0 (mm Hg), were calculated by Antoine's equation [8]

$$\ln p_i^0 = A - \frac{B}{C + T}. \quad (4)$$

The values of constants A, B, and C for the substances under study are listed in Table 1.

The limiting distribution and activity coefficients of hydrocarbons (hexane, heptane, octane, cyclohexane, benzene, toluene, ethylbenzene, and *o*-xylene) in phenol were measured in the temperature range 308–348 K (Table 2). The distribution coefficients fall within the range from 23 to ~2200, the extreme values being somewhat beyond the optimal applicability range of the static Headspace method [9]. Nevertheless, the resulting values of γ_2^∞ agree (especially at low temperatures) with published data obtained by different methods [10–16]. As temperature increases, a certain divergence of the results (with the maximum value of about 15%) is observed. This is probably due to the possible, in the case of the dynamic GLC method, decrease in the mass of the liquid phase in a column via its uncontrollable vaporization and removal by the gas-carrier, and also to adsorption of the dissolved substances at the phase boundaries between the fixed liquid phase and the solid support.

Positive deviations from Raoult's law are observed in all of the binary systems studied. Values of γ_2^∞ fall within the range 2.3–5.1 for aromatic hydrocarbons and 6.2–18 for alkanes. The data are described by linear dependences on inverse temperature within the experimental error (5–7%) (Figs. 1a–1e).

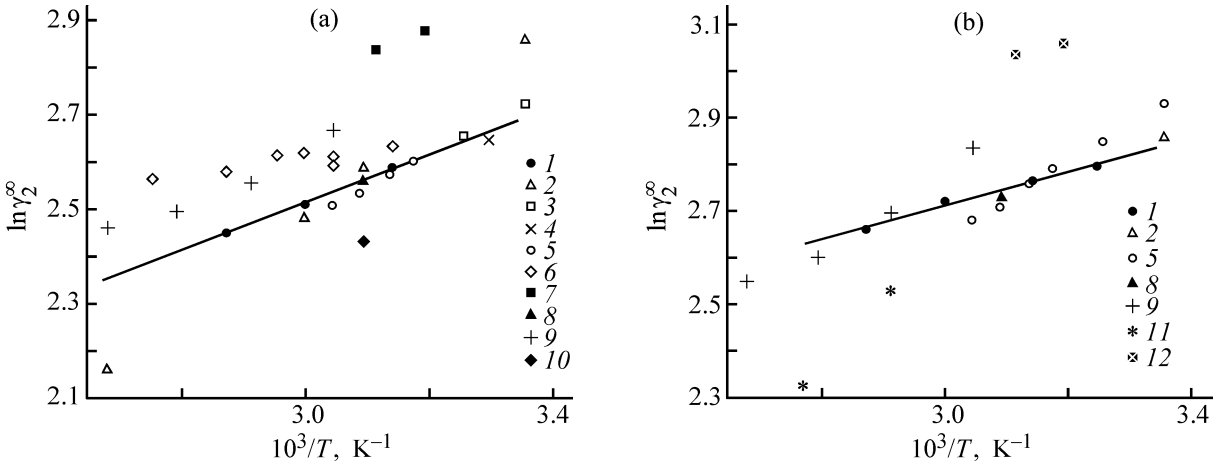

Fig. 1. Limiting activity coefficients γ_2^∞ of (a) hexane, (b) *n*-heptane, (c) cyclohexane, (d) benzene, and (e) toluene in phenol vs. inverse temperature 1/*T*. (*1*) results of this study; (*2–12*) published data [1, 4] obtained by dynamic gas-liquid chromatography methods: (*2*) [10], (*3*) [11], (*4*) [12], (*5*) [13], (*6*) [14], (*7*) [15], (*8*) [16], (*9*) [17], (*12*) [19]; by continuous gas extraction method: (*10*) [14]; by other methods: (*11*) [18].

The limiting activity coefficients for ethylbenzene and *o*-xylene in phenol were measured for the first time. For some hydrocarbons, the values of γ_2^∞ in supercooled liquid phenol were found experimentally at 35°C, which is 5°C below the melting point of phenol. Despite that phenol can be supercooled to room temperature, we did not carry out further measurements because the design of the Headspace analyzer used in the study does not allow thermostating of samples being analyzed below +30°C. Nevertheless, the experimental study of thermodynamic properties of such systems at low temperatures is of particular interest for examining the effect of hydrogen bonds, on which the extractive properties and dissolving power of numerous organic substances depend. The data on γ_2^∞ obtained at 35°C well agree with the values found by extrapolation of the $\ln\gamma_2^\infty$–$1/T$ straight lines to this temperature range (Figs. 1b, 1d, 1e). Thus, the extrapolation of experimental data to the range of metastable equilibria is well justified; however, it is necessary to take into consideration that the error in the thus obtained results can considerably increase. The temperature dependence of the limiting activity coefficients can be used to calculate the partial molar excess enthalpy at infinite dilution, $H_i^{E\infty}$, by the Gibbs–Helmholtz differential equation

$$\left(\frac{\partial \ln \gamma_i^\infty}{\partial (1/T)}\right)_{P, x_i} = \frac{H_i^{E\infty}}{R}. \qquad (5)$$

The dependences $\ln\gamma_2^\infty$–$1/T$ for normal alkanes in phenol (Fig. 2) in the C_6–C_8 homologous series have virtually the same slope, with the value of $H_i^{E\infty}$ equal to 3700 ± 450 (12%) J mol^{-1}. The calculation of the excess thermodynamic functions at infinite dilution from the temperature dependence of limiting activity coefficients can be considered fully reliable.

CONCLUSIONS

(1) Static vapor-phase analysis is a sufficiently simple, rather fast, and reliable method for study of thermodynamic functions at infinite dilution for systems with solute distribution coefficients between the liquid and the vapor of up to 2000. In this method, there are no sources of errors difficult to estimate, which are associated with interphase adsorption and uncontrolled removal of a phase, as in the case of the dynamic GLC based on the retention time.

(2) In contrast to the dynamic variant and continuous gas extraction, the static Headspace analysis

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of Partial Pressures of Components of the Water–Dimethylsulfoxide System with a Double Effusion Chamber

O. V. Surov and M. I. Voronova

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received September 17, 2007

Abstract—Knudsen's method with a double effusion chamber was used to determine the partial pressures of water and dimethylsulfoxide over their solutions and over the water–dimethylsulfoxide–cellulose system.

DOI: 10.1134/S107042720712008X

Knudsen's effusion method is widely and successfully used to study substances with low saturated vapor pressure. However, it has, despite advantages, certain limitations: the upper applicability level of Knudsen's method does not exceed a pressure of 10 Pa, and the radius of the effusion orifice, 1 mm. This is due to the fact that the conditions of molecular outflow of a vapor from the effusion orifice are only satisfied in the case when the mean free path of molecules within the cavity of the effusion chamber substantially exceeds the diameter of the effusion orifice. When pressures substantially exceeding 10 Pa are measured, various corrections are commonly introduced to take into account deviations of the vapor outflow mode from the molecular conditions [1]. Provided that an appropriate calibration is carried out, the effusion method can be successfully used to determine the equilibrium water vapor pressure and calculate the thermodynamic characteristics of the desorption process [2].

The aim of our study was to develop a technique for determining the partial vapor pressures of components of a binary mixture with the use of a double effusion chamber. This method markedly extends the number of systems accessible to study and enables analysis of real technological processes that commonly occur at pressures exceeding the Knudsen limit (10 Pa).

EXPERIMENTAL

The experimental effusion installation and the method for determining the equilibrium water vapor pressure were described in detail in [2]. We chose as object of study the system water–dimethylsulfoxide (DMSO) previously examined with an MI-1201 mass spectrometer [3]. We used a double effusion chamber schematically shown in Fig. 1. Under our experimental conditions, changes in the mixture composition during measurements were negligible. Thus, the whole body of the data obtained can be related to the state of the system, which is characterized by the starting composition.

A solution to be analyzed was placed in chamber *I* (evaporation chamber). After the solution was heated to a temperature T, vapors of its components passed through a connecting channel into chamber *II* (effusion chamber), where the effusion occurred. With this design of the effusion unit, the pressure in the effusion chamber $\sum_{i=1}^{n} p_{2i}$ at a given temperature T will be determined by the vapor pressure in the evaporation chamber, $\sum_{i=1}^{n} p_{1i}$, and by the relative throughputs of

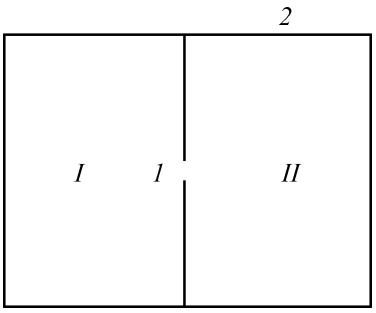

Fig. 1. Schematic of a double effusion chamber. Chamber: (*I*) evaporation and (*II*) effusion; (*1*) connecting channel and (*2*) effusion orifice.

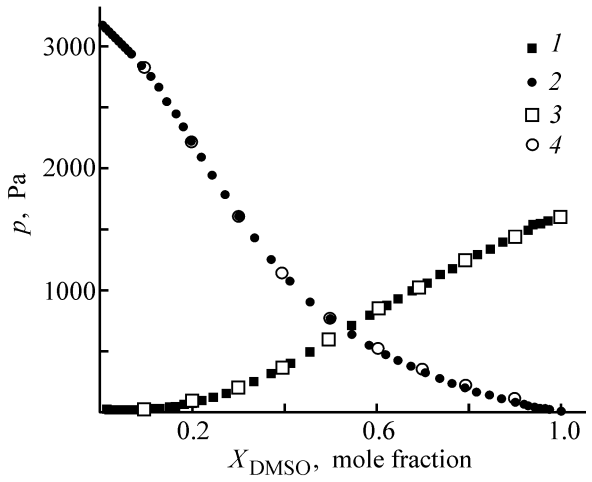

Fig. 2. Partial saturated vapor pressures p of (*1*, *3*) DMSO and (*2*, *4*) water over solutions of various compositions at 298 K. (X_{DMSO}) DMSO concentration in the mixture; the same for Fig. 3. (*1*, *2*) Data of [4]; (*3*, *4*) results of experiments performed in this study. The partial pressures of DMSO are multiplied by 20.

the connecting channel (S_1L_1) and effusion orifice ($S_{ef}L_{ef}$). The flux ρ_1 arriving into the effusion chamber is given by

$$\rho_1 = S_1L_1\Sigma A_i\Sigma p_{1i}, \quad A_i = (2\pi M_iRT)^{-1/2}, \qquad (1)$$

where ρ_1 is the flux of a mixture of n gases leaving the evaporation chamber in unit time (mol m^{-2} s^{-1}); S_1, cross-sectional area of the connecting channel (m^2); L_1, Clausing coefficient characterizing the resistance of the connecting channel to a vapor flow; M_i, molecular mass of ith component of the mixture (kg mol^{-1}); R = 8.314 J mol^{-1} K^{-1}, universal gas constant; T, absolute temperature (K) $\sum_{i=1}^{n} p_{1i}$; total pressure of a mixture of n gases in the evaporation chamber (Pa); and p_{1i}, partial pressure of ith component of the mixture in the evaporation chamber (Pa).

The flux ρ_2 leaving the effusion chamber is given by

$$-\rho_1 = S_1L_1\sum_{i=1}^{n} A_i\sum_{i=1}^{n} p_{2i} + S_{ef}L_{ef}\sum_{i=1}^{n} A_i\sum_{i=1}^{n} p_{2i}, \qquad (2)$$

where S_{ef} and L_{ef} are the cross-sectional area of the effusion orifice and the Clausing coefficient, respectively, and p_{2i} is the partial pressure of ith component of the mixture in the effusion chamber (Pa).

In the steady-state mode, the fluxes are equal ($\rho_1 = \rho_2$) and we have

$$\sum_{i=1}^{n} p_{2i} = [S_1L_1/(S_1L_1 + S_{ef}L_{ef})]\sum_{i=1}^{n} p_{1i}. \qquad (3)$$

The experiment can be performed in two ways. In the first case, a water–DMSO solution with a known concentration of the components is placed in chamber *I*, and water, in chamber *II*. If chamber *II* contains pure water, analysis of Eqs. (1)–(3) shows that, in this case, the water vapor pressures in chambers *I* and *II* will be the same and equal to the saturated water vapor pressure at the temperature of the experiment. This situation will be preserved while pure water is in chamber *II*. In this case, DMSO will evaporate from chamber *I*, and water will only evaporate from chamber *II* and will act as a seal that prevents evaporation from chamber *I*. In the second variant, pure DMSO is in the effusion chamber, and a two-component water–DMSO solution of known concentration, in the evaporation chamber. In this case, the role of a seal is played by DMSO, which prevents evaporation of DMSO from chamber *I*, so that only water evaporates from chamber *I*. Generally speaking, it is necessary, when recording the fluxes ρ_1 and ρ_2, to make a correction for the transfer of a component from a chamber with a lower partial pressure into that with a lower partial pressure, because the concentrations of the solutions vary in the closed isolated space in such a way that the vapor pressures over the solutions tend to equalize. However, it is shown below that this correction can be neglected under the conditions of a not-too-long effusion experiment. The dismountable design of the effusion unit makes it possible to record the loss of mass by a solution in each chamber during the experiment and to vary the throughput capacities of the connecting channel and effusion orifice to achieve the optimal conditions of the experiment. The loss of mass by the solution, temperature of the effusion unit, and evaporation time were used to calculate the vapor pressure in the effusion and evaporation chambers by the Knudsen equation. The vapor pressure of ith component in the effusion chamber, p_{2i} (Pa), is given by

$$p_{2i} = (\Delta m_i/\alpha\tau S_{ef}L_{ef})(2\pi M_iRT)^{1/2}, \qquad (4)$$

where Δm_i is the mass of substance effused from the effusion unit (kg); τ, evaporation time (s); and α, condensation coefficient.

Then, with account of Eq. (3), we can express the vapor pressure of ith component in the evaporation chamber as

$$p_{1i} = (\Delta m_i/\alpha\tau S_{ef}L_{ef})[(S_1L_1 + S_{ef}L_{ef})/S_1L_1](2\pi M_iRT)^{1/2}. \qquad (5)$$

Thus, measuring the loss of mass by a solution in the evaporation chamber in two variants of the exper-

iment, we can obtain the partial pressures of the solution components in relation to concentration. We used in the experiment an effusion orifice with a throughput $S_{ef}L_{ef}$ of 8.206×10^{-10} m^2. The throughput of the connecting channel S_1L_1 was varied as follows: 6.6×10^{-11}, 5.66×10^{-10}, and 1.09×10^{-9}. The procedure described in detail in [2] was used to construct a calibration plot relating the water vapor pressure calculated by the Knudsen equation (5) to the true pressure. It was also found that the condensation coefficient α in Eq. (5) is 0.63 for pure DMSO. Further, we used this value to calculate partial pressures of DMSO in water–DMSO solutions.

Figure 2 shows the partial pressures of water and DMSO, obtained at 298 K using the procedure described above, in comparison with published data [4]. It can be seen that the agreement is very good.

In addition, we determined the equilibrium partial pressures of water and DMSO over the cellulose–water–DMSO system. The procedure used to measure the water vapor pressure over cellulose samples was described in detail in [2]. With account of the specific features of analysis of a two-component water–DMSO solution, the method consists in the following. A preliminarily dried cellulose sample is wetted with a minor amount of the water–DMSO solution and an effusion experiment is carried out using a double effusion chamber. In the experiment, the partial pressures of water and DMSO vapors were determined at 298 K over a cellulose sample wetted with water–DMSO solutions of various concentrations. The content of a component in cellulose, α_i, at which the equilibrium vapor pressure p_i of the component starts to deviate from its saturated vapor pressure p_{i0} at the temperature of the experiment (298 K), i.e., the ratio pD_i/p_{i0} starts to deviate from unity, corresponds to the maximum sorption of the component by cellulose at a given concentration of the solution [2]. In this way, we obtained individual isotherms of water and DMSO sorption by cellulose from a water–DMSO mixture at 298 K.

Figure 3 shows individual isotherms of water and DMSO sorption by cellulose from a water–DMSO mixture at 298 K, obtained in three different ways: (1) by determining the total absorption of the solution by cellulose (cellulose swelling) [5], (2) by calculated from an experimental isotherm of composition variation [6], and (3) by the method described in the present study.

The method for calculating individual sorption isotherms of components from the isotherm of variation of the mixture composition has been described in detail in the literature [7], whereas the method for

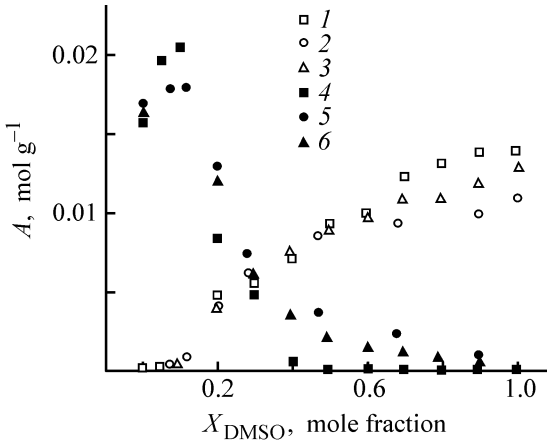

Fig. 3. Individual isotherms of (*1–3*) DMSO and (*4–6*) water sorption *A* from a water–DMSO mixture on cellulose at 298 K. (*1*, *4*) Obtained by determining the total absorption of the solution by cellulose; (*2*, *5*) calculated from an experimental isotherm of composition variation (data of [6]); (*3*, *6*) obtained using the method described in the present study.

determining the total absorption of a solution by cellulose requires a more detailed description. A sample of cellulose wetted with a water–DMSO solution was centrifuged at 8000 rpm for 15 min. These conditions make it possible to remove the solution mechanically bound to cellulose and obtain a cellulose sample with the content of components equal to the physical sorption on cellulose [5]. The content of DMSO in the cellulose sample was determined by extraction of DMSO into a fixed volume of water. The concentration of the resulting solution was found by refractometry. The water content of the sample was calculated from the total mass of the solution sorbed by cellulose (after the centrifugation) and the DMSO content of the sample.

It can be seen from Fig. 3 that the dependence of water sorption by cellulose from a binary water–DMSO solution has an extremum: the maximum sorption of water is observed at DMSO concentrations X_{DMSO} = 0.05–0.1 mol fraction. The possible reasons for the appearance of an extremum in the water sorption curve for the water–DMSO system was discussed in detail in [6]. It is important to note here that three independent methods for obtaining individual sorption isotherms of components in the water–DMSO–cellulose system give well-consistent results. This confirms the adequacy of these methods.

CONCLUSIONS

The method for determining the partial pressures of the components of a two-component mixture with

the use of a double effusion chamber shows good agreement with the results of other independent methods and can be used as a proximate technique for determining the partial pressures of two-component mixtures with vapor pressures considerably exceeding the common upper applicability limit of Knudsen's method (10 Pa).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Liquid–Vapor Equilibrium in the System Acetone–Methanol–*N*-Butylpyridinium Hexafluorophosphate

A. V. Kurzin, A. N. Evdokimov, V. B. Antipina, and O. S. Pavlova

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received July 24, 2007

Abstract—The liquid–vapor equilibrium in the system acetone–methanol-*N*-butylpyridinium hexafluorophosphate was studied at 313.15 K.

DOI: 10.1134/S1070427207120091

Azeotropic mixtures can be separated either by varying the pressure in the course of distillation or by using selective methods such as, e.g., frequently used salt distillation [1]. In this method, the relative volatility of components of an azeotropic mixture is changed by adding an appropriate salt until complete disappearance of the azeotrope. In the modern versions of salt distillation, both organic salts with bulky ions and ionic liquids readily soluble in organic solvents are used.

In this study, we examined, using the headspace gas-chromatographic analysis, the effect of *N*-butylpyridinium hexafluorophosphate on the liquid–vapor equilibrium in the system acetone–methanol-*N*-butylpyridinium hexafluorophosphate at 313.15 K. There are published isothermal and isobaric data on the vapor–liquid equilibrium in the binary system acetone–methanol [2] and in certain ternary systems acetone–methanol–electrolyte (including an ionic liquid) [3].

Our experimental data on the liquid–vapor equilibrium in the system acetone–methanol–*N*-butylpyridinium hexafluorophosphate are listed in Table 1.

Table 1 shows that the minimal concentration of *N*-butylpyridinium hexafluorophosphate required for elimination of the azeotrope in the system acetone–methanol–*N*-butylpyridinium hexafluorophosphate is 0.1 mol kg^{-1}. The phase equilibria in ternary systems containing a binary solvent and an electrolyte are frequently analyzed in terms of the following models of solutions: NRTL, UNIFAC, UNIQUAC, and LIQUAC [4, 5]. In this study, we used the NRTL elec-

trolytic model [6]. This model has been previously used for describing liquid–vapor equilibria in ternary systems containing organic salts with bulky ions [7–9]. The energies of interactions of components in mixed solvents were taken from [3], and the parameters of the salt–solvent interaction were calculated from experimental data on the liquid–vapor equilibria in the corresponding binary systems. The vapor pressures of pure acetone and methanol, used in our calculations, were 54.2 and 34.2 kPa, respectively. The parameters used in our model calculations are listed in Table 2.

The characteristics of liquid–vapor equilibrium in the system acetone–methanol–*N*-butylpyridinium hexafluorophosphate, calculated using the NRTL model, reasonably agree with the experimental values. The mean absolute deviation between the calculated and experimental $|y_i|$ values was 0.007.

EXPERIMENTAL

Acetone and methanol (analytically pure grade) were distilled and dried by standard procedures [10]. The content of main substances in these solvents, determined by gas chromatography, exceeded 99.8%. *N*-Butylpyridinium hexafluorophosphate (Acros), mp 76°C, was used without additional purification.

Ternary mixtures metanol–acetone–*N*-butylpyridinium hexafluorophosphate were prepared gravimetrically. The individual components were weighed with an error not exceeding 0.1 mg. An 8-ml sample of a ternary mixture to be studied was weighed and placed in a preheated hermetically sealed 30-ml vessel. This vessel was kept in a temperature-controlled cell at a prescribed temperature (±0.05°C) with continuous stirring for 6 h. The temperature was measured with an accuracy of 0.1 K. The content of the individual components in the gas phase, y_i, was determined by gaschromatography [5, 11]. In analysis, 0.2-ml samples of gas phase were taken with a syringe. The gas phase was assumed to be ideal. To prevent partial condensation of vapor in the syringe and a shift of the liquid–gas equilibrium in the vessel, both the syringe and vessel were maintained at equal temperatures. The sampled gas phase was analyzed on a Chrom-5 (former Czechoslovakia) gas–liquid chromatograph (glass column, 2.5 m × 3 mm; stationary phase OV-17, 5% on Chromaton N-Super, 0.125–0.160 mm; vaporizer and column temperature 160 and 120°C, respectively; carrier gas argon, 99.9% purity, flow rate 0.5 ml s^{-1}).

CONCLUSIONS

(1) The liquid–vapor equilibrium in the system acetone–methanol–*N*-butylpyridinium hexafluorophosphate at 313.15 K was studied by gas chromatography and adequately described in terms of NRTL electrolytic model.

(2) The minimal concentration of *N*-butylpyridinium hexafluorophosphate for eliminating the azeotrope in the system acetone–methanol–*N*-butylpyridinium hexafluorophosphate is 0.1 mol kg^{-1}.

Abstract—High-performance exclusion chromatography was used to study polysaccharide samples obtained by successive extraction with water, ammonium oxalate, and alkali from waste produced in buckwheat and sunflower processing. The molecular-mass distribution of fractions (protein–polysaccharide complex, polysaccharides, and low-molecular-weight compounds) was analyzed in relation to sources of carbohydrates and methods of their production.

DOI: 10.1134/S1070427207120108

Vegetable polysaccharides constitute a large and rather important group of natural compounds, carbohydrates, and form rapidly replenishable resources of organic substances with unique physicochemical and biological properties, which attract attention of chemists, pharmacists, toxicologists, and other specialists. The properties of polysaccharides are determined by their monosaccharide composition, structure, and molecular mass. The best studied polysaccharides are those produced from sea weeds [1] and higher medicinal plants [2–5] exhibiting a wide spectrum of pharmacological effects. It should be noted that, as a rule, biological activity is exhibited by carbohydrates with medium and low degree of polymerization [3]. In addition, composite materials including various polysaccharides that make a material compatible with a living organism are widely used at present in medicine and allied sciences [6, 7].

Large-tonnage wastes of crops, and primarily of those formed at factories in shelling of seeds (e.g., of buckwheat, rice, sunflower) can serve as raw materials for industrial production of vegetable polysaccharides. However, published evidence about properties of carbohydrates of this origin is scarce. Previously, polysaccharides have been recovered by successive extraction with water, ammonium oxalate, and alkali from wastes formed in processing of rice [8], buckwheat [9], and sunflower [10] grown on the territory of Primorski, Krasnoyarsk, Altai, and Krasnodar krais and their monosaccharide composition has been determined in relation to a botanic species of a plant. It has also been found that carbohydrates produced from rice husk hinder growth of human tumor cells of K562 strain [11], and aqueous, oxalate, and alkaline extracts from rice and buckwheat husk inhibit steel corrosion [12].

The present study, which continues analysis of polysaccharides produced from buckwheat and sunflower wastes [9, 10], is devoted to examination of the molecular-mass distribution (MMD) of their fractions [protein–polysaccharide complex (PPC), polysaccharides (PS), and low-molecular-weight compounds (LC)] by high-performance exclusion chromatography (HPEC).

EXPERIMENTAL

Polysaccharide samples obtained by successive extraction with water, ammonium oxalate, and alkali by procedures described in [9, 10] from buckwheat

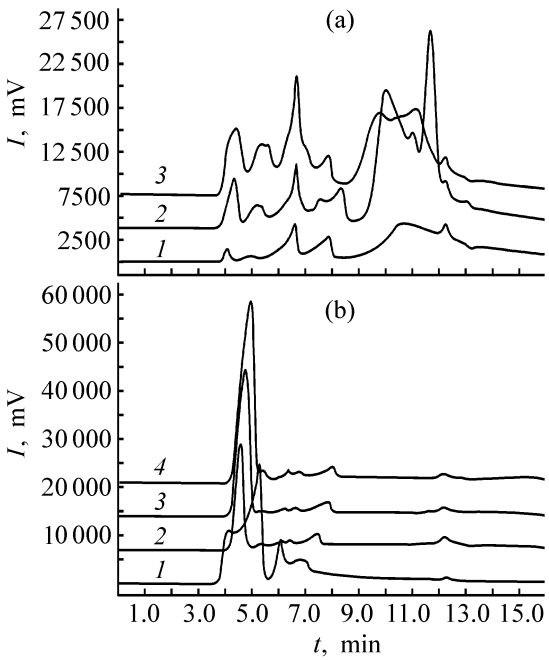

Fig. 1. Chromatograms of polysaccharides recovered from oxalate extracts from (a) buckwheat husk and (b) sunflower husk. (*I*) Intensity and (*t*) time. (a) (*1*) GSh-6, (*2*) GSh-8, and (*3*) GSh-10; (b) (*1*) PSh-1, (*2*) PSh-2, (*3*) PSh-3, and (*4*) PSh-4.

husks GSh-6 (Primorski krai, Izumrud breed), GSh-8 (Primorski krai, Pri-7 breed), and GSh-10 (Minusinsk), buckwheat straws GS-4 (Primorski krai, Izumrud breed) and GS-7 (Primorski krai,Natasha breed), and sunflower husks PSh-1 (Rostov-onDon), PSh-2 (Altai krai), PSh-3 (Kuban), and PSh-4 (Uryupinsk, Volgograd oblast).

The MMD of the polysaccharides was determined by HPEC [13] on a Shimadzu LC-20A Prominence chromatograph (Japan) with an RID-10A refractometric detector and an SPD-M20A diode array detector. The separation was performed on a Shodex Asahipak GS520 HQ column (Showa Denko, Japan),with twice-distilled water as eluent and flow rate of the mobile phase equal to 1 ml min^{-1}. Calibration curves for determining the molecular mass *M* were plotted using pullulan standards manufactured by Showa Denko (Japan) in the molecular mass range 5.9–788 kDa [13]. Chromatograms were recorded and processed using an LCsolution ver. 1.21 hardware-and software complex (Shimadzu, Japan).

To analyze the polysaccharides under study, a precisely weighed portion of a sample (10 mg) was dissolved in 10 ml of distilled water at room temperature. The resulting solution was filtered through a Kurabo 25A membrane filter with a pore size of 0.45 μm and analyzed by HPEC.

It was found in [9] that PS obtained by aqueous or oxalate extraction of all GSh and GS-4 samples are distinguished by increased content of glucose and, in the case of alkaline extraction, have a more complex monosaccharide composition and contain residual amounts of rhamnose, arabinose, xylose, mannose, glucose, and galactose. Aqueous PS from straw (GS-4 and GS-7) contain considerable amounts of inositol (17 and 31 mol %, respectively), whereas in other polysaccharides studied, this compound was observed in trace amounts. Uronic acids are represented in PS from buckwheat wastes mainly by galacturonic acid (GalA). Glucuronic acid (GlcA) was found only in trace amounts and not in all PS samples. All the PS produced by aqueous extraction, from both buckwheat husk and straw, have low content of uronic acids, with the exception of PS from GS-7, in which the amount of uronic acids is comparable with that of hexoses. By contrast, oxalate PS have a high content of uronic acids, with the content of GalA in polysaccharides from GSh-6, GS-4, and GS-7 exceeding by a factor of 2–4 the total content of hexoses. Similarly to aqueous PS, soluble PS produced by alkaline extraction contain a smaller amount of uronic acids (GalA and GlaA, with the former clearly predominant) than the corresponding oxalate PS. Similarly to oxalate PS, insoluble oxalate PS contain a considerable amount of galacturonic acid, especially PS from straw.

Polysaccharides from sunflower husk differ from the buckwheat polysaccharides in a wider diversity of the monosaccharide composition, which depends on a plant variety and extraction method and contain considerable amounts of GalA [10]. For example, xylose is present in PS of aqueous and oxalate extraction in trace amounts, whereas in PS of alkaline extraction, its content occasionally exceeds 50% (PSh-3 and PSh-4). Mannose and inositol are found in minor amounts only in aqueous PS. Residual rhamnose, arabinose, glucose, and galactose are contained in al PS in various relative amounts. Uronic acids are represented only by GalA and are contained in considerable amounts in all of the polysaccharides obtained, with their content being at a maximum in PS of oxalate extraction (55–71 mol %). Their amount is 2–3 times that of arabinose in aqueous PS (or 40–47 mol %), and is the smallest in PS of alkaline extraction (8–12 mol %).

An HPEC study of polysaccharide solutions obtained from buckwheat and sunflower wastes demonstrated that they contain, in addition to the polysaccharide fraction, protein admixtures and low-molecular-weight substances. The molecular-mass distributions of all the fractions are represented in the table, and Figs. 1a and 1b show typical chromatograms of

aqueous solutions of PS recovered from buckwheat and sunflower husks by oxalate extraction of the raw material.

Polysaccharides from buckwheat waste. In analysis of polysaccharides from aqueous extracts from buckwheat husk, the first eluted peak in chromatograms is that of a macromolecular PPC with $M > 300$ kDa. This peak is detected by both refractometric and spectrophotometric (at 280 nm) detectors. The precise molecular mass of this PPC cannot be determined because the exclusion limit of the Shodex Asahipak GS-520 HQ column is 300 kDa. Its content is within the range from 0.6 to 9.6%, depending on a sample (see table). The second eluted peak is that of a polysaccharide with M > 300 kDa, which is detected only by the refractometric detector and shows no absorption at 280 nm. The content of this polysaccharide varies from 6.7 to 7.4%, depending on a sample (see table). This peak is followed by three peaks of pro-

tein-polysaccharide complexes with M of 24.5 to 212.4 kDa. These peaks are not only detected by the refractometric detector, but also show a strong absorption at 280 nm. The content of these complexes varies in the range from 5.7 to 22.4%, depending on the raw material and molecular mass of the fraction. The last to be eluted are low-molecular-weight impurities with $M < 10$ kDa, which are detected only by the refractometric detector.

Analysis of polysaccharides obtained from oxalate extracts from buckwheat husk shows that, in their chromatograms (see Fig. 1a), as also in chromatograms of PS from aqueous extracts, the first eluted peak is that of macromolecular PPC. After this peak, a peak of the polysaccharide fraction is eluted, followed by peaks of protein–polysaccharide complexes, and the last to appear are peaks of low-molecular-weight fractions. The molecular-mass distribution of fractions in the PS from oxalate extracts from buckwheat husk somewhat differs from the distribution for PS from aqueous extracts (see table). The main difference is in that the content of low-molecular-weight impurities in PS from oxalate extracts from buckwheat husk substantially exceeds that in PS from aqueous extracts and show strong absorption at 280 nm.

In analysis of PS from alkaline extracts from buckwheat husk, the first chromatographic peak to be eluted is that of the polysaccharide fraction, followed first by peaks of protein–polysaccharide complexes and then by peaks of low-molecular-weight impurities. The molecular-mass distribution of fractions in PS from alkaline extracts from buckwheat husk markedly differs from the distributions in PS from aqueous and oxalate extracts (see table). The difference is due to the absence of macromolecular PC in PS from GSh-8 and GSh-10. In addition, the PS from the alkaline extracts contains a considerably larger amount of the polysaccharide fraction, whose content is 10.6 to 34.9%.

Polysaccharides from sunflower husk. In the chromatograms of PS recovered from aqueous extracts from sunflower husk, the first eluted peak is that of macromolecular PPC. This peak is followed, first, by a peak of the polysaccharide fraction, then, by peaks of protein–polysaccharide complexes, and finally, by a peak of low-molecular-weight impurities. Their content is shown in the table. However, in contrast to similar PS from aqueous extracts from buckwheat husk, sunflower husk contains a considerably smaller amount of low-molecular-weight impurities. Different PS from aqueous extracts from sunflower husk rather strongly differ in the PPC composition and content of the polysaccharide fraction, which is presumably due both to breed characteristics of plants and to climatic features of places in which the raw material grows.

A chromatographic analysis of PS from oxalate extracts from sunflower husk demonstrated (see Fig. 1b) that they noticeably differ in fractional composition from the PS from aqueous extracts: the content of a macromolecular PPC in the former is as high as 68.8–84.2%, depending on the plant breed (see table).

The eluted peaks of fractions of the PS from alkaline extracts from sunflower husk indicate that the main component of these carbohydrates is the polysaccharide fraction (see table). Its content is high as 39.5 to 52.8%, which considerably exceeds that in PS recovered from other extracts from sunflower husk or in a similar PS from buckwheat husk.

CONCLUSIONS

(1) It was found using high-performance exclusion chromatography that polysaccharides obtained by successive extraction with water, ammonium oxalate, and sodium hydroxide from buckwheat and sunflower husks contain not only polysaccharide fractions, but also protein–polysaccharide complexes and low-molecular-weight compounds.

(2) It was shown that the composition of the polysaccharide fraction, protein–polysaccharide complex, and low-molecular-weight compounds depends on the plant species and breed and on extraction conditions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Structure of Products Formed in Chemisorption of Titanium Tetrachloride by Porous Silicas

Abstract—IR and diffuse-reflectance spectroscopies were used to study the effect of the porous structures of the starting silica and temperature conditions of thermal pretreatment of the matrix and $TiCl_4$ chemisorption on the structure of titanium oxochloride complexes formed on the silica gel surface.

DOI: 10.1134/S107042720712011X

The chemisorption of $TiCl_4$ on various kinds of silicas (silica gels of varied origin and aerosils) has been extensively studied [1–14]. However, mostly the chemical aspects of transformations occurring in an interaction of the matrix with a low-molecular-weight reagent have been considered. At the same time, the structure of new functional groups being formed on the surface can largely determine the reactivity, catalytic activity, and selectivity of modified silicas. A rather important influence is exerted on the structure of the surface groups formed in $TiCl_4$ chemisorption by the origin and thermal pretreatment of the support, which determine the composition and topography of the hydroxo groups of the starting silica [6, 9, 15].

The present study is concerned with the effect of the pore size of silica and arrangement of hydroxo groups on its surface on the structure of the titanium oxochloride complex formed on the support surface via $TiCl_4$ chemisorption.

The methodological aspects of synthesis and analysis of products formed in interaction of a $TiCl_4$ vapor with the surface of porous silica have been considered in detail [16]. To compare the chemical composition of the surface groups formed on various matrices, their titanium content was related to 1 g of anhydrous silica (g_0) [1, 17]. IR spectral studies were performed in the in situ mode on an IKS-29 spectrometer in a flow-through quartz cuvette combined with a reactor [18]. Diffusion-reflection spectroscopy (DRS) was performed on an SF-26 spectrophotometer with a PDO-5 attachment, which enabled analyses without contact with the atmosphere in the spectral range 300–1000 nm [19]. A-300 aerosil calcined at 600°C was used as optical reference.

It has been shown previously [15] that, after treatment of wide-porous silica (ShSKG) in the temperature range of pretreatment of the starting silica (T_0) and chemisorption (T_{cs}) (200–600°C) with a titanium tetrachloride vapor, hydroxyls unreacted with $TiCl_4$ remain on the silica surface. Their amount is, depending on T_0, 25–45% relative to the total amount of OH groups in the starting silica gel. The amount of unused hydroxo groups may be so large for several reasons. First, these hydroxyls can be inaccessible to $TiCl_4$, e.g., because of their position in long narrow pores or at places of contact between globules [20]. Second, they can be shielded by chemisorbed titanium oxochloride groups [4, 21], including those cases in which coordination bonds are formed between grafted surface groups and closely situated silanols [22, 23].

Let us consider the possible contributions of each of these factors. To determine the influence exerted by the porous structure of the starting silica at $T_{cs} = T_0 = 200$°C, we studied the chemical composition of silica gels with an effective pore size in the range 2.3–15.6 nm and changes in their specific surface area after chemisorption of $TiCl_4$ (Table 1). The amount of chemisorbed titanium per unit mass grows for the silicas under consideration, as the specific surface area of the starting matrix increases, from 1.08 mmol g_0^{-1} (ShSKG) to 2.48 mmol g_0^{-1} (KSM-5) (with the exception of the KSM-6S sample). The decrease in the content of titanium on the KSM-6S silica gel is presumably due to partial inaccessibility of the micropore space (d_p = 2.3 nm) to new portions of $TiCl_4$ molecules. However, the amount of chemisorbed titanium per 1 m^2 of the surface of the starting silicas is smaller than that for the coarse-porous silica gel ShSKG and the specific surface area of the samples after chemi-

* Error in determining the structural characteristics of the silicas was 3–4%, and that for the chemical composition of grafted groups, ≤2.6% [16].

sorption of the halide is significantly smaller ($\Delta S > 100\ m^2\ g^{-1}$). This indicates that micropores are also blocked for silica gels of the KSS and KSM brands, which should lead to appearance of structurally inaccessible silanols.

At 200°C, 3.94 μmol of Ti per square meter is chemisorbed on the surface of the ShSKG silica gel (one titanium oxochloride group per 0.421 nm^2), which is in good agreement with the results obtained in [1, 8, 9] under the same conditions on various coarse-porous silicas (3.8–4.25 μmol m^{-2} and 0.413 ± 0.016 nm^2, respectively). Thus, it can be concluded that the contribution of structurally inaccessible silanols to the total number of unreacted hydroxyls is insignificant for coarse-porous silica gels.

Let us consider the possibility of hydroxo group shielding by chemisorbed groups without formation of coordination bonds, as it was observed in $TiCl_4$ chemisorption on aerosils with strong surface curvature in [4]. In this case, the frequency of stretching vibrations of a shielded OH group of silica gel (3750 cm^{-1}) should remain unchanged after chemisorption of $TiCl_4$. However, comparison of the IR spectra of samples, obtained before and after chemisorption of $TiCl_4$ at different T_{cs} (Fig. 1), shows that the clearly pronounced absorption band of single hy-

* Calculated.

droxyls in the spectral range of stretching vibrations of OH groups disappears after interaction with the halide, although the amount of hydroxo groups that did not enter into the chemical reaction is 44, 28, and 31% at $T_{cs} = T_0 = 200$, 400, and 600°C, respectively [15]. Thus, the IR spectral data obtained suggest that "pure" shielding of OH groups, similar to that observed for A-300 and A-380 aerosils [4], is untypical of silica gels. The disappearance of the band at 3750 cm^{-1} from IR spectra after chemisorption of $TiCl_4$, with the broad absorption band in the range of stretching vibrations of OH groups bound by hydrogen bonds (3300–3700 cm^{-1}) simultaneously preserved, may be due to partial involvement of hydroxyls in fixation of titanium oxochloride structures on the silica gel surface, probably as various coordination complexes.

To examine the coordination state of titanium in titanium oxochloride structures formed on the surface of porous silica in the temperature range 200–800°C, we synthesized products whose chemical composition is presented in Table 2. A DRS study of modified silica demonstrated (Fig. 2a) that the DRS spectra have an intricate shape, which is probably due to simultaneous presence on the silica surface of several types of titanium oxochloride structures with different electron transition energies. To determine characteristics of electron transition ranges, we resolved the spectra obtained into components on the assumption that the electron transitions are described by the Fermi–Dirac distribution [24]. An example of such a resolution is shown in Fig. 2b. The results of a mathematical processing of the spectra (Table 2) enable suggestions concerning the fundamental aspects of formation of element oxochloride groups on the silica gel surface.

As T_0 is raised, samples of modified silica gel show an increase in the reflectance (R_D) in the longer-wavelength part of the spectrum ($\lambda > 450$ nm), which reaches its maximum value at $T_0 \geq 600$°C (Fig. 2a) and is virtually independent of the amount and chemical composition of surface titanium oxochloride groups. The reflectance of these samples apparently changes because trace amounts of organic impurities, which are carbonized in an oxygen-free medium during chemisorption of $TiCl_4$ (a known active carbonization catalyst) and serve as a "gray filter" absorbing light in the whole spectral range under consideration, are removed from the surface of the starting silica [25]. At the same time, an insignificant amount of organic impurities does not affect reactions on

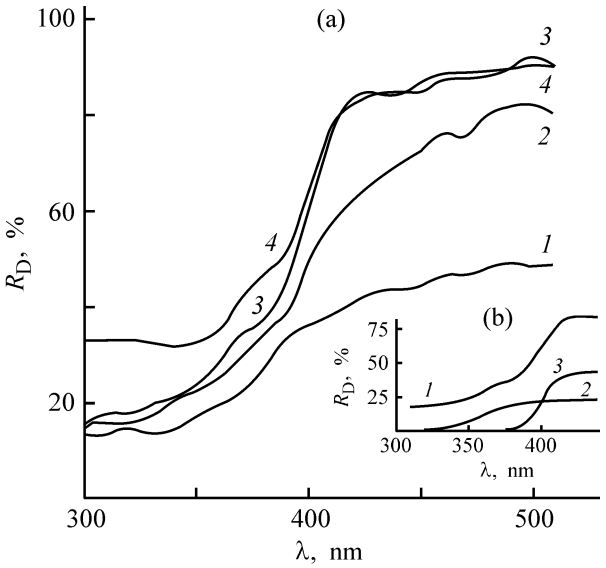

Fig. 2. (a) DRS spectra of samples synthesized on the ShSKG silica gel at $T_{cs} = T_0$ of (*1*) 200, (*2*) 400, (*3*) 600, and (*4*) 800°C and (b) an example of a mathematical resolution of a DRS spectrum into two components. (R_D) Diffuse reflectance and (λ) wavelength. (b) (*1*) Initial spectrum and (*2*, *3*) components of the DRS spectrum.

the surface of the matrix and the chemical composition of the forming titanium oxochloride structures [15, 16].

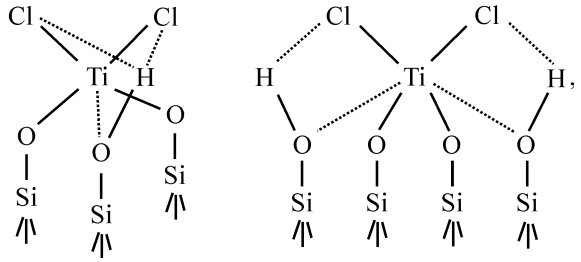
A mathematical processing of DRS spectra (Fig. 2) demonstrated that two electron transitions characteristic of groups with different coordination environments of the titanium atom are simultaneously present in all the spectra (Table 2). The electron transitions centered at 345–370 nm (E = 3.4–3.6 eV) are characteristic of tetrahedrally coordinated titanium (coordination number CN_{Ti} = 4), and those centered at 385–405 nm (E = 3.0–3.2 eV) are observed for octahedrally coordinated titanium (CN_{Ti} = 6) [19].

As T_{cs} is raised, the middle of the electron transition corresponding to the presence of a titanium oxochloride with CN_{Ti} = 4 on the surface steadily shifts from 344 to 369 nm (which corresponds to a decrease in the activation energy of the electron transition from 3.61 to 3.36 eV). This effect may be due to a certain decrease in the degree of distortion of titanium oxochloride groups via equalization of the angles and lengths of interatomic bonds in the surface group, which presumably occurs because of an increase in the mobility of near-surface silicon-oxygen tetrahedra of the silica matrix at higher T_{cs} [26].

It should be noted, when analyzing the region of electron transitions for groups with CN_{Ti} = 6, that the group formed on the surface at T_{cs} = 200°C has a transition energy of 3.21 eV. This is rather close to the energy gap of TiO_2 in the anatase modification, whereas at $T_{cs} \geq 400$°C, the electron transition energy of the complex (3.06–3.08 eV) is close to the energy gap of the high-temperature modification of TiO_2, rutile [27].

An IR spectral study of samples synthesized at different T_{cs} (Fig. 1) demonstrated that Si–O–Ti bonds between the substrate and titanium oxochloride groups are formed as a result of $TiCl_4$ chemisorption on silica gel. This is manifested in the appearance of an absorption band peaked at 910–920 cm^{-1} (Fig. 1, curves *2*). Published data on the peak of absorption by the Si–O–Ti bond are rather contradictory [7, 12, 28–34]. For example, an absorption band at 959 cm^{-1} is attributed to the structural fragment Si–O–Ti–Cl with CN_{Ti} = 4 [28]. Close values (950–960 cm^{-1}) have been observed in numerous studies in pyrogenic titanosilica [29] or that synthesized by cohydrolysis of alkoxy compounds and then calcined [30]. However, some researchers have also observed lower absorption peak positions: 935–945 [31, 32], 930 [33], 924 [12], 919–925 [34], 920 [7], and even 900 cm^{-1}, with the appearance of the absorption band at 900 cm^{-1} attributed by Shalumov and co-workers to an increase in CN_{Ti} to 5 [30].

Thus, we can conclude, based on the above published data, that the absorption band peaked at 910–920 cm^{-1}, observed in our case, is presumably due to the formation on the silica surface of a Si–O–Ti bond with titanium atoms whose degree of coordination increases because of the formation of additional coordination bonds with oxygen atoms from adjacent siloxane bridges or from silanols unused in the course of $TiCl_4$ chemisorption. However, there is no absorption band of single hydroxyls at 3750 cm^{-1} in the IR spectra of samples treated with a $TiCl_4$ vapor (Fig. 1, curves *2*). This may indicate that, despite the only partial utilization of silanols in the chemisorption reaction (Table 2), OH groups are involved in the formation on the silica gel surface of titanium-containing structures in which titanium has a coordination higher than that in $TiCl_4$. At the same time, as T_0 is raised, the DRS spectra show (Fig. 2a) a considerable amount of a tetrahedrally coordinated titanium, despite the increasing number of strained siloxane bridges. This may indicate that the oxygen from the siloxane bridges contributes to a considerably lesser extent to an increase in the coordination of titanium atoms. Thus, in chemisorption of $TiCl_4$, part of silanols form with surface titanium oxochloride groups coordination compounds of the type



in which the CN of titanium increases to 5–6, rather than entering into a chemical reaction with the tetrachloride.

The possible formation of coordination bonds between the titanium oxochloride group and silanols is also indicated by quantum-chemical calculations of the structure of a cluster formed in $TiCl_4$ chemisorption, performed for the (111) and (110) surfaces of β-cristobalite [35]. As follows from Fig. 3, the CN_{Ti} increases on the surface because of the coordination interaction with adjacent silanols, despite the distortions appearing in the crystal lattice of the matrix. It is noteworthy that, for the (111) face, coordination bonds can only be formed for $TiCl_3$ groups, whereas

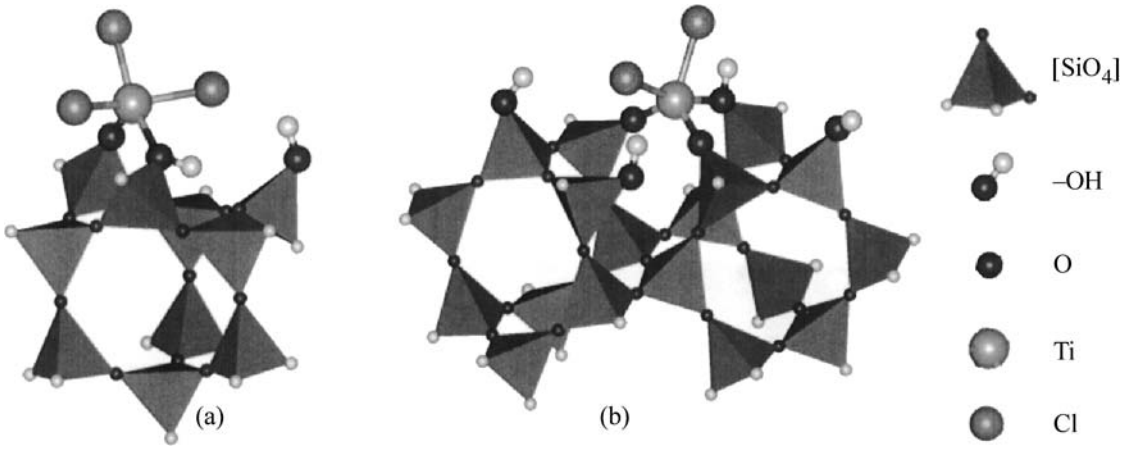


Fig. 3. Model structures of products of $TiCl_4$ chemisorption on (a) (111) and (b) (110) faces of β-cristobalite.

at the (110) face, an increase in CN_{Ti} is also possible for double-bonded ($=TiCl_2$) groups (Fig. 3b).

CONCLUSIONS

(1) Products formed in $TiCl_4$ chemisorption on porous silicas were subjected to an integrated study with the use of results of chemical analyses, IR spectroscopy, and DRS, which are in agreement with quantum-chemical calculations of clusters formed on the (111) and (110) faces of β-cristobalite. A conclusion was made that, in addition to the formation of Si–O–Ti chemical bonds via an electrophilic substitution of protons of silanol groups by titanium oxochloride structures, coordination bonds are formed between chemisorbed groups and used silanols, which is accompanied by an increase in the coordination number of titanium atoms to 5–6.

(2) It was shown that the siloxane bonds present on the silica surface are virtually not involved in the formation of coordination complexes, which is manifested in the preferential formation of titanium oxochloride structures with $CN_{Ti} = 4$.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Control over *m*-Nitrotoluene Concentration in Products of Heterogeneous Mononitration of Toluene

Abstract—Heterogeneous mononitration of toluene with sulfuric–nitric acid mixtures, occurring in the charged interfacial monolayer with high *para* selectivity, was studied. Ways to suppress the *meta* substitution in the toluene mononitration stage by controlling the nitrating mixture composition, process parameters, and catalytic additives were found.

DOI: 10.1134/S1070427207120121

The isomeric distribution of dinitrotoluenes (DNT) in the second stage of toluene nitration (2,4-/2,6-DNT ratio and concentration of *ortho* isomers) is significant in production of toluylene diisocyanate (TDI), whose world-wide annual output is about 1 million tons [1]. The DNT isomer ratio in the second nitration stage is controlled by largely the yield ratio of mononitrotoluene isomers in the first stage.

The problem of control over the nitrotoluene (NT) isomer ratio can be subdivided into two main tasks: (1) to change the *o*-/*p*-NT ratio and (2) to decrease the concentration of *m*-nitrotoluene (*m*-NT), which is an undesirable by-product in production of di- and trinitrotoluene [2].

Table 1 summarizes the published data [2–4] on the *m*-NT content of NT isomer mixtures obtained in titration of toluene with nitric acid and sulfuric–nitric acid mixtures at various temperatures. As can be seen, the *m*-NT content changes moderately (by no more than a factor of 2) over a wide temperature range from –30 to +60°C. Nevertheless, the *m*-NT content increased with temperature in all the cases.

It is known that the activation energy of toluene nitration at the *meta* position is higher than that at the *para* position by 1.1 kcal mol^{-1} [5] (1.62 [3]). Therefore, an increase in temperature accelerates nitration at the *meta* position to a greater extent. Evidently, as temperature increases, the competition of these reactions results that the *m*-NT content grows, which is consistent with the available experimental data.

Another factor having a considerable effect on the yield of *m*-NT is the nitrating power of the acid mixture. For example, Orlova [2] reported that, in toluene nitration with sulfuric–nitric acid mixtures containing 10 wt % HNO_3 at 55°C, an increase in the H_2SO_4 concentration in the acid mixture from 28 to 47 mol %, which corresponds to rise in the nitrating acid efficiency factor from 68 to 82%, lowers the yield

Table 1. Influence of the temperature and acid mixture composition on the *m*-NT content of the NT isomer mixture [2–4]

60	5.1	–	–	–	4.9	4.9	–	–

* (1) 55–61% HNO_3, (2) 94% HNO_3, (3) 23.8% HNO_3 + 58.7% H_2SO_4, (4) 13.7% HNO_3 + 64.4% H_2SO_4, (5) 5.5% HNO_3 + 71.4% H_2SO_4 + 1.75% HNO_2, (6) 0.5% HNO_3 + 71.7% H_2SO_4; (7) HNO_3 in the system CF_3COOH–H_2O (95.0% CF_3COOH); and (8) $HNO_3 : H_2SO_4 : (CH_3CO)_2O$ = 1 : 1 : 30.

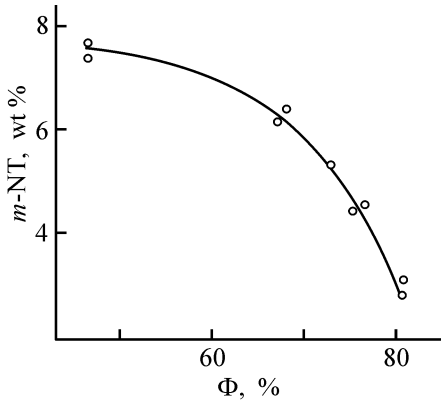

Fig. 1. Yield of *m*-NT vs. the nitrating acid efficiency factor Φ in heterogeneous nitration of toluene with sulfuric–nitric acid mixtures (10 wt % HNO_3) at constant temperature [3].

of the *meta* isomer by a factor of 2.4 (Fig. 1). Because toluene nitration with the indicated acid mixtures is accompanied by the formation of di- and trinitrotoluenes, data presented in Fig. 1 were obtained by recalculation of the amounts of *o*-dinitrotoluenes (3,4-, 2,3-, and 2,5-DNT) and asymmetrical isomers of TNT, contained in trotyl, to the *m*-NT content of the mononitration product. Similar results were obtained in heterogeneous nitration of toluene diluted with *n*-heptane, thus confirming the generality of this trend (Table 2) [3].

Thus, in nitration of toluene with acid mixtures commonly used in industrial processes, the yield of *m*-NT, and, therefore, of the so-called *ortho* isomers of DNT, formed in the second nitration step, can be reduced by carrying out nitration at low temperatures and, probably, by using more concentrated nitrating mixtures [2, 3]. Unfortunately, the technically feasible temperature variation range is rather narrow, and the composition range of the industrial acid mixtures used in the mononitration step is limited for a number of reasons as well.

Table 2. Influence of the sulfuric acid content on the *m*-NT percentage in the isomer mixture [3] (35 mol % HNO_3, 30°C, mineral to organic phase volume ratio 100 : 1, 5% toluene in heptane)

m-NT, %	H_2SO_4	
	mol %	wt %
4.04	32.0	71.7
2.70	46.0	82.0
1.49*	62.0	89.88

* *m*-NT content was estimated taking into account the 2,5-, 3,4-, and 2,3-DNT concentrations in the second stage [2].

The yield of the *meta* isomer can be influenced by various additives. Addition of sodium nitrite allows reduction of the yield of the *meta* isomer [2]. However, it should be pointed out that addition of $NaNO_2$ in amounts above 6% produces remarkable amounts of side products:

Yield of *m*-NT in toluene nitration in the presence of $NaNO_2$ [2] (Φ 73%, HNO_3 content of the acid mixture 10 wt %)

$NaNO_2$, wt %	0	1.5	3.0	4.5	5.9	8.6	11.0
m-NT, wt %	5.4	4.3	4.1	3.5	2.8	2.7	2.6

Hanson et al. [6] reported the effects of the solvent and external electric field on the isomer ratio in the continuous mononitration of toluene. Since the temperature was constant, and the amount of *m*-NT remained unchanged throughout the experiment, primarily the *ortho*/*para* isomer ratio was considered, which ranged from 1.20 to 1.97. In the cited paper, an empirical model was suggested, which allows prediction of the *ortho*/*para* isomer ratio from the electrical and physical properties of the solvent and field-induced dipole moment.

A low (1.6%) *m*-NT yield can be achieved in toluene nitration in the system $HNO_3 : H_2SO_4 : (CH_3CO)_2O$ = 1 : 1 : 30 at 50°C [7]. A zero yield of *m*-NT has been reported for toluene nitration with a mixture of 32% HNO_3 and 68% $(CH_3CO)_2O$ at 10°C [3]. However, in these cases, an abnormal *ortho*/*para* isomer ration was obtained (88 and 12%, respectively), which is unsuitable in the common TDI production process.

The mass-exchange effect on the regioselectivity of nitration of toluene and other aromatic hydrocarbons is an important aspect of the problem of two-phase heterogeneous nitration. This aspect was discussed in [8, 9] in terms of the mechanism of nitration in the interfacial adsorption monolayer, which is suggested to be operative along with the ordinary nitration mechanism (in the bulk of the acid phase). Modak and Juvekar [8] examined the nitration of mononitrobenzene and suggested that the approach they used is applicable primarily to nitration of polar molecules, such as mononitro derivatives of aromatic hydrocarbons.

The key point of the interfacial nitration mechanism is that nitroaromatic molecules adsorbed at the interfacial monolayer react with the nitronium cations from the acid phase. Evidently, the electric field formed at the interface as a result of the adsorption of polar molecules affects the nitration regioselectivi-

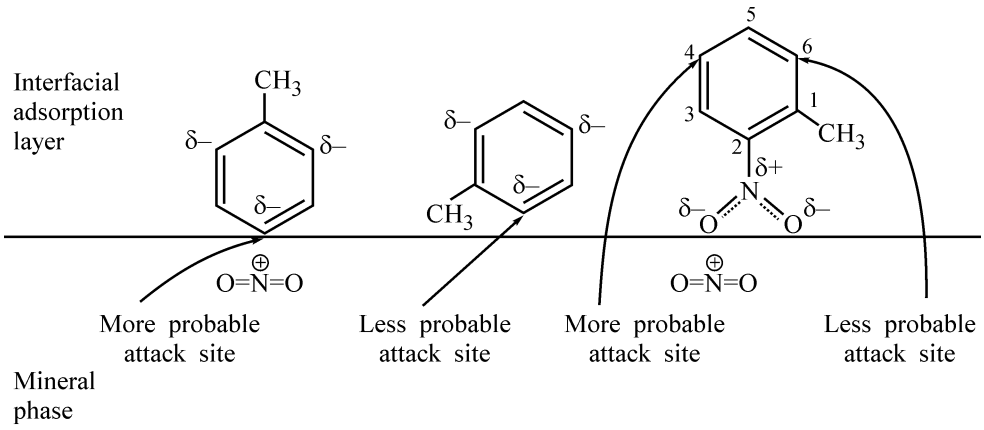

Fig. 2. Orientation of toluene and mononitrotoluene molecules at the interface.

ty in this region. The total nitration selectivity with respect to a given isomer is a weighted average of the bulk and interfacial selectivities. When passing across the interface, nitrotoluene molecules are oriented in the interfacial layer so that the hydrophobic methyl groups are directed toward the organic phase as a result of repulsive action of the hydrophilic mineral layer (Fig. 2) [8].

The contribution of the interfacial mechanism is controlled by the interface area, i.e., by the stirring rate. It should be expected that the above statements are valid for a relatively slow nitration of nitrobenzene and other mono- and dinitro derivatives of aromatic hydrocarbons, i.e., for the cases when diffusion of the substrate to the bulk of the acid phase is not a rate-determining stage under common process conditions, in contrast to the nitration of the starting hydrocarbons.

Since the starting aromatic hydrocarbons are low-polar, one may expect that the adsorption of NO_2^+ at the interface is insignificant if the organic phase contains no nitration products. At the same time, if the organic phase contains nitro derivatives, the negative charge of the interfacial layer facilitates adsorption of the NO_2^+ cation, thus favoring interfacial nitration.

Based on the common knowledge, it can be suggested that the contribution of the interfacial mechanism to the nitration of aromatic hydrocarbons, such as toluene and benzene, can be raised in three cases: (1) when the reaction rate in the interfacial layer is higher or well-comparable with the rate of substrate diffusion across the interface to the interfacial layer, as it occurs in nitration of aromatic hydrocarbons with acid mixtures with high sulfuric acid content (above 35 mol %); (2) when the reaction proceeds in an intermediate mode between the diffusion and kinetic control, which occurs in nitration of aromatic hydrocarbons with sulfuric–nitric acid mixtures of low nitrating efficiency at high stirring rate (>3000 rpm); and (3) in continuous nitration of aromatic hydrocarbons, i.e., at a sufficiently high concentration of a nitro derivative in the organic phase.

Previously [8–10], it has been demonstrated that the selectivity of the interfacial nitration differs from that in the bulk of the acid phase, and the *ortho*/*para* isomer ratio can be altered by changing the contribution of any of the two principal nitration mechanisms.

EXPERIMENTAL

Toluene nitration was carried out in a 30-ml glass reactor equipped with a temperature-control jacket, four-blade turbine stirrer, vertical baffle walls, and thermocouple for measuring the temperature of the reaction mass. The baffle walls were arranged at right angles relative to each other to avoid formation of a whirlpool and projected by 5 cm over the reaction mass to improve the aeration of the acid mixture. In the experiments, the stirring rate was varied from 200 to 5000 rpm.

The gas content of the acid mixture was determined from the increase in the reaction mass volume under given conditions with or without stirring. The mixture was poured into the reactor up to the lower overflow level. The temperature was raised to a desired value by circulating water in the jacket, and the reaction mass was allowed to stand for 10 min without stirring. The volume of the acid mixture remaining in the reactor, V_1, corresponded to the loss for thermal expansion. Similarly we determined the mixture volume V_2 after stirring for 5 min. The gas content

Γ (vol %) of the mixture under given conditions was estimated as

$$\Gamma = \frac{V_1 - V_2}{V_1} \times 100.$$

The results are listed in Table 3 for various temperatures and stirring rates.

In the experiments, we used nitric and sulfuric acids of pure grade and chromatographically pure toluene. The composition of the acid mixtures was determined titrimetrically to within 0.02%. The acid mixtures were prepared by successive mixing of the concentrated acids with double-distilled water at 0°C. The compositions of the acid mixtures are specified in the tables.

The isomeric composition of the products and residual toluene content were determined by gas chromatography on a KhROMOS 1000.1 instrument with a flame ionization detector (SUPELCO column, 30 m × 0.32 mm; stationary phase 5% polydiphenyl + 95% polydimethylsiloxane; carrier gas helium, flow rate 30 ml min^{-1}). The relative error of determination of NT isomers and DNT was ±5%.

In toluene nitration, a calculated amount of toluene was introduced with a syringe into the reactor with an acid mixture at a fixed temperature with stirring. After a fixed time, stirring was switched off, and the reaction mass was poured into a fivefold volume of cold water (10–15°C). The nitration products were extracted twice with chloroform taken in an amount of 6 ml per gram of toluene used for nitration. The combined extracts were washed with the equal volume of water. Finally, the products were analyzed for mono- and dinitro derivatives.

The main focus of this study was to characterize parameters controlling the reaction zones in which particular NT isomers are preferentially formed and to elucidate factors that could decrease the formation rate and yield of *meta*-nitrotoluene.

Our results show that, in toluene nitration with sulfuric–nitric acid mixtures with low molar concentration of sulfuric acid (acid mixtures were prepared from 50% H_2SO_4) and high content of HNO_3 and water, an increase in the temperature remarkably changes the *o*- and *m*-NT contents, but only slightly, the *p*-NT content (Fig. 3, Table 4).

As a hypothesis we suggested that the *para* selectivity of nitration is higher in the charged interfacial monolayer in which the nitrating agent reacts with the spatially oriented substrate molecules, and

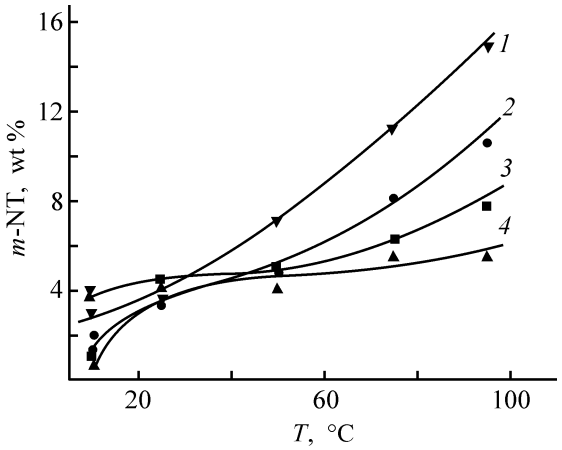

Fig. 3. Yield of *m*-NT vs. the temperature *T* in heterogeneous nitration of toluene with sulfuric–nitric acid mixtures. HNO_3 : toluene molar ratio 1.5. Acid mixture composition, mol %: (*1*) HNO_3 42.54, (*2*, *3*) H_2SO_4 10.2, and (*4*) H_2SO_4 7.60. N, rpm: (*1*, *2*, *4*) 300 and (*3*) 800.

ortho- and *meta*-nitrotoluenes are predominantly formed in the bulk of the acid phase.

Indeed, the observed decrease in the *m*-NT yield with increasing nitration efficiency factor of the acid mixture, accompanied by a decrease in the *o*-/*p*-NT ratio (Fig. 1) [2, 3], also suggests that an increase in the H_2SO_4 molar concentration promotes the interfacial nitration, whose rate grows with the H_2SO_4 concentration much more strongly than does the rate of the reaction in the bulk of the acid phase [8]. It follows from the aforesaid that, in the interfacial monolayer, the nitronium cation attacks essentially the *para* position, thus reducing the relative content of *o*- and *m*-isomers in the product.

To check this hypothesis for consistency, we carried out a series of experiments on toluene nitration under conditions similar to those indicated above with sulfuric–nitric acid mixtures containing various contents of sulfuric acid (14.07, 35.70, and 52.62 mol %). We

believed that it is sulfuric acid that controls the acidity of the nitrating mixture, and, therefore, the reaction rate, depending on the stirring rate, gas content, and temperature (Tables 5, 6).

Our results show that the effects of the stirring rate, gas content, and temperature on the *m*-NT yield are more clearly pronounced in toluene nitration with an acid mixture of low nitration activity (14.07 mol % H_2SO_4, Φ 48). At low stirring rate (400 rpm), the *m*-NT yield is higher than ordinary, 3–4%, and tends to increase with temperature (Table 5, run nos. 1–4). With increasing stirring rate, the temperature dependence of the *m*-NT yield becomes more complex (Table 5, run nos. 25–29, 34–37). At a constant temperature, the *m*-NT yield steadily decreased in most of the experiments from 6.5 to 2.5–2.7 at 3000 rpm with increasing stirring rate and gas content of the reaction mass. This additionally confirmed our concept that an increase in the contribution of the interfacial nitration mechanism can reduce the *o*- and *m*-NT content of the isomer mixture (Fig. 4).

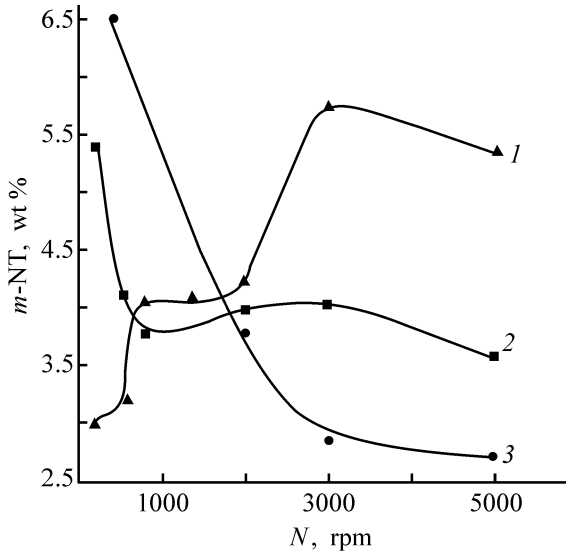

Fig. 4. *m*-NT content of toluene nitration products vs. the stirring rate N at 50°C. H_2SO_4 concentration in the mixed acid, mol %) (*1*) 52.62, (*2*) 35.70, and (*3*) 14.07.

In toluene nitration with an acid mixture with an initial sulfuric acid content of 35.70 mol % at a 4% molar excess of nitric acid, the *m*-NT yield also tends to decrease from 5.4 to 3.6% with increasing stirring rate. Note that this tendency is considerably less pronounced than that in nitration with the low-activity acid mixture containing 14.07 mol % H_2SO_4 (Fig. 4; Table 6, run nos. 38–43).

However, in toluene nitration with a high-activity acid mixture (initial sulfuric acid concentration 52.62 mol %, 4% molar excess of nitric acid), the *m*-NT yield increases with the stirring rate. In this case, the *m*-NT yield significantly increases at a stirring rate exceeding 2000 rpm, when the reaction mass is saturated with air bubbles. The increase in

the contribution of the interfacial nitration is also evidenced by the decrease in the *ortho*/*para* ratio approximately by half as the stirring rate is raised from 400 to 5000 rpm (Table 6, run nos. 44–50).

The observed increase in the *m*-NT yield with the H_2SO_4 concentration can be attributed to specific solvation of the toluene molecules with sulfuric acid. The solubility of toluene in sulfuric acid is more than doubled as the H_2SO_4 content is raised from 35.70 to 52.62 mol % [2]. This suggests that association occurs via formation of hydrogen bonds with the π-electron system of toluene, the hydrogen bonding being the strongest in the areas with the maximal electron density, i.e., at the *ortho* and *para* positions of the aromatic ring. In such associates, the hydrogen bonds partially block the *ortho* and *para* positions, while the meta position of the ring remains accessible to the attack by the nitronium ion [11].

This suggestion is confirmed by low *m*-NT content of the products of toluene mononitration with nitration agents of low acidity, e.g., with mixtures of nitric acid with acetic anhydride, trifluoroacetic acid, or nitronium salts [2, 11].

The hydrogen bonding in toluene–H_2SO_4 associates is accompanied by at significant loss of entropy, which is particularly pronounced for the reaction in the bulk of the mineral phase. At the same time, the entropy loss caused by the formation of hydrogen bonds should be less significant in the case of the interfacial nitration, when the toluene molecules are spatially oriented. Therefore, the effect of specific solvation of toluene is more pronounced at the highest stirring rates, when the contribution of the interfacial nitration dominates.

Our experiments show that, in toluene nitration with low-activity acid mixtures with a sulfuric acid content of 7.60–14.07 mol %, at low stirring rate (below 1000 rpm), i.e., when the effect of specific solvation of toluene is insignificant, an increase in the H_2SO_4 concentration at a fixed temperature results in a decrease in the *m*-NT yield (Fig. 3; Table 4, run nos. 1–10 and others).

To study the possibility of controlling the *m*-NT yield by changing the diffusion and kinetic contributions to the total nitration rate, we carried out experiments on toluene nitration with acid mixtures containing various concentrations of sulfuric acid and various molar excesses (25, 50, and 75%) of nitric acid, as influenced by the temperature. Selected results are presented in Figs. 5 and 6.

At the minimal (4%) molar excess of nitric acid, the dependence of the *m*-NT yield on the sulfuric acid content is rather complex with a distinct minimum at an H_2SO_4 content of 28–35 mol % (Fig. 5). In this case, the temperature effect is not the least important of the factors.

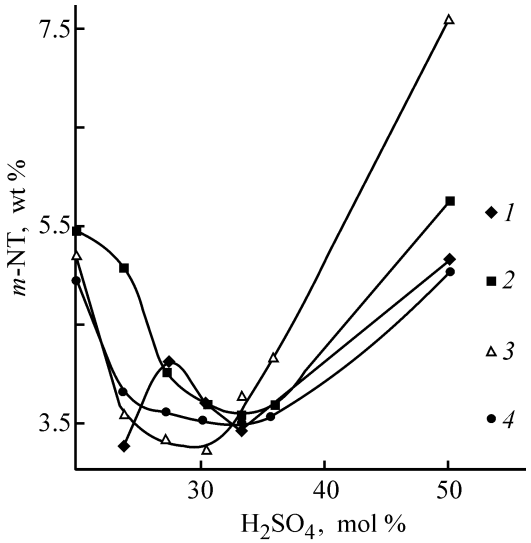

Fig. 5. *m*-NT yield vs. the H_2SO_4 concentration in the acid mixture. HNO_3/toluene molar ratio 1.04, N = 800 rpm. T, °C: (*1*) 10, (*2*) 50, (*3*) 75, and (*4*) 95.

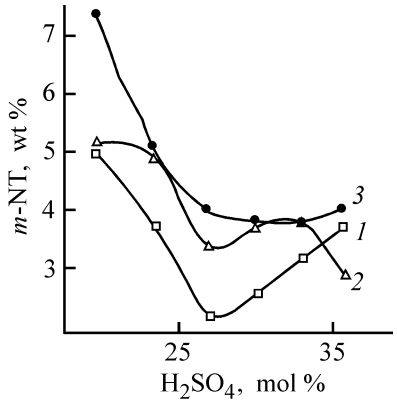

Fig. 6. *m*-NT yield vs. the H_2SO_4 concentration in the acid mixture. N = 800 rpm, T = 50°C. HNO_3/toluene molar ratio: (*1*) 1.25, (*2*) 1.5, and (*3*) 1.75.

At a high molar excess of nitric acid (see Fig. 6, HNO_3/toluene 1.25, 1.50, and 1.75) and at fixed temperature (50°C), the *m*-NT yield tends to decrease the H_2SO_4 content is raised to 27–30%. With a further increase in the H_2SO_4 content, the *m*-NT yield remains unchanged or only slightly increases. Evidently, the reaction zone shifts toward the bulk of the acid phase by virtue of the increase in the toluene solubility with the HNO_3 content os the sulfuric–nitric acid mixtures. As the H_2SO_4 content increases, and, therefore, the nitration rate grows, the rate of sub-

Table 7. Influence of alkali metal nitrates on the NT isomer ratio [Φ = 75.1; HNO_3/toluene molar ratio 1.04, T = 50°C, nitration time 15 min; H_2SO_4 74.55, HNO_3 1.11, and H_2O 24.34% (H_2SO_4 35.70, HNO_3 0.83, and H_2O 63.47 mol %)]

strate diffusion from the organic phase to the acid phase becomes insufficient for the acid phase to be saturated with toluene, and the reaction zone shifts toward the interface, where, as demonstrated above, the nitration proceeds with a higher *para* selectivity. At the same time, raising the H_2SO_4 content to above 30 mol % provides a slight increase in the *m*-NT yield as a result of an enhanced specific solvation of toluene.

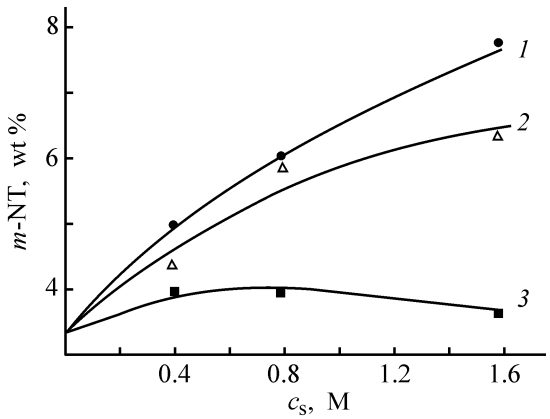

Fig. 7. *m*-NT yield vs. the inorganic salt concentration c_s in the acid mixture of the composition (mol %): H_2SO_4 35.70, HNO_3 0.83, and H_2O 63.47. HNO_3/toluene molar ratio 1.04, 50°C, N = 800 rpm. (*1*) $NaNO_3$, (*2*) $LiNO_3$, and (*3*) KNO_3.

To study the effect of inorganic salt additives on the formation of *m*-NT and on the *ortho*/*para* ratio, we performed a series of experiments on toluene nitration with an acid mixture containing 35.70 mol % H_2SO_4 and 4% molar excess of HNO_3 in the presence of Li, K, and Na nitrates. All the salts were calcined and added to the mixed acid just prior to use.

The salt concentrations were chosen taking into account the data from [4, 7]. Some of the results obtained are listed in Table 7 and presented in Figs. 7 and 8.

Our results show that the salt additives promote the formation of the *meta* and *para* isomers, and the *ortho*/*para* ratio decreases (Table 7). In the presence of the inorganic nitrates, the *m*-NT yield is more than twice that in the experiments without salt additives (Table 7, run nos. 51–65; Fig. 7). It is known [11] that the dipole moment of the nitrotoluene mol-

ecules and, therefore, of the π complexes with the nitronium ion, increases in the order *o*-NT < *m*-NT < *p*-NT. Therefore, addition of the electrolytes should primarily affect the *meta* and *para* selectivity, which is confirmed by the experimental data (Fig. 8; Table 7, run nos. 56–59, 62–65, and others).

The effect of the salt additives on the regioselectivity of toluene nitration decreases in the order $Na^+ > Li^+ > K^+$. The maximal increase in the *m*-NT yield and the maximal decrease in the *ortho*/*para* ratio were observed as the concentration of sodium nitrate in the acid mixture increased, but not with increasing concentration of lithium nitrate, as would be expected, i.e., this trend is inconsistent with the order in which the cation charge density grows (Fig. 7). Evidently, the lithium cation is considerably more strongly solvated in the acid mixture than the sodium cation. As a result, the effective radius of the lithium solvate is higher, and, therefore, it is more weakly adsorbed at the interface and increases the charge of the electric double layer to a lesser extent, compared to the sodium solvate. Thus, the increase in the contribution of the interfacial nitration is more clearly pronounced in the presence of the sodium cation.

Upon addition of $LiNO_3$, which has a higher affinity for water and exists as a crystal hydrate under ambient conditions, the *m*-NT yield increases against the reference experiment, and the dependence of the *m*-NT yield on the stirring rate passes through a maximum (Fig. 8). As the stirring rate is raised above 2000 rpm, i.e., when the gas content of the reaction mass starts to be an important factor, the *m*-NT yield decreases, probably due to a rise in the contribution of the interfacial nitration, as demonstrated by an increase in the *p*-NT yield and a decrease in the *ortho*/*para* ratio (Table 7, run nos. 62–65 and others).

Presumably, these salts bound water to form stable hydrates, thus making higher the nitration activity of the acid mixture and shifting the reaction zone toward the interface, i.e., promoting the interfacial nitration and raising the para selectivity.

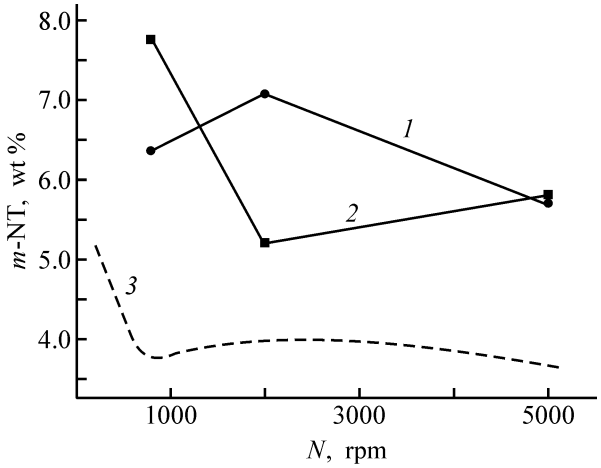

Fig. 8. *m*-NT yield vs. the stirring rate *N* (rpm) in heterogeneous nitration of toluene with the acid mixture of composition (mol %): H_2SO_4 35.70, HNO_3 0.83, and H_2O 63.47 in the presence of alkali metal nitrate additives (1.58 M): (*1*) $LiNO_3$, (*2*) $NaNO_3$, and (*3*) KNO_3. HNO_3/toluene molar ratio 1.04, 50°C.

CONCLUSIONS

(1) *Para*-selective two-phase toluene nitration with sulfuric–nitric acid mixtures proceeds in the charged interfacial monolayer, in which the nitrating agent reacts with the spatially oriented toluene molecules, while the formation of *ortho*- and *meta*-nitrotoluenes occurs essentially in the bulk of the acid phase.

(2) To reduce the *meta*-substitution rate in toluene nitration, it is necessary to diminish the mass-transfer effect on the total reaction rate and to raise the contribution of the interfacial reactions. This can be done lowering the reaction temperature, raising the sulfuric acid concentration in the acid mixture, and raising the stirring rate to 3000–5000 rpm, when a gas-filled emulsion is formed the reaction mass is saturated with air bubbles).

(3) Addition of alkali metal nitrates affects the rates of both the interfacial and bulk nitration. The former effect is caused by an increase in the positive charge in the electric double layer at the interface, and the latter effect, by a decrease in the steady-state toluene concentration in the bulk of the acid phase (salting-out effect).

(4) Introduction of alkali metal nitrates raises the yields of *meta*- and *para*-nitrotoluenes by promoting the nitration at the *para* and *meta* positions of the aromatic ring, since the corresponding reaction intermediates have a higher dipole moment, compared to *ortho*-nitrotoluene.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Intermolecular Interactions and Properties of Mixtures of Triethylene Glycol with Ethanol and Isopropyl Alcohol

E. I. Grushova and A. V. Kuchuk

Belarussian State Technological University, Minsk, Republic of Belarus

Received January 12, 2007

Abstract—Density and viscosity of solutions formed in the systems triethylene glycol–ethanol and triethylene glycol–isopropyl alcohol were studied in the full concentration range at 20, 40, 50, and 60°C. The thermodynamic activation functions of viscous flow were calculated. The contribution of specific interactions to these functions was determined.

DOI: 10.1134/S1070427207120133

Although numerous studies aimed to develop efficient methods for recovery of aromatic hydrocarbons from oil fractions have been carried out [1–3], liquid extraction with triethylene glycol (TEG) as separating agent remains important. To improve the extractive properties of TEG, it has been suggested to use additives of polar compounds, coextractants [4–6]. However, wide application of coextractants requires that the mechanism of their effect on the main solvent should be known.

In this study, solvents of compositions TEG–ethanol and TEG–isopropyl alcohol were objects of analysis. Methods described in [7, 8] were used to study in the temperature range 20–60°C their viscosity ν^{60} and density ρ_4^{60} and to determine the thermodynamic functions of activation of viscous flow ($\Delta G_\nu^\#$ is the activation energy of viscous flow; $\Delta S_\nu^\#$, enthalpy; and $\Delta H_\nu^\#$, entropy) and the average degree of association of the solvents, f_{60}, in the flowing state. The experimental data obtained and the results of calculation are listed in Table 1. The relative error in viscosity measurements did not exceed 0.02%. The error in determining the activation parameters was ±2.5–5%. The reliability of these results is confirmed by comparison of the value of f for ethanol at 20°C (Table 1) with published data [9].

According to the data in Table 1, an increase in the alcohol concentration leads to a steady decrease in the density, kinematic viscosity, and free activation energy of the viscous flow, which points to destabilization of the liquid-phase structure. In this case, an increase in the concentration of the second component causes a decrease in the entropy of activation of viscous flow for the TEG–ethanol system, whereas for the system TEG–isopropyl alcohol, $\Delta S_\nu^\#$ slightly increases. This may be due to the ability of isopropyl alcohol molecules introduced into the solution to fill free cavities in the solution structure.

In general, the concentration dependences of the enthalpy of activation of viscous flow for both the systems are similar, i.e., $\Delta H_\nu^\#$ decreases as the alcohol concentration increases, and this behavior is more pronounced for the TEG–ethanol system. Moreover, the $\Delta H_\nu^\#$ and $\Delta S_\nu^\#$ dependences pass through a minimum at low ethanol concentrations. The average degree of association of the solutions in the flowing state also steadily decreases as the alcohol concentration in both systems increases.

The concentration dependences of the specific activation energy of viscous flow [8] and of the density of the enthalpy of activation of viscous flow [5] are shown in Figs. 1a and 1b. According to the graphical data, only small ethanol additives cause deviations of the above parameters from the corresponding values calculated using the additivity rule.

Because hydrogen bonds can be formed between molecules of the solutions under study, it was of interest to determine the contribution of specific and nonspecific interactions to the enthalpy of activation

of viscous flow, $\Delta H_\nu^\#$ [8]. For this purpose, we determined the kinematic viscosity of dilute solutions of TEG–ethanol solvents in carbon tetrachloride. In these systems, specific interactions between molecules of the solvents under study are virtually nonexistent. Further, the linear part of the $\nu = f(x)$ dependences, where x is the molal concentration of the solvent studied, was extrapolated to $x = 1$ to obtain the viscosity

of hypothetical solvents and calculate the thermodynamic activation functions of the viscous flow. The results obtained are listed in Tables 2, 3.

As can be seen, the viscosity parameters and thermodynamic characteristics of the hypothetical solvents strongly differ from the corresponding parameters of real systems (Table 1). Presumably, the higher values of $\Delta S_\nu^{\#}$ indicate that the hypothetical solvents containing 5 and 10 mol % ethanol have a more ordered structure.

However, the enthalpy of activation of viscous flow, $\Delta H_\nu^{\#}$, for these solutions is considerably lower than that for real systems. It can be seen from the data in Table 3 that the contribution of the specific interaction to $\Delta H_\nu^{\#}$ increases upon addition of small amounts of ethyl alcohol to TEG. At the same time, the parameter $\Delta H_\nu^{\#}/V$, suggested in [5] for characterizing the density of the attraction energy in a flowing liquid, decreases. This parameter linearly correlates with the solvent capacity, which, according to [1], is estimated by the reciprocal limiting activity coefficient of benzene in the separating agent. Consequently, the dissolving capacity of the solvent increases upon addition of minor amounts of ethanol to TEG, but the contribution of specific interactions to the enthalpy of activation of viscous flow grows, too.

The results obtained were compared with the parameters of extraction of the benzene–hexane model system with the solvents under study at 20°C. The benzene : hexane : solvent volume ratio was 1 : 1 : 2. As can be seen from Fig. 2, additions of ethanol and isopropyl alcohol differently affect the selective and dissolving properties of TEG. At small concentrations, isopropyl alcohol affects only slightly the distribution coefficient of benzene and the separation selectivity. If, however, ethanol is added to TEG, the dissolving power of the extractant and the separation selectivity are improved. These data are in agreement with the results of a viscometric study of TEG–alcohol systems.

Thus, it follows from the aforesaid that a viscometric study and comparative analysis of the properties of real solvents and of the corresponding hypothetical solvents can be used to gain better insight into the mechanism of formation of extractive properties in development of new solvents and coextractants.

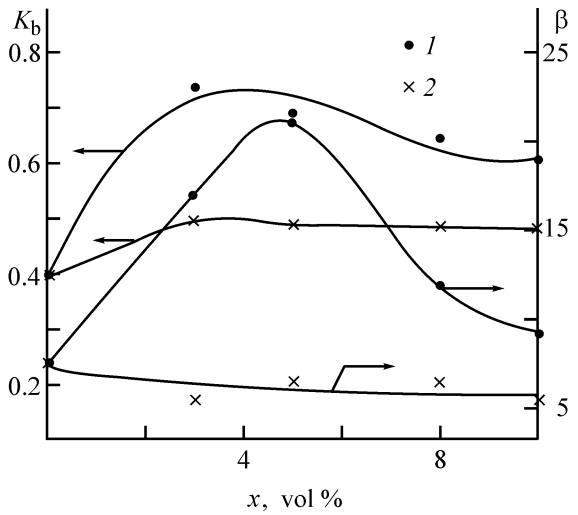

Fig. 2. Distribution coefficient of benzene, K_b, and separation selectivity β vs. the concentration x of (*1*) ethanol and (*2*) isopropyl alcohol in TEG.

CONCLUSION

The extractive properties of the systems triethylene glycol–ethanol and triethylene glycol–isopropyl alcohol are determined by the density of enthalpy and by the activation energy of viscous flow per structural unit of the associate.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Photochemical Reactions in Solutions of the Platinum(II) Complex with 8-Quinolinol

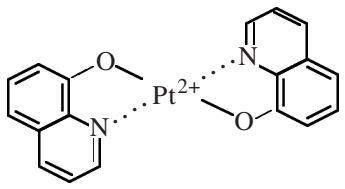
Abstract—The rate of photochemical reaction in solutions of luminescent platinum(II) complex with 8-quinolinol was studied in relation to the type of solvent, irradiation time, photon energy and intensity of a luminous flux, concentration of the complex, and presence of oxygen. The structure of the photochemical reaction product was studied by X-ray photoelectron, IR, and electronic absorption spectroscopy. The quantitative kinetic parameters and quantum yield of the photochemical reaction performed under various irradiation conditions are reported.

DOI: 10.1134/S1070427207120145

Platinum(II) complexes exhibit a unique combination of optical, catalytic, and luminescence spectral properties [1–13]. An important feature is that platinum(II) complexes can aggregate or polymerize to give photosensitive and luminescent supramolecular ensembles [1–4].

Among these compounds are platinum(II) complexes with Schiff bases like [PtSalen], which exhibit photochemical activity and can electrochemically polymerize. The study of photo- and electrochemical reactions of platinum complexes with Schiff bases can provide an insight into the mechanism of formation of dimers and polymers [2–4]. In this study, we examined photochemical reactions of the platinum(II) complex with 8-quinolinol, a bidentate ligand coordinated to platinum via oxygen and nitrogen atoms. The structure of $[Pt(qol)_2]$, where qol is 8-quinolinol, is as follows:



The electronically excited states (EESs) of $[Pt(qol)_2]$ were characterized by luminescence spectral methods [8, 13–16]. However, the possibility of deactivation of EESs by a photochemical reaction and structural rearrangement of the complex are still poorly understood. These data are of practical importance since $[Pt(qol)_2]$ can be used as monomer in electrochemical synthesis of thin-layer conducting polymers [17].

The aim of this study was to analyze photostimulated aggregation of $[Pt(qol)_2]$ to form new molecular structures.

EXPERIMENTAL

The complex $[Pt(qol)_2]$ was prepared by the modified procedure [14] from potassium tetrachloroplatinate(II) K_2PtCl_4 and 8-quinolinol C_9H_7ON (Merck) recrystallized from ethanol.

Since the platinum complex is a photochemically labile compound in the presence of atmospheric oxygen dissolved in the solution [10, 14], its synthesis and preparation of its solutions for photochemical experiments and recording of absorption and luminescence spectra were performed in the dark.

8-Quinolinol and its platinum complex were identified by electronic absorption spectroscopy and X-ray photoelectron spectroscopy (XPS). The UV-Vis absorption spectra of $[Pt(qol)_2]$ were recorded on SF2000 and Shimadzu UV-2401 PC spectrophotometers.

The X-ray photoelectron spectra were measured on an Axis Ultra electron spectrometer (Kratos Analytical, UK) using monochromatic Al_{K_α} radiation

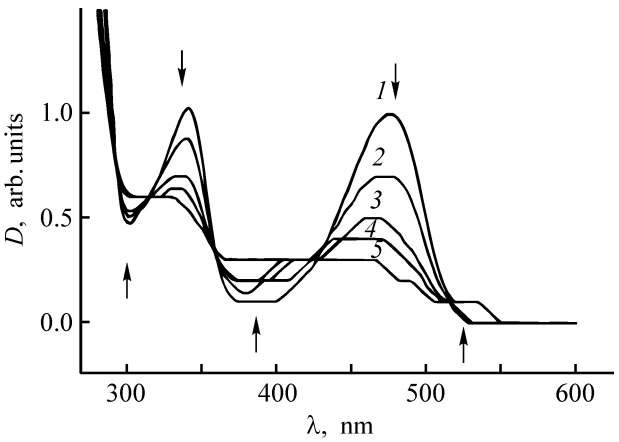


Fig. 1. Absorption spectrum of 1×10^{-4} M air-saturated solution of $[Pt(qol)_2]$ in CH_2Cl_2 irradiated with unfiltered light for τ_{irr} (min): (*1*) 0, (*2*) 1, (*3*) 3, (*4*) 5, and (*5*) 7. (*D*) Optical density and (λ) wavelength; the same for Figs. 2 and 3.

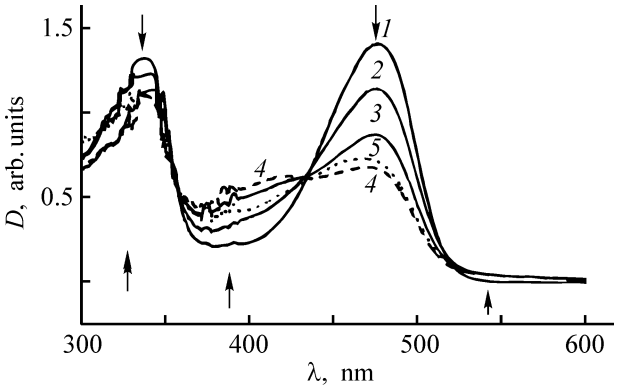

Fig. 2. Absorption spectrum of 2×10^{-4} M air-saturated solution of $[Pt(qol)_2]$ in DMF irradiated with unfiltered light for τ_{irr} (min): (*1*) 0, (*2*) 5, (*3*) 10, (*4*) 25, and (*5*) 60.

(1486.6 eV). The working residual pressure in the spectrometer was 5×10^{-7} Pa. The spectra were processed using Vision2 software (Kratos Analytical, UK). The binding energy scale was calibrated against the C1*s* line of aromatic carbon (E_b = 285.0 eV). The atomic concentration was determined with an accuracy of 10%.

The photochemical experiments were performed in quartz cells (l = 1 cm) under continuous exposure of the solution to light from a DRSh-1000 lamp for a required time. The IR light was cut-off with a water filter. THe light with wavelengths λ 315–320, 436, and 480 nm was obtained with the aid of a set of glass filters. The light intensity was determined with a ferrioxalate actinometer [18, 19]. The experiments were performed in a solution saturated with air or oxygen or deaerated with argon. We used dimethylformamide (DMF), dichloromethane, and acetonitrile (ultrapure grade) as solvents.

The quantum yields of the photochemical reactions were determined from the experiments performed in dichloromethane. We showed that luminescence in the dichlorometahne solutions exposed to monochromatic light was the most intense and the equilibrium in these solutions was rapidly attained.

The IR spectra of a dry photolyte sample (KBr pellets) were recorded on an IFS-88 IR Fourier spectrometer in the range 500–16000 cm^{-1}. The phosphorescence and excitation spectra in deaerated solution in DMF and dichloromethane at T = 298 K were measured on a Flyuorat-02-Panorama spectrofluorimeter (Lyumeks Joint-Stock Company). The excitation was performed with a high-pressure xenon lamp. The excitation wavelength was adjusted with a monochromator. Prior to each experiment, the solutions were deaerated by bubbling of high-purity argon for 20 min.

The phosphorescence in frozen DMF : toluene (1 : 1) solutions at T = 77 K was recorded on a KSVU-1 unit; the spectra were excited with an LGI-21 nitrogen laser (λ = 337 nm, τ_{pulse} = 10 ns).

The quantum yield was measured with fluorescein (Φ = 0.85) and $[Ru(bipy)_3]Cl_2$ (Φ = 0.0284) as references [18, 19].

The electronic absorption spectra of $[Pt(qol)_2]$ in dichloromethane are consistent with published data [8, 16] and contain two strong bands with vibronic structure (Fig. 1, curve *1*). The high-energy band at λ_{max} = 345 nm (ε = 8000) is due to intraligand π–π^* transitions, and the low-energy band at λ_{max} = 475 nm (ε = 6900) is assigned to intraligand charge transfer from oxygen atom of the phenol moiety to the nitrogen atom of the pyridine ring (ILCT band) [8]. It is known that the spectra of most of transition metal complexes with organic ligands contain in this range metal-to-ligand charge-transfer (MLCT) bands with extinction coefficients not higher than 2000–3000 $l\,mol^{-1}\,cm^{-1}$ [3, 4]. Therefore, this band may be a superposition of ILCT with a less intense MLCT band.

As can be seen from Figs. 1–3, with an increase in the irradiation time of a solution, the intensity of both bands decreases, i.e., the $[Pt(qol)_2]$ concentration decreases. At the same time, the absorption in the range in which the $[Pt(qol)_2]$ absorption is minimal or absent increases. The appearance of new weak bands and the presence of isobestic points in the spectrum suggest that a product being in the equilibrium with the initial complex is accumulated in the course of the photochemical reaction. The most intense new band is observed at λ_{max} = 425 nm (shoulder) in the spectrum of a DMF solution irradiated for 25 min (Fig. 2). The intensity of this band decreases, and

the isobestic points caused by the presence of two or more absorbing species being in the equilibrium are disturbed after irradiation of the solution for 60 min.

It should also be noted that the appearance of new poorly resolved bands in the ranges 350–425 and 520–600 nm, red-sifted with respect to the bands of the initial complex, suggests that molecular associates are formed in the course of the photochemical reaction. A strong bathochromic shift of the absorption bands of the photochemical reaction product with respect to the spectrum of the initial monomer complex is typical [1–3] of electro- or photostimulated dimerization or polymerization.

As the irradiation time increases, the color of the solution of the platinum complex changes from orange to green-yellow. It is significant that the transformations in the solution determined visually and spectroscopically are preserved for indefinitely long time after irradiation completion. A dark brown compound was isolated by evaporation of the irradiated solution. The absorption and emission spectra of a solution of this compound in various solvents are similar to the corresponding spectra recorded immediately after the irradiation completion. Thus, the product of the photochemical reaction is stable and does not transform into the initial complex in the dark.

We found that the solvent affects the reaction kinetics and does not affect the spectrum transformations. The maximal concentration of the reaction product in a dichloromethane solution is observed after its exposure to polychromatic light for 5–6 min. A similar result in acetonitrile and DMF was obtained in 20–30 min. Probably, the viscosity and dielectric constant of the solvent ($\eta = 0.411 \times 10^3$ Pa s and $\varepsilon = 8.93$ for dichloromethane, $\eta = 0.340 \times 10^3$ Pa s and $\varepsilon = 36.02$ for acetonitrile, and $\eta = 0.796 \times 10^3$ Pa s and $\varepsilon = 36.7$ for DMF) have the most significant effect on the photoreaction kinetics. The high rate of the photochemical reaction in dichloromethane is due to its low viscosity and dielectric constant. Hence, the viscosity of the solvent affects the rate of diffusion and recombination of primary photolysis products, which is typically observed in formation of dimers or oligomers.

It is known that the quantum yield and the accumulation rate of the products of photochemical reactions whose order differs from unity depend on the reagent concentrations. We found that the accumulation rate of the product formed by irradiation of $[Pt(qol)_2]$ in DMF depends on the concentration of the initial complex. This dependence is extremal. The concentration of the initial monomer was 0.05, 0.1, 0.2, 0.4, and 0.8 mM. The rate of the photochemical reaction was maximal at a $[Pt(qol)_2]$ concentration of 0.2 mM.

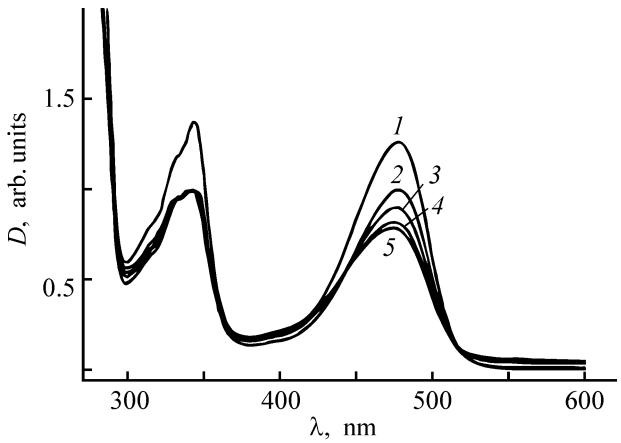

Fig. 3. Absorption spectrum of 1×10^{-4} M air-saturated solution of $[Pt(qol)_2]$ in CH_2Cl_2 irradiated for τ_{irr} (min): (*1*) 0, (*2*) 5, (*3*) 30, (*4*) 60, and (*5*) 90. $\lambda_{irr} = 480$ nm, $I_{luminous\ flux} = 9 \times 10^{-9}$ einstein s^{-1}.

To reveal the kinetic features of the photochemical reactions, we studied the influence of the intensity and wavelength of the irradiation on the spectral transformations of the examined solutions. It should be noted that the rate of the photochemical reaction decreases and the time required for formation of the reaction product increases when a solution is irradiated with monochromatic light (λ = 315–320, 436, and 480 nm) instead of unfiltered light. For example, when a dichloromethane solution was irradiated with a monochromatic light (λ = 480 nm), the time required for formation of the reaction product in the maximal yield was as long as 90 min (Fig. 3), whereas on exposure of the solution to unfiltered light the product was formed within 7 min. The shape of the spectrum of $[Pt(qol)_2]$ solution recorded in the final steps of irradiation with monochromatic light (Fig. 3, curve *5*) was similar to that of the solution exposed to unfiltered radiation for 2–3 min (Fig. 1, curve *3*). Thus, the composition of the reaction products prepared under different irradiation conditions is similar but their yields depend to a greater extent on the intensity of luminous flux.

To determine the type of the electronically excited state formed in the course of photochemical transformation of the complex, we performed several experiments with different wavelengths of the exciting light. Exposure to 436- and 480-nm light whose wavelength is close to the peak of the low-energy band in the absorption spectrum of CH_2Cl_2 significantly decreases the optical density of this band, whereas

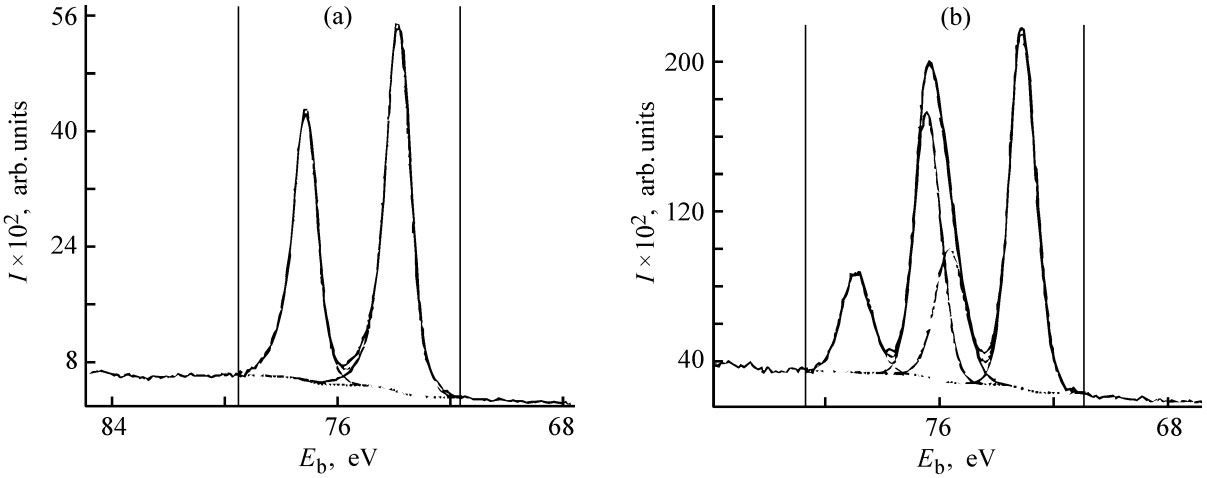

Fig. 4. Pt 4*f* XPS spectra of (a) initial $[Pt(qol)_2]$ and (b) reaction products formed on exposure of an air-saturated solution of $[Pt(qol)_2]$ in CH_2Cl_2 to unfiltered light for 7 min. (*I*) Intensity and (E_b) binding energy.

the intensity of this band only slightly changes on exposure to UV light (315–320 nm).

Thus, the products of photochemical reactions initiated with light of different wavelengths and intensities are formed at different rates. Therefore, the efficiencies of deactivation of a Franck–Condon electronically excited state into a photochemically active EES differ. It is most likely that specifically the electrons involved in the intraligand charge transition from the oxygen atom of the phenol moiety to the nitrogen atom of the pyridine ring of 8-quinolinol [8] and in MLCT mainly take part in the formation of the photochemically active state.

* Samples obtained by irradiation of a $[Pt(qol)_2]$ solution in CH_2Cl_2 for 10 min.

To estimate the influence of atmospheric molecular oxygen on the photochemical reactions, we studied the photoreaction kinetics and the photolysis products in solutions deaerated with argon and aerated with pure oxygen.

We found that the rate of photochemical reactions in oxygen-free solvents is lower. The rate of the photochemical reaction in deaerated dichloromethane solutions is lower by a factor of 2 than that in the air-saturated solutions. The isobestic points in the spectrum of $[Pt(qol)_2]$ solutions saturated with pure oxygen are distorted after exposure to 480-nm light for 15 min. Hence, it can be concluded that atmospheric oxygen affects the mechanism of photolysis.

To determine the composition and structure of the photolysis product, solid samples obtained by evaporation of the reaction mixture were studied by XPS and IR spectroscopy. The spectrum of the photolysis product contains, unlike the spectrum of the initial complex, a new line with E_b = 75.6 eV (Fig. 4), which suggests partial oxidation of Pt(II) to Pt(IV) during photolysis. These data confirm our assumption that the electronically excited $[Pt(qol)_2]$ formed by metal-to-ligand charge transfer is involved in the photochemical reaction.

The XPS spectrum of the photolysis product contain strong oxygen lines. A quantitative analysis of XPS data (Table 1) showed that the concentration of oxygen atoms in the product is higher by a factor of 4 than that of nitrogen atoms. The concentration ratio of these heteroatoms in the initial complex is 1 : 1.

Resoluting the XPS spectrum into the Gaussian components showed the presence of new carbon lines

with binding energies of inner electrons of 288.1 and 289.2 eV typical of –C=O and $-COO^-$ (–COOR) groups, respectively (R is a hydrocarbon radical). The content of carboxyl (ester) oxygen is higher by a factor of two than that of carbonyl oxygen.

The IR absorption spectrum of the solid photolysis product is shown in Fig. 5. The spectrum in the range of stretching vibrations of the C=C, C=N, and C–H bonds of the aromatic ring (1500–600 cm^{-1}) is similar to that of the initial complex. However, the spectrum of the photolysis product contains new stretching bands. The band at 1726 cm^{-1} can be assigned to unsaturated esters whose absorption is observed in the range 1730–1710 cm^{-1}. The bands in the range 2960–2850 cm^{-1} are due to the presence of methylene groups $-CH_2-$, which can be formed by partial saturation of the –CH=CH– bonds via cleavage of the phenol rings and loss of aromaticity.

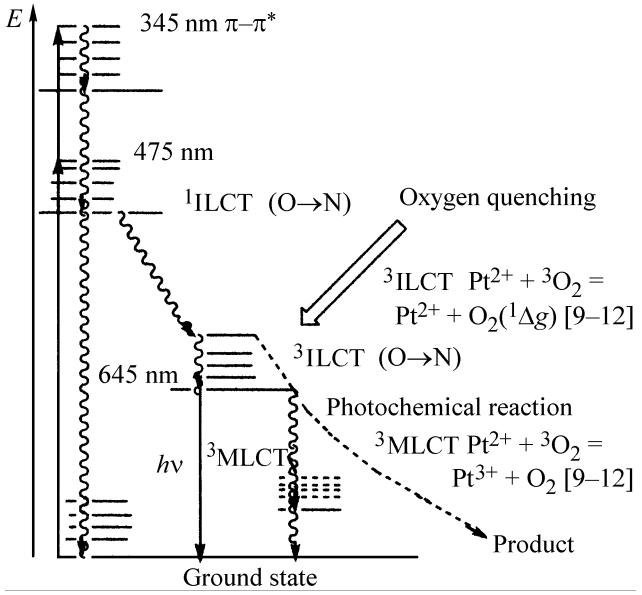
The absence of absorption in the range typical of conducting polymers (14000–4000 cm^{-1}) [20–24] confirms the degradation of the conjugated chain in the course of trimerization and conductivity loss.

To study the properties of the photolysis product and the type of the electronically excited intermediate, we compared the luminescence spectral parameters of the initial complex $[Pt(qol)_2]$ [10, 14–16] and its photolysis product isolated in different irradiation steps.

The luminescence spectrum of $[Pt(qol)_2]$ strongly depends on temperature and the type of solvent [8, 16]. Emission at $\lambda_{max} = 650$ nm with the lifetime $\tau = 3.5$ μs was observed in a DMF solution of this complex at 293 K [15]. Donges et al. [8] showed that the emission was caused by ^{3}ILCT from the single lowest EES.

The luminescence spectrum of an unirradiated solution of the platinum complex in dichloromethane ($c = 1 \times 10^{-4}$ M) at 298 K is shown in Fig. 6 (curve *1*). The maximal emission is observed at $\lambda_{max} = 645$ nm.

An analysis of the EES in $[Pt(qol)_2]$ [15] showed that luminescence from low long-lived triplet state can be quenched with atmospheric oxygen. However, a series of experiments showed that the rate of the photochemical reactions in the presence of oxygen was noticeable. We suggest that the photochemical reaction and radiative deactivation involve ^{3}ILCT EES and are competing processes. Formation of mixed (^{3}ILCT + ^{3}MLCT) EES is possible, which is conformed by the presence of Pt(IV) in the photolysis product (XPS data). The relaxation of electronically excited $[Pt(qol)_2]^*$ in a dichloromethane solution can be described by the following scheme:



As can be seen from Fig. 6, the luminescence intensity of $[Pt(qol)_2]$ solutions decreases as the irradiation time increases, with the emission maximum (λ_{max} = 645 nm), quantum yield, and lifetime of phosphorescence remaining the same. The shape and intensity of the luminescence spectra are independent

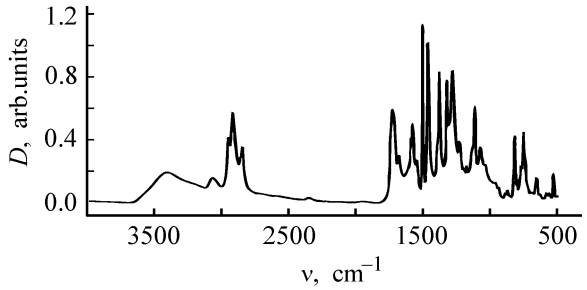


Fig. 5. IR absorption spectrum of the product formed upon exposure of an air-saturated $[Pt(qol)_2]$ solution in CH_2Cl_2 to unfiltered light for 7 min. (*D*) Optical density and (ν) wavenumber.

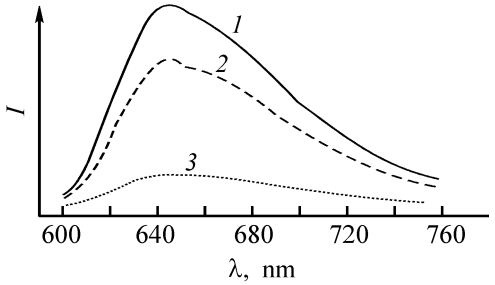

Fig. 6. Luminescence spectrum of 1×10^{-4} M solution of $[Pt(qol)_2]$ in CH_2Cl_2 preliminarily irradiated with unfiltered light for $\tau_{prelim.\,irrad}$ (min): (*1*) 0, (*2*) 5, and (*3*) 10. T = 298 K and λ_{ex} = 485 nm. (*I*) Intensity and (λ) wavelength; the same for Fig. 7.

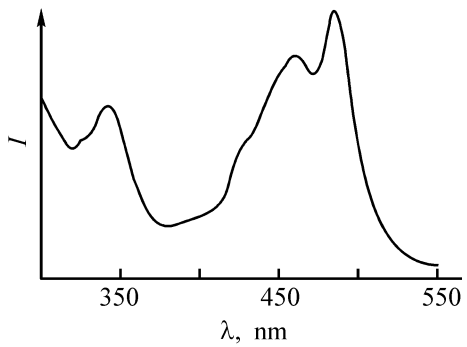

Fig. 7. Excitation spectra of irradiated 1×10^{-4} M solution of $[Pt(qol)_2]$ in CH_2Cl_2. T = 298 K, λ_{rec} = 645 nm.

of the wavelength of the preliminary irradiation (λ 337, 345, 436, and 475 nm). Therefore, phosphorescence of the photolyte in the solution occurs from triplet ILCT EES.

Since the photochemical reaction occurs in a homogeneous solution in which the initial complex is in equilibrium with its photolysis product, it is unclear what complex is the luminescent species. To determine the luminescent species, we compared the excitation and absorption spectra of irradiated and unirradiated solutions of $[Pt(qol)_2]$. The excitation spectra were measured at a wavelength equal to the maximum of the band in the spectrum of the peak solutions examined (λ = 645 nm). The excitation spectra of both solutions are similar (Fig. 7). This spectrum is similar to the absorption spectrum of monomeric $[Pt(qol)_2]$ and differs from that of the photolysis product (Fig. 1). Thus, the photolysis product does not luminesce, and its emission is due to the presence of unchanged $[Pt(qol)_2]$.

The structure of the photolysis product was suggested on the basis of an analysis of the electronic absorption and emission spectra and of the XPS and IR data. As can be seen from Table 1, the atomic concentration ratio of Pt(II) and Pt(IV) in the photolysis products is 2 : 1. Therefore, the primary product of this composition is presumably a trimer in which platinum(IV) atoms are covalently bonded with two axial oxidized fragments of the initial palladium(II) complex. The ratio of the carbonyl and ester groups determined in dry samples of the photolysis product by IR spectroscopy and XPS, is 1.26 : 2.79 (~1 : 2). These groups are probably formed by oxidation of the phenol moieties of $[Pt(qol)_2]$ with atmospheric oxygen. As demonstrated previously [25–27] for the example of photocatalytic oxidation of phenol, the aromatic ring can open under the attack by a cation of dissolved oxygen to form mono- and dibasic acids and(or) aldehydes. In addition, in the course of quenching of $[Pt(qol)_2]$ phosphorescence with molecular oxygen, electronically excited complexes can sensitize formation of singlet oxygen and(or) superoxide ion which can enter into reaction with the sensitizer in the ground state (see scheme) [9–12].

As noted above, the strong batochromic shift of the absorption in the spectrum of the photolysis product with respect to the spectrum of the monomer suggests that a trimer is formed. It is known that the energy gap between the lowest unoccupied and highest occupied molecular orbitals decreases upon molecular association, which simplifies the LUMO-HOMO transition and results in the bathochromic shift of the absorption band. In addition, the bathochromic shift can be due to the presence of platinum(IV) compounds which absorb in a longer-wavelength range as compared to platinum(II) complexes.

Thus, successive photooxidation steps of the ligand and platinum yield the following compound:

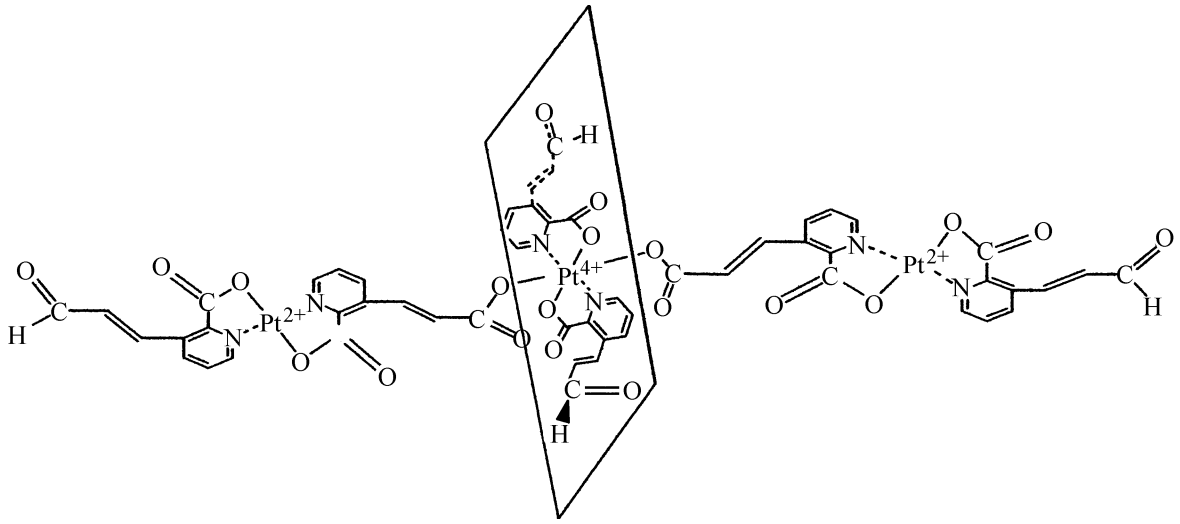

Table 2. Rate of formation and quantum yield of the photolysis product under various irradiation conditions

Irradiation conditions	Formation rate of photolysis product V, ml min^{-1} l^{-1}	Quantum yield of photoreaction Φ, mol $einstein^{-1}$
Unfiltered light:		
air-saturated solution	2.7×10^{-6}	
deaerated solution	1.6×10^{-6}	
Monochromatic light:		
λ = 480 nm, air-saturated solution	0.8×10^{-6}	1.1×10^{-2}
λ = 315–320 nm, deaerated solution	0.4×10^{-6}	0.5×10^{-2}

The overall photochemical reaction can be described by the equation

$$3[Pt(C_9H_6NO)_2] + 7O_2 \rightleftarrows [Pt_3C_{54}H_{34}O_{20}] + H_2.$$

The rate of accumulation of the photolysis product in different irradiation steps was quantitatively determined on the assumption that the reaction product is a trimer and the concentration quenching is absent in the solutions of the initial complex. The rates were calculated from the change in the residual concentration of the initial complex, which, in turn, was determined from a decrease in the luminescence of the reaction mixture (Fig. 8). The rates of accumulation of the trimer and the quantum yields of the product are listed in Table 2.

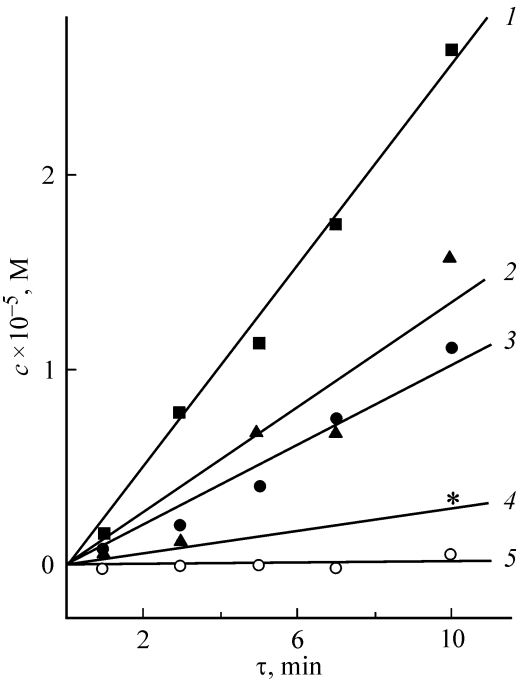

Fig. 8. Concentration c of the photolysis product vs. irradiation time τ. Irradiation of: (*1*) air-saturated and (*2*) deaerated solutions with unfiltered light; (*3*) air-saturated and (*5*) deaerated solutions with monochromatic light (λ_{irr} = 480 nm); (*4*) air-saturated solution with monochromatic light (λ_{irr} = 315–320 nm).

CONCLUSIONS

(1) Complex $[Pt(qol)_2]$ can undergo photostimulated oxidative aggregation in solution.

(2) The electronically excited state of the complex responsible for photochemical processes involves ^{3}ILCT and ^{3}MLCT.

(3) The XPS, IR, and electronic spectroscopy data suggest that the photolysis product has a trimeric structure.

(4) The product of the photochemical reaction does not luminesce.

(5) The rate and quantum yield of the photoreaction are maximal on exposure of an air-saturated solution of the complex to unfiltered light and are minimal on exposure of deaerated solutions to monochromatic light (λ = 315–320 nm).

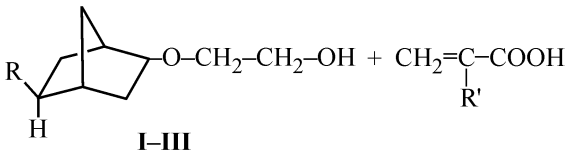
Abstract—New reactive monomers, bicyclo[2.2.1]hept-2-yloxyethyl acrylates, were prepared by esterification of monoethers derived from ethylene glycol and bicyclic alcohols with acrylic acid, using naphthalene-1,5-disulfonic acid as a new effective catalyst. The related propionates and isobutyrates were prepared by hydrogenation of these acrylates.

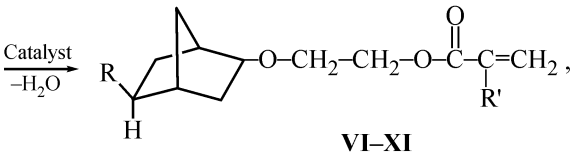
DOI: 10.1134/S1070427207120157

Esters of alicyclic alcohols and acrylic acids are widely used as reactive monomers for preparing plastics [1, 2], superadhesives [3], printer's inks [4], and lenses for protection from UV radiation [5]. Previously, we have developed procedures for preparing acrylic and methacrylic acid esters of bi- and tricyclic alcohols [6–8] and showed that these compounds can be used as monomers for preparing valuable macromolecular compounds [9].

In this study, we performed esterification of monoethers derived from ethylene glycol and bicyclic alcohols with acrylic acidwith the aim to prepare new reactive alicyclic functional monomers. We found that the reaction mainly follows the pathway of formation of bicyclo[2.2.1]hept-2-yloxyethyl acrylates:



I–III



VI–XI

where R = H (**I**, **VI**, **IX**), CH_3 (**II**, **VII**, **X**), CH_3CH_2 (**III**, **VIII**, **XI**); R' = H (**VI**–**VIII**), CH_3 (**IX**–**XI**).

To choose an effective esterification catalyst, and study its catalytic activity for the example of the reaction of bicyclo[2.2.1]hept-2-yloxyethanol (BEL) with acrylic acid (AA), we tested sulfuric acid, naphthalenesulfonic acid (NSA), KU-2 and KU-2-8 ion-exchange resins, *p*-toluenesulfonic acid (TSA), and naphthalene-1,5-disulfonic acid (NDSA), which were taken in an amount of 2.5 wt % (in terms of sulfo groups) relative to the starting compounds. The reaction was performed until the water evolution ceased. The results are listed in Table 1.

We found (Table 1) that, among the catalysts tested in synthesis of bicyclo[2.2.1]hept-2-yloxyethyl acrylate, NDSA is the most effective, because it provides a product yield as high as 91.2%, whereas with the other esterification catalysts the yield is 52–74%.

Therefore, experiments on the synthesis of other related monomers by esterification of bicyclo[2.2.1]-hept-2-yloxyethanol and its alkyl derivatives with acrylic and methacrylic acids were performed with NDSA as catalyst. The results are listed in Table 2.

The results obtained show (Table 2) that, with NDSA as catalyst, the yield of acrylates and methacrylates reaches 50.2–55.0 g (87–94%)

It should be noted that, with alkyl-substituted bicycloheptyl monoether of ethylene glycol as starting compound, the yield of acrylates and methacrylates tends to decrease with increasing molecular weight. This is caused by steric hindrance and a certain decrease in the activity of the OH group.

We determined the physicochemical constants and elemental composition of the synthesized 2-(bicyclo-

The experimental conditions and yields of the synthesized unsaturated esters are listed in Table 4. The physicochemical constants and elemental composition of the synthesized 2-bicyclo[2.2.1]hept-2-yloxyethyl propionates and isobutyrates and of the corresponding alkyl derivatives are listed in Table 5.

The composition and purity of the synthesized compounds were determined by GLC analysis, and their structure was confirmed by IR and ^1H and ^{13}C NMR spectroscopy. The synthesized ethylene glycol monoether monoesters were 99.0–99.5% pure.

The IR spectra of all the synthesized acrylic acid esters contain strong absorption bands of C–C and C–H bonds in three regions: 3000–2800, 1400–1300, and about 700 cm^{-1}. The C=C stretching vibrations in the ester molecules are manifested at 1645 cm^{-1}, and the C=C bending vibrations in *exo*-5-alkylbicyclo-[2.2.1]hept-*exo*-2-yloxyethyl esters, at about 980 cm^{-1}. The bands at 1725 and 1190 cm^{-1} are indicative of the presence of the ester (C=O) group, the bands at 810 and 890 cm^{-1} belong to the vinyl group, and the band at 1380 cm^{-1}, to the methyl group.

The ^1H and ^{13}C NMR spectra of some of the synthesized esters of unsaturated and saturated acids are given in Table 6. The compounds prepared are transparent liquids, some of which exhibit a pleasant odor with fruit tints. As analogs of bicyclo[2.2.1]hept-2-yloxyethyl esters of saturated acids, they can also be used as components of perfume formulations. Acrylates and methacrylates readily polymerize to form transparent polymers, which are of scientific and practical interest for preparation of new macromolecular compounds containing a bicyclo[2.2.1]hept-2-yloxy group.

EXPERIMENTAL

The composition and purity of the synthesized ethylene glycol monoether monoesters were determined by GLC on an LKhM-8 MD chromatograph [column length 1.5 m, liquid phase 10% poly(ethylene glycol succinate) on Sferokhrom, temperatures of the column, detector, and vaporizer 140–150, 200–220, and 250–270°C, respectively; detector current 120 mA; carrier gas flow rate 45 ml min^{-1}].

The IR spectra were recorded on a UR-20 spectrophotometer, and the ^1H and ^{13}C NMR spectra, on a Varian FT-80 spectrometer (USA) at a working frequency (^1H) of 80 MHz from CCl_4 solutions, with HMDS as internal reference.

The esterification of the monoether of bicyclic alcohols and ethylene glycol with acrylic acids in the presence of NDSA catalyst was performed in benzene with azeotropic distillation of water using a Dean–Stark trap. To prevent polymerization of the starting acrylic acids, an inhibitor (hydroquinone) was added in an amount of 0.01 wt %. After the reaction completion, NDSA was neutralized with an equimolar amount of $Ca(OH)_2$, the liquid phase was separated from the precipitate, and the target product was isolated by vacuum distillation.

The catalyst and the starting compounds had the following characteristics: NDSA, mp 240–245°C [10]; 2-(bicyclo[2.2.1]hept-*exo*-2-yloxy)ethanol, bp 71°C/5 mm Hg, d_4^{20} 1.0152, n_D^{20} 1.4718; 2-(*exo*-5-methylbicyclo[2.2.1]hept-*exo*-2-yloxy)ethanol, bp 95–96°C/5 mm Hg, d_4^{20} 1.0040, n_D^{20} 1.4726; 2-(*exo*-5-ethylbicyclo[2.2.1]hept-*exo*-2-yloxy)ethanol, bp 110–111°C/5 mm Hg, d_4^{20} 1.0002, n_D^{20} 1.4738.

Bicyclo[2.2.1]hept-2-yloxyethanols were prepared by addition of ethylene glycol to the corresponding bicyclic olefins in the presence of a catalyst. The physicochemical properties of these monoethers and of the acrylic acids used agreed with reference data [11, 12].

The hydrogenation of the synthesized bicyclo-[2.2.1]hept-2-yloxyethyl acrylates was performed in a 1-l stainless steel rotating autoclave. The catalyst, Ni on kieselguhr, was taken in an amount of 10 wt % relative to the acrylate. The reaction was performed under a hydrogen pressure of 80 atm at 100°C until the hydrogen uptake ceased (3 h). After the reaction completion, the mixture was filtered, and the target products, bicyclo[2.2.1]hept-2-yloxyethyl propionates and isobutyrates, were isolated by vacuum distillation.

CONCLUSIONS

(1) Bicyclo[2.2.1]hept-2-yloxyethyl acrylates, which are new reactive monomers, were prepared in 87–93% yield by esterification of bicycloheptyloxyethanol with acrylic acids in the presence of an effective catalyst, naphthalene-1,5-disulfonic acid.

(2) Bicyclo[2.2.1]hept-2-yloxyethyl propionates and isobutyrates were prepared by hydrogenation of the synthesized bicyclo[2.2.1]hept-2-yloxyethyl acrylates in the presence of Ni on kieselguhr. These compounds can be used as components of synthetic perfumes.

Abstract—Electrochemical fluorination of benzotrifluoride in the presence of triallylamine as depolarizer was studied. The possibility of preparing perfluoromethylcyclohexane and its isomers with high current efficiency and substance yield in combination with perfluorinated tertiary amines was examined.

DOI: 10.1134/S1070427207120169

Electrochemical fluorination (ECF) in anhydrous HF on nickel anodes is one of frequently used methods for conversion of hydrocarbons and partially fluorinated organic compounds into their perfluorinated analogs, with the preservation of the functional group or structure of the starting compound containing a heteroatom. This method was described for the first time in the late 1940s by Simons and then was developed by many researchers [1] who used it for fluorination of organic compounds containing C–O, C–N, C–S, or C–P bonds.

Perfluorocycloalkanes are not usually mentioned among numerous functional perfluorinated compounds that have found practical use after they became accessible by ECF, because attempts to prepare these compounds by electrolysis of their hydrocarbon analogs, which are insoluble in the electrolyte, have been not very successful.

However, the development of a method for preparing these compounds remains an important practical problem, because they exhibit unusual combinations of physicochemical properties: low boiling points, critical temperatures, and critical pressures at high molecular weights, densities in the liquid state, and coefficients of expansion and compressibility. The last two provide a very low speed of sound in these media. These compounds have considerably lower, compared to other liquids, surface tension and refractive index. They have excellent electric-insulation properties and unique chemical and biochemical stability, making them "virtually nontoxic."

Nyberg [2–4] has reported on a synthesis of perfluoromethylcyclohexane (PFMCH) in poor yield by ECF of toluene. With benzotrifluoride as starting compound, the yield is 47%, but the electrolysis cannot be performed in the continuous mode because of the electrolyte tarring [5].

As shown in [6], these effects can be restricted by adding a depolarizer fixing the steady-state electrolysis mode. This is particularly important when the ECF substrate is insoluble in HF and nonconducting, because this additive provides both the conductivity of the electrolyte and the solubility of the substrate in it.

In this study, we made an attempt to use ECF for preparing perfluorinated cyclic paraffins using an electrolytic additive whose electrolysis occurs without tarring and yields products that are of practical interest.

In this context, we performed a comparative study of the dependence of the PFMCH yield in ECF of toluene and benzotrifluoride in the presence of a depolarizing additive, triallylamine $(CH_2{=}CHCH_2)_3N$ (TAA), whose ECF occurs in the steady-state mode under conditions of continuous electrolysis and gives in high yield a mixture of perfluorotripropylamine with nitrogen-containing heterocycles, in particular, perfluoro-*N*-(*n*-propyl)-*cis*-3,4-dimethyl- and perfluoro-*N*-(*n*-propyl)-*trans*-3,4-dimethylpyrrolidines and perfluoro-*N*-(*n*-propyl)-3-methylpiperidine [7].

EXPERIMENTAL

As starting products for preparing perfluoromethylcyclohexane by ECF we used compounds formed in electrolysis of mixtures of benzotrifluoride or toluene with triallylamine as electrolytic additive.

The electrochemical fluorination was performed in a 660-ml carbon steel Simons electrolyzer equipped with a water-cooled coil and a stack of nickel electrodes with the surface area of the anodes of 500 cm^2. The electrolyzer was also equipped with a reflux condenser for condensing HF entrained by electrolysis gases and returning it into the electrolyte. The current during the experiments was constant, 15 A, and the current density was 0.034 A cm^{-2}.

As an electrolyte we used a solution of 5 wt % benzotrifluoride or toluene and 5 wt % triethylamine in liquid anhydrous HF. The concentration of the organic substrate in the electrolyte was maintained constant by feeding a mixture of the starting organic compounds once or twice an hour in amounts corresponding to their consumption coefficients. In ECF of a mixture of toluene with triallylamine, the excess amount of the consumed electricity (Q) (over the calculated value) was considerably larger than that in ECF of benzotrifluoride.

The ECF products, whose density was higher than that of the electrolyte, were collected in the lower part of the electrolyzer and drained at equal intervals. The crude product was discharged beneath a water layer and neutralized with sodium carbonate. After that, the crude product was purified by treatment with aqueous-alcoholic alkali to remove incompletely fluorinated products and dried over silica gel. The dried crude product was distilled on a column to obtain three fractions: head fraction (bp 53–54°C), target fraction (bp 76–78°C), and heavy fraction (bp 129–131°C).

The products in the fractions were identified by ^{19}F NMR on a Bruker Spectrospin AM-500 spectrometer (operating frequency 470.572 MHz) in C_6F_6 as solvent and internal reference. The products were also analyzed by GLC on a Tsvet-100 device equipped with a thermal conductivity detector, using a column

127.4(0.87)	121.0(0.89)	440	41.4(0.14)	236(0.67)	82.2(0.21)	93(0.35)	24(0.105)

with 20% α,α,α-tricyanoacetophenone on Silokhrom-80 as stationary phase. The composition determined by GLC is well consistent with the signal intensities in the ^{19}F NMR spectra.

In the head fraction with the empirical formula cyclo-C_6F_{12}, we identified two compounds: perfluorocyclohexane and the product of ring contraction, perfluoromethylcyclopentane.

The target fraction with the empirical formula cyclo-C_7F_{14}, boiling at 76–78°C, contained up to 80% perfluoromethylcyclohexane CF_3-cyclo-C_6F_{11}, whose ^{19}F NMR spectrum agrees with that described in [7], and its isomers, products of ring contraction: perfluoro-1,1-dimethylcyclopentane, perfluoroethylcyclopentane, and stereoisomeric perfluoro-1,2-dimethyl- and perfluoro-1,3-dimethylcyclopentanes. The characteristic signals in the ^{19}F NMR spectra of the isomers present in the target fraction are listed in Table 1.

The heavy fraction was a mixture containing perfluorotri(*n*-propyl)amine (20.3 wt %) and cyclic products of the empirical formula $C_9F_{19}N$, in particular, perfluoro-*N*-(*n*-propyl)-*cis*-3,4-dimethylpyrrolidine (41.2 wt %), perfluoro-*N*-(*n*-propyl)-*trans*-3,4-dimethylpyrrolidine (18.7 wt %), and perfluoro-*N*-(*n*-propyl)-3-methylpiperidine (19.3 wt %). Their spectra were described in [7].

The conditions and results of ECF of mixtures of toluene and benzotrifluoride with triallylamine are listed in Table 2.

The observed substance yields and current efficiencies do not contradict the published data [2–5], and the use of *n*-triallylamine as an electrolytic additive allows the yield of useful fluorination products to be raised to 78%.

The target fraction from ECF contains up to 20% products of contraction of the cyclohexane ring. These isomers, forming a eutectic with PFMCH, depress the freezing point of the mixture down to –65°C, i.e., by 30°C relative to PFMCH.

Because the electrolysis process is stable in time, our study opens up prospects for producing in a common process a series of organofluorine products for medicine and engineering in high yields by ECF of benzotrifluoride in a mixture with triallylamine.

CONCLUSIONS

(1) The possibility of preparing perfluoromethylcyclohexane by electrochemical fluorination in the presence of triallylamine as electrolytic additive was demonstrated. The process occurs with a good current efficiency and is stable in time and practically feasible.

(2) The electrolysis additionally yields perfluorinated tertiary amines, which are widely used in industry, medicine, and defense technology.

Received March 23, 2007

Abstract—Sulfur-containing oligoethers were prepared by polycondensation of thiodiglycol in the presence of acid catalysts. These oligoethers are oligomers with terminal hydroxy groups, comprised of oxyalkyl sulfide units.

DOI: 10.1134/S1070427207120170

Development of oil- and gas-resistant materials is an urgent task faced by modern polymer chemistry. One of the ways to accomplish this task consists in incorporation of sulfur atoms into the polymer matrix. For example, vulcanizates of Thiokols are well known to be resistant to fuels and oils [1]. Their large-scale production is hindered, however, by imperfect technology of production of polysulfide oligomers, yielding abundant wastewater. Wastewater utilization entails large costs, which increases the price of Thiokols. Also, materials based on polysulfide oligomers have poor strength characteristics. A high strength is exhibited by SKU-PFL commercial polyurethane based on oligo(oxytetramethylene) glycol (OOTMG). This is currently the most demanded castable polyurethane, but its oil and gas resistance is low.

In this context, it was of interest to replace OOTMG in synthesis of SKU-PFL polyurethane with a sulfur-containing oligoether diol and compare the properties of the new material with those of the OOTMG-based material. It could be expected that the new material would combine the properties of Thiokols and polyurethanes.

EXPERIMENTAL

As the initial compound for preparation of the oligoether with sulfur atoms in the backbone served thiodiglycol (TDG) synthesized by the reaction between ethylene chlorohydrin and sodium sulfide [2, 3]:

$$2HO–CH_2–CH_2–Cl + Na_2S \rightarrow HO–CH_2–CH_2–S–CH_2–CH_2–OH.$$

Oligothiodiglycols (OTDGs) with a molecular weight of 800–1200 were prepared by TDG polycondensation [4]:

$$n HO–CH_2–CH_2–S–CH_2–CH_2–OH \rightarrow HO–[–CH_2–CH_2–S–CH_2–CH_2–O–]_nH + (n – 1)H_2O.$$

For synthesis, we used both "crude" TDG (TDG-C) and that freed from impurities by distillation. The process was run at 110–115°C in a toluene medium with azeotropic distillation of water; sulfuric acid served as the catalyst.

The content of the hydroxy groups in the oligoethers was determined by acetylation with acetic anhydride in the presence of pyridine according to GOST (State Standard) 252–61. The concentration of isocyanate groups was determined by the "amine equivalent" method [5]. The IR spectra were recorded for oligoether films on a PE FTIR 1720 Perkin–Elmer (UK) spectrophotometer, and the ^{1}NMR spectra, in a perdeuteroacetonitrile solution on a Bruker MSL-400 (Germany) device at 400 MHz.

Quantum chemical calculations were carried out by B3LYP ab initio hybrid method in the STO 3-21G basis set with the use of the GAUSSIAN 03 software package [6]. The calculations involved full optimization of the configuration of the compounds. The initial optimization of the configuration was carried out by RM3 semiempirical method, and the resulting data were used for further calculations.

Polyurethanes were prepared via synthesis of a prepolymer by the reaction between OOTMG or

Table 2. Enthalpies ΔH_f^0, entropies ΔS_f^0, and Gibbs free energies ΔG_f^0 of formation of butanediol, thiodiglycol, and the products of their reactions with methyl isocyanate at 298 K

Compound	ΔH_f^0, kcal mol^{-1}	ΔS_f^0, cal mol^{-1} K^{-1}	ΔG_f^0, kcal mol^{-1}
HO–CH_2–CH_2–CH_2–CH_2–OH	–48.15	99.12	–16.36
HO–CH_2–CH_2–S–CH_2–CH_2–OH	–24.45	107.65	–49.96
CH_3–N=C=O	4.60	76.15	10.04
CH_3–NHCOO–$(CH_2)_4$–OH	–68.51	132.86	–18.63
CH_3–NHCOO–$(CH_2)_2$–S–$(CH_2)_2$–OH	–50.23	143.13	–58.16

OTDG and 2,4-toluylene diisocyanate (TDI), followed by curing with 4,4'-methylenebis(*o*-chloroaniline). The molar ratio of the reactants was 1 : 2 : 0.8.

The physicomechanical properties of the polyurethanes were determined by conventional techniques. The thermomechanical curves were measured on an automatic recording setup with a sample exposed to a permanent load of 0.64 MPa. The heating rate was 2 deg min^{-1}. The height of the samples was 2 mm, and diameter, 4 mm.

Table 1 compares the characteristics of OTDG and OOTMG. The theoretical sulfur content of OTDG reasonably agrees with that determined experimentally. The viscosity of OTDG is higher than that of OOTMG at comparable molecular weights. The increased viscosity of OTDG is consistent with the fact that vacant *d* orbitals of the sulfur atoms in it can interact with the occupied *p* orbitals of the oxygen atoms. This should result in the formation of intermolecular donor–acceptor bonds. This phenomenon cannot be observed in the case of OOTMG.

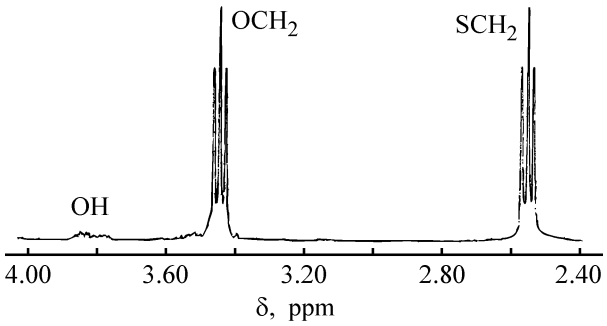

Fig. 1. NMR spectrum of OTDG. (δ) Chemical shift.

The IR spectra of the OTDG samples contain absorption bands at, cm^{-1}, 3400 (stretching vibrations of the HO groups), 2860 (stretching vibrations of the CH_2 group), and 1105 (stretching vibrations of the C–O–C moiety). A group of bands at 600–800 cm^{-1} belongs to the C–S bond.

In the ^{1}NMR spectra (Fig. 1), the protons of the methylene groups at the sulfur atom appear as a triplet at 2.60–2.40 ppm, and the protons of the methylene groups at the oxygen atom, as a triplet at 3.5–3.4 ppm. The protons of the hydroxy groups give a broadened signal at 3.80–3.90 ppm.

These data suggest that the TDG polycondensation product is indeed an oligomer with terminal hydroxy groups, containing sulfide and ether bonds in the chain.

To elucidate the difference between the pathways of the reactions of isocyanates with OOTMG and OTDG, we carried out quantum-chemical calculations of the thermodynamic parameters of the model reactions of TDG and 1,4-butanediol with methyl isocyanate. Table 2 lists the thermodynamic param-

eters of formation of the compounds examined, and Table 3, the thermodynamic parameters of the transformations discussed.

The reactions examined are characterized by large negative entropies and enthalpies. The enthalpy of the reaction between isocyanic acid and methanol in the gas phase, calculated from the enthalpies of formation of isocyanic acid (–24.3 kcal mol^{-1} [7]), methanol (–48.07 kcal mol^{-1} [8]), and methyl urethane (–101.6 kcal mol^{-1} [9]), is –29.23 kcal mol^{-1}. The enthalpy of the reaction between phenyl isocyanate and 1-butanol was estimated at –20.1 in [10] and at –25.1 kcal mol^{-1} in [11]. These enthalpies of the reactions are close to the experimental data.

The reaction of methyl isocyanate with TDG is much more exothermic than that with 1,4-butanediol. Accordingly, the equilibrium constants of formation of urethane from TDG strongly exceed those in the case of 1,4-butanediol. Our data suggest that incorporation of the thiodiglycol moiety into the polyurethane structure should increase the stability of the urethane group.

A kinetic study of the reaction of OTDG and OOTMG with TDI showed that the time corresponding to 50% conversion of the isocyanate groups is 45 and 60 min, respectively (Fig. 2, curves *1*, *2*), which suggests a slightly higher activity of OTDG. Thus, introduction of the sulfur atom into the glycol moiety not only improves the thermodynamic stability of the urethanes but also accelerates their formation.

A different situation is observed when OTDG is replaced with OTDG-C (Fig. 2, curve *3*). In this case, the isocyanate groups are fully consumed already in 15 min. Such a fast decrease in their concentration is evidently due to the presence in the system of impurity metal compounds introduced with the oligoether because of the use for its synthesis of "crude" TDG (the TDG preparation technique involves the use of sodium sulfide containing an impurity iron sulfide). These impurities accelerate not only the formation of urethanes, but also the formation of allophanates and isocyanurates, undesirable for the prepolymer preparation [12]. This made OTDG-C unsuitable for synthesis of polyurethanes via the prepolymer stage.

Then we identified the temperature areas of serviceability of the polyurethanes synthesized. Figure 3 shows the thermomechanical curves (TMCs) for the polyurethane elastomer whose flexible segment is formed by OTDG, in comparison with SKU-PFL. It is seen that the profile of the TMCs depends on

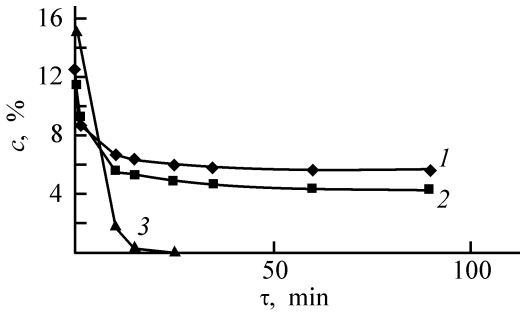

Fig. 2. Kinetic curves of the loss of NCO groups in the reaction between oligoether diols and TDI at 60°C. (*c*) Content of NCO and (τ) time. (*1*) OOTMG, (*2*) OTDG, and (*3*) OTDG-C.

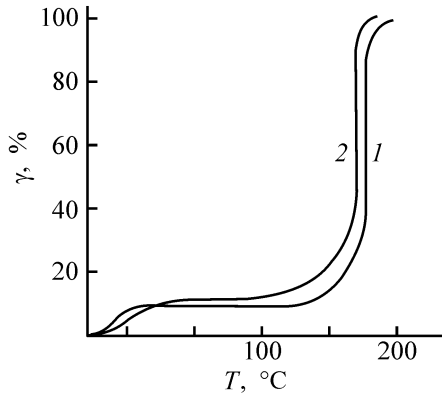

Fig. 3. Thermomechanical curves of the polyurethanes based on (*1*) OOTMG and (*2*) OTDG. (γ) Strain and (*T*) temperature.

Table 4. Properties of the cast polyurethanes based on OTDG and OOTMG

Parameter	Oligoether	
	OTDG	OOTMG
Nominal tensile strength, MPa	8.4	36.2
Relative elongation at break, %	80	380
Relative elongation set, %	4.0	0
Rebound elasticity, %	29.0	38.0
TM-2 hardness, arb. units	90.0	94.0
Degree of equilibrium swelling, %:		
in transformer oil	1.0	9.2
in toluene	10.2	48.4
Glass transition point, °C	–24	–38
Flow point, °C	190	200

the nature of the oligoether component. In going from OOTMG to OTDG, the glass transition point increases, whereas the flow point, by contrast, decreases (Table 4). This is accompanied by narrowing of the hyperelasticity area.

These data suggest that, upon introduction of sulfur atoms into the flexible segment of the polymer, the kinetic section of the material increases and the density of its physical network decreases. In the polymers examined, the formation of the 3*D* network is mainly due to hydrogen bonding. This is associated with taking a minor excess of isocyanate for synthesis.

The physicomechanical properties of the polymers (Table 4) suggest that the sulfur-containing polyurethanes unfavorably compare with those based on OOTMG in the tensile strength, relative elongation, and elasticity, but considerably exceed them in the resistance to solvents. For example, the equilibrium degree of swelling in transformer oil is by an order of magnitude, and that in toluene, by a factor of 5, higher.

Thus, polyurethanes based on oligoether diol comprised of oxoalkyl sulfide units are of interest for manufacture of articles contacting with oils and hydrocarbon solvents during exploitation.

CONCLUSIONS

(1) Polyurethanes based on oligothiodiglycol are characterized by high resistance to swelling in hydrocarbons, but lower level of physicomechanical properties.

(2) Introduction of the sulfur atom into the glycol moiety increases the thermodynamic stability of the urethanes and accelerates their formation.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of Perfluoro-Substituted Derivatives of 1,3-Diazines and 1,2,4-Triazoles

L. M. Popova and S. V. Vershilov

St. Petersburg State Technological University of Plant Polymers, St. Petersburg, Russia

Received May 30, 2007

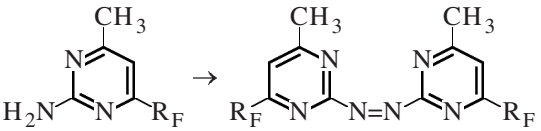
Abstract—Oxidation of 6-perfluoro-substituted 2-amino-4-methylpyrimidines and 5-amino-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole with potassium permanganate and of 3-perfluoro-substituted 5-mercapto- and 5-amino-1,2,4-triazoles with hydrogen peroxide in alkaline solution was studied.

DOI: 10.1134/S1070427207120182

In the development of new composite materials containing fluorinated surfactants, it is important to understand chemical transformation of these compounds under the action of oxidants. Proceeding with studies of fluorinated azine [1] and azole [2, 3] derivatives, we examined oxidation of 6-perfluoro-substituted 2-amino-4-methylpyrimidines **I**–**V** and 5-amino-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole **XI** with potassium permanganate in alkaline solutions to the corresponding azobis(diazine) derivatives **VI**–**X** and 5,5'-azobis[3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole] **XII**.

In addition, we performed oxidation of 3-perfluoro-substituted 5-mercapto- (**XIII**, **XIV**) and 5-amino-1,2,4-triazoles (**XI**) with hydrogen peroxide in alkaline solution and obtained 5-hydroxy derivatives **XV** and **XVI**.

The strarting 2-aminopyrimidines **I**–**V** were prepared by intermolecular cyclocondensation of unsymmetrical fluorinated β-diketones with guanidine [4], and 5-amino-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole **XI** and 3-perfluoro-substituted 5-mercapto-1,2,4-triazoles **XIII** and **XIV**, by intramolecular condensation of perfluoro(1,4-dimethyl-2,5-dioxaoctyl)aminoguanidine and base cyclization of perfluoroacylthiosemicarbazides [2].



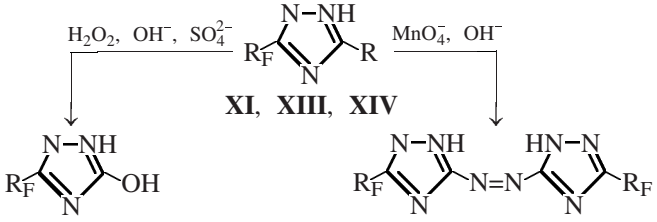
I–**V** → **VI**–**X**

R_F = C_6F_{13} (**I**, **VI**); C_8F_{17} (**II**, **VII**); $CF(CF_3)OC_3F_7$ (**III**, **VIII**); $CF(CF_3)OCF_2CF(CF_3)OC_3F_7$ (**IV**, **IX**); $CF(CF_3)[OCF_2CF(CF_3)]_2OC_3F_7$ (**V**, **X**).

4,4'-Dimethyl-6,6'-bis(perfluoro)-substituted 2,2'-azobispyrimidines **VI**–**X** were prepared by oxidation of the corresponding 2-aminodiazines **I**–**V** with a 10% aqueous-alcoholic solution of potassium permanganate in alkaline medium at room temperature for 6 h. Azo coupling products **VI**–**X** were isolated after treatment of the reaction mixture with 5% HCl to pH 4–5 followed by extraction with Freon 113. After distilling off the solvent and drying, the yield of **VI**–**X** reached 60–70%. Perfluoro-substituted azobispyrimidines were viscous oils with a specific odor.

The IR spectra of 6,6'-bis(perfluoro)-substituted azobispyrimidine derivatives **VI**–**X** contained stretching vibration bands of methyl groups at 3392–2850 cm^{-1}, skeleton vibration bands of the heteroring at 1770–1405 cm^{-1}, and C–F stretching vibration bands at 1350–890 cm^{-1}.

It was also interesting to evaluate the resistance of perfluoro-substituted 5-aminotriazoles to oxidants. For example, oxidation of 3-perfluoro-substituted 5-amino-1,2,4-triazole **XI** with $KMnO_4$ in 10% aqueous KOH at room temperature for 6 h gave 5,5'-azobis derivative **XII** in 65% yield:



XI, **XIII**, **XIV** → **XV**, **XVI**; **XII**

R = NH_2, R_F = $CF(CF_3)OCF_2CF(CF_3)OC_3F_7$ (**XI**), (**XII**); R = SH, R_F = C_6F_{13} (**XIII**), (**XV**); $CF(CF_3)\cdot OCF_2CF(CF_3)OC_3F_7$ (**XIV**), (**XVI**).

The action of alkali without an oxidant caused no changes in the structure of 3-perfluoro-substituted 5-amino-1,2,4-triazole **XI** but merely converted it into the corresponding salt.

The composition and structure of **XII** were confirmed by elemental analysis and spectroscopic data. For example, in the IR spectrum of 5,5'-azobis[3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole] **XII** there are NH stretching vibration bands at 2995–3505 cm^{-1}, skeleton vibration bands of the heteroring at 1459–1734 cm^{-1}, and C–F stretching vibration bands at 1350–890 cm^{-1}.

It is known that 5-mercapto-1,2,4-thiazole derivatives can undergo desulfurization under the action of both oxidants and reductants [5]. In particular, treatment of 5-mercapto-1,2,4-triazole derivatives with hydrogen peroxide in acid solution on heating [6] and with concentrated nitric acid [7] resulted in replacement of the thiol group by hydrogen.

By treatment of 3-perfluoro-substituted 5-mercapto-1,2,4-triazoles **XIII** and **XIV** with 50% hydrogen peroxide in alkaline solution at room temperature for 2 h, we prepared the corresponding 5-hydroxy derivatives **XV** and **XVI**, which were isolated in 66–75% yield after testing the reaction mixture for the absence of residual peroxide and acidifying with 10% HCl to pH 3–4.

Compound **XVI** was also prepared in 66% yield by oxidation of 3-perfluoro-substituted 5-amino-1,2,4-triazole **XI** with 30% hydrogen peroxide under reflux for 3 h. The IR spectra of 3-perfluoro-substituted 5-hydroxy-1,2,4-triazoles **XV** and **XVI** contain stretching vibration bands of the OH group at 3500 cm^{-1} and of the NH group at 3000–3300 cm^{-1}, heteroring vibration bands at 1435–1735 cm^{-1}, and a mixed vibration band of the C–F and C–O bonds at 1100–1400 cm^{-1}.

EXPERIMENTAL

The IR spectra were recorded on a Shimadzu IR-470 spectrophotometer (Japan) from thin films. The UV spectra were measured on an SF-48 spectrophotometer from 10^{-4} M aqueous-alcoholic solutions; the layer thickness was 1 cm. The reaction progress and product purity were monitored by TLC on Silufol UV-254 plates. The starting 6-perfluoro-substituted 2-amino-4-methylpyrimidines **I**–**V** were prepared according to [4], and 5-amino- (**XI**) and 5-mercapto-1,2,4-triazoles (**XIII**, **XIV**), according to [2].

2,2'-Azobis(4-methyl-6-perfluorohexylpyrimidine) VI. A solution of 0.9 g (0.014 mol) of KOH in 20 ml of water was added dropwise to a solution of 1.2 g (0.0028 mol) of 2-amino-4-methyl-6-perfluorohexylpyrimidine **I** in 10 ml of ethanol. Then a solution of 0.44 g (0.0028 mol) of $KMnO_4$ in 15 ml of water was added, and the mixture was allowed to stand for 6 h. After that the mixture was acidified with 5% HCl to pH 4–5, extracted with Freon 113, washed with water, and dried, after which the solvent was distilled off. Yield 0.7 g (60%), yellow oil. IR spectrum (thin film), ν, cm^{-1}: 3280, 3180 (C–H); 1740, 1680, 1610, 1580 (heteroring); 1350, 1145 (C–F).

Found, %: C 30.85, F 57.90, N 9.62.
$C_{22}H_{68}F_{26}N_6$.
Calculated, %: C 31.08, F 58.09, N 9.88.

2,2'-Azobis(4-methyl-6-perfluorooctylpyrimidine) VII was prepared similarly to **VI** from 2.1 g (0.004 mol) of 2-amino-4-methyl-6-perfluorohexylpyrimidine **II**. Yield 1.3 g (63%), yellow oil. IR spectrum (thin film), ν, cm^{-1}: 3392, 2915, 2870 (C–H); 1770, 1685, 1550, 1460 (heteroring); 1390–890 (C–F).

Found, %: C 29.45, F 61.19, N 7.88.
$C_{26}H_8F_{34}N_6$.
Calculated, %: C 29.73; F 61.50; N 8.00.

2,2'-Azobis[4-methyl-6-perfluoro(1-methyl-2-oxapentyl)pyrimidine] VIII was prepared similarly to **VI** from 2.0 g (0.005 mol) of 2-amino-4-methyl-6-perfluoro(1-methyl-2-oxapentyl)pyrimidine **III**. Yield 1.4 g (70%), yellow oil. IR spectrum (thin film), ν, cm^{-1}: 3200, 3180 (C–H); 1680, 1620, 1540, 1440 (heteroring); 1300–1280 (C–F).

Found, %: C 30.29, F 53.13, N 10.39.
$C_{20}H_8F_{22}N_6O_2$.
Calculated, %: C 30.71, F 53.43, N 10.74.

2,2'-Azobis[4-methyl-6-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)pyrimidine] IX was prepared similarly to **VI** from 2.2 g (0.004 mol) of 2-amino-4-methyl-6-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)pyrimidine **IV**. YIeld 1.4 g (65%), light yellow oil. IR spectrum (thin film), ν, cm^{-1}: 3480, 3390, 3120, 2910, 2850 (C–H); 1680, 1620, 1590, 1440 (heteroring); 1340–980 (C–F).

Found, %: C 27.89, F 58.17, N 7.34.
$C_{26}H_8F_{34}N_6O_4$.
Calculated, %: C 28.03, F 57.97, N 7.54.

2,2'-Azobis[4-methyl-6-perfluoro(1,4,7-trimethyl-2,5,8-trioxaundecanyl)pyrimidine] X was prepared similarly to **VI** from 7.23 g (0.005 mol) of 2-amino-4-methyl-6-perfluoro(1,4,7-trimethyl-2,5,8-trioxaundecyl)pyrimidine **V**. Yield 4.4 g (60%), light brown oil.

IR spectrum (thin film), ν, cm^{-1}: 3392, 3110, 2900 (C–H); 1769, 1683, 1405 (heteroring); 1309–995 (C–F).

Found, %: C 26.14, F 60.05, N 5.33.
$C_{32}H_8F_{46}N_3O_6$.
Calculated, %: C 26.57, F 60.42, N 5.81.

5,5'-Azobis[3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole XII. A solution of 5.6 g (0.1 mol) of KOH in 20 ml of water was added dropwise to a solution of 12.0 g (0.025 mol) of 5-amino-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole **XI** in 10 ml of ethanol. Then a solution of 0.63 g (0.025 mol) $KMnO_4$ in 30 ml of water was added with vigorous stirring, and the mixture was allowed to stand for 4 h. After acidification of the mixture with 5% HCl to pH 4–5, the product was extracted with Freon 113, washed with water, and dried; the solvent was distilled off. Yield 7.8 g (65%), colorless crystals, mp 89–91°C. IR spectrum (Freon 113, 5%), ν, cm^{-1}: 3505, 3225, 3125, 2995 (N–H); 1734, 1670, 1647, 1600, 1540, 1459 (heteroring); 1340, 1100–980 (C–F). UV spectrum (*i*-PrOH), λ_{max}, nm (log ε): 198 (3.88), 245 (3.68). TLC (acetone–water, 1 : 1): R_f 0.37.

Found, %: C 22.46, H 0.28, F 60.59, N 10.38.
$C_{20}H_2F_{34}N_8O_4$.
Calculated, %: C 22.58, H 0.18, F 60.70, N 10.53.

5-Hydroxy-3-perfluorohexyl-1,2,4-triazole XV. To 21 g (0.05 mol) of 5-mercapto-3-perfluorohexyl-1,2,4-triazole **XIII** in 100 ml of 10% aqueous KOH, 12 ml of 50% H_2O_2 (d^{20} 1.2) was added dropwise, and the mixture was left for 2 h. After testing for the absence of residual peroxide, the mixture was acidified with 10% HCl to pH 3–4. The precipitate was filtered off and washed with water to neutral reaction. The product was dissolved in alcohol, the solution was filtered, the solvent was distilled off, and the residue was dried. Yield 15.1 g (75%), mp 112–113°C. IR spectrum (Freon 113, 5%), ν, cm^{-1}: 3500 (O–H); 3280, 3180 (N–H); 1735, 1680, 1610, 1580 (heteroring); 1350, 1140 (C–F, C–O).

Found, %: C 23.97, F 61.14, N 10.35.
$C_8H_2F_{13}N_3O$.
Calculated, %: C 23.84, F 61.27, N 10.42.

5-Hydroxy-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole XVI was prepared similarly to **XV** from 16.5 g (0.03 mol) of 5-mercapto-3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole **XIII**. The product was extracted with ethyl acetate, the extract was filtered, the solvent was distilled off, and the residue was dried. Yield 10.6 g (66%), amorphous substance. IR spectrum (thin film), ν, cm^{-1}: 3500 (O–H); 3300, 3120, 3000 (N–H); 2850, 1735, 1620, 1590, 1435 (heteroring); 1340, 1100 (C–F, C–O).

CONCLUSIONS

(1) Oxidation of perfluoro-substituted derivatives of 1,3-diazines and 1,2,4-triazoles with 10% aqueous-alcoholic solution of potassium permanganate in alkaline solution at room temperature yields azobispyrimidine derivatives and 5,5'-azobis[3-perfluoro(1,4-dimethyl-2,5-dioxaoctyl)-1,2,4-triazole].

(2) Treatment of 3-perfluoro-substituted 5-mercapto- (at room temperature) and 5-amino-1,2,4-triazole (under reflux) with an aqueous-alkaline solution of hydrogen peroxide yields the corresponding 5-hydroxy derivatives.

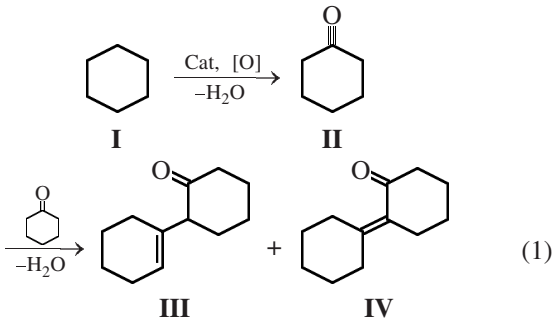
Abstract—The possibility of preparing epoxides from α,β- and β,γ-unsaturated bicyclic ketones formed as by-products in liquid-phase oxidation of cyclohexane with atmospheric oxygen (a stage in production of caprolactam, adipic acid, and other products) was examined. The reaction products were analyzed by gel chromatography and mass spectrometry.

DOI: 10.1134/S1070427207120194

Epoxy compounds are valuable and demanded intermediates for both basic and fine organic synthesis. They are used as effective modifiers, stabilizers, and thinners of polymeric masses with the aim to obtain polymeric materials with required properties. Many heterocyclic epoxides are biologically active compounds or their precursors.

It is known that liquid-phase oxidation of cyclohexane **I** with atmospheric oxygen, performed in industry with the aim to obtain cyclohexanone **II**, is accompanied by side reactions yielding α,β- and β,γ-unsaturated cyclic ketones: 2-cyclohexylidenecyclohexanone **III** and 2-(1-cyclohexenyl)cyclohexanone **IV**, forming the "light fraction" of X-oils:



(1)

According to the estimates based on data of [1–3], the amount of such by-products is 80–100 kg per ton of converted **I**. It is known [4] that compound **III** is thermodynamically unstable and isomerizes into **IV** at 150°C. The isomerization is reversible, and an equilibrium mixture obtained under common conditions consists of **III** and **IV** in an approximately 9 : 1 ratio. This mixture can be separated by low-temperature crystallization.

One of promising ways to perform epoxidation of various organic substrates is phase-transfer catalysis in combination with the use of bifunctional homogeneous nanostructured catalysts based on peroxopolyoxotungstates [5–14]. Studies using various physicochemical methods (NMR, IR, Raman, UV spectroscopy, etc.) have shown that the peroxo complexes formed in the systems H_2O_2–H_3PO_4–Na_2WO_4 and $H_3PW_{12}O_{40}$–H_2O_2 are fairly stable, and the most active in oxidation is the $\{PO_4[WO(O_2)_2]_4\}^{3-}$ anion (Fig. 1) [7, 8, 10, 11]. The use of phase-transfer catalysts, quaternary ammonium cations Q^+, in combination with the oxidation catalyst, peroxopolyoxo anion, allows the oxidation to be performed as a one-pot process in two-phase solutions.

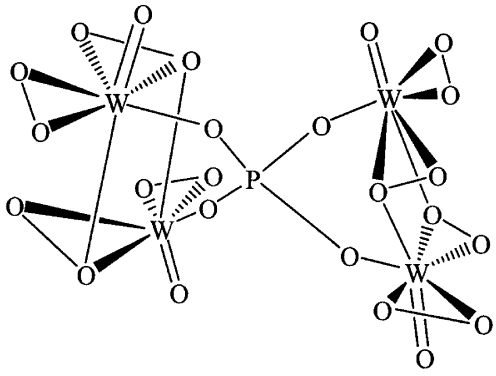


Fig. 1. Structure of the peroxo anion $\{PO_4[WO(O_2)_2]_4\}^{3-}$.

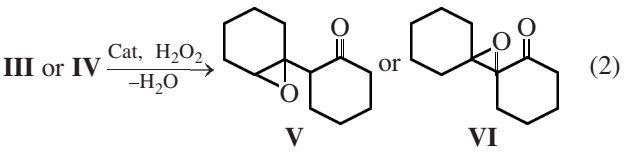
In this study, we examined the possibility of preparing epoxides from α,β- and β,γ-unsaturated cyclic ketones, by-products from oxidation of cyclohexane with atmospheric oxygen.

The expected products of catalytic oxidation of cyclic ketones **III** and **IV** containing C=C bonds with hydrogen peroxide are 2-(7-oxabicyclo[4.1.0]hept-1-yl)cyclohexanone **V** and 13-oxadispiro[5.0.5.1]tridecan-1-one **VI** [15]:



(2)

EXPERIMENTAL

As substrate we used a mixture isolated by vacuum distillation from the "light" fraction of X-oil from cyclohexanone production (Azot Joint-Stock Company, Kemerovo). It was a light yellow oily liquid (density 1.1 g cm^{-3}).

As catalyst we used a quaternary ammonium salt of tetra(oxodiperoxotungstato)phosphate, $Q_3\{PO_4 \cdot [WO(O_2)_2]_4\}$, where Q is the cation of tetra-*n*-butylammonium chloride $[(C_4H_9)_4N]Cl$ (95%) or *N*-hexadecylpyridinium chloride $[1\text{-}C_5H_5N(CH_2)_{15}CH_3]Cl$ (Acros). The catalytic systems were prepared by the procedure described in [11].

The epoxidation was performed in a duck-shaped catalytic vessel shaken at a rate of 300–400 double rockings per minute and equipped with a reflux condenser and a temperature-control jacket. The reaction temperature (55–65°C) was maintained with a water thermostat with an accuracy of ±1.0°C.

The reaction mixture was analyzed by gel chromatography–mass spectrometry (GC–MS) (Saturn 2000 device, USA; quartz capillary column 30 m long, stationary phase CP-SIL 8 CB; ionizing electron energy 70 eV. Quantitative processing of the chromatographic data was performed using normalization [16].

First we analyzed by GC–MS the substrate (light fraction of X-oil) with the aim to determine its composition. We detected (Fig. 2) residual amounts of **I**, ketones **III** and **IV**, and also 1,2,3,4,6,7,8,9-octahydrodibenzo[*b*, *d*]furan **VII** and compounds giving a molecular ion at *m*/*z* 258, which corresponds to the molecular weight of tricyclic ketones, 2,6-dicyclohexylydenecyclohexanone **VIII** and 2,6-di(1-cyclohexenyl)cyclohexanone **IX**. It should be noted that the tricyclic ketones formed by condensation of three cyclohexanone molecules, like bicyclic ketones, form isomers:

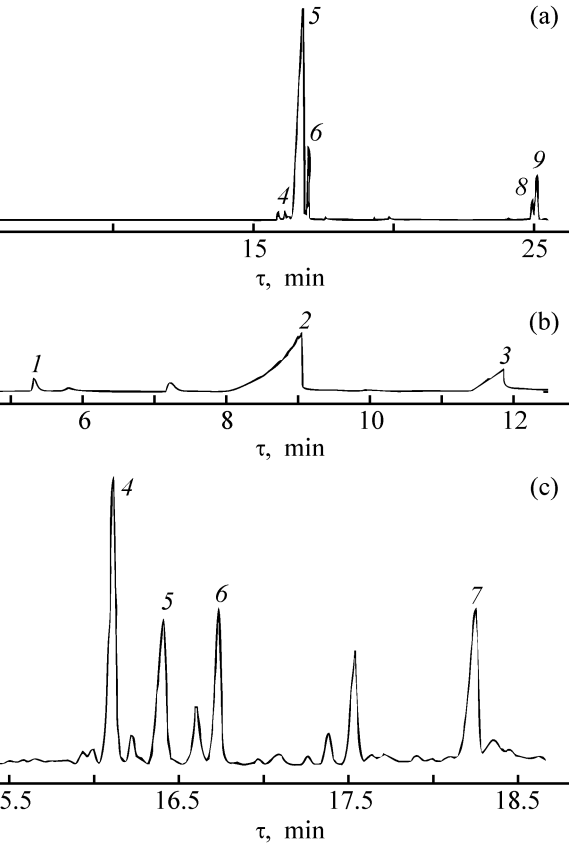


Fig. 2. Chromatograms of the organic phase of the reaction mixture. (τ) Retention time. (a) Substrate; (b, c) fragments of the chromatogram of the reaction mixture after the oxidation. (*1*) Cyclohexanone **I**, (*2*, *3*) carboxylic acids, (*4*) dibenzofuran **VII**, (*5*, *6*) ketones **IV** and **III**, (7) epoxide **VI**, and (*8*, *9*) tricyclic ketones **VIII** and **IX**.

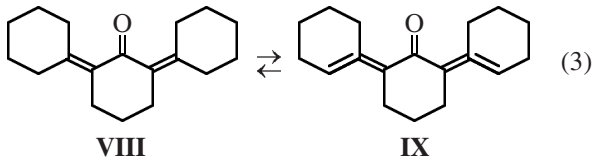

(3)

On the whole, the results of the GC–MS analysis (see table) were consistent with the composition of the light fraction of X-oil given in [2].

We performed a series of experiments on catalytic oxidation of the substrate containing a mixture of ketones **III** and **IV**. In these experiments, we varied the catalyst and the reaction temperature. We revealed a difference in the catalytic activity of peroxopolyoxotungstate complexes, depending on the structure of the phase-transfer catalyst. The most active catalytic

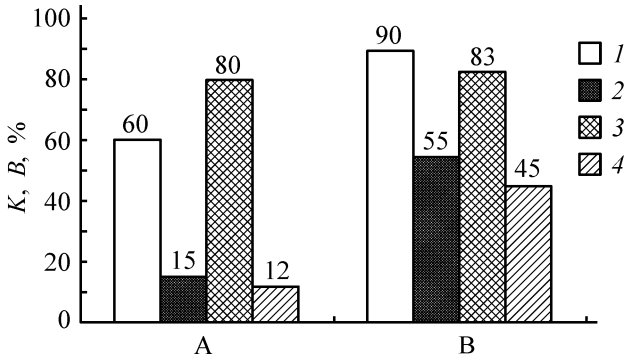

Fig. 3. Effect of catalyst cation on the conversion *K* of ketones and epoxide yield *B*. Reaction conditions: $[H_2O_2]$/[substrate] = 3, [substrate]/[catalyst] = 200, solvent dichloroethane, 65°C, 3 h. Catalytic complex: (A) $[(C_4H_9)_4N]_3 \cdot \{PO_4[W(O)(O_2)_2]_4\}$, and (B) $[C_5H_5N(CH_2)_{15}CH_3]_3 \cdot \{PO_4[W(O)(O_2)_2]_4\}$. (*1*) Conversion of **III**, (*2*) conversion of **IV**, (*3*) selectivity with respect to epoxide **VI**, and (*4*) yield of **VI**.

system (Fig. 3) is *N*-hexadecylpyridinium tetra(oxodiperoxotungstato)phosphate. In the presence of this catalytic system, 13-oxadispiro[5.0.5.1]tridecan-1-one **VI** is obtained in 45% yield at 90% conversion of **III** and 55% conversion of **IV**. The weaker catalytic activity of $[(C_4H_9)_4N]_3\{PO_4[W(O)(O_2)_2]_4\}$ is consistent with the lower lipophilicity of the phase-transfer agent, $[(C_4H_9)_4N]^+$, compared to *N*-hexadecylpyridinium.

A decrease in the temperature of the catalytic oxidation from 65 to 55°C, with *N*-hexadecylpyridinium tetra(oxodiperoxotungstato)phosphate as catalyst, does not appreciably affect, under equal other conditions, the yield of epoxide **VI**. However, we detected an untypical of these conditions increase in the concentration of cyclopentanecarboxylic acid as epoxidation by-product (Fig. 2b): from 8 to 12% in the product mixture.

Composition of the light fraction of X-oil

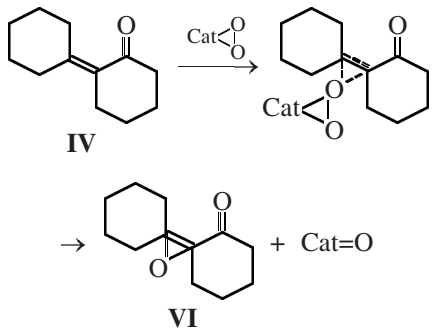
Compound	Content of components	
	mol %*	wt % [2]
Cyclohexanone **I**	0.2	3.6**
2-(1-Cyclohexenyl)cyclohexanone **IV**	78.5	90.6
2-Cyclohexylidenecyclohexanone **III**	7.8	
Tricyclic ketones **VIII** and **IX** (cyclohexanone trimerization products)	8.6	
1,2,3,4,6,7,8,9-Octahydrodibenzo[*b*,*d*]furan **VII**	1.0	5.8
Unidentified products	3.9	

* Results of GC–MS analysis.
** Content of cyclohexanone and cyclohexanol.

The presence of carboxylic acids in the reaction products raises the acidity of the reaction mixture, which may promote opening of the oxirane ring. To lower the acidity, we added AV-17-8 anion-exchange resin in the OH form to the reaction mixture. A GC–MS analysis of the mixture after the oxidation showed the absence of carboxylic acids in the organic layer of the reaction mixture. However, addition of the anion exchanger had a strong effect on the conversion of the starting compounds, and it cannot be recommended for synthesis of the epoxides as target products.

Comparison of our results with published data [17–19] reveals certain analogies. The following most probable mechanism of the oxidation of the starting α,β- and β,γ-unsaturated cyclic ketones **III** and **IV** can be suggested.

Formation of epoxide **VI** from ketone **IV** with involvement of the oxygen atom of the peroxy group of the catalyst occurs in the organic phase:



(4)

Regeneration of the catalyst with hydrogen peroxide occurs at the phase boundary.

Identification of the other components of the reaction mixture is complicated by the presence of a large amount of background fragment peaks in the mass spectra of the products. Nevertheless, comparison of the results of our mass-spectrometric analysis with published data [17–20] suggests that one of the reaction products is 1,2,3,4,6,7,8,9-octahydrodibenzo[*b*,*d*]-furan **VII**, whose concentration in the organic layer after the reaction completion was about 11% against 1% in the starting substrate (see table). A comparison of the reference mass spectrum of pure **VII** with the mass spectrum of component 5 (Fig. 2c) revealed a full coincidence of the peak positions and a 62% coincidence of the peak intensities.

The formation of compounds containing a furan ring was described in [18]. Namely, 2-cyclohexylidenecyclohexanone **III** transformed in a very acidic medium into **VII**. Creese and Smissman [17] described the mechanism of cyclic dehydration of 2-(1-cyclohexenyl)cyclohexanone epoxide **V** to give of octahydrodibenzofuran **VII**. Therefore, we can assume that the precursors of 1,2,3,4,6,7,8,9-octahydrodibenzo[*b*, *d*]furan **VII** are ketone **III** and also cyclohexanone **I** and tricyclic ketones present in the reaction mixture.

CONCLUSIONS

(1) Epoxides of bicyclic ketones, and also dibenzofuran derivatives and carboxylic acids are formed from the light fraction of X-oils (by-product from caprolactam production) under the conditions of phase-transfer catalysis in two-phase solutions. Oxidation with hydrogen peroxide occurs under mild conditions: atmospheric pressure, temperature ≤65°C, low catalyst concentrations ([substrate] : [catalyst] = 200).

(2) Oxidation of 2-cyclohexylidenecyclohexanone with hydrogen peroxide in the presence of a homogeneous bifunctional catalyst, *N*-hexadecylpyridinium tetra(oxodiperoxotungstato)phosphate, gives an epoxide, 13-oxadispiro[5.0.5.1]tridecan-1-one, with 83% selectivity at 55% conversion of the starting ketone.

(3) Oxidation of 2-(1-cyclohexenyl)cyclohexanone with hydrogen peroxide in the presence of *N*-hexadecylpyridinium tetra(oxodiperoxotungstato)phosphate mainly yields 1,2,3,4,6,7,8,9-octahydrodibenzo[*b*, *d*]-furan and cyclopentanedicarboxylic acid.

ACKNOWLEDGMENTS

The authors are grateful to A.S. Noskov for support of our studies and to V.A. Utkin for performing the GC–MS analysis.

The study was financially supported by the Federal Target Scientific and Technical Program "Research and Development in Priority Fields of the Scientific and Technological Complex of Russia in 2007–2012" (State Contract no. 02.515.11.5009) and by the Division of Chemistry and Materials Science of the Russian Academy of Sciences (project no. 5.6.3).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Recovery of Anthocyan Dye from Aqueous-Salt Solutions with Polyethylene Glycol PEG-5000

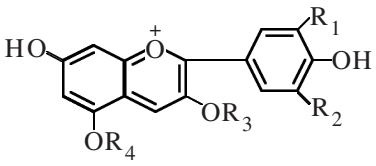
Abstract—Extraction with PEG-5000 was studied as a method for recovering and concentrating a natural anthocyan dye from sodium and ammonium sulfate solutions. The effects of the type of salt cation, pH, and addition of aliphatic alcohols on the dye recovery were examined.

DOI: 10.1134/S1070427207120200

The involvement of synthetic dyes in carcinogenesis makes natural dyes, which are harmless and, what is more, useful, preferable for food and pharmaceutical industries [1, 2]. Among these natural dyes are red pigments (anthocyans) causing coloration of red wines and fruit juices. Anthocyans belong to the group of phenolic flavonoid compounds [3]:



where R^1, R^2 are H, OH, or OCH_3, and R^3, R^4 are H atoms or carbohydrate residues.

Anthocyan extracts contain biologically active components (vitamins, microelements, organic acids) and aliphatic alcohols, added to aqueous solutions to facilitate dye extraction from the vegetable raw material [4].

For recovery and concentration of the natural dyes from aqueous solutions, the extraction with water-soluble high-molecular-weight compounds forming a separate aqueous-organic phase in the presence of salting-out agents shows promise. Polyethylene glycols (PEGs), which are nontoxic compounds used as thickeners and binders in pharmaceutical industry and cosmetology [5], belong to such polymers. Two-phase aqueous systems based on PEG are successfully used in extraction recovery and separation of organic and inorganic substances of various classes [6–8].

The goal of this study was to optimize the conditions of the recovery and concentration of the anthocyan dye from aqueous solutions, using dye extraction with PEG-5000 from aqueous-salt solutions.

EXPERIMENTAL

THe anthocyan dye was recovered from black-currant berries with ethanol at 50–55°C by the known method [9]. The dye distribution was studied in systems constituted by an aqueous solution and solution of sodium or ammonium sulfate. The polymer manufactured by Loba Chemie Co. with a molecular weight of 5000 and salting-out agents and aliphatic alcohols of chemically pure grade were used.

A 15-ml portion of an anthocyan dye solution containing $(NH_4)_2SO_4$ (40 wt %) or Na_2SO_4 (15 wt %) was placed in a flask with a ground-glass stopper, 3 ml of PEG solution (0.1–20 wt %) was added, and extraction was performed on a vibromixer for 3–5 min (time in which the phase equilibrium is attained).

The efficiency of the extractive recovery of the dye was evaluated by the degree of dye recovery, R (%):

$$R = (A_0 - A)/A_0 \times 100,$$

where A_0 and A are the optical densities of the aqueous solutions before and after extraction.

The optical densities of the solutions were measured on a KFK-2MP photocolorimeter at 490 nm using optical cells of thickness 1 and 3 cm. The content of the red pigment in the anthocyan dye was determined

by the known method, using a standard solution of $CoSO_4 \cdot 7H_2O$ [10]. Aliphatic alcohols were introduced into aqueous-salt solutions in experiments aimed to study the hydrotropic effect on the dye extraction.

Two-phase aqueous–polymeric systems were prepared by salting-out of the polymer from its aqueous solutions with certain salts [6]. Polyethylene glycols form such systems in the presence of sulfates of alkali metals and ammonium. The most efficient salting-out agents are $(NH_4)_2SO_4$ and Na_2SO_4. To attain the maximal volume of the aqueous-organic phase of the polymer, salt solutions close to saturation are used.

The degree of the anthocyan dye recovery from aqueous-salt solution depends on the polymer concentration and salt cation (Fig. 1).

Water in the phase containing ammonium sulfate is almost completely incorporated in the solvation spheres of ammonium ion; sodium ions are hydrated to a lesser extent [11]. Therefore, irrespective of the PEG concentration, systems with $(NH_4)_2SO_4$ are more effective. For example, on adding 0.3 wt % PEG to the aqueous solution, more than 75% of the dye is extracted from the saturated $(NH_4)_2SO_4$ solution, whereas in the presence of Na_2SO_4 only about 40% of the dye is recovered under similar conditions. Differences in the R values become less pronounced as the polymer content of the aqueous solution increases. In a single extraction, the maximal degree of dye recovery (97%) is attained in salting-out from ammonium sulfate solutions.

The high efficiency of extraction systems containing PEG is associated with the formation of PEG complexes with the dye via hydrophobic interactions of ethylene groups of the polymer with aromatic groups of the dye and formation of hydrogen bonds between OH groups of the polymer and dye.

We studied the influence of aqueous solution pH on the anthocyan dye recovery of the (Fig. 2). As can be seen, the efficiency of recovery is virtually constant within the pH range from 1 to 4. At a PEG content of 1.67 wt %, 94 and 97% of the dye is recovered from solutions with pH 1 and 4, respectively. The insignificant influence of pH on the dye recovery is caused by the large contribution of hydrophobic interactions in the extraction systems studied. In alkaline media, the extraction was not studied because the dye is unstable at pH > 7 [12].

To recover the anthocyan dye from vegetable raw materials, various organic solvents, including aliphatic alcohols, are used [4, 9]. Therefore, we studied the effect of ethanol, 1-propanol, 1-butanol, and 3-methyl-1-butanol added to the aqueous phase on the extractive recovery of the anthocyan dye and on the formation of the two-phase system (see table).

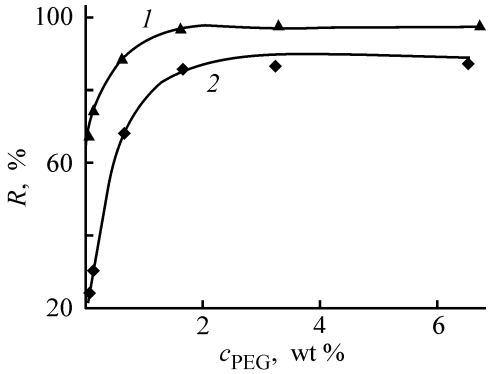


Fig. 1. Degree R of anthocyan dye recovery vs. PEG-5000 content c_{PEG} of the aqueous solution in the presence of a salting-out agent. (*1*) $(NH_4)_2SO_4$ and (*2*) Na_2SO_4.

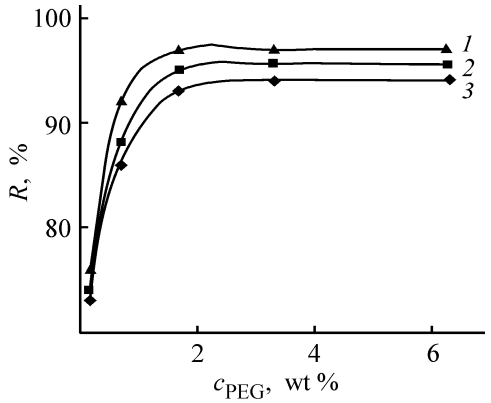

Fig. 2. Influence of pH on the degree of recovery of the anthocyan dye R in the presence of $(NH_4)_2SO_4$. (c_{PEG}) Polyethylene glycol content. pH: (*1*) 4, (*2*) 3, and (*3*) 1.

Correlation of equilibrium volumes of aqueous and organic phases and degree of recovery of the anthocyan dye with polyethylene glycol from aqueous ammonium sulfate solutions in the presence of alcohols

Alcohol	c_{PEG} = 1.67 wt %		c_{PEG} = 0.67 wt %	
	$V_w : V_o$	R, %	$V_w : V_o$	R, %
None	15 : 0.4	97	15 : 0.2	91
Ethanol	15 : 0.5	89	15 : 0.4	84
1-Propanol	15 : 1.4	86	15 : 0.9	76
1-Butanol	15 : 2.0	88	15 : 1.5	86
3-Methyl-1-butanol	15 : 1.5	73	15 : 1.5	67

The following competing processes occur when alcohols are introduced into the aqueous solution: low-molecular-weight alcohols increase an dye solubility in water (hydrotropic effect); alcohols are extracted by the polymer phase; and hydrophilic alcohols are salted-out, with the organic phase containing PEG and alcohol formed.

In the presence of ammonium sulfate, irrespective of the PEG content, the dye recovery is maximal in the absence of alcohols and in the systems with ethanol. Introduction of highly hydrated ethanol decreases the dye recovery from 97 to 89% (c_{PEG} = 1.67 wt %) and from 82 to 57 % (c_{PEG} = 0.67 wt %), i.e., the hydrotropic effect of ethanol is observed. The volume of the equilibrium organic phase, V_o, changes insignificantly. An increase in V_o in the systems PEG-1-propanol and PEG-1-butanol is caused by the different solubilities of alcohols in aqueous-salt solution. The degree of dye recovery and the volume V_o are maximal in the presence of 1-butanol, probably because of the optimal relationship between the competing processes as compared to the extraction in the presence of 1-propanol and 3-methyl-1-butanol.

In the series of the alcohols studied, 3-methyl-1-butanol is the most hydrophobic and hence is recovered by the forming polymer phase to a greater extent, but coordination-active PEG groups are shielded by the alcohol, and, as a result, the degree of dye recovery decreases.

CONCLUSIONS

(1) For virtually complete (97%) recovery of anthocyan dye from aqueous solutions, systems with 1.67 wt % PEG-5000 and 40 wt % ammonium sulfate, pH 1–4, can be used.

(2) The presence of hydrophilic alcohols in the aqueous phase decreases the dye recovery by 10–14%.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Titanium Dioxide Xerogel Modified with Powder Cellulose in Oxidation of Trimethylhydroquinone

Abstract—A procedure was developed for modification of titanium dioxide xerogel by addition of powder cellulose in the stage preceding hydrolysis of tetramethoxytitanium. The resulting catalytic systems based on the new material were studied in a model liquid-phase catalytic process of oxidative dehydrogenation of trimethylhydroquinone with atmospheric oxygen.

DOI: 10.1134/S1070427207120212

Titanium dioxide is widely used as a sorbent and a catalyst support. The efficiency of its application is mainly governed by the structural and texture characteristics, development of the surface, and accessibility of its active centers throughout the entire volume.

Synthesis of xerogels of element oxides by any method is accompanied by their shrinkage and, as a result, by a decrease in the specific surface area on drying. There are several ways to eliminate this phenomenon: variation of the composition of dispersion medium, drying for longer time, and the use of special additives [1–9].

The aim of this study was modify titanium dioxide with powder cellulose (PC) and to study the resulting materials in a model catalytic process of oxidative dehydrogenation of trimethylhydroquinone (TMHQ) with atmospheric oxygen.

EXPERIMENTAL

Powder cellulose was prepared by hydrolysis of kraft cellulose produced at the Baikal Paper and Pulp Plant (Technical Specification OP 13-027 94 88-08–91) in 2.5 N hydrochloric acid at 100°C. Hydrolysis was performed for 2 h. The resulting product was washed with distilled water on a filter until neutral pH of the aqueous extract. The product was dried at 100°C.

Three samples of titanium dioxide xerogels K1, K2, and K3 were prepared as follows: 1.5, 3, and 9 ml of tetrabutoxytitanium (TBT), respectively, was dissolved in 20 ml of methanol. Hydrolysis was performed with 500 ml of water at 20°C. The precipitate was washed on a filter until the absence of butanol in the wash water and dried at 100°C.

To prepare modified xerogels (MXs) with the TiO_2 : PC ratios of 0.45 : 0.55, 0.26 : 0.74, and 0.06 : 0.94, 9-, 3-, and 1.5-ml portions of TBT, respectively, were dissolved in 20 ml of methanol. To each of these solutions, 1 g of PC was added. Hydrolysis was performed at 20°C in 500 ml of water with stirring. The solutions were kept for 10 min and by this time the major fraction of the precipitate settled. The aqueous phase was decanted from the modified TiO_2. The precipitate was treated as described above.

The TiO_2 and TiO_2 : PC gels of compositions 0.31 : 0.69, 0.62 : 0.38, and 0.81 : 019 were prepared from a solution of 9 ml of TBT in 20 ml of methanol. Modification was performed by addition of 2, 1, and 0.5 g of PC, respectively, to the solution. Hydrolysis was performed in 500 ml of water. The precipitate was separated on a filter without preliminary decantation and washed. After completion of washing, the paste was placed in a flask filled with 50 ml of water.

The IR spectra of the samples in the form of solid powders were recorded on a Perkin-Elmer Spectrum One IR Fourier spectrophotometer in the range 4000–370 cm^{-1} using diffuse reflection attachment (DRA). The sorption of 1,4-hydroquinone (HQ) was performed by addition of a solution of HQ in methanol into MX [weight ratio HQ : MX = 1 : (0.25–8)], followed by

drying of the sample at room temperature for 3 days. The bands were assigned on the basis of reference data [10]. The intensities of the spectra were processed using the spectrometer software.

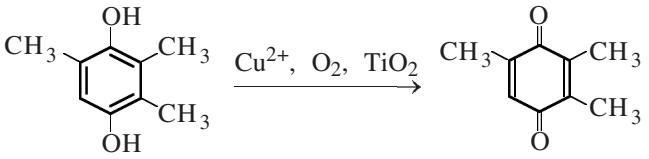
The kinetic experiments were carried out in a temperature-controlled reactor equipped with a reflux condenser, with stirring of the aqueous-methanol solution (volume ratio water : methanol = 1 : 1) by air bubbling. The air flow rate was 3.1 $1\,h^{-1}$.

TMHQ was oxidized at 50 ± 0.2°C. The concentration of the substrate was 66, and that of $CuCl_2 \cdot 2H_2O$, 6 mM.

The kinetic measurements were performed by stopping the reaction and determining the content of the starting substance. The resulting functions of concentrations were subjected to polynomial approximation. The initial reaction rates were found by numerical differentiation and interpolation. The error in their determination was no more than 10%. The TMHQ content was determined by gas-liquid chromatography on a Chrom-4 chromatograph [11].

The resulting cellulose-inorganic materials were studied by IR spectroscopy. The IR spectrum of titanium dioxide xerogel contains a strong absorption band peaked at 340 and 560 cm^{-1}, which can be regarded as a superposition of vibrations of the Ti–O bonds and water librations. In the range 1000–1200 cm^{-1}, there are three extremely weak peaks, which can be assigned to bending modes of the Ti–OH groups (1192, 1168, and 1090 cm^{-1}). For modified samples of TiO_2, there are no changes in the range of vibrations of the Ti–O bonds. Weak peaks corresponding to the Ti–OH groups are not observed on the background of the bands of PC. The IR spectrum of cellulose is mainly determined by absorption of three hydroxy groups incorporated in a glucopyranose unit. In the spectrum of PC there are the following absorption bands: 3348 cm^{-1}, stretching modes of hydroxy groups; in the range 3000–2800 cm^{-1}, stretching modes of methylene and methine groups of cellulose; 1640 cm^{-1}, δ_{HOH}, bending modes of water of crystallization. The band at 1451 cm^{-1} corresponds to δ(OH); 1427, to $\delta(CH_2)$ + δ(CH); 1369, to δ(CH); 1335, to δ(OH) (in-plane); 1315, to $\delta(CH_2)$ (wagging vibrations); 1281, 1248, 1235, and 1203, to δ(OH) + δ(CH) [12]. According to published data [13], the band at 1159 cm^{-1} corresponds to asymmetric stretching modes of the C–O–C bridge; however, in some publications [14] this band is assigned to the C–O stretching or O–H bending modes of the C–OH group. The band at 1054 cm^{-1} is assigned to the stretching modes of the C–O bond in the C^3H–OH group, and the band at 1035 cm^{-1}, to the stretching modes of the primary alcoholic group in various conformations. In the spectrum of PC in the range 860–400 cm^{-1}, there is a broad diffuse absorption on whose background a series of ill-defined bands characterizing various vibrations of the pyranose ring and bending modes of hydroxy groups are observed. The interaction of PC with hydrated titanium dioxide in the modified samples results in variation of the intensities of the absorption bands corresponding to hydroxy groups (the band ν_{as} at 2900 cm^{-1} was used as an internal reference). The most significant increase in the intensity (by a factor of 1.2–2) is observed for the bands at 1159, 1054, and 1035 cm^{-1}. Variations in the spectrum of PC increase with the fraction of the inorganic component in the sample. Thus, variation of the spectral characteristics of PC suggests that its hydroxy groups are involved in interparticle interaction with TiO_2 via hydrogen bonds.

Previously, [15] we have studied the model catalytic liquid-phase oxidation of TMHQ with atmospheric oxygen in the medium of TiO_2 gel:



It has been established by ESR spectroscopy [16] that, depending on the Cu(II)/TiO_2 ratio, several types of Cu(II) compounds are formed in the titanium dioxide phase: mono complexes, associates of mono complexes, copper(II) hydroxide, and polynuclear bridged compounds. The last kind of compounds was the most reactive.

Addition of powder cellulose does not affect the course and parameters of the catalytic process. Apparently, Cu(II) does not react with PC under the reaction conditions.

The dependences of the initial rate of TMHQ oxidation on the Cu(II) content of the MX phase for the samples of various compositions are shown in Fig. 1. The dependences are nonlinear because of the formation of various Cu(II) compounds and also because of limitations imposed by the sorption capacity of xerogel for Cu^{2+} ions. The maximum observed in the dependences is caused by the formation of the most catalytically active Cu(II) species on the surface of titanium dioxide. The number of these compounds increases with the fraction of PC in the sample. The sample of the composition of TiO_2 : PC = 0.06 : 0.94 did not affect the reaction due to the small

amount of TiO_2 in the weighed portion, whose increase hampers stirring of the reaction mixture.

One of the ways to produce gels of element oxides with various specific surface areas is to vary the concentrations of substances being hydrolyzed [17]. However, these distinctions are lost in the course of drying to the xerogel state (Fig. 1, curve *1*). Modification of PC allows us to prevent to a certain extent these undesirable changes.

To elucidate the interactions occurring in the system MX–substrate, we studied the sorption of hydroquinone on MX by IR spectroscopy. The choice of HQ is caused by its resistance to air, minimal overlapping of the spectra of HQ and MX, fairly simple spectrum of HQ, and higher intensity of its bands, allowing detection of HQ in the analytical range of optical densities even at its low content in the system. The absorption bands of the aromatic ring, ν 1515 and 1470 cm^{-1}, are manifested fairly clearly in the IR spectra, and analysis using these bands presents no problems.

The absorption bands of hydroquinone were assigned on the basis of published data [10]. The absorption bands corresponding to the skeleton vibrations of aromatic rings are manifested at 517, 1009, 1470, and 1515 cm^{-1}. The stretching absorption bands of OH groups appear at 3255 cm^{-1}; the absorption bands of C–OH group appear at 1240 (C–O stretching modes) and 1210 cm^{-1} (bending modes).

In the spectrum of HQ sorbed on TiO_2 : PC = 0.45 : 0.55 at the ratio HQ : MX = 1 : 0.5, we observed redistribution of the intensities of the absorption bands corresponding to the skeleton vibrations of the aromatic ring of HQ, ν 1515 and 1470 cm^{-1}. At the ratio HQ : MX = 1 : 1, a shoulder at 1500 cm^{-1} appears in the band at 1514 cm^{-1}; at the ratio HQ : MX = 1 : 4 the band at 1515 cm^{-1} is shifted to 1500 cm^{-1} and the intensity of the band at 1470 cm^{-1} decreases. The apparent variation of the intensities of the bands corresponding to vibrations of the C–C bonds of HQ suggests that the MX surface interacts with the π-electron system of the ring. Analysis of the other bands of HQ is difficult because of super-position of the spectra of HQ and PC.

The spectral changes observed are in good agreement with data on sorption of HQ on previously obtained TiO_2 gels [15]. Based on this fact and also on the insensitivity of the homogeneous catalytic reaction to addition of PC, we can conclude that the sorption-active component in MX is its inorganic component.

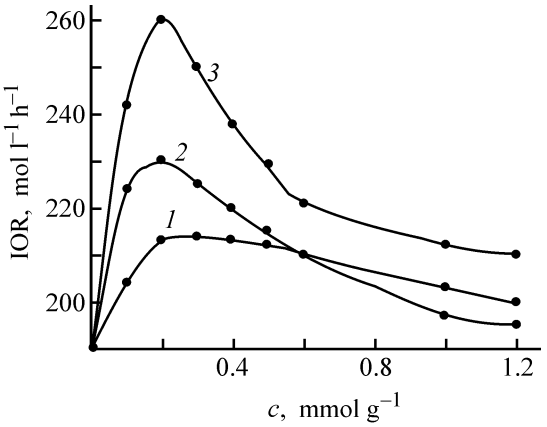


Fig. 1. Initial rate of TMHQ oxidation (IOR) vs. the Cu(II)/MX ratio c in the reaction area. Concentration of Cu(II) 6 mM; the same for Fig. 3. (*1*) K1-K3, (*2*) PC : TiO_2 = 0.35 : 0.45, and (*3*) PC : TiO_2 = 0.74 : 26; the same for Fig. 3.

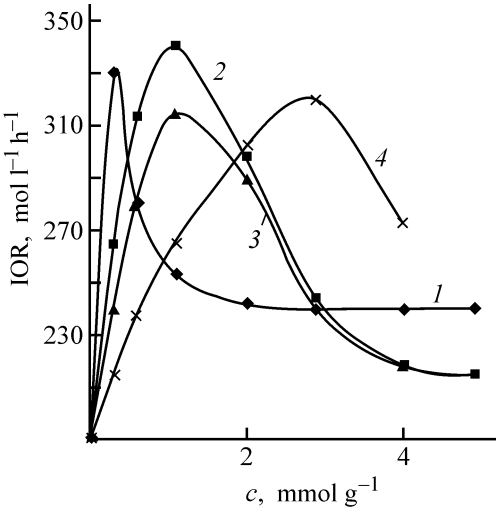

Fig. 2. Initial rate of TMHQ HCO oxidation (IOR) vs. the Cu(II)/TiO_2 ratio c in the reaction area. Gel: (*1*) TiO_2, (*2*) TiO_2 : PC = 0.81 : 0.19, (*3*) TiO_2 : PC = 0.62 : 0.38, and (*4*) TiO_2 : PC = 0.31 : 69.

The kinetic data recalculated to TiO_2 are presented in Fig. 2. For the samples of MX, the maximum of copper activity is shifted to higher Cu(II)/TiO_2 ratios as the PC fraction increases, i.e., the most catalytically active polynuclear Cu(II) compounds in the material phase are formed at a lower amount of TiO_2. This fact is caused by an increase in the specific surface area of titanium dioxide in MX with increasing PC/TBT ratio in the stage of hydrolysis.

To elucidate which stage of xerogel formation is influenced by the modifying additive, it was of interest

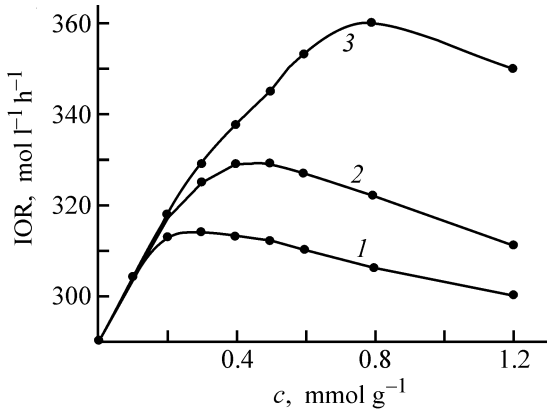

Fig. 3. Initial rate of TMHQ HCO oxidation (IOR) vs. the Cu(II)/TiO_2 ratio c in the reaction area.

to perform the model reaction with the modified TiO_2 gels. The data obtained are presented in Fig. 3.

For the modified gels, the effect similar to that for xerogels is observed, i.e., the maximum of the activity is shifted to higher Cu^{2+}/TiO_2 ratios. Thus, the influence of PC goes beyond the stage of drying, but is manifested even in the stage of gel formation and results in the formation of more sorption-active TiO_2 particles of a smaller size.

CONCLUSIONS

(1) Samples of titanium dioxide xerogels modified with powder cellulose with various ratios of TiO_2 to the modifying additive were prepared.

(2) The activity of Cu(II) in the matrix of modified samples in catalysis of oxidative dehydrogenation of trimethylhydroquinone is higher than that in the process occurring in the presence of unmodified titanium dioxide xerogel.

Abstract—Kinetics of butanol-2 oxidation by hydrogen peroxide on titanium silicalite was studied. The experimental data obtained were used to calculate parameters of the kinetic model suggested.

DOI: 10.1134/S1070427207120224

A priority avenue of the modern technological progress consists in development of efficient, technologically convenient, and ecologically safe processes for synthesis of a number of chemical products and, in particular, methyl ethyl ketone. The most promising method for industrial synthesis of methyl ethyl ketone is liquid-phase heterogeneous-catalytic oxidation of *n*-butane with hydrogen peroxide on titanium silicalite (TS-1) to give butanol-2 and methyl ethyl ketone in the first and second stages, respectively. However, there is no published evidence about the kinetic aspects of the reaction of *n*-butane oxidation by hydrogen peroxide. This communication presents the results of a study of the fundamental kinetic aspects of *n*-butane oxidation by hydrogen peroxide on titanium silicalite TS-1.

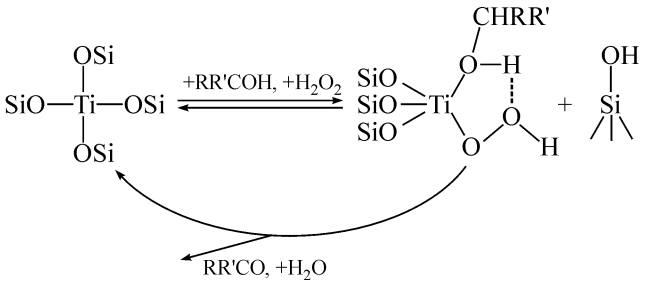
EXPERIMENTAL

The following reagents were used in the study: butanol-2 of pure grade, TU (Technical Specification) 6-09-4620-784, preliminarily distilled and dehydrated; methyl ethyl ketone of pure grade, TU 38.10243–80; hydrogen peroxide of technical grade, GOST (State Standard) 177–88; the catalyst TS-1 was produced using the method described in [1].

The experiments were performed in the temperature range 30–80°C at the following concentrations of the reagents (M): butanol-2 0.1–10, hydrogen peroxide 0.1–0.9, water 3–8, methyl ethyl ketone 0.1–1; the content of TS-1 remained constant (5 wt %) in all the experiments. The reaction of butanol-2 oxidation was performed in a glass reactor equipped with a reflux and thermometer. The reaction mass was agitated with a magnetic stirrer. Required amounts of butanol-2 and TS-1 were charged into the reactor, the magnetic stirrer was switched on, and the reactor was thermostated at a prescribed temperature. The instant at which hydrogen peroxide was charged into the reactor was regarded as the reaction onset time.

The components of the reaction mixture were analyzed by GLC on a Tsvet 500 chromatograph (3 m × 3 mm) glass column; 15 wt % Carbowax supported by Chromaton-N-AW as a sorbent; flame-ionization detector; carrier-gas nitrogen; flow rate of nitrogen through the column, 30 ml min^{-1}). The temperatures of the evaporator and column thermostat were maintained at 150 and 80°C, respectively. Hydrogen peroxide was determined by iodometric titration.

In the opinion of many authors [2, 3], the reaction of alcohol oxidation can proceed via an intermediate having the form of a complex of hydrogen peroxide with active Ti-centers and a molecule of an alcohol. It was shown in [4] that the total energy of the system decreases upon the formation of a five-membered complex involving hydrogen peroxide, active Ti-centers, and an alcohol molecule, and this decrease accounts for the high oxidation rate of alcohols even at a low concentration of titanium silicalite. The mechanism of the oxidation reaction is the following:



Results of the calculation and the statistical parameters of the regression*

Constant	E, J mol^{-1}	log A	R^2	S
k_1	22 660 ± 1699	15.6 ± 1.2		
K_1	13 480 ± 850	2.1 ± 0.2	0.92	0.144
K_2	11 200 ± 300	17.3 ± 1.7		

* R^2, Pearson's multiple correlation coefficient; S, root-mean-square deviation; E, activation heat of the oxidation kinetics; and log A, pre-exponential factor in the kinetic equation.

The oxidation reaction occurs in several stages: (1, 2) adsorption of hydrogen peroxide and butanol-2 on the surface of titanium silicalite to give a five-membered complex, (3) chemical reaction, and (4) desorption of methyl ethyl ketone:

$$\text{S–ROH} + \text{H}_2\text{O}_2 \overset{K_1}{\rightleftharpoons} \text{S–ROH–H}_2\text{O}_2, \quad (1)$$

$$\text{S} + \text{ROH} \rightleftarrows \text{S–ROH}, \quad (2)$$

$$\text{S–ROH} \cdot \text{H}_2\text{O}_2 \xrightarrow{k_1} \text{S–M} + \text{H}_2\text{O}, \quad (3)$$

$$\text{S–M} \overset{K_2}{\rightleftharpoons} \text{S} + \text{M}. \quad (4)$$

The experiments demonstrated that the rate of the oxidation reaction increases with the hydrogen peroxide concentration. This suggests that the surface reaction, rather than the adsorption of hydrogen peroxide, is the rate-determining stage of the process. Methyl ethyl ketone, butanol-2, and hydrogen peroxide can compete for adsorption on active Ti-centers. Because of this circumstance, the adsorption of methyl ethyl ketone can affect the process kinetics.

The kinetic model based on the Langmuir–Hinshelwood model was constructed on the assumption that the chemical reaction is the rate-determining stage of the process and all the adsorption processes are equally important.

On the basis of the assumptions made and the suggested reaction scheme, the kinetic model of the process of butanol-2 oxidation can be represented as

$$r_{\text{MEK}} = \frac{k_1 K_1 c_{\text{H}_2\text{O}_2}}{1 + K_1 c_{\text{H}_2\text{O}_2} + K_2 c_{\text{MEK}}}, \quad (5)$$

where k_1 is the rate constant of the surface reaction (M s^{-1}); K_1, constant of the adsorption equilibrium for hydrogen peroxide (M^{-1}); K_2, constant of the adsorption equilibrium for methyl ethyl ketone (M^{-1}); $c_{\text{H}_2\text{O}_2}$ and c_{MEK}, concentrations of hydrogen peroxide and methyl ethyl ketone, respectively (M).

The effect of temperature on the rate constants of the chemical reaction and adsorption equilibria is described by the Arrhenius and Van't Hoff equations, respectively.

The kinetic equation was integrated by the modified Euler method with a variable integration step, and the constants of the kinetic equation were found by the nonlinear Newton method from the condition of the minimum sum of squared deviations between the calculated and experimentally found concentrations:

$$S = \sum_{m=1}^{L} (c_m^{\text{calc}} - c_m^{\text{exp}})^2,$$

where c_m^{calc} and c_m^{exp} are the calculated and experimentally found concentrations of methyl ethyl ketone (M).

The calculation results and the statistical parameters of the regression equation are listed in the table.

It can be seen in the table that the suggested mechanism is adequately described by the Langmuir–Hinshelwood equation. The multiple correlation coefficient is 0.92, and the root-mean-square deviation $S = 0.144$.

Analysis of the kinetic model obtained shows that the reaction rate increases with the hydrogen peroxide concentration. Because methyl ethyl ketone and hydrogen peroxide compete for adsorption on active Ti-centers, an increase in the concentration of methyl ethyl ketone markedly decelerates the oxidation reaction.

CONCLUSIONS

(1) A kinetic model of butanol-2 oxidation, which can be represented as Eq. (5), was suggested on the basis of the presumed reaction scheme with account of the assumptions made.

(2) The parameters of the kinetic model were calculated using experimental data. It was shown that the butanol-2 oxidation is described by the Langmuir–Hinshelwood model and the reaction proceeds via formation of an intermediate complex of hydrogen peroxide and an active Ti-center, stabilized by butanol-2.

Abstract—Methods for calculating the coefficients of the thermal equation of water vapor sorption by polymeric materials were developed. These methods enable calculation of the equilibrium amounts of sorption in a wide temperature range from the cohesion energy of a polymer.

DOI: 10.1134/S1070427207120236

Under working conditions, polymeric materials are in contact with water vapor (humid air), and drying is the final technological operation for most of them. To calculate the drying, it is necessary to know equilibrium data on the water vapor sorption in a wide temperature range and the sorption heat. "Inert" sorbates are absorbed in accordance with the adsorption laws, i.e., with layer-by-layer coverage of the surface and the bulk polymer properties remaining unchanged. Noninert sorbates are distributed throughout the polymer volume, change the energy of intermolecular interaction, and cause a change in the volume of the system (swelling). Just this process, in which sorbed moisture substantially lowers the glass-forming point [1] and strongly affects the mechanical properties of the polymeric material, was the subject of the present study. These factors predetermine the topicality of a search for new methods for calculating the water vapor sorption in a wide temperature range, which is an important applied problem in physical chemistry of polymers.

The first generalizations of mechanisms of sorption processes in polymers have been made and the formalism of their description has been suggested in fundamental studies by a number of authors [2–4]. The general conclusion made in these studies is that the sorption by polymers should be classed with adsorption phenomena. This has been confirmed by a comprehensive examination of polymer systems with the use of a wide variety of instrumental techniques [5]. The physical meaning of the constants of the classical adsorption equations (BET, Langmuir, Henry) was analyzed, as applied to swelling polymer systems, in [6, 7].

A new approach to analysis of the state of a polymer and a sorbate was suggested in [8], where a structural-mechanical model of water vapor adsorption by polymers was developed. New concepts enabled the authors to explain a number of phenomena in polymeric systems, including the mechanism of sorbate clustering and sorption hysteresis. The physicochemical formalism was used to demonstrate the high efficiency of the equation following from the theory of volume filling of micropores (TVFM) for various polymer–water systems.

It was also shown in [9–11] that the TVFM equation can describe the sorption of various vapors by numerous swelling polymeric materials. However, the shape of the isotherm, the adsorption mechanism [12], and the state of the microporous adsorbent sharply differ from those for swelling polymeric systems [6, 8]. Therefore, the parameter n (rank) of Weibull's equation, which is a basis for the TVFM equation, is 2 or 3 for microporous bodies and $n < 1$ for polymeric systems. For this reason, the equation describing the vapor sorption by polymers is named, for swelling polymeric systems, the equation of the theoretical-probabilistic model (TPM). It is of interest to consider the possibility of an a priori (based on reference data or on a minimum amount of experimental data) evaluation of the coefficients of this equation.

The TVM equation of sorption has the form [9, 10]

$$a = a_0 \exp[-(-\Delta\mu_1/E)^n + \alpha(T - T_0)], \qquad (1)$$

where a is the amount of sorption at a partial vapor pressure P and temperature T; a_0, limiting amount of sorption at a saturated vapor pressure P_0 and tem-

perature T_0; $\Delta\mu_1 = RT \ln P/P_0$, change in the chemical potential of water vapor upon sorption; E, characteristic sorption energy; and α, thermal coefficient of sorption:

$$\alpha = \left(\frac{\partial \ln a}{\partial T}\right)_{\Delta\mu_1}. \quad (2)$$

As a rule, sorption occurs only in amorphous regions of a polymer [13], and, therefore,

$$a_0 = a_0^a(1 - x_c), \quad (3)$$

where a_0^a is the limiting amount of sorption in amorphous regions of the polymer, and x_c is the degree of crystallinity of the polymer.

From Eq. (1) follow relations for calculating the thermodynamic functions [10] of the sorption process: partial molar entropy of the sorbate

$$\Delta\overline{S}_1 = -\left(\frac{\partial\Delta\mu_1}{\partial T}\right) = \frac{\alpha E}{n}\left(\ln\frac{a_0}{a}\right)^{1/n-1}, \quad (4)$$

partial molar enthalpy of the sorbate

$$\Delta H_1 = \Delta\mu_1 + T\Delta\overline{S}_1 = E\left[-\left(\ln\frac{a_0}{a}\right)^{1/n} + \frac{\alpha T}{n}\left(\ln\frac{a_0}{a}\right)^{1/n-1}\right], \quad (5)$$

and integral heat of sorption

$$q_i = \frac{Ea_0}{n}(1 - \alpha T)\Gamma(1/n), \quad (6)$$

where $\Gamma(1/n)$ is the gamma function: $\Gamma = 0.8861$ at $n = 0.7$ and 1 at $n = 0.5$.

These relations make it possible to analyze the sorption mechanism for new polymeric materials and calculate heat fluxes in drying of materials [14]. For this purpose, it is necessary to know the coefficients a_0, n, E, and α. At present, there are no theoretical methods for calculation of these coefficients, and, therefore, the aim of our study was to seek relationships between their values, on the one hand, and structural characteristics of polymeric materials, on the other.

EXPERIMENTAL

Polymeric materials (produced on industrial and semi-industrial installations and washed to remove brightening formulations) in the form of fibers and films served as objects of study. The constants of Eq. (1) were analyzed using sorption isotherms measured by the authors and those reported in [15–17].

Water sorption isotherms were measured on a thermostated McBain–Bakr balance with quartz coil constants of 2–4 mg mm^{-1} and a KM-4 cathetometer with a measurement accuracy of ±0.005 mm. Picein was used as a lubricant for ground joints at high temperatures. The time of equilibration at a given water vapor pressure and temperature of 293–303 K was 4–5 days.

The sorption by hydrophobic and moderately hydrophobic [8] materials was measured using the isopiestic (desiccator) method in which large weighed portions of samples can be used and, consequently, the measurement accuracy can be substantially improved. The partial vapor pressures were created with saturated solutions of salt crystal hydrates [18]. The equilibration time at 298 K was 30–40 days. The McBain–Bakr balance and desiccators were placed in air thermostats with a water jacket, with temperature maintained to within ±0.3°C.

The relaxation state of a polymer determines the value of the parameter (rank) n in Eq. (1). It was shown in [9] that the average value of n can be taken to be 0.7 for glassy polymers and 0.5 for elastomers. The data reported in [8] are in agreement with this value and, consequently, the parameter n is a priori known for the object of study.

The limiting sorption a_0 is an extensive quantity dependent on the number of active sorption centers, and, because only amorphous regions of the polymer are accessible to water molecules [10, 13], there appears a relationship between a_0 and the degree of crystallinity. Having analyzed isotherms of water sorption by a number of polymers with known degrees of crystallinity, Van Krevelen suggested an additive method for calculating the amount of sorption a_0 (g g^{-1}) in amorphous regions of polymers, based on the molecular structure of the polymer unit:

$$a_a = \frac{M_{H_2O}\Sigma a_i}{M_{un}}, \quad (7)$$

where a_i is sorption by ith atom or group of atoms in the polymer chain (mol H_2O/mol units); M_{H_2O} and M_{un} are the molecular masses of water and structural unit of the polymer macromolecule.

Values of a_i were reported in [13] for $T = 298$ K and relative pressures $P/P_0 = 0.3$, 0.5, 0.7, 0.9, and 1.0.

Thus, the van Krevelen method can be used to calculate the isotherm of water sorption by a hypothetical amorphous polymer. The sorption isotherm obtained can be further plotted in the linear coordinates of Eq. (1) at $T = T_0 = 298$ K

$$\ln a_a = \ln a_0^a - \frac{1}{E^n}(-RT \ln P/P_0)^n, \quad (8)$$

with the constants of the equations calculated: a_0^a (portion intercepted by the straight line on the ordinate axis, $\ln a_0^a$) and E (slope of the line is $1/E^n$).

Table 1. Constants of Eq. (1) for water vapor sorption by glassy polymers (n = 0.7)

* ΔE^* calculated for the average elemental composition.

Further, we pass at a known degree of crystallinity to the true sorption isotherm. Experience shows that using the published data [13] or direct determination of a_0^a at $P/P_0 = 1$ occasionally leads to a gross error, because the Schreder effect is observed for a number of polymers (especially those with a linear amorphous structure) in this transition region between the saturated vapor and the liquid phase ($\mu_{vap} = \mu_{liq}$ at $P/P_0 = 1$). In an analysis of a new object, its degree of crystallinity can be estimated if sorption is measured at one or several partial pressures of water vapor, e.g., by the desiccator method, and then the sorption obtained is compared with that calculated by the van Krevelen technique:

$$a/a_a = 1 - x_c. \quad (9)$$

The rather high reliability of this method was demonstrated in the monograph [3] for a number of aliphatic polyamides. The following degrees of crystallinity were obtained for fibers of an aromatic polyamide, Kevlar (polyparaphenyleneterephthalamide), by the van Krevelen method at above-mentioned relative pressures: 66, 62, 63, 73, 74% ($x_{av} = 68 \pm 5\%$). According to published data, the X-ray degree of crystallinity is about 70%.

As can be seen from Eqs. (5) and (6), the characteristic sorption energy E and the thermal coefficient of sorption are energy-related parameters of sorption. For example, at $a/a_0 = 1/e$, the enthalpy of sorption is determined only by these parameters: $\Delta\bar{H}_1 = E(-1 + \alpha T/n)$.

The enthalpy of sorption is proportional to the difference between the energy of bonds between macromolecules, which are ruptured in sorption, and the energy of formation of new polymer–sorbate bonds, with account of the change in the volume of the system ($\Delta H = \Delta U + P\Delta V$). Of these terms, only the first, frequently named the cohesion energy, can be rather easily calculated. It was shown in [20] that the cohesion energy taking into account the molecular packing of macromolecules, ΔE^*, can be calculated as an additive quantity $\Delta E^* = \Sigma\Delta E_i$ on the basis of the chemical structure of the polymer unit and energy contributions of separate atoms (ΔE_a) and types of molecular interactions (ΔE_d, ΔE_h, ΔE_r for the dipole–dipole interaction, hydrogen bond, and energy of the six-membered ring, respectively) to the cohesion energy. Equilibrium sorption data are commonly related to the mass of the polymer, rather than to a mole of polymer units. Therefore, we sought a correlation between α and E, on the one hand, and the specific cohesion energy (J g^{-1}), on the other, calculated from the contributions ΔE_i reported in [20]

$$\Delta E^* = \Sigma\Delta E_i/M_{un}. \quad (10)$$

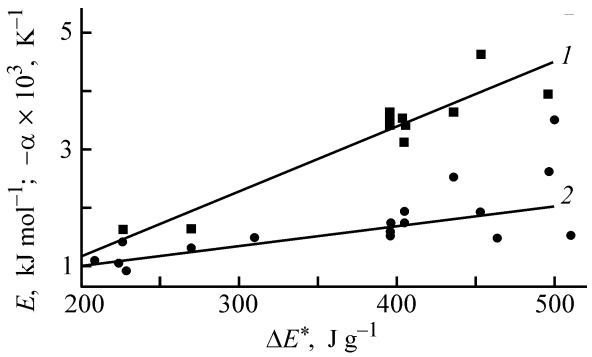

Fig. 1. (*1*) Thermal coefficient of sorption, α, and (*2*) characteristic energy E of water vapor sorption vs. the cohesion energy ΔE^* of glassy polymers.

Table 1 lists values of E and α, calculated from sorption isotherms, and schemes for calculation of ΔE^* on the basis of the molecular structures of units for a number of glassy polymers.

The characteristic sorption energy E is independent of temperature and degree of crystallinity of a polymer [10], but strongly depends on the method used to produce (synthesize) a polymer, drying conditions (i.e., extent to which the structure is not in equilibrium), and other technological factors. Therefore, E may vary rather widely even for the same polymer. For example, E has the following values for cellulose hydrate fibers (kJ mol^{-1}): 2.79 for Siblon, 1.9–2 for rayon cord, and 2.53 for chatelaine. Because of this circumstance, our and published (Table 1) data presented in Fig. 1 show a certain scatter near the linear dependence of the characteristic sorption energy E (J mol^{-1}) on the cohesion energy ΔE^* (J g^{-1}):

$$E = 350 + 3.3\Delta E^* \ (\pm 7.1\%). \quad (11)$$

In most cases, elastomers are low-polar or nonpolar polymers, and, therefore, their interaction with water is accompanied by weak sorption. Table 2 lists certain data on the characteristic sorption energy in relation to the polymer solubility parameter δ, which is proportional to the cohesion energy [13, 20]. No dependence of E on δ is observed in a rather wide range of δ values, and it can be taken, in a rough approximation, that the characteristic sorption energy is independent of the nature of a polymer: $E_{av} = 300 \pm 80$ J mol^{-1}. A similar behavior has been observed previously for sorption of other vapors by elastomers [9]. Probably, this is so because the heats of sorption are small in this case and the decrease in the Gibbs energy is mostly due to an increase in the entropy of sorption ($\Delta S > 0$) and, accordingly, to the rise in the amount of sorption with temperature ($\alpha > 0$). This has been observed in, e.g., sorption of vapors by polyurethanes [21].

Table 2. Characteristic energy of water vapor sorption by elastomers ($n = 0.5$)

Polymer	δ, MPa	E, J mol^{-1}
Spandex	29.9	400
PEM copolymer [15]	26	240
HCPEM copolymer [15]	24	290
Methyl polynorbornene [23]	20.2	440
Butyl polynorbornene [23]	19	230
Hexyl polynorbornene [23]	18.5	150
Decyl polynorbornene [23]	18	330
Copolymer of PA-12 and polytetrahydrofuran [24]	15–16	400–500

The thermal coefficient α characterizes the effect of temperature on the amount of sorption, its sign and magnitude are determined by the energy of interaction of water molecules with the elementary unit of a polymer. For polar polymers, the enthalpy and entropy of sorption $\Delta H < 0$ and $\Delta S < 0$ and, consequently, $\alpha < 0$ in the overwhelming majority of cases [22]. These interactions of water with a macromolecular compound are reflected to the greatest extent by the contributions ΔE_d and ΔE_h (dipole–dipole interactions and energy of the hydrogen bond) to the cohesion energy. The data of Table 1 are generalized in Fig. 1:

$$\alpha = 1.17 \times 10^{-3} - 1.12 \times 10^{-5}\Delta E^* \ (\pm 9.4\%). \quad (12)$$

Here, strong deviations are observed at a sufficiently high degree of linear correlation. Probably, this occurs because the value of α is mostly determined by the contributions ΔH_h and ΔH_d to the cohesion energy, i.e., by the presence of only polar groups in a polymer. For example, for cellulose materials and polyvinyl alcohol (PVA, main contribution from OH groups), the thermal coefficient $\alpha_{av} = -(5.1 \pm 0.3) \times 10^{-3}$ K^{-1}, and for aliphatic, aromatic, and natural polyamides containing OCNH groups, $\alpha = -(3.5 \pm 0.2) \times 10^{-3}$ K^{-1}.

The relations obtained enable calculation of the isotherm of water vapor sorption from a known degree of crystallinity of a polymer sample. Otherwise, it is necessary to measure at least a single point in the sorption isotherm.

Let us demonstrate this for the example of a thermally stabilized PVA fiber in which crystallization begins already in the stage of drying and continues in the course of thermal stabilization ($T = 487$ K).

To find the degree of crystallinity, we measure the amount of sorption at $P/P_0 = 0.7$ and $\alpha = 0.093$ g g^{-1}. Based on the chemical structure of the PVA unit, –CH_2–CHOH– ($M_{un} = 44$), and data of [13], we calculate using Eq. (7) the amount of sorption by amorphous PVA:

$$a_a = \frac{(2 \times 3.3 \times 10^{-5} + 0.75) \times 18}{44} = 0.307 \text{ g g}^{-1}.$$

Then the degree of crystallinity is found from $1 - x_c = 0.093 : 0.307 = 0.30$ to be $x_c = 0.70$.

Using Eqs. (10), (11), and (12), we calculate, respectively, the cohesion energy, characteristic sorption energy, and thermal coefficient of sorption:

$$\Delta E^* = \frac{2\Delta E_C + 4\Delta E_H + \Delta E_O + \Delta E_h}{M_{un}}$$

$$= \frac{2 \times 2305 + 4 \times 200 + 597 + 16\,447}{44} = 510 \text{ J g}^{-1},$$

$$E = 350 + 3.3\Delta E^* = 2030 \text{ J mol}^{-1},$$

$$\alpha = 1.1 \times 10^{-3} - 1.12 \times 10^{-5} \times 510 = -4.6 \times 10^{-3} \text{ K}^{-1}.$$

Using Eq. (1) with $T = T_0 = 298$ K, $a = 0.093$ g g^{-1}, and $P/P_0 = 0.7$, we calculate a_0:

$$\ln a_0 = \ln a + \left(-\frac{8.314 \times 298 \ln 0.7}{2030}\right)^{0.7} = -1.82,$$

$$a_0 = 0.163 \text{ g g}^{-1}.$$

Thus, we found all the constants of Eq. (1), i.e., we know the thermal equation of sorption

$$a = 0.163\exp\left[-\left(\frac{RT \ln P/P_0}{2030}\right)^{0.7} - 4.6 \times 10^{-3}(T - T_0)\right]. \quad (13)$$

Figure 2 shows experimental data on water vapor sorption by a thermally stabilized PVA fiber at 293 and 375 K (temperature close to that in drying) and results of calculations by Eq. (13). The information obtained makes it possible to calculate the integral heat of sorption by Eq. (6), e.g., at a drying temperature of 373 K:

$$q_i = \frac{2030 \times 0.163}{0.7 \times 18}(1 + 4.6 \times 10^{-3} \times 373) \times 0.8861$$

$$= 63.2 \text{ J g}^{-1}.$$

CONCLUSIONS

(1) It was shown that the thermal equation of sorption [Eq. (1)] can be used to calculate the amounts of water vapor sorption by polymeric materials in a wide temperature range.

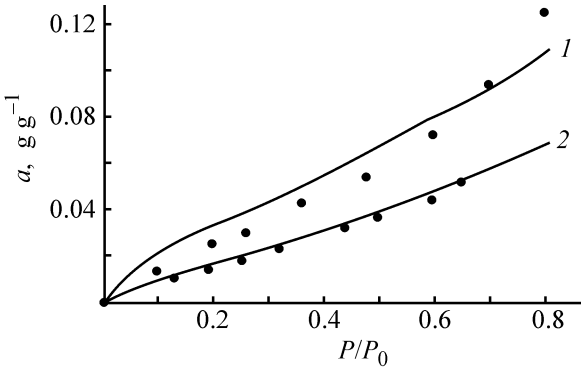

Fig. 2. Isotherms of water sorption a by thermally stabilized polyvinyl alcohol fiber at temperatures of (*1*) 293 and (*2*) 395 K.

(2) Equations relating the characteristic sorption energy and thermal coefficient of sorption to the cohesion energy of a polymer were obtained.

(3) An example calculation of the isotherms of water vapor sorption and heat of sorption was performed on the basis of the molecular structure of the polymer unit.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermal Transformations of a Polymeric Composite Consisting of Poly(Methyl Methacrylate) and Phosphorus-containing Nanodispersed Aluminum Oxide

Abstract—Thermal-oxidative properties of polymeric composites based on poly(methyl methacrylate), containing surface-modified nanosized aluminum oxide as filler, were examined. The possibility of chemical grafting to the Al_2O_3 surface of phosphorus-containing groups to decrease the combustibility of filled polymeric composites was examined by IR spectroscopy.

DOI: 10.1134/S1070427207120248

Inorganic fillers are widely used to improve the performance characteristics of polymeric composite materials [1]; they bring about a wide spectrum of interactions at the polymer–filler interface, thereby substantially affecting the mechanical and physicochemical, in particular, thermal-oxidative, properties of filled polymer system as a whole. The nature of these interactions is governed to a significant extent by the chemical composition of the filler surface [2].

Since recently, the focus of the special attention of researchers has been on highly dispersed (nanosized) fillers. They have a large specific surface area and exhibit enhanced reactivity toward polymer matrix, thereby promoting formation of chemical bonds limiting the mobility of various kinetic units of the polymer. Introduction of highly disperse fillers can change the packing density of the polymer chains, as well as the conformation and orientation of the segments occurring at the polymer–filler interface [3, 4].

Of special interest is chemical modification of fillers, considerably expanding the spectrum of their functions in composite materials. Directed modification of the filler surface aimed to produce groups capable of forming strong chemical bonds with macromolecules or increasing the resistance of polymers to thermal and thermal-oxidative degradation appreciably enhances the stability of filled composite materials [2, 5]. However, various chemical techniques applied to this end should not substantially affect the particle size of highly dispersed fillers and cause agglomeration of nanosize particles.

Among the promising ways of chemical modification of solid surfaces is molecular layer deposition (MLD) [6, 7]. With MLD method, the entire surface being activated is uniformly coated with the additives introduced, which form strong chemical bonds with the surface; the composition can be precisely set at the molecular level, and multicomponent structures with prescribed ratio and mutual position of elements can be formed.

We examined here the thermochemical transformations of a polymeric composite material based on poly(methyl methacrylate) (PMMA), filled with nanodispersed aluminum oxide and products of its surface modification with phosphorus-containing groups by the MLD method.

EXPERIMENTAL

As filler for PMMA served Aeroxide AluC (Degussa) nanodispersed aluminum oxide. Its specific surface area estimated from low-temperature nitrogen adsorption on a SORBI® N.4.1 instrument was 100 ± 3 $m^2 g^{-1}$; the average particle size was 13 nm. Samples of the composite materials were prepared by mixing crushed granules of Altuglas V 825T PMMA

Chemical composition and specific surface area of the fillers

Number of cycles of treatment with PCl_3 and H_2O vapors	Sample	Phosphorus content, mmol g^{-1}	Specific surface area, $m^2\ g^{-1}$
0	Al_2O_3	0	100
1	Al_2O_3-P	0.37	98
2	Al_2O_3-PP	0.55	100

with the initial or modified nanodispersed aluminum oxide on a Haake PolyLab installation at 225°C. The degree of filling for all the composites was 5%, and the mixing time, 10 min.

The filler surface was modified by the MLD method on a flow-type setup, comprised of a system for drying the carrier gas (air), reservoirs containing low-molecular-weight agents, an indirect heating glass reactor, and a system of adsorbers for sorption of gaseous reaction products [5]. As the low-molecular-weight agent served phosphorus trichloride PCl_3 (phosphorus compounds rank among the best flame retardants) [8]. The element oxide groups on the aluminum oxide surface were synthesized at 200 ± 10°C; the dew point of the carrier gas was not higher than –50°C. The chemical reaction occurring on the filler surface can be represented by the following scheme [7]:

$$n(\text{–AlOH}) + PCl_3 \rightarrow (\text{–Al–O–})_nPCl_{3-n} + n\text{HCl}. \quad (1)$$

To replace the chloride ions with OH groups in the composition of the surface structures of aluminum oxide, its surface was treated with water vapor:

$$(\text{–Al–O–})_nPCl_{3-n} + (3 - n)H_2O \rightarrow (\text{–Al–O–})_nP(OH)_{3-n} + (3 - n)\text{HCl}. \quad (2)$$

The phosphorus concentration was raised by repeated alternate treatment of aluminum oxide with

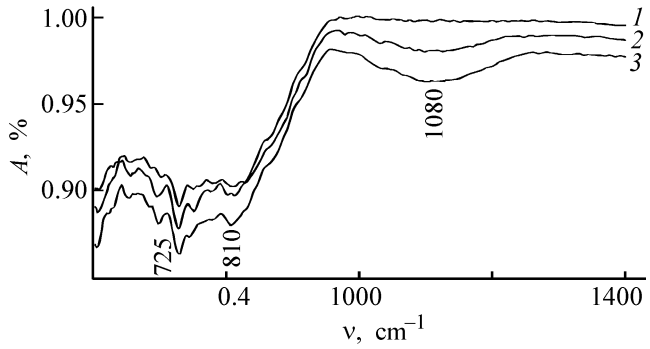

Fig. 1. IR Fourier spectra of the initial and modified aluminum oxide. (*A*) Absorption, and (ν) wavenumber; the same for Fig. 5. (*1*) Al_2O_3, (*2*) Al_2O_3-P, and (*3*) Al_2O_3-PP; the same for Fig. 5.

PCl_3 and water vapor. The flame retardant content of the filler was estimated by chemical analysis according to the known photocolorimetric procedure [9], accurately to less than 10%.

The thermal-oxidative properties of the resulting composite materials were determined by thermogravimetric analysis on a TGA 92 16.18 SETARAM installation in air under dynamic conditions at a constant heating rate of 5 deg min^{-1} and temperatures within 30–700°C. The weighed portion was 10–20 mg. The initial PMMA and PMMA-based composites were tested for combustibility by the cone calorimeter method [10]: samples (100 × 100 × 4-mm plates) were kept under constant external thermal flux of 35 kW m^{-2} and temperature near 650°C. This method allows determination of the maximal heat release Q_{max} and total heat release Q_{tot} for a polymeric material in combustion.

The IR spectra of the initial and phosphorus-containing samples of aluminum oxide, and also of the coke residues for the filled polymer composites after keeping at 650°C, were recorded on a Bruker IFS66 IR Fourier spectrometer equipped with a "golden gate" attachment at 400–4000 cm^{-1} with a resolution of 1 cm^{-1} [11].

To obtain filled polymer composites, we prepared samples of nanodispersed aluminum oxide by treatment with phosphorus chloride and water vapor in one and two cycles. The table lists the chemical compositions and specific surface areas of the initial and modified fillers.

The data in the table show that, as the number of the treatment cycles increases, the phosphorus concentration in the samples grows by nearly a factor of 1.5. It should be noted that synthesis of the phosphorus-containing structures by the MLD method on the Al_2O_3 surface does not substantially raise the size of the nanoparticles, as suggested by the close specific surface areas of the initial and modified samples (see table).

Figure 1 shows the IR Fourier spectra of the initial and modified Al_2O_3. The spectrum of the initial

filler contains absorption bands at 725 and 810 cm^{-1} corresponding to stretching vibrations of the Al–O bond (Fig. 1, curve *1*) [12]. Treatment of nanodispersed aluminum oxide with PCl_3 vapor gives rise a broad absorption band near 1080 cm^{-1}, associated, according to [12], with stretching vibrations of the P–O bond in aluminum phosphate, which suggests that element oxide groups are chemically grafted to the surface [scheme (1)]. This peak grows in intensity with as the modifier concentration increases (Fig. 1, curves *2*, *3*).

Thermogravimetric measurements showed that thermal-oxidative degradation of PMMA proceeds in two stages within the 250–340 and 340–425°C ranges (Fig. 2, curve *1*). Introduction of both the initial and modified fillers does not affect the two-stage character of the degradation of the polymeric composite. Figure 3 shows the temperature dependences of the mass loss for the initial and filled PMMA samples. The heat resistance of the polymer slightly increases upon introduction of aluminum oxide into the composition. The temperature corresponding to a 50% mass loss shifts by 20°C to higher temperatures relative to the initial material (Fig. 3, curve *2*). Also, the temperature corresponding to the maximal degradation rate in both stages increases by 10–20°C (Fig. 2, curve *2*). These changes are, evidently, due to adsorption and chemisorption interactions of the nanodispersed aluminum oxide surface with the polymer molecules, resulting in structure formation in the filled system [2]. The heat resistance of the polymer composite is virtually unaffected by synthesis of phosphorus-containing structures on the filler surface; it corresponds to that of the polymer with nanodispersed aluminum oxide. A probable reason is that the phosphorus concentration in the filled composites is very low, specifically, 0.05 and 0.09%, depending on the number of the cycles of treatment of aluminum oxide with PCl_3 vapor (Fig. 3, curves *3*, *4*).

The influence of chemical modification of the aluminum oxide surface with PCl_3 vapor is manifested most clearly in evaluation of the combustibility of the resulting composite materials. Figure 4 shows the time dependences of the heat release for the samples of the composites. The maximal heat release is 550 kW m^{-2} (Fig. 4, curve *1*). Upon introduction of unmodified oxide and a filler with the phosphorus concentration of 0.37 mmol g^{-1}, this combustibility parameter decreases to 500 kW m^{-2} (Fig. 4, curves *2*, *3*).

The combustibility of the composite tends to further decrease with increasing concentration of the flame retardant in aluminum oxide; the maximal heat release decreases by a factor of 1.35 (Fig. 4, curve *4*), compared to unfilled PMMA. Also, the total heat release, as estimated from the area enclosed by the curves in Fig. 4, significantly decreases, specifically, from 199.8 (initial polymer) to 96.4 MW m^{-2} upon introduction of aluminum oxide with the phosphorus concentration of 0.55 mmol g^{-1}.

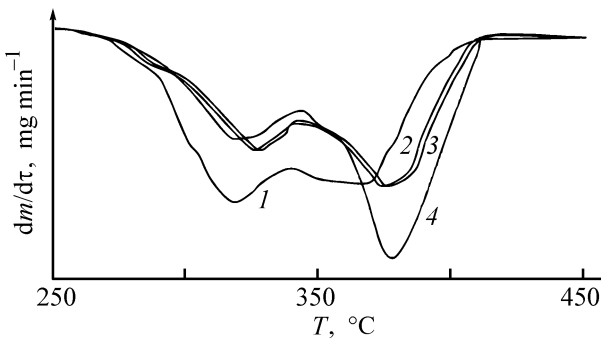

Fig. 2. DTG curves of the initial and filled PMMA samples. (d*m*/dτ) Mass change rate and (*T*) temperature. (*1*) Initial PMMA, (*2*) PMMA + Al_2O_3, (*3*) PMMA + Al_2O_3-P, and (*4*) PMMA + Al_2O_3-PP; the same for Figs. 3, 4.

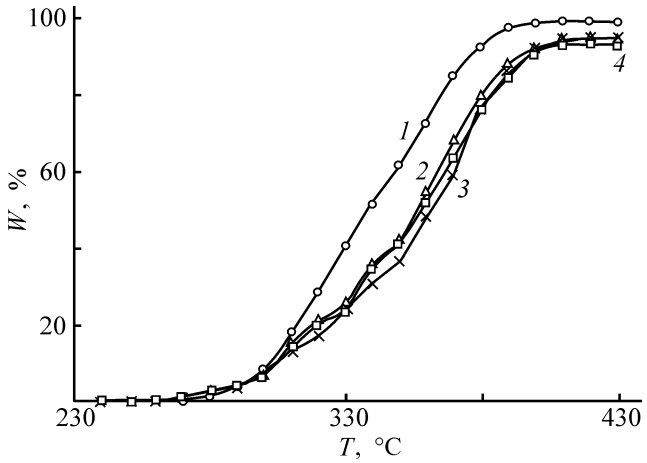

Fig. 3. Variation of the mass loss *W* of the initial and filled PMMA samples with temperature.

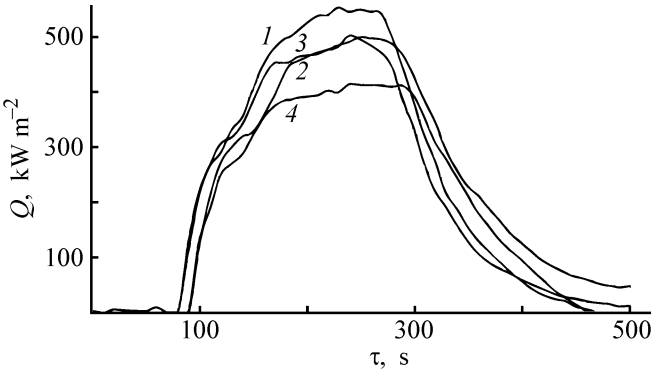

Fig. 4. Heat release *Q* for the composites based on PMMA and aluminum oxide. (τ) time.

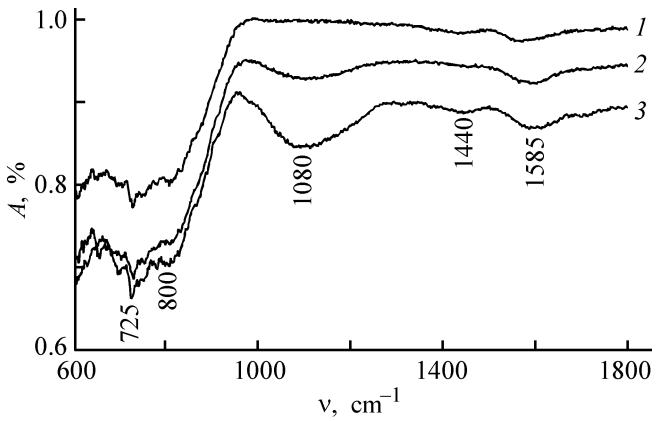

Fig. 5. IR Fourier spectra of the coke residues of the filled composites.

A decrease in the combustibility of the filled samples of the polymer material can be explained as follows. Degradation of PMMA starts with cleavage of weak bonds in the oxygen-containing functional groups. This is followed by cleavage of the bonds in the polymer backbone, accompanied by elimination of low-molecular-weight volatile products. The polymer degrades virtually exhaustively and yields a minor amount of a nonvolatile residue (coke) [2]. Introduction of aluminum oxide into the composite can promote adsorption of the PMMA degradation products on the nanodispersed filler surface [13], which is specifically responsible for a decrease in the heat release parameters in combustion of the composite. According to [8], the inhibiting effect of phosphorus compounds is manifested primarily in the condensed phase and is associated with their catalytic action on the coke formation in polymer materials. The presence of a flame retardant in the filled PMMA, evidently, exerts an additional influence on degradation of the polymer, due to involvement of the volatile pyrolysis products into structure formation in the nonvolatile residue. Stable organophosphorus compounds can be formed [14], which are involved in the coke formation, thereby decreasing further the combustibility of PMMA.

The above assumptions were confirmed by the results of an IR study of the coke residues from the filled samples. The mass loss of the initial PMMA at 650°C was close to 100%. The IR spectrum of the solid phase of the composite containing aluminum oxide contains absorption bands at 725 and 800 cm^{-1}, associated with stretching vibrations of the Al–O bond (Fig. 5). The phosphorus-containing structures in the coke residue are characterized by a band near 1080 cm^{-1}, associated with the stretching vibrations of the P–O bond (Fig. 5, curves *2*, *3*). The appearance of an absorption band at 1585 cm^{-1} and, upon increase in the phosphorus content, of a band near 1440 cm^{-1} (Fig. 5, curve *3*) can be associated with the presence [15] of heat-resistant aromatic compounds involved in formation of the solid phase.

Thermogravimetric data obtained upon heating of the residues formed in calorimetric tests to 1000°C agree with the IR data. The mass loss for the PMMA filled with aluminum oxide was 7.4%. In the presence of the flame retardant, the mass loss increases upon high-temperature treatment, specifically to 9.4 and 14.2% for one and two cycles of treatment of the filler with PCl_3 and H_2O vapors, respectively (see table). Thus, upon introduction of nanodispersed aluminum oxide into a PMMA-based composite, the organic component increases in size, and the phosphorus-containing groups make an additional contribution to the formation of a solid residue owing to heat-resistant aromatic fragments yielded by heat treatment.

CONCLUSIONS

(1) The combustibility and heat resistance of polymer composites can be controlled by chemical modification of the filler surface, as demonstrated for poly(methyl methacrylate)–nanodispersed aluminum oxide system as an example.

(2) Chemical grafting of phosphorus-containing groups to the aluminum oxide surface causes the total heat release of the filled poly(methyl methacrylate) samples to decrease by a factor of 1.5–2.0, depending on the content of the flame retardant in the composite.

(3) Phosphorus-containing structures, presumably, affect the degradation of poly(methyl methacrylate) in combustion; they are involved in the structure formation and coke formation in filled composite materials, as demonstrated by IR studies and combustibility tests.

Abstract—Low-temperature carbonization of polyacrylonitrile was studied in relation to the synthesis procedure, heat treatment conditions, and presence of natural polymers as cocarbonization participants.

DOI: 10.1134/S107042720712025X

Carbonization of polyacrylonitrile (PAN) and specific features of thermochemical transformations of this unique polymer have been the subject of numerous studies summarized in monographs and reviews [1–6]. Certain attention was given in these studies to elucidation of the mechanism of PAN transformation into carbon structures in a wide temperature range. However, the mechanism of this transformation and of its particular steps has not been analyzed in detail. Data on simulation (theoretical and experimental) of thermochemical reactions of PAN on the fundamental level, and not under the specific conditions dictated by practical requirements (feasibility, cost efficiency, environmental safety), are virtually lacking.

The majority of studies have been performed with poorly characterized commercial PAN samples. In this study, we examined thermochemical transformations occurring in the range 20–600°C in various PAN samples prepared in a laboratory.

EXPERIMENTAL

Three types of PAN were examined. The first of these was PAN prepared by anionic polymerization (A-PAN) in the presence of butyllithium by the procedure described in [7]; this polymer has a high molecular weight (MW) and narrow molecular-weight distribution (MWD), it does not contain low-molecular-weight fractions and branchings and has an increased stereoblock structure parameter [8], because it is most similar to the ideal polymer in the molecular structure. The second was PAN prepared by radical polymerization in the presence of a widely used catalytic redox system (R-PAN) [9]; in contrast to A-PAN, R-PAN samples are characterized by high polydispersity, presence of branchings in polymer chains, noticeable content of low-molecular-weight fractions, and presence of oxygen-containing terminal groups. The third was A-PAN partially cyclized in the course of the synthesis (C-PAN). We also used a series of PAN-containing composite systems with addition of 75% chitin, chitosan, cyanoethyl cellulose, allyloxyethyl cellulose, and kraft cellulose.

Let us consider the results of a calorimetric analysis of a series of PAN samples differing in the procedure of polymer synthesis (Fig. 1). The analysis revealed thermophysical processes occurring in the range 400–600°C. A simultaneous TGA of the same samples showed no sharp changes in the weight loss rate. The thermograms of all the three PAN samples demonstrate exo- and endothermic effects. As judged from the peak shape, they reflect melting and crystallization processes. Comparison of the peak temperatures, peak areas, and order in which thermal effects appear shows that the thermal effects are the most pronounced in A-PAN and the least pronounced in R-PAN. This difference is apparently associated with the molecular-weight characteristics of the objects. It is known that thermal cyclization of R-PAN involves release of low-molecular-weight products of thermal degradation [10]. This is associated with a broad MWD and with branchings in R-PAN chains. Therefore, the density of macromolecular packing in R-PAN precipitated from solution is low, and samples undergo more intense oxidation, which is reflected in the temperature and area of the exothermic peak. In contrast to R-PAN, A-PAN samples have a narrow MWD, with no low-molecular-weight fractions and branchings, which, combined with the stereoblock structure, predetermines

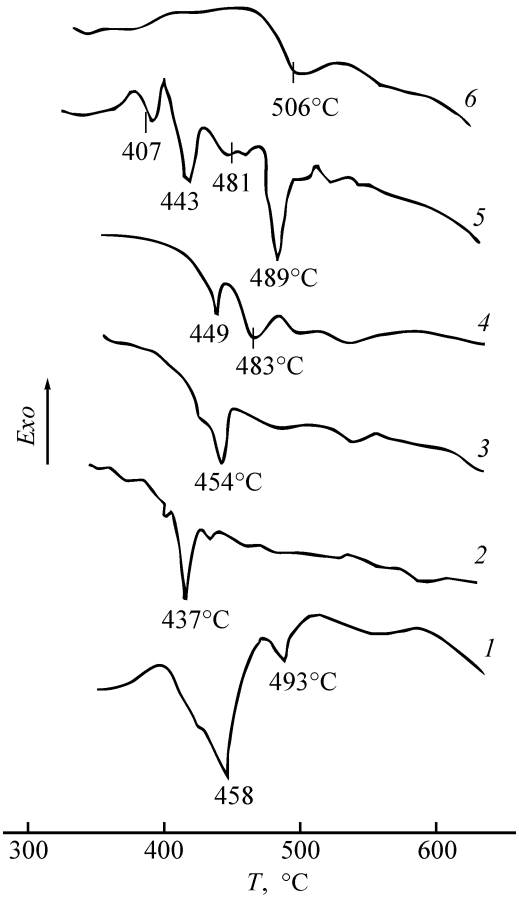

Fig. 2. DTA curves of powdered A-PAN samples annealed in nitrogen at (*2*) 250, (*3*) 270, (*4*, *5*) 350, and (*6*) 400°C for (*2–4*, *6*) 4 and (*5*) 10 h; (*1*) unannealed sample. (T) Temperature; the same for Figs. 3 and 4.

the high density of A-PAN and the corresponding changes in the characteristics of its thermal effects. An additional factor determining the high packing density is the steric ordering of A-PAN macromolecules.

In solution, A-PAN macromolecules form a double-helix structure whose constituent chains are linked by weak bonds between cyano groups and α-H atoms, between cyano groups, and, occasionally, between naphthyridine rings [4, 5, 11]. These structural features of A-PAN result in the preferable cyclization, compared to thermal degradation, and this is reflected in the TG and DTA curves. Furthermore, the stereoblock structure of A-PAN is apparently responsible for the presence of two endothermic effects in the temperature range 400–600°C, each of which reflects melting of an *iso*- or *syndio*tactic block. Ordered blocks may also be present in R-PAN, but their size and relative content are considerably lower than in A-PAN. As for the DTA curve of the C-PAN sample, the shift of the temperatures of its two endothermic effects (491 and 514°C) reflects the increased heat resistance of cyclic stereoblocks formed in the course of the synthesis.

When considering the pattern of low-temperature carbonization of PAN, we should note that, to obtain new condensed structures by transformation of macromolecular compounds, one should take into account the "diffusion factor." This phenomenon, typical of coal fuel chemistry, is associated with control over the release of low-molecular-weight thermal degradation products from the area of thermochemical reactions. As a result, the balance between the degradation and cross-linking is shifted toward cross-linking. The simplest way to reduce the release of low-molecular-weight products is to raise the sample weight and density and to perform an isothermal heat treatment for a longer time. By so doing, it will be possible to follow more clearly the thermophysical phase transformations in the PAN samples.

Figure 2 shows the DTA curves of A-PAN samples annealed in nitrogen at temperatures of the max-

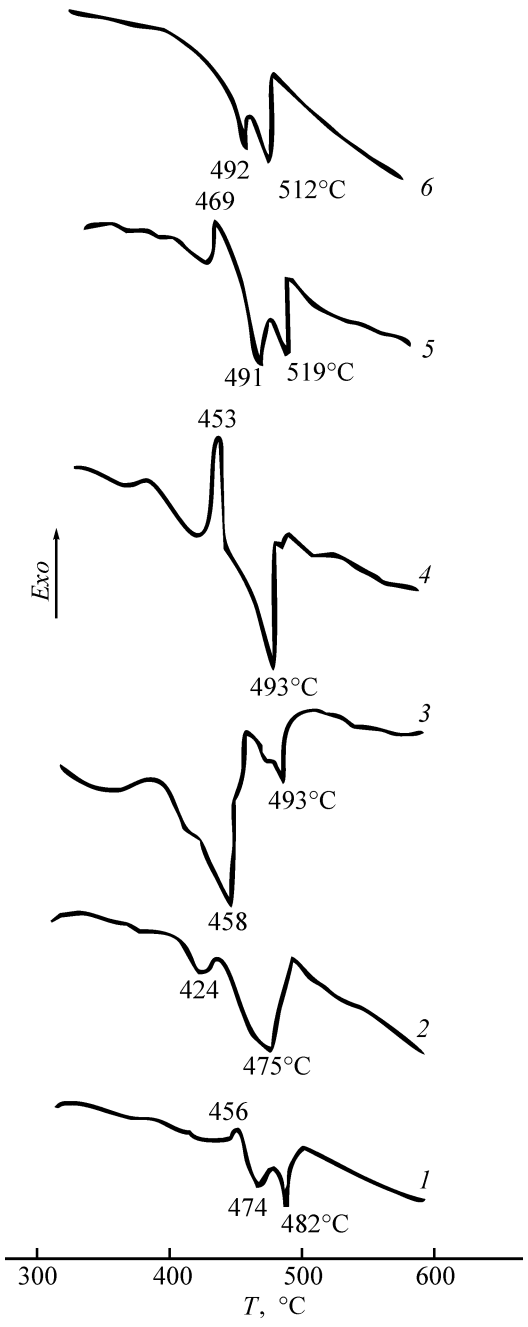

Fig. 3. DTA curves of powdered PAN samples compacted in a closed crucible: (*2*) R-PAN, (*4*) A-PAN, and (*6*) C-PAN; (*1*, *3*, *5*) the same samples in open crucibles.

imal thermal activity of PAN (250–400°C), when the linear structure of PAN transforms into a cyclic structure. As for the thermal effects related to phase transitions and assignable to crystallization and melting of new structural modifications, the clearest pattern is observed on heating an A-PAN sample for 10 h at 350°C. At this temperature, the exothermic process of A-PAN cyclization to give the most oriented stereoblocks of the syndiotactic structure is complete [8]. Because this process is characterized by the lowest activation energy, compared to the corresponding processes in isotactic A-PAN and R-PAN, prolonged heating at 350°C results in the gradual formation of segments of the turbostratic structure, which melt at 407, 443, and 489°C and are characterized by different steric orientations of cyclic blocks formed in the polymer. At lower annealing temperatures, the formation of the block structure is incomplete, and at higher temperatures, degradation of strained cyclic blocks starts, with an increase in the degree of carbonization.

The effect of the diffusion factor is demonstrated in Fig. 3. It is seen that, irrespective of the procedure of PAN synthesis, compaction of the sample and its isolation from the oxidizing medium essentially change the pattern of thermophysical effects in the samples. For some of them, we observe not only an increase in the energy of endothermic effects related to ordered areas, but also appearance of exothermic effects (curves *4*, *5*) assignable to the crystallization of the labile structure of the precarbonizate. Note that, with compaction of the sample, the coke residue increases as compared to powder samples of small weight.

It is interesting to use the phenomena of fractal orientation of PAN macromolecules, discovered when fractal-matrix structurizers (FMS) produced by Airis company were used [12]. In that study, we demonstrated for the examples of A- and R-PAN samples in solution that, on prolonged keeping of R-PAN solutions in the presence of FMS, solutions become more heterogeneous but remain isotropic. Under the same conditions, A-PAN solutions undergo self-orientation with a change in the structural parameters. On prolonged interaction with FMS, anisotropic structures are formed. This phenomenon allows control over the structural orientation of A-PAN and thus enables simulation of the precursors of turbostratic structures before the onset of carbonization.

Proceeding with these studies, we performed experiments in which the time of the action of FMS on the similar solutions of R- and A-PAN was made more than ten times longer. An analysis of the viscous characteristics of the polymer solutions stored for 4 and 10 months, in combination with two methods of polymer isolation (precipitation and solvent evaporation), showed that the fractional separation of the low-molecular-weight fraction occurs in the R-PAN solution, whereas in A-PAN this fraction is not detected. Furthermore, the viscosity of R-PAN solution decreased in the course of keeping with the structurizer

by almost a factor of 3 (without FMS, by a factor of 1.7). Under the same conditions, the A-PAN solution showed no response to the presence of FMS. Thus, longer keeping of PAN solutions both with FMS and without it allows the polydispersity and degree of branching of R-PAN to be decreased. This phenomenon positively affects the mechanical characteristics of films cast from R-PAN solutions. By raising their elasticity, tensile strength, and Young's modulus. As for A-PAN films, their strength and elasticity somewhat decrease because of the increased heterogeneity of the system and of its tendency toward self-organization, which leads to gelation and negatively affects the mechanical properties of the films.

The effect of FMS treatment on the subsequent carbonization of A-PAN cannot be revealed unambiguously. On the one hand, the more pronounced heterogeneity of the structure allows better separation of the thermal effects related to fragments of the A-PAN macromolecule with different stereoblock structures because of the increased mobility of segments with atactic units. On the other hand, there is no direct evidence that the structural organization of these samples remains unchanged after the removal of the solvent.

One more indirect evidence that a structural rearrangement occurs in PAN in the temperature range 400–600°C to give ordered fragments of the turbostratic type is furnished by interpretation of the structural polymorphism of coals in the same temperature interval. According to an X-ray diffraction analysis [13–15], the maximum of the internetwork ordering is observed at 450–525°C, i.e., in the range of the plastic state of coals and formation of a semicoke. As the temperature is raised to 700°C, the mutual ordering of networks that formed carbon structures is distorted, they are disoriented, and then, at temperatures above 1000°C, repeated orientation on the level of graphitizing structures is observed. A decrease in the internetwork ordering at temperatures above 700°C is due to the "wedging" effect of the growing carbon networks, with preservation of strong valence bonds between them through the irregular part of the structure preventing mutual orientation of the networks [16]. Thus, even in such a complex system as coking coals, there is a temperature interval of increased molecular mobility, in which ordered carbon structures with clear orientation parameters are formed. The coincidence of this temperature interval with that of the endo- and exothermic thermophysical effects observed in our case allows us to draw a certain analogy between these processes.

The above-noted similarity in the low-temperature carbonization of PAN and formation of a semicoke

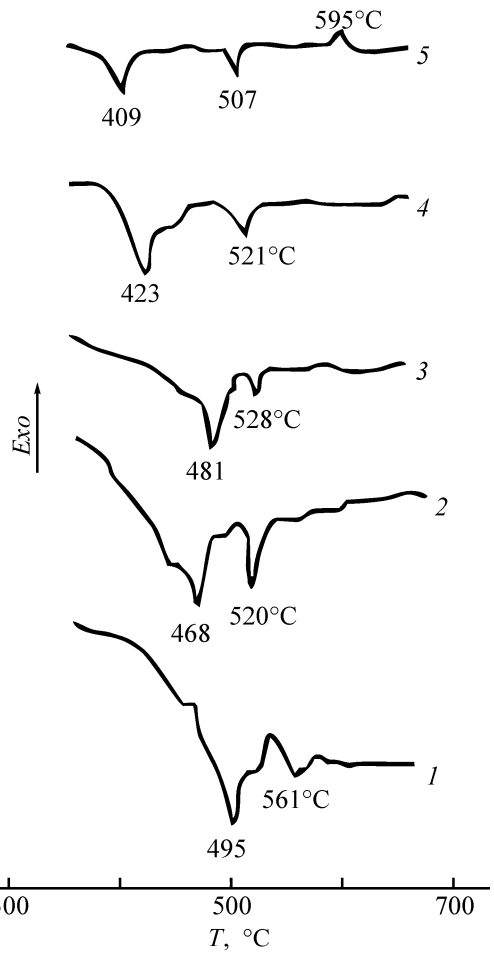

Fig. 4. DTA curves of composite samples of R-PAN with additions of polymers (75 wt %): (*1*) chitosan, (*2*) chitin, (*3*) cyanoethyl cellulose, (*4*) allyloxyethyl cellulose, and (*5*) kraft cellulose.

in the interval of the plastic state of coals confirms the concept of polymer cocarbonization [17], according to which the process occurs as thermochemical reactions of two polymers to give carbon structures whose thermophysical characteristics differ from those produced by the polymers taken separately. Indeed, our experiments revealed the formation of new structures with specific thermal characteristics in the temperature range 400–600°C. Figure 4 shows as an example the DTA curves of PAN cocarbonizates with a series of natural compounds. It is seen that introduction into PAN of 75 wt % of a second polymer (chitin, chitosan, cyanoethyl cellulose, allyloxyethyl cellulose, kraft cellulose, etc. [18–20]) does not decrease the thermal effects of structural organization in this temperature range. This fact confirms the significant influence exerted by the chemical nature of the second component on the formation of the base

structure of oriented carbon products. The role of PAN consists in the formation of nitrogen-containing polyheterocycles favorable for carbonization of the composites and their transformation into carbon structures at lower temperatures, compared to carbon-chain polymers.

CONCLUSIONS

(1) It was shown that polyacrylonitrile prepared by anionic polymerization is the most suitable compound for studies of low-temperature carbonization.

(2) The role of isothermal heat treatment and diffusion factor in the formation of oriented carbonized structures of polyacrylonitrile was elucidated.

(3) The optimal conditions were determined for thermal reactions of polyacrylonitrile with a series of natural polymers with the aim to obtain ordered cocarbonizates.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Enzymatic Polymerization of Vinyl Monomers

N. A. Nesterova, I. I. Gavrilova, and E. F. Panarin

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 5, 2007

Abstract—The possibility of using horse radish peroxidase as a catalyst for polymerization of monomers (vinylformamide and sodium vinylsulfonate) in the presence of hydrogen peroxide and 2,4-pentanedione in aqueous medium at room temperature was studied.

DOI: 10.1134/S1070427207120261

The use of horse radish peroxidase (HRP) and other oxidases for catalysis of radical polymerization of vinyl monomers was first reported in [1]. Horse radish peroxidase is recovered from horse radish roots. It belongs to the group of isoenzymes with the molecular weight of $(38-42) \times 10^3$ and the isoelectric point of 7.2; it is stable in the pH range 4.5–12. Peroxidase consists of colorless glycoprotein and brown-red ferriporphyrin bound to it [2]. Peroxidase catalyzes oxidation of chemical compounds with oxygen of hydrogen peroxide via a series of intermediate complexes [3]:

$$\text{–Fe(III)–} \rightarrow (H_2O_2 \rightarrow H_2O) \rightarrow \text{–Fe(O)(IV)}^{\cdot+}, \quad \textbf{I}$$

$$\text{–Fe(O)(IV)}^{\cdot+} \rightarrow (RH \rightarrow R^{\cdot} + H^+) \rightarrow \text{–Fe(O)(IV)–}, \quad \textbf{II}$$

$$\text{–Fe(O)(IV)–} \rightarrow (RH + H^+ \rightarrow H_2O + R^{\cdot}) \rightarrow \text{–Fe(III)–}. \quad \textbf{III}$$

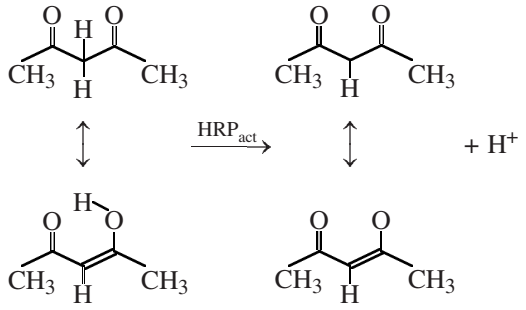
In a series of publications [3–5] devoted to enzymatic polymerization, β-diketones were used as proton donors, along with HRP, as an initiating system for polymerization of acrylamide, methyl methacrylate, and styrene. Based on these publications, we used in this study HRP, 2,4-pentanedione (PD), and H_2O_2 as an initiating system.

The scheme of the stage of polymerization initiation can be represented as:

$$H_2O_2 + 2RH \rightarrow (HRP) \rightarrow 2H_2O + 2R^{\cdot},$$

$$2R^{\cdot} + M \rightarrow RM^{\cdot},$$

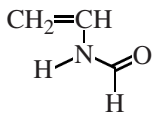
where M is monomer and RH is 2,4-pentanedione:



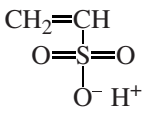
One H_2O_2 molecule produces two catalytically active forms of HRP, each of which oxidizes the initiator (RH) producing free radical ($R^{\cdot}$). Then the radical initiator reacts with monomers (M) to form monomer radicals ($RM^{\cdot}$), which react with other monomers to form a polymer [6].

The use of HRP in the composition of a system initiating the polymerization of monomers by the radical mechanism allows the process to be performed under mild conditions, i.e., in an aqueous medium and at low temperatures, which is extremely important in production of polymers for medical and biological purposes.

The aim of this study was to examine the possibility of polymerization of *N*-vinylformamide (VFA) and sodium vinylsulfonate (NaVS) in the presence of HRP:



VFA



NaVS

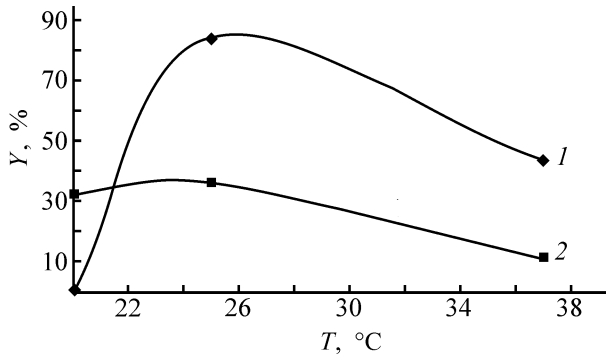
EXPERIMENTAL

We used HRP (Reanal, Hungary) with an activity of 350–500 units per milligram (*o*-diazidine method) and spectral index of purity *RZ* = 0.24. The *RZ* factor was determined on a Specord M-40 spectrophotometer as the ratio of the intensity of UV absorption of an HRP solution in acetate buffer solution (pH 5) at 410 nm to the intensity of the absorption at 275 nm [7]. The H_2O_2 concentration was 3.4% (Krasnodar Pharmaceutical Factory) and was checked by permanganatometric titration [8]. 2,4-Pentanedione (PD) was purchased from the München Co. (Germany), bp 108°C. *N*-Vinylformamide (Aldrich) was purified by vacuum distillation, bp 71°C (3 mm Hg). Sodium vinylsulfonate (Aldrich) was freeze-dried from 25% aqueous solution.

Polymerization was performed in an inert atmosphere (argon) in water at 20, 25, and 37°C in glass ampules. Initially, the monomer was charged into ampules and then HRP dissolved in water (0.4 mg ml^{-1}), H_2O_2 (0.224 mmol), PD (0.082 mmol), and water were added.



Influence of the polymerization temperature *T* on the polymer yield *Y*. Polymerization time 48 h for PVFA and 24 h for NaPVSN, concentration of monomers in water 26 wt %, concentration of HRP 0.4 mg ml^{-1}, H_2O_2 : PD = 0.224 : 0.082 (mmol). (*1*) PVFA and (*2*) NaPVS.

Polyvinylformamide (PVFA) was isolated by precipitation from an aqueous solution into acetone; sodium polyvinylsulfonate (NaPVS) and low-molecular-weight PVFA were isolated by freeze-drying after purification by dialysis.

The molecular weights of the polymers were determined by the viscometric method [9] at 25°C in 1 M aqueous KCl and in 0.2 M aqueous NaCl for PVFA and in 0.5 M aqueous NaCl for NaPVS. The viscometric measurements were performed with an Ostwald viscometer. The molecular weight was evaluated using the Mark–Kuhn–Houwink relationship. For PVFA,

$$[\eta] = 10.7 \times 10^{-3} M^{0.76},\ [\eta] = 8.44 \times 10^{-3} M^{0.78},\ [10];$$

for NaPVS,

$$[\eta] = 2.15 \times 10^{-4} M^{0.65}\ [11].$$

The structure of NaPVS and PVFA was determined by ^{1}H and ^{13}C NMR spectroscopy. The NMR spectra of solutions in D_2O were recorded on an AVANCE 400 spectrometer (Bruker, Germany). The chemical shifts of the resulting polymers are listed in Table 1. The results of experiments on polymerization of VFA and NaVS are presented in Table 2.

The influence of the polymerization temperature *T* (°C) on the yield of PVFA and NaPVS is shown in the figure. For this catalytic system, the optimum reaction temperature is 25°C, at which the yield of the polymers is the highest.

Polymerization of VFA was performed in 8, 26, and 59% solutions of the monomer. Irrespective of the polymerization time, the yield of the polymer did not exceed 16% at 20°C and a monomer concentration of 26 wt %. At 25 and 37°C, the maximal yield reached 84 and 44%, respectively (in both cases, polymerization for 48 h, monomer concentration in aqueous solution 26 wt %). The molecular weight

* At 25°C in 1 M aqueous KCl for sample no. 6; in 0.2 M aqueous NaCl for sample nos. 1–5 and 7–9; in 0.5 M aqueous NaCl for sample nos. 10–16.

of PVFA prepared under the above conditions is in the range from 27000 to 40000. Thus, the optimal conditions for polymerization of VFA are as follows: monomer concentration in water 26%, 25°C, 48 h.

Polymerization of NaVS was performed in 10, 26, and 52% aqueous solutions of the monomer at 20, 25, and 37°C. Irrespective of the other conditions of polymerization, the yield of the polymer at 37°C does not exceed 14%. At 20 and 25°C, the yield reaches 40% (polymerization at 20°C for 93 h, monomer concentration in water 26 wt %). All the obtained samples of NaPVS have low molecular weight, up to 2400.

CONCLUSION

Horse radish peroxidase is suitable for polymerization of water-soluble monomers vinylformamide and sodium vinylsulfonate.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Stability of Transition Metal Complexes with Sulfonated Polymers

V. D. Pautov, T. D. Anan'eva, and I. I. Gavrilova

Received May 23, 2007; in final form, July 2007

Abstract—Stability constants of macromolecular metallocomplexes of transition metal ions (Ag^+, Cu^{2+}, Ni^{2+}, Fe^{3+}) with sulfonated polymers in water and aqueous HCl and NaCl solutions were determined from quenching by transition metal ions of the luminescence of macromolecules labeled with luminescent groups.

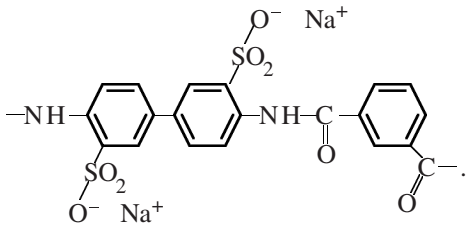
DOI: 10.1134/S1070427207120273

In modern technologies involving combinations of polymers and transition metal ions [1–4], it is frequently necessary to prepare macromolecular metallocomplexes (MMCs) which can be formed in aqueous solutions only in acidic media, as dictated by the solubility of metal salts. Polymers containing weakly acidic (e.g., carboxy) groups at pH < 3 are not noticeably ionized and cannot bind transition metal ions [5]. In an acid medium, only polymers containing strong acid groups and in particular, sulfo groups retain their charge. The complexing ability of such polymers toward transition metal ions in solutions at low concentrations of both metal ($<10^{-4}$ M) and complexing groups of the polymer can be evaluated by the procedure we have developed previously [5]. It is based on quenching of the luminescence of labeled polymers by transition metal ions upon complexation.

This paper deals with evaluation of the stability of MMCs formed by sulfonated polymers with transition metal ions (Ag^+, Cu^{2+}, Ni^{2+}, Fe^{3+}) in aqueous solutions at low concentrations of both metal and polymer and with elucidation of the influence exerted by the metal ion, pH, and ionic strength on the MMC stability.

EXPERIMENTAL

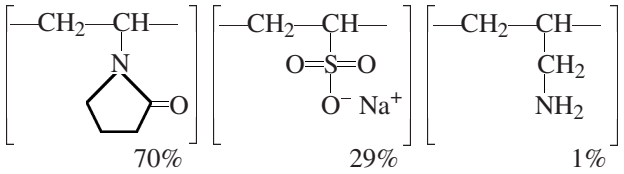
Macromolecular metallocomplexes of water-soluble solfonated polymers were the objects of the study. Water-soluble sodium polyarylenamidosulfonate (**I**) with $M = 7.0 \times 10^3$ prepared from isophthalic acid [6] was taken as a sulfonated polymer:



I

It contains in each monomeric unit two sulfo groups capable of forming electrovalent contacts with metal ions. The luminescence-labeled polymer **I** with 9-alkylanthracene groups as luminescence markers at the ends of the polymer chains was prepared by the reaction of the terminal amino groups of the polymer with 9-anthrylmethyl isocyanate [7].

Copolymer of *N*-vinylpyrrolidone with sodium vinylsulfonate (NaVS) **II** containing 29 mol % NaVS units:



70% 29% 1%

was taken as a polymer in which only a part of units bear sulfo groups.

In polymer **II**, a small (1 mol %) amount of allylamine units was introduced. Polymer **II** labeled with 9-alkylanthracene luminescent marker was prepared by the reaction between amino groups of allylamine units with 9-anthrylmethyl isocyanate [7].

Stability constants K_{st} of MMCs of transition metal ions with sulfonated polymers and the energy of interaction of metal ions with sulfo groups ΔG in solutions at 25°C

Run, no.	Polymer	Ion	Solvent	K_{st}	ΔG, kJ mol^{-1}
1	**I**	Ag^+	H_2O	$(9.9 \pm 0.5) \times 10^1$	11
2		Cu^{2+}	H_2O	$(2.5 \pm 0.3) \times 10^6$	36
3			0.01 M HCl	$(4.3 \pm 0.3) \times 10^5$	32
4		Ni^{2+}	H_2O	$(4.1 \pm 0.4) \times 10^6$	38
5			0.01 M HCl	$(2.6 \pm 0.6) \times 10^6$	37
6		Fe^{3+}	0.01 M HCl	$(3.7 \pm 0.4) \times 10^{10}$	60

8			0.01 M HCl	$(1.4 \pm 0.2) \times 10^6$	35
9			0.01 M NaCl	$(1.1 \pm 0.2) \times 10^6$	34
10			0.1 M NaCl	$(1.5 \pm 0.7) \times 10^5$	30
11		Ni^{2+}	H_2O	$(1.2 \pm 0.3) \times 10^7$	40
12			0.01 M HCl	$(8 \pm 2) \times 10^6$	39
13			0.01 M NaCl	$(6 \pm 2) \times 10^6$	39
14			0.1 M NaCl	$(9 \pm 3) \times 10^4$	28
15		Fe^{3+}	0.01 M HCl	$(2.6 \pm 0.4) \times 10^{11}$	65
16			0.1 M HCl	$(1.1 \pm 0.4) \times 10^{11}$	63
17			0.01 M HCl + 0.09 M NaCl	$(2.3 \pm 0.8) \times 10^{11}$	65

N-Vinylpirrolidone and allylamine monomers were purified by distillation. In copolymerization, we used a 25% aqueous solution of sodium vinylsulfonate (Aldrich). The copolymerization was performed in a sealed ampule in an inert gas atmosphere. The concentration of monomers in the aqueous solution was 45 wt %; azobis(isobutyronitrile) (1% of monomer weight) was an initiator. The reaction was performed at 65°C for 24 h. The polymer obtained was cooled with acetone and dried in a vacuum. The copolymer composition was determined by analysis for the sulfur content and titration of sulfo groups. The content of allylamine units was determined spectrophotometrically from the light absorption of the complex of allylamine units with trinitrobenzenesulfonic acid at λ_{max} = 420 nm. The molecular weight of the copolymer was roughly estimated from the intrinsic viscosity in ethanol at 25°C by the formula

$$[\eta] = 2.3 \times 10^{-4} M^{0.65},$$

reported in [8] for *N*-vinylpyrrolidone homopolymers. The molecular weight of polymer **II** was 1.2×10^4.

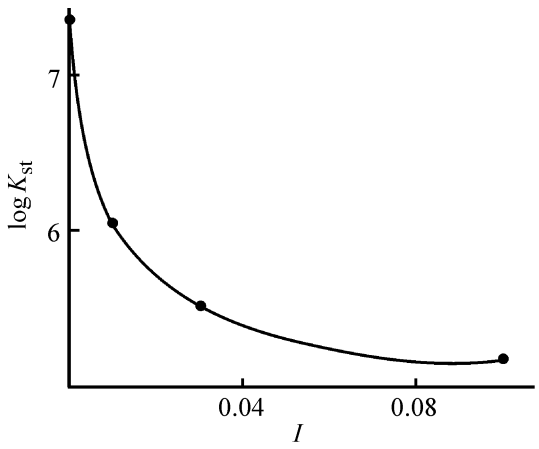
To form MMCs, we took aqueous solutions of $AgNO_3$, $CuCl_2$, $NiSO_4$, and $FeCl_3$. This set of cations allowed us to follow the effect of the metal and its valence on the MMC stability.

The MMC stability constants were estimated according to [5] from data on the quenching by transition metal ions at 25°C of the luminescence of polymers labeled with luminescence markers.

The luminescence spectra were recorded on an LS-100 luminescence spectrometer (PTI Company). The luminescence quenching was estimated from the change in the intensity of the maximum of the luminescence band of the anthracene group (~390, 413, and 440 nm) and from the change in the integral intensity of light emission within the 380–500 nm range. The polymer concentration was varied from 1.5 to 0.05 mg ml^{-1}. The ratio of the molar concentrations of metal ions and sulfonated monomeric units, β, was varied from 0 to 5 for M^+, from 1 to 2 for M^{2+}, and from 0.6 to 1 for M^{3+}.

The effect of metal ion on the structural organization of molecules of sulfonated polymer **II** at MMC formation was estimated by the intramolecular mobility of the metal ion. The relaxation time τ_{IMR} characterizing the intramolecular mobility of the polymeric chains of macromolecules with luminescence markers was determined by the method of polarized luminescence [9]. The luminescence duration was measured on an LS-100 luminescence spectrophotometer.

We found that, in the aqueous solutions with a concentration of units bearing sulfo groups ranging from 10^{-2} to 10^{-4} M, the molecules of sulfonated polymers form MMCs with polyvalent metal ions in both neutral and acidic solutions. The metal valence has the strongest effect on the stability of such complexes. In going from univalent (Ag^+) to bivalent (Cu^{2+}, Ni^{2+}) and then trivalent (Fe^{3+}) metal ions, the MMC stability constants K_{st} and the free energies of interaction between metal ions and polymer sulfo groups ΔG, calculated from these quantities, sharply increase under similar experimental conditions (see table, run nos. 1, 2, and 4; 3, 5, and 6; 8, 12,



Stability constant K_{st} of MMC of polymer **II** with Cu^{2+} vs. the ionic strength I produced by NaCl addition (25°C).

and 15). This means that electrovalent contacts between metal ions and sulfo groups play the decisive role in the formation of MMCs. The contribution of coordination bonds to MMC stabilization is insignificant, in contrast to the interaction of transition metal ions with carboxy groups of carboxyl-containing polymers [5]. This is indicated by the fact that the ΔG values divided by the number of electrovalent bonds of the ion for MMCs formed under the same experimental conditions by ions with different coordination capacities (Cu^{2+}, Ni^{2+}, and Fe^{3+}) [1, 4] are close.

The influence of a polyvalent metal ion on the energy of a single electrovalent bond with sulfo groups depends on the ion size. For Ag^+, whose radius is substantially larger than those of Cu^{2+}, Ni^{2+}, and Fe^{3+} ions (0.126 nm for Ag^+, 0.072 for Cu^{2+}, 0.069 for Ni^{2+}, and 0.064 nm for Fe^{3+} [10]), it is almost two times lower than for the other metal ions studied (see table).

The data obtained show that the influence of the ionic strength on the MMC stability strongly depends on the metal valence. The destabilizing effect of the ionic strength on MMCs of the sulfonated polymer with Ag^+ ions is so strong that the MMC completely decomposes at a solution ionic strength of 0.01. As compared to aqueous solutions, the stability of MMCs with bivalent metals substantially decreases in 0.01 M HCl (see table, run nos. 2 and 3, 7 and 8, 11 and 12). These changes are associated with variation of the ionic strength, rather than lowering of pH. Indeed, an increase in the solution ionic strength to 0.01 upon addition of a neutral salt (NaCl) has a similar effect on K_{st} (see table, run nos. 7, 8, and 9; 11, 12, and 13). The strongest (by almost two orders of magnitude) decrease in K_{st} of MMCs of a sulfonated polymer with ions of bivalent transition metals is observed in the region of low ionic strengths ($\leq$0.03). With a further increase in the ionic strength (to 0.1), K_{st} decreases by only a factor of 2–3 (see figure). The stability of MMC with trivalent Fe^{3+} does not noticeably change within the solution ionic strength range from 0.01 to 0.1 on addition of HCl or NaCl (see table, run nos. 15–17).

The data obtained show that the MMC stability with all the polyvalent ions studied increases (K_{st} increases by a factor of 3–8) in going from polymer **I** (containing two sulfo groups in each unit) to polymer **II** (in which only a part of units contain sulfo groups), i.e., upon replacement of an aryl group as a bearer of sulfo groups with an alkyl support, both in water and in aqueous solutions of HCl or NaCl (see table).

A study of the influence of Cu^{2+} and Ni^{2+} on the intramolecular mobility (IMM) of the polymeric chains of polymer **II** upon MMC formation showed that IMM does not noticeably change upon coordination of metal ions with the polymer. The relaxation time τ_{IMM} characterizing the mobility of the polymeric chains remains on the level of 9–10 ns upon a ~50% substitution of protons with metal ions in sulfo groups of the polymer. This means that the sulfo groups closely situated in the chain are involved in the formation of electrovalent contacts of sulfonic acid groups with a metal ion, and the MMC formation is not accompanied by compaction of macromolecules. In the formation of MMC, the change in the luminescence intensity is relatively small (1.5–3-fold intensity changes), which also indicates that the initial compactness of the macromolecules does not change. If the MMC formation is accompanied by compaction of macromolecules, the luminescence intensity can change by 1–2 orders of magnitude [5].

CONCLUSIONS

(1) Sulfonated macromolecules can be used to form of stable macromolecular metallocomplexes with polyvalent (in contrast to monovalent) transition metal ions in the acid region (pH < 3).

(2) For macromolecular metallocomplexes with bivalent metal ions, the decrease in the complex stability with decreasing pH should be taken into account. This effect is due to a rise in the ionic strength, rather than to an increase in acidity.

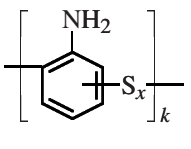
Abstract—Preparation of iron-filled polyaminophenylene sulfides and polyhydroxyaminophenylene sulfides by the metal vapor procedure was studied. Nanocomposites based on these metal-containing polymers and epoxy–isopropylidenediphenol oligomers (ED-20) were prepared and their composition, properties, and structure were studied by X-ray diffraction and thermogravimetric analyses, and thermomechanical methods. The magnetic and dielectric properties of the materials were determined.

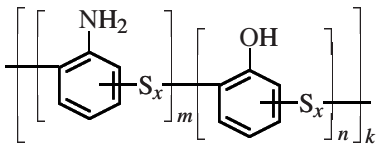
DOI: 10.1134/S1070427207120285

The preparation of magnetic dielectric materials with valuable properties is extensively studied owing to particular interest in the magnetic information carriers, magnetically connected parts of special devices, and other materials. Magnetodielectrics consist of a polymeric matrix and a filler with a magnetic function. However, common magnetodielectrics have certain disadvantages, such as low strength, low thermal stability, and poor dielectric characteristics, because of the high concentration of the filler (metal and its compounds) [1]. Filling of polymers with nanoparticles causes sharp changes in the physicochemical properties of the particles and materials based on them, which can be useful for preparing nanocomposites with required electrical, magnetic, and catalytic properties [2–5].

Previously, low-melting polyaminophenylene sulfoxides (PAPSs) (**1**) and polyhydroxyaminophenylene sulfides (PHAPSs) (**2**) were prepared by direct polycondensation of elementary sulfur with aniline and phenol [6, 7]; these polymers are soluble in THF, dioxane, *N*-methylpyrrolidone, and other solvents.



1



2

Later, network polyepoxides with good thermal characteristics were prepared from these polymers and epoxy–isopropylidenediphenol oligomers (ED-20) [8]. Taking into account the valuable characteristics of the resulting network polyepoxides, it was of particular interest to study the possibility of using polyamino- and polyhydroxyaminophenylene sulfides containing iron nanoparticles as fillers for ED-20 epoxy resin to obtain magnetodielectric materials with improved properties. It was expected that the resulting composites would possess high magnetic and dielectric properties, combined with the inherited thermal and chemical stability of polyphenylene sulfide matrices.

EXPERIMENTAL

In this study we used polyaminophenylene sulfide (**1**) and polyhydroxyaminophenylene sulfide (**2**) prepared and characterized in accordance with [6, 7]. Iron-filled PAPS (**3**) and PHAPS (**4**) were prepared by metal vapor synthesis (MVS) [2–4]. Iron was evaporated by resistive heating from a tungsten at a residual pressure not exceeding 10^{-2} Pa. The vapors of metal and THF were trapped on the reactor walls cooled with liquid nitrogen at the metal : ligand molar ratio of about 1 : 300. Then this cocondensate was heated to melt and the resulting organosol was added to THF solutions of polymers **1** and **2**. After that, the solvent was evaporated, and the result-

ing metal-containing polymers **3** and **4** were dried in a vacuum (residual pressure 1 Pa) at 373 K. The metal-filled composites **5**–**8** (Table 1) based on functionalized polyphenylene sulfide and epoxy–isopropylidenediphenol oligomer ED-20 were prepared by the procedure described elsewhere [8]. To eliminate the possible internal stresses, the composites based on ED-20 filled with PAPS and PHAPS containing iron nanoparticles were cured by the stepwise procedure: 343 K, 1 h; 358 K, 1 h; 373 K, 4 h; 413 K, 4 h; 433 K, 1 h; and 453 K, 1 h. The content of the sol fraction was determined under the conditions described previously [9]. The IR spectra of the samples were recorded on a UR-20 spectrometer using KBr pellets.

The thermomechanical compression curves were recorded at a constant load of 8.8 MPa and a heating rate of 70–80 deg h^{-1}. The thermogravimetric analysis (TGA) and differential thermal analysis (DTA) were performed on an MOM K derivatograph (Hungary) in air at a heating rate of 5 deg min^{-1}.

The magnetic and dielectric properties of the composites were determined in accordance with the procedure described in [10].[1] The powder X-ray diffraction patterns were recorded on a DRON-3 diffractometer in the Bragg–Brentano configuration using Cu_{K_α} radiation (λ 1.5418 Å), a graphite monochromator in the secondary beam, 36 kW × 20 mA generator mode, continuous θ/2θ scanning with a 0.05° step, and scanning rate of 1 deg min^{-1}.

The X-ray absorption spectra and of small-angle scattering curves were measured using synchrotron X-ray radiation [11]. The incident beam energy was selected using a Si(III) monoblock monochromator. The XANES and EXAFS spectra were measured with a scintillation detector as fluorescence yields.

The time of signal accumulation was 15–20 min and 6–8 h for XANES and EXAFS spectra, respectively. The preliminary processing of the EXAFS spectra was carried out using the IFEFFIT software package [12]. The intensity of the small-angle X-ray scattering was measured with a FujiFilm Imaging Plate coordinate detector (sample-to-detector distance 1 m; wavelength of incident X-ray radiation, λ 0.95 Å; 10-min exposure). The curves were processed using the GNOM software [13].

The photoelectron spectra were recorded on an XSAM-800 spectrometer (Kratos, UK). The excitation source was a magnesium anode with a characteristic radiation energy of 1253.6 eV. The power released at the anode in the course of the measurements did not exceed 90 W (15 kV, 6 mA); the pressure in the working chamber was 10^{-8} Pa. A quantitative analysis was performed by the procedure described in [14].

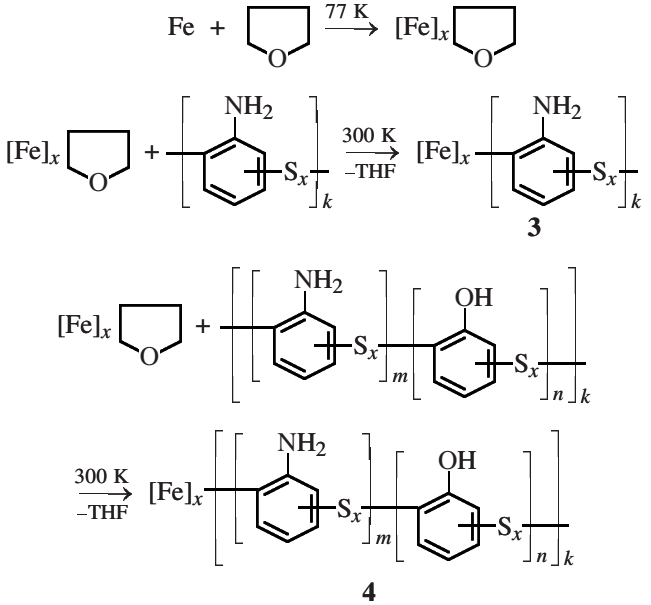
Table 1. Composition of materials **5**–**8** based on ED-20 and PHAPS filled with iron nanoparticles

Component	Nanocomposite composition, wt fraction			
	5	**6**	**7**	**8**
ED-20	100	100	100	100
PHAPS filled with iron nanoparticles*	32.0	33.2	33.6	35.0

* Nanocomposites **5** and **6** contain 6.0 wt % Fe, and **7** and **8**, 8.2 wt % Fe.

The development of magnetodielectric materials involves two main stages: filling of functionalized polyphenylene sulfides **1** and **2** with iron nanoparticles and subsequent curing of ED-20 oligomer with the above products. The filling of PAPS and PHAPS with iron nanoparticles is illustrated by the scheme below.



Scheme of nanoparticle introduction into PAPS and PHAPS matrices.

The iron nanoparticles were prepared by the reaction of the iron and THF vapors at 77 K. The organosol of Fe in THF, obtained after defrosting, was added to solutions of functionalized polyphenyl-

ene sulfoxides in the same solvent. The resulting iron-containing composites **3** and **4** were studied by various physicochemical methods. According to the results of an elemental analysis, the content of iron in the filled samples was 11.4 wt % for polymer **3** and 6.0 and 8.2 wt % for polymer **4**. Data on the chemical state of iron in the filled composites were obtained by X-ray diagnostics including XANES (X-ray Adsorption Near-Edge Structure) and EXAFS (Extended X-ray Absorption Fine Structure), X-ray diffraction, small-angle X-ray scattering, and X-ray photoelectron spectroscopy (XPS).

The XPS spectrum of compound **4** (Fig. 1) indicates that there is no iron in the surface layer (up to 50 Å) of the filled polymeric nanocomposites. No degradation of the samples in the course of measurements was observed. Probably, the active metal particles are effectively encapsulated by the polymer and, as a result, the surface layers contain almost no iron as compared to its total content in the polymer.

Along with the data of elemental analysis, the presence of iron in the polymer samples is confirmed by XANES and EXAFS spectra recorded using the synchrotron radiation. These spectra also furnished data on the chemical state and environment of iron atoms in filled polymers **3** and **4**.

The XANES spectra at the Fe *K*-edge for samples **3** and **4** are shown in Fig. 2 (curves *6* and *7*) in comparison with the standard spectra recorded under similar conditions (curves *1*–*5*). As references we used FeS, FeO, Fe_3O_4, Fe_2O_3, and PAPS sample filled with commercial carbonyl iron (~1-μm average particle size). Comparison of these experimental spectra

shows that the state of iron in the filled polymeric samples strongly differs from that of metallic iron (polymeric sample filled with carbonyl iron) or FeS and is close to that in iron oxides. The profile and position of the absorption edge in the samples are the closest to those in the spectrum of Fe_3O_4 with account of the pronounced shoulder associated with the $1s \rightarrow 3d$ electronic transition. This conclusion was additionally confirmed by the shape of the Fourier-transformed EXAFS spectra (Fig. 2b). The Fourier-transformed spectra of the filled samples exhibit a single pronounced peak corresponding to the Fe–O bond, with no other features belonging to the Fe–S and Fe–Fe bonds observed. Such a pattern is typical of disordered oxide nanoparticles.

The powder diffraction patterns of the initial sample and iron-filled PHAPS composite are shown in Fig. 3. The polymeric matrix is virtually X-ray amorphous. The diffraction pattern exhibits only a broad halo at about 20° and a diffuse maximum at 42°. Nevertheless, some differences between the diffraction curves of these materials are observed; the difference curve is shown in the inset (Fig. 3). As can be seen, two broad diffraction peaks are observed at 35° and 63°; their position is close to that of the two strongest reflections (311) and (400) in the diffraction pattern of crystalline magnetite Fe_3O_4 (marked by arrows in Fig. 3). These data agree with the assumption that iron in the polymeric matrix forms nanoparticles of an oxide close in composition and structure to Fe_3O_4. The size of these oxide nanoparticles can be reliably evaluated from small-angle X-ray scattering data. The experimental curves for the sample of polyaminophenylene sulfide **3** filled with iron nanoparticles and similar sample containing metallic (carbonyl iron) microparticles are shown in Fig. 4.

Both curves show a broad peak at s = 0.35–0.40 Å^{-1}, apparently associated with structural features of the polymeric matrix, and level out at $s >$ 0.6 Å^{-1}. The plateau is determined by the scattering on the polymeric matrix and by the isotropic background of X-ray fluorescence from iron atoms present in the samples (the small-angle X-ray scattering curves were measured using radiation with energy higher than the K edge of iron absorption). Nevertheless, the scattering curve for sample **3** contains a pronounced region of strong scattering in the range s = 0.1–0.2 Å^{-1} which can be reliably attributed to scattering on nanosize iron oxide particles present in the sample. The differential curve, mainly determined by this contribution, was processed using the GNOM software. In the approximation of a polydisperse distribution of

Table 2. Characteristics of magnetodielectric composites **5**–**8** based on ED-20 and PHAPS filled with iron nanoparticles

Parameter	Nanocomposite			
	5	**6**	**7**	**8**
Bulk electrical resistivity at 293 K, $\Omega\,cm^{-1}$	10^{12}	10^{12}	10^{11}	10^{11}
Breakdown voltage, kV	8.7	8.0	9.1	8.8
Relative magnetic permittivity, $V\,N^{-1}$	2.47	2.52	2.67	2.60

rigid spheres, the scattering curve corresponds to a relatively narrow unimodal distribution of spherical particles, centered at approximately 15 Å (particle radius).

The second step in the development of magnetodielectric materials involved curing of ED-20 oligomer with iron-filled composites **3** and **4** prepared and examined in the first step of this study. The temperature mode of curing of ED-20 with PAPS and PHAPS containing iron nanoparticles was similar to that used for preparing network polyepoxides based on ED-20 and unfilled phenylene sulfide oligomers [8] it should be noted that curing of ED-20 oligomer with iron-filled nanocomposites **3** and **4**, and with unfilled polymers **1** and **2**, goes virtually to completion. This is confirmed by the low content of the sol fraction in the resulting samples (0.1–0.35%) and by the absence of the absorption bands at 930 and 960 cm^{-1}, characteristic of free epoxy rings, in the IR spectra of the cured samples [8]. The compositions of composites **5**–**8** based on ED-20 and composite **4** are listed in Table 1.

Analysis of the electrical properties of composites **5**–**8** (Table 2) shows that these composites containing iron nanoparticles exhibit better dielectric properties in the temperature range from 363 to 453 K as compared to iron-containing materials based on ED-20

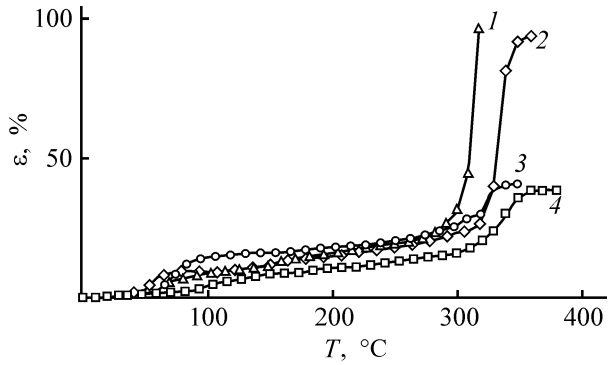

Fig. 5. Thermomechanical curves of ED-20 samples cured with (*1*) PAPS, (*2*) PHAPS, (*3*) PAPS + Fe, and (*4*) PHAPS + Fe. (ε) Strain and (*T*) temperature.

and functionalized polyphenylene sulfides filled with carbonyl iron microparticles. Moreover, use of composites **3** and **4** as curing agents for ED-20 improves the chemical stability of the resulting magnetodielectric materials as compared to the materials based on polymers **1** and **2**.

It should be noted that changes in the metal concentration in composites **5**–**8** do not noticeably affect the magnetic permittivity.

Under similar conditions, magnetodielectric composite **9** based on PAPS was prepared by curing of oligomer ED-20 with composite **3**. At an iron content of 11.4%, the magnetic permittivity of composite **9** was 2.2 $V\,N^{-1}$.

The thermal characteristics of materials prepared previously by curing oligomer ED-20 with polymers **1** and **2** allow us to trace changes in the softening point and heat resistance of composites on passing from unfilled curing agents to iron-filled composites **3** and **4**. The thermal characteristics of the resulting magnetodielectric composites were studied by thermomechanical and thermogravimetric methods. Comparison of the thermomechanical curves of the iron-free and iron-filled samples (Fig. 5) shows that, at 300°C, the samples based on PAPS, PHAPS, and ED-20 are nearly completely deformed under the stress, whereas the strain in the materials based iron-filled composites **3** and **4** and ED-20 does not exceed 20–25% under the similar experimental conditions. It should be noted that the system based on composites **3** is better cross-linked on heating than that based on composite **4**.

In accordance with TGA data, differences in the composition of polymers PAPS and PHAPS do not affect the heat resistance of materials prepared from them and ED-20. A similar pattern is observed with the materials based on ED-20 and iron-filled polymers PAPS and PHAPS. The TGA and DTA curves for composites **2** and **4** with ED-20 are shown in Fig. 6. The heat resistance of composites **2** and **4** with ED-20 in air is similar. The temperature of de-

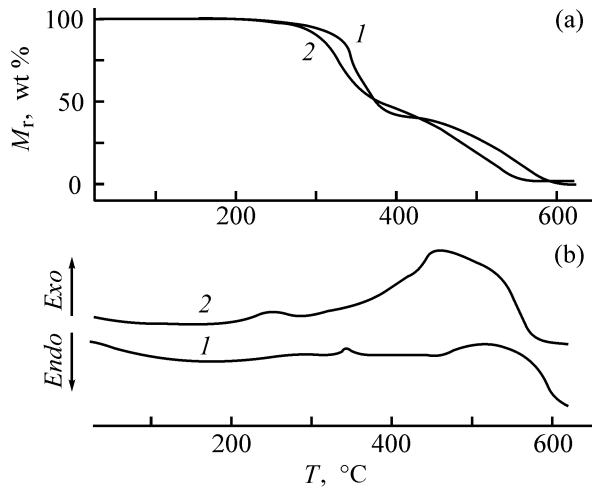

Fig. 6. (a) TGA and (b) DTA curves recorded in air for (*1*) unfilled and (*2*) iron-filled composites based on ED-20 and polyhydroxyaminophenylene sulfide. (M_r) Residual weight and (T) temperature.

gradation onset, i.e., the temperature corresponding to a 5% weight loss by the sample, $T_{5\%}$, for composite **2** with ED-20 is 295°C. Introduction of iron nanoparticles into the composite lowers $T_{5\%}$ to 276°C. As can be seen from TGA (Fig. 6a) and DTA (Fig. 6b) curves, the onset of the weight loss by the composite with iron nanoparticles is preceded by an exothermic peak at 248°C, which is not observed for the initial composite **2** with ED-20. This is probably due to thermal oxidative processes occurring in the composite filled with iron. The low relative deformation of the metal-filled composites noted above may be due to the formation of internal cross-links appearing in the course of thermal oxidation.

CONCLUSION

Combination of thermosetting epoxy matrices with polyamino- and polyhydroxyaminophenylene sulfides filled with iron nanoparticles improves the properties of common materials and allows development of nanocomposites with required magnetic, dielectric, and thermal properties.

Abstract—Polymeric nanocomposites based on aromatic polyamidoimide and nanotubes of magnesium hydrosilicate $Mg_3Si_2O_5(OH)_4$ with a chrysotile structure were obtained and studied for the first time. The morphology and mechanical and transport properties of the composites formed were analyzed, which enabled optimization of their synthesis conditions.

DOI: 10.1134/S1070427207120297

Studies of hybrid nanocomposite materials combining an organic matrix and inorganic fillers arouse considerable interest because of the potential opportunity for synthesis of composites with improved properties. Hybrid systems with physicomechanical characteristics different from those typical of the starting substances have been reported [1, 2]. These differences are the most pronounced in synthesis of materials that belong to the group of filled polymers. This is due to processes of distribution of nanosize inorganic particles in a polymeric matrix and is primarily determined by the following factors: number and nature of reactive groups, hydrophilic–lipophilic balance for each of the components combined, presence in the polymer structure of fragments ("potential ligands") for the chosen filler, and also its size and structure. Filled polymers are used not only in development of new construction materials [3, 4], but also in design of industrial polymeric membranes stable under severe conditions of a separation process [5]. Use of polymeric nanocomposites is appropriate in solution of complicated tasks, such as development of membranes with required transport properties on the basis of materials with improved mechanical characteristics. The reason is in the morphological features of nanocomposites, which are manifested not only in the mechanical properties, but also in permeability and selectivity parameters of nonporous membranes. The structure and transport properties of polyimide-based composites containing zeolite 4A or carbon molecular sieves have been studied [6, 7]. It was shown that, in the case of a good compatibility of components, the ordered structure of the inorganic component is responsible for the gas separation efficiency [6–8]. Widely known are studies in which inorganic additives having in most cases a crystalline structure are introduced into the polymeric matrix in order to enhance the barrier properties with respect to gases and liquids [9]. The decrease in the free volume, which accompanies the formation of composites of the given type, diminishes the region of molecular transport of the permeate because of the insolubility of its molecules in the crystalline regions of the matrix. The transport mainly occurs in the amorphous part of the polymer.

In recent years, publications have appeared concerning the application of carbon nanotubes in membrane materials [10–12]. This is primarily due to the high specific surface area of the material of the nanotubes and to the resulting formation of a considerable number of nanosize voids and hollows. It was demonstrated that carbon-based nanotubes have diffusion and sorption parameters that favorably distinguish them from the known materials. The parameters of N_2 and CO_2 diffusion and sorption in single-wall carbon nanotubes, measured at room temperature, depend on the diameter of the nanotubes [13].

The appearance of studies devoted to synthesis of noncarbon (most frequently oxide and oxyhydroxide)

tubular structures with varied morphology and surface activity [14–16] opens up opportunities for formation of composite membrane materials intended for catalytic and pervaporation purposes. It is known that structural characteristics of nanotubes, their shape, length, and ratio between the inner and outer diameters can predetermine the morphological features [17] of composites. However, general principles of component compatibility and fundamental aspects of gas and liquid transport across membranes of the polymer–nanotubes type have not been studied so far.

Of particular interest in this context is development of new composite materials based on aromatic polyamidoimide, with inorganic nanotubes and, in particular, those composed of $Mg_3Si_2O_5(OH)_4$ with a chrysotile structure as fillers. Also important are studies of the morphological features of the composites obtained and of their mechanical and transport properties. The choice of the filler is governed by the knowledge of the physicochemical foundations of directed hydrothermal synthesis of nanotubes composed of $(Mg, Fe, Ni, Co)_3Si_2O_5(OH)_4$ hydrosilicates, by the existence of routine methods for control over their structure, morphology, and size [18], and by the available data on introduction of hydrosilicate nanotubes into polyimide films, which results in that the mechanical properties of the material substantially improved [3, 17].

EXPERIMENTAL

Poly(diphenyloxyamido-*N*-phenylphthalimide) (PAI) with a molecular mass of 57 000, synthesized by the known procedure, was used as a matrix for synthesis of a hybrid composite material [19].

The following inorganic fillers were used in the composites: natural montmorillonite intercalated with quaternary aliphatic amine; commercial product Cloisite 15A (Southern Clay Products, Inc., USA); and nanotubes (NT) of $Mg_3Si_2O_5(OH)_4$ composition with a chrysotile structure. These NT were produced by hydrothermal treatment of various precursors: magnesium oxide, silicon dioxide, and $MgSiO_3$ with NaOH solutions with NaOH content of up to 3 wt % at temperatures of 250–450°C and pressures of 30–100 MPa by the procedure described in [14, 16]. Nanotubes of composition $Mg_3Si_2O_5(OH)_4$ were used, with a cylindrical morphology and various dimensions: (a) outer diameter d_o = 10–15 nm, inner diameter d_i = 2–3 nm, and length L = 100–250 nm (NT I); (b) d_o = 20–25 nm, d_i = 4 nm, and L = 500–1000 nm (NT II); and (c) d_o = 50–110 nm, d_i = 5–6 nm, and L = 300–700 nm (NT III).

The composites were prepared in *N*-methyl-2-pyrrolidone (N-MP) under ultrasonic agitation of 8-wt % solutions of PAI in air at room temperature. The duration of agitation of the dispersions obtained (up to 20 h) was determined by the required degree of homogeneity of the resulting composites. The content of the inorganic components was varied from 2 to 10 wt %.

The dispersions were applied by casting onto the smooth surface of glass plates, on which thin nonporous films with thicknesses of 20 and 40 μm were formed after removal of the solvent by thermal treatment at temperatures of up to 150°C.

Mechanical tests of the films were performed on a UTS-10 versatile installation (UTStestsysteme, Germany) in the uniaxial tension mode at a tensile load of 0.5 MPa. In the tests, the modulus of elasticity E, plastic limit σ_p, tensile strength σ_t, and breaking strain ε_b.

The membrane morphology was studied by scanning electron microscopy (SEM) with Jeol JSM-35C and FE-SEM JSM 6400-F instruments (Japan).

The pervaporation parameters of solid film membranes were determined for water and in separation of ethanol–water mixtures (50 wt % ethanol) at 40°C on a pervaporation installation with a working area of the membrane equal to 12.4 cm^2. The pressure under the dry membrane (before the pervaporation process) was about 1×10^{-2} Pa. The compositions of the starting solution and of the permeate were determined by refractometry. The membrane selectivity was characterized by the separation factor $F_{i/j}$ calculated for components i and j of the mixture being separated by the formula

$$F_{i/j} = [c_i/c_j]_{per}/[c_i/c_j]_{st},$$

where $[c_i/c_j]_{per}$ is the concentration ratio of the components being separated in the permeate, and $[c_i/c_j]_{st}$, that in the starting (to be separated) mixture.

If the working area of the membrane and the amount of the permeate passed across the membrane are known, the permeate flux Π (kg m^{-2} h^{-1}) can be estimated.

It has been shown in our previous studies that, depending on hydrothermal synthesis conditions, inorganic nanotubes of varied composition, size, and morphology ("cylinder in cylinder," "cone in cone," and "sockets") can be obtained [14, 16, 18]. These results enabled us to consider in this study the morphological parameters of nanotubes as factors that

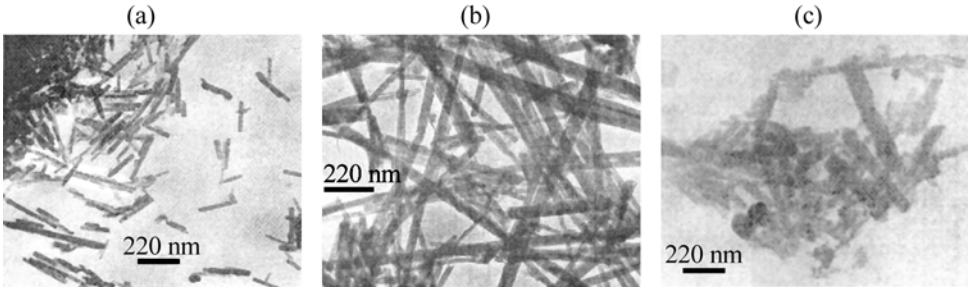

Fig. 1. SEM micrographs of $Mg_3Si_2O_5(OH)_4$ nanotubes. (a) NTI, (b) NTII, and (c) NTIII.

can be used in structural optimization of the PAI–NT composite. This approach is justified by the necessity for obtaining the composite material without introduction of additional organic substances or preliminary treatment of NT with surfactants. Until now, it has been for the most part possible to achieve the best compatibility of the inorganic and polymeric phases via introduction of additional organic components into the polymer–NT medium [20]. However, introduction of even minor amounts of additional substances in synthesis of membrane materials in which liquid or gaseous mixtures are separated by the diffusion–sorption mechanism may lead to a fundamental change in their transport properties. For this reason, the combining conditions of the components were optimized in this study without introduction of organic additives, by varying the structural and concentration parameter and conditions of the distribution process.

As in most of the known cases [21], composites constituted by a polymer and an inorganic filler were formed by vigorous and prolonged agitation of the components in solution. After 10 h of agitation, visually homogeneous PAI–NT I–III dispersions were obtained, of which PAI–NTI and PAI–NTII stratified in the course of 1 h, and PASI–NTIII remained visually homogeneous. This effect can be attributed primarily to different synthesis conditions of nanotubular hydrosilicates. NTI samples were synthesized by hydrothermal treatment of a mixture of oxides, MgO + SiO_2, with aqueous NaOH solutions (1 wt %) at 350°C and a pressure of 70 MPa for 1 h. As a result, the treatment product contained, in addition to the nanotubular hydrosilicate $Mg_3Si_2O_5(OH)_4$, an admixture of magnesium hydroxide and nanotubes had small dimensions and were partly composed of such defective morphological forms as "cylinder in cylinder," "sockets," and tubes with rough surface (Fig. 1a). NTII samples were synthesized from the MgO + SiO_2 mixture in a 1-wt % NaOH solution under the conditions optimal for production of morphologically homogeneous nanotubes (temperature 350°C, pressure 50–70 MPa, duration 24 h). These samples contained no impurities and were composed of cylindrical nanotubes of the hydrosilicate $Mg_3Si_2O_5(OH)_4$, which are free of morphological defects and have virtually the same diameters (Fig. 1b). NTIII samples were obtained by hydrothermal treatment of a $MgSiO_3$ + MgO mixture in a 2-wt % NaOH solution at 300°C and 70 MPa for 48 h. The synthesis product is composed of nanotubes of the hydrosilicate $Mg_3Si_2O_5(OH)_4$, with an admixture of a layered hydrosilicate $Mg_3Si_4O_{10}(OH)_4 \cdot nH_2O$ having a structure of montmorillonite, an intermediate in synthesis of $Mg_3Si_2O_5(OH)_4$ from the $MgSiO_3$ + MgO mixture. The NTIII nanotubes are considerably thicker than NTII and have a rough surface (Fig. 1c). Consequently the stratification of the PAI–NTI and PAI–NTII dispersions can be attributed to a chemical and morphological inhomogeneity of the inorganic components introduced into the polymer solution.

Casting of a visually homogeneous stable dispersion PAI–NTII onto the smooth surface of a glass plate yielded nonporous PAI–NTII(10) films of thicknesses 20 and 40 μm. Figure 2 shows SEM micrographs of the upper (Figs. 2a, 2b) and lower (Figs. 2c, 2d; formed on the glass side) surfaces of the 20-μm-thick film. As can be seen in Fig. 2, the nonporous PAI–NTII(10) films contain fragments with absolutely different morphologies, with the structural inhomogeneities observed across the entire thickness of the film being due to the poor compatibility of the polymeric and inorganic components. The presence of more homogeneous regions near the upper surface led to a conclusion that a homogeneous film can be obtained by making longer the time during which the components are agitated. This was done and Fig. 2 also shows micrographs of the upper (Fig. 2e) and lower (Fig. 2f) surfaces of a film produced by casting of a PAI–NTII(20) dispersion formed as a result of 20-h agitation of the components in solution. These data indicate that a homogeneous dispersion is formed and a uniform composite film is ob-

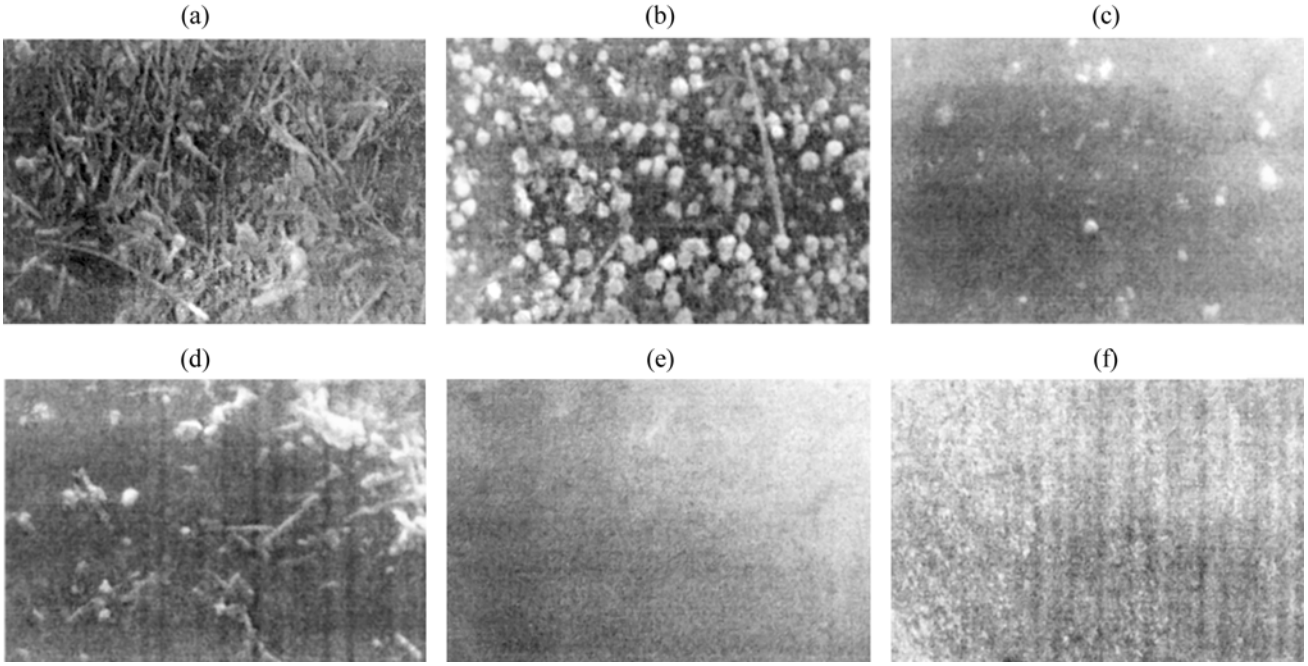

Fig. 2. SEM micrographs of (a, b, e) upper and (c, d, f) lower surfaces of (a–d) PAI–NTII(10) and (e, f) PAI–NTII(20) of thickness 20 μm.

tained, whose surface profiles are similar to the respective profiles of a homogeneous film of the basis PAI polymer.

Introduction of hydrosilicate nanoparticles (nanotube and intercalated montmorillonite MMT-15A) into the PAI matrix resulted in pronounced changes in the mechanical properties of the films obtained from these composites, compared with the films of an unmodified PAI (Table 1). It has been shown [3, 22] that changes in the mechanical behavior of films of heterocyclochain polymers, caused by introduction of nanoadditives into the polymer, are primarily manifested in an increased rigidity of the material: its modulus of elasticity, tensile strength, and, in some cases, strength are higher. Simultaneously with these changes, the failure strain of the films becomes substantially lower, to the point of synthesis of brittle samples.

The first of these tendencies is manifested in full measure in films of nanocomposites obtained in this study. Indeed, introduction of nanotubes and MMT even in small amounts (2 wt %, which corresponds to a volume content of nanoparticles slightly exceeding 1%) leads to a pronounced increase in the modulus of elasticity and tensile limit of the material. It is noteworthy that the results obtained clearly demonstrate the fundamental importance of achieving a high homogeneity of nanoparticle distribution in the poly-

Table 1. Mechanical characteristics of films at different compositions of the corresponding nanocomposites and durations τ of homogenization of their solutions

* c is the concentration of the inorganic component; the same for Tables 2, 3.

Fig. 3. SEM micrograph of the region of low-temperature disintegration of a PAI–NT II(20) film.

mer volume for effective modification of the matrix material. Indeed, the rigidity of the material starts to increase considerably only after a prolonged (20 h) mechanical homogenization of a dispersion of the PAI–NT nanocomposite in a solvent, whereas 10 h of homogenization under the same conditions fails to provide a pronounced change in rigidity. These data are in good agreement with the results of the electron-microscopic study of the films (Fig. 2).

The same is indicated by the results of introduction into PAI of increased (10 wt %) amounts of nanotubes (Table 1). In this case, a film only slightly different from the starting PAI in both the modulus of plasticity and tensile limit. Presumably, this occurs because of the aggregation of nanoparticles in solution, observed on raising their concentration [23, 24].

The mechanical test results demonstrate a significant difference in the behavior of materials containing hydrosilicate nanotubes and MMT nanolayers. On the one hand, MMT-15A is a commercial intercalated product prepared for dispersion in polymeric matrixes. Therefore, it is easier to provide a high quality of its distribution in PAI, compared with introduction of nanotubes: already a 10-h homogenization of a nanodispersion yields films with higher modulus of plasticity and tensile limit, comparable with those obtained after 20 h of homogenization of suspensions with nanotubes. On the other hand, films of nanotube-containing nanocomposites strongly surpass the material modified with MMT in their deformation characteristics.

Indeed, PAI–MMT, as well as quite a number of nanocomposites described in the literature, disintegrates under uniaxial tension already near the tensile limit (breaking strain 5%), which strongly hinders practical use of these films. Introduction into PAI of the same amount (2 wt %) of nanotubes does not lead to any noticeable decrease in the deformability, compared with the starting material: extension of nanocomposite films of this kind leads (as also in the case of PAI films) to formation of a neck, its spreading across a sample, and the subsequent transition to the strain strengthening region, in which the sample disintegrates. Thus, use of hydrosilicate nanotubes for PAI modification can yield films that combine an enhanced rigidity with good deformation properties.

An additional specific feature of the mechanical behavior of PAI–NT II(20) nanocomposite films is associated with the manner in which the material disintegrates at low temperatures. A PAI film shows brittle disintegration at liquid-nitrogen temperature, whereas with films of PAI–NT II(20) nanocomposites, brittle cleavages could not be obtained under the same conditions: the deformation behavior of the material remains plastic at these temperatures. The pattern of plastic disintegration of a film of PAI–NT II(20) nanocomposite at liquid-nitrogen temperature is shown in Fig. 3.

A study of the transport properties of the corresponding films (homogeneous membranes) in pervaporation demonstrated the following. Introduction into the polymeric matrix of porous inorganic particles with tubular structure (nanotubes of the NT I–III types) without their additional treatment (chemical or orienting) leads to an increase in the flux of water across the corresponding film membrane (Table 2,

Table 2. Permeability to water of nonporous films of PAI–NT I–III composites in comparison with a nonporous PAI film in pervaporation at 40°C

Sample no.	Sample	c, wt %	l,* μm	Π, kg m^{-2} h^{-1}	Πl,* kg m^{-2} h^{-1} μm
1	PAI	0	15	0.043	0.645
2	PAI–NT I	2	15	0.044	0.660
3	PAI–NT II	10	15	0.084	1.260
4	PAI–NT III	2	12	0.056	0.672

* l is the sample thickness, and Πl, sample permeability normalized to thickness.

Table 3. Permeate flux ∏ and separation factor for water, F_w, for nonporous composite films (sample nos. 5, 6) in comparison with a nonporous PAI film (sample no. 1) in pervaporation separation (40°C) of an aqueous solution containing 48 wt % ethanol

Sample no.	Sample	c, wt %	l,* μm	∏, kg m^{-2} h^{-1}	F_w
1	PAI	0	15	3.20	5.5
5	PAI–NT II	2	15	3.75	7.9
6	PAI–MMT-15A	2	15	2.35	5.8

* PAI characteristics well correlate with those previously reported in [25].

sample nos. 2–4), which is the most pronounced for NT II in the case of a good compatibility of components of the composite material (Table 2, sample no. 3). Table 3 compares the results of tests of PAI and PAI–NT II(20) (2 wt %) films, and of a composite PAI–MMT-15A (2 wt %) film obtained under the conditions in which PAI–NT II(20) was formed, in dehydration of an aqueous solution of ethanol (48 wt % ethanol) in the course of pervaporation at 40°C. As the content of nanotubes in the composite increases from 2 to 10 wt % (Table 3, sample no. 5 and Table 2, sample no. 3, respectively), the permeability of the material to polar liquids, such as water and ethanol, grows. A possible explanation of this effect is that the permeability is affected by the probable, in principle, appearance of microscopic inhomogeneities or defects (on the nanosize level or coarser) in the nonporous matrix of the composite film upon introduction of the inorganic component. However, this assumption is easily refuted by analysis of the data in Table 3, because introduction of 2 wt % NT II into a PAI film yields a composite for which the separation factor of the water/ethanol mixture not only does not decrease, but even somewhat increases as compared with that for the homogeneous PAI film.

In this property (an increase in permeability to liquids upon introduction of inorganic nanotubular additives), the PAI–NT II(20) composite material obtained strongly differs from typical composites constituted by a polymer and an inorganic filler. As a rule, introduction of inorganic particles into a polymeric matrix results in that an inorganic phase impermeable to gases and liquids is formed in the matrix and the mass-transfer zone becomes narrower. As a result, the permeability on nonporous films falls [26]. For this reason, introduction into the PAI matrix of 2 wt % MMT-15A particles under the same conditions yields a composite material with lowered permeability, as shown in Table 3. Because inorganic MMT-15A particles and hydrosilicate nanotubes are close in chemical composition, no other components are present in the systems under consideration, and the formation conditions remain unchanged, it can be assumed that the nanosize structural features of the films exert a decisive influence on their transport properties.

CONCLUSION

A new nanocomposite material with improved physicomechanical properties and higher permeability in pervaporation to polar liquids and, in particular, aqueous–alcoholic mixtures than the starting polymer was obtained on the basis of poly(diphenyloxyamido-*N*-phenylphthalimide) and layered magnesium hydrosilicate $Mg_3Si_2O_5(OH)_4$ with tubular structure.

ANNIVERSARIES

Evgenii Fedorovich Panarin (to His 70th Birthday)

DOI: 10.1134/S1070427207120303

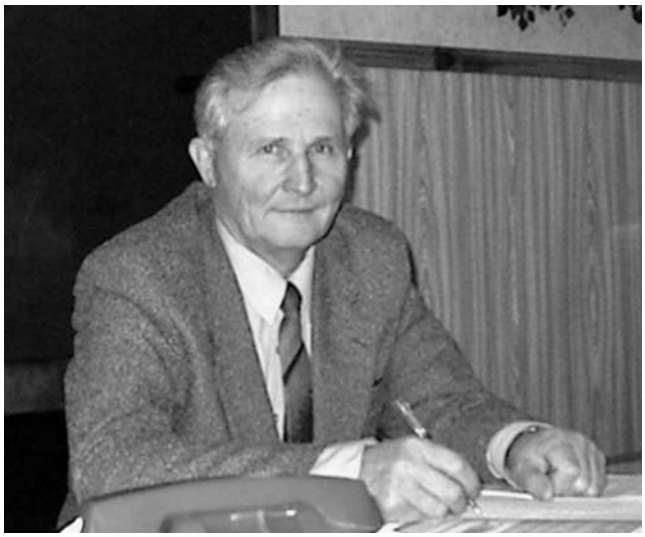
January 17, 2008 is the 70th birthday of Professor, Corresponding Member of the Russian Academy of Sciences, Director of the Institute of Macromolecular Compounds (Russian Academy of Sciences), Evgenii Fedorovich Panarin.

E.F. Panarin graduated from the Lensovet Technological Institute (St. Petersburg) in 1960. After completion of his postgraduate course (1963), he entered the Institute of Macromolecular Compounds, Russian Academy of Sciences (IVS RAS). Since 1987 E.F. Panarin has been working as the director of IVS RAS.

E.F. Panarin is an outstanding scientist who contributed significantly to the progress of chemistry of macromolecular compounds. His scientific activities are associated with applied research in hydrophilic polymers and polymers for biomedical use and with basic research in synthesis of polymeric drugs.

E.F. Panarin has developed foundations for directed modification and correction of the bioactivity of drug preparations with polymers, and methods for synthesis of multipurpose water-soluble polymer carriers bearing diverse functional groups that provide addition of bioactive compounds to a target site of the macromolecule. Such polymers were offered as a model for certain biopolymers, and also as carriers for transportation of bioactive compounds (hormones, antibiotics, enzymes, antiseptics, DNA, etc.) to target organs.

Of great importance are studies of mechanisms of chemical reactions used in synthesis and modification of polymers, including chemical and enzymatic synthesis of vinylsaccharides, preparation of water-soluble polymers from *N*-vinylamides and functionalized vinyl and allyl monomers, and also studies of the reactivity of functional groups of polymers. E.F. Panarin was the first who established the relationship between the chemical structure and intrinsic bioactivity of water-soluble polymers. As a result of this research, a new class of polymers exhibiting antimicrobial, antiviral, antitumor, immunomodulating, growth-promoting, and other kinds of activities has been discovered.



E.F. Panarin has developed foundations and methods for designing polymeric polyfunctional bioactive nanostructured materials. As a result, polymeric nanodrugs Poviargol and Katapol were developed on the basis of biogenic elements and diphilic ions of bioactive compounds.

E.F. Panarin applies basic research results to various practical problems of industry, medicine, agriculture, and environmental protection. Under his guidance, processes for production of novel domestic water-soluble polymers and polymer-based drug preparations have been developed. E.F Panarin contributes significantly to the development of domestic blood substitute Gelenpol (approved for medical use) based on polymeric hemoglobin, and also to the development of novel plant protectors based on bioactive polymers.

E.F. Panarin is a Honored Inventor of the Russian Federation. He is a coauthor of the monographs *Antimikrobnye polimery* (Antimicrobial Polymers) and *Vozbuzhdennye sostoyaniya v khimii polimerov* (Excited States in Polymer Chemistry), of a handbook *Polimery v meditsine i farmatsii* (Polymers in Medicine and Farmacy), and of more than 500 scientific publications and inventions. E.F. Panarin pays great

attention to the problems of organization of science and pedagogical activities. He is at the head of the experimental base of the Department of Medical Biotechnology of the St. Petersburg Polytechnic University at the Institute of Macromolecular Compounds, Russian Academy of Sciences. Ten candidates and six doctors of science were brought up under his guidance.

E.F. Panarin is the Deputy Editor-in-Chief of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) and a member of Editorial Boards of other scientific journals. His multidisciplinary and very fruitful activities were commended with government awards and prizes.

The Editorial Board and Staff of *Zhurnal Prikladnoi Khimii*, E.F. Panarin's friends and colleagues cordially congratulate him on this jubilee and wish him splendid health and creative longevity in scientific and pedagogical activities.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Investigation of Sorption Properties of Carbon Treated with Low-Temperature Plasma

S. L. Buyantuev and I. V. Starinskii

East-Siberian State Technological University, Russia

Received February 12, 2007

Abstract—Plasma based technology for producing active carbon is proposed.

DOI: 10.1134/S1070427207120312

In the modern world there is clear tendency to organization of ecologically pure industrial production. This is connected with the general view that catastrophic and practically throughout environment pollution is a real fact [1]. The main sources of pollution are industrial and domestic effluences containing petroleum products, oil, phenols, pesticides, herbicides, heavy metals and a scope of organic chemicals. All these substances are potential hazards for people and live nature. A significant amount of pollutions is produced by energetic enterprises, the power station using coil in particular. The more and more rigid restrictions concerning various hazardous effluences are issued, and they require development and application of new and more effective materials and technologies providing ecological safety of operation of power stations.

Among the known methods of purification water, its deep purification to any degree of purity provides sorption purification only. This method is based on the application of sorbents, active carbon predominantly [2].

The principal restriction to application of carbons sorbents for energetic ecology is high cost and deficient due to disadvantage of currently used technology. The known technologies of producing carbon sorbents (from coil, wood, nut crust and other) use energy of fuel combustion or electric heating [3, 4]. Alternatively, for producing active carbon by existing methods can be applied energy of low temperature plasma. The low temperature plasma increases considerably efficiency of processing solid fuel and intensifies the process of production of active carbon owing to presence in the plasma of active radicals, ions, electrons, and due to its significant temperature and high specific power [5].

Thus, investigations directed to the study and development of plasma technology for producing sorbents are actual and can result in development of technology for producing active carbon of any type with lower energy consuming.

For the studying processes of plasma pyrolysis and gasification of carbon using electric arc reactor as a generator of low temperature plasma we created an experimental installation (Fig. 1), consisting of the following principal nodes: system of electric feeding, combined type electric arc reactor, direct current electromagnetic coil, vapor generator, system of feeding with carbon and air, system for gas output, cooling and purification, control console, muffle chambers with connecting pipes for gas reagents, separation chambers and chambers for pyrolysis and activation.

During the experiment the active carbon samples from pyrolysis and activation chamber are investigated on sorption activity on iodine, benzene, methylene blue and iron and compared with currently used sorbents (birch active carbon BAC).

In the process of experiments material and heat flows were registered in all nodes of installation. In part, were registered consuming of carbon, vapor, air, graphite electrodes, active carbon, dust and sublimates, and electric power of reactor, heat power, heat loss in plasma reactorm muffle chambers and gas outlet.

Initially, the experiment was conducted in the absence of air and vapor. In the course of experiment the grinded

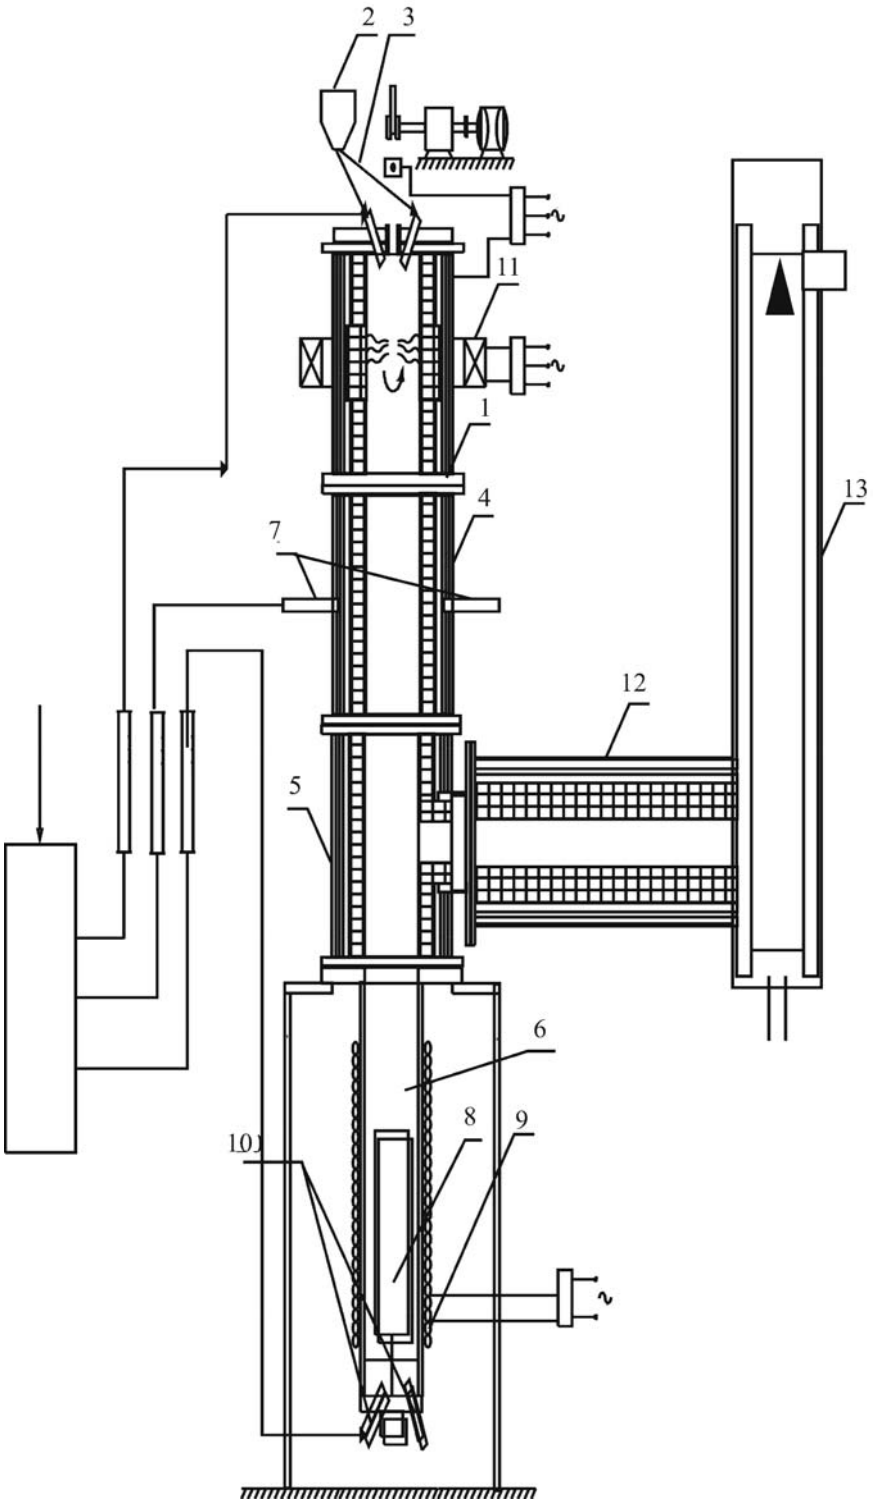

Fig. 1. Module of one-step plasma installation for complex treatment of carbon. carbon is passed through plasma reactor where it is heated in electric arc using energy of combustion of finely dispersed component of carbon. To the end of the experiment was measured carbon combustion loss and were performed analyses of its sorption activity. In the second step were conducted experiments at feeding with vapor for maximum developing porous structure [2]. The results of analyses are listed in Table 1.

In the process of analyses it was found that pouring the carbon treated with low temperature plasma and vapor into water (common water-pipe water was used) results in separation of carbon into two fraction: heavy fraction with is collected at the bottom (Table 1, line 7), and light fraction (line 6), floating up to surface. An insignificant part of carbon particles floated in bulk water.

Light fraction constituted a significant part (76.5%) of the carbon and featured by a very bad wettability and good magnetic properties.

Analysis of sorption properties of the fractions showed that heavy fraction shows high ash content (88.0%) and good chemosorption property (sorption activity on iron is 14.52 mg/g), the light (floated up) fraction shows moderate ash content (32.4%) and good oil sorption property.

The chemosorption properties on iron are not unambiguous. Iron ions are known to have small size even as compared with ultra-micro pores. Therefore binding of iron ions should be connected wuth the presence in the sorbent of mineral fraction inducing cation-exchange processes, that is, chemosorption [6]. Ions of potassium, sodium and calcium can be washed out from the minerals by the ions with higher oxidation number, including Fe^{3+}. Therefore the high sorption capacity of the heavy fraction is well explainable: this fraction contains 88% of mineral part. High sorption capacity of this fraction allows us to suggest that so-called *iron removing* sorbent is obtained, which can be applied to purification effluences and drinking water from iron admixtures. This sorbent acts as cation exchanger and provides high degree of water purification. The light fraction has not high sorption activity on iron, the same as that of parent carbon (see Table 1). Besides, the light fraction shows excellent magnetic properties, that allows to judge that it initially contains much iron. Appears the state of chemical equilibrium, and additional amount of iron can not be absorbed. For heavy fraction no magnetic property was registered. Despite the fact that by 88% it consists of mineral part, it does not practically contains iron. This is why it well consumes iron at the treatment with the solution containing Fe^{3+} ions.

Considering the data on the sorption of benzene vapor One can see that sorption capacity of carbon increases after treatment in all cases (see Table 1). This fact indicates significant increase in number of meso pores in the sorbent structure. The light fraction shows high capacity on benzene: it increases twice as compared with the parent carbon. Low capacity of heavy fraction (Table 1, line 7) is due to insufficient development of meso-porous structure and low content of organic part. Owing to high sorption capacity on benzene and unique hydrophobic properties of light fraction we studied it in more details.

We measured oil capacity of this sorbent. The value of oil capacity (0.48 g/g) is excellent for the sorbents of oil removing type [6]. This sorbent can collect petroleum 4-5 times more than modern industrial solvents allow. Besides, this sorbent shows hydrophobic property, hence, it would not disturb ecology of water layer. The sorbent used for oil consumption can be easily collected. Further, the sorbent impregnated with oil or petroleum products can be used in various directions: as a high-calorie low-ash solid fuel, at stacking asphalt and so on.

Below are given the results of studying microporous structure of carbon before and after treatment with low temperature plasma. The microanalysis was conducted with metallography measuring microscope NEOPHOT-21 at different zoom.

Fig. 2 shows the presence of closed micro pores (1, 2, 3, 4) indicating not developed structure of the parent carbon.

In Fig. 3 many micro pores can be seen: 1–15 nm diameter, combined with other micro pores, joining with 5 nm micropores 2 and 3 is seen clearly. The micro pore 2 is combined with 4 through the transfer micro pore 5.

It is these connections appearing as a fracture (passage) that allow suggest about good sorption ability of the carbon, which is confirmed by chemical analyses of the sorption activity of the carbon on methylene blue, benzene, iodine and iron, and of oil capacity (Table 1).

Fig. 4 shows smaller pores as fractals (canals) 0.1–3 nm width, as confirmed by chemical analyses of sorption activity on iron. The micro pores 1–3 being connected form a pass through whole section of the carbon particle. The micro pore 3 in the right area has 1 nm diameter and in left area achieves 3 nm. The micro

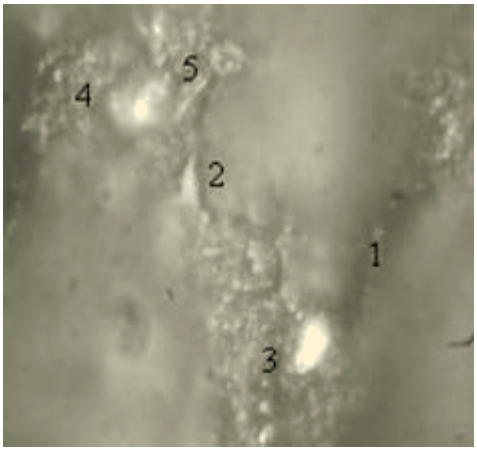

Fig. 3. Structure of carbon particle after treatment in the plasma reactor (zoom 1000:1).

pores 4 and 5 form pass to the sample particle inside and their diameters are approximately 2 and 1 nm, respectively. Calculation shows that the micro pores of this range of the canal width constitute up to 60% of all visible pores on the sample section.

In Fig. 5 is seen many micro fractals passing through the active carbon particle on the whole section area. Two micro pores are clearly seen: 1 passes through whole particle, and its canal structure is well seen. Besides, it goes into the particle body. The micro pore 2 is of less size but also is well seen. In Fig. 5b also are seen canals across the pores 1–3, mostly going into the particle body. Presence of many pores makes the particle density less than that of water, allowing collecting wastes as oil spots from water surface.

The sorbent produced can be used as filling of the filters for purification effluences from petroleum products and other nonpolar (organic) liquids. The

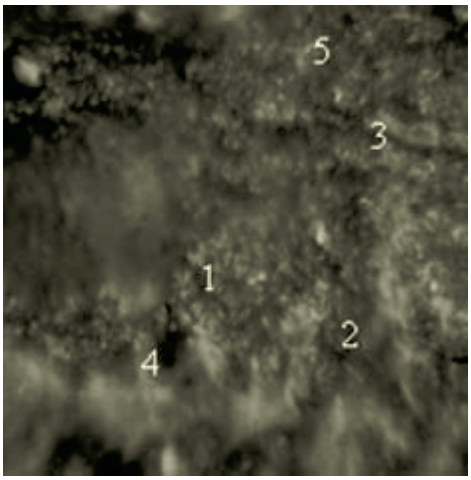

Fig. 4. Structure of a particle of iron removing sorbent (zoom 1000:1).

Fig. 6a. Oil spot on water surface.

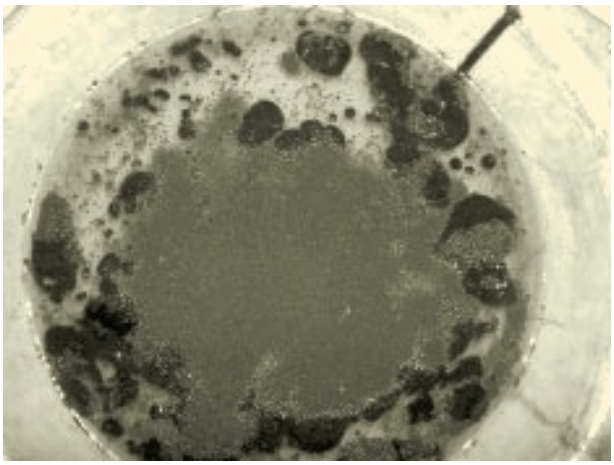

Fig. 6b. Oil spot covered with active carbon.

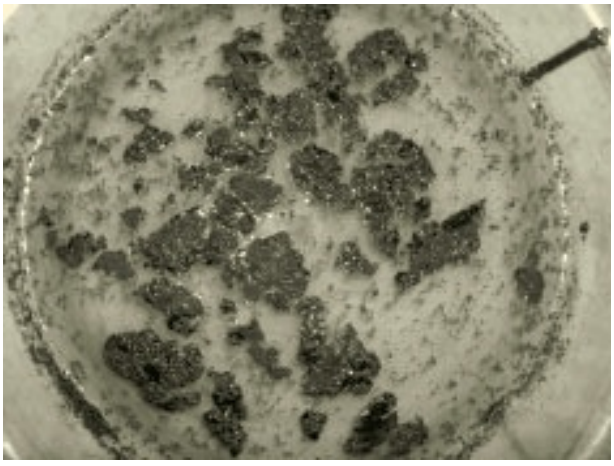

Fig. 6c. Oil spot absorbed with active carbon.

sorption technology based on this sorbent can be used for narrowing propagation and for collection of petroleum wastes in water basins, soil, ground, snow and other surfaces.

Note that in the process of the active carbon production is formed the synthes-gas consisting of: CO_2 1.1%, O_2 0.8%, CO 40.2%, H_2 46.7%; caloricity 3710 kcal/kg.

Comparison of characteristics of active carbon before and after treatment in the plasma reactor shows increase in sorption activity on all tests. The most significant is increase activity on methylene blue, from 21.1 to 133.3 mg/g, evidencing existence of micro pores with diameter over than 1.5 nm. Comparison with birch active carbon (BAC, table, line 8) prepared by traditional procedure shows 4-fold higher characteristic of the sorbent obtained by the plasma technology. The data on benzene and iodine are not so high; this is a result of ohysical structure of the parent raw material [2].

Thus, the proposed plasma technology for producing active carbon is advantageous, as compared with traditional technology, by the following [7]:

– liquid and gaseous fuel is not consumed;

– Potential heat of the initial carbon is consumed completely;

– large size granules of carbon can be quickly heated to high temperature in the zone of gas formation in account of heat of combustion of dust fraction;

– simplicity of the process technology;

– flexible technological parameters in a wide range;

– compactness of the equipment used.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Formation of Charges of Plastic Industrial Explosives by Extrusion

M. B. Generalov

Moscow State University of Engineeric Ecology, Moscow, Russia

Received May 25, 2007

Abstract—Principles of application of extrusion technology for the formation of charges of industrial plastic explosives are considered, including analysis of extruder operation and modeling of extrusion process.

DOI: 10.1134/S1070427207120324

Extrusion. For the hardware forming at the manufacturing plastic composite industrial explosives, extrusion technology is ordinary applied.

Extrusion is a technological process consisting essentially of admitting to the material of required form in the cross-section by pressing it through a profiling unit (the matrix).

By the extrusion technology the plastic composition of an explosive can be transformed into a final product having a certain form: sheet, profile band, cord, rod, pipe, etc.

The principal instruments for working up plastic compositions are single- or multi-screw *syringe machines* or *extruders*. Detailed description of extruder design can be found in [1–3]. One- and two-worm extruders are used not only at producing hardware but also in other technological processes at the manufacturing plastic explosives, as mixer, plasticizer and granulator [4].

Modern extruder is a machine that provide simultaneous heating of polymer material in account energy formed at of internal friction and its homogenization owing to large shift deformations, as well as creating hydrostatic pressure necessary for continuous pressing the material through the profiling unit. Therefore it i possible to define the modern extruder as a pump completely free of pulsation that passes thermally homogenous polymer composition with constant productivity and at the constant pressure.

The most wide application in the industry of polymers workup have found the single-screw extruders. Correspondently, the most developed area of theory of treatment concerns the extrusion process on the single-worm extruders. Therefore let us consider the processes occurring at the extrusion on such single-worm machine (Fig. 1). It consists of: cylindrical body (4) with loading hopper (5) for feeding with granules or pieces of plastic explosive, worm (auger) (3) located in the thrust bearing

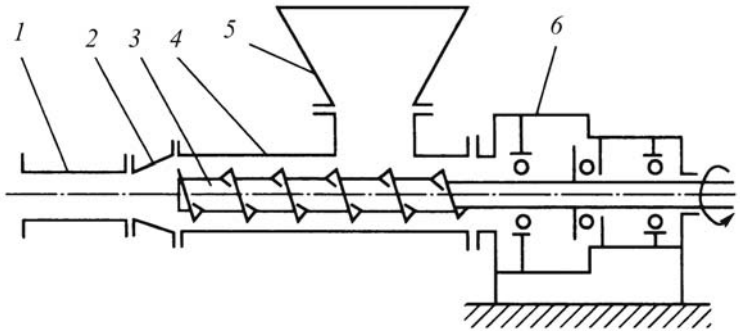

Fig. 1. Extruder: general scheme. See the text.

node (6), press-node consisting of cone tube (2) and forming matrix (1), and a drive. In some types of the extruder the internal surfaces of body and forming matrix are equipped with controlled heating.

The auger is essential working element of extruder. It takes granules of the material from hopper feedthroat hole and passes it uniformly as a homogenous viscous flowing mass to the forming unit.

By the character of the processes in each part of the auger, the latter can be separated along its length into three principal zones: the *feeding* or *loading zone* where the treated material is in solid state, the *compressing zone*, where proceed almost completely its homogenization, and *dozing zone*, where the material becomes viscous-flowing, or plastic.

Qualitative analysis of extruder operation. Commonly the extruders differ by the treated material: for processing elastomers and for thermoplasts. In the first case extruder is feeded by plasticized material, e.g., as pieces of tapes from rolls; in the second case, granulated material is processed.

To the feeding zone the granulated material commonly is passed at the room temperature. After filling the canal, material is moved like hard rod. In the course of moving, the rod is tightening, and owing to friction retarding the moving is compressed in volume. In some cases the pressure in the end of this zone achieves value uo to 10 MPa.

Rate of motion of the block of granules along the auger canal depends on the ratio of friction coefficients between the granules and granules with the surface of the auger and body. Lower the friction coefficient between the body surface and the polymer, higher the rate of the block motion.

For diminishing the friction coefficient, the screw surface is abraded and polished. On the contrary, finishing of internal surface of the body is defined by the reasons of convenience at cleaning of the machine. Often the body internal surface has longitudinal grooves (riffles).

The most significant is thermal regime of operation in the *feeding zone*. Commonly, the temperature of internal surface of body falls to the range 50-80°C, to provide anchncing in plastic properties of the processed material.

The *feeding zone* length is commonly from 4 to 6 diameters of screw.

In the *compression zone* the material transforms from the solid state into viscous flow under the action of heating evolved as a result of shift deformation of the material. The solid block of granules while moves along the auger screw canal exerts circular compression (autohesion) effect due to increasing pressure and cohesion (shifting) effect. As a result, the porous structure of the compressed granules gets properties of monolithic poreless homogenous mass in viscous-flow state.

In the *dozing zone* the screw canal of auger is filled with the polymer in viscous-flow state. From this moment, the polymer moving is similar to the moving of viscous liquid along the canal of a screw pump. Actually the polymer moves in the dozing zone by screw trajectory. Such motion commonly is represented as a sum of two independent motions.

The first one is forward motion (translation) along the axis of the screw canal. The volume flow rate of this motion defines eventually volume productivity of the extruder and hence defines the upper limit of the rate of granular block movement within the feeding and melting zones.

The second one is circular movement of the polymer in the direction at the right angle to the screw canal axis. Moving crosswise in the canal the flow meets the canal wall and turns back. The circular movement provides homogenization of the polymer composition, averages distribution by temperature and allows to use extruder as a mixer.

A part of the material that achieves the canal wall does not turn back but passes ring gap between the wall and the screw. This is a *leaking flow*. Thus the productivity of the dozing zone is defined by the difference between the productivity of compelled and leaking flows.

Interconnection of all the steps of extrusion shows that analysis of the process requires considering all the phases together. The main factor controlling interaction of all phases of the process is constancy of material consuming of the polymer in any section of the auger.

So far as the auger productivity is defined by the *dozing zone*, let us consider the method of mathematical description of operating of this zone.

Mathematical model of extrusion process. By the principle of its operation, the dozing zone of mono-screw extruder is a type of screw pump. Due to high viscosity of the pumped liquid, flow in such screw pump is always

laminar, with the Reynolds number close to unity (so-called *creeping flow*).

The mathematical model of the screw pump can be obtained by join solving a system of equations that express the laws of mass retention, and pulse transfer at laminar flow with the equations describing rheological properties of the pumped liquid.

This problem has been many times considered in the works of both domestic and foreign scientists. The most systematically the mathematic model of screw isothermal flow of a Newtonian fluid has been considered in a series of publications by Charley, Malluk and McKelvey who thus were the parents of hydrodynamic approach to description of the extrusion process.

Let us consider basic equations of the polymer motion in the dozing zone of auger. At the rotation of screw the material becomes located inside a mechanical system which is restricted by moving surfaces of screw (cylindrical base and sides of screw canal) and immovable surface of the auger body. As a result, forced flow becomes established. The material is moved exclusively due to existence of this forced flow. The necessary condition of existence of the forced flow is certain viscosity of the material. A hypothetical material with zero viscosity can not be transported by screw pump, and hence forced flow can not appear.

Figure 2 shows symbols defining the screw geometry and used for denoting its details. For the complete analysis we consider a multiple-thread screw with two parallel channels. The cylinder internal diameter is $D_1 = 2R_1$ defines the distance between internal auger diameter $D_0 = 2R_0$ and the cylinder surface. Radial gap between the external diameter of screw and cylinder surface is c. The step of screw is connected with the angle α of screw line measured at external diameter of screw by the equation:

$$E = \pi(D - 2e)\tan\alpha, \quad (1)$$

where E is screw step.

If W is the canal width, then the screw having m threads the following eqation can be obtained:

$$m(W + e) = E\cos\alpha, \quad (2)$$

where e is thickness of the screw loop.

The screw pump operating occurs when screw is rotated and cylinder remains fixed, although opposite situation is also possible: rotating cylinder and fixed screw. In both the cases the material will be moving in the same direction and with the same characteristics of the process. The design with rotating screw is simpler and such type machines are the most useful.

For hydrodynamic analysis of a screw pump should be considered in details the trajectory of a particle of material (in phenomenological sense, the particle means a material dot of continuous medium moving in the auger canal) in the screw canal relatively to the fixed coordinates. There are two possibilities of defining position of the material particle: relatively to the cylinder or relatively to the screw. Further we consider position of material particle relatively to the screw. We consider the screw as a fixed part, while the cylinder is considered as rotating, that is, we use the principle of inverted motion.

Let us apply a simplification very useful in hydrodynamic analysis: we consider the screw canal as two parallel planes. Conventionally, we uncoil the screw canal and consider it as unmoved rectangular groove with the movable upper plane, the internal surface of cylinder (Fig. 3). The z axis corresponds to the axis of the screw canal, its positive direction is taken the direction of movement of material to the canal outlet; the canal length equals Z.

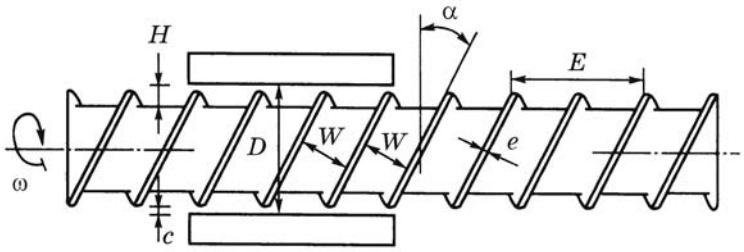

Fig. 2. Sizes of the details of the auger screw canal at vibration thickening.

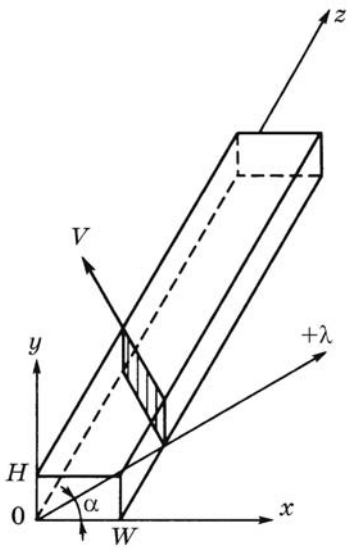

Fig. 3. Scheme for calculations of the extruder dozing zone.

The canal cross section width (the screw pitch width) at right angle to z axis is denoted as W, its height as H. The λ axis directed in parallel with the longitude axis of the auger has total length L and inclined by angle α (that corresponds to the screw ascent) to the x axis. The cross-hatched section is located in the plane at right angle to the λ axis. For the material moving from loading hopper to the auger outlet this section moves to +λ direction.

The rate vector of the material movement in any point of the screw canal can be decomposed into the components v_x, v_y and v_z, acting to te directions in parallel to the corresponding axes of the orthogonal coordinate system.

The upper plane of the canal in which the material is moving is the surface of cylinder of radius R_1, which moves with constant rate in parallel with the $x - y$ plane at the distance H from it. Motion of this plane is described by rate vector V directed at right angle to the λ axis. This vector modulo equals to linear rate of rotation of the cylinder surface

$$V = \omega R_1, \tag{3}$$

where ù is angular rate of the screw rotation.

The transfer rate vector V can be decomposed into two components, V_1 and V_2, directed along z and x axes, respectively, as shown in Fig. 4. Their values are:

$$V_1 = \omega R_1 \sin\alpha \quad V_2 = \omega R_1 \cos\alpha. \tag{4}$$

The rate V_1 defines forced (straight) flow of the material in the screw canal, the rate V_2 defines circular motion of the material in the canal cross section.

The proposed planar-parallel model of cylindrical screw pump operation commonly is used when $(H/D)_1$ ratio is small enough, because in this case the introduced error is small. Theoretical analysis in [11] and experimental study of the screw pump operation confirm this conclusion for many cases.

Thus, any material particle at its motion (starting at the loading hole at $z = 0$) along the screw canal passes enough complicated way. It is difficult to describe its mothion mathematically. Meanwhile, such complete mathematical description is not necessary for calculation pf productivity of auger unit.

The volume productivity can be obtained at integration of equation (5):

$$Q = \int_0^H \int_0^W v_z \, dxdy. \tag{5}$$

For the steady isothermal motion of an incompressible liquid the flow indissolubility equation gets the following form:

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} = 0. \tag{6}$$

We suggest that at the motion of the polymer along z axis $v_x = v_y \equiv 0$, because $v_x << v_z$ and $v_y << v_z$. Then from Eq. (6) follows that vz can be a function of the coordinates x and y only, $v_z(x, y)$.

Using the Navier–Stokes equation, motion of material along flat canal can be written as:

$$v_x \frac{\partial v_z}{\partial x} + v_y \frac{\partial v_z}{\partial y} + v_z \frac{\partial v_z}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial z} \nu \left(\frac{\partial^2 v_z}{\partial x^2} + \frac{\partial^2 v_z}{\partial x^2} + \frac{\partial^2 v_z}{\partial z^2} \right). \tag{7}$$

The terms in the left part of Eq. (7) reflect acceleration which can be omitted in the case of slow motion. Moreover, at low H/W ratio of the auger (strictly speaking, $H/W << 1$), then v_2 little depends on x, and $\frac{\partial^2 v_z}{\partial x^2}$ derivative can be omitted as compared with $\frac{\partial_x^2 v_z}{\partial y^2}$. Then

Eq. (7) can be rewritten as:

$$\frac{1}{\mu}\left(\frac{\partial p}{\partial z}\right) = \frac{\partial^2 v_z^2}{\partial y^2}. \quad (8)$$

Suppose that there is no gap between external diameter of the screw and internal surface of cylinder, then boundary conditions for single-thread screw (m = 1) are: $v_z = V_1$ (at $y = H$) and $v_z = 0$ (at $y = 0$).

Assuming that pressure within a canal section is varying insignificantly, the solution of Eq. (8) obeying above boundary conditions can be written as:

$$v_z = V_1 \frac{y}{H} - \frac{y(H-y)}{2\mu}\left(\frac{\partial p}{\partial z}\right). \quad (9)$$

Join solving of Eqs. (8) and (9) gives for the volume productivity:

$$Q = V_1 \frac{WH}{2} - \frac{WH^3}{12\mu}\left(\frac{\partial p}{\partial z}\right). \quad (10)$$

The first term in (10) characterizes forced flow Q_1 due to screw rotation. The second term gives reverse flow Q_2 due to the pressure generated by the forming press-unit.

Effect of radial gap. Most extruders have although small but defined gap between the screw outer diameter and internal surface of cylinder. Due to this radial gap, leakage of some amount of the material to the direction opposite of transporting is possible, that finally reduces productivity of the auger unit.

The forced flow formula should include a coefficient $(1 - c/H)^2$ accounting for the loss in the forced flow due to the presence of the gap. The area of forced flow is extended not to the cylinder internal surface but from the screw internal diameter to the point $H - c$. Hence, volume productivity of forced flow is:

$$Q_V = Q_1\left(1 - \frac{c^2}{H}\right). \quad (11)$$

The correction factor for productivity of the flow under pressure with the gap is:

$$Q_{corr} = Q_2\left[1 + \left(\frac{c}{H}\right)^3 \left(\frac{W}{e}\right)\left(\frac{1}{\sin\alpha\cos\alpha}\right)^2\right]. \quad (12)$$

Hydrodynamic characteristic of auger. Accounting for eqs. (11) and (12) and resuming the result in the form

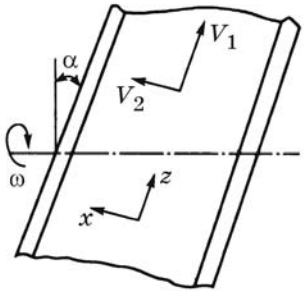

Fig. 4. Velocity diagram.

applicable for an auger with a multi-thread screw (m > 1) and accounting for the fact that for incompressible material Q does not depend on z we obtain from Eq. (10):

$$Q = a N - \frac{b}{\mu}\Delta p, \quad (13)$$

where N is the screw rotation rate, Δp is pressure difference along the screw canal of Z length.

Here:

$$a = \frac{\pi^2 D^2 H \sin\alpha\cos\alpha}{2} \times \left[1 - \frac{2c}{D_1} - \frac{me}{\pi D_1 \sin\alpha}\right]\left[1 - \frac{c}{H}\right]^2$$

$$b = \frac{\pi D_1 H^3 \sin^2\alpha}{12Z}\left(1 - \frac{2c}{D_1} - \frac{me}{\pi D_1 \sin\alpha}\right) \times \left[1 + 2\left(\frac{c}{H}\right)^3\left(\frac{W}{e}\right)\frac{1}{\sin 2\alpha}\right].$$

Equation (13) is hydrodynamic characteristic of auger.

Hydrodynamic characteristic of forming press-unit. At the auger outlet the material is passed through a forming unit (press-unit). If the material retains the properties of Newton fluid, then its volume consuming and pressure drop are connected by the following relation (Eq. 14):

$$Q = \frac{K}{\mu}\Delta p, \quad (14)$$

where K is a constant depending on the geometry of the press-unit of the extruder.

The pressure drop Δp in Eq. (14) means the same as in Eq. (13) if the pressure at the auger inlet is the same as at the outlet.

Volume productivity of extruder. Join solving eqs. (13) and (14) characterizing auger and forming unit, respectively, relatively Δp gives the following expression for volume productivity of extruder on the worked up material:

$$Q = \frac{aK}{b + K} N. \quad (15)$$

Eq. (15) shows that volume productivity is directly proportional to the screw rotation rate. But do not forget that this conclusion is true for a specific case only when reological properties of worked up material are the same as for the flow of Newton fluid under isothermal conditions.

Calculation of technological parameters of extruders accounting for the non-Newtonian reological properties of the worked up polymers and for non-isothermal processes of heat transfer requres much more complicated mathematical solutions.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Carbon Adsorbents for the Sorpting and Concentrating Nobel Metals

Yu. V. Pokonova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 19, 2007

Abstract—Kinetic, sorption and selectivity properties of commercial adsorbents are improved by adding petroleum residues (tar asphaltene concentrates) 13% of whole mass. Obtained adsorbents can be used for selective extraction of nobel metals from multicomponent polymetallic solutions of heavy metals and fro sewages purification for removing arsenic.

DOI: 10.1134/S1070427207120336

In this communication we describe data on modification of commercial carbon adsorbents by addin tar-asphaltene petroleum concentrates (TAC). This does not change industrial technology of manufactiring adsorbents. The improving is achieved using a simple procedure that is reasonable from economic and technology viewpoints. In preceeding publication [1] was shown that oxidative-reductive interaction of sludge with asphalt from propane and gasoline deasphalting the products are formed in 65–92% yield containing consisting of concentrated tar-asphaltene components of sludge, asphalt and asphaltite. These products (residues from residues) were named tentatively as secondary petroleum residues. They costitute a new resource of petroleum raw material with a high reactivity and exclusively low cost. Their utilization can solve an ecological problem of petroleum processing and petrochemical plants that uses sulfuric acid technology for purification of oil and paraffin and processes of sulfonation. As is know, more than 70% of wasted sulfuric acid are collected in ponds where they penetrate soil and escapes to water basins.

For producing tar-asphaltene concentrates we used sludge after purification of transformer and motor oils containing 36.3% of organic mass (including 21.2% of sulfonic acids) and 55.4% of sulfuric acid. A s a reducing component was taken asphaltite from gasoline deasphalting. Properties of the used gasoline asphaltite are listed in Table 1. Carbon adsorbents were formed alongside industrial technology [2,3]. It was impossible to introduce more than 15% of secondary petroleum residue to the mixture because this led to sticking granules together in the process of carbonization, owing to their low softening temperature not appropriate for the technology of sorbent manufacturing.

The porous structure was characterized by benzene vapor adsorption at 20°C using vacuum microbalances [4]. The pres volume was calculated proceeding from the total value of pores obtained from the value of real dencity relatively to water and apparent density determined by mercury procedure. Sorption properties were studied using the method of constant concentration of the targeted component and salt composition by changing

solution alongside the earlier described procedure [5]. Concentration of metal ions in solution after the contact with the adsorbent was measured using atomic adsorption spectrophotometry on a Percin–Elmer model 503 instrument. Selectivity coefficients toward nobel metals were determined from weight fractions of adsorbed silver and gold relatively to the total sum of all metals. Sorption properties toward noble metals was measured from two solutions of which one contained the following elements at the concentrations (mg/g): Au 1.03; Ag 0.83; Nu 93.4; Zn 29.40; Ni 1.02; Co 0.46. Due to faster saturation of the adsorbents with dicyanurates as compared with dicyanoregenerates, for determination of adsorption ability and selectivity toward silver were used solutions with minimum concentration of gold ions. Therefore the second solution had the following composition (mg/g): Au 0.1; Ag 0.9; Cu 63.2; Zn 55.8; Ni 0.48; Co 0.20.

The data obtained showed that using the petroleum residue allows obtaining the sorbent with high capacity factor (micro pores volume expressed in cubic centimeters per 1 cm3 of adsorbent layer) and good transport porosity. Development of the pores of all types is provided by the fact that the secondary petroleum residue contains various tar-asphaltene substances varied by the length of alkyl substituents which are dealkylated in a certain time period.

From the data in Table 2 is obviously that the adsorbent containing 13% of tar-asphaltene substances possess micropores in good enough volume and maximal sorption and selectivity properties can be achieved at conbustion loss 33.2%.

Thus we found that a simple procedure consisting in adding secondary petroleum residue without changing industrial technology the adsorbents with improved sorption and selectivity characteristics as compared with the perfect domestic adsorbent SKT could be obtained. Good selectivity of the obtained adsorbents gives a way for saturation them with metal containing by-products in a high concentration, which makes reasonable to use the latter as secondary raw material.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Reaction of α-Bromocarboxylic Acids with Hydrazine and Dimethylhydrazine

S. A. Malin, B. M. Laskin and A. S. Malin

Russian Scientific center "Applied Chemistry," St. Petersburg, Russia

Received March 13, 2007

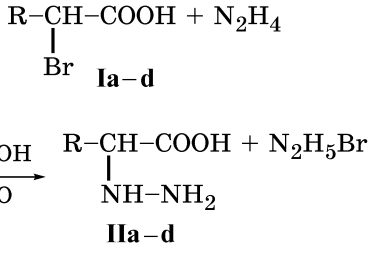
Abstract—Nucleofilic reaction of a series of α-bromocarboxylic acids with hydrazine and dimethylhydrazine is studied. High reactivity of α-bromocarboxylic acids is revealed and a series of α-hydrazinoarboxylic acids and *N*-(1-carboxyalkyl)-*N*,*N*-dimethylhydrazinium bromides are synthesized.

DOI: 10.1134/S1070427207120348

α-Bromocarboxylic acids are known as parent compounds for the synthesis of potentially biologically active compounds, α-hydrazino- and α-dimethylhydrazinocarboxylic acids, the analogs of aminoacids. These latter compounds show antiviral and antitumor activity and can serve as a basis for producing antibiotics, peptidomimetics and related substances [1–3].

Methods for the synthesis of α-hydrazinocarboxylic acids have not been sufficiently studied and the known data are mutually very contradicting in respect both conditions of carrying out the process and product yields [4–6]. Therefore we performed search of appropriate methods for the synthesis of α-hydrazinocarboxylic acids and study of main regularities of the process.

As the model targeted compounds we choose the following α-bromocarboxylic acids: α-bromopropanoic (**Ia**), α-bromobutyric (**Ib**), α-bromo-isovaleric (**Ic**) and α-bromophenylacetic (**Id**). These α-bromoacids were involved to the reaction of nucleophilic substitution with hydrazine and dimethylhydrazine according to the scheme:



where R is Me (**a**), Et (**b**), *i*-Pr (**c**) and Ph (**d**).

We studied influence of the reagents ratio, parameters of duration and temperature and solvent (medium) nature on the reaction proceeding and results. We found that reaction of compounds **Ia–d** with hydrazine proceeds smoothly enough at carrying out the process in the medium of aqueous ethanol at the molar ratio I : hydrazine = 1: 4–6, temperature 70–80°C and reaction dura-tion 6–8 h with high yield (50–70%) of compounds **IIa–d**. Reaction conditions of **IIa–d** are listed in Table 1.

The most smooth process occurs with 40–60% hydrazine hydrate which provides necessary solvation of removing anion in the process of nucleophilic substitution.

Isolation of α-hydrazinocarboxylic acids was carried out by concentrating the reaction solution (by 40 –50%) under vacuum followed by diluting with water and filtrating the product. The crystals formed were filtered off and recrystallized from 40% ethanol (α-hydrazinopropanoic acid or hydrazoalanine), from isopropyl alcohol (α-hydrazinobutyric acid), water (α-hydrazinoisovaleric acid) or ethyl acetate (α-hydrazinophenylacetic acid or hydrazinophenylalanine). The α-hydrazinocarboxylic acids obtained were characterized by means of elemental analysus, IR and ^{1}H NMR spectroscopy.

IR and NMR spectroscopy data (Table 2) and elemental analyses (Table 3) confirmed structure and composition of the obtained compounds.

The high reactivity of the bromine atom in α-bromocarboxylic acids in the reactions of nucleophilic sub-

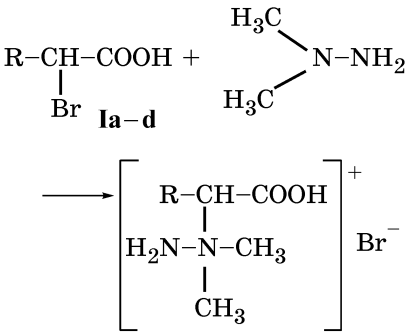
stitution with hydrazine hydrate allowed us to expect that dimethylhydrazine can also be involved in this process. The latter compound is known possessing highr enucleophilicity and basicity as compared with the unsubstituted hydrazine, and this should promote bromine substitution in the α-bromocarboxylic acids and should lead to practically unstudied α-dimethylhydrazinocarboxylic acids. We studied reaction of dimethylhydrazine with compounds **Ia–d**. As might be expected, dimethylhydrazine reacts with compounds **Ia–d** in absolute alcohol or acetonitrile medium smoothly. Small excess of dimethylhydrazine (1.05 to 1.1 mol per 1 mol of α-bromocarboxylic acid) was used and reaction was carried out at 40–60°C during 5–10 h leading to formation of *N*-(1-carboxyalkyl)-*N*,*N*-hydrazinium bromides **IIIa–c** in 60–70% yield according to equation:



Ia–d **IIIa–d**

where R is Me (**a**), Et (**b**), *i*-Pr (**c**) and Ph (**d**).

The data on the synthesis conditions of hydrazonium salts **IIIa–d** are comprised in Table 4.

Isolation of the reaction products included concentrating the reaction solutions under vacuum, cooling from –5 to –10°C, filtrating the crystals formed and recrystallizing them from 2:1 isopropyl alcohol–dioxane mixture. It is noteworthy that the compounds obtained are hygroscopic ones and require use of absolute solvents both in the steps of synthesis and recrystallization.

Nature of the obtained compounds is confirmed by the data of IR and ^{1}H NMR spectroscopy (Table 5) and the data of elemental analysis (Table 6). Presence in the IR spectra of characteristic absorption bands in the region of 3220–3240 cm^{-1}characteristic adsorption attests presence of protonated NH_3^+ group and points probably to zwitter-ionic structure of α-dimethylhydrazinocarboxylic acids. This also is confirmed by ^{1}H NMR spectra where occur signals (multiplet) in the range 3.1–3.5 ppm depending on substituent R (500 MHz, DMSO-d_6) of α-methine fragment; presence of clearly defined signal at 5.6 ppm (4H) and absence of signals of OH and NH_2 groups points probably to zwitter-ionic structure of the compounds.

Like with hydrazinocarboxylic acids, the dimethylhydrazinium salts are characterized by signal of methine group at 3.05–4.3 ppm (multiplet), by signal of methyl groups at 3.5–3.6 ppm (singlet), while the signal at 5.35–5.67 ppm (singlet) is probably in correspondence with the existence of compounds **IIIa–d** as internal salts.

EXPERIMENTAL

^{1}H NMR spectra are registered on a Bruker AM 500 spectrometer (internal reference TMS) in DMSO-d_6. IR spectra are obtained on a IKS-29 spectrmeter from the pastes with Vaseline oil.

General procedure for preparation of α-hydrazinocarboxylic acids IIa–Id. To a three-necks flask equipped with mechanical stirrer, reflux condenser and

Note: Content of bromine ion in compounds **IIIa–d** was analysed by the mercurymetric method.

thermometer was placed 20–30% solution of α-bromocarboxylic acid in 60–80% aqueous ethanol and precalculated amount of 80% hydrzine hydrate (bromocarboxylic acid to hydrazine hydrate mole ratio is 1 : 4–5) was added dropwise. The reasction mixture was heated to slow boiling, kept at this temperature for 4–8 h and then left for 12 h at 0–5°C. The crystals formed were filtered off and recrystallized from water or alcohol, and dried. Yield of α-hydrazinocarboxylic acids 60–70%.

Procedure for preparation of *N*-(1-carboxyalkyl)-*N*,*N*-hydrazinium bromides IIIa–c. To a three-necks flask equipped with mechanical stirrer, reflux condenser and thermometer was placed 20–30% solution of α-bromocarboxylic acid in anhydrous acetonitrile. The solution was cooled to 10–15°C and to it was slowly dozed precalculated amount of 40–50% solution of dimethylhydrazine in acetonitrile (bromocarboxylic acid to dimethylhydrazine mole ratio is 1 : 2–2.5) at the temperature not below 20°C. The reaction mixture was then slowly heated to 40–50°C, kept at this temperature for 3–5 h monitoring continuously formation of mineral bromine (mercurymetry). After completing the process, the reaction mixture was cooled to 0–5°C, the crystals dropped were filtered off, washed with isopropyl alcohol and dried in a vacuum dessicator. Yield of hydrazonium salts **IIIa–d** is 60–75%.

CONCLUSION

The α-hydrazino- and α-dimethylhydrazino-derivatives of a series of carboxylic acids are synthesized, the process of synthesis regularities are revealed, some of physico-chemical properties of the compounds obtained are measured and nature and assumed salt structure of these compounds are established.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Modification of Petroleum Polymer Resin from C9 Fraction with Maleic Acid and its Application to Protecting Treatment of Wood

A. N. Chernaya, O. N. Filimonova, and S. S. Nikulin

Received June 2, 2007

Abstract—Modification of petroleum polymer resin with maleic acid is studied and changes in acid number, molecular weight and bromine number of the forming product in time are determined. The modified petroleum polymer resin is shown useful for enhancing hydrophobic properties of wood.

DOI: 10.1134/S107042720712035X

Wastes and by-products formed and accumulated in the enterprises of chemical and petrochemical profiles are numerous and various both in quality and quantity aspects. Solution of the problem of treatment and use of the formed by-products of industrial and social origin is closely connected with environment saving against pollutions and complex consumption of sources of raw materials whose reserves fall down. Development of new technologies and solutions of treatment of secondary sources increases performance of processes, promotes complete and economical consumption of expensive raw materials and allows to increase assortment of products.

One of such side products is hydrocarbon C_9 fraction. On the basis of this fraction now is produced on commercial scale the petroleum polymer resin used as a film-forming component in paint and varnish compositions [1]. A significant advantage of this material is low color depth (less than 100 units in iodine color scale) which allows applying it in transparent paint and varnish materials. In [1] was described modification of petroleum polymer materials with maleic anhydride and acrylic monomers and esters which allow increasing their resistance to oxidation. The petroleum polymer materials are recommended for application at producing paper, cardboard, plates, etc.

An interesting pathway in this respect is considering a possibility of modification of petroleum polymer resin from C_9 fraction with maleic acid by their join high temperature treating. This process should afford material of complex composition with inclusion of destruction products, the products of reaction of maleic acid with petroleum polymer resin and others. It can be assumed that the macromolecules containing anhydride and acid groups in the chain are interesting for creation of polymer film-forming materials, complexing agents, biologically active substances and other valuable materials [2].

Introducing maleic acid into the petroleum resin composition allows admitting to the latter some useful properties. Appearance of functional groups in the molecules of the polymer increases its polarity. This is significant in particular at the application of these products for protecting wooden materials which contain as a main components cellulose, gemicellulose and lignin bearing many various functional groups. This will promote interaction of the modifying agent and wooden components functional groups with formation of hydrogen bonds and polymer carcass. Such disadvantages of the modifying agent as its washing out from the products and similar at their exploitation decrease. The wooden material density grows and it acquires enhanced strength and water repelling properties. Besides, wood of low value species acquires light-brown to dark-brown tone and by properties approaches to the wood of valuable species.

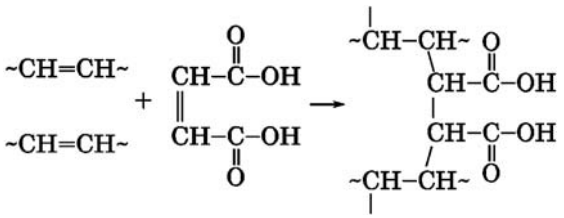
In the first step we carried out modification of petroleum resin based on C_9 fraction produced on commercial scale. The resin main components are: 1,3-cyclopentadiene, styrene, α-methylstyrene, vinyltoluene

and dicyclopentadiene. The following modification procedure was appied:

To reactor was loaded the peroleum resin based on C_9 fraction and introduced maleic acid in amount 2 to 9% of the resin. Reactor was hermetically closed and the process was carried out at 110, 150 or 190°C for 2 to 8 h.

The process was monitored by measuring the system viscosity, molecular weight, acid and bromine numbers, taking samples from the reactor periodically. The results of investigations are listed in Tables 1–3.

Analysis of experimental observations leads to conclusion that increase in content of maleic acid in the polymer resin based on C_9 fraction leads to increase in acid number and molecular weight with simultaneous decrease in bromine number showing its unsaturation. Decrease in unsaturation, that is, in the number of double bonds, can result from the fact that high temperature treatment of the composite leads to grafting maleic acid



to tar components in polymer resin and to cross-linking of oligomer molecules. This is confirmed by increasing in molecular weight of the obtained products. Necessary to note that increase in the process duration to 8 h leads to increase in molecular weight and acid number and decrease in bromine number.

Further increase in duration of the modification process leads to decrease in acid number. This can be connected with maleic acid loss and its transforming into maleic anhydride. Proceeding of decarboxylation reaction is also possible [2]. Molecular weight of the products thus obtained continues to increase, while bromine number falls down. The system viscosity grows.

Study of temperature dependence of the modification process showed that rather high temperature should be maintained, 150°C or higher. Decrease in temperature to 110°C leads to decrease in the rate of molecular weight and acid number and growing and to bromine number falling.

Analysis of experimental data leads to conclusion that modified polymers thus obtained have not high molecular weigh and can be classified as oligomers. Due to low molecular weight and hence small size of the molecules they can relatively easy penetrate porous materials filling up processing defects, increasing strength characteristics and water repelling properties of a hardware. A special interest is application of oligomeric products in wood

treatment industry because wood and materials based on it are particularly sensitive toward various aggressive media.

Next step of this study is revealing effect of the product obtained from petroleum resin C_9 fraction and maleic acid as impregnating material for increase hydrophobic properties of wood.

For the study was used a product obtained with maleic acid content 6%; treatment was carried out for 6 h at 150°C. The product had the following characteristics:

(a) Content of product in solution 50%,
(b) Acid number 11.2 mg of KOH per 1 g,
(c) Bromine number 97 mg of Br_2 per 100 g,
(d) Molecular weight ~ 2000.

We studied the process of modification of birch wood using the method of experiment planning. Effect of such factors as temperature and duration of impregnation, temperature and duration of thermal treating were studied using fourth order Greek-Latin squire plan [3]. For each factor were taken four leves of varying: temperature of

impregnating composition (Factor A) 40, 70, 100 and 130°C, impregnating duration (Factor B) 1, 3, 5 and 7 h, temperature of thermal treatment (Factor C) 110, 130, 150 and 170°C, duration of thermal treatment (Factor D) 1, 3, 5 and 7 h.

Properties of the birch samples after modifying impregnation were revealed by measuring such characteristics as absorption of water, radial and tangential swelling after one and thirty days. The matrix of experiment planning is shown in Tables 4 and 5,

The treatment was conducted as follows: A preliminary dried sample after weighting and size measuring was poured into impregnating bath with petroleum resin based on C_9 fraction modified with 6% of maleic acid and kept for as given period at a given temperature. Impregnated sample was taken out of the bath, dried and treated thermally. After thermal treatment the sample was cooled to room temperature, weighed, and its size was registered. Then the sample was poured to water. Water adsorption was measured by gravimetric method registering change in the wood weight. Content of modified tar-like substance in the wood achieved 50%, depending on the conditions defined by above considered factors. Swelling was determined by measuring cross section of each sample in radial and tangential directions.

After computational treatment of experimental results we obtained regression equations describing contribution of these factors to water resistance after 1 and 30 days.

After one day:

Water absorption,%: $Y_{wa} = 1.58 \times 10^{-4}$ (29.48 – 0.12a)(21.52 – 0.74b)(20.57 – 0.0147c)(19.82 – 0.32d);

Radial swelling, %: $Y_{rs} = 3.39 \times 10^{-2}$ (6.77 – 0.04a)(4.22 – 0.27b)(4.66 – 0.0112c) (3.58 – 0.12d);

Tangential swelling, %: $Y_{ts} = 3.42 \times 10^{-3}$ (11.06 – 0.0497a)(7.82 – 0.29b)(8.30 – 0.0118c)(7.29 – 0.16d);

After 30 days:

Water absorption,%: $Y_{wa} = 2.60 \times 10^{-6}$ (91.34 –0.21a) (90.62 – 4.31b) (71.67 – 0.001c) (74.68 – 0.66d);

Radial swelling, %: $Y_{rs} = 2.51 \times 10^{-3}$ (10.23 – 0.0326a) (8.65 – 0.31b) (9.70 – 0.0166c) (7.89 – 0.13d)

Tangential swelling, %: $Y_{ts} = 9.33 \times 10^{-4}$ (14.85 – 0.0524a) (11.31 – 0.26b) (12.53 – 0.0164c)(11.27– 0.25d);

The best conditions of wood treatment that provides minimum water absorption and swelling of samples are:

Tangential swelling, %	3.54 / 3.13	6.60 / 5.62
Radial swelling, %	0.94 / 0.89	4.68 / 3.27

temperature of impregnating composition 130°C, impregnation duration 7 h, temperature of thermal treatment 170°C, duration of thermal treatment 7 h. From the experimental observation we can conclude that properties of the obtained samples depend mostly on the duration of impregnation and thermal treatment. Effect of temperature of impregnating composition and thermal treatment within the applied range are less significant.

Calculated and experimental values of the characteristics of samples are well matching (Table 6).

CONCLUSIONS

1. Modification of petroleum polymer resin with maleic acid leads to increase in molecular weight of the obtained product and decrease in its bromine number.

2. The petroleum resin obtained can be used for enhancing hydrophobic properties of natural wooden material.

3. It is established that the best properties of impregnated wood samples are achieved at the impregnation temperature 130°C, impregnation duration 7 h, thermal treatment temperature 170°C and duration of thermal treatment 7 h.

Abstract—Upper critical solution temperatures (UCST) and mutual solubilities of phenol and water were studied with 0.45 mmol kg^{-1} (mm kg^{-1}) dodecyl trimethylammonium bromide, trimethylsulphoxonium iodide and methyltrioctylammonium chloride. The surfactants decrease the UCSTs by about 0.51–1.98°C with slight enhancement in mutual solubilities. Mole fractions of surfactants were restricted to 0.002 to 0.005 range, their hydrophilic and hydrophobic interactions enhance solubility of phenol in water by about 0.0456 % as compared to water–phenol systems.

1. INTRODUCTION

Currently immiscible solvent systems are in focus for study of several biological and biophysical processes with different chemical potentials of the solvents. The immiscible solvent systems are of tremendous use due to their energy gradient that becomes a driving force for several auto control processes. The study of energy gradient of several immiscible solvent sysyetms is industrially significant. Electronic configurations of the solvents do develop the energy gradient in the solvent systems, and prevents mutual mixing the solvents. Hence surfactants with hydrophilic and hydrohopobic interactions do interact with respective immiscible solvents and decrease the energy gradient. Such systems become highly potential systems for chemical processes and develop with specific Upper critical solution temperature (UCST). The UCST denotes a temperature above of which the two phase liquid system develops a single phase liquid. It is a system dependent parameter hence for a particular system like water and phenol its value is fixed and due to its nature. It is used as an effective yardstick for additives added to water and phenol and their UCST data are determined. The variation in UCSTs with an additive elucidates structural interactions of solvent systems. The dodecyl trimethylammonium bromide, methyltrioctylammonium chloride and trimethylsulphoxonium iodide have chosen for study and interact with water as well as phenol due to their hydrophilic and hydrophobic parts respectively, and hence are denoted as surfactants and reduce interfacial surface tension of immiscible phases and facilitate intermixing at lower UCST. Hydrophilic and hydrophobic interactions are always of interest due to several [1] uses in nanotechnology, biotechnology and microscale processes. Enormous studies on them are cited but no work in critical solutions is considered. Our work focuses on them in upper critical solutions using three mentioned above different cationic surfactants. Another surfactants (denoted as CTAB, TEAB, CPC, CPB, LDS, SDS, CA, PEG 200, EGMDE) were studied elsewhere [2]. Such study is highly recommended for green and supramolecular chemistries [1] as to how the surfactants influence mutual solubilities that would curtail an excess use of materials to develop microscale and miniaturized processes.

The surfactants are frequently used in several solubility based processes [3–5] like separation of proteins from their natural sources where the UCSTs

are useful. The dodecyl trimethylammonium bromide, trimethylsulphoxonium iodide and methyltrioctylammonium chloride are highly used in biosciences for several purposes so their influence on solubility of solvents assists the separation and extraction processes. The UCSTs are industrially useful [5, 8] (Zhang et al., 2007) to develop the proteins, amino acids and vitamins based bionanoparticle for biochips and DNA biotemplates [6–10]. The critical solutions with surfactants are useful for determination cloud point temperatures especially by food scientists and biophysical scientists [11–13, 4]. Temperature-dependent surfaces and interfacial kinetics remain relatively unexploited in thin-film sensing applications that rely on optical surface-sensitive techniques like surface plasmon resonance spectroscopy. Currently Singh [12] has reported Survismeter and formulated Man Singh equation for friccohesity that focuses interfacial surface forces which influence the intermixing of the immiscible phases [12, 14]. These techniques are inherently sensitive to the optical properties of the bulk solution in contact with the thin films, hence UCST data for the latter at the conditions of interests are useful. The UCST and the refractive index may have interesting correlations.

The UCSTs with a wide range of additives would serve a wider purpose in solution engineering of immiscible solvents for interactions with industrially useful molecules. The UCSTs with hydrophilic and hydrophobic interactions define cloud points with additives of thermodynamic significance with potential uses in soaps, detergents, textiles, inks, paint and pigments, solvent extractions, and disinfectant solutions. Industrially phenol is widely used as a disinfectant where its solubility in different solutions is highly influenced by the ingredients of the solution. Its aqueous solutions with additives could be of some use in biotechnology and biophysics as it is used to inhibit the early degradation of fish meat etc. Similarly the surfactants investigate their influence on the intermixing of the phenol–water phases due to their hydrophilic and hydrophobic interactions.

2. MATERIALS AND METHODS

Stock solutions of 0.5 mm kg^{-1} dodecyl trimethylammonium bromide, trimethylsulphoxonium iodide, methyltrioctylammonium chloride were prepared separately in water, w/v. Initially water and phenol in a 2:8 ratio were taken in optical cells as reference phases, the cell was mounted on a stainless steel stand at normal temperature. The cell with contents was remained dipped in a paraffin oil of the thermostat with ± 0.05°C control measured with a Beckmann thermometer. The contents were heated at a rate of 1°C min^{-1} stirring with a glass stirrer 50 rpm till the phases disappeared where their miscibility increased and approaching to a point where both the components are completely dissolved with a homogenous single phase. This temperature is termed a mutual miscibility temperature (MST). The heating was stopped and the cell with contents was air cooled for reappearance of the phases. The reappearance and disappearance of the phases develop a cloud hence the temperature at which the cloud is developed is called a cloud point temperature it coincides with the MST. Hence the MSTs for disappearance of a cloud point or turbidity and a reappearance of the cloud point were recorded. About 30 subsequent additions of the 2×10^{-1} dm^3 water were made and the MSTs were recorded.

After the water–phenol system, the cell was cleaned and rinsed with the solution in question for cloud point temperature measurements. For MSTs with each additive, a corresponding stock solution was used in place of water. An optical cell was made up of Borosil glass of 15 cm in length and a 1.5 cm radius (r) or a 3 cm inner diameter, the cell capacity was determined with $\pi r^2 h$, the r = 1.5 cm and h = 15 cm, which gave 106 cm^3 cell volume that accommodates more than 30 subsequent additions. About 36 cm^3 vacant volume of the cell was left unoccupied for safety measures for preventing evaporation and an escape of solution. The top end of the cell was properly blocked after inserting contact and Beckman thermom-eters, and an immersion rod. A gentle heating from $T = 298.15$ K of 1 min^{-1} was made with a 25 watt-immersion rod connected to an automatic electric relay through a contact thermometer with smooth stirring (glass stirrer) with wiper motor. The solutions were prepared w/w, using 1×10^{-5} g accuracy 100 DS Dhona balance, Instruments Pvt. Ltd, Calcutta India, and a calibrated thermometer were used to note down the temperatures. The water de-mineralized, de-ionized and degassed was used

2.1. Turbidity Measurements

At a point slightly below the temperature of a disappearance of cloud point, the heating was reduced to 1°C min^{-1}, due to a sharp disappearance. The phase dissolution was viewed with an eye lens of a cathetometer kept 1 m away from the thermostat. Near a point of disappearance of the cloud, the heating was stopped and the temperature at which the turbidity vanished was noted

UCSTs for surfactants, mole fraction of phenol and additives at UCST

Additives	x_{phenol}, %	x_{water}
Phenol	0.0874	0.9126
Dodecyl trimethylammonium bromide	0.0986	0.9014
Trimethylsulphoxonium iodide	0.0711	0.9289
Methyltrioctylammonium chloride	0.1131	0.8868
	$x_{additive}$	UCST ± 0.05 K, °C
Phenol	0	341.4 K
Dodecyl trimethylammonium bromide	0.00136	339.4 K
Ttrimethylsulphoxonium iodide	0.00179	339.9 K
Methyltrioctylammonium chloride	0.00122	339.9 K

as a transition point temperature. After this, the mixture was air-cooled till a clear turbidity reappeared, the temperature of this point was also noted. For the air-cooling, a slightly colder air than the temperature of a paraffin bath was passed around the cell through a copper coil inserted in the paraffin wax bath. The air was propelled with a booster pump at s flow rate of 2000 cm^3 min^{-1} from an air cooler fitted separately.

2.2. Chemicals

Dodecyl trimethylammonium bromide (Sigma, D 5047), trimethylsulphoxonium iodide (Fluka, 92763) and methyltrioctylammonium chloride (Fluka, 69485) and phenol (Merck, 1/17847) were used as received. Demineralized water was triply distilled with KOH and degassed. The chemicals were dried for 24 h, before their mp and stored in a P_2O_5 filled desiccator till use. For each ratio the MSTs were plotted against corresponding phenol mole fractions (x_{ph}). The mole fractions below the curve lead to two phases and above the curve a single phase solutions. The component designated as solvent dissolves another designated as solute either at normal or slightly higher temperatures but initially with compositions of each the cloud point temperatures are higher. Hence wider compositions with lower differences are studied with several subsequent additions. The systems with surfactants are treated as ternary systems and mole fractions of each component are calculated at cloud point temperatures. An apex of a curve is denoted as UCSTs.

2.3. Calculations

The moles of each component were determined for each set of solution along with critical compositions (CS_S) of corresponding MSTs. The MSTs were plotted on the y-axis against corresponding x_{ph} on an x-axis. An apex of this curve gives values of the $UCST_S$ and CS_s, the data are given in Table 1. The mole fractions of each additive were calculated including an amount of previous subsequent additions.

3. RESULT AND DISCUSSION

The UCST and mutual solubilities for phenol + water show a close agreement with those of the literature [15–17] with T = (273.15 ± 0.05) K and ± 0.25°C errors respectively. The UCSTs with additives remain near those of the water"phenol system (Table 1) with greater solubilities of the phenol respectively at lower UCST. The surfactants produce lower UCSTs than of the water"phenol. This infers that they develop hydrophilic and hydrophobic interactions. The UCSTs of surfactants are as trimethylsulphoxonium iodide = methyltrioctyl-ammonium chloride > dodecyl trimethyl-ammonium bromide, the dodecyl trimethylammonium bromide effectively develops the hydrophilic and hydrophobic interaction with higher mutual solubility. However the methyltrioctylammonium chloride and trimethylsulphoxonium iodide show slightly higher UCSTs values by 0.5 than those of the water"phenol, hence these develop weaker hydrophilic and hydrophobic interactions. A close comparison of the molecular structure of dodecyl trimethylammonium bromide with an alkyl chain of 12 carbon atoms develops a stronger hydrophilic interaction but methyltrioctylammonium chloride and trimethyl-sulphoxonium iodide with an alkyl chain of 12 carbon atoms and an alkyl chain with 3 carbon atoms respectively develop weaker hydrophobic and stronger hydrophilic interactions due to N^+ and Cl^- with methyltrioctyl-ammonium chloride and the O atom of trimethylsulphoxonium iodide. Hence surfactants with a longer alkyl chain develop stronger hydrophobic interaction due to higher solubility in phenol rather than that of the water. Hence the surfactants with a longer alkyl chain develop weaker hydrophilic interactions. Further a comparison of halide atoms of their functional groups vis-a-vis UCSTs show their placement as $I^- = Br^- > Cl^-$. Hence the critical review of UCSTs vis-à-vis structures of trimethylsulphoxonium iodide and methyltrioctyl-ammonium chloride infer that hydrophobic 3-CH_3 groups of trimethylsulphoxonium iodide outweigh the hydrophilic interactions due to $O{=}S^+{-}I^-{-}$.

Hence UCST is higher due to higher thermal energy needed for dissolving $O{=}S^+{-}I^-{-}$ water boundaries.

Perhaps the $O{=}S^{+}{-}I^{-}$ likes the geometry of the $O{=}S^{+}{-}I^{-}{-}H_2O$ towards the water phase with stronger dipolar interactions with H_2O but the I^{-} also develops stronger induced potential or polarizability. But methyltrioctylammonium chloride's Cl^{-} atom has a slightly stronger hydrophobic interaction than that of $O{=}S^{+}{-}I^{-}$ due to a 0 carbon atom chain that dominates over the weaker hydrophilic interactions of $N^{+}{-}Cl$, where the Cl^{-} is a small sized anion and does not induce any potential. Thus $O{=}S^{+}{-}I^{-}$ compensates more share to the higher UCSTs and $N^{+}{-}Cl$ does not, but the 12 carbon chain do compensates for the same.

3.1. Atomic Size Do Influences the UCSTs

The UCST of surfactants with halide atoms are listed is as $I^{-} = Br^{-} > Cl^{-}$, and is correlated to the nonbonding electron transitions due to the greater electro negativity of the Cl^{-} atom. The nonbonding electrons on Cl^{-} hardly undergo energy change but of I^{-} on trimethylsulphoxonium iodide is loosely bound and can undergo energy change. They strongly reorient the solvent structures due to a cage model of water that lead to develop weaker interactions with. Perhaps it is difficult to get fitted the hydrophobic part of them in water but aligns towards phenol. Similarly the hydrophilic parts align to water the H_2O. Thus a loose film between phenol and water interface is developed that initiates a soap action on a liquid–liquid interaction model. Hence our studies are restricted to surfaces only where the surfactant molecules get dispersed in phenol"water phases but not at all to penetrate bulk to either. The additives were in water which on contact of phenol aligns to phenol and water surfaces. However for high x_{ph} the @ slightly decreases. Hence the additives are more effective with lower x_{ph} but with lighter x_{ph}. The phenol interaction might weaken the sharper effects of additives hence our studies are useful for bioscience process occurring at slightly higher temperatures.

4. CONCLUSION

The surfactants develop lower UCST values with higher mutual solubility at lower temperatures of immiscible solvents.

PROCESSES AND DEVICES OF CHEMICAL MANUFACTURES

Modeling Pulse Apparatus for Processing Suspension with Periodical Unload of Concentrated Precipitate

R. Sh. Abiev

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received September 11, 2007

Abstract—The principle of work of a new apparatus for processing suspension with periodical unloading of concentrated precipitate is described. Mathematical model of the apparatus is created that allow calculating main technological parameters of the apparatus. The apparatus feature is application of potential energy accumulated by the compressed gas in the pulse chamber for the regeneration of the separating screen. The experiments with laboratory model of the apparatus allow to recommend this mathematical model for practical application.

DOI: 10.1134/S1070427207120373

INTRODUCTION

The apparatuses for processing suspensions are widely used in chemical, food, pharmacy and other related branches of industry. The apparatus described in this publication is the most appropriate for the following processes:

1. Filtration where solid phase particles clog up the pores of the separating element (concentrating suspensions with less than 0.1% content of solid phase), e.g., filtration of juices in the food industry, cellulose solutions at producing artificial fiber, and purification of mineral oil.

2. Concentrating suspension in concentrating filters with the working cycle consisting of filtration and removing the precipitate formed from the separating element by the filtrate back flow.

3. Filtrating with formation of solid phase layer on the surface of the separating element (at concentration of solid phase in the suspension more than 1%).

The process of filtration can be combined with other technological processes such as impregnation of porous material, washing, extraction, ion exchange, heterogenic catalytic reactions. With appropriate filtering separators, a micro filtration process can be performed.

Such apparatus can be recommended in particular for the cases of adhering and compacting precipitates and the precipitates hardly removable from the filtering elements, when traditional filters do not work.

In this publication we describe the principle of working a new energy saving pulse apparatus for processing suspensions, with automatic periodical unloading the concentrated precipitate. We conducted theoretical and experimental investigation of such apparatuses.

At the development of the proposed here apparatus we were aimed at the following tasks:

1. Automatic control of the process of unloading concentrated precipitate from the apparatus with periodical regeneration of filtering screen without consuming additional energy,

2. Use of potential energy of filtrate for the regeneration, which should decrease energy consuming, increase reliability of the apparatus and simplify operating.

CONSTRUCTION AND PRINCIPLE OF ACTION OF THE APPARATUS FOR THE PROCESSING OF SUSPENSIONS

Pulse apparatus for processing suspension [1] (see scheme in Fig. 1) consists of housing body 1 bearing connecting pipe 2 – 5. Filtrating element 6 separates concentrating chamber 7 and filtrate collecting chamber

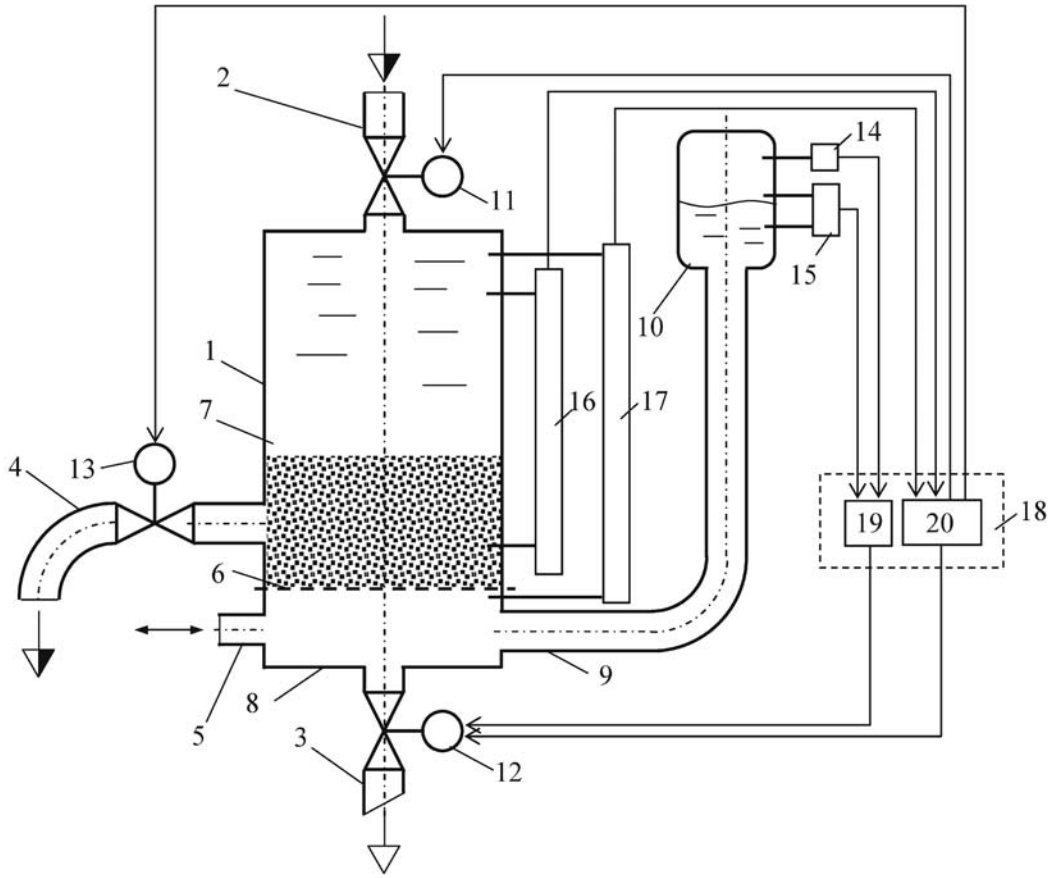

Fig. 1. Scheme of pulse apparatus for processing suspension (concentrating filter). (1) housing body, (2–5) connecting pipes: 2 for feeding with suspension, 3 for filtrate outlet, 4 for concentrated suspension outlet, 5 for passing pulses; (6) filtrating separator, (7) concentrating chamber, (8) filtrate collecting chamber, (9) pipe line, (10) pulse chamber, (11–13) controlled valves, (14–17) probes, (18) control system, (19) control block for valve 12, (20) control block for valves 11–13.

8. Pipe line 9 connects the filtrate chamber 8 with pulse chamber 10. Connecting pipes for feeding with suspension 2, filtrate outlet 3 and concentrated suspension outlet 4 are equipped with control valves 11, 12 and 13, respectively. The apparatus is also equipped with probes 14–17 and control system 18, consisting of two subsystems: block 19 for control over state of valve 12, and block 20 controlling states of valves 11–13.

The apparatus operates in cyclic regime: steps of filtration and regeneration are alternating.

1. Filtration Period

Valve 13 is closed, valve 12 is partially open, valve 11 is open completely. Through connecting pipe 2 the apparatus is feed with suspension. In time on the filtrating separator 6 is formed layer of solid phase while to the chamber 8 through the filtering separator 6 continuously passes filtrate. A part of the filtrate is removed from the apparatus through the connecting pipe 3 and valve 12, another part is passed through the pipe line 9 to the pulse chamber 12 compressing stepwise the gas (air) in the chamber. Thus, pressure in the pulse chamber 10 increases stepwise and the compressed gas accumulates potential energy. Pressure pulses coming to the system through connecting pipe 5 from the pulse generator (not shown) promote periodical disintegration of the solid phase formed on the filtering separator 6 and damage of bonds between the solid phase particles. This improves conditions of filtration through the solid layer and elongates the period of filtration before regeneration. Simultaneously with the filtration process, in the apparatus can proceed the abovementioned processes of chemical reactions and mass exchange.

2. Regeneration Period

During accumulation of solid phase, either resistance of the latter achieves limiting value, or the precipitate fills whole space of the concentrating chamber 7,

resulting in appearance of signals from probes 16 or 17, respectively. Then valves 11 and 12 close connecting pipes and then valve 13 quickly opens pipe 4; at this moment passing pulses through valve 5 can be stopped. Owing to the pressure difference between chamber 10 and atmospheric pressure at the outlet line 4 the liquid in the pulse chamber and pipe line 9 moves up through the filtering separator 6 like a pulse generating hydraulic impact, passes through the solid phase damaging bonds between its particles. Thus the accumulated potential energy is transformed to kinetic energy of moving the liquid interacting with the precipitate, promoting damage of dense structure of the solid phase. The solid layer becomes some diluted with a portion of liquid coming through filtering separator 6 improving mobility of the solid, and the concentrated suspension under the pressure is ejected through the valve 13 and pipe 4 to a collector (not shown). This results in regeneration of filtering separator 6. Then valve 13 closes and next cycle of apparatus work starts.

A feature of the proposed apparatus is automatic control over opening valves 11–13 by the control system 18 using the signals from the probes 14–17. The probes 15 and 16 are two-level, that is, they have upper and lower switching edges. In the first step the valve 12 is partially open, its state is controlled by pressure probe 14 and level probe 15; signals of the two latter achieve control block 19 and passed to valve 12. The valve 19 is completely open and 13 closed, they are controlled by probes 16 and 17 and control block 20. In the second step, the signals from probes 16 and 17 achieve block 20 which closes valves 11 and 12 and opens valve 13.

Thus, formation of dense solid is counterforced by pulses in the filtration period and by impact motion of a part of filtrate in the regeneration period.

MATHEMATICAL MODEL OF PULSE APPARATUS FOR PROCESSING SUSPENSION

Mathematical model of pulse extractor has been described [2]. Its works similarly to the filter that we describe now. A feature of the filter distinguishing it from the batch-operating extractor is the unsteady process of the solid phase accumulation. Our description pays attention to this process mainly.

Let us consider the step of filtration. In an arbitrary time moment the filtrate consumption passing through the filtering screen with solid on it is:

$$Q_{\mathrm{f}}(t) = \frac{\Delta p}{r_{\mathrm{fs}} + r_{\mathrm{pr}}} \tag{1}$$

Consumption of suspension feeding into the filter and consumption of solid phase cantained in the suspension equal, respectively, to:

$$Q_{\mathrm{s}} = \frac{Q_{\mathrm{f}}}{1-\varepsilon_{\mathrm{s}}} \tag{2}$$

$$Q_{\mathrm{sp}} = Q_{\mathrm{s}}\varepsilon_{\mathrm{s}} \tag{3}$$

Gains in volumes during a short time gap Δt are:

– solid phase

$$\Delta V_{\mathrm{solid}} = Q_{\mathrm{sp}}\Delta t \tag{4}$$

– precipitate (including solid particles and pores between them)

$$\Delta V_{\mathrm{pr}} = \frac{Q_{\mathrm{sp}}\Delta t}{\varepsilon_{\mathrm{pr}}} \tag{5}$$

– liquid in the precipitate pores

$$\Delta V_{\mathrm{pore}} = \frac{1-\varepsilon_{\mathrm{pr}}}{\varepsilon_{\mathrm{pr}}} Q_{\mathrm{sp}}\Delta t \tag{6}$$

– liquid below the filtering screen (the filtrate minus the liquid in pores) which equals to diminishing in the gas volume in the chamber for the filtrate accumulation 8 and pulse chamber 10 (see Fig. 1)

$$\Delta V_{\mathrm{gas}} = Q_{\mathrm{f}}\Delta t - \Delta V_{\mathrm{pore}} \tag{7}$$

Gain in the precipitate height during the short period Δt is:

$$\Delta h = \frac{\Delta V_{\mathrm{pr}}}{F} \tag{8}$$

Taking into account that filtration rate is low, we accept isothermal law for changes pressure in the pulse chamber:

$$p_2(t) = \frac{p_{20}V_{20}}{V_2(t)} \tag{9}$$

Resistance of the precipitate layer reduced to the filter section was taken laminar and was calculated through Darsy's filtration constant [3]:

$$r_{pr}(t) = \frac{2\mu\zeta^2 S^2 (1-\varepsilon_{pr})^2}{\varepsilon_{pr}^3 F} h(t) \quad (10)$$

The constructed model can be reduced to Volterra equation of the second kind for the filtrate consumption calculation:

$$Q_f(t) = \frac{1}{r_{filter} + A\int_0^t Q_f(\tau)d\tau}\left(p_1 - \frac{p_2 V_{20}}{V_{20} - B\int_0^t Q_f(\tau)d\tau}\right) \quad (11)$$

where the following constants are used:

$$A = \frac{2\mu\zeta^2 S^2 (1-\varepsilon_{pr})^2 \varepsilon_S}{\varepsilon_{pr}^4 F^2 (1-\varepsilon_S)}, \quad (12)$$

$$B = 1 - \frac{(1-\varepsilon_{solid})\varepsilon_S}{\varepsilon_{solid}(1-\varepsilon_S)} \quad (13)$$

The system of equations (1) – (12) was solved by Euler method. The calculated plots of most important technological parameters against time for the conditions of the carried out experiments are shown in Fig. 2.

The plots obtained allows to trace duration of the filtration cycle $\hat{o}_c$ for achieving minimal allowed consumption of filtrate (in Fig. 2 it is defined equal 0.2 part of starting filtrate consumption, that gives $\hat{o}_c$ = 171 s), after that regeneration of filtering screen seems reasonable.

EXPERIMENTAL

The experiments included solving of the following tasks:

– examining efficiency of installation in the steps of filtration and regeneration.

– experimental testing the constructed mathematical model.

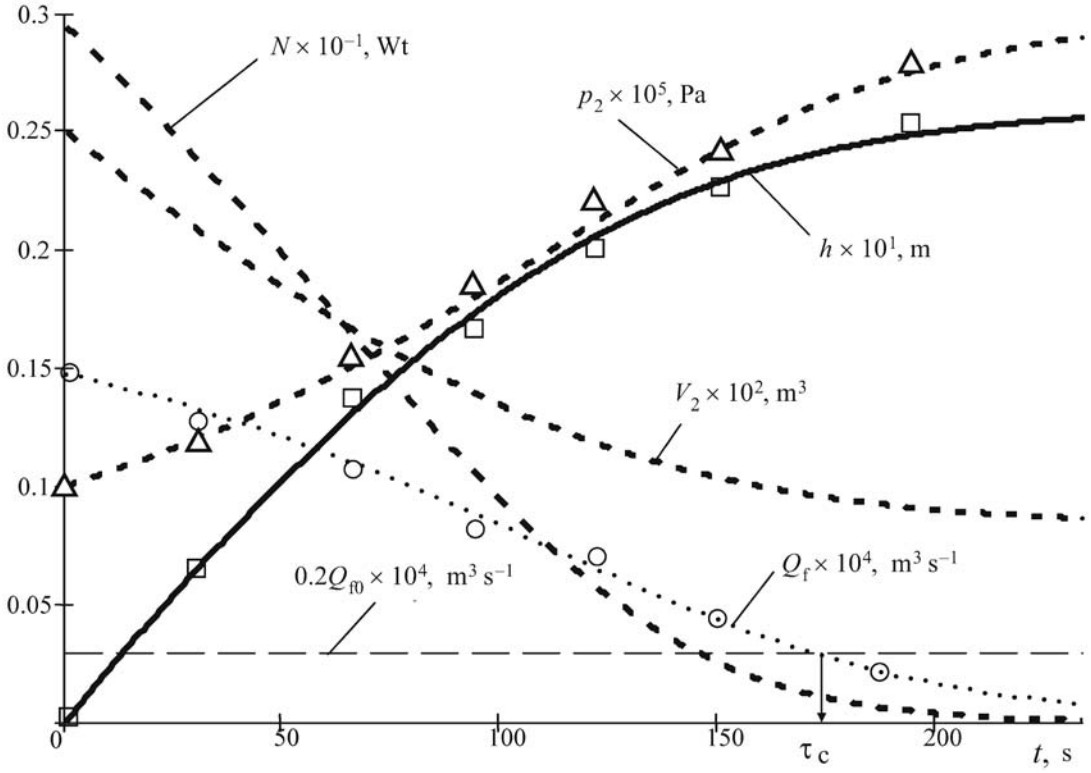

Fig. 2. Time dependence (t, s) of precipitate height h, filtrate consumption Q_f, gas volume V_2 and gas pressure p_2 in the pulse chamber. Horizontal dash line corresponds to 5-fold decrease in filtrate consumption relatively to the initial one. Calculation parameters: F =5.027×10^{-3} m^2; p_1 = 3×105 Pa (abs); p_{20} = 1×10^5 Pa (abs); ε_s = 0.05; ε_{solid} = 0.69; μ = 1.186×10^{-3} Pa s; S = 1.307×10^5 m^{-1}; ζ = 1.177. Dots correspond to experimental data.

Scheme of the experimental installation is shown in Fig. 3. The installation includes receiver 1 in which particles of $CaCO_3$ (average sedimentation diameter 46) μ are maintained suspended by rotor pump 2. From the filter 3 the filtrate passes through filtering screen 4 to collector 5 and to the pulse chamber 7, compressing located there gas, which leads to increase in pressure. Pressure over the suspension surface (induced by compressed air) and in the pulse chamber was measured by an arrow type manometers 9 and 10. At the filter regeneration by blowing with compressed air accumulated in the pulse chamber 7 the concentrated suspension passes to collector 6. All valves are spherical stopcocks controlled manually.

The filtering screen 4 consists of three layers: a fabric layer between metallic gauze and fluoroplast grid. Its resistance found experimentally was: $r_f = 1.36 \times 10^{10}$ Pa s m^{-3}.

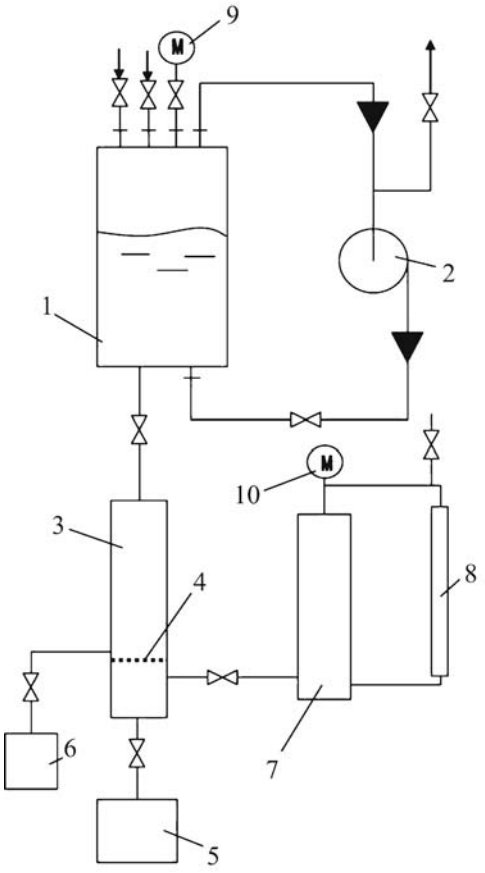

Fig. 3. Scheme of experimental installation. (1) receiver for suspension, (2) circulation pump, (3) filter, (4) filtering screen, (5) receiver for filtrate, (6) receiver for concentrated suspension, (7) pulse chamber, (8) liquid level indicator, (9,10) manometers

In the experimentrs we also measured the precipitate layer heigh, filtrate and concentrated suspension volumes and the filtration process duration. Regeneration was practically instant (approx. 0.2–0.3 s).

The experiments were carried out with suspension containing solid phase fraction $\varepsilon_s = 0.015$, 0.20 and 0.32. Pressure over the suspension surface was varied in the range 0.208 to 0.384 MPa.

By many times repeated experiments was confirmed principally efficiency of the installation not only in the step of filtration but also at regeneration using accumulated potential energy of compressed air.

The experimental results obtained are well corresponding with the calculations. As an example in Fig. 2 are depicted experimental points of filtrate consumption (circles), precipitate layer height (squires) and pressure in the pulse chamber (triangles).

Technical project of the pulse apparatus for processing suspensions based on industrial serially produced receiver type vacuum filter of EGr 1.5-2000K type with the filtrating surface 1.5 m^2.

CONCLUSIONS

The created mathematical mode allows calculation of basic technological parameters of the apparatus and obeys satisfactorily to experimental results.

Experimental examination of the filter 80 mm diameter showed that the developed apparatus for processing suspensions with regeneration of filtrating screen by back flow of the filtrate can be successfully applied under industrial conditions. Although experimentally was studied the case of ultra low frequency pulses, in the industrial practice can turn to be reasonable include additional low frequency treatment of the suspension in the step of filtration (in particular at high concentration of solid phase and in the case of formation precipitate of rigid structure) to elongate period between regenerations.

The apparatus can be recommended mainly for processing suspension with low concentration(not higher than 3 to 4%) as a concentrating filter or for continuous mass exchange processes (washing, impregnating, etc.).

ACKNOWLEDGMENT

The author is grateful to former students of St. Petersburg State Technological Institute (Technical University) M.K. Markaryan and A.V. Chernyaev for

active participation in carrying out experimental part of this investigation.

Received September 11, 2007

Abstract—A problem is considered of enhancing performance of pilot plant installation for manufacturing ethanolamine by replacement of modern packed towers for old type rectification columns. The modernization result is increase in productivity and product quality, and energy saving.

DOI: 10.1134/S1070427207120385

To enhance competition of product and diminish energy consuming it is necessary either to develop new technology and apparatuses design or to improve currently working installations and plants. The second pathway is less cost and time consuming.

Most rectification installations operating now in domestic chemical industry were projected in 60–80th of last century. During the recent years appeared effective types of contact units that are more and more often used for modernization of rectification columns. Among them there are leading packing elements produced by foreign and domestic firms. Examples are the irregular type packing HY-PAK, CASCADE RINGS, Inzhekhim, GIPKh, GIAP and others, and regular types INTALOX, Sulzer, Koch, Ingekhim, Norton, Mellapack and Vacu-Pack [1–5].

The columns with a packing often at the same efficiency as those with air-lift plates are advantageous due to lower hydraulic resistance which is of particular importance for the vacuum columns, and shorter processing duration, which is important at the separation of mixtures inclined to decomposition, polymerization and colorization.

In this communication we consider modernization of rectification columns for ethanolamine distillation in the working plant "Organicheskie Producty" (Organic products) of the open type join stock company "Kazan orgsintez".

The method of manufacturing ethanolamine is based on the reaction of ethylene oxide with ammonia in the presence of water acting as a catalyst. Commercial products are: monoethanolamine technical grade, diethanolamine pure grade, triethanolamine technical grade and monoethanolamine bottom residue.

Monoethanolamine technical grade is a transparent liquid with ammonia smell, color from yellow to dark brown. Diethanolamine is a thick viscous liquid or yellow crystals. Monoethanolamine bottom residue is a liquid of brown to dark brown color.

Current industrial methods assumes producing mono-, di- and triethanolamine, as a rule in equal amounts. Industrial technologies can be classified into two groups. The first group includes "water" technology based on ethylene oxide and aqueous ammonia, the synthesis is conducted at 20 to 200ºC, pressure 1 to 60 atm, ethylene oxide–ammonia ratio is 1–4 : 50. The second group includes technology that uses ethylene oxide and ammonia containing water in a catalytic amount (0.5 to 5%).

Currently etanolamines manufacturing in "Kazan orgsintez" open join stock company (the plant "Organicheskie producty") is performed in a block of reactors operating alongside the "water" technology. For separation of the components a few rectification columns are used, the basic ones are Kn-29, Kn-40, Kn-56 and

Kn-92. Mixtures of ethanolamines is passed to column Kn-29.

Table 1 shows composition of raw material (feeding column Kn-29). Nominal productivity is 2100 kg/h, varying within ±15%. The product from the rectification block in the installation for manufacturing ethanolamines should obey requirements listed in Table 2.

Before modernization, the working columns had the following diameters: Kn-29 1.0 m, Kn-40, Kn-56 and Kn-92 1.6 m each. The columns were equipped with mass exchange plates of different types. The columns structural strength resource was low enough. Basing on the mathematical modeling of the processes in the packing [5] we performed calculations and considered possible technical solutions for replacement of plates by regular and irregular "Inhzekhim" packing. As the calculations showed, for providing productivity on raw material from 1785 to 2415 kg/h the new columns should have the following diameters: Kn-29 0.5 m, Kn-40 1.2 m, Kn-56 1.0 m, Kn-92 0.6 m. Diminishing the size of the columns provides considerable decrease in energy consuming for the process of separation.

Technological regime in Kn-29 assumes atmospheric pressure in the column. Construction of the newly projected Kn-29 column should provide operating both at atmospheric pressure and in a vacuum. Due to decomposition of triethanolamine at the temperature above 170°C, temperature in the column bottom section should be diminished to 166–167°C, and this requires to decrease pressure in the column to 460 mm Hg (absolute pressure). Technological scheme of the separation block is shown in Fig. 1.

The new rectification column Kn-29 is of packing type, 0.5 m diameter. The packing is located in two sections, 3.0 and 3.5 m height.

Distilling off the commercial monoethanolamine is carried out in the column Kn-40. The

feeding liquid enters to the column at the temperature 115–120°C. The new Kn-40 column is of packing type, diameter 1.2 m, with packing in three sections, 1.5, 3, and 3.5 m height.

Commercial monoethanolamine can be withdrawn from the column either as a distillate (in the case of absence of water in the Kn-40 column) or as a side product.

Distilling off the light components from the crude triethanolamine (the bottom residue in the column Kn-40 at the manufacturing monoethanolamine) and

Table 1. Composition of raw material

Existing synthesis block	Composition, wt%
Ammonia	0.5–1.0
Water	7–10
Monoethanolamine	45–55
Diethanolamine	21–31
Triethanolamine	11–15

Table 2. Requirement to the separated products

Product	Content of maun component, wt%	Color units by Hasen
Monoethanolamine	not less 99.8	10 or less
Diethanolamine	not less 99.7	25 or less
Triethanolamine	not less 95.0	50 or less

producing commercial diethanolamoine is carried out in the rectification column Kn-56. The new Kn-56 rectification column is of packing type, diameter 1.0 m. The packing is located in three sections, height 1.8, 4.2, and 3.2 m.

Crude triethanolamine is passed for feeding the Kn-56 column where a mixture of water and monoethanolamine is distilled off and leaves the column in the column head. Commercial diethanolamine is taken as a side product from redistribution plate located below the upper packing section. From the column bottom outgoes the bottom residue consisting of a mixture of diethanolamine and triethanolamine.

Isolation of commercial triethanolamine is carried out in the rectification column Kn-92.

The new Kn-92 column is of packing type, 0.6 m diameter. The packing is located in two sections, height 1.6 and 2.6 m. The column feeding liquid temperature is 100-110°C. From the column bottom is withdrawn the bottom residue consisting of triethanolamine and tar.

The feeding control is performed by a feeding controller with a valve in the pump pressure pipe. The Kn-92 feeding temperature is 100–120°C.

The heat necessary for the rectification is supplied to film type evaporators heated by steam with pressure 25 kg/cm^2.

For choosing the packing type for these columns the following features of the process of ethanolamine separation were taken into account:

1. All the columns except Kn-29 should operate at reduced pressure. In future, the column Kn-29 will also be operating as a vacuum column. Hence, the packing

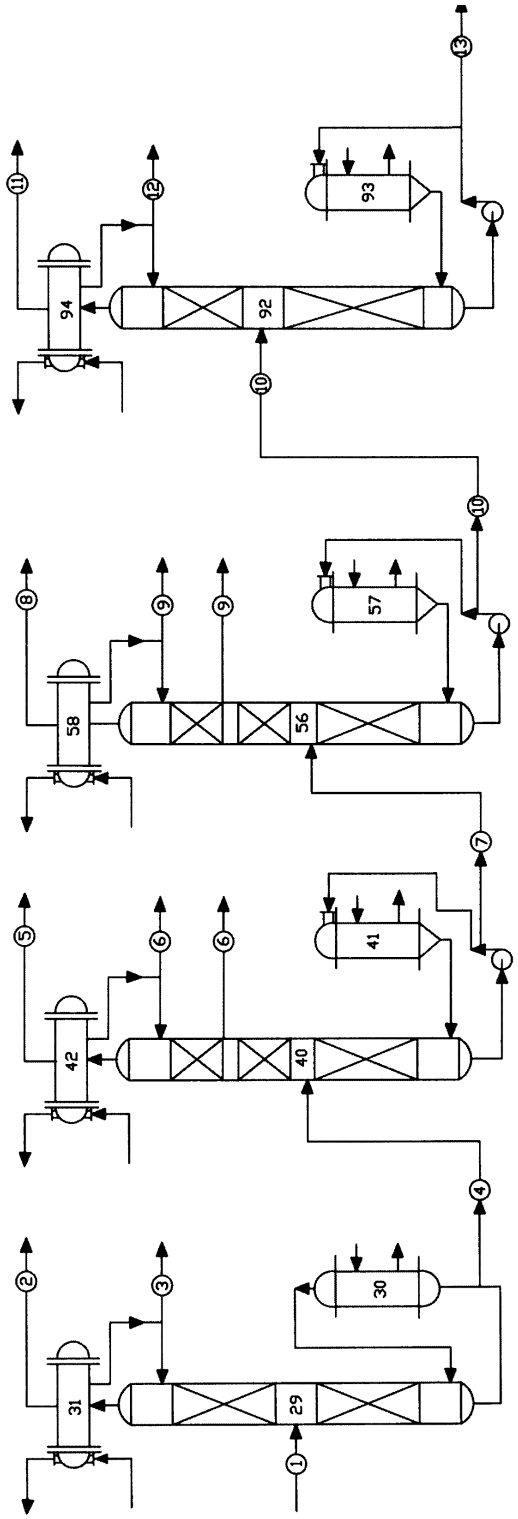

Fig. 1. Scheme of the block of ethanolamine separation. (1, 4, 7, 10) mixture for separation, (2, 5, 8, 11) gas (air) outlet, (3) distillate, (6) monoethanolamine, (9) diethanolamine, (12) triethanolamine, (13) residue (tar), (29, 40, 56, 92) rectification columns, (31, 42, 58, 94) reflux condensers, (30, 41, 57, 93) boilers.

should have low hydraulic resistance at high enough value of vapor factor, up to 2.6 m s $(kg\ m^{-3})^{0.5}$.

2. The packing should provide high enough degree of separation. The minimum height corresponding to one theoretical plate at the projecting the column height is accepted equal to 0.6 m.

3. The packing should provide the required degree of separation at a very low reflux, less than 1 m/h.

4. All the columns are constructed as not disassembling units, that is, the packing construction should provide a possibility of mounting through the column hatches.

Taking all above into account it was decided to use for all the columns except Kn-29 the regular packing "Inzhekhim-IRR-14" [5] (Fig. 2).

While choosing a regular packing we accounted for the positive experience of the Engineering Center "Inzhekhim" on the application of roll type corrugated packing used in the process of separation of ethylene glycol in the "Okis' Etilena" fabric of the "Nizhnekamskneftekhim" join stock company [6]. This process resembles that of ethanolamine separation by both thermophysical properties of the separated mixtures and characteristics of column operation (high value of vapor factor and low reflux).

Table 3 contains principal characteristics of the packing "Inzhekhim IRR-14."

In the column Kn-29 was proposed to use packing "Inhzekhim-2000" (Fig. 3). Technical characteristics of the packing "Inzhekhim-2000" are listed in Table 4.

The new contact units (packing) were examined experimentally on a stand type testing units. Similar packing is used effectively in the rectification columns at join stock company "Nizhnekamskneftekhim," in the "Etilen" plant of join stock company "Kazan orsintez" in a column for alkaline purification of pyrolysis gas and in oil fog separators (oil trappers) [4, 7, 8].

Table 3. Technical characteristics of IRR packing

No.	Characteristic of paching	Units	Value
1	Specific surface area	m^2/m^3	320
2	Free volume	m^2/m^3	0.904
3	Equivalent diameter	m	0.0113
4	Hydraulic resistance at the vapor factor P = 2.6	Pa m^{-3}	120
5	Height corresponding to one theoretical plate	m	0.5÷0.6

Table 4. Technical characteristics of the packing "Inzhekhim 2000"

Nominal size, mm	Specific free volume, m^3/m^3			Specific surface, m^2/m^3	Height equivalent to one theoretical plate
	Characteristic of paching				
	0.3	0.5	1.0		
60	–	0.973	0.945	110	1.0–1.5
35	–	0.965	0.93	140	0.5–1.0
24	–	0.945	0.89	220	0.35–0.6
16	0.949	0.915	–	340	0.15–0.4

During years 2004-2005 the new packing columns were involved into manufacturing of ethanolamines. The results of exploitation of the columns confirmed correctness of calculations and technical solutions. Comparative characteristics of columns are given in Table 5.

During startup and tune-up period and experimental industrial exploitation were elucidated the following features:

– The packing column show by an order of magnitude shorter delay of liquid phase in the column and duration of location it in the column as compared with the plate type columns. Therefore the staff had problem with the control of the process in the startup period. When the actions necessary for process control where developed and an experience was achieved for maintaining steady regime, these problems were solved. Now the packing columns operates stable and provide required efficiency in separation and color of the products.

– Efficiency of separation depends in a great extent on the initial distribution of liquid phase feeding the regular packing. Closing holes in the liquid phase distributing units diminishes efficiency of separation.

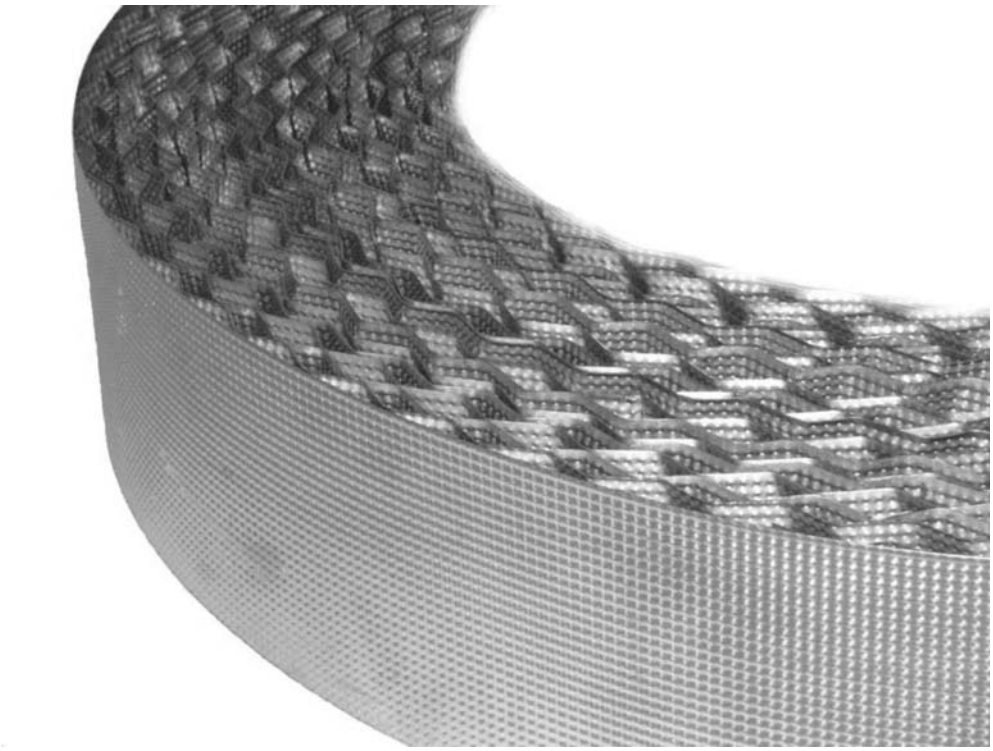

Fig. 2. Roll type regular packing.

INSTEAD OF INTRODUCTION

Academician I.V. Grebenshchikov, the founder of the Institute of the Chemistry of Silicates, Academy of Sciences of USSR, highly prestigious soviet specialist at his time in the area of the chemistry of silicon, dreamed to assign to the Institute the name "Institute of Silicon". However, hard economical and social situation in the country after the Second World War (Patriotic War) required reconstruction of damaged habitable funds and extended erecting industrial buildings, first of all as facility for creation nuclear weapon and atomic power stations.

This all required silicate materials in huge amount, including those possessing earlier unknown properties. It is this situation impelled the USSR government to admit the currently used name to the newly created institute. Unfortunately, at those years the industry of organosilicon compounds in our country just only has been born. Nobody could mind that elemental silicon would became one of the most important elements in the end of 20th and whole 21th centuries and would be providing the vigorous progress of industry and technology. Proceeding from the above epigraph, we decided to consider the history of born elemental silicon that gave rise to most modern technologies of producing semiconductor grade silicon.

* Transdlator's note: All quotations are translated from Russian and may not coincide exactly with original textes.

GENESIS AND EVOLUTION OF THE CHEMISTRY OF ELEMENTAL SILICON

We are existing in the silicon world, the world of the element most abundant in the Earth crust after oxygen. Oxygen compounds of this ubiquitous 14th element of Periodical Table (various forms of silica, silicates and aluminosilicates) constitute three fourth parts of lithosphere, and each sixth atom in the latter is silicon. In the form of solutions or suspensions, oxygen derivatives of silicon are contained in all water basins of the planet. In the Earth atmosphere always presents silica and silicate dusts, including those of cosmic origin. Finally, silicon compounds are included in the composition of all living organisms and play definite, often very important, role in the vital activity. They turned to be necessary for the appearance of living nature on Earth [1,2]. We are surrounded by artificial materials consisting of inorganic silicon compounds. They include the large-tonnage products of industry: cement, concrete, bricks, construction stones, technical ceramic and others. Silicon compounds compose such excellent materials as glass, porcelain, faience, terra cotta, sital (pyroceram), carborundum (silicon carbide abrasive), silica gel (sorbent), aerosil (silica powder), zeolite (base for many catalysts and other materials), asbestos, talk, swollen perlite, stone cotton, water glass, many precious stones, etc.

In the middle last century synthetic organosilicon polymers, the polysiloxanes intruded practically into all branches of industry, agriculture and medicine. The raw material for producing them are organyltrichlorosilanes obtainable by direct synthesis from organyl chlorides

and silicon in the presence of copper (Rochow's method) [3].

Elemental silicon practically not abundant in Earth crust. Only once it has been found in nature in free state, and this finding is considered as a mineralogical rarity. Nevertheless, in the hand made goods it has been presented far ago. For example, it existed in antique bronze and iron alloys since very ancient time.

Discovery of elemental silicon was complex and prolonged process delayed for several decades. To disentangle the tangle of numerous, often mutually contradicting observations and experiments of many sciences in early 19th century who attempted consciously or intuitively obtain formerly unknown element that is the base of silica, one should comprise ability of a chemists, a historian and a detective. Fortunately for the history of the chemistry of silicon, doctor Karl Rumpf in the Gmelin Institute at Frankfurt-am-Main was just such universal scientist. His bibliographic investigations of early history of silicon, extended and very careful, are comprised in his monograph [4]. In our publication his results are considered selectively and are supplemented by many data from original sources.

Prior to consider the history of discovery of 14th element we have to look at the source of its names. The primary source of its name is Latin name of the mineral flint (a form of silica): "*silex*". Since 18th century the flint was naming as Latin "*silica*" (the ending *a* denotes *ground*).

The name *Silicium* proposed ba Davy in 1808 [5] was soon accepted by Brezelius (1809) [6], Clarke (1816) [7] and Boussingault (18210 [8]. The translator of Davy's publications into Germany language avoided term *Silicium* and named this element as *Kiesel Metal* (derived from *Kieselerde*, that means *silica*) [9]. In 1814 Oersted recommended to use for silicon the name *Flintar*, as a derivative of Germany word *Flint* [10]. Later Brandes replaced this name by *Flintel* [11]. But these both names did not survive. Nevertheless, Brezelius used name *Kiesel* for denoting silicon. Germany chemists used both the names, *Silicium* and *Kiesel*. Now name *Silicium* is used in Germany, France, Netherlands, Denmark, Yugoslavia, Czech and Slovenia, and similar words are used in Italy (*Cilic*), Span (*Silicio*) and Romania (*Siliciu*). English transcription *Silicon* was introduced by T. Tompson in 1831 [12] probably by analogy with neighboring nonmetals *Carbon* and *Boron.* Noteworthy that Brezelius much earlier considered application of this name but resolutely rejected it because suggested that silicon is a metal rather than metalloid [13]. Slavish names of 14th element (Russian *kremnii,* Polish *Krzem* and Czech *Kremik*) are derived from slavish word *Kremen'* (flint) [14]. It is pronounced similarly in Ukrainian, Bulgarian (*Kremrk*), Serbo-Croatian and Slovenian languages and is obligated to simple-slavish word *Kremy*. At the same time, in Czech the flit is called as *Kresaci Kamen* (from slavish verb *Kresat'*).

In Russia, the name of the 14th element exerted certain evolution: *Kremnezem* (*Zakharov*, 1810), *Silitsii* (Solov'yev, Dvigubskii, 1824), *Kremnistost'* (Iovskii, 1827), *Kremnezemii* (Gess). The currently used term *Kremnii* was introduced to publications by Gess in 1831.

J.J. Berzelius (1179–1848) who proposed in 1819 chemical symbols for elements that basically are in use currently denoted silicon by the symbol *Si* [15]. Shortly before, in 1810, J. Dalton (1766–1844) who suggested that silica (*Silex*) is an elemental matter (that is, element) denoted it as a triangle placed apex up into a circle [16].

As a birth date of the chemistry of silicon (as well as the chemistry of fluorine) can be accepted year 1771 when Swedish chemist C.W. Sheele (1742–1786) by the action of hydrofluoric acid on silica prepared the first volatile derivative of this element, tetrafluoorosilane SiF_4 [17–20]. His investigation could lead to a conclusion that silica is not an elemental matter, as suggested before, but the oxide of a new element. However, neither Sheele nor his contemporary scientists have attained this conclusion.

It was A. Lavoisier (1743–1794) who made prophetic prediction that silica (he used name *Silex*) "soon will not be considered as an elemental matter" and suggested that it is probably "a substance which is a compound of elemental matter, probably a metal, with oxygen" [21].

In 1790 von Ruprecht also has deduced that elemental earths (that time this term comprised silica) are compounds of oxidized metals (*Metallishe Kalke*) [22]. He succeeded to reduce silica with carbon to obtain a metallic regulus attractable with magnet. This probably was ferrosilicium. However, Ruprecht, his students and other researchers failed to reproduce this experiment, probably because the process temperature was not high enough. In 1790–1791 Westrumb, Savareshy and Tichavsky gained a conclusion that such obtained reguluses consist of iron that contained in the used materials [23, 24]. In 1971, Klaproth confirmed this conclusion in his report in Royal Academy in Berlin [25].

In 1808 English chemist and physicist H. Davy (1778–1829), the Emeritus Foreign Member of St. Petersburg

Academy of Sciences, in his report to London Royal Society noted about failed attempt of decomposition of freshly precipitated silicon dioxide using voltametric battery with up to 500 plates. Despite this fact he concluded that *Silex* is an oxide of unknown metal [5]. Noteworthy that carrying out electrolysis of silicon dioxide solution in melted potassium carbonate between platinum electrodes, Davy observed formation of flakes with metallic flashing, inflaming in air or quickly covering with white spot [5, 9, 26]. Probably it was alloy of silicon and potassium. At heating metallic potassium with alkali earth metal oxides in a sealed glass tube Davy isolated (in 1809) a dark-brown substance, the product of reaction of potassium with glass, probably very crude silicon [5, 9]. Not enough pure silicon was prepared by a year later at the reduction of silica with metallic potassium vapor [26].

In 1809, Berzelius who had convinced himself in the impossibility of electrochemical isolation of silicon attempted to get it by calcinations at 1500°C of a mixture of silica with carbon powder and iron filings. He obtained silvery reguluses which after dissolving in sulfuric acid left snowy-white and black metal-like balls in amount 3.5 wt % of the used iron. Combusting of the latter led to formation of silica only. By insignificant change of the methodology Berzelius succeeded in obtaining the black balls in 19% yield on the weight of the taken iron [27]. Proceeding from these results, Berzelius concluded that "silica is reduced by carbon to form a substance that capable of combining with iron and by its nature should be a metal, because it does not abolish the iron forgeability" [27]. No doubts that Berzelius had in his hands ferrosilicium, which he named as *Kiseleisen*.

F. Stromeyer (1775–1835) has repeated experiments carried out by Berzelius and obtained alloys of iron and silicon containing 2.5 to 9% of silicon, and suggested that he obtained chemical compounds [28, 29]. Stromeyer also was ensured that the new element included to the alloy with iron (base of silica, or silicium) has features of a metal because these alloys at dissolving in acid liberated more hydrogen than corresponds to the amount of iron.

All these numerous but unsuccessful attempts of reduction of silica to silicon can be explained by not enough high temperature achievable at combustion of carbon. Discovery of oxygen-hydrogen flame in 1816 allowed carrying out the thermochemical reactions at the sharply elevated temperature.

E.D. Clarke (1769–1822), professor of mineralogy in Cambridge, who used oxygen-hydrogen flame for reduction of silica mixed with wood carbon and petroleum "only once has obtained a grain of pure white metal, more white and more luminous than the purest silver, which I called *Silicium*. But I failed to obtain this metal repeatedly" [7]. He also succeeded to reduce silica by iron: "When silica being melted in carbon crucible to form a bead was placed together with a piece of iron of the same size to the flame of a blast burner, the iron at such high temperature removed all oxygen from silica, and white metal appeared almost completely consisting of silicon with small content of iron. This alloy by color resembled the silicon that I have obtained in September 1816 by reduction of silica" [30]. To reduce silica using hydrogen-oxygen flame attempted also I.B. Mene, Burnatelli and M. Rudolfi, but failed. They were able to melt silica but not to transform it into metal [31]. J. Mantell, English scientist, in 1817 explained failure at these attempts. He understood that it was caused by too long and too strong heating in the flame of blast burner: the metal again converted to grey substance [32].

Another pathway for obtaining elemental silicon was chosen by French scientists L.J. Thenard (1777–1857) and Gay-Lussac (1778–1850). On May 2, 1808, in their report to the Institute of France they said that potassium being heated in the absolutely dry "gas fluorique silice" (obviously tetrafluorosilane) exerts vigorous combustion and probably decomposes the latter, and captures it completely. Thus formed brown product contained potassium fluoride but not potassium [33, 34].

On June 30, 1808, Davy reported to London Royal Society about similar experiments denoted to reaction of metallic potassium with tetrafluorosilane; the latter was marked as "gas of hydrofluoric acid contacted with glass" [5]. In his early experiments the reaction products was white mass consisting basically of KF and SiO_2. During the reaction an insignificant isolation of hydrogen was observed. This all indicates that Davy has been dealing with silicon tetrafluoride mixed with HF and air. Later, after blowing the retort with hydrogen and excluding air oxygen, Davy obtained in the reaction of potassium with tetrafluorosilane a mass and a sublimate of chocolate color [35]. After prolonged studying this mass that consisted of a mixture of several compounds, Davy established that at contact with water it liberated a gas resembling by odor hydrogen fluoride (undoubtedly it was silane SiH_4). By further studying the transformations of the reaction product from potassium

and tetrafluorosilane Davy got a conclusion: "I understood that this substance can be a compound of silicon and fluorine bases (in a low oxidation state) with potassium. In favor of this assumption said the results of several my experiments for separation of Silex from other substances by boiling it in concentrated fluoric acid. It seemed that this compound did not change and still formed *Silex* at combustion.

Soon after Davy, Gay-Lussac and Thenard have reported their investigations on the reaction of potassium metal with silicon tetrafluoride and on obtained in this reaction brown substance in details. However, they were unable to explain its real nature despite the observation that combustion under oxygen leads to formation of silica only. They generalizd the results of their experiments in a monography, where the following was written concerning the prodicts of potassium combustion in the atmosphere of silicon tetrafluoride: "All these properties attest the presence in the obtained substance of combustible compound. But how to prepare it pure? Nobody succeeded yet... It is very probably that this compound is the radical of hydrofluoric acid" [37].

Thus, Davy, Gay-Lussac and Thenard really got elemental silicon, with contaminants, in their hands, although did not suspect. The studies of these great chemists in the both sides of the Channel have attracted attention of the famous French physicist Andre-Marie Ampere (1775–1836) who attempted to classify the known in his time "simple substances". During his correspondence with Davy in 1810–1812 he concluded that the dark brown powder formed at combustion of potassium in silicon tetrafluoride is nothing else but silicon, "that presents intermediate class between metals and other combustible substances such as boron, phosphorus, carbon, etc., just like its oxide (*Silica*) is intermediate between metal oxides and alkaly, and acids" [38]. The white substance obtained by abovementioned chemists at the combustion of the brown-black substance (isolated in the reaction of 'gas fluoride silice' with potassium and washed with water or hydrochloric acid) was silicon dioxide only... Hence it follows that combustion of potassium in 'gas fluoride silice' probably would lead to formation of pure silicon which to the moment has been obtained only as a compound with iron" [38].

In his reply letter to Ampere in 1813 Davy kept quiet about the elemental silicon. But in his report to the London Royal Society he proposed an assumption that elemental silicon has been isolated in his earlier experiments [39].

In distinct to Davy, Gay-Lussac and Thernad, Berzelius in 1823 really obtained pure amorphous silicon by reduction of silicon tetrafluoride with metallic potassium. For this purpose to a glass retort filled with silicon tetrafluoride was loaded a piece of potassium. After heating the retort, potassium combusted and dark brown silicon powder formed. The powder was washed with cold and hot water (that accompanied with evolution of hydrogen in a large amount) and dried. I another experiment, Berzelius obtained amorphous silicon by reduction of sodium hexafluorosilicate Na_2SiF_6 with potassium. In that case the sikicon obtained appeared as a grayish brown powder not conducting electricity. No acid except hydrofluoric reacted with it.

However, HF dissolved the silicon obtained with vigorous evolution of silicon tetrafluoride. The powder combusted completely in the atmosphere of chlorine forming silicon tetrafluoride. At the incandescence in air it flamed but not combusted completely due to covering by the formed thin layer of silica that stopped its contact with air oxygen. About the obtained results Berzelius has mailed to Davy to the London: " the substance thus obtained you know from your study of the nature of hydrofluoric acid" [41].

Noteworthy that young chemist F. Woehler (1800–1882) who soon became a widely known naturalist, was involved in these Berzelius' studies. Many years latter, Wohler wrote about the Berzelius' scientific exploit: "As is known, pure silicon was first prepared by Berzelius in 1824 by means of silicium fluoride gas or fluorosilicate decomposition with potassium. Helpfully, that time I was his student (since November, 1823 till September, 1824) and I assisted him in obtaining the necessary potassium. Therefore 31 years later I am happy to understand that fate gifted me the ability to follow the work of my older friend; this work was carried out in front of me and has attracted my interest to the element discovered by him. As is known, Berzelius has studied and described all typical features of the silicon with the penetrability and accuracy inherent in him. He obtained amorphous silicon only as a dimly brown powder, and he repeatedly said that it would be very interesting to see this element in the solid crystalline state" [42].

And it was Woehler who first obtained the crystalline silicon. In 1843 he informed Justus von Liebig by a letter that at heating silicon tetrachloride vapor in the atmosphere of hydrogen at the red heat temperature the metallic silicon is formed as black crystals [43]. However, these observations have neither been published

in a periodical journal. Nevertheless, there is no doubts in the reliability of this data. The Woehler's results were confirmed in 1909 by Pring and Fielding [44] who obtained excellent crystals of metallic silicon by the same procedure. Nevertheless, the honor of discovery of the crystalline silicon belongs to Henri Sainte-Claire Deville (1818–1881), the foreign correspondent member of St. Petersburg Academy of Sciences. In 1854 during his experiments on preparation of aluminum he worked up the dark gray aluminum containing 10% of silicon with hot hydrochloric acid. The isolated therewith thin plates with metallic luster that resembled platinum fillings were just crystalline silicon [45]. In this form, the silicon in distinct to aluminum was chemically very stable. It possessed the same chemical properties as brown amorphous silicon discovered by Berzelius. Sainte-Claire Deville has claimed with a good reason: "I not believe that silicon is really a metal. On the contratry, I suggest that this new form relates to the ordinary silicon as graphite relates to carbon".

In 1856, Sainte-Claire Deville prepared rhombohedric crystals of silicon by passing silicon tetrachloride vapor in hydrogen flow over aluminum at the red heat temperature [46]. In 1858, the crystalline silicon was isolated by the same procedure by Russian investigator N.N. Beketov, who replaced aluminum by zinc. That time he worked in the Sainte-Claire Deville's laboratory [47, 48]. In 1856, Woehler, not mentioning his earlier experiments on reduction of silicon tetrachloride with hydrogen, proposed advanced procedure for preparation of crystalline silicon [49]. At the reducing cryolite to aluminum with metallic sodium in a ceramic crusible he observed formation, besides small aluminum reguluses, the "friable beads pierced with a black crystlline substance", which he recognized as crystalline silicon. Woehler suggested that in this process the sodium fluorosilicate is first formed and then it is reduced by aluminum [50]. Actually, in 1856 Woehler has obtained graphite-like silicon by roasting potassium fluorosilicate with aluminum at 960ºC [50-52] or using potassium silicate mixed with cryolite [53] or with ordinary glass [54, 55]. In the first case, a huge excess of K_2SiF_6 was applied, probably because aluminum was very expensive. When aluminum was taken in excess, crystalline silicon was isolated as hexagonal plates [50].

More recently, Sainte-Claire Deville and Caron developed a method for preparation of crystalline silicon based on the thermal reaction of potassium hexafluorosilicate with a mixture of metallic sodium and zinc [56, 57]. In 19th century this method for the preparation of crystalline silicon was considered as classical one. In more recent processes only zinc was used as a reducing agent [58].

Warren succeeded to obtain octahedric crystals of silicon by reduction of K_2SiF_6 (mixed with K_2CO_3 and KCl) with aluminum [59, 60]. He expressed an assumption that silicon that is formed at reduction is dissolved in the melted aluminum and is crystallized from it on cooling [61]. Really, Sainte-Claire Deville and Caron have showd earlier that amorphous silicon can be recrystallized from melted mixture of aluminum with zinc [62]. In 1891, Warren has transformed amorphous silicon into crystals 3.6 cm length by dissolving it in the melted aluminum and thin mixture [60].

In the middle of 20th century Wartenberg studied ability of obtaining pure crystalline silicon by its crystallization from the alloys with the metals not forming silicides [63]. Unfortunately, the silicon crystals thus obtained always contained up to 0.15% of the solvent metal.

Modern industrial manufacturing of crude silicon is based on the results obtained by Henry Moissan (1852 – 1907). In 1895 he reduced silicon dioxide with carbon in the created by him (and named by his name) in he electric arc furnace, that is, at the temperature about 3000°C [65].

Researches carried out in 19th century constituted a basis for vigorous development of chemistry and industrial producing of elemental silicon and inorganic and organic derivatives obtained from it. Technological development in this area achieved top position in 40th of last century and are continued now.

For obtaining technical grade silicon (98% purity) up to now in the industry is used the Moissan's method. High purity silicon for semiconductors currently is produced by the methods discovered far ago: reduction of silicon tetrachloride with metallic zinc (Batelle Process) or with sodium (Westinghouse Process) and by reaction of sodium with sodium hexafluorosilicate. Extremely pure silicon is obtained by thermal decomposition of silane SiH4 (Union Carbide). This process was also discovered in 19th century. As far as in 1858, Woehler first showed that thermal decomposition of silane affords elemental silicon as red-brown mirror [66].

Currently the modern technology uses synthetic ceramic materials based on silicon carbide and nitride,

peso-quartz, various alloys of silicon with metals, or the metal silicides (with iron, copper, magnesium, aluminum, etc.).

We can not imagine modern technology and its further progress without semiconductor silicon, which is among the most important elements of 21th century. This fact is attested by appearance in the early 21th century of over 6000 articles denoted to its synthesis and application. The silicon technology is the ground for creation of elemental base of radioelectronics, microelectronics and optoelectronics. It can not be omitted in cosmic and rocket technology, at creation of telecommunication units, satellite television and in many others creations of human brain.
