Analysis of the concentrates prepared after extraction of products of the reaction of 1,2,4-TMB with chlorine dioxide shows that the 1,2,4-TMB conversion in 1.75 h at 25-fold molar excess of ClO_2 is 90.2%. The possible transformation pathways of 1,2,4-TMB under the action of ClO_2 are shown in Scheme 1.

Among chlorinated transformation products (pathway II), we identified two compounds formed by monochlorination of the benzene ring (5-chloro-1,2,4-trimethylbenzene, **2**; 3-chloro-1,2,4-trimethylbenzene, **3**) and three compounds formed by chlorination of the methyl group: 1-(chloromethyl)-2,4-dimethylbenzene (**4**), 2-(chloromethyl)-1,4-dimethylbenzene (**5**), and 4-(chloromethyl)-1,2-dimethylbenzene (**6**). These compounds are virtually indistinguishable by mass spectrometry, which complicates the peak assignment. However, low intensity of the peak

Table 2. Content of products of 1,2,4-TMB transformations on treatment with ClO_2 aqueous solution

Product	Content $c \times 10^7$, M		Characteristic ions, %
	25-fold excess of ClO_2, 6 h	40-fold excess of ClO_2, 24 h

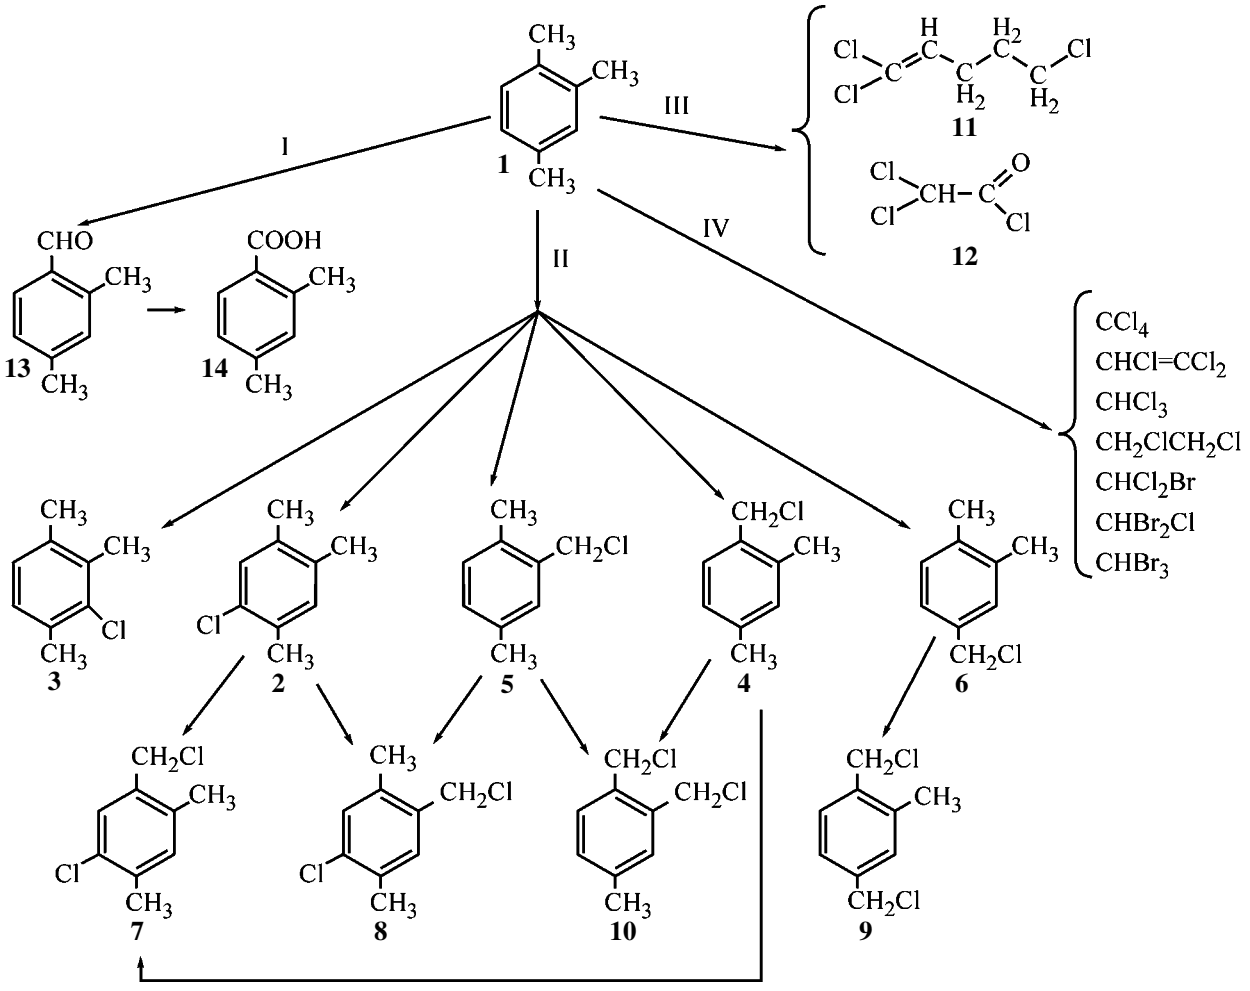
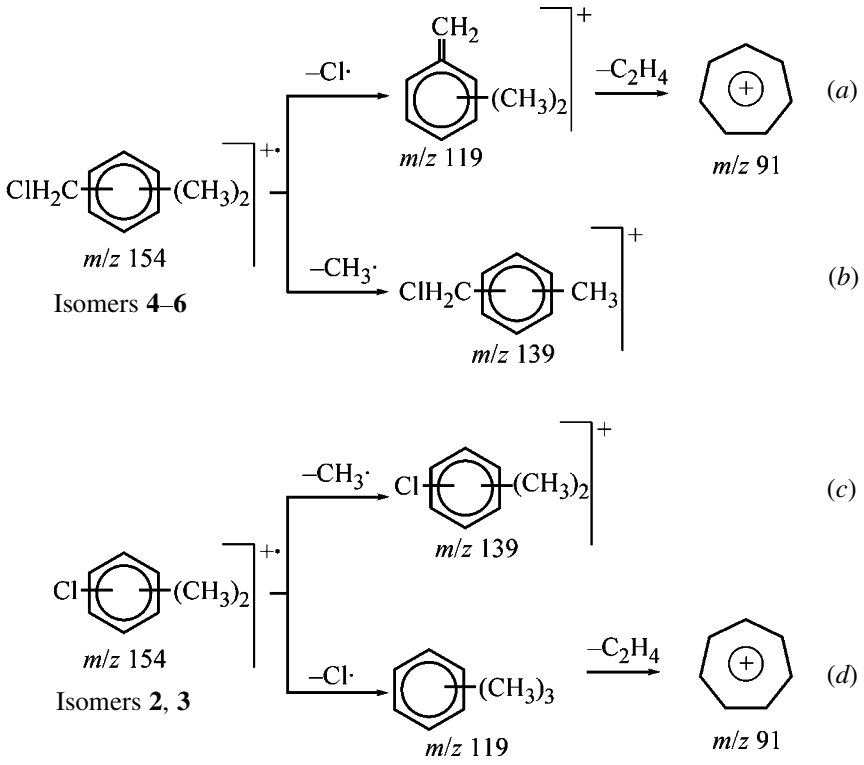
1,2-Bis(chloromethyl)-4-methylbenzene (**10**)	–	0.86	153(100), 115(19), 188(14)
1,1,5-Trichloro-1-pentene (**11**)	+	+	65(100), 137(90), 172(17)
Dichloroacetyl chloride (**12**)	–	+	83(100), 111(17), 146(2)
2,4-Dimethylbenzaldehyde (**13**)	–	+	134(100), 105(57), 77(25)
2,4-Dimethylbenzoic acid (**14**)	–	+	132(100), 150(89), 105(52)

Scheme 1.



Scheme 2.



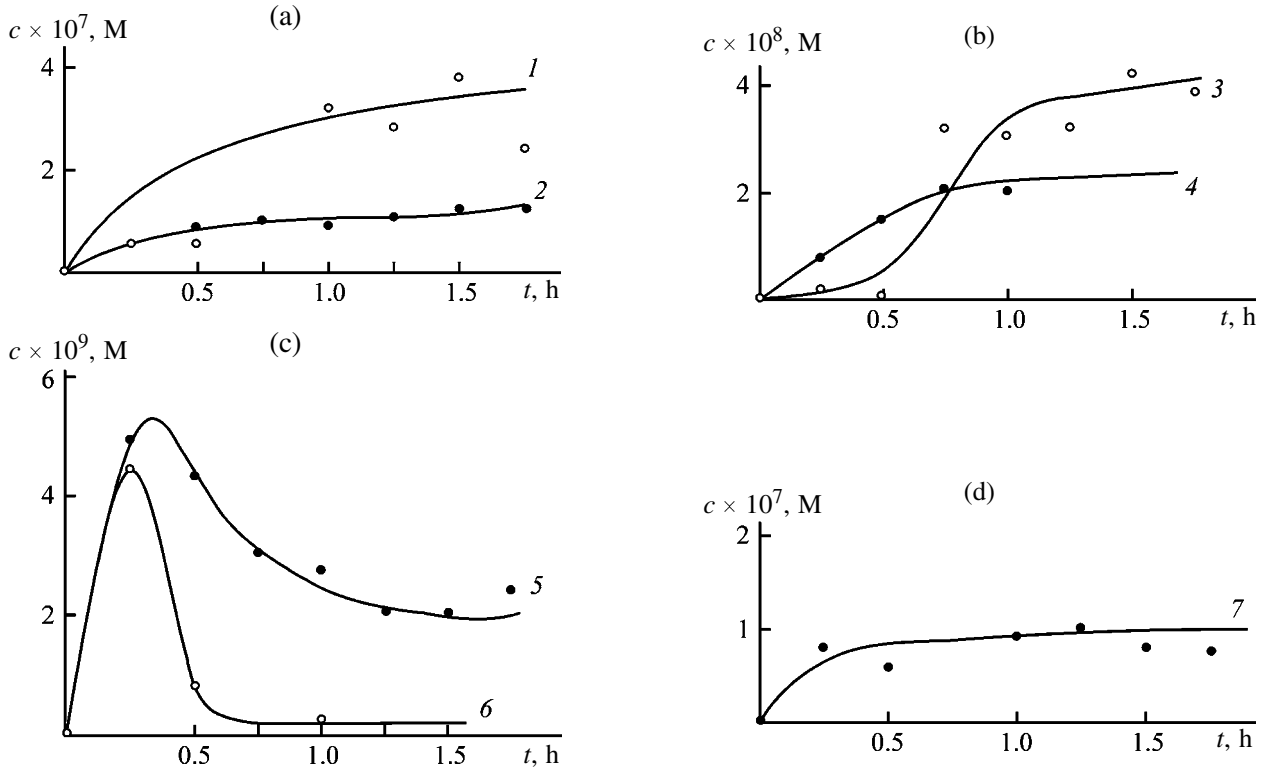


Fig. 1. Variation of VHH concentrations c with time t. [1,2,4-TMB] = 8.32×10^{-5} M; 25-fold excess of ClO_2. (a) (*1*) 1,2-Dichloroethane and (*2*) chloroform; (b) (*3*) bromoform and (*4*) tetrachloromethane; (c) (*5*) bromochloromethane and (*6*) dibromochloromethane; (d) (*7*) trichloroethylene.

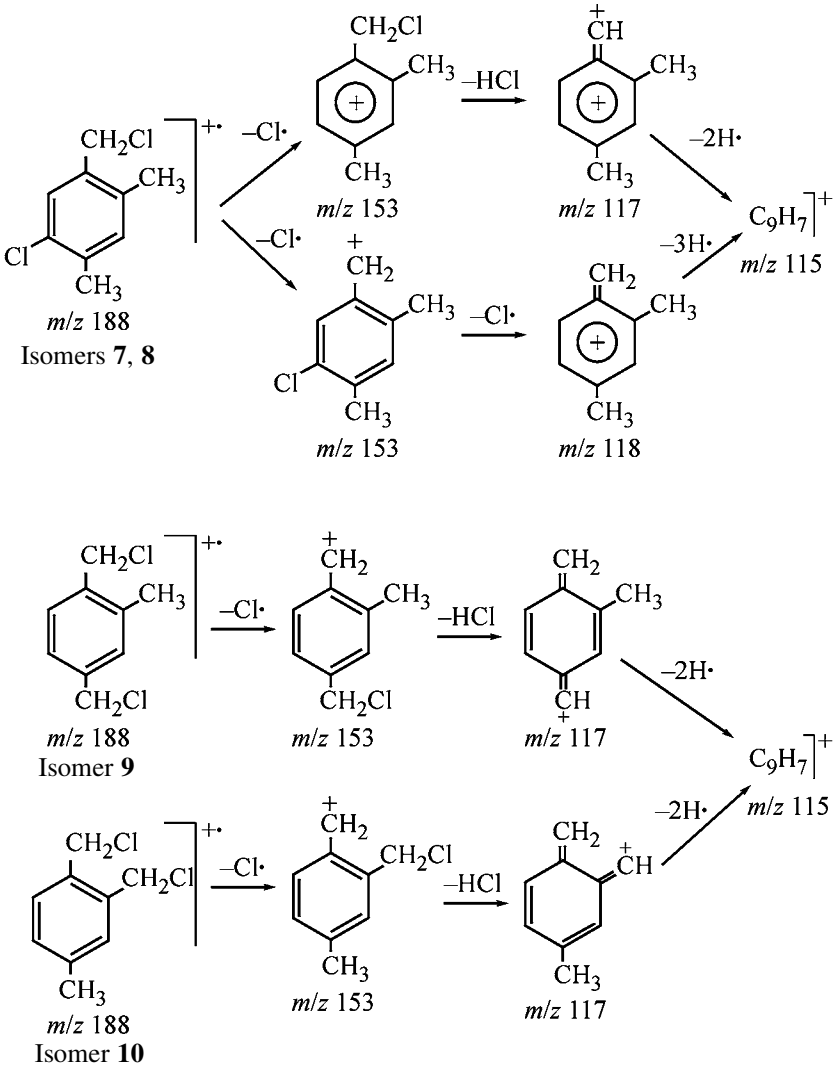
Scheme 3.



at m/z = 139 in the mass spectra of **4**–**6** indicates that their fragmentation mainly occurs through elimination of halogen atom and ethylene molecule from the molecular ion, with the subsequent formation of the tropylium cation (Scheme 2, pathway *a*). According to the fragmentation rules, this pathway is more probable for the 1,2,4-TMB monochloro derivatives containing the Cl atom in the side chain.

The higher intensity of the peak at m/z = 139 in the mass spectra of **2** and **3** (Table 2; Scheme 2, pathway *c*) indicates that the electron density distribution in these isomers facilitates the loss of the methyl groups as compared to **4**–**6** (pathway *b*).

Among dichlorinated products, we identified 5-chloro-1-(chloromethyl)-2,4-dimethylbenzene (**7**), 5-chloro-2-(chloromethyl)-1,4-dimethylbenzene (**8**), 1,4-bis(chloromethyl)-2-methylbenzene (**9**), and 1,2-bis(chloromethyl)-4-methylbenzene (**10**). The strongest peaks correspond to $[M - Cl]^+$, $[M - HCl]^+$, and some other ions formed by dehydrogenation characteristic of all steps of fragmentation of aromatic compounds under electron impact (Scheme 3) [12].

A distinctive feature of the mass spectra of **9** and **10** is approximately three times lower intensity of the molecular peak (m/z = 188) compared to **7** and **8**. This is due to the lower ionization potential of the molecule, its more intense fragmentation, and formation of the larger number of rearranged ions.

In the extracts we also identified 1,1,5-trichloro-1-pentene **11** and dichloroacetyl chloride **12** (pathway III).

In view of the fact that one of major advantages in chlorination of water with chlorine dioxide is forma-

tion of insignificant amounts of VHHs, we determined the content of tetrachloromethane, trichloroethylene, chloroform, 1,2-dichloroethane, bromodichloromethane, dibromochloromethane, and bromoform (pathway IV) in relation to the ClO_2 to substrate ratio and contact time. The results are given in the Fig. 1.

The presence of trihalomethanes among 1,2,4-TMB transformation products is apparently caused by an impurity of molecular chlorine, because the procedure for preparing ClO_2 did not involve removal of traces of Cl_2. The formation of brominated compounds (bromoform, bromodichloromethane, dibromochloromethane) is most probably associated with the presence of bromine-containing salts in sodium chlorite.

At a larger excess of ClO_2, the concentration of the reaction products increases (Table 2). Oxidation occurring on treatment of 1,2,4-TMB with ClO_2 results in the formation of oxygen-containing compounds (Scheme 1, pathways I and III): 2,4-dimethylbenzaldehyde **13**, 2,4-dimethylbenzoic acid **14**, and dichloroacetyl chloride, which were identified in an experiment with a large excess of ClO_2 and a long contact time.

CONCLUSIONS

(1) 1,2,4-Trimethylbenzene reacts with ClO_2 in aqueous solution to form chlorinated and oxygen-containing products.

(2) A scheme of transformations of 1,2,4-trimethylbenzene under the action of ClO_2 in aqueous solution was suggested.

(3) An increase in the ClO_2 to substrate ratio and in the time of contact of the substrate with ClO_2 results in larger number of reaction products, including oxygen-containing compounds and products formed by cleavage of the aromatic ring.

Abstract—Supramolecular inclusion complexes, polyrotaxanes, of β-cyclodextrin with modified polydimethylsiloxane were prepared. The structure and thermal properties of these complexes were studied as influenced by the preparation conditions, component ratio, and molecular weight of the polymer.

DOI: 10.1134/S1070427207070191

Synthesis and preparation of polymeric supramolecular complexes, polyrotaxanes (PRot), containing macromolecular rins strung on linear polymers with bulky terminal groups (blockers) attracts great attention [1–3].

Cyclodextrins (CDs), cyclic oligosaccharides consisting of *D*-glucopyranoside units bound by α-1,4-glucoside bond [4], are widely used as the cyclic component in matrix synthesis of PRot [1–3]. CD molecules have a shape of truncated cone 7 Å long and from 4.5 to 8.5 Å in internal diameter (depending on the modification: α-, β-, and γ-CD). These compounds contain hydroxy groups on the internal and external sides of their molecules and hydrocarbon and ether groups inside the cone. The internal surface of CD molecules is hydrophobic and the external surface is hydrophilic [4]. The linear components used for preparation of inclusion complexes of CD usually have two hydrophilic terminal groups and their internal part is hydrophobic. When both components are dissolved in a polar solvent (e.g., in water), the hydrophobic part of the linear macromolecule is strung on CD, whereas its hydrophilic parts do not enter inside the ring.

Supramolecular host–guest complexes formed by stringing CD (host) on linear polymer chains (guest) of different structure and molecular weights, such as poly(ethylene oxide) [5], poly(propylene oxide) [6], poly-ε-caprolactam [7], etc., have been prepared and characterized. These complexes are used as supports for preparing silicate materials whose pore size depends on the pH of the reaction mixture [8], delivering pharmaceuticals to required parts of stomach [9], as molecular switches [10, 11], etc.

Polyrotaxanes of β-CD and polydimethylsiloxane (PDMS) were prepared for the first time by Harada et al. [12–14]. They found that the geometrical size of α-CD cavity did not match the cross section diameter of PDMS macromolecule and hence the α-CD–PDMS complexes were not formed. At the same time, β-CD forms inclusion complexes with low-molecular-weight PDMS (M_n < 700). γ-CD can be strung on PDMS of higher molecular weight (up to M_n = 3300). The maximal ratio of CD to monomer units of the polymer in the inclusion complexes is 1.5 [12–14].

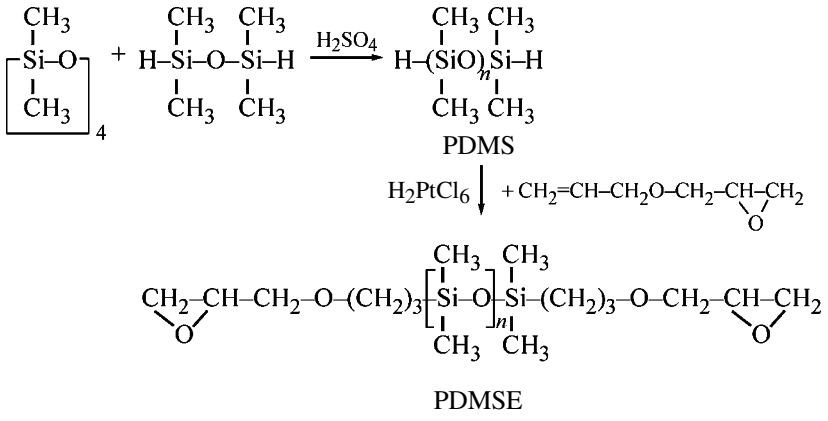
The aim of this study was to prepare PRots of β-CD with PDMS modified with epoxy groups (PDMSE) and to examine their supramolecular structure, morphology, and thermal properties by physical methods.

EXPERIMENTAL

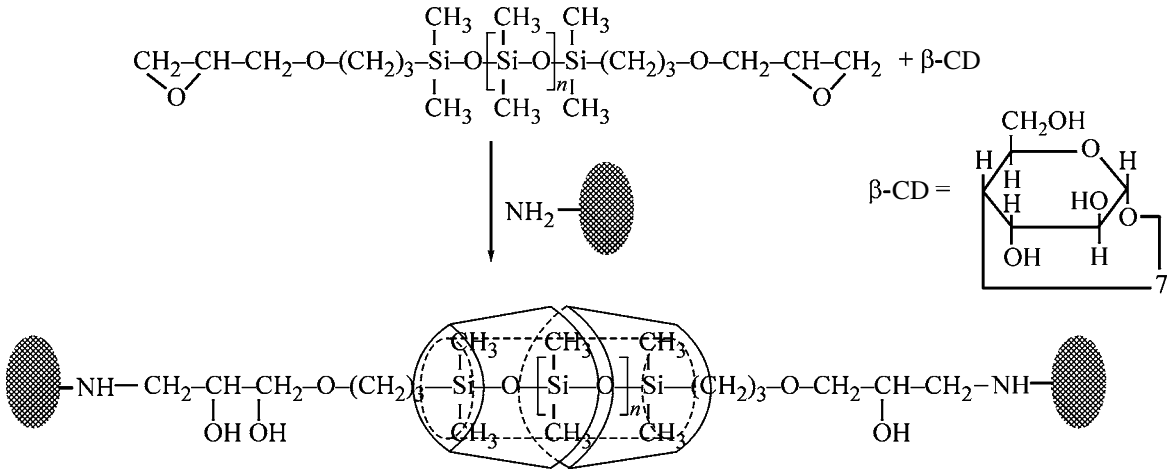
The main component of the inclusion complex, linear PDMSE, was prepared by stepwise synthesis shown in Scheme 1.

The first step is the reaction of octamethylcyclotetrasiloxane with 1,1,3,3-tetramethyldisiloxane at room temperature for 4 h in the presence of 2 vol % H_2SO_4 to form PDMS with different molecular weights, having reactive Si–H terminal group.

Scheme 1. Stepwise synthesis.



Scheme 2. PRot preparation.



The second step involves hydrosilylation of vinyl glycidyl ether with 50 wt % PDMS solution in toluene in the presence of hexachloroplatinic(IV) acid (2% solution in isopropanol) at 100–110°C for 6 h to form PDMSE. The polymer precipitate was heated at 150°C in a vacuum (0.1 mm Hg) to remove impurities and unchanged components. Polymers with molecular weight M_n = 1250 (PDMSE-1) and M_n = 3310 (PDMSE-2) determined by exclusion chromatography were prepared.

The procedure for preparing PRot of β-CD and PDMSE is shown in Scheme 2.

In the first stage, saturated solutions of β-CD and PDMSE in DMF were mixed. The PRot structure was stabilized by reaction of the epoxy groups with the blocker (4-aminophenyltriphenylmethane) dissolved in isopropanol (saturated solution). To determine the influence of the ratio of the PRot components on the structure and physical properties of the complexes, we studied the samples with the following β-CD/SiO molar ratio: 0.253 (PRot-1a), 0.140 (PRot-1b), 0.069 (PRot-1c) and 0.058 (PRot-2) (Table 1). The ratios per Si–O bond were calculated from the ^{1}H NMR spectra. To prepare the PRot-1a sample, the mixture was stirred at 65°C for 72 h, after which the complex was precipitated with water, washed with ethanol, and dried with diethyl ether. To prepare the PRot-1b and PRot-1c samples, the mixture was additionally precipitated two times with aqueous DMF (Table 1).

The ^{1}H and ^{13}C NMR spectra of the intermediates and PRot were recorded on a Bruker DRX spectrometer (400 MHz). The X-ray diffraction analysis of β-CD and PRot was performed on a DRON-3 diffractometer (Burevestnik Research and Production Association, Russia) in the range 2θ = 3°–37° (CuK_α radiation, Ni filter). The thermal properties of the samples were studied on DSM-2M differential scanning calorimeter (Specialized Design Office of Instrument Making, Pushchino, Russia). The sample was heated at a rate of 16 deg min^{-1}. The morphology of the

Table 1. Preparation conditions and properties of PDMSE and PRot

Polymer	M_n	Poly-rotaxane	β-CD Content		Yield, %
			β-CD/SiO molar ratio	free β-CD, %	
PDMSE-1	1250	PRot-1a	0.253	54.1	–
	1250	PRot-1b	0.140	0	96
	1250	PRot-1c	0.069	0	55
PDMSE-2	3310	PRot-2	0.058	5.0	99

samples was studied on a Tesla BS-3001 scanning electron microscope (Czech Republic). The electron micrographs were treated with the aid of the Image-Tool 3.0 software (Texas University, United States).

The X-ray diffraction patterns of β-CD (curve *1*), PRot-1a (curve *2*), and PRot-2 (curve *3*) are shown in Fig. 1. The presence of a large number of reflections in the X-ray diffraction patterns of the samples (interlayer spacings *d* (Å) are summarized in Table 2) suggests their crystallinity. Comparison of *d* of supramolecular inclusion complexes PRot-1a and PRot-2 prepared at a β-CD excess (Table 1) and those of the initial β-CD shows that their crystal structures differ. Complex PRot-1c prepared at a deficiency of β-CD (β-CD/SiO = 0.069) is amorphous. Its X-ray diffraction pattern contains a halo with d = 6.8 Å which is preserved even after heating of the sample at 180°C. Thus, the β-CD/SiO molar ratio and the molecular weight of PDMSE affect the structure of the PRot complexes.

The thermal analysis curves of β-CD and PRot-1a, PRot-2, and PRot-1b complexes are shown in Fig. 2. The thermal analysis curve of β-CD (Fig. 2, curve *1*) is characterized by a sharp endo effect at 100°C due to elimination of bound water, which is consistent with data of [15, 16]. On heating above 250°C, β-CD melts simultaneously with its decomposition [15], which complicates determination of the melting point of the sample by DSC.

Table 2. Interplanar spacings of β-CD and PRot samples

Sample	*d*, Å
β-CD	18.6, 13.6, 8.25, 6.93, 5.80, 4.99, 4.49, 4.28, 3.90, 3.82, 3.30, 3.18, 2.58
PRot-1a	13.6, 9.30, 8.03, 6.67, 5.62, 5.21, 4.99, 4.73, 4.43, 4.18, 3.95, 3.59, 3.27, 2.93, 2.79
PRot-2	12.6, 8.62, 7.22, 6.00, 5.71, 5.06, 4.79, 4.28, 3.74, 2.95

The thermal analysis curve of PRot-1a (Fig. 2, curve *2*) also contains the endothermic effect at 100°C. In addition, an endo effect at 165 and an exo effect at 200°C are observed. We suggest that this complex undergoes polymorphous transformations on

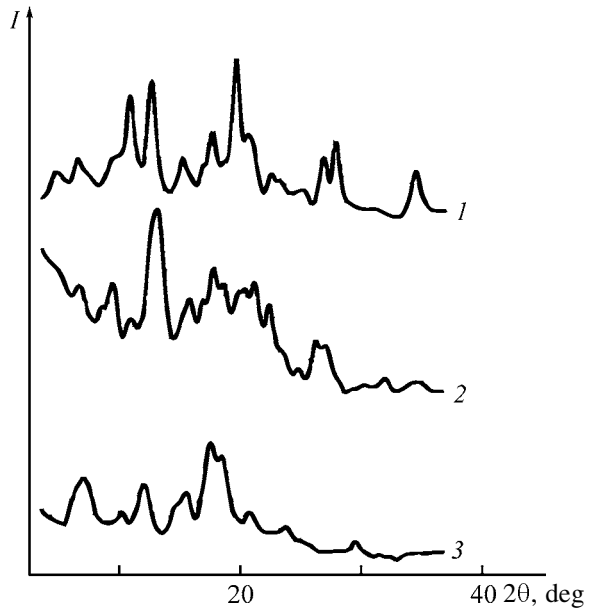


Fig. 1. X-ray patterns of (*1*) β-CD, (*2*) PRot-1a, and (*3*) PRot-2. (*I*) Intensity and (2θ) Bragg angle.

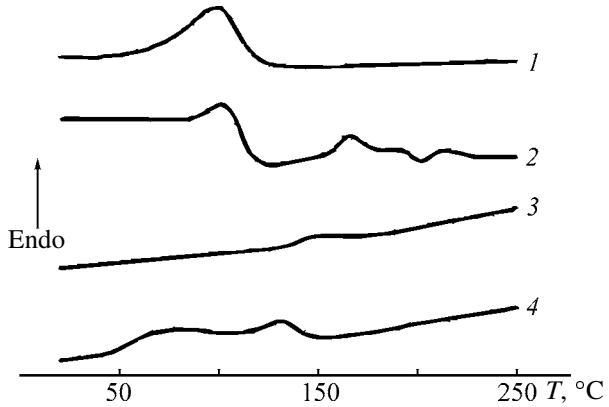

Fig. 2. DSC curves of (*1*) β-CD, (*2*) PRot-1a, (*3*) PRot-2, and (*4*) PRot-1b. (*T*) Temperature.

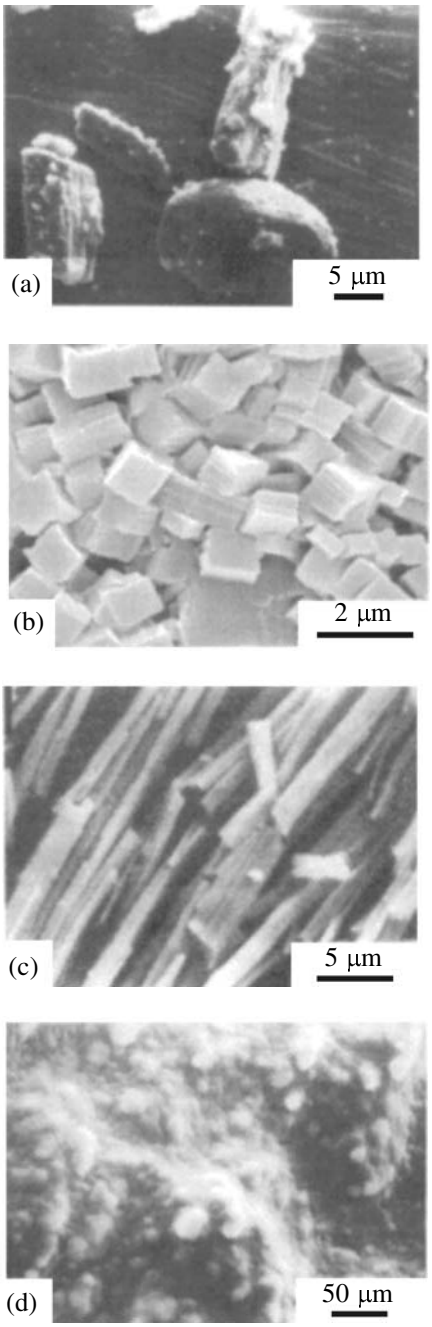

Fig. 3. Electron micrographs of (a) β-CD, (b) PRot-1a, (c) PRot-1b, and (d) PRot-1c.

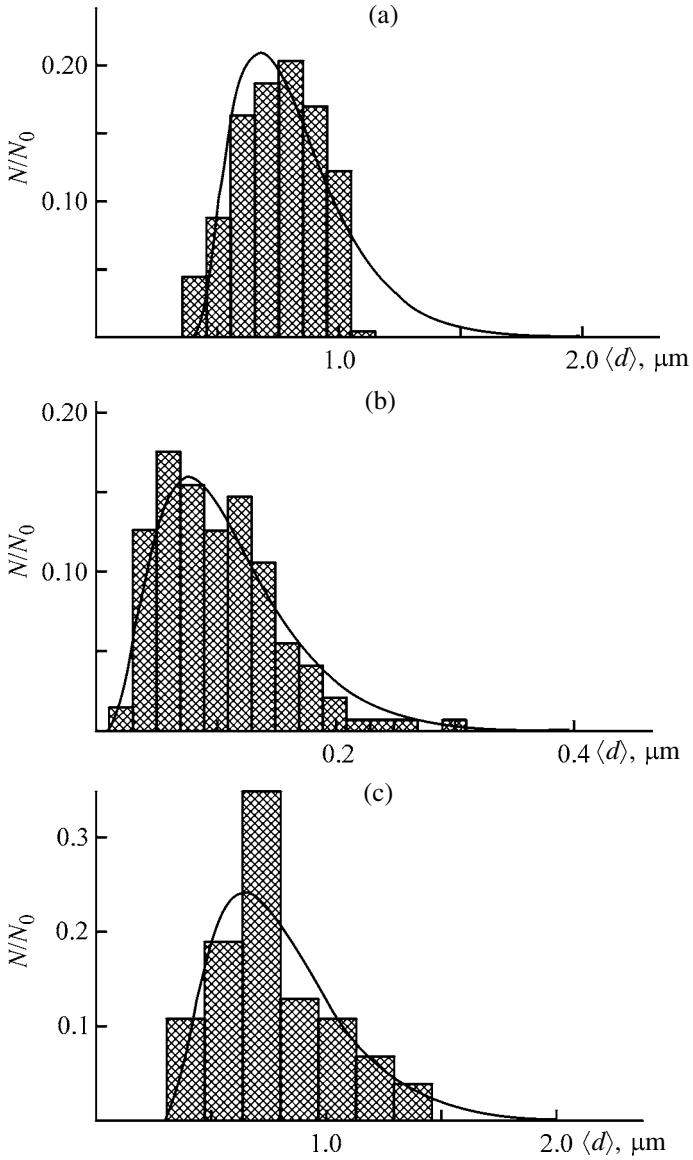

Fig. 4. Particle size distribution N/N_0 in (a, b) PRot-1a and (c) PRot-1c.

heating. The thermal analysis curve of PRot-2 in the range 50–150°C has two sharp endo effects caused by water elimination from the complex (Fig. 2, curve *3*). The thermal analysis curve of PRot-1c (Fig. 2, curve *4*) prepared at a deficiency of β-CD has a very weak endo effect (the enthalpy of the transition is no higher than 3 J g^{-1}) at 150°C due to melting of the sample, i.e., the complex is almost amorphous, which agrees with the X-ray diffraction data. It should be noted that this curve is similar to that of PRot-1a shifted to lower temperatures and having a sharp maximum at 165°C (Fig. 2, curve *2*).

The electron micrograph of β-CD is shown in Fig. 3a. It is seen that β-CD consists of lamellar particles of different shapes, whose size ranges from 1 to 40 μm. Different particle size and the absence of well-defined prevalent shape prevent quantitative analysis of the sample morphology.

Unlike pure β-CD, crystals of PRot-1a complex (Fig. 3b) have a shape of well-edged rectangular parallelepipeds. The results of statistical analysis of the particle size distribution are shown in Fig. 4a.

The particle size distribution is described well by the equation derived in the framework of the reversible aggregation model [17–19]. That is, the aggregates form thermodynamically optimized statistical ensemble [17, 18] with the most probable edge size of 0.81 μm (Fig. 4a). Each aggregate is a stack of square lamellar crystals (lamellas) whose average thickness is 0.1 μm (Fig. 4b).

Analysis of micrographs of well purified PRot-1b complex (Fig. 3c) show that the morphology of this sample is different: it consists of long rod-like crystals whose most probable thickness is approximately 0.8 μm (Figs. 4b, 4c). Interestingly, the most probable thickness of the rods is similar to the face size of crystalline aggregates of PRot-1a (0.81 μm). Complex PRot-1b consists of irregular-shaped amorphous particles whose size ranges from 0.5 to 3 μm (Fig. 3d). As seen from electron micrographs of PRot-2, this complex is crystallized in the form of a dispersion of small particles agglomerated in aggregates, which are difficult to characterize quantitatively.

CONCLUSIONS

(1) The supramolecular structure, morphology, and phase composition of inclusion complexes of β-cyclodextrin with polydimethylsiloxane modified with epoxy groups depends on the preparation conditions (purity and ratio of the components) and the molecular weight of the polymer.

(2) When the polyrotoxanes are prepared at an excess of unchanged β-cyclodextrin, well-edged lamellar crystals with the shape of rectangular parallelepipeds are formed, whereas at the optimal amount of β-cyclodextrin and high degree of purification of the product, rod-like crystalline aggregates are formed. Polyrotaxanes prepared at a deficiency of β-cyclodextrin are amorphous.

Abstract—Cationic oligomerization of disubstituted oxetanes promoted by trifluoroboron etherate in the presence of ethylene glycol was studied. The parameters of molecular-weight and functionality distribution of the resulting oligooxetane diols were determined by gel-permeation and liquid chromatography.

DOI: 10.1134/S1070427207070208

Polyurethane thermoplastic elastomers (TPs) are commercially produced today using diisocyanates, low-molecular-weight glycols, and oligomeric diols based on polyoxyalkylenes, polytetramethylene, and polyesters [1–3]. Oligoether diols derived from disubstituted oxetanes seem to be a promising alternative to low-molecular-weight glycols in the stage of TP synthesis [4]. Therefore, oligomerization of disubstituted oxetanes to prepare polyoxetane diols with given functionality and number-average molecular weight is a topical problem. Data on preparation of oligooxetane diols and, the more so, on the parameters of molecular-weight distribution (MWD) and distribution with respect to functionality types (DFT) of the resulting oligooxetane diols are lacking.

In this work we studied cationic oligomerization of disubstituted oxetanes, prepared oligooxetane diols of various chemical compositions, and evaluated their MWD and DFT parameters.

EXPERIMENTAL

As monomers we used 3,3-bis(azidomethyl)oxetane (BAMO), 3-azidomethyl-3-methyloxetane (AMMO), 3-methyl-3-nitratomethyloxetane (MNMO), and 3-azidomethyl-3-nitratomethyloxetane (AMNMO). The monomer purity was checked by liquid chromatography and IR spectroscopy. Before experiments 1,2-dichloroethane (DCE), ethylene glycol (EG), tetrahydrofuran (THF), heptane, and methyl ethyl ketone (MEK) were purified by standard procedures [5].

Oligooxetane diols were prepared by cationic oligomerization catalyzed by trifluoroboron etherate in the presence of ethylene glycol with continuous addition of the monomer dissolved in DCE [6]. The synthesis was carried out in a glass reactor equipped with a stirrer and a water-cooling jacket. First, the catalyst, EG, and solvent were added into the reactor. Then, oxetane was fed into the reactor using a batcher at a rate at which its current concentration in the system did not exceed the catalyst concentration. After completion of the monomer supply, the reaction mixture was stirred for 3 h at room temperature and kept at the same temperature for 120 h without stirring to attain the quantitative yield of the desired product. The reaction was terminated with water, the mixture was washed to remove the catalyst, and then water and the solvent were removed by the known procedure [6].

The gel-chromatographic study was performed on a Waters gel chromatograph equipped with three Styrogel columns (200, 500, and 1000 Å) using THF eluent at an elution rate of 1.2 ml min^{-1}. The polymer solution with a concentration of 0.2–0.3 wt % was added in one portion (the loop volume was 2 ml). The MWD parameters were calculated from the universal calibration dependence [7], which was used to evaluate the calibration dependences for each oligomer type. The DFT parameters of the resulting oligooxetanes were studied on a GPS II Waters liquid chromatograph using three columns: 250×4 mm (Separon 200 SGX), 150×3 mm (Separon SGX), and 150×3 mm (Separon SGX) [8]. The conditions of

chromatographic analysis of oligooxetane diols were as follows: MEK–heptane volume ratio 34.5 : 65.5 and 26.5 : 73.5 for 3,3-bis(azidomethyl)oxetane diol and 3-azidomethyl-3-methyloxetane diol, respectively.

Our experimental data (Table 1) show that the process with continuous supply of the monomer, developed previously for oxiranes [6], is applicable to cationic oligomerization of substituted oxetanes. Irrespective of the initial monomer type, the yield of the target products is quantitative. It should be noted that the measured molecular weights M_n are close to those calculated from the following equation:

$$M_n = M[\mathrm{Ox}]/[\mathrm{G}],$$

where M is the molecular weight of the monomer and [Ox] and [G] are the concentrations of oxetane and glycol, respectively.

However, polymerization of oxetanes proceeds more slowly than that of epoxides, and complete conversion is attained only after prolonged additional storage of the reaction mixture. This is confirmed by data on the polymerization kinetics. The time dependences of the reaction rates for epichlorohydrin (ECH) and AMNMO are shown in Fig. 1; for ECH the apparent rate constant of polymerization is 6.6×10^{-2} l mol^{-1} s^{-1} (Table 2). As seen, in the case of ECH the steady-state concentration of the monomer at its continuous feeding into the reactor is attained in a short period, and the reaction can be terminated at any moment by stopping of the monomer supply without deterioration of the target polyether quality. The molecular weight of the product thus obtained corresponds to the above ratio.

In the case of AMNMO, attainment of the steady-state mode of the polymerization requires a longer period, which suggests slower process initiation. Moreover, longer reaction is required to attain quantitative yield. The apparent rate constants for oxetanes studied are lower than that for ECH by 1.5–2 orders of magnitude.

The gel chromatograms of polyoxetane diols prepared in the presence of EG and without it are shown in Fig. 2. These data confirm the absence of cyclic products in the resulting oligooxetane diols. Hence, Rose's statement [9] on formation of cyclic tetramers in the course of polymerization of oxetane and its 3,3-dimethyl derivative requires additional verification. Moreover, in a later study [10], no cyclic compounds were found among the products of oxetane polymerization (GPC data).

Table 1. Results of cationic polymerization of oxetanes with the general formula $CH_2CR^1R^2OCH_2$. [Monomer] = 2.6 M, [EG] = 0.2 M, [BF_3] = 0.2 M; oligomerization was performed in DCE at 10°C

Table 4. DFT parameters of oligo-3,3-bis(azidomethyl)-oxetane diol and oligo-3-azidomethyl-3-methyloxetane diol

Oligomer	Concentration, M		DFT		
	EG	catalyst	$f = 0$	$f = 1$	$f = 2$
AMMO	0.45	0.45	0.4	7.9	91.7
	0.52	0.2	1.4	1.9	96.7
BAMO	0.41	0.41	6	9.8	83.5
	0.52	0.2	2.6	4.3	92.6

where M_e is determined form the content of the functional groups.

The DFT parameters of the resulting oligomers were studied by liquid chromatography. The results for oligo-AMMO and oligo-BAMO are listed in Table 4. As seen, in formation of oligo-AMMO the content of bifunctional macromolecules reaches 96.7% and the content of the molecules without functional groups is negligible. In oligo-BAMO the content of bifunctional macromolecules is smaller, and the content of the macromolecules without functional groups reaches 10%.

Thus, our experimental data show that synthesis of oligomers with continuous feeding of the monomer, developed previously for oxiranes, is applicable to oxetanes and allows preparation of oligomers with required properties.

CONCLUSION

(1) Cationic oligomerization of 3,3-bis(azidomethyl)oxetane, 3-azidomethyl-3-methyloxetane, 3-methyl-3-nitratomethyloxetane, and 3-azidomethyl-3-nitratomethyloxetane was studied, the corresponding oligoether diols were prepared, and the possibility of preparing oligooxetane diols using the procedure developed previously for oxiranes was confirmed.

(2) Parameters of the molecular-weight distribution of the resulting oligooxetane diols were determined, their polydispersity index is $M_w/M_n = 1.4–1.6$.

(3) The content of bifunctional macromolecules in oligooxetane diols derived from 3-azidomethyl-3-methyloxetane and 3,3-bis(azidomethyl)oxetane is 92–97 and 85–90%, respectively.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Adhesive Compounds Based on Polyurethane Waste

V. V. Bestuzheva, N. V. Sirotinkin, and A. V. Tokarev

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

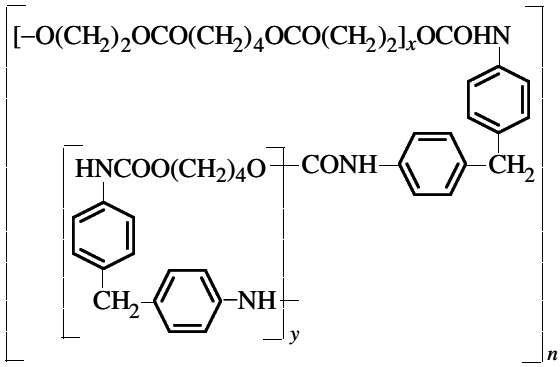
Received March 13, 2007

Abstract—Formulations of adhesives and film materials from polyurethane waste were suggested, and the characteristics of these materials and conditions of their preparation were examined. A versatile resource-saving and environmentally sound procedure was suggested for the reuse of polyglycol adipate urethanes of dense and microcellular structure. The procedure allows transformation of a polymer waste into a reclaim with a high level of service parameters.

DOI: 10.1134/S107042720707021X

Polyurethanes (PUs) of various structures find wide and diverse applications in the modern engineering. However, increase in the production of polyurethane articles is accompanied by formation of hundreds of tons of industrial waste annually, giving rise to environmental problems and requiring undesirable resource expenditure. The diversity of commercially produced PUs additionally complicates the situation, because utilization of different kinds of cured materials requires different approaches. For each material, it is necessary to develop a nondestructive and cost-efficient procedure for reprocessing into valuable products.

Among widely used polyurethanes are poly(ethylene butylene glycol adipate urethanes), segmented ester thermoelastoplastics used in machine-building (integral and foamed PUs), in shoe industry (microcellular PUs), and in load-bearing units (monolithic PUs). The simplified structure of such polymers is as follows:



(1)

The elastomer is formed by addition to an isocyanate pseudoprepolymer of a mixture of a polyester component and a glycol acting as chain-terminating agent. The reaction of the diisocyanate with the glycol yields rigid segments imparting high strength to the material, whereas polyester fragments provide high elasticity [1]. Such products are commonly obtained by the pseudoprepolymer method using high-output casting machines. The amount of waste produced daily by each of these machines reaches 100 kg.

Polyurethane thermoelastoplastics exhibit high level of physicomechanical properties due to cross-linking of the macromolecules by hydrogen bonds formed in the course of curing [2]. This fact complicates reprocessing of PU waste of this type by contact molding methods. Additional problems arise from the porosity of the material and narrow interval between the flow point (at which the reprocessing is possible) and decomposition point.

The physicomechanical transformations of the PUs under consideration in the temperature interval from –40 to +150°C are shown in Fig. 1.

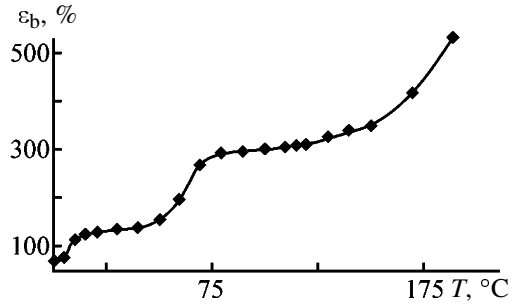


Fig. 1. Thermomechanical curve of monolithic poly(ethylene butylene glycol adipate urethane): (ε_b) relative elongation and (T) temperature.

The curve shape demonstrates the occurrence in the range 40–75°C of the hyperelastic strain of the segments formed by flexible, less oriented and hence more mobile units of polyurethane. At 122–137°C, crystalline units acquire mobility, and an induced plastic state of the thermoplastic is manifested. In the range 140–145°C, the material transforms into a viscous-flow state. Under these conditions, the material is capable of changing shape, and its molding becomes possible.

However, DTA data for commercial poly(ethylene butylene glycol adipate urethanes) show that even at 140–150°C the samples lose weight with the gas evolution.

At a flow temperature, hydrogen and then covalent bonds are broken, i.e., the polymer degrades with drastic deterioration of the physicomechanical properties of the reclaim. Therefore, high-temperature waste reprocessing does not allow preparation of a secondary material with high service characetristics.

Thus, to develop a procedure for utilization of polyurethanes with the preparation of molded articles, it is primarily necessary to decrease the flow point of the starting product. One of the simplest, most widely used, and most efficient ways to do this is plasticization of the material.

EXPERIMENTAL

In the experiments we used the following starting compounds: polyurethanes (monolithic, density 1150 kg m^{-3}, relative elongation 920%; microcellular, density 600 kg m^{-3}, tensile strength 7.5 MPa, relative elongation 450%; integral, density 75 and 800 kg m^{-3}, tensile strength 0.3 and 70 MPa, bending strength 0.2 and 15 MPa for core and crust, respectively); plasticizers [commercially available compounds of various classes meeting GOSTs (State Standards): dimethylformamide (DMF), GOST 20289–74; dimethyl sulfoxide (DMSO), TU (Technical Specification) 6-09-3818–77; cyclohexanone (CH), GOST 24615–81; glycerol (Gl), GOST 6259–75; toluene, GOST 5789–78; and dibutyl phthalate (DBP), GOST 2102–67].

For polymers of the same structure, the plasticization parameters primarily depend on the plasticizer properties. Available data on the thermodynamic behavior of segmented polyurethanes are ambiguous and do not allow prediction of their deformation behavior in one or another medium. We examined the interaction of monolithic polyurethane with plasticizers by the method of equilibrium swelling [3] with simultaneous determination of physicomechanical characteristics at regular intervals. The results are shown in Fig. 2.

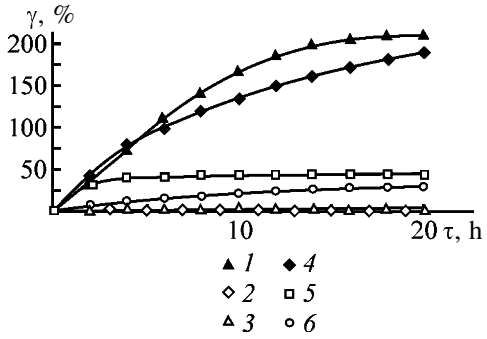

Fig. 2. Degree of swelling γ of STEP as a function of swelling time τ at 20°C. Plasticizer: (*1*) DMF, (*2*) Gl, (*3*) DBP, (*4*) CH, (*5*) DMSO, and (*6*) toluene.

Dibutyl phthalate is moderately absorbed by the polyurethane, and the thermodynamic equilibrium in the system is attained in 5 h at 20°C, 15 h at 40°C, and 20 h at 60°C. In glycerol, the similar state is attained at a concentration of 0.4–0.5%. DBP and Gl only slightly affect the microphase state of the segmented thermoelastoplastic (STEP); practical use of these plasticizers involves problems with ensuring uniform distribution of small amounts of the additive in the cured thermoplastic.

Toluene selectively breaks hydrogen bonds. It is concentrated in the flexible STEP matrix, leaving the structure of domains intact. Monolithic polyurethane can absorb up to 40 wt % toluene. Spectroscopic analysis shows that cleavage of interchain H bonds in the process leads to an increase in the relative content of free NH groups in the elastomer (a band appears at 3390 cm^{-1}, characteristic of associates of NH groups with the π-electron system of the aromatic ring of the solvent). As a result, the physicomechanical characteristics of the polymeric material are drastically deteriorated. Toluene decreases the structural glass transition point of flexible blocks, whereas the rigid microphase remains essentially intact in the process. Thus, the swollen polymer is inhomogeneous and nonuniform in properties.

Cyclohexanone, in contrast to aromatic toluene, contains a carbonyl group in the molecule and occupies an intermediate place between toluene and typical hydrogen acceptors (DMSO, DMF) with respect to processes occurring in its presence. Weakly pronounced proton-acceptor properties facilitate its active insertion into the interchain space of the flexible matrix with the cleavage of hydrogen bonds, but these

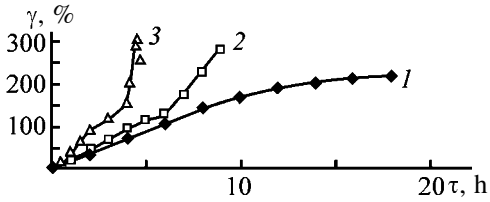

Fig. 3. Degree γ of STEP swelling in DMF as a function of time τ. Temperature, °C: (*1*) 20, (*2*) 40, and (*3*) 60.

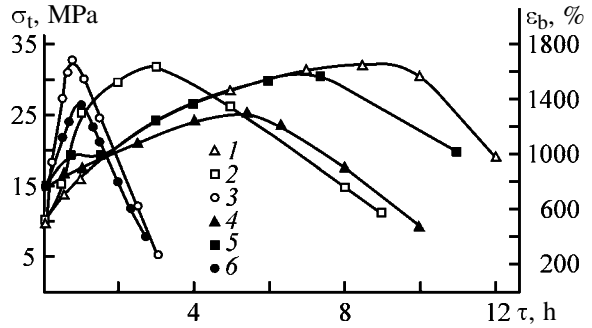

Fig. 4. (*1–3*) Ultimate tensile strength σ_t and (*4–6*) relative elongation ε_b of STEP as functions of swelling time τ in DMF. Temperature, °C: (*1*, *4*) 20, (*2*, *5*) 40, and (*3*, *6*) 60.

bonds are not restored after attainment of the thermodynamic equilibrium in the system. Therefore, the strength and elasticity of STEP in CH decrease from the very beginning of the process, and after keeping for 14 h at 60°C the polymer passes into the solution. Therefore, CH can be used for facilitating the breakdown of polyurethane in its utilization in the form of finely dispersed crumb as an additive to building mixes.

The proton-acceptor groups S=O and C=O present in DMSO and DMF interact with NH groups of the polymer. The breakdown and formation of hydrogen bonds in this case can be considered as a set of concurrent equilibrium processes. In swelling of STEP in DMSO, initially the physical network of molecular chains gets ordered, which enhances the strength of the polymer. Then, because of the exceedingly high penetrating power of the solvent, the whole volume of the polymer is nonselectively diluted and homogenized with the breakdown of both the network of chains formed by hydrogen bonds and the physical network of segmented domains. As a result of breakdown of the polymer matrix of both levels, it ceases to retain the plasticizer and degrades into short-chain fragments, forming a nearly true solution. This is manifested as an extreme decrease in the strength and breaking elongation. Dimethylformamide is more sensitive to steric hindrance and therefore is concentrated in amorphous regions for a longer time and more slowly penetrates into crystalline regions; therefore, the broken bonds have time to be partially restored.

Thus, each of the compounds studied shows, to different extents, the plasticizing power with respect to polyurethane, but the thermodynamic equilibrium is observed at different concentrations and hence the deformation properties are manifested to different extents. Preference should be given to aprotic compounds, and in particular to dimethylformamide, which is fairly active, cheap, and readily available.

The influence of temperature on the behavior of monolithic polyurethane in DMF is illustrated by Fig. 3.

In swelling of real networks in aprotic liquids, the following processes occur in succession: "dilution" of the network, rupture of physical bonds of polymer chains, and rupture of the physical network in segmented domains by molecules of the liquid. The latter process is manifested in the curves illustrating the polymer swelling with time as a characteristic inflection clearly pronounced in the whole temperature range examined.

The degree of swelling of PU after keeping for 5 h in DMF at 40°C is 1.5 times higher, and at 60°C, 4 times higher than at 20°C. Thus, by varying the time and temperature of treatment of the polymer with dimethylformamide, it is possible to vary in a wide range the degree of its swelling and hence the capability for deformation under external loads.

It should be determined, however, to what extent treatment with DMF destroys the polyurethane structure and whether the polyurethane strength can be restored after removal of the plasticizer.

To evaluate the level of physicomechanical properties of the cured monolithic polyurethane treated with DMF at different concentrations, samples in the form of "blades" with the length of the working zone of 2 cm were immersed in the plasticizer and kept there at a prescribed temperature. At equal time intervals, samples were withdrawn from the solvent, dried at 60°C to constant weight, and then tested with an RMI-250 tensile-testing machine. Experiments were continued until a thermodynamic equilibrium was attained in the system. The weight and volume of the swollen samples increased, but after drying the samples fully restored their shape and were suitable for tests.

Figure 4 shows how the ultimate tensile strength σ_t and relative breaking elongation ε_b vary in the course of plasticization at various temperatures. The network

breakdown is manifested as extreme decrease in the strength and breaking elongation.

Thus, the PU structure can significantly change upon introduction of various kinds of modifiers. Addition of plasticizers alters the whole set of properties of the polymer, including the glass transition and flow points, and enhances the capability for strain transformations under given conditions, which is important for processing. Aprotic compounds are the most effective in this respect. Moderate plasticization with dimethylformamide for 7–10 h at 20°C, which corresponds to 130–170% swelling, leads to an increase in the strength and elasticity of the polymer after the removal of the plasticizer.

With an increase in the plasticizer concentration over the equilibrium concentration, the strength and elasticity of the material decrease: For each combination of a polymer and a liquid medium, there is a definite quantitative limit of the plasticizer content in the polyurethane, above which the polymer matrix is destroyed and the plasticized system loses the thermodynamic stability.

Under these conditions, it is possible to prepare from a finely ground vigorously stirred powder a homogeneous viscous-flow mass exhibiting adhesive and film-forming properties. This concerns not only monolithic polyurethane, but also polymeric sheets by rolling microcellular or integral PUs [4–9].

An increase in the polyurethane temperature at its contact with DMF, as well as stirring, decreases the time required for plasticization of the compound. Therefore, homogeneous concentrated solutions of poly(butylene glycol adipate urethane) were prepared in a horizontal mixer with Z-shaped blades at 90°C within 10 h.

The KLEUR adhesives thus obtained are concentrated (60–75%) solutions of polyurethane in DMF; their characteristics are given in Table 1. With respect to the strength of the glued joint, the compound meets typical requirements specification for shoe adhesives.

The compound also shows promise for gluing wood. Wood bars of size 120 × 30 × 8 mm were glued in the butt (via 30 × 8-mm faces) or lap (via 120 × 30-mm planes, length of glued joint 25 mm) modes. The results are given in Table 2 in comparison with the results obtained for the same joints with an epoxy resin as adhesive. After gluing, the specimens were kept for 24 h under a pressure of 0.2 MPa.

It is seen that, with respect to the strength of the

wood glued joint, the compound we developed well competes with the epoxy resin [10]. As the joint made with KLEUR adhesive is highly elastic, in many cases it can be preferable over the joint made with an epoxy resin.

The film formed on dryingt of KLEUR adhesive has the ultimate tensile strength of 12 MPa, relative elongation of 920%, tear resistance of 0.6 kN m^{-1}, and Shore hardness of 72 units. Such parameters allow the viscous liquid compounds based on polyurethane waste to be used for preparing film coatings. We developed filled compounds containing (i) polyurethane acting as a binder for powdered components and providing formation of a protective film on a surface to be treated; (ii) plasticizer imparting the flowability to the compound and allowing application of the mastic onto a support; (iii) filler introduced to enhance physicomechanical characteristics, improve the fire safety, reduce stresses arising in the course of film formation, and decrease possible shrinkage; and (iv) pigment added to provide the required optical and decorative effects (Table 3).

CONCLUSIONS

(1) Waste of cured poly(ethylene butylene glycol adipate urethanes) should be plasticized to decrease the flow point and make it possible to use a low-destructive molding procedure to obtain items with satisfactory service characteristics.

(2) The macrokinetic parameters of equilibrium swelling of monolithic polyurethanes in various kinds of plasticizers were determined.

(3) Dimethylformamide was chosen as a plasticizer decreasing the temperature of reprocessing monolithic and microcellular polyurethane. In dimethylformamide, the material passes into the viscous-flow state within 24 h at 20°C. The resulting adhesive compound has good consumer's properties; it ensures the glued joint strength similar to that reached with epoxy resins.

(4) Preparation conditions and properties of film materials based on plasticized polyurethane waste were determined, and the possibility of using these materials as paint-and-varnish coatings was demonstrated.

Received November 27, 2006

Abstract—Effect of fabrication procedure of rubber stocks on the strength and fatigue performance of composite materials based on modified butadiene–styrene rubber was examined.

DOI: 10.1134/S1070427207070221

For more than a century scientists attempted to obtain a synthetic elastomer with the structure and physical properties close to those of natural rubber (NR). Modern rubber industry uses essentially butadiene–styrene copolymer (SKS) as a source, because of its availability and low cost.

SKS is an elastomer suitable for fabrication of tires and other rubber goods. However, SKS exhibits some disadvantages as compared to NR, primarily, high hysteresis (strong heat liberation in multiple bending) [1].

SKS-based rubbers stocks are prepared at high temperatures. As a result of increased elastic recovery, the stocks exhibit a relatively high shrinkage. Furthermore, oil-filled stocks are characterized by uneven surface. These drawbacks may be overcome through optimization of the formulation, e.g., by combining unfilled with oil-filled SKS, introducing phenol–formaldehyde resins (to improve the adhesiveness) and special plasticizers and carbon black (to improve the workability) [2, 3].

The drawback of all types of synthetic rubber (SR), complicating their use in tire industry, is lower strength (cohesion strength) of raw compounds on their bases as compared to those based on NR, which is due to more perfect macroscopic structure of NR, which facilitates its crystallization at low deformation, and also to the lack of low-molecular-weight fractions [4].

The cohesion strength of SR-based stocks can be considerably improved through functionalization of the macromolecules and also by blending two or more polymers [5–7].

Conditions of fabrication and processing of rubber stocks as well as the use of additives strongly affect their structure and properties [8–10].

In this study we examined the effect of fabrication procedure of rubber stocks on the mechanical characteristics of composites based on modified SKS.

In the experiments we used SKS-30 ARKM-15 (up to 30% styrene, MW 320 000, unsaturation 70 mol %, Mooney viscosity 45); SKI-3 (94% *cis* units, MW 550 000, unsaturation 96 mol %, Mooney viscosity 61); SKS modified with trichloroacetic acid (SKS-I) (chlorine content 0.8 wt %, carboxy group content 0.5 wt %); and SKS modified with alkyl trichloroacetate (SKS-II) (chlorine content 0.6 wt %, carbonyl group content 0.3 wt %). SKS-I and SKS-II were prepared in benzene in the presence of benzoyl peroxide [11].

The rubbers were mixed under laboratory conditions using 160×320 mm rollers at a friction ratio of 1 : 1.24 and a temperature not exceeding 40°C.

The stocks were vulcanized in an electrically heated vulcanizing press at 143°C and hydraulic pressure of 110 ± 5 atm, using 1-mm-thick molds. The tensile tests were carried out on a tensile-testing machine at a strain rate of 200 mm min^{-1}.

We tested the following vulcanizates of polymer blends: (*1*) standard stocks consisting of 100% SKS (mod. SKS) or SKI-3 with 50 wt parts of S301 carbon black (vulcanizing system: sulfur + zinc oxide + Altax + diphenylguanidine); (*2*) standard stocks based on SKS (mod. SKS)/SKI-3 (50 : 50 wt/wt), filled with N242 high-structure carbon black (55 wt %) (vulcanizing system: sulfur + Oktofor-10 alkylphenol–sulfide–formaldehyde oligomer + zinc oxide + *N*-oxadiethylene-2-benzothiazolylsulfenamide (OBTS).

Rubber	Rubber mixing sequence	N_r, thousand cycles
SKS	–	50
SKI-3	–	85
SKS/SKI-3	Addition of SKS to SKI-3 master batch containing all ingredients	100
SKS/SKI-3	Combination of SKS and SKS-3, followed by introduction of ingredients	140
SKS/SKI-3	Combination of master batches of SKS and SKI-3	152
SKS/SKI-3	Addition of SKI-3 to SKS master batch containing all ingredients	305

Diversification of SRs opened the door for progress in developing composite rubbers based on blends of two or more elastomers. On this way, there were obtained blend rubbers with synergetically improved mechanical characteristics, which can be illustrated by an example of the fatigue behavior of rubbers based on *cis*-polyisoprene and *cis*-polybutadiene, as influenced by the component ratio [12]. Another example is the filler or modifier effect on the strength and elastic-relaxation behavior of rubbers based on binary blends of elastomers [13–15].

We studied the mechanical properties of the initial and modified vulcanizates of the resulting formulations, as influenced by the fabrication procedure. The results (average of five measurements) are listed in Tables 1 and 2.

The rubbers to be blended generally differ in their modulus, i.e., the system formed as a result of their combination exhibits different modules of the dispersed and continuous phases. Fracture of a sample upon multiple deformation starts from microcrack growth. If a microcrack is developed in a medium with a lower modulus, approaching a particle of a high-modulus rubber decelerates or even terminates its growth through overstrain relaxation at the crack tip. If a microcrack is developed in a medium with a higher modulus (modulus of the continuous phase is higher than that of the dispersed phase), the overstrains at the tip of the growing crack are readily relaxed on approaching a dispersed phase particle having higher elastic compliance. If a blend rubber consists of two continuous phases, there is no way to fracture of the sample without breakdown of the particles themselves, i.e., only along the phase boundaries [12]. Therefore, most likely, both above crack propagation mechanisms are realized.

Since blended polymers differ in their modulus and strength, an optimal inhomogeneous (microheterogeneous) system is formed, exhibiting a higher breaking strength. This hypothesis is supported by the direct measurements of the crack propagation rate under multiple flexure of a vulcanizate plate with a perforation applied, and also by the fact that the fracture surface of individual rubber vulcanizates appears smoother as compared to that of vulcanizates of polymer blends, especially against the samples with the highest dynamic strength.

The phase transfer of fillers and their transition from the free-disperse state to the state of dispersion in a viscous polymer occur during mechanical mixing. Therefore, the mixing conditions and filler addition mode exert a decisive effect on its phase distribution. An optimal set of mechanical characteristics of a filled polymer blend is provided by the optimal phase distribution of the filler. Note that the optimal distribution is not always equivalent to the uniform distribution. A directed phase distribution of the filler sets such a degree of microheterogeneity that provides the best suited conditions for strain relaxation,

thus eliminating crack propagation and improving the strength and fatigue behavior, as demonstrated in Tables 1 and 2.

As seen from Tables 1 and 2, the best results were obtained for the third mode of filler addition, i.e., on addition of SKI-3 to the SKS master batch containing all the ingredients.

The mechanical characteristics of the vulcanizates of the standard rubbers based on SKI-3, initial and modified SKS, and standard rubbers based on SKS/SKS-3 are summarized in Table 3.

As can be seen, the strength performance of the rubbers based on SKI-3 blend with the initial SKS is worse or the same as the additive values. With the use of modified SKS, the strength performance characteristics are slightly above the additive values (modulus at 300% elongation, tensile strength, relative elongation, and elongation set), the tear resistance being considerably above the additive value.

As expected, blending improved the performance: the crack resistance in the absence of fatigue substances increased by a factor of 7–10, the endurance of rubbers in multilayer systems with bonding to SKI-3 rubber increased, as well as the rubber adhesion to wet surface. The adhesive characteristics of the blend elastomers with respect to St.3 steel with the use of Leikonat glue were found to be much better (by a factor of 2–3) as compared to the initial components.

It is known that introduction of the carboxy groups into the rubber macromolecules improves the mechanical and elastic properties of the products. However, rubber stocks on their basis tend to overcure, and vulcanizates, to scorching. Therefore, it appears preferable to use compounds containing reactive ester groups as elastomer modifiers. The presence of the carboxy and ester groups in the structure of modifiers facilitates their conversion into ionic groups during vulcanization [4].

The observed high performance of vulcanizates of the modified rubbers can be attributed to the formation of bonds of different types (covalent and ionic) in the vulcanization network structure. Compared to the cross-linking via sulfur, the energy of ionic bonds is lower. The ability of these bonds to rearrange provides a possibility of stress relaxation in the vulcanization network and in deformation of the resulting vulcanizates. Stress relaxation is responsible for increasing resistance of rubbers to aging, tear, and multiple deformations.

The effect of improvement of the fatigue and adhesion behavior of the rubbers based on SKS/SKI-3 blends can find practical application in manufacture of rubbers for various purposes, and also of adhesives and specialty coatings.

CONCLUSIONS

(1) Data on the effect of the fabrication procedure of rubber stocks on the properties of composite materials showed that the best strength and fatigue performance were obtained upon adding SKI-3 to the SKS master batch containing all the ingredients.

(2) Introduction of the chlorine atoms, carboxy, or ester groups in the elastomers alters the structure

of the vulcanization network through development of a combination of strong valence and labile ionic bonds, thus improving performance characteristics of rubber.

(3) Preparation of the composites, based on modified SKS, with improved performance characteristics extends the application area of these materials in various branches of industry.

Abstract—Fundamental aspects of the polymerization of butadiene in the presence of a titanium catalyst under intensive agitation of the reaction mixture in the initial stage of polymerization, provided by use of a tubular turbulent divergent–convergent prereactor, were examined.

DOI: 10.1134/S1070427207070233

The stereospecific polymerization of dienes on complex Ziegler–Natta catalysts includes a number of complex physicochemical processes, some of which occur at high rates. To these processes belongs the stage of formation of active centers, which includes a redox reaction of a transition metal compound with an organoaluminum compound, formation of the surface structure of a microheterogeneous catalyst, addition of a first monomer molecule to the active center, etc. It was shown in [1–3] that the occurrence of fast stages in the polymerization process makes advisable use of tubular turbulent divergent–convergent prereactors. In this case, optimal conditions are created, under the conditions of a preliminary turbulent agitation of the reaction mixture, for occurrence of fast processes in the absence of diffusion limitations, with the chain propagation stage subsequently performed in a large-volume mixer with a long residence time of reagents in the reaction zone.

The aim of this study was to examine the fundamental aspects of the polymerization of butadiene in the presence of a $TiCl_4$–Al(i-C_4H_9)$_3$ catalyst under vigorous agitation of the reaction mixture in the initial stage of polymerization because of the use of a tubular turbulent divergent–convergent prereactor.

Butadiene was polymerized in toluene on an experimental installation including the tubular turbulent prereactor described in [3]. The starting reactants were purified by a standard procedure commonly accepted for stereospecific polymerization of dienes on Ziegler–Natta catalysts. The separately prepared catalytic complex $TiCl_4$–Al(i-C_4H_9)$_3$ was kept at 273 K for 30 min. The concentrations of the catalyst and monomer were c_{Ti} = 5 mM and c_m = 1.5 mM. The molar ratio of the components of the catalytic system, which provided the maximum polymerization rate and highest content of 1,4-*cis* links (~75–78%), was Al/Ti = 1.8.

The polymerization process was performed by two methods.

Method 1. The components of the reaction mixture (separately prepared catalytic complex and monomer solution) were mixed directly in the large-volume apparatus (500 cm^3 flask) under slow agitation with a magnetic stirrer. This method modeled the conventional way of polymerization under industrial conditions [4].

Method 2. A preliminarily kept catalytic complex was mixed with a butadiene solution in a tubular turbulent divergent–convergent prereactor in the course of 2–3 s. Then the reaction mixture was delivered into a large-volume apparatus, in which conditions similar to those in method 1 were created.

The number-average (M_n) and weight-average (M_w) molecular weights (MW) and the molecular-weight distribution (MWD) of polybutadiene were determined by gel-permeation chromatography on a Waters chromatograph at 80±0.5°C, with toluene as solvent and elution rate of 1 ml min^{-1}, The chromatograph was calibrated against close-cut (M_w/M_n = 1.1) polystyrene references. * W_p is the initial polymerization rate (mol l^{-1} min^{-1}); c_a, concentration of active centers (M); k_{cp}, k_{al}, and k_m, rate constants of chain propagation and chain transfer to the organoaluminum compound and to the monomer, respectively (l mol^{-1} min^{-1}); Σ, kinetic parameter, which is an arithmetic mean for the constants and a sum for concentration of separate AC types.
** Σ is the kinetic parameter calculated from the data of [5].

strumental broadening was made. The error of the technique was 15–20%. The conversion dependences were obtained using the gravimetric method, with an error not exceeding 1%.

Raising the intensity of agitation of the reaction mixture in the initial stage of the polymerization process because of the use of a tubular turbulent prereactor makes the polymer yield higher (Fig. 1). In order to explain the observed acceleration of the polymerization process, the rate constant k_{cp} of chain propagation and the concentration of active centers (AC) were evaluated as described in [5]. The calculations demonstrated that the rate of polymerization, which is first-order with respect to the catalyst and the monomer, grows because of the 1.7-fold increase in the AC concentration in the polymerization system (see table). Changing the polymerization procedure has virtually no effect on the rate constant of the polymeric chain propagation. At the same time, the initial polymerization rate increases by a factor of up to 4.6 if the tubular turbulent prereactor is used, which can be attributed not only to an increase in the AC concentration, but also to the formation of a homogeneous reaction mixture and uniform particle distribution of the microheterogeneous catalyst.

It is well known that a change in the reaction rate on raising the agitation intensity indicates that the elementary stages of the process occur under diffusion control. Apparently, preliminary agitation of the reaction mixture in the turbulent mode in butadiene polymerization on a microheterogeneous titanium-based catalytic system diminishes the diffusion hindrance in the stage of formation of the surface structure of the catalyst.

According to the kinetic scheme of polymerization of dienes, an increase in the AC concentration should lead to a decrease in the average values of the molecular weight of polybutadiene [5, 6], which is confirmed by the experimental data obtained. In the preliminary forming of the reaction mixture in turbulent flows (method 2), the weight-average MW of polybutadiene substantially decreases (Fig. 2). In this case, a slight change in the number-average MW favors synthesis of a polymer with a narrow MWD (Fig. 3). In the conventional polymerization technique, the MWD curves

of polybutadiene have a unimodal shape and shift, as the monomer conversion increases, into the high-molecular-weight region without any significant change in the distribution width.

The hydrodynamic impact on the reaction mixture in turbulent flows in the initial stage of polymerization predetermines formation of a polymer with a unimodal MWD and a conversion shift of the corresponding curves into the low-molecular-weight region.

It is known that the MWD width is one of the most important and decisive factors determining the service parameters of synthetic rubbers [7], because the M_w/M_n ratio affects such parameters as the Mooney viscosity and cold-flow capacity and predetermines the properties of vulcanized rubbers. The latter is due to the fact that vulcanizates based on polybutadienes with broad MWD have a nonuniform and less dense vulcanization network, which leads to poor physicomechanical characteristics of vulcanized rubbers. It can be assumed that a decrease in the weight-average MW of polybutadiene at an insignificant change in the number-average MW must lead to an increase in the vulcanization network density.

However, the presence of low-molecular-weight fraction enables, because of their plasticizing effect, a flow at high shear stresses. Thus, it seems plausible that the observed decrease in the polydispersity index of polybutadiene, caused by the use of a tubular turbulent divergent–convergent prereactor, will make it possible to enhance the flow capacity of the polymer at high shear stresses and, simultaneously, improve the physicomechanical properties of vulcanizates.

It is known that the reason why the MWD of polydienes synthesized on Ziegler catalytic systems is broad is the polycentric nature of the polymerization AC [8–10]. A solution of the inverse MWD problem by the Tikhonov regularization method demonstrated that, with the conventional polymerization technique (method 1), the catalytic system is characterized by the presence of four types of active centers. The peak positions in the kinetic nonuniformity curves correspond to the following ranges of molecular weights: $\ln M$ = 9.2–10.4 (type I), 11.2–11.4 (type II), 12.9–13.2 (type III), and 14.1–14.7 (type IV), i.e., each type produces its own fraction of the polymer.

In the case of the conventional polymerization method, the kinetic activity of the macromolecule propagation centers of types I and II decreases as the conversion becomes higher, and that of type III and IV centers increases (Fig. 4). Upon a hydrodynamic impact on a separately prepared catalytic complex $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ (method 2), the type I active center producing the low-molecular-weight fraction of polybutadiene ($\ln M$ = 9.2–10.4) disappears (Fig. 4). The kinetic activity of the type II AC in a reaction mixture formed in turbulent flows is substantially higher, compared with method 1. In the course of polymerization, the activity of type III centers changes only slightly, and that of type IV AC producing the high-molecular-weight fraction of polybutadiene remains unchanged and is lower than that in method 1.

The kinetic parameters of butadiene polymerization were calculated for each type of active centers by the method previously described in [11]. It can be seen from the table that the kinetic parameters of the polymerization process estimated in terms of the polycentric model well coincide with the calculations made in accordance with [5]. Upon a hydrodynamic impact on the reaction mixture in the initial stage of polymerization, the concentration of type II AC substantially increases to 99.5% of the total

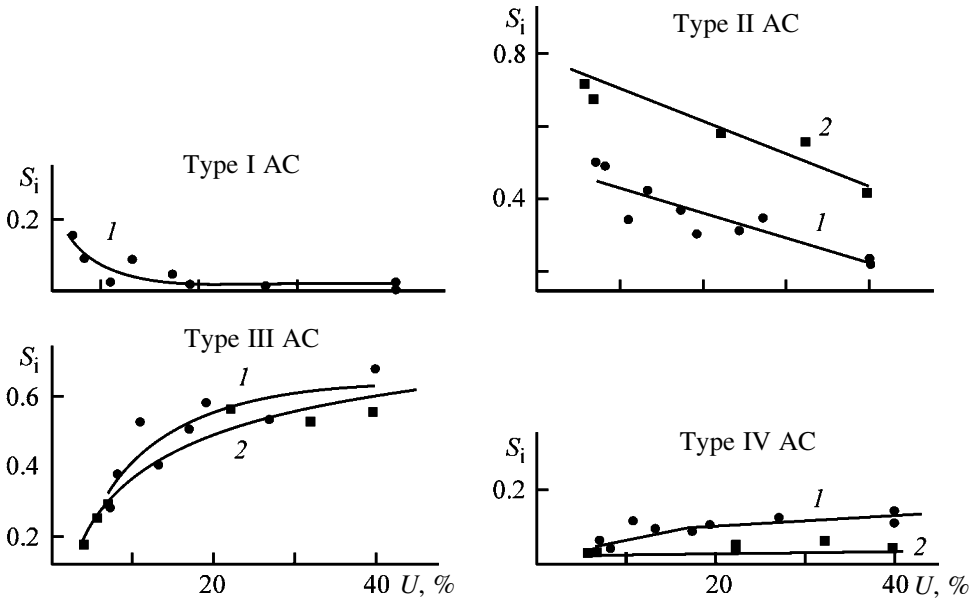

Fig. 4. Kinetic activity S_i of macromolecule propagation centers of various types vs. the polybutadiene yield U.

number of propagation centers in the polymerization system.

Each AC is characterized by a certain ratio of polymer chain termination and propagation constants, i.e., synthesizes macromolecules of certain length. As a consequence, the changes in the MW and MWD of polybutadiene, observed in the case of a preliminary treatment of the reaction mixture in a tubular turbulent prereactor, can be attributed not only to an increase in the total AC concentration, but also to a change in the number of types of AC with a certain set of kinetic constants. For example, presence of the low-molecular-weight fraction in the polymer, which primarily affects the number-average molecular weight, is determined by the reactions of chain transfer to the monomer and organoaluminum compound, whose rate constants are the largest for type I and II AC (see table). These active centers have comparable rate constants for chain transfer reactions, but markedly different rate constants for the chain propagation reaction. Upon a hydrodynamic impact on the reaction mixture (method 2), a pronounced increase in the concentration of type II AC is observed. These centers have a higher rate constant of the chain propagation reaction than type I center, which disappears. In accordance with the kinetic scheme of the process, this results in that the number-average molecular weight of polybutadiene changes only slightly on varying the polymerization method.

The presence of the high-molecular-weight fraction in the polymer is mostly due to type III and IV centers, whose initial concentration in the polymerization system decreases upon a preliminary hydrodynamic impact on the reaction mixture (see table). In addition, in the case of a hydrodynamic impact on the reaction mixture in turbulent flows, the kinetic activity of type IV centers does not change as the conversion increases, whereas an increase in the activity of this type of centers is observed (Fig. 4) in polymerization by the standard method. As a result, preliminary forming of the reaction mixture in the turbulent mode yields a polymer with a lower weight-average molecular weight.

Thus, if the reaction mixture for butadiene polymerization in the presence of $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ is treated in the turbulent mode, the concentration of active centers increases and, as a result, the process rate grows. Use of a tubular turbulent prereactor has virtually no effect on the rate constants of the reactions of chain propagation and chain transfer to the organoalunimum compound and the monomer. Changing the polymerization method leads to disappearance of the active center producing the low-molecular-weight fraction of the polymer ($\ln M$ = 9.2–10.4), with an increase in the number of centers that synthesize a polymer with a molecular weight $\ln M$ in the range 11.2–11.4. In this case, the weight-average molecular weight of the resulting polybutadiene decreases and its molecular-weight distribution becomes narrower.

Use of a tubular turbulent prereactor in preliminary forming of the reaction mixture for butadiene polymerization makes it possible to reduce the expenditure of the titanium catalyst, compared with the conventional

polymerization technique. In particular, the polymerization occurs at an initial rate of 0.0175 mol l^{-1} min^{-1} in a conventional process with c_{Ti} = 5 mM, and use of a prereactor enables a 1.7-fold decrease in the catalyst expenditure (to the extent to which the AC concentration increases). A redistribution of the types of active centers occurs in this case, which results in that a polymer is obtained with a weight-average molecular weight equal to that of the polymer produced by method 1 at a higher catalyst concentration c_{Ti} = 5 mM. The decrease in the polydispersity index of polybutadiene on lowering the catalyst concentration and forming the reaction mixture in the turbulent mode is predetermined by its higher number-average molecular weight.

CONCLUSIONS

(1) Preliminary vigorous agitation of the reaction mixture in a tubular turbulent divergent–convergent prereactor in butadiene polymerization on a titanium catalyst leads to a rise in the process rate because of the increase in the concentration of active centers and a uniform catalyst distribution throughout the reaction volume. Under industrial conditions, this enables a decrease in the expenditure of the catalytic complex.

(2) The partial elimination of diffusion limitations in the stage of formation of the reaction mixture leads to disappearance of the active center responsible for synthesis of the low-molecular-weight fraction of the polymer ($\ln M$ = 9.2–10.4) and to an increase in the concentration of centers that produce macromolecules with molecular weights in the range 73 000–89 000. The redistribution of macromolecule propagation centers leads to a decrease in the weight-average molecular weight of polybutadiene and in the polydispersity index.

Abstract—Mechanical and physicochemical properties of cotton and viscose fibers esterified with aqueous solutions containing orthophosphoric acid and urea in different ratios were studied.

DOI: 10.1134/S1070427207070245

More than 50 types of suture filaments made of synthetic and natural polymers are widely used in modern world surgery. At the same time, none of the known materials are universal. Each of them has its own advantages and disadvantages, which not only requires their differential and purposeful application but also makes urgent preparation of new types of suture filaments.

Cellulose fibers are the most promising natural polymers for preparing suture filaments. Biocompatible materials resorbable in a living body can be prepared by modification of cellulose fibers. The physicochemical and medicobiological properties of cellulose phosphate with a degree of substitution with the phosphate groups of more than 0.2 (the phosphorus content is higher than 1.1 mmol g^{-1}) were extensively studied. The sorption capacity of the modified polysaccharide for inorganic and organic cations is high and this sorbent is not toxic [1, 2]. At the same time, highly substituted cellulose phosphates are prepared under rigid conditions (concentrated orthophosphoric acid, temperature above 145°C), which deteriorates their mechanical properties and makes these polymers unsuitable as suture materials.

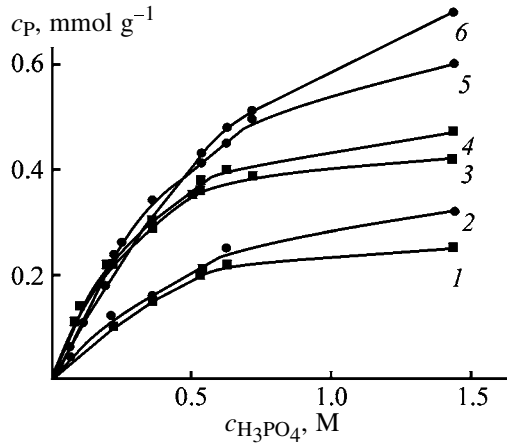
The aim of this study was to prepare low-substituted phosphorylated viscose and cotton fibers, to study their physicochemical and mechanical properties, and to determine the possibility of their use for preparing suture materials.

EXPERIMENTAL

We studied viscose cordage (Svetlogorsk, Khimvolokno Production Association) and cotton (Grodno, Groniteks) fiber with the line density of 184 and 100 tex, respectively.

The cellulose fiber was phosphorylated in several steps [1]. The main steps are as follows: preliminary impregnation of the fiber with an esterifying mixture for 30 min at 80±2°C and a 1 : 10 liquor ratio (g ml^{-1}); squeezing to remove excess mixture down to 100% weight gain; drying to constant weight at room temperature; chemical modification at 145±2°C for 1 h; washing; treatment with 0.1 N HCl and drying to the air-wet state.

As esterifying agent we used aqueous solutions of orthophosphoric acid containing urea. The anhydroglycoside unit (AGU) : H_3PO_4 : $CO(NH_2)_2$ molar ratio was varied. The phosphorus content c_P (mmol g^{-1}) in the modified cellulose fiber was determined by the molybdate procedure [3]. The nitrogen content was determined by the Kjeldahl method [4]. The exchange capacity (EC) (mg-equiv g^{-1}) was measured by potentiometric titration with a sodium hydroxide solution [1]. The degree of swelling Q (g g^{-1}) was determined gravimetrically [1]. The IR spectra of the samples in the form of KBr pellets were recorded on a Thermo Nicolet FT-IR Nexus spectrophotometer. The X-ray diffraction analysis of cellulose samples was performed on a Carl Zeiss diffractometer (CuK_α, Ni filter, HZGb-4A). The crystallinity index was calculated using an internal reference [5]. The mechanical properties were estimated from the relative strength (ratio of the tensile strengths of dry and wet phosphorylated cellulose fibers and the fiber tied in a knot, measured on a PM-3-1 tensile-testing machine, to the linear density) and relative elongation ε (%) [6]. The linear density was deter-



Phosphorus content c_P of (*1, 3, 4*) cotton and (*2, 5, 6*) viscose fibers as a function of the orthophosphoric acid concentration $c_{H_3PO_4}$. Urea concentration in the solution, M: (*1, 2*) 0.83, (*3, 5*) 3.33, (*4, 6*) 4.17.

mined from the data of [6]. Each relative strength P (sN tex^{-1}) and T is an average of no less than 10 measurements. The scatter of the relative strength did not exceed 10%. The strength loss ΔP (%) of the fibers after their phosphorylation was calculated by the equation

$$\Delta P = (P_{in} - P_{ph}) \times 100/P_{in},$$

where P_{in} and P_{ph} is the relative strength of the initial and phosphorylated fibers, respectively (cN tex^{-1}).

The phosphorus content of cellulose fibers rapidly increases during the first hour of their heat treatment at 145±2°C. Then the esterification substantially decelerates. This is typical for the heterogeneous reaction of cellulose and is due to different reactivity of the hydroxy groups of the polymer. It should be noted that the optimal time of phosphorylation of cellulose fibers is 1 h. Longer heat treatment deteriorates the mechanical properties of the polymer.

The content of fixed phosphorus in cellulose fibers depends on the concentration of orthophosphoric acid and urea in the solution (see figure), all other conditions (time and temperature of impregnation and heat treatment, squeezing, washing) being the same. The phosphorus content of the sample c_P ranges from 0.05 to 0.5 mmol g^{-1} when the concentration of orthophosphoric acid changes from 0.15 to 0.63, and that of urea, from 0.83 to 3.33 M. The content of fixed nitrogen in the fibers prepared under these conditions is fairly high. This is due to the fact that cyanic acid formed during heat treatment at temperatures higher than the melting point of urea reacts with hydroxy groups of cellulose to form carbamate groups [1, 7].

Formation of carbamate groups under these conditions is confirmed by IR spectroscopy. The IR spectra of phosphorylated cellulose fibers prepared at different AGU : H_3PO_4 : $CO(NH_2)_2$ ratios, unlike the IR spectra of the initial cellulose, contain the band of carbonyl group (C=O) at 1710 cm^{-1}. The intensity of this band increases with an increase in the fixed nitrogen content. It should be noted that the content of fixed nitrogen and hence of carbamate groups in the samples of low-substituted cellulose phosphates is equal to, or even higher than that of phosphorus (Table 1). The c_N increases with increasing concentration of both orthophosphoric acid and urea in the esterifying solution.

The bands at 790 (out-of-plane bending band of the P–O–H groups) and 830 cm^{-1}, the shoulder at 980 cm^{-1} (stretching vibration of the P–O bonds), and a complex band with the maximum in the range 1200–1220 cm^{-1} (P=O vibrations) in the IR spectra of the samples unambiguously confirm the presence of phosphate groups in the samples [7, 8].

As seen from Table 1, the phosphorus content of the phosphorylated fibers is lower by a factor of 2 than their exchange capacity determined by potentiometric titration. This can be due to the fact that the main esterification product is monosubstituted cellulose phosphate [1].

The content of functional groups in cellulose modified at low concentrations of orthophosphoric acid (0.5 M) and urea (0.83 M) in the solution is almost independent of the structural features of the fiber. The fact that at higher orthophosphoric acid concentration (0.5–1.5 M) in the impregnating solution the content of the phosphate groups in the viscose fibers is higher than that in cotton fibers can be caused by features of supramolecular structure of the initial cellulose fibers whose hydroxy groups are accessible to the esterifying agent.

The structural differences of the cotton and viscose fibers are clearly seen from their X-ray diffraction patterns. The X-ray diffraction pattern of the cotton fiber is typical of cellulose I (C–I), and its index of crystallinity (IC) calculated using internal references is 0.69. The X-ray pattern of the initial viscous fiber contains reflections at $2\theta = 22°$ (strong) and $2\theta = 12°$ and is similar to that of cellulose II (C-II). The index of crystallinity of these cellulose samples is in the range 0.35–0.38.

The X-ray patterns of phosphorylated cotton cellulose and viscose fiber are similar to those of the initial

cellulose samples. The IC of the cotton fiber phosphorylated at c_P = 0.7 mmol g^{-1} is 0.67.

Some broadening and blurring of the reflections at 2θ 15° and 16° [(101) and (10$\bar{1}$)] suggests that these interplanar spaces of the cellulose fiber are the most accessible to the esterifying mixture. The results of a comparative IR study of the supramolecular structure of cellulose phosphate are completely consistent with the X-ray diffraction data. The index of asymmetry of the OH band in the range 3100–3600 cm^{-1} in the IR spectra of the phosphorylated samples changes insignificantly, and the maximum of this band remains the same. These transformations of the IR spectra of the modified cellulose samples suggest [10] insignificant change of the supramolecular structure during the modification.

Thus, the content of phosphate and carbamate group in the amorphous fraction of the cotton fiber is higher by a factor of 2 than that in the viscose fiber at the same degree of phosphorylation. Hence, the chemical composition of the viscose fibers esterified under all the conditions is more uniform, which undoubtedly affects their mechanical properties.

Data on the loss of the relative strength of the cellulose fiber after modification at different concentrations of orthophosphoric acid and urea in the esterifying solution are summarized in Table 2. It is seen that phosphorylation of the cellulose fibers decreases their relative strength, with the decrease being stronger for the cotton fiber. An increase in the concentration of phosphoric acid and urea in the esterifying solution affects in different manners mechanical properties of the phosphorylated fibers: the relative strength of

the fiber decreases with increasing H_3PO_4 concentration and increases with increasing urea concentration. The maximal preservation of the relative strength of dry cellulose fibers that have similar content of the phosphate groups but were prepared at a higher urea concentrations in the esterifying solution corresponds to the higher relative elongation and degree of swelling (Table 3). These data suggest that at least two competing processes affecting the mechanical properties of the fiber [11, 12] occur at a higher urea concentration in the impregnating solution. The fiber strength (1) decreases owing to a decrease in the strength of intermolecular bonds in the cellulose structure and (2) does not change owing to a decrease in the degree of cellulose degradation with increasing urea concentration in the solution.

In addition, it should be noted that weakening of the hydrogen bond network has a dual affect on the mechanical properties of cellulose fibers. Weakening of intermolecular interactions can favor more uniform distribution of stresses in the bulk of the fiber and increase the flexibility of the macromolecules [11]. The increase in the mobility of the structural elements and hence an increase in the degree of ordering before rupture increase the fiber strength.

These processes are parallel, but their intensity differs. As a result, as determined experimentally, the loss of the relative strength of phosphorylated cellulose fibers decreases with increasing urea concentration in the esterifying solution.

Comparison of the mechanical properties of cellulose phosphate fibers prepared from viscose and cotton fibers under the optimal conditions (0.25–0.72 M H_3PO_4 and 3.33 M urea) show that the strength of low-substituted phosphorylated viscose and cotton fiber is lower than that of the initial fibers by 25.3 and 62.0%, respectively. We suggest that stronger loss of the relative strength of the cotton fibers phosphorylated in the H_3PO_4–$(NH_2)_2CO$–H_2O system is caused by their structural and chemical nonuniformity which promotes degradation and disordering of macromolecules in the amorphous fraction and increases tension in the bulk of the polymer. An increase in the strength of wet cotton fibers confirms the influence of the internal tensions on the decrease in the mechanical strength of the fibers. Water molecules plasticize cellulose, affect the mobility of the macromolecules in the bulk of the polymer, change the mechanism of stress relaxation, and promote ordering of the macromolecules along the external force.

It should be noted that the tensile strength of low-phosphorylated viscose fibers in a dry knot is similar to that of the know absorbable suture filaments such as catgut, collagen, Oktselon, Katselon, etc. To increase the strength of low-phoshporylated cotton fibers, stronger initial fibers should be used and additional cross-linking of cellulose macromolecules is required.

CONCLUSIONS

(1) Monosubstituted cellulose phosphates with the phosphate content from 0.1 to 0.7 mmol g^{-1} were prepared from viscose and cotton fibers. The conditions for phosphorylating cellulose fibers with the maximal preservation of the relative strength in the dry and wet state (heat reatemnt for 30 min, 0.22–0.72 M orthophosphoric caid, 3.33 M urea) were determined.

(2) The content of carbamate groups in phosphorylated fibers is equal to, or higher than that of the phosphate groups and increases with increasing con-

centration of both orthophosphoric acid and urea in the impregnating solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Hydrophilic–Oleophilic Properties of Sulfate Lignin

S. B. Selyanina and N. V. Selivanova

Abstract—Effects of extractive resinous substances, type of wood, and pH on the hydrophilic–oleophilic behavior of solid lignin recovered from sulfate delignification liquors were evaluated.

DOI: 10.1134/S1070427207070257

Pulp industry is a primary consumer of wood, the yield of the final product being as low as about 50%. The sulfate cooking provides for total utilization of spent cooking liquors. This process necessarily involves recovery of sulfate soap as micellar aggregates, followed by production of tall oil by acid treatment. In this case, kraft lignin transferred into the soap emulsion with black liquor forms an insoluble solid product [1–3]. In the presence of lignin, a stable heterogeneous system (so-called lignotall emulsion or lignin phase) is formed. According to the modern views [4, 5], the lignin phase represents an oil-in-water emulsion. Lignin tends to concentrate at the interface, screening the surface of the oil droplets distributed throughout the bulk of the liquid and thus preventing their coalescence, i.e., stabilizing the emulsion. Therefore, the stability of such systems appears to be controlled by the characteristics of the stabilizer surface [6].

In this study, we examined the hydrophilic–oleophilic behavior of kraft lignins, as one of their most important characteristics as emulsion stabilizers.

Generally, the hydrophilic–oleophilic properties of surfaces are characterized by the ratio of the work of adsorption of a substance from the hydrocarbon (oil) and aqueous phases using the Bancroft rule [7], or by the conventional Rebinder relationship [8] for saturated hydrocarbons and water.

The classical method for determination of the gas adsorption on the surface of solid lignin is the gravimetric method with the use of a McBain quartz spring balance. This method is quite descriptive, being, however, characterized by complex hardware implementation and long time of analysis. The vacuum-static method is simpler and allows analysis of several samples in parallel [9]. This method is widely used for characterization of various sorbents. However, we found no indications in the literature for its use in analysis of lignin.

The lignin samples were allowed to stand in an adsorption cell until saturation, i.e., to constant weight of the sample. The final result was obtained as an average of three replicate experiments; the data scatter did not exceed 10% relative to arithmetic mean ($P = 0.95$).

The degree of hydrophilicity α was estimated by Eq. (1):

$$\alpha = \Gamma_w/(\Gamma_w + \Gamma_h), \quad (1)$$

where Γ_w and Γ_h are the limiting adsorptions of water vapor and hexane, respectively (mol g^{-1}).

The degree of oleophilicity β was estimated as the difference

$$\beta = 1 - \alpha. \quad (2)$$

When the adsorption cell was not evacuated prior to the experiment, the degree of oleophilicity estimated from the experimental specific adsorptions of hexane and water was within 0.13–0.16, while that determined with the McBain balance was 0.53–0.58 and 0.65–0.70 in coniferous and deciduous lignins, respectively [5].

As seen from Fig. 1, preliminary evacuation of the adsorption cell does not affect the specific adsorption of water vapor on the lignin surface, being, however, a crucial factor in adsorption of hexane, which is probably due to the difference in the vapor pressure.

The specific adsorption of hexane vapor approaches the equilibrium value at a residual pressure in the ad-

sorption cell of 0.07 MPa and lower. In this case, the hydrophilicity and oleophilicity differ by no more than 10% from those obtained using the McBain balance.

Therefore, the adsorptions of water and hexane vapors can be used as parameters for characterization of lignin samples and selection of samples with remarkably different hydrophilic–oleophilic properties, to clearly elucidate the effect of the lignin origin on the stability of emulsions.

To study the effect of extractive substances on the surface properties of lignin, distilled tall oil obtained from the distillation plant of the Solombala Pulp and Paper Combine (SPPC) was added stepwise to semiconcentrated black liquor [density 1200 kg m^{-3}, dry residue 38.1%, residual gummosity (recalculated to dry residue) 0.80%] after recovery of sulfate soap until complete dissolution. Distilled tall oil was selected as an additive, because it is a pure product similar in the composition to extractive resinous substances of black liquor. Lignin was precipitated from the resulting solution by acidification with 30% sulfuric acid to pH 2.1–2.5 with heating on a water bath. Then lignin was separated by centrifugation, washed, and dried at 50±1°C, to avoid its degradation [10].

Analysis of the hydrophilic–oleophilic behavior of lignins recovered in the presence of tall oil shows (Fig. 2) that increasing concentration of extractive resinous substances in black liquor from 0.8 to 2.2% (recalculated to dry residue) decreases the hydrophilic–lipophilic ratio by more than an order of magnitude by virtue of simultaneous decrease in the hydrophilicity and increase in the oleophilicity. The dependences of the specific adsorption of water and hexane vapors on kraft lignin on the concentration of extractive resinous substances in the initial liquor are nonlinear, which is more clearly pronounced in the case of water sorption, being reflected in the hydrophilic–oleophilic ratio.

Thus, we may conclude that the presence of extractive resinous substances in black liquors causes some uncertainty in characterization of the hydrophilic–oleophilic properties of lignin recovered from them, considerably increasing the oleophilicity and decreasing the hydrophilicity.

To eliminate this uncertainty, in the subsequent experiments, lignin samples were recovered from the liquors obtained in laboratory cooking of preliminary deresined wood chips of sound wood of pendent white birch and common spruce. The deresination was carried out in two steps. In the first step, wood chips were treated with an organic solvent (ligroin) to remove a part of resin and fatty acids along with neutral compounds. Then the residual solvent was removed by steam distillation, and extraction chips were soaked in aqueous sodium hydroxide to remove oxidized substances (readily soluble in alkali) and residual resin and fatty acids.

As known, lignins recovered from different kinds of wood differ considerably in the molecular weight distribution and functional composition [11], which can affect their hydrophilic–oleophilic and, therefore, emulsifying properties. The birch and spruce lignin samples recovered by the above procedure were characterized by the composition, molecular weight distribution (MWD), and hydrophilic–oleophilic properties [9, 12, 13] (Table 1, Fig. 3).

Table 1. Characteristics of spruce and birch lignin samples

Characteristic	Lignin

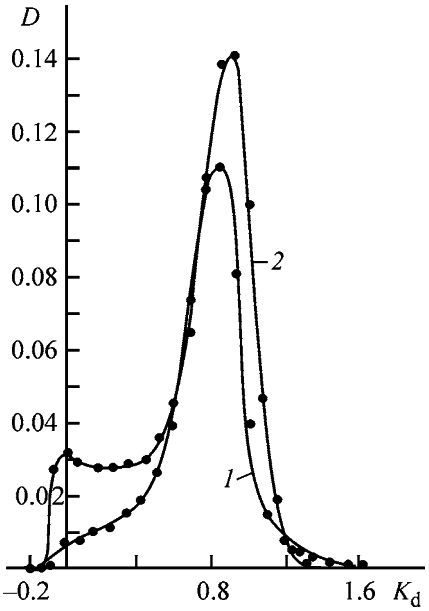

Fig. 3. Gel chromatograms of kraft lignins: (*1*) spruce and (*2*) birch. (*D*) Optical density at 280 nm and (K_d) distribution coefficient.

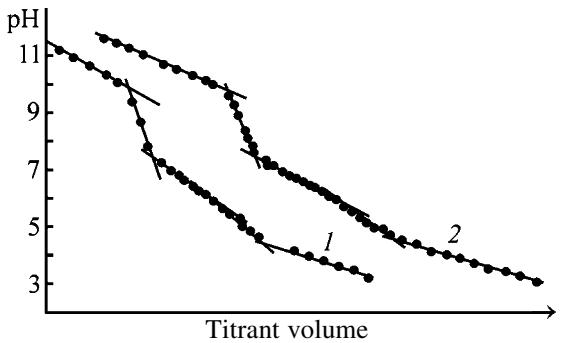

Fig. 4. Potentiometric titration curve of black liquor obtained in sulfate cooking with 0.1 HCl: (*1*) birch and (*2*) spruce.

The C, O, and H contents in our samples were well consistent with the published data obtained for similar lignins [11]. The oxygen content was found to be higher in the spruce lignin, which is due to the difference in the guaiacyl, syringyl, and *p*-hydroxyphenylpropane units in coniferous and deciduous lignins. The decreased Klason lignin content [14] in the sample recovered from birch wood can be attributed to a higher content of the acid-soluble fraction, which is typical of birch lignins.

It follows from the MWD curves (Fig. 3) that the samples in hand are polydisperse, the spruce lignin being characterized by a higher content of the high-molecular-weight fraction. As a result, spruce lignin has a higher weight-average molecular weight as compared to birch lignin (Table 1).

Differences in the composition of birch and spruce lignins are reflected in their hydrophilic–oleophilic properties. The absolute value of the adsorption of hexane vapor on higher-molecular-weight spruce lignin is higher by a factor of 3 than that on birch lignin, the adsorption of water being practically the same on both lignins. As a result, the hydrophilic–lipophilic ratio in birch lignin is higher by a factor of 3.1.

It is commonly accepted that properties of lignins are strongly affected by the recovery procedure, particularly pH. As seen from the potentiometric titration curves of black liquor (Fig. 4), substitution of the sodium ions for hydrogen in the acidic groups of kraft lignin proceeds after neutralization of excess alkali at pH 6.2–4.3. Despite the fact that, in sulfate cooking, lignin passes into the solution as various sodium compounds (lignosulfonates, lignophenolates, and lignoenolates), it appears impossible to distinguish some

sections in the potentiometric titration curves corresponding to the interaction of different groups with the acid. The solution becomes slightly turbid at about pH 6, but a precipitate can be separated only at pH 5 and below. Therefore, to study the effect of pH on the surface properties of lignin, the pH of precipitation was varied from 1 to 5 (Table 2).

Differences in the structure of native birch and spruce lignins [11] cause the need in more stringent cooking conditions for birch wood, to obtain the same degree of delignification as for spruce wood. In this case, birch lignin passes into the solution as finer species. All the spruce lignin samples have higher MW as compared to birch lignins (Table 2). It should be pointed out that, in the investigated biopolymers, the change in the weight-average molecular weight by 1000–1700 au corresponds to the change in the size of their macromolecules by 5–8 phenylpropane units. Keeping in mind the polydispersity of the investigated samples (Fig. 3), such a change in the weight-average molecular weights could not be considered as significant. Nevertheless, one could establish a fact of slight increase in MW of the samples recovered under more stringent conditions.

Analysis of the sorption characteristics of lignins shows (Table 2, Fig. 4) that, upon acidification to pH ~5, molecules having the minimal sorption capacity for hexane and increased adsorption of water are primarily recovered. In this case, the yield of lignin is rather low, and the mother liquor retains a darkbrown coloration, because of incomplete precipitation of lignin. Evidently, in this stage, sodium is replaced primarily in the phenol groups that contribute considerably to the hydrophilicity of the sample.

At pH < 4, the precipitation is more complete, and the mother liquor after recovery of lignin is light in color. In this case, lignin samples exhibit practically the same sorption capacities for both water and hexane. With decreasing pH to about 1, the adsorption of water increases in both birch and spruce lignins. The samples are highly hydrophilic, as demonstrated by the water sorption experiments. Taking into account that the molecular weights of all the investigated samples of birch and spruce lignins are similar, one may conclude that the ratio of the hydrophilic and hydrophobic fragments in the lignin molecule depends on both the functional group content and effect of modification of the lignin surface after sulfuric acid treatment.

CONCLUSIONS

(1) Lignin samples, recovered from sulfate liquors obtained in cooking of deresined wood, are characterized by an increased hydrophilic–oleophilic ratio. Increase in the content of extractive resinous substances in black liquor decreases this ratio through decreasing hydrophilicity and increasing oleophilicity of the lignin surface.

(2) The kind of wood has a considerable effect on the surface properties: birch lignin exhibits an increased sorption capacity for water vapor and decreased sorption capacity for hexane vapor, as compared to spruce lignin.

(3) The sorption capacity of lignins for hexane and water vapors depends on pH of their recovery. Lignins recovered at pH ~5 (incomplete precipitation), as well as lignins whose properties were altered by strong acid treatment, exhibit enhanced hydrophilicity.

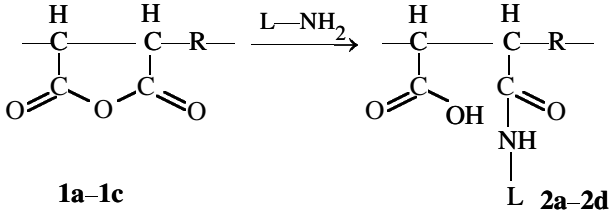
Abstract—New amphiphilic polymers derived from maleic acid copolymers and containing stearyl or oleyl residues were prepared. Their physicochemical properties were studied, and the possibility of using them as carriers for antifungal agents was examined with Amphotericin B as example.

DOI: 10.1134/S1070427207070269

Amphiphilic polymers (APs) contain in their chains both hydrophilic and hydrophobic groups. Many biopolymers (phospholipids, nucleic acids, proteins) are polyampholytes and amphiphiles. The association ability of APs in aqueous solutions opens prospects for using APs, e.g., in petroleum production, biotechnology, and also in production of pharmaceuticals to solubilize drugs and stabilize micro- and nanoaggregates containing bioactive substances [1]. There are two synthetic approaches to such APs: (co)polymerization of amphiphilic monomers or introduction of hydrophobic groups into hydrophilic polymers. The second approach seems preferable because of the possibility of varying the degree of hydrophobic substitution of a polymer without affecting the length of macromolecules. In this case, the hydrophobic ligand is randomly distributed along the macromolecular chain. Preparation and use of water-soluble carbon-chain APs were reported recently [2–4].

The goal of this study is synthesis of new APs based on maleic acid copolymers with *N*-vinylpyrrolidone, styrene, or ethylene by introducing into these copolymers stearyl or oleyl groups and examination of the physicochemical properties of the products and of the possibility of using them as carriers for antifungal agents:



1a–**1c** **2a**–**2d**

where R = —H_2C—CH— (N, O), L = $C_{18}H_{37}$ (**a**);

R = —H_2C—CH— (C$_6$H$_5$), L = $C_{18}H_{37}$ (**b**);

R = —H_2C—CH_2—, L = $C_{18}H_{37}$ (**c**);

R = —H_2C—CH— (N, O), L = $C_{18}H_{35}$ (**d**).

It is well known [5] that copolymers of maleic acid or anhydride have a constant composition (1 : 1), with strict alternation of monomeric units in the polymer chain. The anhydride groups of the maleic anhydride fragments can react with amino groups of an introduced hydrophobic ligand under mild conditions without condensing agents. Maleic anhydride copolymers were widely used previously as a base for preparing various polymeric reagents and carriers, in particular, for developing affine sorbents [6].

EXPERIMENTAL

Copolymer of maleic anhydride with *N*-vinylpyrrolidone **1a** was prepared according to [5] (*M* 40 kDa); copolymer **1b** (*M* 50 kDa) was produced by Sterlitamak Chemical Combine; **1c** (*M* 25 kDa), by Monsanto (the United States); and stearyl- and oleylamines,

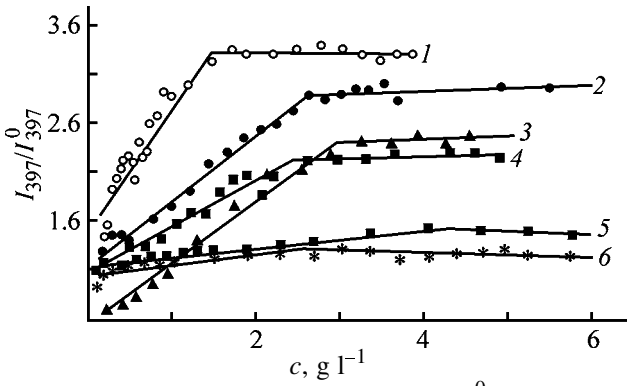


Fig. 1. Relative fluorescence intensity I_{397}/I_{397}^0 of pyrene solubilized with amphiphilic polymers **2a**–**2d** as a function of the AP concentration c. Emission wavelength 397 nm. (*1*) **2c** (DS 5%), (*2*) **2a** (DS 10%), (*3*) **2a** (DS 5%), (*4*) **2d** (DS 10%), (*5*) **2d** (DS 5%), and (*6*) **2b** (DS 5%).

by Aldrich. Pyridine (Khimspektr Limited Liability Trading Company) was purified by distillation from BaO; dimethylformamide was distilled from toluylene diisocyanate. For physicochemical studies we used deionized dust-free water. Hydrophobic ligand was introduced into polymers in an amount of 1–15 wt %.

The typical procedure for preparing AP is as follows: 3 g of copolymer **1a, 1b,** or **1c** was dissolved in 10 ml of dimethylformamide, and a solution of 0.3 g (10 wt %) of stearyl- or oleylamine in 5 ml of pyridine was added. After stirring for 2 h at room temperature, the mixture was poured with stirring into 100 ml of acetone (or chloroform for **1b, 1c**). The precipitate was filtered off and dissolved in water. The solution was filtered and dialyzed against an acetic acid solution (pH 5) and then against water, after which it was freeze-dried. Yield of polymers **2a**–**2d** 70–80%.

The structures of polymers **2a**–**2d** were confirmed by IR spectroscopy (KBr, ν, cm^{-1}): 3300 (N–H), 3200 (O–H), 1720–1730 (C=O), 1650 (C–N of pyrrolidone ring for **2a**). The characteristic frequencies of alkylamides, 1570 (C–N) and 1650 (C=O), were the most pronounced in the spectra of **2b** and **2c**.

The amount of the introduced hydrophobic ligand was confirmed by ^{1}H NMR spectroscopy (250 MHz, D_2O). Signals of stearyl residue, ppm: 0.74–0.97 (CH_3), 1.15–1.33 [$(CH_2)_{16}$], 1.58–1.61 (CH_2–N); the oleyl residue also gives a signal at 5.3 ppm (CH=CH).

It is well known that in aqueous solutions the behavior of charged AP macromolecules is affected by competing attraction (hydrophobic, van der Waals interactions, hydrogen bonds) and repulsion (Coulomb interactions) forces. The association and subsequent aggregation of APs are intensified with an increase in their concentration in solution to a threshold level, so-called critical aggregation concentration (CAC).

In this study, CAC was determined by the Wilhelmy method and by fluorescence spectroscopy with water-insoluble pyrene as a probe.

As seen from the table, CAC decreases with an increase in the degree of hydrophobic substitution of AP. As the major contribution to the formation of polymeric aggregates is made by the interaction of hydrophobic domains, an increase in the lipophilicity of a macromolecule can lead to enhancement of the hydrophobic interactions. Figure 1 shows how the relative fluorescence intensity depends on the concentrations of APs differing in the chain structure and hydrophobic ligand.

It can be noted that APs based on copolymers of *N*-vinylpyrrolidone (**2a**) and styrene (**2b**) with maleic acid, containing the octadecyl group as hydrophobic ligand (degree of substitution DS 5%), have approximately equal CAC (0.34 and 0.39 g dl^{-1}, respectively). The copolymer of ethylene with maleic acid (**2c**), with octadecyl groups introduced (DS 5%), has a more flexible macromolecular chain, with less pronounced conformation hindrance; therefore, its CAC is appreciably lower (0.7 g dl^{-1}).

Comparison of the copolymers of *N*-vinylpyrrolidone and maleic acid with various ligands (stearyl, **2a**, 5%; oleyl, **2d**, 5%) shows that the AP with the oleyl residue has a higher CAC (0.54 g dl^{-1}). Since the length of the hydrocarbon chain in the substituents in these APs is the same (C_{18}), this difference can be attributed to the higher rigidity of the ligand chain in **2d** (presence of double bond).

The dependence of the relative fluorescence intensity on the AP concentration in solution (Fig. 1) shows that, at $c \le$ CAC, two processes, association and aggregation, occur simultaneously, with the hydrophobic interactions making the major contribution to the aggregation. The further slight increase in the quantum yield of the fluorescence, continuing at $c >$ CAC, is attributable fo the continuing intermolecular aggregation.

A turbidimetric study of the stability of the associated polymeric systems at concentrations exceeding CAC revealed gradual occurrence of the further aggregation of AP particles, accompanied by coagulation and precipitation. For example, at a 2 g dl^{-1} concentration of AP **2a** (DS 15%), the precipitation started after keeping the system at room temperatrue for

12 days; with **2a** (DS 10 and 5%), it started in 13 and 16 days, respectively.

The hydrodynamic radius of AP particles in solution in CAC points was determined by dynamic light scattering (see table). As seen from the table, particles of **2a** with different degrees of substitution have similar size. At the same time, particles of the *N*-vinylpyrrolidone copolymers containing an oleyl group (**2d**) in the CAC point have a larger hydrodynamic radius, suggesting formation of an aggregate consisting of polymer macromolecules with a looser, less compact structure compared to macromolecules of **2a** with octadecyl (stearyl) residues, or of an aggregate containing a larger number of macromolecules.

A considerable increase in the weight of AP particles in solution relative to hydrolyzed polymers **1a**–**1c** was revealed by static light scattering. For example, at a concentration of AP **2a** (DS 5%) of 0.25 g dl^{-1} (below CAC), the particle weight increased by almost an order of magnitude, to 360 kDa (0.1 N NaCl).

In the Zimm diagram, we observed no curvatures of scattering indicatrices at small angles, typical of polymer systems whose polydispersity is determined by the presence of very large particles. That is, in the sample under consideration, the particle-size distribution is presumably quasiunimodal, without formation of very large aggregates.

Taking into account the fact that the aggegation can be governed not only by hydrophobic interactions, but also by the capability of carboxy and amide groups of the polymers for hydrogen bonding, we can suggest the occurrence of both intramolecular and intermolecular aggregation in the solution under consideration (0.1 N NaCl). This assumption accounts for a considerable increase in the AP particle weight. To confirm it, it was necessary to examine the rheology of AP solutions.

It is known that the interaction of hydrophobic groups affects the rheological properties of polymers. In aqueous solutions, hydrophobic groups of amphiphilic polymers containing no charged groups can favor formation of both intramolecular associates and intermolecular aggregates. The probability of coil overlap in a dilute solution is low, and therefore mainly intramolecular associates are formed. Their formation results in contraction of the polymeric coil (and hence in a decrease in its radius), which results in lower viscosity of a solution of an associating polymer compared to that of solution of the related polymer containing no associating groups. In a semidilute solution, polymer coils start to overlap, and intermolecular contacts become prevalent, which results in a sharp increase in a solution viscosity and formation of a physical gel in which polymeric chains play the role of cross-links between the aggregates.

Critical aggregation concentrations and mean hydrodynamic radii of particles of amphiphilic copolymers in CAC points

* Wilhelmy method/pyrene method.

For strongly charged polymer chains, long-range Coulomb interactions of chains are prevalent and determine the rheological behavior of the system. However, in weakly charged polyelectrolytes, nonelectrostatic interactions efficiently compete with Coulomb interactions. To reveal the major factors affecting the rheological behavior of the APs under consideration in aqueous solutions, we measured the viscosity of AP solutions by capillary viscometry. The viscosity was measured in the concentration range 0.1–1.0 g dl^{-1}; the solutions whose concentration exceeded CAC were diluted.

In aqueous solutions of APs at pH 5 in the absence of a low-molecular-weight electrolyte, the isotherms of the reduced viscosity had a shape classical for polyelectrolytes: With dilution, the viscosity increased owing to polyelectrolytic swelling of the polymer macromolecules. With increasing degree of hydrophobic substitution, the effect of polyelectrolytic swelling became less pronounced: The slope of the linear portion of the isotherms relative to the abscissa decreased.

For AP solutions containing a low-molecular-weight salt (0.1 N NaCl), at the same pH, we obtained the reduced viscosity isotherms and calculated the intrinsic viscosity [η] of the amphiphilic copolymer samples by extrapolation to infinite dilution:

Sample	**1a**	**2a**	**2a**	**2a**	**2a**	**2a**
DS, wt %	0	1	2	5	10	15
[η], dl g^{-1}	0.17	0.23	0.25	0.36	0.44	0.48

As seen from the above data, with an increase in the degree of hydrophobic substitution (in the series

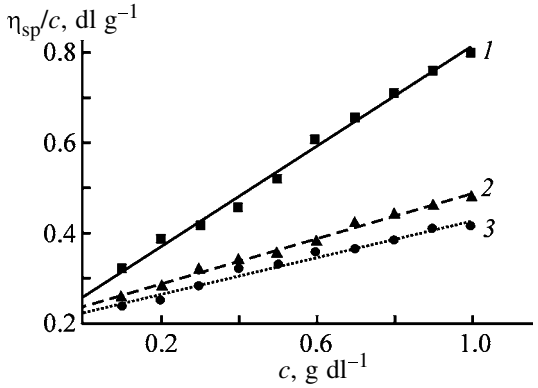

Fig. 2. Isotherms of reduced viscosity η_{sp}/c vs. AP concentration c in solution: (*1*) **2a** (DS 0), (*2*) **2a** (DS 5%), and (*3*) **2a** (DS 10%).

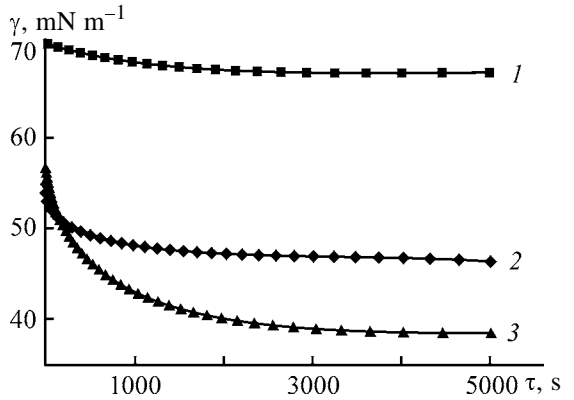

Fig. 3. Variation of the surface tension γ with time τ for APs with different nature of macromolecular chain. AP concentration 0.3 g dl^{-1}. (*1*) **2c** (DS 5%), (*2*) **2b** (DS 5%), and (*3*) **2a** (DS 5%).

of AP **2a**) [η] increased, indirectly suggesting an increase in the polymer coil size. Since in our study the Coulomb (electrostatic) interactions were not decisive, this trend should be attributed to changes in the nonelectrostatic interactions.

However, an increase in the amount of hydrophobic groups (and hence enhancement of hydrophobic interactions) should make the macromolecular coil more compact and thus decrease the hydrodynamic radius of the particle and the viscosity. The opposite trend we observed can be accounted for as follows: With an increase in the degree of hydrophobic substitution of carboxy groups in AP in the initial aqueous solutions, at concentrations above CAC, strong intermolecular aggregates were formed. These aggregates were not broken down under the conditions of dilution and shear deformations to which the system was subjected in the course of measurements with a capillary viscometer. The size of these aggregates and, apparently, their strength increased with an increase in the degree of hydrophobic substitution of AP, i.e., the major factors determining the hydrodynamic state of AP particles in solutions were hydrophobic intermolecular interactions, and also the presence of a complex network of hydrogen bonds between macromolecules. In other words, the rheological behavior of the APs in solution at pH 5 is determined by the integral effect of the above-indicated factors on the system.

To eliminate the effect exerted on the association by hydrogen bonds involving carboxy groups, we performed an experiment in which viscometric measurements were performed at the same ionic strength of the solution (0.1 M) in a glycine buffer (pH 9), in which the carboxy groups of the maleic acid units of the copolymer were virtually completely ionized. The reduced viscosity isotherms we obtained are shown in Fig. 2. As can be seen, the outflow pattern observed with AP solutions in the buffer with pH 9 differs from that observed with the solutions in 0.1 M NaCl with pH 5: With an increase in the degree of hydrophobic substitution, the slope of the isotherms decreases, i.e., the viscosity of the systems is the lower, the higher the degree of substitution. In infinitely dilute solutions (extrapolation to zero concentration), the effect of the hydrophobic substituent on the polymer particle size is levelled off: The intrinsic viscosities of the starting unmodified polymer **1a** and its hydrophobic derivatives **2a** with DS 5 and 10% are close.

Thus, at pH 9 in semidilute AP solutions we revealed the effect exerted on the hydrodynamic state of the system by hydrophobic interactions, namely, the dominating role of these interactions in the molecular aggregation of AP.

Self-organizing systems of water-soluble amphiphilic polymers are adsorbed on the water|air phase boundary, decreasing the surface tension of water. The driving force of such adsorption is hydrophobic interaction of the hydrophobic segments of polymer macromolecules with the air phase, accompanied by an increase in the entropy of the system due to break of the ordered structure of hydration shells formed around polymer chains. Figure 3 shows typical surface tension isotherms for a series of APs with the same degree of substitution. Two portions can be distinguished in these curves: the first portion in which the surface tension sharply decreases and the second portion in which the surface tension decreases more slowly and flattens out.

In the first portion of the isotherm, the polymer macromolecules take a more unfolded conformation on the interface and are adsorbed on it, with the hydrophobic groups oriented toward the nonpolar phase (air). Further decrease in the surface tension during

a longer time is controlled by the diffusion of macromolecules and their aggregates (associates) from the bulk of the solution to the phase boundary surface, their adsorption, and diffusion of surface-active segments of the adsorbed macromolecules inside the adsorption layer.

The APs under consideration showed higher interphase activity compared to the starting polymers without hydrophobic substituents. As expected, with an increase in the AP concentration and in the degree of hydrophobic substitution, the surface tension of polymer solutions decreased. In particular, for samples **2a** (0.2 g dl^{-1} in water) with DS 5, 10, and 15 wt %, the surface tension was 64.0, 62.0, and 61.0 mN m^{-1}, respectively.

It should be noted that the surface tension increased with an increase in the hydrophobicity of the macromolecular chain (Fig. 3). For example, the AP based on copolymer **2b** of maleic acid with styrene showed higher surface tension than the AP based on the more hydrophilic copolymer of *N*-vinylpyrrolidone with maleic acid (**2a**). Apparently, in **2b** the intramolecular hydrophobic aggregation occurs via hydrophobic interaction involving both hydrocarbon substituents and hydrophobic domains of the chain (styrene residues). At such aggregation, the macromolecule is adsorbed on the interface by its core, with the hydrophilic sites oriented inside the polar phase (water). The same reasoning is apparently applicable also fo AP **2c**.

In the case of **2a**, as already mentioned, the interphase adsorption of the macromolecules apparently occurred via hydrophobic interactions of hydrocarbon ligands with the air phase; as a result, the surface tension was lower compared to polymers **2b** and **2c**. From the viewpoint of thermodynamics, such adsorption mechanism is more favorable energetically for the "looser" macromolecule of **2a** containing, along with maleic acid residues and hydrophobic ligand, also *N*-vinylpyrrolidone fragments.

Thus, the surface properties of the samples correlated with their composition: higher interphase activity was exhibited by more hydrophobic samples whose higher hydrophobicity was determined both by the higher content of hydrophobic ligand and by the contribution from the hydrophobic comonomer (styrene and, to a lesser extent, ethylene).

Preparation of stable foams and emulsions is extremely important for their use in various branches of industry. Amphiphilic polymers decreasing the surface tension favor formation of foams and can act as foam and emulsion stabilizers.

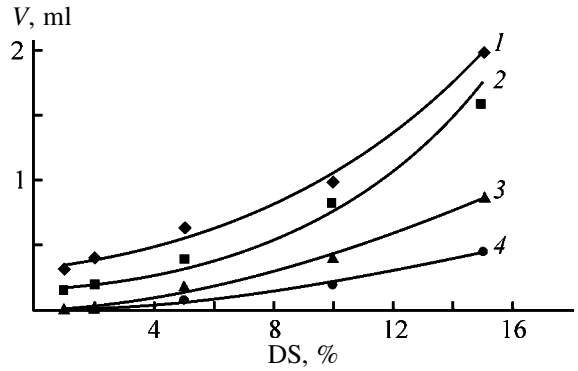

Fig. 4. Foam formation (foam volume *V*) as a function of the degree of substitution DS of amphiphilic copolymer **2a** with the hydrophobic ligand. Time, min: (*1*) 0, (*2*) 15, (*3*) 210, and (*4*) 1590.

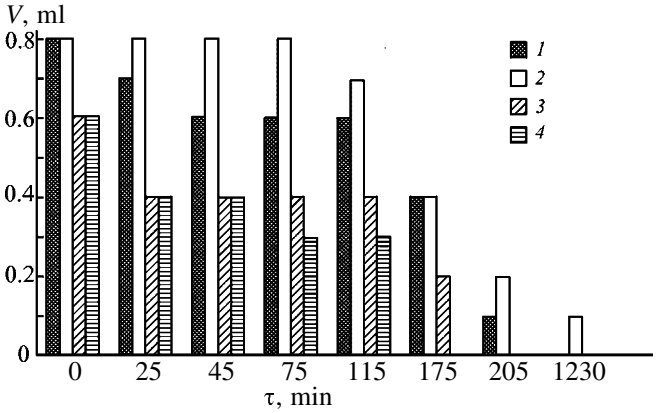

Fig. 5. Data on foam stability for copolymer **2d** (DS 5%) at its different concentrations. (*V*) Foam volume and (τ) time. *c*, g dl^{-1}: (*1*) 0.5, (*2*) 0.25, (*3*) 0.17, and (*4*) 0.08.

As expected, the foaming power of APs increased with an increase in the content of the hydrophobic ligand (Fig. 4). This parameter also depended on the AP concentration (Fig. 5).

The set of properties of the suggested amphiphilic polymers allows their use, e.g., for preparing water-soluble noncovalent conjugates with Amphotericin B antibiotic (AmB), which is virtually insoluble in water. The procedure for evaluating the antifungal activity (AA) is described elsewhere [7]. Figure 6 shows how the antifungal activity of the conjugates of the amphiphilic copolymers with Amphotericin B varies with time. It is seen that these conjugates affect the micellar growth of *Fusarium oxysporum* plant pathogen.

The activity of the polymer unmodified with the antibiotic, compared to complexes of AP with AmB, was relatively low and tended to decrease with time. Polymeric fungicides derived from **2a** (DS 2%) and **2c** (DS 5%) showed the highest antifungal activity within

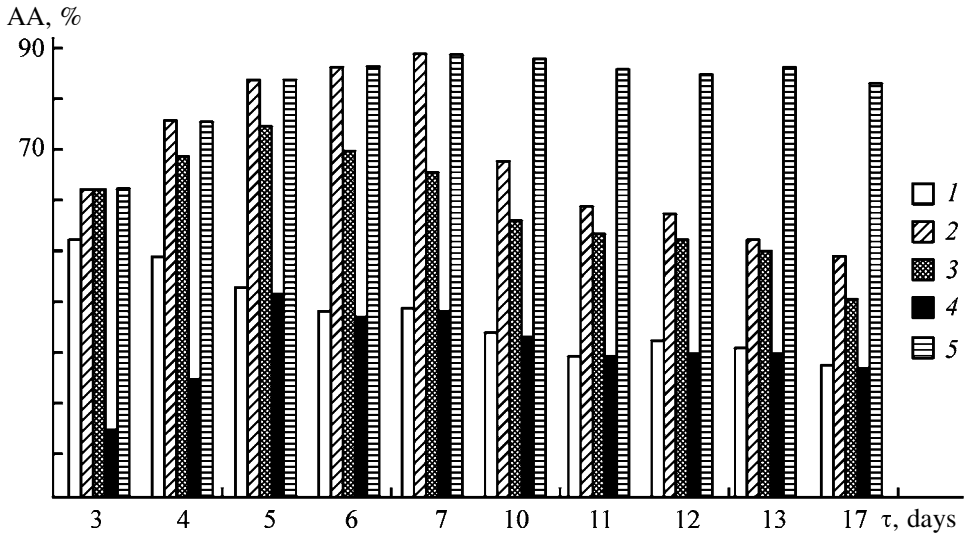

Fig. 6. Antifungal activity AA of polymeric conjugates of Amphotericin B (AmB) toward *Fusarium oxysporum* as a function of time τ. (*1*) Conjugate of hydrolyzed polymer **1a** with AmB (**1a**–AmB), (*2*) **2a** (DS 2%)–AmB, (*3*) **2a** (DS 5%)–AmB, (*4*) **2b** (DS 5%)–AmB, and (*5*) **2c** (DS 5%)–AmB. AmB content of complexes with amphiphilic copolymers 0.5 wt %.

the first seven days of the experiment. Then AA of **2a** (DS 2%)–AmB and **2a** (DS 5%)–AmB decreased to 46.8 and 38.3%, respectively (by the 17th day), whereas polymeric fungicide **2c** (DS 5%)–AmB showed high activity (~80%) up to the end of the experiment. Polymeric fungicide **2b** (DS 5%)–AmB suppressed the micellar growth to a considerably lesser extent; its AA by the 17th day was similar to that of **1a**–AmB (~25%). Higher activity of **2c** (DS 5%)–AmB is apparently associated with the faster release of AmB from the polymer matrix, which provided higher AmB concentration in the system.

CONCLUSION

New amphiphilic polymers, hydrophobically modified copolymers of maleic acid with *N*-vinylpyrrolidone, styrene, and ethylene, show much promise.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sulfation of Dextran with Chlorosulfonic Acid in Organic Solvents

Abstract—Solutions of chlorosulfonic acid in dichloroethane and formamide are suggested for incorporation of sulfo groups into macromolecules of polysaccharides. The influence of temperature, reaction duration, and reactant ratio on the yield of sulfated dextran and also the influence of the reaction conditions on hydrolytic stability of the polymer were studied.

DOI: 10.1134/S1070427207070270

Polysaccharides containing sulfo groups are widely used in medicine. Among the existing procedures of production of these valuable polymers, the best known procedure is sulfation of polysaccharides with solutions of sulfuric anhydride in organic solvents or its complexes with tertiary amines, pyridine, and other related bases [1]. However, SO_3 should either be prepared from sulfurous anhydride or desorbed from oleum, which complicates the process equipment and makes the process hazardous. In this connection, chlorosulfonic acid produced on the industrial scale and widely used in synthesis of various drugs (saccharin, thrombovar, sulfanilamides, etc.) is of great interest. Chlorosulfonic acid found application for production of dextran sulfate [2]. However, that study involved the use of toxic pyridine [maximum permissible concentration (MPC) 5 mg m^{-3}], whose exhaustive removal from the target product presents difficulties.

The aim of this study was to develop a procedure of sulfation of polysaccharides with chlorosulfonic acid in the medium of less toxic (MPC 10 mg m^{-3}) and readily removable 1,2-dichloroethane (DCE) in the presence of formamide (FA).

EXPERIMENTAL

Chemical modification of polysaccharides was performed by the scheme

$$[C_6H_7O_2(OH)_3]_n$$
$$\xrightarrow{HSO_3Cl} [C_6H_7O_2(OH)_2(OSO_3H)]_k[C_6H_7O_2(OH)_3]_{n-k}$$
$$\xrightarrow{MOH} [C_6H_7O_2(OH)_2(OSO_3M)]_k[C_6H_7O_2(OH)_3]_{n-k},$$

where M is Na or K.

Sulfation of polysaccharides was studied by the example of the reaction of dextran with chlorosulfonic acid.

A suspension of polysaccharide in a mixture of DCE and FA was stirred for 1 h at room temperature; then, a solution of chlorosulfonic acid in DCE was added, and the mixture was heated at 35–65°C for 1–4 h. After the reaction completion, the mixture was neutralized with a solution of potassium hydroxide and dialyzed against water to remove low-molecular-weight impurities. The dialyzate was concentrated in a vacuum, and the product was precipitated with ethanol. The precipitate was washed with ethanol and dried in a vacuum.

The reaction product was a white amorphous powder soluble in water and insoluble in ethanol.

In the IR spectrum of dextran sulfate, the absorption bands at 1250 cm^{-1} can be assigned to stretching modes of sulfo group $\nu_{S=O}$ [3].

The degree of sulfation C_s (number of sulfo groups per monosaccharide unit) was evaluated from the results of conductometric titration and acid hydrolysis of sulfo groups [4].

An attempt of dextran sulfation with chlorosulfonic acid in DCE without FA at 3–5°C by the procedure developed previously for sulfuric anhydride [4] resulted in tarring of the reaction mixture. A decrease in temperature of the reaction mixture to –5°C allowed us to avoid polymer blackening, but C_s appeared to be 3 times lower than that after the reaction

Degree of sulfation of dextran C_s at various times and FA : chlorosulfonic acid ratios (T = 50°C)

Run no.	τ, h	FA : chlorosulfonic acid molar ratio	Degree of sulfation C_s
1	1	5 : 1	0.22
2	2	5 : 1	0.31
3	3	5 : 1	0.42
4	4	4 : 1	0.64
5	4	8 : 1	0.51
6	4	12 : 1	0.44
7	4	15 : 1	0.22
8	4	20 : 1	0.16

with sulfuric anhydride under the similar conditions (0.24 against 0.79).

This result may be due to the fact that active species in sulfation of alcohols with chlorosulfonic acid in DCE is sulfuric anhydride [5] formed by dissociation of chlorosulfonic acid:

$$HSO_3Cl \rightleftarrows SO_3 + HCl.$$

Apparently, in nonpolar DCE the degree of dissociation is low; therefore, sulfation proceeds slowly, and at temperatures above zero chlorosulfonic acid decomposes the polysaccharide.

Addition of formamide, which forms a complex with sulfuric anhydride, promotes dissociation of chlorosulfonic acid. In this case, the probable active species in the sulfation of the polysaccharide are both sulfur trioxide and its complex with formamide.

The use of formamide allowed the temperature of dextran sulfation with chlorosulfonic acid to be increased to 50°C without tarring of the reaction mixture. However, the rate of dextran sulfation by this procedure is lower than the rate of the similar process with sulfur trioxide in DCE. For example, the use of sulfuric anhydride allows preparation of the polymer with C_s = 0.79 at 5°C, and in the case of chlorosulfonic acid C_s is 0.64 at 50°C. This is apparently caused by the fact that the active species in sulfation of the polysaccharide with chlorosulfonic acid in DCE–FA is mainly the complex FA–SO_3, which is less active than free SO_3. The complex FA–SO_3 readily dissociates, but in the presence of a large excess of FA dissociation of the complex is suppressed, which results in decreased concentration of free SO_3 and lower reaction rate.

To prove this assumption, we studied the influence of the chlorosulfonic acid : formamide ratio on the amount of sulfo groups incorporated into the polymer. The results are presented in the table.

We found that, with increasing amount of formamide N_{FA} from 5 to 20 mol per mole of chlorosulfonic acid, C_s decreases from 0.64 to 0.16. The dependence is linear:

$$C_s = -0.033N_{FA} + 0.7894; \quad R^2 = 0.9388, \ n = 5.$$

The procedure we suggest allows the reaction to be performed in a wide temperature range without tarring of the reaction mixture. In addition, we studied the effect of temperature on the amount of sulfo groups incorporated into the polymer.

As expected, with increasing reaction temperature from 35 to 65°C C_s increases; however, because of possible degradation of the polymer most of the experiments were performed at 50°C.

Variation of sulfation duration τ in the range from 1 to 4 h also allows incorporation of different amounts of sulfo groups into the polymer (see table):

$$C_s = 0.148\tau + 0.022; \quad R^2 = 0.974, \ n = 4.$$

One of the most important requirements in the development of a procedure for modification of polysaccharides is avoiding their depolymerization. Under the suggested conditions of polysaccharide sulfation, chlorosulfonic and hydrochloric acids can promote rupture of glycoside bonds of the polymer, especially under heating. In this connection, we performed a comparative analysis of dextran and dextran sulfate by gel chromatography.

Commercial dextran is a mixture of fractions with various molecular weights and cannot be used for such a comparison. Therefore, it was fractionated with ethanol [6], and the homogeneity of fractions was estimated by gel chromatography on a column packed with Sephadex G-200. The eluate was collected in portions and analyzed quantitatively by the photometric method based on a color reaction of sugars in the presence of sulfuric acid [6].

The homogeneous fraction of dextran was sulfated with chlorosulfonic acid by the procedure we developed, at 50°C for 4 h at the molar ratio FA : chlorosulfonic acid = 5 : 1. The product was isolated and analyzed as described above. We obtained a sample of dextran sulfate containing 0.35 sulfo group per monomer fragment of the polysaccharide.

The results of gel chromatography of the homo-

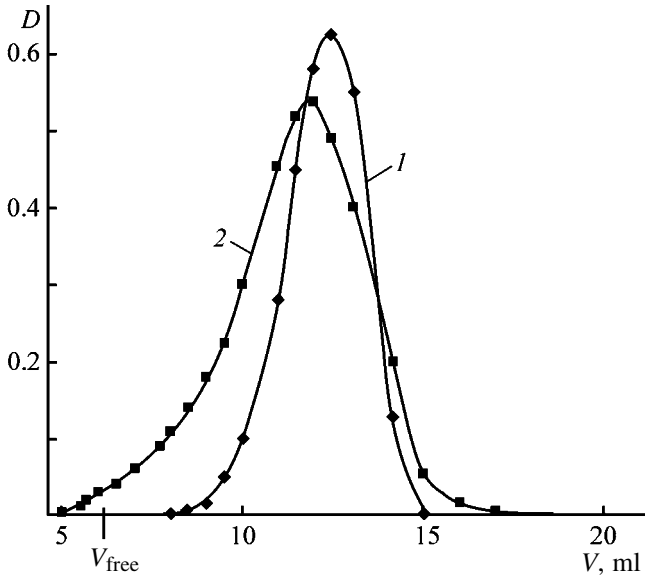

Fig. 1. Gel chromatogram of homogeneous fraction of dextran (*1*) before and (*2*) after sulfation. (*D*) Optical density and (*V*) eluate volume.

geneous fraction of dextran and its sulfated derivative are presented in the figure. As seen from the gel chromatograms, sulfation of dextran with chlorosulfonic acid does not distort the homogeneity of the fraction, which indicates that the polysaccharide does not degrade in the process.

CONCLUSIONS

(1) Chlorosulfonic acid in the formamide–dichloroethane medium can be used for sulfation of polysaccharides without their degradation.

(2) Addition of formamide to the reaction mixture allows sulfation of polysaccharides at 35–65°C; the maximum degree of sulfation is observed at the formamide : chlorosulfonic acid ratio equal to 5 : 1.

(3) The obtained dependences of the degree of sulfation on the reaction duration and amount of formamide allow control over the amount of sulfo groups incorporated into the polymer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis in a Gel as a New Procedure for Preparing Carboxyethyl Chitosan

Abstract—A fundamentally new procedure of synthesis of carboxyethyl chitosan in a physical gel, ensuring higher degree of substitution at lower temperatures and lower consumption of time and chemicals, compared to the existing procedures, was developed. The structure of the resulting products was examined by diffuse reflection IR and ^{1}H NMR spectroscopy in solutions and also ^{1}H and ^{7}Li broad line NMR.

DOI: 10.1134/S1070427207070282

Chitosan, a natural amino polysaccharide, has a unique set of useful characteristics, such as environmental safety, biological activity, and high sorption characteristics and therefore finds wide use [1–2]. With respect to these characteristics and applications, chitosan derivatives are highly competitive with the initial polymer and in some cases surpass it. For example, carboxyethyl chitosan (CEC) has a number of additional useful characteristics: solubility in water in a wide pH range [3], excellent antioxidant characteristics, significant antimutagenic activity [4], high sorption selectivity to transition metal ions [5], and better biodegradability [6] than chitosan proper. CEC turned out to be a suitable mediator for transport of hydrophilic drugs through the skin [7] or a substrate for introduction of nitrogen oxide for medical purposes [8].

Well-known methods of synthesis of this compound, based on addition of acrylic acid (AA) and its derivatives, have certain drawbacks. When using AA in a dilute solution of chitosan (concentration approximately 0.5–1%), significant time expenditures are required; in this case, the degrees of substitution (DS) remain low [6]. An increase in the concentrations of chitosan and AA decreases the synthesis duration, but DS remains less than 1 [9]. An increase of the reactivity of acrylic reactant by using it as ethyl ester does not solve the problem, since in this case the degree of substitution equal to 1 is reached only in 240 h (in so doing, the product should be saponified) [10]. The common drawback of the above procedures is the need to use dilute solutions (due to low concentration of chitosan solutions in aqueous acids and limited solubility of methyl or ethyl acrylate in water), which requires large consumption of solvents (water or aqueous methanol) and decreases the product yield per unit volume of the apparatus. Thus, the existing procedures show little promise for commercial use.

EXPERIMENTAL

The following chemicals were used: chitosans Sonat (degree of deacetylation DD = 0.84, molecular weight MW = 250 kDa, ash residue 0.19%), Aldrich low (DD = 0.84, MW = 40 kDa), Aldrich medium (DD = 0.91, MW = 200 kDa); AA, potassium hydroxide, and lithium, sodium, potassium, and cesium carbonates of analytically pure grade. The degree of deacetylation was estimated by ^{1}H NMR spectroscopy, and the molecular weight, viscometrically by the procedure described in [11].

The ^{1}H NMR spectra of the mother liquors and model compounds in D_2O (reference DSS) were recorded on a Bruker DRX 400 spectrometer; the ^{1}H and ^{7}Li broad line NMR spectra, on an upgraded Tesla BS-477 spectrometer; and the IR diffuse reflection spectra, on a Perkin–Elmer Spectrum-One spectrometer. The C,H,N analysis was performed on a Perkin–Elmer automatic analyzer. The thermograms were obtained on a Netzsch STA-409PC derivatograph.

The synthesis was performed by three procedures:

(1) 3.3 g (0.02 mol) of chitosan was dissolved with stirring in 230 ml of water containing 2.7 ml (0.04 mol) of AA. The solution was heated with continuous stirring at 60°C for 24 h, cooled, and 2.24 g

of potassium hydroxide in 20 ml of water was added. The product was precipitated with acetone and dried in a vacuum at 25°C to constant weight.

(2) A mixture of 3.3 g (0.02 mol) of chitosan and 2.7 g (0.04 mol) of AA in 11 ml of water was kept at room temperature until a gel formed, heated at a required temperature for a required time, and cooled; then, 80 ml of 2.8% aqueous potassium hydroxide was added. The product was precipitated with acetone and dried in a vacuum at 25°C to constant weight.

(3) 0.33 g (0.002 mol) of chitosan was added to 20 ml of water in which 0.14 ml (0.002 mol) of AA was preliminarily dissolved. 0.54 ml (0.008 mol) of AA was dissolved in 10 ml of water, and 0.0046 mol of appropriate alkali metal (lithium, sodium, potassium, or cesium) carbonate was added. After the release of carbon dioxide, the resulting mixture was added to the chitosan solution, stirred, and allowed to stand at 60°C for 2 days. The product was precipitated with acetone, reprecipitated two times, and dried in a vacuum at 25°C to constant weight.

The degrees of substitution of the resulting products, determined from the ^{1}H NMR spectra (total DS, degree of monosubstitution DS_m, and degree of disubstitution DS_d), were evaluated by the formulas

$$DS = (m + 2n)/(1 - DD + m + n),$$

$$DS_m = m/(1 - DD + l + m + n),$$

$$DS_d = 2n/(1 - DD + l + m + n),$$

where m is the mole fraction of monocarboxyethylated glucosamine units; n, mole fraction of dicarboxyethylated glucosamine units; and l, mole fraction of glucosamine units.

The signal assignment and evaluation of m, n, and l from the corresponding integral intensities were performed according to [9] (due to the high viscosity of the solutions, the spectra were recorded in D_2O/DCl_{conc} at 343 K, polymer concentration 15 mg ml^{-1}).

The degree of substitution was also determined by elemental analysis of the resulting products using the formula

$$DS = [(n_C/n_N)_{product} - (n_C/n_N)_{chitosan}DS_{an}]/3,$$

where n_C/n_N is the molar ratio of elements in the product and in the initial chitosan, respectively.

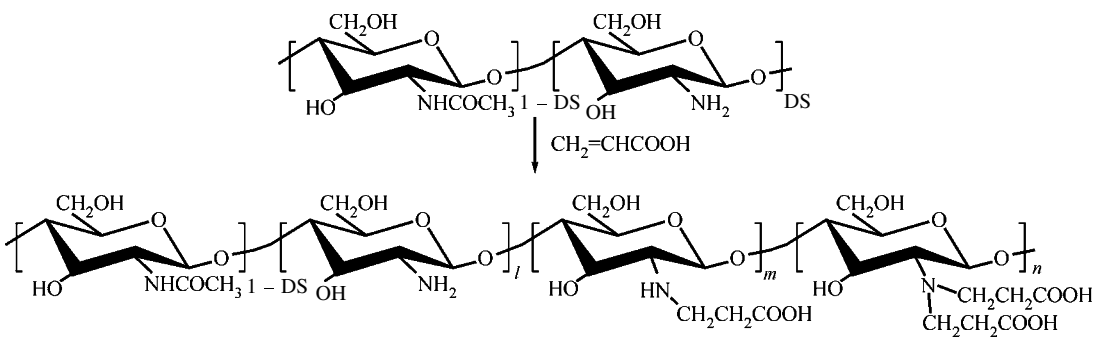
Initially, to prepare the product with a higher degree of substitution, i.e., to prevent deactivation of amino groups of chitosan due to formation of the ammonium salt, we neutralized a part of AA with alkali metal carbonates (60°C, 48 h). Thus, in fact chitosan was treated with a mixture of AA and the corresponding acrylate, which increased pH of the solution:

M_2CO_3	Without base	Li	Na	K	Cs
DS*	0.44	0.33	0.31	0.33	0.37

* Only monosubstitution was observed.

As seen from these data, with increasing pH the degree of substitution decreases; in this case, the type of the base does not noticeably affect its value. This fact indicates that the reactivity of AA decreases faster than increases the nucleophilicity of the amino group of chitosan. Thus, the total reactivity of AA and ammonium salt of chitosan is higher than the total reactivity of the acrylate and amino group of chitosan, i.e., partial neutralization of AA does not give a positive effect.

The principal improvement of the process is parallel increase in the concentrations of AA and chitosan. Considering valuable characteristics of CEC and the lack of published data on convenient and cost-efficient procedures of its synthesis, we suggested a fundamentally new procedure of polymer-analogous transformations by the reaction of chitosan with acrylic acid in mixtures with high concentration of reactants, i.e., synthesis in a gel. Chitosan was modified by the scheme



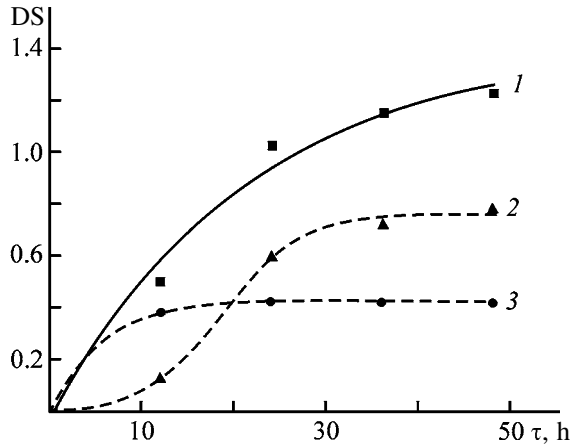


Fig. 1. Degree of substitution DS as a function of duration of chitosan treatment with AA τ at a ratio of 1 : 5 at 50°C. Degree of substitution: (*1*) total, (*2*) DS_d, and (*3*) DS_m.

2 : 1 (Sonat)	70	12	0.63	0.49	1.12

Contrary to the existing methods, we suggest to perform the reaction at a concentration of approximately 20%. In this case, the reaction mixture is a rigid gel in which this conversion is realized under heating. After the reaction completion, the mixture was treated with aqueous alkali and CEC was isolated in the form of the corresponding salt.

Table 2. Degree of substitution of CEC, according to ^{1}H NMR data and elemental analysis (EA)

Sample no.	Found, %			DS according to	
	C	H	N	EA	^{1}H NMR
1	41.45	5.81	5.86	0.61	0.51
2	39.94	5.52	4.70	1.15	1.1
3	39.49	5.02	4.43	1.30	1.15
4	38.90	4.70	4.11	1.57	1.45

It is seen from the dependence of the degree of substitution via nitrogen on the duration of chitosan treatment with AA (DS was determined by ^{1}H NMR [9]) that with increasing reaction duration the degree of substitution increases (Fig. 1); in this case, the degree of monosubstitution has a limit of saturation after 12 h of treatment. The subsequent increase in the total degree of substitution is caused only by addition of AA to the already carboxyethylated amino groups. It is likely that further formation of the disubstitution product is limited by the long-chain nature of the polymeric reagent (interaction between neighboring units, configuration, conformation of molecules in gel).

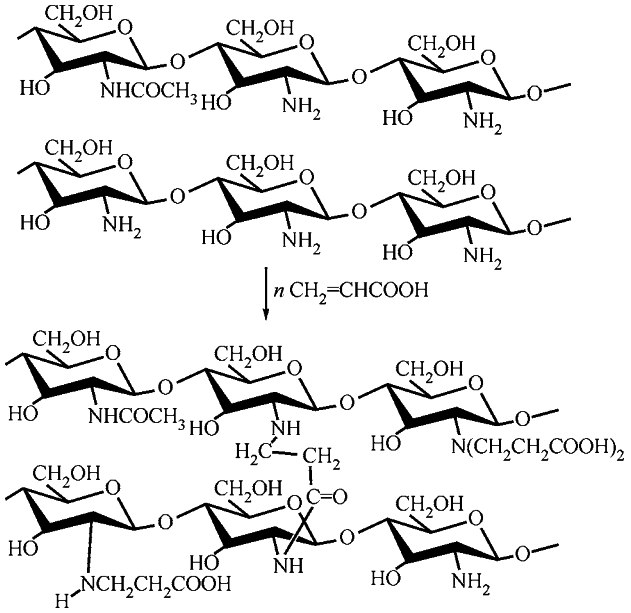
The influence of other reaction parameters on the degree of substitution of the product is presented in Table 1. Heating accelerates the addition reaction. An increase in the molar excess of AA increases the degree of substitution insignificantly. At a higher temperature this difference is leveled out. Passing from the solution to gel (increase in the chitosan concentration) abruptly increases the degree of substitution. Twofold treatment provides the highest DS. On the whole, to reach the degree of substitution of the order of 1, it will suffice to use a twofold molar excess of AA. The result of the process is only slightly influenced by particular brand of chitosan.

The degree of substitution determined by elemental analysis is somewhat higher (by 4–16%), which suggests partial addition via hydroxy groups (Table 2).

An important feature of this transformation is the occurrence of side processes, which to a certain extent prevent the addition process and affect the structure of the resulting product.

The ^{1}H NMR data for mother liquors suggest that the side products are β-hydroxypropionic acid and 2,2-dicarboxydiethyl ether (correlation of signals was performed by comparison with the spectra of model

compounds), i.e., water molecules are added to AA molecules. The occurrence of these reactions results in no-purpose consumption of AA and, taking into account the law of mass action, restricts the possibility of its addition. The side process in conversion of the polymer is formation of a small amount of bridging amide bonds; therefore, the crude product is insoluble in water:



To break the cross-links of the macromolecules, the product isolation should involve treatment with an alkali. As known, amide bonds can also be ruptured using hydrazine; in so doing, excess AA is also removed. After extraction of CEC with hydrazine hydrate in a Soxhlet apparatus, the product is insoluble in water. Apparently, new cross-links are formed via terminal aldehyde groups. The crude product can be dissolved in hydrochloric acid under heating. However, in so doing, hydrolysis of glycoside bonds is possible, leading to a decrease in the molecular weight.

To confirm formation of amide bonds, we recorded the IR diffuse reflection spectrum of $CEC_{DS=1.0}$ untreated with alkali. It is impossible to reveal a new amide bond against the background of the strong absorption band of the amide bond of the residual acetyl groups (1655 cm^{-1}) at DD = 0.84. However, on subtraction of the spectrum of $CEC_{DS=1.0}$, obtained in the solution and containing no amide groups [3], from the given spectrum, the absorption band corresponding to a new amide bond at 1652 cm^{-1} is observed in the differential spectrum. Formation of an amide bond is additionally proved by the appearance of the signal at 169 ppm in the ^{13}C NMR spectra of the resulting products. This signal corresponds to the carbonyl carbon of the acrylamide group, contrary to the signal corresponding to the carbonyl carbon atom of acetamide group at 176 ppm.

For additional estimation of the structure of the resulting solid compounds we used broad line ^1H NMR spectroscopy. The spectrum of $CEC_{DS=1.0}$ in the form of lithium salt and resolution of the spectrum into components corresponding to the lines of one-, two-, and three-spin proton groups are presented in Fig. 2. The assignment of these components to

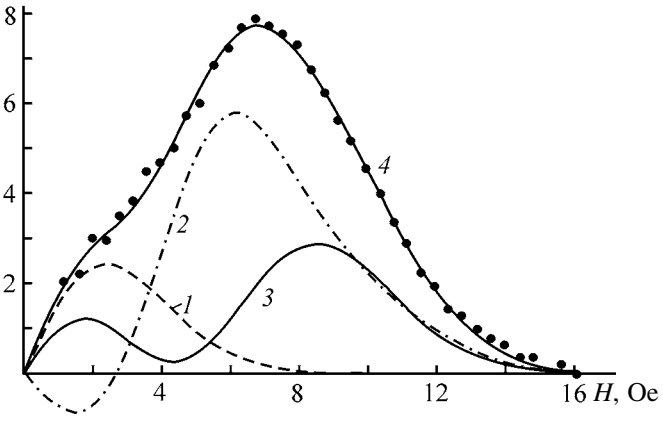


Fig. 2. ^1H NMR spectrum of a sample of lithium salt of $CEC_{DS=1.0}$ (85 MHz, –150°C). (*I*) Intensity and (*H*) magnetic field strength. Lines: (*1*) H^+, R_3NH^+, (*2*) H_2O, (*3*) OH_3^+, and (*4*) sum of components of the spectrum resolution. Points: experimental data.

Table 3. ^{1}H broad line NMR data

Line	Assignment	Content of protons of given group, % of total amount in sample				
		chitosan HCl	$CEC_{DS=0.5}$	$CEC_{DS=1.0}$	$CEC_{DS=0.5}$ (Li)	$CEC_{DS=0.5}$ (Li)
1	H^+, R_3NH^+	5.5 (H^+)	10.7 (H^+)	8.7	7.6(H^+)	7.0
2	H_2O	63.7 (H_2O)	67.8	62.1	60.1	57.2
3	OH_3^+, $ChNH_3^+$	30.8	21.5	29.2	32.3	35.8
Total contribution of lines 1 and 3		36.3	32.2	37.9	39.9	42.8

the corresponding proton groups entering into composition of the samples studied is given in Table 3.

The above data suggest that a decrease in the fraction of two-spin systems with a parallel increase in the fraction of the sum of one- and three-spin systems corresponds to an increase in the degree of substitution, i.e., in the amount of alkylammonium groups. The variation of the amount of three-spin systems is also of interest. In passing from chitosan hydrochloride to hydrochloride of $CEC_{DS=0.5}$, a part of protons of the amino group of chitosan are replaced by the carboxyethyl group, and protons of the carboxy group are bonded with excess amino groups. As a result, the total content of alkylammonium and hydroxonium ions decreases. In passing to hydrochloride of $CEC_{DS=1.0}$, the increased amount of carboxy groups results in significant increase in the amount of hydroxonium ions, which results in increased contribution of the sum of lines 1 and 3. At first glance, the presence of hydrogen ions in the structure of lithium salts of CEC seems paradoxical. Considering polyampholytic nature of the polymer [3], in this case, significant buffer power of CEC should be assumed. With the aim to study these characteristics in more detail, data on measurements of local pH should be used [12].

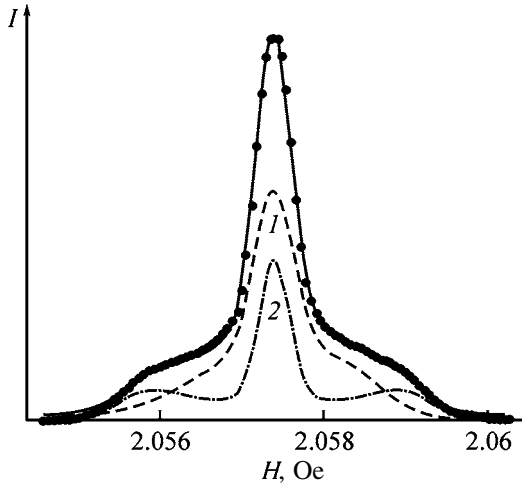

Fig. 3. ^{7}Li broad line NMR spectrum of the lithium salt $CEC_{DS=1.0}$ (Li) (33 MHz, 20°C). (*1*, *2*) Components of spectrum resolution.

A comparison of the data for two-spin systems with the data of thermal gravimetric analysis of the samples of chitosan and CEC hydrochlorides shows that, for both hydrochlorides and lithium salts, with increasing degree of substitution the absorption power with respect to water slightly decreases, which is apparently caused by better crystallinity of the polymer [13]:

Compound	Water loss, % (approximately to 150°C)
Chitosan HCl	10.59
$EC_{DS=0.5}$	6.63
$CEC_{DS=1.0}$	6.00
$CEC_{DS=0.5}$ (Li)	4.49
$CEC_{DS=1.0}$ (Li)	5.10

It is interesting that a calculation of the amount of hydrogen ions using ^{1}H broad line NMR data for chitosan hydrochloride gives 0.51 mol kg^{-1}. The actual concentration of HCl is 5.06 mol kg^{-1}, which suggests 10% dissociation of the hydrochloride. For the other compounds, the given mole fractions correspond to the sum of the signals of two different groups; therefore, more detailed conclusions about their concentration are impossible.

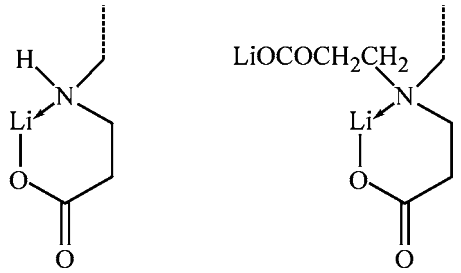
A comparison of the ^{7}Li broad line NMR spectra (Fig. 3) for lithium salts of $CEC_{DS=0.5}$ and $CEC_{DS=1.0}$ shows that lithium in each sample is located in the same crystallographic position, since the central line is the same, but positions of lithium atoms are different in their charge surrounding: in each spectrum there are two pairs of satellites. These spectra were resolved into components.

As follows from Table 4, the content of lithium ions with less symmetrical charge surrounding somewhat increases in passing to the sample of CEC with a higher degree of carboxyethylation, since lower quadrupole interaction constant corresponds to more symmetrical charge surrounding. It is well known that polycarboxylic amino acids form complexes even with

Table 4. Parameters of hyperfine interaction of lithium nuclei obtained from the ^{7}Li NMR spectra

Parameter	$CEC_{DS=0.5}$ (Li)		$CEC_{DS=0.5}$ (Li)	
	line 1	line 2	line 1	line 2
Isotropic shift K_{iso}	–0.0046	–0.0046	–0.005	–0.005
Quadrupole interaction constant (ν_Q), MHz	0.028	0.056	0.028	0.056
Integral intensity of component S, %	60.49	39.51	55.56	44.44

lithium and sodium [14]. Thus, the phenomenon observed suggests the presence of a complex of not only mono-, but also disubstituted derivative, which decreases the symmetry of the charge surrounding of lithium:



It should be noted in conclusion that chemical characteristics of carboxyethyl chitosan are close to those of carboxymethyl chitosan. The suggested procedure of CEC synthesis is undoubtedly simpler in practice than any methods of synthesis of the carboxymethyl derivative. The initial raw material for the synthesis of the first product is AA, and for the synthesis of the second product, chloroacetic acid: these compounds are equally available, but chloroacetic acid is somewhat more toxic. A set of these advantages makes carboxyethyl chitosan more advantageous for further applications.

CONCLUSIONS

(1) The suggested procedure for preparing carboxyethyl chitosan by synthesis in a gel allows the volume of the reaction mixture to be decreased by a factor of 50 compared to the synthesis in aqueous solution. The reaction does not require stirring and use of organic solvents and occurs under mild conditions (50–90°C). These advantages make the procedure very convenient.

(2) A study of mother liquors and the resulting polymers by ^{1}H NMR and IR Fourier spectroscopy showed that, during the reaction, a part of acrylic acid adds water to form β-hydroxypropionic acid and 2,2-dicarboxydiethyl ether. In addition, polymer molecules are cross-linked via amide bonds.

(3) A ^{1}H broad line NMR study of carboxyethyl chitosan hydrochlorides showed that an increase in the degree of substitution corresponds to a decrease in the fraction of two-spin systems with a parallel increase in the fraction of sum of one- and three-spin systems. The ^{7}Li broad line NMR data suggest the presence of different lithium complexes in carboxyethyl chitosan salts with different degrees of substitution.

Abstract—The concentration dependences of the relative viscosity of a mixture of precondensates of epoxy–4,4'-isopropylidenediphenol and phenol–formaldehyde resins in a Cellosolve solution were examined. The surface tension curves at the solution–air interface at concentrations c = 0.5–45 % were obtained. The optimal concentration modes of preparation of coatings from solutions of precondensates of the resin mixture were calculated on the basis of the cluster model. Using electron microscopy with silver chloride surface decoration, the cluster structure parameters of the chemical network of the epoxy–phenol polymer were determined for coatings with high protective performance.

DOI: 10.1134/S1070427207070294

We found earlier [1, 2] that a transition from dilute to concentrated solutions of mixtures of epoxy–4,4'-isopropylidenediphenol and phenol–formaldehyde oligomers (EO and PO, respectively) is accompanied by formation of discrete aggregates and an infinite molecular cluster. Such transition causes changes of the density ρ and fractal dimension D of the aggregates, as well as of the degree of aggregation of the molecules in solution near the threshold concentration c^* with formation of an infinite cluster [2, 3]. In solutions of the EO–PO mixture in Cellosolve, stable hetero complexes are formed via intermolecular hydrogen bonding between the oligomers [4]. The size and structure of the EO–PO aggregates are determined by the molecular weight (MW), composition of the oligomer mixture, and thermal history of the solution [1–5].

Preparation of polymer coatings on metals via thermal curing of the EO–PO mixtures involves preliminary precondensation of the oligomers in solution in the presence of orthophosphoric acid [6]. Upon introduction of H_3PO_4 into the EO–PO mixture, dihydrogen phosphate, hydrogen diphosphate, and triphosphate esters of EO and PO are formed in the initial stage [4]. Mixed EO–PO dihydrogen phosphate is the most stable "elementary" aggregate of these molecules, yielded by the reaction of the H_3PO_4 molecule with the epoxy group in EO and hydroxy group in PO at the molar ratio $N_1(\text{EO})/N_2(\text{PO}) \approx 1$ [4, 5]. Thermal curing of the precondensates of the oligomer mixture involves chemical reactions between the methylol (butoxy) groups of PO and epoxy (hydroxy) groups of EO in the coating [5].

Earlier [7–10] we suggested a cluster mechanism of precondensation of oligomers in solution, comprising three stages of precondenstion of the EO–PO mixture and the corresponding topologic types of the chemical network of the epoxy–phenol polymer prepared by curing of EO and PO in various stages of the process [2]. These stages are as follows: breakdown of individual aggregates of EO and PO molecules, formation of mixed EO–PO aggregates, and formation of an infinite cluster of the molecules [9].

The cluster model of aggregation of oligomers allows substantiation of the concentration and kinetic regimes of pecondensation of the EO–PO mixture in solution [10]. We found earlier [7] that the run of the curves corresponding to the time dependences of the viscosity $\eta(t)$ and the precondensation time for the EO–PO mixture vary with the $N_1(\text{EO})/N_2(\text{PO})$ molar ratio and the orthophosphoric acid concentration N_3. In the final stage of precondensation of the EO–PO mixture ($N_1/N_2 = 1$) at the molar ratio $N_3/(N_1 + N_2) \approx 0.1$ we revealed the minima for the viscosity η and density ρ of the EO–PO aggregates in Cellosolve solutions [8].

The cluster structure of the epoxy–phenol polymer prepared by thermal curing of the EO–PO mixture is predetermined by the lattice density ρ of the chemical

Table 1. Molecular characteristics of E-05 epoxy–4,4'-isopropylidenediphenol and DFFr phenol–formaldehyde resins and samples of precondensates (PCs) of E-05 and DFFr mixtures in a Cellosolve solution at 298 K

Sample no.	Oligomer	N_1/N_2	c_1/c_2	[η], dl g^{-1}, ±5%	M_n, ±10%	M_w/M_n	σ(c*), mN m^{-1}
1	E-05	–	–	0.134	2850	2.7	28.6
2	DFFr	–	–	0.061	1030	3.8	31.8*
3	PC	0.7	2.2	0.115	2320	2.4	–
4	PC	0.8	2.4	0.131	2400	2.5	–
5	PC	1.0	2.9	0.148	2700	2.8	30.8

Notes: The parameters M_n and M_w/M_n for sample nos. 3–6 at precondensation time of 2 h. For sample no. 5, precondensation of E-05 and DFFr in a Cellosolve solution was carried out at c_1 = 26.7 and c_2 = 9.12 g dl^{-1}; σ(c*) is the surface tension at the threshold concentration c* of the oligomers (Table 2).

* For the DFFr concentration in solution c = 26 g dl^{-1}.

network cross-links [1, 2, 8]. The uniform chemical network of the epoxy–phenol polymer is characterized by the EO-to-PO molecular weight ratio close to 3 : 1 and the optimal M_n(EO) = 2800–3500 [1].

The lattice density of two infinite clusters of the decorating silver chloride particles, representing the cross-links of the uniform chemical network of the epoxy–phenol polymer based on the precondensate of the EO–PO mixture (N_1/N_2 = 1), is close to the percolation threshold of the particles on a triangular lattice at $N_3/(N_1 + N_2) \approx 0.1$ [7, 8]. In this case, the degrees of filling of the coating surface with these clusters are nearly identical, which suggests formation of a uniform chemical network for the two components, EO and PO [8].

It should be noted that the density of the EO–PO aggregates in solution and the structural parameters of the chemical network of the epoxy–phenol polymer vary both with the composition of the EO–PO mixture and the concentration c of the precondensate in solution [7–10]. At the same time, the relationships in formation of EO–PO aggregates in solution and of the chemical network of the epoxy–phenol polymer with varying N_1(EO)/N_2(PO) ratio and the precondensate concentration in solution c still remain to be elucidated in detail [6–8]. This hinders reliable optimization of the concentration modes in formation of protective coatings with high performance characteristics.

We report here the results of examination of the concentration dependences of the relative viscosity of the EO–PO precondensates and of the surface tension at the solution–air interface. Based on the fractal cluster model, the structural parameters of formation of the EO–PO aggregates were calculated, as well as the threshold concentrations of formation of an infinite cluster in solutions of precondensates of different compositions. Using electron microscopy with silver chloride surface decoration, the characteristics of the cluster structure of the uniform chemical network of the epoxy–phenol polymer were determined. Also, the concentration modes of formation of epoxy–phenol coatings with high protective performance were elucidated.

EXPERIMENTAL

The characteristics of E-05 epoxy–4,4'-isopropylidenediphenol and DFFr phenol–formaldehyde resins (Pigment Holding Company) were determined by capillary viscometry and gel-permeation chromatography [11]. The number-average MW M_n and the M_w/M_n ratios (M_w is the weight-average MW) for samples of E-05 and DFFr, as well as of the precondensates of the resins, are listed in Table 1.

Precondensation of a mixture of E-05 and DFFr resins was carried out in a Cellosolve solution at 333 K. The N_1(E-05)/N_2(DFFr) molar ratio was varied from 0.7 to 1.5 (c_1/c_2 = 2.4–4.5) (Table 1, sample nos. 3–6); the precondensation time was 2 h. Phosphoric acid was introduced into the mixture in the initial stage of the process; the H_3PO_4 concentration was 85 rel % (100% was taken for 0.25 g of H_3PO_4, calculated for 36 g of the E-05–DFFr mixture [6]), which corresponds to $N_3/(N_1 + N_2) \approx 0.1$ [7, 8].

The relative η_{rel} and intrinsic [η] viscosities of sample nos. 1–6 in Cellosolve solutions were measured on an Ubbelohde capillary viscometer (solvent outflow time 81 s, shear rate 100 s^{-1}) at 298 K with the relative error of 3%. The concentration curves of the relative viscosity $\eta_{rel}(c)$ of the precondensate sample nos. 3–6 in a Cellosolve solution were examined at concentrations c = 5–45% (Fig. 1, Table 1).

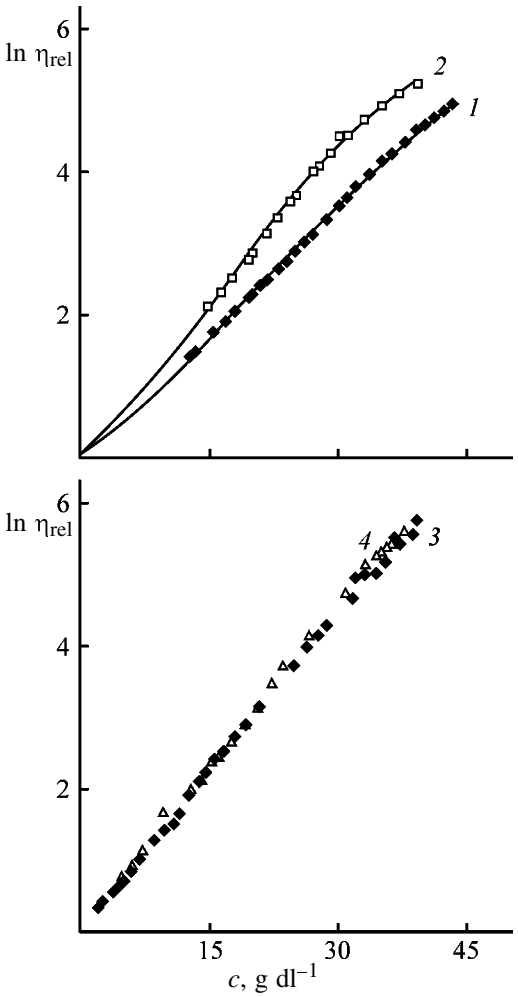

Fig. 1. Concentration dependences of the relative viscosity η_{rel} of the precondensates of a mixture of E-05 and DFFr resins in a Cellosolve solution in the $\ln \eta_{rel}$–c coordinates at 298 K. Sample no: (*1*) 3, (*2*) 4, (*3*) 5, and (*4*) 6; the same for Figs. 4 and 5. N_1/N_2: (*1*) 0.7, (*2*) 0.8, (*3*) 1.0, and (*4*) 1.5; the same for Figs. 4 and 5.

The surface tension σ of the EO and PO solutions at the solution–air interface was measured with a Du Nouy tensometer at 298 K [12, 13]. The relative error of 10 replicate measurements of σ was 0.3%.

The epoxy–phenol coatings with a thickness of 6–20 μm were obtained by casting the precondensate solution in Cellosolve with the concentration c = 18–30% (N_1/N_2 = 1, Table 1, sample no. 5) onto the electrolytic tin-plated sheet metal. Next, the coating was cured in air for 15 min at 483 K [5, 6]. The protective characteristics of the epoxy–phenol coatings were determined by the procedure from [6] in the following model media: 3% aqueous solutions of sodium chloride and acetic acid and 2% aqueous solution of tartaric acid and distilled water for 1 h at 393 K and pressure of 120 Pa.

To examine the cluster structure of the epoxy–phenol polymer, we carried out thermal sputtering of silver chloride on the coating surface at 1.33×10^{-3} Pa to the effective layer thickness of 0.4 nm. Coal replicas with the AgCl decorating particles, prepared by the procedure from [8], were examined with an EVM 100 L electron microscope. The mechanism of interaction of AgCl with the functional groups of PO consists in partial reduction of AgCl with quinonemethide groups of the epoxy–phenol polymer [14], yielded by thermal curing of the precondensates [5]. The silver particle nuclei are the nucleation sites for large AgCl particles.

Computer processing of the electron micrographs of the polymer coating surface (Figs. 2a–2e) was carried out on the basis of the cluster model [3]. We calculated the function of the radial distribution of the AgCl particles over the surface $g(R)$ [15] and the dependences of the lattice density ρ_l of the clusters on the radius R of the circumference incorporating the particle cluster. The correlation radius ξ and fractal dimension D of the clusters were estimated from the $\rho_l(R)$ curves using the expression $\rho_l(R) \sim R^{D-2}$ on the $R < \xi$ and $R > \xi$ scales [3]; the coordination number of the lattice m was determined from the area enclosed by the first maximum of the $g(R)$ function (Fig. 3).

The concentration dependences of the relative viscosity $\eta_{rel}(c)$ of the EO–PO mixture precondensates in Cellosolve solutions at c = 5–45% are described by the expression $\ln \eta_{rel} = ([\eta]c)^{(3-D/D)}$ [2], where $[\eta]$ is the intrinsic viscosity of sample nos. 3–6 in solution; c, concentration, g dl^{-1}; and D, fractal dimension of the aggregates of the mixed EO–PO molecules (Fig. 1 and Tables 1, 2). To estimate the threshold concentration c^* near which the degree of aggregation of the EO–PO molecules in Cellosolve solutions increases, we calculated the $f(x)$ parameter by the expression

$$f(x) = [\eta]c/\ln \eta_{rel} = x^{(2D-3)/D}, \quad x = [\eta]c. \qquad (1)$$

As expected [2], the $f(x)$ curves in the logarithmic coordinates, plotted for Cellosolve solutions of sample nos. 3–6 of EO–PO precondensates, consist of several portions differing in the slope and fractal dimension D of the aggregates of particles (Fig. 4, Table 2).

The degree of aggregation of the oligomers s and dimensionless lattice density ρ of the mixed EO–PO aggregates in Cellosolve solutions were calculated

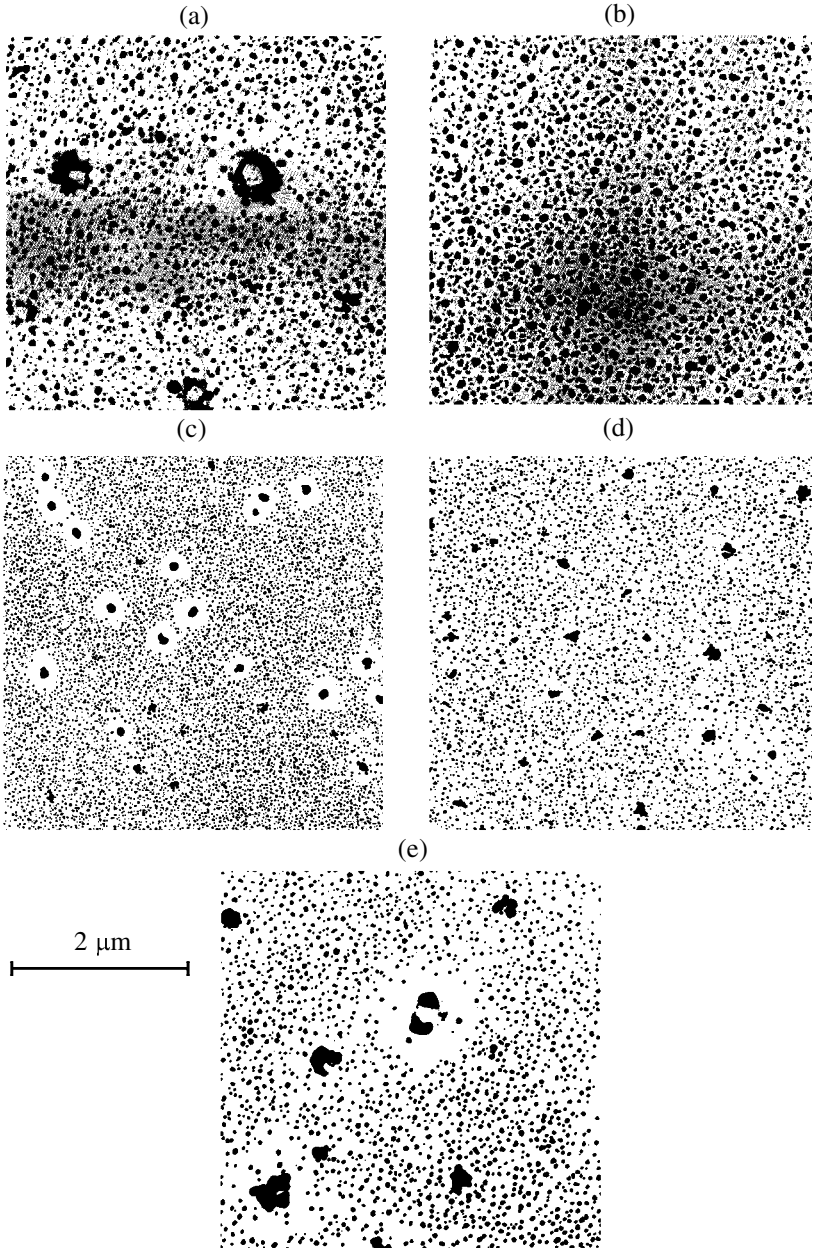

Fig. 2. Electron micrographs of the decorating silver chloride particles on the surface of epoxy–phenol coatings on sheet metal (sample no. 5). Magnification × 10000. Precondensate concentration in Cellosolve solution c, %: (a) 18, (b) 19, (c) 20, (d) 23, and (e) 25.

by the expressions [2, 10]

$$s = (\langle R\rangle/R_0)^D \approx [f(x)]^{D/(2D-3)}, \quad (2)$$

$$\rho = sR_0^3/\langle R\rangle^3 = w^{(1-3D)/D}[f(x)]^{(3-D)/(3-2D)}, \quad (3)$$

where R_0 is the radius of the "elementary" aggregate of E-05 and DFFr molecules of 2.1 nm, and w = 0.637, random packing coefficient of rigid spheres [3].

The average radius of the E-05–DFFr aggregates was determined by the expression [2]

$$\langle R\rangle = R_0 w^{-1/D}[f(x)]^{1/(2D-3)}. \quad (4)$$

It should be noted that formation of an infinite cluster in Cellosolve solutions is characterized by infinite growth of the degree of aggregation s of EO near the threshold concentration c^* = 26.7 g dl^{-1} (Table 2, sample no. 1). The degree of aggregation s of the EO molecules in Cellosolve solution near c^* is

Table 2. Parameters of the aggregates of the oligomer molecules in E-05 and DFFr solutions, as well as of the mixed EO–PO molecular aggregates in Cellosolve solutions of precondensates of the E-05–DFFr mixture at 298 K

Sample no.	c_{min}, g dl^{-1}	ρ_{min}, ±5%	D_1, ±7%	s_1	$\Delta\sigma(c_{min})$, mN m^{-1}	c^*, g dl^{-1}	ρ_{max}, ±5%	D_3, ±7%	s_3	$\Delta\sigma(c^*)$, mN m^{-1}
1	12.3	0.40	1.56	92	1.2	26.7	0.53	1.83	340	–3.2
2	19.8	0.22	1.34	1.3	1.5	26	0.20	1.25	~3	0.0
3	25.0	0.15	1.44	2	–	36	0.28	1.80	14	–
4	24.4	0.20	1.51	2	–	26	0.25	1.67	11	–
5	14.0	0.22	1.57	2	3.4	20.5	0.67	1.67	18	–1.0
6	17.0	0.12	1.47	8	2.0	29.0	0.40	2.04	34	–0.3

Note: Fractal dimension D of the aggregates and degree of aggregation s of the oligomer molecules are given in the first and third portions of the $f(x)$ curves. The density of the aggregates for the Euclidean dimensionality $E = 3$ are given for the minimum and maximum of the curves $\rho(c)$, characterized by c_{min} and c parameters. The $\Delta\sigma(c) = \sigma(c) - \sigma_1$ parameters were calculated for σ_1(Cellosolve) $= 31.8 \times 10^{-3}$ N m^{-1} [13].

two orders of magnitude higher ($s > 300$) than that of the PO molecules in solution at $c = 26$ g dl^{-1} ($s \approx 3$, sample no. 2).

Three portions in the $f(x)$ curves for Cellosolve solutions of the precondensates at $x = 0.4–4.5$ are associated with the fractal–fractal transitions from elementary EO–PO molecular aggregates with $D_1 = 1.57$ ($s_1 \approx 2$, aggregate radius $\langle R \rangle = 3.1$ nm at $c \le 14$ g dl^{-1} [2]) to larger and denser EO–PO aggregates with $D_3 \approx 1.7$ ($s_3 = 18$, $\langle R \rangle$ 18 nm at $c = 20$ g dl^{-1}) and infinite cluster of particles at $c \ge 20.5$ g dl^{-1} ($s \to \infty$, $c > c^*$) (Table 2, precondensate sample no. 5). In these portions of the $f(x)$ curves, the degree of aggregation s of the EO and PO molecules in the mixed aggregate is much lower than that in the EO solution in Cellosolve but much higher than that in the PO solution [2].

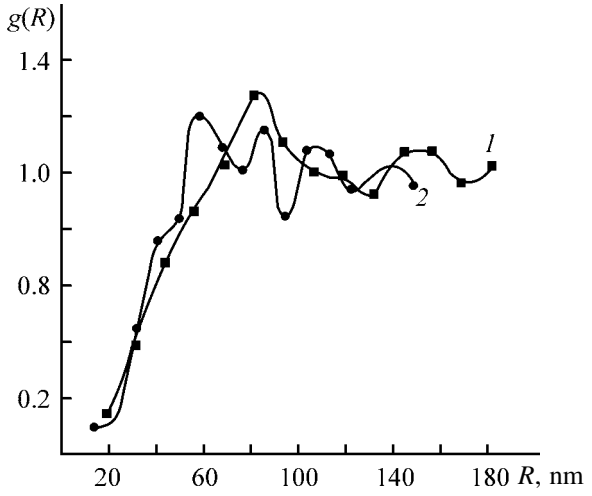

Fig. 3. Radial distribution function $g(R)$ for the decorating silver chloride particles on the surface of epoxy–phenol coatings on sheet metal (sample no. 5). (R) Particle radius, nm. Precondensate concentration in Cellosolve solution c, %: (*1*) 19 and (*2*) 30.

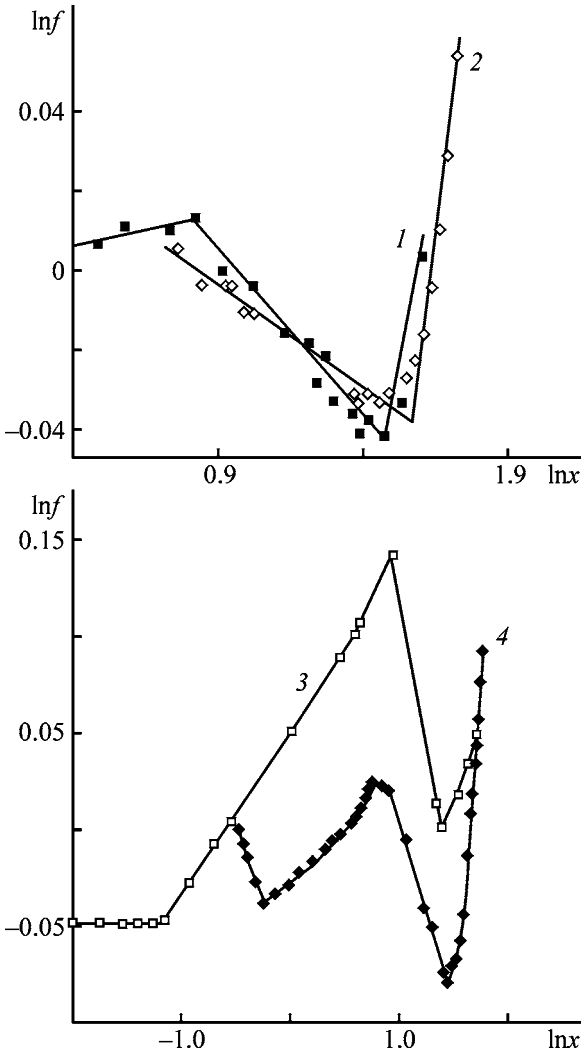

Fig. 4. $f([\eta]c)$ curves for precondensates of the mixture of E-05 and DFFr resins in Cellosolve solution in the ln$f$–ln$x$ coordinates ($x = [\eta]c$ is a dimensionless parameter). (*1–4*) See caption to Fig. 1.

In the first portion of the $f(x)$ curves, the degree of aggregation s_1 of the EO and PO molecules is nearly 2 for all the precondensate samples, except for sample no. 6 (N_1/N_2 = 1.5). In the third portion of the $f(x)$ curves, the degree of aggregation s_3 of the EO and PO molecules depends on the N_1/N_2 ratio, being much higher at N_1/N_2 = 1.5 than at N_1/N_2 = 0.7–1.0 (Table 2, Fig. 4).

The density ρ of the aggregates of the EO molecules and of mixed EO–PO aggregates varies nonmonotonically with growing concentration of the oligomers in solution at $[\eta]c$ = 0.5–6. The position of the extrema in the $\rho(c)$ curves for the EO–PO precondensates in the concentration c scale depends on the N_1/N_2 ratio (Fig. 5). The minimum of the density $\rho(c)$ of the mixed EO–PO aggregates corresponds to c_{min} which is at a minimum at N_1/N_2 = 1 (Table 2).

The density ρ is at a maximum near the threshold concentration c^* of the EO–PO precondensates in solution and then attains saturation at $c > c^*$. For sample no. 5 (N_1/N_2 = 1, Table 2) we revealed a maximal density $\rho(c^*)$ of the aggregates close to 0.69 and corresponding to percolation of the particles in a simple cubic lattice [3]. In other cases ($N_1/N_2 \neq 1$), the density of the aggregates ρ near c^* is much lower due to the departure from the optimal (1 : 1) composition of the mixed EO–PO aggregates (Fig. 5).

The concentration curves of the surface tension $\sigma(c)$ at the EO–PO solution–air interface are characterized by local extrema (Fig. 6). These curves can be described in terms of the Flory–Huggins–Prigogine lattice model by the expression [12]

$$\sigma(c) = \sigma_1 + (kT/\omega q)[\ln(1 - \varphi_2^{sur})/(1 - \varphi_2^{vol})], \quad (5)$$

where σ_1 and σ_2 are the surface tensions of the solution and solvent, respectively; ω, area of the particle in the surface phase; φ_2^{sur} and φ_2^{vol}, volume fractions of the oligomer in the surface phase and solution, respectively, and k, Boltzmann's constant (q = 1 for the oligomers).

The cluster model [3, 16] states that the area ω occupied by a particle in the aggregate is $\pi\langle R\rangle^2 s^{-1}$, where $\langle R\rangle$ is the aggregate radius. For the degree of aggregation s of the particles near the threshold concentration c^*, $s \approx (\langle R\rangle/R_0)^D$, where R_0 is the particle radius [2, 3]. Hence, the area ω occupied by a molecule in the aggregate is equal to $\pi\langle R\rangle^{2-D}R_0^D$. In the surface phase near the threshold concentration c^*, the fractal dimension of the aggregates D is close to 2 ($D \approx 1.89$ at the percolation threshold $p_c \approx 0.5$, the Euclidean dimensionality E = 2 [3]), hence ω

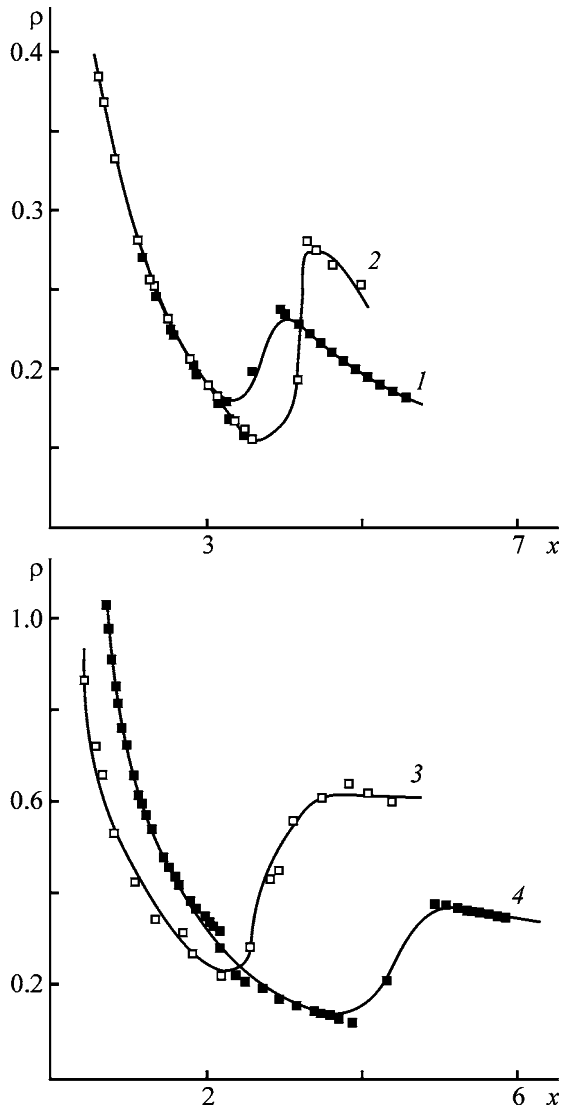

Fig. 5. Density ρ of the aggregates of the oligomer molecules vs. $x = [\eta]c$ for precondensates of the E-05–DFFr mixtures in Cellosolve solution. (*1*–*4*) See caption to Fig. 1.

$\approx \pi R_0^2$. Since at $c < c^*$ the fractal dimension of the particle aggregates $D < 2$, $\omega = \pi\langle R\rangle^{2-D}R_0^D$ exceeds πR_0^2.

Based on the relationship for the density of the particle aggregates in solution $\rho \sim (\langle R\rangle/R_0)^{D-3}$ (E = 3) [3], we can relate $\Delta\sigma(c)$ to the density ρ of the aggregates and the dimensionless parameter $x = [\eta]c$

$$\Delta\sigma(c) = \sigma(c) - \sigma_1 = kT\pi^{-1}\rho^{(D-2)/(D-3)}R_0^{-2} \times [\ln(1 - \varphi_2^{sur})/(1 - \varphi_2^{vol})], \quad (6)$$

$$\Delta\sigma(c) = kT\pi^{-1}w^{(2-D)/D}x^{(D-2)/D}R_0^{-2}[\ln(1 - \varphi_2^{sur})/(1 - \varphi_2^{vol})]. \quad (7)$$

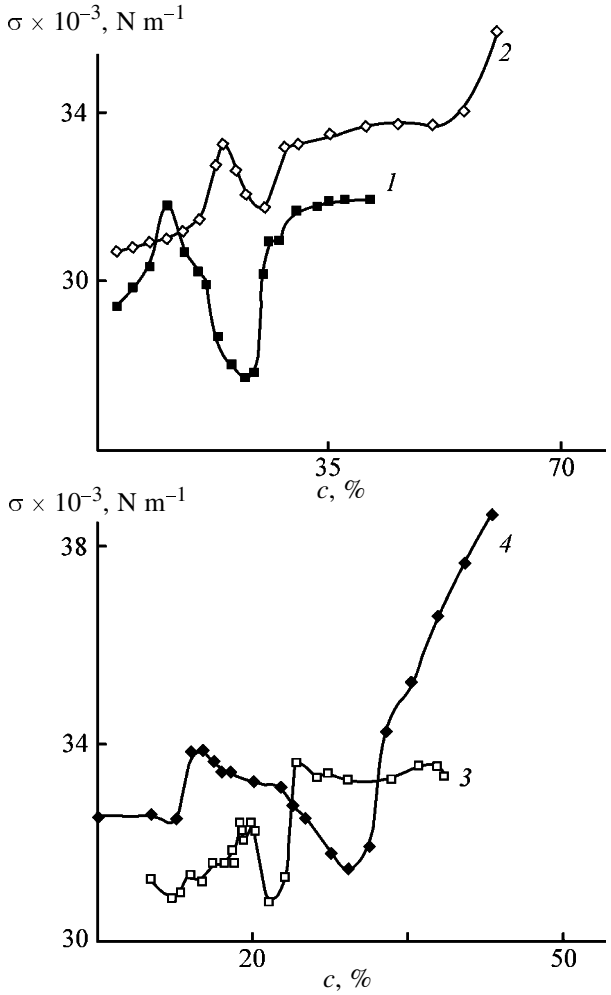

Fig. 6. Surface tension σ, at the solution–air interface vs. the concentration c of (*1*) E-05 and (*2*) DFFr and (*3, 4*) of the precondensates of the E-05–DFFr mixture in Cellosolve solution at 298 K. Precondensate sample no. (*3*) 5 and (*4*) 6.

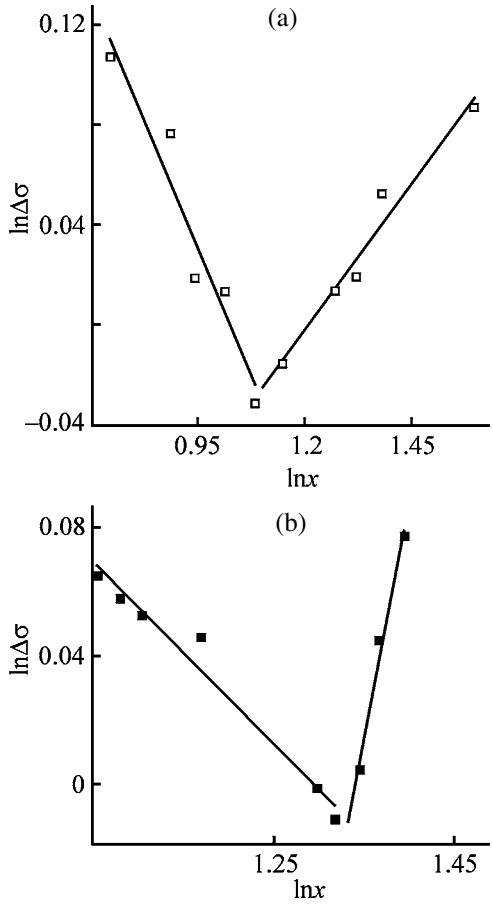

Fig. 7. Surface tension increment Δσ as a function of $x = [\eta]c$ in the $\ln \Delta\sigma$–$\ln x$ coordinates. Precondensate sample no. in a Cellosolve solution: (a) 5 and (b) 6. Fractal dimension D of the aggregates, calculated from the slope of the curves by expression (7), is equal to (a) 1.4 and (b) 1.8 at $c < c^*$, and (a, b) 2.6 at $c > c^*$.

Near the local maximum of the surface tension curves $\sigma(c)$ at $c < c^*$, $d\sigma/dc < 0$ and $\Delta\sigma(c) > 0$ ($D < 2$), for the minimum $\sigma(c)$ near c^*, $d\sigma/dc = 0$ and $\Delta\sigma(c) \approx 0$ ($D = 2$), and at $c > c^*$, $d\sigma/dc > 0$ and $\Delta\sigma(c) > 0$ ($D > 2$) (Fig. 7). The maximum in the $\sigma(c)$ curve corresponds to the minimum of the density $\rho(c)$ of the aggregates at c_{min}, and the minimum in the $\sigma(c)$ curve, to the maximum of the density $\rho(c)$ of the aggregates near c^* (Figs. 5, 6).

Data in Table 2 for the EO and PO solutions in Cellosolve support these predictions of the cluster model. The minima in the $\sigma(c)$ curves are due to the fact that the second derivative of the Gibbs free energy d^2F/dc^2 is equal to zero at the threshold concentration c^* ($D = 2$). The increment in the Gibbs free energy $\Delta F(c) = \Delta\sigma\omega\varphi_2^{sur}N_A$ (N_A is the Avogadro number) [12] is at a minimum near c^* ($d\sigma/dc = 0$). This is consistent with the thermodynamic criterion of stability of multicomponent systems [17]. At $c < c^*$, ΔF has a maximum coinciding with that of the concentration c_s of the aggregates of particles with $D < 2$ [2], and at $c > c^*$, $\Delta F > 0$ ($\Delta\sigma > 0$).

This fact suggests that the optimal concentration of the precondensate in formation of the coatings should correspond to the conditions of formation of an infinite cluster of particles and wetting of the substrate surface, $\sigma(c) \le \sigma_1$ [12]. For sample no. 5, the threshold concentration c^* of the precondensate in solution fully satisfies these conditions (Table 2).

The patterns of distribution of the decorating particles on the surface of the epoxy–phenol coatings reveal the cluster structure of the polymer, represented by the areas of localization of fractions of small (20–

* Lattice densities ρ_l (Euclidean dimensionality E = 2) are given for large AgCl crystals.

30 nm) and large (150–500 nm) AgCl particles (Figs. 3a–3e). Nonuniform energy microrelief of the coating surface is due to different strengths of the bond linking the AgCl particles with the substrate, as well as to the characteristics of distribution of the functional groups of E-05 and DFFr. Accumulations of small AgCl particles strongly bound to the polymer surface predominantly reflect the distribution of the functional groups of E-05 [1, 2]. Accumulations of large particles are formed by the mechanism of coalescence of small particles and topologically correspond to distribution of the functional groups of DFFr [8].

Microdecorograms of the coatings show that the most uniform distribution of the small and large AgCl particles corresponds to the precondensate in the Cellosolve solution with c = 19% (Table 3, sample no. 8; Fig. 2b). With departure from c = 19% the average distance between the large AgCl particles and their size tends to increase for all the samples, except for samples of coatings obtained at c = 25–30% (Table 3). At c = 18, 20, and 23% the coatings contain microheterogeneous segments lacking in the coatings at c = 19, 25, and 30%. For coating samples at c = 18–23%, the homogeneous segments correspond to clusters of the particles forming two sublattices, and the clusters of the particles in microheterogenous segments form only one lattice.

We estimated the dimensionless lattice density ρ_l, correlation radius ξ, coordination number m, and fractal dimension D of the clusters [1] in the microheterogeneous segments of the coatings from the data for the small fraction of AgCl particles. In the epoxy–phenol coatings (Table 3, sample nos. 7, 9–10), for which we revealed segregation into two phases, those of small and large particles, the small-sized fraction particles form only one lattice. The $\rho_l(R)$ curves corresponding to microheterogeneous segments of the coatings consist of three portions and are characterized by two values of the correlation radius ξ and fractal dimension D of the clusters in the first two portions (Fig. 8).

The most uniform structure of the chemical network of the epoxy–phenol polymer is characteristic for the coating formed at c = 19%. It can be represented as two infinite clusters forming two sublattices of small and large AgCl particles and reflecting, respectively, the distribution of the functional groups in the network segments containing E-05 and DFFr moieties (Fig. 3). In this case, the $\rho_l(R)$ curves for the small and large fractions of the decorating AgCl particles consist of two portions, and the correlation radius ξ is at a minimum, the lattice density of the clusters ρ_l is at a maximum, and the coordination number of the quasilattice $m \approx 6$ corresponds to the triangular lattice [3] (Fig. 8, Table 3).

Thus, at c = 19%, two infinite clusters are formed that are inserted into each other and contain two types of the decorating particles. The lattice densities of the two clusters are close. The topological structure of the infinite clusters suggests formation of a uniform and common for the two oligomeric components chemical network of the epoxy–phenol polymer [8, 17]. Such a structure of the chemical network of the epoxy–phenol polymer should provide high protecting characteristics of the corresponding coatings in aggressive media [6].

Notes: The adhesion characteristic is given in points: (1_1) high adhesion and (2_1) medium adhesion.
* Upon introduction into the precondensate solution of additional 0.3% of KO-815 oligomer according to the formulation of the EP-547 lacquer [6].

To support this conclusion, we studied the protective characteristics of the coatings obtained by curing of the precondensate (sample no. 5) in a Cellosolve solution at c = 18–30% (Table 4). The maximal resistance of the coatings in aggressive media and high adhesion to the support are achieved at c = 20% (sample no. 9) which is virtually identical to the threshold c* derived using other methods (Tables 2, 3).

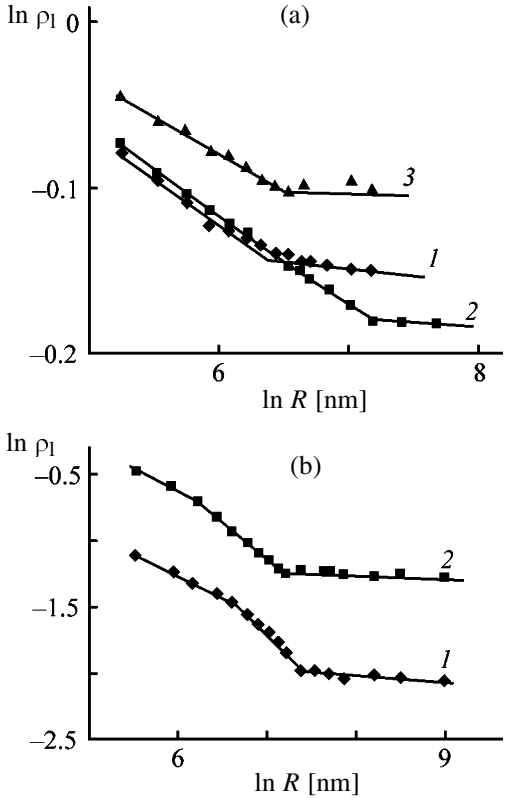

Fig. 8. Lattice density ρ_l of the decorating AgCl particles vs. the scale of the radius of the circumference R incorporating the cluster, nm. Segments of the epoxy–phenol coatings on sheet metal: (*1*) homogeneous and (*2*) heterogeneous. Sample no. 5, concentration c of the precondensate in a Cellosolve solution, %: (*1*) 18, (*2*) 20, and (*3*) 19.

Worsening of the protective and strength characteristics of the coatings (Table 4, sample nos. 7, 10–12), as well as of their ability for pressing [6] upon departure from the optimal concentration c* can be due to the breakdown of the uniform and common for the two components chemical network of the epoxy–phenol polymer into fairly long segments of the chemical network of epoxy–4,4'-isopropylidenediphenol resin, and discrete and microheterogeneous fragments of the chemical network of phenol–formaldehyde resin (Table 3, sample nos. 7, 9, 10). Such breakdown of the chemical network of the epoxy–phenol polymer upon departure from the threshold concentration c* of the precondensate in solution, deteriorating the structural uniformity of the coatings, can be predicted on the basis of viscometric and surface tension data.

CONCLUSIONS

(1) Near the threshold concentration c* of formation of an infinite cluster of particles in solutions of precondensates, the density of the mixed aggregates of epoxy–4,4'-isopropylidenediphenol and phenol–formaldehyde oligomers is at a maximum for the N_1/N_2 molar ratio of 1. In this case, the density is close to 0.69, which corresponds to percolation of the particles in a simple cubic lattice. In other cases ($N_1/N_2 \neq 1$) the density of the aggregate is much lower due to the departure from the optimal (1 : 1) composition of the mixed aggregates.

(2) The formulation concentrations of the oligo-

mers in formation of coatings from the solutions of the precondensates of a mixture of epoxy–4,4'-isopropylidenediphenol and phenol–formaldehyde oligomer should correspond to the concentration mode of formation of an infinite cluster, as well as to the condition for wetting of the substrate surface with the precondensate solution.

(3) The most uniform distribution of the decorating AgCl particles on the surface of epoxy–phenol coatings corresponds to the threshold concentration c^* of the precondensate in solution, with two infinite clusters of small and large AgCl particles formed that are inserted into each other. The lattice densities of such clusters are close, and their coordination numbers correspond to a triangular lattice. Such a structure of infinite clusters is due to formation of a homogeneous and common for the two components (epoxy–4,4'-isopropylidenediphenol and phenol–formaldehyde oligomers) chemical networks of the cross-linked polymer.

(4) The maximal resistance of the polymer coatings in aggressive media and high adhesion to the support are achieved at the threshold concentration c^* of the precondensate in solution. Upon departure from the threshold concentration c^*, the uniform and common for the two oligomeric component chemical networks of the epoxy–phenol polymer break down into discrete and microheterogeneous segments. Breakdown of such network disturbs the structural uniformity and deteriorates the protective and strength characteristics of the polymer coatings.

Abstract—The composition and content of polysaccharides recovered from various samples of sunflower husks by their sequential treatment with water, ammonium oxalate (or oxalic acid), and alkali were examined. The products were analyzed by X-ray diffraction and IR spectroscopy.

DOI: 10.1134/S1070427207070300

Agricultural wastes are a promising source of chemical compounds, as in most cases recovery of natural biologically active substances from these materials is more profitable than the chemical synthesis. Among such secondary resources is sunflower (*Helianthus annuus L.*) production waste.

Sunflower seeds are mainly used by food industry for the production of vegetable oil. Their processing at oil-extracting plants (OEPs) is accompanied by accumulation of husks. This is a large-tonnage waste, and each enterprise solves the problem of its utilization independently. Usually a part of this waste is incinerated in steam boilers and the other part is dumped, deteriorating the environmental situation in the region. Numerous procedures have been suggested for processing of sunflower husks, but the majority of them involve incineration or utilization in the hydrolytic industry for the production of xylose, furfural, and protein yeast [1]. It is also suggested to produce sorbents [2, 3], fertilizers [4–7], forage additives [8], and products exhibiting ion-exchange and bactericidal properties [9]. However, the lack of exhaustive information on many processes involved in treatment of sunflower husks prevents the development and application of efficient (flexible and low-waste) technologies.

To reveal how sunflower strain features affect the composition of husks as a promising raw material for chemical industry, we collected a series of husk samples from OEP waste in various regions of Russia and examined their compositions (organic and inorganic components).

The goal of this study was to analyze the composition and structure of carbohydrates recovered by various extraction procedures from sunflower husks (SH).

EXPERIMENTAL

We examined four SH samples from OEPs in Rostov-on-Don (SH-1, 2003), Altai krai (SH-2, 2004), Krasnodar krai (SH-3, 2004), and Uryupinsk, Volgograd oblast (SH-4, 2004). Visual examination of husks showed that they belonged to different strains.

Husk samples with the particle size no less than 2 mm were washed with water and air-dried to constant weight.

Polysaccharides (PSs) were recovered from SH by sequential extraction with water, ammonium oxalate solution, and alkali solution, after which their qualitative and quantitative compositions were determined. For this purpose, an SH sample (70 g) was poured over with water (solid : liquid weight ratio ~1 : 10) and heated on a water bath for 3 h. The residue was filtered off, the solution was concentrated on a rotary evaporator and centrifuged to remove residual raw material (4500–5000 rpm, 210–25 min), after which the polysaccharides were precipitated with acetone (volume ratio of the solutions 1 : 4). The polysaccharide precipitate was separated by centrifugation, dissolved in water, and freeze-dried to obtain water-extracted polysaccharides [PS(H_2O)]. Depending on the sampling site (and hence on the plant strain), the yield of these polysaccharides was 1.46–2.11 wt % (Table 1).

* Monosaccharides were determined in the form of polyol acetates (method 1) and methyl glycoside acetates (method 2).
** Monosaccharides: (Rha) rhamnose, (Ara) arabinose, (Xyl) xylose, (Man) mannose, (Glc) glucose, (Gal) galactose, and (Int) inositol; (GalA) galacturonic acid; (Pen) pentoses and (Hex) hexoses. (+) Detected as traces.
*** Structure (X-ray diffraction data): (a) amorphous and (c) crystalline.

The residue after the aqueous extraction was poured over with a 0.5 N solution of ammonium oxalate (solid : liquid weight ratio ~1 : 10) and heated on a water bath for 3 h. The undissolved raw material was filtered off. The filtrate was dialyzed against running water for 2–3 days and then against distilled water for 1 day, after which it was concentrated on a rotary evaporator, and a fourfold volume of acetone was added. The precipitate was separated by centrifugation, dissolved in water, and freeze-dried to obtain oxalate-extracted polysaccharides. Their yield was 2.46–3.09 wt % (Table 1).

The SH solid residue after the treatment with water and ammonium oxalate was suspended in 0.5 N NaOH and heated on a water bath for 2 h. The solution was separated by centrifugation and worked up as described above to obtain alkali-extracted polysaccharides in a yield of 4.58–5.67 wt % (Table 1).

The qualitative and quantitative monosaccharide

compositions of the recovered PSs were determined, after acid hydrolysis of the samples with 1 N trifluoroacetic acid (TFA) at 100°C for 4–5 h, by paper chromatography (PC), gas–liquid chromatography (GLC), and GLC–mass spectrometry (GLC–MS) in the form of polyol acetates (method 1). Descending PC was performed on Filtrak FN-12 paper in the solvent system 1-butanol–pyridine–water, 6 : 4 : 3 (by volume). Monosaccharides were detected with an alkaline solution of silver nitrate. Gas–liquid chromatography was performed on an Agilent 6850 chromatograph (the United States) equipped with a flame-ionization detector, using an HP 5 MS capillary column (30 m × 250 μm × 0.25 μm) coated with poly(methyl–5% phenyl)siloxane. The column temperature was as follows: 150°C, 1 min; heating to 230°C, 3 deg min^{-1}; 230°C, 10 min. The GLC–MS analysis was performed with a Hewlett–Packard 6890 chromatograph (the United States) equipped with the similar capillary column and interfaced with a Hewlett–Packard 5973 mass spectrometer (the United States); the temperature conditions were similar.

Uronic acids were detected by GLC in the form of methyl glycoside acetates after methanolysis of PSs (acetyl chloride–methanol, 1 : 10 by volume, 100°C, 7–8 h), followed by acetylation.

Data on water-, oxalate-, and alkali-extracted polysaccharides recovered from SH samples are given in Table 1. All the SHs are brown or gray-brown. The total PS yield ranges from 8.80 (SH-2) to 10.48% (SH-4) relative to the raw material weight and depends on the plant strain and extraction procedure. The highest yield of polysaccharides from all the samples was ensured by alkaline extraction, and the lowest yield, by aqueous extraction.

It should be noted that neutral monosaccharides (rhamnose, arabinose, xylose, glucose, galactose, and mannose) were identified and quantitatively determined by GLC and GLC–MS in the form of polyol acetates. Uronic acids do not give polyols under these conditions; therefore, their qualitative and quantitative determination was performed in the form of methyl glycoside acetates (method 2). Neutral monosaccharides, especially if there are several of them (Table 1), in analysis in the form of methyl glycoside acetates give a complex difficult-to-identify mixture of anomers (from two to four for each monosaccharide); therefore, at best, it is possible to determine only the total content of pentoses and hexoses, rather than the content of separate (individual) monosaccharides.

The qualitative and quantitative monosaccharide composition of the recovered polysaccharides is diverse and depends on the origin of the raw material and on the recovery procedure. For example, in water- and oxalate-extracted PSs xylose is present in trace amounts, and in alkali-extracted PSs its content sometimes exceeds 50% (SH-3, SH-4). Mannose and inositol in small amounts were detected only in water-extracted PSs. Residues of rhamnose, arabinose, glucose, and galactose are present in all the PSs in different ratios. Uronic acids are represented only by galacturonic acid and are present in small amounts in all the recovered polysaccharides (Table 1); their content is maximal in oxalate-extracted PSs (55–71 mol %). In water-extracted PSs, their content is 2–3 times higher (40–47 mol %) than that of arabinose, and in alkali-extracted PSs their content is the lowest (8–12 mol %).

Comparison of the monosaccharide composition of PS samples from sunflower husks with that of the related substances recovered previously from rice husks and meal, buckwheat husks, and buckwheat straw [10, 11] shows that extracts from sunflower husks have a richer qualitative composition and contain large amounts of galacturonic acid.

The structures of the PSs were examined by X-ray phase analysis (DRON-2 diffractometer, CuK_α radiation) and IR spectroscopy (IR Prestige spectrophotometer, Shimadzu, Japan) in the range 400–4000 cm^{-1} by standard procedures. Samples for IR measurements were prepared as KBr pellets.

The X-ray diffraction data (Table 1) show that the PSs recovered from various SH samples have amorphous or amorphous-crystalline structure.

The IR absorption maxima of the examined polysaccharides are given in Table 2, and typical spectra of the substances recovered by extraction of sunflower husks with water, oxalate, and alkali are shown in Fig. 1. The absorption bands were identified using the available structural-spectroscopic data on polysaccharides [12, 13].

The structure and intensity of absorption bands in the IR spectra (400–4000 cm^{-1}) of polysaccharides recovered from sunflower husks noticeably vary depending both on the procedure for polysaccharide recovery (Fig. 1) and on the plant strain (Fig. 2).

Comparison of the characteristic bands of natural polysaccharides recovered by similar procedure but from different raw materials (buckwheat husks) also shows that hydrocarbons having different monosaccharide compositions (Table 1) [10, 11] can be characterized in relation to the kind of the raw material.

Table 2. IR absorption maxima of polysaccharides recovered from sunflower husks

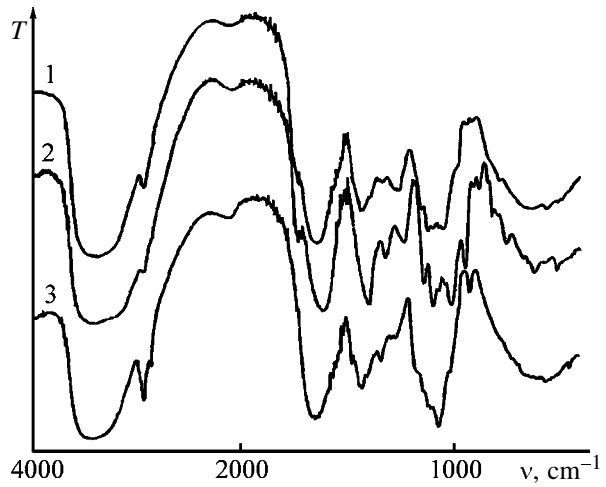

Fig. 1. IR absorption spectra of acetate residues of SH-1 polysaccharides after (*1*) aqueous, (*2*) oxalate, and (*3*) alkaline extraction. (*T*) Transmission and (ν) wavenumber; the same for Fig. 2.

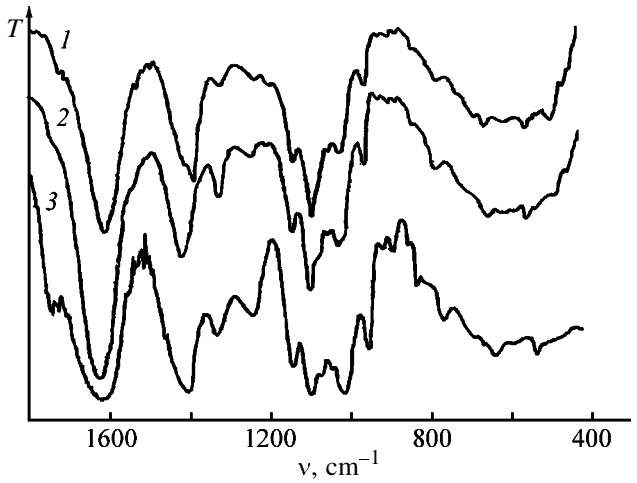

Fig. 2. IR absorption spectra of oxalate-extracted polysaccharides from samples (*1*) SH-1, (*2*) SH-2, and (*3*) SH-3.

The properties of PSs from sunflower husks are poorly studied yet, although it was found that, as a rule, the biological activity is exhibited by carbohydrates with medium and low degree of polymerization [14]. The strongest inhibiting effect is shown by samples recovered from rice husks by oxalate and alkaline extraction [15].

CONCLUSIONS

(1) The chemical composition of polysaccharides recovered by sequential extraction from sunflower husks differs from that of polysaccharides recovered similarly from buckwheat and rice husks in the richer qualitative composition of the monosaccharides. The quantitative ratio of monosaccharides depends on the raw material (plant strain, vegetation site), extraction procedure, and extractant used. The total yield of polysaccharides from sunflower husks varies from 8.8 to 10.5 wt % based on dry raw material. The largest amount of polysaccharides is recovered by alkaline extraction, and the smallest amount, by aqueous extraction.

(2) Uronic acids consist of galacturonic acid only. Its content is comparable to, or exceeds the total content of neutral monosaccharides incorporated in the examined polysaccharides. The highest yield of galacturonic acid was attained in oxalate extracts from sunflower husks.

(3) The polysaccharides are amorphous or amorphous-crystalline substances. IR spectroscopy allows prompt preliminary characterization of the carbohydrate product in relation to the processing conditions and origin (plant strain).

Abstract—The features of degradation of the chitosan films prepared from acetic acid solutions using Collagenase KK enzyme preparation were studied.

DOI: 10.1134/S1070427207070312

The use of chitosan (CH) as a drug seems rather promising [1, 2]. Incorporation of proteolytic enzymes into CH can improve its pharmaceutical properties. It is believed that, in the absence of chemical bonding with the polymer, the enzymes will be released owing to the diffusion of the protein macromolecules from the polymer matrix into the environment and owing to the enzymatic degradation of chitosan.

In this work we simulated biodegradation of chitosan films containing a proteolytic enzyme.

EXPERIMENTAL

In this study we used chitosan [TU (Technical Specifications) 6-09-05-296–76, Khimmed Company, Russia] prepared by alkaline deacetylation of the crab chitin (75% degree of deacetylation, M_η 120000) and Collagenase KK proteolytic enzyme preparation from hepatopancreas of commercial crab species (Immunopreparat State Unitary Enterprise, Ufa, Bashkortostan, Russia). CH films were prepared by casting a polymer solution onto the glass surface. The weight concentration of CH in the initial solution was 2 g dl^{-1} in 1% acetic acid. In all the experiments the film thickness was constant, 0.1 mm. The enzyme preparation preliminarily dissolved in a small amount of water was added into the CH solution just before casting. The content of the enzyme in the film was varied from 0.5 to 10 wt% with respect to CH weight.

Biodegradation of chitosan under the effect of the enzyme added into the film was studied by viscometric method in a buffer solution containing 0.3 M acetic acid and 0.2 M sodium acetate according to the standard procedure [3]. The experimental error was no more than 5%. To simulate the enzymolysis, the chitosan film was placed on a support wetted with a solution of the enzyme preparation and kept at 35°C for a certain period (up to 1 h). The concentration of the enzyme preparation in the solution being in contact with the chitosan film was varied from 0.1 to 50 wt %. The degradation kinetics was evaluated from the viscometric data. The enzymolysis of chitosan with the enzyme preliminarily added into the films was also studied by viscometric procedure.

Addition of the Collagenase KK enzyme into the CH solution in the stage of the film preparation leads to the following results. As seen from Fig. 1a, with increasing content of collagenase in the film, the intrinsic viscosity of CH gradually decreases, which suggests that the molecular weight of chitosan decreases owing to biodegradation under the effect of the enzyme added.

Using viscometric data and Mark–Kuhn equation for CH solutions [4] in acetate buffer ($[\eta] = 1.38 \times 10^{-4} M^{0.85}$), we can evaluate a relative decrease in the intrinsic viscosity and in the molecular weight of CH (see table).

A similar decrease in the intrinsic viscosity is also observed in the case when the chitosan film prepared without enzyme in placed on a support wetted with a collagenase solution (Figs. 1b and 2a). The following trends are observed.

(1) Sharp decrease in the intrinsic viscosity is observed only in the first 10–15 min of the film contact with the enzyme solution (Fig. 2a). Longer enzymolysis does not noticeably affect the intrinsic viscosity of the CH solutions.

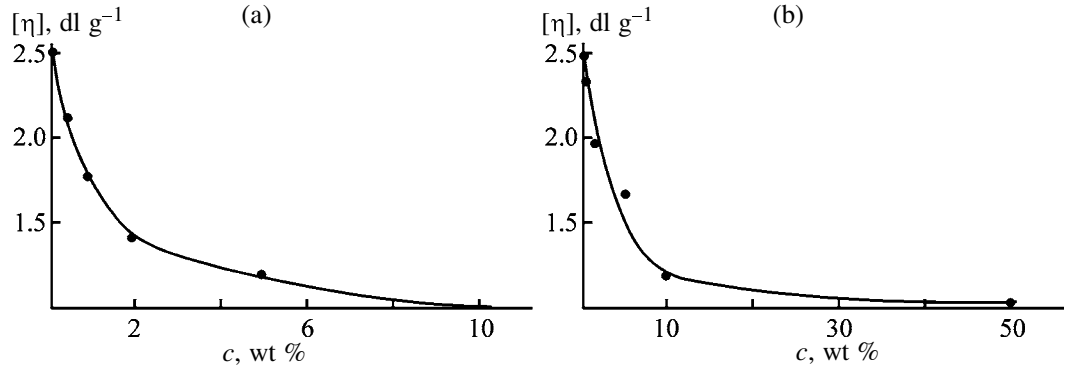

Fig. 1. Intrinsic viscosity [η] of CH recovered (a) from the enzyme-containing film, as a function of the content of Collagenase KK enzyme preparation in the film *c*, and (b) from the enzyme-free film after its contact with a solution of Collagenase KK enzyme preparation for 1 h, as a function of its content in the solution *c*.

5	46.4	4	27.0
10	54.9	10	46.4
		50	54.9

* *c* is the concentration of Collagenase KK in the CH film.
** *c* is the concentration of Collagenase KK in the solution being in contact with CH (contact time 1 h).

(2) Increase in the collagenase concentration in solution that is in contact with the CH film leads to faster decrease in the intrinsic viscosity and molecular weight (see table). Enzymolysis of the CH film for 1 h at a high concentration of the enzyme in solution decreases the molecular weight of chitosan by a factor of about 2.

In principle, proteolytic enzyme should not cause degradation of CH, which is a polysaccharide. However, the Collagenase KK preparation is a complex of enzymes and this complex exhibits high glycosidase activity. Thus, enzymatic degradation of chitosan films in the presence of collagenase is most probably due to the reaction of enzymes with a glycosidase function on CH. For example, collagenase is accompanied by hyaluronidase enzyme, which can split

the glycoside bond not only in hyaluronic acid but also in CH.

These features of the CH degradation are probably due to the fact that the accessibility of the CH units for interaction with enzyme is low, the more so as the enzyme is also a polymer. As a result, the intrinsic viscosity of the CH solutions changes nonmonotonically and flattens out. This fact can be explained as follows. Glycosidase reacts only with accessible CH units and subsequent increase in the concentration of Collagenase KK preparation (and, correspondingly, of glycosidases) or in the contact time of the film and solution does not affect the CH unit accessibility.

To simulate the process of biodegradation of the enzyme-containing preparation, the film (in which the enzyme was introduced in the course of formation) was placed on a support wetted with a collagenase solution. It was found that the rate of decrease in the CH intrinsic viscosity and, thus, in its molecular weight is determined by the amount of the enzyme contained in the film.

As seen from Fig. 2b, with increasing amount of the enzyme in the film the degree of the CH degradation at its contact with the enzyme solution decreases. At a relatively high content of the enzyme in the film (~5–10 wt %), contact of the CH film with a support wetted with a collagenase solution does not provide further decrease in the intrinsic viscosity of the solution. Apparently, in such films glycosidases already break down all the accessible glycoside bonds in CH and, thus, addition of new portions of the enzyme does not lead to the film enzymolysis. It should be noted that an increase in the enzyme concentration in a solution occurring in contact with the film from 4 to 10 wt % and more does not provide additional decrease in the intrinsic viscosity.

Thus, when the enzyme-containing film is placed on the wetted support, the film skeleton is broken across the glycoside bonds and, as a result, the introduced collagenase passes from the film into the solution.

The released collagenase does not lose its proteolytic activity, which is confirmed by enzymolysis of denatured albumin (after Tugolukov). This fact suggests that the CH films containing collagenase enzyme are promising for medical purposes.

CONCLUSIONS

(1) The intrinsic viscosity of chitosan in the form of films prepared from acetic acid solutions decreases under the effect of the Collagenase KK enzyme preparation both upon incorporation of the enzyme directly into the film and upon contact of the film with a support wetted with the enzyme-containing solution.

(2) The enzymatic degradation of chitosan was attributed to the action of glycosidases present in the Collagenase KK enzyme preparation.

(3) Degradation of the films under the effect of glycosidases leads to liberation of the proteolytic enzymes (collagenases), which retain their activity, for example, with respect to enzymolysis of denatured albumin.

Abstract—The features of enzymatic degradation of modified chitosan films prepared from acetic acid solutions using Collagenase KK enzyme preparation was studied.

DOI: 10.1134/S1070427207070324

The possibility of enzymatic degradation of chitosan (CH) is one of its advantages in preparing various medical-purpose materials such as films, sutures, coatings, and gels [1, 2]. However, too rapid enzymatic degradation, which decreases their operation life, can restrict their use.

In this work we studied enzymatic degradation of chitosan films and procedures of the film modification to improve their operation life. At least two ways to solve this problem are known. The first way is to change the supramolecular structure of CH, increase its packing density, and decrease accessibility of the CH units and, thus, degree of biodegradation. The second way is to prepare CH in water-insoluble form.

EXPERIMENTAL

In this work we used chitosan [TU (Technical Specifications) 6-09-05-296–76, Khimmed Company, Russia] prepared by alkaline deacetylation of the crab chitin (75% degree of deacetylation, M_η 120000) and Collagenase KK proteolytic enzyme preparation prepared from hepatopancreas of commercial crab species (Immunopreparat State Unitary Enterprise, Ufa, Bashkortostan, Russia).

CH films were prepared by casting a polymer solution onto the glass surface. The concentration of CH in the initial solution was 2 g dl^{-1}; 1–70 wt % acetic acid was used as solvent. In all the experiments the film thickness was constant, 0.1 mm. Films were dried to constant weight. To simulate the biodegradation process, a chitosan film was placed on a support wetted with a collagenase solution and kept at 35°C for a certain period (up to 1 h). The biodegradation kinetics was studied by the viscometric method in a buffer solution containing 0.3 M acetic acid and 0.2 M sodium acetate. Chitosan was converted into the alkaline form by keeping of the formed film in 0.1 M NaOH for 1 h with subsequent washing in distilled water. Thermal modification of the film was performed by heating of the formed film to 120°C. The degree of swelling of the film samples was studied gravimetrically.

Principal possibility of the CH enzymatic degradation under the effect of Collagenase KK enzyme preparation was shown previously in [3]. It was found that the conformation and supramolecular state of chitosan in the film and the rate of its enzymatic degradation strongly depend on the degree of protonation of the CH amino groups, which, in turn, is determined by the concentration of the acid used. Certain differences in the CH states in acetic acid solu-

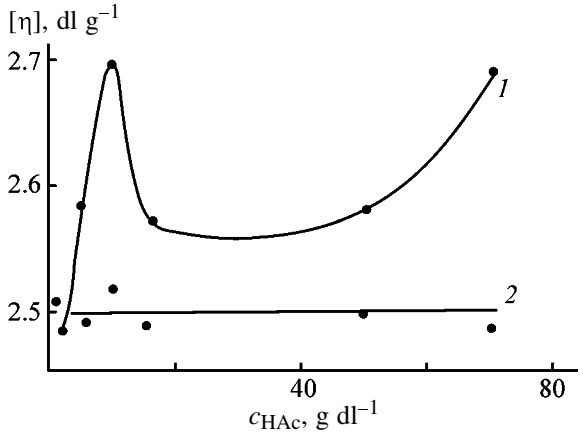

Fig. 1. Intrinsic viscosity of CH films [η] occurring in the (*1*) salt and (*2*) alkaline forms (before degradation) as a function of the acetic acid concentration in the initial solution *c*.

Properties of the CH film samples prepared from acetic acid solutions of various concentrations; keeping time in collagenase solution 1 h, molecular weight of the initial chitosan 1.26×10^5 ([η] 3.0 dl g^{-1})

Film form	Δ[η], dl g^{-1}, after enzymolysis at indicated concentration of acetic acid in the initial solution, %						
	1	5	10	15	20	50	70
Salt	1.03	1.28	1.33	1.15	1.08	1.12	1.59
Alkaline	0.51	0.46	0.63	0.51	0.60	0.65	0.72

tions of various concentrations are confirmed by differences in the intrinsic viscosity of CH before its contact with the enzyme (Fig. 1, curve *1*).

For all the CH films, the dependences of the intrinsic viscosity on the time of contact with the enzyme preparation are similar (Fig. 2). The most significant decrease in the intrinsic viscosity is observed in the first 15–20 min. With a further increase in the treatment time, changes in the intrinsic viscosity are insignificant. It should be noted that, both at short and long contact times, only one trend is observed: the changes in the molecular weight of the polymer are the smallest for the films prepared from 1% acetic acid, whereas molecular weights of the polymers prepared from 10 and, especially, 70% acetic acid change significantly (see table).

The CH films prepared in the salt form (sodium acetate) are highly soluble in water and exhibit high water-absorbing capacity (Fig. 3). Undoubtedly, high water-absorbing capacity is an advantage of chitosan; however, high solubility promotes rapid mechanical failure of the polymer film.

Chitosan in the salt form can be converted into the alkaline form by keeping in 0.1 M NaOH solution for 1 h [4]. This conversion into the alkaline form is characterized by strong increase in the packing density of the CH macromolecules with the corresponding decrease in the accessibility of the CH units for enzymes. The consequences of these changes in the chemical and supramolecular structure of CH in the films are as follows. (1) Conversion of the CH films into the alkaline form strongly decreases the degree of swelling of the film samples (Fig. 3, curve *2*). (2) The intrinsic viscosities of the CH films are leveled (Fig. 1, curve *2*), whereas for CH films in the salt form the intrinsic viscosities vary in a wide range (Fig. 1, curve *1*). (3) Although the shape of the dependence of the intrinsic viscosity on the time of contact with the solution of Collagenase KK preparation (Fig. 4) is similar to that for the films prepared in the salt form, the degree of degradation of the film samples noticeably decreases (see table).

It should be noted that, as in degradation of the salt films, the strongest decrease in the polymer molecular weights is observed for alkaline films prepared from 70% acetic acid. However, the overall degree of degradation of CH prepared in the alkaline form is significantly smaller as compared to CH in the salt form.

Smaller degree of enzymatic degradation of CH films in the alkaline form is their indubitable advant-

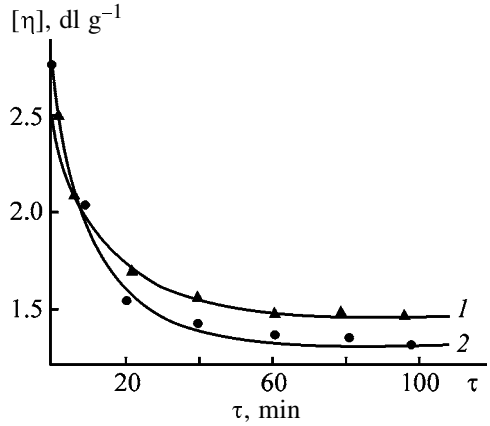

Fig. 2. Intrinsic viscosity of CH solutions [η] obtained from the film samples in the salt form prepared from (*1*) 1 and (*2*) 10% acetic acid as a function of the time of contact with the enzyme τ.

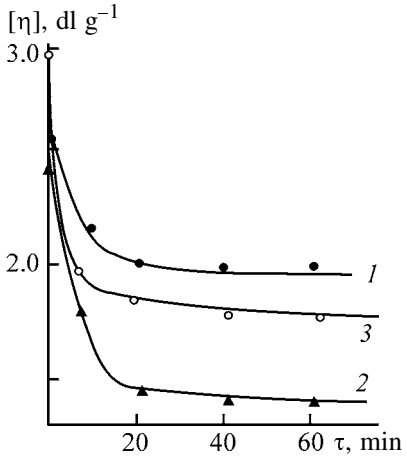

Fig. 4. Intrinsic viscosity of CH solutions [η] obtained from the film samples prepared from 1% acetic acid solution in the (*1*) salt and (*2*) alkaline forms and (*3*) heated at 120°C for 1 h, as a function of the time of contact with the enzyme solution τ.

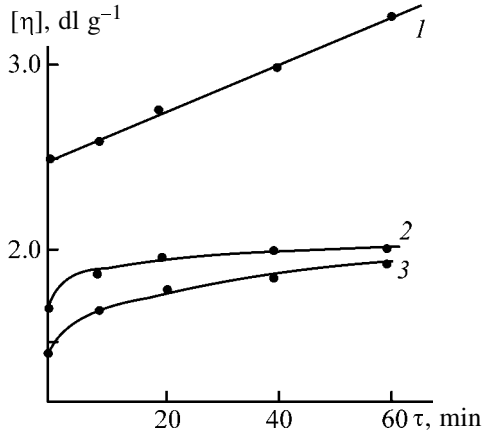

Fig. 5. Intrinsic viscosity of CH film samples [η] prepared from 5% acetic acid solution as a function of the time of thermal treatment τ. (*1*) Films not subjected to contact with the enzyme; contact time, min: (*2*) 10 and (*3*) 30.

age. At the same time, mechanical properties of these films are very poor; they are brittle and inelastic. Moreover, the water-absorption capacity of these films is low, which suggests their small absorption capacity with respect to the separated liquid and makes these films unsuitable.

It should be noted that thermal modification allows preparation of films that are poorly soluble in water but retain high degree of swelling. It is known [5] that heating to the CH films for 3 h at ~120°C causes strong rearrangement of its chemical structure, but does not even affect its swellability (Fig. 3, curve *3*). Since the resistance to degradation of the films insoluble in water cannot be analyzed, we studied the samples subjected to thermal treatment for 1 h, after which the films remain water-soluble. Nevertheless, as seen from Fig. 5, the intrinsic viscosity of the initial CH films noticeably increases with increasing time of thermal treatment (Fig. 5, curve *1*). This increase in the intrinsic viscosity is obviously due to the cross-linking of CH on heating. Moreover, with increasing time of thermal treatment, the stability of the modified films to enzymatic degradation also increases. In fact, degradation of such modified films proceeds down to viscosities close to that of the alkaline films (Fig. 4, curve *3*), but, in contrast to them, modified films are characterized by high mechanical properties.

Thus, both chemical modification of chitosan films by treatment of the formed film with alkaline solution and its thermal treatment allow preparation of polymer coatings with enhanced resistance to enzymatic degradation.

CONCLUSIONS

(1) Modified films of chitosan in the alkaline form exhibit poor solubility and small water-absorption capacity as compared to unmodified samples. These films are highly stable to enzymatic degradation, which is essentially independent on the features of the film preparation.

(2) The chitosan films modified by thermal treatment are virtually insoluble in water and are characterized by high levels of water-absorption capacity, mechanical strength, and elasticity. With increasing time of thermal treatment, the stability of the chitosan films to enzymatic degradation increases.

BRIEF COMMUNICATIONS

Thermodynamics of Reactions Involving Zinc and Cadmium Ions in Alkaline Solutions

A. I. Demidov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received February 28, 2007

Abstract—The standard Gibbs energies of assumed reactions in aqueous solutions involving zinc and cadmium ions were calculated.

DOI: 10.1134/S1070427207070336

Zinc(II) ions $Zn(H_2O)_4^{2+}$ and cadmium(II) ions $Cd(H_2O)_4^{2+}$ can be hydrolyzed [1] to form the ions $ZnOH^+$, $[Zn(OH)_3]^-$, $[Zn(OH)_4]^{2-}$, $CdOH^+$, $[Cd(OH)_3]^-$, and $[Cd(OH)_4]^{2-}$. Zinc(II) and cadmium(II) hydroxides are formed as a gelatinous white precipitate when solutions of zinc and cadmium salts are treated with solutions of alkalis [2]. In the crystalline state $Zn(OH)_2$ exists in the form of five (α, β, γ, δ, and ε) modifications, of which only ε-$Zn(OH)_2$ is stable in water at room temperature.

Equilibria (1)–(4) are shifted toward the formation of Zn^{2+}, $[Zn(OH)_4]^{2-}$, Cd^{2+}, and $[Cd(OH)_4]^{2-}$ ions and zinc and cadmium hydroxides, as shown by our thermodynamic calculations of these reactions carried out using the data of [3, 4]:

$$2ZnOH^+ = Zn^{2+} + \varepsilon\text{-}Zn(OH)_{2(s)},\ \Delta G^0_{298} = -36.5\ \text{kJ};\quad (1)$$

$$2[Zn(OH)_3]^- = \varepsilon\text{-}Zn(OH)_{2(s)} + [Zn(OH)_4]^{2-},\quad \Delta G^0_{298} = -21.3\ \text{kJ};\quad (2)$$

$$2CdOH^+ = Cd^{2+} + Cd(OH)_{2(s)},\ \Delta G^0_{298} = -38.1\ \text{kJ};\quad (3)$$

$$2[Cd(OH)_3]^- = Cd(OH)_{2(s)} + [Cd(OH)_4]^{2-},\quad \Delta G^0_{298} = -25.7\ \text{kJ}.\quad (4)$$

Thus, Zn^{2+}, Cd^{2+}, $[Zn(OH)_4]^{2-}$, and $[Cd(OH)_4]^{2-}$ ions are the most stable forms of zinc and cadmium in aqueous solutions. Zinc(II) and cadmium(II) ions can be hydrolyzed according to schemes (5) and (6):

$$Zn^{2+} + 2H_2O = \varepsilon\text{-}Zn(OH)_{2(s)} + 2H^+,\ \Delta G^0_{298} = 65.7\ \text{kJ}.\quad (5)$$

At unit activities of ε-$Zn(OH)_{2(s)}$, Zn^{2+}, and water, pH is 5.75.

$$Cd^{2+} + 2H_2O = Cd(OH)_{2(s)} + 2H^+,\ \Delta G^0_{298} = 78.3\ \text{kJ}.\quad (6)$$

At unit activities of $Cd(OH)_{2(s)}$, Cd^{2+}, and water, pH is 6.86. In turn, the hydrolysis of zinc and cadmium hydroxides is accompanied by the formation of minor amounts of $[Zn(OH)_4]^{2-}$ and $[Cd(OH)_4]^{2-}$ ions:

$$\varepsilon\text{-}Zn(OH)_{2(s)} + 2H_2O = [Zn(OH)_4]^{2-} + 2H^+,\quad \Delta G^0_{298} = 169.5\ \text{kJ}.\quad (7)$$

At unit activities of $[Zn(OH)_4]^{2-}$, ε-$Zn(OH)_{2(s)}$, and water, pH is 14.8.

$$Cd(OH)_{2(s)} + 2H_2O = [Cd(OH)_4]^{2-} + 2H^+,\quad \Delta G^0_{298} = 191.3\ \text{kJ}.\quad (8)$$

At unit activities of $[Cd(OH)_4]^{2-}$, $Cd(OH)_{2(s)}$, and water, pH is 16.8.

As noted above, the treatment of solutions of zinc(II) and cadmium(II) salts with solutions of alkalis results in the formation of zinc and cadmium hydroxides:

$$Zn^{2+} + 2OH^- = \varepsilon\text{-}Zn(OH)_{2(s)},\ \Delta G^0_{298} = -94.1\ \text{kJ}.\quad (9)$$

$$Cd^{2+} + 2OH^- = Cd(OH)_{2(s)},\ \Delta G^0_{298} = -81.5\ \text{kJ}.\quad (10)$$

The reactions of zinc and cadmium hydroxides with hydroxide ions are accompanied by the formation of minor amounts of tetrahydroxozincate and tetrahydroxocadmate ions:

$$\varepsilon\text{-}Zn(OH)_{2(s)} + 2OH^- = [Zn(OH)_4]^{2-},\ \Delta G^0_{298} = 9.7\ \text{kJ}.\quad (11)$$

$$Cd(OH)_{2(s)} + 2OH^- = [Cd(OH)_4]^{2-},\ \Delta G^0_{298} = 31.5\ \text{kJ}.\quad (12)$$

The comparison of the equilibrium constants of reactions (5)–(12) suggests that reactions (9)–(12) bring the main contribution to the precipitation of zinc and cadmium hydroxides. When a zinc electrode is

ionized in an alkaline solution, tetrahydroxozincate ions are formed [5]:

$$Zn + 4OH^- = [Zn(OH)_4]^{2-} + 2e,\ E^0 = -1.200\ V. \quad (13)$$

These ions can dissociate by reaction (14):

$$[Zn(OH)_4]^{2-} = \varepsilon\text{-}Zn(OH)_{2(s)} + 2OH^-,\ \Delta G^0_{298} = -9.7\ kJ. \quad (14)$$

The standard potential of reaction (13) calculated in this study agrees well with the analogous value $E^0 = -1.196 \pm 0.01$ V found on the basis of experimental data of various authors [6]. The solubility of potassium zincate $K_2[Zn(OH)_4]$ in potassium hydroxide solutions (6–10 M) is 1–2 M [7]. When the solution is saturated with potassium zincate, the equilibrium of reaction (14) is shifted to the right, and its product, zinc hydroxide, covers an electrode surface, which results in a sharp increase in the polarization owing to difficult access of hydroxide ions to the electrode surface. The standard potential of reaction (15) calculated in this study agrees well with the reference data [8]:

$$Zn + 2OH^- = \varepsilon\text{-}Zn(OH)_2 + 2e,\ E^0 = -1.250\ V. \quad (15)$$

Zinc oxide ZnO is the most stable form and the final product of all transformations at alkali concentrations in solution higher than 8 M [7]. The results of thermodynamic calculations of reactions (16) and (17) support this experimental fact:

$$[Zn(OH)_4]^{2-} = ZnO + H_2O + 2OH^-,\ \Delta G^0_{298} = -11.7\ kJ; \quad (16)$$

$$\varepsilon\text{-}Zn(OH)_2 = ZnO + H_2O,\ \Delta G^0_{298} = -2.0\ kJ. \quad (17)$$

The theoretical value of the emf of nickel–zinc battery, calculated on the basis of standard potentials of the reactions occurring on positive [9] and negative electrodes, is 1.741 V. This value agrees well with the theoretical emf value of 1.74 V given in Bagotskii and Skundin's monograph [7].

The solubility of $Cd(OH)_2$ in alkaline solutions is insignificant and increases from 9×10^{-6} to 1.5×10^{-4} M on increasing potassium hydroxide concentration in solution from 1 to 10 M [10]. Hence, on the ionization of a cadmium electrode, the alkaline solution becomes practically immediately saturated with cadmium hydroxide. Therefore, the electrode reaction should be written as

$$Cd + 2OH^- = Cd(OH)_{2(s)} + 2e,\ E^0 = -0.825\ V. \quad (18)$$

The resulting standard potential of the cadmium electrode in alkaline solution considerably differs from that given in the handbook [8], $E^0 = -0.809$ V. This is apparently due to the fact that usually the standard Gibbs energy of the formation of amorphous (active) cadmium hydroxide is used in the calculation:

$$Cd + 2OH^- = Cd(OH)_{2(amorph)} + 2e,\ E^0 = -0.807\ V. \quad (19)$$

The theoretical values of the emf of a nickel–cadmium battery, calculated on the basis of standard potentials of the reactions occurring on positive and negative electrodes [reactions (18) and (19)], are 1.316 and 1.298 V, respectively. The theoretical emf value of a nickel–cadmium battery given in Bagotskii and Skundin's monograph is 1.30 V [7].

CONCLUSIONS

(1) The most stable species of zinc and cadmium in aqueous solutions are Zn^{2+}, Cd^{2+}, $[Zn(OH)_4]^{2-}$, and $[Cd(OH)_4]^{2-}$ ions.

(2) The standard potentials of the reactions occurring on the discharge of zinc and cadmium electrodes in an alkaline solution were calculated.

Abstract—A new source of effective polymerization inhibitors for petrochemical industry was suggested: polyphenols recovered from wood and other vegetable raw materials.

DOI: 10.1134/S1070427207070348

Structural reorganization of the chemical industry of the Russian Federation after disintegration of the Soviet Union led to the loss of such an important line as production of inhibitors and/or inhibiting formulaitions for various petrochemical processes. The revival of the Russian industry of effective and relatively cheap polymerization inhibitors is based, as previously in the Soviet Union, on the primary use of by-products or wastes from chemical industry. The most widespread raw materials for the synthesis of this class of auxiliary reagents for petrochemistry are phenols [1] and phenol-containing fractions of coal and wood processing [2, 3]. The experience of using the sum of phenolic fractions from thermal processing of coal and wood as inhibitors of undesirable thermal polymerization in the distillation processing of pyrocondensates showed that the fractions obtained, known as FCh-16 and DSI, have serious drawbacks making their use in the modern petrochemical industry virtually impossible.

For by-product coke phenols [2], an engineering solution was found that opens prospects for the development of a new generation of effective inhibitors: directional cross-linking of phenols to obtain oligomers that are insoluble in water but soluble in organic solvents and exhibit, compared to the starting unmodified phenols, increased inhibiting activity and higher level of other process characteristics [4].

As for phenols prepared from wood, it was found experimentally that the drawbacks of DSI [3], especially the low inhibiting activity of pyrolytic wood phenols, are inherent and it is necessary to develop novel processes for recovery of phenolic compounds from vegetable tissues, not involving pyrogenic treatment of the raw material. Since vegetable phenols contain a significant fraction of polyhydric phenols [5], the development of a process for their selective recovery seems promising. For example, DFV agent (dihydroquercetin) was experimentally tested as inhibitor of industrial radical processes (undesirable thermal polymerization) [6]. This natural condensed phenolic compound, belonging to flavonoids, contains two dihydric phenolic fragments: pyrocatechol and resorcinol fragments. Dihydroquercetin showed a very high inhibiting effect in thermal processing of the pyrocondensate from EP-300 installation of the Angarsk Polymer Plant under the laboratory conditions (130°C, 1 h). The inhibiting effect reaches 67.3% even at the inhibitor content as low as 0.01 wt %. The highest inhibiting activity of DKV, 77.8%, is observed at its content of 0.03 wt %. These parameters of the inhibiting activity are close to those of the known imported individual synthetic inhibitors, e.g., *tert*-butylpyrocatechol [7].

Dihydroquercetin is widely used today in medical, pharmaceutical, and food industry as the most effective natural antioxidant, nontoxic preservative, and prophylactic agent for strengthening the cardiovascular system [8–10]. As the source of raw materials for this product in Russia is virtually inexhaustible (coniferous wood) and the process for its extractive recovery from wood tissues is relatively simple [11–13], we can speak of a new source of effective inhibitors for petrochemical processes. Experimental trials showed, however, that wide application of this product to petrochemical industry requires elimination of certain drawbacks of DKV as inhibitor of industrial polymerization processes. In particular, it should be modified

to make it insoluble in hot water. Phenolic compounds of vegetable origin are environmentally safe products considerably differing in the organoleptic and toxicological properties from technogenic phenolic fractions. In particular, they are odorless and tasteless and have low toxicity and low solubility in cold water.

CONCLUSION

Dihydroquercetin, a well-known vegetable polyphenol and effective antioxidant, exhibits high antiradical activity, which makes this class of compounds promising as polymerization inhibitors for industrial petrochemical processes.

Received March 16, 2007

Abstract—Polyphenylmethylsiloxane resin exhibiting a strong fungistatic effect was prepared by hydrolysis of phenyltrichlorosilane production bottoms with addition of phenyltrichlorosilane and methyltrichlorosilane.

DOI: 10.1134/S107042720707035X

Phenyltrichlorosilane is an intermediate in the production of lacquers based on phenylsiloxane resins and used, in particular, in electrotechnical industry [1–4]. The bottoms from the production of phenyltrichlorosilane, which is synthesized in Russia by high-temperature condensation of chlorobenzene with trichlorosilane, account for 1.5–3 wt % of the condensate [5, 6].

In this study we developed a procedure for utilization of the bottoms by their conversion to a heat-resistant phenylmethylsiloxane resin exhibiting fungistatic activity. The composition of the bottoms was determined by gas chromatography–mass spectrometry:

Composition of phenyltrichlorosilane production bottoms*

Component	Content, wt %
Phenyltrichlorosilane	24.0
Monochlorodiphenyl	26.3
Diphenyl	15.4
Dichlorodiphenyl	11.0
Trichlorosilyldiphenyls	17.6
Trichlorosilyldichlorodiphenyls	3.1
Chlorobenzene	2.6

* From Sibirskii Silikon Joint-Stock Company, Usol'e-Sibirskoe, Irkutsk oblast.

The procedure is based on the cohydrolysis of the bottoms with phenyltrichlorosilane and methyltrichlorosilane in aqueous butanol. The toluene solution of the resin (F-XIV) thus prepared is a transparent viscous dark brown liquid (KO-XIV organosilicon lacquer). In the physicochemical and technical parameters, the lacquer meets the requirements of GOST (State Standard) (Table 1) [7].

Lacquer coatings prepared from a solution of F-XIV resin exhibit high fungistatic activity. For F-XIV polyphenylsiloxane resin, it is 1 point against mold fungi in a humid chamber over water plane and 2 points in Petri dishes with Czapek medium (in the 6-point scale, Table 2). The tests were performed according to GOST 9.050–75; infection with an aqueous suspension of *Aspergillus flavus* + *Aspergillus niger* + *Cladosporium herbarum* + *Fusarium moniliforme* + *Paccilomyces varioti* + *Trichoderma viride* spores.

EXPERIMENTAL

A 2-l four-necked flask equipped with a stirrer, a reflux condenser, a dropping funnel, and a thermometer was charged with 320 ml of butanol, 320 ml of toluene, and 320 ml of water. The mixture was stirred for 30 min, after which a mixture of 30 ml of bottoms, 150 ml of phenyltrichlorosilane, and 7.5 ml of methyltrichlorosilane was slowly added over a period of 2 h, keeping the temperature at approximately 10°C (cooling with water). The mixture was stirred for an additional 2 h at 60–65°C and allowed to stand for 2 h at 20–22°C without stirring. The upper toluene layer was separated and washed three times with water to pH 6. The solvent was distilled off. The residue was heated for 30 min at 125–130°C. Yield of polyphenylmethylsiloxane resin 186.4 g.

Table 1. Main characteristics of KO-XIV organosilicon lacquer

Parameter	Standard (GOST 11066–74 with revisions 1, 2, 3, 4)	Analysis results
External appearance	Transparent dark brown liquid with minor mechanical inclusions	Transparent dark brown liquid
Weight fraction of nonvolatile substances, %	33–37	52
Viscosity (outflow time) at 20.0±0.5°C	12–16*	–
	10–13**	11.3
Acid number, mg KOH/g lacquer, no more than	10	1.3
Time of film drying to degree 3, no more than:		
in air, h	2	2
at 150±2°C, min	10	10

* VZ-1 viscometer (2.5-mm tip).
** VZ-4 viscometer (4-mm tip).

Table 2. Fungus resistance of F-XIV resin at 28°C*

Exposure conditions	Exposure time	Results
Resin in suspension of fungus association	48 h	3.2% germination (in control, 87.6%)
Resin applied onto brick in humid chamber (90% humidity)	14 days	No germination
Resin in Petri dishes with Czapek medium	14 days	All fungi (except *Trichoderma viride*) are fully suppressed; 68–80% inhibition of *Trichoderma viride* growth

* According to data of the Research Institute of Biology, Irkutsk State University.

CONCLUSIONS

(1) A procedure for utilization of phenyltrichlorosilane production bottoms was developed.

(2) Lacquers based on F-XIV polyphenylmethylsiloxane resin can be used for protecting various materials from the damage by mold fungi at a humidity of up to 100%.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

To Eightieth Anniversary of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry)

DOI: 10.1134/S1070427207070361

On December 28, 1867, in St. Petersburg was opened the First Congress of Russian Natural Scientists and Physicians. By the initiative of the chemical section of the Congress, the question about organization of the Russian Chemical Society was raised on January 3, 1868. The participants of the Congress supported this idea and an appropriate resolution was adopted at the final plenary meeting of the Congress on January 4, 1868 [1]. The statute of the society, worked out at the organizational meetings on February 15 and September 19, 1868, was submitted to approval by the Minister of public education. Thanks to the vigorous efforts of D.I. Mendeleev (1834–1907) and N.A. Menshutkin (1843–1907), the first meeting of the Russian Chemical Society at St. Petersburg Imperial University was held already on November 6, 1868. N.N. Zinin (1812–1880), professor of Medical-Surgical Academy in St. Petersburg, academician of St. Petersburg Academy of Sciences since 1865, outstanding scientist in the field of organic chemistry, and organizer of a prominent scientific school, was elected the first president of the society [1, 2]. Menshutkin was entrusted with edition of *Zhurnal Russkogo Khimicheskogo Obshchestva* (Journal of the Russian Chemical Society).

In 1876, the Russian Chemical Society merged, at Mendeleev's suggestion, with the Russian Physical Society founded in 1872 and the Russian Physicochemical Society (RFKhO) was formed with two departments and a common journal having physical and chemical parts. In 1906, the RFKhO journal was divided into two independent journals of the physical and chemical departments.

The RFKhO journal (chemical department) was long the only chemical journal in Russia, with both theoretical and applied articles published. World War I (1914–1918) strongly affected the development of scientific studies in Russia. Despite the noticeable advances in chemical science and development of scientific schools, the level of the chemical industry in the country was insufficient. Russia had vast mineral resources, but their mining and processing were not organized. In 1904–1914, a rather rapid rise in the industrial production was observed in Russia, but, on the whole, it remained insufficient and Russia was not prepared to long war in many respects [3, 4]. It was understood already in the first months of war that the dramatically increased demand for powders and explosives cannot be satisfied because of the deficiency of nitric and sulfuric acids, as well as of benzene and toluene, lack of chemical warfare, deficiency of medicinals, and shortage of fuels and lubricants. Urgent and drastic measures were necessary.

On the initiative of Academician V.I. Vernadsky (1863–1945), an outstanding scientist and public figure, supported by a number of other scientists at St. Petersburg Academy of Scientists, the Permanent commission for study of natural productive forces of Russia (KEPS) was organized in February 1915. Vernadsky was elected its chairman, and A.E. Fersman (1883–1945, academician since 1919) became the secretary of the Commission. The main tasks of the Commission were to study natural resources and enable their industrial use. The Military-chemical committee was formed in October 1915 in Petrograd at the Russian Physicochemical Society in order to "unite the efforts of Russian chemists for joint systematic work on problems related to the needs of the State defense" [4, 5]. Particular mention should be made of the activities of the Chemical committee at Chief artillery department. Academician V.N. Ipat'ev (1867–1952), one of the most outstanding chemists of the first half of the XX century, was appointed head of this Committee in April 1915. Ipat'ev became world known because of his fundamental works in catalysis and catalytic organic synthesis [6–9]. He was the first who started use of high pressures and temperatures in heterogeneous catalytic processes, introduced a large number of previously unused catalysts into laboratory and technological practice, and demonstrated for the first time that use of mixed catalysts dramatically improves the potentialities of heterogeneous catalysis and enables purposeful modification of the properties of solid catalysts. During the years of World War I, professor of the Artillery Academy in St. Petersburg and lieutenant-general

Vyacheslav Evgen'evich Tishchenko.

Ipat'ev supervised the reforming and development of military-chemical industry in Russia. Data demonstrating the fast rise in the manufacture of explosives, war gases, and other most important chemical products already by the end of 1916 can be found in [7, 10]. The vigorous scientific and organizational activities of Ipat'ev also continued in the post-war period. V.I. Lenin named Ipat'ev "head of our chemical industry" [8]. In 1917–1926, Ipat'ev controlled the organization of chemical research, functioning of chemical industries, and development of new technologies.

The development of chemical research in Russia in the early XX century (1901–1917) and in the later period (1918–1941) was the subject of D.N. Trifonov's essays [11–14].

In 1918–1920, a number of scientific institutions, which later became the basis for most prominent research institutes, were created in Petrograd and Moscow on the initiative of KEPS despite the difficulties caused by the civil war. In particular, the Russian Institute of Applied Chemistry [later, State Institute of Applied Chemistry (GIPKh) and then Prikladnaya Khimiya Russian Scientific Center] was founded in 1919 in Petrograd for solution of most important problems in chemistry and chemical technology. The exploitation of natural resources of the country (Verkhnekamskoe deposit of potassium and magnesium salts, Tikhvin bauxites, Khibiny apatites, and phosphorite and mirabilite deposits), which was commenced soon after, and the need to solve other problems (synthesis of ammonia, industrial manufacture of synthetic rubber, production of plastics and artificial fibers, etc.), which required that the research in applied chemistry should be expanded, made coordination of these works in a specialized scientific journal an imperative necessity.

At the meeting of the chemical department of RFKhO on December 2, 1926, an appeal of a large group of scientists and staff members of industrial plants, concerning organization of the Department of Applied Chemistry in RFKhO, was considered. The appeal, in particular, said that the Department could unite active workers in the field of applied chemistry on the all-Union scale and would enable organization of a journal for publication of the relevant original research works. It was pointed out as an example that the American Chemical Society publishes, together with the main chemical journal (Journal of the American Chemical Society, published since 1879), also a journal devoted to problems of applied chemistry (Industrial and Engineering Chemistry, published since 1909). Among those who signed the appeal that the Department of Applied Chemistry should be organized in RFKhO were most prominent chemists of that time: M.S. Vrevskii, A.I. Gorbov, I.V. Grebenshchikov, S.N. Danilov, V.I. Ipat'ev, I.A. Kablukov, S.V. Lebedev, A.E. Porai-Koshits, V.E. Tishchenko, A.E. Favorskii, and others (a total of 95 signatures). Later, all those who signed the appeal became founder-members of the Department.

The general meeting of RFKhO on January 23, 1927, decided that organization of the Department of Applied Chemistry is rather desirable and timely. After the necessary authorizations, the decision to organize the Department of Applied Chemistry in RFKhO was made in April 1927. The organization meeting of the Department was held on May 12, 1927, eighty years ago. V.E. Tishchenko (1861–1941), one of the oldest members of RFKhO (since 1883), disciple of Mendeleev and A.M. Butlerov (1828–1886) was elected the Chairman of the Department [16, 17]. A scientist with broad interests, Tishchenko was equally successful in theoretical and applied chemistry. He was a prominent specialist in organic and technical chemistry and forest chemistry and paid a considerable attention to the history of chemistry. Tishchenko was among those who initiated the organization of the Institute of Applied Chemistry and worked for a long time (1919–1939) at this institute. He became a member of the Academy of Sciences of the USSR in 1935.

On November 17, 1927, at the first meeting of the Department of Applied Chemistry Tishchenko reported the agreement with state organizations about publication of *Zhurnal Prikladnoi Khimii* (ZhPKh), beginning in 1928. Most prominent scientists of that time: Ipat'ev, I.A. Kablukov (1857–1942), E.I. Orlov (1865–1944), V.E. Tishchenko, and A.E. Chichibabin (1871–1945), became members of the Editorial Board of the journal.

Academician Ipat'ev's achievements were already mentioned. Kablukov, professor of Moscow University and honorary member of the Academy of Sciences of the USSR since 1932, who became a member of the Editorial Board, was a known physical chemist with broad scientific interests, author of textbooks on inorganic and physical chemistry, and science popularizer. Electrochemistry of nonaqueous solutions was the preferred area of his scientific studies. E.I. Orlov (academician of the Academy of Sciences of the Ukrainian SSR since 1929) was a chemist-technologist with rather broad interests, engaged in the technology of manufacture of both organic (ethylene, formaldehyde) and inorganic materials (silicates, mineral pigments). In 1911–1927, he was a professor at Kharkov Technological Institute, and in 1932, he became professor at Moscow Institute of Chemical Engineering. The main object of interest of A.E. Chichibabin, one of the most prominent Russian organic chemists and academician of the Academy of Sciences of the USSR since 1928, was the chemistry of heterocyclic compounds, and primarily that of pyridine [18]. In 1909–1930, Chichibabin was a professor of Moscow Higher Technical College, he created a prominent scientific school and was the author of the known textbook *Osnovy organicheskoi khimii* (1925) (Fundamentals of Organic Chemistry), which ran into seven editions. Chichibabin made a major contribution to the creation of chemical-pharmaceutical industry in Russia. Professor A.I. Gorbov (1859–1939), an active propagandist of chemical science in our country, Butlerov's and Mendeleev's disciple, prominent scientist, and broadly educated man, was appointed executive secretary of ZhPKh. Main Gorbov's scientific studies were performed in military technology: analysis of properties of concretes and other materials used in construction of defense fortifications, development of methods for production, purification, and storage of hydrogen for aerostatic purposes, and participation in the development of gas masks. According to the recollections of contemporaries [19–21], Gorbov paid his undivided attention to his duties as editor of ZhPKh and to work with Journal's authors.

Aleksandr Ivanovich Gorbov.

In 1928, 60 printer's sheets were allocated for the Journal, and the first issue was published in February 1928 (1200 copies). The structure of the Journal provided publication of original papers, review articles, abstracts, chronicles, bibliography, personalia, and reference materials. On the whole, this structure has been preserved during all the 80 years of publication of *Zhurnal Prikladnoi Khimii*.

In the first issue of the first volume of ZhPKh were published materials concerning the history of RFKhO, organization of the Department of Applied Chemistry in the society, articles written by known scientists: "On Aging of Caoutchouc" by B.V. Byzov, "On Dyeing with Dyes Substantive for Cotton" by Porai-Koshits, and papers about new methods for analysis of platinum metals by O.E. Zvyagintsev and E.Kh. Fritsman. The chronicles section presented information about memorable days: centennial anniversaries of the birthdays of a French chemist M. Berthelot and Butlerov, and about the forthcoming V Mendeleev Congress on pure and applied chemistry and other scientific conferences. The bibliography section presented a brief list of chemical books published in 1927.

Beginning in the first years of publication of the Journal, the subjects of the articles it contained were rather diverse. Together with technological papers (basic chemical technology, technology of silicates and organic substances), it published results of topical

Sitting (from right to left): Editor-in-chief N.I. Nikitin; executive secretary L.K. Simonova; members of the editorial board: P.P. Budnikov, N.P. Fedot'ev, V.V. Pigulevskii, and D.V. Tishchenko; L.D. Anisimova, head of the editorial staff. Standing (from right to left): members of the editorial board: M.E. Pozin, Yu.A. Gorin, M.M. Koton, P.G. Romankov, N.A. Toropov, and V.V. Skorcheletti (mid-1960s.)

studies in analytical chemistry, applied electrochemistry, and physicochemical analysis of salt, metallic, and other systems. In the first decade of existence of the Journal, its authors included Ipat'ev, Kurnakov, Vrevskii, S.Z. Roginskii, P.F. Antipin, and other prominent scientists and their coworkers. A considerable attention was given to the Mendeleev Congress held in 1934 (and devoted to the centennial anniversary of Mendeleev's birthday). Detailed information about all meetings of the Congress was published [22].

Already in the first decade of publication of the Journal, its editorial board was substantially expanded. In different years, it included the following academicians: N.S. Kurnakov (1860–1941), N.D. Zelinskii (1861–1953), D.N. Pryanishnikov (1865–1948), A.A. Baikov (1870–1946), S.V. Lebedev (1874–1934), E.V. Britske (1877–1953), A.E. Porai-Koshits (1877–1949), I.V. Grebenshchikov (1887–1953), and a number of younger scientists.

Till 1931, ZhPKh was published by the Russian Physicochemical Society, and after 1931, by the State Technical-Theoretical Publishing House (Moscow, Leningrad). Since 1938, the Journal has been under authority of the Academy of Sciences of the USSR (later, Russian Academy of Sciences). At present, the publication of the Journal is supervised by the Department of Chemistry and Materials Science of the Russian Academy of Sciences).

Gorbov headed ZhPKh during 10 years and did much for its becoming a well-known journal. During this time, the number of journal issues increased to 12 in a year (the journal has been published monthly since 1936). Later, this periodicity was preserved, and only during the war years (1941, 1942, and 1945) there were several violations of this rule [23]. In 1939, Professor O.E. Zvyagintsev (1894–1967) became executive editor. Beginning in the first years of publication of the Journal, he was personal secretary of the executive editor, and became a member of the editorial board of the Journal in 1931. Many years, his scientific activities were associated with chemistry of noble metals and with the creation and development of the national industry of platinum metals [4, 24]. Zvyagintsev was the author of a number of monographs on refining of gold, silver, and platinum metals and paid much interest to the history of chemistry and scientific activities of Russian scientists. A known chemist, he remained an active member of the Editorial Board of ZhPKh till 1967. Zvyagintsev was also an organizer of *Zhurnal Neorganicheskoi Khimii* (Russian Journal of Inorganic Chemistry), deputy editor-in-chief of this journal, and member of the Editorial-Publishing Council of the Academy of Sciences of the USSR.

In 1942, Academician Porai-Koshits, a known scientist in the field of organic chemistry, organizer of a prominent scientific school of chemical technology of dyeing and fibrous substances [24], was appointed editor-in-chief of ZhPKh. Beginning in 1905 and till the end of his life, the pedagogical and scientific activities of Porai-Koshits were associated with the Technological Institute in St. Petersburg.

In 1949, N.I. Nikitin (1890–1975, corresponding member of the Academy of Sciences of the USSR since 1939), an organic chemist and prominent specialist in wood chemistry, was appointed editor-in-chief of ZhPKh. In 1925, he created at the Forestry Academy in Leningrad the first chair of wood and cellulose chemistry and headed this chair during many years. Nikitin is the author of quite a number of monographs devoted to wood chemistry. Beginning in 1959, he supervised, together with working at the Forestry Academy, research in the field of wood chemistry at the Institute of Macromolecular Compounds, Academy of Sciences of the USSR. Nikitin was editor-in-chief of ZhPKh during 25 years. In the interesting book of recollections written by him, he mentioned with high respect the prominent specialists who were members of the Editorial Board of the Journal in those years; L.K. Simonova, executive secretary of the Editorial Board; and L.D. Anisimova, head of the Editorial Office.

In 1976–1988, the Editorial Board of the Journal was headed by P.G. Romankov (1904–1990, corresponding member of the Academy of Sciences of the USSR since 1964), a prominent specialist in the field of processes and apparatus of chemical technology. He worked at the chair of processes and apparatus at the Leningrad Technological institute beginning in 1934 and headed the chair in 1943. In 1950–1980, he was pro-rector for scientific work at the Technological institute.

In 1989, Academician V.S. Shpak, a known scientist in the field of organic and technical chemistry, prominent science organizer, and member of the editorial board of the journal since 1976, was appointed Editor-in-Chief of ZhPKh. Beginning in 1931, he was engaged in pedagogical and research activities at the Leningrad Technological Institute; in 1953–1977, he was director of GIPKh. He became Chief chemist for heavy organic synthesis at the Ministry of Chemical Industries in 1977, and advisor of the director general of Prikladnaya Khimiya Russian scientific center in 1993. In 2006, the duties of the Editor-in-Chief of ZhPKh were entrusted to Academician G.F. Tereshchenko (Russian Academy of Sciences).

Aleksandr Evgen'evich Porai-Koshits.

Petr Grigor'evich Romankov.

In the post-war years, the editorial board of ZhPKh included academicians: S.I. Vol'fkovich (1896–1980), N.V. Ageev (1903–1983), I.V. Tananaev (1904–1993), and M.M. Shul'ts (1919–2006); and corresponding members of the Academy of Sciences of the USSR: P.P. Budnikov (1885–1968), N.A. Toropov (1908–1968), M.M. Koton (1908–2005), and V.B. Aleskovskii (1912–2006). During many years, professors V.V. Pigulevskii, M.E. Pozin, V.A. Proskuryakov, A.L. Rotinyan, V.V. Skorcheletti, M.M. Sychev, D.V. Tishchenko, and N.P. Fedot'ev took active part in the work of the Editorial Board of the Journal and in refereeing of the submitted articles.

At present, ZhPKh is the only Russia's wide-scope journal devoted to applied chemistry. In the breadth of the issues covered, the Journal has no analogs among world's periodic editions. In the last fifteen years, the following classification of the articles published, which clearly reflects the scope of the Journal, has been was introduced:

Inorganic Synthesis and Industrial Inorganic Chemistry;
Physicochemical Studies of Systems and Processes;
Sorption and Ion-Exchange Processes;
Applied Electrochemistry and Corrosion Protection of Metals;
Catalysis;
Environmental Problems of Chemistry and Technology;
Processes and Equipment of Chemical Industry;
Nanomaterials and Nanotechnologies;
Organic Synthesis and Industrial Organic Chemistry;
Macromolecular Compounds and Polymeric Materials;
Chemistry of Fossil Fuels;
Brief Communications;
History of Chemistry and Chemical Technology;
Book Reviews;
Information.

At present, ZhPKh annually publishes 440–450 articles (abstracts of papers submitted by the editorial board for deposition at VINITI, Russian Academy of Sciences, not included). Scientometric analysis of the publications of the last five years (2002–2006) demonstrates that the rubric devoted to macromolecular compounds contains 25–27% of the total number of the papers. The rubrics devoted to inorganic technology, sorption and ion-exchange processes, and applied electrochemistry show about the same in the number of the articles published: each covers 9 to 13% of the total number of papers.

After the geopolitical changes of 1991, 76 to 82% of papers come in the following years from scientific institutions of Russia. The shares of Ukraine and Belarus are 8–12 and 4–8%, respectively.

A considerable attention is paid by ZhPKh to publication of review articles that systematize, analyze, and generalize studies in a topical area of chemical technology and its theoretical foundations. In the last ten years (1997–2006), 47 reviews have been published, of which the following can be mentioned: "Integrated Processing of Deposits of the Kola Peninsula" [27], "Niobium in Molten Salts: State in Melts and Electrochemical Behavior" [28], "Physicochemical and Technological Studies of Desulfation of Lead-Containing Materials" [29], "High-Temperature Protonic Solid Electrolytes: Possible Applications" [30], "Lithium-Conducting Polymeric Electrolytes for Chemical Power Cells" [31], "Fullerene-Containing Chalcogenide Glass-Forming Materials" [32], "Electron–Proton Effect in Chemistry of Catalysis" [33], "New Methods for Control over Chain Growth in Polymerization of Vinyl Chloride" [34], "Hydrogen Bonds in Cellulose and Their Influence on Its Solubility in Aqueous and Nonaqueous Media" [35], "Applied Importance of Polyimides" [36], and "Laser Initiation of High-Energy-Capacity Compounds in Science and Technology" [37]. The topics covered by the reviews point to the wide diversity of problems discussed in ZhPKh.

According to the tradition established from the beginning of publication of the Journal, it continues to pay attention to various jubilee dates. In particular, the following articles have been published in the last decade: those devoted to the role played by the Academy of Sciences in the development of research in the field of chemistry and chemical technology in Russia (in connection with the 275th foundation anniversary of the Academy) [38], involvement of chemists of St. Petersburg in the development of science and industry in Russia (in connection with the 300th anniversary of St. Petersburg) [39], 80th anniversary of the State Institute of Applied Chemistry [40], 70th anniversary of the Apatit Combine [41], and 100th anniversary of the first Nobel Prize in chemistry [42]. Quite a number of papers have been devoted to Russian and foreign chemists in connection with various memorial dates.

During many years, *Zhurnal Prikladnoi Khimii* has been completely translated into English and published under the title Russian Journal of Applied Chemistry (Translation of *Zhurnal Prikladnoi Khimii*). Since 1993, the Journal has been simultaneously published in Russian and English in accordance with the License agreement between the Russian Academy of Sciences and Pleiades publishing house (the United States). The English version of the Journal is prepared in St. Petersburg.

The author is grateful to Academician Vladimir Stepanovich Shpak (Russian Academy of Sciences) for his permanent interest in studies in the field of history of chemistry and chemical technology.

BOOK REVIEWS

Andrievskii, R.A. and Ragulya, A.V., *Nanostrukturnye materialy: Uchebnoe posobie dlya studentov vysshikh uchebnykh zavedenii* (Nanostructured Materials: Textbook for Higher School Students)

Moscow: Akademiya, 2005, 192 pp.

DOI: 10.1134/S1070427207070373

An important component of nanotechnology as an interdisciplinary research area formed in the world science in recent 15–20 years is the development of nanostructured materials (nanomaterials). Thanks to a unique set of properties, these materials occupy the leading position in modern materials science. The information flow constituted by the educational and monographic literature, reviews, and original papers concerned with nanotechnologies and nanomaterials has substantially increased, quite a number of specialized international scientific journals have appeared, and numerous conferences and symposia are being held.

The textbook offered to the readers' attention was written on the basis of the courses of lectures delivered by the authors in quite a number of domestic and foreign higher school institutions. The book comprises a foreword, five chapters, and supplements. Brief Chapter 1 (pp. 5–11) presents general evidence concerning the history of appearance of the nanotechnology, lists its priority areas, and explains certain terms.

Chapter 2 (pp. 12–44) presents a general structural characterization of nanomaterials. Particular attention is given by the authors to the structure of polymeric, biological, and carbon nanomaterials. Chapter 3 (pp. 45–113) discusses specific physical, mechanical, and chemical nanomaterials and gives notion of dimensional effects. Elucidation of the nature of dimensional effect is one of the most important problems of the materials science of nanostructured objects. Chapter 4 (pp. 114–149) describes the fundamentals of technologies for synthesis of nanomaterials of various kinds: consolidated nanomaterials, nanosemiconductors (nanoparticles, heterostructures, porous silicon), and polymeric, porous, tubular, and biological nanomaterials. Chapter 5 (pp. 150–179) considers various application fields of nanomaterials.

Each of the chapters is provided with control questions and rather extended lists of basic and supplementary literature. These lists are important by themselves because they contain detailed bibliographic descriptions of monographs, reviews, and original papers of domestic and foreign authors, which, as a rule, have been published in the last five to ten years.

The supplement presents information about the most important instruments used to study nanomaterials: scanning tunnelling microscope, atomic-force microscope, high-resolution transmission and scanning electron microscopes, and nanoindenters.

The book is recommended as a textbook for students specialized in physical materials science, it may be of use for students of other allied specialties.

Received April 19, 2005

Abstract—Analysis of mass and heat balance in the reaction node of the process of ethylene dimerization into but-1-ene under the industrial conditions is performed. It is found that ethylene concentration in the reactor liquid phase by a complex way depends on the reactor temperature, pressure and but-1-ene concentration in the liquid phase. Optimal process temperature is 80–90°C, operating pressure in the reactor is 0.6–0.8 MPa. Increase in pressure above 1 MPa practically excludes heat withdraw via but-1-ene evaporation and makes the system of heat withdrawing ineffective.
DOI: 10.1134/S1070427207070385

But-1-ene is the most widespread, after ethylene and propylene, monomer of olefin series and it is more and more used in the plastics industry for the synthesis of linear medium and low density polyethylene, isotactic polybutene, polybutylene oils and copolymers with propylene. For the solving a problem of obtaining but-1-ene of polymerization purity grade, a new technology of high-selective catalytic dimerization of ethylene into but-1-ene has been developed.

Now in the world industrial practice two variants of technology for manufacturing but-1-ene of polymerization purity are in application:

—The variant "Alfa-okhtol" [1–3] developed in the Institute of Probems of Chemical Physics, Russian Academy of Sciences in cooperation with industrial branch institutions and applied in the beginning of 80th of 20th century in the biggest plants in Kazan and Budenovsk for manufacturing polyethylene; its principal scheme is shown in Fig. 1.

—The variant "Alfa-butol" of the French Oil Institute, applied in 80th of 20th century [4], based on the investigations of the Institute of Probems of Chemical Physics, Russian Academy of Science.

In both these variants the process of ethylene dimerization is perrgformed in liqid phase with the homogenous catalytic system tetrabutoxytitan–tralkylaluminum–modificator. As a solvent basically is applied a mixture of isohexenes (hereinafter in the text hexenes) formed as by-products in the process of ethylene dimerization, or a mixture of but-1-ene and hexenes. In the process of dimerization a mixture of but-1-ene and hexenes of the following composition is formed: hex-1-ene 10 wt %, 2-ethylbut-1-ene 60 wt %, 3-methylpent-1-ene 30 wt %. Besides hexenes, as a side product in a small amount are formed octenes and a polymer, which in the further consideration are not accounted for.

Mathematic model of the reaction of ethylene dimerization into but-1-ene on the $Ti(OR)_4$–AlR'_3 catalytic system has been considered in [5].

The technology of dimerization in the "Alfa-okhtol" variant (Fig. 1) assumes *heat withdrawing* by circulation of evaporating liquid phase from the reactor I as a vapor-gas mixture (g_3 flow) through condenser II with further returning of the gas phase (g_6 flow) and a part of liquid phase (g_9 flow) from the condenser II into reactor I. The material flows by this scheme are shown in Fig. 2.

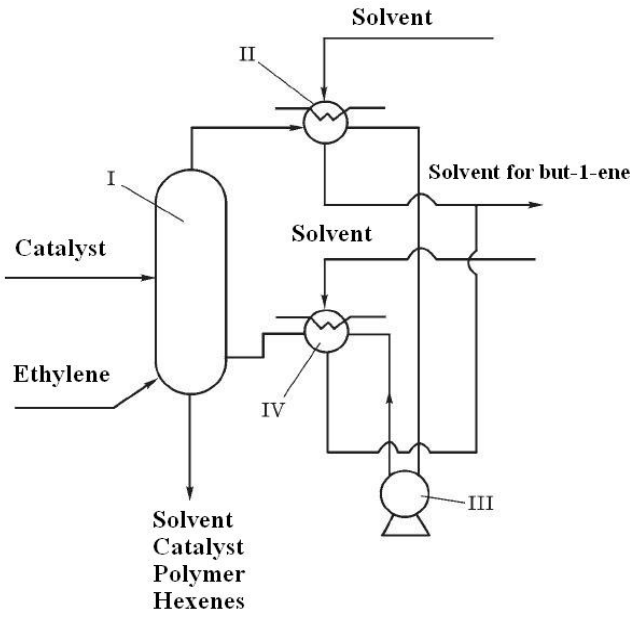

Fig. 1. Principal technological scheme of reaction node for ethlene to but-1-ene dimerizationaccording in "Alfa-okhtol" process. (I) reactor, (II, IV) condensers, (III) circulation compressor.

Such a technology is used in the processes of polymerization of low molecular weight olefins [6] and in suspension ethylene and propylene copolymerization [7].

When liquid phase presents in the reactor and condenser, all abovementioned hydrocarbons are in equilibrium. The ethylene, but-1-ene and hexenes concentrations in gas and liquid phases depend on several factors:

The process temperature,
Pressure in the reactor I,
The process selectivity,
Values of the flows g_2, g_5 and g_6, (Fig. 2),
Ratio of the flows g_3/g_4 and g_9/g_7.

Taking into account a large number of variables defining composition of liquid and gas phases, it was attempted to develop algorithms of mass and heat balances proceeding from the suggestion that gas and liquid phase are in equilibrium and the relations below are fulfilled.

For the reactor I:

$$Y^p_{c2} + Y^p_{c4} + Y^p_{c6} = 1, \quad (1)$$

$$X^p_{c2} + X^p_{c4} + X^p_{c6} = 1, \quad (2)$$

$$K^p_i = Y^p_i / X^p_i . \quad (3)$$

$$g_4 = g_3 (I - E^p) / E^p, \quad (4)$$

where g_3, g_4 denote amount of gas and liquid, respectively, leaving reactor I, kgmol/h; Y^p_{c2}, Y^p_{c4}, Y^p_{c6}, X^p_{c2}, X^p_{c4}, X^p_{c6} are molar fractions of ethylene, but-1-ene and hexenes in gas (Y) and liquid (X) phases of the reactor, K^p_i are the constants of phase equilibrium for ethylene, but-1-ene and hexenes at the temperature and pressure that occurred in the reactor (elucidated by

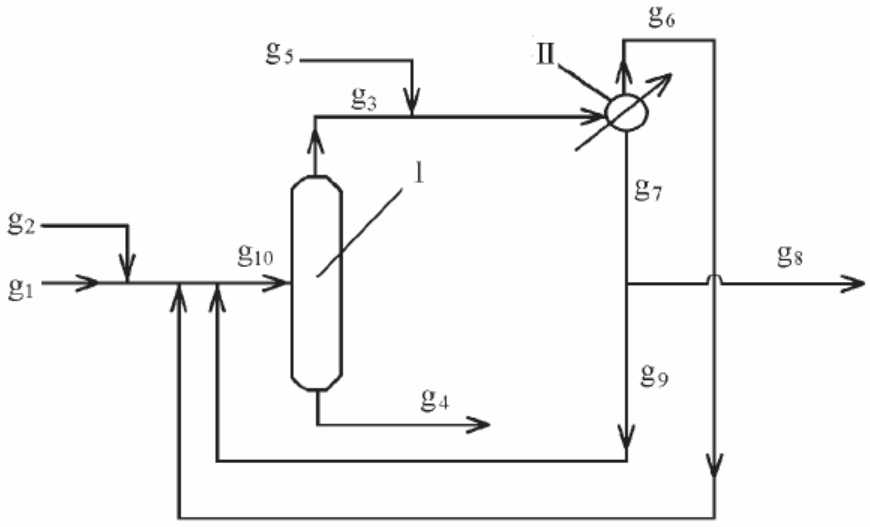

Fig. 2. Scheme of material flows in the reaction node for ethylene to but-1-ene dimerization by "Alfa-okhtol" process. (I) reactor, (II) condenser. Flows: (g_1) ethylene, (g_2, g_5) hexenes, (g_3) vapor-gas mixture from the reactor to condenser, (g_4) liquid phase from the reactor bottom, (g_6) gas phase from condenser to the reactor, (g_7) liquid phase from condenser, (g_8) liquid phase from condenser to rectification, (g_9) liquid phase from condenser to reactor, (g_{10}) the sum of flows g_1, g_2, g_6, and g_7.

calculation or from published data); E^p is mole fraction of distillate of the g_{10} flow feeding into the reactor

$$g_{10} = g_3 / E^p. \quad (5)$$

For the determination of olefins (ethylene, but-1-ene and hexenes) concentrations in the reactor liquid or gas phase it should be defined concentration of one of them and operating conditions in the reactor, e.g.:

$X^p_{c4} = 0.1; 0.25; 0.5; 0.75$

Temperature 50, 60, 70, 80, 90°C

Pressure 0.6, 0.8, 1.0 MPa

For condenser II:

$$Y^x_{c2} + Y^x_{c4} + Y^x_{c6} = 1, \quad (6)$$
$$X^x_{c2} + X^x_{c4} + X^x_{c6} = 1, \quad (7)$$
$$K^x_i = Y^x_i / X^x_i, \quad (8)$$
$$g_7 = g_6 (I - E^x) / E^x, \quad (9)$$

where g_6, g_7 denote amount of gas and liquid, respectively, leaving condenser II, kgmol/h; Y^x_{c2}, Y^x_{c4}, Y^x_{c6}, X^x_{c2}, X^x_{c4}, X^x_{c6} are molar fractions of ethylene, but-1-ene and hexenes in gas (Y) and liquid (X) phases of the condenser, K^x_i are the constants of phase equilibrium for ethylene, but-1-ene and hexenes at the given temperature and pressure 0.6, 0.8, 1.0 MPa; E^x is mole fraction of distillate of the g_{11} flow (under the conditions occurred in the condenser), hence

$$g_{11} = g_6 / E^x, \quad (10)$$
$$g_{11} = g_3 + g_5, \quad (11)$$
$$g_5 = g_3 \cdot A. \quad (12)$$

The A value can vary in the range 0–1.0, optimally 0–0.1.

The liquid phase from the condenser (g_7 flow) is devided into two flows:

1. The flow g_8 is directed to rectification.

2. The flow g_9 is returned to the reactor for heat withdrawing

$$g_9 = B \cdot g_7. \quad (13)$$

The B value can vary from 0 to 1, and further we take it equal to 0.1; 0.5; 0.9.

Relations between the concentrations of components in the reactor gas phase and condenser liquid phase are expressed as follows:

$$X^x_{C2} = Y^p_{C2}/(I+A)[E^x(K^x_{C2} - 1) + 1], \quad (14)$$
$$X^x_{C4} = Y^p_{C4}/(I+A)[E^x(K^x_{C4} - 1) + 1], \quad (15)$$
$$X^x_{C6} = Y^p_{C6} + A/(I+A)[E^x(K^x_{C6} - 1) + 1]. \quad (16)$$

The reactor mass balance of dimerization on the but-1-ene is expressed as:

$$g_3 \cdot Y^p_{C4} + g_4 \cdot X^p_{C4} = g_6 \cdot Y^x_{C4} + g_9 \cdot X^x_{C4} + G_{C4} \quad (17)$$

where G_{C4} is amount of the formed but-1-ene in kgmol/h, other flows are shown in Fig. 2 and by relations (1, 2, 6, 7).

Using above relations (1)–(16) we transform relation (17) to otain the following dependence:

$$G_{C4} = g_3 X^p_{C4} \cdot [E_p(K^p_{C4} - 1) + 1/E_p - K^p_{C4} \cdot E_x(K^x_{C4} - B) + B/E_x(K^x_{C4} - 1) + 1] \quad (18)$$

The amount of ethylene g^{C4}_{C2} consumed for the formation of but-1-ene in kgmol/h equals:

$$g^{C4}_{C2} = 2G_{C4} \quad (19)$$

The total amount of ethylene used for the formation of but-1-ene and hexenes g^{C4+C6}_{C2} is expressed by the relation:

$$g^{C4+C6}_{C2} = 2G_{C4} \quad (20)$$

where S is the process selectivity of dimerization on but-1-ene.

The mass balance on ethylene is expressed as:

$$g_1 = g_{эт}{}^{C4+C6} + g_4 X^p_{C2} + g_8 X^x_{C2} \quad (21)$$

The mass balance on hexenes is expressed by the relations below:

Amount of the formed hexenes

$$G_{C6} = 2G_{C4}(1-S)/3S. \quad (22)$$

$$g_1 = g_3 \left(\frac{2X^P_{C_4}}{S} \left[\frac{E^P \left(K^P_{C_4} - 1\right) + 1}{E^P} - \frac{K^P_{C_4} E^X \left(K^X_{C_4} - B\right) + B}{E^X \left(K^X_{C_4} - 1\right) + 1} \right] + X^P_{C_2} \left[\frac{1 - E^P}{E^P} + \frac{K^P_{C_2} (1 - B)(1 - E^X)}{E^X \left(K^X_{C_2} - 1\right) + 1} \right] \right),$$

$$g_2 = g_3\left(X^P_{C_6}\left[K^P_{C_6} + \frac{1 - E^P}{E^P}\right] - \left(K^P_{C_6}X^P_{C_6} + A\right)\left[B\left(1 - E^X\right)(1 + A) + \frac{E^X}{E^X\left(K^X_{C_6} - 1\right) + 1}\right]\right) -$$
$$- g_3\frac{2X^P_{C_4}(1 - S)}{3S}\left[\frac{E^P\left(K^P_{C_4} - 1\right) + 1}{E^P} - K^P_{C_4}\frac{E^X\left(K^X_{C_4} - B\right) + B}{E^X\left(K^X_{C_4} - 1\right) + 1}\right] .$$

Amount of hexenes G_{C6}^{g3+g4} leaving reactor with the flows g_3 and g_4:

$$g_{C6}^{g3+g4} = g_3 \cdot Y^p_{C6} + g_4 X^p_{C6}. \quad (23)$$

Amount of hexenes formed in the dimerization process and incoming with the flows g_6 and g_9

$$g_{C6}^{g6+g9+Gc6} = g_9 X^x_{C6} + g_6 Y^x_{C6} + G_{C6}. \quad (24)$$

and

$$g_2 = g_{C6}^{g3+g4} - g_{C6}^{g6+g9+Gc6}. \quad (25)$$

Transforming relations 21 and 25 and using (1) to (20) we obtain expressions for g_1 and g_2 showing (see Fig. 2) that they are functions of the flow g_3, but-1-ene concentration in the liquid phase of the reactor X^p_{c4}, phase equilibrium constants K_i at the temperatures in the reactor and in condenser, and of B value:

The flow value g_1 will be shown to depend also on ethylene concentration in the reactor liquid phse X^p_{c2} and flow g_2 on the hexenes concentration X^p_{c6}, A value and the process selectivity.

Such a system has many solutions, and for obtaining certain relations it is necessary:

define flow g_3 = 1 kgmol/h

define molar concentration X^p_{c4} = 0.1, 0.25, 0.5

define A = 0, 0.1

define B = 0.1, 0.5, 0.9

At the given dimerization conditions on temperature and pressure, the values of all flow can be calculated. These values will be true when the reactor heat balance is fulfilled.

Income of heat into the reactor is expressed by the relation

$$Q_{income} = Q_1 + Q_6 + Q_9 + Q_2 + Q_{reaction}, \quad (26)$$

where Q_{income}, Q_1, Q_6, Q_9, Q_2 and $Q_{reaction}$, are the amount of heat incoming to the reactor totally, of the flows g_1, g_2, g_6, g_9, and of the reaction heat, respectively.

The heat outcome from the reactor is expressed by the relation:

$$Q_{outcome} = Q_3 + Q_4 + Q_{loss}, \quad (27)$$

where $Q_{outcome}$, Q_3, Q_4, and Q_{loss} are respectively total outcoming heat, the heat of flows g_3, and g_4 and the

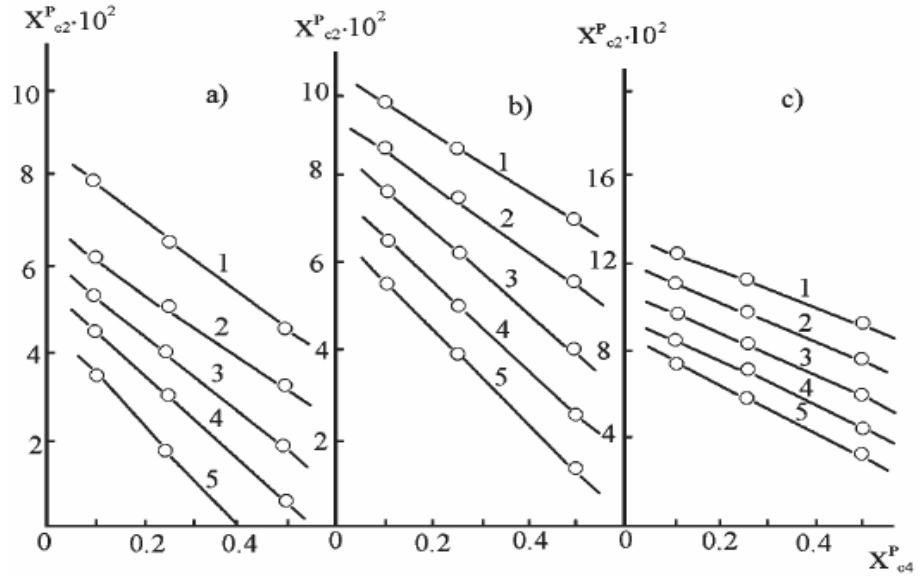

Fig. 3. Plots of ethylene concentration in the reactor liquid phase on but-1-ene concentration in the reactor liquid phase at different temperature and pressure. Pressure, MPa: (a) 0.6, (b) 0.8, (c) 1.0. Temperature, ºC: (1) 50, (2) 60, (3) 70, (4) 80, (5) 90.

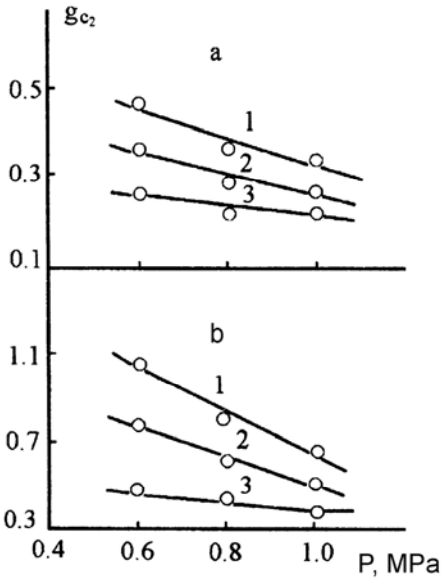

Fig. 4. Plots of ethylene amount g_{C2} consumed for the formation of but-1-ene and hexenes, on the process pressure, at $X^{p}_{C4} = 0.1$; B= 0.1, 0.5, 0.9; (a) at the temperature 80ºC, (b) at the temperature 90ºC.

Fig. 5. Dependence of maximum productivity of reaction node G on the pressure; (1) A = 0; (2) A = 0.1.

losses of heat to environment.

$$Q_{income} = Q_3 + Q_4 + Q_{outcome}\,. \qquad (28)$$

Join solution of the above relations allows to analyze influence of temperature and pressure on the process rete in the bubble type reactor.

The rate and selectivity of the dimerization process an hence the values of g_1, g_2 flows are affected by the concentration of ethylene in the recator liquid phase which in turn, as seen from Fig. 3, depends on the following factors: pressure, temperature and but-1-ene concentration in the reactor liquid phase.

Analysis of the data obtained shows that increase in pressure from 0.6 to 1.0 MPa increases ethylene concentration by the factor 1.5 to 2; increase in the process temperature from 50°C to 90°C decreases ethylene concentration in the reactor liquid phase by the factor 1.5 to 3, increase in but-1-ene concentration in the reactor liquid phase leads to decrease in ethylene concentration by the factor 1.5 to 2. Hence, maximum ethylene concentration occurs at the pressure 1.0 MPa, Δt = 50°C, and at mimimum concentration of but-1-ene in the reactor liquid phase.

Further analysis shows that temperature and pressure affect oppositely the ethylene concentration in the reactor liquid phase and on the amount of consumed ethylene.

Despite the increase of ethylene concentration in the reactor liquid phase, the amount of ethylene consumed for the formation of but-1-ene and hexenes falls down. The plots obtained are shown in Fig. 4.

The reaction node productivity as a dependence on the pressure is defined by the expression:

$$G = \frac{g_6 \cdot g_{c2} \cdot P_{work}}{E_x\,(1 + A)}\ \text{kgmol/h},$$

where g_6 is is circulation compressor discharge (flow g_6), Ex is the distillate fraction in condenser, g_2 is amount of ethylene consumed in the process of ethylene dimerization at the value of flow g_3 = 1 kgmol/h, P_{work} is working pressure.

The calculations show that maximum output of the reaction node falls by factor more than 3 in the pressure range 0.6 to 1.0 MPa (Fig. 5). Hence, it can be said that increase in pressure over 1.0 MPa practically excludes heat withdraw in account of evaporation of but-1-ene and makes this system of heat withdraw ineffective.

The dependence of ethylene amount on the temperature in the reactor or on the temperature difference between reactor and condenser Δt ($t_{condenser}$ = 40ºC), which can be consumed for the dimerization reaction

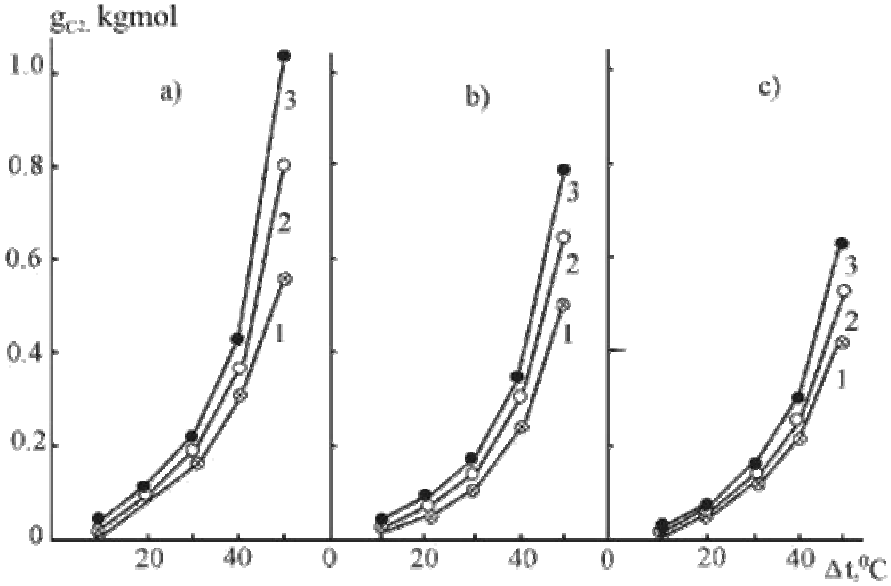

Fig. 6. Plots of ethylene amount g_{C2} consumed for the formation of but-1-ene and hexenes, on the difference in the reactor and condenser temperatures Δt. Pressure, MPa: (a) 0.6, (b) 0.8, (c) 1.0; parameters: X^{p}_{C4} = 0.1; A = 0; B: (1) 0.1, (2) 0.5, (3) 0.9.

without disturbance of heat and mass balances, is shown in Fig. 6. As seen, at Δt = 10°C the reaction node maximum output is minimal, while at Δt = 40 to 50°C it increases sharply. Depending on the pressure and B value the output at Δt = 40°C grows by the factor 10 to 20, at Δt = 50°C by factor 20 to 70. It should be noted that B value does not affect output at the Δt = 10°C, while at Δt = 50°C increase in B from 0.1 to 0.9 leads to increase in output by factor 1.5 to 2.

Thus, considering two characteristics of the industrial process of ethylene to but-1-ene dimerization in the bubble type reactor, the reactor productivity (amount of ethylene consumed g_1) and ethylene concentration in the reactor liquid phase it possible to conclude:

– Increase in the process temperature to 90°C leads to grow in amount of consumed ethylene.
– Increase in pressure is not reasonable because grow in the reaction node productivity is much lower than increase in ethylene concentration in the reactor liquid phase and besides is restricted by the conditions of heat withdraw.
– Ethylene concentration in the reactor liquid phase by complicate way depends on the reactor temperature, pressure and but-1-ene concentration in liquid phase.

Hence, for the considered scheme of technological process the optimum temperature in the reactor is 80 to 90°C, the optimum pressure is 0.6 to 0.8 MPa.

Abstract—A comparative economical analysis of reasons for application the solvents of various type in the process of ethylene to but-1-ene dimerization and of technological schemes of rectification of the products of ethylene dimerization with use of different solvents. The optimal solvent for the currently working industrial process of ethylene to but-1-ene dimerization is hexane fraction forming in the process of ethylene dimerization.
DOI: 10.1134/S1070427207070397

The highly selective process of manufacturing but-1-ene by catalytic dimerization of ethylene has been first developed in the Institute of Problems of Chemical Physics RAS and in cooperation with joint-stock companies Stavrolen and Kazanorgsynthes realized in industry [1–3]. In [4] we performed analysis of mass and heat balances of the reaction node for the process of ethylene dimerization under industrial conditions.

The process of ethylene dimerization is performed with homogenous catalyst $Ti(OR)_4 - AlR|_3 -$ modificator in the medium of hydrocarbon solvent. As the solvent can be used individual or mixed hydrocarbons, including the products of dimerization.

The solvent in the process of dimerization bears several functions:

–as a reaction medium for the process,
–solving ethylene and dimerization products,
–maintaining required temperature regime,
–promoting heat withdraw.

In this connection, the solvent should obey the following requirements:

–it should be chemically inert to the catalyst components, monomer and dimerization products,
–should contain minimum admixtures reacting with the catalyst components and the catalyst whole,
–should have certain composition on hydrocarbons providing stable proceeding of the process in time,
–should provide simple by technology method of separation of the dimerization products,
–should be accessible, accepted in the industrial scale and advantageous economically.

Taking into account these requirements, investigations for evaluation of various solvents and selecting the perfect one have been conducted.

Among the solvents for the ethylene to but-1-ene dimerization could be used the following solvents:

–individual paraffin hydrocarbons (hexane, heptane and others and their mixtures),
–naphthene solvents (cyclohexane),
–aromatic solvents (benzene, toluene and others),
–unsaturated hydrocarbons (but-1-ene, hexenes),
–halohydrocarbons (chloroethane, bromoethane),
–ethers (diethyl, diisopentyl),
–industrial hydrocarbon fractions C6 or C7 (Nefras "A", Nefras "C", BR-1, BR-2 and others).

In [5] was reported that the solvent nature affects

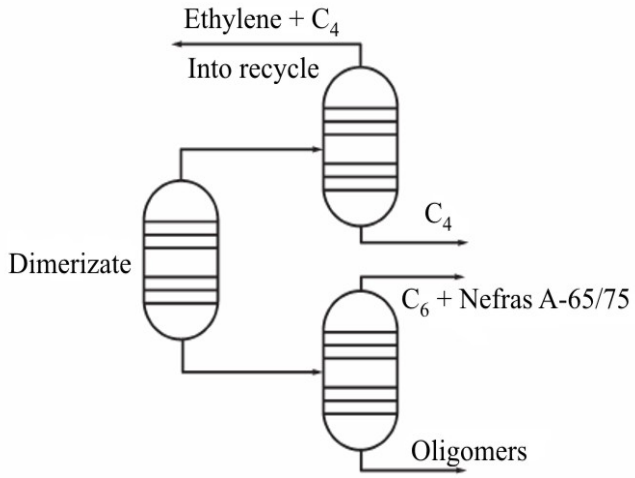

Fig. 1. Scheme of separation of the products of ethylene dimerization with Nefras "A" 65/75 as a solvent.

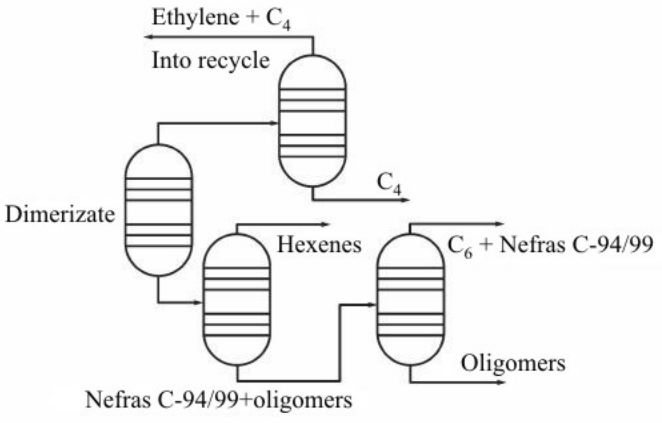

Fig. 2. Scheme of separation of the products of ethylene dimerization with Nefras "C" 94/99 as a solvent.

activity and selectivity of the process and increases them in the order: aromatic hydrocarbons; naphthene, paraffin hydrocarbons and industrial hydrocarbon fractions; chlorinated hydrocarbons, unsaturated hydrocarbons, ethers. This order can vary with increase in the process temperature.

From the viewpoint of the catalyst discharge, use of ethers as the solvent is disadvantageous due to enhanced consumption of organoaluminum component owing to necessity in higher $AlR'_3/Ti(OR)_4$ ratio, up to (10–20):1 instead of (4–3):1 in all other cases, explained by their chemical interaction with formation of strong $AlR_3 \cdot R_2O$ complex. The cost of halohydrocarbons such as bromoethane or chloroethane is too high and therefore their application is also unreasonable.

The most accessible solvents produced industrially are Nefras "A" 65/75 and Nefras "C" 94/99, and but-1-ene and hexenes formed in the process of ethylene dimerization as well. Estimating all the abovesaid, we have analyzed for the industrial application the possibility of use of hydrocarbon solvents of Nefras type, isopentane, and hexanes forming in the process of dmerization, and their mixtures.

Certain choice can be made after comparison of various schemes for isolation of but-1-ene, hexenes and polymer. The choice becomes the simplest when technological scheme of separation of the products of dimerization is analyzed.

ANALYSIS OF THECNOLOGICAL SCHEMES FOR THE SEPARATION OF THE PRODUCTS OF DIMERIZATION

In the process of ethylene dimerization various olefins are formed: but-1-ene, but-2-ene, hexenes (hex-

5	Column top composition	wt %	Nefras “A” 45.5, but-1-ene 4.0
6	Column bottom composition	wt %	Hexenes 40.0, Nefras 50.0, oligomers 10.0

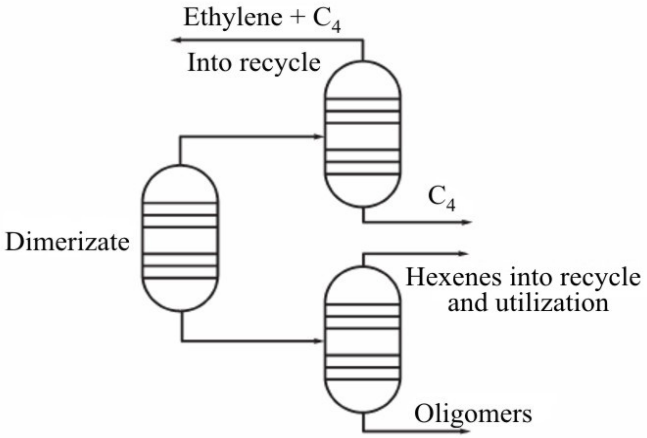

Fig. 3. Scheme of separation of the products of ethylene dimerization with hexenesas a solvent.

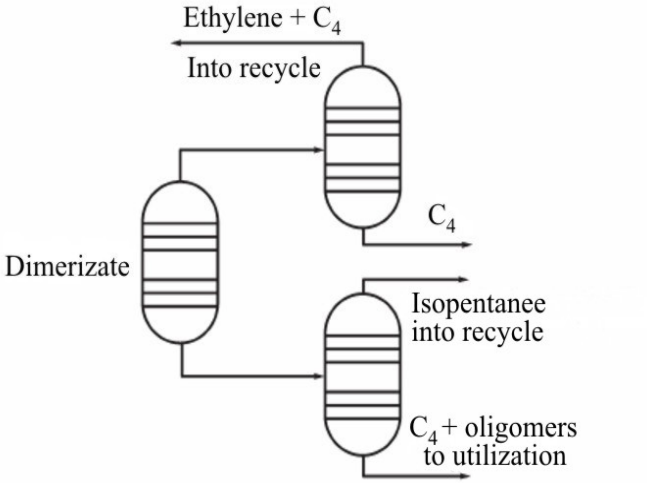

Fig. 4. Scheme of separation of the products of ethylene dimerization with isopentane as a solvent.

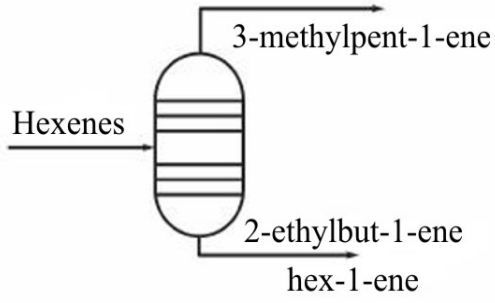

Fig. 5. Principal technological scheme for separation of hexenes.

schemes we omit separation into components of C_4 fraction, which composition is controlled by the dimerization process.

Depending on the nature of the chosen solvent, the principal technological schemes of rectification appear as seen in Figs. 1–5. As seen from the schemes, when Nefras "A" 65/75 is taken as a solvent in the ethylene dimerization, it can not be separated from the forming hexenes due to closeness of their boiling temperatures (Table 1, Fig. 1).

Application of Nefras "C" 94/99 allows isolation of hexenes, but additional column should be installed for its separation from oligomers (Fig. 2).

The most rational scheme is seems which uses hexenes (Fig. 3) or isopentane (Fig. 4) as a solvent. In these cases individual 3-methylpent-1-ene and 2-ethylbut-1-ene with hexane admixture can be isolated (Fig. 5).

For the drying reaction node and separation nodes, a node for azeotropic drying of solvent is needed; its principal scheme is shown in Fig. 6.

The drying node can operate continuously or in periodical regime.

All the schemes include first a column for separation of ethylene and C_4 fraction. Its characteristics are listed in Table 3. The characteristics of the column for separation Nefras "A" 65/75 and hexenes from oligomers are listed in Table 4, for Nefras "C" 94/99 in Table 5. The characteristics of the column for separation of hexenes from Nefras "C" are given in Table 6.

For separation of 3-methylpent-1-ene and 2-ethylbut-1-ene is used a column which characteristics

6	Column bottom composition	wt %	solvent 100.0

–those forming hexenes in the process of dimerization
–isopentane.

Use of hexenes rather than isopentane is economically advantageous because the hexenes formed in the process of ethylene dimerization after their separation from but-1-ene do not require any drying to remove water or purification for removing other admixtures which could partially deactivate the catalyst.

Abstract—Complex investigation is conducted, directed to development of contacting materials (forcontacts) and catalysts for the protecting layer in the process of hydrorefining petroleum distillates taking into account their specificity and extensively attracting local raw materials. Forcontact FZS-7 is developed which, besides the function of uniform distribution of crude material over the reactor section, diminishes tarring and performs, owing to low nickel content, mild hydrogenation of unsaturated compounds. The proposed kaolin-bset catalyst of the protecting layer with low content of molybdenum oxide works reliably with the residual crude material with high content of iron and displays high enough demetallization activity.
DOI: 10.1134/S1070427207070403

Currently in Fergana's oil refining plant (FORP) is refined rather heavy hydrocarbon raw material from various fields in Uzbekistan, which is characterized by high content of paraffin, sulfur, and tarring compounds mixed with gas condensate. The refining scheme is defined by the local conditions: chemical composition of the petroleum distillates, nomenclature of demand by market petroleum products, and by technological potential of the facility for refining petroleum fractions.

Among the targeted processes in FORP a significant is producing basic lubricating oils with certain set of exploitation characteristics. The most problematic are enhanced colorization, compatibility with addition agents and low viscosity index. Correction of principal parameters of basic oils is performed at hydrorefining on G-24 installation where fractions of deparaffined distillate and deasphalted residue are treated in separate cycles. The tar-asphaltene substances colorizing petroleum products are mostly removed at deasphalting, but due to their volatility they contaminate oil distillates where they are undiserable due to high corrosion activity and deactivating effect on alumocobalt-molybdenum catalyst of hydrorefining. Design of the currently opertaing installation does not allow regeneration of deactivated catalyst directly in the reactor, therefore when reactor os sealed by deposits the process shold be interrupted. From the reactor after cooling are removed ceramic rings and upper, the most wasted and damaged part of catalyst. Then fresh catalyst is loaded and on it the ceramic rings cleaned from edges and deposits are placed. Thus, the main mass of catalyst is used for long time without regeneration, and raw material often containing admixture of unsaturated compounds feeds into the zone of relative high temperature and active catalyst. Unsaturated compounds initiates formation of sealing products which leads to faster increase in pressure difference and poisoning of hydrorefining catalyst. To improve quality of lubricating oil and the process parameters it is reasonable to perform multilayer loading of catalytic pacjage with additional forcontact and protecting catalyst layers.

Successful experimental-industrial testing of kaolin-phosphate forcontact (KPC) [1] in the reactor of Diesel distillate hydrodesulfrization in Fergana petroleum plant allowed considering of its application as front layer in treatment of heavier raw material. However, testing on a pilot-plant installation showed progressing grow of tarring components concentration in oil distillate, in residual fraction in particular, after contact with KPC under the process parameters analogous to those at the oil hydorefining (Table 1).

One probable reason for this observation is acceleration of polymerization reactions under the action of strong Bronsted acid centers [2] at lower hydrogen pressure compared to hydrodesulfurization of Diesel fuel. Really, testing the catalytic properties of KPC forcontact on a flow-type microinstallation in the temperature range 523–573 K revealed its ability of accelerating steric isomerization reactions of α-olefins and double bond migration into molecule followed by oligomerization. Yield of the products of intermolecular interaction of isomeric hexenes grows with temperature (Table 2), however, no surface coking was detected in the studied samples. Therefore for lowering the catalyst surface acidity excess to retard undesired reactions of to enhance hydrogenating function the KPC granules were impregnated with nickel compounds followed by thermal treatment. Studying showed that synthesis at lov pH values leads to dectrease in size of both large and small pores while impregnation of KPC by neutral solution increases fraction of pores 12-18 nm in diameter which leads to increase in sorption activity of the sample toward the largest test-molecules [3].Taking into account the coarse-pored structure and low specific surface of KPC, their impregnation conditions were taken to provide maximumm nickel concentration 1.3–1.5% inthe granules surface layer at the total NiO content 0.4–0.5% (sample FZS-7). IR spectrum of scrap from KPC granule surface showed decrease in the fraction of acid phosphites correlating with the change in acidity of the acid centers from $pK_a > 1.5$ on the surface to $pK_a < -3$ on the internal slice of granule. Modification of the forcontact with nickel compounds in neutral medium leads to relative increase in activity toward backbone isomerization of hex-1-ene and hydrogenation of forming unsaturated compounds.

Use of nickel salt solution with lower pH at impregnating KPC provides three-fold increase in concentration of surface acid centers with $pK_a < -3$ and more homogenous distribution of nickel compounds in the bulk granule (sample FZS-1). This leads to obvious strengthening of polymerization function in a model

reaction and sharp fall in colorization of oil fractions at hydrorefining due to intense tarring. On the contrary, passing residual fraction through FZS-7 layer leads to decolorizatiun of product by 1-2 TsNT (colorimetric standard) units. Besides, occurs certain increase in hydrocarbon chain branching, probably owing to isomerization followed by hydrogenation of unsaturated components, which leads in some increase in viscosity (Table 1) and decreases freezing temperature by 1–2°C. Appearance of hydrogen sulfide in gas phase together with practical absence of C_1–C_5 hydrocarbons attests proceeding of hydrogenation of the less stable sulfur compounds in oil fraction without C–C bond cleavage. Investigation of KPC samples and modified forcontact FZS-7 after their application to hydrorefining fraction III of oil distillate under the same condi-

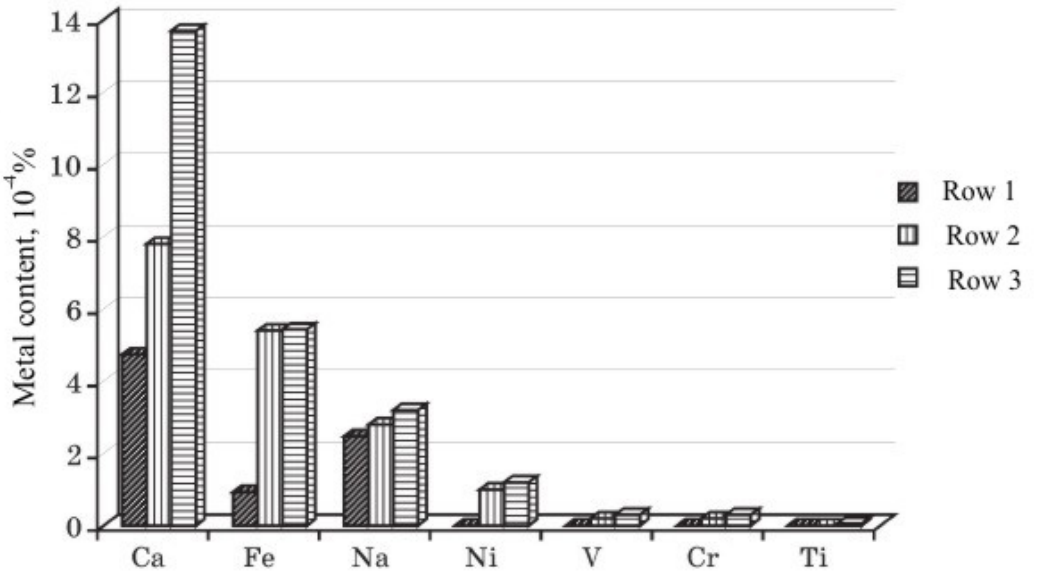

Fig. 1. Changes in metal content: 1 – in residual fraction, 2 – after hydropurification on FZS-7 forcontact, 3 – on AKBM protecting layer catalyst

tion in a pilot-plant installation revealed decrease in content of dry cake from 5.76% to 2.6 and of tar-asphalt substances extractable with benzene-alcohol mixture from 1.2% to 0.8%. On the FZS-1 forcontact surface was detected 11.2% of insoluble carbon-containing compounds. Comparison of decrease in concentration of metals in starting material and in the hydrogenizates (Fig. 1)with their distribution in "dry" cake and in extracts of caked samples allows to conclude that the forconacts partially trap alkaline and alkaline-earth metals, probably in the form of corresponding naphthenates dissolving in hydrocarbons. By the method of electron-sounding analysis we registered presence of sodium, potassium and calcium, mainly in ashed residues of oil fractions and in extracts of used up forcontact and catalyst of protecting layer (below). Concentration of typical catalyst poisons in the residual fraction, the vanadium, nickel and iron organic metallocomplexes, remains practically unchanged after passing oil through FZS-7 layer at hydrorefining, which attest low demetalliation function of this forcontact.

To avoid deactivation of cobaltmolybdenum catalyst in the process of work up heavy fractions, we prepared and studied a series of molybdenum-containing catalysts of protecting layer on the ground of clay minerals of Uzbekistan origin with by-products of local plants for their transformations. When carrier is prepared from bsevdobemit with 25% of kaolin, new very strong Si–O–Al bonds are formed between SiO_4 fragments of kaolinit and AlO_6 octahedrons of aluminum hydroxide. Optimal combination of strength and porous characteristics was achieved, in our opinion, with alumokaolin carrier modified with boric acid (Table 2).

The process of applying active metal from aqueous solution is significantly affected by state of hydroxyl shell of carrier, because change in solution pH is defined by dissociation of water molecules at the action of field strength of dominating aprotic adsorption centers. Study of acid-base properties of the smples dehydroxylated at 823 K showed that introducing kaolin to psevdobemit composition in strong acid medium enhances concentration of coordination-unsaturated aluminum ions on the surface of the calcined carrier, but on the other hand this promotes formation of Bronsted acid centers typical for alumosilicates [1]. Thus, the dehydroxylated alumokaolin carrier (AK) surface ears simultaneously fixed not mutually interacting strong aprotic and protic acid centers ($pK_a \leq -5$) and weak aprotic basic centers. On immersing the AK sample into water occurs emphasized alkalization of the medium (pH from 5.9 to 6.8) rather than at the hydration of aluminum γ-oxide prepared by pseudobemit calcination at 873–923 K [4], that is, the ratio of primary (acid) and secondary (basic) Lewis centers is shifted in favor of the latter and surface pK_a grows to 8.2. This is stipulated by formation of additional basic centers at the thermal decomposition of doped alkaline-earth

metal hydrocomplexes which in the process of plasticizing of the kaolin – bseudobemit mixture with nitric acid are washing out from kaolinit interpackage space, and further at thermal treating they are passed to the granule surface through capillary canals. De to irregular distribution of different type OH groups on the alumokaolin carrier surface, before formation of required monolayer, an "island" polymolybdate film is formed which contains up to 20% of water soluble molybdenum in the catalyst composition (AKM). The high content of water soluble mixed structures Mo^{6+}_{Td}–O–Mo^{6+}_{Oh} manifests itself as a bend at 33.3 kcm−1 in electronic diffuse reflectance spectrum, attesting weak enough interaction of active component with the carrier.

For strengthening granules and admitting proton-donor property to surface of hydrorefining catalyst for facilitating desorption of hydrogenolysis reaction products, to the catalyst compositionis introduced boric acid. Modifying aluminum oxide with boric acid in the absence of kaolin leads to formation of carrier (AB) with high concentration of Bronsted acid centers ($-8 < pK_a < -4$) on its dehydroxylated surface. In the first moment its hydration proceeds presumably by basic type affording H+ ions to the surrounding medium and decreasing pH value from 5.9 to 5.6. Then pH grows to 6.0, which points to the presence of two hydroxyl centers of two sorts capable of ion exchange, as well as Lewis acid centers capable of binding active component by sorption. Acidification of the medium due to ion exchange between surface groups of AB carrier and ammonium para-molybdate water solution shifts equilibrium to the side of formation in solution of polymolybdate structures, while fraction of water-soluble oxidomolybdene clusters in the final sample achieves 15%.

Modified alumokaolin carrier with optimal B_2O_3 concentration (AKB) the surface alumoborates formed after calcination at 773 K cover ¼ of monolayer. In couple with alumosilicate structures they provide formation of bronsted acid centers in the pK_a range from –4 to –1.5, regularly distributed on the carrier surface. At the contact of AKB with water the medium pH begins to change from 5.9 to 5.6, then becomes constant on 6.3 level, while pH of the carrier surface after hydration becomes equal to 7.2. Intoduction to this system of ammonium para-molybdate ammonia solution results in ion exchange reactions with surface structures and formation of Mo–O–Al, Mo–O–Si and Al–O–B–O–Mo bonds fied on the surface at thermal treatment. Applying of molybdenum oxide does not change spectrum of distribution by strength of acid centers on the AKB carrier, but increases concentration of Bronsted acid centers on the catalyst surface (AKBM).

Extraction treatment of the prepared catalyst showed absence of molybdenum water-soluble forms, although the fraction of active molybdenum extracted by ammonia is high enough. IR spectrum of AKBM in KBr pellet registered with reference KBr containing equivalent amount of AKB for compensation of the carrier bands contain bands near 920 cm^{-1}, which in conjunction with the data of electron diffuse reflectance spectroscopy evidences that molybdenum ions are in tetrahedral coordination and its significant part is in the composition of associates Mo_{Td}–O–Mo_{Td}, which are characterized by inflection point at 33.7 kcm^{-1}. Clear absorption band in the region of 40.0–43.3 kcm^{-1} is assigned to formation of amorphous alumomolybdenborates revealing high catalytic activity in the process of hydrocracking of heavy petroleum [5].

Express testing of catalytic properties of the catalyst on a microcatalytic installation of flow type, on the samples not containing molybdenum in the temperature range 473 – 673 K predominantly occurs reactions of stereoisomerization and double bond shift into the chain of normal acyclic α-olefin. Increase in concentration of acid centers pKa –5.6 leads to increase in the rate of formation of branced olefins due to backbone isomerization, but concentration of products of their hydrogenation decreases.

Hydrogenation of cyclohexene is accompanied with backbone isomerization with formation of methylcyclopentane and methylcyclopentenes. The same reaction products: cyclohexane, methylcyclopentane and various methylcyclopentene were formed bof in hydrohenation reaction and due to hydrogen redistribution in the experiments with inert gas. Although in the second case the products of backbone isomerization were formed in much less amount, their enhanced concentration on the samples with maximum acidity evidences unequivocally the principal role of strong acid centers in this process. We found that hydrogenating function of the catalysts correlates with concentration of water insoluble molybdenum, the maximal activity showed the catalyst on the carrier with the predominating strength of acid centers in the range $-4.5 < pKa < -1.5$. On the carries with stronger acidity (pKa below –5) the hydrogenation reaction are less successful and in the hydrogenizate increases fraction of undesired products of oligomerization.

We performed continuously testing of optimal forcontact samples FZS-7 and of protecting layer catalyst AKBM on a pilot-plant installation of high pressure hydrorefining fractions III and resifual fraction af oil distillates. The forcontact FZS-7 improves characteristics on color and iodine number of oil fraction before their passing on the catalyst of hydrorefining. Depending on the process parameter, on the protecting layer catalyst AKBM stable decreases colorization and sulfur content, increases viscosity index at minimal decrease in viscosity, and effectively trapped iron and other metal ions.

TECHNOLOGY OF ORGANIC AND INORGANIC SUBSTANCES

Copolymer from the Waste Products of Styrene and Maleic Acid Production

O. N. Filimonova

Voronezh State Tecchnological Academy, Voronezh, Russia

Received February 9, 2007

Abstract—Influence of the process conditions on the production of "STAM" copolymer from waste products formed at join producing of styrene and propylene oxide, the acetophenone bottom residue at styrene rectification, with maleic acid. Effects of temperature, copolymerization process duration, weight ratio of acetophenone bottom residue to maleic acid and styrene content in the bottom residue are studied.
DOI: 10.1134/S1070427207070415

Solving the problem of targeted treatment of waste products require introduction of new processes based on the knowledge of composition and properties of the waste product as a physicochemical system, and mechanisms of their stimulated targeted reactions. The novelty consists in control over the process via kinetic modeling on the ground of chemical processes leading to predictable correlation of the model of initial physicochemical system and the copolymer quality as a reaction product. All steps of the process were studied in the sense of their interrelations.

We considered and solved the following problems: Maximum use of whole mass of bottom residue at styrene rectification, the waste product at the styrene manufacturing, that is, to minimize wastes at the treatment the bottom residue. Producing not toxic product in respect of residual styrene and other dangerous compounds [1].

Reaction of styrene with maleic acid in the presence of methylphenylcarbinol and acetophenone, the main components of the bottom residue in the join production of styrene and propylene oxide, leads to formation of polymer product ("STAM") which can show properties of a film forming material [2]. This is a multistep and multifactor process. Study of its steps allows to get a basis for the process separate steps and to reveal the most significant factors affecting yield and quality of the "STAM" copolymer.

The aim of this study is producing the "STAM" copolymer from the waste products at the styrene manufacturing, with maleic acid, namely, study if influence of the process temperature and duration, weight ratio of acetophenone bottom residue and maleic acid, styrene content in the bottom residue on the copolymer "STAM" yield. However, estimation of join effect of these factors on the producing the targeted substance in view of complexity in the study of this process requires application of the methods of mathematical modeling. Study of these factors and creation of the model require careful experiment planning.

The plan of experiments on the synthesis of "STAM" copolymer was based on the Greek-Latin 4-th order squire. The advantage of this method of planning is a significant diminishing the scope of experiments for revealing and estimating effects of certain factors and obtaining regression equations allowing simultaneous estimation of the effects of all factors and elucidating the range of each factor within limits of its varying, providing best experimental results in respect of a certain criterion that characterize the product quality or process efficiency. This is especially important in the cases where there is no interactions between the factors or such interaction is negligible. Structure of the squire is defined by the theory of planning experiments.

Experimental study of the copolymer production included the following:

–choice of the process temperature and synthesis duration, reagents ratio and styrene content in the initial bottom residue, as the principal parameters influencing the copolymerization process;

–estimating the basic parameters of the copolymerization process providing within a given range of their varying the highest yield of copolymer with required quality;

–revealing the dependence of the factors characterizing the polymer, on the condition of the synthesis.

The "STAM" copolymer synthesis was performed in a glass reactor equipped with reflux condenser, Dean-Stark trap and stirrer and located into a thermostat for maintaining required process temperature. The initial acetophenone bottom residue had the following composition (wt%): acetophenone 35, methylphenylcarbinol 14, styrene content was varied from 15 to 45 according to the plan of experiment, and all other was the tar which included polystyrene and other high-boiling compounds. Acetophenone bottom residue and maleic acid in a given ratio were loaded to the reactor simultaneously and then the reactor was heated stepwise to a given temperature which then was maintained within ±2.5°C. Reaction proceeding was monitored by the methods of chromatography and viscosimetry. After completing the synthesis, acetophenone and not polymerized compounds were distilled off in a vacuum at residual pressure 5–8 mm Hg and temperature 165–170°C.

As the factors affecting the process we consider: factor *A*, temperature of the synthesis, °C (*t*); factor *B*, the synthesis duration, h (τ); factor *C*, styrene content in the initial acetophenone bottom residue, wt% (*c*); factor *D*, amount of loaded maleic acid, wt%(*d*). The plan of experiment is shown in Table 1.

According to the plan of experiment, the coplymerization process consists of three steps, each step has its own temperature and duration. As response functions are taken: copolymer yield, its molecular weight, acid and ester numbers. Choice of these target functions is defined by the fact that they define the copolymer main properties and areas of its application. For estimation of the target functions and for prognosis of their values the experiment results were represented as regression equations,

$$Y = SF_1(t)\, F_2(\tau)\, F_3(c)\, F_4(d), \qquad (1)$$

where Y is the target function, S is a coefficient, $t=t_2t_3/t_1\text{-}(t_2t_3/t_1)_{min}$, t_1, t_2, t_3 are temperatures in first, second and third reaction steps, respectively, °C; $\tau = \tau_2\tau_3/\tau_1 - (\tau_2\tau_3/\tau_1)_{min}$, τ_1, τ_2, τ_3 are the durations of first, second and third steps, respectively, h; index min means that the minimal of possible values of monomials t_2t_3/t_1 and $\tau_2\tau_3/\tau_1$ are taken; *c* is styrene content in the acetophenone bottom residue, wt%; *d* is maleic acid doze, wt%; F_n is a function of one variable: $F_1=F_1(t)$, $F_2=F_2(\tau)$, $F_3=F_3(c)$, $F_4=F_4(d)$, F_1–F_4 characterize influence of temperature and duration regimes, styrene content and maleic acid dozing on the target function value.

in third step	τ_3	5–8
Temperature index	t	0; 4.54; 9.11; 13.80
Duration index	τ	0; 4.50; 1.83; 5.83
Styrene content, wt%	c	15–45
Maleic acid content, wt%	d	1–10

Functions $F_1(t)$ and $F_2(\tau)$ in the equation (1) are discrete, and obey t and τ values within the ranges shown in Table 2.

The t and τ values are chosen taking into account convenience in calculation of $F_1(t)$ and $F_2(\tau)$, and are approximated by third degree equations. As far as levels of A and B factors are represented by scope of three values each, it is insufficient to characterize them by one value. Functions $F_1(t)$ and $F_2(\tau)$ in the accepted interpretation are discrete ones and reproduce experimental results only. Functions $F_3(c)$ and $F_4(d)$ are continuous ones, the possible experimental errors are smoothed assuming that this function can be represented by a second order polynomial.

Actual regression equations (2) – (5) for calculation of copolymer yield Y_{YD}, average molecular weight Y_{MW}, acid number Y_{AN} and ester number Y_{EN}, after mathematical treatment by means of computers with accounting for geometric mean values over the factors look as follows:

$$Y_{YD} = 2.14\cdot10^{-6}(75.3+0.335t—7.69\cdot10^{-2}t^2+ +6.24\cdot10^{-3}t^3)(76.8+7.47\tau—3.40\tau^2+0.375\tau^3)\times \times(42.0+2.05c—0.0251c^2)(69,1+2.91d—0.187d^2), \quad (2)$$

$$Y_{MW} = 8.51\cdot10^{-5}(17.4+4.53t–0.542t^2+1.63\times \times10^{-2}t^2)(22.5–0.108\tau–0.775\tau^2+0.162\tau^3)\times \times(29.3–0.449c+6.80\cdot10^{-3}c^2)(19.4+1.17d– –6.44\cdot10^{-2}d^2), \quad (3)$$

$$Y_{AN} = 6.85\cdot10^{-4}(12.6–0.571t+8.06\cdot10^{-2}t^2– –3.72\cdot10^{-3}t^3)(10.5+1.77\tau–0.239\tau^2– –1.39\cdot10^{-2}\tau^3)(5.92+0.287c–3.03\cdot10^{-3}c^2)\times \times(5.73+0.148d+0.151d^2), \quad (4)$$

$$Y_{EN} = 4.16\cdot10^{-5}(37.9–5.22t+0.691t^2– –2.72\cdot10^{-2}t^3)(22.2+13.2\tau–3.83\tau^2+ +0.299\tau^3)(18.6+0.517c– –4.95\cdot10^{-3}c^2)(11.8+2.78d+0.122d^2), \quad (5)$$

Average divergence of experimental values and the values calculated with the regression equations describing the process are, %: for copolymer yield 5.0, for average molecular weight 16.4, for acid number 3.6, for ester number 8.4. The ranges of response functions values according to the plan of experiment are given in Table 3.

The equations gives enough reliable prognosis of the possible results under the conditions differ from those used by the Greek–Latin 4th order squire and

Table 3. Experimental values ranges corresponding to the response functions

Data	Value

Ester number, mg KOH / g	11–81

allow varying the technology parameters and polymer composition depending on the conditions and area of its application to attain higher yield and necessary commercial properties.

The results of experiments allow assuming the polymer chain composition: it includes carboxyl, anhydride and ester functions. In all the cases the ester number defining presence of ester groups in the substance predominates over the acid number. This allows a suggestion that the ester groups are formed both in the process of reaction of maleic acid with methylphenylcarbinol and in reaction of methylphenylcarbinol with carboxylic groups in the polymer chain. Presence of all three groups of polymer chain is confirmed by the data of IR spectroscopy.

The presence of anhydride and carboxylic groups in the copolymer is defined not only by the presence of maleic acid in the reaction mixture. Number of such groups also is affected by the presence and content of styrene, to the side of increase. The effect of styrene content on the number of anhydride and carboxyl groups can be explained by the fact that the copolymer chain is formed as a result of reaction of styrene with maleic acid and anhydride. It is obvious that the more chains and longer each chain, the more anhydride and carboxylic groups they bear. Although, if we characterize effect of temperature defined as weighted average logarithms of temperature over synthesis steps, a tendency to decrease in the content of anhydride and carboxylic groups in the copolymer chain is revealed. It is very probably that this results from the insignificant changes in temperature (5°C) characterizing temperature regime and from reversibility of the copolymerization reaction [4].

Analysis of experimental data shows a significant increase in content of anhydride and carboxylic groups in the copolymer with increase in content of maleic acid in the initial reaction mixture.

Thus, the evidenced presence of anhydride and carboxylic groups in the copolymer is a direct sequence of copolymerization of styrene with the maleic acid and anhydride, and analysis of the results aimed at the elucidation of the copolymer chain structure shows, proceeding from the data on ester number, presence of ester groups in the copolymer. Formation of the ester groups can be stipulated by two circumstances: ester formation directly from maleic acid and methylphenylcarbinol and their exclusive formation in the reaction of methylphenylketone with carboxylic and anhydride groups belonging to the copolymer chain, because only one source of these groups is reaction of alcohol with carboxylic and anhydride groups [5].

The principal possibility of the first process has been substantiated for various modes of esterification reaction [6]. Being formed, the ester is involved into copolymerization similarly to the maleic acid itself or anhydride. The second mode which assumes reaction of methylphenylcarbinol with carboxylic and anhydride groups involved into copolymer chain also takes place. The possibility of ester formation is evidenced by both direct experiments using model mixtures in acetophenone medium and on the acetophenone bot-

Table 4. Chemical analysis of functional groups in the raw material and copolymers

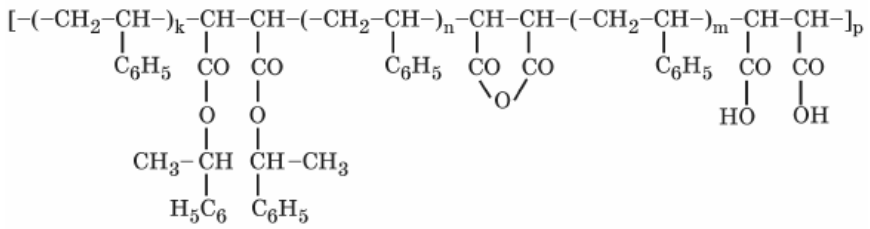
Product	Acid number mg KOH/g	Bromine number g Br_2/100	Hydroxyl number mg NaOH/g	Iodine number g I_2/100	Ester number mg KOH/g	Carbonyl number mg NaOH/g
Initial acetophenone bottom residue	4.21	72.01	74.60	64.72	56.10	68.70
Copolymer without a coreagent	0.85	14.72	36.08	16.92	14.72	21.00
"STAM" copolymer	9.26	28.02	20.08	16.75	78.54	59.80
Copolymer with maleic anhydride	10.38	36.01	19.04	19.04	14.03	32.72

tom residue at styrene rectification.

Chemical analysis on functional groups of initial acetophenone bottom residue and copolymers based on it is shown by Table 4. It also confirms formation of esters. Also, it is confirmed by the data of IR spectroscopy: a series of bands at 1270, 1220 and 1180 cm^{-1} evidences presence of ester group, ν(C–O–C).

In a typical spectrum of the copolymer obtained on an IKS-29 instrument in the region 600–3200 cm^{-1} the presence of polystyrene ground is confirmed by the absorption bands at 1640, 1030, 906, 750 and 700 cm^{-1}. Strong absorption in the region of 1820 and 1770 cm^{-1} is characteristic of anhydride bands (styrene – anhydride conjunction in the polystyrene chain) and of maleic anhydride. The band 1710 cm^{-1} characterizes the maleic acid itself, ν(C – O), dimer. The shoulder on this band at 170–1660 cm^{-1} confirms existence of double bond ν(C=C) with *cis* arrangement of substituents. Anhydride band in the region of 1800–1500 cm^{-1} and absorption at 1740 cm^{-1} are due to ester group [7].

On the basis of chemical analysis and IR spectroscopy data we can assume structure of the obtained "STAM" copolymer as follows:



Thus, the experimental results which allow elucidate conditions for joint treatment of acetophenone bottom residue of styrene distillation and maleic acid for producing "STAM" copolymer are taken as a base for the technology operational description at the projecting experimental pilot-plant installation for producing "STAM" lacquer.

CONCLUSIONS

1. Using waste products at joint production of styrene and propylene oxide, the acetophenone bottom residue at styrene rectification, and maleic asid bcan be produced a copolymer possessing film-forming properties.
2. By experimental investigations is established that for producing this copolymer a three-step model of synthesis with the steps differ by temperature and duration is technologically reasonable.
3. The highest yield of the copolymer obeying commercial requirements can be achieved under the following conditions: in the first step temperature is 125–130°C and duration 2–3 h, in the second step temperature is 150–160°C and duration 4–5 h, in the third step temperature is 175–180°C and duration 7–8 h.
4. Content of styrene and methylphenylcarbinol in the acetophenone bottom residue should be not less than 25 and 4 wt%, respectively.
5. Content of maleic acid in the reaction mixture for copolymerization should be 4 to 7 wt%of the amount of acetophenone bottom residue.

PLASTIC COMPOSITE EXPLOSIVES (OR PLASTIC EXPLOSIVES)

These explosives are a cross-linked polymer composition with polymer material as a continuous binding phase (matrix). In the polymer matrix a solid disperse mixture of explosives and specific additives is distributed like a filler.

Preparing the binding compounds consists in the following. As a binder in the polymer compositions usually are used various resins, which simultaneously are combustible components. A resin in viscous-flowing state is mixed with additives: plasticizers, vulcanizer, catalyst, dye and other special additives. The use of special additives is connected with the necessity of admitting required physico-mechanical properties to the commodity.

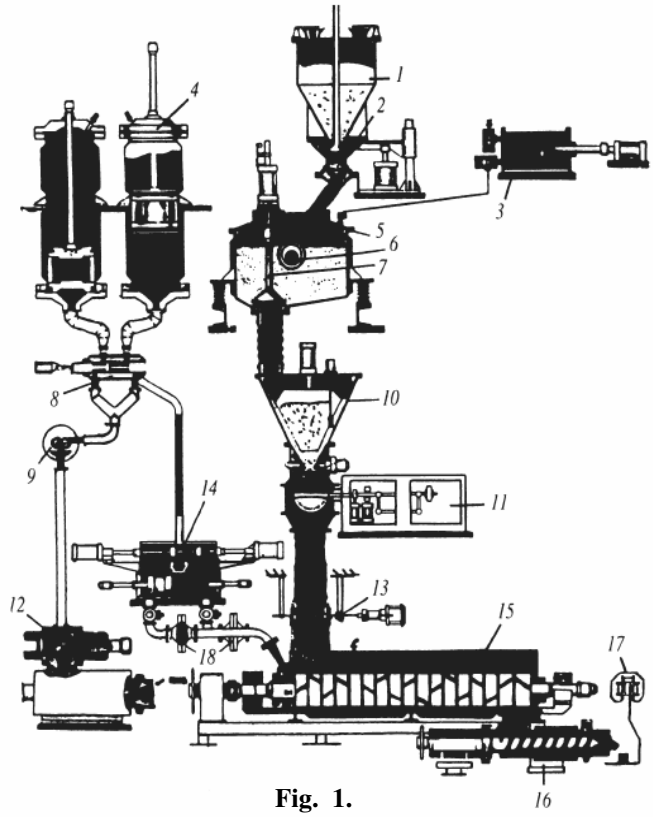

Fig. 1.

Preparation of friable substances is performed alongside the traditional technology considered earlier for the friable compositions of industrial explosives.

For preparation of explosive mass, a mixture of brisant explosive with additives is mixed with liquid binder in a mixer with periodical loading (blade, anchor or planetary type) or continuously operating (auger, two-screw type, two-blade type, rolls, etc.). Mechanical properties of the filled polymer explosives in a great extent depend on the size, distribution on size of the filler particles, their shape, homogeneity in distribution in the polymer matrix, degree of orientation (for anisotropic fillers) and interface properties. Content of filler in plastic explosives can vary in a wide range. In high-filled compositions it sometimes is over the polymer content. For example, the explosive "Hexoplast GP-87K" contains, %: hexogen 82.5, butyl rubber 13, fluoroplast 1.5, zinc white pigment 3, lecithin 0.1 [3].

The filled polymer explosive material in a general case can be solid amorphous (with partial crystallization) or in glass-like state, in solid highly elastic state, or in liquid viscous-flow state. The physical state of explosive material, partial or full bulk crystallinity and depending on it complex of its mechanical properties defines character of its application. The plastic explosive which are glass-like at ambient temperature or the explosives partially or fully crystalline are as a rule rigid materials and are known as plastics or plastids.

Plastic explosives in high-elastic state are known as elastomers or elastids, and posses properties of gum. The main advantage of the viscous-flow state polymer compositions is ability of most this type compositions to be molded and thus converted into a commercial mechanically shaped product.

The elastid charges are shaped as cords, tapes, plates by means of pressing, extrusion, rolling, pressure-die casting and by other methods.

Fig. 1 shows technological scheme of an installation for continuous producing plastic explosives [6].

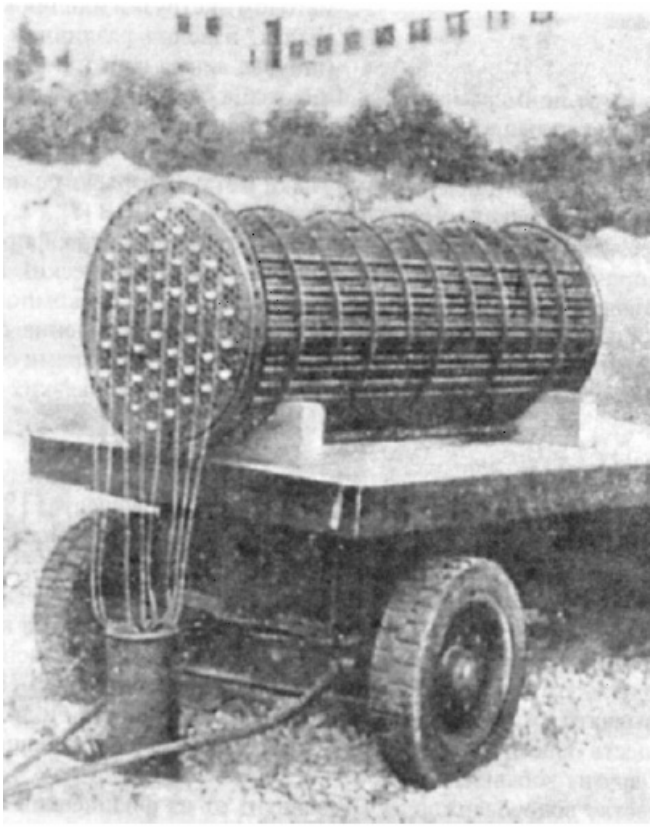

Fig. 2.

The power-saturated material from a hopper 1 through a loading unit 2 feeds into vibration mixer 5 equipped with a disbalance shaft 6. To the same mixer from a feeder (by volume) 3 is sprayed industrial oil. In the mixer the solid particles are covered by thin oily layer providing retardation, but the mixture remains friable. After completion the mixing process, through open ram 7 the friable mixture is passed into hopper 10 and then by vibrating feeder is passed into the unit for dozing by weight 11. Passing vibration screen 3, the friable mixture enters into the double spindle mixer 15 for stirring with plasticized polymer binder which feeds into the mixer from the feeder 14 dozing ratio by volume through filters 18. Into the feeder the polymer binder is loaded from alternately operating bunkers 4 via plunger pump distributer 8, volume pump 9 and ratio dozing feeder 12.

Before achieving the outlet of operating double spindle mixer the polymer binder and friable filler are transformed into homogenous two-component explosive mixture with a given ratio of components. In the auger unloading unit 16 the explosive plastic material is formed as separate blocks which are passed to loading unit of transporter 17.

Further the blocks are used for molding ware of different shape (cords, tapes, etc.) by, e.g., extrusion or rolling. As an example, Fig. 2 shows installation for rolling out tubes in the face lattice of a heat exchanging unit using cord charges of plastic explosive. Fig. 3 shows schematically cutting of metal by cumulative tape-shaped charges of plastic explosive.

Explosives containing nitric esters. The nitroester-containing (precaution) explosives ("Uglenit") are produced by two-step technology. Initially, friable components are mixed and hydrophobized by stearates. Final mixing of friable components with poorly gelatinized nitric esters is performed in a double blade mixers for plastic high-viscous materials [3].

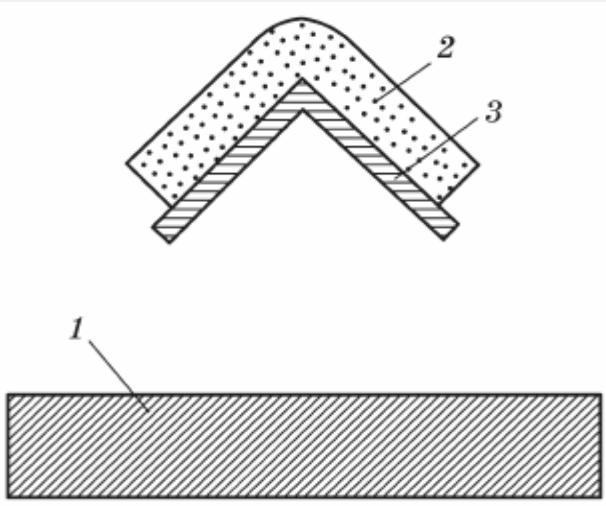

Fig. 3.

WATER-CONTAINING INDUSTRIAL EXPLOSIVES

Gel-like explosive mixtures. Basic idea in the technology of water-containing explosives consists in the use of saturated aqueous solution of an oxidizer (ammonium, potassium or sodium nitrate or mixtures of these compounds) as a continuous dispersion medium. In this water-containing composition is dispersed a mixture of friable material (TNT, alumotol, hexogen), combustible compound (aluminum powder), thickening agent (gel forming compound) and other additives.

Quality of the water-containing explowsives depends on their stability. Stability distortion appears as a stratification with formation of two layers leading to

unsteady detonation or even to failures. A reliable mean for stabilization explosives is introducing high-molecular thickening agents to increase viscosity of liquid phase.

Stabilization of water-containing explosives consisting of ammonium nitrate, granulated TNT and water can be achieved by introduction of 4% solution of carboxymethyl cellulose pure grade or 7% solution of carboxymethyl cellulose technical grade, and 1-2% of polyacrylamide [8, 10].

To provide stability of explosive containing 85% solution of ammonium nitrate as liquid phase its temperature should be below 68°C. For explosives with 80% solution temperature should be below 50°C. At lower temperature viscosity grows sharply. The lower temperature limit (critical temperature) is defined by pour point of the gel-like structure.

The method of keeping stability of gel-like explosives by maintaining optimal temperature is simply accomplishing: the required temperature of explosive mixture can be easily achieved by varying temperature of ammonium nitrate solution at mixing with solid components.

Among the most important parameters of gel-like explosives is considered their consistency, that is, content of solid phase by volume or weight. The system consistency defines explosive and technological properties of the gel-like explosives. It affects the explosion heat and power, the explosive mixture rheology (viscosity, shear stress yield), hydrodynamic parameters of transportation and thermal properties of the explosive.

Technological process of producing gel-like explosive includes the following principal phases [10]:

preparation of oxidizer solution,

preparation of solid friable components (TNT, granutol, alumotol and others),

preparation of combustible additives (aluminum powder),

mixing the components with binder to form gel-loke explosive or loading the components separately into mixing-charging device.

EMULSION EXPLOSIVES

All water-emulsion explosives contain high concentration solution of ammonium nitrate (sometimes with addition of sodium or calcium nitrate) and liquid petroleum product (Diesel fuel, industrial oil, mazut, etc.). The oxidizer solution heated to 60–90°C is dispergated and emulsified by adding small amount of a dispersing agent dissolved in the petroleum product achieving covering of each solution droplet by the petroleum product film.

Approximate composition of emulsion explosive components is as follows [8, 9], (wt %):

Ammonium nitrate	60–63
Sodium nitrate	16–19
Emulsifier	1–1.5
Oil (petroleum product)	7
Water	15
Nitric acid	below 0.3

The technological process of producing emulsion explosives is shown in Fig. 4 [8, 10].

The installation includes several modules: (1) preparing and loading oxidizers, including technological blocks for preparation water solutions of ammonium or sodium nitrate, the solution keeping and dozing; (2) preparing petroleum product, emulsifier and their mixture and the mixture dozing; (3) (additionally) the blocks for keeping and purifying cleaning sewers and the blocks of hydro-, electro- and pneumatic equipment; (4) preparing sodium nitrite and gas-generating additive (GGA); (5) emulsifying; (6) mixing-charging unit (MCU).

Preparing and loading oxidizer. Ammonium nitrate (GOST 2-85) from 60 kg bags in a treading down unit with a screw (auger) conveyers is loaded alternatively to one of dissolving units. Sodium nitrate (GOST 828-77) when necessary is loaded into dissolv-

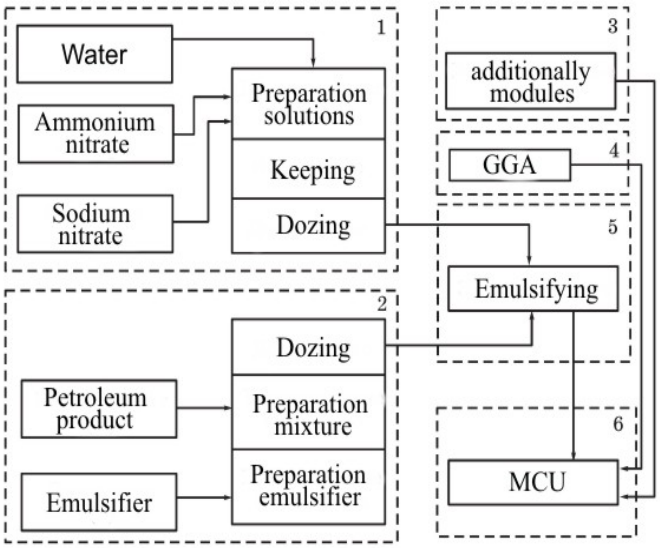

Fig. 4.

ing unit similarly.

A dissolving unit is vertical cylindrical receiver with a snake-like steam heater and equipped with a stirrer with electric motor. To the receiver loaded consecutively water by a pump up to required level and at working stirrer oxidizer (ammonium and sodium nitrate) in required amount. Then the mixture is stirred and heated until it achieves temperature 80ºC and required density, and thus prepared solution pumped into accumulating receivers. For preparing emulsion of commercial quality the solution of oxidizer(s) is passed to the module for preparing emulsion by dozing pumps.

Preparing petroleum product and emulsifier. A petroleum product (e.g., industrial oil, GOST 20799-88) from the receiver where it stored is pumped into mixing unit where it is heated to 40 – 70ºC. Emulsifier from a barrel is passed into the mixing unit uploaded by petroleum product by means of a sucking device which includes receiver and sucking pipe. If environmental temperature is below 10ºC, the barrel with emulsifier should be heated in a chamber.

To the mixing unit the petroleum product and emulsifier are pumped in a required ratio. The mixture is heated to 65–70ºC and stirred for a few minutes. From the mixer the petroleum product with emulsifier is passed by dozing pump into the module for preparing emulsion.

Preparation of solution of gas-generating additives (GGA). Sodium nitrite from 40 kg bags by screw transporter via inlet funnel is loaded into a dissolving unit filled preliminary up with water in required amount. Solution is prepared at the temperature 75–80ºC. The prepared solution of GGA is pumped into the bunker of mixing-charging device when necessary.

Emulsifying. To the mixer for preparing emulsion, solution of oxidizer and mixture of petroleum product with emulsifier are loaded continuously through dozing units. The products are dispersed at 80–85ºC to achieve formation of emulsion of "water in oil" type. The emulsion obtained by a special pump is passed to a storage tank or directly to mixing-charging machine.

Loading material into mixing-charging machine. The mixing-charging machine has tanks for filling it with hot water, GGA solution and emulsion. Loading emulsion is performed by pump in the emulsifying module or by gravity feed from storage tank. Filling with GGA solution is allowed also after loading emulsion. At low external temperature (below −10ºC) prior to loading material into the machine its tanks are heated by live steam.

As an example, Fig. 5 shows loading components of emulsion explosive into mixing-charging machine [8]. The final explosive mixture is formed directly in a bore hole.

TECHNOLOGY OF INDUSTRIAL EXPLOSIVES IN MINES AND OPEN PITS

Methods of producing plastic explosives. Water-containing and simplest explosives can be produced applying one of the following technology: (i) in a plant with packaging; (ii) in a stationary installation near a mine, an open pit, a well, with transportation of prepared mixtures from a charging machine to the place of blasting; (iii) separate transporting of the explosive components to the place of blasting, preparing the ex-

Fig. 5.

plosive mixture in a movable mixing-charging machine and charging.

The first method does not allow change the mixture recipe in a wide range, expensive and dangerous. The water-containing gel-like explosives made in a plant and used for charging bore hole under pressure are often more diluted and more sensitive, otherwise they are rather difficultly pumped through a hose into the bore hole. The sensitive explosive are transported by common roads without a binder, the latter is added prior to charging into bore hole for providing required viscosity and avoiding the slurry stratification at the charging.

By the second technology, the industrial explosive is produced near the user in a small scale mobile modules. The modules include chemical laboratory, tanks for saving the explosive components, a rolling train for preparation of the explosive (crushers, sieves, dozers, mixers), and are completed as a rule by the means for transporting explosives to the place of blasting. Such mobile modules allow easier varying content of explosive depending on the user query and conditions of blasting. For scaling up, an additional module line can be assembled in such a mini-plant.

The third technology is much more useful and safe, because not an explosive, but its separate components are transported. In a field work area near the pit is provided separate feeding the mixing-charging machine with friable components, nitrate solution (for emulsion explosives), emulsion gas-generating additives (for emulsion explosives), or by granulated ammonium nitrate and petroleum product or petroleum suspension with combustible material (for simplest industrial explosives of AN-DF type). The explosive mixture is formed only after mixing the ingredients and charging them into the bore hole.

Current statistics shows increase in consuming and extension of types of the explosives produced from nonexplosive ingredients near the blasting places. In 2001 their fraction was a half of all mass of the explosives consumed for blasting work [11].

TECHNOLOGY OF SIMPLEST INDUSTRIAL EXPLOSIVES

Producing of simplest industrial explosives, e.g., granulites and igdanites, includes a step of preparing ammonium nitrate and Diesel fuel or petroleum oil, and disperse combusting material (aluminum powder or alloys) [8,10].

Ammonium nitrate preparing consists in the operations of disclosing bags, sieving, crushing, loading into the saving bunker. For unpacking, a few types of devices are used:

vibration devices moving a bag with ammonium nitrate by oriented vibration and cutting by a knife,

rotating drums where the bag is moved through fixed knifes.

Simultaneously in these devices the granulated ammonium nitrate is sieved and crushed. The devices can also be used for preparing granulated explosives of TNT, granulotol and alumotol types and others.

Preparing combustible materials consists in the following. Tank of a hydrovacuum mixer is filled with Diesel oil and evacuated. The cans containing aluminum powder are disclosed and by vaccuum transport the aluminum powder is passed to mixer through flexible pipe. Then Diesel fuel and aluminum powder are circulated using a pump to formation of homogenous suspension with the fuel as continuous dispersion medium and solid aluminum as the disperse phase.

The final operation is mixing the components. The suspension is passed to auger mixer where suspension or fuel is sprayed over disperse particles of ammonium nitrate in the process of continuous mixing.

The process of producing granulits (igdanits) is monitored by measuring level of suspension (Diesel fuel) in the hydrovacuum mixer and by quantity of ammonium nitrate at its feeding from bunker into auger mixer and when necessary the quantity is controlled by a feeder slide bar driven with electric motor.

Complexes for producing water-containing explosives. The complex includes sections for preparing oxidizer solution and dry components, the line for preparing disperse metallic combustible additives, sections of charging and transportation [10].

Mixing-charging machines. For blasting in open pits are used charging machines for moving explosives from store into bore hole and mixing-charging machines for the transporting ingredients which are not explosive before mixing. In the mixing-charging machines the explosives are produced in the process of charging the bore hole.

The machines depending on the type of the used explosive are classified as working with explosives made of ammonium nitrate – Diesel fuel mixture and those working with water-containing explosives (gel-like or emulsion).

By the type of used explosive, all the charging and mixin-charging machines are classified into those

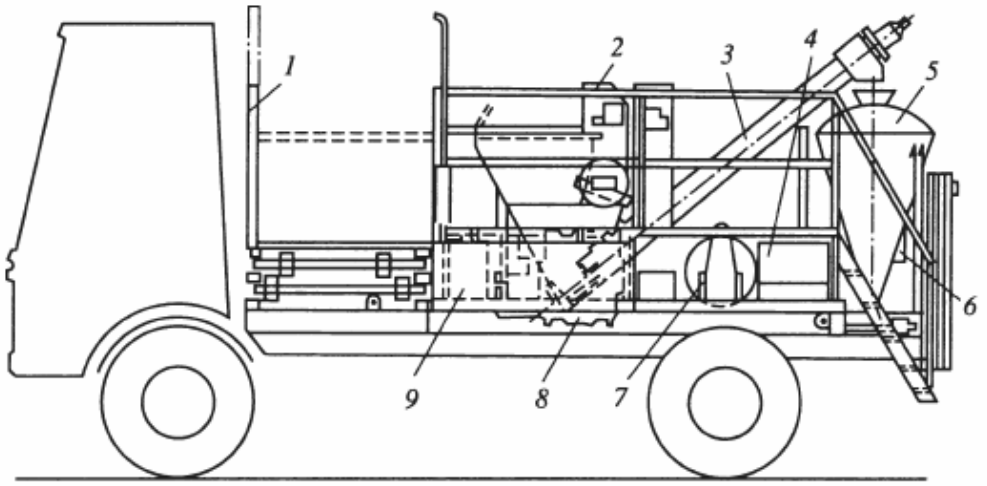

Fig. 6. "Emico" installation for preparation of AN–DF (ammonium nitrate – Diesel fuel) type explosives (1) lifting platform, (2) receiving container for ammonium nitrate, (3) auger loader, (4) system for Diesel fuel feeding, (5) charger, (6) control point, (7) compressor, (8) oil station, (9) hydraulic system.

working with explosives of AN-DF (ammonium nitrate – Diesel fuel) type and with water-containing explosives (gel-like and emulsion).

Mixing-charging machine for explosives of AN-DF type. By the method of feeding explosive mixture into the bare hole these machines are classified as pneumatic and auger type. Ingredients, e.g., ammonium nitrate and Diesel fuel placed to tanks in the process of charging are passed simultaneously into mixing chamber in a required ratio. The mixer is a chamber with sprayers spraying Diesel fuel at the moment when ammonium nitrate is feeding to the chamber by means of auger or vibrating transporter from the bunker through a closing device with hydraulic gear. Prepared mixture is passed into bare hole by compressed air or unloading auger.

The machine can be mounted on a trailer (Fig. 6) or as a stationary unit (Fig. 7).

Mixing-charging machine for explosives for water-containing explosives are based on the same principle of transportation of the non-explosive ingredients and saving them in separate tanks and bunkers. Feeding with the solid components is performed through feeders (auger or vibration type) with constant or controlled rate into a mixing unit. Feeding of liquid components is conducted by pumps.

For gel-like explosives of required consistency to the mixer is added binder. For emulsion explosives to the blending chamber is added sodium nitrite as a gas generating additive and dry components.

The most widely known suppliers of mixing-charging machines are the companies: Ireco hemicals (USA), Canadian Industries, Ltd. (Canada), African Explosives and Chemicals (SAR), Nitro Nobel (Sweden) and others. The machines as a rule are equipped with instruments showing consistency of explosive mixture, flow rate and consumption of explo-

sive. Control of the processes of blending, pumping, aeration, passing the mixture into bare hole is realized in automatic regime from electronic panel in cabin or in back part of machine. The machines allow varying ingredients ratio in the process of charging, forming charges differ by structure and programmable varying components ratio in the process of charging.

Additional details concerning charge-transporting and charge-mixing devices allowed for using in Russian Federation are described in [10, 11].

Abstract—For enhancing octane number and improving ecological characteristics of internal combustion engines nitrogen-containing compounds of amine class are applied. Although these additives are inferior to the additives based on iron and manganese organoelement compounds (iron dicuyclopentadienyl, manganese methylcyclopentadienyltricarbonyl and others), but superior to oxygen-containing additives (low alcohols, methyl tert.-butyl ether and alone and mixed with tert-butanol and others). The nitrogen-containing compounds are ashess addition agents, thus they are advantageous over the addition agents based on organometallic compounds. A significant advantage of these additives is polyfunctionality. Being effective enough antiknock agents, they also possess antioxidant, stabilizing and anticorrosive properties.
DOI: 10.1134/S1070427207070439

This work is denoted to:

–Elucidation of mechanism of amine action with various fuels in the combustion chamber,
–Comparative analysis of efficiency of different amines in dependence of their molecular structure,
–Revealing the possibility of prognosis of most effective compounds for application, not inferior and even superior to the well known antiknock agents as aniline and monomethylaniline.

The initial position proceeds from the statement proceeding from the theory of chain reactions that over the pistion the preflame reactions on the frontier in going from combustion to explosion and detonation of the combustion products develop too vigorously. This leads to accumulation of many radicals developing and branching the chain reaction.

Development of chains [1] in time $n(t)$ depends on the probability ratio of interrupting (b) and continuing (a) the chain. It is therefore naturally that in the fuel charge the process of increase in the reaction rate below the critical value is closely connected with the ratio of these probabilities:

$$n(t) = \frac{n_0}{a - b}\left(e^{(a-b)t} - 1\right), \qquad (1)$$

where n_0 is initial rate of generation of radicals.

It is naturally that in each group of fuel the process of growing of reaction rate to critical value is connected with own probability ratio.

For increasing detonation resistance of fuel it is necessary to introduce the additives trapping radicals, thus increasing probability of chain interruption, which leads to smooth process of combustion the fuel charge. That is, efficiency of an additive is defined completely by the value of probability (b).

Due to fast exponential accelerating and, respectively, decelerating reaction in cylinder, even small increase in probability (b) leads to sharp deceleration of the process and respectively to increase in duration of growing number of radicals $n(t)$ in (1) to critical value (Fig. 1).

From relation (1) follows and in Fig. 1 is seen that in very beginning of the chain process of chain propagation the concentration of active radicals $n(t)$ is proportional to time and rate of increase in reaction rate to critical value depends significantly on the initial, start-up concentration of radicals n_0. Start-up radicals appear in the fuel charge spontaneously as a small portion of active high-energy particles in Maxwell distribution, or are created artificially, e.g. at illumination in photochemical processes.

The authors of out-of-engine express-method of estimation of octane number [6, 7] established experimentally that induction period of spontaneous ignition well correlates with octane number and symbasic cor-

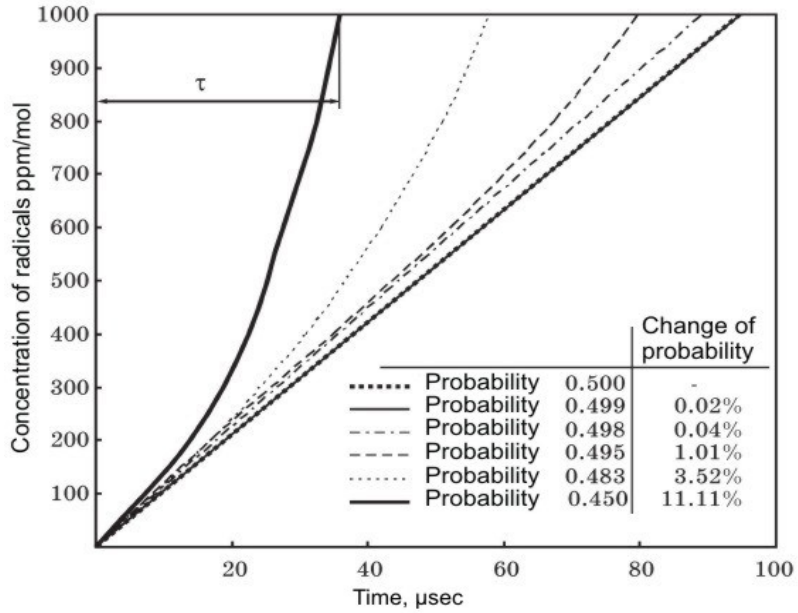

Fig. 1. Increase in radical concentration plotted against probability of chain break.

relation of these parameters is valid.

From relation (1) for short time period can easily be found connection of spontaneous ignition induction period τ and start-up rate of radical generation n_0.

$$E\tau = \frac{C}{n_0}, \quad (2)$$

where C is critical reaction rate at ignition, individual for each engine.

This indicates opposite correlation, now between induction period and n_0 value, and, eventually, similar correlation between octane number and n_0.

Thus, twice-triple increase in start-up generation rate (n_0) leads to reciprocal decrease in time of increase reaction to critical. This explain physical sense of octane numbers for various fuels. Increase in start-up rate of generation of radicals (n_0) is connected directly with shortening in time for achieving critical combustion rate which defines decrease in octane number of a fuel.

Further we have to classify fuels in correspondence with experimental data on the effect of amines on octane number. By this parameter three groups of fuel can be distinghished:

(1) fuel with octane number 86–90 relates to group I with low initial value n_0,

(2) fuel with medium octane number value 60–70 relates to group II characterized by n_{02} value,

(3) fuel with very low octane number 42 relates to group III characterized by large n_{03} value.

As is known, active particles in the process of combustion are atomic hydrogen, hydroxyl radical, hydrogen peroxide, various hydroperoxides and others. All these kinetical units either activate combustion by acceleration spreading of the flame front or lead to chain propagation and branching. The introduced additives should serve as traps for these units.

Relation (2) corresponds to correlation between additive-free fuel. In the case of additives, their influence on octane number should be taken into account. It can be made by taking into account three terms in expansion of exponent into a series, which shows the following relation between induction period and characteristics of radical, namely start-up rate of their generation n0 and probabilities of chain interruotion:

$$\tau \gg \frac{2}{a-b} + \frac{C}{n_0}. \quad (3)$$

Here a and b are probabilities of chain propagation and interruption, respectively.

This relation differs from (2) by appearance of a new term and it has transparent physical sense. First, it does not depend on conditions of combustion in the engine. Second, it characterizes only the radical and only the additive which we introduce to the fuel.

The additives increasing value of probability (a) are promoters of combustion, they decrease τ and hence decrease octane number. The additives increas-

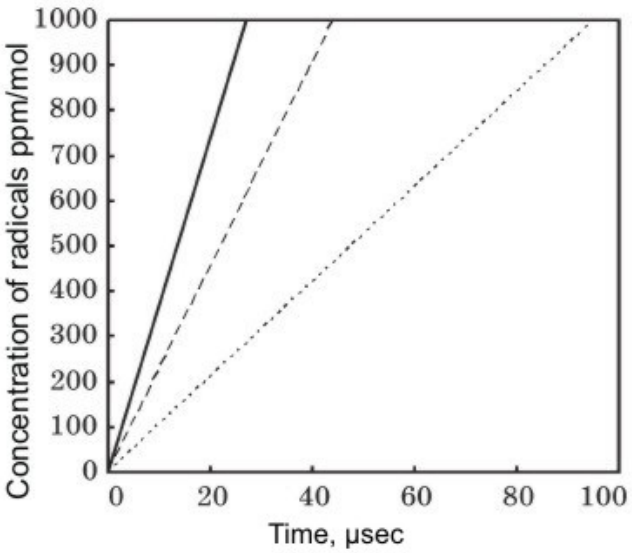

Fig. 2. Time shortening for achieving critical rate of radicals formation at decrease in the fuel octane number and, respectively, of increase in start rate of their generation, $n_0 = 10$, $n_{02} = 20$, $n_{03} = 30$.
.···· Start generation rate n_0,
- - - - Start generation rate n_{02},
—— Start generation rate n_{03}.

ing value of probability (b) increase induction period τ and eventually increase octane number.

Thus, the situation is simple in the case of model fuel (mono-fuel, for example pure heptane or pure isooctane). In a practical case the fuel consists of a complicated mixture of hydrocarbon fractions differ by nature. Thus at combustion of such mixture of hydrocarbons the ingredients convert with different rates, and integral experimental induction period is defined by the rate of "leading" reaction; in a process can be a few such reactions. In such a case the effective induction period is the sum of partial ones:

$$\frac{1}{t} = \sum_i \frac{1}{t_i} \quad . \tag{4}$$

Following to the idea in [6] we can say that if octane number in linear approximation is in line with induction period, it can be represented by the following relation:

$$ON = Kt = \frac{K}{\sum_i \frac{1}{t_i}} \quad , \tag{5}$$

Where K is proportionality factor between induction period and octane number (ON), is partial induction period, I is number of start-up chain (n_{0i}).

As follows from experiments and from this model approach, regime of fuel combustion can be controlled by both selection of hydrocarbon composition of the fuel and intoductio of antiknock additives.

Now, going back to influence of amines on the fuel combustion we have to note that mechanism of this process is defined by the effect of additive on the radical promoter. The additive "trap" for some time binds active radical and thus excludes it from the process. This is equivalent to increase in probability of chain interruption (b).

Our further consideration is based on the process of binding active particles by amines via electrostatic interaction or formation coordination and hydrogen bonds between amine hydrogen atoms aned oxygen atoms of hydroperoxides or between hydroperoxide protons and amine nitrogen atoms. An answer to the question "which bonds are more probable?" should be obtained from statistical correlation analysis.

Among whole array of amines (aliphatic and alicyclic, heterocyclic and aromatic) we have to select the most typical groups. As a first model approximation it is reasonable to consider two large groups differ by two typical structural attributes:

(1) primary amines,

(2) secondary amines.

Of course, such approach neglects fine physicochemical characteristics of these compounds, however, the further analysis will show that this is reasonable.

Let us consider influence of primary amines on the octane numbers of gasoline. Initial experimental data on primary amines are taken from publications [2–4]. All data on additives are recalculated and assigned to 2% concentration and normalized per mole. The datqa are listed in Table 1. Physico-chemical characteristics of some compounds were calculated using package of application programs ChemSiteSW [5] and also are listed in Table 1.

We consider the fuel of group II, for which there are many experimental data on octane number for individual compounds.

Increase in octane number for fuel with various amines as additives was attempted to correlate with certain molecular characteristics to find an approach to elucidation of mechanism of actions of amines. The following phenomenological correlations were attained:

–with molecular weight of amine (M), correlation

coefficient 0.911;

– with the value proportional to the rate of heat motion of molecules ($M^{0.5}$), correlation coefficient 0.907;

– with the value proportional to relative rate ($M^{0.5} - M_0{}^{0.5}$) of molecular motion of trapping molecule (amine) (M) and rate of motion of active radicals (M_0) (hydroperoxides with molecular weight M_0=40) with correlation coefficient 0.907.

The uncertainty in the promoter molecular weight appears due to the fact that the process of combustion affords a spectrum of the chain propagating radicals. Therefore the M_0 parameter means a molecular weight averaged over all radicals involved in the process by the proposed mechanism.

The proposed methodology operates with a parameter which is proportional to relative rates of the molecules:

$$\frac{1}{\sqrt{M_0}} - \frac{1}{\sqrt{M}}, \qquad (6)$$

where M_0 is molecular weight of promoter molecule, M is that of amine molecule.

For the most typical amines we performed correlation analysis for elucidation of the most probable representative among all possible promoters. From publications [7, 8] is known that as the promoters can be considered O–, HO–, H_2O_2, CH_3OOH and others, with their molecular weights M_0 = 16, 17, 34, 48 and higher. For all the array of amines for the fuel of group I we varied M_0 value with increment equal to 4 and calculated correlation coefficients. The results obtained showed (see Fig. 4) that correlation coefficients fall to a wide bell-shaped curve with the maximum in the region of promoter weight equal to 42. Hence it can be concluded that at combustion of this group fuel in the fuel charge occur pre-flame chain processes with all abovementioned compounds as promoters, but statistical weights of hydrogen peroxide and methane hydroperoxide, 34 and 48 respectively, predominate over all others.

Thus, the analysis shows that it is most probable that amines capture hydrogen peroxide and radical of methane hydroperoxide. The mechanism of amine effect thus consists in appearance of H-bonds between amine hydrogen atoms and peroxide oxygen atoms.

It seems reasonable to assume that the probability of chain breaking is the probability of the process of creation a bond between the molecules moving relatively to each other, and it is higher when the rate of relative motion is lower and the contact period is longer, $L/(M_0^{-0.5} - M^{-0.5})$. In a first approcimation it can be defined as a quotient at dividing molecule size (L is maximal diameter) by their relative motion rate.

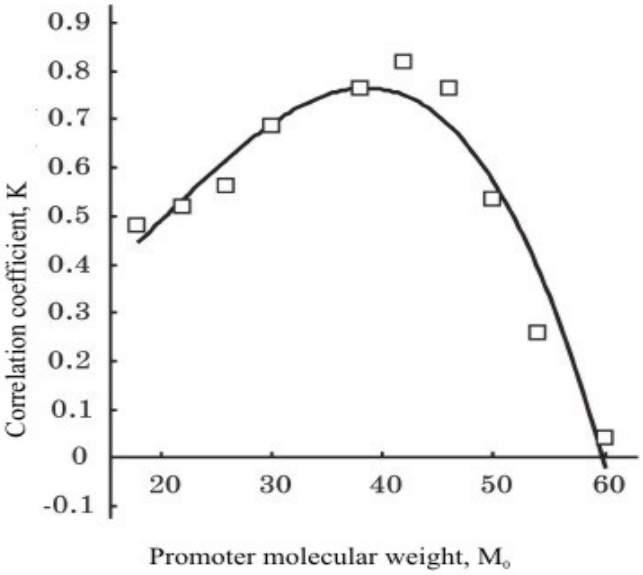

Fig. 3. Correlation coefficient plotted against the promoter molecular weight.

The molecule sizes are calculated by means of ChemSiteCW program. For the reaction proceeding is necessary realization of both imperative and adequacy conditions, respectively saturation of chemical bonding and steric conformity. The active zones of reacting molecules should coincide: a reagent molecule has to not only reach its partner, but also turn to it by active site. Therefore the process is expected to correlate clearly with the rate of rotation of molecules. This value is reciprocal to squire root of the molecule inertia moment ($M^{05}R_{g1}$). Actually, analysis shows that such correlation occurs, with correlation coefficient 0.862.

For the considered series of amines this is not surprisingly, but this factor will be shown to be very important in the case of diamines.

Above correlations show that the most active amines are those with the highest negative charge on nitrogen atom or, respectively, highest positive charge on the amine proton. Therefore for elucidation of the hydrogen bonds really involved in the process it seems reasonable to consider correlation accounting for these charges. Fig. 4 shows dependence of increase in octane number on contact period multiplied by the value of charge on the amine hydrogen atom.

Similar correlation analysis was carried out for the

charge on nitrogen atom. Here also occurs good enough correlation with coefficient equal to 0.918.

Comparison of the correlations allows to conclude that probably for this series of amines the most significant are hydrogen bonds between amine protons and peroxide oxygen atoms.

As to sequence of positions of the additives in toluidine series (3*, 4, 5, see Table 1), it can be simply explained by stability of molecule rotation around main inertia axis which is directly related to the molecule inertia moment $J=2/5\ M\cdot R_{g2}$ (the ball inertia moment). Rg is so-called inertia radius, a parameter in a program which puts ball with radius R_g in correspondence to the real molecule with the same inertia moment.

The higher inertia moment, the more stable motion of molecule in space. Among toluidine isomers (see Table 1), from R_g values follows that ortho-isomer (5) owing to its low symmetry moves in space the most irregularly.

Similar situation occurs in xylidine series (Fig. 5).

Comparison of correlations allows to conclude that probably in this series of amines is significant the appearance of hydrogen bonds between amine hydrogen and peroxide oxygen atoms.

The fuels of group I (octane numbers 86 to 91) were also tested on similar correlations, and expected correlation was actually found for this large group of amines.

Among the features of the studied group of amines we note, first, that fuel with high octane number show small increments of octane numbers, in correspondence with the proposed mechanism: at high octane number and, respectively, low n_0 values the bimolecular reaction rate of trapping promoter falls down. This situation lowers effect of adding additional quantity of additive.

Further, considering monoamines for the fuel of II group, they were compared also with diamines. Naturally, the diamines found more active and they fall well to the proposed correlation. This group includes the amines with rather wide spectrum of molecular weight and thermal motion rates. By the same methodology we correlated octane number increments with:

–molecular weight M, correlation coefficient is 0.271,

–rate of thermal motion (from the mas $M^{0.5}$) , correlation coefficient 0.213,

Further correlations accounting for:

–relative motion rate $M_0^{-0.5} - M^{-05}$, correlation coefficient 0.213,

–contact period $L/(M_0^{-0.5} - M^{-05})$, correlation coefficient 0.233,

–contact period multiplied by amine proton charge (Fig. 4), correlation coefficient 0.797 showed significantly improved correlation.

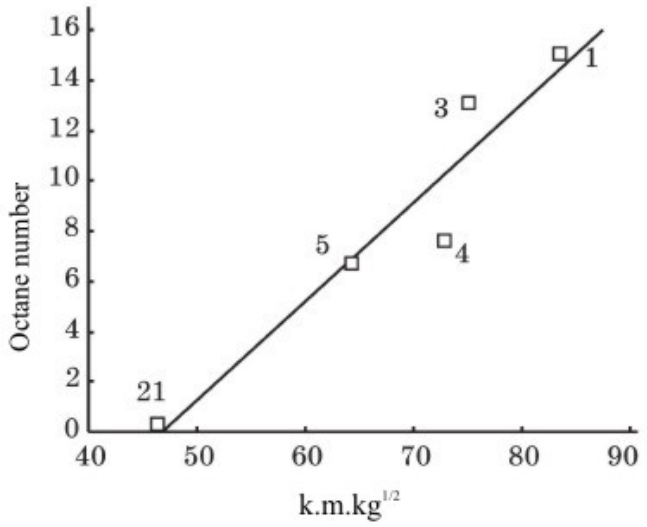

Fig. 4. Correlation of octane number gain with the charge on the amine proton multiplied by molecular contact duration for the radical C_2H_5COO – with molecular weight $M_0 = 61$. Points in the diagram correspond to numbers of the amines in Table 1. Correlation coefficient K = 0.969.

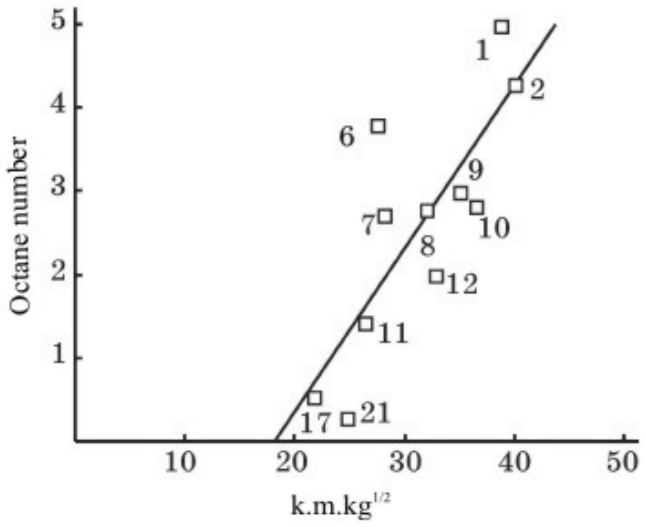

Fig. 5. Correlation of octane number gain with the charge on amine proton multiplied by molecular contact duration, $M_0 = 48$. Correlation coefficient K = 0.818.

Accounting for the charge on nitrogen atom leads to significant loses in correlation. This fact again confirms the statement that the main role in binding "bad" radicals in pre-flame processes play the hydrogen bonds between amine protons and peroxide oxygen atoms.

Consideration of symmetry allows setting xylidines in a sequence by efficiency. Here the situation is quite different compared to toluidines. Actually, the inertia moments of xylidines fall in in correspondence with R_g values in the order *meta* → *para* → *ortho*, thus defining their positions by increase in octane number.

The correlation shown in Fig. 4 shows that amines with large charge on the proton are comparatively more efficient. This statement seems to be not obeying by diamines which compete successfully with amines while possess less charge.

This inconsistence is avoided when steric factor is taken into account. To enter in a reaction, the reagent should occupy certain steric position at the partner, that is, the molecule has to be turned. The correlation shown below just is for such a case. The turning rate or rotation frequency is reciprocal to its inertia moment, therefore for such symmetrical molecules as diamines the statement is true that thy should not turn around not completely, but by half turn only. Formally this means twice increase in rotation rate, thus contact duration or charge increases by squire root of two.

This consideration explains anomalous "castling" of diamines, as shown in Fig. 6where correction of diamine rotation rates sharply improved correlation to the coefficient 0.887. Even more, when unsymmetrical ortho-xylidine molecule (12) is excluded from the data array, the correlation achieves to coefficient value 0.95.

In this array of amines another notable situation concerns ethylene diamine. Similar correction of ethylene diamine rotation frequency does not improve correlation, and therefore it was considered without taking into account its bifunctionality.

For $M_0 = 48$ (methane hydroperoxide) the correlation coefficient fall down to 0.483. Thus, the resilts of correlation shows that it is better conforms to the assumption that amines capture pure hydrogen peroxide rather than alkylhydroperoxide radicals.

Using the data of [4] we analyzed fuels with octane number 91.5 with the following amines as additives: aniline, methylamine, ethylamine, isopropylamine and *n*-butylamine in concentration 0.1 mol. For the group of the amines we also performed correlation analysis

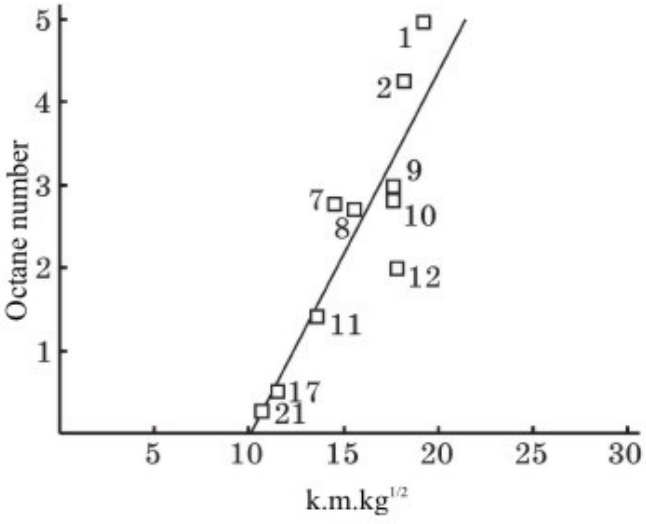

Fig. 6. Correlation of octane number gain with the charge on amine proton qH multiplied by molecular contact duration at relative rotation ($R_g\,{}^1M_0^{0.5} - R_g\,{}^1M^{0.5}$) for molecular weight $M_0 = 34$. Correlation coefficient 0.887. Points in the diagram correspond to numbers of the amines in Table 1.

for elucidation nature of promoters. We varied M_0 values with increment 4 withinnthe range from 16 to 68 weight units and calculated correlation coefficient. The results are shown in Table 7.

Consideration of correlation coefficient in dependence on the promoter molecular weight shows 4 maxima at M_0 = 16, 36, 48, and 64. These data with correlation coefficient 0.976 shows that we most probably deal with atomic oxygen or hydroxyl radical. With low statistic weight into the pre-flame processes can also be involved pure hydrogen peroxide and higher peroxide radicals. In this case also correlation of gain in octane number in dependence on charge on the amine proton multiplied by duration of molecular contact $\delta q \cdot L/(M_0^{-05} - M^{-05})$ shows correlation coefficient 0.885 and it is much better than correlation with the charge on nitrogen atom.

Comparison of correlations allows for this fuel group also conclude that or this series of amines significant are hydrogen bonds between amine protons and peroxide oxygen atoms. The correlations obtained (Fig. 8) lead to one more conclusion: the correlations are improved when M_0 value is taken equal 17 (which corresponds OH radical). The correlation coefficient is maintained on the level 0.885 for amine proton and 0.951 or 0.714 for nitrogen atom. When $M_0 = 34$ (hydrogen peroxide), then correlation coefficient falls down to complete absence of any correlation, k = 0.042.

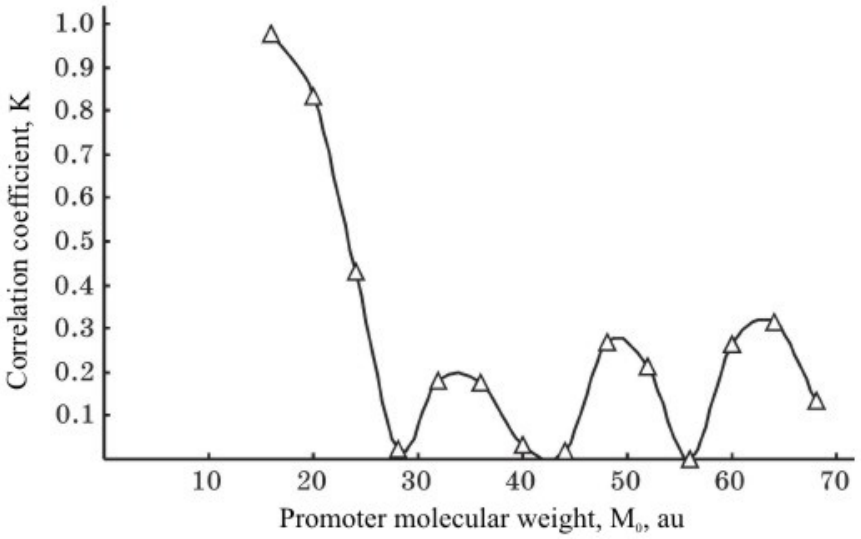

Fig. 7. Dependence of correlation coefficient on the promoter molecular weight.

The possibility of same mechanism of additives influence was tested for secondary amines. All required properties of the amines are listed in Table 2 [2–4]. By above considered methodology was revealed correlation for the fuels of group I at the adding amines.

Correlation of gain in octane number with amine proton charge multiplied by contact duration showed much lower correlation coefficient, for M_0 = 34 it was 0.541 only. Here interesting to note castling of t-butylfurfurylamine and piperidine. In the first compound the charge on proton is much lower, but structure of its molecule shows a feature: nitrogen atom and oxygen of keto group are close together, the distance is approximately corresponds to the length of hydrogen peroxide molecule. This fragment of the molecule can bind hydrogen peroxide molecule by two hydrogen bonds simultaneously: between peroxide proton and ketone oxygen and between the amine hydrogen and peroxide oxygen atoms. That is, this amine is bifunctional one.

The amines listed in Table 2 were added to the fuel in concentratiion 0.1 mol. The results of correlation alongside the abothe methodology showed that the best correlation coefficient is attained with hydrogen peroxide, M_0 = 34. In other words, the trapping compounds bind better hydrogen peroxide.

To a conclusion we note that we failed to explain high efficiency of dimethyl-*t*-butylamine which has anomalously low charge δq = 0.046 in the framework of the proposed mechanism. A feature of this molecule is its branched structure. In [7] with moderfuels was studied the process of pre-flame oxidation of a mixture of linear (*n*-heptane) and branched (isooctane) hydrocarbons and it was found that branched hydrocarbon under the conditions of pre-flame temperature does not oxidize due to its higher temperature of oxidative cracking. In a direct experiment was established that adding isooctane to n-heptane leads to proportional decrease in the tempera-

ture for the mixed fuel. This can be considered as dilution of reactive *n*-heptane with chemically inert under same conditions isooctane. Thus isooctane in this case plays the role of inhibitor of pre-flame oxidation process. In [9] also was considered difference between *n*-heptane and isooctane which have polar values of octane number. Here chemical passivity of compact branched molecules is explained with low value of collision section and hence the pre-exponential factor in the rate constant of chemical reaction much increases.

It may be therefire concluded that brancged molecules practically are not involved into pre-flame oxidation processes due to both high activation energy and low pre-exponent in the reaction rate constant. Probably the considered tertiary amine wirks by this mechanism. By the mechanism of formatinon of hydrogen bonds it can not work at all because it does not possess labilehydrogen atoms in its molecule. Affecting octane number by dimethyl-*t*-butylamine is probably connected with local decrease in temperature and therefore by decrease in the initial rate of generation chains of radical promoters n_0 [see (3)–(5)].

Similar correlations were calculated for the fuels of group II. Fig. 9 shows correlation of gain in octane number with charge on amine proton multiplied by contact duration for molecular weight of hydrogen peroxide M_0 = 34. As seen from Fig. 9, the proposed mechanism as not bad for this case also.

SUMMARY

1. A well-founded mechanism of action of amines as additives to fuel for motors with spark ignition.

2. A procedure for analysis of comparative efficiency of various nitrogen-containing additives working alogside tis mechanism is proposed.

3. The regularities established and appearing exclusions can be naturally explained on the basis of consideration fine features of molecular dynamics, structure and properties of the amine molecules.

4. The correlation analysis is performed that allows to conclude that the most probable promoters are hydrogen peroxide and hydroxyl radical, and the amines are the traps just for these promoters.

Abstract—Features of fractionation of reaction mixture in the synthesis of ethylene glycol by hydration of ethylene oxide in a reaction-rectification column are studied. Adequacy of the mathematical model applied to the process is evidenced. The ethylene glycol purity is shown depending on the process chemistry mainly. Side reaction of polyglycols formation restrict obtaining of high purity ethylene glycol: it can be isolated only as sideway stream in the bottom section of the reaction-rectification column.
DOI: 10.1134/S1070427207070440

The most widespread method of manufacturing ethylene glycol is direct hydration of ethylene oxide according to the reaction:

$$C_2H_4O + H_2O = HO–C_2H_4–OH, \quad (1)$$

Simultaneously with the main reaction occur side reactions of glycols with ethylene oxide resulting in formation of diethyleneglycol

$$C_2H_4O + HO–C_2H_4–OH = HO–C_2H_4–O–C_2H_4–OH, \quad (2)$$

trietyleneglycol

$$C_2H_4O + HO–C_2H_4–O–C_2H_4–OH = HO–C_2H_4–O–C_2H_4–O–C_2H_4–OH, \quad (3)$$

and tetraethyleneglycol

$$C_2H_4O + HO–C_2H_4–O–C_2H_4–O–C_2H_4–OH = HO–C_2H_4–O–C_2H_4–O–C_2H_4–O–C_2H_4–OH. \quad (4)$$

For depressing side reaction, the process is performed commonly in liquid phase at elevated temperature (ca. 200°C) and pressure (1.5–2 MPa) with water excess [1].

Technological scheme of the process is enough cumbersome. Besides reactor it includes three evaporation units for removing water excess from the reaction mixture and a block of rectification columns for removing admixture of di-, tri- and tetraethylene glycols from the product to achieve commercial quality. In this process all components except tetraethylene glycol are consecutively evaporated and condensed except; tetraethylene glycol is outlined from the bottom of the last column as liquid phase [1].

In the recent years interest to development of reaction-rectification units [2–4] joining chemical process and separation of products formed has markedly increased. This method gives rise to simplification of technological scheme of the process which allows to decrease basic investment for the facility construction and optimize the whole process [5–11]. The reaction-rectification columns can be also used in such technological processes as esterification, hydrolysis, oxidation, alkylation, isomerization and others, where chemical step proceeds in the temperature range of the components boiling points on the several contact mass exchange units in the column [2], in part, in the process of manufacturing ethylene glycol.

A feature of operating a reaction-rectification column at the ethylene glycol manufacturing is the necessity of circulation of water excess at the practically complete conversion of ethylene oxide [12–14], that is, top part of the column should work eventually in the regime of complete reflux for enhancing fractionation efficiency.

For the investigation of features of reaction-rectification column operating at the ethylene glycol manufacturing, we developed mathematical model of the device.

PRINCIPLES OF MODELING

As a basis for the model of reaction-rectification column we used a model of rectification process in a complex composed column which is equal to a set of simple columns [15]. At the developing this model we provided inlet of raw material to each theoretical plate and partial or full withdrawing vapor and liquid phases from the plate after mass exchange. These phases are passed out as final products or introduced as raw material on the other plates of composition column (Fig. 1, *a*). Such structure of the model allows simultaneous calculation of the system forming basis for optimization whole system. The model of theoretical plate for application to the considered problem is supplemented by blocks of mixing streams of raw and circulating materials and blocks for calculation of chemical process on the theoretical plate bearing simultaneously the function of reaction unit (Fig. 1, *b*). In such a case it is possible to withdraw reflux (which contains circulating water mainly) from an upper plate, mix it with raw material (ethylene oxide) and water stream, perform chemical reaction and separate reaction products on this reaction plate and on all other fractionating plates of the column. Therefore in the calculation of column two methods are joined: analysis of static fractionation on a theoretical plate providing determination of quality of products after separation in the vapor-liquid system via mass exchange, and analysis of kinetics of the chemical process on the reaction plate which allows determination of the contribution of components into composition of reaction mixture and time necessary for determination of acceptable deep of conversion of the raw material. This mathematic model was adapted to the synthesis of glycols by hydratation of ethylene oxide.

At the development of mathematic model of reaction-rectification column the following assumption were accepted:

– Hydrodynamics of contact unity is described by the model of ideal displacing,

– Average relative volatility of the separated components of the mixture in respect of reference component is taken constant along the column height. As the reference component is taken ethylene glycol, as board component of fractionated mixture: along the column, water with some admixture of organic compounds moves up, ethylene glycol containing some water and higher glycols, the products of side reaction, moves down.

The mathematic model of reaction-separation process on a contact unit consists of three blocks: mixing block, block of chemical reaction kinetics, and block of steady state rectification.

The model of mixing block of raw material with circulating water (reflux) in amounts corresponding to

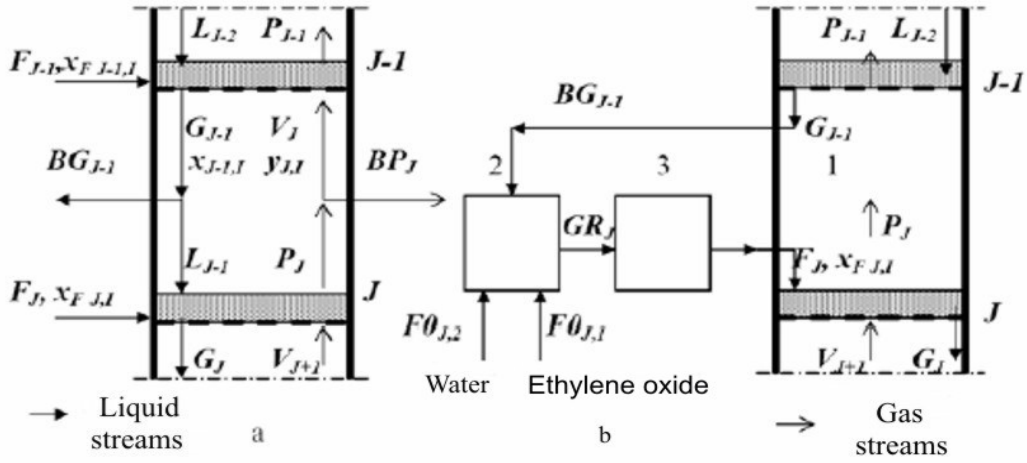

Fig. 1. Block-scheme of streams at the calculation of reaction-rectification column. (a) rectification zone, (b) reaction-rectification zone: (1) fractionating part, (2) mixing of raw material and circulating water streams, (3) reaction part.

overall balance incoming from the upper plate and containing small admixture of all other components, with definition of amount for each of six components (ethylene oxide, water, athylene glycol, diethylene glycol, triethylene glycol and tetrathylene glycol) incoming into reaction block, is performed as material balance equations for each component.

The model of reaction block is a system of differential equations accounting for influence of hydrodynamic situation on the kinetics of chemical process on each component of reaction mixture.

Reaction rate constants K_M is performed according to Arrhenius equation:

$$K_M = K_{M,0}\exp(-E_M/RT), \quad M = 1, 2, 3, 4, \qquad (5)$$

where $K_{M,0}$ is preexponential factor, E_M is activation energy for M-th reaction, T is the process temperature, R is universal gas constant.

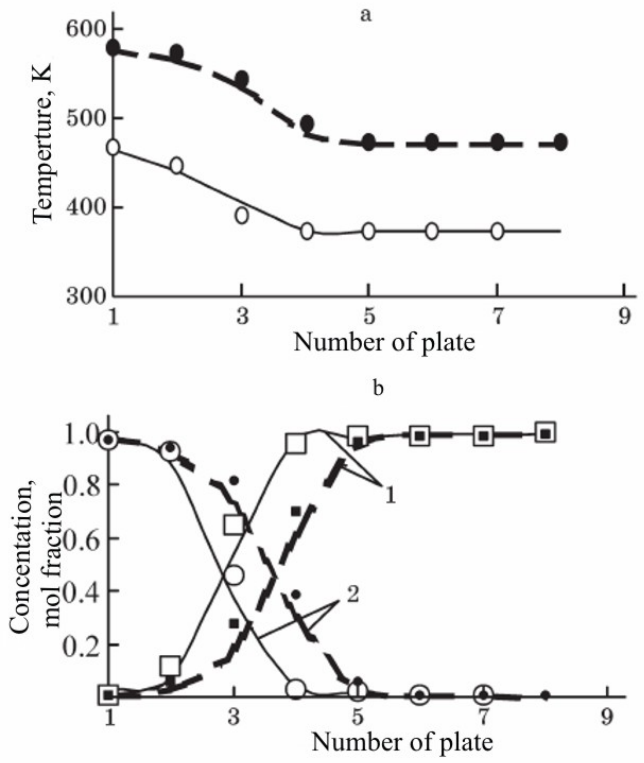

Fig. 2. Variations in temperature (a) and concentration (b) of ethylene glycol (1) and water (2) along the plates of reaction-rectification column (numbering from top to bottom). *Solid curves* – calculation according to the model at the pressure 0.1 MPa, *dashed curves* – calculation according to the model at the pressure 1.5 MPa, *dots* – data of [16].

The values of $K_{M,0}$ and E_M for the reactions (1)–(4) are taken according data of [1].

As a result of calculations of reaction block the quantity was determined of reaction products incoming on the corresponding theoretical plate for the separation of water and ethylene glycol containing admixtures of di-, tri- and tetraethylene glycols.

The model of rectification steady state assumes determination of the mixture composition on a plate after mixing incoming raw material (reaction mixture) with the streams of vapor and liquid incoming from neighboring plates placed below and above, calculation of the fraction of initial mixture outgoing as vapor, determination of the value of phase equilibrium constant of reference component (ethylene glycol) necessary for providing attaining of the given outgoing fraction on the theoretical plate, followed by calculation of composition of the equilibrium streams of liquid and vapor phases and their temperatures.

Calculation of chemical step of the process was performed by the first order Runge–Kutta method with obtaining the kinetic plots on all components of reaction mixture and determination of time for attaining maximum yield of ethylene glycol.

Calculation of rectification step is performed by relaxation method, the task was solved assuming filling the column with pure water as initial conditions. Starting data for the calculation include number of theoretical plates, molar streams of vapor moving up from each plate, positions of raw material inlet, the raw material quantity and composition. Algorithm of the task solution is featured by fast convergence (one variant of the column work takes 102 h for solution) with providing high accuracy of the calculation (one step of integration in calculation chemical step of the process consumes 0.0001 min at the reaction duration 1.5 to 0.5 min, equilibrium constant in the calculation of rectification steady state is calculated with accuracy 0.00001). Calculation is completed when in two consecutive iterations the difference in composition of vapor and liquid on all plates of the column was 10^{-8} mol fraction. For estimation of reliability of the mathematic model we compared results of calculation of manufacturing ethylene glycol alongside reactions (1)–(4) in the reaction-rectification column in the regime of complete reflux with the data obtained in [16] where besides the principal reaction (1) was taken into account the side reaction (2) only, with practically the same starting data (Table 1). As follows from Fig. 2, acceptable coincidence of temperature and concentra-

tion of water and ethylene glycol profile along the column is obtained which attests adequacy of the static-kinetic model of reaction-rectification column.

RESULTS AND DISCUSSION

Preliminary calculations [12–14] showed that solving the task of performing controlled synthesis of ethylene glycol in a reaction-rectification column achieving low content of higher glycols in the reaction mixture and in residue is possible only under conditions of significant increase of water to ethylene oxide ratio in the raw material and, respectively, in the reaction mixture. For example, ethylene glycol concentration in the residue after complete removing water from it can be 0.97–0.99 mol fraction at the water:ethylene oxide ratio in raw material (30 to 100) : 1. Thus, a significant feature in the reaction-rectification column operating is the presence in the device of water in much excess; ethylene oxide converts practically completely; there is necessity of water separation from organic compounds. For estimation of the possibility to perform the process in the reaction-rectification column with obtaining highly pure ethylene glycol, we considered a series of modes of the column operation:

1) Column top part works in the regime of complete reflux without withdrawing distillate at the circulation of water in the column; feeling the column with raw material (water and ethylene oxide) in stoichiometric ratio of components.

2) Withdrawing water as a distillate in amount corresponding to residue in mode 1, water excess circulates in the column, raw material (water and ethylene oxide) is introduced to the column in stoichiometric ratio.

3) Water excess is introduced partially with raw material and is withdrawing as a distillate.

4) Water excess is introduced whole with raw material and is withdrawing as a distillate; from the fractionation viewpoint the device works as a distilling off column.

5) The column top part works in the regime of complete reflux without withdrawing a distillate, water circulates in the column, raw material (water and ethylene oxide) are introduced in stoichiometric ratio of components in parallel streams onto two plates.

6) As distillate, water is withdrew in amount corresponding to residue in mode 1, water excess circulates in the column, raw material (water and ethylene oxide) is introduced in stoichiometric ratio of components, commercial quality ethylene glycol (liquid phase) is taken as the side outflow.

Quantitative characteristics of streams in the reaction-rectification column for consideration of basic modes of the column operation are listed in Table 2. In

all the considered modes the balance water – ethylene oxide ratio is taken equal to 90 : 1, which provides high concentration of ethylene glycol in the reaction mixture. When necessary for completeness of analysis of the problem, this ratio was changed, the number of theoretical plates and pressure in the column were also varied.

Varying water – ethylene ratio in the column working in the regime of complete reflux confirmed that owing to depression of side processes, the efficiency of whole process is enhanced (Table 3) and ethylene glycol content rises from 0.851 to 0.982 mol fraction at increase water – ethylene oxide ratio from 10 : 1 to 110 : 1, therewith it is sufficient to maintain water – ethylene oxide ratio 90 : 1. In the considered regime of the column operating, the raw material, water and ethylene oxide are introduced in 1 : 1 stoichiometric ratio on one of contact units (plate) in the medium part of the column, and mixed with reflux consisting of water with small content of admixtures. Here it enters to chemical reaction to afford ethylene glycol and small admixture of higher glycols. Thus, the process of rectification in the column in essence consists in separation of reaction products from circulating reflux.

A feature of the column working in the regime of complete reflux is virtual independence of quality of the obtained residue from the number of theoretical plates when the number of the plates is 5–6 or higher, because increase in the number of plates leads to formation on some theoretical plates of the peculiar region of constant concentrations where temperature and vapor and liquid compositions remain constant (Table 4). The pressure of vapor in the column does not affect practically efficiency of separation and relative content of glycols in the formed reaction mixture, but an increase in pressure leads to acceleration of chemical reactions which are completed within one – two real plates in the zone of raw material inlet. That is, we can assume that chemical transformation proceeds completely within one theoretical plate.

The variants of column working with complete reflux and as distilling column (Fig. 3) were analyzed with the purpose of diminishing water concentration in the residue, because in the regime of complete reflux it equals 0.008 mol fraction. The best results were obtained for the regime with withdrawing in the top of 0.1 mol of distillate, the water concentration in residue falls to 0.007, ethylene glycol content grows to 0.985 mol fraction (Table 5).

A possible way of diminishing the energy consuming in this process is replacement of discrete feeding the raw material to one reaction plate by distributing feeding over several plates in the column zone where change in the quality of reflux and vapor

Table 4. Dependence of temperature (T) and concentrations of water (x2) and ethylene glycol (x3) in liquid phase flowing down from plates of reaction-rectification column. Pressure in column 0.1 MPa, reflux to ethylene oxide (inlet on 3-rd plate) ratio is 90:1

streams does not practically occur (Fig. 1, e). In the opinion of Cardoso and co-authors [16] this allow to provide much lower reflux quantity while the reflux to initial ethylene oxide ratio in the column remains unchanged. For example, while at the discrete inlet of 100 moles of ethylene oxide, to provide reflux – initial ethylene oxide ratio 100 : 1 the needed reflux stream should be 10000 moles, the inlet of 100 moles of raw material distribution over 2 plates 50 moles on each the necessary reflux is reduced to 5000 moles, the reflux to initial ethylene oxide ratio remains 100 : 1, that is, energy consuming is reduced to a half. However, the ideas in [16] have not been confirmed by calculations or experiments. Therefore we considered a task of comparison the reaction-rectification column operating with discrete (Fig. 3, a) and distributed (Fig. 3, e) inlet of raw material into the column. Table 6 contains results of column calculation according these two regimes.

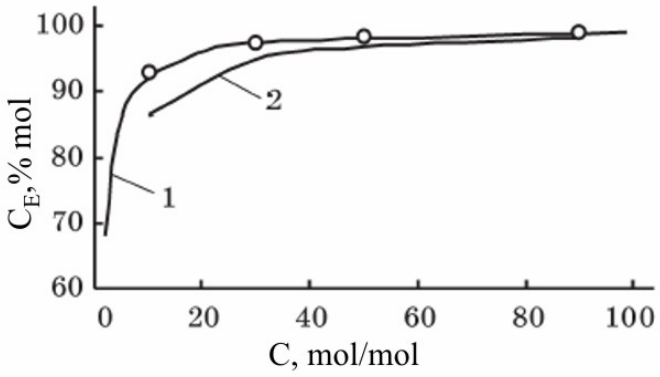

Fig. 4. Dependence of ethylene glycol concentration in residue (C_E) on the reflux to ethylene oxide ratio (C) at the pressure 1.0 MPa. (1) potential content of ethylene glycol in residue plotted against composition of reaction mixture on the plate with discrete inlet (C is water:ethylene oxide ratio); (2) calculated content of ethylene glycol after fractionation of reaction mixture on eight theoretical plates (C is reflux to ethylene oxide ratio); *circles* show potential content of ethylene glycol in residue after precise fractionation of reaction mixture (C is reflux to ethylene oxide ratio) for the curve 2.

first case we considered a possibility of three times reducing the consumed energy. In the second mode of calculation for the column with eight theoretical plates we presumed also a possibility of raw material inlet to third plate at the reflux – initial ethylene oxide ratio 10:1, equal distribution of raw material over five plates (third to seventh) providing real reflux to initial ethylene oxide ratio 50:1, and for comparison discrete inlet of raw material on third plate at the reflux – ethylene oxide ratio 50:1. The second regime would provide possibility of 5-fold energy saving.

The results of calculations (Table 6) show that discrete inlet of raw material does not provide expected energy saving because purity of residue on ethylene glycol at the distributed inlet of raw material is some below than at discrete inlet with the same actual reflux – ethylene oxide ratio. For example, at the actual reflux – initial ethylene oxide ratio 90:1 with discrete inlet of raw material on third plate the ethylene glycol concentration in the residue is 98.20 mol %, while distribution of raw material in equal portions over plates 3,4 and 5 it becomes 95.07 mol %, only slightly higher

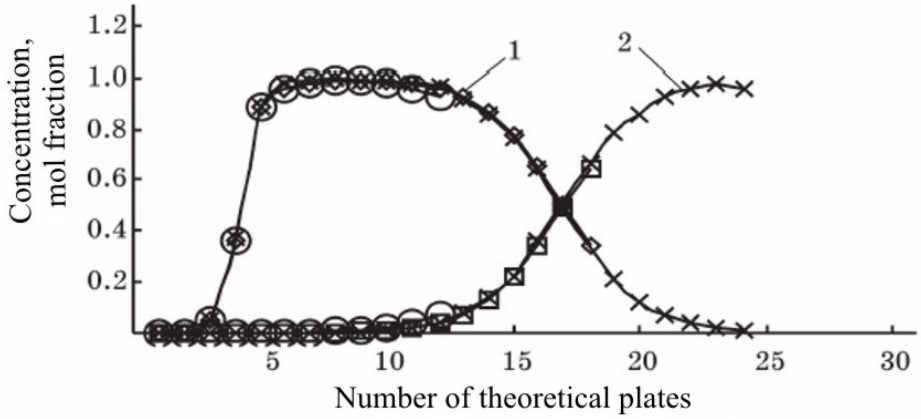

Fig. 5. Changes in ethylene glycol (1) and diethylene glycol (2) concentrations along the reaction-rectification column height at different numbers of theoretical plates in the device. Pressure in column 1.5 MPa, reflux to ethylene oxide ratio is 90 : 1, raw material inlet at third plate, ethylene glycol withdrawing from 8th plate at the total number of plates 12 (circles), and from 9th plate at 18 (rhombs) and 25 (crosses) plates in the column.

In the first mode we performed calculation of a column with 8 theoretical plates and considered discrete feed on third plate at the reflux to ethylene oxide ratio 30:1, equal distribution of raw material over three plates, the third, the fourth and the fifth, which provides real reflux – initial ethylene oxide ratio 90 : 1, and for comparison discrete feed at third plate with reflux to initial ethylene oxide ratio 90 : 1. Thus, in the than at discrete inlet and reflux to ethylene oxide ratio 30 : 1. When raw material is distributed equally over plates 3 to 7 with reflux to initial ethylene oxide ratio 50 : 1 the ethylene glycol content in the residue (86.1 mol %) is found not only below those at discrete inlet, but ever worse than at discrete inlet and reflux to ethylene oxide ratio 10 : 1. This situation can be explained by the fact that at distributed inlet the ethylene

Table 6. Influence of the method of raw material inlet on temperature (T) and concentrations of water (x_2) and ethylene glycol (x_3) in liquid phase (mole fraction) flowing down from plates of reaction-rectification column (pressure in the column 0.1 MPa) at different reflux:initial ethylene oxide ratios on the plate of raw material inlet

oxide feeding into another except first plate in the feeding zone (according to calculation, this is third plate) is contacted with the reaction medium on the plate which contains a considerable amount of ethylene glycol, which enters to the reaction with ethylene oxide affording diethylene glycol, thus yield of ethylene glycol on the fourth, fifth and next plates falls. As follows from data of table 6, content of diethylene glycol in the residue at the distributed feeding increases by factor 2–4 compared to discrete feeding, all other conditions are equal. Potential concentrations of ethylene glycol in residue (that is, at complete distilling water off from the residue) were obtained the same regardless the method applied for the estimation, by calculation either the process in the reaction-rectification column or composition of reaction mixture on a reaction plate (Fig. 4).

Thus, quality of residue at the fractionation of reaction mixture depends, first of all, on the completeness and quality of chemical process in the reaction zone of the device. Purity of ethylene glycol can be higher only if polyglycols are separated from it. This problem can be solved by withdrawing ethylene glycol from side outlet in the medium part of the column between the zones of raw material inlet and residue outlet (Fig. 1, *F*). The calculations show that purity of both side output and residue depends on the number of theoretical plates N between the feeding zone and residue outlet (Fig. 5). At N values 4, 9 and 16 plates the ethylene glycol concentration in side outlet equals respectively 0.987, 0.991 and 0.994 mol fraction, and diethylene glycol concentration in reidue is 0.069, 0.646 and 0.981 mol fraction, respectively. This allows producing ethylene glycol and diethylene glycol in one column containing 25 theoretical plates (Table 7).

CONCLUSION

1. By the method of mathematical modeling were studied various modes of operating a reaction-rectification column in a wide range of pressure and reflux to initial ethylene oxide ratio.

2. At the operating column in the regime of complete reflux the quality of obtained residue practically does not depend on the number of theoretical plates between the zones of raw material inlet and residue outlet where a ragion of constant concentrations is formed.

3. Discrete and distributed modes of raw material inlet into the reaction-rectification column for ethylene glycol producing is analyzed. It is shown that distributed inlet can not result in energy saving because quality of residue at fractionation of reaction mixture depends first of all on the completeness and quality of the chemical process realization in the reaction zone of device: distributed inlet leads to lower ethylene glycol

concentration in the residue as compared with discrete feeding.

It is shown that better quality of ethylene glycol can be achieved at withdrawing ethylene glycol from the medium part of column and diethylene glycol from column bottom part.

Received December 16, 2006

Abstract—By the method of Flicker Noise Spectroscopy (FNS) we studied the process of sodium chloride dissolving in water (3.5 wt %) at 294 K on the level of long-range order formation in liquid. It is established that the process of dissolving the salt includes the following steps: formation of instable colloid particles, instable solvate clusters of the salt ion pairs (iSCIP), instable dissolved polymers of globular type, and 12 h later beginning of a new process of formation stable solvate clusters of the salt ion pairs (sSCIP) and stable polymer globules on their basis. Stroke diagrams of the cluster nano-structure and a model of aging the salt solution are presented. Influence of atmospheric pressure on the SCIP average weight is demonstrated. It is concluded that on the SCIP surface there is a porous layer of solvate water with membrane properties. The cluster structure of the 3.5 wt % solution prepared by dissolving the salt is shown to differ from that of the solution obtained by dilution. The solutions long-range order is formed by the nano dispersion of the water solvated salt crystal nuclei. The mechanism of the solution aging is discussed.
DOI: 10.1134/S1070427207070452

INTRODUCTION

The methods of preparing solutions, the dissolving processes and the solution keeping are of great importance in the chemical technology processes. First of all this concerns stabilization of quality, rational consumption of resources, knowledge of the role of salt state in solution, understanding the dissolving and solution aging processes.

The mechanism of dissolution of sodium chloride and the state of the salt ions in solution are considered in many publications [1–6]. However, there is no publications denoted to understanding this mechanism in view of long-range order formation and evolution on the level of static assembles (clusters) in water and in the solution of the salt in the initial steps of formation of thermodynamically stable solution as well as on the dynamics of the process of solution aging. Understanding this mechanism would allow to attain a new quality in performing technological processes, in understanding the processes in geochemistry, biochemistry and even in cookery.

This work is aimed at the study of the mechanism of sodium chloride dissolving in distilled water and the solution aging using the method of Flicker Noise Spectroscopy (FNS) [7, 8].

This method allows to measure weight fractions of cluster type formations by short period action of weak energy fields thus introducing minimum of possible distortion in the formation of static assembles in the liquid.

EXPERIMENTAL

As an object of the study was taken rapidly cooled water ($\chi = 20 \pm 5 \times 10^{-8}$ Ω^{-1} cm^{-1}) and crystalline NaCl (99.9%) with average crystal size 100 μ. A vessel for the salt dissolving is made of polyethylene (500 ml), the liquid was stirred by magnetic stirrer. The FN (flicker noise) spectra were registered on and Aist H&C GmbH (Germany) instrument [7, 8] three times with 15 sec intervals and distortions induced by $2000 \times 3 = 6000$ shock waves passed through the studied liquid were analyzed. The FNS sensor analyzing long-range order in the solution sample of 1.25 cm^3 volume was located in the center of the vessel and 3 cm from walls. The measurements were performed before stirring (Fig. 2, *1*, water before salt adding),

then at stirring (Fig. 2, *2*, water before salt adding), after adding salt powder (Fig. 2, *3*), after ending the stirring of the salt solution (Fig. 2, *4*), after completing the solution stirring (Fig. 2, *5*, beginning of solution aging) and then after 9, 10, 20 min, 0.5, 3.5, 12.5, 280, 320, 500 h of the solution formation. During all the experiment time the cell was maximum isolated from the influence of external energy fields (light, shaking, heat flows). At the moment of a FNS registration the stirrer was switched off. The temperature control accuracy was ±1K. The oscillator mass was calculated with the equation $T=2\pi(m/c)^{0.5}$ using our found constant $c=(6.2\pm0.8)\cdot10^{-15}$ N/m [8]. The instrument calibrating on the oscillator mass was made on the oscillation band of the cluster $(H_2O)_{280\pm1}$ (m=5.040) in twice-distilled water at 4350±50 Hz in the region of small clusters (http://www.lsbu.ac.uk/water/index.html), on the oscillations at 2451 Hz of the lisocime ferment globule with m=15.754 Da for the medium area of the spectrum and on the ocillations of polystyrene cluster [9] and silicon carbide globules [10] (m=3139.886 Da, 173.4 Hz) in the far part of the spectrum. Error in the determination of an oscillator mass can be 15% in the range of lg m from 0 to 2, less than 6% in the lg m range from 2.5 to 4.5 and up to 15% in the lg m range from 5.5 to 6.5.

The FNS method is based on the known methods of statistical treatment of weak signals [11,12]. The principal approach is application of fast Fourier transformation algorithm (FFT) in conjunction with mathematical analysis (authocorrelation) of ordered sequence of correlated random values (hip:// en.wikipedia.org/wiki/Fast_Fourier_Transform). The digraph of extraction of real signals of the clusters assumes saving initial signals from both the cells containing substance and without it, refining these signals, abstracting the cell signal from the signal of the cell with the sample, and saving thus obtained spectrum of the sample itself.

The positive signal (*f*) in the FNS method results from the energy release by expanded cluster, their compacting and crystallization. The negative signal (*–f*) corresponds to the energy absorption at the interaction of the shock wave with a dense cluster and melting the cluster. The fraction of the dense clusters is taken conveniently with minus while the fraction of expanded clusters with plus. This is made also for better understanding and separation of the clusters by their density in graphics. The fraction (*f*) of a cluster is the ratio of its signal intensity to the sum of absolute values of the signal intensities of all detected signals of clusters in the spectrum [8]. Each point of measuring energy release/absorption for a given range of oscillator mass is obtained as a result of statistical analysis of the noise from 6000 of weak shock waves passed through the sample. The broad band (by energy) weak shock waves were generated by a film, the film energetic characteristics (vibration frequency and intensity) were used for detection. The *f* value reflects energy of interaction of a series of shock waves from the spectrometer with condensed masses in the studied sample. Note that interaction of shock wave with a hinder describes density, strength and energy characteristics of the latter and allows to reveal its shape. The nonlinear character of the oscillators interaction with shock waves however restricts observation of principal results of such interaction in the trend of development of nonlinearity for a given case and material [13, p. 32]. It turns out that individual deviations from the nonlinearity of some of multitude oscillators shows stable reproducibility, and for a family of relative oscillators can be created quasi-linear algorithm of their evolution. "Enhancement" of the data obtained using chemistry logics and published data give rise to successful identification of clusters by means of FNS method. However, the key problem remains in concern the energetic description of the clusters oscillation and energy of their formation. It also can be solved because the number of the cluster types is not too high (40 – 160) and the number of the most significant types is a few units. A not trivial task is calibrating SN spectra on energy due to the absence of reliable internal reference, especially in complicated systems (solutions, gels, biological systems). It is more so, because the energy depends on many factors, first of all on the character of interaction with environment: the stronger interaction, the smaller is their formation energy, the mass cluster is more "spread", not condensed. Energy of clusters formation in water have been published [8]. For natural water and for solutions of various salts it is difficult to make the instrument calibration due to absence of reliable internal reference or starting point, therefore we represent the FNS data as *f* values.

As a criterion of globular structure of the clusters was the harmonization of the physical model of oscillating ball (the rotating ball inertia moment $J = (2/5)mr^2$, where *m* is mass, *r* is radius and *J* is inertia moment) with the data of computer modeling of water clusters by Chaplin (http://www.lsbu.ac.uk/water/ index.html) for the clusters consisting of 280 and 1890 water molecules, and unsatisfactorily correlation at the

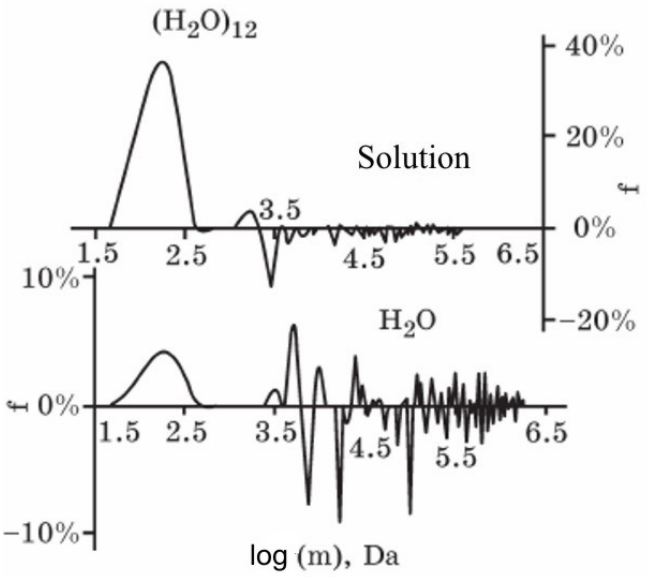

Fig. 1. Survey FN spectra of distilled water after fast cooling of vapor to 294 K and of 3.5 weght % solution after salt adding and 3-min stirring, 294 K. *f* is ratio of signal intensities of an oscillator (*f*i) in the spectrum to the sum of all signals modulo $\Sigma|fj|$ detected in the spectrum (*–f* are conventionally negative values for dense clusters, *+f* for extended clusters), m is oscillator mass, Da.

modeling with other rotation figures including full or empty cylinder, cone or free-rotating body (J=0.5π·ρ·∫·r4·dx, where ρ is the density of the rotating body, π = 3.14, integration (∫) is fom x_1 to x_2). A criterion of globular structure of the salt ion pairs (SCIP) is the same but in respect of the possible models of rotating dimers, tetramers, etc. [7]. These criterions obey successfully the general thermo-dynamic view on the minimization of body surface for a cluster in liquid.

DISCUSSION

Fig. 1 shows FNS data for water and salt solution. As seen, both water and salt solution are nanodisperce systems. The clusters distribution oscillating at the action of weak shock wave is not homogenous. Adding the salt to water leads to distortion of cluster structure of the latter and to almost complete disappearance of expanded clusters (+*f*) except water clusters consisting of the molecular associates up to $(H_2O)_{12}$ [14]. The salt ions which are represented by a wide set of SCIP [7] allows water to form small clusters only, while medium and large statistical forms in the bulk solution are distorted. The spectrum of water shown in the figure differs slightly from that of distilled water obtained by water melting and heating to 300 K [8] due to bigger number of instable clusters (carcass clusters) and due to difference in the history of the liquid. Such water is mostly used in chemical technology at the preparation of salt solutions.

Fig. 2 shows dependence of average oscillator mass in water and in the salt solution in the process of its formation. It is seen that mechanical action in the process of stirring leads to sharp decrease in the average cluster mass and adding of the salt powder accelerates this process. The value of M_{FNS} falls down by factor more than 3.

Dissolving the salt stabilizes the process of strong change in M_{FNS} even at stirring the solution. Then stir is stopped, after 1 min occurs some increase in average oscillator mass, which then again decrease and stabilizes at the level of 96 ± 5 kDa with certain trend to the growing M_{FNS}. This curve running shows that occurs the process of redistribution in cluster structure of solution, its evolution and further aging. These processes can be visualized by representation of FNS data as dash codes (Fig. 3). The dash codes represent presence or absence of a cluster with given mass regardless intensity of corresponding signal in the FN spectrum.

From Fig. 3 is seen that in the process of saltdissolving occur the processes of change in cluster structure of the liquid. Adding the salt leads to appearance in water of giant oscillators with the size comparable with colloid particles (> log m = 6.31). It can be suggested that they are oscillating colloid particles, the fragments of difficultly dissolving fragments of solid

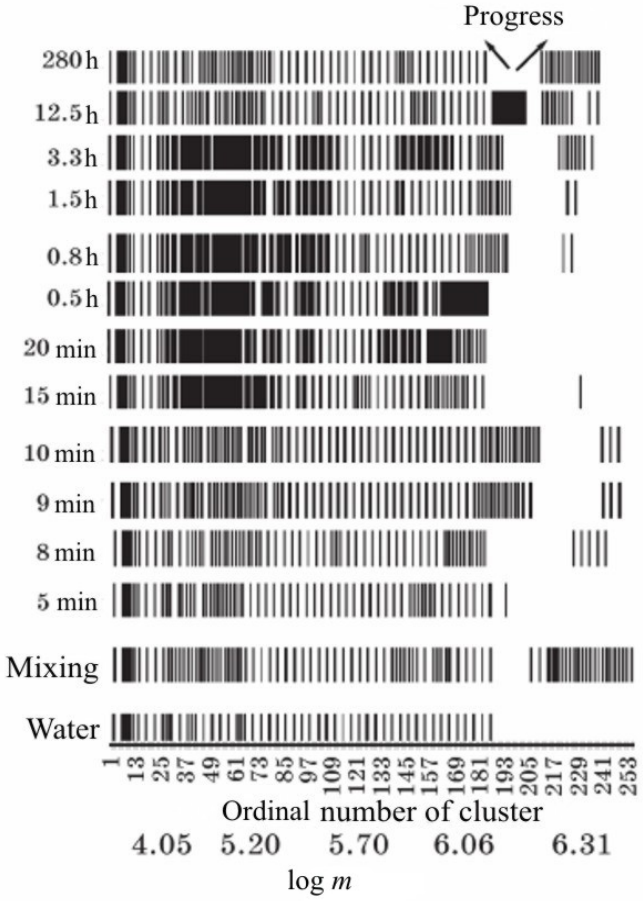

Fig. 3. Dashed representation of presence/absence of clusters in a liquid in the process of formation and aging its statistical structure (long-range order). The clusters ordinal numbers correspond to their order in FN spectra tentatively (step of observation raster).

salt with minimum defects in their crystal structure.

In the region of medum size clusters (log m from 4.05…5.25) is seen appearance of new oscillators, not typical for water. They can be polymeric solvate clusters of the salt ion pairs (pSCIP) [7, 15].

Stirring the solution for next 3 min leads to disappearance of the giant oscillators and to establishing of new thermodynamic equilibrium of SCIPs in the regions of mefium and big clusters. This equilibrium however is intermediate and not stable.

When stirring is stopped, the solution cluster structure evolution still continues. The dash spectrum (Fig. 3) expands to the side of appearance of very large oscillators with simultaneous compression of dashes in the region of medium and large clusters. Such a phenomenon continues for 2–3 min after stopping stirring and it can be explained by the formation of instable SCIPs (iSCIP) and their polymerization with formation of polymer globular and oscillating structures.

The iSCIPs after 15th minute become quickly aging and destroying (Fig. 3). The process of aging is accompanied with restructuring due to depolymerization of the most instable globules ad formation of oscillating low molecular weight stable SCIPs (sSCIP) of new structure which is in better harmony wih the clusters of mass between log m = 4.62 and log m = 5.6. In Fig. 3 this process is seen as disappearance of dashes in the region of giant clusters and strong increase in density of the dashes in the medium region (oligomeric clusters).

From 7th min to 12.3 h another trend occurs – the process of distribution of dashes over all the spectrum. This phenomenon we connect with formation of new thermodynamic equilibrium in the region of oligomeric clusters (numbers 77 to 100) leading to polymerization of iSCIPs and formation of new, more stable, high molecular oscillators with numbers 130 to 185.

After 0.8 h in the spectra again appear giant clusters whose number increases with the solution aging. The reasons for their appearance can be polymerization of new low molecular thermodynamically stable SCIPs.

After 3.5 h aging of the solution, occurs certain decrease in the number of SCIPs in the medium area of spectrum and increase in the number of oscillators in the region of big clusters. To 12.5 h these changes become obvious and dominating. In the region of oligomeric (medium) clusters the dashes density decreases to the level occurred at the moment of mixing salt and water, but in the region of giant clusters the dashes density increased sharply.

Note that the cluster dashes Nos. 70 to 150 remain the most stable during all the experiment. They can be assigned to the carcass clusters of the solution forming its long range order structure.

To 500 h the solution structure becomes mainly formed, but the process does not stops. In the solution the processes of attaining thermodynamic equilibrium continue, which are accompam\nied by the dividing of cluster structure into two big groups: wit the masses < log m = 6.2 and > log m = 6.36 (Fig. 3, progress vectors). The formation of two big groups of submicro particles has been reported in [15]. These data confirm that there are no ideal solutions and the old theory of ideal solutions should be declined. This, liquids can

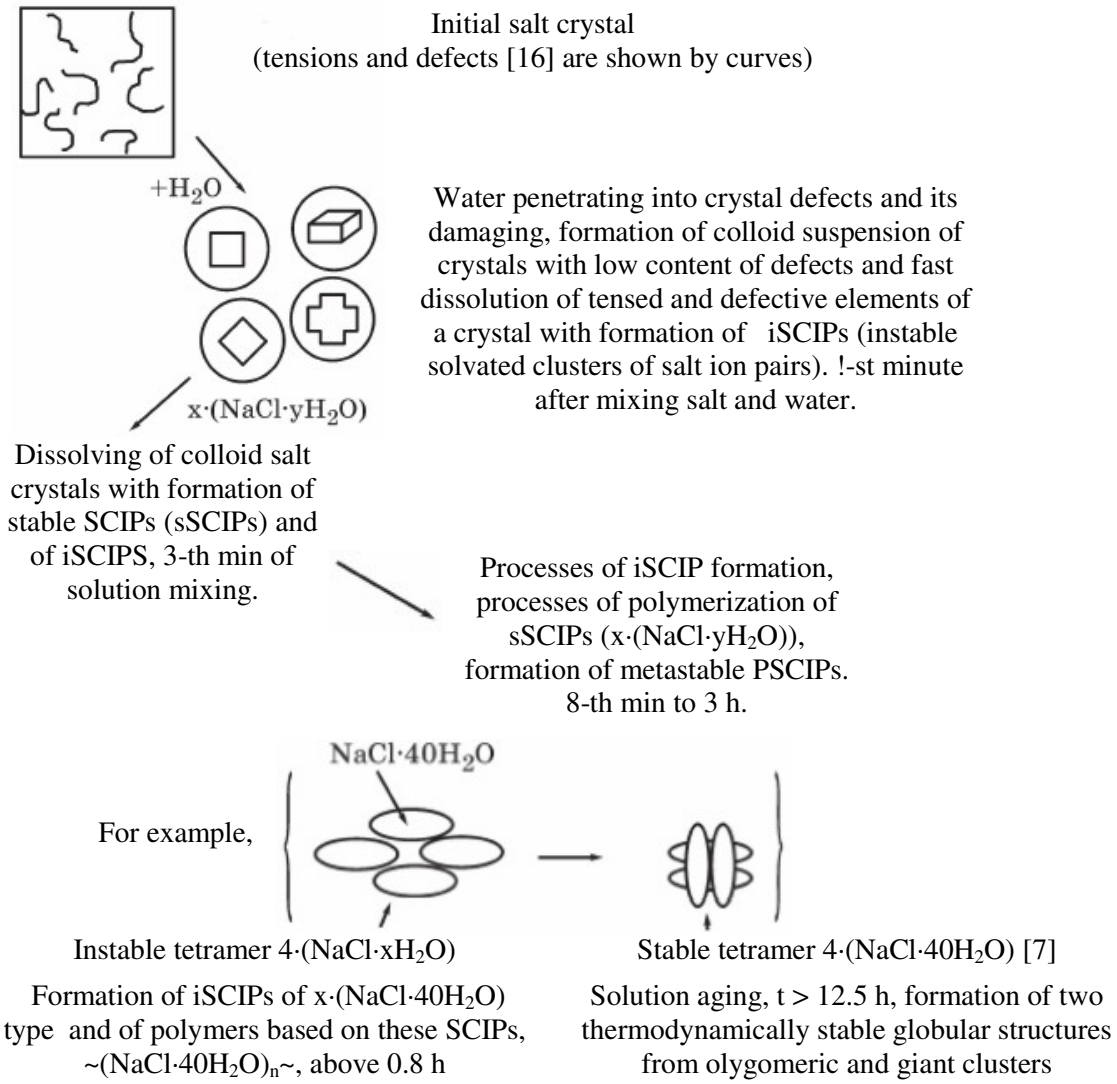

Fig. 4. Model of dissolution of salt in water.

not be considered as homogenous systems, they are heterogenic on the nano level, the level defining sensible chemical and biochemical processes which will be dominating in the 21th century technologies.

The processes of SCIP formation and their polymerization (polycondensation) pass a few steps in their evolution which can be represented as dissolving of salt in water (Fig. 4). The evolution of dashes represented in Fig. 3 also attests the presence of fluctuations in formation of thermodynamically stable salt solution.

The signals of oscillating clusters in FNS prove globular structure of the latter. Therefore the structure of completely formed solution of salt can be considered as thermodynamically stable nanodisperse suspension of polymer solvate cluster ion pair (PSCIP) in water. Therewith, the salt solution long-range order is defined on the level of structural constru cting of PSCIP and associates based on it.

The PSCIP should differ by anisotropy at least in surface layers contacting with the bulk solution. In [5] was found that solvate shell of an alkali metal in water has layers in two levels, internal and external, the external layer is rather porous (expanded) and differ by structure from both internal layer and surrounding solution. In [17] was reported that in NaCl solutions the h-bond bridges between water molecules are much longer than in pure water. These facts attest in favor of presence in SCIP of ex[anded surface layer consisting of water molecules.

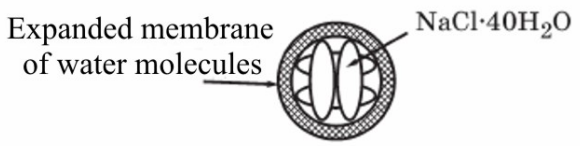
It seems logically that at polymerization of SCIPs they approach each other up to the level of internal (condensed) layers of solvating water while expanded layer will be formed on the surface of the polymer globule at the solution frontier. Similar phenomenon which is characteristic of claster structure of water was described by Yoshiteru [18]. He found that 22% of water molecules have one H-bond bridge only and 77% have two bridges. We also modeled water clusters which allowed us to understand that surface layer consists of the molecules with one H-bridge (22%) and internal layers of the molecules with two H-bridges (78%). In other words, the density of the SCIP surface layers should differ by density from the overall liquid density and from the density of clusters inside construction.

It seems possible to detect this layer by, for example, changing pressure over the solution. If the layer exists, then, according to the osmosis laws (van't Hoff's equation, $\pi = icRT$, where π is osmotic pressure, R is gas constant, T is absolute temperature, c is the solution molar concentration) it should response to the change in pressure. In this equation the i factor is connected with the electrolyte degree of dissociation (α) in a diluted solution ($i = 1 + \alpha(\nu - 1)$, where ν is number of ions formed at the dissociation of the electrolyte) [19] and can reflect changes in the SCIP structure. The influence of pressure on the clusters distribution and their average mass can be reliably measured using the FNS method.

We found that weak changes in atmospheric pressure correlate with the character of SCIP distribution in the solutions of salt, values of M_{FNS} parameter and the number of oscillators in the solution (Fig. 5). Thus, the change in pressure of atmospheric air over the solution (+10%) for 1 sec results in significant changes of these parameters after tens of minutes and brings the system to the new thermodynamic equilibrium on hours. These parameters vary adequately with the change in pressure. The correlation of solutions physical properties (osmotic pressure, vapor pressure over the solution) with the ion hydration numbers was also reported earlier [20, 21].

Thus, SCIP has surface solvate shell which can play the role of membrane commutating with environment, e.g., for the tetramer $4(NaCl{\cdot}40\ H_2O)$ it can be represented by the following model (this layer is dashed, Scheme 1).

Scheme 1.



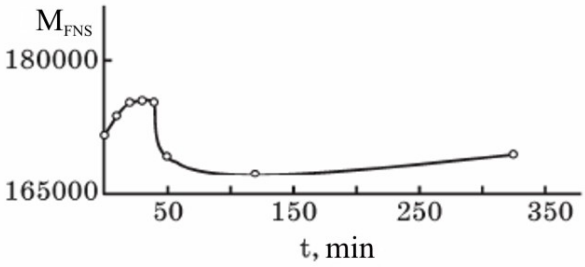


Fig. 5. M_{FNS} responce of 0.1 wt % salt solution (analogue of physiological salt solution) on sharp change in air pressure over the solution, ΔP=11%. Number of oscillators after 30 min increases by 35%.

We detected dependence of the cluster ordering hierarchy of the salt solution on the method of preparation of the solution.

In [7] the salt solutions were prepared by us by means of consecutive dilution of concentrated (26%) solution and keeping them for 2 weeks excluding carefully action of light, shaking and changes of temperature, while in the current work the 3.5% salt solution (Fig. 1) was prepared directly by dissolving salt in water. Comparison of FN spectra of the prepared in current work 3.5% salt solution after 328 h keeping with the spectrua in [7] showes that they are not completely identical in the region of small clusters (lg m from 2.6 to 3.6), but it is identical with the spectrum of 26% salt concentration below lg m = 3.7 which also was prepared by direct dissolving of the salt and keeping it for 320 h.

In the 3.5% solution obtained by direct dissolving of salt were found dimeric SCIPs $2(NaCl{\cdot}40H_2O)$ only in expanded form. The number of oscillators in the solution obtained by salt dissolving is by 56% higher than in the solution obtained through dilution.

Thus, the FNS method allows to obtain some data on the solution origin, namely, did it obtain by either diluting or direct dissolving.

Technologists long ago noted that many processes of chemical technology with solutions depend not only on the order of mixing, conditions of stirring, duration of "ripening," etc., but also on weather situation

(pressure jumping). We suggest that solutions of salts have long-range order analogous to that found in [7] and represented in the scheme 1 structure of SCIP. Such SCIPs are sensitive to change in pressure in apparatus and in vessels with open surface, and their changes can be used in fine chamical synthesis, for enhancing quality of products and certain reactions selectivity. Long time for establishing thermodynamic equilibrium in a salt solution can be used by technologists for protection of inventions and formation of "know how."

Advance biological systems are known to be very sensitive to pressure changes. Probably atmospheric pressure affects solvate shells of not only SCIPs, but also of dissolved compounds involved into biochemical processes and as a sequence to distorts metabolism in people organism (head-ache, joint-ache). Modern medicine still can not explain source of such diseases.

Evolutionary aging of salt solution according to the model shown in Fig. 4 and found by us phenomenon of dependence of cluster arrangement on the solution origin can assist understanding of existence in ocean stable layers and streams of water with equal salt content by differ in temperature which are not mixing together.

CONCLUSION

The process of salt dissolving in water is multistep one and includes the following steps: formation of instable colloid systems, metastable solvate clusters of the salt ion pairs, formation of instable globular polymeric structures in the solution, formation of thermodynamically stable structures SCIP and globular polymers based on them. This process for 3.5 weight % salt solution at 294 K requires basically hundreds hours. The SCIP surface consists of expanded layer ofsolvate molecules behaving as a membrane in the osmotic processes of informational interaction of clusters with environment. Dash codes of lon-range cluster organization in liquids can be used for estimation of their quality, archiving and modelling physical, chemical, hydrochemical and biochemical processes. FNS method allows obtaining certain data on the solution origin history (is it obtained by diluting or by direct dissolving). The salt solution is not an ideal solution, as has been suggested earlier.

e-mail: - insane_ul_haq@ici.com

Received June 19, 2007

Abstract—Unsaturated polyester resins containing long chain fatty acids and styrene as cross-linking agents are easily available in Pakistan. I have made use of these resins in the preparation of overprint varnish, ornaments, synthetic marble and other related substances. The octates of manganese, cobalt, calcium and lead along with peroxide were used for jelling and drying of the resins. The effects of metal driers, aluminium stearate , peroxides and unsaturated long chain fatty acids in the composition as mentioned in the experimental section were also studied. The merits and demerits developed in the end products resulting from the variation of these chemicals in the compositions were also noted at their respective places.

INTRODUCTION

Polyester. Polyester is a class of polymer containing reoccurring −C(=O)−O− group in the main chain and generally are prepared from dihydric alcohols and dicarboxylic acids.

The polyesters are classified in to the following types:

(1). Linear unsaturated polyesters.
(2). Linear saturated polyesters of low molecular weights.
(3). Linear saturated polyesters of high molecular weight.
(4). Network polyesters.

1. Linear Unsaturated Polyesters

Linear unsaturated polyesters are generally prepared from a saturated acid such as phthalic, isophthalic, adipic or azelic and an unsaturated acid i.e. maleic anhydride or fumarolic anhydride, which are condensed with dihydric alcohols. A three dimensional structure is formed by cross linking polyester back ground with a vinyl monomer, most commonly styrene is used.

2. Linear saturated polyesters of low molecular weight

The polyesters, which are formed in a linear saturation chain having molecular weight less than 10,000, belong to this type. These are mainly used as plasticides. They are obtained by condensation of diol-dicarboxylic acids. Often a mono-hydric alcohol or a mono carboxylic carboxylic acid is used as to control the molecular weight.

3. Linear saturated polyester of high molecular weight

Poly (ethylene terephthalate) is of significant importance in this category. Poly (ethylene terephthalate) fiber is being used extensively as Mylar, Terylene, Dacron, and Terepak.

4. Net work Polyesters

The network polyesters are mainly used in surface coatings. The most important polyesters of this type are derived from phthalic anhydride and glycerin.

HISTORY

It was the beginning of the Second World War, which accelerated research work in the field of fundamental and applied chemistry. It was about the same period when important work was carried out on understanding chemistry of polyesters and their technical uses, although they know polyester a kind since seventeenth century.

Berzelius in 1847 pioneered work on synthesis of polyester from tartaric acid and glycerol. Lorenzo was successful in 1863 to manufacture polyester by heating

[1] The article was submitted by the author in English.

ethylene glycol with succinic acid, having the following formula.

$$-(-OCH_2\,CH_2\,OCOCH_2\,CH_2\,CO-)-$$

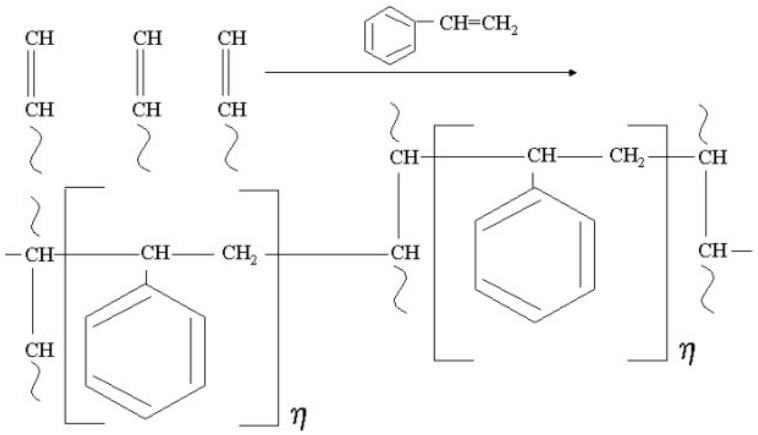
Kraut after about six years was able to produce a concept of polyester chain structure. Blaise and Marcilly in 1904 gave a chain formula to polyesters prepared from hydroxide pivalic acid. In 1916 the product prepared by the reaction of phthalic anhydride and glycerin was used for coating both wood and metals. It was in 1927 the term Alkyd (derived from Alcohol and Acid) was introduced by R.H.Kienle.

Standingers 27,28, and Carothers were able to prepare polyesters with well-defined polymeric structure. Carothers carried out fundamental research work on polymers including polyesters and established their importance in industry.

In the late thirties Broadly together with Kropa and Johnston reported that unsaturated polyester become insoluble and infusible on drying because of the presence of unsaturated double bonds in polyester chains. At the same time Ellis discovered that the rate of cure of unsaturated polyester could be increased by more than thirty times if unsaturated monomers were used. This discovery lead to the commercial application of unsaturated polyester on a wide scale.

Unsaturated polyester resin prepared from maleic anhydride-2-napthol, maleic anhydride and propylene glycol, may be co polymerized with styrene was reported by Jedlinsk. This unsaturated polyester had a regular net work structure.

The cross linking of an unsaturated linear polyester by means of a vinyl monomer such as styrene is presented as follows:



The average value of n in the above structure may be deduced from both spectroscopic and degradation studies.

USES

United States Rubber Company in 1942 used polyester made from diethylene glycol and maleic anhydride in the presence of styrene for reinforcing glass fibre.21.

The commercial production of glass fiber reinforcing polyester laminates was established in 1947 and become very important for preparation of boat hulls, lorry cabs, roofing plans, chemical plants and several seaplane floats and similar mouldings were made. It is used as thermosetting moulding compositions, casting resins and solvent less lacquers.

Polyester is further used in aircraft industry, protective covering over radar scanning apparatus for electrical industry. It is being used for the measurement of the concentration of abnormal red blood cells in human blood by preparing microprobes membrane for blood filtration.

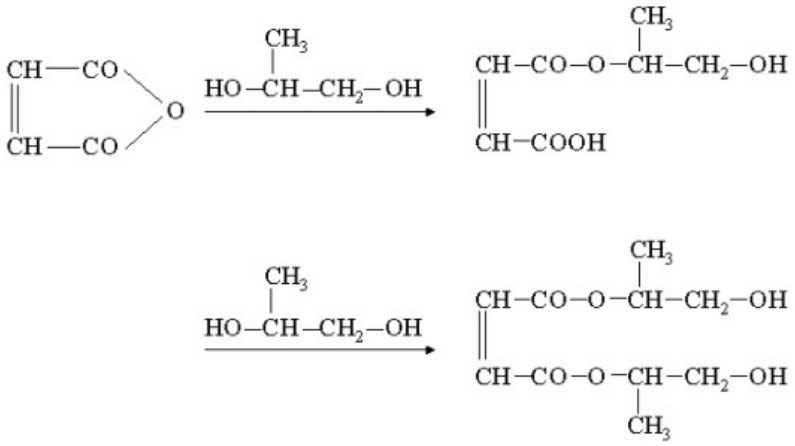
These are useful as moulding compounds having good resistance to wrap and cracks. The sheet-moulding compound is prepared by using unsaturated polyester resin syrup, which has an excellent tensile strength.

It is used for the production of serving trays, lampshade, flat sheets, and corrugated sheets for building industry, ammunition boxes, disposable glass tanks and various containers.

Of the total resin use in reinforcing plastics market 93% is polyester 36.

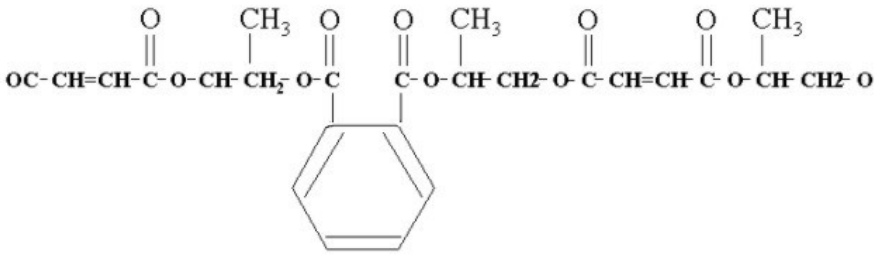
Chemistry of polyester resin. The monomers, which are required for the production of polyester resins, are dicarboxcylic acid, anhydride, dihydric alcohols, monomers for cross linking and an inert solvent for refluxing. Catalyst is sometimes used to accelerate the reaction and reduce the reaction time. Inhibitors are also required.

The reaction between a hydroxide compound and anhydride proceeds in two distinct steps. In the first step, esterification of the anhydride occurs to form a free acid group, which is then esterified in the second step. The following reaction between maleic anhydride and propylene glycol is given as follows.



The first step proceeds more rapidly than the second since the anhydride group is more reactive than the free acid group. A glycol and anhydride may react through a sequence of reaction to yield linear polyester.

A segment of the polyester obtained from propylene glycol, maliec anhydride and phthalic anhydride may have the following structure.



The cross linking of unsaturated linear polyester involves the reaction of the unsaturated sites in the polymer chain with a monomer which may be of vinyl type such as styrene or acrylonitrile etc. Cross-linking of unsaturated polyesters is a free radical reaction. These types of initiating systems are commonly employed for this reaction, namely

Those, which are effective at, elevated temperatures.

Those, which are effective at room temperatures.

The initiators, which are used at elevated temperatures, are peroxides such as benzyl peroxide. For the reaction at room temperature, methyl ethyl ketone peroxide is used as an initiator. Moreover peroxides along with octates of cobalt and manganese can initiate the reaction at room temperature.

The aim of this work is to utilize the unsaturated polyester resins, which are being manufactured in Pakistan. Every year Pakistan imports a huge amount of lacquers and varnishes. Unsaturated polyester resins

are the basic raw materials to manufacture a large variety of lacquers and varnishes. Moreover, these resins can be used for many other purposes e.g. in the manufacturing of artificial pearls and ornaments. The synthetic marble is another application of this resin. The author had worked on the aforesaid projects and hopes that if proper attention is given to these projects, and then a large amount of foreign exchange can be saved.

EXPERIMENTAL

Preparation of overprint varnish *1. General procedure*). Resins based on linseed oil, pentaernthrol, glycerin and unsaturated long chain fatty acids were taken in a 100ml beaker. Several kinds of driers like octates of manganese, cobalt, calcium, zirconium and aluminium stearate of different concentrations as shown in the following compositions were added in the resin mixture. They were thoroughly stirred and the resulting mixture was applied as a very thin layer on the different kinds of printing papers. The resin-coated papers were kept at room temperature to see their drying times. The drying time of each composition was noted.

2. Compositions based on manganese drier. In this experiment, the amounts of resins and linseed oil were fixed while the amount of manganese was varied from 0.3ml to 1.0 ml. The varnish was prepared using the method given in the general procedure.

2,a	Linseed oil	3 ml
	Resin	10 gm
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
2,b	Linseed oil	3 ml
	Resin	10 gm
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
2,c	Linseed Oil	3 ml
	Resin	10 gm
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
2,d	Linseed Oil	3 ml
	Resin	10 gm
	Manganese drier (10%)	1.0 ml (0.1 gm metal)

Result: No one composition worked well. In all compositions results were found be unsatisfactory.

3. Compositions based on aluminium stearate and manganese drier. In this experiment, the amount of stearate was fixed, while the amount of manganese octate was varied from 0.3ml to 1.0ml.the instructions given in the general procedure were followed for its preparation and application.

3,a	Linseed oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.3 gm
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
3,b	linseed oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.3 gm
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
3,c	linseed oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.3 gm
	Manganese drier (10%)	0.7ml (0.07gm metal)
3,d	linseed oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.3 gm
	Manganese drier (10%)	1.0 ml (0.1gm metal)

Result: It was found that the viscosity of each compound has increased very much. All compositions failed to work and the resulting product did not dried even after 24 hours.

4. Experiment number 3 was repeated using fixed amount of aluminium stearate (0.1gm) in order to control the viscosity of the product. The amount of manganese octates was varied to increase the drying power of the varnish.

4,a	linseed Oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.1 gm
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
4,b	linseed Oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.1 gm
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
4,c	linseed Oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.1 gm
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
4,d	linseed Oil	3 ml
	Resin	10 gm
	Aluminium stearate	0.1 gm
	Manganese drier (10%)	1.0 ml (0.1 gm metal)

Result: Unsatisfactory results were obtained.

5. Compositions based on manganese and calcium driers. In this experiments the amount of calcium octate was fixed (0.3 ml) and the amount of manganese octates was varied from 0.3 ml to 1.oml.

5,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
5,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
5,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
5,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	1.0 ml (0.1 gm metal)

Result: Unsatisfactory results were obtained

6. This experiment is very similar to experiment no.5. In this case, we have raised the amount of calcium octate (0.6 ml) in each composition. The manganese octate was varied from 0.3ml to 1.0ml.

6,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
6,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
6,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
6,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese drier (10%)	1.0 ml (0.1 gm metal)

Result: The results appeared to be good.

7. In this case, the amount of calcium octate was fixed to 0.9ml and manganese octate was varied. Here, I used the same instructions as given in experiment no.5.

7,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
7,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
7,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
7,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese drier (10%)	1.0 ml (0.1 gm metal)

Result: Unsatisfactory results were obtained.

8. Composition based on calcium, manganese & lead driers. In this experiment, the amount of manganese metal was made equivalent to the amount of lead metal. The amount of calcium drier was fixed to 0.3 ml. The manganese drier was varied from 0.3ml to 1.0ml.

8,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.08 ml (0.03 gm metal)
8,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.138 ml (0.05 gm metal)
8,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.19 ml (0.07 gm metal)
8,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.27ml (0.1 gm metal)

Result: Satisfactory results were obtained. Good shining layer of the resin deposited on the papers. The layer appeared to be water resistant.

9. In this experiment, the amount of calcium metal was fixed while the manganese and lead metal contents in the compositions were varied.

9,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.04 ml (0.015 gm metal)

9,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.07 ml (0.025 gm metal)
9,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.097 ml (0.035 gm metal)
9,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese drier (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.13 ml (0.05 gm metal)

Result: Results obtained were unsatisfactory. The drying time of varnish reduced to 4-5 hours.

10. Use of castor oil in place of linseed oil. In this experiment, linseed oil was replaced by castor oil. The amount of calcium drier was fixed (0.3ml) while the amount of manganese and lead driers were varied.

10,a	Castor oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.125 ml (0.045 gm metal)
10,b	Castor oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.208 ml (0.075 gm metal)
10,c	Castor oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.29 ml (0.105 gm metal)
10,d	Castor oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.3 ml (0.03 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.4 ml (0.15 gm metal)

Result: The drying time of the varnish had reduced to 2-3 hours. The results of the compositions appeared to be good.

11. In this case, the amount of calcium octate was increased from 0.3ml to 0.6ml while the quantities of other driers were varied. Moreover, castor oil was also replaced with China wood oil.

11,a	China wood oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.08 ml (0.03 gm metal)
11,b	China wood oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.138 ml (0.05 gm metal)
11,c	China wood oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.0 6gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.19 ml (0.07 gm metal)
11,d	China wood oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	1.0 ml (0.01 gm metal)
	Lead drier (36%)	0.27 ml (0.1 gm metal)

Result: Excellent results were obtained. The drying times of thin layers yielded from compositions 11(a-d) fall within 2 to 4 hours.

12. In this experiment, the amount of lead metal was made half the amount of manganese metal. The amount of calcium drier was fixed to 0.6 ml. China wood oil was replaced by Soya been oil.

12,a	Soya been	3 ml
	Resin	10 gm
	Calcium drier (10%)	0. 6ml (0.06 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.04 gm (0.015 gm metal)
12,b	Soya been	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.07 gm (0.025 gm metal)
12,c	Soya been	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.097 gm (0.035 gm metal)
12,d	Soya been	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.13 gm (0.05 gm metal)

Result: The drying time of each composition was between 2 to 3 hours.

13. In this experiment, the amount of lead metal is 1.5 times to manganese metal. The amount of calcium drier was fixed to 0.6 ml, while the amount of manganese was varied from 0.3 ml to 1.0 ml. Soya

been oil was also replaced with linseed oil. Polyethlene wax was also added in the varnish to facilitate the application.

13,a	Linseed oil	3 ml
	Resin	10 gm
	Polyethylene wax.	0.5 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.125 gm (0.045 gm metal)
13,b	Linseed oil	3 ml
	Resin	10 gm
	Polyethylene wax.	0.5 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.208 gm (0.075 gm metal)
13,c	Linseed oil	3 ml
	Resin	10 gm
	Polyethylene wax.	0.5 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.29 gm (0.105 gm metal)
13,d	Linseed oil	3 ml
	Resin	10 gm
	Polyethylene wax.	0.5 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.4 gm (0.15 gm metal)

Result: Excellent and compromising results were obtained. The drying times lay in-between 2 to 3 hours.

14. In this experiment, the amount of calcium drier was increased from 0.6ml to 0.9ml. The amount of manganese metal is made equivalent to the amount of lead metal in the following compositions. The amount of manganese drier was also varied from 0.3ml to 1.0ml.Polyethlene wax was also removed from the composition.

14,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.08 gm (0.03 gm metal)
14,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0. 9ml (0.09 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.138 gm (0.05 gm metal)
14,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.19 gm (0.07 gm metal)
14,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.27gm (0.1 gm metal)

Result: Results obtained in all these cases seemed to be good. The drying times of all compositions found to be in-between 2 to 3 hours.

15. I have repeated the experiment No.12. The only difference in this case is that the amount of calcium drier is increased to 0.9 ml.

15,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.0 4gm (0.015 gm metal)
15,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.07 gm (0.025 gm metal)
15,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.097 gm (0.035 gm metal)
15,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.13 gm (0.05 gm metal)

Result: The drying times of the compositions

15,a	2 hrs 48 minutes
15,b	2 hrs 57 minutes
15,c	3 hrs
15,d	3 hrs

Results were satisfactory.

16. I have repeated the experiment No. 13.
The only difference in this case is that the amount of calcium drier is increased to 0.9 ml.

16,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.125 gm (0.045 gm metal)
16,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.5 ml (0.05 gm metal)
	Lead drier (36%)	0.208 gm (0.075 gm metal)

16,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.7 ml (0.07 gm metal)
	Lead drier (36%)	0.29 gm (0.105 gm metal)
16,d	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	1.0 ml (0.1 gm metal)
	Lead drier (36%)	0.4 gm (0.105 gm metal)

Result: The drying time of each composition falls in-between 2 to 3 hours.

17. In this experiment, the amounts of manganese and calcium octates were fixed to 0.3 ml and 0.6 ml respectively. The amount of lead drier was varied as shown in the following compositions.

17,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.0 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.21 gm (0.06 gm metal)
17,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.316 gm (0.09 gm metal)
17,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.6 ml (0.06 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.42 gm (0.12 gm metal)

Result: The results are good. The drying time of each composition is approximately 3 hours.

18. Experiment no.18 is very similar to experiment no.16. In this case, the amount of calcium octate is fixed to 0.9 ml.

18,a	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.21 gm (0.06 gm metal)
18,b	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.316 gm (0.09 gm metal)
18,c	Linseed oil	3 ml
	Resin	10 gm
	Calcium drier (10%)	0.9 ml (0.09 gm metal)
	Manganese metal (10%)	0.3 ml (0.03 gm metal)
	Lead drier (36%)	0.42 gm (0.12 gm metal)

Result: The drying time of each composition is between 4 to 5 hrs.

PREPARATION OF ARTIFICIAL PEARLS AND ORNAMENTS.

Key words: (MEK) Methyl ethyl ketone, (MEKP) Methyl ethyl ketone peroxide, (Ca) Calcium, (Pb) Lead, (Mn) Manganese, (Co) Cobalt**,** (DOP) Dioctyl phthalate.

19. General procedure. In order to prepare artificial pearls and ornaments, styrene based unsaturated polyesters was used. Peroxides of different kinds like benzyl peroxide, methyl ethyl ketone peroxide were used along with Ca, Pb, Mn, Co octates to jell the polyester resins. Pigments of different kinds along with various types of dyes were also used. To prepare any composition, polyester resin of known weight was taken in a beaker. Calculated amounts of pearls and dyes were added in it. Mixed the contents well, and then added peroxides and metal octate.

20. Determination of jelling time of polyester resin. In this experiment, the quantities of polyester resin and cobalt drier were fixed, while the amount of methyl ethyl ketone peroxide is varied from 0.1 gm to 1.0 gm. Then the jelling time of each composition is noted.

20,a	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)

Fig. 1. Papers having coating of over print varnish.

	MEKP	0.1 gm
20,b	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
	MEKP	0.2 gm
20,c	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
	MEKP	0.3 gm
20,d	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
	MEKP	0.4 gm
20,e	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
	MEKP	0.5 gm
20,f	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
Cobalt drier (1%)		0.05 ml (0.0005 gm metal)
Methyl ethyl ketone peroxide		0.3 gm

21. Effects of DOP on polyester resin sheet. In this experiment, the amount of polyester resin, MEKP and cobalt drier were fixed, while the amount of DOP was increased from 0.1gm to 1.0 gm.

Polyester resin	10 gm
Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
Methyl ethyl ketone peroxide	0.3 gm

22. Removal of bubbles problem in polyester resin sheet. The polyester resin sheets obtained from previous two experiments sustained bubbles of gases produced during the reaction. To eliminate the bubble problem, a small centrifugal machine was made. The polyester resin and other materials were added in this machine. The machine was allowed to revolve horizontally at a speed of 100,200,300,400,500,600 revolutions per minute respectively. The inner walls of the centrifugal machine were lubricated with DOP in order to produce anti sticking properties against polyester resin sheet.

The following composition was tried in this experiment.

22,a	Polyester resin	10 gm
	Cobalt drier (1%)	0.05 ml (0.0005 gm metal)
	MEKP	0.3 gm

Result: The polyester resin sheet obtained at the speed of 600 revolutions per minute was fine and free from any kind of blisters, cracks etc.

23. Selection of proper quantity of polyester resin. The basic purpose of this experiment is to select a proper quantity of polyester resin to obtain a suitable width of the walls of the polyester sheet.

23,a	Polyester resin	40 gm
	Cobalt drier (1%)	0.2 ml (0.0002 gm metal)
	MEKP	1.2 gm
23,b	Polyester resin	60 gm
	Cobalt drier (1%)	0.3 ml (0.0003 gm metal)
	MEKP	1.8 gm
23,c	Polyester resin	80 gm
	Cobalt drier (1%)	0.4 ml (0.0004 gm metal)
	MEKP	2.4 gm
23,d	Polyester resin	100 gm
	Cobalt drier (1%)	0.5 ml (0.0005 gm metal)
	MEKP	3.0 gm

Result: Composition 23,d gives a suitable width of the polyester sheet. So it was selected for further experimentation.

24. Addition of different pigments. In this experiment, different types of pigments were used to make large varieties of polyester resin sheets for multiple purposes. The following compositions were conceived and tried.

Polyester resin	100 gm
Cobalt drier (1%)	0.5 ml (0.0005 gm metal)
MEKP	3.0 ml

25. Problems relating to pigment distribution. Solid pigments settled down in the polyester resin and made the distribution uneven in the resin sheet. In this connection, various kinds of thickening agents were

Sr#	Amount of DOP	Remarks
1	0.1 gm	By increasing the amount of DOP, the softness and shining of the polyester sheet was also increased.
2	0.2 gm	
3	0.3 gm	
4	0.4 gm

5	Nitrocellulose	gm	Nitrocellulose did not dissolve in polyester resin.
6	DOP	gm	Flexible sheet was obtained.
7	Barium sulphate	2.0 gm	Slightly greenish colored sheet.

28. Use has more than one pigment. In this experiment, two or more than two types of pigments were added in the polyester resin.

28,a	Polyester resin	100 gm
	MEKP	3.0 gm
	Cobalt drier (1%)	0.5 ml (0.005 gm metal)
	Blue pigment paste	0.53 gm
	Pink pigment paste	0.26 gm
28,b	Polyester resin	100 gm
	MEKP	3.0 gm
	Cobalt drier (1%)	0.5 ml (0.005 gm metal)
	Blue pigment paste	0.35 gm
	Pink pigment paste	0.35 gm
	Golden pigment paste	1.0 gm
28,c	Polyester resin	100 gm
	MEKP	3.0 gm
	Cobalt drier (1%)	0.5 ml (0.005 gm metal)
	Golden pigment paste	0.8 gm
	Blue pigment paste	0.35 gm
	Pink pigment dye	0.35 ml
	Dissolved in MEK	
28,d	Polyester resin	100 gm
	MEKP	3.0 gm
	Cobalt drier (1%)	0.5 ml (0.005 gm metal)
	Copper pigment paste	0.8 gm
	Yellow transparent dye	0.5 ml
	Dissolved in MEK	

Results: The polyester resin sheets obtained are very beautiful and give multicolor shades.

PREPARATION OF SYNTHETIC MARBLE

29. General procedure. In order to prepare synthetic marble, styrene based unsaturated polyester was used. Peroxides of different kinds like benzyl peroxide, methyl ethyl ketone peroxide were used along with octates of Ca, Pb, Mn, Co in order to jell the polyester resin. Fillers of different kinds along with various types of dyes were also used.

30. Addition of different fillers in polyester resin. In this experiment, different kinds of fillers were added in the polyester resin in different quantities. The general procedure was adopted to prepare compositions. The following three inputs have the fixed quantities throughout the experimentation.

Polyester resin	80 gm
MEKP	2.4 gm
Cobalt drier (0.5%)	0.8 ml (0.004 gm metal)

The fillers and their quantities were varied as shown below.

Fig. 2. Artificial ornaments prepared from unsaturated polyester resin.

Sr#	Amount of Cao	Remarks
1	10 gm	By increasing the amount of CaO , the hardness of polyester resin sheet increases.
2	20 gm

RESULTS AND DISCUSSION

The aim of this work is to find the various uses of industrial resins that are being manufactured in Pakistan. In this connection, two types of unsaturated resins based on unsaturated long chain fatty acids and styrene are selected. They are easily available from market. The resin, which we like to use in printing industry, is made of linseed oil, glycerin, erythretol and phthalic anhydride.

In Pakistan, there is more than fifty thousands printing press of various sizes. They use lacquers and varnishes to protect the printings on various substrates. The substrate may be in the form of books, decorating sheets, eid cards, wedding cards, packing materials and calendars etc. A huge amount of foreign exchange is being spent for the import of these lacquers and varnishes. In this connection, I have prepared a varnish from local raw materials, which is being used in the offset printing machines.

In this connection, several compositions were prepared and tried. In compositions 2(a-d), 3(a-d), 4 (a-d), I used manganese octate and a mixture of manganese octate and aluminium stearate. We found that aluminium stearate increased the viscosity and slippery power of the varnish. On the other hand, the drying of thin layer obtained from this varnish took a long time. In addition manganese octate did not help so much in the drying of varnish. The results obtained after the application of each composition on printing system were mentioned at the end of each experiment.

In compositions 5(a-d), 6(a-d), 7(a-d), a mixture of manganese octate and calcium octate was used. Their quantities were varied from minimum to maximum but none of them was found to be useful.

Thereafter lead octate was incorporated with the octates of manganese and calcium. The amount of each metal was varied keeping other factors constant. In this way, I have conceived several compositions as mentioned in the experimental section. I found that the compositions 12 (a-d) appeared to be the best and gave good results in terms of reflection, durability, water and light resistance. Moreover, I found that addition of Soya been oil, china wood oil and polyethylene waxes had enhanced the quality of varnish.

Driers and drying. Varnish driers are organic acid soaps or salts of certain metals. This act as catalysts to accelerate the drying of surface coatings, either by oxidation or polymerization.

The activity of a drier depends largely on the particular metal and its quantity. The organic acid radical functions as a carrier for the metal quantity. The organic acid radical functions as a carrier for the metal and contributes to its solubility in oils, solvents and paint media.

Air drying films. The catalytic action of a drier is a function of oxidation and reduction equilibrium and hence involves valency changes in the metal. In the case of air-drying films, oxidation and polymerization are accelerated greatly by the use of driers of certain

metal types. These metals, which are known as primary driers, are cobalt, lead and manganese. Certain other metals are used to provide auxiliary drier compounds. These when used with the primary driers, perform useful functions in a varnish film drying mechanism. Some important auxiliary driers are those based on zirconium, calcium and zinc.

Drying mechanism. The drying mechanism of unsaturated oils proceeds along with free radical reaction. The mechanism involves two steps.

1. Oxidation on the surface of film.
2. Polymerization throughout the depth of the film.

The oxidation at the surface of film produces hydroperoxides, the methylene groups in the fatty acid chain. This decomposition reaction produces free radicals, which initiate polymerization of the molecules via the unsaturated bonds in the fatty acid chains. Reactions taking place during polymerization are not thoroughly understood but there seems to be an indication that the fatty acid chains are linked together both directly and via oxygen.

Unsaturated polyester resins based on styrene has been extensively used in various fields e.g. the manufacturing of buttons, water storage tanks, lamination of wood and steel structures, plastic sheets, electric goods etc. Now this resin is also available in our country and I would like to use in the manufacturing of ornaments and synthetic marble. Several kinds of peroxides were reported for it's jelling. I used methyl ethyl ketone peroxide in my experiments. I found that it did not jell the resin whatever its amount might be. On the other hand, when it was incorporated with cobalt drier, then it became very effective and jelling of the resin did occur. In order to find the optimum amount of MEKP and cobalt octate, I performed a series of experiments as had mentioned in the experimental section. I found that increase in amount of MEKP dramatically decreased the jelling time of the resin but the quality of the end product was badly affected. Contrary, increase or decrease in amount of cobalt octate did not effect the jelling time of the resin. So after adjusting the amount of MEKP and cobalt octate in compositions 20 (a-d), I concluded that 5 to 6 % MEKP and 0.6 to 1.0 % cobalt drier were the optimum quantities that jell the unsaturated polyester resin within 15 to 20 minutes. The plastic sheets obtained in this connection had excellent properties in all characters. Moreover various kinds of pigments like silver, gold, copper, pink etc were mixed in the resin and centrifuged in the rotary drum. Excellent shinning colored sheets were obtained. In this connection, several kinds of compositions 24, 25, 26 (a), 27, 28 (a-d) as shown in the experimental section were tried.

Compositions 28 (a-d) were found to be excellent and end products were attractive. The results obtained in each case were mentioned at the bottom of each composition respectively. In this way, any substrate of any shape could be made using polyester resin of aforesaid composition in the desired mould.

Similarly synthetic marble, tiles and related things were also prepared. In this case, we used various kinds of fillers like calcium carbonate, calcium oxide, vulkasilk, barium sulphate, kaolin, marble chips etc. In each case, a good quality of end product was obtained. It was seen that natural marble and other ceramic material used in the construction of building, especially at the seashore were badly effected with the gases coming off seawater. The use of synthetic marble had eliminated this problem to a considerable extent. The tiles made of unsaturated polyester appeared to be good in every respect when used in acidic and basic environment. The role of peroxide and cobalt octate was found to be crucial in jelling the polyester resin. The variation from the exact quantities of methyl ethyl ketone peroxide and cobalt octate used in the composition had badly affected the properties of the final product.

Abstract—Potassium-aluminum phosphate glasses with different concentrations of Ti(III) activator were prepared and their spectral properties were studied.

DOI: 10.1134/S1070427207080010

Crystals based on Al_2O_3 remain among the most widely used compounds in quantum electronics. They possess a unique combination of physical and chemical properties.

Methods for growth of activated Al_2O_3 crystals are well developed, but require special conditions and expensive equipment. In this context, an attempt to obtain glass-based lasing substances might be promising. Glasses are inferior to crystals in certain physicotechnical parameters; however, most of glasses are considerably more technologically convenient than crystals.

The goal of this study was to obtain titanium(III) oxide for preparing multicomponent oxide glasses.

EXPERIMENTAL

We studied series of multicomponent oxide glasses containing potassium, aluminum, silicon, and phosphorus oxides [potassium-aluminum silicophosphate (PASP) glasses, e.g., glasses based on the oxides, Al_2O_3–P_2O_5, Al_2O_3–SiO_2–P_2O_5, and K_2O–Al_2O_3–SiO_2–P_2O_5].

In this study, we examined glasses of composition $33.5\,K_2O$–$14.01\,Al_2O_3$–$38\,P_2O_5$ (mol %), activated with trivalent titanium in concentrations varied within the range 0.1–0.9 mol %. The greatest attention was paid to obtaining trivalent titanium and its introduction into glasses.

A review of the literature [1–16] and preliminary experiments allowed us to select the most convenient and promising procedure for obtaining trivalent titanium.

We tested and compared the following methods for $Ti^{4+} \rightarrow Ti^{3+}$ reduction in glassy systems K_2O–Al_2O_3–SiO_2–P_2O_5 and Al_2O_3–SiO_2–P_2O_5: reduction with ammonia (NH_3), ammonium tartrate, and hydrogen. The reduction of tetravalent titanium to trivalent titanium with hydrogen was found to be the most promising method. The other methods for obtaining titanium(III) oxide proved to be unsuitable for solving the basic problem of creating glassy lasing materials activated with trivalent titanium.

We constructed a special-purpose installation for reduction of tetravalent titanium with hydrogen. The installation is shown schematically in Fig. 1. All

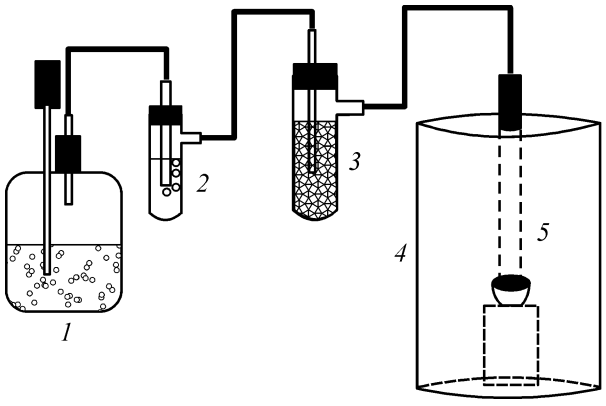

Fig. 1. Schematic of the installation for titanium reduction: (*1*) hydrogen gas generator, (*2*) gas-meter with an alkaline solution for H_2 purification, (*3*) tube with silica gel for drying of H_2, (*4*) furnace, and (*5*) crucible with TiO_2.

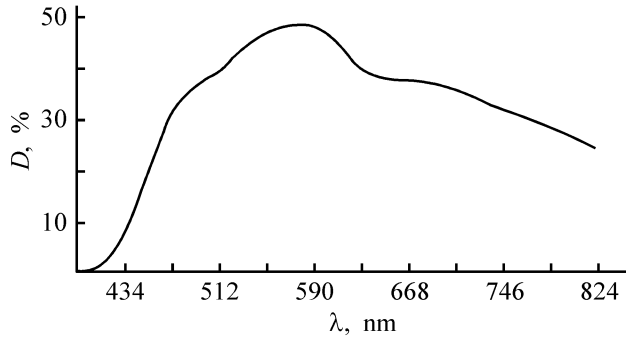

Fig. 2. Absorption spectrum of the $33.5\,K_2O$–$14.01\,Al_2O_3$–$38\,P_2O_5$ (mol %) glass activated with Ti^{3+}. Concentration $c_{Ti^{3+}} = 2.6$ M. (D) is optical density and (λ) wavelength.

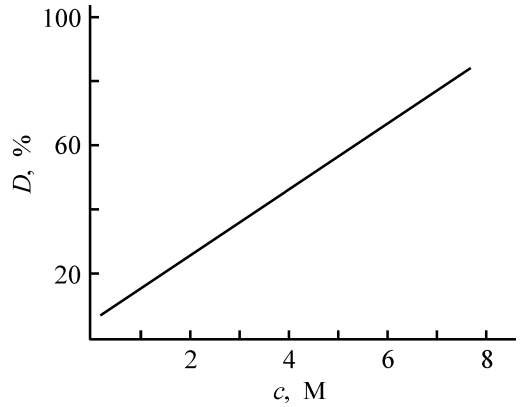

Fig. 3. Optical density D vs. titanium(III) oxide concentration c at 595 nm.

details of obtaining titanium(III) oxide by other methods, their advantages and disadvantages were also described in [16].

The reduced titanium was analyzed by spectrophotometry in the spectral range 340–850 nm on an SF-20 spectrophotometer and a pulsed tau-meter with an exponential sweep, fabricated by a standard technique. A series of glasses with varied concentration of trivalent titanium was prepared. The electronic absorption spectra show only a single broad band peaked at around 590 nm, with a pronounced shoulder at 660–800 nm, characteristic of trivalent titanium in condensed systems. It is necessary to note that the absorption peak in these glasses is shifted to longer wavelengths as compared with the spectra of sapphire crystals [1]. This indicates that the symmetry of the environment of Ti^{3+} ions changes, which is confirmed by the data of [16–18]. A spectrum of the glass series prepared is shown in Fig. 2. It differs from the other spectra of this series in that the intensity of absorption bands varies with the titanium concentration in the glass.

Table 1. Effect of titanium(III) concentration on physical and optical characteristics of $33.5\,K_2O$–$14.01\,Al_2O_3$–$38\,P_2O_5$ (mol %) glasses

$c_{Ti^{3+}}$, M	ρ, g cm^{-3}	n_D	ε, l mol^{-1} cm^{-1}
0.2	2.5165	1.51	15.4
0.33	2.4897	1.51	12.1
1	2.5129	1.51	16.1
2.6	2.5119	1.51	23
7.7	2.5175	1.51	12
$Al(PO_3)_3$–0.5%Ti^{3+}	2.66 [20]	1.497 [20]	
Al_2O_3–Ti^{3+}	3.5–4 [29]	1.765 [29]	

Further treatment of the spectra obtained confirms the results reported in [9, 10, 12, 13, 19–20] and leads to a conclusion that, in synthesis of a glass containing aluminum oxide as a component, Ti^{3+} isomorphously replaces aluminum in the unit cell of the glass, with the main Ti^{3+} term split.

The dependence of the optical density D on the titanium concentration (Fig. 3) is linear, which corresponds to Bouguer–Lambert–Beer law:

$$D = \varepsilon l c.$$

Here, ε is the extinction coefficient; l, glass thickness; and c, concentration of titanium(III) oxide in the glass.

This dependence can be used to calculate the average molar extinction coefficient ε_{av} (Table 1). The molar extinction coefficient ε is known to depend on the degree of covalence of the bond between metal ions and ligands. For example, the extinction coefficient of the Ti^{3+}-containing glass based only on sodium metaphosphate is 5 l mol^{-1} cm^{-1}. It increases to 8 l mol^{-1} cm^{-1} when chloride ions (in the form of NaCl) strongly depolymerizing the polymeric phosphate chains are introduced into the metaphosphate. For PASP glasses containing Ti^{3+}, the increase in the extinction coefficient 10 l mol^{-1} cm^{-1} is due to the presence of aluminum ions in the structural network. Their influence is expressed in a noticeable shortening of polymeric phosphate chains and in a decrease in the degree of Ti–O bond covalence [13]. It is seen from Table 1 that the deviation from this value is possibly associated with experimental and calculation errors. There is no need to obtain luminescence spectra, because the value of the extinction

coefficient fully confirms the presence of trivalent titanium in the glass.

It is necessary to note that the maximum luminescence intensity is observed for Ti^{3+} at a wavelength of 890 nm, with a clearly pronounced shoulder at 780–820 nm [20, 24–28]. Analysis of luminescence spectra was not among the goals of this study. Luminescence spectra for the given series of glasses will differ only in the intensity determined by the concentration of trivalent titanium in a glass.

The series of glasses under study was used to find the so-called concentration-induced quenching of luminescence, which is one of types of nonradiative transfer of the electronic excitation energy, with the help of luminescence decay curves.

By processing the luminescence decay curves (Fig. 4) by the method suggested in [30], we obtained the averaged coefficients of luminescence decay duration, τ_{av}, listed in Table 2.

As demonstrated by mathematical processing, the decay curves can be best described by the power function $\tau = 13.245c^{-0.0899}$, with an approximation reliability coefficient of about 0.8. This plot shows an approach to the titanium–titanium concentration quenching, which corresponds to the Ti^{3+} concentration range 4.6–7.7 M. Further increase in the activator (trivalent titanium) concentration does not improve significantly the optical and lasing properties. As demonstrated by the experiment, the physical properties of the glass are also impaired: the glass becomes more fragile and less completely melted because of the increasing viscosity. The latter requires that the temperature of glass melting should be raised because the melting point of titanium oxide is higher than 1500°C. An increase in the activator concentration by more than 7.7 M results in degradation of optical properties of glasses and leads to larger experimental errors.

Spectrophotometric studies of the glasses obtained confirmed the efficiency of the procedure suggested for trivalent titanium reduction. Plotting the dependence of the optical density on the titanium concentration in a glass can be used as a method for monitoring the completeness of reduction of trivalent titanium. Determination and study of the concentration range in glass, in which the concentration quenching is observed, enables control over lasing properties of other types of PASP glasses activated with Ti^{3+}. Hence follows that use of trivalent titanium as an activator in PASP is of current interest for fabrication of lasers with a wide range of emission wavelengths and good physical, optical, and lasing characteristics.

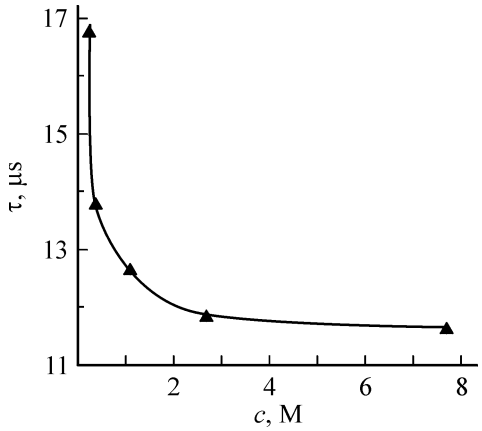

Fig. 4. Decay coefficient τ vs. titanium(III) concentration c in the glass at a luminescence wavelength of 890 nm.

CONCLUSIONS

(1) Several methods for $Ti^{4+} \rightarrow Ti^{3+}$ reduction were experimentally tested, their advantages and disadvantages were analyzed. The reduction with hydrogen was found to be the most promising procedure for this purpose.

(2) For the chosen procedure, an installation in which trivalent titanium is more easily obtained and the efficiency of this process is improved was created.

(3) The titanium(III) oxide obtained was used in making potassium-aluminum phosphate glasses. The optical properties of potassium-aluminum phosphate glasses activated with trivalent titanium were studied. The dependence of the optical and physical properties of the glass on the concentration of Ti^{3+} ions was revealed.

Table 2. Effect of Ti (III) concentration on the duration of luminescence decay in $33.5\,K_2O$–$14.01\,Al_2O_3$–$38\,P_2O_5$ (mol %) glass

Abstract—Solubility of yttrium, praseodymium, neodymium, and gadolinium sulfates in the presence of sodium and potassium ions and the composition of solid phases were studied at 20°C in relation to the concentration of acids in sulfuric acid, phosphoric acid, and sulfuric-phosphoric acid solutions containing up to 36 wt % H_2SO_4 and 33.12 g l^{-1} H_3PO_4.

DOI: 10.1134/S1070427207080022

A technique for recovery of lanthanides from phosphogypsum, based on sulfuric acid leaching and spontaneous crystallization of lanthanides from a sulfuric-phosphoric acid solution, has been suggested [1, 2]. To understand the fundamental aspects of crystallization of lanthanides from sulfuric-phosphoric acid leaching solutions containing admixtures of sodium and potassium ions, it is necessary to know the solubility of lanthanides in these solutions and the composition of the equilibrium solid phases.

Previously, the solubility of lanthanum and cerium sulfates, which are the main constituents of the sum of lanthanides of the Khibiny apatite, has been studied [3]. It was shown that, in the presence of stoichiometric amounts of sodium and potassium, the equilibrium solid phases are double sulfates of composition $LnM(SO_4)_2 \cdot H_2O$, where Ln = La, Ce and M = Na, K, and the solubility of the lanthanides in sulfuric-phosphoric acid solutions is determined by the solubility of these double sulfates.

The aim of this study was to complete the analysis of the solubility of double sulfates of the cerium-group lanthanides (praseodymium, neodymium) and to examine the solubility of yttrium and gadolinium sulfates.

It is known that, at 25°C and comparatively low Na_2SO_4 concentrations (≤2.39 wt %), $Y_2(SO_4)_3 \cdot 8H_2O$ crystallizes in the system $Y_2(SO_4)_3$–Na_2SO_4–H_2O, with the solubility of $Y_2(SO_4)_3$ being equal to 5.21–5.52 wt % and somewhat increasing with the Na_2SO_4 concentration. In the Na_2SO_4 concentration range 3.02–17.74 wt %, the solid phase is composed of $YNa(SO_4)_2 \cdot H_2O$ at a solubility of 5.20–2.15 wt % in terms of $Y_2(SO_4)_3$. As the Na_2SO_4 concentration increases further, $Na_2SO_4 \cdot 10H_2O$ is found in the solid phase. Although the solubility of $Y_2(SO_4)_3$ decreases as the content of Na_2SO_4 becomes higher (≥3.02 wt %), it still remains sufficiently high (about 4.2 g l^{-1} in terms of Y_2O_3) even at a Na_2SO_4 content of 21.88 wt % [4].

A similar behavior has been observed for the system $Y_2(SO_4)_3$–K_2SO_4–H_2O: at low K_2SO_4 contents (up to 4.93 wt %) only $Y_2(SO_4)_3 \cdot 8H_2O$ crystallizes [5]. The main distinction was the even higher maximum solubility of $Y_2(SO_4)_3$, up to 8.17 wt % at a K_2SO_4 content of the solution equal to 6.01 wt %.

The increase in the $Y_2(SO_4)_3 \cdot 8H_2O$ solubility on raising the concentration of alkali metal sulfates (at their low concentrations) indicates that associates, precursors of the corresponding double sulfates, exist in solutions.

The solubility in the systems $Ln_2(SO_4)_3$–M_2SO_4–H_2O (Ln = Pr, Nd, Gd) has not been studied, but the existence of double sulfates $LnM(SO_4)_2 \cdot H_2O$, and

also $2Nd_2(SO_4)_3 \cdot 3Na_2SO_4 \cdot 2H_2O$ and $2Ln_2(SO_4)_3 \cdot 3K_2SO_4 \cdot 4H_2O$, has been reported [6]. Data on the solubility of $Ln_2(SO_4)_3$ (Ln = Y, Pr, Nd, Gd) in sulfuric-phosphoric acid solutions containing sodium or potassium ions are unavailable.

EXPERIMENTAL

For the most part, the experimental procedure corresponded to that described previously [3]. The main distinction was that equimolar mixtures of a lanthanide and an alkaline metal, rather than preliminarily synthesized double sulfates, were introduced into the sulfuric-phosphoric acid solutions prepared.

The solubility of $Y_2(SO_4)_3$ was studied in sulfuric acid solutions with a concentration $c_{H_2SO_4}$ = 0–36 wt %, and that of $Ln_2(SO_4)_3$ (Ln = Pr, Nd, Gd), in sulfuric acid solutions with $c_{H_2SO_4}$ = 0–36 wt % and $c_{H_3PO_4}$ = 0–27.6 g l^{-1}. The experimental data obtained are listed in Tables 1–6.

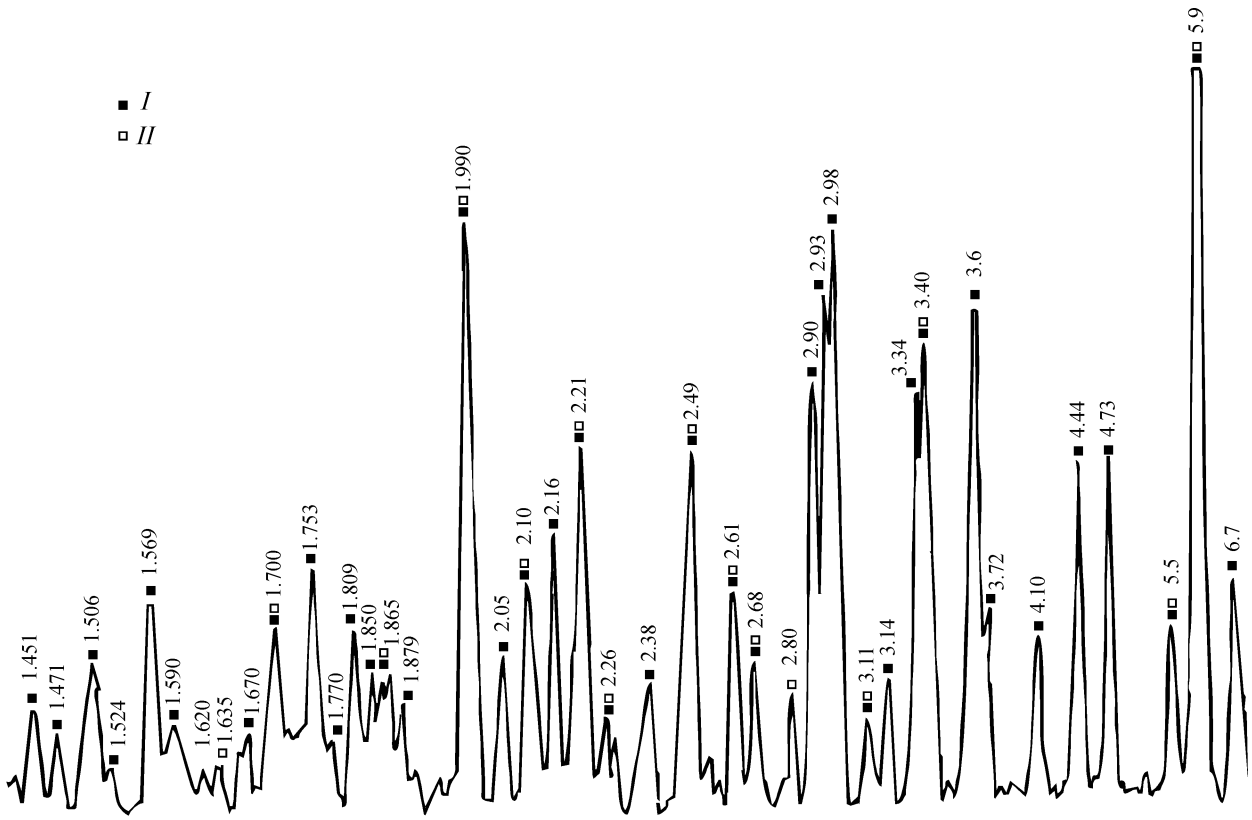
* (I) $Y_2(SO_4)_3 + Na_2SO_4$, (II) $Y_2(SO_4)_3 + K_2SO_4$, (III) $Pr_2(SO_4)_3 + Na_2SO_4$, (IV) $Pr_2(SO_4)_3 + K_2SO_4$, (V) $Nd_2(SO_4)_3 + Na_2SO_4$, (VI) $Nd_2(SO_4)_3 + K_2SO_4$, (VII) $Gd_2(SO_4)_3 + Na_2SO_4$, (VIII) $Gd_2(SO_4)_3 + K_2SO_4$.

In sulfuric acid and sulfuric-phosphoric acid solutions, the molar ratio of cerium-group lanthanides (praseodymium, neodymium) and alkaline metals, as well as as that of gadolinium and sodium, varied within the range 0.99–1.13 (Table 7). This indicates that double sulfides with a 1 : 1 atomic ratio of a lanthanide and an alkaline metal are formed and congruently dissolve. This is confirmed by the results of an X-ray phase analysis of the equilibrium solid phases. Yttrium is present in the bottom phase in a sulfuric acid solution as $YNa(SO_4)_2 \cdot H_2O$ at $c_{H_2SO_4}$ = 0–4 wt % and as a mixture of $Y_2(SO_4)_3 \cdot 8H_2O$ and $YNa(SO_4)_2 \cdot H_2O$ at $c_{H_2SO_4}$ = 8–36 wt % (see figure). The double sulfate $YK(SO_4)_2 \cdot H_2O$ existed only in the aqueous medium. It dissolved congruently in sulfuric acid solutions with the concentrations studied. No double sulfates of gadolinium and potassium were found.

The manner in which the solubility of praseodymium and neodymium sulfates changes in sulfuric-phosphoric acid solutions containing sodium or potas-



X-ray diffraction pattern of the bottom phase formed in the system $Y_2(SO_4)_3$–Na_2SO_4–H_2SO_4–H_2O at $c_{H_2SO_4}$ = 8–36 wt %. (*I*) $Y_2SO_4 \cdot 8H_2O$ and (*II*) $YNa(SO_4)_2 \cdot H_2O$.

sium ions is identical to that observed for lanthanum and cerium [3]. The solubilities of praseodymium, neodymium, and cerium sulfates in solutions of the same composition are virtually equal.

The solubility of yttrium sulfate in aqueous solutions containing Na_2SO_4 was found to be approximately 25% higher than that in [4]. The solubility of yttrium sulfate in aqueous solutions containing K_2SO_4 is close to that in [5].

At 20°C the solubility products in water for $PrNa(SO_4)_2 \cdot H_2O$, $NdNa(SO_4)_2 \cdot H_2O$, $GdNa(SO_4)_2 \cdot H_2O$, $PrK(SO_4)_2 \cdot H_2O$, and $NdK(SO_4)_2 \cdot H_2O$ are 7.28×10^{-8}, 7.84×10^{-8}, 3.09×10^{-6}, 3.02×10^{-6}, and 1.70×10^{-6}, respectively.

The data obtained previously [3] and in the present study do not confirm the data of [6], according to which the solubility of double sulfates dramatically increases in acid solutions.

For all the lanthanide sulfates studied, except yttrium, their solubility in solutions containing sodium ions is considerably lower than that in solutions with potassium ions. In sulfuric acid solutions, lanthanides forming poorly stable double sulfates (systems with sodium and potassium ions for yttrium) or forming no double sulfates (system with potassium ions for gadolinium) have a higher solubility. As, however, $c_{H_2SO_4}$ increases in the range 4–36 wt %, the relative decrease in the solubility of lanthanide sulfates exceeds that for double sulfates.

In an aqueous solution containing 27.6 g l^{-1} H_3PO_4, double sulfate of sodium and gadolinium decompose, as also do double sulfates of the rest of the lanthanides studied, to give, presumably, a poorly soluble gadolinium phosphate. However, in contrast to the cerium-group lanthanides, the solubility of gadolinium in sulfuric acid solutions containing minor amounts of phosphoric acid noticeably increases, especially in solutions containing ions of potassium, with which gadolinium forms no double sulfate.

Despite the high solubility of yttrium and gadolinium sulfates in sulfuric-phosphoric acid solutions containing sodium or potassium ions, which markedly exceeds their concentration in solutions for sulfuric acid leaching of lanthanides from phosphohemihydrate, it has been found that they are rather effectively transformed into a spontaneously crystallizing concentrate of lanthanides [7]. This suggests that there

occurs isomorphous co-crystallization of yttrium sulfate with the precipitating double sulfates of lanthanides, which is favored by the sufficient similarity of their crystal structures.

The data obtained confirm the previous assumption [3] that the low solubility of double sodium sulfates with cerium-group lanthanides is the reason for the limited accumulation of lanthanides in solutions in sulfuric acid leaching of phosphogypsum and phosphohemihydrate.

CONCLUSIONS

(1) The solubility of equimolar mixtures of yttrium, praseodymium, neodymium, or gadolinium sulfates with sodium or potassium sulfates in water, sulfuric acid, and sulfuric-phosphoric acid solutions containing 0–36 wt % H_2SO_4 and 0–27.6 g l^{-1} H_3PO_4 was determined.

(2) In water and sulfuric acid and sulfuric-phosphoric acid solutions, praseodymium and neodymium form with sodium and potassium ions, as also does gadolinium with sodium ions, incongruently soluble double sulfates with a 1 : 1 atomic ratio between the lanthanide and alkali metal ions. Double sulfates of yttrium are poorly stable in a sulfuric acid solution: $YK(SO_4)_2 \cdot H_2O$ is stable only in aqueous solutions, and $YNa(SO_4)_2 \cdot H_2O$, in solutions with a H_2SO_4 content of about 4 wt %.

(3) At 20°C, the solubility products in water for $PrNa(SO_4)_2 \cdot H_2O$, $NdNa(SO_4)_2 \cdot H_2O$, $GdNa(SO_4)_2 \cdot H_2O$, $PrK(SO_4)_2 \cdot H_2O$, and $NdK(SO_4)_2 \cdot H_2O$ are 7.28×10^{-8}, 7.84×10^{-8}, 3.09×10^{-6}, 3.02×10^{-6}, and 1.70×10^{-6}, respectively.

(4) In acid solutions of similar compositions, the solubilities of double sulfates of praseodymium, neodymium, and cerium in water and sulfuric acid solutions are virtually the same and lower than those of analogous double sulfates of lanthanum. The solubility of $GdNa(SO_4)_2 \cdot H_2O$ markedly exceeds that of the analogues studied. For all of the lanthanides studied, except yttrium, the solubility in sodium-containing solutions is substantially lower than that is solutions with potassium ions. As the concentration of sulfuric acid is raised, the solubility of the double sulfates studied first increases and then, after passing through a maximum, decreases. Raising the concentration of phosphoric acid, within the range studied, at a constant concentration of sulfuric acid affects the solubility of lanthanides in sulfuric acid solutions only slightly.

(5) The solubility of yttrium sulfate in sulfuric acid solutions containing sodium or potassium ions, and that of gadolinium sulfate in sulfuric acid and sulfuric-phosphoric acid solutions containing sodium or potassium ions, markedly exceeds their concentration in solutions formed in sulfuric acid leaching of lanthanides from phosphohemihydrate.

(6) The low solubility of double sulfates of sodium with cerium-group lanthanides is the key factor hindering the accumulation of lanthanides in solutions formed in sulfuric acid leaching of lanthanides from phosphohemihydrate.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Stratification in a Ternary Liquid System $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–Exide 100 Solvent at Various Temperatures

Abstract—Phase diagram of a ternary liquid system $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–Exide 100 solvent was studied at 298.15–333.15 K.

DOI: 10.1134/S1070427207080034

It has been found previously that the phase diagrams of ternary liquid systems (TLS) constituted by $[Ln(NO_3)_3(TBP)_3]$, (RED), and Exide-100 solvent (E-100) (Ln = Nd, Yb; TBP, tri-*n*-butyl phosphate; RED, extractive dearomitized diluent) comprise a region of homogeneous solutions and that of stratification into two liquid phases. To enable practical use of extractive systems based on mixtures of TBP, RED 1, and E-100 under complete saturation of the organic phase with nitrates of rare-earth metals(III) to give $[Ln(NO_3)_3(TBP)_3]$, it is necessary to partly replace paraffin solvents with hydrocarbon diluents containing up to 20% aromatic compounds for total homogenization of the systems at low temperatures.

In [2, 3], the phase diagrams of TLS constituted by $[Th(NO_3)_4(TBP)_2]$, $[UO_2(NO_3)_2(TBP)_2]$, and decane (tetradecane) were studied at 298.15–333.15 K. The ternary liquid system has a region of homogeneous solutions and that of two-phase liquid systems (systems with stratification), in which one phase (I) is enriched in $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$, and the other (II), with hydrocarbon diluents.

This study is concerned with the effect of temperature on stratification processes in the system $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–E-100, which is of practical interest in the technology for separation of uranium and thorium.

EXPERIMENTAL

Vacuum-distilled TBP (density $\rho_{298.15} = 0.9727$ g cm^{-3}) and E-100 solvent (saturated hydrocarbons with addition of 20 vol % aromatic hydrocarbons, $\rho_{298.15} = 0.8241$ g cm^{-3}) were used in the study. The solvates $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$ were produced by 3–4-fold interaction of concentrated aqueous solutions of thorium(IV) and dioxo uranium(VI) with TBP. The concentrations and densities of the solvates were as follows: $[Th(NO_3)_4(TBP)_2]$, 1.80 ± 0.01 M, $\rho_{298.15} = 1.7022 \pm 0.0013$ g cm^{-3}; $[UO_2(NO_3)_2(TBP)_2]$, 1.82 ± 0.01 M, $\rho_{298.15} = 1.4215 \pm 0.015$ g cm^{-3}.

The binodal curves of the ternary systems were obtained using Alekseev's visual polythermic method, with account of the improvements reported in [1–4]. Solutions containing a mixture of thorium(IV) and dioxo uranium(VI) nitrate solvates were analyzed as follows. The content of dioxo uranium(VI) nitrate solvate in the organic phase was found directly by the Sakharov method [5, 6], and that of thorium(IV) nitrate solvate in the organic phase, by complexometry [7]. It was found in preliminary experiments that the change in the volume of the organic phase on mixing solutions of E-100 and thorium(IV) and dioxo uranium(VI) solvates did not exceed 0.3 vol %. The compositions of the coexisting phases (vol %) were recalculated to mass fractions with account of the solution densities. The bimodal

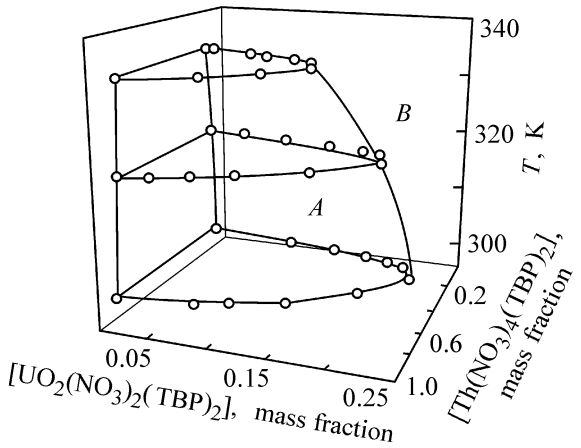

Fig. 1. Phase diagrams of the ternary system $[Th(NO_3)_4 \cdot (TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–E-100 at different temperatures. (*T*) Temperature. (*A*) Region of stratification into two liquid phases and (*B*) region of homogeneous solutions.

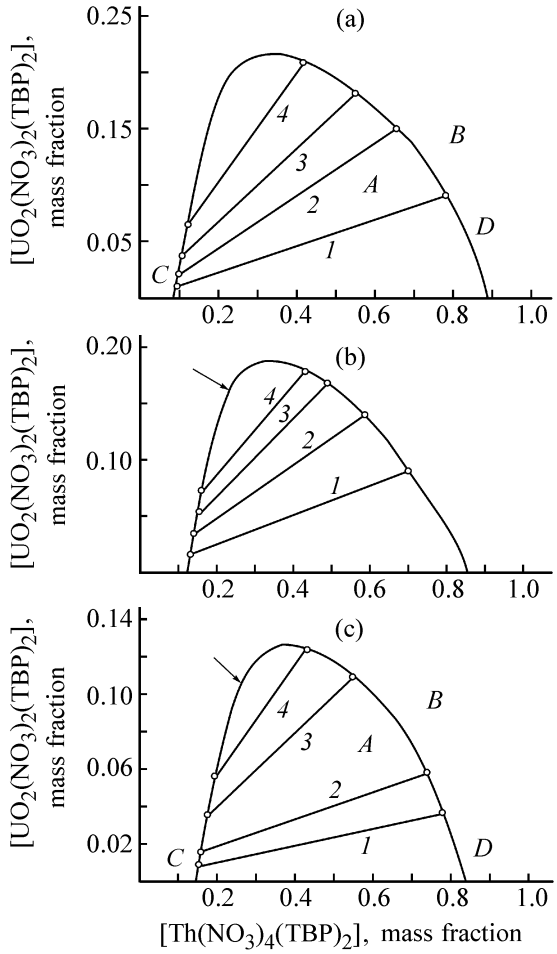

Fig. 2. Cross-sections of the phase diagram of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–E-100. (*1–4*) Nodes; the critical composition is shown by the arrow. (*A*) Region of stratification into two liquid phases, (*B*) region of homogeneous solutions, and (*CD*) bimodal curve. Temperature (K): (a) 298.15, (b) 318.15, and (c) 333.15.

curves were approximated with a third- or fourth-order polynomial.

The phase diagrams of TLS in relation to temperature (Figs. 1, 2) are presented using the second Roseboom triangle: rectangular coordinates for two TLS components, with the mass fractions of the components (ω_1, ω_2, and ω_3; $\omega_3 = 1 - \omega_1 - \omega_2$). The errors in determining the mass fractions of the components did not exceed ± 0.001–0.002, and that in measuring the temperature, ± 0.2 K.

The binary system $[UO_2(NO_3)_2(TBP)_2]$–E-100 is a liquid single-phase system, and the binary system $[Th(NO_3)_4(TBP)_2]$–E-100, a liquid two-phase system in the entire range of temperatures studied (298.15–333.15 K) (Figs. 1, 2). Raising the temperature from 298.15 to 333.15 K leads to an only slight increase in the mutual solubility of the components of the system $[Th(NO_3)_4(TBP)_2]$–E-100 (Figs. 1, 2). It is impossible to determine the upper critical temperature for this system, because raising the temperature above 373.15 K leads to evaporation of E-100 and, in particular, of its aromatic components, rather than to homogenization of the system.

The ternary liquid system $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–E-100 has a region of homogeneous liquid solutions (region *B*) and a two-phase region *A*, delimited by bimodal curves at different temperatures (Figs. 1, 2). An increase in temperature in the range 298.15–333.15 K makes narrower the region of stratification into two phases in three-component systems, which is particularly clearly manifested on going from 318.15 to 333.15 K (Fig. 1). Analysis of the nodes of TLS at different temperatures (Fig. 2) shows that, in the heterogeneous regions, two phases are typically formed, one of which is enriched in $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$ (phase I), and the other, in E-100 (phase II).

As the temperature is elevated from 298.15 to 333.15 K, the mass fraction of $[Th(NO_3)_4(TBP)_2]$ at points of the critical TLS composition increases from 0.185 to 0.255 and that of $[UO_2(NO_3)_2(TBP)_2]$ decreases from 0.17 to 0.10 (Fig. 2), with the mass fraction of E-100 remaining virtually unchanged (~0.65).

Figure 3 shows the distribution diagrams of $[UO_2(NO_3)_2(TBP)_2]$, $[Th(NO_3)_4(TBP)_2]$, and E-100 among phases I and II. A characteristic feature is, according to Fig. 3, the preferential distribution of $[UO_2(NO_3)_2(TBP)_2]$ into phase I, despite that the binary system $[UO_2(NO_3)_2(TBP)_2]$–E-100 is single-phase at any of the temperatures studied. Probably, this is due to a dipole-dipole interaction between the

solvates $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$. The preferential distribution of $[UO_2(NO_3)_2(TBP)_2]$ into phase I results in that, contrariwise, $[Th(NO_3)_4(TBP)_2]$ is redistributed into phase II (opposite runs of the isotherms for U and Th), and E-100 is redistributed from phase II into phase I (Fig. 3).

For practical use of extractive systems based on mixtures of TBP and E-100 under complete saturation of the organic phase with thorium(IV) and dioxo uranium(VI) nitrates to give $[UO_2(NO_3)_2(TBP)_2]$ and $[Th(NO_3)_4(TBP)_2]$ without stratification of the organic phase, it is necessary to use the extractive agent (TBP) in a diluent, with the mass fraction of the diluent not exceeding 0.6 (up to approximately 50 vol %). Further decrease in the TBP concentration is unadvisable because of the possible formation of three-phase liquid systems.

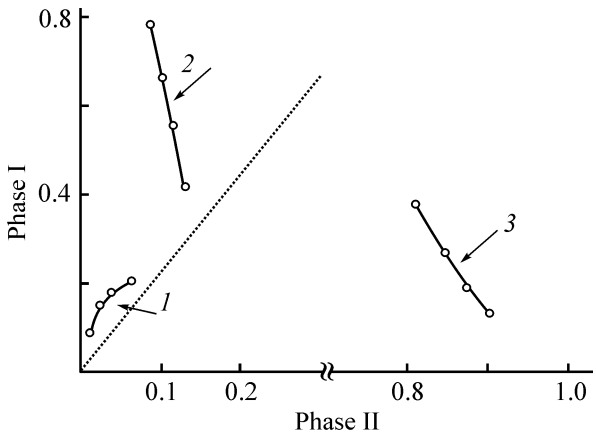

Fig. 3. Distribution diagram of (*1*) $[UO_2(NO_3)_2(TBP)_2]$, (*2*) $[Th(NO_3)_4(TBP)_2]$, and (*3*) E-100 among phases I and II at 318.15 K. Phase enriched: (I) in $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$ and (II) in E-100.

CONCLUSIONS

(1) The binary system $[Th(NO_3)_4(TBP)_2]$–E-100 is limited in the mutual solubility of its components. Changing the temperature from 298.15 to 333.15 K has no significant effect on the mutual solubility of the components.

(2) The phase diagram of the ternary liquid system $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–E-100 shows a region of homogeneous solutions and that of two-phase liquid systems (systems with stratification), in which one phase (I) is enriched in $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$, and the other, in E-100 solvent. An increase in the temperature (298.15–333.15 K) makes narrower the region of stratification into two liquid phases in the ternary liquid system.

(3) To enable practical use of extractive systems based on mixtures of tri-*n*-butyl phosphate and E-100 under complete saturation of the organic phase with thorium(IV) and dioxo uranium(VI) nitrates to give $[UO_2(NO_3)_2(TBP)_2]$ and $[Th(NO_3)_4(TBP)_2]$ without stratification of the organic phase, it is necessary to use the extractive agent (tri-*n*-butyl phosphate) in a diluent, with the mass fraction of the diluent not exceeding 0.6 (up to approximately 50 vol %).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Foaming Activity of Foam Compounds Based on Hexadecylammonium Chloride and Sodium Carboxylates

Abstract—Formation of R_1R_2 associates between hexadecylammonium chloride and sodium carboxylates (octanoate, laurate, and palmitate) was studied by IR spectroscopy and chemical methods, and their foaming activity was characterized.

DOI: 10.1134/S1070427207080046

In flotation concentration of sylvinite ores, aqueous solutions of higher aliphatic amine salts (cationic surfactants) are currently used as collectors. As applied to flotation of high-clayey sylvinite ores, aliphatic amine salts have such disadvantages as high adsorption affinity for clay minerals, toxicity, and insufficient availability. Therefore, to replace higher aliphatic amines or reduce their a consumption, search for new efficient and more available flotation agents and modifiers for amines is a topical issue. In this relation, promising reagents are mixed solutions of cationic and anionic surfactants. In solutions of cationic (aliphatic amine salts $R_1^+X^-$) and anionic (sodium carboxylates $R_2^-Y^+$) surfactants, the presence of donor–acceptor centers in their molecules enable formation of associates of the type $R_1^+R_2^-$, whose surface activity is considerably higher than that of the initial components [1]:

$$R_1^+X^- + R_2^-Y^+ \rightleftarrows R_1^+R_2^- + Y^+X^-.$$

Previously [2] we have studied the adsorption and foaming activities of a mixture of hexadecylammonium chloride (HDAC, cationic surfactant) and sodium carboxylates C_4–C_{12} (Na-CAS) in flotation of potassium ores.

It was demonstrated that the amount of the amine adsorbed on KCl crystals depends on the chain length of a carboxylate and its concentration in solution. Even at a 1 : 1 ratio of these components, the amine is totally adsorbed (to 96–97%) in the presence of short-chain sodium carboxylates (butanoate, pentanoate, and hexanoate). In the case of octanoate and adipate, present in a mixture in concentrations of 15 and 25%, only 70% of the amine is adsorbed on KCl crystals. As the carboxylate concentration decreases to 50%, the adsorption of the amine falls to 20%. The experiments on sorption of the amine on KCl crystals were carried out according to the procedure described in [3].

The results obtained in studying the flotation dressing of sylvinite ore with mixed solutions of octadecylammonium chloride (BATZ grade) and sodium carboxylates also demonstrated a high flotation efficiency of these mixtures. Mixtures of the amine with short-chain carboxylates (butanoate, pentanoate, and hexanoate) appeared to be the most effective, which is consistent with the adsorption data. These results were interpreted in terms of formation in these mixtures of $R_1^+R_2^-$ associates, which are more efficient hydrophobizing agents for the particles to be floated as compared to the individual components.

Here we report chemical and IR spectroscopic data confirming the association of sodium carboxylates with hexadecylammonium chloride, and also data on the foamig activity of the resulting associates.

The R_1R_2 associates were prepared as follows. A stoichiometric amount of HDAC as a 0.5% solution was added to aqueous sodium carboxylate (octanoate, laurate, oxalate, and adipate) solutions of certain concentrations. The resulting precipitate was filtered off (Schott filter no. 4), washed with cold water (5°C), transferred into a Petri dish, and dried initially in air and then over P_2O_5.

The chemical composition of the precipitates was determined by the HDAC content in them [3]. It was demonstrated that 1 : 1 and 1 : 2 associates are

formed with monobasic (octanoic, lauric) and dibasic (oxalic, adipic) carboxylic acid salts, respectively.

The association was also confirmed by IR spectra recorded on a UR-20 spectrophotometer using KBr technique. Figure 1 shows the absorption spectra of the precipitates separated from the solutions containing HDAC and sodium laurate or adipate (curves *1*, *3*), and also of the mixtures of the solid components (curves *2*, *4*). The spectra of the mixtures show absorption bands at 1390–1620 cm^{-1} due to ionized carbonyls and NH groups of amines (in-plane bending vibrations). The spectra of the precipitated solids (curves *1*, *3*) show a slight low-frequency shift of the COO^- and NH bands and the appearance of a new strong band at 1500 cm^{-1}, which can be considered an indirect evidence in favor of the association.

Thus, the IR spectroscopic and chemical data suggest the formation of R_1R_2 associates in mixed solutions of hexadecylammonium chloride and sodium carboxylates.

Among factors controlling the performance of surfactants as flotation agents is their foaming activity. Therefore, we studied the foaming activity of mixtures of HDAC with sodium carboxylates. It was demonstrated that the foaming activity depends on the nature and concentration of carboxylates (Table 1).

Table 1 shows that the foaming activity of the mixtures increases with the carboxylate concentration. Individual solutions of sodium concentrates do not form foams at concentrations indicated in Table 1. At an HDAC concentration of 2.4×10^{-4} M (no carboxylate additive), the foam layer height is 22 mm. In the presence of 0.28×10^{-4} and 1.21×10^{-4} M sodium pentanoate, the foam layer height increases to 38 and 45 mm, and in the presence of 0.42×10^{-4} and 0.9×10^{-4} M sodium octanoate, to 57 and 45 mm, respectively. With long-chain carboxylates (laurate, palmitate), even at their concentrations of 0.15×10^{-4} and 0.12×10^{-4} M, the foam layer height decreases from the initial 22 mm to 12 and 6 mm, respectively. Thus, the dependence of the foaming activity of the mixtures on the chain length of the carboxylates passes through a maximum corresponding to sodium octanoate.

Furthermore, we found that the foams formed in the presence of sodium pentanoate and octanoate are more stable than those obtained with an individual amine. For example, a foam obtained with the individual amine was broken in 1 h, whereas that formed in the presence of the carboxylate additives retained 44.7–84.2% of its initial height even after 2 h. The opposite effect was exerted by the long-chain (C_{12}–C_{16}) carboxylates. On introduction of sodium palmitate into the amine solution, the foam was practically totally broken in several minutes. Evidently, soluble R_1R_2 associates are formed, in the mixed solutions of the amine with short-chain carboxylates, and these associates, being adsorbed on the gas–liquid interface,

form saturated adsorption layer of increased mechanical strength, thus enhancing the foaming activity of the reagents. In the case of long-chain carboxylates, the associates are poorly soluble, and their precipitation decreases the surfactant concentration at the interface and thus diminishes the foaming. Therefore, long-chain carboxylates, such as sodium laurate and palmitate, serve as defoaming agents.

Since many industrial processes occur in the presence of inorganic salts, it was of interest to examine their effect on the foaming activity of solutions containing HDAC and sodium carboxylates. It is well known that the adsorption of ionic surfactants at the solution–air interface increases in the presence of electrolytes, which is due to partial dehydration of the polar groups, compaction of the diffusion part of the electrical double layer, caused by the transfer of a part of counterions to the Stern layer, and weakening of the electrostatic repulsion between the surfactant molecules. It is a common knowledge that properties of ionic surfactants are most strongly affected by counterions. Therefore, in studying the electrolyte effects, we used salts with cations of varied nature and charge, but with the same anion (KCl, NaCl, $CaCl_2$, and $AlCl_3$) (Fig. 2).

Figure 2 shows that addition of small amounts of the salts (0.23×10^{-5}–8.5×10^{-4} M) to the mixed HDAC–carboxylate solutions enhances the foaming. However, further increase in the electrolyte concentration decreases the foaming, depending on the nature and concentration of both carboxylates and electrolytes.

For example, in the system HDAC–sodium pentanoate, the inorganic additives have a stronger effect than in the system with sodium laurate (Fig. 2). In the former case, at a NaCl concentration of 6.7×10^{-4} M, the foam height was 77 mm, whereas in the latter case, it was only 30 mm, against 20 and 15 mm without electrolyte additive, respectively. A similar effect was also observed with the other salts. It should be pointed out that, with increasing charge of the cation, the maximal foam layer height was observed at a lower electrolyte concentration: 4.7×10^{-5}, 2.25×10^{-4}, 6.7×10^{-4}, and 8.5×10^{-4} M for $AlCl_3$, $CaCl_2$, NaCl, and KCl, respectively. Furthermore, electrolyte additives considerably increase the foam stability, depending on their nature (Fig. 3). In the system HDAC–sodium pentanoate, addition of NaCl, KCl, and $CaCl_2$ increased the foam layer height after 3 h from 7 mm to 25, 17, and 12 mm, respectively (Fig. 3a). In the presence of $AlCl_3$, the foam was broken virtually totally in this time (molar ratio HDAC : car-

boxylate = 0.9 : 0.1 at a total concentration of 2.24 M). In the system HDAC–sodium laurate (Fig. 3b), inorganic electrolytes also improved the foam stability.

As can be seen, low electrolyte concentrations favor the formation of a denser adsorption layer of the surfactant at the gas–liquid interface, thus increasing the foaming activity of the solutions and foam stability. As the inorganic salt concentration is raised further, the surfactant is precipitated, and its concentration in the solution decreases. As a result, the foaming activity and foam stability decrease. The foam breakdown is also preceded leakage of the fluid from the foam (foam syneresis). The foam syneresis is characterized quantitatively by the increase in the volume of a liquid below the foam–solution interface in a fixed period. The time dependence of the fluid leakage rate from the foam can be described by an equation derived in [4]:

$$(K_1/2)\tau = \tau/V_1 - 1/W_0,$$

where K_1 is a constant; V_1, volume of the fluid leaked from the foam per unit cross section of a vessel (m); W_0, initial leakage rate (m s^{-1}); and τ, time (s).

The applicability of this equation to foams was confirmed in [4–6] and in this study. We examined the effect of the electrolyte (KCl, NaCl, $AlCl_3$) concentration on the leakage rate of a fluid from the foams in the systems amine–sodium pentanoate and amine–sodium laurate (HDAC:carboxylate = 0.9 : 0.1 at a total concentration of 2.24 M) (Table 2).

Table 2 shows that introduction of the electrolytes into the systems containing short-chain carboxylates (pentanoate, caprylate) decreases the leakage rate from 2×10^{-2} to 7×10^{-3} m s^{-1}. In the systems with long-chain carboxylates, this effect was insignificant (Table 2). These results are consistent with data presented in Fig. 3, i.e., the higher the foam layer height, the lower the leakage rate from the foam.

Finally, foam formation in HDAC solutions can be controlled by adding appropriate sodium carboxylates and inorganic electrolytes. The HDCA–sodium carboxylate systems can be used as foaming reagents in flotation dressing of potassium ores.

CONCLUSIONS

(1) IR spectroscopic and chemical data suggest that R_1R_2 associates are formed in aqueous solutions

containing hexadecylammonium chloride and sodium carboxylates.

(2) Addition of short-chain sodium carboxylates (pentanoate, octanoate) to hexadecylammonium chloride increases the foaming activity and foam stability.

(3) Introduction of inorganic electrolytes (KCl, NaCl, $CaCl_2$, and $AlCl_3$) into the amine–sodium carboxylate–water system decreases the initial rate of fluid leakage from the foam, which is consistent with data on the effect they exert on the foaming activity.

Abstract—Analysis of the mechanism of congruent dissociative evaporation of solid substances led to a suggestion that potassium permanganate can be used as a possible kinetic standard in thermal analysis.

DOI: 10.1134/S1070427207080058

A search for an appropriate kinetic standard for studies in thermal decomposition of solid substances and their melts is an interlaboratory scientific project initiated about 20 years ago by the Committee for kinetics at the International Confederation for Thermal Analysis and Calorimetry [1]. In experts' opinion [2], the main requirements to an ideal kinetic standard are the following.

(1) The reaction corresponding to thermal decomposition should be irreversible.

(2) The absolute value of the enthalpy of the reaction should be low to restrict the effects of self-cooling or self-heating of the reagent.

(3) The decomposition temperature should not be too high to preclude errors in maintaining this temperature.

(4) The reagent should not react with the ambient atmosphere and the decomposition rate is to be pressure-independent.

(5) The reaction should be independent from sample preparation techniques and particle size.

(6) Relative changes in mass in the course of decomposition should be sufficient for use of small samples.

As demonstrated by the results of interlaboratory tests, summarized by the Committee for kinetics in 1994 [2], the reaction of $Li_2SO_4 \cdot H_2O$ dehydration, chosen (rather arbitrarily) as a possible kinetic standard, proved to be absolutely unsuitable for this purpose. This primarily refers to the fulfillment of requirements 1 and 3–5. Depending on the conditions of thermal decomposition (in particular, presence of H_2O vapor), the parameter E in the Arrhenius equation varied within the range 57–220 kJ mol^{-1}. The negative outcome of these tests strongly diminished the interest in this problem. In the opinion of a participant of the project (D. Dollimor [2]), "the search for the kinetic standard may prove unfruitful because of the dependence of kinetic measurements on reaction pathways and on the effect of various factors on these pathways."

In contrast to the previously employed purely empirical search for a kinetic standard, a new thermochemical approach to the mechanism and kinetics of thermal decomposition processes, developed in the last decade and summarized in the monographs [3, 4], opens up an opportunity for its purposeful choice based on a preliminary theoretical analysis. Let us consider reactions suitable for this purpose. The most important of the above requirements to an ideal kinetic standard are conditions 1 and 4, which predetermine the irreversibility of the reaction and independence of the decomposition rate from the pressure and composition of the gaseous medium. These requirements can only be satisfied in those cases when all the primary products are in states that differ from their equilibrium states. To these cases belong, in particular, reactions of the general form

$$R(s) \rightleftarrows A(g)^* + B(g)^* \rightarrow A(s) + B(g), \qquad (1)$$

where $A(g)^*$ is a poorly volatile product condensed at the instant of decomposition, and $B(g)^*$ is a gaseous

product that is in a nonequilibrium state at the decomposition temperature, e.g., in the form of free O or N atoms which undergo association at the instant of decomposition to give equilibrium molecules O_2 and N_2.

Under these conditions, the partial pressures of the primary products $A(g)^*$ and $B(g)^*$ and, consequently, the decomposition rate of the reagent R(s), too, depend only on the stoichiometry and thermochemical characteristics of the reaction and should be independent of the composition and pressure of the gas in the reactor. An additional condition for constancy of the decomposition rate is the inertness of solid (equilibrium) decomposition products in the presence in the reactor of O_2, H_2, CO_2, H_2O vapor, etc.

Of particular interest among those classes of substances that have been studied so far and decompose to give oxygen and nitrogen in the atomic form [3, 4] are lead superoxide, which decomposes by the scheme

$$Pb_3O_4(s) \rightleftarrows 3PbO(g)\downarrow + O, \quad (2)$$

and, as first noted in the monograph [4], potassium, rubidium, and cesium permanganates. These permanganates have a crystal structure of barite ($BaSO_4$), which decomposes by the scheme [5, 6]

$$BaSO_4 \rightleftarrows BaO(g)\downarrow + SO_2 + O. \quad (3)$$

Taking into account that $BaSO_4$ and the permanganates mentioned above have the same crystal structure, we could expect that the primary stage of their decomposition also occurs with evolution of atomic oxygen:

$$2KMnO_4(s) \rightleftarrows K_2O(g) + 2MnO(g) + 5O \rightarrow K_2MnO_4(s) + MnO_2(s) + O_2. \quad (4)$$

All attempts of the authors of this study to use lead oxide as a kinetic standard failed. Experimental studies revealed that a reverse process, PbO oxidation by oxygen to Pb_3O_4, is superimposed on the process of Pb_3O_4 decomposition, which leads to a decrease in the decomposition rate in the presence of oxygen. A certain limitation on use of Pb_3O_4 is the only slight change (~2.3 wt %) in the mass of the reagent in reaction (2).

The thermal decomposition of potassium permanganate has been the subject of a huge number of studies. During 190 years after the appearance of the first publication in 1817 [7], the mechanism and kinetics of its decomposition have been analyzed by virtually all authoritative laboratories in the world and, in particular, by the authors of [8–16]. Beginning from [7], the equilibrium (resultant) reaction has been represented by the scheme

$$10KMnO_4(s) \rightleftarrows 5K_2MnO_4(s) + 5MnO_2(s) + 5O_2, \quad (5)$$

which is equivalent to the scheme of reaction (4), or by the scheme

$$10KMnO_4(s) \rightleftarrows 3K_2MnO_4(s) + 7MnO_2(s) + 2K_2O(s) + 5O_2, \quad (6)$$

suggested by Rüdorf more than 100 years ago [8]. The difference between these schemes is in the relative amounts of solid products and free oxygen, whose amount varies in the range 10–12 wt %.

EXPERIMENTAL

The main goal of our experiments was to verify the expected independence of the decomposition rate of $KMnO_4$ from the composition and pressure of the gas in the reactor. For this purpose, we measured by isothermal thermogravimetry the absolute decomposition rate of $KMnO_4$ in argon (1 bar) and air (at a pressure of 1 and 4×10^{-4} bar). These data were used to calculate the molar enthalpy of the reaction.

The change in the mass of a sample in unit time, $\Delta m/\Delta t$, and its temperature were measured with a Netzsch STA 429 thermal analyzer. A finely crystalline potassium permanganate (of analytically pure grade) was ground in an agate mortar and compacted into pellets 5.0 mm in diameter and about 0.5 mm thick. The mass of the pellets varied within the range 19.8–20.9 mg. A pellet was placed in a corundum crucible with an inner diameter of 5.7 mm and height of 4.0 mm and the crucible was closed with a small plug of glass wool (~10 mg) to prevent discharge of sample particles upon heating. The rate of sample heating from the ambient to a final temperature varied within the range 493–504 K was 10 deg min^{-1}. The measurements were made in argon (at a pressure of 1 bar) and air (1 and 4×10^{-4} bar) under isothermal conditions. Depending on the temperature of the experiment, the time of complete decomposition (with the stage of heating and the induction period disregarded) was 90 to 50 min. Table 1 lists as an example the results obtained in measuring the absolute decomposition rate of $KMnO_4$ in argon at 493.6 K and calculated values of the molar enthalpy of the reaction.

Let us explain the main stages of the calculation (the calculation scheme was described in detail in [3, 4]). The input parameters automatically recorded by the instrument in the thermogram are the relative loss of mass by a sample, $\Delta m/m$, in a chosen time interval Δt between signal measurements. In this study, Δt was chosen to be 5 min, or 300 s. Hence we found using the apparent formulas the quantities $\Delta m/\Delta t = m_0(\Delta m/m)/\Delta t$ and $\Delta\alpha = (\Delta m/m)/0.11$, where m_0 is the initial mass of a sample and 0.11 is the average, for reactions (5) and (6), fraction of the gaseous product (O_2) with respect to the mass of the reagent. The degree of decomposition at the instant of measurement, α_m, was calculated by summing values of $\Delta\alpha$ during the period of time preceding the measurement, with account of the loss during the time elapsed from the instant of furnace heating to the beginning of measurements. The absolute decomposition rate of powdered samples was calculated by the formula [3, 4]

$$J_p = \frac{\Delta m/\Delta t}{2.8S_m} = \frac{\Delta m/\Delta t}{2.8S_0(1 - \alpha_m)^{1/2}}, \quad (7)$$

where 2.8 is the empirical factor that accounts for the difference in the decomposition rates of the powder and the single crystal; and S_0 and S_m are the effective surface areas of a sample at the beginning of the experiment and at the instant of measurement, respectively.

In our calculations, we took into account that the surface area of a sample decreases as a result of its partial decomposition. It was found experimentally that the relative decrease in area, S_m/S_0, is $(1 - \alpha_m)^{1/2}$. This dependence can be interpreted as resulting from a decrease in the effective area of a compacted pellet with its diameter ("contracting disc" model).

The molar enthalpy of the decomposition reaction was calculated by the third-law method. The equilibrium pressure of atomic oxygen [primary product of reaction (4)] was found using the Hertz–Langmuir equation [3, 4]:

$$P_{eqp} = \frac{(2\pi MRT)^{1/2}}{\gamma M} J_p, \quad (8)$$

where M is the molar mass of oxygen atoms; R, gas constant (8.3145 J mol^{-1} K^{-1}); and γ, conversion factor for recalculating the pressure from pascals to bars (10^5 Pa bar^{-1}), in which units thermodynamic calculations are carried out.

Further, we calculated, taking into account the number ν of moles of the reaction products and the coefficient δ that accounts for the congruent nature of the decomposition [3, 4], the equilibrium constant of reaction (4)

$$K_p = (P_{eqp})^{\nu}/\delta. \quad (9)$$

It was shown in [4] that the congruence factor is determined by the molar masses and stoichiometric coefficients for the decomposition products. For reaction (4), which involves three products (A, B, and C), this factor is given by

$$\delta_C = (\beta_A^C)^a(\beta_B^C)^b, \quad (10)$$

where

$$\beta_A^C = \frac{c}{a}\left(\frac{M_C}{M_A}\right)^{1/2}, \quad (11)$$

$$\beta_B^C = \frac{c}{b}\left(\frac{M_C}{M_B}\right)^{1/2}. \quad (12)$$

Substituting tabulated values of the molar masses of the products of this reaction and the corresponding stoichiometric coefficients ($a = 1$, $b = 2$, $c = 5$), we obtain $\delta = 2.907$.

The enthalpy of the reaction was calculated by the equation

$$\Delta_r H_T^0 = T(\Delta_r S_T^0 - R\ln K_p), \quad (13)$$

where $\Delta_r S_T^0$ is the entropy of the reaction.

Because of the poor reliability of the tabulated values of entropy for some components of reaction (4), we used the averaged value of the molar entropy $\Delta_r S_T^0/\nu$, equal to 160 ± 9 J mol^{-1} K^{-1} in the case of decomposition of the reactants to metal products in the molecular form [3, 4, 17].

As can be seen in Table 1, J_p remains virtually constant (within ±10%) and equal to 7.0 ± 0.7 mg m^{-2} s^{-1} during 45 min of decomposition (with Δm increasing from 0.3 to 0.9). The scatter of $\Delta_r H_T^0/\nu$ from the average value (146.2 ± 0.4 kJ mol^{-1}) is even narrower, ±0.3%.

The method we described was used to determine the absolute decomposition rates and molar enthalpies of the reaction in $KMnO_4$ decomposition under the conditions of all the experiments (Table 2). Analysis of the data obtained suggests the following.

(1) The presence of O_2 in the reactor (0.21 bar) in decomposition of the permanganate in air has no effect on the decomposition rate, which indicates that

	4×10^{-4}	500.3	20.1	0.36–0.95	18.2 ± 6	2.3×10^{-7}	144.3 ± 1.3

oxygen is released in the form of free atoms. This conclusion is confirmed by the results of [16].

(2) A decrease in the pressure of a foreign gas (air) in the reactor by more than three orders of magnitude has nearly no effect on the decomposition rate. A minor increase in the decomposition rate and a decrease in the molar enthalpy (by approximately 2 kJ mol^{-1}), made noticeable by the high precision of the third-law method, may be due to a decrease in the thermal conductivity of the medium, which accelerates the exothermic reaction.

(3) The steady-state decomposition mode is preserved as α varies from 0.3 to 0.9.

(4) An increase in temperature within the range 493–504 K is accompanied by a monotonic rise in the decomposition rate of $KMnO_4$ by approximately a factor of 2–3, but has virtually no effect on the molar enthalpy. The average value of $\Delta_r H_T^0/\nu$ over all the seven experiments is 145.7 ± 1.0 kJ mol^{-1}. The error characterizing the deviation of the results of separate experiments from the average exceeds by only a factor of 1.5–2 the error in determining these values in a single run.

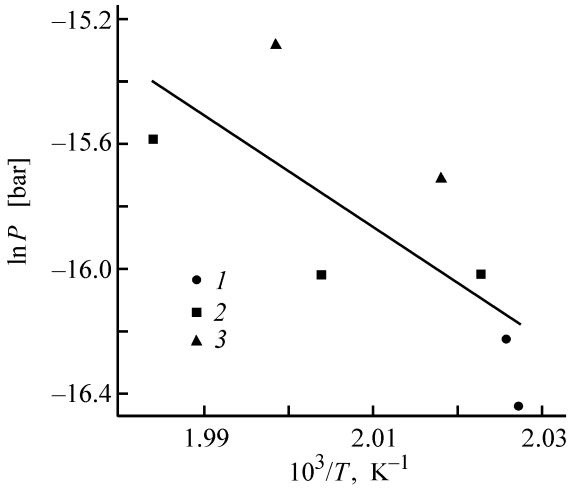
(5) The average value of the molar enthalpy of the reaction (145.7 ± 1.0 kJ mol^{-1}), calculated by the third-law method, agrees with the results obtained in other studies by the method of Arrhenius plots (kJ mol^{-1}): 150 ± 12 [11], 142 ± 13 [13], 165 ± 10 [15], and 143 [16]. The value of the parameter E, found from our data (Table 2) by the sec-

ond-law method (see figure), is 151 kJ mol^{-1}. Because the temperature range of our measurements is narrow (only 10°), the ratio $T_{max}/\Delta T \approx 50$. This results in that the random determination error is 50 times that for the third-law method and reaches 50 kJ mol^{-1} [18].

An analysis of the data obtained in [12, 15, 16] led us to certain additional conclusions in favor of the choice of $KMnO_4$ as a kinetic standard. Erofeev and Smirnova convincingly demonstrated [12] that the kinetic decomposition curves are close for unground crystals and thoroughly ground powders. It was shown that "grinding of a preparation does not lead to any significant change in the kinetics of thermal decomposition of potassium permanganate" [12]. In particular, the maximum degree of decomposition is $\alpha = 0.47$ for the unground preparation (average over eight experiments) and $\alpha = 0.51$ for the ground sample (six runs). Thus, the effect of the particle size on the decomposition rate should not be strong (requirement 5 to the kinetic standard). These observations are confirmed by the data obtained by Brown and coworkers [15], who found no differences in the rates and molar enthalpies of the reactions for freshly prepared $KMnO_4$ crystals (grown from solution) and ground powders. The only distinction consisted in that the induction period decreased (by 10–15 min) for ground preparations. Another important result of [15] was the conclusion that the H_2O vapor does not affect (at pressures of up to 3.5 Torr) the kinetics of $KMnO_4$ decomposition.

Herbstein and co-authors demonstrated [16] by an exquisite experiment with a mixture of $KMnO_4$ crystals labeled with oxygen isotopes (O^{16} and O^{18}) that oxygen evolving as a result of decomposition (analyzed by mass-spectrometry) is composed of a 1 : 1 : 2 mixture of O_2^{32}, O_2^{36}, and O_2^{34}. The formation of O_2^{34} molecules indicates that oxygen is primarily released as free O^{16} and O^{18} atoms, which associate upon mutual collisions into O_2^{34} molecules. The same conclusion was made on the basis of a more complex decomposition mechanism by the authors of [16].

The present study should be regarded as only the beginning of a deeper research, which will be extended to single-crystal $KMnO_4$ samples, other media (in particular, H_2 and CO_2), various thermal analyzers, and measurement techniques (including those of nonisothermal nature). Of particular interest is interpretation of the by no means apparent exothermic nature of the $KMnO_4$ decomposition process, revealed by DTA and DSC [16].



Logarithm of the equilibrium pressure P of atomic oxygen vs. inverse temperature for decomposition of a $KMnO_4$ pellet in various media. $y = -18.14x + 20.589$; $E = 150.8$ kJ mol^{-1}; $r^2 = 0.5571$. (*1*) Argon, (*2*) air (1 bar), and (*3*) air (4×10^{-4} bar).

CONCLUSIONS

(1) The assumption that the reaction of $KMnO_4$ decomposition can be used as a kinetic standard in thermal analytical measurements, made on the basis of a theoretical analysis of the mechanism of congruent dissociative evaporation of solid substances, was confirmed by the results of preliminary thermochemical measurements.

(2) It was shown that the molar enthalpy of the corresponding reaction, found by the third-law method, remains unchanged (145.7 ± 1.0 kJ mol^{-1}) irrespective of the composition (air, argon) and pressure (1 and 4×10^{-4} bar) of the medium.

ACKNOWLEDGMENTS

The authors are grateful to A.K. Galwey for the suggestion to use glass wool to preclude discharge of preparation particles from a crucible in the course of decomposition.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of the Electrothermal Method for Control over Combustion Velocity under Atmospheric Pressure of Energetic Condensed Systems Based on Ammonium Nitrate

Abstract—Experimental results obtained in the initial stage of studies of the electrothermal method for control over the combustion velocity under atmospheric pressure of energetic condensed systems based on an ammonium nitrate oxidizing agent for use in controllable solid-fuel power units are presented.

DOI: 10.1134/S107042720708006X

A topical field of research in aerospace technology still is, together with the development of new formulations for energetic condensed systems (ECS), a search for promising methods for physical control over working processes in solid-fuel gas-generating installations whose operation is independent of the hydrodynamic conditions in the combustion chamber and energy characteristics of the fuels used [1].

The method suggested in [2–4] is based on the fact that, under normal conditions, the composite solid fuel (CSF) is an insulator and the condensed phase (c-phase) of the reaction (combustion) zone has a high electrical conductivity because of the presence of components in the liquid phase, e.g., oxidizing agents (nitrates or perchlorates of alkali metals) or molten metals, or presence of free carbon on the ECS combustion surface with a negative oxygen balance. Passing an electric current through the reaction zone of the c-phase will lead to a rise in temperature and, in accordance with the Arrhenius law, to a change in the kinetics of the initial stages of oxidation reactions, and primarily to acceleration of rate-determining reactions or diffusion processes in heterogeneous systems, with the resulting increase in the combustion velocity.

To implement this method for control over the combustion velocity, a set of metallic electrodes is built in the solid-fuel charge in the combustion chamber. These electrodes provide a permanent contact between the conducting zone and a controllable power source, via which an electric current is passed through the reaction zone of ECS. All other conditions (chemical composition, initial temperature of the fuel, temperature and pressure in the chamber, etc.) being the same, the decomposition rate of the condensed phase will be a function of the current flowing through the electrically conducting layer. As the fuel combustion front moves and the electrodes in the form of thin metallic foil or a grid pass into the flame zone, they can burn out at the interface between the condensed and gaseous phases, i.e., can be involved in chemical reactions as a fuel.

EXPERIMENTAL

We used in our experiments model formulations (CSF) with edge burning, based on ammonium nitrate (AN) and ammonium perchlorate (APC) taken in various mass ratios. The fraction of the binder, ED-20 epoxy resin with urotropin as curing agent, was the same and equal to 10%. To prepare a charge, dried fractions of the oxidizing agents with 100–200-μm particles were mechanically mixed with the binder and then the fuel mass (20–25 g) was placed in special rectangular cassettes ($21 \times 15 \times 50$ mm) and compacted under a pressure of 8 ± 0.5 MPa. After that the binder was cured at 75–80°C for 18–20 h. The average combustion surface area of the samples was 3.2 cm^2.

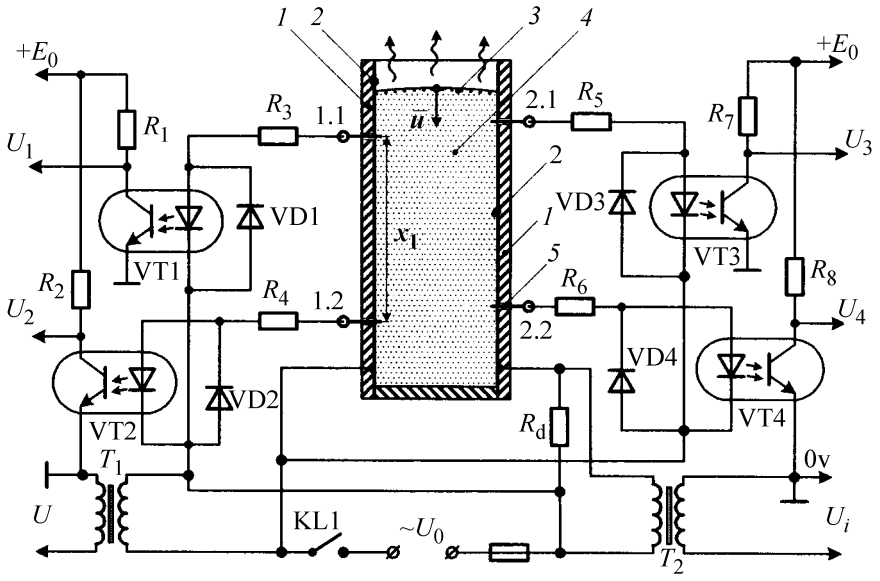

Fig. 1. Measuring unit of the experimental installation. (*1*) Charge case, (*2*) metallic foil, (*3*) combustion surface (front), (*4*) fuel mass, (*5*) electrodes (1.1, 1.2, 2.1, 2.2) of the combustion front position sensor; u is the motion velocity of the combustion front.

The procedure used to measure the charge combustion velocity [5] and the current and voltage in the reaction zone of ECS is schematically illustrated by Fig. 1. The two opposite sides of the dielectric case are made of plates of foil-clad textolite *1*, whose copper layers *2* face the fuel mass *4* and are connected to an electric voltage source ($\sim U_0$). The plates have apertures into which 0.4-mm-thick electrodes *5* are mounted so that they are insulated from the copper foil. The distances x_n between the electrodes were measured with an MBS-10 microscope. Thus, the chamber design is that of a flat capacitor. Under normal conditions, in the absence of adsorbed moisture on the open surface of the charges, the fuel masses have a resistance exceeding 20 MΩ (measured with V7-38 meter), which probably corresponds to a resistivity close to that of the binder.

In the course of combustion, the moving front of the heated electrically conducting reaction zone of the condensed phase of the fuel, having a thickness of about 0.1 mm, successively passes across the wire electrodes, which become connected to the voltage source ($\sim U_0$) at these instants of time, with the result that the optoelectronic switches VT1–VT4 are opened. When finding themselves in the flame zone, the electrodes melt and burn-out together with the case. The distances between the corresponding pairs of electrodes and the response instants of the switches VT are used to calculate the average combustion velocities on two sides of the charge. The choice of the number and positions of the electrodes is determined by the goals of an experiment.

Because the combustion of ECS may be rather fast, all the parameters being measured are recorded on-line with a computer connected via a multichannel analog data input interface (L-264 manufactured by L-card Co.), with the subsequent processing of the oscillograms with a special software [6]. The procedure used to determine the combustion velocity of ECS, which employs the electrical conductivity of the reaction zone, has a faster response as compared with the classical method of burning-out metallic threads, introduces the minimum perturbations into the combustion process, but is only applicable to measurements of comparatively steady-state processes along short control distances. Its application is reasonable in the absence of special acoustic (ultrasound) or optical measuring installations.

The velocity u of CSF combustion under the action of an electric current was measured at atmospheric pressure by the two-factor scheme: $u = F(\chi, U_x)$, where χ is the chemical composition of ECS, and U_x is the voltage applied to the charge. Five series of experiments with varied chemical composition (see table) were carried out, with 6–8 runs in each series at different effective ac (50 Hz) voltages in the range 2–235 V. All other factors affecting the combustion velocity were maintained constant. The calculation was made using the following for-

Sample composition and voltage ranges

Sample no.	Content of components χ^*, %	Density** $\rho \times 10^{-3}$, kg m^{-3}	ΔU_x, V
1	90 NA + 10 ED20	1.48	50–170
2	85 NA + 5 PBC + 10 ED20	1.51	2–235
3	90 [75 NA + 25 APC] + 10 ED20	1.52	30–200
4	90 [50 NA + 50 APC] + 10 ED20	1.56	50–235
5	90 [25 NA + 75 APC] + 10 ED20	1.60	2–200

* PBC is potassium bichromate.

** At a densification factor of 0.9.

mulas: $U_x = U_0 - U_{rd}$, voltage applied to the charge (V); $I = U_{rd}/R_d$, current in the reaction zone of the c-phase of ECS (R_d = const) (A); $R_x = U_x/I$, resistance of the reaction zone (Ω); $N = IU_x = I^2R_x = U_x^2/R_x$, electric power dissipated in the reaction zone (W); $Q = N/m''$, specific energy expenditure for control over the mass expenditure (kJ kg^{-1}); and $m'' = \rho Su$, mass (per-second) expenditure of the fuel (kg s^{-1}), where S is the combustion surface area; ρ, ECS density; and u, combustion velocity.

The experimental results we obtained are shown in Figs. 2–6. The approximating straight lines are plotted using the least-squares method. The measurement errors are mostly due to the scatter of physicochemical parameters of separate samples, which is due to their preparation technique.

Figures 2 and 3 show how the electric voltage and current affect the combustion velocity of composite solid fuels. The maximum increase in the combustion velocity (by a factor of 4.5) in the voltage range studied was observed for the [75 AN + 25 APC] fuel. The current and, accordingly, the thermal power released in the reaction zone is determined by its active resistance.

The numerical values of the resistances of the reaction zones, related to the geometric dimensions of the combustion surface (21 × 15 mm), can be found from the slopes of the straight lines in Fig. 4. It can be seen that the conductivity of the reaction zones decreases as the mass fraction of ammonium perchlorate in the CSF becomes higher. The linear run of the current–voltage (I–V) characteristics suggests that the electrical conductivity of the reaction zone is described by the Ohm's law in the ranges of steady combustion of the fuels studied.

It was found that the heating of the reaction zone by the electric current leads to accelerated ignition (from an external flame source) and stable combustion of CSF of all the compositions studied, under atmospheric pressure. At the same time, initial ignition and independent combustion in the absence of a voltage was only observed for [AN + PBC] and [25 AN + 75 APC] samples. Thus, the action of an electric current of a certain power can enable stable

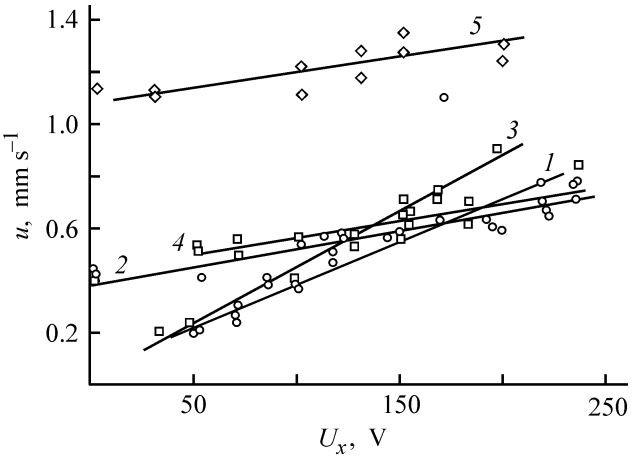

Fig. 2. ECS combustion velocity u vs. votage U_x. (*1*–*5*) sample nos.; the same for Figs. 3–6.

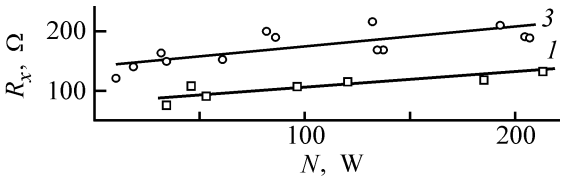

Fig. 6. Variation of the resistance R_x of the reaction zones with the power *N* released by the electric current.

combustion of solid fuels under pressures that are considerably lower than the critical threshold of the minimum pressure of the gas phase ($P_{cr} > 1$ MPa).

It follows from Fig. 5 that, under atmospheric pressure, the energy consumed for changing the mass expenditure of the fuel decreases for the samples studied by nearly an order of magnitude as the mass fraction of APC increases, i.e., the energy content of CSF becomes higher. The practical range of control over the mass expenditure by the gas-generating device can be primarily limited by the electric power of the current source used.

As the power released by the electric current grows, the resistances of the reaction zones become higher (Fig. 6), which can be attributed to an increase in the degree of their gasification and to a decrease in the resultant density of the liquid layer.

There exists an upper limit to the electrothermal acceleration of the combustion velocity of ECS, which depends on the chemical composition of the fuel. This is due to an increase in the degree of gasification of the liquid reaction zone and to discharge of molten fragments of CSF into the gas phase, which is reflected in a deviation of the forced combustion from the linear behavior.

For the CSF formulations [25 AN + 75 APC] and [85 AN + 5 PBC], which are capable of stable combustion under atmospheric pressure, we measured the amplitude-frequency dependences of the electrical conductivity of the reaction zones. For this purpose, we connected a G3-110 program-controlled sinusoidal voltage generator to the charge as a $\sim U_0$ voltage source (Fig. 2). During the ECS combustion, the frequency of the applied voltage $U_0 = 2$ V was discretely changed in a cyclic way every 0.8 s in the range from 50 Hz to 20 kHz. The generator output voltage $U_0(t)$ and the voltage $U_{rd}(t)$ across the resistor R_d were recorded by a computer with a sampling frequency dt = 10 kHz. In this frequency range, the voltage applied to the charge, $U_x(t) = U_0(t), - U_{rd}(t)$, remains constant and no phase shift between $U_0(t)$ and $U_x(t)$ is observed.

Similar results were obtained for CSF samples with potassium bichromate; however, the physical reasons for this similarity may be of some other nature. In this case, the formulation has a large negative oxygen balance and the combustion is accompanied by the formation on the surface of a considerable amount of a condensed carbon residue with electronic conduction. As a result, the AN melt in the reaction zone can be shunted by free carbon and the ionic type of conduction will not be manifested.

The results we obtained suggest that, in the cases studied, the electrical conductivity of the reaction zones has a predominantly electronic nature because the resistance of the combustion surface is frequency-independent in the frequency range specified. Thus, the reaction zone of the c-phase is an active load for

the current source. By contrast, pure melts of nitrates (NH_4NO_3, KNO_3) have ionic conductivity (NH_4^+, K^+, NO_3^-) and show a nonlinear frequency dependence of the conductivity.

Analysis of the effect of electrolysis on the kinetics of chemical reactions in the reaction zone requires a separate study. For example, electrochemical processes may be manifested in the case of a dc current in a difference between the ECS combustion velocities in the near-electrode regions of the cathode and anode.

We experimentally observed flame quenching and repeated ignition of (AN + APC) charges, with restoration of the combustion velocity, upon changes in the working voltage to, respectively, below and above a certain critical threshold (30–40 V). The repeated ignition occurred, if the reaction zone remained in the electrically conducting state, upon an increase in the effective power released by the flowing electric current. In fact, controlled combustion is a possible solution to the difficult problem of providing recurring short-time operation modes of solid-fuel installations by controlling the temperature of the reaction zone of the c-phase of ECS at the stable combustion threshold under the current thermodynamic conditions.

CONCLUSIONS

(1) An electrothermal method for control over the combustion velocity of energetic condensed systems was experimentally implemented.

(2) A stable combustion of samples of composite solid fuels (without catalysts) was obtained at atmospheric pressure under the action of electric current.

(3) The widest variation range of the combustion velocity (by a factor of up to 4.5) was observed for the formulation with 75% ammonium nitrate and 25% ammonium perchlorate. The specific energy consumption for control over the mass expenditure becomes lower as the energy content of the system increases (ammonium perchlorate concentration becomes higher).

(4) It was shown that the electronic conduction dominates in the reaction zones of the condensed phases of energetic condensed systems based on ammonium nitrate and ammonium perchlorate.

(5) It was concluded that the probable reason why the combustion velocity of the systems increases under the action of electric current is the occurrence of the electrothermic effect and the increase in the rate of chemical reactions in the condensed phase with temperature in accordance with the Van't Hoff rule and Arrhenius equation.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Application of the Zdanovskii Rule to Liquid Metal Systems with Strong Interaction of Components

A. G. Morachevskii and T. V. Butukhanova

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received June 27, 2007

Abstract—Applicability of the Zdanovskii rule to liquid metal systems with strong deviations from ideal behavior is discussed for the example of the lead–thallium–sodium system.

DOI: 10.1134/S1070427207080071

Seventy years ago Zdanovskii [1] established, based on a study of a large number of aqueous electrolyte solutions, a simple law, which became known as the Zdanovskii rule: the activity of water remains unchanged on mixing isopiestic solutions of different electrolytes that do not interact chemically with each other. In other words, there is a large number of ternary systems A(1)–B(2)–H_2O(3) in which lines of equal chemical potentials of water remain straight in a wide range of solution compositions. The main condition for this rule to be obeyed is the absence of a chemical interaction between the solutes. If we denote the molalities of components in the initial binary solutions by m_1^0 and m_2^0, and the molalities of the same components in the resulting mixed solution by m_1 and m_2, we can write down

$$m_1/m_1^0 + m_2/m_2^0 = 1, \quad (1)$$

$$m_2 = m_2^0 - m_1 m_2^0/m_1^0. \quad (2)$$

In a geometric representation of ternary systems described by the Zdanovskii rule, the plot of the $m_2 = f(m_1)$ dependence in the rectangular coordinate system (first Rosebome's method for representation of the composition of ternary systems [2]) is a straight line that intersects the coordinate axes at points corresponding to the component concentrations in binary mixtures with equal activities of the solvent (component 3, which is water in the case in question).

Later, the relationship under consideration was substantiated thermodynamically, which made it possible to distinguish among aqueous systems a special class of isoactive electrolytes described by the Zdanovskii rule [3–7]. Zdanovskii and other researchers also successfully applied the additivity principle to calculations of electrolyte properties, such as density, heat capacity, and heat of dissolution [8, 9].

The Zdanovskii rule can be used for a thermodynamic description of multicomponent electrolytes. Let us denote the molality of components in the initial binary solutions of a multicomponent system by m_i^0 (i = 1, 2, 3, ...), and the molality of the same components in the mixed system by m_i. Then, provided that the initial binary solutions are in an isopiestic equilibrium between each other and with the multicomponent solution formed, the mathematical form of the Zdanovskii rule for systems with n components will look like

$$\sum_{n}^{n-1} \frac{m_i}{m_i^0} = 1. \quad (3)$$

This rule is valid not only for solutions of salts with the same anion, as it was assumed originally, but for any mixed solution, irrespective of outward characteristics of systems. It was shown by Zhichang [10] that Eq. (3) retains its form irrespective of how the concentration is expressed, i.e.

$$\sum_{n}^{n-1} \frac{m_i}{m_i^0} = \sum_{n}^{n-1} \frac{x_i}{x_i^0} = \sum_{n}^{n-1} \frac{w_i}{w_i^0} = 1. \quad (4)$$

Here x_i and w_i are the respective mole and weight fractions of ith component in the initial binary solutions.

In this case, all the three expressions for the composition can be extended not only to the activity, but also to other partial molar functions.

* Section: I, Pb–Na; II, ($x_{Pb} : x_{Tl} = 4 : 1$)–Na; III, ($x_{Pb} : x_{Tl} = 1 : 1$)–Na; IV, ($x_{Pb} : x_{Tl} = 1 : 4$)–Na; V, Tl–Na.

In this study, we considered in detail the application of the Zdanovskii rule to liquid ternary metal systems including two boundary systems with a strong interaction between the components. The thermodynamic properties of the liquid systems Pb(1)–Tl(2)–Na(3) were studied by the electromotive-force method along sections with constant ratios of mole fractions of lead (x_1) and thallium (x_2) equal to 4 : 1, 1 : 1, and 1 : 4 at temperatures from the liquidus line up to 883 K [11]. The thermodynamic properties of the boundary systems Pb–Na and Tl–Na have also been studied in detail [12, 13]. In both systems, significant negative deviations from ideal behavior are observed (Fig. 1), whereas in the Pb–Tl system, both components are so close in properties that the system they form is nearly regular (Fig. 2) [14].

The compositions of liquid alloys of ternary system Pb–Tl–Na along the lines with constant sodium activ-

ity, found from experimental data (Fig. 3), are listed in Table 1. If the Zdanovskii rule is obeyed, the compositions along the sodium isoactivity lines should satisfy Eq. (4) written for the ternary system:

$$x_1/x_1^0 + x_2/x_2^0 = 1. \quad (5)$$

It is seen from Table 2 that deviations from the Zdanovskii rule for the compositions lying on sodium isoactivity lines do not exceed 1.5%, i.e., fall within the accuracy limits of the experimental method and the plotting procedures. Thus, as already noted [3], the Zdanovskii rule can be extended to ternary systems of varied nature, in which two components rather actively interact with a third component, conditionally regarded as a "solvent", and weekly interact (or virtually do not interact at all) with each other. From the thermodynamic standpoint, the systems described by the Zdanovskii rule belong to the class of systems in which isopotentials of one of the components (component 3, which is sodium in our case) are straight lines. The linearity of isopotentials of one of the components of a ternary system simplifies solution of quite a number of problems in a thermodynamic description of systems of this kind [3, 11].

CONCLUSIONS

It was shown that, during the seventy years of existence of the Zdanovskii rule, it has found application in description of the thermodynamic properties of ternary and more complex systems of substances of various classes. The applicability of the Zdanovskii rule to liquid alloys of the ternary system lead–thallium–sodium (850 K) was demonstrated.

SORPTION AND ION-EXCHANGE PROCESSES

Specific Features of Absorption of Cu^{2+}, Zn^{2+}, Co^{2+}, and Pb^{2+} Cations from Aqueous Solutions by Calcium Phosphates

Abstract—Kinetic characteristics of the interaction of trisubstituted calcium phosphate $Ca_3(PO_4)_2 \cdot xH_2O$ with Cu^{2+}, Zn^{2+}, Co^{2+}, and Pb^{2+} ions in aqueous solutions were studied.

DOI: 10.1134/S1070427207080083

Compared with the conventional sorbents and ion-exchange resins, calcium phosphates can absorb considerably larger amounts of heavy and nonferrous metals from aqueous solutions. The absorption proceeds by the chemisorption mechanism as a chemical reaction of substitution of calcium ions in the starting phosphate with ions of other metals and occurs in those cases when the forming product has a lower solubility than the starting phosphate.

It has been shown previously [1] that the reactivity of amorphous trisubstituted calcium phosphate $Ca_3(PO_4)_2 \cdot xH_2O$ in interaction with lead ions is largely determined by its porous structure. Macroporous calcium phosphates have high chemical activity and their theoretical sorption capacity is rapidly utilized when they are brought in contact with aqueous solutions containing Pb^{2+} ions. With calcium phosphate with a porous structure used as a sorbent, the stage of fast initial absorption is followed, depending on the reaction conditions, either by deceleration or by termination of the reaction. This occurs as a result of accumulation of chemisorption products and blocked access of Pb^{2+} ions to unreacted areas on the surface of the starting material. As the time of contact between the solid phase and the solution, which may occasionally be no less than 10–20 days, increases, chemisorption is resumed and proceeds to full completion. In this case, the theoretical sorption capacity of both meso- and macroporous samples for lead ions is utilized.

A study of this process by X-ray phase analysis and optical microscopy demonstrated that the resumption of the reaction between calcium phosphate and lead is due to crystallization of the final product, change in the volume of the substance, and dispersion of the starting phosphate particles into finer fragments.

The above pattern of interaction between calcium phosphates of varied porous structure and lead may be markedly different in absorption of other ions because of the differences in the chemical and phase composition of the final products, specific features of their crystallization, and physicochemical properties.

To elucidate the influence exerted by the nature of an ion being absorbed on the chemisorption activity of calcium phosphates, we studied the kinetics of absorption of copper, zinc, lead, and cobalt ions by macro- and mesoporous calcium phosphates.

EXPERIMENTAL

Phosphate samples of varied porous structure were obtained by chemical precipitation [1]. For this purpose, 5% solutions of calcium nitrate or ammonium hydrophosphate (both of (chemically pure grade) were alkalized with ammonia solutions to pH 10 and then were rapidly poured together. The volume ratio of the poured-together solutions was chosen so as to provide the required ratio Ca : P = 1.5 : 1.0. The gel-

Basic characteristics of macro- (B) and mesoporous (A) calcium phosphates

Series	Water content, wt %	Ca : P	S_{sp}, $m^2\ g^{-1}$	V_s	V	d, g cm^{-3}	
				$cm^3\ g^{-1}$		true	apparent
A	2.0 ± 0.1	1.56 : 1	115 ± 5	0.32 ± 0.01	0.30 ± 0.2	2.4 ± 0.01	1.4 ± 0.03
B	6.1 ± 0.1	1.57 : 1	56 ± 5	0.21 ± 0.01	2.8 ± 0.3	1.9 ± 0.01	0.3 ± 0.03

like precipitates obtained were washed on a Buchner funnel with a weak NH_4OH solution and dried in air, first at room temperature and then at 70°C. In one case (series A), the gel was not subjected to any additional treatment before drying. In the other (series B), the gel was preliminarily treated, when preparing coarsely porous phosphates, with ethanol in order to rapidly remove the main part of water from the humid precipitate and then was placed in a drying box. Calcium phosphate xerogels were ground in a mortar and the 125–160-μm fraction was screened out and further used in the study.

The samples obtained were dissolved in concentrated hydrochloric acid and analyzed for the content of calcium (complexometric titration with eriochrome black) and phosphorus (by photocolorimetry after formation of phosphor-molybdenum blue). The structural parameters, specific surface area S_{sp} ($m^2\ g^{-1}$) and sorption pore volume V_s ($cm^3\ g^{-1}$), were found from adsorption isotherms of carbon tetrachloride (measured on a weighing vacuum-adsorption installation with a spring balance), adsorption isotherms of nitrogen (obtained using a NOVA 2200 instrument), and low-temperature adsorption of nitrogen by the Klyachko–Gurvich method. The specific surface area was calculated by the BET method [2]. The residual content of water in the samples was found from the loss of mass upon calcination at 300°C for 1 h.

The absorption of ions of divalent metals from 0.01–0.05 M solutions of $M(NO_3)_2$ (analytically pure, M = Pb^{2+}, Co^{2+}, Zn^{2+}, Cu^{2+}) was studied under static conditions at room temperature. A 0.05-g portion of a substance from the screened-out 125–160-μm fraction was poured over with solutions of $M(NO_3)_2$ salts at a certain value of R characterizing the ratio between the liquid (ml) and solid (g) phases. When determining the chemisorption capacity for the metal ion M^{2+} and carrying out kinetic experiments, R was varied within the range from 200 to 1000 (10 to 50 ml of a solution per 0.05 g of the sorbent) so as to provide, irrespective of the concentration, a constant content of a metal in solution in an amount necessary for complete transformation of the starting sorbent into the final product. The thus obtained water–salt systems were kept, with periodic agitation, at a prescribed temperature (20°C) for various intervals of time (5 min to 60 h). Then, the precipitates were separated from the solution, washed with water, and dried for further study. The equilibrium liquid phase was analyzed for the content of M^{2+} by complexometric titration with methyl thymol blue as indicator in an acetate buffer solution at pH 5.

An X-ray phase analysis of the starting phosphates and reaction products was performed with a DRON-3 diffractometer with Cu_{K_α} radiation.

A MIN-8 microscope was used for visual inspection of processes occurring at the phase boundary.

The table lists the averaged results of chemical analyses of the samples synthesized and data on their specific surface area S_{sp} and sorption (V_s) and total (V) pore volumes calculated from the difference of the inverse apparent and true densities [22].

As can be seen from the table, the Ca : P ratio in the precipitated products is rather close to the stoichiometric value of 1.5 : 1.0, characteristic of tertiary calcium phosphate $Ca_3(PO_4)_2 \cdot xH_2O$, and, as demonstrated by experimental results [1], is independent of the phosphate preparation conditions.

Calcination of samples in air at 800°C yields anhydrous tertiary calcium phosphates, which is confirmed by the fact that tertiary salts containing no acid or basic impurities are obtained.

As follows from the results of an X-ray phase analysis, phosphates of series A are poorly crystalline products. Samples of series B are amorphous [1]. The ordering of the crystal structure of calcium phosphate probably creates more favorable conditions for removal of water, and, therefore, samples of series A contain a smaller amount of residual water (see table).

The results obtained in a study of the pore structure of the samples synthesized were reported in [1]. Figure 1 shows typical isotherms of carbon tetrachloride sorption by calcium phosphates of series A and B.

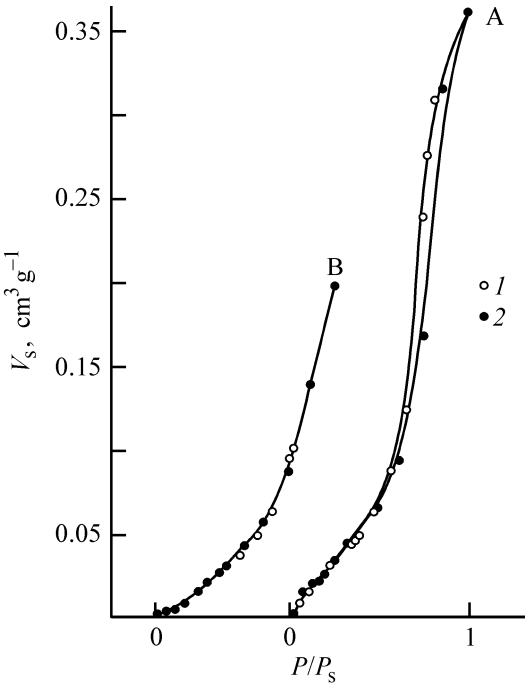

Fig. 1. Typical isotherms of CCl_4 sorption by calcium phosphates of series A and B. (V_s) Limiting sorption volume and (P/P_s) relative pressure. (*1*) Starting phosphate and (*2*) $Ca_3(PO_4)_2 \cdot 8H_2O$.

As follows from the data in the table and Fig. 1, the samples obtained markedly differ from each other in physical characteristics. For example, the sorption and total pore volumes found from the difference of the inverse apparent and total densities are virtually identical, whereas the total volume of pores in sample B markedly exceeds their sorption volume. This is a direct evidence that sample B contains macropores that are not filled by a liquefied vapor of the adsorbate in the course of adsorption.

Thus, sample A is a mesoporous sorbent according to the results of adsorption analysis (see table, Fig. 1). The absence of a hysteresis loop in the sorption isotherm, comparatively small specific surface area, and considerable difference between the sorption and total pore volumes of the phosphate sample B suggest that this sample is coarse-porous. In this case, the method of capillary condensation is unsuitable for determining the position at which the differential porosity and pore space volume are at a maximum because of the limited applicability of the Kelvin equation [2].

Figures 2a–2d show kinetic curves of absorption of Cu^{2+}, Zn^{2+}, Co^{2+}, and Pb^{2+} ions by calcium phosphate samples with macro- (B) and mesoporous (A) structure.

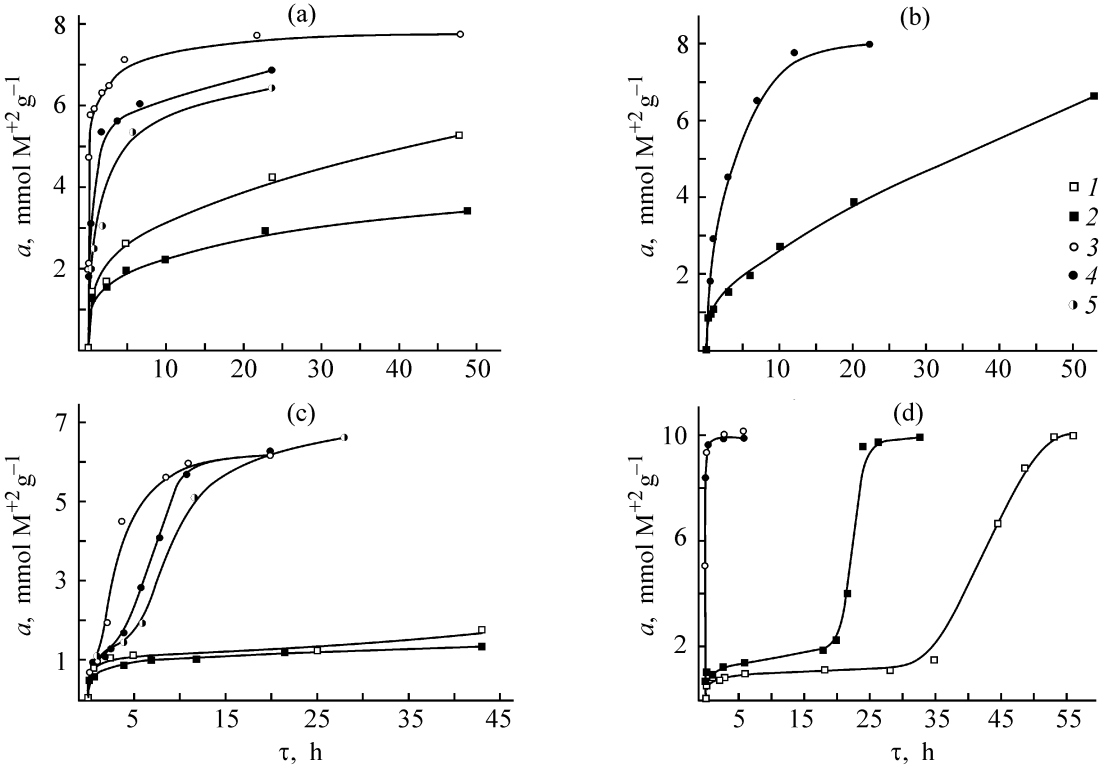

Fig. 2. Kinetic curves of absorption of (a) Cu^{2+}, (b) Zn^{2+}, (c) Co^{2+}, and (d) Pb^{2+} ions by calcium phosphate samples of series (*1*, *2*) A and (*3*–*5*) B from aqueous solutions at 20°C. (*a*) Amount of absorption and (τ) interaction time. M^{2+} concentration (mM): (*1*, *3*) 50, (*2*, *4*) 25, and (*5*) 10.

It follows from the results obtained (Fig. 2) that, in contrast to mesoporous phosphates, macroporous phosphates exhibit a higher activity in interaction with metal ions in aqueous solutions. In this case, the amount of absorption is as high as 10 (Pb^{2+}), 7–8 (Zn^{2+} and Co^{2+}), and 6.5 mmol (Cu^{2+}) per gram of the starting phosphate in a time $\tau \approx 5$–25 h, which constitutes 93, 72–83, and 67% of the theoretical value, respectively.

According to the results of an X-ray phase analysis, the final reaction products are the tertiary phosphates $Cu_3(PO_4)_2 \cdot 3H_2O$, $Zn_3(PO_4)_2 \cdot 4H_2O$, $Co_3(PO_4)_2 \cdot 8H_2O$, and in absorption of lead ions, pyromorphite $Pb_5(PO_4)_2OH$. In our case, all these reaction products, except copper phosphate, have a well-formed crystal lattice.

No indications that a new phase is formed are observed in the initial stage ($a < 1$ mmol g^{-1}) of absorption of Cu^{2+}, Zn^{2+}, Co^{2+}, and Pb^{2+} ions by calcium phosphate of series A. This is possibly due to a lag of crystallization processes behind the chemical stage of the reaction. For a macroporous sorbent of series B this lag becomes even more pronounced, as it is shown for the example of absorption of Co^{2+} ions by calcium phosphates (Fig. 3).

As the time of contact between the solid phase and an aqueous solution becomes longer, the degree of crystallization of the final product grows even in those cases (e.g., in sorption of lead) when the process of ion absorption virtually ceases. The reason for this effect is related to the crystallization mechanism of the reaction products. Specific features of this stage of the process are considered in detail in what follows.

X-ray phase analysis data are in good agreement with the results of a visual inspection with an optical microscope. For example, the initial absorption is characterized in all cases by absence of any indications of a chemical reaction, with the exception of a slight coloration of the surface of phosphate particles in their interaction with Co^{2+} or Cu^{2+} ions.

A specific feature of the chemical transformations that occur at the phase boundary is that the shape of kinetic curves, and their formal similarity or dissimilarity, give no way of making any unambiguous conclusions about the mechanism of a particular chemical process. This requires additional studies and, in particular, a phase analysis and visual monitoring of changes experienced by the starting solid phase and by the intermediate and final products formed in the course of the reaction.

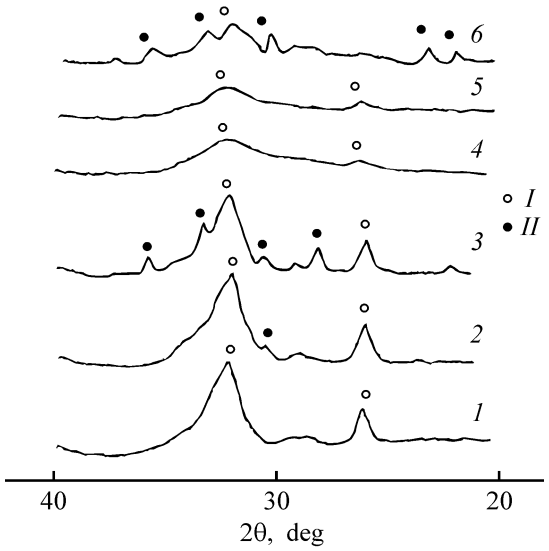

Fig. 3. X-ray diffraction patterns of calcium phosphates and products of their interaction with Co^{2+} ions in an aqueous solution. ($c_{Co^{2+}}$ = 25 mM). (2θ) Bragg angle. (*I*) Starting phosphate and (*II*) $Ca_3(PO_4)_2 \cdot 8H_2O$. (*1*) Starting $Ca_3(PO_4)_2$-A; (*2*) a = 1.0, τ = 18; (*3*) a = 2.1, τ = 0.96; (*4*) starting $Ca_3(PO_4)_2$-B; (*5*) a = 1.5, τ = 4; and (*6*) a = 2.8, τ = 6.

As shown previously [1], the reason for a dramatic decrease in the rate of absorption of Pb^{2+} ions by calcium phosphate of series A after the initial fast stage is the formation of a dense pseudo-amorphous layer of the reaction product, which hinders supply of metal ions to unreacted parts of the starting phosphate. The formation of the pseudmorphosis in the initial stage of the transformation does not change the outward appearance of a particle. The crystallization of the amorphous product is accompanied by a noticeable increase in the volume of a substance and its self-dispersion, followed by vigorous resumption of the reaction (Fig. 2d).

According to the results of a microscopic analysis, virtually no dissolution of the pseudomorphosis or reprecipitation of pyromorphite is observed in the course of the transformation near the surface of calcium phosphate A, and, therefore, the contribution of these processes to the subsequent self-acceleration of the reaction cannot be significant. Presumably, the resumption of the reaction and the avalanche rise in its rate are due to crystallization of pyromorphite within the pores of the starting phosphate and to disintegration of sorbent particles under the action of mechanical stresses, which surpass the ultimate strength of substance particles.

As demonstrated by the experimental data obtained, the absorption of Cu^{2+} ions by calcium phosphates

of series A and B occurs, untill full completion of the reaction, bypassing the stage of dissolution of pseudomorphosis. In this case, the reaction is not accelerated (Fig. 2b). After the absorption of Cu^{2+} ions is complete, phosphate particles retain their original dimensions and integrity, as it is observed in interaction of coarsely porous phosphate $Ca_3(PO_4)_2$ (B) with Pb^{2+} ions.

Despite the formal similarity of the sets of kinetic curves (Figs. 2a and 2b, and to a lesser extent Figs. 2c and 2d), noticeable differences are observed in absorption of Cu^{2+} and Zn^{2+} ions, and, respectively, Co^{2+} and Pb^{2+} ions, by calcium phosphates from aqueous solutions. For example, the final products of interaction of phosphates A and B with Co^{2+} and Zn^{2+} ions crystallize in all cases without exception via the stage of pseudomorphosis dissolution. The reprecipitation process occurs both at particle boundaries and in the near-surface layer of the solution. The certain discrepancies in the absorption rate of Zn^{2+} and Co^{2+} ions by phosphates A and B (Figs. 2b, 2c) and the appearance of inflections in the kinetic curves (Fig. 2c) can probably be attributed to the state of the starting substance (density, porosity, permeability) and to the properties of the intermediate pseudomorphoses obtained and, in particular, to their chemical composition and dissolution rate.

The results obtained are in good agreement with the known topochemical rule, according to which the physicochemical characteristics of the starting solid phase can strongly affect the properties of the forming product and the rate at which it passes through intermediate states. In our case, the wide diversity of the effects observed is due not only to the state of the starting calcium phosphate, but also to the different chemical compositions and properties of intermediate pseudomorphoses.

The experimental data were mathematically processed in terms of the known topokinetic equation $\alpha = 1 - e^{k\tau^n}$, where α is the degree of conversion of the starting substance; τ, time; and k and n, rate constant and kinetic parameter of the reaction [3], respectively. It was found that, in most cases, the absorption of Cu^{2+}, Zn^{2+}, Co^{2+}, and Pb^{2+} ions is limited, already in initial stages, by their diffusion to the unreacted surface of the phosphate across a layer of a poorly crystallized reaction product. The obtained values of the kinetic parameter n are 0.10–0.58, which is typical of diffusion processes. The permeability of the pseudomorphosis and the mechanism and rate of its crystallization predetermine the ability of calcium phosphate to absorb ions of heavy and nonferrous metals from aqueous solutions, as well as the rate and extent of the reaction.

CONCLUSIONS

(1) The chemisorption activity of tertiary calcium phosphates in interaction with ions of heavy and nonferrous metals in aqueous solutions is largely determined by their porous structure.

(2) The chemical composition and properties of chemisorption products and the rate and mechanism of crystallization of pseudomorphoses depend on the nature of a cation being absorbed.

(3) Specific features of the crystallization of the final reaction product are factors that can change the rate and extent of the chemisorption process.

SORPTION AND ION-EXCHANGE PROCESSES

Anion Exchangers Based on Modified Shungites

A. M. Akimbaeva and E. E. Ergozhin

Bekturov Institute of Chemical Sciences, Almaty, Kazakhstan

Received September 26, 2006; in final form, January 2007

Abstract—Modification of shungite with polyamines, followed by cross-linking with epoxy compounds, yielded chemically and thermally stable polyfunctional anion exchangers. The effect of the nature of a polyamine and epoxy compounds and of the carbon content of shungites and the process conditions on the ion-exchange properties of the samples obtained was studied.

DOI: 10.1134/S1070427207080095

The intensive use of carbon sorbents in various fields of science and technology requires that the assortment of carbon materials should be made wider and scientifically substantiated methods should be developed for synthesis from these materials of ion exchangers with improved characteristics and high selectivity, whose application could solve numerous ecological problems. To sorbents of this kind belong varieties of shungites. It has been found that the organic substance of shungite is mainly represented by aliphatic saturated hydrocarbons and their oxygen-containing derivatives, ketones and esters, with a minor admixture of aromatic compounds [1], which favor compatibility of a filler with the polymeric matrix. A conclusion was made on this basis that the compositions of the organic substances contained in shungite rock and rocks with varied content of carbon are close. It is assumed that compounds of this kind are effective surfactants which combine into a single system fragments of the amorphous carbon phase and an inorganic phase, which thereby favor compatibility of the filler and the polymeric matrix. The importance of the practical use of these latter makes rather interesting the development of methods for their modification [2–4].

The authors suggest to chemically modify shungite with amino and epoxy compounds in order to obtain anion exchangers.

EXPERIMENTAL

The shungite rock (Sh) used in the study was natural shungite from Eastern-Kazakhstan oblast, with carbon content c_{sh} of about 20%. Demineralized samples were obtained from this rock by flotation and acid-alkaline dressing (c_{sh} 60 and 80%) [5].

Distilled glycidyl methacrylate (GMA) had the following properties: d_4^{20} = 1.03337 and n_D^{20} = 1.4480. Epychlorohydrin (ECH) of chemically pure grade was dried with calcium hydroxide and distilled to obtain a fraction boiling at 115–116°C/689 mm Hg, with n_D^{20} = 1.4380. Polyethylenamine (PEA) was kept over a granulated alkali for 5–6 days (MM = 30×10^3. The content of titrable nitrogen in an anhydrous sample was 29.3%. Poly-2-methyl-5-vinylpyridine (PMVP) had MM = 10×10^3 and content of titrable nitrogen equal to 8.6%.

Modification experiments were performed by treatment of natural shungite with polyamines (PEA, PMVP) in dioxane (100°C, 30 min), followed by cross-linking with epoxy compounds (GMA, ECH), with varied treatment duration τ (min), process temperature (°C), and mass ratio of the starting components. The samples were treated with hydrochloric acid to obtain an anion exchanger in the Cl^- form, washed to a neutral reaction of the washing water, and converted to the OH^- form by an appropriate treatment with an alkali.

The quality of the resulting ion-exchange material was evaluated by a set of parameters: static exchange capacity (SEC for Cl^-, mg-equiv g^{-1}), content of nitrogen and chlorine, and physicochemical parameters. The static exchange capacity and the physicochemical properties of the ion exchangers were determined in accordance with GOSTs (State Standards) 10 898.1–74 and 10 898.5–74.

The concentration of functional groups in the polymer phase, which corresponds to the SEC (mg-equiv g^{-1}) of the ion exchanger, was calculated by the procedure described in [6].

To determine the chemical and thermal resistance of an anion exchanger in the OH^- form, its weighed portions (each 1.0 g in terms of the dry product) were placed in 250-ml round-bottomed flasks. A 5 N solution of sulfuric acid was poured into one of these, a 5 N solution of sodium hydroxide into another, and distilled water into the third, with each liquid portion equal to 100 ml. The contents of the flasks were kept for 30 min (chemical resistance) and 24 h (thermal resistance) on a boiling water bath. Then the mixture was cooled in air to room temperature, the filtrate was separated from the ion exchanger, and the latter was converted into the hydrogen form, after which its SEC was determined.

The chemical and thermal resistance Y (%) was calculated by the formula

$$Y = 100E_1/E_0,$$

where E_0 and E_1 are the SEC (mg-equiv g^{-1}) before and after treatment of an ion exchanger.

The concentration of hydrogen ions was monitored with an I-130 ion meter with ESL-43-07 and ESL-63-07 glass electrodes calibrated against buffer solutions. The concentrations of the acid and alkali solutions used in the study were determined by titrimetry, with methyl orange and phenolphthalein as indicators.

Micrographs were taken on an S-6D Leica stereo microscope with a built-in DC300 video camera.

IR spectra of the samples were recorded with a NIKOLET-5700 Fourier spectrophotometer in pellets with KBr in the spectral range 400–4000 cm^{-1}. Spectra of solid samples (natural bentonite and organomineral ion exchangers) were measured for a powdered sample (0.5–1.0 mg) compacted into a pellet with optically pure KBr (200–250 mg). IR spectra of liquid samples (GMA) were measured with the samples placed between KRS plates.

Oxygen-containing functional groups present on the surface of carbon adsorbents are identical in chemical composition to the same groups contained in individual chemical compounds. Therefore, they can be identified and quantitatively determined by the methods commonly accepted for these purposes. Experiments were carried out on determining the presence and content of acid and base functional groups, and the static exchange capacity of a sample of natural shungite was calculated. The content of surface acid groups was found by neutralization with a 0.1 N KOH solution for 24 h and subsequent titration of the alkali residue in the filtrate with a 0.1 N solution of HCl. In a similar way was calculated the concentration of OH groups (mg-equiv g^{-1}) retained by anion-exchange centers on the shungite surface.

It was found that the concentration of the acid solution brought in contact with a sorbent changes only slightly upon completion of a run, whereas the alkali concentration changes significantly, compared with its initial value. Consequently, shungite possesses amphoteric properties with predominance of acid functional groups, compared with base groups. The SEC (mg-equiv g^{-1} shungite) for cations, determined by the commonly accepted method from data on KOH sorption from a 0.1 N aqueous solution, is 3.8 mg-equiv g^{-1}, and that found for a 0.1 N HCl solution, 1.5 mg-equiv g^{-1} (s : l = 1 : 100).

In the presence of chemically active oxygen-containing groups, modifier molecules can be attached to the external surface by chemisorption bonds. As shown above, the predominant acid properties of the shungite surface will probably favor formation of new chemical bonds in the case of its modification with amines.

After modification of the natural sorbent with PEA (100°C, 30 min), the absorption bands in the spectrum of the modified product, associated with the mineral fraction of shungite, remain virtually unchanged (Fig. 1a). The positions of the absorption bands associated with the organic component of the rock are somewhat changed. The frequency range 3426–3621 cm^{-1} belongs to stretching vibrations of the N–H bond and free NH, NH_2, and OH groups. The frequency 1597 cm^{-1} is related to terminal $–CH_2NH_2$ groups. An increase in the time of interaction of shungite with the polyamine (60 min, 100°C) shifts this band to higher frequencies (1626 cm^{-1}), which corresponds to deformation vibrations of amino groups. The frequency of 2955 cm^{-1} disappears, which is probably due to interaction of amino groups with OH groups on the surface of the mineral. The band at 1715 cm^{-1}, associated with vibrations of the C=O bonds of the carboxy group in aromatic and aliphatic acids, and that at 1261 cm^{-1}, related to stretching vibrations of the C=O bonds of the phenol and carboxy groups, are shifted. This indicates that the functional groups of shungite are involved in the formation of a modifying layer.

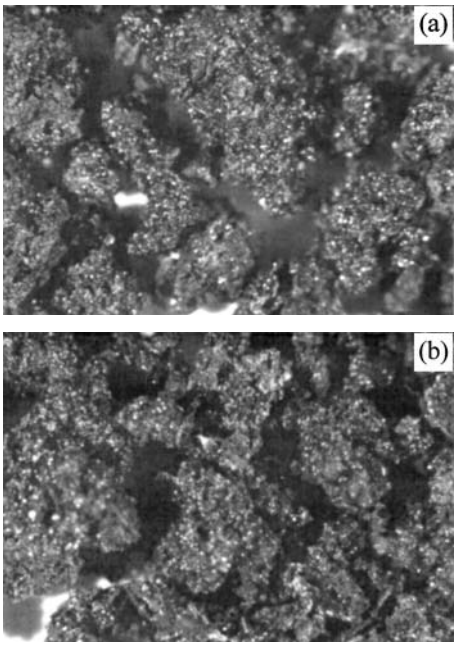

Fig. 2. Micrographs of anion exchangers (c_{sh} = 20%). (a) Sh–PEA–ECH and (b) Sh–PEA–GMA. (Magnification ×40).

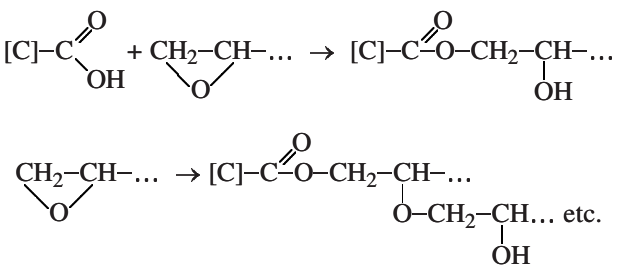
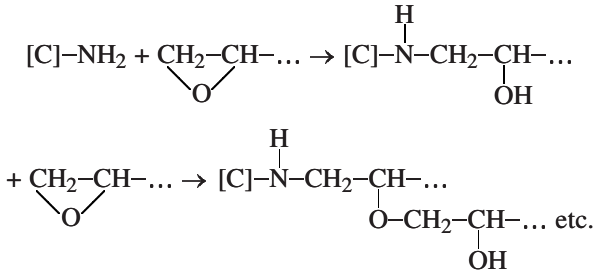
Epoxy compounds, such as GMA and ECH, enable firm fixation of functional groups on the shungite surface. The reaction with polyamines involves both the epoxy group and the bound chlorine atom, which was not found in the products. The cleavage of the oxirane ring in interaction of GMA with amino groups is accompanied by heat release, which, in turn, leads to polymerization at the double bond. As a result of chemical modification under the conditions suggested, shungite acquires anion-exchange properties. No acid properties are found in this case. Probably, the surface-active groups of shungite interact with amino groups. As a result, the content of "inactive" nitrogen in the products increases.

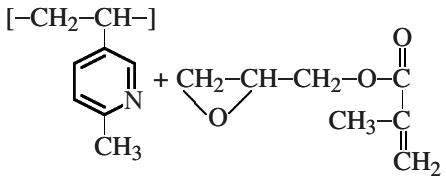
Presumably, ECH and GMA interact with COOH and NH_2 groups on the surface of a dispersed carbon substance upon heating of the formulation by the mechanism of curing of epoxy compounds by organic acids, their anhydrides, and amines:

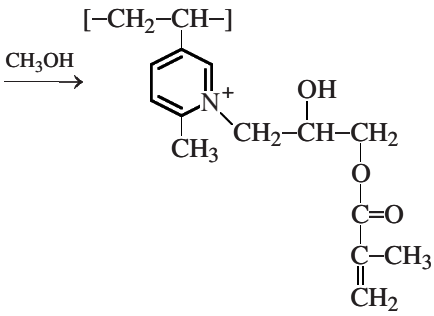


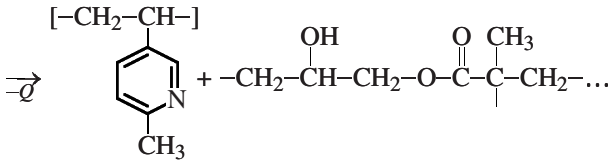


where [C] stands for shungite.

The heat released in chemical modification of the epoxy groups of GMA promotes polymerization of the monomer at the double bond:







In the IR spectra of the anion exchangers, measured at 500–1000 cm^{-1} (Fig. 1b), the characteristic frequencies of deformation vibrations of epoxy groups at 762–944 cm^{-1} disappear, which points to their chemical transformation upon modification. In the final product, the absorption bands related to the mineral (461, 555 cm^{-1}) and organic (695–797 cm^{-1}) components of shungite have a lower intensity.

As can be seen in the micrographs in Fig. 2, the anion exchangers have the form of particles with a developed surface, whose shape and texture are identical to that of analogous organopolymer sorbents.

The modification was performed on shungites with varied content of carbon (20–80%). It was shown that an increase in the content of an aminating agent affects in different ways the exchange properties and

the content of nitrogen in the products (Table 1). To exclude the stage of preliminary treatment of shungite and simplify the process, natural shungite (c_{sh} = 20%) was used in further studies.

One of the main parameters that enable control in a wide range over ion-exchange properties of adsorbents is the reagent ratio. A strong influence is exerted by the content of a polyamine in the reaction mixture. It was found that raising the amount of PEA and PMVP leads to an increase in the exchange capacity and in the nitrogen content, irrespective of the nature of the epoxy compound (Table 2). A further increase in the content of PEA to more than 3 mass fractions and in that of PMVP to more than 2 mass fractions impairs the ion-exchange properties of the anion-exchangers. This is due to the poorer curing conditions of the products. An analysis for the nitrogen content of the samples by the Kjeldahl method demonstrated that the total amount of nitrogen exceeds that in functional groups (exchange nitrogen).

At the optimal contents of PEA, found in this study, the influence exerted by the amount of the epoxy components on the exchange properties of the products obtained was analyzed (Table 3). An in-

crease in the concentrations of the epoxy components leads to a decrease in the SEC of the anion exchangers. It was shown that, after titration with a 0.1 N solution of HCl, the ion-exchange capacity for Cl^- becomes as high as 6.98–7.00 mg-equiv g^{-1} at mass ratios of 1 : 3 : 1 and 1 : 3 : 1.5 for the anion exchangers based on Sh–PEA–GMA and Sh–PEA–ECH, respectively.

For the anion exchanger based on the aromatic polyamine, SEC reaches a value of 3.00 mg-equiv g^{-1} under the experimental conditions upon titration with a 0.1 N solution of NaCl. The ion exchanger samples are composed of irregularly shaped gray-black particles ($d \leq 0.25–0.5$ mm).

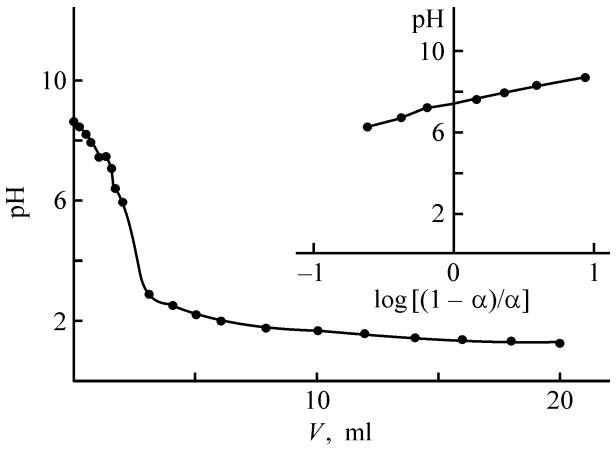

Fig. 3. Potentiometric titration curve for Sh–PEA–GMA anion exchanger (c_{sh} = 20%) and the dependence of the solution pH on $\log[(1 - \alpha)/\alpha]$. ($V$) Volume of the 0.1 N solution of HCl.

A study of the effect of the process duration and temperature demonstrated (Table 4) that the anion exchangers with Sh : PEA : GMA = 1 : 3 : 1 and Sh : PEA : ECVH = 1 : 3 : 1.5, which have high exchange parameters, are formed at a modification temperature of 100°C in 5–8 h. A decrease or increase in the process duration with respect to the range specified above leads to a decrease in SEC, which is presumably due to deterioration of the strength properties or to densification of the sorbent structure, respectively. The decrease in the ion-exchange properties of the products at high temperatures is due to an increase in the density of cross-linking bonds between macromolecules and the resulting hindered accessibility to ion exchange.

Under industrial conditions, ion exchangers may come in contact with solutions of acids and alkalis of various concentrations, as well as with water and aqueous solutions at elevated temperatures. This can cause chemical destruction leading to decomposition of ion exchangers and to a decrease in their capacity. As the resistance parameter was taken the change in capacity in relation to the time of contact between ion exchangers and corrosive solutions. Stability studies demonstrated that the chemical and thermal resistance of the anion exchangers synthesized is 91–97% (Table 5). Thus, the medium-basic anion exchangers can successfully work at elevated temperatures in various media. The bulk density of the anion exchangers is 0.20–0.24 g ml^{-1}, and the swelling capacity, 3.20–4.25 ml g^{-1}.

An important factor characterizing the functional groups of ion exchangers and determining the degree of their dissociation is the pH of the medium. The method of potentiometric titration was used to study the acid-base properties of the Sh–PEA–GMA anion exchanger. The acid dissociation constant p_{K_α} was found for the ionogenic groups of the ion exchanger from the potentiometric titration curves in Fig. 3. The dissociation constant of the anion exchanger under study, $p_{K_\alpha} = 7.35$, characterizes it as a medium-basic polyfunctional ion exchanger and falls within the limits reported in the literature for the known brands of anion exchangers.

CONCLUSIONS

(1) It was found that modification of shungite with various polyamines, followed by cross-linking with epoxy compounds, leads to formation of anion-exchange groups on the surface of the natural adsorbent.

(2) A method for synthesis of chemically and thermally resistant anion exchangers with a shungite matrix was developed on the basis of the results obtained.

(3) It was shown that the ion-exchange properties of the samples depend on the ratio between the reacting components, nature of modifiers, and parameters of modification of the starting material.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Elecrodeposition of Lustrous Zinc Coatings from Sulfate Electrolyte

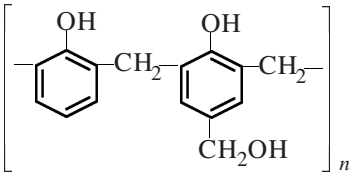
Abstract—Electrodeposition of lustrous zinc coatings from a sulfate electrolyte containing $ZnSO_4$, Na_2SO_4, buffer additives, and fixers (products of phenol-formaldehyde condensation) was studied.

DOI: 10.1134/S1070427207080101

Lustrous zinc coatings on articles of simple configuration are deposited from sulfate electrolytes containing various brightening additives (aldehydes, ketones, sulfo compounds, and various condensation products of complex composition [1–4]).

In this study, we examined the electrodeposition of zinc from a sulfate electrolyte containing a fixer, product of phenol-formaldehyde condensation with the structural formula



The study was performed in an electrolyte containing ($g\ l^{-1}$): $ZnSO_4 \cdot 7H_2O$ 200–250, $Na_2SO_4 \cdot 10H_2O$ 50–100, $Al_2(SO_4)_3 \cdot 18H_2O$, H_3BO_3, aminoacetic acid 25–30, and fixer 0.5–5, at 18–25°C and pH 2–5. Zinc plates served as anodes. A 6–15-μm-thick zinc layer was deposited onto unpolished St.3 steel. Polarization curves were recorded with a P-5828 potentiostat. The luster was measured on a FB-2 photoelectric luster meter. The leveling power P of the electrolytes was determined by a direct profile measurement of the sample surface with a sinusoidal microprofile. P was calculated by the formula [5]

$$P = 2.3a/2\pi h_{av} \log (H_0/H_i),$$

where a is the sine wave amplitude of the microprofile; h_{av}, average thickness of the coating (10 μm); H_0 and H_i, initial and final amplitudes of the sinusoidal microprofile, respectively.

The capacitance of the electric double layer was measured in the course of electrolysis with a P-5021 ac bridge at a frequency of 30 kHz in a series equivalent circuit. A zinc-coated platinum wire placed at the center of a platinum-coated cylinder served as the working electrode. The pH value in the near-electrode layer was measured by the method described in [6]. The degree of surface filling with organic additives, Q, was estimated using the polarization curves [7] by the formula

$$Q = 1 - \exp(\Delta E/b),$$

where ΔE is the potential shift in cathodic polarization, and b is the Tafel constant found from the polarization curves plotted in the semilog scale.

The internal stresses and microhardness of the coatings were determined as described in [8].

The results obtained in a study of the influence exerted by the fixer concentration, nature of the buffer additive, and current density on the outward appearance of the coatings show that dark gray coatings with a rough surface are formed from an electrolyte containing $Al_2(SO_4)_3$ buffer additive and a fixer at i_c = 1–11 A dm^{-2}. At the same time, lustrous coatings are formed from an electrolyte containing H_3BO_3

Table 1. Effect of buffer additives, fixer concentration, and current density on the outward appearance of zinc coatings [electrolyte composition (g l^{-1}): $ZnSO_4 \cdot 7H_2O$ 200 and $Na_2SO_4 \cdot 10H_2O$ 50; pH 3–4, T = 20°C]

and aminoacetic acid. As can be seen in Table 1, the outward appearance of the coatings varies in this case with the fixer concentration and with the cathode current density.

The widest range of current densities at which lustrous coatings are formed is observed at fixer concentrations of 1–2 g l^{-1}. In this case, the current densities vary in the range from 2 to 10 A dm^{-2} in an electrolyte containing H_3BO_3, and from 1 to 8 A dm^{-2} in an electrolyte containing aminoacetic acid. At higher fixer concentrations (c = 3–5 g l^{-1}), the range of current densities at which lustrous coatings are deposited is markedly narrower.

In the electrolytes studied, the pH value should be within the range 3–4. At pH < 3, the i_c range providing deposition of lustrous coatings and the current efficiency decrease. At pH > 4 lustrous coatings are deposited, but the electrolyte exhibits an unstable behavior. The current efficiency by zinc in the electrolytes yielding lustrous coatings varies from 85 to 97%. In the electrolyte containing aminoacetic acid, the current efficiency is the highest (Fig. 1, curves *1*, *2*).

Cathodic polarization curves were measured in the zinc-plating electrolytes. As can be seen in Fig. 2, the presence of a fixer enhances the cathodic polarization (Fig. 2, curves *1*, *2*). The inhibition effect of the fixer on the electrodeposition of zinc is due to its

(*1*) Electrolyte; (*2*) electrolyte + H_3BO_3, 30 g l^{-1}; (*3*) electrolyte + $Al_2(SO_4)_3 \cdot 18H_2O$, 30 g l^{-1}; (*4*) electrolyte + aminoacetic acid, 30 g l^{-1}.

adsorption on the cathode surface. This is confirmed by the results obtained in measuring the capacitance of the electric double layer. In the electrolyte containing no fixer, the capacity-vs.-potential dependence has a minimum (C = 20 μmF cm^{-2}) at a potential of –0.8 V (Fig. 2, curve *3*). Introduction of a fixer into the electrolyte lowers the double layer capacitance to 9 μmF cm^{-2} at E = –0.8 V (Fig. 2, curve *4*). An increase in the capacitance is observed at more negative potentials, which is due to partial desorption of the fixer from the electrode surface [9].

The electrolytes yielding lustrous zinc coatings exhibit the leveling effect. The leveling power varies from 0.2 to 0.4, depending on the cathode current density. The throwing power of the electrolytes is 8–12%. The microhardness of the zinc deposits varies within the range 80–100 kg mm^{-2}. The lustrous zinc coatings have small internal stresses (IS = 100–150 kg cm^{-2}).

As is known [3], the deposition of lustrous coatings is due to smoothing of the submicrometer surface roughness. For a dull coating to be formed, it suffices that an additive is adsorbed on the cathode surface and the electrocrystallization overpotential is raised, whereas formation of a lustrous coating, requires that an adsorption layer of a certain composition should be present on the cathode surface. Such layers can be formed from organic substances and products of secondary reactions in the near-cathode layer. In the case of a simultaneous metal deposition and hydrogen evolution, the adsorption layer may consist of hydroxides and other basic compounds [3].

The suggestion that zinc hydroxides are formed in the near-cathode space is confirmed by the results of pH measurements in the near-cathode layer (pH$_s$). As can be seen from Fig. 3, pH$_s$ varies at i_c = 1–10 A dm^{-2} from 4 to 6, depending on the nature of the buffer additive. In the electrolyte containing aminoacetic acid, the range of pH variation is the narrowest (curve *4*). It should be noted that the pH of hydrate formation in the zinc-plating electrolyte is 6.4. These results suggest that presence of zinc hydrates in the near-cathode layer is not necessary for lustrous coatings to be deposited. Apparently, lustrous coatings are deposited if a highly dispersed adsorption layer is formed on the surface [3].

Apparently, buffer additives control the dispersity of the adsorption layer. In their presence, the adsorption layer may change because of the formation of difficultly soluble zinc borates in the near-cathode space. It is not improbable that complex compounds of orthoboric and aminoacetic acids with zinc ions, as well as intracomplex (chelated) compounds of H_3BO_3 with the fixer, can be formed.

An important issue in elucidating the mechanism of formation of lustrous coatings, is determining the degree of filling of the cathode surface with the adsorbed additive. The dependences of the degrees of luster (curve *1*) and surface filling (curve *2*) on the cur-

rent density are shown in Fig. 4. It can be seen that, as the cathode current density increases, the degree of luster of the coatings passes through a maximum, whereas the degree of filling decreases. At the current densities studied, the degree of surface filling varies from 24 to 10%. This shows that lustrous coatings are formed at a well-defined degree of surface filling.

To elucidate the mechanism by which the fixer affects the electrodeposition of zinc, we carried out a quantum-chemical study of a system constituted by hydrated ions present in the electrolyte and fixer molecules. To find the degree of polymerization, n, of the fixer molecule, its molecular weight was determined by the cryoscopic method. The results of these measurements demonstrated that $n = 1$. Consequently, the electrolyte also contains a monomeric product of phenol-formaldehyde (F) condensation.

The quantum-chemical calculation was performed by the semiempirical PM3 method [11, 12]. Compared with other semiempirical methods and ab initio calculations with different basis sets [13], this method describes rather well the parameters of intermolecular interactions. The energy of interaction between the particles constituting the system under consideration was calculated as the difference between the total electronic energy of the system and the sum of the total electronic energies of its constituents. For example, we calculated for the system Zn_{49}–$[ZnF]^{2+}$, first, the energy of interaction between a complex-forming ion and the ligand in the complex $[ZnF]^{2+}$ ion

$$\Delta E_c = E_{[ZnF]^{2+}} - (E_{Zn^{2+}} + E_F),$$

and then the energy of interaction of the complex ion with the cluster

$$\Delta E_{cl} = E_{Zn_{49}-[ZnF]^{2+}} - (E_{[ZnF]^{2+}} + E_{Zn_{49}}).$$

The results of the calculation show that, similarly to the case of 2-butyne-1,4 diol [14], the interaction of Zn^{2+} ions with the formaldehyde molecules is more energetically favorable than the formation of a hydrated shell of the ion. In a sulfate zinc-plating electrolyte, complex ions of composition $[Zn(H_2O)_x(F)_y]^{2+}$, where $x = 1$–5, $y = 1$–3, are most likely to exist in the electrolyte bulk.

In the near-cathode layer, mixed aqua hydroxo complexes of various compositions with formaldehyde molecules can be formed via alkalization. In view of the fact that formaldehyde molecules displace water molecules from the Zn^{2+} aqua complexes (Fig. 5), the formation of $Zn(OH)_2$, $Zn(OH)^+$, and $[ZnF]^{2+}$–

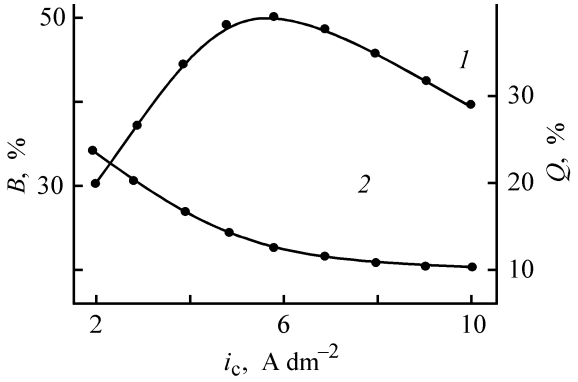

Fig. 4. Degree of luster B (*1*) and degree of the surface filling Q (*2*) vs. the current density i_c.

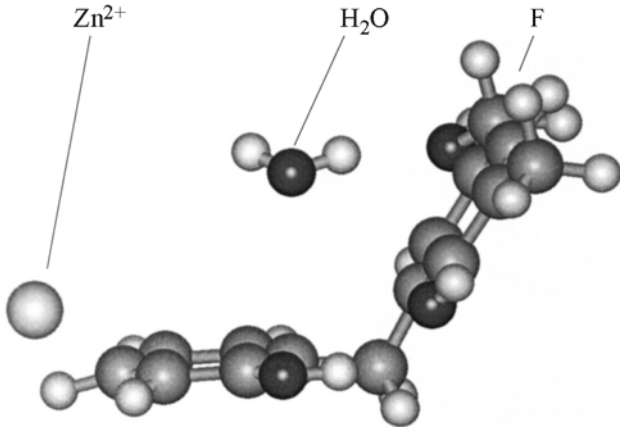

Fig. 5. Structure of a Zn^{2+} complex with a monomeric product of phenol-formaldehyde (F) condensation and a water molecule, according to the results of a quantum-chemical calculation Formaldehyde molecule: hydrogen atoms, white; carbon, gray; and oxygen, dark gray.

$[Zn(OH)F]^+$ species is most likely in the near-cathode layer. Less probable is the formation of $[Zn(OH)_2F]$ species.

In the next stage, we carried out a quantum-chemical study of the structure of complexes with formaldehyde molecules at the electrode–solution interface. In doing so, we modeled the surface of the zinc electrode with a cluster formed by 49 atoms arranged in two layers having the hexagonal form. The clusters were chosen as recommended in [15].

To simulate the reduction of Zn^{2+} on the surface of the zinc electrode, the zinc cluster system Zn_{49}–Zn^{2+}–F was calculated. It was shown that the highest interaction energy with the Zn_{49} cluster is observed for $Zn(OH)^+$ species. The formaldehyde molecules in the complex constitute, as they approach the cluster, a stable system at a distance of 418 pm from the cluster. In this case, the interaction energy is 437 kJ mol^{-1}, which considerably exceeds the value for interaction of the cluster with

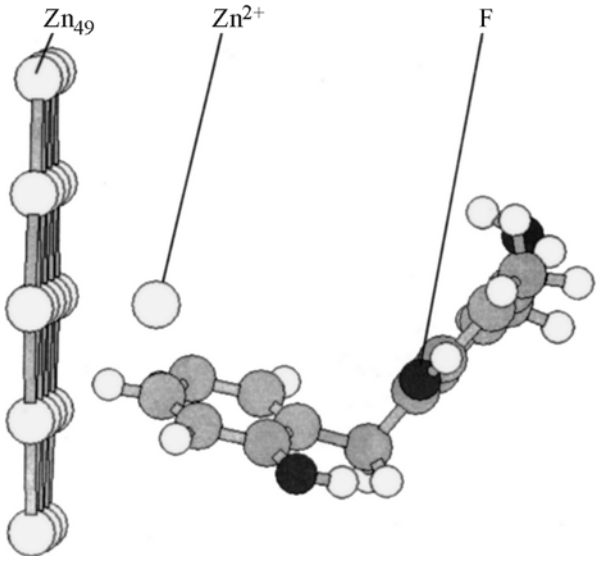

Fig. 6. Structure of a Zn^{2+} complex with a monomeric product of phenol-formaldehyde (F) condensation on the surface of the Zn_{49} cluster, according to the results of a quantum-chemical calculation.

a hydrated zinc ion (200 kJ mol^{-1}) and a $[Zn(OH)F]^+$ species. The presence of a formaldehyde molecule in the complex species makes distance between the zinc ion and the cluster surface considerably larger. This may result from the spatial structure of the forming complexes, which creates, owing to the large size of the formaldehyde molecule, steric hindrance to approach of zinc ions to the cluster (Fig. 6). It is noteworthy that, without Zn^{2+} ions, the formaldehyde molecule forms no stable system with the cluster.

The rather wide variety of complex species formed in the near-cathode layer suggest that their discharge can occur by different pathways. To assess the probabilities of these pathways, we calculated the change in the total energy of the reaction products (Table 2) in comparison with the total energy of the starting substances. In doing so, we took into account that the energy necessary for an electron to be involved in each of the above processes is constant. In the given case, the reactions involving and not involving formaldehyde molecules were considered.

Table 2. Changes in the total energy of the products in comparison with the total energy of starting substances

Reaction	Reaction equation	ΔE, kJ mol^{-1}
(1)	$Zn(OH)_2 + e = ZnOH + OH^-$	271
(2)	$ZnOH^+ + e = ZnOH$	–897
(3)	$[ZnF]^{2+} + e = Zn^+ + F$	–874
(4)	$[Zn(OH)F]^+ + e = ZnOH + F$	–662
(5)	$[Zn(OH)_2F] + e = ZnOH + OH^- + F$	173

It follows from the data in Table 2 that reactions (2)–(4) yielding ZnOH species and Zn^+ ions are the most probable from the energy standpoint. Presumably, of all three reactions, reaction (2) is the first to occur. The species forming in this case enter into the following electrochemical reactions:

$$ZnOH + e = Zn + OH^-,$$

$$Zn^+ + e \rightarrow Zn.$$

Thus, our quantum-chemical calculations demonstrated that, in a sulfate zinc-plating electrolyte containing formaldehyde molecules, the probability of existence of complex ions $[Zn(H_2O)_x(F)_y]^{2+}$ in the electrolyte bulk is the highest, whereas in the near-cathode space, $[Zn(OH)]^+$, $[ZnF]^{2+}$, and $[Zn(OH)F]^+$ are electrically active particles owing to alkalization.

The study we performed enabled us to develop a sulfate zinc-plating electrolyte of simple composition for deposition of lustrous coatings with smoothed surface. The electrolyte composition is as follows (g l^{-1}): $ZnSO_4 \cdot 7H_2O$ 200–250, $Na_2SO_4 \cdot 10H_2O$ 50–100, H_3BO_3 25–30, and fixer 1–2. The process is performed at i_c = 2–10 A dm^{-2}. The electrolyte temperature is 18–25°C, pH 3–4, and CE = 84–97%. The anodes are made of zinc. Aminoacetic acid (c = 25–30 g l^{-1}) can be taken instead of H_3BO_3. In this case, lustrous coatings are obtained at i_c = 1–8 A dm^{-2} with CE = 86–97%.

CONCLUSIONS

(1) A study of zinc electrodeposition from a sulfate electrolyte containing a fixer (product of phenol-formaldehyde condensation) and buffer additives demonstrated that the fixer taken together with H_3BO_3 or aminoacetic acid yields lustrous zinc coatings with smoothed surface at i_c = 1–10 A dm^{-2}.

(2) The system constituting hydrated zinc ions and fixer (formaldehyde) molecules was studied using the quantum-chemical method. It was shown that complexes of composition $[Zn(H_2O)_x(F)_y]^{2+}$ are most likely to be present in the electrolyte bulk. In the near-cathode layer, $[Zn(OH)]^+$, $[ZnF]^{2+}$, and $[Zn(OH)F]^+$ are electrically active species owing to alkalization.

(3) Sulfate electrolytes for deposition of lustrous zinc coatings with smoothed surface were developed.

Received January 31, 2007

Abstract—Cyclic potentiodynamic voltammetry and X-ray photoelectron spectroscopy were used to study the electrochemical behavior and composition of bismuth sulfide coatings deposited by successive ionic layer adsorption and reaction on glassy carbon in a colloid solution of bismuth(III) compounds, with Na_2S as a sulfidizing agent.

DOI: 10.1134/S1070427207080113

In the last decade, semiconducting bismuth sulfide films have been intensely studied owing to their wide use in electronic industry. Close attention is paid to methods for synthesis of crystalline Bi_2S_3 and study of their semiconducting properties. Methods of vacuum deposition, anodic oxidation of bismuth in alkaline sodium sulfide solution, chemical, electrochemical, photochemical deposition in aqueous and nonaqueous solutions, etc. have been described [1–5]. The authors of [6] came to a conclusion that Bi_2S_3 films formed by chemical deposition from aqueous solutions are always amorphous and those electrodeposited are crystalline. Amorphous Bi_2S_3 is transformed to the crystalline state by thermal treatment [5]. Sulfide coatings of metals, including bismuth, used as current-conducting sublayers for decorative and functional metallization of insulators, are most frequently deposited by a simple and low-cost method of successive ionic layer adsorption and reaction (SILAR). The thus deposited layers of nonstoichiometric copper sulfide and Co_2S_3 are widely used in practice. The processes of their electrochemical reduction have been studied not only in supporting electrolytes, but also in nickel- and copper-plating electrolytes. It has been shown [7] that the electrodeposition of metals should be preceded by reduction of a sulfide to the metal. It is known that nickel can be electrochemically deposited onto Bi_2S_3 coatings [8]. However, the electrochemical behavior of Bi_2S_3 has been studied only in alkaline solutions containing sulfide ions. In these studies, the main attention was given to the kinetics and mechanism of formation of sulfide films in anodic oxidation of bismuth [1]. The run of the reduction curves depends on the Bi_2S_3 composition.

The aim of this study was to examine the electrochemical behavior in acid and alkaline solutions of Bi_2S_3 coatings deposited by SILAR onto glassy carbon from a colloid solution of Bi(III) compounds with the help of sodium sulfide and to determine the composition of these coatings.

EXPERIMENTAL

An electrically conducting Bi_2S_3 layer was deposited by the SILAR method, i.e., by successive treatment of the electrode in a 0.1 M BiO(OH) and(or) $Bi(OH)_3$ colloid solution, followed by washing with deionized water, sulfidation in 0.1 M Na_2S solution, and washing with water at room temperature [8]. The times of treatment in bismuth compound solutions and sulfidation were 1 min each, and the time of each washing with water, 30 s. The deposition cycle was repeated twice in electrochemical experiments and six times for a study of the coating composition by X-ray photoelectron spectroscopy (XPS). The colloid solution was prepared from $Bi(NO_3)_3 \cdot 5H_2O$, ammonia, and a special colloid-stabilizing ligand.

SU-1200 glassy carbon polished with 1-μm diamond particles served as a working electrode. Its working surface area was 1 cm^2. The inoperative area of the electrode was insulated with a PVC lacquer.

The electrochemical behavior of the Bi_2S_3 coatings was studied by cyclic potentiodynamic voltammetry

in solutions containing (M): NaOH 0.1, H_2SO_4 0.05, and Na_2S 0.001. The solutions were prepared from reagents of chemically pure grade and distilled water. The experiments were performed in a YaSE-2 cell at $20 \pm 1°C$. A platinum grid was used as auxiliary electrode, and a saturated silver chloride electrode, as reference. The potentials are given relative to a standard hydrogen electrode. Potentiodynamic voltammograms were measured with a PI-50-1 potentiostat and a PR-8 programming unit and recorded with an XY Recorder A3 potentiometer. The potential sweep rate was 5×10^{-2} and 5×10^{-3} V s^{-1}.

The composition of the Bi_2S_3 coatings was studied by XPS on a Vacuum Generator Scientific ESCALAB-MK II spectrometer (UK). A magnesium anode served as a source of soft X-ray radiation (1253.6 eV, 300 W). The pressure in the analytical chamber of the spectrometer was 1.33×10^{-8} Pa. Bi 4*f*, S 2*s*, and O 1*s* spectra were recorded. The empirical sensitivity factors for these elements were taken from the literature [9] and the spectra recorded were compared with reference spectra [10].

The voltammogram obtained in a 0.1 M NaOH solution on a glassy carbon electrode without a bismuth sulfide coating at the cathodic sweeping of the potential from its steady-state value E_{st} = +0.8 V to –1.8 V is shown in Fig. 1 (curve *1*). In this range of potentials, no current peaks associated with the side redox processes are observed. It can be seen that, up to $E = -1.3$ V, the cathode current does not exceed 5×10^{-4} A cm^{-2} and the anode current is even lower up to +0.8 V.

The run of the potentiodynamic curves significantly changes on treating the electrode in a colloid solution of trivalent bismuth and washing with water (Fig. 1, curve *2*). The cathodic branch of the curve shows a broad current peak K_1 at potentials in the range from –0.7 to –1.35 V. This peak is due to the reduction of Bi(III) hydrolysis products to metallic Bi. The hydrogen evolution occurs at $E < -1.5$ V. In a reverse sweep of the potential toward positive values, when $E > -0.3$ V, an anodic current peak A_1 is observed. In this range of potentials, metallic Bi can be oxidized to Bi_2O_3 by the reaction:

$$2Bi + 6OH^- - 6e \rightarrow Bi_2O_3 + 3H_2O. \quad (1)$$

Because the standard potential for reaction (1) is –0.46 V [1, 11] and the calculated equilibrium potential at pH 13 is –0.4 V, it may be suggested that the reaction proceeds under these conditions. However, the shape of the A_1 peak indicates that several anodic reactions occur in this range of potentials. It

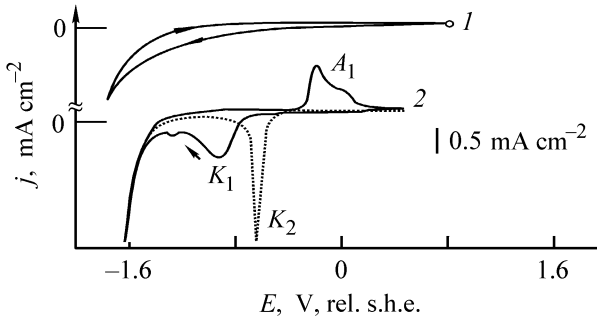

Fig. 1. Cyclic voltammetric curves obtained in a 0.1 M NaOH solution on (*1*) glassy carbon electrode and (*2*) glassy carbon electrode after a sixfold treatment in a colloid solution containing Bi(III) ions. Fig. 2. Cyclic voltammetric curves obtained at different potential sweep rates in a 0.1 M NaOH solution on a glassy carbon electrode coated with bismuth sulfide. *V* (V s^{-1}): (*1*) 5×10^{-2} and (*2*) 5×10^{-3}.

was shown in [12] that electrochemical oxidation in a 1 M KOH solution of bismuth deposited on Pt can yield, along with $Bi(OH)_3$, also Bi(IV) compounds, which can be chemically oxidized to Bi(V). Cathodic current peaks corresponding to these oxidation processes were also observed. Only a single cathodic peak K_2 associated with the reduction of Bi(III) oxide compounds is observed in the second-cycle potentiodynamic curves at potentials of –0.5 to –1.0 V in potential sweep toward the anodic side after a cathodic cycle to –1.6 V. Therefore, we can suggest that no Bi(V) is formed.

Cyclic voltammograms obtained in alkaline solution in reduction of a Bi(III) sulfide coating deposited onto a glassy carbon electrode are shown in Fig. 2. These curves were recorded at different potential

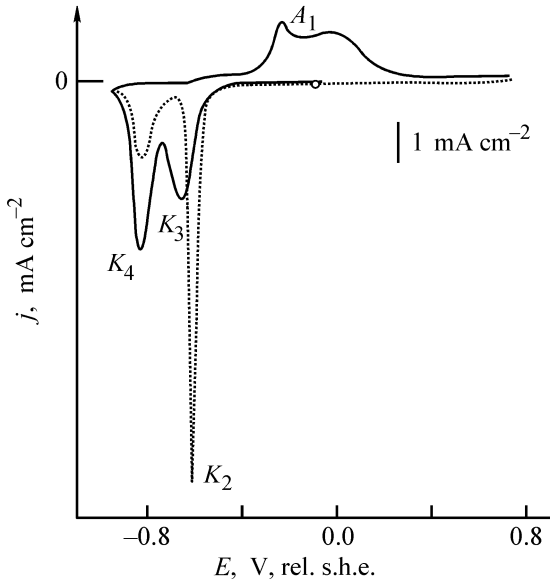

Fig. 3. Cyclic voltammetric curves obtained in a 0.1 M NaOH solution on a glassy carbon electrode coated with bismuth sulfide, with potential sweep from the steady-state value to –0.9 V.

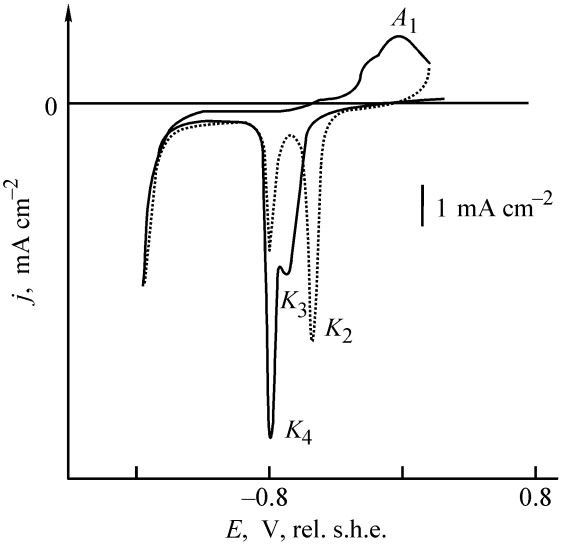

Fig. 4. Cyclic voltammetric curves obtained on a glassy carbon electrode coated with bismuth sulfide in a solution containing (M): NaOH 0.1 and Na_2S 0.001.

sweep rates V of 5×10^{-2} and 5×10^{-3} V s^{-1} (curves *1* and *2*, respectively). In a potential sweep from the steady-state value to –1.6 V, two current peaks, K_3 and K_4, are observed on each cathodic branch: at –0.64 and –0.77 V (curve *1*) and –0.51 and –0.72 V (curve *2*). With the potential sweep in the reverse direction, toward positive values, an anodic current peak A_1 appears (Fig. 2, curves *1*, *2*). Because the current peaks K_3 and K_4 are observed at both potential sweep rates, it can be suggested that they are due to reduction of different Bi(III) compounds [13]. On changing the potential sweep rate from 5×10^{-2} to 5×10^{-3} V s^{-1}, the K_3 and K_4 peaks shift toward positive potentials and their area markedly decreases. The cathodic peaks K_3 and K_4 are shifted by 0.13 V and 0.05 V, respectively.

It should be noted that, in reduction of the sulfide coating in a 0.1 M NaOH supporting electrolyte, with the potential swept from the steady-state value E_{st} (–0.054 V) to –0.45 V and then back in the anodic direction to +0.6 V, no current peak A_1 is observed in the anodic branch of the curve. This means that no redox processes occur in the bismuth sulfide coating in this range of potentials. The peak A_1 appears in the anodic curve of the voltammogram only after a potential of –0.9 V is reached in the cathodic cycle (Fig. 3). Undoubtedly, the anodic peak A_1 is due to oxidation of metallic Bi formed in reduction of the bismuth sulfide coating at potentials of –0.4 to –0.85 V (current peaks K_3, K_4). However, further studies demonstrated that the reduction of the sulfide coating in this range of the potentials is incomplete (Fig. 3). Two more current peaks, K_2 and K_4, appear in the cathodic branch of the curve after the first cycle in a potential sweep from –0.9 V toward the cathodic side (second cycle). It can be assumed that K_2 is due to reduction of Bi oxide compounds, and K_4, to reduction of Bi_2S_3. The current peak K_4 in the second cycle is not observed if a potential of –1.6 V, i.e., the potential of vigorous hydrogen evolution, is reached in the first cathodic cycle (Fig. 2, curve *1*).

The cyclic voltammogram obtained in reduction of a bismuth sulfide coating in a 0.1 M NaOH solution containing 0.001 M Na_2S is shown in Fig. 4. It is virtually identical to that obtained in a NaOH solution without addition of sulfide ions (Fig. 2, curve *1*). However, a difference between the curves in Figs. 2 and 4 is manifested in the second cathodic cycle: curve *1* (Fig. 2) has in the second cycle only a single current peak K_2 associated with the reduction of Bi(III) oxide compounds, whereas the cathodic portion of the second-cycle curve (Fig. 4) shows, alongside with the K_2 peak, also the peak K_4, in whose potential range probably occurs reduction of Bi_2S_3 formed in the anodic cycle owing to the presence of sulfide ions in the supporting electrolyte. Bi_2S_3 is reduced in an alkaline medium by the reaction

$$Bi_2S_3 + 6e \rightarrow 2Bi - 3S^{2-}. \quad (2)$$

The equilibrium potential, calculated for reaction (2) in a 0.1 M NaOH solution by taking into account that the standard potential is –0.818 V [14], is equal to

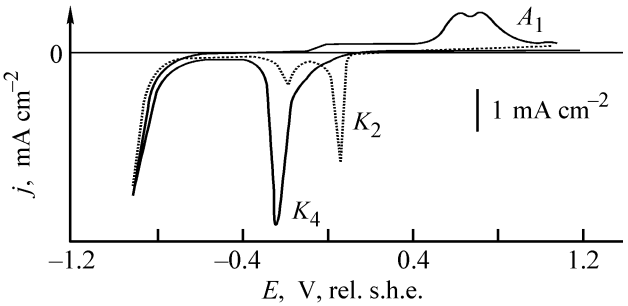

Fig. 5. Cyclic voltammetric curves obtained in 0.05 M H_2SO_4 solution on a glassy carbon electrode coated with bismuth sulfide.

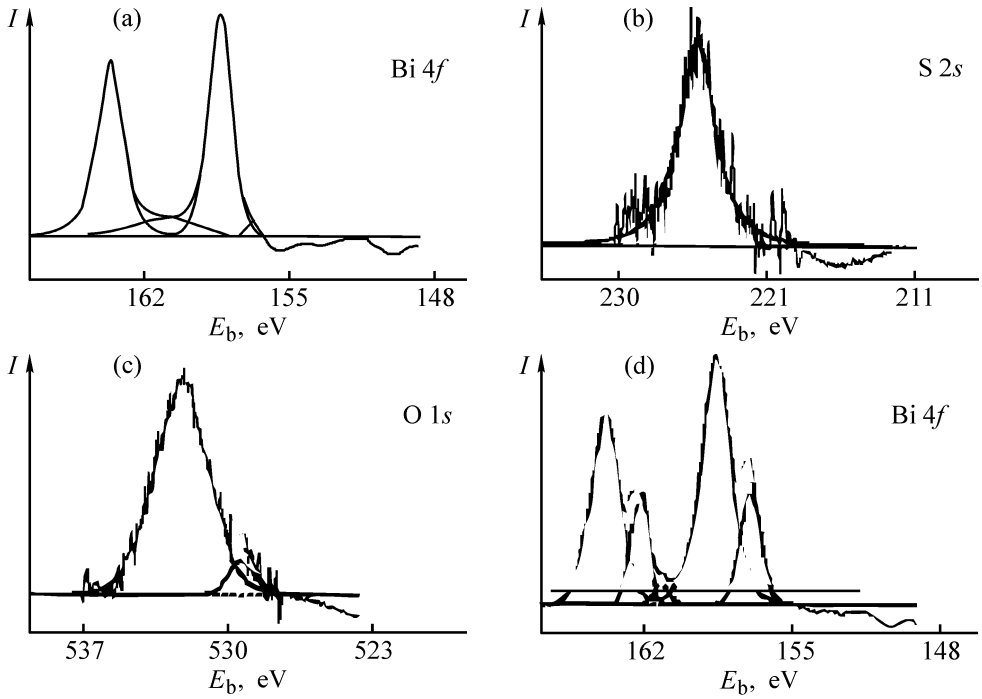

Fig. 6. XPS spectra of the surface of the bismuth sulfide coating. (I) Intensity and (E_b) binding energy. Spectrum: (a) Bi 4f, (b) S 2s, (c) O 1s, and (d) Bi 4f (after reduction of the coating in 0.1 M NaOH solution, with the potential swept from steady-state value to –0.9 V.

–0.73 V. These results demonstrate that reduction of Bi_2S_3 to metallic Bi is thermodynamically possible in the range of the current peak K_4.

The acidity of the supporting electrolyte strongly affects the run of the voltammograms. The current peak K_4 at $E = -0.24$ V and a slight increase in current in the range of the K_3 peak are observed in the cyclic voltammogram obtained in a 0.05 M H_2SO_4 solution on an electrode coated with bismuth sulfide, in a cathodic potential sweep from E_{st} to –1.0 V (Fig. 5). Probably, oxide or other compounds of Bi(III) dissolve in the acid, and the K_3 peak corresponding to their reduction of is not observed in the voltammogram.

Studies of the electrochemical behavior of sulfides of other metals deposited by adsorption demonstrated that elementary sulfur is also present in the composition of such coatings. Possibly, sulfur yielded in the formation of bismuth sulfide is reduced in the region of the K_3 current peak. However, this suggestion was not confirmed because a 10-min treatment of the coating at 80°C with sulfur solvents, such as tetrachloroethylene or toluene [15], had no effect on the character of the cyclic voltammogram obtained in a 0.1 M NaOH solution. The current peaks K_3 and K_4 were also observed in the cathodic portion of the curve after the treatment.

In an XPS study of the bismuth sulfide coating, primary attention was given to the distribution of Bi, S, and O elements. It was found that these elements are present on the surface in the following amounts (at, %): 10.34 Bi, 11.81 S, 18.08 O, 56.6 C, and 3.17 N.

The Bi4$f_{5/2}$ and Bi4$f_{7/2}$ spectra recorded show the range of binding energies, E_b = 163.7 and 158.4 eV, which corresponds to Bi_2S_3 (Fig. 6a). The Bi4*f* spectrum also shows a spectrum of S2*p* sulfur, peaked at E_b = 160.98 eV, which is characteristic of sulfide sulfur. Because of its being overlapped with the Bi4*f* spectrum, the spectrum of S2*s* (E_b = 225.38 eV) [10] was recorded separately (Fig. 6b).

The O1*s* spectrum in Fig. 6c shows two peaks: one, at E_b = 529.3 eV, is due to oxygen adsorption, and the other, at E_b = 523.31 eV, corresponds to the OH^- group [10] (Fig. 6c).

The theoretical Bi/S ratio in a sulfide coating is 0.66, and that found experimentally from XPS data, 0.88. For Bi_2S_3, the published value of the binding energy E_b is 158.9 eV [10], and that found experimentally, E_b = 158.4 eV. This difference suggests that other Bi(III) compounds are also deposited when Bi_2S_3 is formed from a colloid solution. These assumptions agree in part with the voltammetric data. As already shown, two current peaks, K_3 and K_4, are observed in the cathodic portion of the curve in reduction of a sulfide coating, and several Bi(III) compounds are reduced in their range of potentials (Fig. 2, curves *1*, *2*). Along with Bi_2S_3, oxide compounds, such as BiOOH or BiOHS [12, 13, 16], can be formed. However, the binding energies E_b of these compounds could not be found in the literature. It was noted in [17] that Co(III) compounds, CoOOH and CoOHS, are also deposited when CoS and Co_2S_3 are formed.

A study of the electrochemical behavior of metal sulfides demonstrated that some of them, e.g., Co_2S_3 cannot be reduced to metal in supporting electrolytes. Bismuth sulfide coatings are rather easily reduced both in alkalis and in dilute acid solutions. This is well seen in Fig. 6d, in which the Bi4*f* spectrum separates into the metallic and oxide components after reduction of a bismuth sulfide coating in a 0.1 M NaOH solution, with a potential sweep in the cathodic direction from E_{st} to –0.9 V. Comparison of the bismuth spectra in Figs. 6a and 6d shows that two peaks with binding energies of Bi_2S_3 (158.4 eV) and metallic Bi (156.8 eV) are observed in the Bi4*f* spectrum (Fig. 6d) after the reduction of the sulfide coating.

CONCLUSIONS

(1) It was shown that a bismuth sulfide coating is reduced in a 0.1 M NaOH supporting solution to metallic bismuth at potentials ranging from –0.4 to –0.85 V. The cathodic current peak at E = –0.64 V may be due to reduction of oxide compounds of Bi(III), and that at E = –0.77 V, to reduction of Bi_2S_3.

(2) X-ray photoelectron spectroscopy revealed the presence of the following elements on the surface of the sulfide coating (at %): about 10.34 Bi, 11.81 S, 18.08 O, 56.6 C, and 3.17 N. The experimentally measured ratio Bi/S is 0.88, which exceeds the theoretical value of 0.67. It was suggested that oxide compounds of Bi(III), BiOOH or BiOHS, are also deposited in the formation of Bi_2S_3.

Abstract—Electrolysis of 0.01–0.1 M $TeCl_4$ solutions in dimethyl sulfoxide, dimethylformamide, and acetonitrile was studied in the temperature range 20–60°C. The microscopic structure of cathode deposits was analyzed.

DOI: 10.1134/S1070427207080125

The electrochemical deposition of tellurium has been studied in most detail in acid [1, 2] and alkaline [1, 3] aqueous solutions containing hydrated cations $[Te(H_2O)_n]^{4+}$ and oxo anions TeO_3^{2-}, respectively. The instability of water at elevated electrode potentials and the tendency of tellurium(IV) salts to undergo hydrolysis result in a number of side electrochemical and chemical reactions, which leads to difficulties in obtaining pure cathode deposits of tellurium.

Use of organic solvents makes it possible, in some cases, to eliminate these drawbacks and to obtain tellurium in a wide range of potentials from solutions of simple salts [4, 5].

This study, concerned with the electrochemical deposition of tellurium from organic aprotic solvents, continues the systems analysis of the electrochemical behavior of metals in the nonaqueous medium specified [6, 7].

EXPERIMENTAL

Electrode processes were studied in 0.01–0.1 M $TeCl_4$ solutions in dimethyl sulfoxide (DMSO), dimethylformamide (DMF), and acetonitrile (AN) in the temperature range 20–60°C. The organic solvents were of chemically pure grade, and $TeCl_4$ was synthesized by the procedure described in [8]. A PI-50-1.1 potentiostat with a standard electrochemical cell, platinum auxiliary electrode, and silver-chloride reference electrode was used.

Polarization curves were measured at a potential sweep rate of 2.0 mV s^{-1}. The cathode processes were studied using a graphite rod with a diameter of 6 mm and lateral surface insulated with a fluoroplastic tape. The anode processes were examined with tellurium press-fitted in a fluoroplastic cartridge. Before each experiment, graphite samples were trimmed with a fine-grained emery paper, polished with a velvet cloth, and washed with ethanol. To study the morphology of cathode deposits, the electrolysis was carried out with a soluble tellurium anode. Tellurium was deposited onto the edge surface of the graphite rod. The morphology of the anode surface was examined on a cleaved surface of metal lumps. In all cases, the electrolysis was carried out at a constant potential without stirring until a coating with an average thickness of 5 μm was obtained. The resulting cathode deposits remaining on a graphite sample, and anodically etched tellurium plates were washed with an appropriate aprotic solvent and acetone, dried in air at 60°C, and examined with a REMMA-102-02 scanning electron microscope.

A 200–300-mV plateau is observed in the cathodic polarization curves obtained in DMSO (Fig. 1a) and DMF (Fig. 1b) solutions, which points to a strong polarization of tellurium. In acetonitrile solutions (Fig. 1c), the polarization is less noticeable. In addition, the currents in AN considerably exceed those in DMSO and DMF at equal cathode potentials. This is primarily attributable to the fact that the donor numbers (DN) of DMSO and DMF markedly exceed the donor numbers of AN (DN_{SbCl_5} for DMSO, DMF, and AN are 29.8, 27.0, and 14.1, respectively [9]). Therefore, the stability of solvated tellurium(IV) cations in dimethyl sulfoxide and dimethylformamide

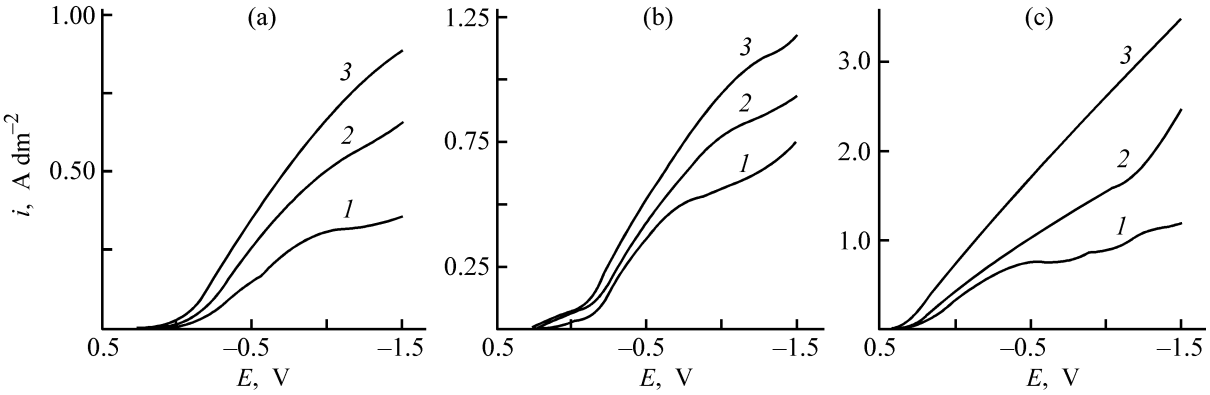

Fig. 1. Cathodic polarization curves obtained in $TeCl_4$ solutions in (a) dimethyl sulfoxide, (b) dimethylformamide, and (c) acetonitrile at different temperatures (c_{TeCl_4} = 0.05 M). (*i*) Current density and (*E*) potential; the same for Fig. 3. Temperature (°C): (*1*) 20, (*2*) 40, and (*3*) 60.

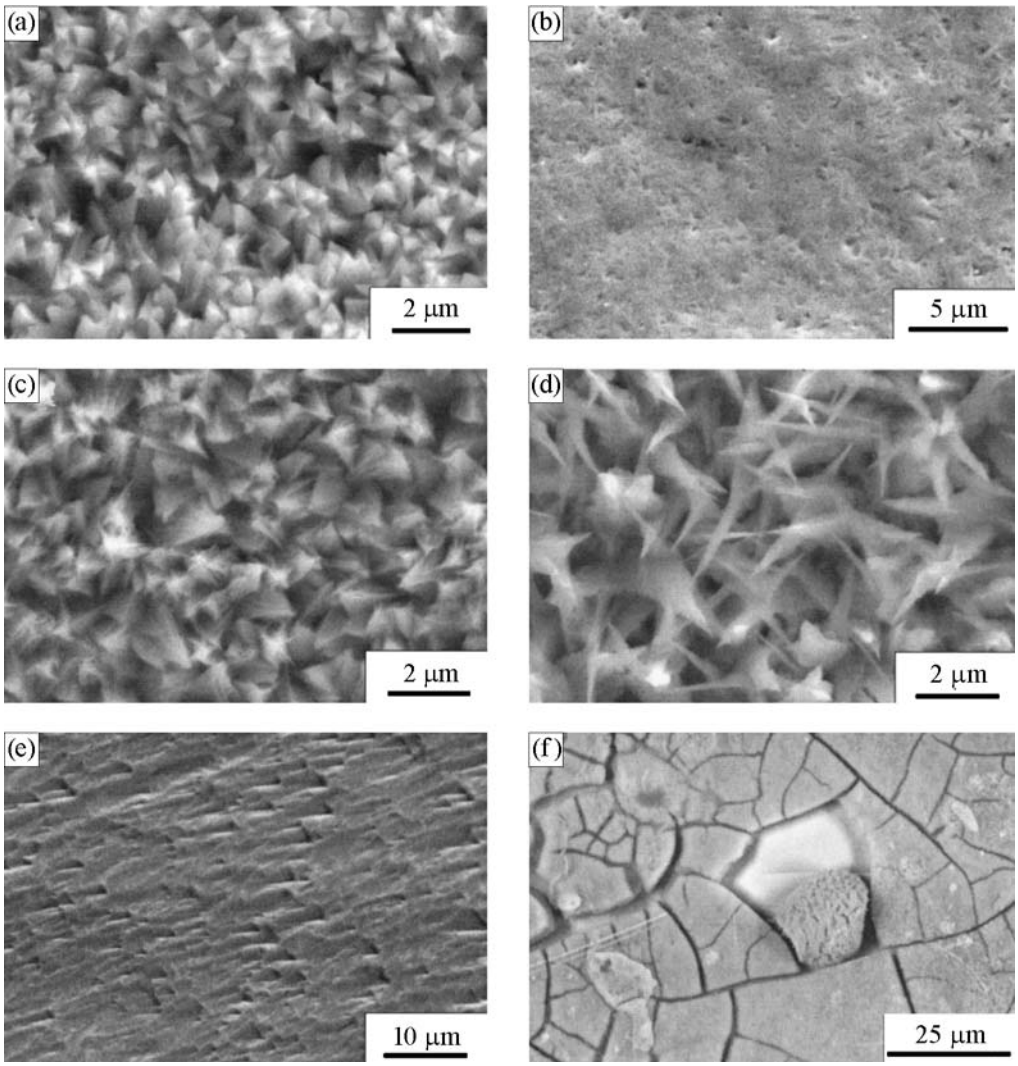

Fig. 2. Morphology of (a, d) tellurium cathode deposits on a graphite substrate and (e, f) tellurium surfaces after anodic dissolution in 0.005 M $TeCl_4$ solutions in (a, d, e) DMSO, (c, f) DMF, and (d) AN at different potentials. Potential (V): (a) –0.5; (b)–(d) –1.0; (e, f) 1.0. Magnification: (a, c, d) 10 000; (b) 5000; (f) (COMPO mode) 1200.

solutions is higher than that in acetonitrile solutions. Furthermore, the solvents specified strongly differ in viscosity: 2.003, 0.796, and 0.328 cP for DMSO, DMF, and AN, respectively [9], which is also an important factor of electrode polarization.

The increase in the cathode currents with temperature does not exceed 25% per 10° (Fig. 1). This indicates that the cathodic deposition of tellurium occurs under the diffusion control. As the concentration of $TeCl_4$ increases from 0.01 to 0.1 M, the cathode currents grow virtually proportionally.

In deposition of compact tellurium from DMSO, DMF, and AN solutions, comparatively solid and uniform coatings (Fig. 2) are formed. At low cathode potentials, crystallites with distinct configuration (Fig. 2a) are formed. As the potential (current density) increases in the DMSO medium, there occurs a kind of flattening and branching of the crystallites (Fig. 2b), which is manifested in that the coating becomes smoother and more lustrous. The tendency toward smoothing of the surface of a tellurium coating with increasing cathode potential (current density) is also observed in DMF solutions. However, this is mostly due to a decrease in the size of the crystallites and to an increase in their packing density (Fig. 2c). In AN, no smooth films are deposited (Fig. 2d). In this case, as the cathode potential increases, the crystallites decrease in size and coarsely crystalline dark gray coatings turn into finely crystalline black velvety crystals.

As demonstrated by the results of the study, the nature of a substrate chemically indifferent toward tellurium affects the morphology of a cathodic deposit only slightly. For example, the microscopic structure of the tellurium coating and the shape and sizes of crystallites on titanium and graphite samples differ only slightly in identical solvents at close cathode current densities (potentials).

The anodic dissolution of tellurium in DMSO and DMF solutions, as well as the cathodic deposition, occurs with polarization (Fig. 3, curves *1* and *2*). At potentials of 0.3–1.5 V, the anode currents depend virtually linearly on potentials, which points to an unhindered dissolution of tellurium.

Comparison of the initial surface tellurium with that after the anodic dissolution in DMSO solutions of $TeCl_4$ (Fig. 2e) shows that crystallites are etched-out in electrolysis. In this case, the surface becomes corrugated, but single-phase. In DMF solutions, a new phase appears in electrolysis on the tellurium surface

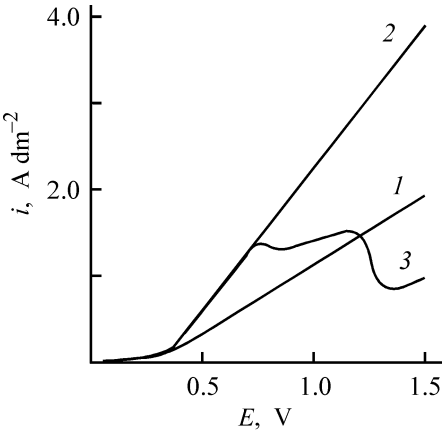

Fig. 3. Anodic polarization curves obtained on tellurium in 0.005 M $TeCl_4$ solutions in (*1*) DMSO, (*2*) DMF, and (*3*) AN at 40°C.

(Fig. 2f), as indicated by electron-microscopic studies in the COMPO. According to the energy-dispersion X-ray microanalysis, this phase contains chlorine. Thus, the anodic dissolution of tellurium in DMF occurs via formation of a solvated salt film. A similar pattern is observed in acetonitrile solutions. However, the film formation in DMF does not passivate the anode, as can be seen from the shape of the polarization curve (Fig. 3, curve *2*), whereas in AN, tellurium is passivated (Fig. 3, curve *3*).

CONCLUSIONS

(1) In dimethyl sulfoxide and dimethylformamide solutions of $TeCl_4$, the cathodic deposition of tellurium occurs with an appreciable polarization.

(2) Smooth films are formed on a graphite substrate in dimethylformamide, and smooth and lustrous coatings, in dimethyl sulfoxide. In acetonitrile, tellurium is deposited in the form of velvety coatings.

(3) In dimethyl sulfoxide solutions of $TeCl_4$, there occurs uniform electrochemical dissolution of tellurium, without accumulation of anodic products on the surface. This makes it possible to use soluble anodes in deposition of tellurium films in dimethyl sulfoxide.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Intrinsic Characteristics of Cathode and Anode Materials for Lithium-Ion Batteries

Abstract—Fundamental aspects of solving the problem of how the working capacity of lithium-ion batteries in prolonged cycling can be raised and the basic tendencies in the relationship between the intrinsic parameters of active materials of various brands and the electrochemical behavior of anodes and cathodes fabricated from these materials are considered.

DOI: 10.1134/S1070427207080137

The world industry of lithium-ion batteries (LIB) is characterized by a large number of manufacturers of various anode (based on graphite) and cathode ($LiCoO_2$, $LiNi_{1-x}Co_xO_2$, etc.) materials. Despite that materials from different manufacturers may strongly differ in their intrinsic characteristics (structural parameters, size and shape of particles, particle size distribution, specific surface area, surface morphology), they are all successfully used to create LIB competitive on the world market. Consequently, technological procedures and approaches adapted to a material of a particular type should be employed to enable effective use of active materials.

The study is devoted to a search for scientific criteria to be used in solving the problem of compatibility of certain intrinsic characteristics of the wide variety of the available materials with the rather large number of possible technological procedures employed in manufacture of LIB and with a certain electrochemical behavior of separate elements of LIB, including that in cycling.

EXPERIMENTAL

The samples studied had the form of finely dispersed powdered materials (SLA-1115, SLC-1520, SLC-1520P, and CZ-50 for anodes; $LiCoO_2$ manufactured by Merck and Baltiiskaya Manufaktura for cathodes). The samples were studied by electron microscopy and X-ray diffraction analysis. Histograms displaying the particle size distribution were plotted for the powder samples. Samples of anode and cathode materials, prepared by the standard technique commonly used in manufacture of LIB, were subjected to electrochemical testing in cells of C/Li and $LiCoO_2$/Li types, fabricated in CR-20 cases.

Of interest under the conditions of increasing demand for lithium-ion batteries that are capable of prolonged operation and can sustain a large number of cycles is a search for ways to choose the most preferable cathode material for LIB from those available, because practical electrochemical testing is time-and-labor consuming. The materials used as the active component of cathodes for lithium-ion batteries can be produced by various methods and, consequently, may have each its own individual impurity composition and homogeneity. The homogeneity and crystal perfection of an active material of the cathode largely determine the efficiency of an electrochemical system as a whole and its behavior in cycling. Without considering details of the preparation methods, we compared in this study cathode materials ($LiCoO_2$) purchased from two different manufacturers, Baltiiskaya Manufaktura and Merck, by means of X-ray diffraction analysis and electrochemical testing.

The starting $LiCoO_2$ powders were virtually identical in X-ray diffraction data. Minor differences in the interplanar spacings are due to their individual impurity compositions. Moreover, it is important to note that the structure identified for the samples under study belongs to the trigonal crystal system, which

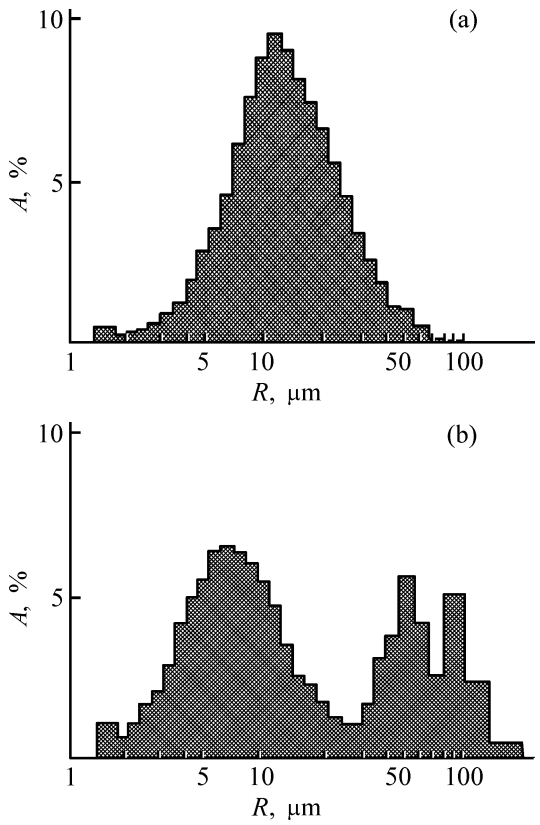

Fig. 1. Histograms of the distribution A of particles with respect to their size R in lithium cobaltate powders from (a) Merck and (b) Baltiiskaya Manufaktura Research-and-production company.

supplements published data indicating that there exist $LiCoO_2$ samples with a hexagonal structure [1]. This circumstance shows that conditions for an additional structural ordering in cobalt and lithium planes appear as $LiCoO_2$ is produced and the symmetry decreases to trigonal. Thus, the lithium and cobalt planes are mixed, which, in fact, makes it possible to distinguish one starting material from another by determining the "history" of a material in the course of lithium deintercalation.

The electrochemical behavior of cathodes fabricated from the powders under study was the same, at least in the first cycles (the testing was done at low current densities, $I = 0.3$ mA cm^{-2}). At the same time, reports have appeared recently, in which attempts were made to relate the identified properties of a sample to its behavior in cycling, with only the initial state of the sample considered. Probably, this way is not the best, because each sample acquires its "history" in the course of cycling, and, therefore, it is more appropriate to extrapolate to a large number of cycles some characteristics of a more changeable, farther from equilibrium, state of the structure than the initial state.

We identified $LiCoO_2$ phases which can or cannot restore their structural parameters in the course of lithium deintercalation. In particular, it was found that the initial $LiCoO_2$ phase in a sample with electrochemically deintercalated lithium, kept at 70°C for 30–35 days, turns into a mixture of spinel and trigonal phases. This process reflects the nonequilibrium and instability of the lithium-deintercalated state. Indeed, the nonequilibrium state of the structure is due to the presence of distortions and defects, and, because the process of lithium extraction is equivalent to a shift of the sequence of CoO_2 layers, it would be expected that the characteristic diffraction peak (003) will be broadened in the course of lithium deintercalation. X-ray diffraction patterns of samples with electrochemically lithium-deintercalated samples show a certain broadening of the peak, compared with its initial state, in the course of lithium deintercalation. In addition, the corresponding diffraction peaks for samples from different manufacturers should be dissimilar because of the different impurity compositions, "histories" of the materials, and particle size distribution histograms. Therefore, we suggest a semiquantitative criterion for determining the structural perfection of lithium-deintercalated $LiCoO_2$, the ratio between the halfwidth of the diffraction peak and its height, which can be used for extrapolation to a larger number of cycles and for evaluation of the quality of cathode materials in cycling.

It is also important to note that the samples of the powders studied have different histograms of particle size distributions (Fig. 1). The cathodes fabricated from the $LiCoO_2$ powders of the types under consideration exhibit virtually the same electrochemical behavior at low current densities in the first cycles. Nevertheless, the type of a distribution histogram is one of the most important intrinsic characteristics in the incoming control of the material, because it determines the efficiency of an electrochemical system in discharge and the intensity of degradation processes in charging. It can be assumed that the identical irreversible losses for the cathodes based on the powders under study at the current densities used are a consequence of the similar particle size distributions at small particle sizes in the histograms (left-hand parts of the histograms).

It is known that the main ways to improve cathode materials is their doping and development of mixed formulations [2]. However, there is no way of disregarding the way that relies upon the crystallochem-

ical aspect, i.e., analysis of a material, as such, from the standpoint of its crystal perfection and chemical composition. This way would enable a leap forward in the production technology of LIBs and yield batteries sustaining a larger number of cycles and operating for a longer time. For example, it would be preferable to obtain lithium cobaltate with a structure belonging to the hexagonal crystal system, because any structural ordering (trigonal in the case of lithium cobaltate) stabilizes the structure in the energetic regard, but impairs its reversibility with respect to the corresponding structural parameters in intercalation/deintercalation.

Carbon anode materials are finely dispersed powders whose particles have a structure of graphite. Studies aimed to synthesize new brands of graphite and change their intrinsic characteristics to lower the production cost and obtain higher-quality devices have been carried out during the entire history of development and improvement of the technology of LIB manufacture and are intensively carried out now [3].

In contrast to the case of cathode materials, it is unadvisable to impose particularly stringent requirements to the structural perfection of anode materials, both in their initial state and after being involved in an electrochemical process. The latter is due to the fact that the degradation process in graphite, i.e., its amorphization, is accompanied by loss of individual features by its structure and by a transition to a higher symmetry. This, in turn, points to an increase in the entropy of the system and to a higher thermodynamic stability of the newly formed phase, which can sustain intercalation and deintercalation during a rather large number of cycles. In addition, materials produced from natural graphite, which are successfully used in LIBs, contain a less thermodynamically stable rhombohedral β-modification, together with the hexagonal α-form. For example, natural graphite contains approximately 30% β-modification. In the fabrication technology of LIB, to compensate for the presence of the ordered β-form, and, consequently, to preclude its effect on the operation of LIB in prolonged cycling, it is advisable to use a certain excess of graphite (20–30%), compared with its amount used if only the equivalent amount of the cathode material and the amount of graphite consumed for formation of the passivating layer are taken into account. Therefore, we considered the intrinsic characteristics of graphite powders with the aim to develop LIB anodes exhibiting the nominal electrochemical behavior.

X-ray diffraction analysis was used to find the interplanar spacings d_{002} in the direction {002}, specific surface area of powdered active materials, and histograms of the distribution of particles over their size R_{av} (see table). The shapes and surface morphologies of particles were compared by electron microscopy.

Parameters of graphite powders and graphite anodes*

Graphite	d_{002}, Å	σ_{sp}, $m^2\ g^{-1}$	R_{av}, μm	ΔQ, %	Q, mA h g^{-1}
CZ-50	3.363	2.7	23	10	370
SLC-1520	3.347	0.95	29	35	250
SLC-1520P	3.367	1.1	27	40	270
SLA-1115	3.348	1.2	25	15	350

* Q is the specific discharge capacity, and ΔQ, irreversible loss.

It can be seen that the graphite structures somewhat differ in interplanar spacings. As a result, it would be expected that the diffusion characteristics of lithium in these materials and the electrochemical kinetics of interaction within the electric double layer will be also different. Indeed, it was shown in [4] that, on passing to graphites having an interplanar spacing different from a certain value (which is its own for each graphite brand), the irreversible loss of anodes fabricated from these graphites vary by the parabolic law with the structure parameter. This indicates that, not being an absolute physical constant, the interplanar spacing can be used, to a certain approximation, in incoming control of the active material for the anode.

An analysis of the polarization characteristics demonstrated that no noticeable differences are observed at high potential sweep rates providing that the electrochemical process of anodic polarization occurs in the kinetic mode. In addition, the differences in the specific surface areas of the powders did not reflect upon the on-off curves, i.e., these curves were virtually identical in the charging-discharge modes C/5 and C/10. Figure 2 shows discharge curves characterizing the nominal electrochemical behavior of anode made of graphites of (a) CZ50 and (b) SLA-1115 brands. Anodes fabricated from graphites of SLC-1520 and SLC-1520P brands show a high irreversible loss (35–40%) and lowered discharge capacity (see table). The decrease in the observed specific parameters of graphite, compared with the calculated values, are presumably due to specific features of the technological approach used. This is so because, as the content of binder is lowered from 10 to 8% and 3 to 5 wt % Ensaco carbon black is introduced, anodes made of SLC-1520 and SLC-1520P graphites exhibit, in electrochemical testing, specific parameters close to the calculated values. This is due

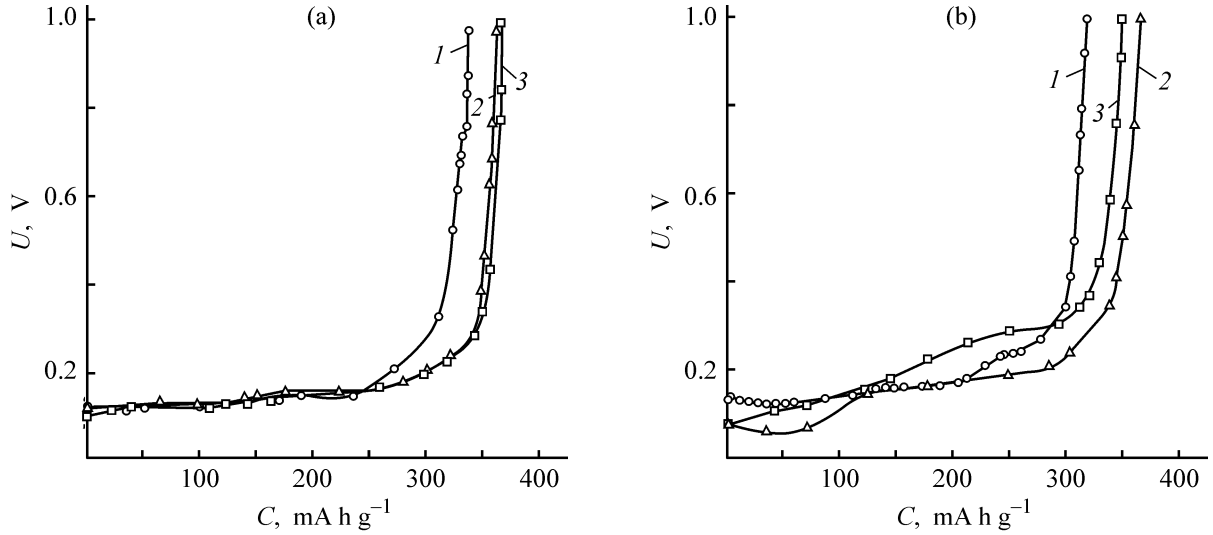

Fig. 2. Discharge curves for anodes made of graphites of (a) CZ-50 and (b) SLA-1115 brands. (*U*) Voltage and (*C*) capacity. Cycle: (a) (*1*) 1st, (*2*) 2nd and (*3*) 3rd; (b) (*1*) 1st, (*2*) 4th, and (*3*) 13th.

to specific features of the surface morphology of particles of the active material contained in the anode. Electron micrographs of particles of CZ-50 and SLC-1520 graphite powders show that the surface morphology of SLC-1520 graphite powder particles is more developed. In addition, the lack of any physical correlation between the polarization characteristics of the anodes and the intrinsic characteristics of the materials involved shows that not only the diffusion parameters of these materials, but also the true current densities, are close. Consequently, it should necessarily be taken into account that the binder material and its quality affect the mechanism of blocking of the active material.

CONCLUSIONS

(1) It was demonstrated that the structural features of active cathode materials are of key importance for solving the problem of raising the working capacity of lithium-ion batteries in prolonged cycling.

(2) It was found that the intrinsic parameters of the active materials, considered in the study, affect the electrochemical behavior of these materials. It was, in particular, shown that lithium cobaltate having a hexagonal symmetry is preferable to lithium cobaltate belonging to the trigonal crystal system.

(3) No physical correlation was observed between the polarization characteristics of the anodes and the intrinsic parameters of the active anode materials under study.

Abstract—Various methods for synthesis of heterogeneous membranes based on MSC-H and Purolite CT-275 sulfocation-exchange resins were considered. The efficiency of a combined method for fabrication of membranes, based on casting followed by rolling, was analyzed.

DOI: 10.1134/S1070427207080149

Industrial membranes used in fuel cells and in purification and drying of alcohols are rather sensitive to the action of polar solvents. To make longer the service life of these membranes, manufactures of fuel cells operating on alcohols deposit onto the membrane surface a barrier layer of polybenzimidazole or sulfated polyvinyl alcohol, which leads to a dramatic increase in the production cost of the membranes. Coatings in the form of a protective alcohol-resistant film reduce the proton conductivity of membranes [1].

In contrast to linear polymers (Nation and its analogues), cross-linked polymers of the MK-40 type (Vladimir, Russia) are insoluble in alcohols and esters, and only somewhat swell in these solvents, which does not affect the physicochemical parameters [2] of membranes fabricated from these polymers. A disadvantage of these membranes is their poor thermal stability (up to 100°C), which restricts their use in medium- and high-temperature processes. Therefore, obtaining membranes that would combine high proton conductivity with chemical resistance and thermal stability up to 150°C is a rather topical task.

EXPERIMENTAL

It is known that an acceptable combination of the characteristics specified above is observed for heterogeneous membranes composed of an acid ion-exchange resin and a macromolecular polymeric binder [3, 4].

As an active component in fabrication of membranes were chosen granulated sulfocation-exchange resins based on copolymers of styrene and divinylbenzene: KU-2-8chS (Azot Research and Production Co., Cherkassy, Ukraine), MSC-H (Dow, USA), and Purolite CT-275 (Purolite Int. Ltd., UK) (Table 1). To form

Table 1. Parameters of the cation exchangers used

Parameter	KU-2-8chS	MSC-H	Purolite CT-275
Ionic form (commercial)	H^+	H^+	H^+
Density of functional groups per unit mass of dry substance, mg-equiv g^{-1}	4.8	4.9	5.4
Number of sulfo groups per benzene ring	1	1	>1
Mass fraction of moisture, wt %	48–58	53.0	50–60
Grain size, mm	0.4–1.25	0.3–1.2	0.3–1.2

membranes, a cation-exchanger was ground on an electric mill at 5000 rpm and the 50-μm fraction of the resin was taken and dried at 100±5°C for 12 h, which provides drying to constant weight.

To improve the elasticity of a membrane, a binder compatible with ion-exchanger particles was introduced into its composition. Among a number of binders, we chose low-pressure polyethylene [PEND, TU (Technical Specification) U 20908-040] and chlorosulfonated polyethylene (KhSPE-20i) with a mass fraction of chlorine equal to 30 ± 4% (TU 6-55-9–90). KhSPE-20i polyethylene was used in the form of a 12.5–16% solution in toluene.

The membranes were formed by the conventional methods of polymer processing: compaction, rolling, casting, and combination of these [3, 4]. The membrane were reinforced with Lavsan (TU U 17-16 305 440.012–2002; thickness 0.3–0.5 mm, elongation to break 21–25%). Unreinforced membranes were also fabricated (Table 2, sample no. 1).

Membranes were formed by rolling on a FEB laboratory rolling machine in the temperature range 50–70°C. First, the polymeric matrix was rolled for 10–15 min and then, with rolls working, a powdered cation exchanger was gradually added. Filled films were further rolled for 10 min and then cooled to 20–30°C and removed. The mass ratio of the dry cation exchanger and the polymer was 1 : 1 (Table 2, sample no. 1).

In forming of membranes by compaction, the cation exchanger and PEND (≤50-μm fraction), taken in a mass ratio of 2.5 : 1, were thoroughly mixed and deposited onto an inert Lavsan support. The resulting material was kept in a mold at 135°C for 20 min and then cooled (sample no. 2).

In forming of membranes by casting, a dried cation exchanger was added to, and thoroughly mixed with a solution of KhSPE-20i in toluene. The resulting mixture was poured into a fluoroplastic mold. After it was uniformly spread over the mold, a Lavsan support was submerged in the mixture. The solvent was evaporated at room temperature in the course of 24 h. The mass ratio of the components was 1 : 1 (sample no. 3).

The forming of membranes by the combined method assumes that membranes are fabricated by joint use of casting and rolling. A weighed portion of a cation exchanger was kept to swelling in toluene and then a solution of KhSPE-20i in toluene was added. The mixture was thoroughly agitated and then deposited in five steps as a thin layer onto a Lavsan support until a uniform solid coating was obtained. After

each deposition step, the film was dried at 40–50°C. To smooth the surface of the film obtained, it was rolled at 100–110°C (sample nos. 4–7).

To remove organic solvents, the heterogeneous membranes fabricated by each method were boiled in a 30% aqueous solution of propanol-2 for 2–3 h and then washed six times with hot distilled water.

The chemical resistance of the membranes was evaluated by the time of keeping in ethanol and propanol-2 at temperatures of up to 145°C, necessary for a 10% loss of mass by the membranes.

The total static exchange capacity of the membranes was determined in accordance with GOST (State Standard) 17553–72 and 20255.1–89, and the moisture capacity, in accordance with GOST 17553–72 and 10898.1–84.

The degree of swelling of the membranes in water was calculated by the formula

$$K_{sw} = B_1/B_2, \quad (1)$$

where K_{sw} is the degree of swelling; B_1, thickness of a membrane kept in distilled water for 24 h (average over five measurements); and B_2, thickness of a membrane dried to constant weight.

The hydrodynamic permeability of the membranes was determined as the volume of a liquid (water or alcohol) transferred across the membrane via unit area in 1 h at the temperature of the experiment (as an average over 6 h) [5].

The methods used in determination of the gas permeability under atmospheric pressure and in gas-chromatographic analysis for hydrogen were described in [6].

The proton conduction was studied at a dc voltage of 12 V across the electrodes in the temperature range 25–95°C under atmospheric pressure [7]. The setup for measuring the proton conductivity had the form of a two-chamber steam-water cell with chambers separated by a membrane under study. Protons were generated in an electrolyte solution (distilled water) in the anode chamber, transferred across the membrane to the cathode chamber, and reduced in the latter to molecular hydrogen, with release of water. The anode was fabricated from compacted graphite, and the cathode, from nickel-plated stainless steel.

The proton transport number t_{H^+} was found by the formula

$$t_{H_2} = Fn_{H_2}/(I\tau), \quad (2)$$

where F is the Faraday number (C mol^{-1}); n_{H_2}, amount of hydrogen released at the cathode (mol); I, current strength (A); and τ, experiment duration (h) [8].

The proton conductivity of the membranes, σ (S cm^{-1}), was calculated using the formula [9]:

$$\sigma = (It_{H^+}l)/(US), \quad (3)$$

where l is the membrane thickness (cm); U, voltage across the electrodes (V); and S, cross-sectional area of the membrane (cm^2).

An analysis of the physicochemical parameters of the membranes obtained demonstrated that they surpass in exchange capacity the industrial membranes Nafion and MF-4-SK and are comparable in this regard with MK-40L (Table 2). All the four methods for membrane forming are applicable to their fabrication, but the most efficient is the combination of casting with rolling (sample nos. 4–7). The swelling coefficients of the membranes developed are 1.24–1.28 and satisfy the requirements of the standard. All the membranes studied sustained boiling in water for two hours.

A study of the permeability of the membranes to water and alcohols demonstrated that their permeability to water exceeds by two orders of magnitude that for industrial perfluorinated samples and is an order of magnitude lower than that for the analogue, MK-40 membrane (Table 3). The data obtained are accounted for by the high hydrophobicity of fluorine-containing polymers (Nafion and MF-4-SK). The decrease in the permeability of the membranes developed, compared with MK-40, is accounted for by densification of membranes and narrowing of their transport channel in forming with KhSPE, which does not occur in forming of KU-2-8ChS with polyethylene.

The permeability of the membranes based on sulfocation-exchange resin Purolite CT-275 (Table 2, sample nos. 6, 7) is twice that of MSC-H (sample nos. 4, 5). This is due to the difference in the total exchange capacities of both the starting cation exchangers and the resulting membranes, which is, in turn, determined by the degree of sulfonation of the active components. Because just the sulfo groups are responsible for the transport of water molecules across a membrane, it should be higher for membranes in which the concentration of these groups per benzene ring is higher (Purolite CT-275) and

Table 3. Permeability of membranes to liquids

Membrane	Water		Alcohol					
			methanol		ethanol		propanol-2	
	T, °C	permeability, $cm^3\,cm^{-2}\,s^{-1}\,atm^{-1}$	T, °C	permeability, $cm^3\,cm^{-2}\,s^{-1}\,atm^{-1}$	T, °C	permeability, $cm^3\,cm^{-2}\,s^{-1}\,atm^{-1}$	T, °C	permeability, $cm^3\,cm^{-2}\,s^{-1}\,atm^{-1}$

							68	8.77×10^{-6}
							90	6.3×10^{-6}
MF-4-SK	25	4×10^{-6} [10, 11]						
Nafion	25	3×10^{-8}–2×10^{-6}, [10, 11]	22	1.5×10^{-7}, [5]				
			60	3.4×10^{-6}, [5]				

should increase with the content of the active substance in the membrane (from 0.5 to 0.6).

An analysis of the concentration transport of an alcohol across the membranes demonstrated that it is considerably lower than that for water (Table 3). This fact is accounted for both by sorption factors and by steric and dynamic factors: the molecular volume of alcohols exceeds that of water, which causes a significant steric hindrance and makes lower the mobility of alcohol molecules. In contrast to water, the permeabilities to alcohols are close for all types of membranes, irrespective of the nature of an alcohol and origin of a membrane.

It was found that, as temperature increases, the diffusion rate of the alcohols passes through a maximum (Fig. 1). For propanol-2, the bending point is observed at T = 68–72°C. Further increase in temperatures leads to a decrease in the amount of diffusion.

In the narrow temperature range 68–72°C, in which the bend in the curve in Fig. 1 occurs, tetrameric associates of a liquid alcohol disintegrate to the mono- and dimeric state [12]. This effect builds up as an avalanche as temperature increases further. On heating to above 80°C, alcohol passes from the liquid state into the gaseous state and the diffusion rate decreases.

This is confirmed by the dependences shown in Fig. 2. It can be seen that the diffusion of liquid ethanol is two times faster than that of its vapor. Apparently, when the alcohol passes into the gaseous

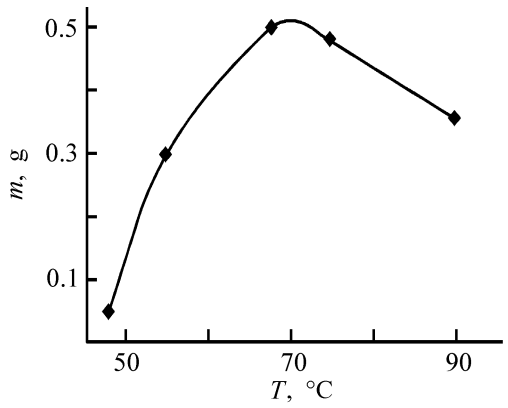

Fig. 1. Diffusion of propanol-2 across MK-40L membrane (P = 0.1 MPa) vs. temperature T. (m) Mass of propanol-2.

Table 4. Permeability of the membranes to hydrogen

Membrane	Permeability, $cm^3\ cm^{-2}\ s^{-1}\ atm^{-1}$
ECM-1-0.6	3.11×10^{-4}
MK-40L	4.35×10^{-3}
Nafion	2×10^{-3} [10, 11]
Composite of polyamide and polyesters	1.8 [10]
Polyimide on Al_2O_3 (tubes)	2.26×10^{-2} [13]
Polyimide on tetrafluoroethylene	4.02×10^{-2} [13]

Table 5. Time of a 10% loss of mass by membranes

Membrane	Solvent	Working temperature, °C	Time till 10% loss of mass, h
MK-40L	Propanol-2	≤100	~720
MF-4-SK	Propanol-2	≤160	≤4
	Ethanol	≤160	≤6
ECM-1-0.6	Propanol-2	≤145	≥1440
	Ethanol	≤145	≥1440

state, the membrane is dried and the motion of diffusing molecules along pores becomes more difficult.

It was, in particular, shown that raising the temperature from 55 to 140°C (with a simultaneous increase in pressure to 0.6 MPa) leads to a decrease in the permeability of the ECM-1-0.6 membrane to ethanol by nearly an order of magnitude (from 2.3×10^{-6} to 3.62×10^{-7} $cm^3\ cm^{-2}\ s^{-1}\ atm^{-1}$). The decrease in the permeability of the membrane during the second hour, compared with that in the first hour of an experiment, observed in Fig. 2, is accounted for by a change in the moisture content of the membrane because of the dehydration of sulfo groups by the alcohol. Further minor increase in permeability occurs because of the equalization of the concentrations of the supplied alcohol and water contained in the membrane.

Comparison of the results obtained with the known published data indicates that the heterogeneous membranes fabricated under laboratory conditions from the sulfocation exchangers MSC-H and CT-275 show a satisfactory diffusion permeability to water and alcohols.

Comparison of the gas permeabilities of the membranes MK-40L and ECM-1-0.6 to molecular hydrogen at 80°C and atmospheric pressure shows that the diffusion of H_2 across the MK-40L membrane (4.35×10^{-3} $cm^3\ cm^{-2}\ s^{-1}\ atm^{-1}$) exceeds by an order of magnitude that for the laboratory sample (3.11×10^{-4} $cm^3\ cm^{-2}\ s^{-1}\ atm^{-1}$) (Table 4). In other words, the heterogeneous membranes fabricated under laboratory conditions are gas-impermeable and safe in operation.

It was shown that the chemical stability of the membranes against polar solvents (ethanol and propanol-2, in particular) exceeds 1440 h, in contrast to that of the MF-4-SK membrane (Table 5).

It was found in measurements of the current through the measuring cell with ECM-1-0.6 and ECM-2-0.6 membranes at 12 V that the absolute current strength across the ECM-2-0.6 membrane is higher (Fig. 3). This is accounted for by the higher specific exchange capacity of ECM-2-0.6, compared with ECM-1-0.6 (Table 1). The share of the proton component for the sample based on Purolite CT-275 is lower than that for MSC-H (t_{H^+} = 0.60-0.65 against 0.75–1.0, respectively).

The calculated proton conductivities σ at 85°C and atmospheric pressure for the ECM-1-0.6 and ECM-2-0.6 membranes (2.3×10^{-4} and 1.04×10^{-4} S cm^{-1}) are comparable with the values obtained under the same conditions for MF-4-SK and MK-40L (4.8×10^{-4} and 8.6×10^{-5} S cm^{-1}).

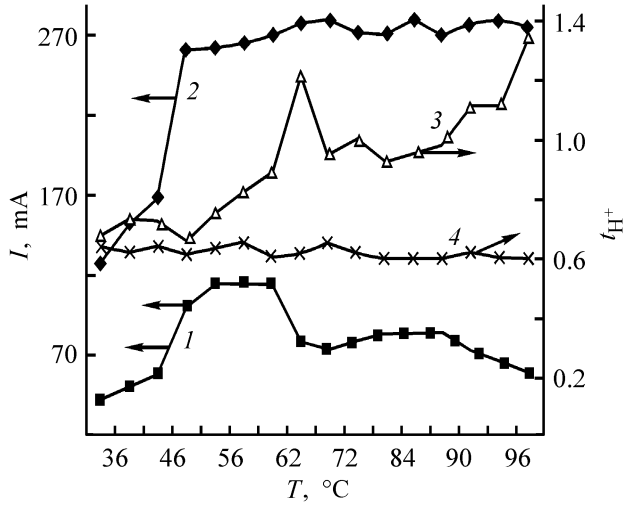

Fig. 3. (*1*, *2*) Total current strength *I* and (*3*, *4*) proton transport number t_{H^+} across membranes (*1*, *3*) ECM-1-0.6 and (*2*, *4*) ECM-2-0.6 vs. temperature *T*. *U* = 12 V, water as electrolyte.

CONCLUSIONS

(1) An analysis of various methods for fabrication of heterogeneous membranes based on the sulfocation exchangers MSC-H and Purolite CT-275 revealed that the most efficient of these is the combined method for membrane forming. The membranes produced using this method exhibit a unique resistance (>1440 h) to the action of polar solvents at a temperature of 145°C and pressure of 0.6 MPa.

(2) The membranes obtained are comparable in exchange capacity (2.0–3.0 mg-equiv g^{-1}) with MK-40L (2.3–2.9 mg-equiv g^{-1}). The swelling coefficients of the membranes are 1.24–1.28.

(3) The permeabilities of the membranes to polar liquids and molecular hydrogen are within $(2.3–8.7) \times 10^{-6}$ and 3.11×10^{-4} $cm^3\ cm^{-2}\ s^{-1}\ atm^{-1}$, respectively. At 90°C, the proton conductivity is as high as $(1–2.3) \times 10^{-4}$ S cm^{-1}, which is comparable with that of the known industrial membranes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Double Layer Capacitance of Gas-Diffusion Electrodes Made of Acetylene Black and Expanded Natural Graphites and Evaluation of the Surface Area Wetted by the Electrolyte

G. A. Kolyagin and V. L. Kornienko

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received December 26, 2006

Abstract—Cyclic voltammetry was used to determine the capacitance of the double layer in hydrophobized porous gas-diffusion electrodes made of acetylene black and expanded natural graphites. The average radius of pores by with an alkaline electrolyte, the area of these pores, and the true current density in electroreduction of oxygen were evaluated.

DOI: 10.1134/S1070427207080150

It is known that carbon-graphite materials and composites on their base are widely used as construction materials and electrodes [1] in various electrochemical devices employing aqueous electrolyte solutions: electrolyzers, power cells, electrochemical sensors [2], and capacitors [3–6]. In most cases, these materials have a pronounced porosity and highly developed internal surface. A knowledge of their structural characteristics and dynamics of their interaction with aqueous solutions is necessary for improvement of articles fabricated from these materials.

One of methods used to study and determine the structural characteristics of electrically conducting porous materials impregnated with an electrolyte solution is cyclic voltammetry (CVA) with linear potential sweep [7, 8–13]. This method is convenient in that, with a knowledge of the specific capacitance of materials under study, one can rapidly obtain necessary evidence concerning the interaction of porous bodies with a liquid medium under real operation conditions of electrodes without their disintegration or any change in their characteristics. If the specific capacitance of a material under study is unknown, the relative effects of various factors on the true working surface area of electrodes can be evaluated. For example, it was shown in [13] that the electric activity of carbon materials is proportional to the surface area evaluated by CVA, rather than to that given by BET. Recently, CVA has been frequently used to study expanded natural graphites (ENG) and fibers and articles made of these materials. For example, the possibility of using CVA to study articles made of ENG with a thickness of 2–6 mm and density of 160–470 g dm^{-3} at a potential sweep rate of 0.2–50 mV s^{-1} in order to determine the surface area, average pore radius, and porosity was demonstrated in [7].

It can be assumed that, under conditions of partial wetting of a porous body by water (porous hydrophobized gas-diffusion electrodes, electrically conducting composite materials, etc), CVA can be used to determine the surface area wetted by an aqueous solution. It is known that the activity of gas-diffusion electrodes strongly depends on the surface area wetted by the aqueous electrolyte; the knowledge of this parameter is necessary both for theoretical calculations and for applied studies, e.g., in finding the rate-determining stage of the process of current generation in the electrode.

This study continues research in the field of ENG-based hydrophobized gas-diffusion electrodes [1]. The aim of the study was to evaluate the surface area of hydrophobized gas-diffusion electrodes, wetted by an aqueous solution, by the CVA method and to correlate this surface area with the activity of electrodes in electroreduction of oxygen. To compare ENG with other carbon materials, electrodes fabricated from A-437E acetylene black with a specific surface area of 100 $m^2 g^{-1}$ were also studied.

Table 1. Parameters of electrodes fabricated from ENG of various brands and their activity in electroreduction of oxygen in 3 M KOH

EXPERIMENTAL

Powders of expanded graphite were obtained by heating of intercalation compounds synthesized by the electrochemical method of intercalation with nitric and sulfuric acids. The electrolyzer for electrosynthesis of intercalation compounds, parameters of the graphites used, and procedures employed to obtain ENG and fabricate electrode pastes and electrodes were described in [1]. The graphite brands, acids, and quantities of electricity passed in electrosynthesis of intercalation compounds are listed in Table 1. The powders obtained were used to produce a hydrophobized electrode paste (with an aqueous suspension of fluoroplastic-4D as hydrophobizer), from which electrodes were fabricated by compaction in the form of discs with a thickness of 0.5 mm, mass of about 0.3 g, porosity of 60 vol %, and fluoroplastic-4D content of 10 wt %. Acetylene-black electrodes were fabricated with a thickness of 1 mm and porosity of 69 vol % from a paste containing 8 wt % fluoroplastic-4D. To enhance the mechanical strength and electrical conductivity, the acetylene-black electrodes were reinforced with a nickel grid of thickness 0.1 mm.

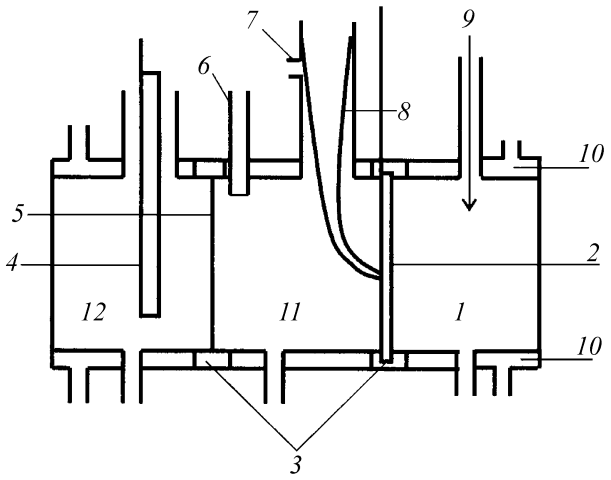

Fig. 1. Schematic of an electrolyzer cell with a hydrophobized gas-diffusion electrode: (*1*) gas chamber, (*2*) hydrophobized electrode, (*3*) fluoroplastic cartridges, (*4*) platinum counter electrode, (*5*) MF-4SK-100 ion-exchange membrane, (*6*) thermometer, (*7*) pipe for removal of gaseous products, (*8*) Luggin capillary, (*9*) supply of oxygen or inert gas, (*10*) thermostating jacket, and (*11, 12*) cathode and anode chambers filled with an aqueous electrolyte solution.

Electrochemical measurements were made at 20°C and atmospheric pressure in a 3 M KOH solution in a glass cell shown in Fig. 1. The catholyte volume was 0.023 l. A 1 M H_2SO_4 solution served as anolyte. The geometric current density was calculated per unit visible frontal surface area of the electrode (5 cm^2). The averaged true current density was calculated per unit electrolyte-wetted area, found in the study. The electrode potential was measured relative to a saturated silver chloride reference electrode. Oxygen was passed at atmospheric pressure via the gas chamber, wherefrom it was delivered into the electrode from its back side. Polarization curves were measured at a potential sweep rate of 4 mV s^{-1}. An inert gas was passed through the gas chamber when measuring the double layer capacitance. The charging current was determined at potentials of –0.14…0.0 V at rates of linear potential sweep ranging from 1 to 80 mV s^{-1}, with the electrode preliminarily kept at a zero potential. The charging current of the double layer was calculated at –0.075 V by dividing by two the absolute value of the current obtained by summation of the currents in the forward and reverse potential sweeps. Further, the slope of the dependence of the charging

current on the potential sweep rate was used to find the electrode capacitance and calculate the surface area [7] ($I = C_d S v$, where I is the charging current; C_d, specific capacitance per unit area; S, electrode surface area wetted by the electrolyte; and v, potential sweep rate). The calculations were made using published values of the specific capacitance of acetylene black and expanded graphite: 4.5 [9. 14] and 13.7 μF cm^{-2} [7], respectively. The average radius of pores wetted by the electrolyte was calculated by the formula [7] $r = 2V/S$, where V is the volume of electrolyte-wetted electrode pores, and S is the surface area wetted by the electrolyte. The volume of wetted pores was found by hydrostatic weighing of the electrodes [1] in 3 M KOH after experiments. The electrolyte porosity of the electrodes studied was 4–15 vol %. The characteristics of the electrodes and their activity in electroreduction of oxygen are listed in Table 1 and shown in Fig. 2.

Figure 3 shows typical examples of cyclic voltammograms obtained with expanded-graphite electrodes, which are similar to the dependences obtained for carbon materials [5], e.g., on graphite fabric [12], expanded-graphite fibers [4], or on carbon black and ultradispersed diamond [13]. It can be seen that the presence of polytetrafluoroethylene in a porous electrode does not affect the run of voltammograms.

Figure 4 shows dependences of the charging current on the potential at different potential sweep rates, obtained on the acetylene-black electrode. It can be seen that, in the potential range –0.05…–0.15 V, the charging current is directly proportional to the potential sweep rate and is independent of the electrode potential, which means that the ohmic loss is virtually zero [5]. Figure 5 shows dependences of the charging current on the potential sweep rate, obtained with different electrodes. The dependences obtained on electrode nos. 2 and 3 (Table 1) virtually coincide, and, therefore, Fig. 5a shows only the dependences obtained for one of these electrodes (no. 3). The nonlinearity of the dependences in Fig. 5b is due to ohmic loss in the electrodes. The larger the surface area and the higher the electrolyte porosity, the more linear the dependence of the charging current on the potential sweep rate and the smaller the error in determining the surface area by the CVA method, which means that higher potential sweep rates can be used [7]. To diminish the effect of the ohmic loss, the double layer capacitance of the electrodes was calculated from the slopes of the tangents to the cur-

ves at the origin of coordinates (Fig. 5b). The results of these calculations are listed in Table 2.

It follows from the data in Table 2 that the ENG surface area wetted by the electrolyte in the electrodes is smaller by a factor of 10 and more than that in the starting ENG powders (70–40 m^2 g^{-1} [1]). In the electrodes, the average radius of pores wetted by the electrolyte solution is an order of magnitude larger than the pore radius in ENG, found from the nitrogen adsorption (20–30 nm [1]). This can be attributed to blocking of graphite particles and narrow pores by fluoroplastic particles and to the impossibility of their wetting by the electrolyte solution. A similar effect of a polymer was described, e.g., in [6], where polyvinyl fluoride introduced in an amount of 20% reduced severalfold the original surface area of the carbon-graphite material because of the blocking of micropores. The decrease in the wetted area is also favored by working conditions of the electrode, because the back side of the electrode serves for delivery of a gaseous reagent into the electrode and is not in contact with the electrolyte. It is known that articles fabricated from expanded graphite exhibit hydrophobicity, closed porosity, and anisotropy of physical properties, which largely depend on their density [7, 15, 16]. This circumstance fundamentally distinguishes carbon blacks from ENG and leads to only a fourfold decrease in the surface area of the blacks and to a higher geometric current density on carbon-black electrodes, compared with those fabricated from ENG, at a lower true current density. The study failed to reveal the influence exerted by the nature of graphites and by the conditions of their processing on the wetted surface area and activity of hydrophobized electrodes. Only a slight effect of the amount of electricity passed in electrosynthesis of intercalation compounds on the true current density in electroreduction of O_2 was observed (Table 1). For example, the true current density is 0.0175 mA cm^{-2} on passing 0.15–0.17 A h g^{-1} and decreases to 0.0125–0.008 mA cm^{-2} at 0.21–0.22 A h g^{-1}. It is known [2, 4] that the method used to prepare ENG can affect its properties, e.g., the surface area and the capacitance of expanded carbon fibers. The following tendency is observed for all

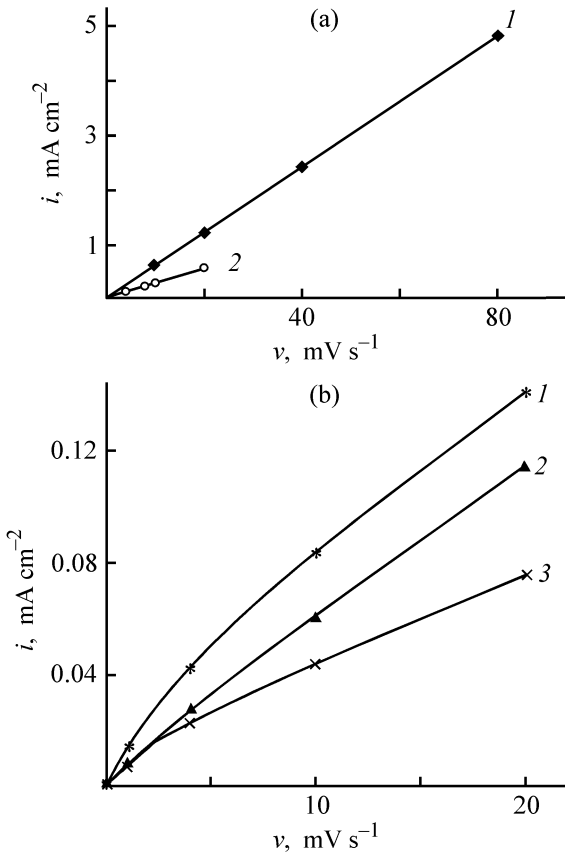

Fig. 5. Dependence of the charging current density i at –0.075 V on the potential sweep rate v, obtained on ENG electrodes. Electrode (Table 1): (a) (*1*) no. 1 and (*2*) no. 3; (b) (*1*) no. 5, (*2*) no. 4, and (*3*) no. 6.

the electrodes: as the density of the electrode increases, the capacitance, wetted surface area, and geometric current density decrease and the average diameter of hydrophilic pores grows, i.e., the fraction of pores with a smaller radius decreases. This is presumably due to the effect of fluoroplastic-4D particles, because, as the density of porous articles fabricated from the starting ENG increases, the average pore radius becomes smaller and the surface area decreases not so strongly [7, 15, 16].

As follows from the data in Table 2, all the electrodes can be divided into three groups with respect to their increasing density and decreasing capacitance and surface area. The highest capacitance and most developed surface is observed for the acetylene-black electrode, and then follow electrode nos. 2 and 3 and electrode nos. 4–6. In the same order varies the activity of the electrodes in electroreduction of oxygen (Fig. 2). It should be noted that the activities of electrode nos. 2, 3 and 4–6 virtually coincide, and, therefore, Fig. 2 shows as an example only a single curve for each group. Thus, it can be seen from the data obtained that there is a correlation between the wetted surface area and the geometric current density, despite that the wetted surface area is only roughly estimated.

No unambiguous dependence of the geometric current density on the surface area was found in the study, because the values of specific capacitance, used to calculate the area, were not for this particular material. It should also be noted that a direct dependence of the activity of electrodes on the electrolyte-wetted surface area takes place only in the kinetic mode with equal exchange currents, whereas in this study, the electrodes operate in the diffusion-kinetic mode.

CONCLUSIONS

(1) It was shown that cyclic voltammetry can be used to determine the double layer capacitance (1.1–0.24 F g^{-1}) and evaluate the wetted surface area (25–1.7 m^2 g^{-1}) of porous hydrophobized electrodes fabricated from carbon black and expanded natural graphites. The geometric current density in electroreduction of oxygen is proportional to this area. The averaged true current density decreases as the quantity of electricity expended for intercalation of acids into graphite grows. The larger the specific surface area determined and the smaller the ohmic loss, the more linear is the dependence of the charging current on the potential sweep rate.

(2) It was demonstrated that hydrophobized electrodes, the surface area accessible to the electrolyte sharply decreases, compared with that for the starting expanded natural graphite, from 70–40 to 6.5–1.7 m^2 g^{-1}, and the average radius of wetted pores increases from 20–30 to 43–330 nm. In contrast to graphites, the surface area of carbon black decreases by only a factor of 4, which is due to the significant difference between the properties of these materials.

(3) It was found that, as the density of the electrodes increases, their total capacitance, wetted surface area, and geometric current density in electroreduction of oxygen decrease and the average diameter of electrolyte pores becomes larger.

Abstract—Electrochemical oxidation of dopamine on a composite glassy carbon electrode with an electrodeposited iridium layer coated with a Nafion film was studied. A procedure for voltammetric determination of dopamine on the composite film electrode was developed.

DOI: 10.1134/S1070427207080162

Dopamine [2-(3,4-dioxyphenyl)-ethylamine; DA] is one of the most important biogenic catecholamines and plays an important role of a neuromediator in the activities of the central and peripheral nerve systems. It is included in the list of prohibited preparations, energy stimulators, used by athletes in the form of nutritional additives and pharmaceutical preparations. Therefore, development of fast and simple methods for determining the content of this catecholamine in biological fluids is of indubitable interest not only for diagnostics of psychic diseases, but also for doping control of athletes.

Various physicochemical methods are used for quantitative determination of DA. These include titrimetry [1], spectrophotometry [2], chemiluminescence [3], potentiometry [4], and high-performance liquid chromatography (HPLC) [5]. In addition to advantages, these methods have certain limitations. A shortcoming of spectrophotometry, potentiometry, and titrimetry is their low concentration sensitivity, and HPLC requires a preliminary sample preparation, occasionally including preliminary derivatization. Direct voltammetry with unmodified electrodes also has a number of disadvantages associated both with the irreversible oxidation of DA at large potential shifts from equilibrium and with the lack of reproducibility of the electrochemical signal from a substratum under study. Use of chemically modified electrodes (CME) with mediator properties improves the reliability and makes it possible to lower the DA oxidation overvoltage and raise the sensitivity of determination of this compound. As CME mediators in voltammetric determination of DA are used gold, platinum metals, and electrically conducting polymeric-organic and inorganic films [6–9]. However, with CME used, the detection limit cannot be lowered to the level in which DA is present in physiological fluids and the effect of accompanying components of physiological fluids (e.g., ascorbic and uric acids) on its oxidation cannot be prevented.

This study was concerned with electrooxidation and voltammetric determination of DA on a composite electrode based on glassy carbon (GC) with an electrodeposited iridium layer coated with a Nafion (NF) film. This enabled development of a high-sensitivity voltammetric method for determination of DA, which combines concentration in a polymeric film and electrocatalysis.

EXPERIMENTAL

Cyclic voltammograms were recorded with a PI50-1.1 potentiostat in a three-electrode cell. A GC electrode with a working surface area of 0.096 cm^2 and Ir-GC, NF-GC, and NF-Ir-GC electrodes were used as a working electrode. A silver chloride electrode served as reference, and a platinum wire, as auxiliary electrode. Cyclic voltammograms were measured at a potential sweep rate of 20 mV s^{-1}.

The film electrode was fabricated using Nafion (5% solution in a mixture of aliphatic alcohols: 50% alcohols and 45% water) of pure grade, purchased from Aldrich. Polymer solutions of various concentrations were prepared by dilution of the starting commercial Nafion with ethanol in the range 2.5–0.25%. The polymer was deposited onto the GC surface by the method of drop evaporation, with the subsequent cyclic variation of the potential in the range from –0.1 to +1.0 V in a 0.1 M solution of H_2SO_4. Iridium was electrodeposited from an aqueous solution of its salt, prepared from $IrCl_3$ purchased from Aldrich. Prior to the modification of the electrode, the GC surface was subjected to a pretreatment: the electrode was polished on filter paper, washed with twice-distilled water, and activated by multiple potential sweeping in the range –0.5…+0.5 V, in 0.1 M H_2SO_4. The electrode surface was refreshed mechanically.

A 5% solution of DA served as the standard solution. Solutions of lower concentrations were obtained by successive dilution of the starting standard.

As supporting electrolytes served 0.1 M solutions of H_2SO_4 and Na_2SO_4. To obtain a certain pH value, NaOH was added to a solution. The pH values of the solutions under study were measured with pH-150 pH-meter.

Preliminarily, the electrochemical behavior of iridium deposited onto GC was studied. A voltammogram measured on GC with an electrically deposited iridium layer (Ir-GC) in 0.1 M H_2SO_4 is shown in Fig. 1. The first pair of peaks at potentials of about 0.0 V is associated with the sorption–desorption of weakly and firmly bound form of hydrogen H^+ and release of H_2 and confirms the presence of the metallic phase of iridium on the GC surface [10]. In addition, the anodic branch of the cyclic voltammogram obtained on GC with an electrodeposited iridium layer shows a wave at $E^{1/2}$ = 0.45 V, and the cathodic branch, a peak at E_p = 0.15 V.

The prewave observed at $E \approx +0.4$ V corresponds to the formation of a hydrated Ir(III) oxide (hydroxide) [10–12]:

$$2Ir + 6H_2O \rightleftarrows Ir_2O_3 \cdot H_2O + 6H^+ + 6e. \quad (1)$$

Hydrated Ir(III) oxide is stable only in alkaline and deaerated solutions. In acid solutions, the metal oxidizes to Ir(IV) via the stage of formation of an intermediate Ir_2O_3, which immediately oxidizes to $IrO_2 \cdot H_2O$:

$$Ir_2O_3 + H_2O \rightleftarrows 2IrO_2 + 2H^+ + 2e. \quad (2)$$

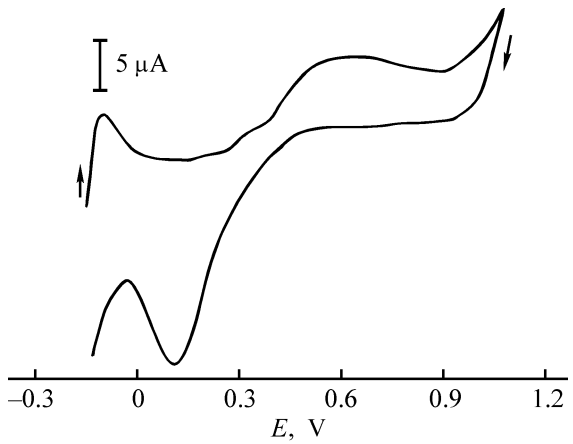

Fig. 1. Cyclic voltammogram obtained on Ir-GC in a 0.1 M H_2SO_4 solution. (*E*) Potential; the same for Figs. 2, 4, and 6.

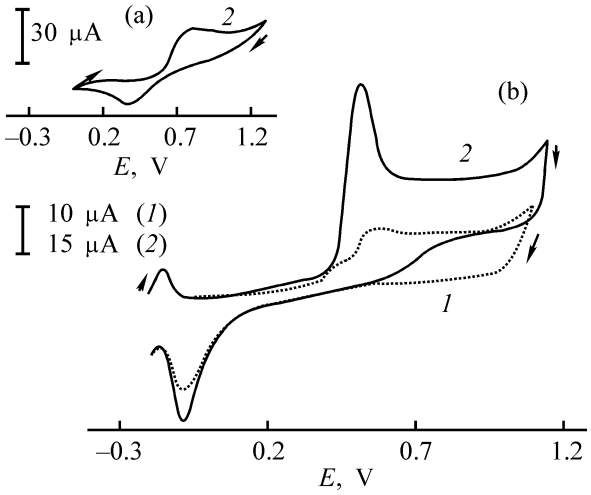

Fig. 2. Cyclic voltammogram obtained on (a) GC and (b) Ir-GC in a 0.1 M H_2SO_4 solution (*2*) with and (*1*) without dopamine. Dopamine concentration 5×10^{-3} M; the same for Figs. 4, 6.

In acid media, this process occurs at $E^{1/2}$ = 0.45 V. The cathodic peak at E_p = +0.15 V corresponds to reduction of hydrated Ir(IV) oxide to hydrated Ir(III) oxide. The overall cathodic and anodic processes at potentials more positive than +0.2 V can be described by the equation

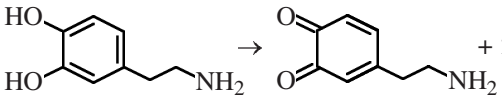
$$Ir + (n + 2)H_2O \rightleftarrows IrO_2 \cdot nH_2O + 4H^+ + 4e. \quad (3)$$

Dopamin oxidizes on GC irreversibly and with an overvoltage at E_p = 0.80 V. In this case, the cyclic voltammogram shows a pair of anodic–cathodic peaks strongly extended along the potential axis (Fig. 2a).

Table 1. Catalytic effect in oxidation of dopamine on an Ir-GC electrode under various electrochemical conditions of iridium deposition

Potentiostatic deposition				Potentiodynamic deposition			
E, V	i_{cat}	i_{med}	i_{cat}/i_{med}	Potential range, V	i_{cat}	i_{med}	i_{cat}/i_{med}
	μA				μA		
0.00	37	6.5	5.6	+0.90…+1.10	–	1.5	–
–0.05	39	6.7	5.8	+0.60…+1.10	–	1.7	–
–0.10	41	7	5.8	+0.40…+1.10	17	3.8	4.3
–0.20	63	10	6.3	+0.20…+1.10	30	6.2	4.8
–0.30	70	16	4.3	+0.00…+1.10	40	7.5	5.3

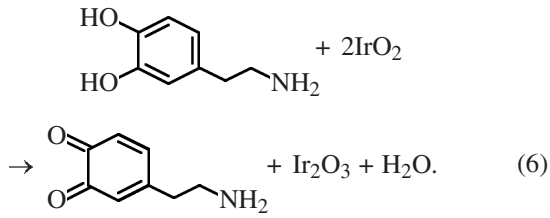
The slope of the anodic wave of the cyclic voltammogram is 80 mV, which exceeds the value for the reversible process. The electrode reaction occurring at GC in a DA solution includes a two-electron process accompanied by transfer of two protons to give an *ortho*-quinoid fragment in the structure of the product formed in DA oxidation. In this case, the electrochemical process is described by the overall equation [13]:



(4)

Figure 2b shows cyclic voltammograms obtained on an electrode with an electrodeposited iridium layer without (curve *1*) and with DA (curve *2*). The anodic branch of the cyclic voltammogram recorded on Ir-GC in the presence of DA (Fig. 2b, curve *2*) shows an increase in current up to a potential E = +0.50 V, with the background curve (Fig. 2b, curve *1*) exhibiting at the same potential a current peak characteristic of the redox pair Ir_2O_3/IrO_2. This means that DA is oxidized at mediator oxidation potentials. The current of the DA peak recorded on Ir-GC linearly depends on its concentration. The manyfold increase in current, decrease in the overvoltage potential of substratum oxidation (to 300 mV), and the value obtained for the Semerano coefficient [14] ($\Delta\log i_p/\Delta\log v$ = 0.3, where i_p is the peak current, and ν is the potential sweep rate) suggest that this process should be regarded as electrocatalytic. The catalytically active species are iridium(IV) oxo species, which oxidize the substratum diffusing toward the electrode surface and are regenerated in the process to iridium(III) oxo species. The mechanism of electrocatalysis can be represented as

$$Ir_2O_3 + H_2O \rightleftarrows 2IrO_2 + 2H^+ + 2e, \quad (5)$$



(6)

The dependence of the peak current of dopamine oxidation on the iridium electrodeposition conditions: duration and potential of electrolysis in the case of potentiostatic deposition, and the range of cyclic variation of the potential in potentiodynamic deposition. As can be seen from Table 1, higher mediator oxidation (i_{med}) and catalytic (i_{cat}) currents and a stronger catalytic effect in DA oxidation on CME (expressed as the i_{cat}/i_{med} ratio) are recorded if the electrode is formed by potentiostatic electrolysis. In this case, the increase in the catalytic current of DA oxidation is observed upon a shift of the iridium deposition potential into the cathodic region, in which the mediator is in the metallic form. A shift of the deposition potential into the anodic region leads to formation on the GC surface of a hydrated Ir(III) oxide unstable in an acid medium. The electrochemical characteristics of DA oxidation on Ir-GC, recorded under these conditions, differ little from those obtained on unmodified GC. Thus, the maximum catalytic effect is obtained at an iridium deposition potential of –0.20 V. The weaker catalytic effect in deposition of iridium at E < –0.30 V is probably due to release of H_2 in this range of potentials and to the resulting partial shielding of the catalytically active centers of the metal by hydrogen.

In addition, the catalytic effect depends on the metal deposition time. As can be seen in Fig. 3, a larger i_{cat}/i_{med} ratio is observed at a deposition time of 15 s, which is probably due to the formation of metallic iridium the nanoparticles having a higher mediator activity, compared with the catalytic activity of macroparticles.

Using the composite modified electrodes based on platinum metals coated with an NF film markedly improves the sensitivity of catecholamine determination because of the accumulation of the substratum in the polymeric matrix. Therefore, it was necessary to determine, when developing a composite electrode of this kind, the conditions in which an NF film is deposited and DA is accumulated in this film in order to record better electrochemical characteristics.

The cyclic voltammogram of DA oxidation on an electrode modified with an NF film (NF-GC) shows a current peak at E = +0.68 V (Fig. 4), whose amplitude is many times that of the peak of DA oxidation on GC without NF ($i_{NF\text{-}GC}/i_{GC} \approx 5.0$). The manyfold increase in the amplitude of the peak current of DA oxidation, recorded on NF-GC, is due to the accumulation of protonated DA molecules in hydrophilic channels of NF, which contain negatively charged $-SO_3H$ groups [15].

The polymer was deposited onto the GC surface by the method of drop evaporation from a solution prepared by successive 2-, 5-, 10-, 20-, and 50-fold dilutions of the starting 5% polymer solution with ethanol. As can be seen in Fig. 5 (curve *1*), the current of DA oxidation grows with the NF content. This is due to an increase in the number of ionogenic groups in the polymer film with the Nafion content of the solution deposited onto the GC surface. For example, the maximum current is recorded at a Nafion content of 5%. However, cracks appear on the electrode surface if the film is deposited from this solution. That is why a solution containing 2.5% Nafion was chosen for depositing the NF film. In addition, the current of DA oxidation differs only slightly in this case from the peak current obtained on the NF-GC electrode in the presence of the substratum under study. As the content of NF grows, the potential of DA oxidation shifts to more positive values (Fig. 5a, curve *2*), which is due to an increase in the thickness of the nonconducting polymeric film.

A study of the effect of the solution pH on the electrochemical characteristics of DA oxidation demonstrated that the current of DA oxidation increases as pH decreases (Fig. 5b, curve *1*). Because the NF film is a cation exchanger, its matrix will accumulate

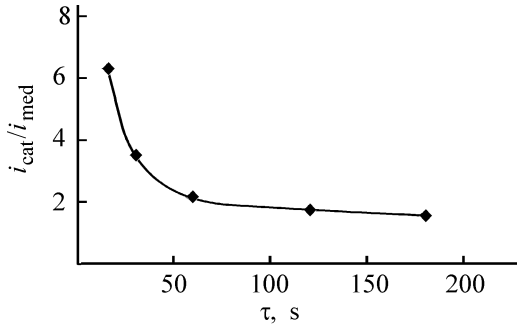


Fig. 3. Effect of the time τ of iridium deposition at E = –0.2 V on the catalytic effect (i_{cat}/i_{med} current ratio) in DA oxidation on Ir-GC.

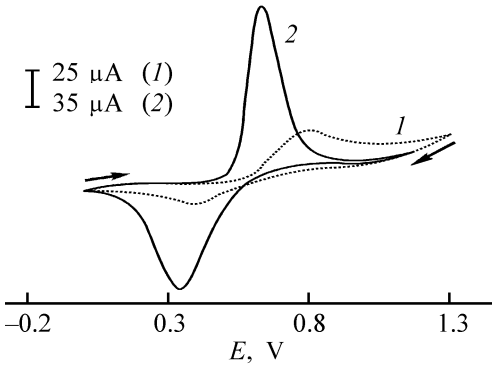

Fig. 4. Cyclic voltammograms obtained on (*1*) GC and (*2*) NF-GC in a 0.1 M solution of H_2SO_4 in the presence of DA.

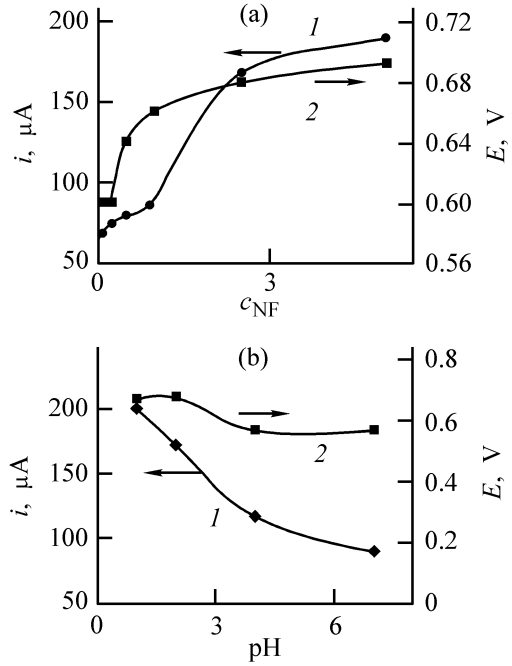

Fig. 5. Influence exerted by (a) content of Nafion in solution, c_{NF}, and (b) solution pH on (*1*) peak current i and (*2*) peak potential E of DA oxidation.

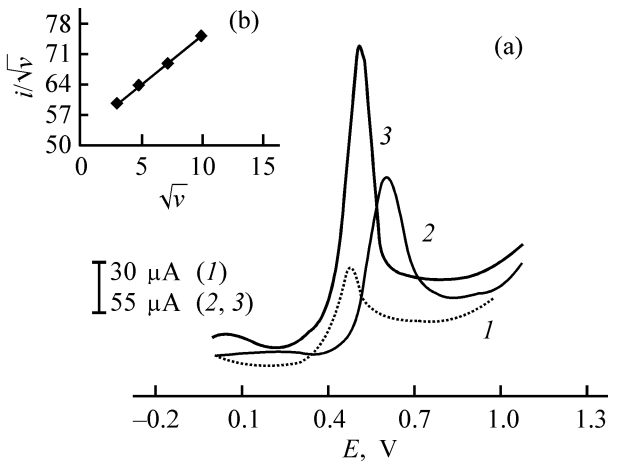

Fig. 6. (a) Voltammograms obtained on (*1*) Ir-GC, (*2*) NF-GC, and (*3*) NF-Ir-GC in the presence of DA and (b) dependence of the peak current of DA oxidation on the square root of the potential sweep rate.

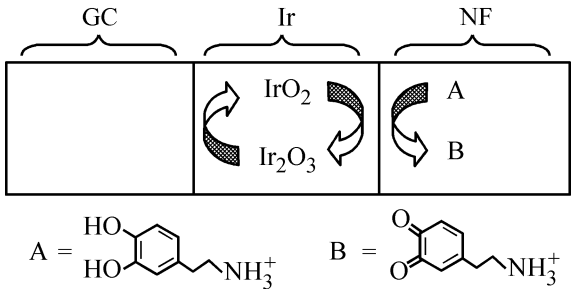
only protonated molecules of catecholamine, and this is, indeed, observed at low pH values. The decrease in the current of DA oxidation in a neutral medium is due a decrease in the fraction of protonated DA species at pH > 5.13 ($pK_a = 14 - pK_b = 14 - 8.87 = 5.13$ [15]). As the solution pH increases, the potential of DA oxidation shifts into the cathodic region, which is typical of electrode processes that occur with release of protons (Fig. 5b, curve *2*).

In a repeated potential sweep, the peak current at $E_p = +0.68$ V increases. This suggests that protonated DA molecules are accumulated in the polymeric matrix of Nafion. Therefore, the dependence of the peak current on the time of DA accumulation, t_{acc}, was studied in an agitated solution. As can be seen in Table 2, the peak current of substratum oxidation grows as the accumulation time increases to t_{acc} = 1 min. As t_{acc} increases further, the peak current remains virtually unchanged, which is due to the saturation of the polymeric matrix.

Table 2. Peak current of dopamine oxidation at various accumulation times in the polymeric matrix of NF-GC and NF-Ir-GC electrodes and times of iridium electrodeposition at $E_d = -0.20$ V

NF-GC		NF-Ir-GC			
τ_{acc}, min	i, μA	τ_d, s	i, μA	τ_{acc}, min	i, μA
0	167	15	195	0	285
1	310	30	220	1	510
2	315	120	275	2	505
3	317	180	285	3	485

With a composite electrode based on GC with an iridium layer coated with an NF film (NF-Ir-GC), it was possible to lower the overvoltage of DA oxidation by 170 mV and raise the current of substratum oxidation by a factor of 2 and 4 relative to the current of oxidation on NF-GC and Ir-GC electrodes, respectively (Fig. 6a). DA oxidizes on the NF-Ir-GC electrode, as well as on the Ir-GC, at $E = +0.50$ V, i.e., at potentials characteristic of the IrO_2/Ir_2O_3 redox pair. In this case, too, Ir(IV) oxo species act as a mediator. The plot of the dependence of $i/\sqrt{v}$ on $\sqrt{v}$ has a positive slope (Fig. 6b). This indicates that the adsorption is the rate-determining stage of DA electrooxidation on the composite electrode. With account of the aforesaid, the following mechanism of DA electrooxidation on the composite electrode NF-Ir-GC can be suggested: the electrode process includes modifier electrooxidation to give iridium(IV) species, which further oxidize the substratum accumulated in the NF film. The electrocatalysis process can be schematically represented as



It was found that the extent to which the peak current of DA oxidation increases depends on the iridium deposition time (Table 2). As this time increases, the number of active centers on the GC surface, involved in the electrocatalytic oxidation of DA accumulated in the NF matrix, grows, which leads to a rise in the DA oxidation current. As already mentioned, the peak current of DA oxidation also increases in preliminary accumulation of the substratum on CME before recording a cyclic voltammogram. Table 2 lists the peak currents of DA oxidation in relation to the time τ_{acc} of DA accumulation in the polymeric matrix of the NF-Ir-GC electrode. The current of catecholamine oxidation on the NF-Ir-GC electrode first increases and then, at $\tau_{acc} > 1$ min, decreases, which is probably due to shielding of the catalytically active centers of the metal by the forming products of DA oxidation.

DA was determined on an electrode modified with a composite polymeric film with an iridium layer

as follows. A 10-ml volumetric flask was charged with a fixed volume of an analyte solution and 5 ml of a 0.2 M solution of H_2SO_4, and the solution was brought to the mark with distilled water. The solution was transferred to an electrochemical cell. Then the CME and the auxiliary and silver chloride electrodes were submerged in the solution under study. Before recording a cyclic voltammogram, catecholamines were preliminarily accumulated from the solutions under study for 1 min; the voltammogram was recorded in the potential range 0.00–1.20 V and used to find the peak current of oxidation at E_p = 0.50 V.

The peak current is proportional to the DA concentration in the range 1×10^{-6}–1×10^{-3} (for Ir-GC) and 1×10^{-8}–1×10^{-3} M (for NF–Ir-GC). These dependences are described by Eqs. (6), (8), respectively:

$$i_p = (6.4 \pm 0.4) + (1.0 \pm 0.3) \times 10^4 c, \quad r = 0.9999, \quad (7)$$

$$i_p = (10.05 \pm 0.5) + (0.11 \pm 0.02) \times 10^6 c, \quad r = 0.9998, \quad (8)$$

where i_p is the peak current (μA) and c is the concentration (M).

Thus, with a composite film electrode NF-Ir-GC, the range of determinable concentrations can be extended and the detection limit lowered by two orders of magnitude, compared with the Ir-GC electrode. This becomes possible because of the combination of concentration, provided by the ion-exchange properties of the polymeric film, and electrocatalysis associated with the mediator properties of the platinum-group metal.

The procedure was verified by the introduced-found method (Table 3). The reproducibility of the analytical signal increases on passing to the composite polymeric electrode. In this case, the relative standard deviation S_r does not exceed 5% in the whole range of concentrations studied.

CONCLUSIONS

(1) It was found that iridium species deposited onto a glassy-carbon electrode exhibit electrocatalytic activity in dopamine oxidation. A catalytic peak was observed at E_p = +0.50 V in the range of oxidation of Ir(III) oxo species. The optimal conditions of dopamine concentration on a glassy-carbon electrode coated with a Nafion film were determined.

(2) The conditions in which a composite electrode with an iridium deposit coated with a Nafion film can be obtained and the maximum catalytic effect can be recorded on this electrode in dopamine oxidation were determined. The use of the composite film electrode led to an increase in the oxidation current of the substratum being studied because of the combination of the electrocatalytic properties of iridium and ion-exchange properties of the polymeric matrix of Nafion.

(3) A chemically modified electrode with an electrodeposited iridium coated wit a Nafion film was used for voltammetric determination of dopamine. The dependence of the oxidation current of dopamine on its concentration is linear in the range 1×10^{-8}–1×10^{-3} M.

Table 3. Metrological characteristics of dopamine determination on CME (n = 6, P = 0.95)

Electrode	Dopamine concentration, μM		S_r
	introduced	found	
Ir-GC	5.0	4.8 ± 0.2	0.05
	10.0	9.9 ± 0.4	0.04
	100	101 ± 2	0.02
NF-Ir-GC	5.0	4.9 ± 0.2	0.04
	10.0	10.2 ± 0.3	0.03

Abstract—Cement-containing GTT catalysts based on manganese, copper, and nickel oxides were developed and introduced into practice in processes employing ozone technologies and in oxidation of toxic organic compounds. Physicochemical methods were used to study the process of catalyst formation and the influence exerted by various brands of manganese salts and by preparation conditions and, in particular, calcination temperatures and grain molding technique on the characteristics of the catalytic systems obtained. Several commercial batches of GTT catalysts were manufactured.

DOI: 10.1134/S1070427207080174

At present, one of the most efficient and ecologically safe ways to purify drinking water, wastewater, and water in swimming pools is ozonation. The use of ozone is due to its oxidizing and bactericidal properties; however, the acrid smell and toxicity of ozone (MPC = 3.3 $\mu g\ m^{-3}$) makes topical the problem of destruction of residual ozone [1]. Photochemical, thermal, and catalytic methods of ozone decomposition are possible. The optimal in economical efficiency and simplicity of technological apparatus is the catalytic decomposition of ozone [2].

The industrially employed catalyst for ozone decomposition, hopcalite, is composed of 60% manganese oxide, 25% copper oxide, and 15% binder (bentonite clay). It has an important disadvantage, poor mechanical strength, to the point of grain disintegration under the action of moisture drops [3]. The known catalysts [4], distinguished by stability and operation efficiency under humid conditions, contain noble metals and, in particular, silver and are rather expensive.

Catalysts composed of oxides of nonprecious transition metals and exhibiting stable operation under various conditions have been created by developing cement-containing catalysts of GTT and GT brands, based on manganese, copper, and nickel oxides [5–9]. The activity of these catalysts in a dry flow is close to that of hopcalite and exceeds it by a factor of 1.5–2 in operation in a humid flow. These catalytic systems have high mechanical strength and water resistance, and their grains preserve shape when brought in contact with water. In a dry gas flow, the catalysts work at room temperature. In a humid flow, the working temperature range is 20–120°C. In case of a decrease in activity in a corrosive humid medium, the catalysts can be regenerated at 250–300°C in 2–3 h.

Tests demonstrated that GTT is efficient not only in ozone decomposition, but also in oxidation of carbon monoxide, methane, benzene, styrene, isopropylbenzene, butyl acetate, and other compounds. The GTT catalyst possesses the necessary developed surface, thermal stability, and resistance to coking in

[1] N.I. Murashov, Zh.V. Myasnikova, S.G. Dormidontova, and L.D. Kvasova took part in catalyst preparation on laboratory, pilot, and industrial installations, and also in catalytic activity tests and determination of other characteristics of catalysts.

Table 1. Basic characteristics of the cement-containing GTT catalyst (for extrudates)

Parameter	Grains of dark brown to black color
Bulk density, kg dm^{-3}, no more than	1.3
Mechanical strength, kg mm^{-1} grain diameter, no less than:	
average	1.1
minimum	0.6
Porosity Π, %, no less than	40
Specific surface area S_{sp}, $m^2\ g^{-1}$, no less than	100
Ozone decomposition factor* γ in a gas flow, no less than:	
dry gas flow	1.1×10^{-4}
humid gas flow	0.55×10^{-4}

* The quantity γ, the fraction of active, i.e., leading to decomposition, collisions of ozone molecules with the catalyst surface, is taken as a measure of the catalyst activity. The ozone decomposition factor is given by the Lunin–Popovich–Tkachenko formula [3] $\gamma = 4w[\ln(c_0/c)]V_tS$, where c_0 and c are the ozone concentrations at the reactor inlet and outlet, respectively; w, volumetric gas flow rate; V_t, thermal motion velocity of molecules; and S, total external surface area of catalyst grains. The parameter γ is proportional to the effective rate constant of the heterogeneous decomposition of ozone.

oxidation of the chemical products mentioned above. The basic technical characteristics of GTT are listed in Table 1.

The technology of GTT fabrication has been implemented at the catalyst shop of NIAP. The catalyst is manufactured as compacted pellets $d \times h = 6 \times 3$ (5×3) mm^2 and in the extruded form [extrudates with a diameter of 1.5 to 5 mm and length of 5 to 15 mm; pellets with $d \times h = 5 \times 3$ (4×3) mm^2].

The aim of this study was to examine, using a set of physicochemical techniques, the influence exerted by the preparation conditions and composition of the starting manganese-containing concentrate on the formation of the Mn–Cu–Ni–Al–Ca system and to determine the relationship between the phase composition of the catalyst and its catalytic activity in decomposition of ozone and oxidation of benzene.

EXPERIMENTAL

The catalyst was fabricated by the method of hydrothermal synthesis (HTS) [10, 11], which includes mixing of the starting components in the presence of aqueous ammonia and granulation of the resulting paste, followed by keeping of the grains first in a humid-air medium and then in hot water in the stage of hydrothermal treatment (HTT). After that the catalyst is dried and calcined.

An X-ray diffraction analysis was carried out on a DRON-3 diffractometer (graphite monochromator, Cu_{K_α} radiation, reflected beam). IR spectra were measured on a Specord 75-IR spectrophotometer, with samples prepared by compaction with KBr. The specific surface area of catalyst samples was determined by the low-temperature adsorption technique (BET). The total porosity was found from the true and apparent densities. The apparent density was calculated by dividing the mass of a sample by its geometric volume. The true density was determined by pycnometry, from the volume of toluene absorbed by a sample. The error in determining the total porosity was $\pm 5\%$.

An X-ray phase analysis (XPA) demonstrated that the synthesis of the catalyst involves, in stages of molding, humid-air treatment, HTT, and drying, the reaction of interaction (heterogeneous ion exchange) between hydroxocarbonates of copper (CHC) and nickel (NHC) and calcium aluminates (talum: CA, CA_2[2]) to give hydroxo aluminates (HA) of nickel and copper and calcite $CaCO_3$ [12]. XPA does not reveal any interaction of the starting $MnCO_3$ with the above components, whereas IR spectroscopy indicates [13] that a certain amount of manganese ions can be incorporated into the lattice of gibbsite formed as a result of talum hydration.

The temperature at which a catalyst is calcined strongly affects its formation and catalytic activity. For GTT samples calcined at 100–800°C, the phase composition and catalytic activity in ozone decomposition and benzene oxidation were determined. At low calcination temperatures (100–200°C), the starting

[2] CA, CA_2 are designations used in cement chemistry: CA = $CaO \cdot Al_2O_3$ and $CA_2 = CaO \cdot 2Al_2O_3$.

metal hydroxocarbonates and products of talum hydration and ion exchange are present. At higher temperatures, metal hydroxocarbonates decompose to the respective oxides. The starting manganese-containing component decomposes to oxides of various compositions. In the temperature range 300–350°C, a phase close in X-ray diffraction characteristics to MnO_2 appears in the sample composition, the intensity of Mn_2O_3-related peaks increases, and the Mn_3O_4 phase is weakly pronounced. At temperatures of 350–600°C, the content of Mn_3O_4 increases, that of Mn_2O_3 decreases, and MnO_2 disappears. At 700–800°C the main manganese containing phase in Mn_3O_4.

Samples calcined in the temperature range 300–600°C show an ozone decomposition factor γ of no less than 1.5×10^{-4} (Fig. 1). Samples calcined at 400–600°C exhibited the highest activity in ozone decomposition [$\gamma = (2.38–2.45) \times 10^{-4}$], and those calcined at 300–400°C, in benzene oxidation, with the temperature of benzene oxidation at 50% conversion equal to 230–240°C (Fig. 1). The decrease in the catalytic activity at calcination temperatures higher than 600°C is presumably due to recrystallization of the NiO and CuO phases. In accordance with this circumstance, the optimal temperature of catalyst calcination was chosen to be 350–400°C for ozone decomposition and 300–350°C for benzene oxidation.

The catalyst was prepared from different batches of a Mn-containing stock (Table 2) supplied under the brand Manganese hydroxocarbonate, which, according to XPA and IR spectral data, is anhydrous manganese carbonate, occasionally containing the Mn_2O_3 phase. For example, the IR spectrum of sample no. 1 contains, together with absorption bands at 1420–1440, 870, and 730 cm^{-1}, which characterize the carbonate anion in the composition of manganese carbonate, also strong absorption bands at 580–530 cm^{-1}, related to the presence of an oxide phase (Fig. 2). According to XPA data, this is Mn_2O_3. The study revealed that no $MnCO_3$ decomposition is observed up to 200°C; and at 300°C manganese oxides Mn_3O_4 and MnO_2 appear, together with $MnCO_3$ and Mn_2O_3, in stock sample nos. 1 and 2 and only Mn_3O_4 in sample no. 3. The MnO_2 phase was not found in any of the stock samples at 400°C, and in the range 400–800°C Mn_2O_3 is gradually converted to Mn_3O_4, which becomes the main manganese-containing phase at 800°C.

The above-mentioned brands of $MnCO_3$ were used to prepare GTT catalyst samples under laboratory conditions. XPA data for GTT catalyst samples calcined at 300–500°C are listed in Table 3. The decomposition of $MnCO_3$ in the catalyst occurs similarly to

Table 2. Phase composition of the manganese-containing stock at calcination temperatures of 200–800°C

T, °C	Phase composition		
	no. 1 $MnCO_3$ Sedema, supply from Belgium	no. 2 $MnCO_3$	no. 3 $MnCO_3$ (supply from Russia)
200	$MnCO_3$, Mn_2O_3	$MnCO_3$	$MnCO_3$
300	$MnCO_3$, Mn_2O_3, Mn_3O_4, MnO_2	$MnCO_3$, MnO_2, Mn_3O_4, Mn_2O_3	$MnCO_3$, Mn_3O_4

Table 4. Physicochemical characteristics and catalytic activity of GTT samples calcined at T = 400°C

GTT catalyst	Chemical composition: active components, %	γ	$T_{benz.ox}$, °C, at 50% conversion	S_{sp}, $m^2\ g^{-1}$	Π, %
no. 1 $MnCO_3$ Sedema, supplied from Belgium	Mn_3O_4, 29.3, CuO, 19.6, NiO, 10.1; Σ = 59	1.88×10^{-4}	250	100	70
no. 2 $MnCO_3$, supplied from Belgium	Mn_3O_4, 28.6, CuO, 21.2, NiO, 10.3; Σ = 60.1	1.85×10^{-4}	220	100	50
no. 3 $MnCO_3$, supplied from Russia	Mn_3O_4, 29.6, CuO, 20.6, NiO, 10.9; Σ = 61.1	1.85×10^{-4}	230	100	60

the content of this phase decreases and that of the oxides Mn_2O_3 and Mn_3O_4 increases, whereas in sample no. 3, mostly the content of the Mn_3O_4 phase grows. Also, the degree of crystallinity of the copper oxide phase is higher at these temperature than that of nickel oxide. This is due to the fact that mostly the nickel hydroxoaluminate phase is formed in the preceding stages, and especially in the HTT stage, and this leads to formation of a dispersed phase of nickel oxide in calcination.

Table 4 lists physicochemical parameters of samples calcined at T = 400°C. The total amount of the active component in samples of a finished catalyst is 59 to 61%. The specific surface areas of the samples are virtually the same (~100 $m^2\ g^{-1}$). The highest porosity (~70%) is observed for GTT sample no. 1.

Activity tests of samples prepared from different stock batches demonstrated that, at close compositions and surface areas, all the samples exhibit high activity in ozone decomposition, $\gamma = (1.81–1.88) \times 10^{-4}$. Consequently, presence of the Mn_2O_3 phase in the starting manganese-containing component does not exert any significant influence on the GTT activity in ozone decomposition. However, a minor decrease in activity is observed in benzene oxidation: the difference in benzene oxidation temperature at 50% conversion is 20–30°C.

Extrudates were prepared on a pilot apparatus from $MnCO_3$ of Sedema brand, supplied from Belgium, and $MnCO_3$ from Russia. The ozone decomposition factor for batch no. 1 (extrudates 1.5 mm in diameter), synthesized from $MnCO_3$ containing an admixture of Mn_2O_3 is 1.13–1.25 times lower than that for batch no. 2 (extrudates 1.5 mm in diameter), produced from $MnCO_3$ of domestic manufacture, in which the Mn_2O_3 phase is either absent or present in a minor amount. GTT no. 1 is inferior to GTT no. 2 in specific surface area, porosity, and total amount of the active com-

No. 7, molded pellets, $d \times h$ = 5 × 3 mm, June 2005, based on $MnCO_3$, supplied from Bulgaria	CuO, Mn_3O_4, MnO_2, $MnCO_3$, CA_2, $CaCO_3$, NiO, aragonite, trace amounts, CA	2.35×10^{-4}	230	110	70	Mn_3O_4, 27.1, CuO, 20.5, NiO, 9.0; Σ = 56.6

ponent (Table 5), which can also account for the decrease in γ. The catalytic activities of these batches in benzene oxidation do not differ significantly.

Molded pellets were produced on industrial equipment (FP-025 pellet-granulator, manufactured by Dzerzhinsk NIIkhimmash federal state unitary enterprise) from manganese carbonate from Belgium, which contains an insignificant amount of Mn_2O_3 (GTT catalyst batch nos. 5 and 6), and manganese carbonate manufactured in Bulgaria, which contains no Mn_2O_3 (catalyst batch no. 7) (Table 5). It was found that the ozone decomposition factor γ for GTT no. 7 is, on average, 1.4 times that for GTT nos. 5 and 6. It is, however, impossible to state unambiguously that the brand of $MnCO_3$ affects the catalytic activity of GTT in ozone decomposition in the case of industrial batches. It can be seen from the data presented that there is difference in porosities (by a factor of 1.17–1.5) even for batches prepared from the same brand of raw material, manganese carbonate manufactured in Belgium. The catalytic activities of these batches in benzene oxidation do not differ significantly.

A comparison of the basic characteristics of GTT batches produced under pilot-industrial conditions (extrudates of various diameters) and manufactured under industrial conditions (molded pellets) at the same calcination temperature demonstrated that that the activity of extrudates in ozone decomposition exceeds that of molded pellets by, on average, a factor

of 1.1–1.7 and that in benzene oxidation is lower (benzene oxidation temperature at 50% conversion is, on average, 30–40°C higher) (Table 5). These batches show insignificant differences in porosity, specific surface area, and amount of the active component. It can be assumed that the changes in activity are due to specific features of the decomposition of the starting manganese carbonates in the extrudates and pellets in the calcination stage. It has been found previously that the type of a manganese-containing phase formed is sensitive to the calcination temperature. In the range T = 300–350°C, the MnO_2 phase is formed in extrudates (Table 3), with the benzene oxidation temperature at 50% conversion equal to 230°C (Fig. 1) and $\gamma = (2.22–2.38) \times 10^{-4}$. In the range T = 400–450°C, Mn_3O_4 is the main manganese-containing phase, with $T_{benz.ox}$ = 240–280°C and $\gamma = 2.45 \times 10^{-4}$. In molded pellets, the MnO_2 phase is still present at T = 400–430°C, the benzene oxidation temperature at 50% conversion is 220–230°C, and $\gamma = (1.58–2.35) \times 10^{-4}$ (Table 5). Presumably, the predominance of the manganese-containing phase Mn_3O_4 in GTT samples (extrudates, pellets) at calcination temperatures in the range 300–450°C favors an increase in the activity of the catalyst in ozone decomposition, and the presence of the MnO_2 phase positively affects the activity in benzene oxidation.

According to the quality regulations for manganese-containing raw materials, the mass fraction of sulfur in terms of sulfates should not exceed 0.04%. The content of sulfur in the manganese-containing starting component, especially of domestic or Bulgarian manufacture, fails to satisfy these requirements. A number of test batches were prepared in the form of extrudates based on manganese carbonates containing 0.16 to 0.23% sulfates (SO_4^{2-}). In the finished catalyst, the content of sulfates varied from 0.08 to 0.11%. In this case, the ozone decomposition factor was $\gamma = (2.1–2.7) \times 10^{-4}$, which points to a high activity of the catalyst. Also, the benzene oxidation temperature at 50% conversion was found to be 240–260°C for this catalyst.

When preparing molded pellets, manganese carbonates containing 0.0076–0.026, 0.56–0.69, and 0.77–1.14% sulfates were used. The mass fractions of SO_4^{2-} in the finished catalysts were 0.0065–0.025, 0.032–0.15, and 0.197–0.36%, respectively. In this case, the ozone decomposition factors are $(1.35–1.85) \times 10^{-4}$, $(1.85–2.4) \times 10^{-4}$, and $(2.0–2.4) \times 10^{-4}$, respectively, which corresponds to a high catalytic activity in ozone decomposition. The catalytic activities of these batches in benzene oxidation were evaluated by the benzene oxidation temperature at 50% conversion: 210–230, 220–230, and 220–230°C, respectively.

Laboratory samples were produced with manganese carbonates containing 0.008 and 0.7% sulfates. The mass fraction of sulfates in the finished catalyst was 0.004 and 0.12%, respectively. The samples exhibited virtually the same activity in ozone decomposition: $\gamma = (1.9 \pm 0.2) \times 10^{-4}$. The benzene oxidation temperature at 50% conversion was 220 and 240°C.

It can be seen from these data that the mass fraction of sulfur in terms of sulfides in the starting manganese-containing component has no effect on the catalytic activity of the GTT catalyst in both ozone decomposition and benzene oxidation. It is known that a requirement to the purity of starting components affects their cost. Consequently, less expensive raw materials can be used in GTT manufacture. Industrial batches of the catalysts developed have been manufactured to order of TIMIS Research-and-Promotion Firm, Limited Liability Company at Novomoskovsk Institute of nitrogen industries and successfully work in ozonizer installations at more than 40 plants of Russia, Ukraine, Thailand, and Switzerland [14–16].

GTT catalysts are also effectively used in gas-convectors of the gas-discharge type, intended for purification of ventilation gases and recycled and influent air to remove toxic substances, such as butanol, styrene, toluene, phenol, benzene, formaldehyde, aniline, etc., formed in operation of motor transport, technological equipment, and public feeding facilities. Air is purified in a gas-convector under the action of an electric discharge on molecule of gases present in the discharge zone.

CONCLUSIONS

(1) An integrated study of the process in which catalysts for ozone decomposition are formed from copper and nickel hydroxocarbonates, manganese carbonate, and calcium aluminates (talum) demonstrated that a heterogeneous ion exchange occurs between the components in the course of preparation, to give precursors of the active phase.

(2) It was shown that presence of the manganese-containing phase Mn_3O_4 in GTT samples (extrudates, pellets) favors, at calcination temperatures of 300–450°C, an increase in the catalytic activity in ozone decomposition, and presence of the MnO_2 phase positively affects the activity in benzene oxidation. The optimal GTT calcination temperatures for ozone decomposition and benzene oxidation were determined.

(3) It was demonstrated that the catalytic activity of the GTT catalyst in both ozone decomposition and benzene oxidation is not affected to any significant extent by the composition of the manganese-containing raw material and by the amount of sulfur (in the concentration range studied) in the starting components.

(4) Extrudates with a diameter of 1.5–5 mm and length of 5–15 mm and molded pellets [($d \times h$ = 5×3 (4×3) mm^2] were produced. The catalyst obtained exhibits high activity and mechanical strength in operation in both dry and humid gases.

Abstract—The kinetics of clarification of a kaolin suspension and turbid natural water in the presence of coagulants (aluminum sulfate and aluminosilicate) and flocculants (nonionic, cationic, and anionic Praestols) was studied in relation to the concentrations of coagulants and flocculants.

DOI: 10.1134/S1070427207080186

Polyacrylamide coagulants and flocculants are widely used for treatment of natural and waste waters and for concentration and dehydration of suspensions [1–3]. However, the relationship between the characteristics of the agents and their coagulation and flocculation properties is poorly understood. Previously, we have studied the influence exerted on treatment of natural water by a mixture of a coagulant and a flocculant {aluminum sulfate (AS) + partly hydrolyzed polyacrylamide (PAA) [4] or copolymer of acrylamide and sodium acrylate [5]; AS and aluminum polyoxychloride + anionic [6] and cationic [7] Praestols (coagulants widely used in Russia)}.

In this paper, we make a comparative analysis of the clarification kinetics of the kaolin suspension and turbid natural water in the presence of aluminum sulfate and aluminosilicate (ASC) coagulants and nonionic, cationic, and anionic Praestol flocculants.

EXPERIMENTAL

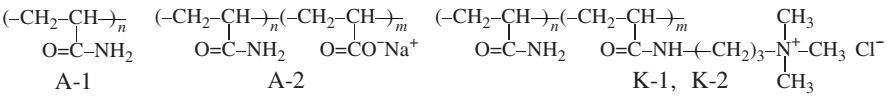
In our experimenrs, we used nonionic Praestol (PAA), anionic Praestols [copolymers of acrylamide (AA) with sodium acrylate (Na-AA)], and cationic Praestol [copolymers of acrylamide (AA) with *N*-acrylamidopropyl-*N*,*N*,*N*-trimethylammonium chloride (APTMAC)] produced by Moscow–Stockhausen–Perm Russian–German Joint-Stock Company. The properties of Praestol flocculants are listed in the table.

As coagulants we used technical-grade (purified) aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ (AS) with

Properties of Praestol flocculants*

Sample	Praestol brand	$[\eta]$, $cm^3\,g^{-1}$	$\overline{M}_\eta \times 10^{-6}$	Content of units in copolymer, mol %		
				AA	Na-AA	APTMAC
A-1	2500	1550	8.7	97	3	–
A-2	2530	1800	4.4	80	20	–
K-1	650 VS	678	–	80		20

* Structure of units in macromolecule:



16.35 wt % content of Al_2O_3 and aluminosilicate $[(K,Na)_2SO_4 \cdot Al_2(SO_4)_3 \cdot mH_2O \cdot mH_2O + 2SiO_2 \cdot nH_2O]$ (ASC) [d_4^{20} 1.10 g cm^{-3}, 2.02 and 1.18% content of AlO and SiO groups, respectively], which was prepared by treatment of nepheline with sulfuric acid.

The experiments were performed with KE-1 brand kaolin [$Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$ with admixtures of Fe_2O_3, MnO, Na_2O, K_2O, and TiO_2] from the Eleninskoe deposit, which is characterized by high uniformity of the particle size distribution (average particle size 0.2×10^{-6} m). We also used turbid water (dispersed phase concentration c_d 0.23%) sampled from the water treatment system of the water supply point in the course of filter unloading.

All solutions were prepared using distilled water and chemicals of chemically pure grade.

The sedimentation kinetics was studied using 0.15% kaolin suspensions in turbid natural water in a cylinder with a VT-500 torsion balance. The sedimentation rate was determined from the weight of the precipitate accumulated on the balance dish in time t after tenfold mixing of the suspension by back-and-forth motion of a perforated disk.

The potentiometric measurements were carried out on a pH-121 pH-meter equipped with measuring (ESL 65-07) and auxiliary (silver chloride, EVL 1M3) electrodes.

First, we studied sedimentation of 0.15% kaolin suspensions using solely the coagulants. The experiments were performed at various coagulant concentrations c_c. Typical kinetic curves of accumulation of the precipitate on the balance dish, depending on the concentration of ASC coagulant, are shown as an example in Fig. 1. Similar dependences were obtained for SA coagulant. As can be seen from Fig. 1, the rate of precipitate accumulation P increases with c_c. This is due to the formation of positively charged aluminum hydroxide particles formed upon addition of the coagulant, which, being added to the suspension, is adsorbed on the oppositely charged kaolin particles (–4.2 mV ζ potential) and neutralizes them, causing aggregation and sedimentation of the system.

First, we calculated from the slopes of the initial portions of the kinetic curves the sedimentation rate v and then the flocculation parameter D_c, using the following equation:

$$D_c = (v - v_0)/v_0,$$

where v and v_0 are the rates of sedimentation of the kaolin suspension in the presence of coagulant and without it, respectively.

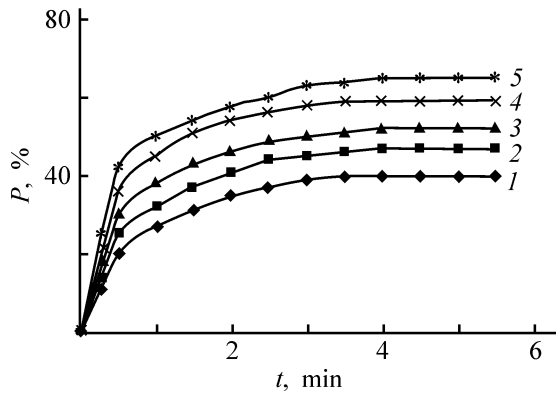


Fig. 1. Degree of kaolin sedimentation P vs. time t at various contents of Al_2O_3 in ASC. Al_2O_3 concentration, $c \times 10^4$, %: (*1*) 0.5, (*2*) 1.0, (*3*) 1.5, (*4*) 2.0, and (*5*) 2.5.

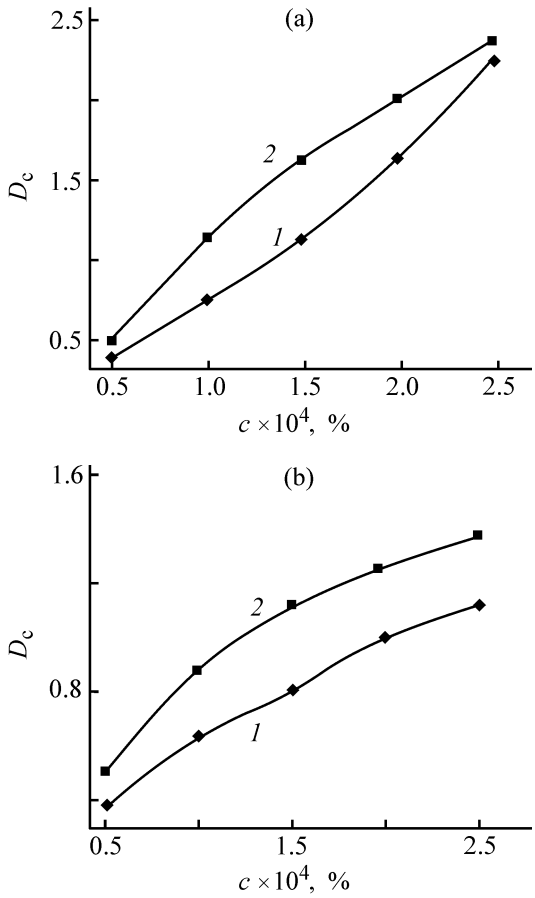

Fig. 2. Flocculation parameter D_c in clarification of (a) kaolin suspension and (b) natural water vs. the concentration of Al_2O_3 c in (*1*) AS and (*2*) ASC.

The effect of the Al_2O_3 content of the coagulant on D_c is illustrated in Fig. 2. As can be seen, the coagulation effect increases with the coagulant concentration, and at $c_{Al_2O_3}$ = const, D_c grows on passing from AS to ASC (from curve *1* to curve *2*, Fig. 2a).

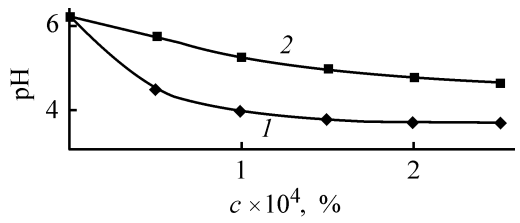

Fig. 3. pH of clarified water after kaolin sedimentation for 30 min vs. Al_2O_3 content c of (*1*) ASC and (*2*) AS.

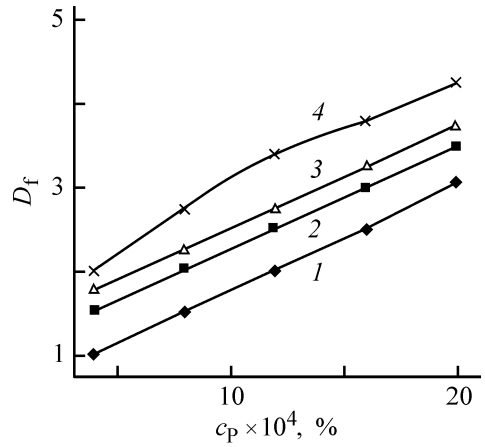

Fig. 4. Flocculation parameter D_f for kaolin sedimentation vs. the concentration c_P of cationic Praestol (K-1) at various concentrations of Al_2O_3 in (*1*, *2*) AS and (*3*, *4*) ASC at pH 7. Concentration of Al_2O_3 $c \times 10^4$, %: (*1*, *3*) 0.5 and (*2*, *4*) 2.0.

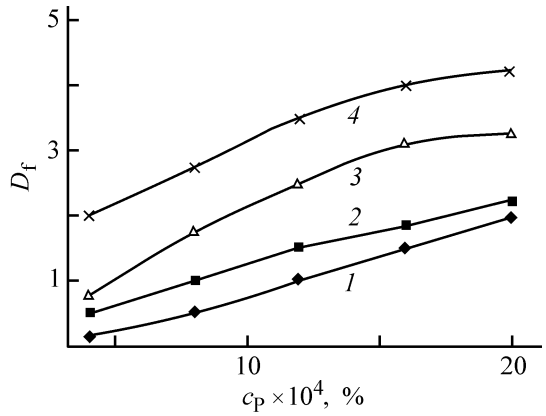

Fig. 5. Flocculation parameter D_f for kaolin sedimentation vs. the concentration of (*1*, *2*) anionic Praestol (A-2) and (*3*, *4*) cationic Praestol (K-1) at various concentrations of Al_2O_3 in AS. Concentration of Al_2O_3 $c \times 10^4$, %: (*1*, *3*) 0.45 and (*2*, *4*) 1.81.

It should be noted that the variation of pH with c_c in water can affect the coagulation; data on the effect of c_c on the solution pH are shown in Fig. 3. It can be seen that, as c_c increases, pH decreases owing to an increase in the concentration of H^+ ions in the course of coagulant hydrolysis. Apparently, hydrolysis of ASC is more pronounced, causing more significant changes in pH as compared to AS (at the same $c_{Al_2O_3}$). To eliminate the possible effect of pH on the coagulation and flocculation, all further tests were performed at pH 7 adjusted with NaOH (introduced 1 min after adding the flocculant).

To evaluate the dependence of sedimentation of the kaolin suspension on the concentration of the flocculant, flocculants were added to the suspension 1 min after adding the coagulant. The flocculation parameter D_f was calculated from the following expression:

$$D_f = (v - v_0)/v_0,$$

where v and v_0 are the rates of sedimentation of the kaolin suspension in the presence of flocculant and without it, respectively.

The $D_f = f(c_P)$ dependence for cationic Praestol (sample K-1), used together with AS and ASC, is shown in Fig. 4. As can be seen, D_f increases with c_P upon addition of the flocculant with AS (curves *1*, *2*) and with ASC (curves *3*, *4*). Moreover, D_f increases with the coagulant concentration (passing from curves *1*, *3* to curves *2*, *4*, respectively). These data indicate that the flocculation in the presence of cationic Praestol (K-1) in combination with ASC is more efficient than that with AS (Fig. 4, passing from curves *3*, *4* to curves *1*, *2*).

The dependences of the flocculation parameter D_f on the concentrations of anionic Praestol (A-2) (curves *1*, *2*) and cationic Praestol (K-1) (curves *3*, *4*), taken in combination with AS coagulant are shown in Fig. 5. As can be seen, D_f increases with c_P of both flocculants. This is due to the elevated adsorption of the flocculant macromolecules on the coagulated particles. The adsorbed cationic Praestol neutralizes the negative charge of the kaolin particles, and anionic Praestol neutralizes the positive charge of aluminum hydroxide particles formed by the coagulant hydrolysis. The resulting coarse particles lose their sedimentation stability and precipitate.

Figure 5 allow comparison of the flocculation activities of the anionic and cationic Praestols, because samples A-2 and K-1 have the same content of the ionic groups (see table). Comparison of the data at fixed c_P and similar concentrations of AS shows that D_f increases on passing from anionic to cationic Praestol (passing from curves *1*, *2* to curves *3*, *4*). Moreover, for both flocculants, D_f increases with c_c.

Similar dependences were obtained for ASC coagulant in the presence of both anionic and cationic Praestols.

We also compared the flocculation effect of nonionic Praestol (A-1) and anionic Praestol (A-2), as influenced by the presence of AS and ASC coagulants; the results are shown in Fig. 6. As can be seen from the comparison at c_P = const, D_f is higher when the above flocculants are used in combination with ASC, compared with AS (Fig. 6, curves *2*, *4* and *1*, *3*). Moreover, D_f increases on passing from anionic Praestol (A-2) to nonionic Praestol (A-1), which is probably due to the higher $\overline{M}_\eta$ of the nonionic Praestol (see table). With increasing molecular weight of the flocculant, the effective size of macromolecular globules $(\bar{r}^2)^{1/2}$ in solutions gorws, i.e., macromolecules can bind a larger number of kaolin particles. Therefore, formation of coarse floccules promoted their sedimentation and, thus, increased D_f. These experimental results agree well with well-known dependences of the flocculation effect of various water-soluble polymers on their molecular weight, which have been determined previously for natural water [2] and model kaolin suspensions [3].

Let us analyze the data on clarification of a turbid natural water containing 0.23% disperse phase under the effect of coagulants in the presence and absence of the flocculants. The effect of the Al_2O_3 content of the coagulants on D_f in the absence of flocculants is shown in Fig. 2b. As can be seen, D_f increases with the Al_2O_3 content of both coagulants, and this effect becomes more pronounced upon replacement of AS with ASC (Fig. 2b, passing from curve *1* to curve *2*). These data well agree with the results obtained for sedimentation of the kaolin suspension (Fig. 2a).

The dependences of D_f on c_P for cationic (K-1) and anionic (A-2) Praestols, used together with AS and ASC, are shown in Fig. 7. As can be seen, D_f increases with c_P in all the cases studied. Comparison of experimental data at $c_{Al_2O_3}$ = const and c_P = const shows that the efficiency of water treatment with cationic Praestol (K-1) is higher than that with anionic Praestol (A-2) (Fig. 7, passing from curves *1*, *3* to curves *2*, *4*), and ASC as the second component (coagulant) shows better performance than AS (passing from curves *3*, *4* to curves *1*, *2*). These results agree well with the data on sedimentation of kaolin suspensions, shown in Fig. 5. Our experimental data indicate that sedimentation of kaolin suspensions and clarification of natural water can be intensified by using cationic Praestol (K-1) in combination with ASC.

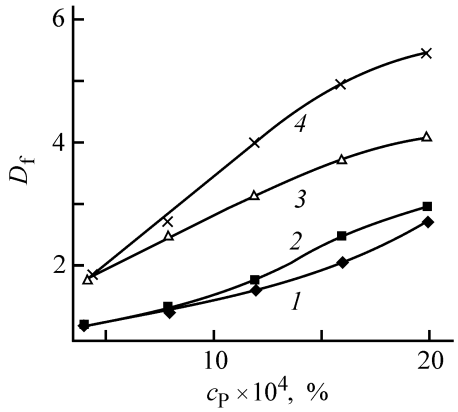

Fig. 6. Flocculation parameter D_f at kaolin sedimentation vs. the concentration c_P of (*1*, *2*) anionic Praestol (A-2) and (*3*, *4*) nonionic Praestol (A-1) in the presence of (*1*, *3*) AS and (*2*, *4*) ASC at pH 7. Concentration of Al_2O_3 1×10^{-4}%; the same for Fig. 7.

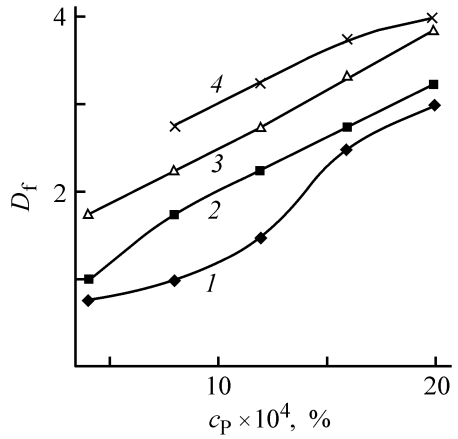

Fig. 7. Flocculation parameter D_f at water clarification vs. the concentration c_P of (*1*, *3*) anionic Praestol (A-2) and (*2*, *4*) cationic Praestol (K-1) in the presence of (*1*, *2*) AS and (*3*, *4*) ASC at pH 7.

CONCLUSIONS

(1) The dependences of sedimentation of kaolin suspensions and of clarification of natural water in the presence of aluminum sulfate and aluminosilicate (coagulants), used in combination with nonionic, cationic, and anionic Praestols (flocculants), show that the substitution of aluminosilicate for aluminum sulfate in the presence of flocculants and without them enhances the flocculating and coagulating effects, respectively.

(2) The flocculating effect increases with the concentration of aluminum sulfate and aluminosilicate and of nonionic, cationic, and anionic Praestols. In the case of flocculants, the flocculation effect in-

creases in the order cationic > anionic + nonionic > anionic. The strongest flocculation effect is attained when cationic Praestol is used in combination with aluminosilicate.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Hydrodynamics and Mass Exchange in a Rotary Apparatus

I. A. Lyutarevich and V. A. Markov

Belarussian State Technological University, Minsk, Belarus

Received February 9, 2007

Abstract—Results of an experimental study of carbon dioxide desorption from water in a rotary apparatus are presented. The manner in which the volume mass-transfer coefficient in the fluid phase and the efficiency of mass transfer vary with a number of mode parameters was determined. Analytical dependences for calculating the hydraulic resistance and the rotor drive power were derived. These dependences will allow development of a procedure for engineering calculations of apparatus of this type.

DOI: 10.1134/S1070427207080204

The quality of products and the ecological parameters of a process (primarily, the content of impurities in fluid and gaseous industrial wastes) are important factors associated with improvement of technological processes. Of particular importance is carrying out effective mass exchange between flows at minimum energy expenditure.

A commonly accepted promising way to solve this problem is use of rotary apparatus with phase interaction in a swirling flow for mass-exchange processes.

Analysis of published evidence [1–3] shows that the efficiency of mass transfer in apparatus with external energy supply exceeds that for contact devices with the conventional types of phase interaction in gas–fluid systems. This favors a pronounced decrease in the apparatus dimensions.

Thus, rotary dispersion-film apparatus, in which the phase interaction occurs in the zone of intensive dispersion of a fluid by a spraying device and phases subsequently come in contact in the zone of a film-type flow of a fluid, should be distinguished among surface-type, spraying, bubbling, and rotary apparatus. In addition, use of a swirling flow in apparatus of this kind can intensify the processes performed and markedly raise the gas load at a comparatively low hydraulic resistance of an apparatus.

EXPERIMENTAL

We developed a two-stage design of a rotary dispersion-film apparatus for interaction of gas–fluid systems in a swirling flow (Fig. 1). It includes a cylindrical case *1*, tangential inlet *2* and outlet *3* for the gas, and fluid-dispersing devices *4* fixed on shaft *5* driven by electric motor *6*. The frequency control unit is used to set the required shaft rotation rate. The dispersing device has the form of a hollow perforated cylinder with flanges preventing fluid overflow.

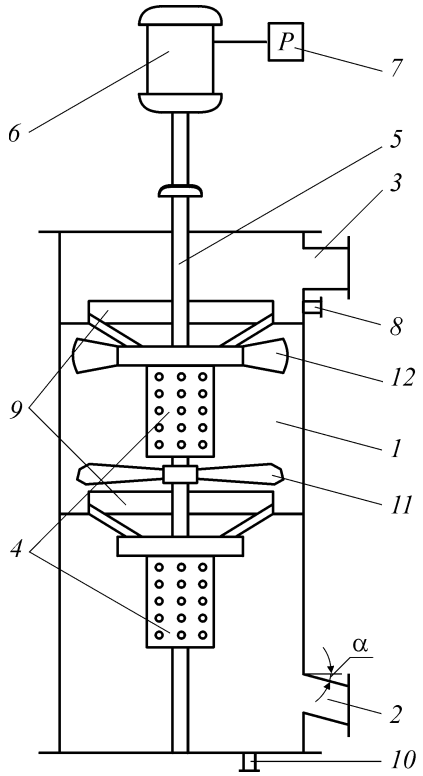

Fig. 1. Schematic of the experimental installation: (*1*) case, (*2*) inlet pipe, (*3*) outlet pipe, (*4*) dispersing unit, (*5*) shaft, (*6*) electric motor, (*7*) frequency control unit, (*8*) fluid supply pipe, (*9*) overflow unit, (*10*) fluid discharge pipe, (*11*) impeller, (*12*) blade swirler.

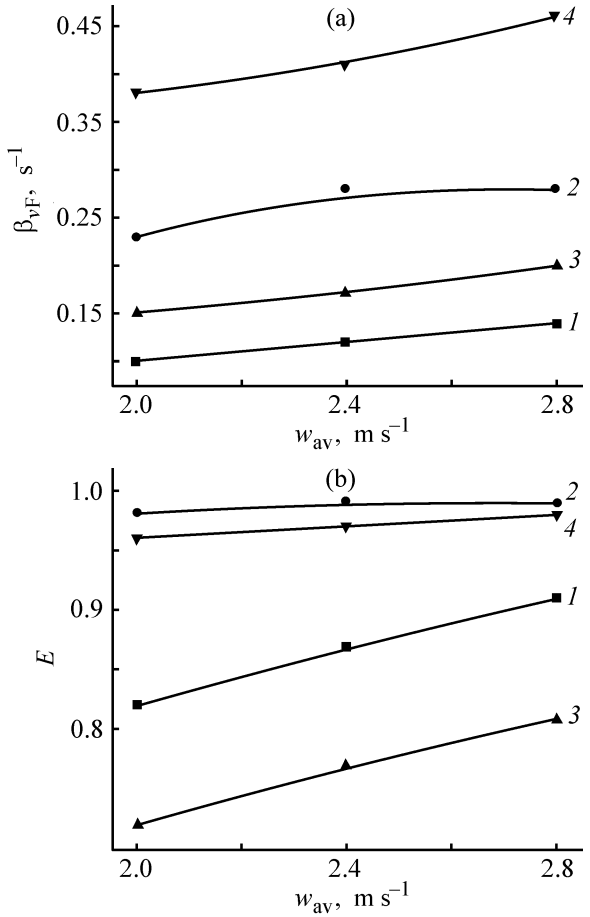

Fig. 2. (a) Volume-related mass-exchange coefficient β_{vf} and (b) mass-exchange efficiency E vs. gas flow velocity w_{av} at rotor rotation rate n = 23.3 rps. Spraying density q ($m^3\ m^{-2}\ h^{-1}$): (a) 3.266 and (b) 4.976. (*1*, *3*) Upper and (*2*, *4*) lower stages of the contact apparatus.

The diameters of the apparatus and dispersing unit are 0.195 and 0.054 cm, respectively; the inlet pipe is mounted at an angle of 7° to the horizontal.

The apparatus operates as follows: gas (air) is delivered into the apparatus from below and, on passing through the inlet pipe *2* tangential to the case, is swirled. The fluid (distilled water), saturated with CO_2, is delivered through pipe *8* via the overflow unit *9* into a rotating unit *4* and is dispersed into drops. Further, the fluid flows down the apparatus wall to a lower-lying contact stage, where the dispersion process is repeated, and is discharged via pipe *10*. The flow swirling in the upper stage is maintained by impeller *11* with helical blades, mounted on the shaft. The impeller also serves to separate fluid drops carried away from the lower stage of the contact apparatus. The gas flow cannot carry away fluid drops from the apparatus because an additional blade swirler *12* is mounted in the upper dispersing cylinder. Thus, the gas interacts with the fluid phase in both the dispersed and film modes.

The aim of our study was to examine the influence exerted by operation mode parameters of a rotary apparatus on the mass-exchange process and to obtain new experimental data and analytical dependences for calculation of the hydraulic resistance and power consumed by the rotor of the design we developed.

We studied mass exchange under laboratory conditions in desorption of CO_2 from water. Using the experimental data obtained, we calculated important parameters determining the number of stages and height of the apparatus, such as the efficiency of a stage of the contact apparatus and mass-transfer coefficient.

The content of CO_2 was found by measuring the acidity of the medium with a standard pH-meter. By processing the experimental data, we obtained a relation for determining the CO_2 concentration in water as a function of the solution acidity. At pH 5–7 this concentration was calculated by the formula [4]:

$$c = 2.69 \times 10^{5-\mathrm{pH}}. \quad (1)$$

In the course of our experiments, the initial solution acidity changed by no more than 0.03 pH units. The temperature of the gas and fluid was 15–18°C. The spraying density was varied in the range 3–8 $m^3\ m^{-2}\ h^{-1}$. The flow-rate average gas velocity in the apparatus was varied from 2 to 3.6 m s^{-1}.

For each operation mode parameter of the apparatus, we measured the initial and final CO_2 concentration in water and calculated the mass-transfer efficiency. In CO_2 desorption from water with air, it was calculated by the formula [5, 6]:

$$E_f = (c_{in} - c_{fin})/c_{in} = 1 - c_{fin}/c_{in}, \quad (2)$$

where c_{in} and c_{fin} are the initial and final CO_2 concentrations in water (%).

The mass-transfer coefficient in the liquid phase, related to the working volume of the apparatus, was found by the formula

$$\beta_{vf} = (L/V)\ln(c_{in}/c_{fin}), \quad (3)$$

where L is the flow rate of the fluid phase, and V is the working volume of the apparatus (m^3).

Having expressed the mass-exchange efficiency in terms of β_{vf}, we obtain

$$E_f = 1 - 1/\exp(\beta_{vf} V/L). \quad (4)$$

Figure 2a shows dependences of the volume-related mass-exchange coefficient in the fluid phase on

the gas flow velocity in the apparatus for different spraying densities. It can be seen that β_{vf} grows with the gas flow velocity and spraying density. This occurs because, as the spraying density increases, the volume of a mass-exchange apparatus contains at any instant of time a larger amount of a fluid, and, consequently, particles having about the same size as that at low spraying density are formed in a greater number. In this case, an increase in the gas flow velocity leads to turbulization of flows of the interacting phases.

The dependence of the efficiency of mass exchange on the gas flow velocity in an apparatus is shown in Fig. 2b for different spraying densities. It can be seen from the plot that the efficiency grows. This can be attributed to an increase in the tangential stresses at the phase boundary and to swirling of the fluid film on the apparatus wall upon an increase in the gas flow velocity in the apparatus. This leads to a longer residence of the fluid in the apparatus and, accordingly, to a rise in E. As the spraying density increases, the fluid film becomes thicker, which favors a faster flow of this film down the apparatus wall and, consequently, impairs the mass-exchange efficiency.

An important characteristic of mass-exchange apparatus, which determines the energy expenditure for the process, is their hydraulic resistance. It was found in our experiments that the spraying density and rotor rotation rate have no significant effect on the hydraulic resistance. Figure 3 shows how the hydraulic resistance depends on the gas flow velocity. The hydraulic resistance can be found using the relation obtained by processing of experimental data:

$$\Delta P = 94.984\, w_{av}^{2.205}. \quad (5)$$

The difference between the values calculated by Eq. (5) and found experimentally does not exceed 2.6%.

In addition to the hydraulic resistance, one more factor, power consumed for rotor rotation, will affect the specific energy expenditure. This effect is determined as the difference between the values of power N, consumed by the electric motor with and without the rotor mounted on the shaft (Fig. 4). The consumed power becomes lower as the gas flow velocity increases because the gas flow interacts with the impeller mounted on the shaft and thus promotes rotor rotation.

The dependence of the power consumed by the rotor on the rotor rotation rate and flow-rate average gas velocity in the apparatus was approximated with the following relation:

$$N = 13.42 + 24.32\, w_{av} - 0.994\, n - 0.215 w_{av} n\, w_{av}^2 + n^2. \quad (6)$$

The difference between the consumed power calculated by expression (6) and that found experimentally does not exceed 5.6%.

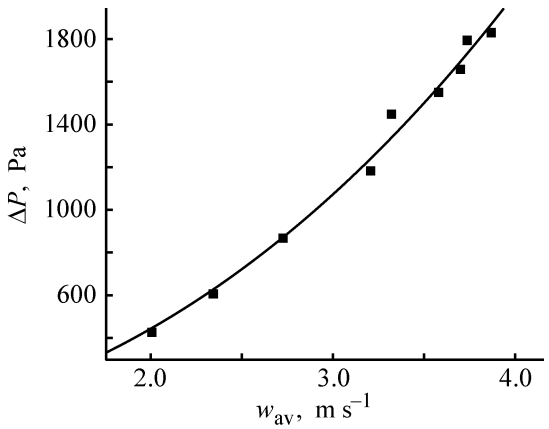

Fig. 3. Hydraulic resistance ΔP vs. gas flow velocity w_{av}.

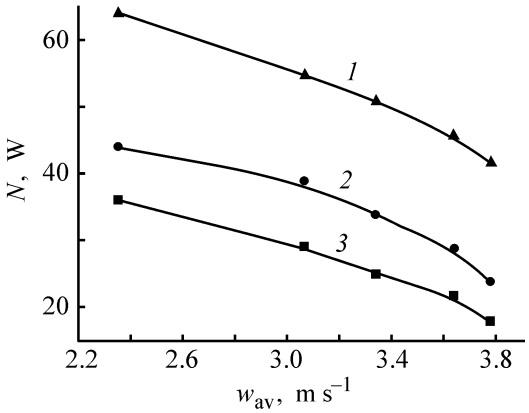

Fig. 4. Power N consumed by the rotor vs. gas flow velocity w_{av}. n (rps): (*1*) 23.3, (*2*) 16.7, and (*3*) 10.

CONCLUSIONS

(1) A study of specific features of mass exchange in CO_2 desorption by air in a rotary apparatus in interaction of phases in a swirling flow demonstrated the high efficiency of the design developed.

(2) Effect of operation mode parameters of the apparatus on the volume-related mass exchange coefficient in the fluid phase and on the efficiency of mass exchange was revealed.

(3) Equations for calculating the hydraulic resistance and power consumed by the rotor were suggested.

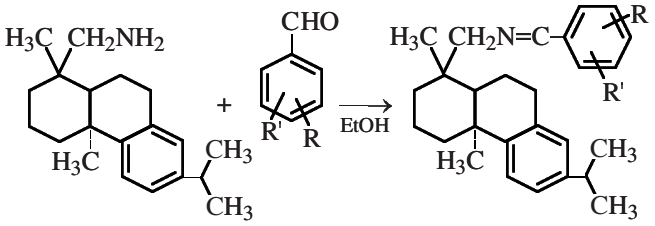
Abstract—Previously unknown Schiff bases were prepared from dehydroabietylamine and substituted benzaldehydes. Their physicochemical properties were determined, and the bactericidal activity toward some microorganisms was evaluated.

DOI: 10.1134/S1070427207080216

Schiff bases derived from primary amines and substituted benzaldehydes exhibit antibacterial, anticancer, and antitumor activity. Numerous studies have shown that such an activity of Schiff bases is caused by the presence of the >C=N– functional group. It is also known [1] that many amines derived from resin (diterpene) acids exhibit a wide spectrum of biological activity. In particular, Borglin has shown that dehydroabietylamine is an effective bactericidal and fungicidal agent [2]. It would be expected that Schiff bases derived from dehydroabietylamine will exhibit enhanced biological activity. However, data on the synthesis and properties of Schiff bases derived from dehydroabietylamine are lacking.

Here we report on the synthesis and biological activity of Schiff bases derived from dehydroabietylamine and substituted benzaldehydes. These Schiff bases were prepared in high yields (85–95%) by direct condensation in ethanol:



where R = R'= H (**a**); R = H, R' = *p*-OMe (**b**); R = H, R' = *p*-Cl (**c**); R = H, R' = *p*-F (**d**); R = H, R'= *o*-OH (**e**); R = *o*-OH, R' = *p*-NO_2 (**f**); R = *o*-OH, R' = *p*-Cl (**g**); R = *o*-OH, R' = *p*-OMe (**h**).

The rate of this reaction is fairly high. All the Schiff bases precipitate from the reaction mixture virtually immediately after the reactants solutions are mixed. They are insoluble in water and in ethanol at room temperature and soluble in dimethylformamide, chloroform, dimethyl sulfoxide, and some other solvents.

Table 1. Physicochemical properties of the Schiff bases

The physicochemical parameters of the azomethines prepared are listed in Table 1.

The structures of the compounds were confirmed by IR and ^{1}H NMR spectroscopy (Table 2). The IR spectra of all the compounds contain a strong absorption band of the >C=N– group at 1660–1610 cm^{-1}. Its position only slightly depends on the structure of the compound and on substituents in the phenyl ring of the benzaldehyde moiety. The spectra of **e**–**h** also contrain a well-defined band of OH stretching vibrations at 3460–3410 cm^{-1}. In the spectra of the other compounds, this band is absent.

In the ^{1}H NMR spectra, the –N=C–H signal is observed at 8.2–8.4 ppm, and the OH signal, at 13.6–15.0 ppm.

The bactericidal activity of the compounds was studied with test cultures of *E. Coli*, *B. Subtilis*, and *S. Aureus*. The activity was evaluated by the diameter of the inhibition zone (cm) arising 48 h after introducing into the cultural medium 2×10^{-6} g ml^{-1}

Table 3. Bactericidal activity of Schiff bases

Bacteria	Diameter of the inhibition zone, cm, for indicated compound							
	a	**b**	**c**	**d**	**e**	**f**	**g**	**h**
S. Aureus	1.05	0.95	1.20	1.65	0.90	1.25	1.10	1.10
B. Subtilis	0.95	1.20	1.72	1.32	0.85	0.90	1.20	0.90
E. Coli	1.15	1.01	1.12	0.90	0.90	0.80	0.85	0.92

solutions of the Schiff bases in dimethylformamide (Table 3).

All the compounds prepared exhibit bactericidal activity. Compound **c** derived from Cl-substituted benzaldehyde is the most active toward *B. Subtilis* (diameter of inhibition zone 1.72 cm), and compound **d** derived from fluorinated benzaldehyde, toward *S. Aureus* (diameter of inhibition zone 1.65 cm). It should be noted that the most active agent toward *E. Coli* is compound **a** derived from unsubstituted benzaldehyde (diameter of inhibition zone 1.15 cm); introduction of substituents into the benzaldehyde moiety does not enhance the bactericidal activity of the Schiff base.

Thus, introduction of substituents into the phenyl ring of the benzaldehyde moiety appreciably affects the bactericidal activity of Schiff bases. However, this effect is ambiguous and depends on numerous factors, primarily on the structure of the molecule, presence and nature of substituents in the dehydroabietylamine and benzaldehyde moieties, and particular microorganism.

EXPERIMENTAL

All the chemicals used for preparing Schiff bases (dehydroabietylamine; benzaldehyde and its derivatives) were of chemically pure or analytically pure grade and were used without additional purification.

Elemental analysis was performed with an RE-2400CHN device. The IR spectra were recorded on a Bio-Rad FTS-185 IR spectrophotometer using KBr cells. The ^{1}H NMR spectra were measured on a DPX-300 Bruker Avance 300 spectrometer (solvent $CDCl_3$, reference TMS). The melting points were determined with an XT-5 device.

Syntheses were performed in a vessel equipped with a stirrer, reflux condenser, and dosing unit. The vessel was charged with a solution of 10 mmol of dehydroabietylamine in 200 ml of ethanol, after which a solution of 10 mmol of benzaldehyde or its derivative in 100 ml of ethanol was slowly added from the dosing unit. The mixture was stirred for 3 h at 20°C. The crystals of the Schiff bases were filtered off, recrystallized three times from ethanol, and dried in a vacuum.

The bactericidal activity of each of the Schiff bases synthesized was evaluated by measuring the diameter of the inhibition zone [3, 4]. For this purpose, 0.5 ml of a suspension of spores of each test culture was added to a sterile agarized cultural medium just before its solidification, after which the mixture was poured into sterile Petri dishes (9 cm in diameter) and allowed to solidify. Solutions of the Schiff bases in dimethylformamide (2×10^{-6} g ml^{-1}) were prepared. Then sterile disks made of filter paper (7 mm in diameter) were wetted in a solution of appropriate Schiff base and placed into the Petri dishes. The Petri dishes were kept at 35°C for 48 h, after which the inhibition zones of bacterial growth were revealed and the diameter of each zone was measured. Three replicate experiments were performed with each Schiff base.

CONCLUSION

The Schiff bases synthesized from abietylamine and substituted benzaldehydes exhibit noticeable bactericidal activity toward certain microorganisms. The correlation between the molecular structure and biological activity is ambiguous.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Asymmetric Diene Synthesis of Bicyclo[2.2.2]octenes in the Presence of Lewis Acids

E. G. Mamedov, G. F. Mamedova, O. B. Gadzhieva, and A. V. Nagiev

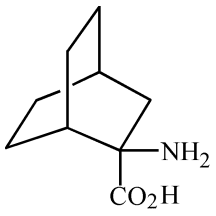
Abstract—Asymmetric diene synthesis of substituted bicyclo[2.2.2]octenes from (–)-menthyl acrylate and cyclohexa-1,3-diene in the presence of achiral Lewis acid catalysts ($TiCl_4$, $AlCl_3$, BBr_3, $AlCl_3 \cdot OEt_2$, $BBr_3 \cdot OEt_2$) was studied. The influence of various factors on the isomeric composition, yield, and enantiomeric purity of the compounds prepared was examined.

DOI: 10.1134/S1070427207080228

Many drugs, fragrant compounds, and chemicals for agriculture are produced today in the optically active form.

Bicyclo[2.2.2]octane and bicyclo[2.2.2]octene moieties are essential fragments of many important natural and synthetic biologically active compounds [1]. Therefore, synthesis of these compounds in the optically active form is of practical interest. A considerable researchers' interest is given today to optically active bicyclic amino acids important for organic and bioorganic chemistry, e.g., to 2-aminobicyclo[2.2.2]-octane-2-carboxylic acid:



I

Synthesis of this acid in the optically active form by asymmetric diene synthesis (ADS) was described in [2].

Asymmetric diene synthesis from cyclohexa-1,3-diene (CHD) in the presence of catalysts is one of promising routes to chiral bicyclo[2.2.2]octane derivatives. The first asymmetric diene synthesis from CHD was performed by Cervinka and Kriz [3]. This reaction was carried our without a catalyst. After removal of the chiral reagent, the optical yield of the adducts was low (3.3%).

Here, we report on the synthesis of chiral bicyclo-[2.2.2]octenes by [4+2]-cycloaddition of (–)-menthyl acrylate to CHD in the presence of achiral Lewis acid catalysts ($TiCl_4$, $AlCl_3$, BBr_3, $AlCl_3 \cdot OEt_2$, $BBr_3 \cdot OEt_2$). The reaction was performed at temperatures from 0 to 80°C in various solvents (CH_2Cl_2, C_6H_6, $C_6H_5CH_3$, C_6H_5Cl). The reaction follows the scheme

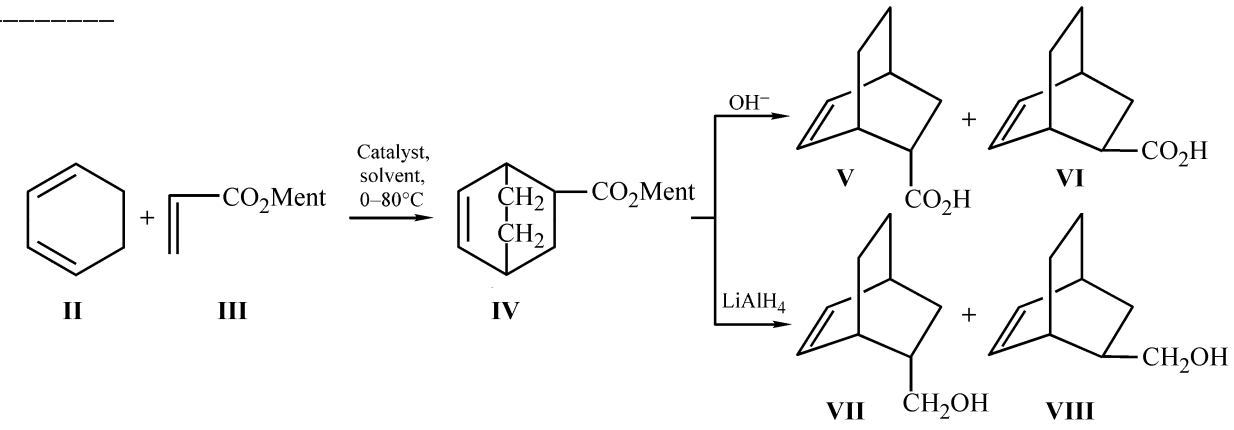


Table 1. Influence of the reaction conditions on the total and optical yields of **IV**, **V**, and **VII** in the reaction of CHD with (–)-menthyl acrylate in the presence of Lewis acids

Table 2. Properties of the bicyclo[2.2.2]octenes synthesized

Compound	bp, °C/mm Hg, or mp (solvent)	Found, % / Calculated, %		Formula	IR spectrum, ν, cm^{-1}
		C	H		
IV	160–162/2	78.80 / 78.14	10.38 / 10.35	$C_{19}H_{36}O_2$	1730 (C=0), 1110 (C–O), 3030 (=C–H), 1625 (C=C)
V	56–57 (petroleum ether)	71.41 / 71.10	7.10 / 7.0	$C_9H_{12}O_2$	1735 (C=0), 1110 (C–O), 3031 (C=C–H), 1630 (C=C)
VII	75–76/10	77.91 / 78.30	10.31 / 10.4	$C_9H_{14}O$	3550 (O–H), 1625 (C=C), 3030 (=C–H)

The chiral auxiliary agent, menthyl (Ment) residue in adduct **IV**, was removed by base hydrolysis or reduction with $LiAlH_4$.

We examined the effect of the reaction conditions on the total yield, optical purity, and isomeric composition of the products.

Table 1 shows that the total yield of the product increases with temperature, reaching 58% at 80°C in the presence of BBr_3 (molar ratio to dienophile 0.25). At lower temperatures, the enantiomeric purity is higher: At 0°C in the presence of BBr_3 (molar ratio to dienophile 0.25) in CH_2Cl_2 the enantiomeric purity of **VII** reaches 87%. With increasing temperature, the endo selectivity decreases.

Table 1 also shows that the solvent effect on the total and optical yields is insignificant.

Under comparable conditions, different catalysts give similar results as regards the enantioselectivity, stereoselectivity, and total yield. In all the experiments, we obtained, after removing the chiral agent, dextrorotatory products **V**–**VIII**.

The isomeric composition of the adducts was determined by GLC analysis (7% polypropylene sebacate on Poravina). *Endo* and *exo* isomers of **V**–**VIII** were separated chromatographically (Merck Lirchromogorov [Silikat] Si–Go, eluent petroleum ether–ethyl acetate, 1 : 2). Only *endo* isomers **V** and **VII** were collected. The amount of the *exo* isomers was negligible, and they were not further studied in detail. The constants of the compounds prepared are listed in Table 2.

The composition and structure of the compounds were confirmed by elemental analysis and by IR (Table 2) and ^1H NMR spectroscopy.

The IR spectra of **V** and **VI** contain stretching vibration bands of C=O at 1730–1735, C–O at 1110, C=C at 1625–1630, and =C–H at 3030 cm^{-1}. The spectrum of **VII** contains stretching vibration bands of O–H at 3350, C=C at 1625, and =C–H at 3030 cm^{-1}.

In the ^1H NMR spectra of **IV**, **V**, and **VII**, the olefinic protons appear as a multiplet at 6.25–6.27 ppm (J 5.62 Hz); the OH proton in **VII** gives a singlet at 4.0 ppm, and the COOH proton in **V**, a singlet at 12.0 ppm.

The optical yield of **V** and **VII** (%) was determined by comparing their specific rotations with those of the enantiomerically pure samples of the same compounds [3]. THe correlation of the optical rotation sign for the compounds described in [3] allowed us to assign the 2R configuration to dextrorotatory isomers of **V** and **VII**.

EXPERIMENTAL

The IR spectra were measured on a UR-20 spectrophotometer in the range 4000–400 cm^{-1} from thin films or KBr pellets. The ^1H NMR spectra were recorded on a Tesla BS-487C spectrometer (80 MHz, CCl_4, internal reference HMDS). The optical rotation was measured with a Perkin–Elmer-141 polarimeter. Chromatographic analysis of the products and determination of their purity were done on an LKhM-8MD chromatograph equipped with a thermal conductivity detector (300 × 0.3-cm column, 7% polypropylene sebacate on Poravina, carrier gas He, flow rate 40 ml min^{-1}, column temperature 155°C, vaporizer temperature 250°C).

(–)-Menthyl acrylate III was prepared as described in [4]; $[\alpha]_D^{20}$ = –76° (c 4.4, EtOH).

(–)-Menthyl bicyclo[2.2.2]oct-5-ene-2-carboxylate IV. A solution of 1.25 g (0.005 mol) of BBr_3 in 10 ml of CH_2Cl_2 was added at –10°C to a solution of 4.2 g (0.02 mol) of (–)-menthyl acrylate **III** in 15 ml of CH_2Cl_2. Then the temperature was increased to 0°C, and a solution of 1.6 g (0.02 mol) of cyclohexa-1,3-diene **II** in 10 ml of CH_2Cl_2 was added dropwise. The mixture was stirred for 3 h at 0°C, after which it was treated successively with dilute HCl and 5% $NaHCO_3$, washed with distilled water, and dried over $MgSO_4$. The solvent was removed, and the residue was vacuum-distilled. Yield of adduct **IV** 1.914 g (33%), bp 160–162°C (2 mm Hg), $[\alpha]_D^{20}$ (c 0.5, EtOH).

The other experiments on synthesis of **IV** were performed similarly (for specific conditions and results, see Table 1).

(2R)-(+)-Bicyclo[2.2.2]oct-5-ene-5-carboxylic acid V was prepared by base hydrolysis of **IV**. Compound **IV** (5.8 g) was refluxed in 30 ml of a 5% solution of KOH in methanol for 2 h. After removing the solvent, the residue was dissolved in 30 ml of water, and the reaction products were extracted with ether. The aqueous layer was treated with dilute HCl, and the ether extraction was repeated. The extract was washed with water and dried over $MgSO_4$. After removing the solvent, compound **V** was obtained in a yield of 2.77 g, mp 56–57°C (from petroleum ether), $[\alpha]_D^{20}$ = +29.9° (c 0.2, EtOH).

(2R)-(+)-2-Hydroxymethylbicyclo[2.2.2]oct-5-ene VII. A solution of 5.8 g of adduct **IV** in 30 ml of absolute ether was added dropwise to a suspension of 4 g of $LiAlH_4$ in 200 ml of absolute ether. Excess $LiAlH_4$ was decomposed with water. Cooled dilute HCl was added to the resulting mixture, and the ether layer was separated, washed with 5% $NaHCO_3$ and water to neutral reaction, and dried over $MgSO_4$. The solvent was removed, and the residue was vacuum-distilled. Yield of **VII** 2.2 g (88%), bp 75–76°C (10 mm Hg), $[\alpha]_D^{20}$ = +4.6° (c 0.11, EtOH).

CONCLUSIONS

(1) Asymmetric diene synthesis from (–)-menthyl acrylate and cyclohexa-1,3-diene in the presence of achiral catalysts $TiCl_4$, $AlCl_3$, BBr_3, $AlCl_3 \cdot OEt_2$, and $BBr_3 \cdot OEt_2$ yields chiral bicyclo[2.2.2]octenes with the (2R)-(+) configuration.

(2) As temperature is lowered, the optical yield of bicyclo[2.2.2]octenes increases and reaches 87% at 0°C; as temperature is elevated, the total yield increases, and the *endo* selectivity decreases.

(3) The nature of the solvent and catalyst affects the optical and chemical yields of the products insignificantly. As the amount of the catalyst increases, the optical yield varies insignificantly, and the total yield grows.

Abstract—Interaction of ITA-31 polyimide binder with a series of industrial sorbents based on styrene and vinylpyridine derivatives was studied.

DOI: 10.1134/S107042720708023X

Utilization and disposal of wastes is among the most pressing technological problems. Some kinds of wastes and, in particular, wastes from nuclear power plants and chemical industry are a long-term environmental hazard because of their long half-life or slow degradation under natural conditions. There are many approaches to solving this problem, including immobilization of environmentally significant pollutants and radionuclides using sorbents and porous matrices. The experience gained in using various sorbents [1–6] reveals that among the problems on this way is low resistance of the basic industrial sorbents to many endo- and exogenic factors in long-term storage. In this context, the most important criteria of the applicability of sorbents are chemical and radiation resistance, and the heat resistance as well, stimulating the interest in development of composites based on carbonized heat-resistant polymers and carbonaceous materials [7]. Therefore, a new promising approach is to provide an additional thermal insulation of sorbents through use of heat-resistant binders. To our knowledge, such an approach has not been considered in the literature so far.

This study is a continuation of our previous works on polyimide binders [8] as insulating coatings for industrial sorbents for various pollutants, among them radionuclides.

EXPERIMENTAL

In the experiments, we mostly used VP-1AP anion-exchange resin, which is a modified copolymer of 2-methyl-5-vinylpyridine and divinylbenzene (DVB) as a cross-linking agent. The DVB content of the commercial sorbents ranges from 8 to 12%. Alkylation of this copolymer yields VP-1AP. The latter is a strongly basic resin with quaternary ammonium functional groups. Furthermore, we used in this study such anion-exchange resins as AV-17, ARA-8p, Amberlite IRA-400, and Dowex 1×4, which are also strongly basic resins. They are synthesized on the basis of styrene, trimethylamine, and DVB (4–8%).

As a test nuclide, we used iodine in the form of the iodide anion adsorbed on the resins in the static mode. As a binder, we used ITA-31, a fusible polyimide synthesized from 3,3',4,4'-benzophenonetetracarboxylic acid dianhydride and bis(4-acetylaminophenyl) ether [9].

Composite materials (CMs) were prepared as 2-mm-thick rigid plates on the basis of ELUR reinforcing additive and ITA-31 binder by hot pressing [10]. At a certain stage of molding, a sorbent was added, to make heat-resistance and compatibility tests.

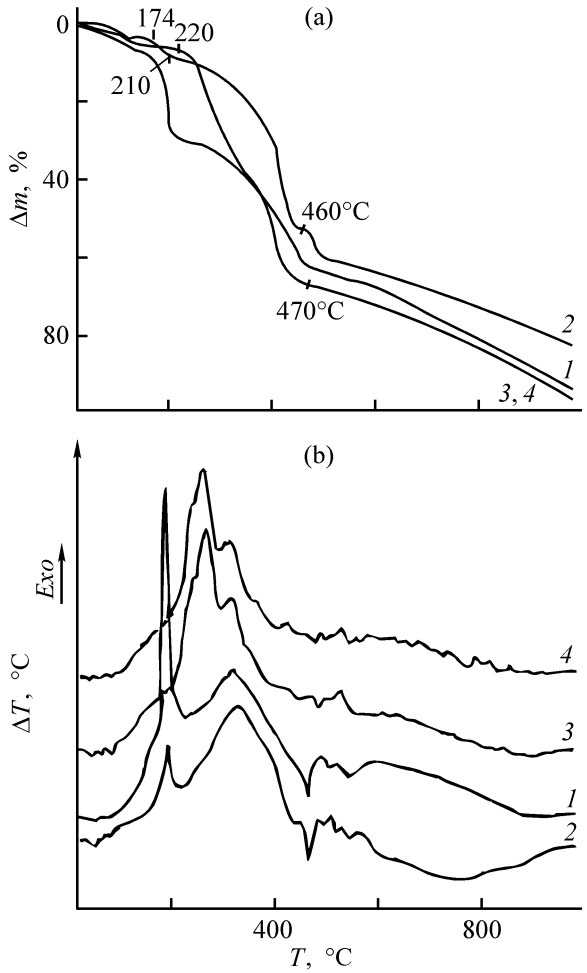

Fig. 1. (a) TG and (b) DTA curves of (*1*, *3*) initial and (*2*, *4*) isothermally heated (150°C, 3 h) sorbents: (*1*, *2*) VP-1AP and (*3*, *4*) AV-17. (Δ*m*) Weight loss and (*T*) temperature; the same for Figs. 2–5.

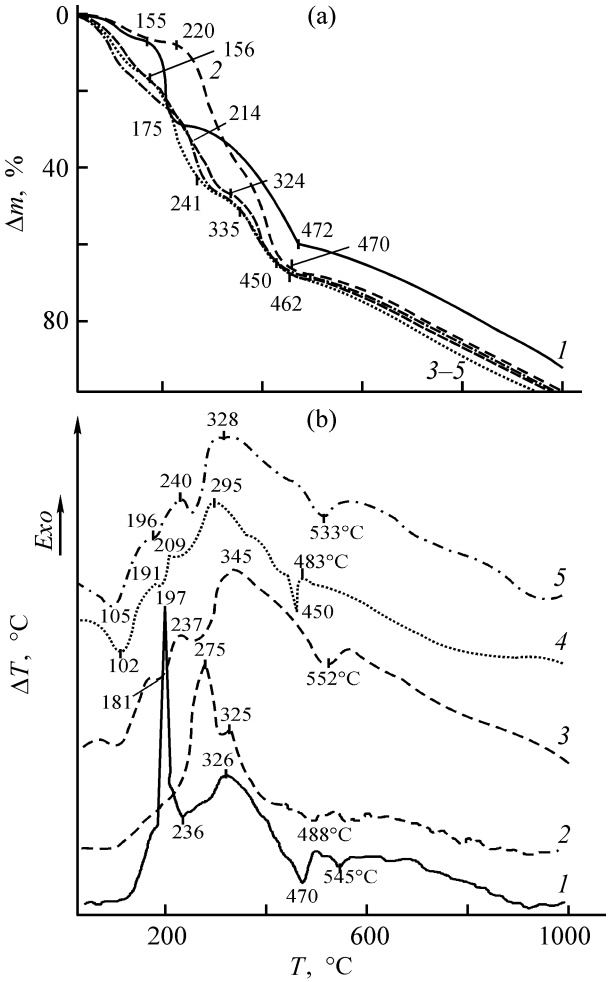

Fig. 2. (a) TG and (b) DTA curves of sorbents in the NO_3^- and OH^- forms: (*1*) VP-1AP (NO_3^-), (*2*) AV-17 (NO_3^-), (*3*) AV-17 (OH^-), (*4*) ANKB-2, and (*5*) Amberlite IRA-400 (OH^-).

We have analyzed the thermochemical transformation of ITA-31 in detail previously [8]. The focus of the present study is how this process is influenced by various anion exchangers added to fix iodine or other model nuclides. Our results demonstrated that, in the course of composite preparation, heating significantly alters the performance characteristics of the sorbents. Figure 1 shows as an example thermograms of the initial and isothermally heated VP-1AP and AV-17. The difference in thermal degradation kinetics between the two samples can be attributed to the cross-linking agent (DVB) content of the resins. For example, on heating to 250°C, VP-1AP decomposes in three stages, and AV-17, in two stages. A considerable difference between these samples was also observed when they were heated at 150°C for 3 h: VP-1AP gradually loses 24% of its weight, and AV-17, 12% of its weight, and this process ceased after 80 min. Comparison of thermal effects (Fig. 1b) accompanying the degradation of these samples shows that isothermal heating of AV-17 does not affect its thermal behavior, while for VP-1AP, thermal stability increases, especially in the initial stage of thermal degradation. Therefore, one may conclude that preliminary thermal analysis of sorbents in the temperature range of formation of the ITA-31-based prepreg allows prediction of the thermal behavior of the initial sorbents and adsorbed pollutants.

Similar experiments with the other sorbents studied showed that the thermal oxidative degradation occurs in several steps, depending on a particular resin. Characteristic features of this process are the effect of counterions and the weight loss dynamics in the course of heating from room temperature to 455–475°C. Over the indicated temperature range, degradation of

the sorbents in the OH form occurs in 3–4 overlapping steps with a weakly pronounced exothermic effect (Fig. 2). For VP-1AP and AV-17 in the nitrate form, there are two clearly pronounced regions of weight loss starting at 155 and 220°C, respectively, and also well distinguished exo effects corresponding to thermal oxidative degradation, which remarkably differs from the behavior of the same sorbents but in the OH form. Evidently, this is due to residual nitric acid, which acts as an additional oxidant for the sorbent at elevated temperatures. Another feature of the thermal behavior of the resins under study is the occurrence of the common to all of them final step in weight loss, which can be attributed to gradual carbonization, typical of carbon-chain polymers. On reaching the carbonization onset temperature, the samples lose about 66–68% of weight, except VP-1AP, for which this value is 58% and the coke number (CN) at 1000°C is 5.4%.

The preparation process of ITA-31 suggests that introduction of any of the anion exchangers studied into the melt involves a certain risk of thermal degradation of the sorbents and, therefore, of release of the compound adsorbed before solidification of the melt. To minimize these effects, it is necessary to optimize the time and concentration conditions of introduction of the sorbent into ITA-31 melt. In this case, the optimal conditions are those providing the required viscosity of the melt without impairing structural stability of the sorbent. Based on an analysis of the thermal characteristics of ITA-31 and sorbents under study, the optimized preparation conditions of ITA-31 melt are as follows: heating at 250–260°C for 10 min followed by introduction of the sorbent (1 : 1 w/w) in 1.5–2 min with stirring. Finally, the resulting mixture is cooled, powdered, and used to prepare a composite material with ELUR as a reinforcing additive [10]. Thermal analysis of CM containing anion exchangers suggests that interaction of VP-1AP with the matrix enhances the heat resistance of the composite. For example, addition of about 25% resin to CM decreases the weight loss by 1% at 300°C, 4.2% at 400°C, 10% at 500°C, 12.6% at 600°C, and 3% at 700°C against the reference sample containing no resin. The effect is leveled off only at 800°C, when the weight losses of both samples become equal (36.6%).

Thus, the resin interacts with the matrix to form a carbonizate, which differs in its heat resistance from the ITA-31 matrix. The TG and DTA curves of ITA-31 and its initial compounds with VP-1AP (Fig. 3), obtained under conditions similar to those in the first stage of composite preparation, suggest that, over

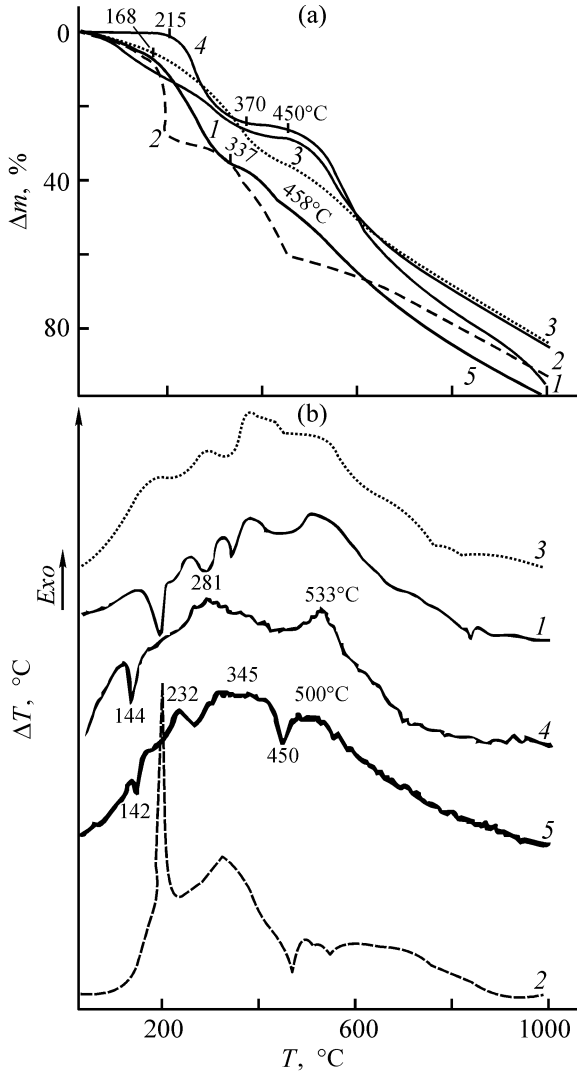

Fig. 3. (a) TG and (b) DTA curves of model mixtures of ITA-31 with various sorbents (1 : 1 w/w): (*1*) ITA-31, (*2*) VP-1AP, (*3*) ITA-31 + VP-1AP, (*4*) initial components of ITA-31, and (*5*) initial components of ITA-31 + VP-1AP.

the temperature range 200–260°C, a thermochemical reaction between ITA-31 and VP-1AP occurs to give a carbonizate differing in its characteristics from the starting components. For example, up to 340°C, the weight loss decreased by 5–12% relative to even ITA-31. At 340–600°C, ITA-31 demonstrates higher heat resistance. The increase in the weight loss can be attributed to the thermal degradation of VP-1AP (its weight loss is about 35% over the same temperature range). However, with further increase in the temperature to above 600°C, the heat resistance of the mixture of ITA-31 with the anion exchanger is higher. In this case, the composite is a new carbonized structure with a coke number of 19% at 1000°C (for ITA-31 CN = 5%). The DTA curves (Fig. 3b) give

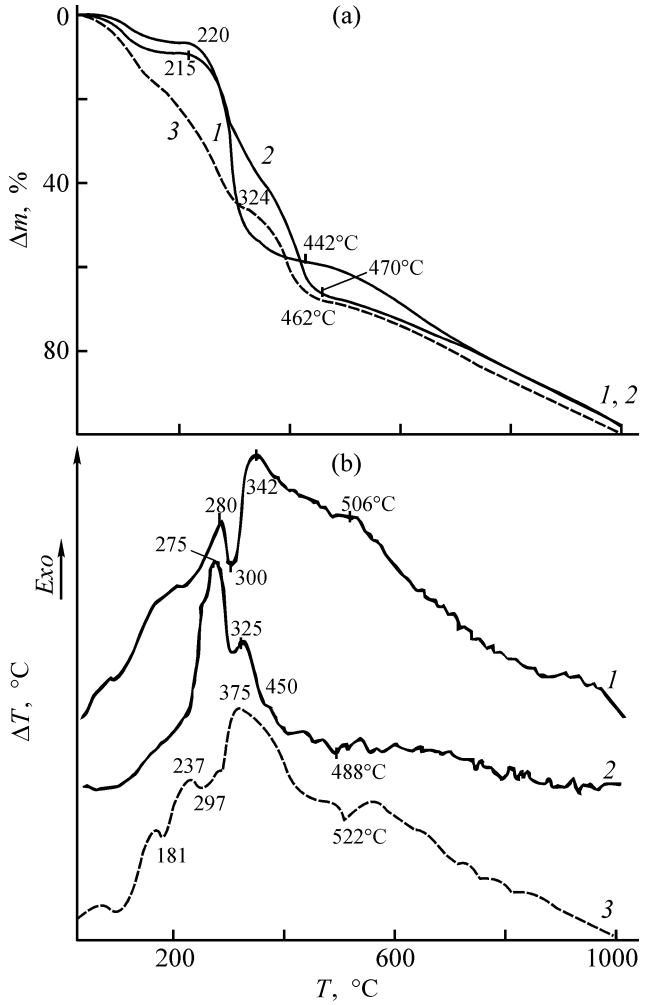

Fig. 4. (a) TG and (b) DTA curves of AV-17 resin in various ionic forms: (*1*) I^-, (*2*) NO_3^-, and (*3*) OH^-.

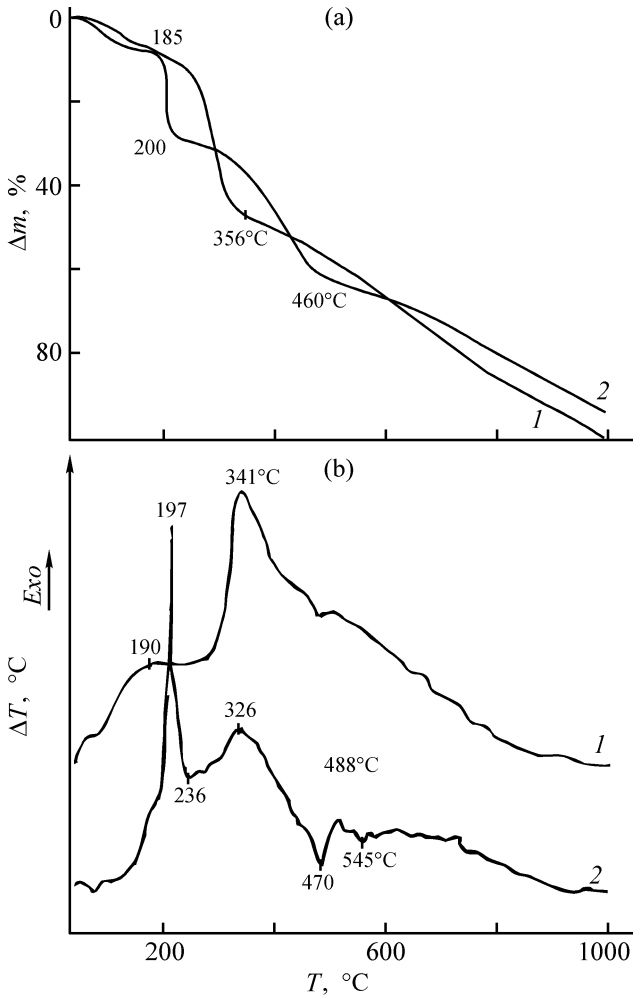

Fig. 5. (a) TG and (b) DTA curves of VP-1AP anion exchanger in various ionic forms: (*1*) I^- and (*2*) NO_3^-.

further evidence in favor of the above concept, by demonstrating thermal effects different from those of the starting components. Thus, thermal analysis of the mixtures of ITA-31 binder with the selected anion exchangers demonstrates the possibility of their use as sorbents working at elevated temperatures.

In further experiments, we examined the effect of a component sorbed on the resin over the temperature range typical of the working conditions of the composite. We selected aqueous potassium iodide as such a component. The procedure of introduction of iodine into the sorbent was designed so as to provide its final content (after all operations including sorption and washing) in the sorbent of about 50% relative to the initial weight of the sample. The thermograms of the resins (VP-1AP, AV-17, Amberlite IRA-400, and Dowex 1×4) containing sorbed iodine showed a remarkable difference from the straight sorbent in the kinetics of weight loss in dynamic heating in air. Comparison of the TG curves of these samples (Figs. 4a, 5a) shows two features. The first is that there is no longer a multistep weight loss over the temperature range (185–215)–(370–420)°C. The second feature is the increase in the weight of the residue, which undergoes 45–60% carbonization with simultaneous decrease in the onset temperature of this process. These features, as well as the thermal effects corresponding to these stages, depend on a particular sorbent.

Therefore, as also in the case of ITA-31, the mechanism of thermal degradation of the sorbents studied changes in the presence of a second component, iodine.

It remains to be understood in what stage of thermal degradation the sorbent releases iodine, in what chemical form iodine is released, and what is the onset temperature of iodine release. Analysis of the ther-

mograms suggests that the major part of iodine is liberated from the sorbent at 320–360°C, the minor part remaining in the carbonizate up to 700°C. More exact data could be obtained by identification and determination of volatile products of carbonization.

Our result that the sorbents studied may be involved in thermochemical reactions with a binder and sorbate allows conclusion about the possibility of modification of ITA-31-based polymeric composites with derivatives of polystyrene and its copolymers. The observed increase in the heat resistance of ITA-31 carbonizates through introduction of anion-exchange resins initiated a further thermochemical study of CMs based on ITA-31 and a reinforcing additive. As reported in [8], the interaction of ITA-31 with ELUR (carbonized PAN fiber) is characterized by the formation of a relatively weak chemical bond, which can be defined as π-electron interaction of the condensed units of ELUR fiber with separate aromatic fragments of carbonized ITA-31. As a result, the CN at 800°C of this composite did not exceed 60%, and the onset temperature of thermal degradation was in the range 280–300°C. Introduction of VP-1AP resin (25% by weight) raised CN to 78%, and the degradation onset temperature, to 420–430°C. Such an effect appeared to be possible due to the first principle of cocarbonization [11]: cocarbonization was carried out in the temperature range in which both ITA-31 and VP-1AP exhibit the highest thermal reactivity, thus providing a preferential cross-linking.

CONCLUSION

In cocarbonization of blends of industrial anion-exchange resins based on modified styrene and ITA-31 fusible polyimide binders, the heat resistance of the resins increases, and the resulting carbonizates are capable of retaining iodine.

Abstract—The products of base hydrolysis of tetraethoxysilane in the presence of polymeric nitrogen bases poly-1-vinylpyrazole, poly-1-vinylimidazole, poly-4-vinylpyridine, and poly-2-methyl-5-vinylpyridine were isolated. The conditions of their formation, chemical composition, structural characteristics, and sorption properties with respect to noble metals (Ag, Au, Pt, and Pd) were studied. These products are highly dispersed thermally stable interpenetrating copolymers poorly soluble in water and organic solvents. Their composition and properties are governed by the kind of the polymeric nitrogen base.

DOI: 10.1134/S1070427207080241

Hybrid organic-inorganic composite materials containing an inorganic component (silicon, titanium, tin, zirconium, or aluminum oxide) chemically bound with an organic component are widely used in various field of science technology. The development of methods for preparing such materials and studies of their properties contribute to the development of chemistry and technology of nanomaterials [1–3].

An actively developing method for preparing hybrid organic-inorganic materials and coatings is based on a sol–gel process involving hydrolysis of alkoxysilanes in the presence of organic compounds [4, 5]. Currently the sol–gel technology is the main technique for purposeful synthesis of hybrid silicate and silica-carbonaceous materials (nanomaterials, coatings, membranes, sorbents, biologically active compounds, catalysts, etc).

It was reported in [6] that, in the first stage of hydrolysis of tetraethoxysilane in ethanol in the presence of polyvinylbutyral, poly-1-vinylimidazole, poly-4-vinylpyridine, or poly-1-vinyl-2-pyrrolidone, a homogeneous solution is formed. In further prolonged storage, these solutions become gelatinous and then solid compounds precipitate. It is believed that the supramolecular structure of these compounds is stabilized by numerous hydrogen bonds between the silanol groups and the electron-donor atoms (N, O) of the organic polymers. The sorption capacity of these materials for Cu^{2+} varies from 25 to 280 mg g^{-1}.

In this study, we isolated highly dispersed hybrid organic–inorganic composite materials by hydrolysis of tetraethoxysilane in the presence of poly-1-vinylazoles and polyvinylpyridines and examined their structural characteristics and thermal and chemical stability. These materials were also tested as sorbents for noble metal ions.

EXPERIMENTAL

1-Vinylpyrazole and 1-vinylimidazole were prepared by the reaction of pyrazole or imidazole with acetylene, as reported in [7, 8].

The commercial monomers 4-vinylpyridine and 2-methyl-5-vinylpyridine were purified by vacuum distillation.

Poly-1-vinylpyrazole (PVPz), poly-1-vinylimidazole (PVIm), poly-4-vinylpyridine (PVPy), and poly-2-methyl-5-vinylpyridine (PMVPy) were prepared by polymerization of the respective monomers by the methods reported in [9, 10].

Table 1. Elemental composition and properties of copolymers formed by hydrolysis of tetraethoxysilane in the presence of polymeric nitrogen bases

Copolymer	Elemental composition, %				Ratio of SiO_2 and nitrogen base units	Yield, %	S_{sp}, $m^2 g^{-1}$	T_{dec}, °C
	C	H	Si	N				
SiO_2 : PVPz	24.69	3.37	25.04	10.96	2.3 : 1	50.7	20.3	250
SiO_2 : PVIm	22.84	2.85	27.13	10.96	2.5 : 1	49.6	10.3	270
SiO_2 : PVPy	36.62	3.45	17.29	6.64	1.3 : 1	69.5	4.9	330
SiO_2 : PMVPy	55.49	6.00	12.81	8.45	0.8 : 1	68.3	33.7	314

The polycondensation of tetraethoxysilane (TES) was carried out in a solution of NaOH in an alcohol-water mixture.

The base hydrolysis of TES in the presence of a polymeric nitrogen base was carried out at room temperature as follows. TES (1.0 g) and 0.1 M aqueous NaOH (2.55 ml) were successively added to a polymeric nitrogen base (0.3 g) dissolved in ethanol (5 ml). On adding aqueous NaOH, the resulting mixture first became turbid and gel-like, and then an insoluble hybrid composite copolymer precipitated. This precipitate was repeatedly washed and then dried in a vacuum desiccator to constant weight.

The elemental analysis of the reaction products was carried out on a Thermo Finnigan gas analyser. The IR spectra (KBr pellets or mulls in mineral oil) were recorded on an IFS-25 spectrometer.

The surface structure of the organic-inorganic copolymers was examined on a Philips-525-M scanning electron microscope.

The specific surface area of these composite materials was measured by a method based on sorption of nitrogen on their surface at various pressures in a graduated high-vacuum unit.

The enthalpy of mixing was measured at 298 K on a Calvet calorimeter equipped with sensitive calorimetric cells (0.032 V W^{-1}). The experimental data were processed with a special software.

The thermogravimetric analysis was carried out on a Paulik–Paulik–Erdey derivatograph (MOM, Hungary) in air at a heating rate of 5 deg min^{-1}. The maximal temperature was 700°C, and the DTA sensitivity, 1/5 to 1/10.

The sorption properties of the composite materials were characterized with respect to Ag(I), Au(III), Pd(II), and Pt(IV) in model solutions of $AgNO_3$, $HAuCl_4 \cdot 4H_2O$, $PdCl_2$, and $H_2PtCl_6 \cdot 6H_2O$ (chemically pure grade) of concentration 0.2–5.0 (mg metal) l^{-1} in distilled water. The metal content of the aqueous phase was determined photometrically with a KFK-2 photocolorimeter [11, 12].

It is known that TES is hydrolyzed in alkaline media containing ethanol, and the hydrolysis products undergo polycondensation to form 3*D* cross-linked hydrated silicon dioxide $[SiO_2 \cdot nH_2O]_m$ of low molecular weight [13]. This product is isolated in the form of amorphous globular particles with the predominant diameter (>80%) of 37–74 nm and specific surface area of 175 $m^2 g^{-1}$.

A base hydrolysis of TES in the presence of poly-1-vinylazoles (PVPz, PVIm) and polyvinylpyridines (PVPy, PMVPy) for several minutes yields glass-like colorless hybrid copolymer precipitates. These products containing Si, N, C, O, and H atoms are thermally stable and poorly soluble in aqueous acids and organic solvents. Their main characteristics are listed in Table 1.

It has been reported [6] that the SiO_2 : nitrogen base units ratio in the composites precipitated in hydrolysis of TES (without base catalysis) in the presence of PVPy and poly-vinyl-2-pyrrolidone is close to 1 : 1, whereas that in the presence of PVIm this ratio is close to 2 : 1. It is believed [6] that this difference is caused by the difference in the basicities of the polymeric nitrogen bases.

In this study, we found no correlations between the hybrid copolymer composition and the basicity (pK^+_{BH}) of the nitrogen heterocycle (pK^+_{BH} of 1-vinylpyrazole, 1-vinylimidazole, 4-vinylpyridine, and 2-methyl-5-vinylpyridine is 1.7, 7.52, 5.62, and 5.67, respectively. In a copolymer prepared by base hydrolysis of TES in the presence of polyvinylpyridine, the ratio of SiO_2 to nitrogen base units is 0.8 : 1 for PVPy and 1.3 : 1 for PMVPy. In the case of copolymers based on TES and polyvinylazoles, this ratio is 2.3 : 1 for PVPz and 2.5 : 1 for PVIm (Table 1).

Table 2. Static sorption capacity SSC and limiting sorption capacity LSC of hybrid copolymers for noble metals and the distribution ratios D of noble metals between copolymers and aqueous solutions

Copolymer	SSC, mg g^{-1} / LSC, mg g^{-1}				D, cm^3 g^{-1}			
	Pd(II)	Pt(IV)	Au(III)	Ag(I)	Pd(II)	Pt(IV)	Au(III)	Ag(I)
SiO_2 : PVPz	139/457	582/840	115/849	273/465	1030	6150	500	28180
SiO_2 : PVIm	182/434	760/799	140/807	70/443	860	20500	1030	500
SiO_2 : PVPy	480/538	704/1010	302/1000	222/548	10660	89000	1430	2060
SiO_2 : PMVPy	370/635	420/1168	110/1180	47/647	1140	2500	980	420

In the system TES-PVPz containing no NaOH, the sol–gel process is complete only in two days, and the SiO_2 : nitrogen base units ratio in the resulting copolymers is close to 1 : 1. Thus, the composition of the hybrid copolymers significantly depends on the rate of base hydrolysis of TES and the latter, in turn, increases with pH [13].

The IR spectra of all the copolymers under consideration contain a strong absorption band (1200–1250 cm^{-1}) typical of the Si–O–Si stretching vibrations. The IR spectra of copolymers of SiO_2 with PVPy and PMVPy contain a shoulder at 1630 cm^{-1}. In the case of copolymers prepared in the presence of PVPz and PVIm, the copolymerization is manifested as a shift of the absorption bands of the azole rings from 1480 to 1520 cm^{-1}. We believe that these changes in the IR spectra of the copolymers obtained in the presence of polymeric nitrogen bases are caused by coordination of the "pyridine" nitrogen atom with the silicon-containing component.

The above hypothesis about chemical interactions between the silicon dioxide and organic components in the copolymers is consistent with the fact that the mixing of silicon dioxide and poly-1-vinylazoles is an exothermic process. The enthalpies of mixing in the systems SiO_2–PVPz and SiO_2–PVIm are –44.3 and –47.9 J g^{-1}, respectively.

The electron micrograph of the hybrid copolymers show that these compounds consist of globules of regular shape with a typical size of about 300 nm. Thus, the particles of hybrid copolymers are coarser than the particles of SiO_2 formed by hydrolysis of tetraethoxysilane in the absence of polymeric nitrogen bases. As can be seen from Table 1, this coarsening of particles causes a decrease in their specific surface area. The copolymers under consideration are multilayer nanoparticles consisting of a core (SiO_2) coated with an organic polymer.

The sorption properties of the copolymers based on PVPz, PVIm, and PVPy were examined for the example of sorption of Ag^+ from solutions of $AgNO_3$ in aqueous nitric acid and of Au(III), Pd(II), and Pt(IV) from their solutions in aqueous hydrochloric acid where these metals are present in the form of anionic complexes $[AuCl_4]^-$, $[PdCl_4]^{2-}$, and $[PtCl_6]^{2-}$ [14, 15]. We found that the degree of sorption recovery of these metals slightly decreases as the HNO_3 and HCl concentration increase from 0.1 to 5.0 M. We believe that this decrease in sorbability is caused by the competitive coordination of HNO_3 and HCl with the nitrogen atom in the pyridine ring of the copolymers. The static sorption capacity of the copolymers for noble metals (SSC) and the distribution ratios of these metals between the copolymers and 1 M aqueous HNO_3 and HCl (D) are listed in Table 2. These data show that the maximal sorbability is exhibited by Pt(IV), which is consistent with the known fact that anionic Pt(IV) chloride complexes are more strongly coordinated with the nitrogen-containing ligands than Ag^+ cations and anionic Au(III) and Pd(II) chloride complexes [14, 15]. It is known that similar correlations are typical of most of complexing sorbents containing nitrogen functional groups [16, 17], including silicon-containing sorbents [18].

In order to estimate the degree of saturation of the nitrogen functional groups of the copolymers with the noble metals in our sorption experiments,

Table 3. Degree of binding of nitrogen functional groups of copolymers with noble metal ions

Copolymer	Pd(II)	Pt(IV)	Au(III)	Ag(I)
	%			
SiO_2 : PVPz	30	69	14	59
SiO_2 : PVIm	42	95	17	16
SiO_2 : PVPy	89	70	30	40
SiO_2 : PMVPy	58	36	9	7

we calculated the limiting sorption capacity LSC of the copolymers for these metals, assuming that one nitrogen base unit of the copolymer coordinates one metal ion. The molecular weight of a structural unit of the copolymers containing one nitrogen functional group was calculated from the elemental composition of the copolymers (Table 1). As can be seen from Table 3, the ratio of SSC and LSC varies from 0.36 to 0.95 for Pt(IV) and from 0.30 to 0.89 for Pd(II). The degree of saturation of the copolymers with Ag(I) and Au(III) in our experiments appears to be appreciably lower.

In sorption of noble metals on the hybrid copolymers from acidic solutions, the protonated nitrogen atoms of the pyrazole, imidazole, and pyridine functional groups are coordinated with both Ag^+ cations and anionic Au(III), Pd(II), and Pt(IV) chloride complexes to form stable solid compounds [19]. The formation of the N–metal coordination bonds in the copolymers saturated with respect to the metals is manifested as new absorption bands (400–300 cm^{-1}).

CONCLUSIONS

(1) In base hydrolysis of tetraethoxysilane in the presence of poly-*N*-vinylazoles and polyvinylpyridine, mixed organic-inorganic copolymers are formed.

(2) The structure of mixed copolymers is built by interpenetration of the networks of hydrated silicon dioxide and polymeric nitrogen bases.

(3) The hybrid copolymers have high thermal and chemical stability, highly dispersed structure, and the developed surface area.

(4) The hybrid copolymers efficiently sorb noble metal ions from acidic solution.

Abstract—The effect of solvents on the kinetics of synthesis and molecular properties of copolymers formed by radical copolymerization of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate in water and in methanol–water (75 : 25, 50 : 50, 25 : 75), ethanol–water (50 : 50), and isopropanol–water (50 : 50) solutions in the presence of potassium persulfate initiating agent at pH 9 and 60°C was studied.

DOI: 10.1134/S1070427207080253

Water-soluble copolymers of acrylamide (AA) and sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS) can be used as effective flocculants for water treatment, thickening agents and emulsifiers for drilling, and stabilizing and antistatic agents for photomaterials [1, 2]. Because of a set of valuable properties of these polymers and scarcity of data on their preparation in various media, the development of procedures for direct synthesis of AA–Na-AMS copolymers with various characteristics is of particular importance. As is known [3–5], the reaction kinetics in radical polymerization of water-soluble monomers and properties of the resulting polymers strongly depend on the reaction medium. Hence, synthesis of water-soluble polymers can be efficiently controlled by changing the nature and composition of binary solvents. Previously we have studied copolymerization of AA and Na-AMS in aqueous–salt [5], aqueous–dimethyl sulfoxide [6], and aqueous–ethanol [7] solutions. In this study, we examined the dependences of copolymerization of acrylamide with sodium 2-acrylamido-2-methylpropanesulfonate in water–alcohol (methanol, ethanol, and isopropanol) mixtures, which exhibit different solvating and ionizing powers.

EXPERIMENTAL

2-Acrylamido-2-methylpropanesulfonic acid (H-AMS) was purchased from Lubrizol Corp. (UK) (mp 185°C). It sodium salt was prepared by potentiometric titration of aqueous H-AMS solutions with aqueous solution of NaOH to pH 9. Acrylamide was purchased from Mitsubishi Chem. Ind. Ltd. (Japan) (mp 84.5°C). Before experiments, potassium persulfate (PP) of chemically pure grade was twice recrystallized from aqueous solutions. The content of the main compound, determined by the redox method, was 97.8%. The working solutions were prepared using distilled water and other reagents of chemically pure grade.

Copolymerization was carried out to low conversions ($x < 2.5\%$) in glass dilatometers (8.4 cm^3 volume), and to high conversions in 50 cm^3 glass weighing bottles. Before copolymerization, Na-AMS was dissolved in water or water–alcohol mixture and neutralized with a 20% NaOH solution to pH 9. Then, the required amount of AA was added and the total volume of the reaction mixture was brought to 9.5 cm^3 with distilled water. The aqueous solution of PP (0.5 cm^3) was mixed with the resulting mixture, and finally, an appropriate alcohol (10 ml) was added. Then, the resulting solutions were transferred into a dilatometer or a weighing bottle with a long-needle syringe and heated at 60°C, using an EZE immersion thermostat (Germany). After copolymerization, the resulting polymers were precipitated from aqueous solutions with acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum oven at 50°C.

The yield of the copolymers was determined gravimetrically. The content of ionic units Na-AMS in the copolymer was determined from the content of sulfur [8].

The molecular weight of a copolymer M was determined from the intrinsic viscosity [η], because, according to the Mark-Houwink equation, $[\eta] \approx M$. The intrinsic viscosity [η] of copolymer solutions was measured in a 0.5 M NaCl solution at 30°C, using a VPZh-3 viscometer (d_c = 0.56 mm). Because the kinetic energy correction did not exceed 2% it was disregarded in calculations of the reduced viscosities η_{sp}/c_p, where c_p is the copolymer concentration. The experimental dependence of the reduced viscosity on the copolymer concentration was plotted. Then, using the linear dependence $\eta_{sp}/c_p = f(c_p)$, we determined the intrinsic viscosity:

$$[\eta] = \lim(\eta_{sp}/c_p) \text{ at } c_p \to 0.$$

The kinetic measurements were performed by the dilatometric procedure, and the initial rates of copolymerization (v_0) at small conversions ($x < 3\%$) were calculated. The conversion (%) was calculated from the following expression:

$$x = (\Delta V/VK) \times 100,$$

where ΔV and V (cm^3) are the change in the volume and the initial volume of the reaction mixture at the copolymerization temperature, respectively, and K is the contraction factor at the experimental temperature, which was determined from the composition of the initial monomer mixture from the following equation:

$$K = K_{\text{Na-AMS}} W + K_{\text{AA}}(100 - W)$$

where $K_{\text{Na-AMS}}$ and K_{AA} are the contraction factors for homopolymerization of Na-AMS and AA, respectively, and W is the content of Na-AMS units in the initial monomer mixture.

The values of $K_{\text{Na-AMS}}$ and K_{AA} were calculated as follows:

$$K_{\text{Na-AMS}}(K_{\text{AA}}) = (\rho_p - \rho_m)/\rho_p,$$

where ρ_p and ρ_m are the densities ($g\,cm^{-3}$) of the polymer and monomer, respectively.

In our calculations, the following correction was introduced:

$$K' = K[1 + \alpha_m(T_1 - T_2)],$$

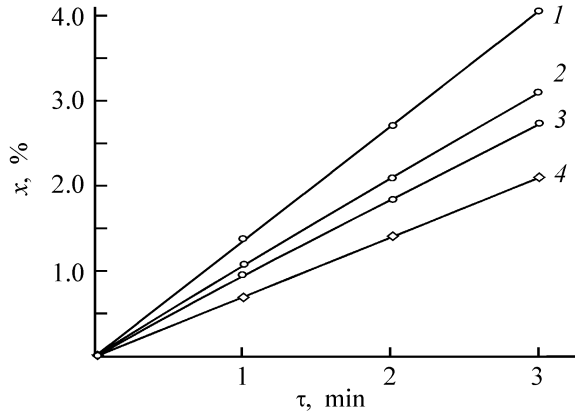

Fig. 1. Initial portions of kinetic curves of copolymerization of AA with Na-AMS v_0 in (*1*) water and (*2–4*) water–methanol mixtures. (x) Conversion and (τ) time. Water : methanol, vol%: (*2*) 75 : 25, (*3*) 50 : 50, and (*4*) 25 : 75; the same for Fig. 6.

where α_m is the volume expansion coefficient, and T_1 and T_2 are the temperatures of the experiment and monomer at filling of the dilatometer, respectively.

$$\alpha_m = (1/V)\,dV/dt,$$

where dV and V are the change in the volume and the initial volume of the reaction mixture, respectively.

The solution acidity was measured with a pH-121 pH-millivoltmeter equipped with an ESL-65-07 working glass electrode and an EVL 1M-3 silver chloride auxiliary electrode.

Copolymerization of AA (M_1) with Na-AMS salts (M_2) was carried out in 20% aqueous–alcoholic solutions of monomers at pH 9 and 60°C in the presence of potassium persulfate initiating agent ([PP] = 7.4×10^{-4} M). A constant pH 9 was maintained in the reaction mixture to provide high initiation efficiency [9] and its independence from the solution ionic strength [10] because of the change in the concentration of Na-AMS in the initial reaction mixture, and to preclude hydrolysis of AA in concentrated aqueous solutions. Copolymerization proceeds under the homogeneous conditions in aqueous–methanol and aqueous–ethanol solutions and under heterogeneous conditions in aqueous isopropanol. In all the cases no spontaneous polymerization was observed.

The reaction rate was monitored by the dilatometric procedure. Typical initial portions of the kinetic copolymerization curves are shown in Fig. 1. As can be seen, the initial portions of the kinetic curves are linear, and we determined from them the initial copolymerization rates v_0 at low conversions ($x < 4\%$).

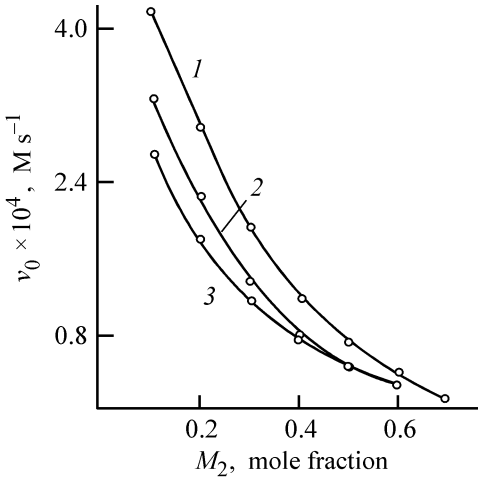

Fig. 2. Initial rate of copolymerization of AA with Na-AMS v_0 in aqueous–alcoholic (50 vol %) solutions vs. the mole fraction of Na-AMS in the initial monomer mixture M_2. Alcohol: (*1*) methanol, (*2*) ethanol, and (*3*) isopropanol; the same for Figs. 3 and 4.

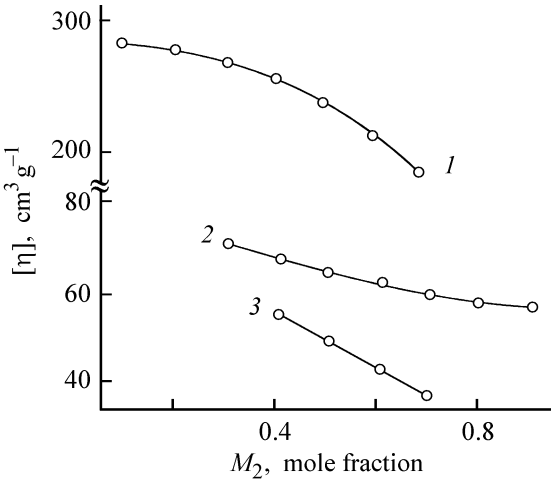

Fig. 3. Intrinsic viscosity of AA–Na-AMS copolymers [η] vs. the mole fraction of Na-AMS in the initial monomer mixture M_2 in copolymerization in aqueous–alcoholic (50 vol %) solutions.

To find out how the composition of the initial monomer mixture affects the features of copolymerization in aqueous-alcoholic solutions, we determined v_0 and [η] (Figs. 2, 3). As can be seen, both v_0 and [η] of the copolymers decrease as the content of Na-AMS in the initial monomer mixture increases, and these dependences are similar for all the binary solvents studied. These data suggest a higher activity of AA in copolymerization as compared to Na-AMS. As can be seen from Fig. 3, copolymers with the highest molecular weights are formed by copolymerization of AA with Na-AMS from the initial monomer mixtures enriched in AA.

Comparison of the above experimental data (Figs. 2, 3) at fixed M_2 shows that v_0 and [η] vary in the following order: water–methanol > water–ethanol > water–isopropanol.

The above-mentioned change in v_0 in the given solvents was promoted by the increase in the viscosity (Table 1) of the initial monomer mixture (at M_2 mole fraction of 0.2, c_p 0.2 g cm^{-3}, and 30°C), which makes weaker the reagent diffusion. Comparison of [η] at M_2 = const (Fig. 3) shows that the molecular weights of the copolymers prepared in water–methanol solutions are an order of magnitude higher than those of the copolymers prepared in water–ethanol and water–isopropanol solutions. This is apparently due to the higher activity of ethanol and isopropanol, compared to methanol, in chain-transfer reactions.

The yields of the copolymers are listed in Table 2. It can be seen that, in all of the systems studied, copolymerization proceeds to high conversions.

Changes in the instantaneous composition of AA–Na-AMS copolymer in the course of copolymerization

Table 1. Parameters of copolymerization of AA with Na-AMS in aqueous–alcoholic (50 vol%) solutions (viscosities of the monomer mixtures were measured at M_2 mole fraction of 0.2, c_p 0.2 g cm^{-3}, and 30°C)

Solvent	Viscosity of the monomer mixture (outflow time, s)	r_1	r_2	Analytical method
Water–methanol	25.2	1.06 ± 0.03	0.94 ± 0.05	Fineman–Ross
		1.08 ± 0.03	0.95 ± 0.05	Kelen–Tudos
Water–ethanol	33.3	1.42 ± 0.01	0.23 ± 0.01	Fineman–Ross
		1.43 ± 0.01	0.23 ± 0.01	Kelen–Tudos
Water–isopropanol	41.7	2.17 ± 0.05	0.01 ± 0.03	Fineman–Ross
		2.18 ± 0.03	0.01 ± 0.03	Kelen–Tudos

Table 2. Yield of AA–Na-AMS copolymers prepared in aqueous–alcoholic (50 vol %) solutions at various compositions of the initial monomer mixture

M_2, mole fraction	Yield, %			M_2, mole fraction	Yield, %		
	water–methanol	water–ethanol	water–isopropanol		water–methanol	water–ethanol	water–isopropanol
0.1	–	45	38	0.4	85	82	40
0.2	–	–	44	0.5	70	68	–
0.3	86	81	–	0.7	74	71	51

in various aqueous-alcoholic solutions (50 vol %) at low conversions ($x < 4$) in relation to the composition of the initial monomer mixture are shown in Fig. 4. It can be seen that, in a wide range of compositions of the initial monomer mixtures in all of the solvents studied, we obtained copolymers enriched in AA units. From the dependences $m_2 = f(M_2)$ (Fig. 4), we estimated the effective relative activities r_1 (AA) and r_2 (Na-AMS):

$$r_1 = k_{11}/k_{12} \text{ and } r_2 = k_{22}/k_{21}.$$

As can be seen from Table 1, the Fineman–Ross and Kelen–Tudos procedures gave consistent values of r_1 and r_2. In all the solutions, $r_1 > r_2$, which confirms the higher reactivity of AA in copolymerization as compared to Na-AMS. Comparison of experimental data in Fig. 4 at M_2 = const shows that the content of Na-AMS units in the copolymer increases in the order water–isopropanol < water–ethanol < water–methanol, which is due to an increase in r_2 and a decrease in r_1. At the same time, the effect of heterogeneity in the water–isopropanol solutions also cannot be ruled out.

In view of the highest v_0 and [η] for the copolymerization in water–methanol (50 vol %) solutions, compared to the other aqueous–alcoholic solutions (Figs. 2, and 3), we examined in more detail the influence exerted by the composition of the water–methanol mixtures on the copolymerization. Figures 1 and 5 show that v_0 and [η] increase with the content of water in water–methanol mixtures. These results agree well with published data on the copolymerization of AA in aqueous-organic solutions [11]. The dependences shown in Fig. 5 are due to an increase in the proton-donor power of the medium with the content of water in water–methanol binary mixtures, which makes higher the concentration of hydrogen bonds between the C=O groups of both monomers and the solvent. In this case, the polarity of the double bond increases, which is confirmed by the spectral

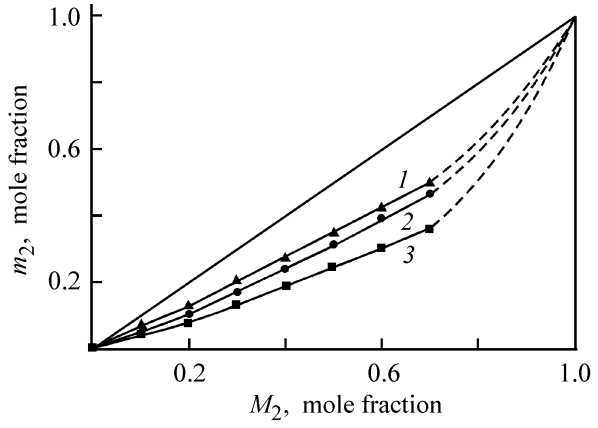

Fig. 4. Mole fraction of Na-AMS units m_2 in the copolymer at low conversions ($x < 4\%$) vs. the mole fraction of Na-AMS in the initial monomer mixture M_2 in copolymerization of AA with Na-AMS in aqueous–alcoholic (50 vol %) solutions.

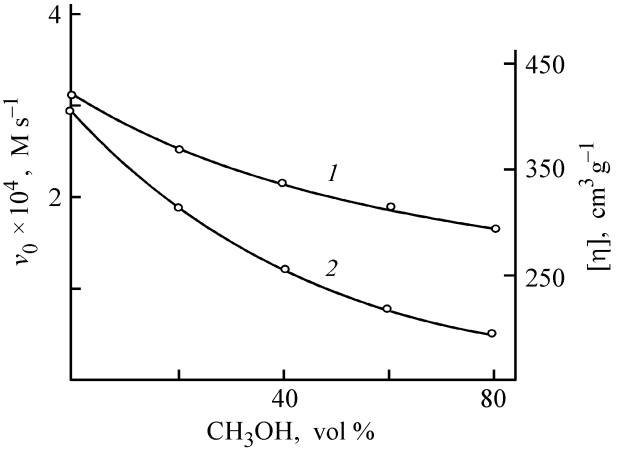

Fig. 5. (*1*) Initial rate of copolymerization v_0 of AA with Na-AMS and (*2*) intrinsic viscosity of copolymers [η] vs. the methanol content in the water–methanol mixture.

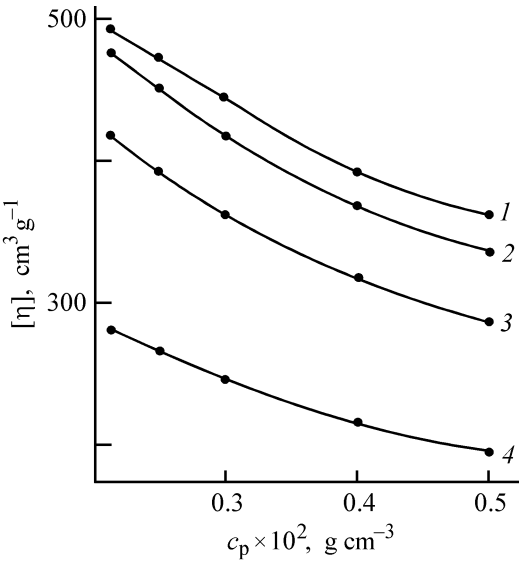

Fig. 6. Reduced viscosity of copolymers η_{sp}/c_p vs. the concentration c_p of copolymer of AA with Na-AMS ([η] 83 cm^3 g^{-1}, content of Na-AMS units 15.9 mol %) in (*1*) and (*2–4*) water–methanol mixtures at 30°C.

data for AA [11]. As a result, the monomer reactivity and v_0 increase.

The decrease in [η] (Fig. 5) with increasing methanol content in the water–methanol mixture can be due to enhanced chain transfer to the methanol molecule because of the presence of labile hydroxyl hydrogen atoms.

On addition of water to methanol, the solution polarity and the degree of ionization of the ionic Na-AMS groups and its units in the macroradicals increase. This alters the conformation state of the propagating chains, which is indirectly confirmed by viscometric data for AA–Na-AMS copolymer in water and in water–alcohol mixtures of various compositions (Fig. 6). As seen, the dependences of η_{sp}/c_p are typical of polyelectrolytes, which suggests a significant role of electrostatic interactions for AA–Na-AMS copolymers in the solvent systems studied. Analysis of experimental data at c_p = const shows that η_{sp}/c_p increases with the content of water in the solvent (Fig. 6, passing from curve *4* to curve *1*). This is due to an increase in the solvent polarity, which makes higher the degree of ionization of the Na-AMS units in the copolymer macromolecules. As a result, the electrostatic repulsion between the sulfate anions along the chain is enhanced, which causes unfolding of the polymer coils and an increase in η_{sp}/c_p. Under the copolymerization conditions studied, the electrostatic repulsion between the uniformly charged Na-AMS monomer and macroradical with the terminal Na-AMS unit increases with the solvent polarity. As a result, the reaction rate constant k_{22} and r_2 decrease in passing from water–methanol (50 vol %, r_2 0.94) to water (r_2 0.11) [6]. We believe that changes in the conformation state of macromolecules and in electrostatic interactions of the reacting units with increasing water content of the water–methanol mixtures also lead to a raised in v_0 in the systems studied.

CONCLUSIONS

(1) Water-soluble high-molecular-weight copolymers of acrylamide and sodium 2-acrylamido-2-methylpropanesulfonate with required properties can be prepared by radical copolymerization in aqueous–alcoholic (alcohol: methanol, ethanol, and isopropanol) solutions.

(2) The initial copolymerization rate and intrinsic viscosity of copolymers increase with the content of acrylamide in the initial monomer mixture and with the water content of the water–methanol mixtures; these quantities decrease in the order water–methanol > water–ethanol > water–isopropanol.

(3) The content of the ionic groups of sodium 2-acrylamido-2-methylpropanesulfonate in the copolymer increases with the content of this salt in the initial monomer mixture and decreases in the order water–methanol > water–ethanol > water–isopropanol, because of a decrease in r_2 (sodium 2-acrylamido-2-methylpropanesulfonate) and an increase in r_1 (acrylamide). In all the aqueous-alcoholic solutions, $r_1 > r_2$.

Abstract—Spontaneous copolymerization of 2-acrylamido-2-methylpropanesulfonic acid with acrylamide and acrylonitrile in concentrated acidic aqueous solutions was studied.

DOI: 10.1134/S1070427207080265

Copolymers of salts of 2-acrylamido-2-methylpropanesulfo acid (AMPSA) with acrylamide (AA) and acrylonitrile (AN) are well known as promising drilling reagents [1, 2]. One of the procedures used for synthesis of these copolymers is radical polymerization in concentrated aqueous solutions. It has been shown recently that, under certain conditions, AMPSA [3] and AA [4] are capable of spontaneous homopolymerization in highly concentrated aqueous solutions. It was found that spontaneous polymerization of these monomers proceeds only in acidic medium, and, in the presence of sulfuric acid, the initial rate of spontaneous polymerization of AA linearly increases with acidity. For a series of other (meth)acrylic monomers, spontaneous polymerization can proceed in a neutral or weakly alkaline medium; in this case, addition of inhibitors of radical polymerization effectively prevents the process [5]. Based on a comprehensive study of the process [6], we suggested the mechanism of initiation of spontaneous polymerization in aqueous solutions, common to all (meth)acrylic monomers. We believe that, in concentrated aqueous solutions, monomers are associated to form intermediates having orientation of the C=C bonds favorable for polymerization. In these intermediates, radical initiating species are generated by a redox reaction involving anions present in the system and the C=C bonds.

Spontaneous polymerization in binary monomer systems is of interest from theoretical and practical standpoints, but remains poorly studied. There are published data on spontaneous polymerization that occurs in aqueous or alcoholic solutions containing *N*,*N*-dimethylaminoethyl metacrylate in combination with other vinyl monomers. For example, alternating copolymers of the above monomer with 2-methyl-5-vinylpyridine or AA have been prepared [7]. In acid-catalytic initiation in aqueous solution of the same amino ester and AMPSA, the homopolymer of the amino methacrylate is formed and AMPSA molecules only play the role of counterions. This fact is of particular interest since, when taken separately, AMPSA and *N*,*N*-dimethylaminoethyl methacrylate actively spontaneously polymerize in concentrated aqueous solutions under similar conditions [3, 9].

Polymerization in binary aqueous solutions of AMPSA and nonionic acrylic monomers in the absence of initiators has not been studied previously. In this study we examined the products and features of spontaneous copolymerization in the systems AMPSA–AA–H_2O and AMPSA–AN–H_2O.

EXPERIMENTAL

Before use, acrylonitrile was purified by distillation. AA was twice recrystallized from benzene. AMPSA was recrystallized from acetic acid. The copolymerization of AMPSA with AA or AN was performed in water at 50 ± 0.2°C in glass ampules. In all

experiments, including measurements of the solution viscosity, AMPSA was neutralized with sodium hydroxide to 50% (it has been found previously [3] that this degree of neutralization provides the highest rate of spontaneous polymerization of AMPSA). The total initial concentration of the monomers was 1.5–2.5 M. The individual concentrations of monomers in the reaction mixtures were estimated by liquid chromatography (AMPSA and AA) and gas–liquid chromatography (AN). For liquid chromatography, we used a Praha chromatograph equipped with a UV detector (λ = 254 nm) and a 150 × 4.6 mm steel column packed with modified silica gel Silasorb C_{18} (particle size 10 μm); acetonitrile was used as an eluent. The gas–liquid chromatographic measurements were performed on a Tsvet-500 device with flame-ionization detector and a column 2 m long and 3 mm in diameter, packed with 10% PEGA on Chromaton N-AW; the flow rate of carrier gas (nitrogen) was 2×10^{-3} $m^3\,h^{-1}$; vaporizer temperature 70°C, column temperature 40°C. The specific viscosity of aqueous solutions of the monomers was measured at 25 ± 0.1°C in an Ubbelohde viscometer with a capillary diameter of 0.56 mm.

It has been shown previously [3] that spontaneous polymerization of AMPSA and its salts proceeds in aqueous solutions only if the initial concentration of the monomer is no less than 1.0–1.2 M. For individual solutions of AA, polymerization starts in the presence of sulfuric acid (50 mol % relative to amide) at initial concentrations of no less than 2.0–2.2 M. Experiments performed with systems AMPSA–AA–H_2O showed that spontaneous (co)polymerization starts at a noticeable rate at the total concentration of the monomers exceeding 1.2 M (i.e., approximately as in solutions of the sulfonic acid taken separately).

The data on the kinetics of spontaneous homopolymerization of AMPSA and the total consumption of the monomers in the system AMPSA–AA–H_2O are compared in Fig. 1. As can be seen, the polymerization proceeds, upon substitution of AA for a small part of AMPSA at a rate close to the rate of AMPSA homopolymerization, and at a monomer ratio of 1 : 1, the total rate of the process somewhat decreases.

Data on the composition of copolymers prepared at various initial concentrations of the monomers by spontaneous copolymerization in the system AMPSA–AA–H_2O are listed in Table 1. At the concentration of the monomers of 1.5 and 1.75 M, the copolymer is enriched in AA units in the initial steps of the process. With more concentrated solutions, the composition of the copolymer abruptly changes: the content of AA units decreases from 60 to 16%. It should be noted that the trend toward enrichment of the copolymer in sulfonic acid comonomer (though considerably less pronounced) was observed in [10] in copolymerization of the above monomers in the presence of initiators.

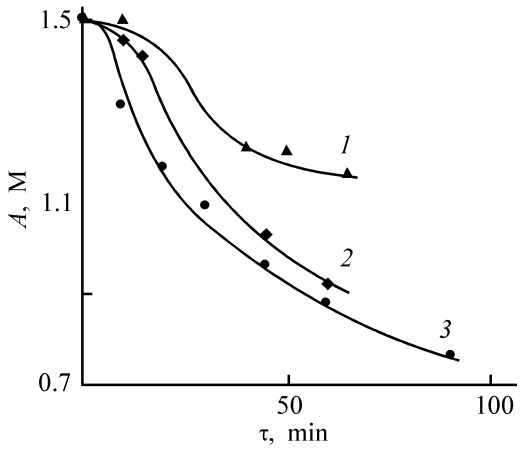

Fig. 1. Total consumption of monomers in the system AMPSA–AA–H_2O. ΣM_0 = 1.5 M, 50°C. (*A*) Total concentration of monomers and (τ) time; the same for Fig. 2. AMPSA : AA: (*1*) 50 : 50, (*2*) 86 : 14, and (*3*) 100 : 0.

Substitution of AN for AA leads to significant changes in the features of spontaneous polymerization. Preliminary experiments showed that, contrary to AA, AN does not polymerize spontaneously within the limits of its solubility. Spontaneous copolymerization in the system AMPSA–AN–H_2O starts only at the total concentration of the monomers exceeding 2.0 M and at a significant excess of the ionic monomer with respect to the nitrile. For example, as

Table 1. Influence of the total concentration of the monomers on the content of AA units in the copolymer ($[AMPSA]_0 : [AA]_0$ = 5 : 5)

Total concentration of monomers, M	Content of AA units in copolymer, mol %, at indicated conversion, %	
	10	20
1.5	60	59
1.75	60	50
2.0	26	42
2.5	16	20

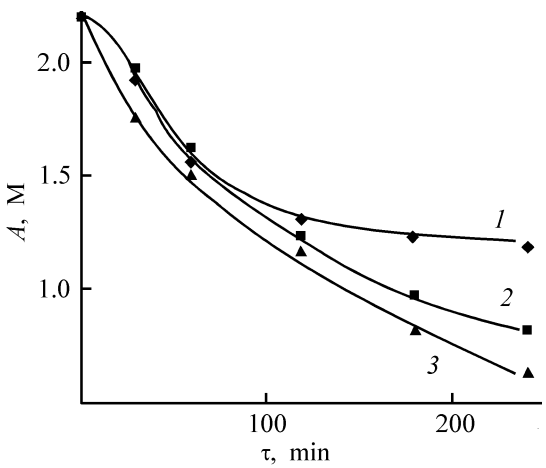

Fig. 2. Total consumption of monomers in the system AMPSA–AN–H_2O. ΣM_0 = 2.2 M, 50°C. AMPSA : AN: (*1*) 86 : 14, (*2*) 90 : 10, and (*3*) 95 : 5.

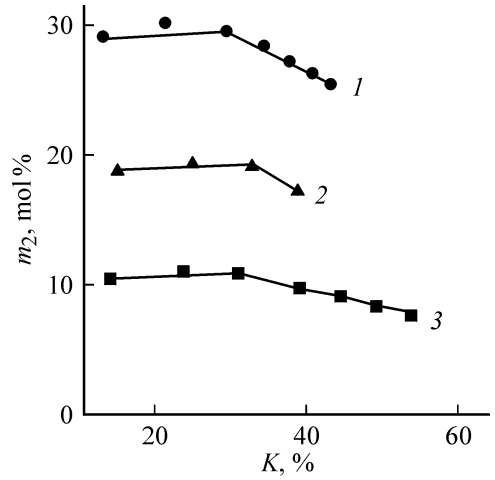

Fig. 3. Content of AN units, m_2, vs. degree of conversion, K in copolymerization of AMPSA with AN. ΣM_0 = 2.19 M, 50°C; the same for Fig. 4. AMPSA : AN: (*1*) 86 : 14, (*2*) 90 : 10, and (*3*) 95 : 5.

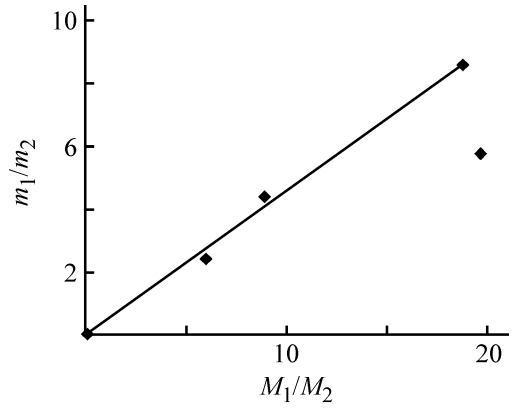

Fig. 4. Ratio of monomer units, m_1/m_2, in AMPSA–AN copolymer vs. the composition of the initial monomer mixture, M_1/M_2.

the content of nitrile increases to more than 15% (at a total concentration of 1.5 M) and to more than 20% (at a total concentration of 2.2 M), spontaneous polymerization does not proceed. Data on the total consumption of the monomers at their same total molar concentration and various ratios are presented in Fig. 2. As can be seen, addition of even a small amount of the nitrile to the AMPSA solution results in a decrease in the total copolymerization rate.

The composition of the AMPSA–AN copolymers obtained at various initial ratios of the monomers is plotted in Fig. 3. It should be noted that the copolymers are enriched in nitrile units and also that the compositions of the products do not vary up to an approximately 30% conversion. Figure 4 shows that the initial ratio of units in the polymers is in direct proportion to the ratio of monomers in the starting mixture; in this case, the coefficient of proportionality is close to 2. Summarizing the experimental results, we can emphasize the following regular trends in spontaneous polymerization in the systems AMPSA–AA–H_2O and AMPSA–AN–H_2O.

(1) Addition of AA to AMPSA solutions does not significantly affect the minimal monomer concentration at which spontaneous polymerization occurs; addition of AN raises this concentration.

(2) As the initial content of AA increases, the rate of the spontaneous process decreases insignificantly; with increasing fraction of the nitrile in the initial mixture, the decrease in the rate is more pronounced (to the point of complete suppression of the reaction).

(3) The degree of enrichment of the resulting polymers in the more active monomer strongly varies with both the total initial concentration of the monomers and their initial ratio.

Because spontaneous homopolymerization is caused by association of monomers [6], we studied, in order to account for the features of spontaneous copolymerization in the systems in hand, the features of intermolecular interactions of the reactants in aqueous solutions. Association processes are usually monitored by viscosimetry, measurements of electrical conductivity and surface tension, as well as by IR and ^{13}C and ^{1}H NMR spectroscopy. In particular, a certain run of the concentration dependences of the solution viscosity can confirm that association occurs in a solution [11].

The viscosity-concentration dependences (VCDs) of aqueous solutions of individual monomers and

their binary mixtures are shown in Figs. 5 and 6. In the range of its solubility in water, acrylonitrile does not tend toward association; this is suggested by the linear shape of curve *2* (Fig. 5a). In the case of acrylamide monomers (AMPSA and AA) capable of formation of stable hydrogen bonds, the specific viscosity of the solution increases with the concentration, which suggests aggregation of the monomers. As can be seen from the curves shown in Figs. 5a and 5b, AMPSA is a more actively associating agent than AA. In addition, the VCDs of these monomers, plotted on an enlarged scale show clearly pronounced bends between virtually linear portions. These inflections are observed for AA at concentrations of 6, 22, and 32% (Fig. 5a, curve *1*), and in the case of AMPSA, at 4, 10, 16, 22, and 26% (Fig. 5b). According to [12], the bends in the VCD curves are caused by transformation of the associates formed. Spontaneous polymerization of AA starts in the concentration range between the first and second bends, and, in the case of AMPSA, between the third and fifth bends. This is apparently caused by the fact that only definite structures of associates are favorable for spontaneous polymerization.

To study the binary association of the monomers, we recorded VCDs of aqueous solutions of monomer pairs. As can be seen from Fig. 6 (curves *1*, *2*), the viscosity increases more intensively on adding AN to an AMPSA solution; in this case, it starts at lower concentrations than that in the corresponding individual solution of sulfonic acid (although at the same total concentration of the monomers in the binary system the viscosities are somewhat lower, compared to the AMPSA solutions). Thus, AA molecules can be involved in AMPSA associates, laregly preserving their structuring. This fact, apparently, explains why addition of AA does not decrease the initial concentration of spontaneous polymerization.

By contrast, addition of even a small amount of AN to the AMPSA solution decreases the specific viscosity of the solution (Fig. 6, curves *2*, *3*), which is apparently caused by destabilization of sulfonic acid associates with nitrile molecules. Hydrophobic molecules of AN should tend to pass into fairly hydrophobic amide associates; however, in this case, nitrile molecules having no labile protons are not bound by strong bonds to amide molecules. This should result in a distortion of the ordered structure of AMPSA associates, causing difficulty in initiation of spontaneous polymerization (especially at a relatively high content of AN in the initial mixture).

* [AN] = 2.65 wt %.

Similar conclusions can be made from the ^{1}H NMR spectra. According to the data in Table 2, the ^{1}H NMR signals of Na-AMPSA are shifted downfield and broadened as the concentration of the monomer increases. Previously [13], similar trends have been attributed to a decrease in the molecular mobility in a study of the influence of polymer additions on the association of surfactant monomers. The decrease in the mobility can be caused by packing of molecules in an associate, displacement of water molecules from it, and, the resulting increase in its hydrophobicity. It is of interest that, on adding AN to a dilute aqueous solution of Na-AMPSA, the position and halfwidth of the ^{1}H NMR signals of the sulfonic acid do not change noticeably, i.e., the nitrile does not exert under these conditions a significant effect on associates of sulfonic acid monomer (they are insufficiently hydrophobic, and AN molecules do not pass into the area of these hydrophilic associates).

In more concentrated solutions of Na-AMPSA, when, according to viscometric data, the viscosity of the monomer solution significantly increases (Fig. 5), addition of AN results in a significant decrease in the halfwidths of the ^{1}H NMR signals of Na-AMPSA; in this case, their values become close to those in dilute solutions of the sulfonic acid (Table 3). These data confirm the assumption that, in rather concentrated solutions, nitrile molecules can penetrate into associates of sulfonic acid and "loosen" them. In this case, introduction of AN into Na-AMPSA associates is accompanied by only insignificant variations of the characteristic signals of nitrile (small downfield shift of ^{1}H NMR signals and narrowing of these signals).

Thus, the results of a viscometric analysis and NMR study allow explanation of the experimental data on spontaneous polymerization in the systems AMPSA–AA–H_2O and AMPSA–AN–H_2O. First, the close correlation between spontaneous polymerization of the monomers and their association is confirmed. Second, the resulting polymers are enriched in that monomer which shows under these conditions a stronger tendency to be incorporated into associates. This tendency is caused by both the capability of the monomers for self-aggregation and their hydrophobicity (more hydrophobic monomers should show stronger tendency to pass into the arising associates).

In spontaneous copolymerization of AMPSA and AN in concentrated solutions, more hydrophobic molecules of AN actively pass into hydrophobic areas of associates formed by AMPSA molecules. As a result, the local concentration of nitrile in an associate becomes higher than its average concentration and exceeds the fraction of associated AMPSA molecules. Because polymerization occurs more readily in associates, the copolymer is enriched in AN units. In solutions of AA and AMPSA, binary associates are formed even in rather dilute solutions due to a strong tendency of both monomers toward association. However, they do not involve significant fraction of the initial comonomers; therefore, the polymer is enriched with more mobile and active AA molecules. In going to more concentrated solutions, the fraction of associated

molecules significantly increases; specifically, these molecules are predominantly incorporated into the copolymers at low and moderate degrees of conversion. Furthermore, in going to higher concentrations, the associates become more hydrophobic; therefore, the content of the more hydrophobic monomer (AMPSA) in the associates increases and, correspondingly, the fraction of its units in the polymer molecules grows.

CONCLUSIONS

(1) The possibility and rate of spontaneous polymerization, and also the composition of products formed in the systems 2-acrylamido-2-methylpropanesulfonic acid–acrylamide–water and 2-acrylamido-2-methylpropanesulfonic acid–acrylonitrile–water are governed by binary association of monomers.

(2) In the system 2-acrylamido-2-methylpropanesulfonic acid–acrylamide–water, polymerization proceeds at a concentration of monomers exceeding 1.2 M; in this case, the copolymer composition depends essentially on the total initial concentration of monomers: its increase results in a relative enrichment of the product in units of sulfonic acid monomer.

(3) In the system 2-acrylamido-2-methylpropanesulfonic acid–acrylonitrile–water, polymerization starts only at a low content of the nitrile and concentration of the monomers exceeding 2.0 M, and the resulting copolymers are enriched in acrylonitrile units.

Abstract—The plasticizing and stabilizing power of new oligomeric additives containing sulfide, hydrosulfide, and sterically hindered phenolic groups was examined.

DOI: 10.1134/S1070427207080277

As a rule, polymers are not used without special additives increasing their storage and service life (stabilizers) and allowing processing under milder conditions (plasticizers).

In particular, polyvinyl chloride (PVC) cannot be molded without adding a plasticizer and is not used without stabilizers because of the poor resistance to oxygen and elevated temperatures [1].

The most widely used plasticizers for PVC are polyesters and, in particular, dioctyl phthalate (DOP) and dioctyl sebacate (DOS) [2]. However, low-molecular-weight additives show tendency toward volatilization and washout from the polymer. Polymeric stabilizers are free of these drawbacks, but, in this case, the effect of the functional groups is lower [3]. Apparently, use of oligomeric stabilizers would be the best solution.

To this end, we developed a procedure for preparing potential polyfunctional stabilizers based on an oligomeric sulfur-containing polyether [4]. The molecules of these additives contain sterically hindered phenolic (SHP) fragments scavenging peroxy radicals, which are primary products of polymer oxidation. Furthermore, they contain sulfide and hydrosulfide groups catalyzing the decomposition of hydroperoxides formed in the course of further oxidation. The polar ether bonds present in the additives may impart to them the plasticizing properties [5].

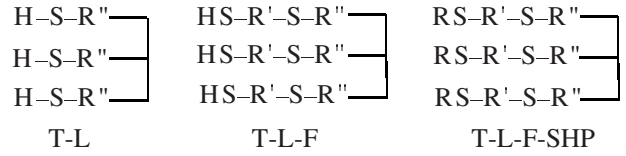
In this study, we examined the stabilizing and plasticizing performance of the new oligomeric additives with respect to PVC.

EXPERIMENTAL

In the experiments, we used suspension PVC of the S-7058-M brand and 4-dimethylaminomethyl-2,6-di-*tert*-butylphenol (Mannich's base, MB), mp 93–95°C.

Oligomeric additives were prepared from Laprol 373 commercial oligoether [TU (Technical Specification) 6-05-2042–87] [6]. Sulfur-containing Laprol with SH terminal groups (T-L-F) was prepared as follows: A flask equipped with a stirrer, reflux condenser, and thermometer was charged with chlorinated Laprol, prescribed amount of ethanol, sodium hydrogen sulfide, and formal. The mixture was stirred at 90–100°C for 4 h. The reaction progress was monitored by variation of the pH of the medium (≥9). After the reaction completion, the mixture was cooled to 30°C and excess NaSH was neutralized with orthophosphoric acid (to pH 5.5–6.5). A synthesis without formal (product T-L) was performed similarly. Polyfunctional additives with SHP fragments were prepared by reactions of T-L and T-L-F with MB. For this purpose, a flask equipped with a stirrer, reflux condenser, thermometer, and bubbler was charged with the sulfur-containing oligomers and with a calculated amount of MB (corresponding to the prescribed conversion of the SH groups of the oligomer). The mixture was stirred at 100–120°C in a nitrogen flow for 3–3.5 h. The reaction progress was monitored by the release of dimethylamine, which was absorbed by 0.1 N H_2SO_4 (with Methyl Orange as indicator). When the release of dimethylamine ceased, the reaction was considered to be complete.

The structures of the products can be schematically shown as follows:



T-L T-L-F T-L-F-SHP

where R' = $CH_2CH_2OCH_2OCH_2CH_2$; R" = $[CH_2CH_2(CH_3)]_n$; R = H,  .

The physicochemical characteristics of the products are listed in Table 1.

The content (wt %) of SH groups was determined by a laboratory procedure according to GOST (State Standard) 12812–80, and the total sulfur content, according to [7].

The kinetics of the hydroperoxide (HP) decomposition in the presence of the synthesized sulfur-containing compounds was monitored by iodometric titration. The reaction was performed in isopropanol at 90–95°C, with ethylbenzene hydroperoxide (EBHP) as example [8]. The stoichiometry of HP consumption ν was determined at an HP concentration of 0.2–0.25 M and the additive concentration ranging from 1×10^{-3} to 1×10^{-4} M. The coefficient ν was calculated by the formula

$$\nu = ([ROOH]_0 - [ROOH]_\infty)/[InH]_0,$$

where $[ROOH]_0$ and $[ROOH]_\infty$ are the initial and final concentrations of EBHP, respectively, and $[InH]_0$ is the initial inhibitor concentration.

The resistance of PVC to thermal oxidation was evaluated as the time until the onset of the polymer dehydrohalogenation, according to GOST 14041–91 (ISO 182/1–90). PVC samples to be tested were prepared as 0.1–0.2-mm-thick films on a K-403 laboratory microroller at 160°C (rolling time 15 min).

The oxidation temperature and weight loss by the polymer were determined by differential thermal and thermal gravimetric analyses with an MOM derivatograph (Hungary) at a heating rate of 5 deg min^{-1}.

The glass transition point of the PVC material was determined thermomechanically with a Hoeppler consistometer at a heating rate of 2 deg min^{-1} and a cantilever load of 50 g. Samples were prepared as pellets 5 mm high and 5 mm in diameter, using an electrically heated hydraulic press (GOST 12019–66). The pressing was performed at 180°C for 20 min. The minimal press force was 1 MN, and the plate size, 600 × 600 × 36 mm. The mold was cooled under pressure.

The oxidation of carrbon-chain polymers occurs as a chain reaction involving alkyl and peroxy radicals in the chain propagation steps [9]. The main agent branching the oxidation chain is HP; therefore, obtaining quantitative characteristics of the HP decomposition in the presence of an antioxidant is an important criterion in evaluating the stabilizing power of additives. As already noted, decomposition of HP can be catalyzed by compounds containing sulfur atoms [10]. The products prepared contain both sulfide and hydrosulfide groups.

Figure 1 shows the experimental data on the EBHP decomposition in the presence of the oligomeric addi-

tives synthesized. The sulfur-containing oligomers without SHP fragment (T-L, T-L-F) show an induction period before the onset of EBHP decomposition. Introduction of the SHP fragment eliminates the induction period of the HP decomposition. The occurrence of an induction period suggests that a secondary catalyst is formed in the course of HP decomposition with the synthesized additives. The experimental data show that all the additives catalytically decompose the HP (Table 2).

According to the experimental data, introduction of the SHP fragment leads to a sharp increase in the stoichiometric coefficient. Presumablly, the catalytic center formed in this case exhibits a higher selectivity in the process.

The stabilizing performance of the oligomers was evaluated in accordance with the appropriate GOST as the time τ until the onset of PVC dehydrochlorination in the presence of the synthesized oligomeric additives without other additives (Table 3), and also as the time until the onset of release of acidic products from PVC films. The tests were performed in an oven in air at 170°C. They showed that the time until the onset of HCl release from PVC increases upon addition of the organoelement compounds synthesized.

The stabilizer performance was also evaluated by DTA from the temperatures of polymer oxidation T_o (°C) and of 5, 10, and 50% weight loss (Table 4). The results obtained show that the oligomeric sulfur-copntaining additives based on polyethers increase the oxidation temperature and the onset temperature of the weight loss, compared to the control sample without additives.

The plasticizing effect of the oligomeric sulfur-containing additives was evaluated by depression of the glass transition point T_g. All the additives synthesized decrease T_g to different extents (Fig. 2). The largest depression of T_g of PVC films is observed with the additives containing –S– bonds and SHP fragments.

CONCLUSIONS

(1) Polyvinyl chloride can be stabilized with additives based on a polyether and containing several centers inhibiting the polymer oxidation (sulfide and hydrosulfide groups, sterically hindered phenolic fragments).

(2) The synthesized products catalytically decompose hydroperoxides.

(3) Introduction of the new additives into polyvinyl chloride leads to the depression of the glass transition point of polyvinyl chloride films and increases the time until the onset of polymer oxidation and release of hydrogen chloride.

Abstract—Copolymerization of sulfuric acid salt of *N*,*N*-dimethylaminoethyl methacrylate with acrylonitrile and acrylamide in aqueous solution was studied.

DOI: 10.1134/S1070427207080289

Polyelectrolytes based on *N*,*N*-dimethylaminoethyl methacrylate (DMAEM) salts and acrylamide (AA) are widely used for treatment of household and industrial wastewater [1]. The copolymerization of these monomers is often performed in relatively concentrated aqueous solutions. Studies of radical copolymerization of some vinyl monomers in water have revealed some interesting effects observed under certain conditions, e.g., effect of the initial concentration of the monomers on the chain propagation rate constant k_p [2, 3], abnormal acceleration of the process at high concentrations of the monomers [4], and constancy of the copolymer composition up to high conversions in copolymerization of monomers with essentially different relative activities [5]. Various authors attribute these effects to interaction of monomers and/or propagating macroradicals with the solvent [6], to variation of the ionic strength of solution in the course of copolymerization of ionic monomers [7], and to the influence exerted by association of the polymer chains [8]. More and more evidence is obtained that the polymerization of vinyl monomers in aqueous solutions is affected by association of the monomers. It has been shown that AA [9] and its *N*-substituted derivatives with ionic and nonionic substituents [10] form monomeric aggregates in concentrated aqueous solutions. Association of the monomers is mainly responsible for some abnormal phenomena observed in polymerization of acrylic acid [2, 3], AA [11], and *N*-isopropylacrylamide [12]. As shown in [13, 14], DMAEM and its salts also show increased tendency toward association in water.

In this study, we examined the influence exerted by the initial concentrations of the monomers and initiator on the composition of products in copolymerization of sulfuric acid salt of *N*,*N*-dimethylaminoethyl methacrylate (DMAEM · SA) with acrylonitrile (AN) and acrylamide in aqueous solutions.

EXPERIMENTAL

DMAEM and AN were distilled before use. AA was recrystallized from benzene. DMAEM · SA was prepared by adding an equivalent amount of a sulfuric acid solution to an aqueous solution of the monomer. The copolymerization of DMAEM · SA with AA and AN was performed in aqueous solution at 50°C in glass ampules. The total concentration of the monomers was 0.5–3.5 M. The initiator (potassium persulfate) concentration was varied in the range 0.075–2 mol % relative to the sum of the monomers. The concentrations of individual monomers were estimated by liquid (DMAEM · SA and AA) and gas–liquid (AN) chromatography.

Liquid chromatography was performed with a Praha chromatograph equipped with a UV detector (λ = 254 nm) and a 150 × 4.6-mm steel column packed with Silasorb C_{18} (particle size 10 μm). The eluent was acetonitrile. Gas–liquid chromatography was performed with a Tsvet-100 device equipped with a flame-ionization detector and a steel column, 2 m long and 3 mm in diameter, packed with 10% poly-(ethylene glycol adipate) on Chromaton N-AW. The carrier

gas was N_2 (flow rate 2×10^{-3} $m^3 h^{-1}$); vaporizer and column temperatures 70 and 40°C, respectively. The specific viscosity of aqueous solutions of the monomers was measured at 25 ± 0.1°C on an Ubbelohde viscometer (capillary diameter 0.34 mm); the relative error did not exceed 0.5%. The statistical processing of the data followed standard procedures [15, 16]. The specific viscosity was averaged over three measurements. The points were fitted with a straight line with a correlation coefficient exceeding 0.997. The adequacy of the regression equations to the experimental data was estimated with Fisher's test.

Figure 1 shows how the initial concentration of the monomers affects the composition of the forming copolymers in copolymerization of equimolar amounts of DMAEM · SA and AA in aqueous solutions. It can be seen that, for all the copolymers, there are portions in which the copolymer composition is independent of the conversion. The limiting conversion, at which the copolymer composition starts to change, largely depends on an initial concentration of the monomers. For example, in the experiment with the initial total monomer concentration of 1.2 M, the copolymer composition remains constant up to 30% conversion. At the total monomer concentration increased to 2.9 and 3.5 M, the copolymer composition does not change up to 45% and 50% conversion, respectively. Thus, appreciable changes in the running concentrations of the monomers with conversion do not lead to changes in the copolymer composition until a definite degree of conversion is reached. Also, an increase in the initial total monomer concentration from 1.2 to 3.5 M leads to a more than 10% decrease in the content of the DMAEM · SA units in the copolymers in the initial copolymerization steps.

In copolymerization of DMAEM · SA with AN, some features differ from those observed in copolymerization of DMAEM · SA with AA. Figure 2 shows that the copolymer of DMAEM · SA with AN is also enriched in the amino ester salt units, but the product composition steadily varies with the conversion (in experiments with the initial mole fration of AN exceeding 10%). To estimate the concentration effect, we performed experiments at different initial concentrations of the monomers (Fig. 3). In copolymerization of DMAEM · SA with AA (Fig. 1), an increase in the initial total monomer concentration led to a decrease in the content of the amino ester units, whereas in the copolymerization with AN, by contrast, the product was enriched with ionic monomer units.

The experiments show that the initial total monomer concentration strongly affects both the initial copolymer composition and the dynamics of its variation. The occurrence of the pronounced concentration effects and the available data on the capacity of (meth)acrylic monomers for self-association suggest that the association of the monomer plays an import-

ant role in the process. Therefore, it was of interest to specially examine the association of the monomers in the systems under consideration.

To this end, we obtained the viscosity–concentration dependences (VCDs) for solutions of individual monomers DMAEM · SA, AA, and AN and of their binary mixtures. Figures 4a and 4b show that the specific viscosity of AN solutions is a linear function of the concentratiuon, whereas for the other two monomers, significant deviations from linearity are observed. As judged from the extent of these deviations and from the concentrations at which they are observed, the capacity of the monomers for self-organization decreases in the order DMAEM · SA > AA > AN.

The viscosity–concentration dependences for DMAEM · SA and AA indicate that the structures of the forming associates vary as the concentration of the monomer solution increases. This follows from the existence of several inflection points corresponding to the critical association concentrations (CACs): for AA, at concentrations of approximately 6, 22, and 32% (Fig. 4b); for DMAEM · SA, at concentrations of approximately 2, 10, 18, and 26% (Fig. 4a, curve *1*). On the enlarged scale (Figs. 4c, 4d), it is clearly seen that the VCDs consist of several linear portions separated by bends (the dashed line shows the continuation of the initial linear portion). It should be noted that, in aqueous solutions of (meth)acrylic monomers showing pronounced surface activity, the inflections in the concentration dependences of the physical properties are associated with transitions from spherical to anisotropic micelles and then to lamellas [17]. The existence of several CACs in DMAEM · SA and AA solutions is also attributable to transformations of the forming associates.

We also examined the viscosity–concentration dependences for the systems DMAEM · SA–AA–H_2O

and DMAEM · SA–AN–H_2O. Figure 5 shows that introduction of AA into a solution of the amino ester salt leads to a certain decrease in the CAC values corresponding to inflections in the viscosity–concentration dependence (to 4, 10, 14, and 20%). Furthermore, the presence of AA in a DMAEM · SA solution causes an increase in the viscosity as compared to solutions of the individual amino ester salt. The viscosity of individual AA solutions is lower than that of DMAEM · SA solutions (Figs. 4a, 4b), i.e., a synergic increase in the viscosity is observed in the binary systems. Hence, mixed associates DMAEM · SA–AA–H_2O are more stable than aggregates of each of the monomers taken separately. The existence of monomeric associates of different compositions should affect the copolymerization processes involving DMAEM · SA and AA, because the polymerization primarily occurs in the associates. At low concentrations, the monomeric associates and hence the copolymers are preferentially formed by DMAEM · SA molecules (more strongly tending to associate). With an increase in the total monomer concentration, the relative content of AA molecules in mixed associates becomes higher, which leads to an increase in the relative content of the amide in the copolymer.

Addition of AN to a solution of the amino ester salt, by contrast, makes the viscosity of the monomeric solution lower and CAC higher (to 5, 15, and 25%). This fact indicates that DMAEM · SA associates are more stable than binary associates with AN. As the concentration of the initial solutions is raised, the relative content of associated DMAEM · SA molecules grows, which leads to an increase in the fraction of DMAEM · SA units in the copolymer. Raising the initial fraction of DMAEM · SA units in the starting monomeric mixture also leads to an increase in the relative content of the associated molecules in the solution; as a result, the deviations of the copolymer composition from the linear trend with the conversion become less noticeable as the relative content of DMAEM · SA in the starting mixture increases. At a large excess of the amino ester salt relative to the nitrile (9 : 1), the copolymer composition does not change up to 50% conversion (Fig. 2).

Thus, the features of the copolymerization in the systems DMAEM · SA–AA and DMAEM · SA–AN are largely governed by the structure of the initial monomeric associates. With the progress of the polymerization, the monomeric associates become monomeric-polymeric. Incorporation of hydrophobic macromolecules should affect the structure of the associates and hence the further reaction course. According to the model taking into account selective solvation of

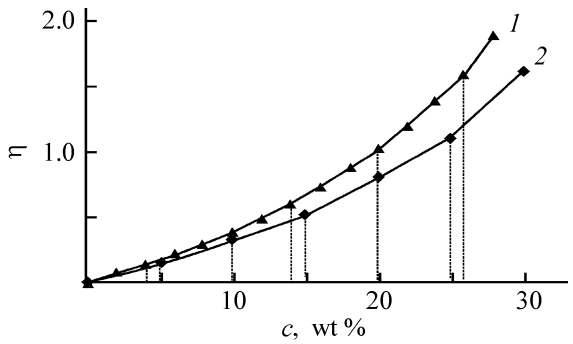

Fig. 5. Specific viscosity η of aqueous solutions of DMAEM · SA in the presence of (*1*) AA and (*2*) AN at 20°C vs. the DMAEM · SA concentration *c*. DMAEM · SA : M_2 ratio 5 : 5.

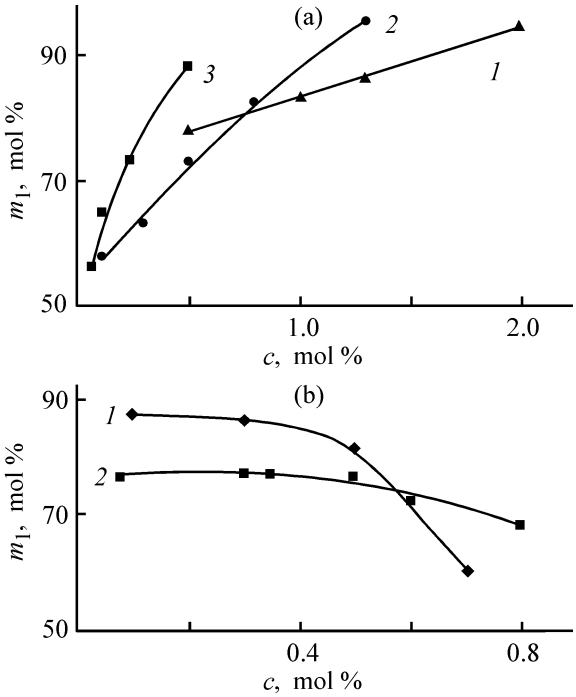

Fig. 6. Content m_1 of DMAEM · SA units in copolymers vs. initiator ($K_2S_2O_8$) concentration *c* in copolymerization of DMAEM · SA with (a) AN and (b) AA. Total monomer conversion 10%, DMAEM · SA : M_2 = 5 : 5. $[DMAEM \cdot SA]_0$, M: (a) (*1*) 0.25, (*2*) 0.50, and (*3*) 1.0; (b) (*1*) 0.50 and (*2*) 1.0.

macroradicals with monomers [18], the concentration of the hydrophobic monomer in polymeric associates increases owing to specific solvation, which leads to a rise in its content in the copolymer. This process should be favored by an increase in the molecular weight of the polymeric chains. In particular, this effect was attained with decreasing initiator concentration in experiments on copolymerization of styrene with methacrylic acid [19].

Figure 6a shows data on the influence of the initiator concentration on the composition of the DMAEM ·

SA–AN copolymer. It can be seen that as the initiator concentration in this system decreases, the copolymer gets enriched in units of the more hydrophobic monomer, AN. It should be noted that this effect is weakened as the initial concentration of the monomers decreases. This trend is consistent with the known fact that the role of monomeric solvation of polymerizing molecules in dilute solutions is weakened because of the competing effect of the solvent molecules [19].

A decrease in the initiator concentration in the DMAEM · SA–AA system (Fig. 6b) also leads to enrichment of the copolymers with units of the more hydrophobic monomer, amino ester salt. However, in contrast to the DMAEM · SA–AN system, the influence of the initiator concentration on the copolymer composition becomes considerably weaker as the initial concentration of the monomers increases. We attribute this difference to the fact that, as the solution concentration in the DMAEM · SA–AA system increases, both reagents are incorporated in monomeric associates to a greater extent; therefore, the formation of polymeric molecules only weakly affects the product composition (at least, at low conversions).

Thus, the experimental data obtained indicate that the composition of copolymers formed by copolymerization of DMAEM · SA with AN or AA in aqueous solutions is largely governed by association of the starting monomers and solvation of the propagating macroradicals by the monomers.

CONCLUSIONS

(1) The composition of copolymers formed in the systems *N*,*N*-dimethylaminoethyl methacrylate sulfuric acid salt–acrylamide and *N*,*N*-dimethylaminoethyl methacrylate sulfuric acid salt–acrylonitrile depends on the total initial concentration of the monomers.

(2) The concentration dependences of the specific viscosity of aqueous solutions of the monomers show that *N*,*N*-dimethylaminoethyl methacrylate sulfuric acid salt, acrylamide, and their mixtures are capable of association.

(3) The relative content of the hydrophobic monomer in the copolymer increases with the molecular weight of the products. This effect is partly eliminated off in copolymerization of *N*,*N*-dimethylaminoethyl methacrylate sulfuric acid salt with acrylonitrile in dilute solutions and with acrylamide in concentrated solutions.

(4) The decisive influence is exerted on the copolymer composition by association processes involving monomeric and polymeric molecules.

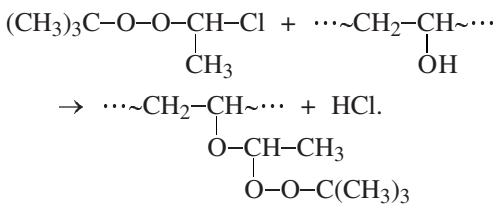
Abstract—A polymeric peroxide was prepared by the reaction of α-chloroethyl *tert*-butyl peroxide with polyvinyl alcohol. Procedures for modification of wool and polycaproamide textile materials with this peroxide were suggested.

DOI: 10.1134/S1070427207080290

Peroxides accomplishing diverse functions are widely used in preparation and processing of polymers. For example, in treatment of textile materials, they play the role of oxidants in the bleaching and finishing processes [1]. At the same time, the majority of peroxides have serious drawbacks: low stability, toxicity, and strictly specific effect. Therefore, it becomes necessary to permanently expand the assortment of peroxides and comprehensively study their physicochemical properties. Preparation and application of new peroxides with improved properties is one of important problems of the modern chemical industry, including the chemical technology of textile materials.

One of the ways to solve this problem is to prepare polymeric peroxides by polymer-analogous transformations. It seems promising to prepare polyfunctional polymeric peroxides containing reactive hydroxy groups in the side chain.

Proceeding with studies in the field of synthesis of peroxides and their applications to chemical technology of textile materials in the finishing step [2, 3], we prepared a polymeric peroxide with –O–O– groups in pendant chains by the reaction of α-chloroethyl *tert*-butyl peroxide (α-CETBP) with polyvinyl alcohol (PVA), an agent widely used in finishing, in accordance with the scheme



The starting α-CETBP was prepared by the reaction of acetaldehyde with *tert*-butyl peroxide according to the previously described procedure [2].

1-(*tert*-Butylperoxy)ethyl ether of polyvinyl alcohol (α-TBPE PVA) was prepared in chloroform.

From the structure and properties of the synthesized α-TBPE PVA, we made conclusions concerning its possible applications and, in particular, that for modification of textile materials with the aim to improve their properties. We proceeded from the fact that the textile finishing technology involves fairly wide use of textile modification processes based on interaction of reactive polymers with functional groups of the fiber, and also on graft copolymerization of vinyl monomers to the fiber by the radical mechanism in the presence of oxidants as initiators [1].

Therefore, we made laboratory trials of procedures for modification of textile materials using α-TBPE PVA both as reactive polymer and as initiator of graft copolymerization of a vinyl monomer (acrylamide) to the fiber. Trials were performed with specimens of polycaproamide and wood textile linen of various structures, and the initial and modified materials were compared.

The modification of polycaproamide textile linen was performed by treatment of the specimens with an aqueous 40–50 g l^{-1} solution of α-TBPE PVA, followed by washing and drying. The modification of wool textile materials was performed by treatment of the specimens with an aqueous acrylamide solution in the presence of α-TBPE PVA as initiator, at a total concentration of the components of 60–70 g l^{-1} and

Table 1. Properties of modified textile materials

Parameter	Polycaproamide woven fiber	Wool tricot fiber
Interweaving	Linen weave	Interlon
Surface density, g m^{-2}	110	185

Length shrinkage after five launderings, %	–	4.8/15.3
Wear resistance, cycles	–	1710/1235

* The parameters for the initial textile materials are given in the denominator.

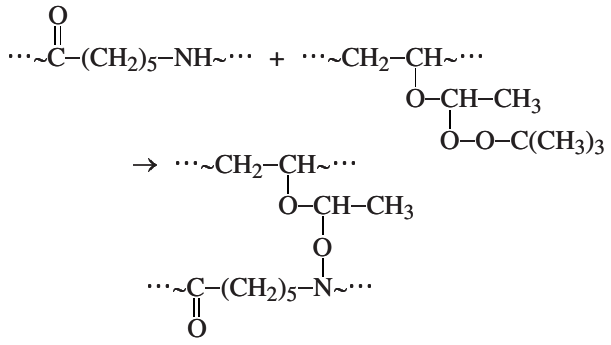
acrylamide : initiator weight ratio of (1–5) : 1, followed by washing and drying.

The treatment parameters were optimized with the aim to provide a reproducible improvement of the processing and consumer's properties of the modified textile materials. The treatment temperature (95–100°C) was determined by the onset of thermal decomposition of α-TBPE PVA. The characteristics of the modified textile materials are listed in Table 1.

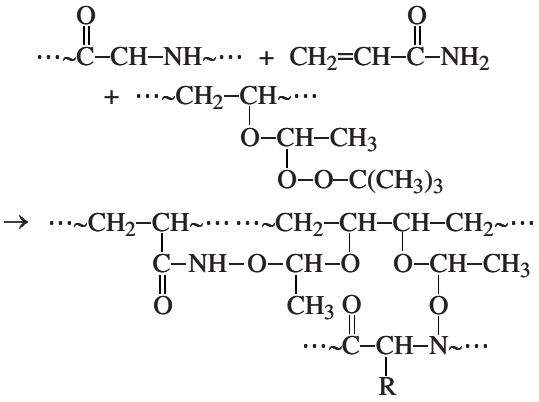
Table 1 shows that the processing and service properties of the modified textile materials are improved. For polycaproamide materials, the hygroscopicity increases by 50–60%, the material becomes more resistant to various chemicals, and the electrifiability decreases by an order of magnitude, compared with the unmodified specimens; for wool materials, the resistance to shrinkage and wear increase by 65–70 and 35–40%, respectively. The loss of strength by the modified textile materials is insignificant (12–13%), being close to the experimental error (7%).

The effect obtained upon the modification can presumably be understood as follows: the methyl and polymeric radicals formed by thermolysis of α-TBPE PVA at 95–100°C in the course of treatment of a textile material initiate the formation of polymeric macroradicals and their grafting to the fiber, and are also directly involved in these processes. This ensures formation and firm retention of a modifying polymer layer on the surface of a textile material. Taking this fact into account, we can describe the modification of polycaproamide and wool materials by the following reaction schemes.

(1) Polycaproamide + α-TBPE PVA → modified polycaproamide:



(2) Wool (keratin) + acrylamide + α-TBPE PVA → modified wool:



Thus, being an initiator of radical polymerization of the vinyl monomer (in modification of wool textile materials) and of the chemical reaction (grafting) of the polymer with a textile material, α-TBPE PVA simultaneously acts as a modifier of the fibrous substrate, incorporated in the forming modifying polymer layer. As a result, a firmly fixed thin polymer layer is formed on the material surface, imparting to the material increased hygroscopicity and resistance to various chemicals and making it less electrifiable.

EXPERIMENTAL

Chloroform used as solvent in the synthesis of 1-(*tert*-butylperoxy)ethyl ether of polyvinyl alcohol was purified by the standard procedure [4]. A reactor equipped with a stirrer, thermometer, and reflux condenser was charged with 100 ml of dried chloroform and 4.4 g (0.1 mol of monomer units) of polyvinyul alcohol. The mixture was heated at 60°C until the PVA dissolved completely. Then 15.2 g (0.1 mol) of α-CETBP was added. The mixture was vigorously stirred at 60°C for 3.5 h.

In the course of the synthesis, HCl was continuously removed from the reaction mixture by bubbling dry nitrogen and was absorbed in a NaOH solution. The reaction progress was monitored by titration of OH groups [5] in samples taken at regular intervals.

The optimal reaction parameters are 60°C, 3.5 h. A longer reaction does not lead to an increase in the product yield, and higher temperatures cause decomposition of the starting chlorinated peroxide.

After the synthesis, the mixture was washed first with 15% aqueous $NaHCO_3$ to neutral reaction and then with water, after which it was dried over anhydrous $MgSO_4$. Then the solvent was removed in a vacuum, and the product was analyzed.

The synthesized α-TBPE PVA is a yellowish odorless powder soluble in water at 60°C.

The structure of α-TBPE PVA was confirmed by IR spectroscopy, titration, and elemental analysis.

The IR spectra were taken on a Specord UV-VIS spectrophotometer in the range 500–4000 cm^{-1} from thin films. The IR data allowing identification of the corresponding structural fragments are listed in Table 2.

The content of the available oxygen was determined by iodometric titration [7]. A quantitative analysis of hydroxy groups and available oxygen showed that the degree of substitution of OH groups in the resulting polymeric peroxide, α-TBPE PVA, was 61.5%, and the available oxygen content, 6.15%. The results of elemental analysis are as follows:

Found, %: C 58.08, H 9.43.
Calculated, %: C 60.36, H 9.90.

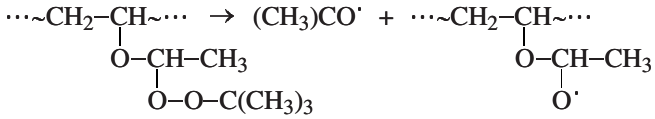
A thermogravimetric analysis (TGA) was performed with an MOM derivatograph (Hungary), with heating from 10 to 500°C at a rate of 10 deg min^{-1}. The weight loss by the synthesized α-TBPE PVA on heating was

Table 2. IR characteristics of α-TBPE PVA

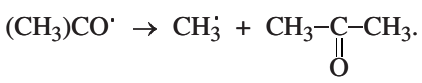
Group	IR spectrum, ν, cm^{-1}	
	experiment	[6]
–O–O–	860	890–820
C–H	2920	3600–2500
C–O–C	1150	1300–1000
–OH (bending)	1310	1300–1250
–OH (stretching)	3200	3600–2500

determined by TGA. The product shows insignificant weight loss in the range 20–95°C, followed by 65% weight loss at 96–290°C, apparently attributable to degradation of the pendant ether chains (including cleavage of –O–O– bonds) and further decomposition of the fragments. In the initial step, decomposition of α-TBPE PVA to give radicals is possible:

(1)



(2)



The weight loss in the range 300–400°C is insignificant. On further heating above 410°C, the sample undergoes complete degradation with a substantial weight loss.

The TGA data show that the α-TBPE PVA synthesized exhibits an enhanced heat resistance, compared to the most widely used commercial peroxides (decomposition temperature above 95°C). This expands its processing possibilities, making it no less valuable as an oxidant. Furthermore, the computational estimation of the ecological characteristics by pattern recognition methods [8] gives grounds to expect a low toxicity of the product (estimated hazard class III–IV).

In modification of polycaproamide textile materials, a specimen of polycaproamide fiber was immersed in an aqueous solution (50 g l^{-1}) of α-TBPE PVA prepared in an Erlenmeyer flask (solid : liquid = 1 : 30). The mixture was heated at 95–100°C for 30 min. The product was washed with water and dried to constant weight in an oven at 80°C.

The tensile strength of the specimens was determined in accordance with GOST (State Standard)

3813–72, and the hygroscopicity and electrifiability, in accordance with GOSTs 3816–81 and 19616–74. The resistance of specimens of polycaproamide textile materials to various chemicals was evaluated by the loss of strength after keeping in 40% H_2SO_4 and 40% NaOH solutions for 30 min at 50°C.

In modification of wool textile materials, a specimen of wool linen was immersed in an aqueous solution of α-TBPE PVA and acrylamide (total concentration 70 g l^{-1}, weight ratio acrylamide : α-TBPE PVA 1 : 1), prepared in an Erlenmeyer flask (solid : liquid = 1 : 30). The mixture was heated at 95–100°C for 60 min. The product was washed with water and dried to constant weight in an oven at 80°C.

The shrinkage and wear resistance were evaluated in accordance with GOSTs 8710–84 and 18976–73.

CONCLUSIONS

(1) A procedure was suggested for modification of polycaproamide textile materials with a formulation based on 1-(*tert*-butylperoxy)ethyl ether of polyvinyl alcohol. The properties of the modified material were studied.

(2) A procedure was suggested for modification of wool textile materials with a formulation based on a vinyl monomer and 1-(*tert*-butylperoxy)ethyl ether of polyvinyl alcohol. The properties of the modified material were studied.

Abstract—Trimerization of ethylene was examined as a route to isohexenes [in particular, 3-methyl-2-pentene (*cis* + *trans*)] inaccessible by dimerization of propylene.

DOI: 10.1134/S1070427207080319

Oligomerization of ethylene is of considerable scientific and practical interest as a route to linear and branched monoolefins. Linear olefins are key intermediates in production of detergents, plasticizers, and other chemicals; branched olefins are of independent interest as high-octane additives to motor fuel [1]. The commercially implemented SHOP process (Shell) allows highly selective (selectivity up to 97%) synthesis on nickel catalysts of linear α-olefins with a broad molecular-weight distribution of the oligomeric products (from C_4 to C_{20}), but the relative content of the trimers is as low as 13% [2]. On chromium catalysts patented by BP Chemicals, ethylene oligomerizes with up to 91% selectivity with respect to linear trimers (1-hexene) [3]. Catalysts based on $(PPh_3)_2 \cdot NiBr_2$ in combination with methylalumoxane or CH_3AlCl_2 allow preparation with an up to 95% selectivity of ethylene trimers; their major components are isohexenes (total content up to 75%), with an up to 47% relative content of 3-methyl-2-pentene [4].

Catalysts based on bis(acetylacetonato)palladium and boron trifluoride etherate exhibit high potential in transformations of unsaturated hydrocarbons. They show high performance (high selectivity and high conversion of the starting substrates to the target products), in particular, in positional isomerization of α-alkenes [5, 6], dimerization of vinylaromatic hydrocarbons [7, 8], telomerization of dienes with secondary amines [9–11], and polymerization of norbornene and its derivatives [12, 13].

In this study, we examined the influence exerted by various factors, including the conditions of catalyst formation, solvent, and amount of acetylacetone as an astoichiometric modifying additive, on the catalytic properties of active complexes (ACs). The goal of this study was to gain additional information on the nature of the catalytic effect of systems based on bis(acetylacetonato)palladium and boron trifluoride etherate in transformations of unsaturated hydrocarbons, with the trimerization of ethylene as example.

EXPERIMENTAL

Oligomerization of ethylene was performed in a temperature-controlled glass vessel with continuous feeding of the substrate and shaking. A solution of $Pd(Acac)_2$ in an aromatic hydrocarbon was kept in an ethylene atmosphere at a chosen temperature for 10 min, BF_3OEt_2 was added, and the oligomerization was started. After the reaction completion, the catalyst was decomposed with 3% HCl, and the organic layer was separated and dried over $CaCl_2$. The products were separated by distillation.

The ethylene oligomerization products were analyzed by GLC on a Chrom-4 gas–liquid chromatograph equipped with a flame-ionization detector. A 100 m × 0.5 mm i.d. copper capillary column was coated with vacuum oil. The ^1H NMR spectra were recorded on a Varian VXR-500S spectrometer, and the IR spectra in the range 1800–400 cm^{-1}, on a Specord M-80 spectrophotometer. The cells and

Isopropylbenzene	84.5	15.5	–	87.2	12.8	550

ampules were filled under argon. The solvents (benzene, toluene, isopropylbenzene) were dehydrated by the standard procedure and, just before use, were degassed on a vacuum installation and recondensed into an ampule over sodium mirror. The water content of the solvents was in the range 1×10^{-3}–3×10^{-3} M, as determined by Fischer titration [15]. Argon was thoroughly dried and deoxygenated [16]. Ethylene was of polymerization grade. Before use, boron trifluoride etherate was twice distilled in an argon atmosphere from calcium hydride. Acetylacetone was distilled in an argon atmosphere just before use; $Pd(Acac)_2$ was prepared according to [17], recrystallized from acetone, and vacuum-dried (1.333 Pa) at a temperature not exceeding 323 K.

In the experiments on ethylene oligomerization under the action of the catalytic system $Pd(Acac)_2$ + $30BF_3OEt_2$ (Table 1), we monitored how the ratio of ethylene dimers, trimers, and tetramers and the isomeric composition of ethylene trimers vary with time.

In the initial period, ethylene predominantly dimerizes into butenes, with 95–97% content of 2-butene (*cis* + *trans*), according to GLC. As butenes accumulate in the reaction volume, they start to codimerize with ethylene. In the next period (1.5 h after the start of the experiment), octenes (products of codimerization of hexenes with ethylene) appear in the reaction volume. Butenes, apparently, do not enter into homodimerization, otherwise octenes would appear in the reaction volume from the beginning of the experiment. The major components of ethylene oligomers by the end of the process are hexenes. Their content in the oligomer mixture reaches 61%. The isomeric composition of hexenes varies insignificantly in the course of ethylene oligomerization. The relative content of 2-methyl-2-pentene (*cis* + *trans*) by the end of the experiment is 80%.

We examined the influence exerted on the selectivity of ethylene trimerization into 3-methyl-2-pentene (*cis* + *trans*) by the solvent, B/Pd atomic ratio, catalyst concentration, and temperature.

The content of trimers in the oligomer mixture drastically decreases in the series of aromatic solvents benzene > toluene > isopropylbenzene (from 65.7 to 15.5%, Table 2). This trend may be due to competition between olefins and aromatic hydrocarbons for the vacancies in the AC coordination sphere. With an increase in the solvent polarity, secondary processes of ethylene oligomerization associated with the formation of hexenes and octenes are suppressed.

Table 3. Influence of the B/Pd atomic ratio on the conversion of ethylene into oligomers and composition of oligomers ($c_{Pd} = 8.33 \times 10^{-3}$ M, solvent benzene, $V_0 = 30$ ml, synthesis time 1.5 h)

318	64.0	36.0	–	86.1	13.9	1800

Variation of the B/Pd atomic ratio in the range 5–40 (Table 3) does not lead to noticeable changes in the selectivity of ethylene oligomerization. The ethylene conversion grows as the B/Pd atomic ratio increases to 20, as in dimerization of propylene [18]. Further increase in the B/Pd atomic ratio to 40 does not noticeably affect the ethylene conversion.

The total conversion of ethylene into oligomers is strongly influenced by the catalyst concentration. At a relatively low catalyst concentration ($c_{Pd} = 1.67 \times 10^{-3}$ M), the conversion of ethylene into oligomers can reach 3000 mol of ethylene per 1 g-at. of Pd (Table 4).

With a decrease in the catalyst concentration from 16.7×10^{-3} to 1.67×10^{-3} M, the content of butenes in the oligomer mixture rapidly increases. The fraction of ethylene dimers in the oligomer mixture also grows with decreasing reaction temperature (Table 5). By contrast, the conversion of ethylene into oligomers passes through a maximum. This is due to the fact that, on the one hand, the stability of the catalytic system and the C_2H_4 : Pd ratio increase with decreasing catalyst concentration and temperature and, on the other hand, the catalyst becomes less active with decreasing temperature. The latter factor becomes decisive at temperatures below 303 K and is

Table 6. Influence of acetylacetone additions on the conversion of ethylene into oligomers and composition of oligomers ($c_{Pd} = 8.33 \times 10^{-3}$ M, 318 K, solvent benzene, $V_0 = 30$ ml, synthesis time 1.5 h)

16.7	5.8	73.8	20.7	84.1	15.9	420

manifested in a decrease in the ethylene conversion from 3000 to 1600 mol of ethylene per 1 g-at. of Pd at 298 K. The major factor responsible for the decrease in the ethylene conversion at elevated temperatures is thermal decomposition of the catalyst to give a metallic mirror on the walls of the reaction vessel.

To raise the conversion of ethylene specifically into 3-methyl-2-pentene (*cis* + *trans*), we studied the oligomerization of ethylene in the presence of the catalytic system $Pd(Acac)_2/BF_3OEt_2$ modified with acetylacetone additions (Table 6). At the AcacH/Pd ratio of 8, the content of hexenes in the oligomer mixture reaches 81%.

Data on the oligomerization of ethylene on the catalytic system $Pd(Acac)_2$ + 5AcacH + $30BF_3OEt_2$ at 328 K are listed in Table 7. At a catalyst concentration $c_{Pd} = 3.33 \times 10^{-3}$ M, ethylene oligomerizes predominantly into 3-methyl-2-pentene (*cis* + *trans*). At the 3-methyl-2-pentene (*cis* + *trans*) content in the mixture of hexenes of up to 87.5%, and of hexenes in the oligomer mixture of up to 84.2%, the conversion of ethylene specifically into 3-methyl-2-pentene (*cis* + *trans*) is about 1000 mol of ethylene per 1 g-at. of Pd, or 74% of the total conversion of ethylene into oligomers (Table 7).

It is known that reactions of individual Pd(0) complexes of the type $Pd(PR_3)_2$ with Brønsted acids of the type HBF_4 or HBF_3OH [19–21] yield palladium hydride complexes, e.g., $HPd(PCy_3)_2BF_3X$, where X = F or OH, which can be regarded as models of complexes $HPd(L_2)BF_4$ active in transformations of alkenes.

To understand the modifying effect of acetylacetone on the catalytic system $Pd(Acac)_2$–BF_3OEt_2 in selective trimerization of ethylene, we studied the reaction of acetylacetone with boron trifluoride etherate by ^{1}H NMR and IR spectroscopy, at the ratio BF_3OEt_2 : AcacH = 2 : 1. The IR spectrum of the reaction products contains bands at 529 and 522 cm^{-1}, characteristic of the BF_4^- anion, and the ^{1}H NMR spectrum contains a signal at δ 9.7 ppm from the proton in HBF_4 apparently formed by the reaction

$$\text{AcacH} + 2BF_3OEt_2 \xrightarrow{-2OEt_2} HBF_4 + BF_2(\text{Acac}). \quad (1)$$

Thus, the modifying effect of acetylacetone can be accounted for by preliminary in situ formation of HBF_4 in the reaction mixture, followed by its involvement in the regeneration of AC by the reaction with Pd(0):

$$Pd(0) + HBF_4 + 2C_2H_4 \rightarrow [H\text{–}Pd(C_2H_4)_2]^+BF_4^-, \quad (2)$$

$$[H\text{–}Pd(C_2H_4)_2]^+BF_4^- \rightleftarrows H\text{–}Pd(C_2H_4)_2F \cdot BF_3. \quad (3)$$

CONCLUSIONS

(1) In modification of the catalytic system $Pd(Acac)_2/BF_3OEt_2$ with acetylacetone, the selectivity of formation of 3-methyl-2-pentene in low-molecular-weight oligomerization of ethylene reaches 87% relative to the sum of hexene, which, in turn, amounts to 84% of the sum of the oligomers.

(2) The modifying role of acetylacetone may consist in formation of HBF_4 in its reaction with $BF_3 \cdot OEt_2$.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Synthesis Conditions of Emulsion Poly(Methyl Methacrylate) on the Surface Structure of the Specimens

Abstract—The surface structure of poly(methyl methacrylate) specimens prepared by emulsifier-free emulsion polymerization of methyl methacrylate was examined in relation to the synthesis conditions (pH of the medium, initiator concentration, and addition of organosilicon compounds).

DOI: 10.1134/S1070427207080320

A considerable attention is received today by polymeric periodic nanosize structures, the so-called colloid crystals [1–10]. Research efforts in this field are aimed to prepare monodisperse colloid particles capable of strictly ordered stacking. A source of such particles can be found, e.g., in products of emulsion polymerization, such as polystyrene (PS) [1, 2], copolymers of styrene with methacrylic acid or glycidyl methacrylate [3, 4], poly(methyl methacrylate) (PMMA) [3, 5], poly-*tert*-butyl methacrylate [6], copolymers of methyl methacrylate (MMA) with styrene [7–9], and copolymers of 2-hydroxypropyl methacrylate with 4-vinylpyridine, obtained in the presence of organosilicon compounds [10].

The above-mentioned materials [1–10] have been synthesized by emulsifier-free emulsion polymerization yielding stable polymer dispersions with particles of identical size in water. Dispersions of this kind have been used for preparing photonic crystals [2–10]. It should be noted that the most extensively studied was the emulsifier-free polymerization of hydrophobic styrene monomer in water in the presence of a hydrophilic initiator, potassium (sodium, ammonium) persulfate [1].

The major task to be accomplished now is to find the best conditions for preparing strictly ordered colloid crystals. This makes it necessary to examine the crystal structure in relation to the preparation technique of colloid particles.

In this study, we examined the particle-size distribution of PMMA latexes as influenced by the conditions of emulsifier-free emulsion polymerization of MMA (pH of the medium, initiator concentration, and additions of alkoxysilanes). Also, we analyzed the suitability of these dispersions for preparation of colloid crystals.

EXPERIMENTAL

The PMMA specimens were prepared by emulsifier-free emulsion polymerizations of MMA in acid, neutral, and alkaline media (pH 3, 5, 7, 9, 10) with 0.07, 0.08, 0.35, and 1.00% potassium persulfate $K_2S_2O_8$ as initiator. The pH value was adjusted with 0.1 M HCl or 0.1 M NaOH, introduced into tvice-distilled water; it was measured on a Potential laboratory potentiometric titrometer. We did not introduce buffer additions to avoid further complication of the system. During polymerization, the pH of the system tends to decrease owing to decomposition of the initiator [1, 12]. In selected experiments, a prescribed amount (1, 3, 5, 7, 10, and 20 wt%) of tetraethoxysilane (TEOS) was added to the reaction mixture.

Water (10 ml) with a known pH of the medium was poured into a 50-ml three-necked flask equipped with a reflux condenser, stirrer, and capillary for argon supply, and heated to 80°C. When the desired temperature was achieved, 1.0 ml of the monomer, MMA, was added, and the mixture was stirred for 5 min. Next, 1.0 ml of a solution of the initiator, potassium persulfate (0.07, 0.08, 0.35, and 1.00% of the weight of the mixture) was added (in selected

12	10	1.00	10	260–700	485	24	〃

experiments, a prescribed amount of TEOS was also added). After that, the reaction mixture was stirred for 3–5 h at 80°C in an argon stream.

The resulting emulsion was poured onto a horizontal glass surface. After evaporation of the dispersion medium, the specimens were dried in a vacuum desiccator at 20 mm Hg and 60–80°C for 4–6 h. The dried specimens were ~400-μm-thick white opaque plates or scales, several millimeters in size (see table).

The surface of the specimens was examined by atomic-force microscopy (AFM) on Smena-A and Solver-P47 microscopes. The number-average diameter of the submicrometer particles was determined by AFM (no less than 100 measurements of the particle diameter in each case).

The emulsifier-free emulsion polymerization of MMA was carried out in the presence of potassium persulfate as initiator. Previous studies of the decomposition of potassium persulfate at 60°C in water with and without a monomer [1] have shown that the rate constant of initiator decomposition with styrene exceeds that without the monomer by an order of magnitude (8.6×10^{-5} against 5.02×10^{-6} s^{-1}). Presumably, a similar effect is also observed in the case of MMA. The initiation scheme can be represented by the equation

$$S_2O_8^{2-} + MMA \rightarrow \underset{\mathbf{A}}{SO_4^{-\cdot}} + \underset{\mathbf{B}}{{}^{-}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}\text{–}O\text{–}MMA^{\cdot}}. \quad (1)$$

Free radical **B** in reaction (2) with the monomer is converted to a macroradical:

$$\begin{aligned} &{}^{-}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}\text{–}O\text{–}MMA^{\cdot} + n\,MMA \\ &\rightarrow {}^{-}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}\text{–}O\text{–}(MMA)_n\text{–}MMA^{\cdot}. \end{aligned} \quad (2)$$

Free radical **A** can be involved in reactions (3) and (4) with water and with the monomer:

$$SO_4^{-\cdot} + H_2O \rightarrow HSO_4^{-} + {}^{\cdot}OH, \quad (3)$$

$$SO_4^{-\cdot} + MMA \rightarrow {}^{-}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}\text{–}O\text{–}MMA^{\cdot}. \quad (4)$$

Reactions (1), (2), and (4) yield macromolecular surfactants with a biphilic structure comprising an ionic hydrophilic group at the chain end and a hydrophobic part of the macrochain consisting of MMA units.

$$K^{+}\,{}^{-}O\text{–}\overset{\overset{O}{\|}}{\underset{\underset{O}{\|}}{S}}\text{–}O\text{–}\sim\!\sim$$

During polymerization in an aqueous medium, the biphilic macromolecules acting as surfactants become self-organized and form a colloid system of polymer-monomer particles. A major stabilization factor for the colloid system in emulsion-free polymeriza-

tion of styrene or MMA in the presence of potassium persulfate is electrostatic repulsion of the particles having an electric double layer on the surface [1].

Let us analyze the experimental data in the context of the influence of various polymerization conditions on the stability of the colloid system and, hence, on the uniformity in shape and size of the resulting polymer particles. It is known [2] that uniformity in shape and size of the latex particles is one of the major preconditions for preparation of colloid crystals from these particles.

Figure 1 and the table (run nos. 9–12) show that the particle-size distribution is especially broad in the case of polymerization of MMA with the maximal concentration of the initiator, 1.0 wt %.

It is well known [12] that addition of inorganic salts (electrolytes) to a colloid system causes an increase in the ionic strength of the dispersion medium (water), compression of the electric double layer on the surface of the particles, and decrease in the stability of the dispersion. At a certain, relatively low, concentration of the salt (coagulation threshold), the colloid system breaks down (coagulates) [12]. Probably, potassium persulfate, which is an inorganic salt, impairs the stability of the polymer-monomer particles at a concentration of 1.0 wt %. This is responsible for the broad particle-size distribution (see table, run nos. 9–12). These latexes are unsuitable for preparation of colloid crystals (Fig. 1).

The latex obtained by polymerization of MMA at an initiator concentration lower by an order of magnitude (0.08 wt %) in the neutral medium gives a specimen whose surface consists of nanoparticles with identical sizes and shapes (see table, run no. 3; Fig. 2a). The specimen surface becomes iridiscent.

Polymerization of MMA at a low initiator concentration (0.07, 0.08 and 0.35 wt %) in a neutral (pH 7) or weakly alkaline (pH 9) medium (see table, run nos. 2–5) yields latexes that give a strictly ordered, densely packed structures (Figs. 2–4), with the regular stacking preserved up to 20 μm. An exam-

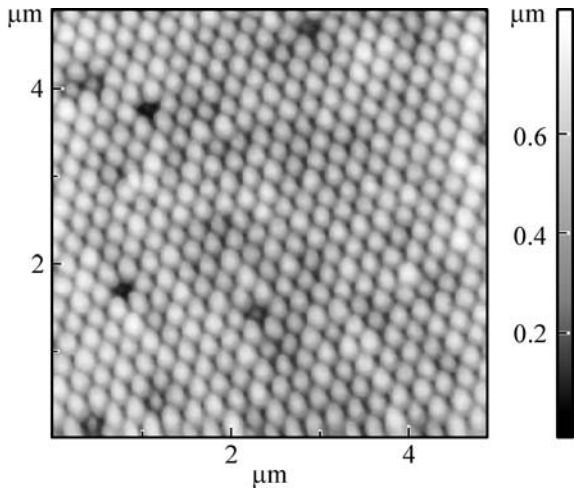

Fig. 3. Surface topograph of a PPMA emulsion obtained at pH 9 at the initiator concentration of 0.07 wt %.

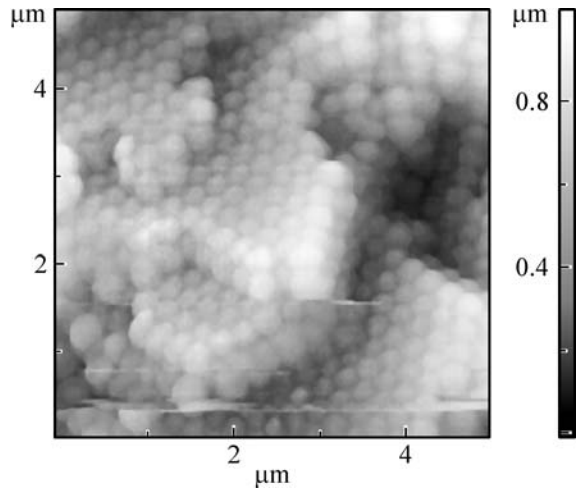

Fig. 4. End face topograph of PPMA emulsion obtained at pH 7 at the initiator concentration of 0.08 wt %.

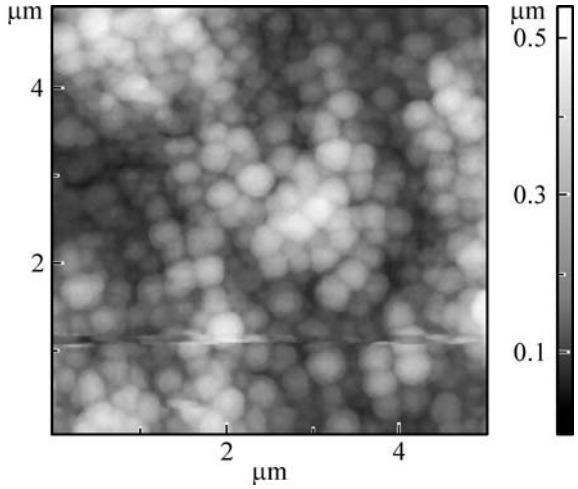

Fig. 5. Surface topograph of PMMA emulsion obtained at pH 3 at the initiator concentration of 0.07 wt %.

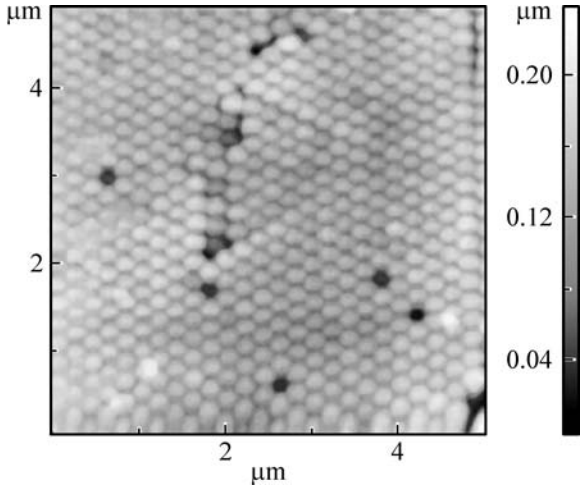

Fig. 6. Surface topograph of PMMA emulsion obtained at pH 7 at the initiator concentration of 0.07 wt %, with 20.0 wt % TEOS added.

ination of the topology of the end face of these specimens showed that, in the polymer bulk, particles of the same size are packed similarly (Fig. 4). Thus, these polymer specimens are 3*D* colloid crystals containing nearly a hundred of periods of submicrometer particles.

Acid medium (pH 3–5) in emulsifier-free emulsion polymerization of MMA causes, even at low initiator concentrations, the stability of the latex particles to decrease and their size distribution to broaden (see table, run nos. 1, 7). These latexes give specimens with a weakly ordered surface structure (Fig. 5).

As is known [11], hydrogen ions (acid medium) catalyze thermal decomposition of potassium persulfate in an aqueous medium. The activation energy of thermal decomposition of potassium persulfate in neutral and alkaline media (0.1 M NaOH) is 33.5 kcal mol^{-1}, and that in an acid medium (0.1 M $HClO_4$) is considerably lower, 26.0 kcal mol^{-1} [11]. Moreover, thermal decomposition of potassium persulfate proceeds by a different mechanism in an acid medium. The catalytic thermal decomposition of the initiator is described by the equations

$$S_2O_8^{2-} + H^+ \rightarrow HS_2O_8^- \rightarrow SO_4 + HSO_4^-, \quad (5)$$

$$SO_4 \rightarrow SO_3 + 1/2O_2. \quad (6)$$

There are no data on the kinetics and mechanism of catalytic decomposition of potassium persulfate

in an acid medium in the presence of monomers (styrene, MMA).

The data reported in [1, 11] suggest that reactions (5) and (6), characterized by a decreased activation energy, will compete with reaction (1), which is the basic reaction of synthesis of a biphilic surfactant stabilizing the colloid system. This will decrease both the surfactant concentration and the stability of the colloid system.

Interestingly, the emulsifier-free emulsion polymerization of MMA in a neutral medium with a low concentration of the initiator (0.07 wt %) and 20 wt % TEOS added yields a latex forming the most perfect colloid crystal (see table, run no. 8; Fig. 6). The same process with 1 wt % initiator yields latexes with the broadest particle-diameter distribution (see table, run nos. 9–12).

Upon drying in a vacuum desiccator at 60–80°C for several hours, the spherical particles in the specimens of the colloid crystals undergo minor deformations (Figs. 2–4). In the presence of TEOS, the MMA polymerization is paralleled by a sol-gel process yielding a thin layer of cross-linked silicon oxide on the surface of the latex particles. Probably, this layer prevents deformation of the latex particles, and their initial spherical shape is better preserved upon drying of the colloid crystal (Fig. 1).

Thus, formation of a strictly ordered surface structure of the colloid crystal from the latex prepared by emulsifier-free emulsion polymerization of MMA is most probable in the neutral medium with the minimal percentage (by weight) of the initiator and without alkoxysilane additions.

CONCLUSIONS

(1) Emulsifier-free emulsion polymerization of methyl methacrylate, initiated by potassium persulfate, yields colloid particles of identical shape and size at the lowest, within the range examined (0.07–0.35 wt %), concentration of the initiator in the reaction mixture.

(2) Formation from latex of a strictly ordered surface structure of the poly(methyl methacrylate) specimens suitable for preparation of colloid crystals is most probable when the emulsion polymerization of methyl methacrylate is performed in a neutral medium with the minimal percentage (by weight) of the initiator.

Abstract—New thin polymeric films were prepared electrochemically on the basis of Ni(II), Pd(II), and Pt(II) complexes with 8-quinolinol, and conditions of synthesis were optimized. Basic characteristics of the films such as the thickness, charge transfer rate in the polymeric matrix, and photovoltaic effect were determined.

DOI: 10.1134/S1070427207080332

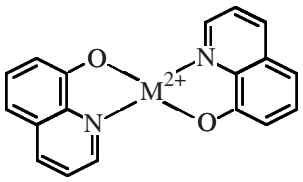
This study was aimed at solving fundamental problems related to synthesis and characterization of new thin-film organometallic polymers. Among basic characteristics of these materials are the electrical conductivity, electrochromism, photosensitivity, and luminescent properties. The necessity for improving electrochemical and photoelectrochemical characteristics, including the efficiency of charge transfer in the bulk of the polymer phase, stimulates a search for new organometallic polymers that can be used in devices for accumulation and conversion of solar energy (environmentally friendly solid-state voltaic cells and photosensors), and also as corrosion inhibitors, catalysts, materials for electrochromic devices, and chemical sensors. Studies in this field are actively pursued today.

Previously, a series of electroactive and photosensitive polymers have been synthesized by electrochemical oxidation on the basis of transition metal complexes with tetra- and bidentate Schiff bases containing such coordination cores as $N_2O_2^-$, N_4^-, and NO^- [1–5].

In this study, we examined transition metal complexes with another bidentate ligand, 8-quinolinol (qol), which, like Schiff bases, contains two functional groups with N and O heteroatoms involved in coordination to the central atom. In this case, the nitrogen atom is arranged in the pyridine ring of 8-quinolinol, in contrast to the previously studied ligand meSal [2], which coordinates to the metal via the nitrogen atom of the imino group.

Another distinctive feature of complexes with qol ligand, compared to complexes with Salen-like ligands, is their *trans* geometry. Therefore, one of the main goals of this study was to understand the effect of the qol ligand structure and coordination mode to the metal center on the electropolymerization of the complex.

Electropolymerization of complexes $[M(qol)_2]$, where M = Ni(II), Pd(II), and Pt(II),



was carried out according to the procedure described in [2–5]. First, we optimized the synthetic conditions. The largest thickness of poly$[Ni(qol)_2]$ films (0.17 μm) was obtained by 15-fold cycling of the potential of a Pt wire electrode from 0.0 to 1.3 V in the acetonitrile solution of the complex (Fig. 1). As can be seen, potential cycling is accompanied by an increase in both the anodic and cathodic current peaks in the cyclic voltammograms and also by a gradual shift of peaks. As a result, by the 15th cycle, when the growth of the current peaks virtually ceases, there are one anodic peak at E_{pa} = 1.0 V and one cathodic peak at E_{pc} = 0.5 V. It has been demonstrated previously that an increase in the hight of the anodic and cathodic peaks is caused by the growth of the electroactive polymer film on the electrode, which can be observed visually. In this case, the transfer from the reduced form to the oxidized form is accompanied by an electrochromic effect (originally light green color becomes reddish yellow).

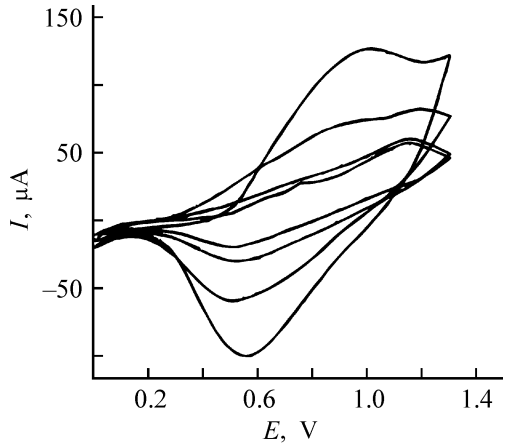


Fig. 1. Cyclic voltammograms after 1, 2, 5, and 15 potential sweep cycles (1 mM $[Ni(qol)_2]$ in 0.1 M Bu_4NClO_4/CH_3CN; v_s = 0.05 V s^{-1}). (*I*) Current and (*E*) potential.

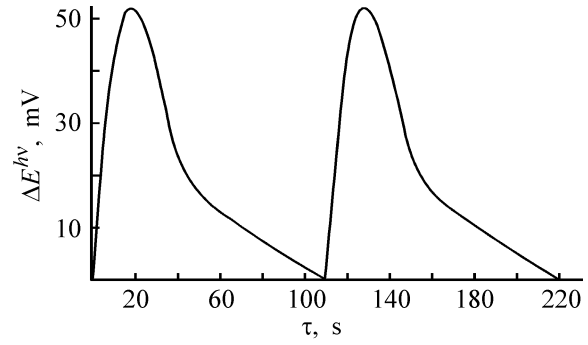

Fig. 2. Change in the potential $\Delta E^{h\nu}$ on the electrode with a deposited polymer film of $[Pd(qol)_2]$ (h_f = 0.07 μm) vs. the time τ of irradiation with polychromatic light in 0.1 M CH_3CN/Bu_4NClO_4.

Electrochemical synthesis of the polymer on the basis of the Pd complex under similar conditions gives a thinner (0.07 μm) and, therefore, less stable conducting layer. It was demonstrated in studying the possibility of oxidative polymerization of $[Ni(qol)_2]$ that an electroactive polymer is not formed in the potentiostatic mode at accumulation potentials *E* of +0.8, +0.9, +1.0, +1.1, and +1.2 V and fixed accumulation time of 10 min, suggesting that mechanisms of electropolymerization of the complexes in the dynamic and static accumulation modes are different.

A distinctive feature of $[Pt(qol)_2]$ is that it can be polymerized in the static mode at an accumulation potential E_{ac} = 1.0 and time τ_{ac} = 30–40 min in a dichloromethane solution of the supporting electrolyte. In this case. the thickness of the resulting films are even thicker (up to 2.2 μm) higher than that obtained with [PtSalen] [3].

The most important feature of poly$[M(qol)_2]$ is that they can occur in thin films in both oxidized and reduced forms. The IR spectra of poly$[Pt(qol)_2]$ confirmed the suggestion that the oxidized form is conducting, while the reduced form exhibits dielectric properties [1]. Poly$[Pt(qol)_2]$ in the oxidized form is characterized by a virtually full absorption ($T \sim 0$) in the near IR range (14000–4000 cm^{-1}), which confirms the presence of free charge carriers in the polymer matrix. At the same time, for the reduced form, the transmission increases, which suggests a decrease in the concentration of the radical cations [6] and loss of the conductivity.

Therefore, it is the ability of polymeric systems of this kind to undergo reversible electro- and photoinduced transitions from one form to another that is responsible for their conductivity, electrochromism, and photoelectrochemical activity. In this context, it was important to study features of charge transfer in the bulk of the polymer phase. Quantitatively, the charge transfer rate is characterized by the diffusion coefficient. The maximal diffusion coefficient of poly$[Ni(qol)_2]$ is 1.4×10^{-12} cm^2 s^{-1}, which is well consistent with that of Ni(II) complexes with Salen and MeSal in the films of similar thickness (~0.2 μm) [2, 4, 5]. The highest charge-transfer rate in the polymer matrix was observed for poly$[Pt(qol)_2]$ (D_{ct} = 8.0×10^{-11} cm^2 s^{-1}), which accounts for the high degree of reversibility of redox processes and for the resulting considerable electrochemical stability.

All the polymers investigated exhibit photoelectric activity. Photons excite some molecular fragments of the polymer, and oxidized fragments of the complex are accumulated by virtue of photoexcitation of the reduced form of the polymer and chain charge transfer, causing an abrupt change in the potential and the photovoltaic effect. The leveling off of the curve can be attributed to the attainment of a steady state in the system under irradiation, in which the rates of formation of excited fragments and of their deactivation are equal. In repeated photoexcitation of the electrode–polymer system, the photovoltaic effect is reproduced, which suggests the stability of the polymer to the action of light and reversibility of charge transfer in the bulk of the polymer phase.

In the supporting electrolyte solution continuously irradiated with polychromatic light, we observed an increase in the potential of the electrode with a deposited poly$[M(qol)_2]$ film in the reduced or partially oxidized state ($\Delta E^{h\nu}$). The maximal photovoltaic effect in 0.17-μm thick poly$[Ni(qol)_2]$ and 0.07-μm thick poly$[Pd(qol)_2]$, synthesized in the potentiodynamic mode in acetonitrile as a solvent, was 80 and 50 mV, respectively (Fig. 2). These values are well

comparable with the photovoltaic effect in poly-*trans*-[Ni(MeSal)$_2$] ($\Delta E^{h\nu}$ = 85 mV) [2]. However, for 1.6-μm thick film of poly[Pt(qol)$_2$], prepared in the static mode in the dichloromethane solution of the supporting electrolyte, we obtained $\Delta E^{h\nu}$ = 350 mV, which is among the highest values ever obtained for thin-film organometallic polymers, being well comparable with such classical photoelectroactive system as poly[PtSalen] ($\Delta E^{h\nu}$ = 370 mV) [3].

Finally, an important feature of [Pt(qol)$_2$] is that it can act (in contrast to other investigated monomeric complexes) as a monomeric unit in electrochemical synthesis of thin-film conducting polymers. Also, it can effectively form macromolecular ensembles via a photochemical reaction in the presence of atmospheric oxygen.

CONCLUSIONS

(1) Poly[Ni(qol)$_2$] and poly[Pd(qol)$_2$] films with the best characteristics (maximal thickness of the conducting layer and diffusion coefficient) are formed in the potentiodynamic mode with potential cycling from 0.0 to 1.3 V.

(2) [Pt(qol)$_2$] can be electrochemically polymerized in both static and dynamic modes. Under static conditions at E_{ac} = 1.0 V, the thickest and most electrochemically stable films are formed.

(3) Charge transfer in thin films of [M(qol)$_2$]-based polymers under the action of polychromatic light is characterized by high rate and high degree of redox reversibility ($\Delta E^{h\nu}$ = 50–370 mV).

Abstract—A method for preparing highly permeable polyelectrolytes by the reaction of homo- and copolymers of vinyloxyethylamine with various glycidyl ethers of phenol-aldehyde compounds was developed. The physicochemical characteristics of these polyelectrolytes were studied.

DOI: 10.1134/S1070427207080344

In the development of ion-exchange polymeric mamerials based on various polymers of monoethanolamine vinyl ether, not only the composition and characteristics of functional groups but also the features of the structure of epoxy compounds as cross-linking agents are very significant. From this standpoint, nitrogen- and oxygen-containing aromatic epoxy compounds are of great interest for synthesis of polymers with high softening point and heat resistance. Ion-exchange polymers based on these compounds have a set of unique service characteristics. They are widely used for solving various chemical and technological problems, e.g., in recovery of ions of noble, rare, and nonferrous metals and purification of medical products [1–5]. Therefore, one of ways to improve physicochemical characteristics of ion exchangers of the polycondensation type is to introduce phenolic fragments into the structure of epoxy compounds. The homogeneity of functional groups of commercially available glycidyl ethers of phenol- and aniline-phenol-formaldehyde compounds and also the presence of alternating aromatic nuclei in their structure improves the chemical and thermal stability and also the regularity in the steric structure of the polyelectrolytes.

In this study, we prepared polyfunctional ion exchangers by polycondensation of homo- and copolymers of vinyloxyethylamine (VOEA) with glycidyl ethers of phenol-formaldehyde compounds and studied their physicochemical characteristics.

EXPERIMENTAL

Phenol epoxy compounds (PECs), namely, glycidyl ethers of phenol-formaldehyde (PFC), phenol-acetaldehyde (PAC), and aniline-phenol-formaldehyde (APFC) compounds, were synthesized by standard procedures [6]. Polymers based on VOEA, namely, homopolymer of VOEA (PVOEA) and copolymers of VOEA with *N*-vinylpyrrolidone (VOEA–NVP) and 2-methyl-5-vinylpyridine (VOEA–MVP), were synthesized at a 25 : 75 molar ratio of the monomers by the well-known procedure [7].

Highly permeable ion exchangers were synthesized by polycondensation of homo- and copolymers of VOEA with PECs in isobutanol at 60–120°C for 8–10 h [8]. The reaction mixture was poured off on a pan and the solvent was evaporated at 80°C. The final product was crushed, washed with ethanol to remove unchanged substances, dispersed, and a fraction with a grain size of 0.25 mm was taken [9, 10].

To evaluate the chemical resistance of ion exchangers to acid and alkaline solutions [9], two 1-g portions of ion exchanger were placed in 250-ml round-bottomed flasks. One portion was poured over with 100 ml of 5 N H_2SO_4, and the other, with 100 ml of 5 N NaOH. The mixtures were heated with a reflux condenser on a boiling water bath for 30 min. Then the mixtures were cooled to room temperature and the ion exchanger was separated by filtration. If necessary, the sorbent was converted to the OH form,

washed with distilled water, and its static exchange capacity (SEC) was determined. The chemical resistance X (%) was determined by the formula

$$X = (\mathrm{SEC}/\mathrm{SEC}_0) \times 100,$$

where SEC and SEC_0 are the static exchange capacities before and after treatment with acid and alkaline solutions, respectively.

To determine the chemical resistance of ion exchangers to oxidant solutions, a weighed portion of ion exchanger (1 g) was poured over with 100 ml of 10% H_2O_2 and kept at room temperature for 48 h with intermittent stirring. The polymer was separated by filtration, converted to the OH form, washed with distilled water, and its SEC for HCl was determined.

A study of how the ratio of the initial components, time, and curing temperature affect SEC showed that, as the concentration of VOEA polymers is raised from 1 : 1 to 1 : 4 (Table 1), the SEC of ion exchangers increases. In the case of APFC : VOEA–NVP, as the SEC of the ion exchanger decreases, concentration of copolymer is raised, because *N*-vinylpyrrolidone units contain no ionic groups.

The conditions of prepolymer curing significantly affect the characteristics of the resulting ion exchangers. We found (Tables 2, 3) that the gels synthesized should be cured at 80–100°C, depending on the condensation temperature and nature of VOEA polymers, for 8–10 h.

The samples of the polyelectrolytes synthesized under optimal conditions have SEC for HCl (0.1 N)

within the range 1.3–10.9 mg-equiv g^{-1} and a limited specific swelling capacity. In treatment with concentrated 5 N H_2SO_4, 5 N NaOH, and 10% H_2O_2 solutions, the loss of the exchange capacity does not exceed 6%.

The resulting polyelectrolytes extract selectively gold ions from hydrochloric acid solutions in a wide concentration range. A study of the kinetics of sorption of gold ions by ion exchangers showed that the nature of epoxy compound does not affect the extraction rate. For example, for the ion exchangers based on FPC, the maximum degree of sorption is reached within 3 h, and in the first 0.5 h of contact, the sorbents absorb 50% of metal ions.

Thus, anion exchangers based on VOEA polymers and various PECs are highly efficient sorbents for recovery of gold ions from hydrochloric acid solutions. These anion exchangers extract 94.0–99.9% of gold ions; in so doing, they keep their sorption characteristics in a wide range of HCl concentration, which suggests their high chemical stability and selectivity.

CONCLUSIONS

(1) New ion exchangers were prepared by condensation of commercially available glycidyl ethers of phenol-aldehyde and aniline-phenol-formaldehyde compounds with homo- and copolymers of vinyloxyethylamine.

(2) The chemical stability of ion exchangers based on glycidyl ethers of phenol-aldehyde compounds and vinyloxyethylamine polymers in solutions of 5 N acids and alkalis and in 10% H_2O_2 is 95–99%.

(3) The polyelectrolytes synthesized selectively extract gold ions from hydrochloric acid solutions in a wide concentration range. The degree of sorption reaches 98–99%.

Abstract—Low-expenditure method for synthesis of $K_2[VO(O–O)_2F]$ was developed. The solubility of this compound in water and the stability of its aqueous solutions were determined and its bactericidal activity, exceeding that of hydrogen peroxide by a factor of 1.5, was analyzed.

DOI: 10.1134/S1070427207080356

Peroxovanadates are widely used as catalysts for reactions of hydroxylation of aliphatic and aromatic hydrocarbons, epoxidation of olefins, and other processes [1]. However, they have not been used as carriers of active oxygen so far, although, e.g., $K_3[V(O–O)_4]$ contains 21.6% O_{act}, which corresponds to 45.9% H_2O_2.

Fully substituted peroxovanadates of alkali metals are poorly soluble in water. Until recently, partly substituted $M_3[VO_n(O–O)_{4-n}]$ have not been obtained in individual state. Synthesized $K_3[VO(O–O)_3]$ has also been found to be poorly soluble in water, which creates difficulties in attempts to find ways to use compounds of this group as sources of active oxygen in the field of, in particular, disinfection.

Fluorine-substituted peroxovanadates are soluble in water. Fluoroperoxovanadates of various compositions are known: $M_2[V(O–O)_3F]$, (M = NH_4, K, Na); $(NH_4)_3[V(O–O)_2F_4]$; $(NH_4)_3[VO(O–O)F_4]$; hydrated $M[VO(O–O)F(H_2O)_2]$, (M = K, Rb, Cs, NH_4); and hydroxylated forms $(NH_4)_2[VO(O–O)F_2OH]$ [1]. The most stable among fluoroperoxovanadates are the compounds $M_2[VO(O–O)_2F]$, (M = K, Rb, Cs, NH_4 [2–4].

In this study, a low-expenditure method for synthesis of $K_2[VO(O–O)_2F]$ was developed, its solubility in water was determined, stabilizers for its aqueous solutions were chosen, and the bactericidal activity of the vanadate was found to be 1.5 times that of hydrogen peroxide.

EXPERIMENTAL

According to published data, V_2O_5 or KVO_3, KF, and a solution of hydrogen peroxide serve as starting materials for synthesis of $K_2[VO(O–O)_2F]$. The fluoroperoxovanadate of this composition was first obtained in [2] by dissolution of V_2O_5 in water and addition to the resulting solution of potassium fluoride and a 30% solution of hydrogen peroxide. At –10°C, a precipitate was formed, which was filtered, washed with acetone, and dried.

In [2], the compound was synthesized by mixing solutions of H_2O_2, KF, and KVO_3. The product was precipitated with ethanol. To obtain salts of Na, K, Rb, Cs, and NH_4, a mixture of V_2O_5 and the respective fluoride was dissolved in dilute hydrogen peroxide, and a concentrated solution of the corresponding alkali was added with heating. The potassium salt was obtained in the form of crystals in [4] by dissolution of a dry mixture of V_2O_5 and KF in a 15% solution of hydrogen peroxide. Under the conditions of natural evaporation of water at 20°C, coarse yellow crystals precipitated.

Using the simplest method [4], the dependence of the composition of the forming fluoroperoxovanadate on the ratios KF : V_2O_5 and H_2O_2 : V_2O_5 between the starting components was studied.

Experiments were performed by dissolution of a ground mixture of V_2O_3 and $KF \cdot 2H_2O$ in hydrogen peroxide of various concentrations. The resulting transparent yellow solution was placed on a polymeric tray and water and an excess of H_2O_2 were removed

at 20°C with a directed flow of air until a mixture half-composed of a solid phase was obtained. The precipitate was filtered off using a polymeric film with fine openings, washed with ethanol, and dried in a desiccator over sulfuric acid. The product was analyzed for the content of hydrogen peroxide by permanganatometry. Potassium was determined by the weighing method. The results obtained are listed in Table 1.

As can be seen in Table 1, the amount of potassium fluoride, sufficient for $K_2[VO(O–O)_2F]$ to be formed, corresponds to the molar ratio KF : V_2O_5 = (8.1–8.3) : 1. Apparently, there is little point in introducing potassium fluoride [2, 3] with a KF : V_2O_5 ratio of approximately 20 : 1. The amount of hydrogen peroxide can be reduced from H_2O_2 : V_2O_5 = 29 : 1 to 19 : 1.

Lowering the introduced amount of hydrogen peroxide further leads to a decrease in the content of active hydrogen in the solid product. In addition, hydrogen peroxide should not be used as a 30% solution, because it is difficult to remove its excess in such a concentrated form with ethanol. The yield of fluoroperoxovanadate is 56–60%.

According to [2], potassium fluoroxodiperoxovanadate is stable in storage in a closed state. Under polythermal conditions, the vanadate decomposes at 150°C. No quantitative data on the solubility of $K_2[VO(O–O)_2F]$ in water could be found in the literature. The study performed demonstrated that a saturated solution of the vanadate contains $4.9 \pm 0.2\%$ H_2O_2 at 20 ± 2°C. On the assumption that the dissolution process is not complicated by side reactions and occurs in accordance with the equation

$$K_2[VO(O–O)_2F] + 2H_2O = KVO_3 + K + 2H_2O_2,$$

the content of the peroxovanadate in the saturated solution is 16.4%.

Solutions of potassium fluoroxodiperoxovanadate in water are unstable. At H_2O_2 concentrations in the range 1.2–4.9%, they lose more than half of hydrogen peroxide in 24 h. In the presence of stabilizers, the loss of hydrogen peroxide decreases (Table 2).

As follows from Table 2, the most efficient stabilizer is sodium diphosphate; however, the decrease in the loss of hydrogen peroxide upon addition of this stabilizer in an amount of 4–8% is insufficient for the solutions to be stored for more than 24 h.

Measurements of the rate constant of inactivation of a suspension of *Bac. anthracoides* (strain 250, concentration $n \times 10^7$ cfu ml^{-1}) at 20±2°C [5] demonstrated that the constant K^{II} for $K_2[VO(O–O)_2F]$ is 0.1245, which is 1.5 times larger than the value of K^{II} for hydrogen peroxide (0.08±0.015) and 1.2 lower than K^{II} for $KF \cdot H_2O_2$ (0.1485±0.0124).

Apparently, potassium fluoroxodiperoxovanadate, stable in the solid state, can find use in disinfection with a limitation that its aqueous solutions should be used not later than 24 h after being prepared.

In view of the adaptation of microorganisms to permanently used disinfectants, development of new antibacterial preparations will ever be a topical task.

Potassium fluoroxodiperoxovanadate supplements the store of effective disinfectants in use.

It should be noted that solutions of fluoroxodiperoxovanadate contain, in addition to hydrogen peroxide, catalytically active vanadium compounds. It is known that peroxo complexes of vanadium are used as catalysts in oxidation of hydrocarbons with hydrogen peroxide. Oxidation of sulfides to sulfoxides is also carried out with compounds of vanadium(V) used as catalysts [7]. Probably, the increased, compared with hydrogen peroxide, bactericidal activity of the fluoroperoxovanadate solution is determined by the catalytic effect of vanadate. However, it is also possible that the decontaminating activity increases because the solution contains potassium fluoride, whose fluoride ions bind part of hydrogen peroxide into the complex anion $[F\ldots H–O–O–H]^-$ [8]. Hydrogen peroxide bound with the fluoride anion is deformed and more reactive than free or hydrated molecules of H_2O_2. It is these two factors that predetermine the increase in the decontamination constant of $K_2[VO(O–O)_2F]$ solutions, compared with hydrogen peroxide itself. Possibly, not only solutions of peroxovanadates, but also hydrogen peroxide solutions will exhibit an increased bactericidal activity upon introduction into the latter of a certain amount of fluoroperoxovanadates as catalysts.

CONCLUSION

The optimal synthesis conditions of potassium fluoroxodiperoxovanadate $K_2[VO(O–O)_2F]$ were found. The solubility of the vanadate in water at 20±2°C is 16.4 wt %, or 4.9±0.2% in terms of H_2O_2. The vanadate exhibits a bactericidal activity that is 1.5 times that of hydrogen peroxide.

Abstract—Effect of fullerene black additives on the antifriction properties and wear resistance of F-4 and F-4K20 fluoroplastics in sliding friction against steel with water lubrication was examined.

DOI: 10.1134/S1070427207080368

Polytetrafluoroethylene (PTFE) of F-4 brand [GOST (State Standard) 10007–80, Russia] possesses good antifriction properties and, at the same time, exhibits enhanced wear and cold flow under load. This makes is suitable as a structural material only under low loads. The wear resistance of F-4 can be improved by introduction of fillers [1, 2].

Most widely used materials based on F-4 fluoroplastic are the materials with various concentrations of carbon powder fillers. For the support surfaces of tribotechnical systems operating in water, the filler of choice is coke. The most widely used composition, F-4K20 [3], contains 80% F-4 and 20% coal coke. This composition exhibits a high wear resistance, low deformation under load, and low hygroscopicity. The major drawback of F-4K20 is the rather high friction coefficient (2–3 times that of F-4). To improve the wear resistance, the concentration of a carbon-containing filler is occasionally raised to 40–50%. However, introduction of over 20% filler into F-4 sharply decreases the strength of the composite.

In this study, we prepared and examined a fairly inexpensive antifriction polymeric material (APM) combining the low friction coefficient of F-4 and the high wear resistance of F-4K20.

EXPERIMENTAL

We used fullerene black (FB) produced by the Neo-Tek Research and Production Company, St. Petersburg [4]; it was introduced into F-4 in amounts of 1, 3, 5, or 10%. The fullerene black yielded by the initial extraction of fullerenes with toluene (FBE) was introduced into F-4 and F-4K20 in an amount of 1%. In all the cases, the soot introduction was in conforming with the technical specifications concerning F-4K20 preparation [3].

The tribological tests were run on a 2070 SMT-1 standard roller friction machine by the previously developed technique [5]. The samples tested were 10-mm-thick flat plates with rectangular cross sections. As a counterbody served a roller fabricated from 18Kh2N4MA steel [GOST (State Standard) 4543–71], rotating at 400 rpm, which corresponds to a sliding velocity of 1 m s^{-1}. The circularly polished working cylindrical surface of a roller with a width of 16 mm had the roughness R_a = 0.65 μm and was immersed by 6 mm into a water bath during the tests.

On the sample surface, a wear groove with an area of 30–50 mm^2 was preliminarily formed, so that the subsequent tests were made with conform counterbodies with a run-in friction contact. Successively

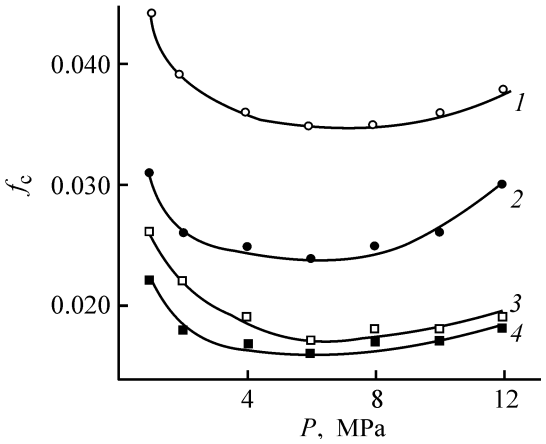

Fig. 1. Friction coefficient f_c vs. contact pressure P for sliding friction against steel with water lubrication: (*1*) F-4 and (*2*–*5*) F-4 + FB, %: (*2*) 1, (*3*) 3, and (*4*) 5.

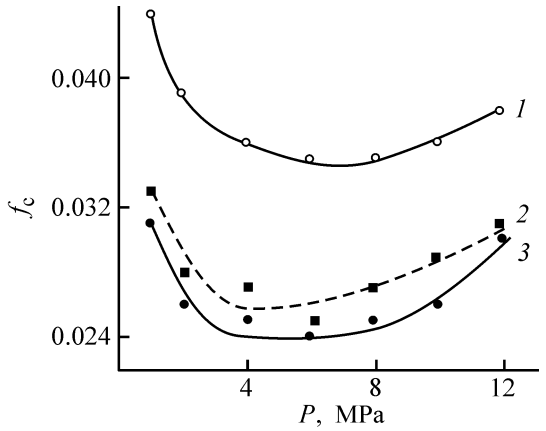

Fig. 3. Friction coefficient f_c vs. contact pressure P for friction against steel with water lubrication: (*1*) F-4, (*2*) F-4 + 1% FBE, and (3) F-4 + 1% FB.

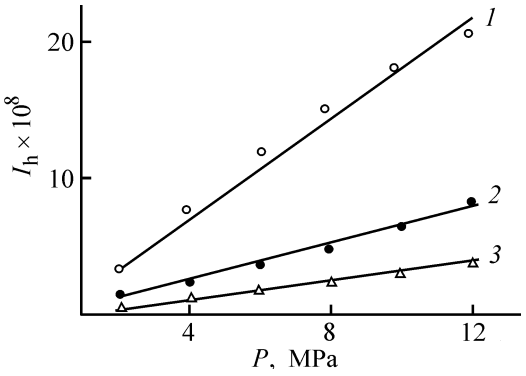

Fig. 2. Linear wear rate I_h vs. contact pressure P for sliding friction against steel with water lubrication: (*1*) F-4 and (*2*, *3*) F-4 + FB, %: (*2*) 1 and (*3*) 10.

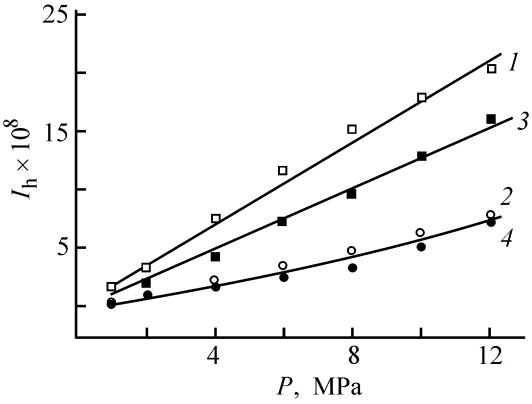

Fig. 4. Linear wear rate vs. contact pressure P for friction against steel with water lubrication: (*1*) F-4, (*2*) F-4 + 1% FB and F-4 + 1% FBE, (*3*) F-4K20, and (*4*) F-K420 + 1% FBE.

increasing normal loads F_N were applied to the sample. The time of tests at each load was 300 s. We determined the friction coefficients f_c and linear wear rates I_h, averaged over each test. Three to six tests were run for each load. The tribological parameters were determined as arithmetic means. The relative rms errors were within 5–10%.

At the working pressures within 1–10 MPa, addition FB causes the friction coefficient f_c to decrease to 0.015–0.021 (Fig. 1), and the linear wear rate I_h, to $(0.39–2.9) \times 10^{-8}$ (Fig. 2), i.e., f_c decreases by a factor of 1.5–2, and I_h, by a factor of 2–7.5.

Tests of samples of fluoroplastics F-4 and F-4K20 with addition of FBE revealed only minor deterioration of the characteristics relative to those FB (Figs. 3, 4). Both kinds of fullerene black produce virtually identical effects. It should be noted that adding only 1% of either fullerene black to F-4 leads to a significant reduction in I_h under water lubrication (in this parameter, F-4 is superior to F-4K20), and simultaneously, the friction coefficient tends to decrease (Figs. 3, 4). At contact pressures within 1–14 MPa, both the friction coefficient f and linear wear rate I_h decreased 2–3-fold.

In tests on friction against steel with water lubrication, as little as 1% FBE added to the F-4 and F-4K20 samples caused the permissible working pressure in friction contacts to increase by 25 and 20%, respectively.

It should also be noted that the efficiency of fullerene black additives may be insignificant at a small pressure on the contact but strongly grows with increasing pressure (Figs. 2, 4). Therefore, the efficiency of fullerene-containing additives can be conclusively judged only after testing the materials over a fairly wide pressure range.

As to mechanisms of the strengthening action of fullerene blacks in friction, the following conclusions can be made now. It is known that mechanical failure of polymers is accompanied by mechanical degradation of the polymer chains at the mouths of the cracks formed. Apparently, a similar process occurs at the mouths of the numerous cracks responsible for the formation of wear particles. Free radicals yielded by degradation can readily add to the fullerene molecules and form a fullerene-polymer network. Polymer radicals yielded by thermal degradation of many polymers [polystyrene, poly(methyl methacrylate), polyethylene glycol, poly-*N*-vinylpyrrolidone] have been shown to readily react with C_{60} [6, 7]. Thus, formation of a network from PTFE macromolecules and fullerenes is highly probable. Hence, the microcracks formed during tests are presumably closed (healed) on the fullerene molecules owing to their high electron-accepting power, instead of propagating around the fullerene-containing particles as common inclusions.

Our data show that fullerene black additives improve the antifriction properties and wear resistance of fluoroplastics. The efficiency of fullerene black additives should be evaluated by taking into account not only the technical potentialities of the new samples, but also the cost of their manufacture. Manufacturers report that adding 1 and 10% FB increases the cost of F-4 by 30% and more than 4-fold, respectively. Combined with the results of our tests, these data suggest that the best concentration of FB is 1%, because, with a further increase in its concentration, the tribological parameters are improved to a lesser extent than grows the cost of the materials.

FBE additives provide an even more substantial decrease in the cost of the new materials whose tribological properties remain virtually unaffected. These fullerene blacks are formed as waste in fullerene production and have no consumer value so far. However, it is necessary to take into account the cost of FBE drying (after extraction of fullerenes with toluene) and of its conversion into a commercial product. Therefore, drying could eliminate the gain from the low cost of FBE. Apparently, with all technical and economic factors taken into account, 1% FB should be recommended for commercial application.

The beneficial action on the antifriction properties and wear resistance of the PTFE-based fluoroplastics, exerted by addition of fullerene blacks, makes them candidates for use as APMs in sliding friction units against steel, operating both without [8] and with water lubrication.

The APMs suggested in this study can be manufactured on a large scale on existing plants by using the available processes for preparation of fluoroplastics and fullerene blacks.

CONCLUSIONS

(1) The antifriction properties and wear resistance of fluoroplastics F-4 and F-4K20 were examined as influenced by additions of fullerene blacks: the initial FB produced in the plasma electric discharge and FBE that remained after extraction of fullerenes with toluene from the initial fullerene black. The best concentration of the blacks was estimated at 1–3%.

(2) Both kinds of fullerene blacks are nearly equal in efficiency. However, the technical and economic analysis suggests that, for commercial application, 1% addition of FB to the fluoroplastics should be recommended.

Abstract—New viscosity additives to oils, based on copolymers of alkyl methacrylates and allyl monomers, were developed.

DOI: 10.1134/S107042720708037X

The formulations of lubricating oils include additives of various functional actions and, in particular, viscosity additives (VAs). Various oil-soluble vinyl polymers have been studied as VAs. Viscosity additives of poly(alkyl methacrylate) type show advantages in that they are prepared by a simple and environmentally safe procedure (radical polymerization), are readily modified, and ensure better viscosity–temperature characteristics of oils, compared to oils modified with other additives. However, like other VAs, poly(alkyl methacrylates) exhibit poor resistance to degradation and do not meet the requirements of modern engineering in this respect. Therefore, the development of highly stable additives of the poly(alkyl methacrylate) type is a topical problem of modern petrochemistry.

It has been shown [1, 2] that one of simple procedures for preparing VAs resistant to degradation is copolymerization, i.e., chemical modification of the existing VAs.

This study deals with the copolymerization of alkyl methacrylates with allyl monomers.

EXPERIMENTAL

As alkyl methacrylates we used butyl methacrylate (BMA) (in synthesis of VAs to ester oils) and decyl methacrylate (DMA) (in synthesis of VAs to petroleum oils), and as allyl monomers, allyl alcohol (for the copolymerization with DMA) and *o*-allylphenol (for the copolymerization with BMA). The comonomers with the OH functional group were chosen with the aim of further transformations to obtain polyfunctional additives exhibiting also the thickening effect.

We used commercial monomers, except decyl methacrylate, which was synthesized in laboratory and had the following characteristics: M = 226, n_D^{20} = 1.4414, d_4^{20} = 0.8765, bp 290°C. All the monomers were distilled just before use and had 98–99% purity.

Copolymerization was performed in the presence of a freshly recrystallized radical polymerization initiator, azobis(isobutyronitrile) (AIBN), taken in an amount of 0.8–1 wt % relative to the sum of the monomers, at 65–70°C for 3–4 h. We examined the effect of various factors on the reaction results. We found that allyl monomers exert an inhibiting effect on the copolymerization, which is reflected in the yield and molecular weight of the products. Therefore, the molecular weight of the copolymers can be controlled by varying the content of allyl compounds in the starting monomer mixture, without using any additional means. After the copolymerization was complete, the mixture was kept in a vacuum to remove the unchanged monomers.

We prepared the copolymers of molecular weight $(8–14) \times 10^3$ in the case of copolymerization of DMA with allyl alcohol and $(12–17) \times 10^3$ in the case of copolymerization of BMA with *o*-allylphenol; the content of allyl monomer fragments was 5–10%.

The composition and structure of the copolymers were studied by elemental analysis and by IR and ^{1}H NMR spectroscopy. We found that allyl monomers form no homopolymers. We also revealed bonds between units of monomers taken for the copolymerization, which confirms the formation of a copolymer, rather than a mixture of homopolymers of the starting monomers. This result is consistent with the well-known fact that allyl monomers are used for preparing copolymers with regularly alternating monomeric units [3].

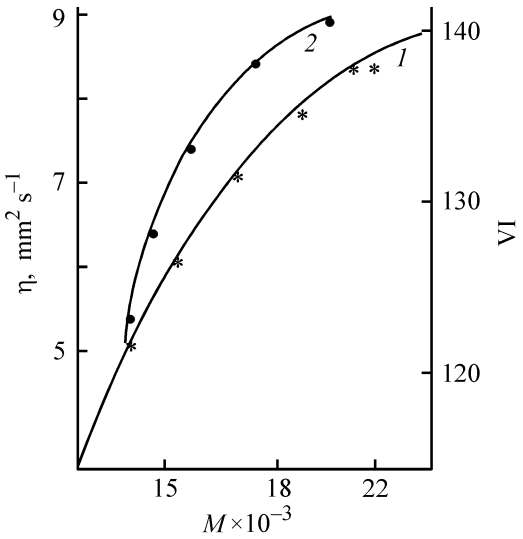
Influence of copolymer concentration on the viscosity–temperature characteristics of I-12A oil

Copolymer concentration, wt %	Kinematic viscosity at 100%, $mm^2 s^{-1}$	Viscosity index
0	3.90	90
1	4.1	125
3	6.70	150
3.5	7.30	150
4	8.20	152
5	10.60	152

Copolymers of DMA with allyl alcohol were tested as VAs to petroleum oils. With I-12A oil as an example, we examined how the copolymer concentration affects the viscosity–temperature characteristics of the oil (see table).

The table shows that the trend observed when the VA concentration is raised is typical of thickened oils: The viscosity index increases with the additive concentration to a certain level and then tends to a constant value. Dissolution of 4 wt % copolymer in I-12A oil yields a thickened oil meeting the existing requirements: viscosity at 100°C 8 ± 0.5 $mm^2 s^{-1}$, viscosity index no less than 125 units.

In addition, we studied the thermal degradation of the copolymers, in comparison with the DMA homopolymer of equal molecular weight (10 000), in a solution in turbine oil of L brand. The copolymer appeared to be more resistant to degradation (the solution viscosity decreased by 4%) than the DMA homopolymer (the viscosity decreased by 9.5%). Thus, the chemical structure of the copolymer ensures its higher stability, compared to the DMA homopolymer.



(*1*) Viscosity η and (*2*) viscosity index VI of pentaerythritol ester oil vs. the molecular weight of the copolymer *M*. Amount of allylphenol 10 wt %, copolymer concentration 1%.

The content of the allyl monomer does not noticeably affect the extent to which the copolymers improve the viscosity–temperature characteristics of the oils, i.e., introduction of allyl alcohol units into the DMA polymeric chain does not impair the viscosity–temperature properties of the thickened oils.

Copolymers of BMA with *o*-allylphenol were tested as VAs to a synthetic ester oil derived from pentaerythritol. Firstly, these copolymers do not dissolve in petroleum oils. Secondly, ester oils are used under more severe conditions than petroleum oils. Therefore, we chose a shorter-chain monomer, BMA, and copolymerized it with an aromatic compound (*o*-allylphenol) to make the macromolecules more resistant to thermal oxidation.

The figure shows how the molecular weight of the copolymer affects the viscosity characteristics of the pentaerythritol ester. An increase in the molecular weight of the copolymers leads to a rise in the viscosity index and kinematic viscosity at 100°C. However, an increase in the molecular weight of VAs makes them less resistant to thermal degradation. Therefore, the choice of the molecular weight and concentration of a VA is governed by specific requirements to a lubricating oil.

Thus, from alkyl methacrylates and allyl compounds we prepared VAs to petroleum and synthetic oils, exhibiting high resistance to degradation.

CONCLUSIONS

(1) Radical copolymerization of alkyl methacrylates with allyl monomers was performed.

(2) The copolymers obtained were tested as viscosity additives to lubricating oils. It was found that introduction of phenolic fragments into a polymeric chain makes the copolymers more heat-resistant.

ANNIVERSARIES

Academician Vladimir Aleksandrovich Tartakovskii is 75

DOI: 10.1134/S1070427207080381

Academician Vladimir Aleksandrovich Tartakovskii is an outstanding specialist in organic chemistry and high-energy substances.

Vladimir Aleksandrovich Tartakovskii was born in Moscow on August 10, 1932. In 1955, he graduated from Lomonosov University in Moscow and went to work at Zelinskii Institute of Organic Chemistry, Academy of Sciences of the USSR. He successfully defended his candidate dissertation in 1959 and doctoral dissertation in 1966. Tartakovskii was elected a corresponding member of the Academy of Sciences of the USSR in 1987 and an academician of the Russian Academy of Sciences in 1992.

The main area of research by Academician Tartakovskii is chemistry of nitro compounds and their use in high-energy formulations. The variety of problems that have been solved under Tartakovskii's supervision and with his participation is extremely wide. These are nitration techniques, and new nitrating agents, and a broad spectrum of new nitro compounds. The results of his studies have been initiating, during many years, re- search in a number of specialized institutes and have opened-up many new issues in chemistry of nitro compounds.

Academician Tartakovskii and his co-workers have created a new area in chemistry of nitro compounds, which made it possible to extend the number of methods for synthesis of new heterocyclic systems. A Butlerov Prize was awarded to Tartakovskii for this series of works by the Academy of Sciences of the USSR in 1967.

The most prominent achievement of Academician Tartakovskii is the discovery of a new class of polynitrous compounds. The results of this study have been officially recognized as a discovery. The industrial implementation of this discovery and particular formulations acquired a State importance. Tartakovskii and his co-workers became Lenin Prize laureates in 1976. Tartakovskii's personal contribution to the practice of synthesis of these compounds and their use in various articles is tremendous. The broad erudition and outstanding talent enable Tartakovskii to solve equally thoroughly both theoretical and practical problems. Under his supervision, a system for engineering of structures with prescribed properties and a concept of prognostication of new polyheteroatomic organic compounds have been developed.

Academician Tartakovskii continues to be deeply involved in scientific and scientific-organizational activities. The laboratory headed by him is engaged in basic research in the field of high-energy compounds. He performs duties of the Academician-secretary of the Department of chemistry and materials science, Russian Academy of Sciences, and works in editorial boards of several journals published by the Russian Academy of Sciences.

The Editorial board and editorial staff of Zhurnal Prikladnoi Khimii (Russian Journal of Applied Chemistry) heartily congratulate Vladimir Aleksandrovich Tartakovskii on his jubilee and wish him sound health and every creative success.

ANNIVERSARIES

Professor Mikhail Mikhailovich Vetyukov is 90

DOI: 10.1134/S1070427207080393

Mikhail Mikhailovich Vetyukov was born on August 1917 into a peasant's family at Shuiskoe village in Vologda province.

In 1935, Mikhail Mikhailovich finished with excelence a secondary school and went to work at the chair of electrometallurgy of nonferrous metals angrad Polytechnic Institute. Since that time, his life has been associated with this chair and this institute. Only in 1941, after graduating from the institute, he worked during a year at Ural aluminum plant (Sverdlovsk oblast) and after that served in the Soviet army till 1946.

Since demobilization in 1946 and until now, Mihail Mikhailovich has been working at Leningrad Polytechnic Institute (now St. Petersburg State Polyechnic University), at the chair of electropyrometallurgy of nonferrous metals (now Theoretical foundaions of the metallurgy of nonferrous metals,) as junior research worker, postgraduate student, docent, and professor. He defended his candidate dissertation in 1950 and doctoral dissertation in 1973. He headed the chair from 1975 till 1990.

The main field of Vetyukov's scientific and pedagogical activities is the theory and technology of electroytic manufacture of aluminum. He is acknowledged authority in this area not only in Russia, but in Europe as well.

He studied for the first time the thermodynamic properties of cryolite-alumina melts, obtained data on their density and viscosity, and determined kinetic characteristics of the electrode processes in manufacture of aluminum. He studied the behavior of sodium at the furnace bottom in order to proong the service life of aluminum electrolyzers. For the same purpose, he used new refractory compounds as electrolyzer lining.

During many years, Vetyukov had been a member of dissertation councils at Leningrad Polytechnic Intiute, Mining Institute, and VAMI (All-Russia Aluminum-Magnesium Institute). Twenty-six candidate disertations and 2 doctoral dissertations have been deended under his supervision. Vetyukov prepared and delivered a course of lectures on electrometallurgy of

nonferrous metals and created a laboratory course of metallurgy of light metals. He is the author of more than 150 scientific publications and inventions, monoraphs, and textbooks. His textbooks and monographs *Teoreticheskie osnovy metallurgii alyuminiya* (Theretical Foundations of the Metallurgy of Aluminum, 1953), Elektroliz rasplavlennykh solei (Electrolysis of Molten Salts, 1966), and *Elektrometallurgiya alyuminiya i magniya* (Electrometallurgy of Aluminum and Magnesium, 1987), written in co-authorship with Yu.V. Baimakov, G.A. Abramov, and others, still remain reference books of specialists in metallurgy. His theoretical papers devoted to kinetics of cathodic and anodic processes in electrolysis of aluminum, properties of cryolite-alumina and chloraluminate melts have been published in journals *Tsvetnye metally*, *Zhurnal Prikladnoi Khimii*, *Elektrokhimiya*, and others.

Numerous Vetyukov's students and postgraduate students have become prominent specialists, scientists, heads of institutes and ministries in Russia and other countries (Vietnam, Egypt, Hungary, Ghana, etc.).

Mikhail Mikhailovich Vetyukov has been awarded the title of Honored Professor of St. Petersburg State Polytechnic University.

At his age of 90, Vetyukov is deeply involved in the chair's activities and shares his scientific and life experience. He is still distinguished by interest in scientific and technological achievements of the electrometallurgy of aluminum as a whole and in works, achievements and success of his pupils, in particular.

Mikhail Mikhailovich is an open-hearted and well-wishing man. His house is always open for friends, pupils, friends, and all those who need his advice or friendly sympathy.

Staff members of the chair of theoretical foundations of metallurgy of nonferrous metals at St. Petersburg State Technical University and the Editorial board and editorial staff of Zhurnal Prikladnoi Khimii heartily congratulate Mikhail Mikhailovich on his jubilee and wish him sound health and further success in his scientific and pedagogical activities.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Technology for Production of Calcium Carbonate with Prescribed Properties

A. R. Kobeleva and V. Z. Poilov

Perm State Technical University, Perm, Russia

Received October 30, 2006; in final form, March 2007

Abstract—Physicochemical conditions for production of calcium carbonate with prescribed size and shape of particles and crystal structure by reaction of $CaCl_2$ and Na_2CO_3 solutions were studied. A technology for manufacture of calcium carbonate with prescribed properties was developed.

DOI: 10.1134/S1070427207090017

Calcium carbonate and products obtained from this compound are widely used in various fields of economy: in building, as a component of finishing materials; for manufacture of cement, glass, and ceramics; in pharmacology, to manufacture toothpastes and antacid preparations; in cosmetics, to produce creams; in water treatment, as filter materials; in paper industry, to manufacture cigarette, chalk-overlay, and tracing paper; in production of plastics and artificial leather; finely dispersed powdered chalk serves as a filler or pigment in cable, paint-and-varnish, polymer, rubber, and petrochemical industry; etc.

In all these fields, various requirements are imposed on calcium carbonate: on its chemical composition and size and shape of crystalline $CaCO_3$ particles, on which depend the commercial characteristics of calcium carbonate and fields of its use (Table 1).

Technologies for production of precipitated calcium carbonate from various raw materials: natural carbonates and solid carbonate wastes and solutions, have been and are being developed. Different processes are used, depending on a starting raw material and requirements to the final product. A technology widely used in Russia is that in which calcium carbonate is produced by carbonation of a $Ca(OH)_2$ suspension with carbon dioxide, with the subsequent separation of the precipitate from the solution and drying and calcination of the resulting product [1–4]. A disadvantage of this technology is that it is difficult to obtain the $CaCO_3$ product with prescribed properties.

Of practical interest is development of a technique based on $CaCO_3$ precipitation in a chemical reaction of technical soda Na_2CO_3 and a $CaCl_2$ solution produced from waste formed in manufacture of soda ash (distiller fluid) or by dissolution of natural chalk. The main development direction of this technology is production of calcium carbonate with prescribed physicochemical properties (definite particle size and shape, crystal structure, impurity content).

The process of calcium carbonate synthesis includes the chemical reaction

$$CaCl_2 + Na_2CO_3 = CaCO_3\downarrow + 2NaCl.$$

In this study, we examined conditions in which calcium carbonate is obtained in different reactant supply modes, ion concentration ratios $[Ca^{2+}]/[CO_3^{2-}]$, starting reactant concentrations, temperatures, and hydrodynamic modes of chemical precipitation of $CaCO_3$ in the presence of various modifiers.

In the batch mode of chemical precipitation of $CaCO_3$, a certain amount of a calcium chloride or soda solution was poured into the reactor and heated to a certain temperature, after which the second reactant was fed at a constant rate by a peristaltic pump. In the continuous mode of $CaCO_3$ synthesis, the reactants were permanently fed by pumps at a constant rate into the reactor filled to the stirrer blade level with distilled water. The process was performed with agitation during a certain time at a constant rate of rabble rotation. The resulting $CaCO_3$ precipitate was filtered off and washed on the filter with distilled water. The calcium carbonate paste was dried in a drying box at 100°C. The dried calcium carbonate was examined with a KS optical microscope at a $1500\times$ magnification in transmitted light. Photomicroscopic studies were performed by photographing $CaCO_3$ microcrystals with an Olympus C 500 digital

Table 1. Application fields of calcium carbonate with different characteristics and physicochemical properties

Crystal structure	Density, g cm^{-3}	Particle shape	Particle size, μm	$CaCO_3$ product characteristics	Main application fields

camera. The information obtained was processed on a computer, using Photoshop and Camedia software. The maximum, average, and minimum sizes of $CaCO_3$ crystals were measured and their shapes were determined. The particle sizes were found using a micrometer grid scale. The error in determining the particle sizes in the range 1–30 μm did not exceed 7%.

The laboratory studies revealed that the parameters of precipitate particles are strongly affected by the ion concentration ratio $[Ca^{2+}]/[CO_3^{2-}]$ (Table 2).

It was found that finely dispersed calcium carbonate particles of diameter $d \approx 1$–3 μm are formed in the stationary mode in the case of an excess of Ca^{2+} ions. If, however, CO_3^{2-} ions are in excess, coarsely dispersed particles of diameter $d \approx 2$–6 μm are obtained. At an excess of CO_3^{2-} anions, the solubility of calcium carbonate increases because of the formation of soluble complexes of the $[Ca_x(CO_3)_y]$ type, which makes lower the supersaturation and, accordingly, the primary nucleation rate [5]. The size of the forming $CaCO_3$ crystallites can also be controlled by varying the concentration of the reactants supplied (Table 3).

In the stationary precipitation mode, the crystallite size decreases as the concentration of the reactant solutions becomes higher. Because the reactant supply rate was maintained constant, an increase in the reagent concentrations results in higher flow rate of substances into the reactor.

The flow rate W_i was calculated by the formula

$$W_i = vc/V_r,$$

where v is the volumetric flow rate of a solution of ith substance (m^3 s^{-1}); c, concentration of ith substance (kg m^{-3}); and V_r, volume of the reaction medium in the reactor (m^3).

An increase in the flow rate of a substance into the reactor leads, in accordance with the mass action law, to a rise in the rate of the chemical reaction between Ca^{2+} and CO_3^{2-} ions. As a result, the supersaturation created in the solution becomes higher,

* Mode: run nos. 1–3, stationary; nos. 4–11, nonstationary.

which accelerates the nucleation process and gives rise to a large number of fine crystalline particles.

In the nonstationary (batch) precipitation mode, the residence time of particles in the reactor exhibits a wide scatter and the concentration ratio of reagent ions, $[Ca^{2+}]/[CO_3^{2-}]$, permanently changes, which leads to size scatter and multitude of forms of calcium carbonate particles.

An increase in temperature markedly accelerates the chemical interaction between the ions, makes faster the primary nucleation (which results in the formation of finely dispersed precipitates), weakens the strength of binding between microblocks in the forming crystalline agglomerates (which favors their disintegration), and, to a lesser extent, leads to an increase in the face growth rate of crystalline particles (Fig. 1a).

The size of calcium carbonate particles is strongly affected by the hydrodynamic operation mode of the crystallizer (Fig. 1b). As the agitation rate increases from 3.3 to 11 rps, the crystallite size decreases by a factor of nearly 2. The reason is that both the primary nucleation rate and the disintegration rate of the forming unstable agglomerates of $CaCO_3$ particles increase.

The effect of organic and inorganic modifiers on the size of $CaCO_3$ crystalline particles was studied. For this purpose, a certain amount of an additive was introduced into a calcium chloride solution (Table 4).

Organic modifiers lead to a decrease in the size of $CaCO_3$ particles. In the presence of additives of this type, calcium carbonate crystals less than 1 μm in size can be obtained, which is predetermined by adsorption of molecules on the surface of nucleating crystals and by blocked growth of crystalline particles.

Inorganic modifiers favor an increase in the size of

$CaCO_3$ crystals by a factor of 1.5–2. This effect of inorganic modifiers is possibly due to selective adsorption of modifier ions and to a change in the charge on crystal faces (Table 4).

The shape of calcium carbonate particles (Fig. 2) is affected by the following parameters: ion concentration ratio $[Ca^{2+}]/[CO_3^{2-}]$, process temperature, and presence of a modifier.

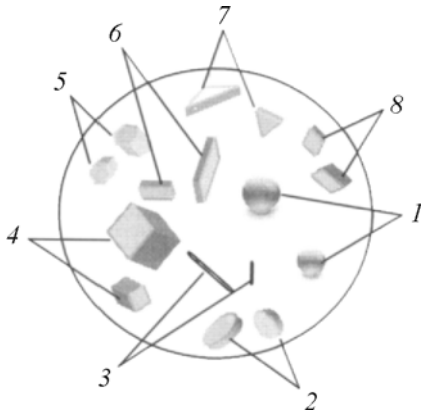

Fig. 2. Types of crystal habits: (*1*) spheres, (*2*) rounded plates, (*3*) needles, (*4*) cubes, (*5*) hexagons, (*6*) rectangular plates, (*7*) triangular plates, and (*8*) rhombic plates.

The effect of the ion concentration ratio $[Ca^{2+}]/[CO_3^{2-}]$ on the shape of $CaCO_3$ particles is presumably due to the sign and amount of charges of excess ions adsorbed on the surface of $CaCO_3$ particles being precipitated. For example, triangular, hexagonal, and rounded platelike particles are formed at a large excess of CO_3^{2-} anions. In this case, the triangular shape is the primary form, and the hexagonal and rounded forms are derivative products of disintegration and wear of triangular $CaCO_3$ particles upon their collisions with other particles, stirrer, and reactor walls. If the excess of CO_3^{2-} anions becomes less pronounced and the ion concentration ratio $[Ca^{2+}]/[CO_3^{2-}]$ approaches the stoichiometry, the platelike shape tends to pass to a three-dimensional, more compact shape of $CaCO_3$ particles: cubic and spherical [6].

A change in the precipitation temperature is reflected in the shape of the resulting calcium carbonate particles. At low temperatures, mostly particles of three-dimensional shape are formed, whereas at high temperatures (>90°C), $CaCO_3$ particles become needle-like, which points to an unequal acceleration of the growth of different faces of $CaCO_3$ particles (Fig. 3).

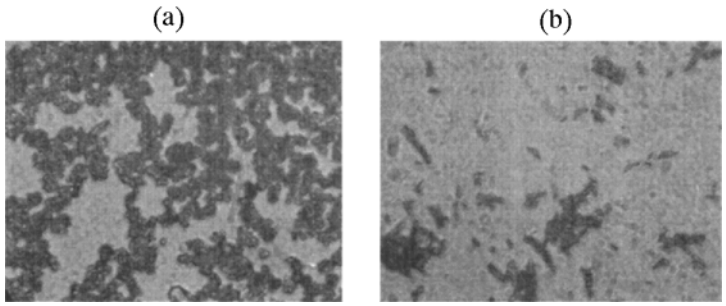

Fig. 3. Photographs of $CaCO_3$ particles obtained at (a) 23 and (b) 90°C. Magnification 1500×.

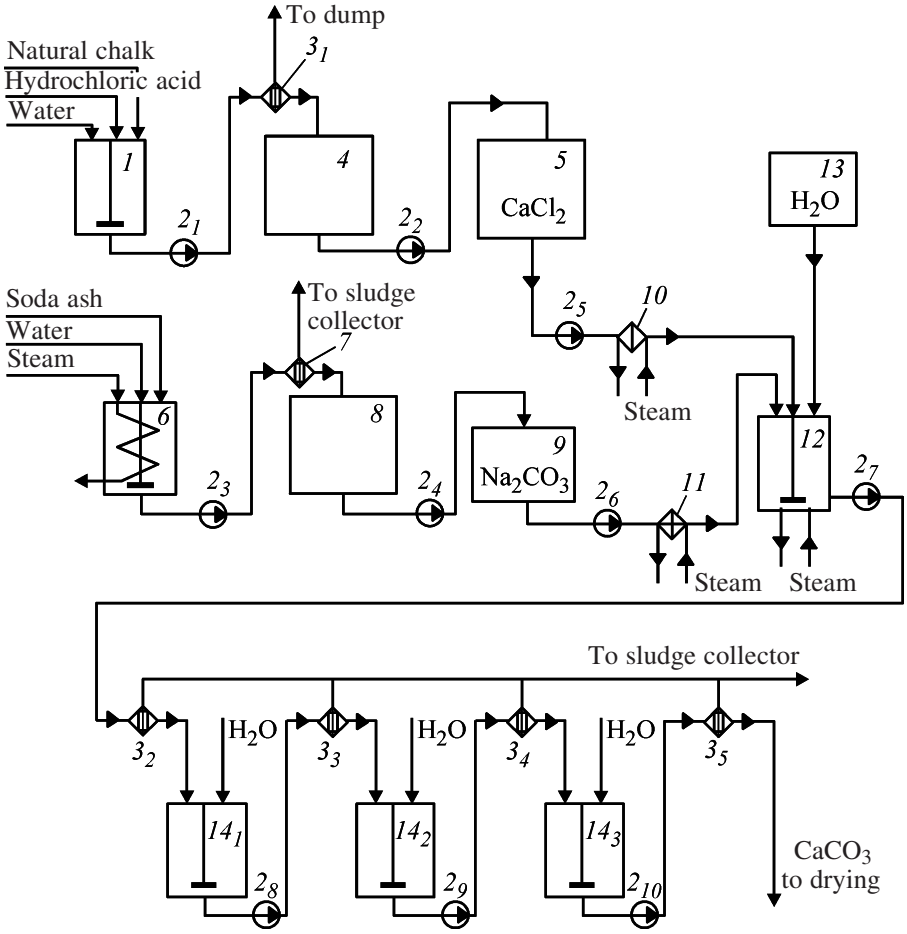

Fig. 4. Flowsheet for production of calcium carbonate. (*1*) Reactor for preparing a calcium chloride solution, ($2_{1–10}$) centrifugal pumps, ($3_{1–5}$) vacuum filters, (*4*) collector for the calcium chloride solution, (*5, 9*) receiving tanks, (*6*) reactor for preparing a soda solution, (*7*) plate-and-frame filter-press, (*8*) collector for the soda solution, (*10, 11*) heaters, (*12*) reactor for synthesis of calcium carbonate, (*13*) water supply tank, and ($14_{1–3}$) repulpers.

Adsorption of modifiers on active centers of the crystals can change the growth rate of their different faces to different extents, which leads to a change in the crystal habit. Inorganic modifiers (NH_4Cl, $PbCl_2$) favor an increase in the number of forms of $CaCO_3$ particles, with rounded, oblong, squared, and polygonal shapes obtained.

Also, ways to control the crystal structure of calcium carbonate and the possibility of obtaining products of different modifications were studied. The crystal structure of $CaCO_3$ was examined by X-ray diffraction analysis. Calcium carbonate with a phase composition of calcite can be obtained in continuous chemical precipitation from solutions containing cal-

cium and sodium ions in the presence of NH_4Cl, urea, and amine hydrochloride additives. Depending on an additive used, calcite crystals have different configurations: rhombic with NH_4Cl, cubic with urea, oval with the amine, and squared in the presence of surface-active anions (SAA).

Vaterite crystals are formed as spherulites or plates in the case of a continuous chemical precipitation from solutions containing calcium and sodium ions at 60°C and concentrations of the starting solutions equal to 116 and 180 g l^{-1}, respectively. In this case, $CaCO_3$ crystals become platelike.

Calcium carbonate with a phase composition of aragonite can be obtained in a continuous chemical precipitation from solutions containing calcium and sodium ions at 20°C and concentrations of starting solutions equal to 116 and 230 g l^{-1}, in the presence of a minor amount of sucrose.

Because $CaCO_3$ particles are formed in the presence of a NaCl solution, there is a stage of washing to obtain a purer product. The effect of washing on the size and shape of precipitated calcium carbonate particles was studied. A multistage washing can lead both to an increase and a decrease in the average diameter of product particles (Table 5). This change in the size and shape of the particles can be attributed to occurrence of ripening processes in the suspension (Ostwald phenomenon), with a simultaneous mechanical deformation of crystals and their disintegration as a result of agitation, which leads to a poorer uniformity of particles, and the crystal habit takes a characteristic shape with rounded corners and edges.

The results of the study were used to develop a process installation shown in Fig. 4. Calcium carbonate is produced in several stages: (1) preparation of a calcium chloride solution from natural chalk, (2) clarification of the calcium chloride solution, (3) preparation of a soda solution, (4) chemical precipitation and filtering-off of the calcium carbonate precipitate, (5) separation of the precipitate from the solution and desorption of impurities from the calcium carbonate precipitate, and (6) drying of the precipitate.

This procedure allows synthesis of $CaCO_3$ products with different properties on the same equipment unit.

CONCLUSIONS

(1) The technology developed enables control over the characteristics and consumer properties of the product in a wide range.

(2) The properties of the $CaCO_3$ product obtained upon precipitation can be controlled by changing the precipitation mode (temperature, rate at which supersaturation is created, and the rate and method of reactant supply), using complexing substances or modifier additives affecting the shape and size of $CaCO_3$ particles, and introducing a $CaCO_3$ seed.

(3) Finely dispersed and ultradispersed powders can be obtained in $CaCO_3$ precipitation by using not only aqueous, but also organic media and dispersing additives that prevent aggregation of $CaCO_3$ particles.

Abstract—Specific features of structure formation in dispersed salt systems based on potassium chloride were studied from the standpoint of a relationship between the physicochemical properties of binder reagents, granulation conditions, and grain strength.

DOI: 10.1134/S1070427207090029

Granulated fertilizers have a number of advantages in agriculture over those finely grained: lower dusting and transportation loss, lower caking, higher agrochemical efficiency because of the decrease in washing-out of soluble salts from soil, etc. The compaction and pelletization are widely used for granulation of dispersed materials [1, 2]. In pelletization, the structure of a material is formed under dynamic conditions. The uninterrupted motion of a material being granulated, on the one hand, leads to formation and growth of grains and, on the other hand, causes disintegration of grains having the lowest strength. In the case of simultaneous occurrence of these counteractive processes, grains close in shape, size, and properties are formed. The pelletization efficiency can be improved by controlling the dispersity of particles and the state of their surface, which provides a compact "packing" of particles and a higher number of contact points [2, 3]. The pelletization has a number of advantages over compaction, the main of which is the lower specific energy consumption and better product quality because of the lower content of the dust fraction.

When using binder additives in order to raise the granulation efficiency and improve the grain quality, it is necessary to take into account the fact that the mechanisms of contact interaction in compaction and pelletization are different. Compaction at elevated pressures and temperatures of finely grained potassium chloride treated with binder reagents leads to formation of a three-dimensional structure from the particles and to bulk densification of the material. Pelletization yields, as a result of treatment of the material with binders or film-forming substances and the subsequent drying, a layered structure in which particle layers are attached to each other not only by crystallization–condensation contacts between particles, but also by the binding action of an additive. In the general case, use of additives in pelletization raises the grain strength by a factor of 3 and more, whereas in the case of compaction, this parameter can be only raised by 20–30% [4].

In granulation of KCl, the following features of dispersed salt systems should be taken into account: dissolution of the surface layer of KCl upon moistening with binder solutions; surface hydrophobicity of powdered fertilizers being granulated, caused by use of organic reagents in dressing of potassium ores; etc.

In view of the fact that pelletization has not been used as a method for potassium chloride granulation and approaches to use of binders in manufacture of granulated potassium fertilizers have been for the most part empirical, a study of the relationship between binder properties, conditions of structure formation in pelletization, and grain strength is topical.

EXPERIMENTAL

Powdered KCl of chemically pure grade with an average particle size of 0.5 mm was used in the study.

The following binders were used: polyethylene glycol, molecular weight $M = 12 \times 10^3$ (Loba Feinchemie, Germany) (P1); Na-carboxymethyl cellulose, $M = (4–5) \times 10^4$ (P2); and polyacrylamide (PAA) of Praestol brand (Degussa Eurasia Limited Liability Company, RF), $M \approx 14 \times 10^6$ (P3). Oligomeric products of urea polycondensation with formaldehyde [urea–formaldehyde resin (UFR), GOST (State Standard) 14231–88] (Kh1) were also used.

Potassium chloride was pelletized on a laboratory

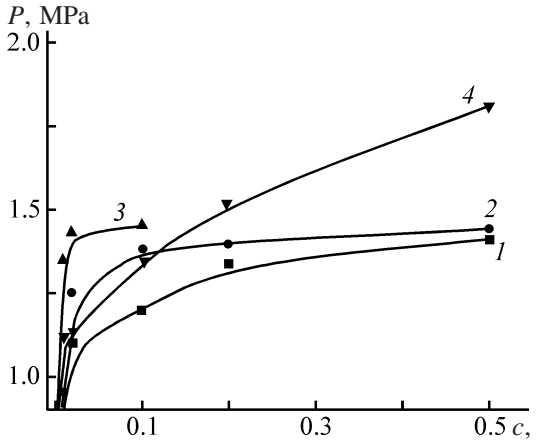

Fig. 1. Grain strength P vs. binder content c. (*1*) P1, (*2*) P2, (*3*) P3, and (*4*) Kh1.

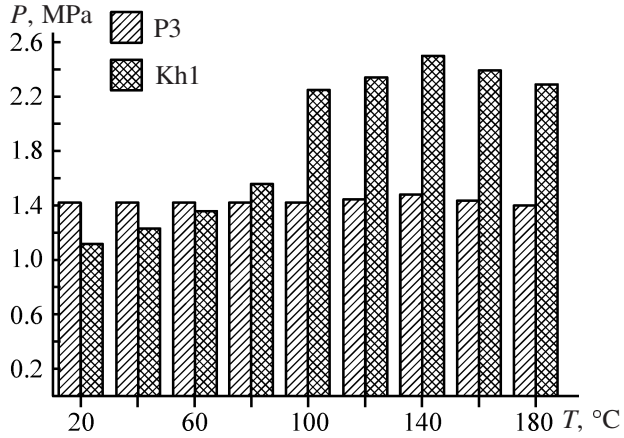

Fig. 2. Effect of temperature T on the strength P of grains treated with a polymer (P3) and oligomers (Kh1).

drum granulator under the same conditions (drum rotation rate, time and temperature of pelletization, weighed portion and moisture content of a material). After the pelletization was complete, grains were dried at different temperatures (40–180°C) for 12 h.

The static grain strength P (MPa) was used as an integral parameter characterizing the strength of contact interactions. The method for determining the static grain strength is based on measuring the mean breaking strength for 20 grains with an IPG instrument. The static strength was calculated by the equation

$$P = \sum_{i=1}^{20} F_i/20S_m,$$

where S_m is the mean area of the diameter cross section of a grain (mm^2), and F_i is the breaking strength (N).

Samples for IR measurements were prepared by deposition of aqueous solutions of polymers (in individual state and as a mixture of aqueous solutions taken in equimolar ratio) onto KCl, with the subsequent thermal treatment at 20, 40, 60, 80, 100, 120, 140, and 180°C for a certain time. Treated samples (mass 10 g) were reduced and the fraction with a particle size of less than 0.2 mm was taken for the measurements. The spectra of the thus prepared samples were recorded in the range 4000–400 cm^{-1} on an Avatar-330 Fourier spectrometer with a diffuse reflection attachment. Untreated KCl served as a reference.

The water-soluble polymers used in the study for treatment of KCl (P1–P3) can form films on the particle surface, which become denser in the course of heat treatment in the stage of grain stabilization [4]. The use of film-forming polymeric binders in pelletization enhances the grain strength (Fig. 1). As the amount of the polymer increases, the number of contacts between particles grows and, consequently, the strength of the structure is enhanced. Raising the polymer content at an invariable moisture content of the material impairs the reagent distribution over the particle surface and leads to a local increase in the thickness of the polymer films at places of contacts, which does not enhance the strength of the structure.

The efficiency of film-forming additives depends on the molecular weight of the polymer (Fig. 1): the higher the molecular weight, the smaller the amount of the polymer, necessary for grain strengthening. Use of polymers, especially those with high molecular weight, is hindered by the high viscosity of the solutions used, which precludes uniform distribution of the binder. Raising the dose at low polymer concentrations leads to excess moistening of the material.

The urea–formaldehyde resin (UFR) (Kh1) is a low-molecular-weight reactive oligomer capable of further chemical transformations under relatively mild conditions. Under the action of temperature, the functional groups of the resin react with each other to form a rigid and strong skeleton providing a high strength of the structured dispersed system.

The influence exerted by the grain treatment temperature on the strength of potassium chloride grains was studied. The results obtained (Fig. 2) indicate that an increase in temperature has virtually no effect on the physicomechanical properties of grains treated with a film-forming polymer additive (P3) and raises the grain strength by a factor of nearly 2 upon treatment with a reactive binder additive (Kh1).

Apparently, it is advisable to improve the granulation of KCl under dynamic conditions by using, on the one hand, the advantages of the high-molecular-weight binder as a film-forming reagent, which provides the required plasticity of a material being pelletized, and, on the other, the ability of the reactive oli-

gomers to form a strong structure in thermal treatment.

Use of a mixture of film-forming and reactive additives can markedly raise the grain strength, compared to the cases of individual components (Fig. 3).

The processes occurring in thermal treatment of a high-molecular-weight film-forming reagent (PAA), reactive oligomers (UFR), and mixtures of these were studied by IR spectroscopy.

The IR spectra of UFR samples contain absorption bands at 1550 (amide II) and 1660 cm^{-1} (amide I) due to vibrations of carbonyl and amide groups. The absorption bands at 1020 and 1250–1260 cm^{-1} can be attributed to vibrations of primary alcohol and ether groups [5, 6]. The intensities of the absorption bands at 1020, 1250, 1550, and 1660 cm^{-1} decrease as the temperature is elevated. This is due to interaction of alcohol, ether, and amide functional groups of the resin at elevated temperatures.

An increase in temperature had virtually no effect on the intensity of characteristic absorption bands in the PAA spectrum. And only elevating the temperature to above 120°C changes the spectrum and leads to a certain decrease in the intensity of the absorption band at 1660 cm^{-1}, associated with vibrations in the amide groups of the polymer, which points to imidization and appearance of cross-linked structures.

Special-purpose experiments demonstrated that thermal treatment of aqueous solutions of PAA at 120 and 140°C to complete removal of water yields a product that completely dissolves in 24 h, when brought in contact with water. Apparently, rare cross-links in the polymer chain containing amide groups cannot provide, in thermal treatment of the polymer, a strength of the three-dimensional structure, sufficient for making insoluble the heat-treated polymer.

IR spectroscopy was also employed to study samples of a mixture of UFR and PAA. The absorption bands associated with vibrations of carbonyl groups and N–H bonds in amide groups are close in the UFR and PAA spectra, which hinders their identification in a study of the component interaction. For this reason, spectra of a mixture prepared from aqueous solutions of the components (Fig. 4, spectrum *1*) and of their mechanical mixture (Fig. 4, spectrum *2*) not subjected to thermal treatment were compared. In view of the similar conditions of sample preparation, and equal contents of the polymers in the mechanical mixture and in the mixture of solutions, it can be stated that the difference in the spectra at 1450–1550 cm^{-1} is due to interaction of the components in the aqueous solution.

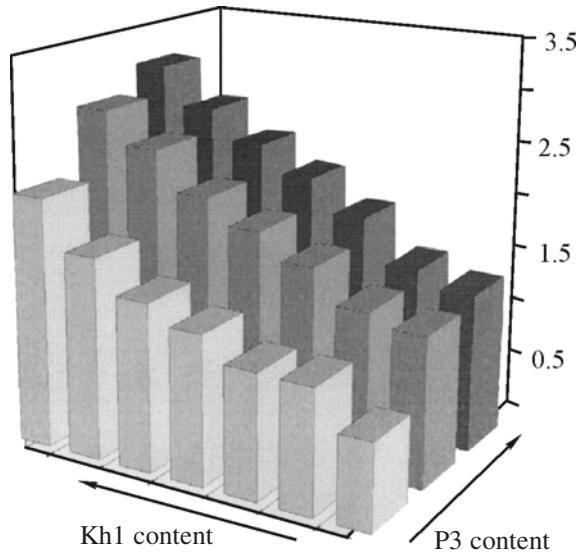

Fig. 3. Grain strength *P* of potassium chloride upon integrated treatment with binder reagents. Drying temperature 100°C.

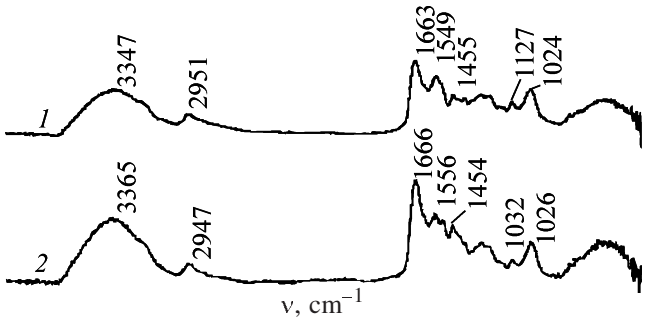

Fig. 4. IR spectra of (*1*) mixture prepared from aqueous solutions and (*2*) mechanical mixture of PAA and UFR.

In the case of a thermal treatment of the mixture of aqueous solutions, the intensity of the absorption bands at 1020, 1250, 1550, and 1660 cm^{-1} decreases, but the extents to which *D* changes on elevating the temperature are different for UFR in the individual state and in a mixture with PAA. Figure 5 shows values of *D*, which characterize the ratio between the intensity of an absorption band being analyzed in the spectrum of a sample thermally treated at temperatures of 40 to 180°C and the intensity of the same absorption band in the spectrum of a sample at 20°C, with data presented only for those absorption bands whose intensity changes on elevating the temperature. It can be seen that, as temperature increases, the intensity of the absorption bands at 1550 and 1020 cm^{-1} decreases to a greater extent for the UFR + PAA mixture, compared to UFR in the individual state. The extents to which the intensities of the band at 1250 cm^{-1} change are similar for UFR and the mixture. For the absorption band at 1660 cm^{-1}, the temperature dependences

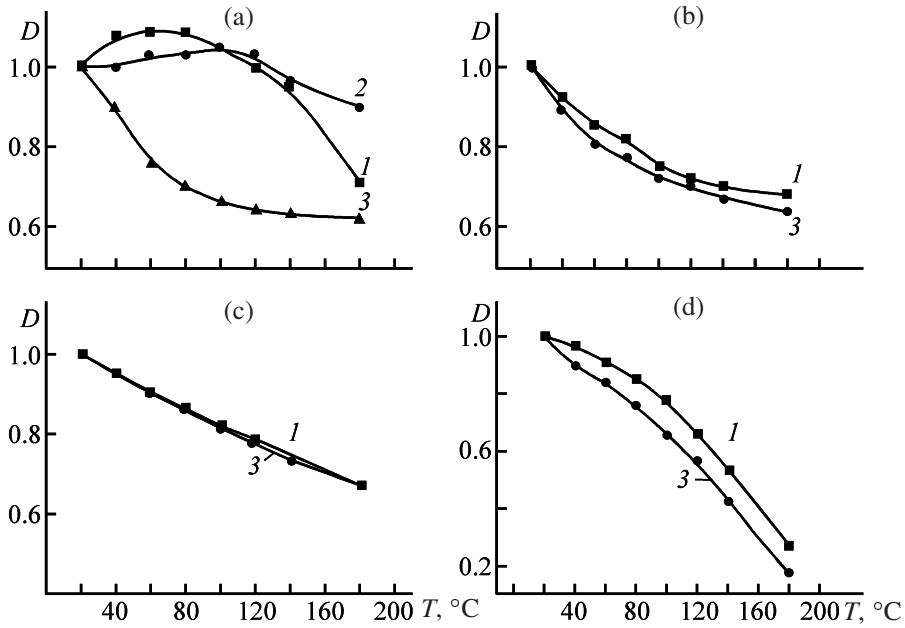

Fig. 5. *D* vs. thermal treatment temperature *T* for the absorption bands at (a) 1660, (b) 1550, (c) 1250, and (d) 1020 cm^{-1}. (*1*) UFR, (*2*) PAA, and (*3*) mixture of PAA and UFR.

of *D* are different for the individual components and their mixture.

The results obtained in the study suggest that, upon mixing of aqueous solutions of UFR and PAA and thermal treatment of the mixture, the functional groups of the components react with each other: there occur reactions between the carboxy groups formed in partial hydrolysis of PAA, amide groups of PAA, and alcohol and ether groups of UFR; also possible is the reaction of PAA with formaldehyde released upon heating of UFR. The observed quantitative difference between the changes in the intensities of the absorption bands indicates that the mechanisms by which the structural networks are formed in the cases of individual components and in their mixture are different.

CONCLUSIONS

(1) A study of the efficiency of the structure-forming action of polymers of the film-forming type and reactive oligomers in pelletization of potassium chloride demonstrated the advantage of a high-molecular-weight component in formation of a layered plastic shape of a grain and the ability of the oligomers to yield a firm structure in thermal treatment.

(2) Joint use of film-forming polymers and reactive oligomers enables control over the granulation process of potassium chloride in different stages: in the initial stage of pelletization under dynamic conditions, presence of a polymer (polyacrylamide) provides a high plasticity of the material and change in the shape of grains without their disintegration and improves the distribution of the binder additive over the potassium chloride surface. In the subsequent stages, structural formation occurs under the action of temperature, with the reactive oligomer (urea–formaldehyde resin) and a polymer involved. The strength of potassium chloride grains produced by pelletization can be markedly raised by taking into account the type of a binder additive (synergism of the action of the film-forming and reactive components), its physicochemical properties, and structure formation conditions.

Abstract—Optimal conditions of the synthesis of ammonium sulfate peroxy solvate stabilized by carboxylic acids were developed.

DOI: 10.1134/S1070427207090030

The majority of peroxy solvates of salts of inorganic acids show low stability, which is caused by susceptibility of their component, hydrogen peroxide, to catalytic decomposition. However, hydrogen peroxide, both coordinated to salts and free, can be substantially stabilized by introducing various additives. For example, a wide set of stabilizers substantially enhancing the stability were found for potassium fluoride peroxy solvates $KF \cdot nH_2O_2$ (n = 1–3). The monoperoxy solvate $KF \cdot H_2O_2$ stabilized by potassium hydrofluoride decomposes within 7 years at an average rate of 0.47%/year, i.e., to 3.32% in this period of time [1]. Carboxylic acids are no less effective stabilizers for potassium fluoride monoperoxy solvate [2]. A new generation of disinfectants with a wide spectrum of antimicrobial action was developed on the basis of $KF \cdot H_2O_2$ [3].

The development of effective stabilizers for one group of peroxy solvates suggests that these or related compounds may exert a stabilizing effect also on less stable solvates of other salts. This would expand the range of solid forms of hydrogen peroxide for use in the fields of disinfection science and bleaching, and also in other fields depending on the properties of salts that are carriers of hydrogen peroxide. The ability of ammonium sulfate to solvate hydrogen peroxide was mentioned by Schumb et al. in [4]. The study of $(NH_4)_2SO_4$ solubility in anhydrous hydrogen peroxide has shown that the maximal amount of coordinated H_2O_2 corresponds to the composition $(NH_4)_2SO_4 \cdot H_2O_2$ [1].

In this study we found the optimal conditions of the synthesis, stabilization, and storage of $(NH_4)_2SO_4 \cdot H_2O_2$, providing the retention of available oxygen (observation time more than 100 days). Carboxylic acids were used as stabilizers.

EXPERIMENTAL

The peroxy solvate $(NH_4)_2SO_4 \cdot H_2O_2$ was synthesized by the reaction of chemically pure grade ammonium sulfate and hydrogen peroxide of various concentrations. Water and excess hydrogen peroxide were removed with a warm (50–55°C) air flow passed over a surface of the solution placed in a polymeric pan.

The experiments have shown that, at the molar ratio $H_2O_2 : (NH_4)_2SO_4$ = 1 : 1 and H_2O_2 concentration of 34 wt %, the solid product contains 13.7% hydrogen peroxide, which corresponds to the composition $(NH_4)_2SO_4 \cdot 0.65H_2O_2$. The increase in the amount of hydrogen peroxide up to the ratio $H_2O_2 : (NH_4)_2SO_4$ = 3 : 1 at the same its concentration slightly increases the content of H_2O_2 in the solid product. At a fivefold excess of hydrogen peroxide of the same concentration, the solid phase is the pure monoperoxy solvate $(NH_4)_2SO_4 \cdot H_2O_2$ (Table 1). Further increase in the H_2O_2 concentration to 60 wt % and an increase in its amount introduced into the reaction to 5 mol per mole of the salt does not lead to the formation of a solvate with a higher content of hydrogen peroxide. These results confirm the previous data that ammonium sulfate monoperoxy solvate is the compound with the maximum H_2O_2 content [4].

Ammonium sulfate peroxy solvate is a colorless crystalline product soluble in water. Its solutions are

stable: the H_2O_2 content of a solution, 2.61% (pH 4.1), does not vary within the observation time longer than 7 days. The X-ray pattern of $(NH_4)_2SO_4 \cdot H_2O_2$ was recorded on an ADP-2-01 diffractometer (CuK_α radiation, Ni filter) using the program developed for DRON X-ray diffractometers and intended for automation of data acquisition, processing, and analysis. The thermograms were recorded on a Q-1500-D instrument with a Pt/Pt–Rh thermocouple and Al_2O_3 reference at a heating rate of 5 deg min^{-1}.

Table 3. Loss of H_2O_2 from ammonium sulfate peroxy solvate $[(NH_4)_2SO_4 \cdot H_2O_2]$ stabilized by carboxylic acids. Storage in a closed container, 20°C, 76 days

Stabilizer, wt %	Decomposition rate, % H_2O_2/day	H_2O_2 loss, % of initial content

succinic, 0.5	0.14	10.6
succinic, 1.0	0.28	21.1
fumaric, 0.5	0.25	19.1
fumaric, 1.0	0.10	7.4
No stabilizer	0.32	24.4

Interplanar spacings and relative intensities of the X-ray reflections of $(NH_4)_2SO_4 \cdot H_2O_2$ are given in Table 2. The comparison with the X-ray pattern of the starting $(NH_4)_2SO_4$ [5] shows that we synthesized a pure peroxy solvate, as the reflections of the starting ammonium sulfate were absent.

The solvate partially dissociates under polythermal conditions at 100°C with the release of hydrogen peroxide into the gas phase. The endothermic dissociation gives way to the exothermic irreversible decomposition of H_2O_2 at 110–125°C.

When the solvate is kept in an open container at room temperature (20±2°C) and a relative humidity of 50%, it loses hydrogen peroxide at an average rate of 4% per day. Carboxylic acids as stabilizers appeared inefficient under these conditions: the rate of the solvate decomposition in their presence did not decrease noticeably. The decomposition of $(NH_4)_2SO_4 \cdot H_2O_2$ stabilized by carboxylic acids on storage in closed polymeric containers occurs much more slowly (Table 3). Table 3 shows that the nonstabilized sample decomposes at an average rate of 0.32% in the course of 2.5 months and the total loss in this time is 24%. Succinic acid exerts an insignificant stabilizing effect,

* Similar results were obtained at the following content of acids (%): succinic 1.0, fumaric 0.5.

whereas fumaric acid in an amount of 1.0% reduces the decomposition rate by a factor of 3.

The stability of $(NH_4)_2SO_4 \cdot H_2O_2$ sharply increases on keeping in the presence of a desiccant. The experiments have shown that keeping the solvate in an open polymeric container in a desiccator over magnesium perchlorate or sulfuric acid for more than 100 days is accompanied by only insignificant loss of hydrogen peroxide (no more than 2.2% for a nonstabilized sample), and samples stabilized with carboxylic acids do not lose hydrogen peroxide at all (Table 4). Certain decrease in the H_2O_2 content in the initial stage of storage is due to adsorption of atmospheric moisture by samples during their preparation and loading into the desiccator. Then the adsorbed moisture is evaporated and absorbed by the desiccant.

Similar data on the essential effect of ambient air humidity on the stability of peroxy solvates were obtained previously for sodium carbonate peroxy solvate [6]. Keeping $Na_2CO_3 \cdot 1.5H_2O_2$ for 40 days in an open container in a desiccator without a desiccant gives a decomposition rate constant higher by an order of magnitude compared to keeping under the same conditions over a desiccant [$k_1 = 26.5 \times 10^{-3}$ and $k_2 = 2.6 \times 10^{-3}$ min^{-1} (100°C), respectively]. Obviously, water evolved in the initial stage of the solvate decomposition, or its vapor absorbed from a moist air, forms a microfilm of an alkaline or acid solution on the surface of solvate crystals, producing a catalytic effect on coordinated hydrogen peroxide. The adsorption of water vapor by a desiccant prevents the formation of such a film and makes the solvate more stable.

A desiccant for $(NH_4)_2SO_4 \cdot H_2O_2$ storage can be silica gel, aluminum oxide, or some other granular desiccant placed in a ready sample in a container with a surface permeable to water vapor. Such a technique is used in pharmacology and also in instrument making.

The results of this study indicate that, under the developed storage conditions, ammonium sulfate peroxy solvate along with other solid forms of hydrogen peroxide can be used both in disinfection science and in other fields. Advantages of ammonium sulfate peroxy solvate consist in availability and low price of the starting salt compared, e.g., to potassium fluoride. We believe that ammonium sulfate peroxy solvate shows promise for agriculture as a compact fertilizer with such additional valuable and environmentally safe disinfectant as hydrogen peroxide.

It should be noted that ammonium sulfate peroxy solvate is similar to sodium carbonate peroxy solvate in stability at a room temperature of 20±2°C and 50–

60% humidity. Numeorus effective stabilizers are used for stabilizing $Na_2CO_3 \cdot 1.5H_2O_2$; this problem is the subject of more than 300 patents. Although the mechanism of the stabilizing action is unknown in most cases, the attained stability of percarbonate was so high that it could be widely used in multicomponent detergents. In view of the possibility of using $(NH_4)_2SO_4 \cdot H_2O_2$ in various fields such as disinfection science, bleaching, and agricultural practice, the methods of its stabilization are not exhausted by this study, and their development should be continued using diverse stabilizers, their mixtures, and various application techniques.

CONCLUSIONS

(1) A method of the $(NH_4)_2SO_4 \cdot H_2O_2$ synthesis has been developed.

(2) Conditions for the stabilization and storage under which ammonium sulfate peroxy solvate does not lose available oxygen (observation time more than 100 days) have been found.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Preparation and Characteristics of Zirconium–Aluminum Oxide System

M. A. Kruglova and M. P. Yaroshenko

Novomoskovsk Institute of Nitrogen Industry, Novomoskovsk, Tula oblast, Russia

Received April 18, 2007

Abstract—The possibility of preparing highly dispersed mixed zirconium–aluminum oxides by precipitation of zirconium hydroxide on γ-Al_2O_3 was studied.

DOI: 10.1134/S1070427207090042

Zirconium dioxide and compositions based on it are important catalytic materials. ZrO_2 is used as a component of catalysts for various processes: dehydration, isomerization, alkylation, selective and full oxidation of hydrocarbons, Fischer–Tropsch synthesis, etc. [1–3]. Zirconium dioxide is also one of the most promising catalyst supports, as it is highly chemically and thermally stable in reducing media and has both acid and base centers on its surface [4]. However, application of zirconium dioxide is limited by the metastability of its low-temperature modifications (amorphous, cubic, and tetragonal) and ease of their transition into the stable monoclinic modification exhibiting, as a rule, high crystallinity and low specific surface area [5].

The interest in preparing nanocrystalline materials based on zirconium dioxide led to the development of approaches to stabilization of the ZrO_2 structure in low-temperature modifications. It is known [6] that addition of small amounts of compounds of rare-earth elements, e.g., yttrium, results in a stabilization of the low-temperature metastable tetragonal or cubic phase of zirconium dioxide. The addition to zirconium dioxide of oxides of Group II and III metals with the ionic radii close to that of zirconium makes it possible to prepare anion-deficient solid solutions $Zr_{1-x}(M^{2+})_xO_{2-x}$ or $Zr_{1-y}(M^{3+})_yO_{2-0.5y}$, where x, $y = 0.10-0.15$. Such solid solutions exist in the form of stabilized tetragonal or cubic modifications in a wide temperatures range [7]. Stabilization of metastable modifications of zirconium dioxide by doping with aluminum compounds was also reported [8, 9]; it is noted, however [10, 11], that ZrO_2–Al_2O_3 solid solutions decompose at relatively low temperatures because of appreciable oversaturation. Klimova et al. [5] note that the addition of even small amounts of Al_2O_3 strongly affects the structure of zirconium dioxide and hinders the conversion of the tetragonal ZrO_2 modification to the monoclinic modification, which is accounted for by the limited size of zirconium dioxide crystallites that can be incorporated in the matrix of aluminum oxide.

As a rule, zirconium-containing oxide systems are prepared by the coprecipitation of metal nitrates or chlorides from solutions or by a sol–gel method using metal alkoxides [5]. The precipitation of hydroxides involves serious problems with filtration and washing of gel precipitates [12].

In this study we attempted to obtain a zirconium–aluminum oxide system by precipitating hydrated zirconium oxide on γ-Al_2O_3, which is of interest for searching for a convenient industrial method ensuring, in particular, better filterability of the precipitate. Furthermore, the use of active aluminum oxide seemed to be helpful for further application of the material as catalyst support. The formation of the resulting zirconium–aluminum oxide systems and also the mutual influence of zirconium and aluminum oxides in such systems were examined in this study.

EXPERIMENTAL

Samples of ZrO_2–Al_2O_3 were prepared as follows: 1 M aqueous solution of zirconyl nitrate was mixed with a calculated amount of γ-Al_2O_3, and then NH_4OH_{conc} was added with continuous stirring. The precipitation was finished on reaching pH 9. The resulting precipitates were filtered off, washed with distilled water, and dried at a room temperature for 24 h and then at 120°C for 5 h. The samples were

calcined in air for 3 h at temperatures from 300 to 1000°C. Under the same conditions we prepared a sample of hydrated zirconium oxide (HZO) free of γ-Al_2O_3 additions. For comparison we prepared a sample of γ-Al_2O_3 treated with NH_4OH. The composition of the samples obtained is given in Table 1.

The X-ray experiments were carried out on DRON-3 and DRON-3M diffractometers (CuK_α radiation with a graphite monochromator on the reflected beam). To identify phases, we used a database of the Joint Committee on Powder Diffraction Standards (JCPDS). The average size of coherent scattering areas (CSAs) was determined from the broadening of diffraction peaks by the Selyakov–Scherrer formula. The content of the tetragonal phase of zirconium dioxide was determined from the relationship [13]

$$X_1 = \frac{I_t(111)}{I_m(111) + I_m(11\bar{1}) + I_t(111)},$$

where I_m and I_t are the integral intensities of the diffraction peaks of the monoclinic and tetragonal ZrO_2 phases, respectively.

The differential thermal analysis was carried out on a Q-1500D derivatograph. The heating rate was 5 deg min^{-1}. The specific surface area, pore volume, and pore size distribution were determined by low-temperature adsorption of nitrogen at 77 K on a Micrometrics ASAP 2010N instrument. The acidity of the surface of the samples calcined at 400°C was studied by temperature-programmed desorption of ammonia (TPD NH_3). After a pretreatment, saturation by ammonia mixed with nitrogen, and removal of excess ammonia the experiment was carried out in a He stream at a heating rate of 8 deg min^{-1}. The released ammonia was detected with a thermal conductivity detector.

The X-ray study has shown that a zirconium-containing phase in all noncalcined samples is in the X-ray amorphous state (Table 1). After calcination at 400°C and higher temperatures, essential changes are observed in the phase composition of the samples. The X-ray amorphous phase completely disappears from ZA0 sample above 400°C, and the crystalline metastable tetragonal (t-ZrO_2) and stable monoclinic (m-ZrO_2) phases of zirconium dioxide appear (Fig. 1). As the samples are highly dispersed, which results in considerable broadening of X-ray reflections, it is difficult to determine whether zirconium dioxide is in cubic or tetragonal modification; in what follows, the low-temperature metastable modification of ZrO_2 is referred to as tetragonal phase. Examination of the integral intensities of the t-ZrO_2 and m-ZrO_2 lines shows that after the calcination of the ZA0 sample in the temperature range 400–1000°C the tetragonal ZrO_2 phase is gradually converted to the monoclinic phase. The content of t-ZrO_2 in the sample varies from 45% at the calcination temperature of 400°C to 10–15% after calcination at 800°C, with complete

disappearance of this phase at 1000°C (Fig. 2). The same pattern is also observed on calcination of a mechanical mixture of the dried up ZA0 and ZA100 samples.

Unlike ZA0, in binary samples the X-ray amorphous phase is preserved up to high calcination temperatures. The crystallization of the metastable tetragonal ZrO_2 phase in the samples obtained by precipitation on γ-Al_2O_3 occurs in a wide temperature range (Table 1). For example, the t-ZrO_2 phase appears in the ZA25 sample after calcination at 500°C. In a certain temperature range, it coexists with the X-ray phase which disappears only above 600°C. In the ZA50 and ZA75 samples, the crystallization of t-ZrO_2 from the X-ray amorphous phase starts after calcination at 600 and comes to the end at 800°C (Table 1, Fig. 1). The monoclinic phase of zirconium dioxide is absent in ZA25 up to 700°C, and in the ZA50 and ZA75 samples, up to 1000°C. The t-ZrO_2 content (Fig. 2) of the samples decreases as the calcination temperature increases; however, after calcination at 1000°C this phase remains in the ZA25 sample (30% content), and in the ZA50 and ZA75 samples 95 and 85% of t-ZrO_2 is retained. It is seen from these data that the presence of γ-Al_2O_3 in the synthesized zirconium–aluminum oxide systems promotes an increase in the temperature of zirconium dioxide crystallization and the stabilization of its low-temperature tetragonal phase. The manifestation of this effect becomes stronger as the fraction of the added aluminum oxide increases.

It is known [6] that in binary mixtures containing ZrO_2 the crystallization temperature of a solid solution based on it increases as the concentration of a doping component increases. According to the DTA data, the crystallization of pure zirconium dioxide in the ZA0 sample was accompanied by an exothermic effect at 390°C (Fig. 3). In the case of the ZA25 sample, a weak exothermic effect corresponding to the crystallization of ZrO_2 has a maximum at 440°C. At a 50 wt % content of Al_2O_3 in the sample (ZA50), the pronounced exothermic effect is absent from the thermogram (Fig. 3), and we can speak only of the field of its probable appearance at temperatures above 550°C, corresponding to the temperature range of the onset of ZrO_2 crystallization detected by X-ray diffraction.

Such differences in the crystallization of the samples under discussion can serve as an evidence of a deep interaction in the Zr–Al–O system proceeding with the formation of solid solutions. This is also confirmed by the X-ray data which show that the position

of the (111) t-ZrO_2 line in all binary samples considerably differs from the positions of the corresponding line of the ZA0 sample and of a mechanical mixture of ZA0 and ZA100 (Table 2). In the series of these samples, the largest shift of the (111) line in the temperature range 600–800°C is observed with ZA50 sample with the chemical composition identical to that of the above-mentioned mechanical mixture.

Table 2. Interplanar spacings d_{111} of the tetragonal phase of zirconium dioxide

Sample no.	Interplanar spacing d_{111}, Å, in samples calcined at indicated temperature, °C					
	400	500	600	700	800	1000
ZA0	2.959	2.955	2.955	2.962	2.965	–
ZA25	–	–	2.938	2.940	2.946	2.951
ZA50	–	–	–	2.9346	2.9402	2.9592
ZA75	–	–	–	2.940	2.946	2.963
Mechanical mixture ZA0 + ZA100	2.960	2.960	2.962	2.962	2.965	–

The calcination of the binary samples ZA50 and ZA75 at 1000°C changes the position of the (111) line to values characteristic of pure ZrO_2. This fact is attributable to the separation of a solid solution into layers under the action of high temperature, with the isolation of pure zirconium dioxide. The largest difference in the interplanar spacing observed for the ZA50 sample seems to be due to the strongest effect of γ-Al_2O_3 on the formation of zirconium dioxide in the mixed oxide system of such composition.

Apparently, the effect of components in the synthesized zirconium–aluminum samples is mutual. Aluminum oxide in the structure of binary samples is represented by a single phase, γ-Al_2O_3. At the same time, the ZA100 sample contains after drying gibbsite and bayerite phases along with the γ-Al_2O_3 phase

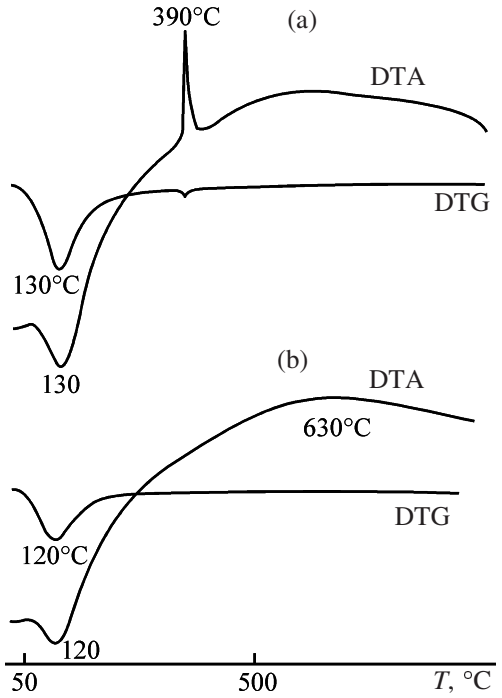

Fig. 3. Thermograms of samples (*1*) ZA0 and (*2*) ZA50. (*T*) Temperature.

(Table 1), suggesting partial hydration of aluminum oxide. Presumably, certain amount of these aluminum trihydroxides is formed also in binary samples but is not detected by X-ray diffraction. This assumption is supported by the presence of the corresponding endothermic effect in the thermogram of the ZA75 sample at 280°C. The simultaneous formation of zirconium and aluminum hydroxides under the synthesis conditions suggests that mixed hydroxides, precursors of Al_2O_3–ZrO_2 solid solutions, can appear.

One more specific feature of the formation of the zirconium–aluminum oxide systems is the presence of a significant amount of the low-temperature Al_2O_3 modification in samples calcined at 1000°C. It is known [14] that the high-temperature modifications θ- and α-Al_2O_3 are characteristic of aluminum oxide in this case, and just these modifications predominate in the ZA100 sample. The presence of foreign cations can hinder the rearrangement of Al_2O_3 into the corresponding forms [15]. Hence, we can assume that zirconium cations are also incorporated in the Al_2O_3 structure in binary samples, which caused stabilization of the low-temperature modification of aluminum oxide.

We have determined the average size of coherent scattering areas of the tetragonal ZrO_2 phase for the samples calcined at various temperatures. It is seen from the represented data (Fig. 4) that the sizes of t-ZrO_2 CSA for the ZA0 and ZA25 samples differ from each other not so strongly as in the case of samples with higher content of aluminum oxide, namely, ZA50 and ZA75. After calcination of these samples at 700–800°C, the size of t-ZrO_2 CSA remains on the level of 10 nm. As the calcination temperature increases to 1000°C, the size of t-ZrO_2 CSA increases sharply, to approximately 30 nm. This size is considered [7, 16] as a critical size of crystallites of the tetragonal phase, which is further converted to the monoclinic phase. However, in the ZA0 and ZA25 samples the conversion of t-ZrO_2 to m-ZrO_2 occurs at

sizes of crystallites much smaller than 30 nm; moreover, the formation of m-ZrO_2 with crystallite sizes of about 15 nm is observed. As the crystallization in one or another modification depends on the ratio of the surface and bulk free energy [4], it is influenced, in addition to the size of crystallites, by the presence of modifying anions and cations, the presence and the distribution of defects, and by other factors. As the above-listed factors differ depending on the composition and conditions of sample preparation, we can assume that in each case crystallites would have their own critical size.

The zirconium–aluminum system seems to be formed through the formation of ZrO_2–Al_2O_3 solid solutions. Their precursors are products of the reaction of zirconium hydroxide with the hydrated surface of aluminum oxide in the precipitation step. Under the conditions of the HZO precipitation, the addition of aluminum ions can terminate the chain of the polymerization of tetrameric complexes $[Zr_4(OH)_8(H_2O)_6]^{8+}$, thus yielding a defective structure of zirconium hydroxide. In turn, zirconium complex ions can be incorporated in the structure of the hydroxide layer of the Al_2O_3 surface on the phase boundary. Such mutually modified phases become precursors of ZrO_2–Al_2O_3 solid solutions with the composition and properties appreciably depending on the ratio of components in the system. The ZA25 sample is close to the ZA0 sample in the character of the structure formation [crystallization of t-ZrO_2 and m-ZrO_2, variation in the position of the (111) diffraction peak of t-ZrO_2, and CSA size]. Possibly, the addition of 25% Al_2O_3 leads to the formation of a solid solution based on zirconium dioxide, whereas the formation of the ZA75 sample seems to be substantially determined by the formation of a solid solution based on the Al_2O_3 structure. The presence of aluminum ions in the HZO structure favors preservation of the X-ray amorphous state of ZrO_2 up to a calcination temperature of 600°C. After crystallization of the ZrO_2–Al_2O_3 solid solution, aluminum oxide acts as a structural promoter hindering the growth of t-ZrO_2 particles beyond a critical size above which the low-temperature tetragonal phase of zirconium dioxide is converted to the stable monoclinic phase. Such promoting effect of aluminum oxide in the binary oxide system is observed within a wide range of ZrO_2/Al_2O_3 ratios. However, this effect is maximal in the case of the ZA50 sample, i.e., systems with a medium aluminum oxide content differ from individual oxides to the greatest extent.

We found that aluminum-containing samples have a larger surface area than the ZA0 sample obtained under similar conditions (Table 1) and preserve the developed surface up to high calcination temperatures (130–140 $m^2 g^{-1}$ at 800°C). The ZA25 sample is an exception, as its specific surface area considerably decreases (to 10–20 $m^2 g^{-1}$), which is also the case with ZrO_2 obtained from HZO. The drastic decrease in the surface area of the ZA25 sample makes it unsuitable as a support. The surface area successively increases in the series of other binary samples as the Al_2O_3 content increases and approaches a level characteristic for γ-Al_2O_3.

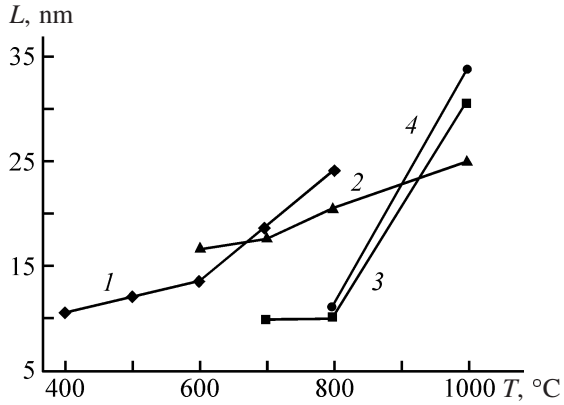

Fig. 4. CSA size in the tetragonal ZrO_2 phase L as a function of calcination temperature of samples T. Sample: (*1*) ZA0, (*2*) ZA25, (*3*) ZA50, and (*4*) ZA75.

The average pore size (Table 3) of γ-Al_2O_3 (5.39 nm) is noticeably larger than that for pure ZrO_2 (4.75 nm), and for the ZA50 sample the average pore size (5.84 nm) exceeds that of ZA100. The size distribution within a wide range characteristic for γ-Al_2O_3 was also preserved in the binary samples. The presence of ZrO_2 in the ZA75 sample shifts the maximum of the pore size distribution curve to the left (Fig. 5), which is caused by the disappearance of the widest pores. On the contrary, the pore size distribution for the ZA50 sample results in a shift of the distribution curve maximum toward wider pores. Thus, the ZA50 sample exhibits not only specific structural features but also specific features of the texture.

The results of the TPD NH_3 study of acid properties of sample surfaces are given in Fig. 6 and Table 3. It is seen that ZrO_2 exhibits two high-temperature desorption peaks with maxima at 490 and 580°C, corresponding to strong acid centers. It also contains certain amount of weak acid centers characterized by the ammonia desorption in the temperature range 100–400°C. Aluminum oxide has a considerable content of weak acid centers of two types, characterized by the desorption peaks at approximately 190 and 310°C. The shape of the thermal desorption curve

Table 3. Pore structure and acid properties of the surface of ZA samples calcined at 400°C

Sample	S_{BET}, $m^2\ g^{-1}$	Pore volume, $cm^3\ s^{-1}$	Average pore diameter, nm	Total number of acid centers, $\mu mol\ g^{-1}$	Density of acid centers, $10^{18}\ m^{-2}$
ZA0	144	0.19	4.75	86.9	0.36
ZA50	255	0.35	5.84	182.2	0.49
ZA75	258	0.30	4.68	54.1	0.13
ZA100	283	0.38	5.39	132.1	0.28

for the ZA75 sample suggests an appreciable mutual influence of components in the binary system, which results in the full disappearance of the weakest acid centers of γ-Al_2O_3 characterized by the desorption at temperatures below 200°C and in the formation of strong acid centers of ZrO_2 characterized by the maximum of NH_3 desorption at 640°C. The most strongly pronounced differences in acid properties

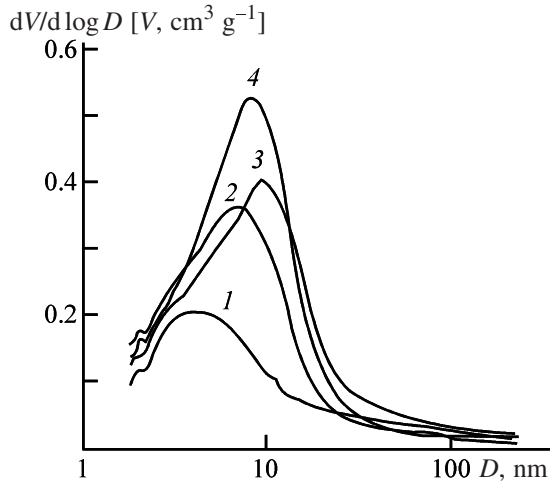

Fig. 5. Pore size distribution of samples calcined at 400°C. (*V*) Pore volume and (*D*) pore size. Sample: (*1*) ZA0, (*2*) ZA75, (*3*) ZA50, (*4*) ZA100.

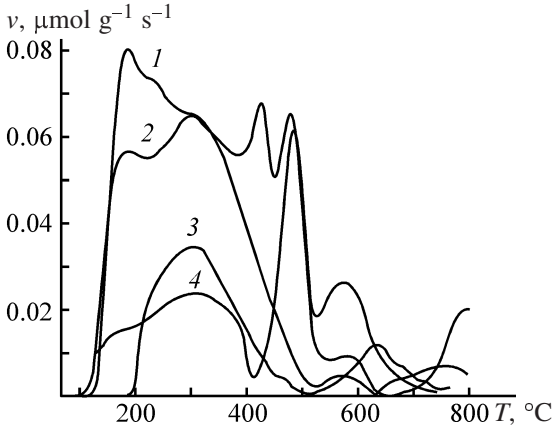

Fig. 6. TPD NH_3 data for samples calcined at 400°C. Sample: (*1*) ZA50, (*2*) ZA100, (*3*) ZA75, and (*4*) ZA0. (*v*) Rate of NH_3 desorption and (*T*) temperature.

of the surface of binary systems are observed for the ZA50 sample. Examination of the thermal desorption curve of this sample shows that, along with the preserved weak acid centers of γ-Al_2O_3 and strong acid centers of ZrO_2, the amount of the weakest centers on the surface (temperature of the maximum 180°C) increased and a significant amount of new acid centers represented by a well-defined peak with a maximum at 430°C appeared. Apparently, the formation of a new type of acid centers should be attributed to the manifestation of the properties arising during the formation of binary zirconium–aluminum oxide systems, namely, to the formation of Zr–O–Al bonds as believed by Li et al. [8].

Variation of the total amount of desorbed ammonia (Table 3) in the series of the samples under discussion also points to appreciable differences in properties of their surfaces. For example, the amount of desorbed ammonia for the ZA75 sample is much lower than that for any of pure oxides, and the greatest amount of desorbed ammonia caused by the highest density of acid centers was detected for the ZA50 sample. Thus, by varying the composition of binary zirconium–aluminum systems, we can adjust the structural and textural characteristics of the samples obtained.

Since the amount of acid centers is important for the practical use of oxide systems as supports, the ZA50 binary system with the maximal density of acid centers can be a promising support. The characteristic features connected with the appearance of new types of surface acid centers also suggest that this system can be used as a catalyst support for a number of processes.

CONCLUSIONS

(1) Binary zirconium–aluminum oxide systems with a developed surface and a high heat resistance can be synthesized by precipitating zirconium hydroxide onto γ-Al_2O_3. This technique ensures formation of well filterable precipitates.

(2) The stability of the highly dispersed ZrO_2

tetragonal phase in the synthesized binary mixtures is ensured in the range of calcination temperatures 600–1000°C, which is accounted for by the modifying effect of aluminum oxide arising from the formation of ZrO_2–Al_2O_3 solid solutions. Temperatures of the crystallization of the tetragonal ZrO_2 phase and of its conversion to the monoclinic phase depend on the composition of the systems obtained.

(3) The pore structure and acid properties of the surface of zirconium–aluminum oxide systems can be adjusted by varying the component ratio. The highest density of acid centers is observed for the samples containing 50 wt % ZrO_2.

(4) The binary systems obtained can be promising for use as sorbents, supports, or catalysts for various processes.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Mixed Cerium–Zirconium Oxides by the Sol–Gel Method

N. N. Gavrilova, O. V. Zhilina, and V. V. Nazarov

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received January 16, 2007

Abstract—Mixed oxides CeO_2–ZrO_2 with the Ce/Zr molar ratios varying in a wide range were synthesized by the sol–gel method. The phase composition of the resulting particles was determined. The specific surface area of the mixed oxide calcined at various temperatures was found.

DOI: 10.1134/S1070427207090054

Mixed cerium–zirconium oxides are widely used in various fields of science and engineering [1]. Depending on composition, they can be employed in manufacture of solid-state oxide cells, gas sensors, and oxygen-conducting materials. Systems with high content of zirconium dioxide are used in production of ceramic materials and ionic conductors, and systems with predominance of cerium dioxide form a basis of various catalysts.

Mixed cerium–zirconium oxides catalyze numerous reactions [2, 3]. Owing to their specific structure, these systems are of particular interest in reactions of hydrocarbon oxidation, both full and selective [4–9].

The different conditions in which these reactions are carried out and the use of different types of supports result in that CeO_2–ZrO_2 are used both as highly dispersed powdered catalysts, coatings, materials with a required pore structure, and high-density materials.

The wide diversity of the properties of the final materials requires that the synthesis method should allow effective control over the properties of the products obtained and have high output capacity and low energy expenditure.

One of the most promising methods for synthesis of mixed oxides CeO_2–ZrO_2 and materials based on these oxides is the sol–gel technique. The possibility of varying the conditions in which separate stages of synthesis are performed allows control over the phase composition, size, and shape of the forming particles in a wide range. Different drying and thermal treatment modes can give products with a required pore structure.

The aim of this study was to obtain mixed hydrosols of CeO_2–ZrO_2 and to determine the basic parameters of CeO_2–ZrO_2 powders.

EXPERIMENTAL

The following chemicals of chemically pure grade were used in the study: cerium(III) nitrate; zirconium oxynitrate; sodium, potassium, and nickel nitrates; and aqueous solutions of ammonium hydroxide and nitric acid.

The concentration of the dispersed phase (in terms of the sum of cerium and zirconium oxides) was found by thermogravimetry, with the dry residue calcined at 650°C. An ultrasonic treatment was carried out in an ultrasonic bath with a working frequency of 25 kHz. The optical density was found turbidimetrically on a KFK-2 instrument at a wavelength of 440 nm (cell thickness 1–10 mm). The pH value was measured with a Schott CG 825 pH-meter with a glass electrode. The electrophoretic mobility was determined by the method of macroelectrophoresis with a mobile boundary. A dispersion medium produced by ultrafiltration of hydrosols served as a contact fluid. The particle size was found by the method of dynamic light scattering on an FK-22 installation including a He–Ne laser (wavelength 632.8 nm, power 5 mW), an F-221 photometer, and a UNICOR SP digital correlometer with 128 high-speed channel processors for on-line calculation of the correlation function (up to 100 ns). The specific surface area of the powders was found by the method of thermal desorption of nitrogen on a GKh-1 installation. The thermogravimetric measurements were made on an MOM Q-1500D derivatograph, with temperature elevated at a rate of

5 deg min^{-1}. The phase composition of the powders was studied by X-ray phase analysis on a DRON-3 diffractometer with CuK_α radiation.

Mixed hydrosols with various Ce/Zr molar ratios were produced by peptization. In this method, water-insoluble hydroxides are obtained from a salt solution and then are peptized in the presence of a strong acid. The OH/M molar ratio in the precipitation of hydroxides was 25. Ammonium hydroxide served as a precipitating agent. Then the precipitate obtained was washed with distilled water to pH 9 in order to remove residual electrolytes and then was peptized in the presence of nitric acid and treated with ultrasound for 2 min. As shown by these experiments, mixed hydrosols can be synthesized in a rather wide range of $[H^+]/[M]$ molar ratios.

The procedure developed can yield mixed CeO_2–ZrO_2 hydrosols with an initial concentration of 1.8 to 6.8 wt %, which can be then concentrated by evaporation or ultrafiltration to 13–43 wt %.

The resulting hydrosols are stable in acidic media at pH 1.0–4.5. Particles of the dispersed phase of the hydrosols are spherical, with an average hydrodynamic radius of 18 to 80 nm, depending on the CeO_2/ZrO_2 molar ratio.

An important factor in fabrication of supported catalysts is the adhesion of hydrosol particles to the support surface. This adhesion is largely determined by the charge on the surface of hydrosol particles. Measurements of the electrophoretic mobility demonstrated that hydrosol particles are positively charged and the ζ-potential, evaluated using the Helmholtz–Smoluchowski equation, is 11 to 32 mV at pH 1.0–4.5.

When sols are used as a basis of various formulations, it becomes necessary to introduce salts of various metals. The basic condition for a high-quality product to be obtained is the aggregative stability of the resulting formulation. To determine the maximum amount of an electrolyte, at which the hydrosols retain aggregative stability, their coagulation thresholds were measured in the presence of various electrolytes. It was found that mixed hydrosols are stable against 1–1 and 2–1 electrolytes. In the presence of $NaNO_3$, KNO_3, and $Ni(NO_3)_2$, coagulation is not observed even in high-concentration solutions of these electrolytes.

The stability of the hydrosols against electrolytes of the 1–1 and 2–1 types allows introduction of required amounts of metal nitrates into the hydrosols, which enables significant modification of the composition of catalytically active formulations.

It should be noted that xerogels produced by drying of concentrated hydrosols retain capacity for spontaneous dispersion in distilled water with pH adjusted to 1.0–4.5. The xerogels were produced by drying of hydrosols in air at 25°C.

A thermogravimetric analysis of these xerogels (Fig. 1) demonstrates that, for all the samples, a sharp weight loss is observed at 250°C, with the following two endothermic effects observed. Below 100°C, capillary and weakly bound water is removed, and the peak at 220–280°C is associated with the decomposition of nitrates. The exothermic effect associated with crystallization of zirconium dioxide is recorded at 380°C (below this temperature, zirconium dioxide is X-ray-amorphous) only for the $Ce_{0.2}Zr_{0.8}O_2$ sample. For other CeO_2/ZrO_2 molar ratios, a broad exothermic peak is observed in the temperature range 300–800°C. This is due to incorporation of Zr^{4+} into the crystal lattice of cerium dioxide.

The data obtained are in good agreement with the results of the X-ray phase analysis (Fig. 2). An analysis of the X-ray diffraction patterns of powders calcined at 600°C demonstrated that $CeZrO_2$ solid solutions are present in a wide range of CeO_2/ZrO_2 molar ratios. However, reflections characteristic of t-ZrO_2 are observed in some cases ($Ce_{0.9}Zr_{0.1}O_2$, $Ce_{0.8}Zr_{0.2}O_2$, $Ce_{0.2}Zr_{0.8}O_2$).

This may occur because the procedure suggested here for synthesis of hydrosols cannot provide full transition of ions into insoluble CeO_2–ZrO_2 compounds. Therefore, the hydrosols contain a certain amount of Ce and Zr in the ionic form, which can lead in further thermal treatment to formation of individual phases. This can be prevented by washing of xerogels with distilled water to complete removal of the ions.

To obtain information about the thermal stability of the mixed oxides synthesized, the specific surface areas of CeO_2–ZrO_2 powders calcined at various temperatures were found. Figure 3 shows the specific surface areas S_{sp} and particles sizes D as functions of calcination temperature and the ZrO_2 content of the system. The average particle size D was evaluated by the formula $D = 6/(\rho S_{sp})$, where ρ is the density of a powder, and S_{sp}, its specific surface area.

As can be seen from these dependences, the largest specific surface area (118 $m^2\ g^{-1}$) after calcination at 450°C is observed for the system $Ce_{0.9}Zr_{0.1}O_2$. However, it exhibits the strongest decrease in the specific surface area as the calcination temperature is raised. An insignificant decrease in the specific surface area

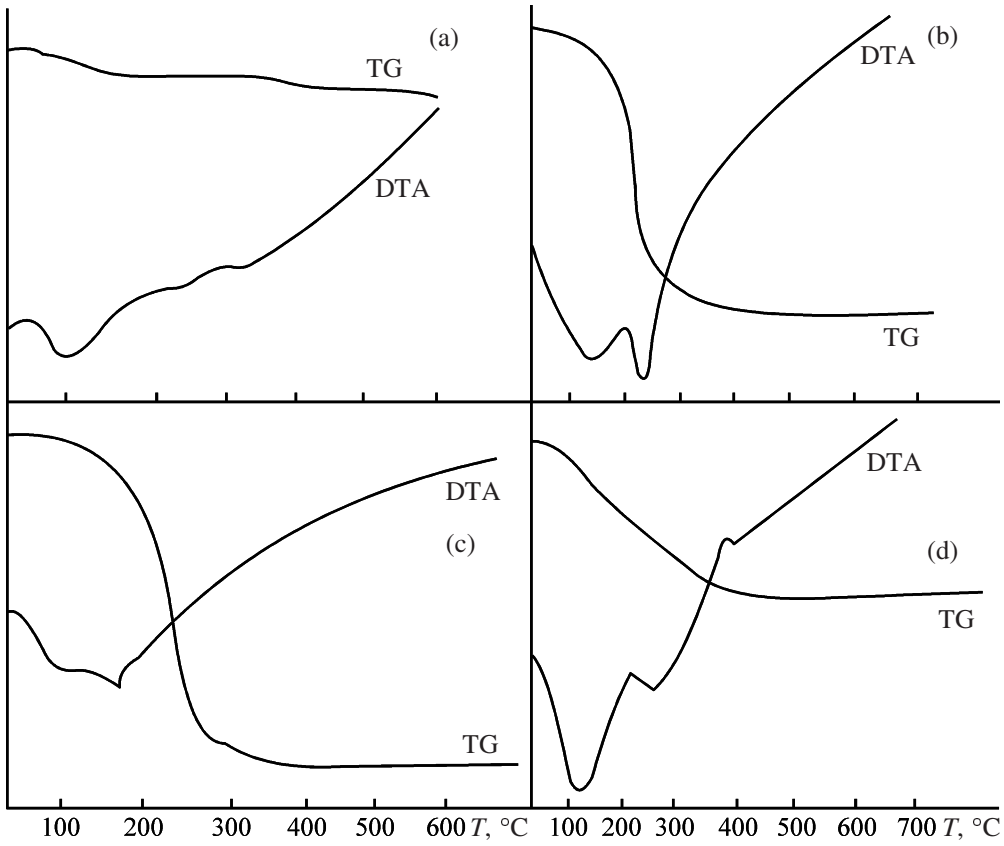

Fig. 1. Thermograms of CeO_2–ZrO_2 xerogels at various CeO_2/ZrO_2 molar ratios. (*T*) Temperature. (a) $Ce_{0.9}Zr_{0.1}O_2$, (b) $Ce_{0.8}Zr_{0.2}O_2$, (c) $Ce_{0.5}Zr_{0.5}O_2$, and (d) $Ce_{0.2}Zr_{0.8}O_2$.

is observed for the systems containing more than 50 mol % ZrO_2.

The hydrosols obtained using this procedure were used to produce various catalysts.

The method of impregnation of a commercial Al_2O_3-based support was used to obtain CeO_2–ZrO_2/Al_2O_3, CuO–CeO_2–ZrO_2/Al_2O_3, and Co_2O_3–CeO_2–ZrO_2/Al_2O_3 catalysts. The activity of these catalysts was studied in the oxidation of CO. The maximum conversion of carbon monoxide was 98%. It was observed in the temperature range 450–650°C, depending on the catalyst composition [10].

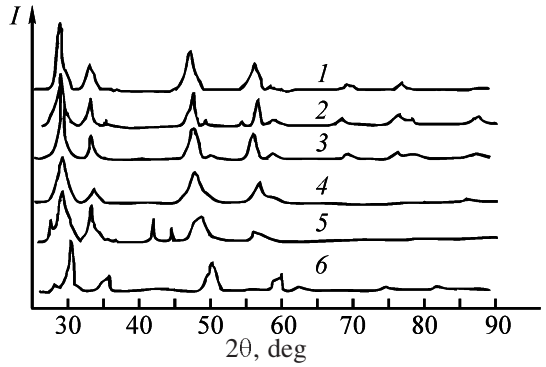

Fig. 2. X-ray diffraction patterns of mixed oxides CeO_2–ZrO_2 at various CeO_2/ZrO_2 molar ratios. (*I*) Intensity and (2θ) Bragg angle. Calcination temperature 600°C. (*1*) CeO_2, (*2*) $Ce_{0.9}Zr_{0.1}O_2$, (*3*) $Ce_{0.8}Zr_{0.2}O_2$, (*4*) $Ce_{0.5}Zr_{0.5}O_2$, (*5*) $Ce_{0.2}Zr_{0.8}O_2$, and (*6*) ZrO_2.

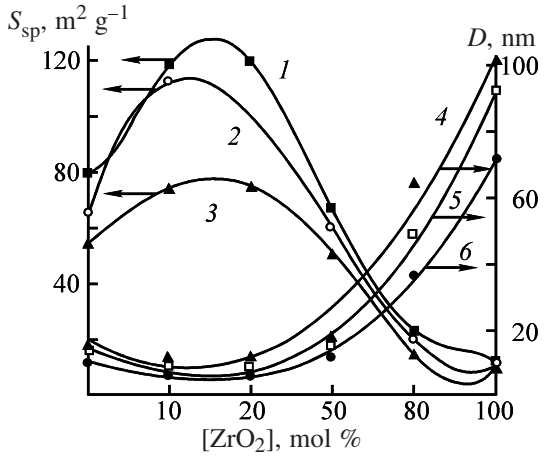

Fig. 3. (*1–3*) Specific surface area S_{sp} and (*4–6*) particle size *D* of mixed oxides CeO_2–ZrO_2 calcined at different temperatures vs. the ZrO_2 content of the system. Temperature, °C: (*1, 6*) 450, (*2, 5*) 600, and (*3, 4*) 750.

The selective oxidation of propane was carried out both on powdered CeO_2–ZrO_2–NiO catalysts and on ceramic membrane units with a catalytically active bed of the same composition. The reaction was studied in the temperature range 300–500°C. It was shown that higher selectivity and output capacity for propylene are achieved with membranes with a catalytically active bed [11].

CONCLUSIONS

(1) The peptization method can be used to obtain aggregatively stable mixed hydrosols of cerium and zirconium dioxides in a wide range of CeO_2/ZrO_2 molar ratios. The resulting hydrosols are stable against introduction of metal nitrates, which allows significant modification of the composition of catalytically active formulations. The hydrosols synthesized can be used for fabrication of both powdered and supported catalysts.

(2) The powders produced by calcination of xerogels have large specific surface area. Their phase composition is mainly represented by CeO_2–ZrO_2 solid solutions. The highest thermal stability is observed for systems with high content of zirconium dioxide.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Low-Temperature Preparation and Properties of Shell Filler Pigments

V. D. Koshevar and V. G. Shkadretsova

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received November 30, 2006

Abstract—The effect of various factors (temperature of drying of the core substance, polymer concentration, concentration of coloring component, mechanical treatment procedures) on the preparation and properties of shell filler pigments was examined.

DOI: 10.1134/S1070427207090066

Much attention is given today in many countries to the development of nontraditional methods for production of pigments in the core, microencapsulated, and hollow forms. It is known that the main functions of pigments (ensuring the required optical density of a medium, color, etc.) are associated with optical phenomena: reflection, absorption, and scattering of light. These phenomena mainly occur in the surface layer. Therefore, to save raw materials (especially nonferrous metal compounds), it is appropriate to use a cheap material as a core and form on its surface a thin film (several tens of nanometers thick) of a more expensive coloring substance. Synthesis of core–shell particles attracts particular interest in materials science [1, 2], because such structures are potential building blocks for the preparation of composite materials with periodically modulated structure, composition, and functions.

Here we report experimental data on the preparation and properties of coloring shell powders. Their formation is based on controllable heterocoagulation followed by baking at temperatures not exceeding 200°C.

EXPERIMENTAL

As a modifying material we used SiO_2 particles of mean diameter 3–4 μm, prepared from phosphoric acid production waste [TU RB (Technical Specification of Belarus Republic) 00 203 714 006–94], and a shell-forming dispersion of polymers and coloring substances. As polymeric components we used latexes of butadiene–styrene, acrylic, and styrene–acrylate copolymers. As coloring agents we used aqueous dispersion of organic dyes, scarlet [TU (Technical Specification) 6-14-946–87] and blue (TU 2463-125-05-05 800 142–2003).

Before deposition of the shell, the surface of core particles was etched in 5% H_2SO_4, washed with water to pH 5–7 of wash waters, and dried at 0–200°C.

Shell powders were prepared from a mixed dispersion of a latex, a core-forming complex, and a coloring agent by various procedures: in a high-speed mechanical mixer, in a SAND ball planetary mill, and in a UZDI-1UCh.2 ultrasonic disperser.

The heterocoagulate was heat-treated in a thermostat at 50°C for 2 h. Then, to check the strength of adhesion of the shell to the core, the heterocoagulate was washed in water at 20°C for 24 h. After washing, the shell powders were dried in air at 20°C.

The stability of the color of the resulting coloring powder depends on the adhesion of the shell to the core and on the water permeability of the shell. These properties were estimated by turbidimetric measurement of the optical density of water from washing of the heterocoagulate. The higher the optical density of the wash water relative to the reference (distilled water), the lower the adhesion and the higher the water permeability of the shell. The optical density was measured with a KFK-3 photoelectric colorimeter at actinic wavelengths.

The sedimentation stability of the shell powders obtained was studied by the joint sedimentation method. For this purpose, 1% aqueous dispersions were placed in a graduated cylinder, and the shift of the dispersion medium–dispersed phase boundary was monitored up to complete clarification.

The formation of shell structures was studied by scanning electron microscopy (JSM-5610 microscope), IR spectroscopy, and derivatography. The IR absorption spectra in the range 400–4500 cm^{-1} were recorded on a GK-20 device using KBr prisms. Differential thermal analysis of the pigments was performed with an MOM derivatograph (Hungary) at a heating rate of 5 deg min^{-1}; the sample weight was 800 mg. Calcined aluminum oxide (chemically pure grade) was used as reference.

The optical density of the powders was measured with a DO-IM densitometer using appropriate color filters.

To examine the atmosphere resistance of the powders, they were treated with various chemical agents (hot distilled water for 2 h at 98°C; 2% NaOH; 4% CH_3COOH; 3% NaCl; 96% ethanol). The color stability was evaluated with an FMSh-56M device from the difference between the reflection coefficients of the specimens before and after reagent treatment.

Figures 1a, 1b, 2a, and 2b show how the core–shell adhesion strength depends on the chemical nature and concentration of latexes and on the temperature of predrying of the core component, SiO_2. It is seen that the dependence of the optical density of wash water on the latex concentration passes through a minimum. Apparently, the adhesion of the shell to the surface of the core SiO_2 particles stronglty depends on the shell thickness, which, in turn, is determined by the latex concentration. In particular, it is known [3] that the adhesion of a coating to a support can appreciably decrease with increasing coating thickness.

Figures 1a, 1b, 2a, and 2b also show that formation of a strong composite shell on the surface of SiO_2 particles, imparting to them an intense red color, depends on the temperature at which the core material was predried before treatment with the shell-forming dispersion. The drying temperature of 100°C appeared to be the best. At this temperature, apparently, physically adsorbed water is removed, which facilitates the access of a shell-forming agent to the SiO_2 surface, but the structural OH groups remain intact. Heating at a higher temperature (150°C) may cause partial dehydration of the OH groups specifically bound to the SiO_2 surface and making it hydrophilic. As a result, the wettability of the core decreases, which, apparently, results in worse adhesion of the shell (Figs. 1, 2, curves *3*: increase in the optical density).

As the concentration of the coloring agents in the shell-forming dispersion increases, a proportional increase in the intensity of the powder color is accompanied by an increase in the optical density of the wash water, with all the latex systems used. At coloring agent concentrations less than 2%, the optical density of wash water is close to that of the reference solution (Figs. 2a, 2b).

	9	10	4.5	1.14

* State Standard.

The dependences obtained allowed determination of the optimal conditions of efficient modification of the SiO_2 surface, at which washing of the ready powders is not required.

An appreciable effect on the properties and morphology of the SiO_2–shell-forming agent heterocoagulate is exerted by various mechanical treatment procedures used for preparing shell powders. Table 1 shows that the dispersions of shell powders prepared by mechanical treatment on a SAND planetary mill exhibit the highest sedimentation stability, and the heterocoagulate formed from dispersions subjected to ultrasonic treatment has the strongest color. Dispersion with a high-speed mixer, compared to the ultrasonic treatment, ensures somewhat lower color intensity. Prolonged treatment in a SAND mill, apparently, leads to certain damage of the shell, manifested as a decrease in the intensity of the powder color. The results obtained are confirmed by electron-microscopic examination. Powders obtained in a mill have, on the average, small particle size compared to the initial core-forming material.

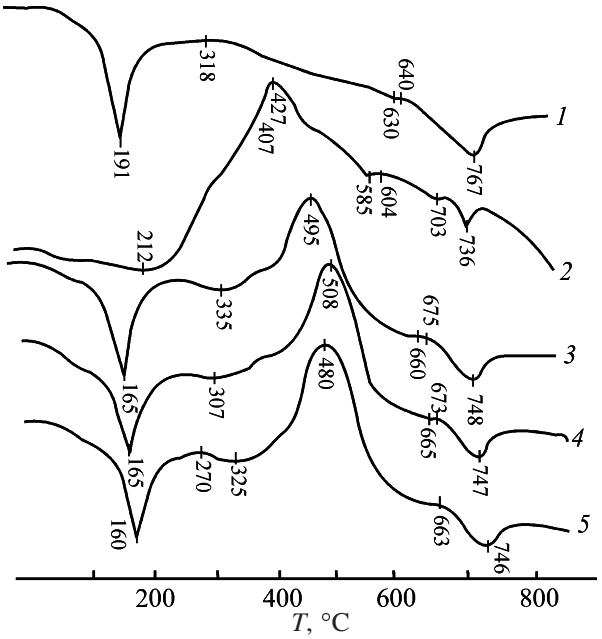

Fig. 3. Thermograms of (*1*) SiO_2, (*2*) blue coloring agent, and (*3*–*5*) powders prepared by various mechanical treatment procedures. (*T*) Temperature. Mechanical treatment with (*3*) high-speed mechanical mixer, (*4*) SAND mill, and (*5*) ultrasonic disperser; the same for Fig. 4.

To reveal the mechanism of formation of shell structures, let us analyze the DTA and IR data. The thermograms of straight SiO_2 and the heterocoagulate show medium-intensity endothermic effects in the range 160–168°C, caused by removal of adsorbed water and onset of the modifier thermolysis (Fig. 3). The relatively weak endoeffect in the range 307–325°C is observed only or the heterocoagulate, suggesting the formation of a relatively strong adsorption complex on the core–shell boundary. The formation of such complex is also indicated by a shift toward higher temperatures of the strong exothermic effect characteristic of the shell-forming substance and associated with its thermal decomposition and oxidation of the decomposition products.

Formation of a complex on the core–shell boundary is also confirmed by IR data (Fig. 4). For example, for the SiO_2–latex heterocoagulate, the coloring agent bands in the range 1520–1250 cm^{-1} almost completely disappeared, and the powder surface became more hydrophilic (especially for the powder prepared with SAND mill); the stretching and bending OH vibration bands of adsorbed water at 3000–3450 and 1750 cm^{-1} increased in intensity.

The core–shell adhesion strength in the powders was estimated, with the SiO_2–(styrene–acrylate

latex)–blue coloring agent composite as example, from the resistance of the powder to boiling water, dilute acids and alkalis, and a medium-polarity organic solvent (Table 2). It can be seen that the powders are resistant to all these reagents, showing no changes in the color intensity (reflection coefficient). That is, the core–shell adhesion is quite strong.

Shell powders of intense red and blue colors were successfully tested as filler pigments in production of water-dispersible paints and dry building mixes.

CONCLUSIONS

(1) Shell powders of intense red and blue colors, exhibiting high atmosphere resistance, were prepared by heterocoagulation of mixed dispersions of latexes and organic coloring agents on the surface of SiO_2 core particles.

(2) The major factors governing the properties of the powders are the temperature of SiO_2 predrying and the latex and coloring agent concentrations in their mixed aqueous dispersion.

(3) Derivatographic and IR studies showed that the required adhesion of the shell to the core is provided by specific interaction of the components on the core–shell interface.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Choice of a Scheme for Desulfurization of Rich Metallurgical Gases

O. I. Platonov

Gipronikel' Institute, Limited Liability Company, St. Petersburg, Russia

Received June 15, 2007

Abstract—Known schemes for production of sulfur from an oxygen-containing sulfurous gas are critically considered with account of the presence of sulfur trioxide in real metallurgical gases. An efficient technology for deep processing of metallurgical gases rich in sulfur dioxide was developed on the basis of a thermodynamic analysis and industrial "methane" technology for reduction of gases formed in autogenous smelting.

DOI: 10.1134/S1070427207090078

In view of the worldwide tendency toward excessive production of sulfuric acid [1] and the geographic separation of places of its manufacture and consumption, the requirements of the environment protection regulations revive interest in utilization of metallurgical sulfurous gases to obtain elemental sulfur, which is more suitable for transportation or prolonged storage than the acid. This is particularly topical for SO_2-rich gases formed in autogenous smelting, whose processing schemes are reviewed in [2]. However, most of these schemes, based on the rich experience of sulfur production from hydrogen sulfide [3], disregard the known specificity of metallurgical gases [4] and, therefore, require a critical analysis.

Flour Co. has developed a number of schemes for production of sulfur from the sulfurous gas. These schemes include stages of deoxygenation, hydrogenation and hydrolysis, Claus reaction, direct reduction, generation of a reducing gas, and purification. All the versions of the schemes suggested [5, 6] involve thermal or catalytic removal of oxygen from the gas, followed by the hydrogenation stage:

$$S + H_2 = H_2S, \quad (1)$$

$$SO_2 + 3H_2 = H_2S + 2H_2O, \quad (2)$$

performed at 200–450°C on a special catalyst. The necessary hydrogen is generated in substoichiometric burning of natural gas in a separate converter or directly in the deoxygenation reactor.

To remove steam, the gas discharged from the hydrogenation reactor is cooled in a boiler-utilizer and then in a contact heat exchanger (quencher) by circulating water, which also catches trace amounts of carbon black (fly ash). To limit the temperature in processing of a concentrated gas, part of the gas from the quencher is returned by a low-pressure blower into the hydrogenation reactor.

Hydrogen sulfide obtained in the hydrogenation reactor is further processed by the Claus method. In most of flowsheets [5, 6], about 1/3 of the initial amount of the sulfurous gas is delivered, bypassing the hydrogenation stage, directly into the Claus reactor, in which hydrogen dioxide reacts with hydrogen sulfide in accordance with the reaction equation

$$2H_2S + SO_2 = 2H_2O + 3/nS_n, \qquad n = 1–8. \quad (3)$$

The flow of the sulfurous gas is similarly divided in a 2 : 1 proportion in the scheme suggested by Worley Parsons [7]. To achieve the maximum yield of CO and H_2, natural gas is also burnt at a substoichiometric ($\alpha \approx 0.6$) air supply and steam feed. After that, the H_2S-rich process gas from the quenching column and the remaining 1/3 of the initial SO_2 are separately heated and after that combined in the first converter of the conventional Claus installation.

An original process for sulfur recovery from an SO_2 flow [7] is based on two known techniques. First, an endothermic reaction of natural gas and vapors of recycled sulfur is carried out in a catalytic reactor (reactors) on active aluminum oxide at 575–650°C:

$$CH_4 + 2S_2 = CS_2 + 2H_2S. \quad (4)$$

After cooling in a medium-pressure (4.2 MPa) boiler-utilizer and condensation of residual sulfur at

150°C, the gas containing H_2S and CS_2 is again heated in a heat exchanger to 210°C and delivered, together with concentrated (to 90 vol %) sulfur dioxide, into the first Claus reactor, in which reaction (3) between H_2S and SO_2 occurs in a fixed catalyst bed to give sulfur. Simultaneously, carbon disulfide is hydrolyzed to H_2S:

$$CS_2 + 2H_2O = CO_2 + 2H_2S. \quad (5)$$

In view of the exothermic nature of reactions (3) and (5), a considerable part of the gas is returned via the utilizing vessel and sulfur condenser into the first reactor of the sulfur recovery unit (SRU) in order to maintain the temperature mode of the Claus reactor. After cooling of the gas in the utilizing vessel to 340°C and condensation of sulfur at 150°C, the gas is delivered to the second and third stages of the Claus installation, with afterburning of the tail gas at 60°C and its discharge into the atmosphere.

Despite the wide variety of suggested schemes [2], the only acting industrial technology for recovery of sulfur from metallurgical gases is the "methane" method.[1]

In this technique [8], a sulfurous gas cleaned to a dust content of about 5 mg m^{-3} and cooled to 20–35°C is preliminarily enriched with oxygen to a concentration $[O_2]$ = 12–18 vol %. Further processing of the oxygen-containing sulfurous gas includes its heating by the heat released in the exothermic reaction of burning of natural gas

$$CH_4 + 2O_2 = 2H_2O + CO_2, \quad \Delta H = -802 \text{ kJ}; \quad (6)$$

thermal (1150–1200°C) reduction in a homogeneous reactor

$$CH_4 + 2SO_2 = 2H_2O + CO_2 + S_2; \quad (7)$$

catalytic conversion of the reduced gas in the target reaction (3); condensation of the resulting sulfur; and subsequent afterburning of the discharge gas. The reduction process is accompanied by decomposition of sulfur trioxide

$$2SO_3 \longrightarrow 2SO_2 + O_2, \quad (8)$$

present in the starting sulfurous gas [4]. The independence from the initial concentration of oxygen and presence of SO_3 predetermines the reliability of the methane method in processing of the real metallurgical gas.

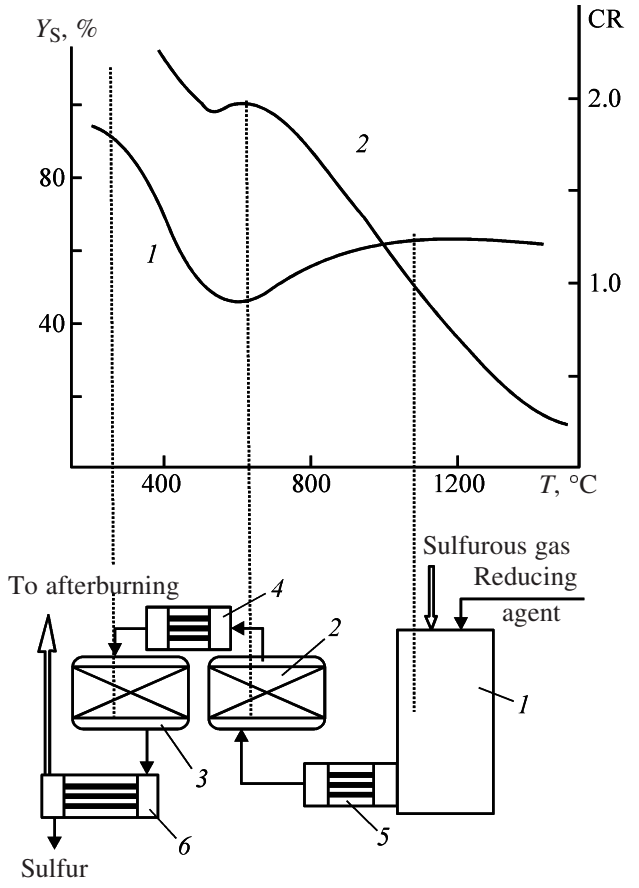
A known disadvantage of this technique is the comparatively high specific expenditure of the reducing agent (natural gas), which is 800–1000 Sm^3 (m^3 under normal conditions) per ton of sulfur. This is commonly believed to be partly due to the high reduction temperature. However, as demonstrated by an analysis in [9], this is more likely associated with thermodynamic and kinetic features of the process. For example, at a stoichiometric expenditure of the reducing agent in reactions (6) and (7), the overall sulfur recovery coefficient does not exceed 65–70%, which is due to the insufficient extent of the single-stage catalytic conversion of the reduced gas [10]. Introduction of two catalytic stages and additional enrichment of the reduced gas with products formed in conversion of natural gas (CO and H_2) [11] raises the extent of sulfur recovery to 94% and lowers the specific expenditure of the reducing agent to approximately 750 Sm^3 per ton (at an initial concentration $[SO_2]_0$ in the sulfurous gas equal to 30 vol %). However, this expenditure of natural gas also seems to be excessive, which presents a problem of the methane method that has not been conclusively resolved.

To make lower the specific expenditure of the natural gas fuel in the methane method, it has been suggested to reduce the sulfurous gas at a lowered temperature (e.g., 750–950°C [12]) on a catalyst, which, as it is commonly believed, will markedly improve the economic efficiency of the methane technique. However, simplest quantitative estimates cast doubt on this "paradigm," because the contribution of the fuel expended for heating of the sulfurous gas to the reduction temperature is not the only factor predetermining the high specific expenditure of natural gas in the methane method.

For example, less than half of the reducing agent is consumed for oxygen binding and heating at common concentrations $[SO_2]_0 \geq 25$ vol % in the sulfurous gas in Vanyukov furnaces and maximum enrichment of the sulfurous gas to a concentration $[O_2]$ = 15% corresponding to the temperature of homogeneous reduction (~1200°C). With account of the afterburning of the discharge gas, the fraction of fuel expended for heating to the reduction temperature in the total expenditure of natural gas does not exceed 1/3. The difference between the minimum (for oxygen binding with heating to 600°C in catalytic processing) and maximum fuel consumption in thermal reduction does not exceed 1/4 of the total consumption of natural gas.

In addition, implementation of the catalytic proc-

[1] This method has been employed since 1987 for utilization of discharge gases from Vanyukov furnaces at the copper plant of the Norilsk Mining-and-Smelting Combine (presently, Norilsk Nickel Mining-and-Smelting Open Joint-Stock Company).



(*1*) Equilibrium yield of elemental sulfur and (*2*) Claus ratio CR vs. temperature *T*, and the flow chart of processing of the sulfurous gas. (*1*) Reducing reactor, (*2*) catalytic reactor, (*3*) Claus reactor, (*4, 5*) boiler-utilizers, and (*6*) sulfur condenser.

essing scheme involves additional operational expenditure (primarily of energy) for pumping of the process gas through the catalyst bed, which nullifies to an even greater extent the potential gain that can be obtained by lowering the process temperature. Therefore, there is no way of expecting a substantial saving of natural gas in the case of low-temperature catalytic processing of the sulfurous gas.

On the whole, qualitative analysis of the schemes suggested for processing of sulfurous gases [2] shows that, despite the scheme contrivances demonstrated by design companies, the substantially more intricate technique (including technologically dangerous processes, as in [7]) does not lead to any significant efficiency improvement. The reason is that, as noted in [13], the processing efficiency is determined in the end by the degree of conversion of sulfurous gases by the Claus reaction (3), which is common to all the known schemes of SO_2 processing.

Rameshni and Santo [7] believe that, compared with to existing methane method, their scheme requires a lower fuel consumption; however, this opinion is refuted by a quantitative analysis of this scheme with account of all heat loss channels. Indeed, the direct reduction process and the Worley Parsons scheme are similar in the overall stoichiometric balance of sulfur formation, which results in that they differ only in the fuel consumption for heating to the reduction temperature. Because the common efficiency of the furnace for flame heating in the scheme suggested by Worley Parsons for processing of the sulfurous gas is low, the total specific expenditure of natural gas will markedly exceed 1000 $Sm^3\ t^{-1}$, despite the apparent saving directly in the "technology" of sulfur recovery.

It should also be noted that all low-temperature techniques for processing of the sulfurous gas are exceedingly vulnerable to the action of sulfur trioxide present in the real metallurgical effluent gas. As assumed in [2], binding of this sulfur trioxide when concentrating the starting SO_2 involves additional capital and operational expenditure comparable with, or even exceeding that of sulfurous gas processing proper. In this case, the preliminary concentration of the gas being processed is not always justified, because it disturbs the temperature mode of the reactors and leads to their more intricate design and connection schemes (with introduction of recycles). This does not rule out the possibility of secondary formation of SO_2, which is especially favored by the temperature range of processing of the starting gas near 600°C. The sulfuric acid corrosion and catalyst poisoning can be eliminated by thermal decomposition of SO_3 by reaction (8), which is an additional positive argument in analysis of the potentialities of the "methane" method.

From the thermodynamic standpoint, the most energetically favorable reduction products in reaction (7), as well as in the Claus reaction (3), are H_2O and CO_2, with sulfur formed as a by-product. This is illustrated by the temperature dependences of the equilibrium yield of elemental sulfur (curve *1*) and of the Claus ratio in the upper part of the figure. These dependences were calculated for the stoichiometric [for reactions (6) and (7)] reduction with methane of the typical effluent gas from Vanyukov furnaces at the copper plant of Norilsk Nickel Mining-and-Smelting Open Joint-Stock Company, which contains (vol %): SO_2 39.65, SO_3 0.055, O_2 16.53, CO_2 0.88, H_2O 7.05, N_2 35.25, and Ar 0.6.

As can be seen from the figure, a Claus ratio CR $\equiv$ $[H_2S]/[SO_2] \geq 2$, acceptable for the subsequent

processing by reaction (3), is reached at catalytic reduction temperatures in the range 450–650°C, in which the equilibrium yield of elemental sulfur, Y_S, does not exceed 60 rel % (at 450°C). This gives no way of achieving a deep recovery of sulfur in a single stage of processing of the sulfurous gas. The kinetic limitations on the reduction process [9, 14] and on the subsequent catalytic conversion of the reduced gas [15] make deep processing of the sulfurous gas an even more complicated task.

Nevertheless, the results of a thermodynamic analysis, shown in the figure, make it possible to improve the technology of sulfur production from metallurgical gases: the flow chart with the main stages of processing of the sulfurous gas related to the working temperature scale is shown in the lower part of the figure.

The optimal scheme of processing of a washed sulfurous gas (see figure) includes enrichment with oxygen to a prescribed concentration and reduction with natural gas (methane) in a homogeneous reactor *1* at a temperature $T \approx 1100$°C. After that, SO_2 is additionally reduced in the catalytic reactor *2* at 400–550°C, elemental sulfur is condensed, conversion in the Claus reactor *3* is carried out, sulfur is condensed and separated, and toxic components of the waste gas are subjected to afterburning.

The stage of catalytic conversion at 400–650°C provides hydrolysis of carbon disulfide by reaction (5) and of carbonyl sulfide:

$$COS + H_2O \rightleftarrows H_2S + CO_2, \quad (9)$$

as well as additional reduction of sulfur dioxide by reactions (2), (3), and (7), and by the reactions

$$2COS + SO_2 \rightleftarrows 2CO_2 + 3/nS_n, \quad n = 1\text{–}8; \quad (10)$$

$$2CS_2 + SO_2 \rightleftarrows 2COS + 3/nS_n; \quad (11)$$

$$2CO + SO_2 \rightleftarrows 2CO_2 + 1/nS_n; \quad (12)$$

$$2H_2 + SO_2 \rightleftarrows 2H_2O + 1/nS_n. \quad (13)$$

Simultaneously, hydrogenation by the reaction

$$H_2 + 1/nS_n \rightleftarrows H_2S \quad (14)$$

and hydrolysis by a reaction reverse to (3) result in that elemental sulfur produced by reduction reaction (7) partly forms hydrogen sulfide. As a result, the Claus ratio at the outlet of the catalytic reactor (converter) *3* reaches at 500–550°C a value CR ≈ *2*. After cooling of the reduced sulfurous gas in the boiler-utilizer to 220–250°C (temperature controlled with a by-pass), its processing in the Claus reactor is identical to that in the conventional Claus process (3).

A specific feature of this flowsheet is that there is no sulfur condenser, mandatory in conventional Claus installations [3], before the first stage of catalytic conversion of the reduced gas. This is due to the insufficient content of hydrogen sulfide (CR ≤ 1) at the outlet of the reducing reactor and to the high temperature (400–550°C) in the first stage of catalytic conversion, which is necessary for effective hydrolysis of organosulfur components by reactions (8) and (9).

The elemental sulfur obtained in the homogeneous thermal reactor and hydrolyzed in the first catalytic stage to hydrogen sulfide reacts, in the subsequent catalytic processing by the Claus method, with sulfur dioxide, being again oxidized to elemental sulfur by the cycle $SO_2 \rightarrow 1/2S_2 \rightarrow H_2S \rightarrow 1/nS_n$. In accordance with the stoichiometry of the Claus reaction (3), processing of hydrogen sulfide yields elemental sulfur in an amount exceeding its content in hydrogen sulfide by a factor of 1.5. Therefore, hydrolysis of organosulfur compounds in the first catalytic stage to give hydrogen sulfide at an initial excess of SO_2 leads to an increase in the overall yield of sulfur.

The industrial experience confirms the fairly high efficiency of hydrogen sulfide generation at 350–450°C on typical aluminum oxide catalysts [15]. However, the high temperature in converter *2*, necessary in accordance with the chemical equilibrium (see figure), requires that a special catalyst stable against hydrothermal aging should be used in this case. Because ordinary aluminum oxide catalysts for the hydrolysis and hydrogenation reactions rapidly lose their activity in the Claus process, it is advisable to use industrial cobalt–molybdenum catalysts [2, 5, 7] or vanadium–titanium catalysts on an aluminum oxide support.

Use of by-passes for temperature control, instead of the conventional gas heaters, rules out any fuel expenditure for repeated heating of the process gas and is technologically justified because the efficiency of reaction (3) in the Claus reactor is independent of the presence or absence of elemental sulfur. Taken together with the lowered temperature of homogeneous reduction, this makes it possible to diminish the fuel expenditure and feeding water consumption and to bring down the capital investment at an increased throughput of the production line.

As applied to utilization of effluent gases from

Vanyukov furnaces, the three-stage processing provides 92–94% recovery of sulfur. In this case, the total (including that for afterburning) specific expenditure of natural gas is about 560 $Sm^3\ t^{-1}$, which is no worse than that in other schemes suggested for catalytic processing of the sulfurous gas [2]. The increase in other operational expense items (and primarily in electric power consumption) in implementation of any version of catalytic processing gives certain advantages to the improved scheme with the industrially mastered thermal reduction of the metallurgical sulfurous gas.

CONCLUSIONS

The analysis made in the study demonstrated that the known schemes of catalytic processing of sulfurous gases have no fundamental advantage over the already employed "methane" technology for sulfur recovery from effluent gases formed in autogenous smelting. At close sulfur recovery parameters (92–96%) and reducing agent consumptions, the key role is played by the extent to which a technology is developed, reliability, and safety, in which the improved technology of direct thermal reduction of a rich metallurgical sulfurous gas has obvious advantages.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Enhancing the Sensitivity of Spectrophotometric Determination of Formic Acid with Mercury(II) Acetate

Yu. G. Khabarov and M. S. Yakovlev

Arkhangelsk State Technical University, Arkhangelsk, Russia

Received December 14, 2006

Abstract—A precise spectrophotometric method was developed for determination of formic acid. The method surpasses in sensitivity the method based on proper UV absorption of formic acid.

DOI: 10.1134/S107042720709008X

Formic acid is widely used in various branches of industry: as stain in dyeing, in textile and paper finishing, in leather treatment, in production of drugs and preservatives. It is often used as chromatographic eluent and as a reagent for organic synthesis, e.g., for preparing formamide, dimethylformamide, and oxalic acid [1–3].

There are diverse procedures for analytical determination of formic acid: alkalimetry, gas chromatography, UV and NMR spectroscopy, capillary electrophoresis, etc. [4–6]. The UV spectroscopic determination of formic acid is based on its absorption at 206 nm [7–9].

EXPERIMENTAL

The following chemicals were used: analytically pure grade mercury(II) acetate, chemically pure grade 85% formic acid, chemically pure grade glacial acetic acid, and chemically pure grade 37% Formalin. The formaldehyde solution was prepared by dilution of Formalin filtered through a paper filter.

The spectra were recorded on a Specord M40 spectrophotometer in the wavelength range 200–330 nm. The optical densities of solutions at 206 and 236 nm were measured with an SF-46 spectrophotometer. These measurements were performed in 1-cm quartz cells against distilled water.

Formic acid solutions were prepared by dilution of the acid. To prepare a solution of mercury(II) acetate, a 100-ml volumetric flask was charged with 1.165 g of the salt and 1.1 ml of glacial acetic acid (to prevent hydrolysis), and the solution was brought to the mark.

The photometric reaction was performed as follows. A 100-ml volumetric flask was charged with 80 ml of a formic acid solution (7.78–72.6 mg l^{-1}), the prescribed volume of the mercury(II) acetate solution was added, the mixture was brought to the mark with water and thoroughly mixed. The optical density of the solution at 236 nm, D_{236}, was measured 10, 20, 30, 60, and 120 min after adding the solution of mercury(II) acetate.

Determination of formic acid by proper absorption was performed by measuring the optical density of the solution at 206 nm, D_{206}.

To study the interfering effect of formaldehyde on the determination of formic acid, to a 100-ml volumetric flask we added in succession 80 ml of a formic acid solution (64.4 mg l^{-1}), the prescribed volume of the formaldehyde solution, and 1 ml of the mercury acetate solution. The mixture was brought to the mark with water. The optical density D_{236} was measured 10, 20, 30, and 60 min after adding mercury acetate.

The reaction of mercury(II) acetate with formic acid is accompanied by appearance of a strong absorption band at 236 nm (Fig. 1). In further experiments we determined the required amount of the mercury(II) acetate solution and examined the influence of the reaction time on the determination results. For this purpose, the photometric reaction was performed with 80 ml of a formic acid solution (51.5 mg l^{-1}) and varied amounts of the mercury(II) acetate solution: 0.2, 0.6, 1.0, 1.4, and 1.8 ml. The optical density of solutions D_{236} (minus the optical density in blank experiments without formic acid) is plotted in Fig. 2 against the amount of mercury(II) acetate added. It is seen that addition of the mercury(II) acetate solution in amounts over 1.0 ml does not lead to a further sig-

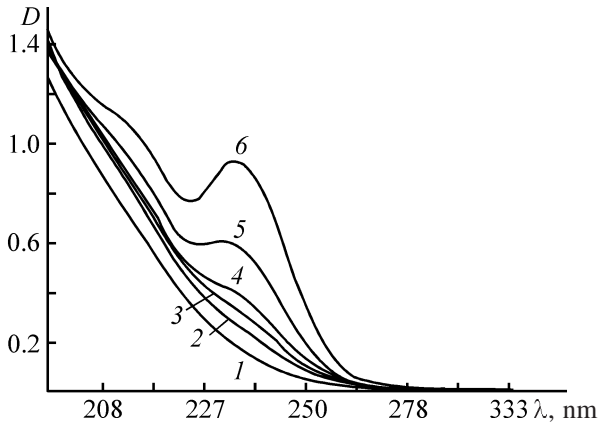

Fig. 1. Variation of the electronic absorption spectrum of the reaction product with the reaction time. (*D*) Optical density and (λ) wavelength. (*1*) Blank mercury(II) acetate solution and (*2–6*) reaction product. Reaction time, min: (*2*) 10, (*3*) 20, (*4*) 30, (*5*) 60, and (*6*) 120.

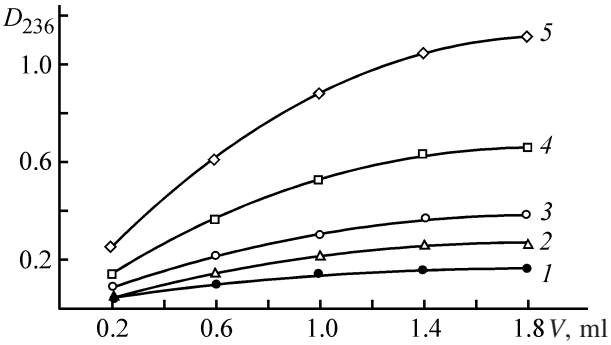

Fig. 2. Optical density of solutions D_{236} as a function of the volume *V* of the mercury(II) acetate solution added. Reaction time, min: (*1*) 10, (*2*) 20, (*3*) 30, (*4*) 60, and (*5*) 120.

nificant increase in the optical density. Therefore, further experiments were performed with addition of 1.0 ml of the mercury(II) acetate solution.

To construct calibration plots, the photometric reaction was performed with various preset concentrations of the formic acid solutions. Two replicate determinations were made for each point; the mean values of D_{236} are listed in Table 1.

Table 1. Mean values of D_{236} of formic acid solutions at various formic acid concentrations *c* and reaction times τ

c, mg l^{-1}	D_{236} at indicated τ, min				
	10	20	30	60	120
6.22	0.158	0.169	0.178	0.213	0.247
16.6	0.189	0.217	0.246	0.326	0.457
27.0	0.215	0.216	0.309	0.429	0.632
37.3	0.246	0.317	0.375	0.550	0.830
47.7	0.277	0.363	0.444	0.662	1.015
58.1	0.318	0.443	0.547	0.815	1.206

By the least-squares method, we calculated the coefficients of the calibration plots $D_{236} = a + bc$, where *c* is the formic acid concentration (mg l^{-1}), and the pair correlation coefficients (Table 2).

The concentration dependences of the optical density are linear, and the optical density of solutions of the photometric reaction product is described by the Bouguer–Lambert–Beer law.

Table 2 shows that the coefficients of the calibration equations strongly depend on the reaction time. Therefore, the calibration equation should include not only the formic acid concentration but also the reaction time. The best fitting of the experimental data was attained with a cubic logarithmic polynomial

$$c = 500 - 144\ln\tau + 8.01\ln^2\tau + 371\ln D_{236} + 62.8\ln^2 D_{236}$$
$$- 96.8\ln\tau\ln D_{236} + 0.494\ln^3\tau + 6.41\ln^2\tau\ln D_{236}$$
$$- 8.24\ln\tau\ln^2 D_{236} + 3.65\ln^3 D_{236},$$

The repeatability and accuracy of the determination were estimated in experiments with formic acid solutions of five different concentrations (four replicate measurements for each point). After performing the photometric reaction, we measured D_{236}, calculated from the three-dimensional calibration plot the formic acid concentrations, and compared them with the preset values (Tables 3, 4).

Tables 3 and 4 show that the suggested method exhibits good repeatability (coefficient of variation ≤3.6%) and accuracy (relative error about 3% on the average).

For comparison, we performed experiments on formic acid determination by proper absorption at 206 nm. For this purpose, we calculated the coeffi-

58.1	0.074	0.076	0.032	0.045	0.057	0.022	38.3

cients of the calibration plot and obtained the equation $D_{206} = 0.028 + 0.000892c$, where c is the formic acid concentration (mg l^{-1}), with the pair correlation coefficient $R^2 = 0.999$.

The repeatability and accuracy of determination were estimated with formic acid solutions of six different concentrations (four replicate measurements for each point); the results are given in Table 5.

Table 5 shows that the repeatability of D_{206} in the range of formic acid concentrations from 6 to 60 mg l^{-1} is very poor.

To evaluate the determination accuracy, photocolorimetric measurements were performed at 206 nm, and the formic acid concentrations were calculated from the calibration plots and compared with the preset values (Table 6).

Table 6. Accuracy of formic acid determination by proper absorption

D_{206}	c_{HCOOH}, mg l^{-1}		Mean error	
	introduced	found	absolute, mg l^{-1}	relative, %
0.016	6.22	0	–6.22	100
0.025	16.6	0	–16.6	100
0.026	27.0	0	–27.0	100
0.029	37.3	1.4	–35.9	96.2
0.033	47.7	5.9	–41.8	87.7
0.057	58.1	32.2	–25.9	44.5

Table 6 shows that the accuracy of formic acid determination by proper absorption in the examined concentration range is also very poor.

Thus, the new spectrophotometric method enhances the sensitivity of the determination (the lower determination limit decreases from 140 to 10 mg l^{-1}).

Since process solutions often contain formaldehyde along with formic acid, we examined the interfering

Table 7. Effect of formaldehyde (F) on formic acid (FA) determination with mercury(II) acetate. Formic acid concentration 51.5 mg l^{-1}

C_F, mg l^{-1}	F : FA weight ratio	D_{236} at indicated τ, min			
		10	20	30	60
0	0	0.286	0.382	0.477	0.702

4070	79	0.277	0.373	0.464	0.694
20400	395	0.288	0.384	0.474	0.705
40700	790	0.293	0.387	0.469	0.688

effect of formaldehyde on the formic acid determination by the new method. The results are given in Table 7. It is seen that even a large excess of formaldehyde does not interfere with the determination of formic acid.

CONCLUSIONS

(1) A new spectrophotometric method was developed for determination of formic acid in solutions. The method is characterized by high accuracy and repeatability of the results at formic acid concentrations down to 10 mg l^{-1}.

(2) The method is more sensitive compared to the determination by proper absorption at 206 nm. Formaldehyde does not interfere with the determinations.

SORPTION AND ION-EXCHANGE PROCESSES

Microporous Carbons and Their Properties

N. K. Luneva and L. I. Petrovskaya

Institute of General and Inorganic Chemistry, State Scientific Institution, National Academy of Sciences of Belarus, Minsk, Belarus

Received December 26, 2006; in final form, April 2007

Abstract— Thermal degradation of saw dust impregnated with phosphorus- and nitrogen-containing solution with ammonium, lithium, and cesium additives in the 20–700°C range was studied by physicochemical methods. The conditions of preparing activated carbon were determined and its adsorption and structural characteristics were studied.

DOI: 10.1134/S1070427207090091

Activated carbons are used in chemical technology, in medicine, in food industry, as sorbents for treatment of gases and wastewater, etc. Wide use of ac tivated carbons is promoted by improvement of their preparation processes and quality and by utilization of cheap wastes from woodworking industry (wood chips, saw dust). Chemical composition and sorption properties of the resulting carbons depend on the nature of impregnation agent and temperature, time, and procedure of thermal treatment and on some other factors, whereas their use is hindered by high cost. As a rule, common procedures for preparing charcoal involve formation of the carbon precursor at 550°C and its further activation to improve the pore structure in the atmosphere of an oxidizing gas at 900–1000°C. A procedure is known for preparing charcoal by pyrolysis of wood impregnated with zinc chloride or phosphoric acid, which is carried out at 700°C for 4–6 h. All the procedures are power-, time-, and labor-consuming. Therefore, development of simple power-saving and environmentally safe procedures for preparing activated carbons is an urgent problem.

This paper concerns preparation of carbon sorbents by low-temperature pyrolysis of impregnated wood and properties of the resulting carbons.

EXPERIMENTAL

We examined the features of thermal degradation at 20–700°C of waste from woodworking industry (saw dust and chips with size from 3 to 30 mm) impregnated with phosphorus- and nitrogen-containing mixture [H_3PO_4–$CO(NH_2)_2$, mixture B] with lithium, cesium, and ammonium nitrate additives and the sorption properties of activated carbons prepared by thermal treatment of the impregnated wood. The weight gain related to the impregnation solution was 170% relative to the dry saw dust. The compositions of the phosphorus- and nitrogen-containing mixtures are listed in Table 1. In the course of thermal treatment at 20–550°C, the cellulose-containing material is carbonized with pore formation in the carbon residue. Impregnation solution catalyzes degradation of the carbohydrate–lignin wood complex. Therefore, dehydration and breakdown of both 1,4-anhydroglucose bonds and C–C and C–O bonds inside the glucopyranose rings occurs at low temperatures as compared to the initial wood. In this case, additives undergo chemical transformations and reorganization upon heating and act as supports in the combustible carbohydrate fraction of the material at shrinkage of the wood raw material, preventing closure of the pores and channels. After thermal treatment of the impregnated saw dust, the carbon residue was washed by multiple immersions in boiling water (liquid-to-solid ratio 20) followed by squeezing, until the wash water became neutral. Then, the residual water was removed by centrifugation and the residue was dried in air for 24 h at room temperature and for 2 h at 45°C. The content of nitrogen in the initial wood and activated carbon samples was

Table 1. Characteristics of phosphorus- and nitrogen-containing impregnation mixtures

1	B	1 : 2.1
2	B + NH_4NO_3	1 : 5.4
3	B + $LiNO_3$	1 : 9.3
4	B + $CsNO_3$	1 : 11.0

* Mixture nos. 2–4 contained nitrate additives.

determined by their wet combustion in concentrated H_2SO_4 by the Kjeldahl procedure [1], and the content of phosphorus, photocolorimetrically by formation of phosphomolybdic blue [2].

The specific surface areas of the resulting carbons were determined gravimetrically by sorption of CCl_4 vapor at 20°C using a vacuum installation with a quartz balance [3]. The activity of carbon to iodine was evaluated in accordance with GOST (State Standard) 17218–74, and the bulk density, in accordance with GOST 14922–77. The static ion-exchange capacity was measured by the procedure given elsewhere [4]. The crystallite size in the carbon residue was calculated from the X-ray diffraction (XRD) patterns using the standard procedure [5]. The XRD patterns of the heat-treated samples were recorded on a DRON-3 diffractometer (CuK_α, Ni filter) in the 2θ 2°–60° range. Thermal analysis of the impregnated saw dust samples was carried out in air on an MOM device (Hungary) at a heating rate of 20 deg min^{-1}. As seen from the experimental data, thermal degradation of the saw dust impregnated with nitrogen- and phosphorus-containing mixtures is most intensive in the temperature range from 80 to 360°C, and then the rate of thermal degradation decreases. The integral and differential dependences of the weight loss are shown in Fig. 1, and characteristics of thermal degradation of impregnated wood are listed in Table 2.

As seen from these data, the yield of the carbon product at 550°C depends on the composition of the impregnation mixture. For example, for mixtures B and B + NH_4NO_3 it amounts to 49.3 and 52.3%, respectively, whereas for $LiNO_3$ and $CsNO_3$ it is 45.5 and 47.0%, respectively. For samples impregnated with straight mixture B and with addition of ammonium nitrate, significant decrease in the degradation rate is observed above 300°C, and with mixtures containing cesium and lithium nitrates, above 360°C. Thermal degradation is the most intense in the 80–210°C range, where two processes occur (Fig. 1) rate and temperature depending on the impregnation mixture. The first process occurs at the maximal rate at 105–145°C, and the second, at 185–195°C. The first rate maximum is probably due to both decomposition of nitrogen- and phosphorus-containing complexes of cellulose and degradation of the polymer [6]. The second rate maximum is probably due to the thermal degradation of more stable condensed phosphate compounds and breakdown of the hydrocarbon structures of cellulose.

The observed features of degradation of impregnated saw dust are due to the differences in the mechanism of thermal degradation, which depends on the composition of the impregnation mixture. This is confirmed by the data of chemical and XRD analysis, namely, by different fractions of nitrogen and phosphorus, by differences in the phase composition, and by the yield of the carbon residue in the washed samples (Table 3). As seen from the data of chemical

anallysis, the highest content of phosphorus and nitrogen is observed in the saw dust samples impregnated with the mixture containing $CsNO_3$ and treated at 180–550°C. To evaluate the effect of various impregnation agents on the carbonization, we used such conventional parameter as retention index, i.e., ratio of the actual content of the element in the sample taking into account the weight loss at given temperature to its initial content in the sample. Thermal treatment of the samples impregnated using mixtures with $LiNO_3$ or NH_4NO_3 additives yields the samples whose retention index is somewhat smaller (from 1.00 to 0.42 for nitrogen and from 0.30 to 0.04 for phosphorus). The retention index for nitrogen and phosphorus was 1.00–0.68 and 0.30–0.14, respectively (Table 4).

As seen from XRD data, only thermally treated and washed saw dust samples impregnated with mixture B + $CsNO_3$ contained crystalline phases of ammonium and cesium polyphosphates, whose d_α values agree with published data for these compounds [7, 8]. It should be noted that the samples treated at 180–260°C contained ammonium polyphosphate phase, and, with increasing temperature to 550°C, the phase of cesium polyphosphate crystallized along with ammonium polyphosphate (Kurrol salt) (Fig. 2). All the other samples prepared by thermal treatment of saw dust impregnated with straight mixture B and with addition of $LiNO_3$ and NH_4NO_3 were X-ray amorphous. The samples prepared using mixture B and mixture B + NH_4NO_3 or $LiNO_3$ contained crystallites of carbon material with a size of 8.7, 9.4, and 10.0 nm, respectively.

It is known that one of the best procedures to study the pore structure is physical sorption of vapors and gases. In accordance with BET method and IUPAC classification based on the hysteresis shape, the adsorption isotherms of carbon coke materials belong to type H_3 of the isotherms of physical sorption of the vapors, typical of microporous samples with pore size ≤1 nm. The apparent sorption volume varies from 0.40 to 0.67 $cm^3\ g^{-1}$ depending on the impregnation agent composition; it was calculated from the Dubinin equation in accordance with the theory of micropore volume filling [9]. Our data show that the largest apparent specific surface area (S_{sp} = 1100 $m^2\ g^{-1}$) is observed for carbon samples impregnated with mixture B + NH_4NO_3, and the smallest (S_{sp} = 690 $m^2\ g^{-1}$), with mixture B + $CsNO_3$. The adsorption and structural characteristics of the carbons prepared by pyrolysis (550°C) of wood impregnated with various mixtures are listed in Table 5.

Analysis of sorption properties (Table 5) shows that the adsorption activity to benzene and water is fairly high for all the activated carbons studied. The highest sorption capacity for benzene is observed for the samples impregnated with nitrogen- and phosphorus-containing mixtures with ammonium or cesi-

um nitrate additives; in both cases, the sorption capacity is 60%. The smallest sorption capacity for benzene (44%) is observed for the sample impregnated with mixture B. The activated carbons prepared exhibit fairly high sorption capacity for iodine (61.4–41.1%). For example, the iodine number for activated carbon impregnated with mixture B + NH_4NO_3 is 41.1%, and with mixture B + $CsNO_3$, 61.4%. As known, microporous sorbents are highly active with respect to small molecules such as benzene (size of C_6H_6 molecule 0.37 nm) and iodine (size of I_2 molecule ≤0.4 nm) and are less efficient in sorption of larger molecules, e.g., Methylene Blue (molecular size 34.9 nm). Our experimental results (Table 5) well agree with published data [10].

The sorption characteristics of some commercial carbons are listed in Table 6 for comparison. Tables 5 and 6 show that the activated carbons we prepared have the pore structure close to that of commercial sorbents produced by two-step procedure at high temperature.

It should be noted that the activated carbons prepared by our procedure also exhibit cation-exchange properties and their ion-exchange capacity for Na^+ is 0.3–0.8 mg-equiv g^{-1}.

* Our experimental data.

CONCLUSIONS

(1) Impregnation of saw dust with nitrogen- and phosphorus-containing mixtures containing NH_4NO_3, $LiNO_3$, and $CsNO_3$ additives, followed by pyrolysis at 20–550°C, yields activated carbons with the specific surface area of 690–1100 m^2 g^{-1} and sorption capacity for benzene and iodine of 44–60 and 41.1–61.4%, respectively.

(2) The resulting activated carbons are microporous sorbents which can be used for sorption of benzene and carbon tetrachloride vapors.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Compatibility of TiO_2 with a CaO–$CaCl_2$ Melt

Abstract—Interaction of TiO_2 with a CaO–$CaCl_2$ melt was studied to determine whether electrolytic production of titanium from oxide raw materials is possible.

DOI: 10.1134/S1070427207090108

Titanium is among the most widely occurring metals and possesses a unique combination of properties. Its wide and efficient use in various fields of national economy is hindered by the high cost of the metal, which is due to the multistage and batch nature of the Kroll process employed in modern titanium industry. Numerous attempts to develop a continuous electrolytic technique for manufacture of titanium from titanium tetrachloride have failed to produce a widely used industrial technique because of the difficulties associated with the polyvalent nature of the metal, its high vapor pressure, and susceptibility of the tetrachloride to hydrolysis.

In recent years, a considerable interest has been observed in the possibility of electrolytic production of titanium from oxide raw materials. It has been found that understoichiometric titanium dioxide has high electrical conductivity and can serve as a cathode both in reduction of titanium oxides to the metal and in removal of dissolved oxygen from titanium.

It was suggested by Chen et al. [1, 2] to perform direct electrochemical reduction of TiO_2 to titanium in molten $CaCl_2$, which is the so-called FFC process. It was shown on laboratory scale that the reduction reaction occurs at 950°C on a cathode made of solid TiO_2, with oxygen anions oxidized on a graphite anode to give CO_2. Pure calcium chloride $CaCl_2$ was chosen as a molten salt electrode because of the high solubility of calcium oxide in this compound.

Ono and Suzuki [3] studied the high-temperature calcium reduction of TiO_2 and developed a process for continuous production of titanium. The electrolysis was performed at a voltage that was higher than the decomposition voltage of CaO, but lower than that of $CaCl_2$. Ca^{2+} ions were reduced at the cathode to Ca; oxygen evolved at the anode reacted with carbon to give CO and CO_2. A cell for continuous manufacture of titanium was developed and the possibility of using inert anode was discussed.

In [4], a TiO_2 powder or a preform was placed in a holder, and a Ca + 18 wt % Ni alloy, onto the electrolyzer bottom. The reduction was carried out without a current, with the electrochemical circuit formed between the TiO_2 cathode and the calcium alloy. In the process, TiO_2 was reduced and calcium ions were deposited at the anode. The alloy was replenished with calcium at regular intervals of time.

It seems that the FFC process is the best developed and ready for implementation [1, 2, 5, 6].

In view of the possible use of CaO as the main component in electrolytic reduction of TiO_2, it is necessary to substantiate the optimal CaO content and to analyze the oxidation kinetics of O^{2-} ions in relation to temperature and CaO concentration. It remains unclear whether TiO_2 is compatible with the $CaCl_2$–CaO melt.

The rich experience of the electrometallurgy of aluminum indicates that the main reason for a decrease in the current efficiency is the reverse reaction of the electrolysis products (aluminum and CO_2), which may lead to contamination of the metal by carbon via formation of carbides. This issue has not been studied for the materials under consideration. Possibly, it is necessary to choose a stable porous diaphragm for separating the cathode and anode spaces in electrolysis. The aim of this study was to elucidate these issues.

Table 1. Gibbs energy of formation of calcium and titanium oxides and chlorides

Substance	$-\Delta G^0$, cal mol^{-1}, at indicated T, K, according to indicated reference					
	[10]			[11]		
	1100	1200	1300	1100	1200	1300

TiO_2	178000	173890	169550	171410	167205	163011
$TiCl_2$	85100	81850	78650	–	–	–
$TiCl_3$	115600	110750	105900	–	–	–
$TiCl_4$	150050	147100	144150	141529	138763	136013

The previously published reports have virtually disregarded the mechanism, and presented no results of analysis, of the reaction between TiO_2 of varied origin with $CaCl_2$–CaO melts of various compositions. At the same time, the possible formation of $TiOCl_2$, $CaO \cdot TiO_2$, and $2CaO \cdot TiO_2$ can strongly affect the parameters and results of the electrolysis.

The solubility of TiO_2 in molten $CaCl_2$ is low, and that of metallic titanium reaches 0.5 wt % at 850°C [7].

The authors of [8] attributed the high residual currents in cathodic deoxidation of titanium in molten calcium chloride to the noticeable solubility of lower titanium oxides in $CaCl_2$.

It has been suggested [9], in an analysis of voltammetric data for oxidized titanium in a molten calcium chloride, that fast oxidation of oxygen ions from the oxide phase causes supersaturation of the $CaCl_2$ melt in CaO, which can react with partly reduced titanium oxide to give titanates of variable composition. The suggestions made in the studies mentioned above have not been directly confirmed.

To elucidate these issues, we made a thermodynamic assessment of the possibility of occurrence of various reactions in the system TiO_2–CaO–$CaCl_2$ and carried out chemical and X-ray phase analyses of the reaction products.

Table 1 lists the standard Gibbs energy of formation of calcium and titanium oxides and chlorides at 1100, 1200, and 1300 K according to [10, 11].

The values recommended by the authors are in reasonable agreement. To determine whether a reaction between titanium oxides and molten $CaCl_2$ is possible, we calculated, using the data in Table 1, the Gibbs energy of the corresponding reactions, ΔG^0_r. The results of these calculations for the temperatures of 1100, 1200, and 1300 K are listed in Table 2.

According to two references, the calculated results virtually coincide. The high positive values of ΔG^0_r indicate that there is no interaction in the systems under standard conditions. Judging from the decreasing value of ΔG^0_r, calculated per gram-atom of titanium, the probability of a reaction with the $CaCl_2$ melt increases in the order TiO_2, Ti_3O_5, Ti_2O_3, and TiO, in qualitative agreement with the suggestions made in [8].

In the system under consideration, perovskite $CaTiO_3$ can be formed in accordance with the equation

$$3TiO_2 + 2CaCl_2 = 2CaTiO_3 + TiCl_4. \quad (1)$$

Table 3 list thermodynamic parameters of the substances involved in reaction (1), according to the reference book [12].

The enthalpy of reaction (1) can be found using the equation

$$\Delta H^0_{r,298} = 2\Delta H^0_{CaTiO_3,298} + \Delta H^0_{TiCl_4,298} - 3\Delta H^0_{TiO_2,298} - 2\Delta H^0_{CaCl_2,298} = 2 \times 1661.7 - 805.96 + 3 \times 944 + 2 \times 797.17 = 297 \text{ kJ mol}^{-1}. \quad (2)$$

The value of ΔH^0_r at a temperature T is given by

$$\Delta H^0_T = \Delta H^0_{298} + \int_{298}^{T} \Delta C_p \, dT, \quad (3)$$

Table 2. Gibbs energy of reactions of titanium oxides with $CaCl_2$

Table 3. Thermodynamic parameters of substances involved in reaction (1)

Substance	$-\Delta H_{298}^0$, kJ mol^{-1}	S_{298}^0, J mol^{-1} K^{-1}	$C_p = a + b \times 10^{-3}T + c \times 10^5 T^{-2}$, J mol^{-1} K^{-1}		
			a	b	c
TiO_2	944.0	50.28	75.24	1.17	–18.21
$CaCl_2$	799.17	113.9	71.93	12.73	–2.51
$CaTiO_3$	1661.7	93.8	127.57	5.68	–28.01
$TiCl_4$	805.96	252.9	106.55	1.0	–9.88

where ΔC_p is the difference between the heat capaciteiss of the reaction products and starting substances, taken with their stoichiometric coefficients,

$$\Delta C_p = -7.89 - 16.61 \times 10^{-3}T - 6.25 \times 10^5 T^{-2}. \quad (4)$$

Integrating this equation, we obtain

$$\int_0^T \Delta C_p dT = -7.89T - 8.305 \times 10^{-3}T^2 + 6.25 \times 10^5 T^{-1}. \quad (5)$$

For 298, 100, 1100, and 1200 K, the values of the integral are –991, –15 570, –18 160, and –20 906 J mol^{-1}, respectively. The differences at 1000, 1100, and 1200 K are –14 580, –17 169, and –19 915 J mol^{-1}, respectively. Substituting these values and the enthalpy given by (2) into Eq. (3), we obtain $\Delta H_{1000}^0 = -282.42$, $\Delta H_{1100}^0 = -279.83$, and $\Delta H_{1200}^0 = -277.09$ kJ mol^{-1}.

We calculate the entropy of reaction (1) at 298 K by the equation

$$\Delta S_{298}^0 = 2S_{CaTiO_3,298}^0 + S_{TiCl_4,298}^0 - 3S_{TiO_2,298}^0 - S_{CaCl_2,298}^0$$
$$= 2 \times 93.8 + 252.9 - 3 \times 50.28 - 2 \times 113.9$$
$$= 61.86 \text{ J mol}^{-1} \text{ K}^{-1} \quad (6)$$

We find ΔS_T^0 as

$$\Delta S_T^0 = \Delta S_{298}^0 + \int_{298}^T (\Delta C_p/T) dT. \quad (7)$$

Taking into account Eq. (4), we can write

$$\int_0^T (\Delta C_p/T) dT = -7.89 \ln T - 16.61 \times 10^{-3}T + 3.125 \times 10^5 T^{-2}.$$

For 298, 1000, 1200, and 1300 K, we obtain –46.38, –70.80, –73.26, and –75.63 J mol^{-1} K^{-1}.

The differences of the integral at a temperature T and at 298 K give values of the integral $\int_{298}^T (\Delta C_p/T) dT$ at T(K), equal to –24.42, –26.88, and –29.25 J mol^{-1} K^{-1} for 1000, 1100, and 1200 K,

respectively. Substituting these values and the entropy given by (6) into Eq. (7), we obtain ΔS_T^0 equal to 37.44, 34.98, and 32.61 J mol^{-1} K^{-1} at 1000, 1100, and 1200 K, respectively.

We find the Gibbs energy of reaction (1) using the equation

$$\Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0. \quad (8)$$

At 1000, 1100, and 1200 K, the values of ΔG_T^0 are, respectively, 244 980, 241 352, and 237 958 J mol^{-1}, or 58 552, 57 689, and 56 873 cal mol^{-1}. It can be seen that these values are markedly (by a factor of nearly 2) lower than the respective values for reaction (I) in Table 2.

All the calculations were made for the standard conditions (component activities equal to unity, vapor pressure of 1 atm). The real activities and component concentrations, especially those of products of reaction (1), markedly differ from unity. According to experimental estimates, the concentrations of CaO and $TiCl_4$ in the final melt are lower than 0.01 mol %. Taking into account that the solubility limit of CaO in $CaCl_2$ at the temperature under consideration is close to 20 mol %, we can estimate the shift of ΔG_{CaO} to negative values by the equation

$$\Delta G_{CaO} = RT\ln(0.01/20) = 8.314T(-7.60) = -63.187T. \quad (9)$$

For 1000, 1100, and 1200 K, ΔG_T is –63 187, –69 513, and –75 833 J mol^{-1}, respectively.

The shift of ΔG_{TiCl_4} to negative values was estimated using the equation

$$\Delta G_{TiCl_4} = RT\ln(0.01/20) = 8.314T(-9.21) = -76.57T. \quad (10)$$

For 1000, 1100, and 1200 K, ΔG_{TiCl_4} is –76 570, –84 229, and –91 886 J mol^{-1}, respectively. The shift of the Gibbs energy of reaction (1) for 1000, 1100, and 1200 K is –202 944, –223 555, and –243 550 J mol^{-1}, respectively.

It can be seen that the values obtained become equal to, and even exceed in magnitude the positive standard values of ΔG_r^0, which indicates that, in principle, reaction (1) is possible.

For reaction (I) in Table 2, ΔG_r^0 is 352 084, 345 624, and 338 904 J mol^{-1} at 1100, 1200, and 1300 K, respectively, and the negative shift of the Gibbs energy, calculated by the equation

$$\Delta G_r = 2\Delta G_{CaO} + \Delta G_{TiCl_4}, \quad (11)$$

is obviously insufficient for compensating the positive values of ΔG_r^0. This means that this reaction is thermodynamically impossible.

Unfortunately, we could not find in reference literature any evidence about thermodynamic properties of the compound $TiOCl_2$. However, at temperatures above 300°C it can decompose to give TiO_2 and $TiCl_4$, and, with account of this circumstance, a thermodynamic analysis of reactions that involve this compound is similar to that of reactions involving $TiCl_4$.

EXPERIMENTAL

The aim of our experimental study was to examine the reaction of titanium dioxide TiO_2 with calcium chloride to elucidate the process mechanism and identify the products formed. We used as starting substances titanium dioxide and calcium chloride of chemically pure grade, subjected to preliminary dehydration.

Being an element of the secondary subgroup of Group IV, titanium is the most stable in the tetravalent state. All soluble compounds of Ti^{4+} are easily hydrolyzed, to TiO_2 upon complete hydrolysis, and to $TiOCl_2$ upon incomplete hydrolysis. According to Bol'shakov's data [13], $TiOCl_2$ decomposes at 300°C, whereas in an oxidizing atmosphere (O_2, H_2O) it can be formed at higher temperatures. Zelikman reported [14] that $TiOCl_2$ soluble in the chlorinator melt can be formed as an intermediate product of TiO_2 chlorination.

Titanium tends to form with alkali (M) and alkaline-earth metals (Me) titanates of the types M_2TiO_3, $M_2Ti_2O_5$, $MeTiO_3$, Me_2TiO_4, and Me_3TiO_5, which can be readily obtained by fusion of TiO_2 with carbonates of the respective metals. These properties of titanium suggest that the interaction of TiO_2 with $CaCl_2$ at temperatures above 800°C may involve reactions (I) (Table 2), (1), and

$$CaCl_2 + 2TiO_2 = CaTiO_3 + TiOCl_2. \quad (12)$$

Experiments were carried out in an electrically heated furnace, with the temperature controlled to within ±5°C. Portions of $CaCl_2$ and TiO_2, weighed with an accuracy as good as 1 mg, were placed in a beryllium oxide crucible and heated to 800°C, at which $CaCl_2$ was in the liquid state. The overheating of the melt over the melting point of $CaCl_2$ was 50°C. Preliminary experiments at a TiO_2 content of the stock equal to 25–30% demonstrated that the melting

Table 4. Conditions and results of interaction in the $CaCl_2–TiO_2$ system

Run no.	Initial weight, g (%)			Gain in TiO_2 weight, g	Weight and content of $TiOCl_2$ in the electrolyte, counting on TiO_2		Completeness of reaction (12) in terms of TiO_2, %
	$CaCl_2$	TiO_2	CaO		g	%	
1	18.731	3.268 (14.9)	–	0.156	0.224	1.30	13.3
2	14.582	2.610 (15.2)	–	0.198	0.285	1.93	21.6
3	14.008	1.920 (11.8)	0.283	0.147	0.211	1.70	22.0

of the components is accompanied by a substantial increase in the viscosity of the melt. This fact suggests a chemical reaction between the components to give low-mobile complex groups. Further, the content of TiO_2 in the stock was lowered to 12–15%. A melt of this composition had relatively low viscosity at 820°C.

The time of contact between $CaCl_2$ and TiO_2 after the melting was 1.5 h, after which the crucible was cooled, together with the melt, to room temperature and weighed. To evaluate the reaction completeness, the fusion cake was dissolved in water. The precipitate was filtered off on an ash-free paper filter. After washing, the precipitate was dried at 100–120°C, calcined to complete burning-out of the filter at 700°C, and weighed. The calcium chloride solution was analyzed for the presence of CaO and titanium ions.

Titanium was determined in the filtrate by photocolorimetry with diantipyrylmethane, which forms with titanium ions a soluble yellow compound with the light absorption maximum at 380 nm. Variation of acidity in the range 0.5–4 N HCl has no effect on the optical density of solutions. The detection limit of titanium is 0.01 $\mu g\ ml^{-1}$, and its molar extinction coefficient, 1.80×10^4. The coloration develops in 45 min and is stable during several months. The optical density of the solutions is proportional to the titanium concentration in a wide range of concentrations.

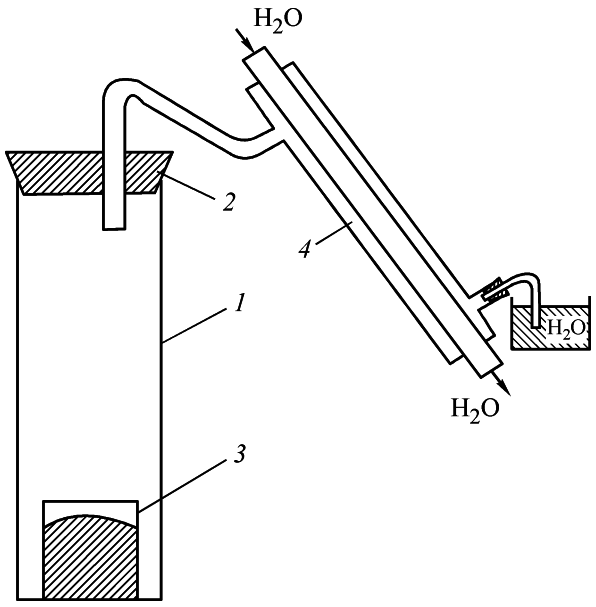
Titanium ions were not found in any of the samples we analyzed. The solutions exhibited a weakly acidic reaction, which confirms the occurrence of hydrolysis.

The mass of the precipitate exceeded that of the starting portion of TiO_2, which indicates that it reacts with $CaCl_2$ to give water-insoluble chemical compounds. The gain in the precipitate weight in run no. 1 (Table 4) was 156 mg (4.8%). Judging from the ratio of the molecular weights, the increase in the precipitate weight is possibly due to the occurrence of a reaction to give $TiCl_4$ and reaction (12) to give $TiOCl_2$. Reaction (I) (Table 2) leads to a decrease in the precipitate weight, because CaO is soluble in water and $TiCl_4$ volatilizes.

To experimentally verify the possibility of titanium tetrachloride formation, we carried out additional experiments (Table 4, run no. 2) in a hermetically sealed cell with a $TiCl_4$ condensation unit (see figure).

A beryllium oxide crucible with the starting substances, $CaCl_2$ and TiO_2, was placed in a hermetic steel cell closed with a rubber plug. After preliminary evacuation at 300–500°C to remove traces of moisture, the stock was heated to 840°C and kept at this temperature for 2.5 h. The condensation unit was cooled with flowing water having a temperature of 15°C.

The $TiCl_4$ vapor pressure is 5.5 mm Hg at 10°C and 10 mm Hg at 20°C. These conditions allow efficient condensation of $TiCl_4$. The end tube of the condensation unit was dipped into water to catch $TiCl_4$ in the case of its breakthrough. In the process, a gel-



Schematic of the installation: (*1*) steel cell, (*2*) rubber plug, (*3*) crucible with a stock, and (*4*) vapor condenser.

like precipitate is to be formed. A visual monitoring of the cell demonstrated that $TiCl_4$ was not formed at all. This compound was found neither in the condensation unit, nor in the final aqueous solution. This indicates that reactions (1) and (I) (Table 2) do not occur. At the same time, the weight of the precipitate that was washed, filtered off, and calcined at 700°C increased by 0.198 g (7.6%). The increase in weight, compared with the first run, was 1.5 times larger. Calculation of the increase in the precipitate weight in terms of reaction (12) demonstrates that obtaining a weight gain equal to 0.198 g requires a TiO_2 expenditure of 0.287 g. The extent of reaction in terms of TiO_2 was 21.6%.

The increase in the precipitate weight is due to the formation of calcium titanate $CaTiO_3$, which can be yielded by two reactions, (1) and (12). Calculation in terms of reaction (1) shows that 1.134 g of TiO_2 should remain in the precipitate ($m^{in}_{TiO_2} - m^{react}_{TiO_2}$ = 2.61 – 1.476 = 1.134) and 1.674 g of $CaTiO_3$ and 1.169 g of $TiCl_4$ should be formed. In this case, the TiO_2 content of the precipitate will be 40.4% and that of $CaTiO_3$, 59.6%. An X-ray phase analysis of the precipitate demonstrated that the content of rutile (TiO_2) was 88.3%, and that of calcium titanate ($CaTiO_3$), 11.7%.[1] Such a significant discrepancy between the results obtained by the calculation of the composition of the precipitate and by its X-ray phase analysis, as well as the absence of a condensate, do not confirm the occurrence of reaction (1).

Calculation in terms of reaction (12) shows that 2.327 g of TiO_2 should remain in the precipitate and 0.481 g of $CaTiO_3$ should be formed. The content of TiO_2 will be 90.5%, and that of $CaTiO_3$, 9.5%. In this case, the calculated increase in the precipitate weight is very close to that furnished by X-ray phase analysis. This suggests that $CaCl_2$ interacts with TiO_2 by reaction (12) to give calcium titanate and titanium oxychloride, which dissolves in the molten salt.

In dissolution of the solidified fusion cake in water, $TiOCl_2$ is hydrolyzed by the reaction

$$TiOCl_2 + H_2O = TiO(OH)Cl + HCl \quad (13)$$

and precipitates. In calcination of the precipitate at 700–800°C, titanium oxychloride hydrate decomposes to TiO_2:

$$TiO(OH)Cl \rightarrow TiO_2 + HCl. \quad (14)$$

The results of run no. 3, performed at 860°C in the course of 3 h, show that a higher temperature and a longer keeping time favor more complete course of the reaction between $CaCl_2$ and TiO_2. The filtrate obtained on washing the precipitate was also analyzed for the content of free calcium oxide and titanium ions, and the calcined precipitate was weighed.

In run no. 3 (Table 4), we tested the effect of calcium oxide addition to the $CaCl_2$ melt on the reaction between TiO_2 and the salt melt. The content of CaO in the electrolyte was 2 wt % (about 4 mol %). The experiment was performed at a higher temperature (870°C), with stock keeping for 1 h. The increase in the weight of the precipitate after its washing to remove $CaCl_2$, filtration, and calcination was 0.147 g (7.7%), which virtually coincides in percentage with the results of run no. 2 (7.6%). This may indicate that the equilibrium state is attained by the system $CaCl_2$–TiO_2–$CaTiO_3$–$TiOCl_2$. The weight of $TiOCl_2$ in the electrolyte in run nos. 2 and 3 was, counting on TiO_2, 285 and 211 mg, respectively, and its content, about 1.9 and 1.7 wt %. The calculated extents of reaction between TiO_2 and $CaCl_2$ in run nos. 2 and 3 are virtually the same (21.6–22.0%).

To determine the content of CaO, the filtrate from run nos. 1–3, exhibiting an alkaline reaction, was titrated with solutions of hydrochloric and nitric acids in the presence of an indicator. The results of analysis of run nos. 1 and 2 point to the complete absence of free CaO in the filtrate. Consequently, the whole amount of calcium oxide formed in the reaction of $CaCl_2$ and TiO_2 passes into the precipitate as calcium titanates as a result of its reaction with excess titanium dioxide [reaction (12)]. In run no. 3, we found in solution 15 mg of CaO, which constituted 5.3% of the amount we charged. The incomplete conversion of calcium oxide to perovskite is presumably due to kinetic limitations.

CONCLUSIONS

(1) Thermodynamic calculations demonstrated that, in principle, titanium dioxide can react with a $CaCl_2$ melt to give perovskite $CaTiO_3$ and $TiCl_4$ or $TiOCl_2$.

(2) Experiments were performed to analyze the reaction of TiO_2 with molten $CaCl_2$ and $CaCl_2$–CaO at 820–870°C. The increase in the weight of the filtered-off and calcined precipitate and its quantitative X-ray phase analysis confirm that there occur reactions of TiO_2 with molten $CaCl_2$ to give perovskite. The extent of the reaction increases with temperature, keeping time, and CaO content of the starting melt.

[1] The X-ray phase analysis was made at the Institute of Solids, Ural Division, Russian Academy of Sciences.

The most probable pathway of the reaction of TiO_2 with the $CaCl_2$ melt is that described by Eq. (12).

(3) The binding of TiO_2 into calcium titanates markedly complicates the electrolytic production of titanium from oxide raw materials. This is so because the activity of TiO_2 in the titanates is substantially lower and it is difficult for CaO to pass from TiO_2 pellets into the $CaCl_2$ melt.

Abstract—The polarization of a graphite anode in a $CaCl_2$–CaO melt in the temperature range 790–870°C at CaO concentrations of 1–8 mol % and current densities of 10^{-2}–10 A cm^{-2} was studied. The temperature and concentration dependences of the limiting current spent for the oxidation of oxygen ions were determined.

DOI: 10.1134/S107042720709011X

The electrode processes occurring at graphite anodes in oxide–halide melts are not yet interpreted unambiguously [1]. Commonly, the mechanism of electrode processes is determined by a simplified method based on using the decomposition potentials of calcium chloride (3.31 V) and calcium oxide (2.70 V) at 1100 K [2] under standard conditions (activity of calcium chloride and calcium oxide is unity, pressure of gaseous Cl_2, CO_2, and CO is 1 atm) instead of real conditions of the processes.

An interesting method for the description of anode processes that occur at the graphite anode in an oxide–halide melt was suggested by Antipin and Khudyakov [3]. They studied the composition of anode gases and the potentials of the graphite anode in electrolysis of cryolite–alumina melts at different current densities. The dependences obtained had characteristic inflections, due to changes in the CO_2 to CO pressure ratio in the anode gases. This result is confirmed by good coincidence of the experimental gas composition vs. anode potential curve with the dependence calculated by the equation of the gas electrode potential

$$E = E_0 - \frac{RT}{2F}\ln(P_{CO_2}/P_{CO}), \quad (1)$$

where R, T, and F have common meaning.

Equation (1) qualitatively describes the run of the whole polarization curves. In particular, the wave observed at the potentials more positive than 0.6 V may be explained by approximately constant composition of the anode gases (85% CO_2), which was found experimentally for the current densities higher than 0.32 A cm^{-2}.

However, Eq. (1) is, strictly speaking, approximate. Indeed, in accordance with the Nernst equation for the equilibrium potentials of the CO_2/C(graphite) and CO/C(graphite) systems, we can write

$$E_{CO_2/C} = E^0_{CO_2/C} + \frac{RT}{2F}\ln[(P_{CO_2})^{1/2}/(a_C)^{1/2}], \quad (2)$$

$$E_{CO/C} = E^0_{CO/C} + \frac{RT}{2F}\ln(P_{CO}/a_C), \quad (3)$$

where $E^0_{CO_2/C}$ and $E^0_{CO/C}$ are the standard potentials of the corresponding systems; P_{CO_2} and P_{CO} are partial pressures of CO_2 and CO, respectively; a_C is the graphite activity.

The shift ΔE of the anode potential to negative values with increasing CO_2 pressure in the gas phase may be presented by the difference in equilibrium potentials (2) and (3), by assuming that graphite activity is constant and equal to unity:

$$\Delta E = (E^0_{CO_2/C} - E^0_{CO/C}) + \frac{RT}{2F}\ln[(P_{CO_2})^{1/2}/P_{CO}]. \quad (4)$$

If a mixture of CO_2 and Cl_2 is evolved on the graphite electrode, then for the equilibrium potential

of the Cl_2/Cl^- system we can write

$$E_{Cl_2/Cl^-} = E^0_{Cl_2/Cl^-} + \frac{RT}{2F}\ln(P_{Cl_2}/a^2_{Cl^-}). \quad (5)$$

In this case, the shift of the anode potential will be determined by the difference between equilibrium potentials (5) and (2) and, on the assumption that the activity of chloride ions in the melts studied is close to unity, can be presented by the equation

$$\Delta E = (E^0_{Cl_2/Cl^-} - E^0_{CO_2/C}) + \frac{RT}{2F}\ln[P_{Cl_2}/(P_{CO_2})^{1/2}]. \quad (6)$$

Figure 1 demonstrates how the second terms in Eqs. (4) and (6), i.e., the ratio of CO_2, CO, CO_2, and Cl_2 partial pressures in the anode gases, affect ΔE. It is seen that the contributions to ΔE made by the CO_2/CO and Cl_2/CO_2 ratios are appreciably different. The characteristic change in the sign of the second derivative takes, however, place at equal partial pressures of the components, to which corresponds the potential ΔE^*. The shift of the anode potential from ΔE^* allows, using the curves presented in Fig. 1, quantitative interpretation of the electrode processes occurring at the graphite anode in oxide–halide melts.

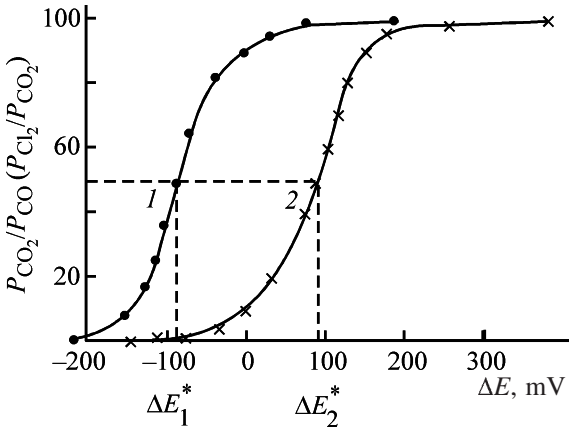

Fig. 1. Influence of partial pressure ratio of (*1*) P_{CO_2}/P_{CO} and (*2*) P_{Cl_2}/P_{CO_2} on the shift of the anode potential ΔE at 820°C.

EXPERIMENTAL

As electrolytic cell (Fig. 2) we used a metallic container closed from the top with a rubber stopper. Holes made in the stopper serve to evacuate air and feed argon and additional portions of CaO, with the latter fed through a quartz pipe. The electrolyte ($CaCl_2 + CaO$) was loaded in an alundum crucible. As anode we used graphite rod inserted into an alundum tube. A part of the graphite rod projecting outward had a constant surface area of 0.2 cm^2. As cathode served metallic lead on the bottom of the crucible. A lead electrode, $Pb/PbCl_2$ (5 wt %) + KCl–NaCl, in the form of an alundum pipe filled with a melt of salts and lead was a reference. Current was fed to the cathode and reference electrode through a molybdenum wire, and to the anode, through a steel wire threaded at the end to ensure contact with the graphite rod.

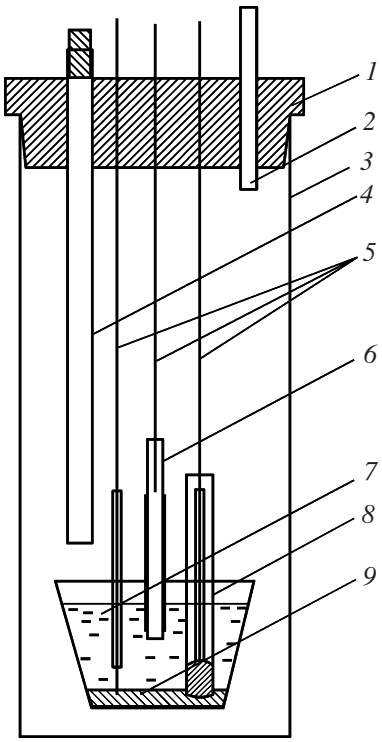

Fig. 2. Electrochemical cell: (*1*) rubber stopper, (*2*) tube for evacuating air and feeding argon, (*3*) metallic container, (*4*) tube for loading CaO, (*5*) current tips, (*6*) graphite anode, (*7*) electrolyte, (*8*) lead reference electrode, and (*9*) lead cathode.

The lead electrode was chosen because of the stability of its potential. At a lead chloride concentration in the electrolyte of 0.76 mol %, its potential relative to a chlorine reference electrode [3] can be calculated by the equation

$$E = 1.737 - 3.1 \times 10^{-4} T.$$

The required current strength was set by stabilized B5-49 power sources ensuring a preset current, irrespective of the electrochemical parameters of the cell. The current was measured with an M2015 ampere meter. The voltage applied to the electrochemical cell (between the anode and the cathode) and the anode potential relative to a lead electrode were meas-

ured with a digital voltmeter and recorded with a RECORDER two-coordinate recording potentiometer. The scheme of the electrical measuring installation made it possible to record the anode potential when the current is switched on and off. The heater was a shaft electrical furnace equipped with an electronic temperature controller. The temperature was maintained constant to within ±5° and measured with a Chromel–Alumel thermocouple.

The solubility of CaO in calcium chloride at 1173 K is 20 mol % [4]. The content of calcium oxide was varied within 1–8 mol %. The temperature range studied (790–870°C) was determined by the $CaCl_2$ melting point (772°C). The experiments were performed in dry argon.

The anode processes at the graphite electrode were studied by recording the polarization curves. The current density was raised stepwise from 0.03 to 3–6 A cm^{-2}. The anode potential relative to a lead electrode was measured, while switching off polarizing current, at each current density. The results obtained are presented in Fig. 3 as example. The values of the anode potential at the instant of switching off the current were used to construct the polarization curves.

The typical polarization curve has three characteristic portions at potentials of 0.47, 0.62, and 0.95 V relative to a lead reference electrode (Fig. 4, curve *2*). The potential of the lead reference electrode relative to a chlorine reference electrode at 820°C is –1.4 V [3]. Against the chlorine reference electrode, the potentials of these portions are –0.93, –0.78, and –0.45 V.

The characteristic waves in the polarization curves are due to several processes that proceed successively and simultaneously at the anode to form CO, CO_2, and Cl_2. In this case, the anode potential varies by more than 0.8 V.

The polarization curves were interpreted in terms of Eqs. (4), (6) for gas electrodes. Under the constant conditions of the electrolysis, the shift of the anode potential is determined solely by the ratio of the partial pressures of jointly evolving gases, and the calculated ΔE vs. $(P_{CO_2})^{1/2}/P_{CO}$ and ΔE vs. $P_{Cl_2}/(P_{CO_2})^{1/2}$ curves (Fig. 1) are suitable for quantitative interpretation of the results of the polarization measurements using the difference between the anode potential at a certain current density and ΔE^*.

CO is the major anode gas at low current densities. For example, at a current density of 0.1 A cm^{-2} the difference between E and ΔE^* is larger than –0.2 V, which corresponds to the relative concentration of CO in the anode gases of 98%. With increasing current density, the CO_2 concentration in the anode gases increases and at i_a = 0.9 A cm^{-2} becomes equal to the CO concentration. A further increase in the current density results in the growing shift of the anode potential toward positive values, which is due to predominance of CO_2 in the released gases. The stabilization of the anode potential at –0.75 V is associated with a nearly constant concentration of CO_2 (95%).

The limiting current i_{lim} for the oxidation of oxygen ions, at which the oxidation of chromium ions begins, is observed at a current density of 4.2 A cm^{-2}. Further run of the polarization curve is determined by change in the relative concentrations of Cl_2 and CO_2 in the anode gases, in accordance with Eq. (6).

The chlorine–oxygen molal ratio can be estimated by the equation

$$N_{Cl_2}/N_{O_2} = 2(i - i_{lim})/i_{lim},$$

where i and i_{lim} (A cm^{-2}) are the current density and the limiting current density for oxygen evolution, respectively.

At $2i_{lim}$, the chlorine to oxygen ratio is 2 and corresponds to the composition of phosgene $COCl_2$.

The potential shift at 1000 K ΔE_{1000} calculated from the Gibbs energy of formation of $COCl_2$ (–43 500 cal [2]) is –0.472 V, in good agreement with the potential of the last portion of the polarization curve.

Decreasing the temperature from 820 to 790°C shifts the anode potential to the negative region by approximately 10–15 mV, whereas increasing the temperature to 870°C shifts the anode potential to the positive region by 15–30 mV. With increasing temperature, the limiting current of oxygen evolution gradually increases, reaching 3.5, 4.2, and 5.2 A cm^{-2} at 790, 820, and 870°C, respectively (Fig. 4). The temperature dependence of i_{lim} is described by the equation

$$\log i_{lim} = 3.22 - 2860/T. \quad (7)$$

The extrapolation of i_{lim} to 960°C, a temperature of the electrolysis of a cryolite–alumina melt, yields a value of approximately 8 A cm^{-2} in the case of the electrolyte containing 4.7 mol % CaO. At the same content of Al_2O_3 in the cryolite–alumina melt, the limiting diffusion current spent for oxygen evolution at the carbon electrode is 4.5 A cm^{-2} [5]. This ratio of the limiting currents confirms the assumption that the degree of complex formation is lower in a $CaCl_2$–CaO melt than in a cryolite–alumina melt.

The anode polarization at other concentrations of CaO in the electrolyte was studied at 820°C (Fig. 5). It should be noted that the transition from the predominant evolution of CO to the predominant evolution of CO_2 is virtually temperature-independent and is mainly determined by the density of the polarizing current.

At a low concentration of CaO in the electrolyte (Fig. 5, curve *1*), the wave corresponding to the predominant evolution of carbon dioxide at a constant CO_2/CO ratio is not observed. Raising the CaO concentration in a calcium chloride melt increases the limiting currents of oxygen evolution.

The i_{lim} vs. CaO concentration curve (Fig. 6) is the linear dependence only up to CaO concentrations not exceeding 2 mol %:

$$i_{lim} = 1.43\, c_{CaO}.$$

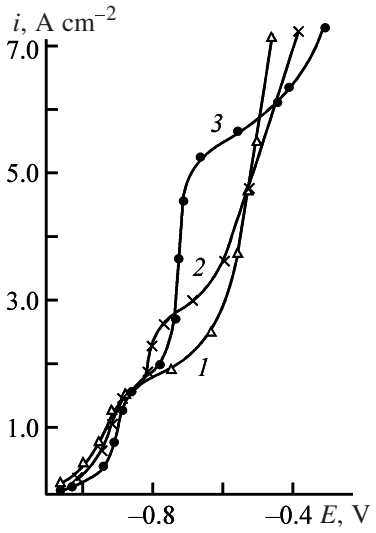

Fig. 5. Anodic polarization curves obtained on graphite at 820°C at various concentrations of CaO. CaO concentration, mol %: (*1*) 1.2, (*2*) 2.4, and (*3*) 8.4.

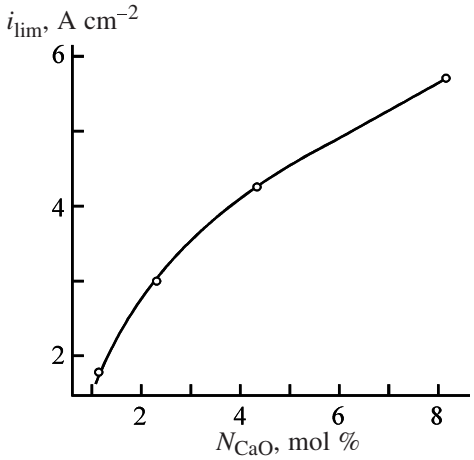

Fig. 6. Limiting current density i_{lim} of oxygen evolution at the graphite anode vs. CaO concentration N_{CaO} in the electrolyte.

The deviation of this dependence at larger CaO concentrations may be due to increase in the viscosity of a salt melt. In this case, adsorption equilibrium at the anode should also be taken into account [6].

The results of our study allow substantiated choice of the optimal concentration of CaO in the melt and of the optimal anode current densities.

CONCLUSIONS

(1) The results obtained in polarizing the graphite anode in a $CaCl_2$–CaO melt showed that the characteristic waves present in the polarization curves are

due to several processes that occur successively and simultaneously at the anode to form CO, CO_2, and Cl_2. The anode potential varies by more than 0.8 V. At high current densities, $COCl_2$, which decomposes in the electrolyte bulk, can also be a gaseous product.

(2) The temperature dependence of i_{lim} at a CaO concentration of 4.7 mol % is described by Eq. (7), whereas the dependence of i_{lim} on the CaO concentration is linear only to CaO concentrations not exceeding 2 mol %. At higher CaO concentrations, a deviation from this dependence is observed, which may be due to increased viscosity of the salt melt.

(3) The study performed allows substantiated choice of the optimal concentration of CaO in the melt and of the anode current densities.

Abstract—Preparation of titanium by the electrochemical reduction of titanium dioxide in a $CaCl_2$–CaO melt in a diaphragm electrolyzer using a graphite anode was studied.

DOI: 10.1134/S1070427207090121

Data on the kinetics and mechanism of the cathodic processes in electrochemical production of titanium from oxide raw materials within the framework of the FFC process [1] are limited:

$$TiO_x + 2xe = Ti + xO^{2-}. \quad (1)$$

The process kinetics is limited by electrical conductivity of the oxide phase [2]. As TiO_2 is reduced, the electrical conductivity of the oxide phase increases, which gives rise to an extremum in the current vs. time dependence.

Chen et al. [3] studied the mechanism of the cathodic deoxidation of oxidized titanium in molten $CaCl_2$ by cyclic voltammetry, with *IR* compensated by an external power source, along with pulsed ac measurements.

The potentials of various cathodic peaks observed in the *I–E* curves are given in Table 1 relative to a current peak potential of the reduction of Ca^{2+} ions to metallic calcium (c_1) [3].

The c_5 and c_6 peaks are due to the reduction of titanium dioxide to Ti_2O_3 and TiO; the c_3 peak, due to removal of dissolved oxygen from metallic titanium; and the c_2 peak, due to reduction to metallic titanium.

We used these data for interpreting the results of this study.

EXPERIMENTAL

Pigment-grade titanium dioxide with a micrometer grain size was used as the starting material for the electrochemical reduction. To fabricate electrodes, titanium dioxide was wetted in distilled water to paste and 1–2 cm^3 pellets were formed by pressing or modeling.

The pressing was performed with a mechanical screw press under a pressure of more than 1000 kg cm^{-2}. The pellets obtained were dried at 50–70°C in air and calcined at 800–850°C for 2–3 h, with the temperature raised at a rate of 300 deg h^{-1}. The mechanical strength of the calcined pellets was low. It was found that the strength of the pressed pellets is lower by an order of magnitude than that of the modeled pellets. After the calcination, the pressed pellets spontaneously separated into layers 2 mm and less thick in a direction transverse to application of the pressure, whereas the modeled pellets showed similar strength in all directions and therefore could be crushed mechanically to necessary pieces. The density of the titanium dioxide was 1.9–2.1 g cm^{-3} for pressed pellets and 1.7–1.9 g cm^{-3} for modeled pellets, and their porosity, evaluated from these values and the true density of TiO_2 (4.1–4.2 g cm^{-3}), was 49–54 and 54–59%, respectively.

An attempt to increase the mechanical strength of the pellets by impregnation with a saturated calcium

chloride solution, followed by modeling or pressing and calcination, did not give positive results. The strength of the pellets decreased considerably. Therefore, the modeled pellets disintegrated to 2–5-mm pieces to avoid spontaneous breakdown were used for electrochemical reduction after the calcination.

Rutile was reduced in a cell (Fig. 1) at 840–960°C in argon. Melted calcium chloride was heated in a vacuum to 500°C to remove water. Current was fed to titanium oxide through a steel wire or perforated steel plate. In the first case, the wire was twisted in the form of a coil, with 0.5–1-mm separation between the turns (Fig. 1, section A–A). The upper part of the wire was enclosed in a ceramic straw to prevent deposition of calcium on it. The coil was placed in an alundum tube 1–1.5 cm in diameter. Onto the coil, a 1.5–2-cm layer of TiO_2 (2–3 g) was poured. In the second case, a layer of the wet paste 3–4 mm thick was deposited onto a perforated iron plate (area 2 cm^2) with the subsequent drying and calcination. A graphite rod served as anode. In some experiments, the same rod served as reference electrode for measuring the cathode potential after switching off the current. The current was set within 0.2–4.7 A with a stabilized power source. The voltage and potential were recorded with a RECORDER two-coordinate potentiometer. The amount of the passed electricity was varied within 60–300% of the theoretical value necessary for TiO_2 reduction.

First, the polarization measurements were performed with a polarizing current switched on for a short time (0.5–5 min), with raising its value from 0.2 to 4.7 A. The current density counting on the geometric surface area of the pellets was from 50 mA cm^{-2} to 2–3 A cm^{-2}. In the course of the main electrolysis, the cathode potential was recorded at the moments when the current was switched off for a short time and at the end of the experiment. After the experiment was complete, the electrodes were withdrawn from the electrolyte, transferred into the cold zone of the cell, and cooled to room temperature in argon. A visual examination of the crucible, electrolyte, and electrodes in the experiments with a carbon electrode revealed the formation of a finely divided carbon foam in an amount increasing with the amount of passed electricity, The amount of carbon foam in the electrolyte containing calcium oxide is the largest.

Presumably, calcium that has not reacted with TiO_2 dissolves in the electrolyte and reacts with gaseous carbon dioxide evolved on the anode to reduce it to amorphous carbon by the reaction

$$2Ca + CO_2 = 2CaO + C. \quad (2)$$

After the experiment was complete, the cathode was thoroughly washed to remove residual salts, dried, and classified with respect to the extent of darkening. It was noted that the parts of the cathode located directly on the iron current lead became dark from the surface and from the inside. The extent of darkening decreases with increasing distance from the current lead. When the excess amount of passed electricity is small, most of the cathode surface remains light, whereas when the excess is considerable (300–500%), virtually the whole bulk of the cathode becomes dark, which shows that the degree of TiO_2 reduction increases.

Table 2. Conditions and results of electrochemical reduction of TiO_2 with graphite anode

Run no.	Electrolyte	T, °C	TiO_2 weight, g	Q, A h (excess, %)	Fraction yield	
					dark	light
1	$CaCl_2$	860	3.2	7.1 (60)	30	70
2	$CaCl_2$+ 10 wt % CaO	880	3.06	10.6 (160)	80	20

The obtained fractions of the reduced product were ground in an agate mortar, their photographs at a magnification of 120 were taken, and X-ray phase analysis was done.[1] The results of the TiO_2 reduction with a graphite electrode are presented in Table 2.

All samples of the ground and reduced product had typical metallic luster and the structure of a titanium sponge (Fig. 2). The size of titanium grains was, however, small (several micrometers and less). In both experiments, the samples had light areas of unreduced rutile and formed perovskite; their amount was larger in the light fractions. An X-ray phase analysis (Table 3) revealed no titanium peaks but revealed peaks of unreduced phases (perovskite and rutile) in a ratio depending on the electrolysis conditions.

The perovskite content is higher at a large excess of the amount of passed electricity (run no. 2 compared to run no. 1). More complete conversion of unreduced rutile into perovskite is associated with the presence of the CaO additive in the electrolyte and with a larger amount of calcium oxide formed inside the cathode.

Finely dispersed metallic titanium was X-ray amorphous: only an increase in the total background intensity was observed in the X-ray diffraction patterns.

The electrolysis using calcium chloride occurred at a stable voltage at each polarizing current. After switching off the current, fast variation of the cathode potential relative to graphite anode was observed, without any phase transitions recorded. This is due to fast removal of chlorine on the anode in the reaction with dissolved calcium, making the anode potential unstable.

With 10 wt % CaO added, the mechanism of the anode process changed. The evolution of oxygen with the subsequent formation of CO and CO_2 were observed on the anode. At the moment of switching off the current, we recorded the reverse emf of the electrochemical cell relative to a graphite electrode, which regularly increased from 0.5 to 3.5 V as the current strength was increased from 1 to 4.7 A. The value of the reverse emf (3.5 V) confirms deposition of metallic calcium at the anode. Then, the cathode potential rapidly changed and stabilized at 1.4 V. The potential difference was 1.5–2.1 V and, according to the data of Table 1, the stabilization potential corresponded to metallic titanium. However, in this case also the anode as reference electrode is insufficiently reliable because of variations of its potential with time in the course of desorption of CO and CO_2 and their reaction with dissolved Ca and CaO.

The cell voltage in an electrolyte containing CaO was very unstable. This may be due to intense deposition of finely divided carbon, which was found after completing the experiment on the electrolyte surface under the anode and over the cathode.

Thus, the electrolysis in a diaphragmless cell using a graphite electrode involves a number of undesirable side processes: formation of $CaCO_3$ by reaction of CO and calcium oxide (Table 3, run no. 2); deposition of finely dispersed carbon leading to carbonization of the melt and formation of titanium carbide; oxidation of calcium dissolved in an electrolyte on the anode and by anode gases (Cl_2, CO_2), which considerably decreases the current efficiency.

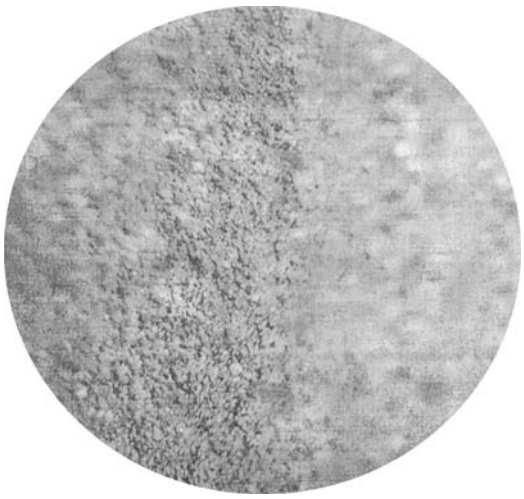

Fig. 2. Structure of the surface of finely divided reduction product (run no. 1). Magnification 120.

[1] X-ray phase analysis was performed at the Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences.

Table 3. Results of X-ray phase analysis of the TiO_2 reduction product

Run no. (sample no.)	Dark fraction, %		Light fraction, %		
	$CaTiO_3$	TiO_2	$CaTiO_3$	TiO_2	$CaCO_3$
1(1.4)	85	15	36.1	63.9	–
2(2.3)	100	–	79.2	–	20.8

Therefore, it was of interest to use a Pb–Ca melt containing 15–25 wt % Ca as anode and pure calcium chloride without calcium oxide additive as electrolyte. The study showed that the mechanism of the anode process principally changed. The dissolution of calcium from a lead alloy, instead of evolution of anode gases, occurred at the anode.

To make the TiO_2 reduction more complete, a smaller portion of TiO_2 (250–300 mg) was applied as paste to a perforated or grid cathode. As reference electrode (Table 4, run no. 3) we used a Pb–Ca alloy prepared directly in an electrochemical cell. To do this, calcium was deposited onto lead to 20 wt % content. In this case, the amount of calcium in lead was higher by an order of magnitude than that necessary for reduction of the TiO_2 portion and affected only slightly the composition of the Pb–Ca alloy in the course of the electrolysis. After the Pb–Ca alloy was formed, a graphite anode was withdrawn from the electrolyte, and evolved chlorine was evacuated. However, these precautions led only to a decreased amount of amorphous carbon. Therefore, in the further experiments a separate cell was used to form the Pb–Ca alloy, which made it possible to eliminate virtually completely the presence of carbon in the electrolyte upon electrochemical reduction of titanium dioxide. The conditions of the experiments are presented in Table 4.

The deposition potential of calcium (1.7 V) and two plateaus of the potential stabilization, at 0.8 and 0.34 V, were revealed by measuring the cathode potential relative to lead reference electrode after completing the electrolysis (run no. 4). The potential difference between the calcium deposition and the second plateau was 1.4 V, which, according to the data of Table 1, corresponds to metallic titanium. The first plateau with a potential difference of 0.9 V corresponds to formation of Ti_2O_3. One more plateau of the potential stabilization at 0.18 V, which corresponds to removal of dissolved oxygen from titanium, was found at short-time polarization of the cathode.

With titanium used as reference electrode (run no. 5), three plateaus of the potential stabilization were recorded after switching off polarization: 1.25 V is the potential of calcium deposition, and potentials pf 1.92 and 0.77 V correspond to c_3 and c_6 current peaks (Table 1). The potential of the TiO formation was not revealed.

The obtained products of the electrochemical reduction contained no light fraction and corresponded in the structure to dark fractions (run nos. 1, 2) with finely dispersed X-ray amorphous metallic titanium. Thus, the fineness of pigment-grade titanium dioxide predetermines the fineness of metallic titanium. Another factor is the formation of the intermediate oxide Ti_2O_3, which was revealed in the X-ray diffraction pattern.

When two-side metallic grid was used as current lead, a plate of precalcined titanium dioxide was placed inside the grid. The TiO_2 pellet was prepared by dry pressing with addition of 5% MgO to enhance its strength. The pressed pellet was dried at 50–80°C for 24 h and calcined for 5 h at 1050°C by raising the temperature at a rate of 300 deg h^{-1} to obtain coarser TiO_2 grains. The strength of the calcined pellet prepared by dry pressing was higher than that of the pellets modeled from a wet paste.

Calcium was deposited on the cathode at 920–930°C by raising the current density stepwise from 0.1 to 2.3 A cm^{-2}, using the Ca–Pb alloy as anode. The electricity was passed in 400% excess. A part of the electrochemical reduction product washed inside the metallic grid was in the form of grains whose size

* Potential of the stabilization plateaus.

exceeded the size of the ground particles obtained in the previous experiments, and the remaining part was in the form of small metal-coated plates about 0.5 mm thick.

As seen from Fig. 3, the reduction product has a pronounced metal structure; grains are partially sintered and their size is substantially increased. By visual observation, most of the product is metallic titanium. However, despite large current excess, inclusions of incompletely reduced forms remained in the metal bulk.

The separation of the anode and cathode spaces with a ceramic diaphragm was necessary not only to make purity of the product higher but also to increase the current efficiency of the electrolysis. In a diaphragmless electrolyzer, most of the current is spent to compensate losses due to back reaction of the electrolysis products. The calcium evolving at the cathode can interact with the chloride and dissolve in it. The calcium solubility at 900°C is about 4 mol %. The dissolved calcium reacts with the anode products (gaseous chlorine or carbon dioxide) and transforms back into calcium chloride and oxide, or is anodically oxidized with the formation of bivalent ions. The occurrence of the side processes of calcium oxidation, first, results in the considerable overexpenditure of the electrical power for the electrochemical reduction of titanium from titanium oxide and, second, leads to a decrease in the efficiency or in the degree of titanium reduction owing to cathode depolarization. In the majority of the experiments performed, the cathode potential at the moment of switching off the current was lower than the deposition potential of metallic calcium, which, according to the results of X-ray phase analysis, mainly resulted in the reduction of titanium to intermediate products.

To decrease the influence of the side processes impeding deposition of metallic calcium on the cathode, the experiments were performed in an electrolyzer with its cathode and anode spaces separated by a diaphragm. As diaphragm we used porous magnesium oxide ceramics containing yttrium and cerium oxides as binders (60% porosity). The ceramics was produced at the Siberian Chemical Combine. The design of the cathode and anode compartments of the electrolyzer is shown in Fig. 4. Wet titanium dioxide for fabricating the cathode was modeled in a pellet 7–10 mm diameter and 1.5–2 cm high (mass 2.5–3 g) inside an alundum tube and was calcined at 950–1000°C to obtain coarser grains. After the calcination, a 1.5–2-mm hole was drilled in the center of the tube, into which a current lead made of iron wire and

Fig. 3. Structure of the surface of finely divided reduction product (run no. 5). Magnification 300.

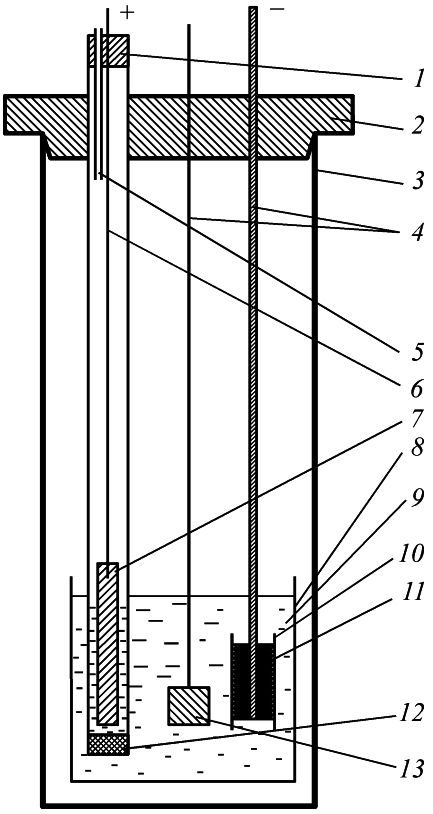

Fig. 4. Design of a diaphragm electrolyzer: (*1, 2*) rubber stoppers; (*3*) steel retort, (*4, 6*) current leads, (*5*) outlet of anode gases, (*7*) graphite anode, (*8*) alundum crucible, (*9*) electrolyte, (*10*) alundum tube, (*11*) rutile pellet, (*12*) diaphragm, and (*13*) titanium reference electrode.

covered with an alundum jacket to avoid contact with a salt melt was inserted.

A graphite rod inside a quartz tube was the anode. A ceramic diaphragm glued into the lower part of the tube impeded passage of dissolved anode gases into the catholyte and of dissolved calcium into the anolyte. A hole in the rubber stopper closing the cell allowed the upper part of the tube to be in contact with the atmosphere, which ensured outlet of the anode gases from the anode space and made their interaction with the catholyte minimal.

The electrolysis was performed in argon over the catholyte at 910–930°C in a calcium chloride melt with and without calcium oxide added. In this case, chlorine or carbon oxides were the anode products. The electrolyzer voltage, current, and the cathode potential relative to titanium reference electrode were recorded in the course of the experiments.

When the electrolysis was performed at low current densities (0.2–0.3 A cm^{-2}), the cathode potential did not reach the deposition potential of calcium, and TiO_2 was reduced with the formation of $CaTi_2O_4$ as major product. In contrast to the diaphragmless electrolysis, the reduction product contained no initial rutile phase. The pressed product showed small electrical conductivity, confirming the occurrence of reduction.

With the current density increased to 1.2 A cm^{-2}, the cathode potential increased to approximately 3.7–3.8 V in the chlorine scale, which corresponds to the deposition potential of metallic calcium. The amount of passed electricity was 450% of theoretical value to ensure higher degree of reduction of complex titanium oxides.

As previously, the washed powdered product was dark gray. As compared to the previous experiment, the amount of metallic fraction increased considerably. The powder did not conduct electrical current in the loose state but exhibited high electrical conductivity in the pressed state. The powder had pronounced pyrophoric properties. It was highly inflammable, which also confirms the presence of a finely divided metallic phase in it.

The reduction of rutile in a diaphragm electrolyzer made it possible to considerably increase the degree of reduction, with the same energy expenditure, and to shift the composition of the product toward formation of metallic titanium.

CONCLUSIONS

(1) The preparation of titanium by the electrochemical reduction of titanium dioxide in a $CaCl_2$–CaO melt using graphite anode is complicated by formation of CO_2 on the anode. CO_2 and CaO, present or formed by the electrolysis, react in the salt melt to give $CaCO_3$, and then the CO_3^{2-} ions are reduced to amorphous carbon with calcium dissolved in the electrolyte. This inevitably results in carbonization of the electrolyte and leads to the formation of titanium carbide. It seems impossible to produce quality metal under these conditions.

(2) Titanium dioxide pellets should be precalcined at 1050–1100°C, which allows considerable coarsening of the grains of the cathodic titanium deposit obtained.

(3) The possibility of the electrochemical reduction of titanium dioxide in a diaphragm electrolyzer was demonstrated. The obtained metallized product has a low concentration of oxygen and a high electrical conductivity and is pyrophoric. The electrolysis efficiency can be increased further by using the bulk reduction of finely divided titanium dioxide and further improving the reductive characteristics of the cathode process by raising its electronegative potential.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Specific Features of Synthesis, Chemical Composition, and Thermal Stability of Anodic Borosilicate Coatings on Silicon

I. L. Baranov, L. V. Tabulina, L. S. Stanovaya, T. G. Rusal'skaya, and Yu. A. Shostak

Abstract—Thickness and resistivity of anodic borosilicate coatings synthesized on *n*-type silicon were studied in relation to the conditions in which the final forming potentials are reached and to the content of boric acid in an ethylene glycol solution. A method for synthesis of the coatings for use in nanoelectronics was suggested on the basis of data on the thermal stability of their chemical composition.

DOI: 10.1134/S1070427207090133

The development of the modern technology of integrated circuits (ICs) is based on use of nanosize intercomponent connections for their fabrication [1]. This brings up an urgent demand for diminishing the smearing of the structural profiles formed in ICs. A promising solution of this problem is use of electrochemical methods for obtaining layers with required properties on the surface of semiconducting silicon. In particular, oxide coatings doped with phosphorus- or boron-containing impurities can be synthesized by anodic oxidation of silicon in ethylene glycol solutions containing phosphoric or boric acid [2–5]. It has been suggested to use films of this kind in the IC technology as thin-film diffusion sources serving to form diode regions with improved switching characteristics in semiconducting silicon.

The advantages of the electrochemical method for synthesis of such diffusion sources, compared to the conventional high-temperature methods, consist in that it is performed at room temperature and the dopant content can be controlled by varying the composition of the electrolytic solution, and the film thickness in the course of growth, by changing the forming voltage [4, 5]. This method requires equipment that is simple in design and convenient in use. Because, in addition, the electrochemical method is based on passing electric current through the semiconductor silicon regions being treated, this provides a highly local transformation of their surface properties. For this reason, it has been suggested to perform selective anodic treatment of thermal silicon oxide layers in order to change their dielectric properties by varying the applied voltage [6, 7]. A particular advantage of the electrochemical method for synthesis of anodic silicon coatings is that it uses low-cost and environmentally safe reagents.

However, despite the indubitable process advantages, this method has not been used in the IC technology so far. The main reason is that the dopant distribution in the forming oxide coatings over the surface of semiconducting silicon is nonuniform. Removal of such coatings after diffusion doping of the starting silicon substrate gives rise to traces of erosion on the surface of the starting material. This adversely affects the electrical characteristics of *p*–*n* junctions. This effect is particularly pronounced in the case of diffusion sources based on anodic borosilicate coatings, whose structure shows increased friability [2, 4, 8].

To eliminate this effect, it has been suggested to use nitrate ethylene glycol solutions containing nitric acid as a current-conducting additive and a mixture of boric and arsenic acids ($H_3BO_3 : H_3AsO_4$ weight ratio 5 : 0.002) as dopant [9]. However, the electrolytic solution suggested is characterized by increased toxicity because of the use of arsenic acid, which is a noxious substance, and by the formation of explosive ethylene glycol nitrate in preparation of this solution from ethylene glycol and nitric acid [2].

This study is concerned with specific features of synthesis of anodic borosilicate (ABS) coatings on

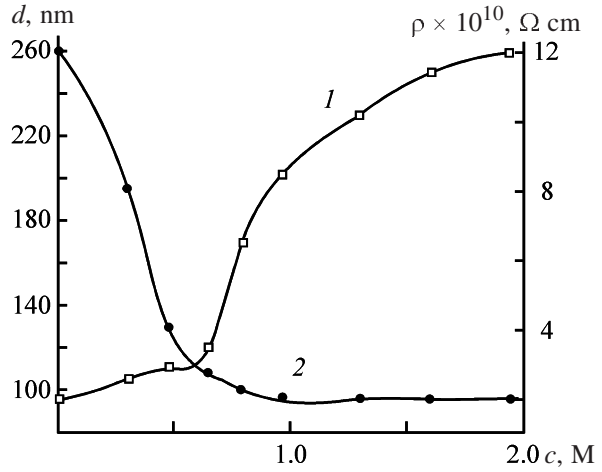

Fig. 1. Effect of the H_3BO_3 concentration c on (*1*) averaged thickness d and (*2*) resistivity ρ of anodic borosilicate coatings. Galvanostatic mode of anodic treatment (j = 6 mA cm^{-2}, U_{form} = 200 V).

the surface of semiconducting silicon in ethylene glycol solutions containing boric acid as dopant and ammonium nitrate as electrically conducting additive. In this case, the final forming potential was set either by a fixed current density (galvanostatic mode) or by current sweeping. The positive effect of the second method on the physicochemical properties of diffusion sources composed of ABS coatings was noted in [10]. Preliminary studies in [10] demonstrated that no *p–n* junctions are formed upon annealing in an inert atmosphere at 1100°C of ABS/Si structures whose oxide layers were synthesized in the current-sweeping mode. This circumstance made necessary a study of the chemical composition of these coatings both after synthesis and upon thermal treatment {at temperatures of 400–600°C at which silanol, Si–OH, and silanediol, Si–$(OH)_2$, bonds are actively dehydrated [11]}.

EXPERIMENTAL

The anodic oxidation was performed on polished, to finish class 14, Si (100) wafers doped with phosphorus to a resistivity of 4.5 Ω cm (KEF-4.5). ABS coatings were synthesized in the galvanostatic mode at current densities of 2–10 mA cm^{-2} [4] with current sweep rate of 0.4 mA cm^{-2} s^{-1} (current density amplitude 10 mA cm^{-2}) [12]. After a prescribed forming potential U_{form} was reached, the anodic treatment was continued in the potentiostatic mode for 60 min (to densify the structure of the ABS coatings). In the process, the initial current decreased by approximately a factor of 10–15. The synthesis was carried out in ethylene glycol solutions containing 0.01 M of ammonium nitrate and boric acid in a concentration varied within the range 0.3–2.0 M. The anodic treatment of silicon wafers with an area S of 5 cm^2 was performed in a cell with a graphite pressure contact. A molybdenum wire served as a cathode. The distance between the surface of the silicon anode and the cathode was 1 cm.

The thickness d of the ABS coatings formed was measured with an LEF-3M-1 laser ellipsometer (measurement error ±1.0 nm). Their breakdown voltage U_{br} was evaluated on a setup for measurement of capacitance voltage characteristics with an indium probe, based on an E-7-12 instrument [13]. The electrical characteristics of the ABS coatings were determined at five points on their surface (at the center and four points along the perimeter). The average values of the breakdown voltage, thicknesses of the oxide layers synthesized, and residual currents I_{res} upon completion of the synthesis process were used to calculate the averaged resistivity ρ by the formula

$$\rho = S U_{br}/dI_{res}.$$

The chemical composition and structure of the ABS coatings were studied by IR spectroscopy. The same method was applied to analyze structural specific features of the annealed coatings. The spectra were recorded on a Specord 75 IR spectrophotometer in the range 400–2200 cm^{-1}. Silicon wafers with coatings were annealed in a nitrogen flow at 400, 500, and 600°C for 10 min.

The variation of the averaged values of the thickness d of the ABS coatings and of the corresponding values of ρ with the concentration of boric acid in the electrolyte is illustrated by Fig. 1. These oxide coatings were synthesized in the galvanostatic mode at a current density of 6 mA cm^{-2} [4, 9] to U_{form} = 200 V. It follows from Fig. 1 that an increase in the concentration of boric acid in the electrolytic solution results in that substantially thicker coatings are formed. This effect is particularly pronounced when the H_3BO_3 concentration in the solution exceeds 0.5 M (Fig. 1, curve *1*). Simultaneously, the resistivity ρ of the coatings formed in electrolyte solutions in which the dopant concentration c varies from 0.2 to 1.0 M steadily decreases. An increase in c above 1.0 M has nearly no effect on the resistivity of the oxide layers (Fig. 1, curve *2*). These data are in agreement with the information about the properties of ABS coatings, reported in [2], where it was noted that these coatings are highly defective and their structure contains pores that extend to the outer surface. Prob-

ably, this intensifies exchange processes at the interface between the oxide layer and electrolyte solution, which makes higher the growth rate of ABS coatings. In this case, the presence of pores in their structure impairs their dielectric properties because of the adsorption of impurities from the electrolyte solution, including the doping additive, in pores. If ABS coatings are synthesized to U_{form} = 200 V in an electrolyte solution containing 0.65 M H_3BO_3, with the anode current density varied, an increase in this synthesis parameter leads to a steady and substantial rise in the average values of their thickness (Fig. 2, curve *1*). The corresponding ρ–j curve passes through a maximum at (6–8) mA cm^{-2} (Fig. 2, curve *2*). At higher current densities, the resistivity of the films synthesized markedly decreases. Thus, an increase in the dopant concentration in the electrolyte solution favors loosening of the structure of the resulting ABS coatings and leads to its enrichment in doping impurities. The same influence on the electrical state of the films being formed is exerted by the anode current density at its values exceeding 8 mA cm^{-2}. This predetermines the specificity of the choice of these parameters for synthesis of ABS coatings to be used as diffusion sources. It should be noted, however, that, at any concentration of boric acid in the electrolyte solution and current density used, these oxide films have a nonuniform thickness distribution over the silicon surface. This circumstance is illustrated by the data in Fig. 3. Their analysis shows that, depending on the H_3BO_3 concentration in the electrolyte solution and the anode current density, the scatter Δd of thicknesses of the ABS coatings on the surface of a silicon

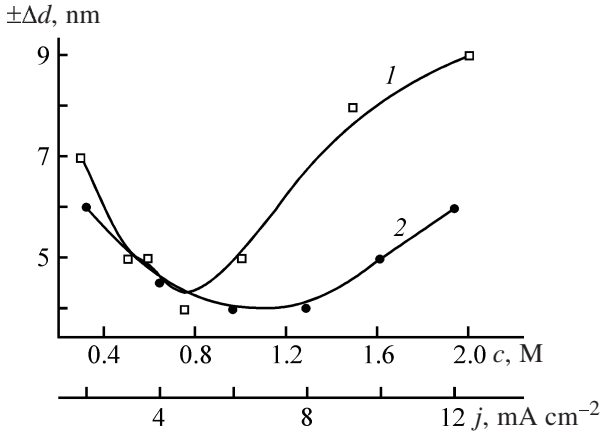

Fig. 3. Effect of (*1*) H_3BO_3 concentration c and (*2*) anode current density j on the thickness scatter $\pm\Delta d$ of anodic borosilicate coatings over the surface of a silicon substrate.

substrate is within ±(4–10) nm. The coatings synthesized in solutions containing 0.6–0.8 M H_3BO_3 at current densities of 4–10 mA cm^{-2} have Δd = ±(4–6) nm (Fig. 3; curves *1, 2*).

The averaged values of d and ρ of the oxide layers synthesized in an electrolyte solution containing 0.65 M H_3BO_3 at a current density of 10 mA cm^{-2} are shown in Fig. 4 (curves *1, 3*) as functions of U_{form}. The figure also presents similar dependences obtained for coatings formed in the same solution with current sweeping to the amplitude value corresponding to 10 mA cm^{-2} (Fig. 4; curves *2, 4*). Comparison of these data shows that the dependence d =

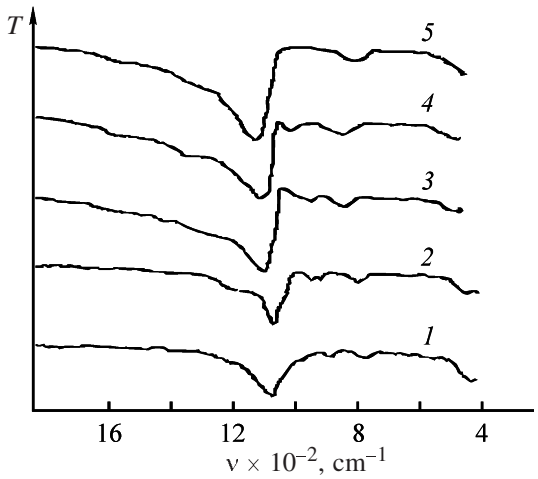

Fig. 5. IR spectra of anodic borosilicate coatings synthesized in electrolyte solution containing (*1*) 0.30 and (*2–5*) 0.65 M boric acid. (*A*) Absorption and (ν) wavenumber. State of the structure: (*1, 2*) initial and (*3–5*) that upon annealing at 400, 500, and 600°C, respectively.

$f(U_{form})$ for the ABS coatings synthesized with current sweeping is more linear and has a lower oxide layer growth coefficient than coatings formed in the galvanostatic mode (Fig. 4; curves *1, 3*). In the former case, the thickness scatter of the films synthesized over the surface of silicon substrates is always lower than the measurement error. In the galvanostatic mode, the scatter of *d* of the corresponding coatings is ±(5–8) nm (a wider thickness scatter is observed for the ABS coatings synthesized at U_{form} = 30–80 V).

Thus, use of current sweeping favors more uniform growth of ABS coatings on the surface of semiconducting silicon. Because this effect is manifested even at U_{form} = 30 V, it follows that the tendency toward such a behavior develops already in the initial stage of anodic oxidation of a silicon substrate. As a consequence, it can be suggested that use of current sweeping in synthesis of ABS coatings strongly affects the degree of structural ordering of the transition layer at the ABS/Si interface, which is characteristic of the crystalline state, as observed in [2].

Analysis of how ρ varies with U_{form} for coatings synthesized with U_{form} reached in different ways shows that, irrespective of specific features of their synthesis, the resistivity of the films steeply falls as U_{form} increases up to 100 V. At higher U_{form}, the dielectric properties of the coatings obtained in the galvanostatic mode remain virtually unchanged (Fig. 4, curve *3*), and those of the coatings synthesized with current sweeping in the initial stage steadily decrease (Fig. 4, curve *4*). The latter circumstance suggests that current sweeping allows a better control over the thickness of ABS coatings and their resistivity by varying the values reached by U_{form}. This is important when the coatings under study are used as diffusion sources in fabrication of *p–n* junctions of prescribed thickness in the nanosize IC technology. However, difficulties have been encountered in this case previously, and the reason for these difficulties can be accounted for by results of an IR spectral analysis.

IR spectral studies were performed on ABS coatings synthesized with current sweeping and U_{form} = 200 V in electrolyte solutions containing 0.30 and 0.65 M H_3BO_3. Their thicknesses were 1000 and 1250 nm, respectively. Their IR spectra (Fig. 5; curves *1, 2*) show strong absorption bands peaked at 1073 cm^{-1}, associated with stretching vibrations of Si–O bonds in silica tetrahedra. Medium-intensity bands at 750–850 cm^{-1} belong to stretching vibrations of Si–O–Si bonds in rings composed of SiO_4 tetrahedra, and those at 900–980 cm^{-1}, to stretching vibrations of Si–O–B bonds [14–16]. It should be noted that the absorption at 900–980 cm^{-1} may also be due to the defective state of the ABS coatings [15] and to superposition of stretching vibrations of Si–O–B and B–O bonds. The highly defective state of the structure of these films is evidenced by the abovementioned steep decrease in their resistivity upon an increase in their thickness (Fig. 4, curve *2*). The presence of Si–O–B bonds and B–O bonds in BO_3 groups is indicated by the appearance of a broad band with two weakly pronounced peaks at 925 and 945 cm^{-1} in the spectrum of a film synthesized in an electrolyte solution with 0.65 M H_3BO_3. The first of these is due to vibrations of Si–O–B bonds [16], and the second, to B–O bonds in which boron ions are not chemically bound to silicon ions [17] (Fig. 5, curve *2*). This indicates that boron ions may be present in the structure of ABS coatings both in a bound state and, probably, as boric acid molecules adsorbed within pores.

The IR spectra of coatings annealed at 400°C contain, in the 900–980 cm^{-1} region, a single band peaked at 925 cm^{-1}. For oxide layers annealed at 500°C, this band shifts to 950 cm^{-1} (Fig. 5, curves *3, 4*). This indicates that, after annealing at 400°C, boron ions in the structure of ABS coatings are mainly in the bound state and form Si–O–B bonds. Annealing at 500°C transforms these bonds to B–O bonds, i.e., boron ions are mainly present in ABS coatings in the form of BO_3 structural groups. Upon annealing at 600°C, the IR spectra of the coatings studied show no band at 900–980 cm^{-1}, which points to the absence of

boron-containing impurities (their amount is below the detection limit of IR spectroscopy) (Fig. 5, curve *5*).

In this context, it can be assumed that annealing at this temperature leads to intensive disintegration of Si–O–B bonds, followed by their transformation to BO_3 groups, with the oxide coating strongly depleted of boron-containing impurities. This probably occurs because of their volatilization from the structure of ABS films in the form of boric acid, which can sublime with water vapor [18].

Use of the coatings in question as diffusion sources in the IC technology involves a high-temperature treatment of the structure constituted by a borosilicate film and semiconducting silicon (1100–1200°C). Therefore, the IR data presented demonstrate that it is necessary to use protective layers on ABS coatings to prevent sublimation of boron-containing impurities from the coatings. In this study, anodic silicon films synthesized in an ethylene glycol electrolyte solution containing no boric acid served as protective layers. Composites of this kind (anodic silicon oxide/ABS coating) were first synthesized with current sweeping in an electrolyte solution containing 0.65 M H_3BO_3 to U_{form} = 160 V. Then, the ABS films obtained were additionally grown without densification to U_{form} = 200 V in an electrolyte containing no boric acid. After that, the films were densified. Fast annealing of the structures constituted by a composite ABS coating and semiconducting silicon at 1100°C for 3 min yielded *p–n* junctions of thickness 0.4 μm (the thickness was found by the method of staining of spherical polished sections [13, 14]). It was found that the corresponding current–voltage curves have no portions of a gradual transition to the breakdown state, which were observed in [4] when ABS coatings synthesized with U_{form} reached in the galvanostatic mode were used as diffusion sources. This suggests that ABS coatings formed with current sweeping in the initial stage of their synthesis can be used as diffusion sources for fabrication of nanosize intercomponent connections in the IC technology.

CONCLUSION

(1) The distribution of the thickness of anodic borosilicate coatings, synthesized with the use of the galvanostatic mode, over the surface of *n*-type silicon depends on the concentration of boric acid in an ethylene glycol solution and on the current density. The narrowest scatter of the coating thickness [~±(4–5) nm] is observed for coatings synthesized at current densities of 4–10 mA cm^{-2} in a solution containing 0.5–1.0 M boric acid.

(2) With current sweeping (sweep rate 0.4 mA cm^{-2} s^{-1}, current amplitude 10 mA cm^{-2}), thickness-uniform anodic borosilicate coatings are formed in an electrolyte solution containing 0.65 M boric acid, irrespective of the final value of the forming voltage. The resistivity of these coatings steadily decreases as the forming voltage is raised from 30 to 200 V. This enables control over the thickness and resistivity of anodic borosilicate coatings in the course of their synthesis.

(3) Borosilicate inclusions are incorporated into anodic borosilicate coatings because of the formation of Si–O–B bonds or in the form of boric acid molecules adsorbed within pores. Annealing at 500°C disintegrates Si–O–B bonds and transforms them into B–O bonds in BO_3 groups. Upon annealing at 600°C, no boron-containing inclusions are detected in the structure of anodic borosilicate coatings by IR spectroscopy. It is suggested that these inclusions sublime as boric acid molecules.

(4) Use of protective anodic layers of silicon oxide on anodic borosilicate coatings makes it possible to regard the electrochemical method for synthesis of these coatings as a promising technique for fabrication of low-temperature diffusion sources for nanoelectronics.

CATALYSIS

Catalytic Activity of Systems Based on Titanium Bis(phenoxy Imine) Complexes: Effect of the Ligand Structure

Abstract—Polymerization of ethylene at 30–70°C in the presence of catalytic systems based on titanium bis(phenoxy imine) complexes of various structures, activated with methylalumoxane, was studied. An attempt was made to systematize the effect of substituents in ligands, to find correlations, to account for the results obtained, and to reveal conditions under which the reaction occurs by the "living" polymerization mechanism. Some properties and structural features of the polyethylenes obtained were determined.

DOI: 10.1134/S1070427207090145

The recently discovered new class of postmetallocene catalysts of ethylene and α-olefin polymerization, based on transition metal phenoxy imine complexes, attracts attention of many research teams. Particularly active studies are performed by the team headed by T. Fujita (Mitsui Chem. Inc.), who published numerous papers on the synthesis of phenoxy imine complexes of zirconium, titanium, and other transition metals and examined their catalytic activity in polymerization of ethylene and α-olefins [1–3]. Somewhat later reviews written by other authors were published [4, 5].

The published studies revealed high capability of phenoxy imine catalytic systems for incorporation into the polymeric chain of α-olefins of various structures, including sterically hindered and even polar monomers. These studies demonstrated the possibility of controlling the formation of the macrochain forming in the course of polymerization and of expanding the assortment of the synthesized polymers by involving new monomers into the copolymerization. It was found that one of the factors responsible for the high catalytic activity of systems based on transition metal phenoxy imine complexes is the polydentate coordination mode, with intense electron exchange between the transition metal ion and unsymmetrical ligands. Therefore, the structure and electronic properties of the ligands exert a strong effect on the activity and selectivity of catalytic systems based on phenoxy imine complexes. Variation of the structure of phenoxy imine ligands is widely used in searching for new catalysts showing high activity and stability under the polymerization conditions.

Even in their first papers [6–8], Fujita et al. considered the dependence of the catalytic activity of phenoxy imine complexes (with methylalumoxane, MAO, as cocatalyst) on the kind of transition metal, with the complexes of Zr, Ti, Hf, and V as examples. They were also the first to analyze the influence exerted on the catalytic activity by the size of substituents in the imine and phenoxy moieties. The main conclusions made in these papers are as follows.

(1) The phenoxy imine catalytic systems containing an aldimine group show higher activity than their analogs with a ketimine group.

(2) Small substituents at the imine N atom do not prevent approach of the monomer to the active center of the propagating chain.

(3) A bulky substituent near the phenoxyl oxygen atom sterically protects it from the electrophilic attack of Lewis acids present in the polymerization medium and favors efficient separation of the cationic active species and anionic fragments of the cocatalyst.

(4) Fluorinated substituents at the imine nitrogen atom ensure the occurrence of the polymerization by the "living" mechanism.

These conclusions were based on the results of experimental studies of a relatively limited number of

zirconium phenoxy imine complexes, and accelerated experimental procedures were used.

In this study we examined a wide range of titanium phenoxy imine complexes and compared their activities. By so doing, we attempted to find a correlation between the structure of titanium phenoxy imine complexes and their catalytic activity in polymerization of ethylene. For this purpose, we tested titanium bis(phenoxy imine) complexes containing various ligands (Table 1) in polymerization of ethylene in the presence of MAO.

EXPERIMENTAL

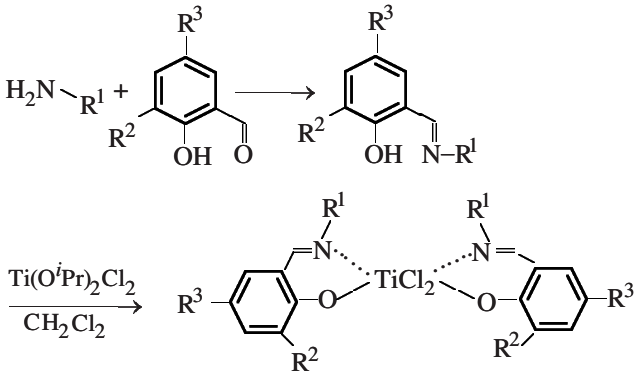
Ultrapure grade toluene was dried for 24 h over calcined alumina, distilled from sodium metal in an argon flow, and stored over sodium metal in an inert gas atmosphere.

Isopropyl alcohol (chemically pure grade) was used without additional purification.

Ethylene (main substance content 99.5%) and Ar (extra grade) prior to feeding into the reactors were dried by passing through columns packed with calcined alumina, after which the moisture content of ethylene and argon did not exceed 10–20 and 10 ppm, respectively.

Methylalumoxane (Witko GmbH, commercial name Eurecen® Al 5 100/10 T) was used as 10% solution in toluene. According to the data of the company, the total aluminum content of MAO was 4.6–5.6 mol %, and the relative content of Al counting on trimethylaluminum was 32–36 mol %.

The catalysts were based on titanium bis(phenoxy imine) complexes synthesized at the Vorozhtsov Institute of Organic Chemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, by the following scheme:



using the procedures described in [8–11].

The structures of the ligands and complexes were confirmed by elemental analysis and by ^{1}H NMR and IR spectroscopy.

Polymerization of ethylene was performed in a 150-ml stainless steel pressure vessel equipped with a detachable jacket and a magnetically driven propeller stirrer. Experiments were performed at a pressure of 0.6 MPa and temperatures from 30 to 80°C. The pressure in the vessel was maintained automatically, and the temperature was controlled by feeding water heated to the required temperature from an ultrathermostat to the jacket.

Before starting polymerization, the reactor was evacuated to a residual pressure of 1×10^{-1} mm Hg at 150–170°C for 1 h, after which it was filled with dry Ar and evacuated again. The procedure was repeated three times.

After cooling to room temperature, the calculated amount of toluene and components of the catalytic system were injected with a medical syringe through the loading tube in a counterflow of Ar. The mixture was saturated with ethylene and simultaneously brought to the required temperature and pressure. After the prescribed period, the reaction was stopped by adding isopropyl alcohol. The liquid phase was separated on a Büchner funnel, and the polymer obtained was washed with isopropyl alcohol and dried at 60°C in a vacuum to constant weight.

The molecular weight (MW) of the polymers obtained was determined from the viscosity data by the equation [12]

$$[\eta] = 6.2 \times 10^{-4} M^{0.70}.$$

The thermal characteristics of the polymers were determined by scanning calorimetry on a Shimadzu DSC-60 device. The specific heats of phase transitions and the characteristic temperatures were measured on the same differential scanning calorimeter at a heating rate of 10 deg min^{-1} and a sample weight of 5–10 mg.

The content of terminal groups in the polymers obtained was determined by IR Fourier spectroscopy on a Shimadzu FTIR-8300 spectrometer.

The catalytic systems under consideration were subdivided into three groups. In the first group, the complexes contained fixed *t*-Bu substituents in the *o*- and *p*-positions of the phenoxy group and varied substituents at the imine N atom. In the second group, the substituents in the phenoxy group were bulkier (cumyl), with varied substituents at the imine N atom. In the third group, the substituent at the imine N atom

was fixed (cyclohexyl), and the substituents in the phenoxy group were varied.

The results of experiments on ethylene polymerization at various temperatrues with the first group of complexes (catalysts **1**–**8**) and the characteristics of the polyethylenes obtained are listed in Table 2.

Table 2 shows that the catalytic activity, molecular weight of polyethylenes obtained, and optimal temperature of catalyst operation are strongly influenced by a substituent at the imine N atom. For example, complex **1** containing an aliphatic substituent at the imine N atom shows moderate catalytic activity (1200–4700 $kg_{PE}\,(mol_{cat})^{-1}\,MPa^{-1}\,h^{-1}$) and the forming polyethylene has relatively low molecular weight (M_η = 220000–300000) with vinyl terminal groups at one or both ends of polymer chains.

Introduction of an alicyclic substituent at the imine N atom (complex **2**) leads to an increase in the catalytic activity. The molecular weight of the PE obtained is also higher. The electronic effects of *n*-Bu and cyclohexyl are similar. Both substituents exhibit donor properties and enhance the electrophilicity of the coordination core. Therefore, the difference between complexes **1** and **2** in the catalytic activity should be attributed to steric effects of *n*-Bu and cyclohexyl. It was shown recently [13] that the state of the active center bound to the transition metal strongly differs in the complexes containing different substituents at the imine N atom. This effect is attributed to differences in the distance between the Cl atom and its nearest neighboring C atom in substituents at the imine group. In the compound with the more "compact" cyclohexyl substituent, this distance is longer than in the complex with the *n*-Bu substituent, and hence the polymerization center can be less shielded, causing higher activity of complex **2** compared to **1**.

The catalytic activity of complex **3** containing an aromatic substituent, phenyl, at the imine group is slightly higher than that of **2**, but the molecular weight of the polyethylene obtained is lower. This difference may be due to different electronic effects of the alicyclic and aromatic substituents at the imine N atom, which can differently affect the titanium polymerization center.

Introduction of a bulky substituent (cyclohexyl) into the *o*-position of the phenyl group at the imine N atom (complex **4**) leads to a decrease in the catalytic activity by more than an order of magnitude. Apparently, the substituent in the *o*-position of the phenyl ring at the imine N atom, located in the vicinity of the polymerization center, prevents access of ethylene to the active center.

Complexes **5**–**8** are systems with further increased steric hindrance. As already noted, this factor prevents access of the monomer to the active center. As a result, the catalytic activity decreases.

It should be noted that substituents at the imine N atom, along with affecting the catalytic activity, can also shift the optimal temperature range of the catalyst functioning. As seen from Fig. 1a, with an increase in the temperature from 30 to 70°C, the curve of the catalytic activity of complexes **1** and **3** passes through a maximum; for complex **2**, the catalytic activity monotonically decreases, and for **4**, increases.

* (*A*) Activity, $kg_{PE}\,(mol_{cat})^{-1}\,MPa^{-1}\,h^{-1}$

The results of studying the activity of the second group of phenoxy imine complexes (**9**–**15**) in ethylene polymerization are also given in Table 2. The most active is complex **9** containing an alicyclic substituent at the imine N atom in combination with a bulky substituent (cumyl) in the *o*-position of the phenoxy group. Comparison with the related complexes of the first group (**9** with **2**, **10** with **3**) shows that the catalytic activity increases by a factor of 3 and more. This fact shows that substituents at the imine N atom and in the phenoxy group exert a conjugated effect on the activity of the catalytic system.

Introduction of an aromatic substituent at the imine N atom (complex **10**) leads to a decrease in the catalytic activity by a factor of ~2 and to an increase in the molecular weight of the forming polyethylene.

Complex **11** containing the ketimine functional group exhibits low catalytic activity compared to the aldimine analog. This fact was already noted in [10].

Replacement of the *p*-methyl substituent in the phenoxy group (complex **10**) by the second bulky cumyl substituent (complex **12**) leads to a decrease in the catalytic activity and in the molecular weight of the forming polyethylenes. Apparently, two bulky substituents in the phenoxy group exert an effect decreasing the activity.

Comparison of the activity of the catalytic systems based on complexes **4**–**6** with that of the system with **13** shows that the position of substituents in the phenyl group bonded to imine nitrogen (Table 1) strongly affects the activity of the catalytic systems. In the *p*-position, even bulky substituents substituents (complex **13**) decrease the catalytic activity by a factor of only 1.5, whereas in the *o*-position even the methyl groups drastically (by more than two orders of magnitude) decrease the activity.

Complexes **14** and **15** containing bulky substituents at the imine N atom, 2-(isobornyl) and 1-(1-adamantyl) ethyl, exhibit virtually no catalytic activity.

Examination of the influence of temperature in the range 30–70°C on the activity of systems based on complexes **9**, **10**, **12**, and **13** showed that the activity of the systems based on **9**, **10**, and **13** decreases with increasing temperature, and that of the system based on **12** passes through a maximum at 50°C (Fig. 1b).

Data on the activity of catalytic complexes of the third group are also given in Table 2.

Complex **16** containing *t*-Bu in the *o*-position and Me in the *p*-position of the phenoxy group shows high activity, and the molecular weight of the resulting polyethylene is high. Replacement of the *o*-*t*-Bu group by a bulkier cumyl substituent (complex **9**) leads to an increase in the catalytic activity by a factor of 3, but the molecular weight of the forming polyethylenes decreases.

Introduction into the *o*- (complex **17**) or *p*-position (complex **18**) of very bulky trityl group drastically decreases the catalytic activity.

Complexes **19** and **20** containing a bulky isobornyl substituent in the *o*-position of the phenoxy group show moderate catalytic activity. The catalytic activity of complex **20** without *p*-substituents is higher.

Complex **21** containing 1-phenylethyl substituent in the *o*-position of the phenoxy group shows fairly high catalytic activity, which is only slightly dependent on temperature. Thus, by properly choosing substituents (and, in particular, their volume) in the phenoxy group, it is possible to ensure high activity of the complex at elevated temperatures.

Data on the effect of temperature on the activity of complexes **16** and **19**–**21** containing different substituents in the phenoxy group are shown in Fig. 1c. The catalytic activity of all the complexes decreases with increasing temperature from 30 to 50°C.

All the phenoxy imine complexes studied ensure formation of linear and highly crystalline polyethylenes, as indicated by the IR and DSC data (Table 2).

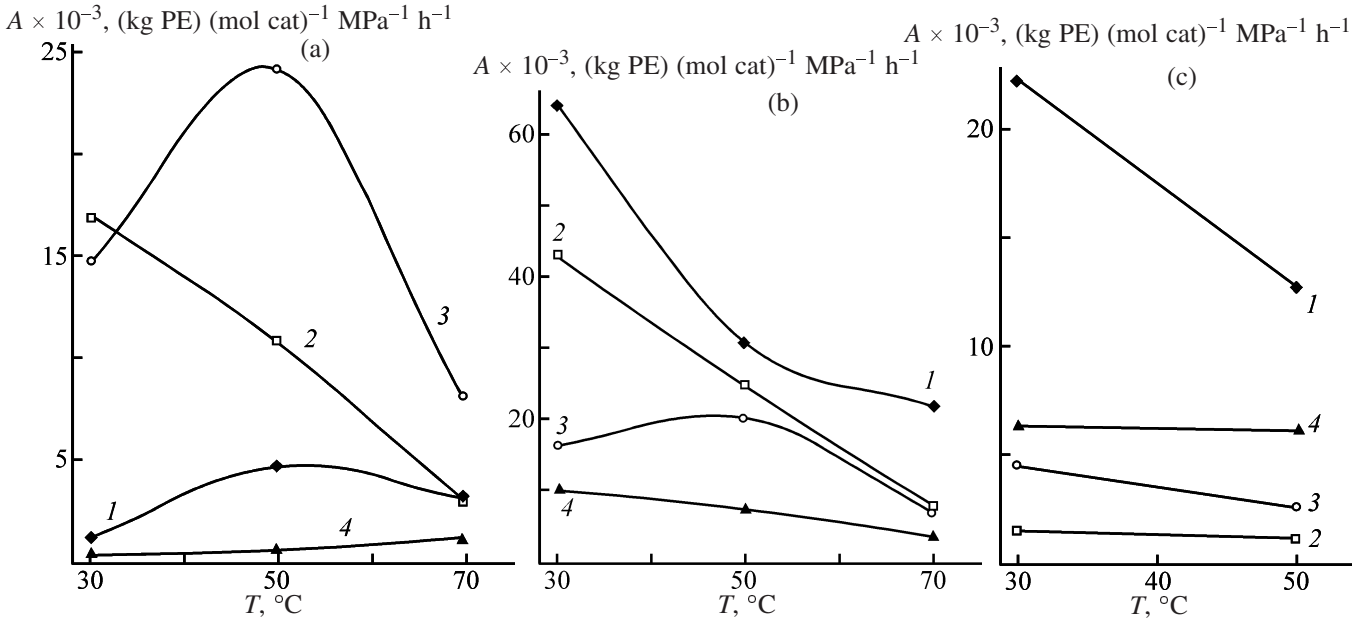

Fig. 1. Catalytic activity A of complexes as a function of polymerization temperature T. Polymerization conditions: $V_{toluene}$ = 50 ml, $P_{C_2H_4}$ = 3 atm. Complex: (a) (*1*) **1**, (*2*) **2**, (*3*) **3**, and (*4*) **4**; (b) (*1*) **9**, (*2*) **10**, (*3*) **12**, and (*4*) **13**; (c) (*1*) **6**, (*2*) **19**, (*3*) **20**, and (*4*) **21**.

With some phenoxy imine complexes, the "living" polymerization mechanism can be realized in the system. Initially this mechanism was established for structures containing perfluorinated aryl groups at the imine N atom [11, 14, 15]. Quantum-chemical MO calculations showed that the features of the living polymerization mechanism with these systems are associated with the electron-withdrawing effect of the F atoms, which can interact with the β-H atoms in the polymer chain, preventing the β-hydride transfer.

In later studies, the living polymerization was performed for the first time with nonfluorinated titanium phenoxy imine complexes [16, 17]. Similar results were noted in a recent review [5].

We attempted to find a correlation between the features of elementary reactions and the ligand structure. The influence of the structure of the complexes on the energy effects of formation of catalytically active species, of formation of a π complex of the catalyst with ethylene, of chain propagation and transfer, and of deactivation of the system was examined by the DFT method [18] for five phenoxy imine complexes of titanium and zirconium. The data obtained explained the differences in the behavior of the Ti and Zr complexes and the dependence of the activity of the catalytic system on the ligand structure. However, this is only the initial step in revealing correlations between the structures of the complexes and features of the elementary reactions in polymerization.

CONCLUSIONS

(1) Effect of substituents in ligands of phenoxy imine complexes on the activity of catalytic systems based on them in polymerization of ethylene depends on the structure of the substituents and their location in the imine or phenoxy moiety.

(2) Different substituents localized in the imine or phenoxy moiety of phenoxy imine complexes exert a conjugated effect on the activity of catalytic systems based on these complexes.

ACKNOWLEDGMENTS

The study was financially supported by the Presidium of the Siberian Division of the Russian Academy of Sciences within the framework of Integration Project no. 4.6 of the Siberian Division of the Russian Academy of Sciences.

The authors are grateful to S.Ya. Khaikin and E.V. Sviridova for the determination of structural and molecular characteristics of polymer samples and to M.G. Eremeeva and V.S. Misin for participation in the preparation of polymerization experiments.

CATALYSIS

Preparation of High-Performance Nanosized Palladium Hydrogenation Catalysts Using White Phosphorus and Phosphine

Abstract—The nature and properties of nanosized palladium hydrogenation catalysts modified with elemental phosphorus and phosphine (PH_3) were studied.

DOI: 10.1134/S1070427207090157

Previously were studied the nature of particles active in hydrogenation that were formed by treatment with different reducing agents of palladium(II) complexes with organic phosphines [1–4]. Microheterogeneous nature of these catalysts was revealed, and the key steps of their formation was determined. In particular, the main reactions of palladium(II) phosphine complexes with hydrogen are reduction of Pd(II) to Pd(0) by hydrogenolysis of the Pd–X bonds (X is an acido ligand); degradation of phosphine ligands in the coordination sphere of Pd(0) by oxidative addition of organophosphorus ligands to Pd(0), followed by hydrogenolysis of the Pd–C bond with hydrogen and formation of polynuclear palladium phosphine and phosphinidene complexes (in the limiting case, palladium phosphides, Pd_6P and $Pd_{4.8}P$); and formation of Pd(0) clusters [2, 3]. Active in hydrogenation are Pd(0) clusters or cluster palladium hydrides [Pd_xH_y] immobilized on polynucliear palladium complexes with phosphide and posphinidene ligands or on palladium phosphides. Since formation of Pd(II) phosphine complexes involves stepwise degradation of organophosphorus ligands to form a heterophase system containing in the limiting case palladium phosphides of different composition and Pd(0) clusters, we suggested that phosphine (PH_3) and white phosphorus (P_4) can be used to modify the catalyst. This approach can simplify preparation of nanosized palladium hydrogenation catalysts. The aim of this study was to examine the nature and catalytic properties of the systems prepared by treatment with molecular hydrogen of mixtures of palladium bisacetylacetonate with white phosphorus or phosphine.

EXPERIMENTAL

The solvents and chemicals were purified by standard procedures used in handling of organometallic compounds [5]. Benzene was additionally dried by distillation from $LiAlH_4$ on a column and was stored in an argon atmosphere in sealed ampules over 4A molecular sieves.

To remove water and amine impurities, dimethylformamide was kept over anhydrous copper sulfate until a green solution was formed. Then the solvent was double-distilled in a vacuum (3 mm Hg) at temperature no higher than 42°C.

Palladium bisacetylacetonate was prepared by the procedure described in patent [6]. ^{1}H NMR: δ(CH) = 5.04 ppm (s, 1H), $\delta(CH_3)$ = 1.76 ppm (s, 6H).

To prepare phosphine, a solution of 25 g of KOH in 25 ml of water was added dropwise to a suspension of 10 g of red phosphorus in 30 ml of toluene, preheated to ~110°C [7]. The liberating gas was successively passed through a Tishchenko bottle filled with a 50% solution of an alkali in an H_2O + DMSO mixture to remove diphosphine impurities and then through columns packed with NaOH and P_2O_5 to remove water traces. Phosphine was collected by dissolution in benzene placed in a finger-like vessel. The phosphine concentration in the benzene solution was determined by ^{31}P NMR spectroscopy using 85% H_3PO_4 as external reference; ^{31}P NMR: δ_P = –238 ppm (q, J_{PH} = 188 Hz).

To remove surface oxidation products of white phosphorus, it was washed with anhydrous benzene. A benzene solution of white phosphorus was prepared

and stored under an inert atmosphere in a finger-like vessel. The design of this vessel allows evacuation and filling with argon. ^{31}P NMR: δ_P = 523 ppm.

Catalytic hydrogenation was performed in a duck-shaped vessel thermostated at 30°C at the initial hydrogen pressure of 1 atm in the presence of the catalytic system formed in situ. To a solution of $Pd(acac)_2$ (0.00304 g, 1×10^{-5} mol) in DMF (9 ml) placed in a duck-shaped vessel, a solution of phosphine (0.3×10^{-5} mol) in benzene (1 ml) was added dropwise in a hydrogen stream. The mixture was stirred for 5 min at room temperature. Then the system was heated to 80°C with stirring in a hydrogen stream. The resulting black-brown "solution" was cooled to 30°C. A substrate was injected with a syringe. It was hydrogenated with vigorous stirring to exclude the diffusion control of the reaction. The reaction course was monitored by GLC. The experiments at other P/Pd ratios and preparation of the palladium catalyst modified with white phosphorus were performed similarly. The optimal time required for preparing $Pd(acac)_2$–nP_4 catalytic system at 80°C was 25–30 min.

The palladium catalysts modified with white phosphorus were prepared in a temperature-controlled duck-shaped glass vessel in hydrogen at 80°C. To a solution of $Pd(acac)_2$ (0.761 g, 2.5×10^{-3} mol) in DMF (90 ml), a solution of phosphine (0.75×10^{-3} mol) (P/Pd = 0.3) in benzene (25 ml) was added drop-wise in a hydrogen stream. The mixture was stirred at a hydrogen pressure of 1 atm and 80°C for 15 min. The solution color changed to dark brown in 2–5 min. After reaction completion, the black suspension was cooled to room temperature and was transferred under an inert atmosphere into a finger-like vessel. Then the solvent was removed in a vacuum (2/3 of the volume). Ether was added until a precipitate was formed. The precipitate was washed with ether in an argon atmosphere and was dried in a vacuum (50°C/1 mm Hg). Yield 0.235 g. Elemental analysis, %: Pd 87.88; P 3.59; C 0.99; H 0.25. IR: no absorption in the range 4000–400 cm^{-1}.

Analysis for Pd and P was performed as follows. A weighed portion of the sample (about 0.01 g) was dissolved in 2 ml of boiling HNO_3. The resulting solution was diluted with water to 50 ml in a volumetric flask. The palladium concentration was determined by atomic absorption spectroscopy on a Perkin–Elmer 403 spectrometer in a propane–air flame. The phosphorus content was determined photocolorimetrically by the standard procedure [8].

The catalyst samples were studied by powder X-ray diffraction on a DRON-3M diffractometer using CuK_α radiation. The NMR spectra were recorded on a VXR-500S Varian pulse spectrometer. The ^{31}P chemical shifts are given relative to 85% phosphoric acid.

The samples were studied by transmission electron microscopy (TEM) on a BS-300 microscope (Czech Republic). A drop of the solution was applied onto a gauze coated with a carbon film and was dried in an argon atmosphere. The electron micrographs were taken under conditions excluding melting and degradation of the samples on exposure to an electron beam.

The procedure for determining Pd(0) is described in [9].

Previously we showed [1–4, 10] that palladium(II) β-diketonate–phosphine complexes became catalytically active in hydrogenation reactions only after their activation with a reducing agent, e.g., with molecular hydrogen. To compare the catalytic properties of the catalysts derived from palladium bisacetylacetonate [$Pd(acac)_2$] modified with white phosphorus and phosphine with those of palladium(II) complexes with organic phosphines (PPh_3, $PHPh_3$, PH_2Ph), these catalysts were prepared similarly in a hydrogen atmosphere at 80°C. It should be noted that at a lower temperature the rate of $Pd(acac)_2$ reduction is lower (Table 1). The properties of palladium catalysts modified with phosphine or white phosphorus were studied in relation to different parameters. It was found that the dependences of the specific activity in styrene hydrogenation on the P/Pd ratio passed through maxima. The most active catalysts are formed at similar ratio P/Pd = 0.3 (Fig. 1). We observed the similar dependence for the $Pd(acac)_2$–PH_2Ph system [10]. The influence of organophosphorus compounds on the catalytic activity of $Pd(acac)_2$ decreases in the following order: $P_4 \cong PH_2Ph$ [10] > PH_3 > $PHPh_2$ [11] > PPh_3 [3].

The most active promoters are white phosphorus and phenylphosphine, all catalytic reaction conditions being the same; the phosphine is slightly less effective; the palladium bisacetylacetonate + triphenylphosphine system exhibits the lowest catalytic activity in alkene hydrogenation (Fig. 2).

It should be noted that the specific activity of the palladium catalysts modified with phosphine (PH_3) increases with decreasing palladium concentration and reaches a maximum [330 (mol styrene) (g-at. Pd)$^{-1}$ min^{-1}] at $C_{Pd} = 5 \times 10^{-4}$ M. Nonlinear dependence of the reaction rate on the $Pd(acac)_2$ concentration in the case of the catalyst modification with both phosphine and phosphorus (Fig. 3) suggests associa-

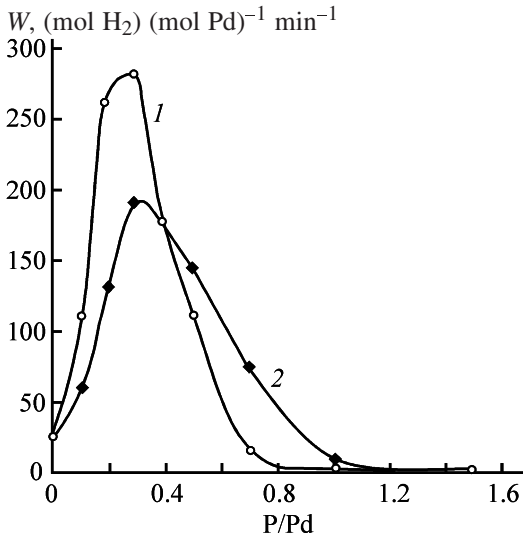

Fig. 1. Hydrogenation of styrene in the presence of palladium catalysts modified with (*1*) white phosphorus and (*2*) phosphine. C_{Pd} = 1 mM, [substrate]/Pd(acac)$_2$ = 870, solvent DMF, T = 30°C, P_{H_2} = 1 atm. (W) Specific activity; the same for Fig. 2.

tion of reactive palladium species in less active aggregates and microheterogeneity of the catalysts.

Palladium species modified with white phosphorus and phosphine are highly active and selective catalysts of hydrogenation of acetylene derivatives and nitro- and carbonyl groups (Table 2). For example, phenylacetylene is successively hydrogenated to styrene and ethylbenzene without its side di- or oligomerization.

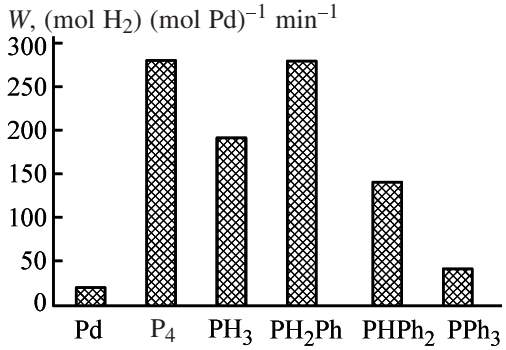

Fig. 2. Influence of the modifier on the specific activity of palladium hydrogenation catalysts.

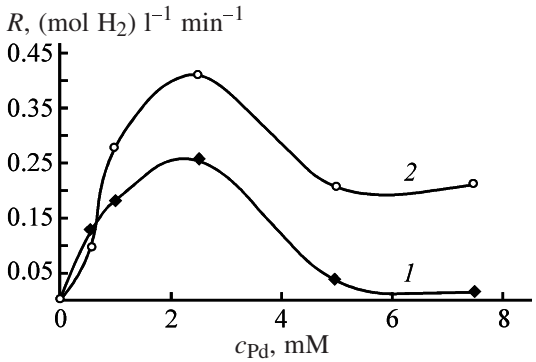

Fig. 3. Rate of styrene hydrogenation R in the presence of catalysts formed by reduction of (*1*) $Pd(acac)_2$–PH_3 and (*2*) $Pd(acac)_2$–P_4 systems as a function of palladium concentration. Solvent DMF, P/Pd = 0.3, T = 30°C, P_{H_2} = 1 atm, [substrate] = 8.7×10^{-3} mol.

At 96% conversion of phenylacetylene, the selectivity with respect to styrene is 94–95%. Nitrobenzene is selectively reduced to aniline.

Thus, the activity of the palladium catalysts modified with white phosphorus and phosphine (PH_3) is not only similar to, but in some cases even higher than that of the previously studied nanosized palladium catalysts prepared from palladium complexes with organic phosphines ($PHPh_2$, PPh_3).

The most active hydrogenation catalysts prepared by treatment of $Pd(acac)_2$ + $0.3PH_3$ (or P_4) system with molecular hydrogen were studied by X-ray diffraction and TEM.

As determined by TEM, the reaction of the $Pd(acac)_2$ + $0.3PH_3$ system with hydrogen yields a microheterogeneous system containing mainly high-contrast particles 7.2–7.8 nm in diameter (Fig. 4a). When the time of hydrogen treatment increases from 15 to 30 min, the system becomes more structured (Fig. 4b). The loose and dendritic structure observed in the micrographs is typical for fractal clusters [12]. These clusters are formed by self-aggregation of nanoparticales of similar size in the absence of stabilizing factors. It should be noted that, in the course of formation of microheterogeneous hydrogenation catalysts in the presence of phosphine ligands, fractal clusters were observed for the first time. Palladium particles formed by reduction of palladium(II) complexes in the presence of tertiary [3], secondary [11], or primary phosphines [10] are more stable to aggregation.

The composition of the black precipitate (sample I) isolated from $Pd(acac)_2$–$0.3PH_3$ system is described by the empirical formula $Pd_{7.5}P_{1.07}H_{2.1}$. As determined by X-ray diffraction, the precipitate is a heterophase mixture containing palladium phosphides of various compositions: Pd_6P (*d*/*n* 2.696, 2.583, 2.368, 2.291, 2.256, 2.232, 2.093, 1.998 Å), $Pd_{4.8}P$ (*d*/*n* 2.439, 2.327, 2.256, 2.232, 2.122, 1.998 Å), Pd_5P_2 (*d*/*n* 2.734, 2.696, 2.439, 2.291, 2.256, 2.232, 2.122, 1.993, 1.858, 1.432 Å) and crystalline palladium (*d*/*n* 2.256, 1.950, 1.375 Å) [13]. Palladium phosphides Pd_6P and $Pd_{4.8}P$ prevail in the sample. The fraction of reduced palladium determined by the chemical method is 31%. Knowing the total content of palladium and phosphorus, the fraction of reduced palladium, and the composition of palladium phosphides, we can describe the composition of sample I by the empirical formula

$$[\{Pd(0)\}_{2.33}\{Pd_6P\}_{0.40}\{Pd_{4.8}P\}_{0.55}\{Pd_5P_2\}_{0.026}].$$

The carbon and hydrogen in the sample most likely originate from the residual solvent (DMF). Hence, the composition will be described by the formula

$$[\{Pd(0)\}_{2.33}\{Pd_6P\}_{0.40}\{Pd_{4.8}P\}_{0.55}\{Pd_5P_2\}_{0.026}\{DMF\}_{0.3}].$$

X-ray diffraction analysis of the catalyst prepared in the presence of white phosphorus [$Pd(acac)_2$–0.3P] shows that the sample consists of palladium phosphide Pd_6P, crystalline palladium, and palladium hydride $PdH_{0.7}$ [13]. The fraction of reduced palladium, determined by the chemical procedure, is 25%. It should be noted that reduction of $Pd(acac)_2$ with hydrogen is an autocatalytic reaction, with the induction period in the presence of white phosphorus increasing from 7 to 18 min. This fact can be explained as follows. Palladium atoms formed in the first steps of hydrogen reduction react with white phosphorus to form palladium phosphides which are not capable to activate molecular hydrogen. After the phosphorus is completely bound into palladium phosphides, $Pd(acac)_2$ is autocatalytically reduced with hydrogen.

Thus, the general feature of formation of hydrogenation catalysts in the system in question is formation of palladium phosphides of different compositions and reduced palladium in the amount of about 25–30%. It should be noted that palladium phosphides as modifiers of organic phosphines, in particular phenyl- and triphenylphosphine, are formed after almost complete degradation of the organophosphorus ligand during treatment of the catalyst with molecular hydrogen at the molar ratio P/Pd ≤ 0.5 [3, 10, 14]. However, a long time required for reduction of $Pd(acac)_2$ with hydrogen in the presence of PH_3 and low stability of the resulting nanoparticles to aggrega-

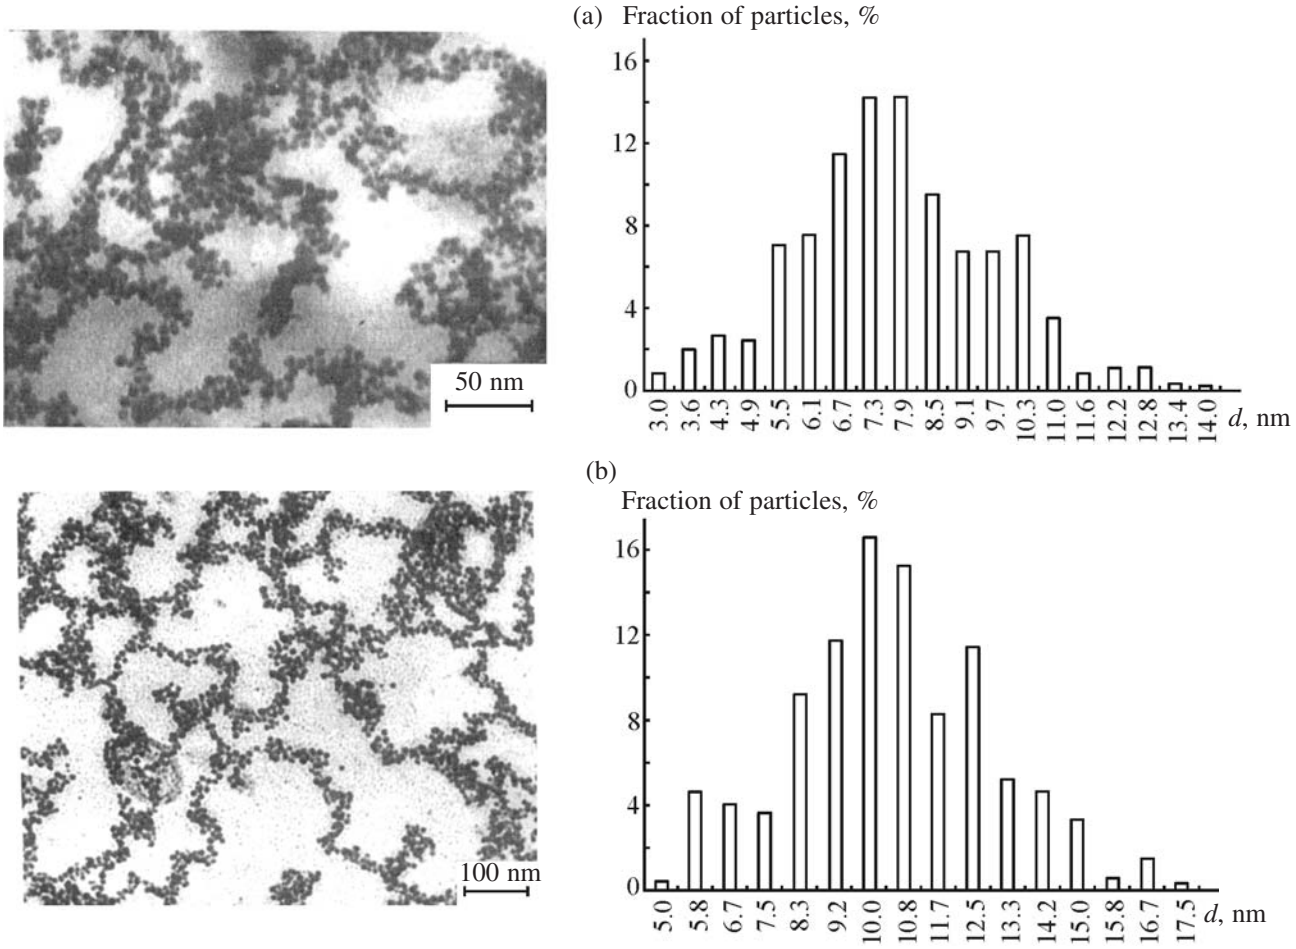

Fig. 4. Electron micrograph of the $Pd(acac)_2$–$0.3PH_3$ system treated with hydrogen at 80°C and particle size distribution. (*d*) Particle size. Treatment time, (a) 15 and (b) 30.

tion lead to a sharp decrease in the activity of the catalyst as compared to the catalysts prepared from $Pd(acac)_2$ and P_4, PH_3, and PH_2Ph.

To determine the mechanism of the promoting effect of the ogranophosphorus compounds on the catalytic properties of the palladium hydrogenation catalysts, we compared the fraction of the surface atoms for the $Pd(acac)_2$–$0.3PH_3$ catalytic system and that of Pd black formed under the similar conditions from $Pd(acac)_2$.

The size of Pd black particles determined by TEM is 25–30 nm, which is larger by a factor of almost 4 than that of particles formed in the $Pd(acac)_2$–$0.3PH_3$ system. It is known that the fraction of the surface atoms for metal particles 8–10 nm in diameter is 20–15%, and it decreases to 3–2% with increasing particle size to 25–30 nm [15]. The increase in the fraction of the surface atoms by a factor of 7 (on the average) correlates with the promoting effect of phosphine. Hence, formation of more finely dispersed system can be one of the reasons determining the promoting effect of phosphine. The assumption that the promoting effect of phosphine is due to an increase in the catalyst dispersity is well consistent with the experimental data for the case when Pd(0) atoms are located on the nanoparticle surface. Based on the results obtained, we suggest that microheterogeneous hydrogenation catalysts consist of nanoparticles whose cores are formed by palladium phosphides with Pd(0) clusters immobilized on the surface.

It should be noted that the high activity of nanosized palladium hydrogenation catalysts cannot be solely due to a small particle size. In particular, the particles of microheterogeneous palladium catalysts prepared from palladium complexes with organic phosphines are smaller (3–5 nm [3, 10]) than particles of the examined systems, but, as noted above, their catalytic activity is lower.

This is due to the fact that transformation of palladium phosphine complexes under the action of molecular hydrogen is a complex multistep process. The general feature of formation of hydrogenation catalysts from $Pd(acac)_2$ and different phosphines in hydrogen is not only formation of microheterogeneous systems but also oxidation of palladium particles after degradation of the phosphorus-containing ligands or reaction of Pd(0) with elemental phosphorus. The ratio of oxidized and reduced palladium changes depending on the ratio of the reduction rates of Pd(II) complexes, aggregation of reduced palladium particles, and degradation of phosphorus-containing fragments in the coordination sphere of Pd(0). In addition, the electron density on Pd(0) clusters can change after their immobilization on palladium phosphides. The structure and catalytic properties of the palladium nanoparticles depend on all of these factors. The particles formed after hydrogen treatment of $Pd(acac)_2$ modified with phosphine and elemental phosphorus have similar structure and a high content of reduced palladium, and hence their catalytic properties in hydrogenation are similar.

CONCLUSIONS

(1) White phosphorus and phosphine (PH_3) were used for the first time as modifiers in synthesis of effective palladium hydrogenation catalysts whose catalytic activity is not only similar to, but in some cases higher than that of nanosized palladium hydrogenation catalysts prepared from palladium complexes with organic phosphines.

(2) Reaction of $Pd(acac)_2$ with hydrogen in the presence of phosphine (PH_3) and white phosphorus yields Pd(0) and palladium phosphides of various compositions.

(3) The promoting effect of phosphine is caused, in particular, by smaller particle size of the catalysts prepared from $Pd(acac)_2$ as compared to Pd black.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Determination of the Conditions of the Sol–Gel Synthesis of Biosorbents for Water Treatment

Abstract—The feasibility of sol–gel synthesis of a series of biosorbents with encapsulated starches, intended for water treatment, was elucidated. The factors governing the morphology of the resulting materials were examined. The performance of the composites synthesized in sorption removal of polyvalent metal ions from water was estimated.

DOI: 10.1134/S1070427207090169

Water pollution with toxicants of different nature is a serious environmental and social problem. Metals have a special place among substances that pose health hazard, as they are, essentially, biotics that acquire toxicity with increasing concentrations [1]. Many countries enacted stringent environmental standards specifying the content of metal ions in water [2]. The principal methods to reduce their content in water include chemical precipitation, ion exchange, adsorption on active carbon, membrane processes, and electrodialysis. However, these methods have limitations like high operation costs or inability to fully satisfy the water quality standards.

Sound environmental protection is possible today only through introduction of advanced technologies and materials, including new sorption materials (adsorption was recognized as the best method for water treatment to remove pollutants) [3]. The most environment-friendly line in the development of materials for water treatment is waste-free production of hybrid nanocomposites [4–6], and the sol–gel method offers wide prospects for preparation of diverse functional materials [5]. For example, in "bionanocomposites," natural polymers encapsulated into an inorganic matrix preserve their activity and spectral properties [6]; bringing water in contact with such sorbents allows reduction of the content of hazardous pollutants virtually to zero [4].

Much research efforts were recently devoted to the development of new sorbents containing biopolymers [7–9]. Among natural polymers, special attention is deserved by polysaccharides because of their specific structure, physical and chemical characteristics, and excellent selectivity with respect to pollutants [8].

In this study, we examined the sol–gel synthesis of biosorbents (BSs) containing encapsulated starches with a view to intensify the removal of metal ions from water.

Starch, second to cellulose widespread biomolecule on the earth [10, 11], is chemically a mixture of two homopolysaccharides, linear amylose and branched amylopectin. Stable forms of starch in the solid state, below the gelation temperature (~60°C), are represented by coil structures; above this temperature in water they uncoil to a substantial extent, and more easily accessible hydroxy groups of the glucose units form hydrogen bonds with the solvent, yielding a gel. With time going, the starch gel slowly resumes its coil structure with formation of a precipitate. Incorporation of reactive functional groups into the starch framework yields products able of removing heavy metal ions from industrial wastewater [12]. However, starch products themselves are hardly suitable as sorbents, since they lack controllable particle size and certain wear resistance, hardness, and porosity. One of the methods to increase the stability of a biosorbent consists in incorporation of a natural polymer into an inorganic material [13]; the resulting hybrid nanocomposites typically exhibit synergism of the properties of the initial components. In this respect, the advantages offered by the silica matrix are chemical stability,

Table 1. Summary of the reagents used for synthesis of biosorbents

Biosorbent	Precursor solution composition (weight ratio)				Polysaccharide
BS-1.1	TEOS (5.3)	–	H_2O (4.35)	HCl (0.25)	Starch (1.0)
BS-1.2					Starch + urea
BS-1.3					Starch + thiourea
BS-2.1	TEOS (5.2)	Ethanol (4.35)	H_2O (0.5)	HCl (0.75)	Starch (1.0)
BS-2.2					Starch + urea
BS-2.3					Starch + thiourea
BS-3.1	TEOS (9.5)	Methanol (20)	H_2O (6.7)	–	Starch (1.0)
BS-3.2					Starch + urea
BS-3.3					Starch + thiourea
S-4	TEOS (9.5)	Methanol (20)	H_2O (6.7)	–	No polysaccharide
S-5	ECH (0.18)	–	H_2O (0.12)	NaOH (0.08)	Starch (1.0)

as well as large specific surface area, porosity, and mechanical strength [14]. Synthesis of silica gel matrix is underlain by polycondensation of silicic acid yielded by hydrolysis of silanes in an aqueous solution [6].

In this study, we examined immobilization of a series of starch products in a silica matrix by the sol–gel method and compared the degrees of sorption of Cu^{2+}, Fe^{3+}, and Al^{3+} on the resulting materials (to elucidate how the method of synthesis and the polysaccharide nature affect the performance of the biosorbent). Also, we compared the synthesized biosorbents with the known sorbents, silica [14] and starch cross-linked with epichlorohydrin [8].

EXPERIMENTAL

We used pure grade water-soluble starch [GOST (State Standard) 10 163–76]; chemically pure grade urea, thiourea, ethanol, sodium hydroxide, hydrochloric acid, and iron, aluminum, and copper chlorides; analytically pure grade tetraethoxysilane (TEOS) (Fluka) and epichlorohydrin (ECH) (Merck); and deionized water ($\chi < 1 \times 10^{-8}$ Ω^{-1} m^{-1}).

Samples of starch products were prepared using the technique from [15] (in part) at different urea : starch molar ratios (calculated from the glucose residue). Native starch was thoroughly mixed with the appropriate amount of the modifier (urea or thiourea) in an agate mortar. Next, the mixture was heated at atmospheric pressure and 100–105°C for 15–17 h and at 125–130°C for 7–8 h; the solid-state reaction was run to completion in a microwave oven (5 min at 900 VA). The resulting material was extracted in a Soxhlet apparatus with 70% aqueous ethanol and dried at 80–90°C.

The polysaccharide (starch or its derivatives) was suspended in an acidified water (pH ~4.0) and left for 1 day; after decantation, starch was washed successively with distilled water and ethanol, dried at 45–50°C, and mechanically activated before introduction of inorganic compounds (precursors) into the composition. The compositions of the precursors used for preparing a series of biosorbents (Table 1) were chosen according to [16].

The sol–gel synthesis procedures were as follows. Biosorbents 1 (BS-1.1–1.3) were synthesized by mixing the components for 5 h at room temperature (starch was added in the last hour), whereupon the resulting gel-like precipitate was dried for 2 days at 25°C and for 1 day at 90°C. The precursor components for biosorbents 2 (BS-2.1–2.3) after mixing were kept for 2 days in a refrigerator (–5°C), whereupon the polysaccharide was added. The resulting mixture was stirred for 30 min and dried for 1 day (90°C). The components of biosorbents 3 (BS-3.1–3.3) were mixed for 2 h; about 70% methanol was allowed to evaporate with exhaust ventilation at room temperature, whereupon starch was introduced into the precursor, and the resulting sample was dried (90°C).

For comparison, we also synthesized sorbent 4 (silica without starch) by the procedure identical to that in preparation of biosorbent 3, to estimate the sorption capacities of the silica matrices, and biosorbent 5 by the known technique [17] involving immobilization with epichlorohydrin. The dried precipitates of the sorbents were crushed and screened to collect 250–500-μm particles for sorption experiments.

To elucidate the role played by the polysaccharides in sol–gel processes, we examined the resulting mate-

rials with a scanning electron microscope (JSV-T20 JEOL). Figure 1 demonstrates the structure of biosorbent 3.1 (Table 1) with a three-dimensional network consisting of intersecting or branched fibers, dissimilar to that of solid nanoparticles in silica-based composite materials [5].

Linear polysaccharides are known to catalyze sol–gel transition in systems containing organosilicon precursors [18]. Catalysis is underlain by hydrogen bonding between the hydroxy groups of the carbohydrate and the silane hydrolysis products. Considering the structural features and chemical composition of starches [11], it can be presumed that the hydroxy groups of amylose enter into a condensation reaction with silanols (≡Si–OH). This results in nucleation of silica on the "fiber" macromolecules and formation of a matrix. The major portion of starch is encapsulated into the resulting silica gel matrix during its formation. It is believed that, in this case, the biomacromolecules preserve the ability for conformation transitions and, consequently, the individual sorption activity in the composite material [6]. The images obtained by atomic-force microscopy (AFM) (Fig. 2; Nanoscope IIIa Dimension 3000^{TM}) demonstrate "loose" island structures on the biosorbent surface, formed immediately after synthesis of the material (Fig. 2a). Within 5–7 days, these structures transformed into clear honeycomb structures with a wall height of about 200 nm (Fig. 2b). Such changes in the topography of the sample suggest that the end structure of the biosorbent was influenced by immobilized starch; retrogradation causes the polysaccharide macromolecules to rearrange into coil structures, thereby imparting a high rigidity to the material [19].

The structural organization of the material was little affected by replacement of starch by its derivatives in synthesis of the biosorbent. A possible reason is that the resulting starch products are neutral compounds, while the density and structure of the network are known to depend on the charge of the macromolecules [5].

Sorption of polyvalent metal ions was carried out as follows. A weighed portion of the biosorbent containing 0.1 g of starch and 100 ml of the appropriate aqueous solution ($FeCl_3$, $AlCl_3$, and $CuCl_2$) was placed into a reaction vessel. The initial concentration of the metal in solution was varied within 10–300 mg l^{-1}; pH of the initial solution (5.0–5.5) was adjusted with HCl and NaOH.

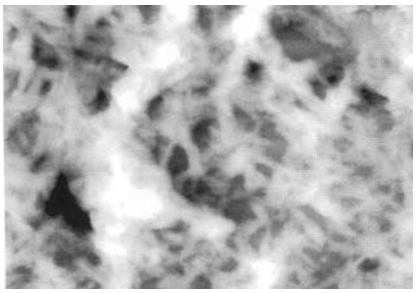

Fig. 1. Images of the biosorbent with immobilized starch. $\times 2 \times 10^5$ magnification, scanning mode.

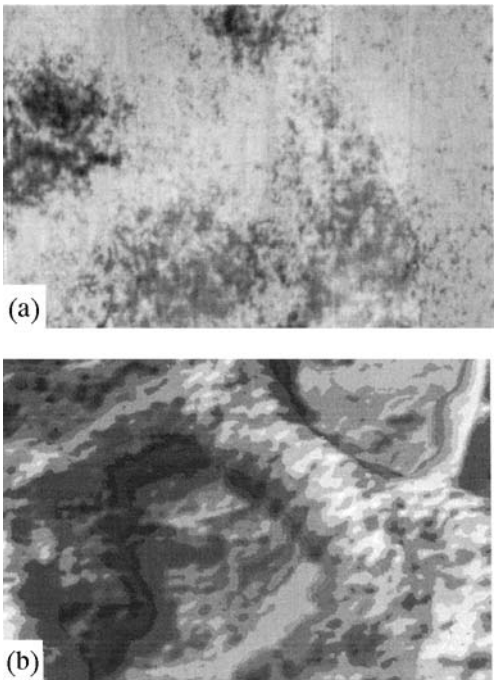

Fig. 2. Images of the biosorbent BS-2.1 surface (a) immediately after preparation of the composite and (b) after 7 days. $\times 5 \times 10^4$ magnification, AFM data.

The reaction mixture was left for 24 h under intermittent stirring at constant temperature (20°C) until the adsorption equilibrium was established. Next, the mixture was filtered, and the content of the cations in the filtrate was determined spectrophotometrically (SPEKOL 11, Carl Zeiss, Jena). The number of the sorbent-bonded ions was calculated by the formula

$$q = (c_0 - c)V/M,$$

where c_0 and c are, respectively, the initial and equilibrium concentrations of metal in the aqueous phase, mg l^{-1}; V, volume of the solution in the test flask, ml; and M, weight of immobilized starch or its derivatives, g.

Table 2. Absorption of metals with the biosorbents containing immobilized starch (c_0 = 50 mg l^{-1})

Biosorbent	q, mg g^{-1}		
	Cu^{2+}	Fe^{3+}	Al^{3+}
BS-1.1	14.05	10.20	7.80
BS-2.1	2.05	1.70	1.75
BS-3.1	25.20	18.25	14.00
S-4*	4.15	3.00	2.30
BS-5	20.00	14.80	11.65

* Calculations took into account the sorbent weight; the same for Table 3.

Table 3. Absorption q of the copper ions with biosorbents containing immobilized starch

Biosorbent	q, mg g^{-1}, at indicated c_0, mg l^{-1}		
	100	200	300
BS-1.1	20.02	24.10	28.90
BS-2.1	5.09	7.75	11.02
BS-3.1	43.63	49.05	52.00
S-4	8.00	10.60	13.25
BS-5	34.15	42.61	45.70

Taking into account the AFM data, the biosorbents were used no earlier than 7 days after synthesis.

For our experiments we chose composite materials, biosorbents with immobilized native starch (Table 2);

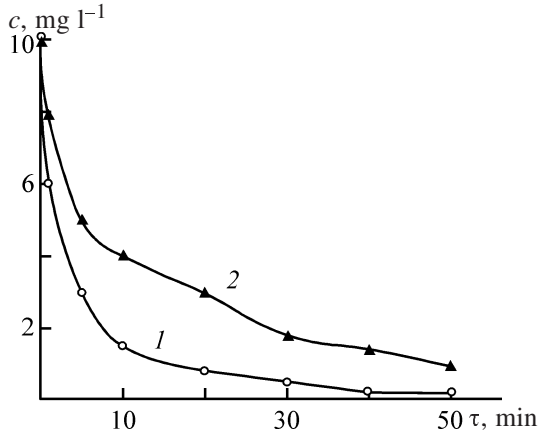

Fig. 3. Sorption of Fe^{3+} (c_0 = 10 mg l^{-1}) with biosorbents vs. time τ, min. (*c*) Concentration of the Fe ions. (*1*) BS-3.1 (starch immobilized in silica matrix) and (*2*) BS-5 (starch cross-linked with epichlorohydrin).

the initial concentration of the metal in water was 50 mg l^{-1}. The highest sorption capacity was exhibited by biosorbents BS-3.1 and BS-5; the weakest bonding of the metal ions was observed for biosorbent BS-2.1, which is a glassy nonporous material with the specific surface area of 3.2 ± 0.5 m^2 g^{-1}.

It should be noted that biosorbents BS-1.1 and BS-3.1 had a much larger specific surface area (210 and 290 m^2 g^{-1}, respectively) than the BS-5 material cross-linked with epichlorohydrin (S_{sp} = 45.0 m^2 g^{-1}). However, the difference in the degree of sorption cannot be attributed exclusively to that in the specific surface area of the sorbents. For example, the specific surface area of BS-3.1 sorbent with immobilized starch exceeds that of S-4 sorbent, silica free from starch (S_{sp} = 260 m^2 g^{-1}), by only 10%, but the sorption capacity of the biosorbent is appreciably larger. Therefore, the presence of immobilized polysaccharide in the structure of the material is essential in this case. The leading role of the polysaccharide is also suggested by the fact (Table 2) that the amount of bound Cu^{2+} is appreciably larger than those of Al^{3+} and Fe^{3+} because of a special affinity of carbohydrates for bivalent metals [20]. In experiments with high initial concentrations, the examined materials exhibited smaller differences in the sorption capacities (Table 3).

Figure 3 presents the kinetics of Fe^{3+} sorption by the biosorbents essentially differing in the method of synthesis, namely, for BS-3.1 (starch immobilized in a silica matrix) and BS-5 (starch cross-linked with epichlorohydrin). All the metals examined (similar curves were obtained for Cu^{2+} and Al^{3+}) were sorbed on BS-3.1 at a higher rate, with both biosorbents having close maximal sorption capacities. This can be explained by easier "accessibility" of the sorption centers of the materials formed from specific interaction of the silica matrix and starch, compared to the biosorbent with a high degree of cross-linking (BS-5), minimizing the metal sorption.

High rates of Cu^{2+}, Fe^{3+}, and Al^{3+} sorption on the biosorbents synthesized make these materials suitable for continuous removal from water of polyvalent metal ions at their low concentrations (≤ 50 mg l^{-1}).

The degree of sorption of the metal ions on the biosorbents containing starch derivatives is higher than that of the biosorbents containing native starch; it varies both with the nature of the modifier and with the valence of the metal sorbed (Fig. 4). The best sorption characteristics were exhibited by biosorbents BS-3.1–3.3, but the general trend is exhibited by all

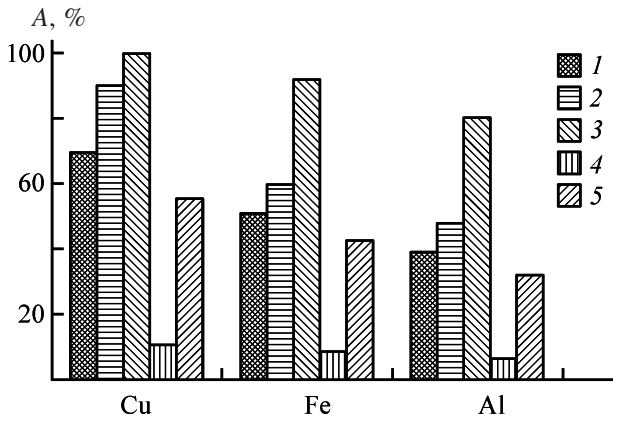

Fig. 4. Degree of sorption A of the cations from the aqueous solutions with various biosorbents. c_0 = 20 mg l^{-1}, M = 0.1 g, Z = 1. (*1*) BS-3.1, (*2*) BS-3.2, (*3*) BS-3.3, (*4*) S-4, and (*5*) BS-5.

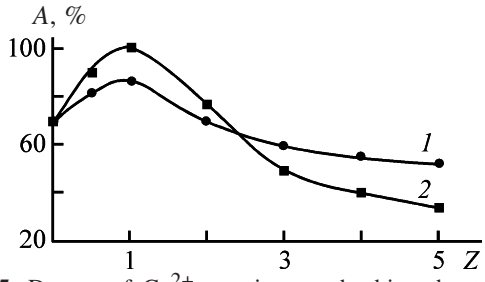

Fig. 5. Degree of Cu^{2+} sorption on the biosorbents containing starch derivatives. (*A*) Degree of sorption and (*Z*) urea/starch ratio. (*1*) Urea/starch and (*2*) thiourea/starch.

the materials synthesized. Even glassy materials with the minimal specific surface area (BS-2.1–2.3) differ in the sorption capacity [e.g., $q_{2.1}$ = 2.05, $q_{2.2}$ = 3.30, $q_{2.3}$ = 3.50 (mg Cu) g^{-1}]. This suggests above all that, under mild conditions of sol–gel synthesis of the composite material, the macromolecule preserves its "individual features," since the resulting biosorbents had virtually identical morphologies.

The difference in the sorption capacities of the starch products can be associated with the ability of the polysaccharides modified with ureas for chelation with metal ions. Reactions of starch with ureas during the solid-state synthesis yield a series of derivatives:

$$C_6H_9O_4(OH) + R^1{-}H \rightarrow C_6H_9O_4{-}R^1 + H_2O, \quad (1)$$

$$2C_6H_9O_4(OH) + H{-}R^2{-}H \rightarrow C_6H_9O_4{-}R^2{-}O_4H_9C_6 + 2H_2O, \quad (2)$$

where R^1 = $H_2N{-}\underset{\underset{O}{\|}}{C}{-}NH{-}$, $H_2N{-}\underset{\underset{S}{\|}}{C}{-}NH{-}$,

R^2 = $-HN{-}\underset{\underset{O}{\|}}{C}{-}NH{-}$, $-HN{-}\underset{\underset{S}{\|}}{C}{-}NH{-}$.

In metal–starch–urea chelates, the ligand is bonded to two metal atoms via the oxygen atom and (more weakly) via the nitrogen atom, and in the thiourea derivatives three metal atoms are bonded to the ligand via the sulfur atom and two nitrogen atoms [21]. Clearly, sorption on a material comprising a tridentate ligand will be larger than that on a biosorbent with a bidentate ligand (Fig. 4).

It should be noted that the degree of sorption on the biosorbents with immobilized starch derivatives varies with the urea : starch ratio (Fig. 5): Initially it tends to grow, attains a maximum, and then very sharply decreases. Starch is a polyoxy compound, and hydrogen bonding strongly affects the accessible surface area of the polysaccharide. Evidently, in the course of the solid-phase dextrinization reaction [11], the accessible starch surface area increases, and the degree of sorption increases due to a high probability of chelation. At the same time, at increased concentrations, ureas begin to act as cross-linking agents [12]. This is responsible for self-polymerization and a decrease in the accessible surface area of the starch product, which sharply decreases the degree of sorption of the metal ions from solutions on the biosorbent.

Thus, high-performance sol–gel-derived biosorbents of polyvalent metals should have the maximal porosity and contain immobilized starch derivatives. Such biosorbents have a good mechanical strength, and the nontoxic composition of the material makes it suitable for tap and potable water treatment.

CONCLUSIONS

(1) A series of biosorbents were synthesized from starch and its derivatives, immobilized in the silica matrix by the sol–gel method with various compositions of the precursors.

(2) The sorption capacity of the biosorbents synthesized varies with the conditions of synthesis; replacement of starch by its derivatives does not influence the morphology of the materials synthesized.

(3) The performance of the biosorbents synthesized in removal of polyvalent metal ions (Al^{3+}, Fe^{3+}, Cu^{2+}) from water varies with the composition of the polysaccharide as starch–thiourea > starch–urea > starch.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Pollution of Environment with Products of Interaction of Stainless Steels with Fuel Combustion Products

Abstract—Composition of condensates formed in flues equipped with stainless steel inserts was studied. Factors affecting corrosion of metallic sections of heating installations were determined.

DOI: 10.1134/S1070427207090170

Chromium and nickel are of particular importance among chemical pollutants of environment because of their high toxicity and carcinogenic action on the human health [1–3]. Corrosion occurring under the effect of atmospheric gases increases their concentration in the environment. Various metallic structures, roofs, house ironworks, and funnels undergo corrosion. The rate of corrosion depends on the season and on climatic and technogenic conditions. The concentration of heavy metals in the environment increases with the start of the heating season. This is due not only to an increase in the exhaust of heavy metals naturally present in the organic fuel and in the corrosion activity of the atmosphere owing to the increase in the concentration of such fuel combustion products as SO_2, NO_x, chlorine-containing compounds, and organic acids, but also due to additional emission of products formed by corrosion of metallic sections of heating installations such as flues, inserts, etc. This problem became topical after oil crises of 1973 and 1979 when production of high-efficiency boilers began. Because of lower temperature of combustion products outgoing from these boilers, a condensate is formed on the flue walls [4, 5]. Sometimes special systems to discharge accumulated condensate into the drainage system are developed. The condensate composition depends on the temperature and properties of the fuel combustion products, humidity, and some other factors. In combustion of natural gas, the condensate pH is 3–4 and for liquid fuel it varies from 1.8 to 3.7, which is due to sulfur contained in the fuel. In the course of combustion, sulfur yields SO_2 which is oxidized to SO_3 and then forms sulfuric acid with water vapor. The condensate destroys brick chimneys and primarily brick joints. To prevent the flue destruction, they are often equipped with inserts of stainless steel with a high content of chromium and nickel. Steel structures are used not only for modernization of the operating brick funnels but also as exhausters for fireplaces, furnaces, and boilers. However, stainless steels also undergo corrosion [6]. Therefore, condensate penetrating into the environment can also contain products of the stainless steel corrosion, including chromium and nickel compounds.

In this study we determined the composition and properties of condensates sampled from flues equipped with stainless steel inserts and evaluated the factors affecting the rate of corrosion of the metallic sections of heating installations.

EXPERIMENTAL

The condensates for studies were sampled from flues equipped with stainless steel inserts, and their pH, density, and contents of chloride ions, iron, nickel, and chromium were determined. To determine the total content of metals, the condensate was mineralized with a mixture of sulfuric and nitric acids [7]. The concentrations of chromium and nickel in the resulting solutions were determined by atomic absorption spectroscopy on an Analyst 100 device, and the iron concentration, by spectrophotometry with potassium thiocyanate [8]. The concentration of chloride ions was determined by titration of the condensates with a mercury nitrate solution. As seen from the results listed in Table 1, at similar pH the content of steel components in the condensates is different. The concentrations of chromium and nickel in the condensates vary from 0.4 to 46.8 and from 0.04 to

* Chemical composition of steels was determined on a Belec 2000 spectrum analyzer.

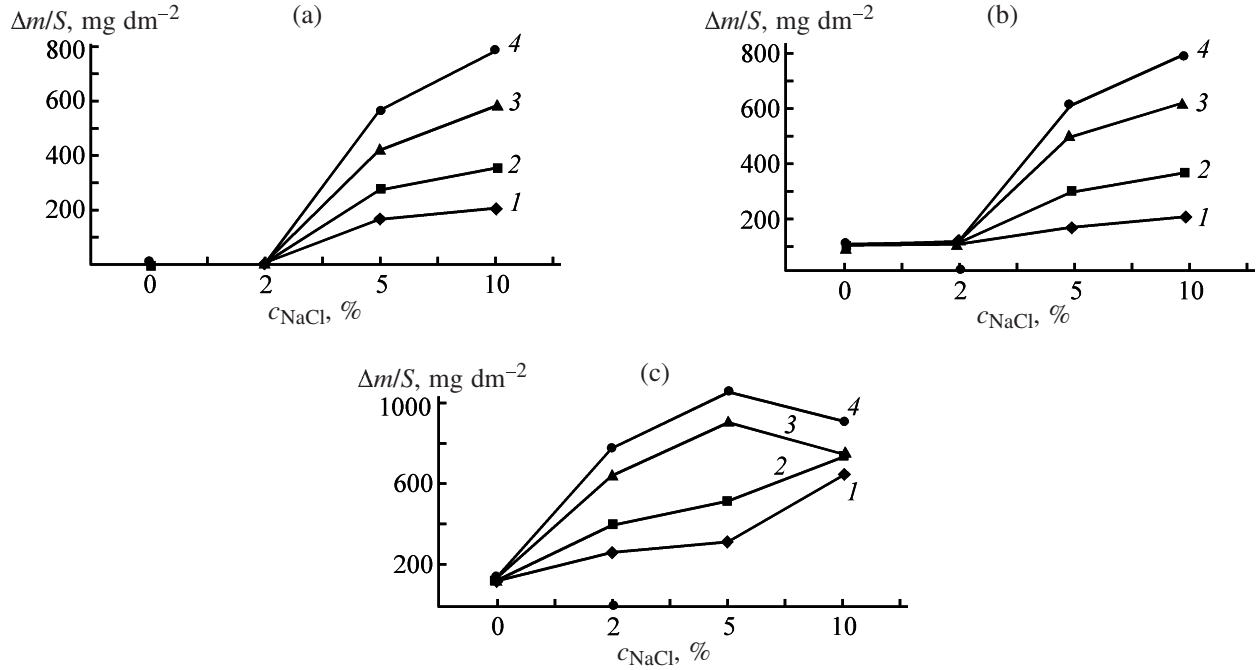

Fig. 1. Weight loss $\Delta m/S$ of stainless steel nos. 1–3 as a function of the content of chloride ions c_{NaCl} in 10% sulfuric acid solutions at various exposure times. Steel samples (Table 2): (a) no. 1, (b) no. 2, and (c) no. 3; the same for Fig. 2. Exposure time, days: (*1*) 5, (*2*) 10, (*3*) 20, and (*4*) 30.

123 mg l^{-1}, respectively. This is probably due to different chemical compositions of the steels, fuel type, composition of the fuel combustion products, design features of the boilers, and modes of their operation. The presence in the combustion area of chloride ions acting as corrosion activators [9] is an important factor accelerating corrosion of metallic parts of the heating systems.

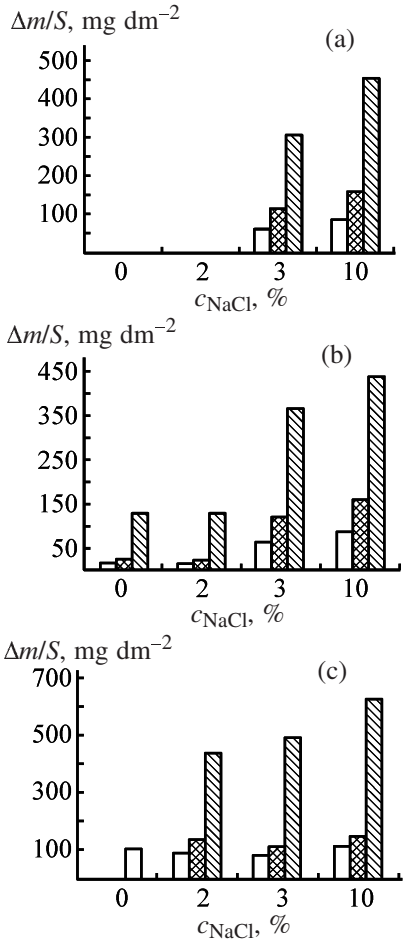

Fig. 2. Weight loss $\Delta m/S$ of components of stainless steel nos. 1–3 as a function of the content of chloride ions c_{NaCl} in 10% sulfuric acid solutions after exposure for 30 days. (a) Nickel, (b) chromium, and (c) iron.

It was of particular interest to compare corrosion resistance of stainless steels of various compositions in the acidic solutions similar to that of the condensate. The chemical composition of the steels is listed in Table 2. Sulfuric acid solutions (10%) with various contencentrations of sodium chloride were used as corrosive solutions. Steels with known composition (Table 2) were kept for a certain time in the above corrosive solutions, and the weight loss was evaluated. The results are shown in Fig. 1. As can be seen, the resistance of stainless steels in 10% sulfuric acid solutions is determined by their chemical composition. Steels containing titanium and molybdenum are the most resistant. After exposure for 30 days in corrosive solution, the weight loss for steel no. 1 (0.52% Ti and 2.05% Mo) was 1.97, and for steel no. 3 (0.01% Ti and 0.32% Mo), 135 mg dm^{-2}. Chloride ions present in solution decrease the corrosion resistance of stainless steel, and the protective effect of molybdenum and titanium is observed only when the concentration of sodium chloride in the sulfuric acid solution was no more than 2%. At higher concentrations of chloride ions, the weight loss of the stainless steels under consideration was similar.

After exposure for 30 days, the contents of iron, chromium, and nickel in the resulting acidic solutions were determined and the weight loss per surface unit was evaluated. The results are shown in Fig. 2. As can be seen, after exposure the solvents contained iron along with alloying components (chromium and nickel), and the weight loss of these elements was determined by both chemical composition of the steel and content of chloride ions in the solution.

CONCLUSIONS

(1) Condensates formed in flues equipped with stainless steel inserts contain the products of steel corrosion including chromium and nickel compounds hazardous for environment.

(2) Steels with elevated content of titanium and molybdenum are the most stable in the aggressive environment. Sound choice of steels for flue inserts being in contact with fuel combustion products not only makes longer the operation life of the installations but also decreases the environmental pollution.

(3) Chlorides present in the combustion atmosphere increase the content of chromium and nickel compounds in the corrosion products of stainless steel.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Specific Features of Operation of a Reaction–Rectification Column in Different Feed Modes

Abstract—Various feeding modes (discrete and distributed) into a reaction–rectification column for production of ethylene glycol are analyzed.

DOI: 10.1134/S1070427207090182

Interest in development of reaction–rectification apparatus [1] combining a chemical process with separation of the reaction products has markedly increased recently. Apparatus of this kind make it possible to simplify the process scheme, diminish the capital expenditure for construction of installations, and optimize the process as a whole [2–6]. Reaction–rectification columns can be used in such processes as esterification, hydrolysis, oxidation, alkylation, and isomerization, in which the chemical stage occurs in the boiling temperature range of components of the reaction mixture on several contact mass-exchange units of the column and, in particular, in synthesis of ethylene glycol.

The most widely employed method for production of ethylene glycol is direct hydration of ethylene oxide, accompanied by a number of side reactions of glycols with ethylene oxide to give diethylene glycol, triethylene glycol, and tetraethylene glycol. To suppress the side reactions, industrial synthesis of ethylene glycol is commonly performed in the liquid phase at elevated temperatures (~475 K) and pressures (1.5–2 MPa) in an excess of water [7].

Previously, a combined static-kinetic model of operation of the reaction–rectification column has been suggested [8]. This model includes calculation of the kinetics of the chemical process in the contact unit of a column with that of the statics of fractionation of the reaction mixture by the relaxation method.

A specific feature of the operation of the reaction–rectification column in synthesis of ethylene glycol is the possibility of recycling excess water within the column to suppress side reactions at virtually complete conversion of ethylene oxide and, accordingly, operation of the upper part of the column in the total reflux mode without distillate takeoff (Fig. 1a), which improves the fractionation efficiency [9]. In this case, the feed (water and ethylene glycol, taken in a 1 : 1 stoichiometric ratio) is introduced into one of the contact units (plates) in the middle of the column, mixed with the reflux composed of water with a minor content of impurities, and subjected to a chemical transformation to ethylene glycol with a minor admixture of higher glycols. Further, the reaction mixture is subjected to fractionation to give ethylene glycol with admixture of water and higher glycols in the bottom part of the column. Thus, the rectification process

Table. 1. Compositions of counterflow nonequilibrium vapor and fluid on adjacent plates of a reaction–rectification column. Pressure in the column 0.5 MPa; reflux : ethylene oxide ratio at the input of 3rd plate 50 : 1

Component	Between 1st and 2nd plates		Between 7th and 8th plates	
	fluid	vapor	fluid	vapor
Ethylene oxide	2.53×10^{-6}	2.53×10^{-6}	1.46×10^{-11}	1.49×10^{-11}
Water	0.99	0.99	0.13	0.13
Ethylene glycol	3.60×10^{-5}	3.60×10^{-5}	0.86	0.86
Diethylene glycol	1.26×10^{-8}	1.26×10^{-8}	4.45×10^{-3}	4.21×10^{-3}
Triethylene glycol	1.35×10^{-11}	1.35×10^{-11}	2.06×10^{-5}	1.72×10^{-5}
Tetraethylene glycol	1.38×10^{-15}	1.38×10^{-15}	6.69×10^{-8}	4.03×10^{-8}

in the column consists, in fact, in separation of the reaction products from the recycled reflux.

In some cases, the operation of a reaction–rectification column can be improved by choosing the optimal place of feed input into the column, with discrete input onto a single plate or that distributed over several plates.

A calculation of the operation of a reaction–rectification column with discrete feeding onto a single reaction plate in a wide range of pressures (0.1–1.5 MPa) and reflux to starting ethylene oxide ratios (10 : 1 to 110 : 1) demonstrated that the compositions of nonequilibrium counterflows of vapor and fluid are rather close for adjacent plates (Table 1). This corresponds to apparatus operation in the total reflux mode.

The pressure in the column has virtually no effect on the separation quality and ratio of glycols in the reaction mixture formed. However, an increase in pressure accelerates the chemical reactions in the column and provides their fast completion within one or two plates in the feed zone, i.e., it can be assumed that the chemical process is complete on a single theoretical plate.

The purity of ethylene glycol discharged from the bottom part of the column is strongly affected by the ratio between the reflux and the starting ethylene oxide (Table 2). For example, at this ratio equal to 10 : 1, the content of ethylene glycol in the residue is 85.1 mol %, and at this ratio raised to 90 : 1, the content of ethylene glycol increases to 97.9 mol %. Of particular importance in this context becomes the high quality of mixing of raw materials delivered into the column with the reflux on the column plate. Because the chemical transformation is rather fast (0.5–1 min), the actual ratio between the reflux and the starting ethylene oxide becomes, in the case of a poor-quality mixing of the feed with the reflux, substantially lower than the calculated value, which leads to a higher intensity of side processes and a lower yield of the target product, ethylene glycol.

A possible way to provide high-quality mixing of the feed with the reflux is to replace the commonly used point input of raw materials into the column with its collector input into the liquid phase in the input part of a plate or even with supply of the feed directly into intensive-agitation zones near plate caps (Fig. 2). To preclude occurrence of side reactions directly in the collector for introduction of a feed with a water : ethylene oxide ratio of 1 : 1, it is necessary to

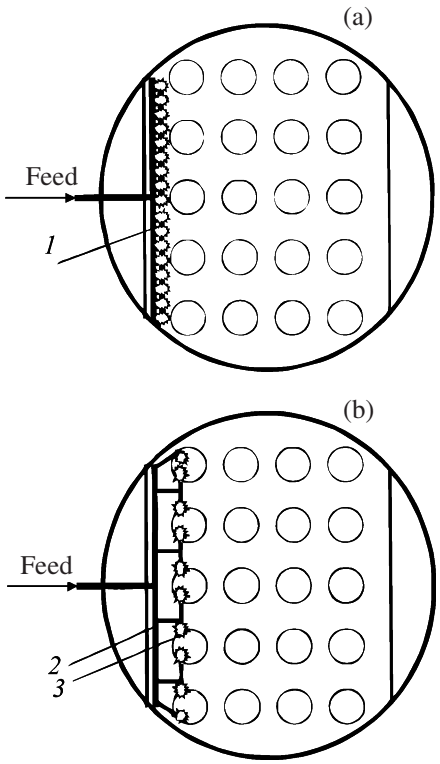

Fig. 2. Methods of feeding directly into a reaction plate. Feed: (a) distributed and (b) local to plate caps. (*1*) Perforated pressure collector, (*2*) pressure collector, and (*3*) nozzle.

deliver a feed into the collector at a temperature lower than 50°C (323 K), at which the hydration of ethylene oxide virtually does not occur at all. The feed leaving the collector will be heated to the required temperature in the course of its mixing with the reflux and the hydration will occur at the required ratio between the reflux and the starting ethylene oxide.

Analysis shows that the purity of ethylene glycol obtained is virtually independent of the number of theoretical plates, beginning with five or six plates. This is so because an increase in the number of plates between the feed and residue discharge zones results in the formation on a number of theoretical plates of a kind of constant-concentration zone, in which the temperature and compositions of vapor and fluid flows remain virtually unchanged. As the number of theoretical plates is raised from 6 to 12, the content of ethylene glycol in the residue varies within a narrow range, 98.1–98.2 mol % (Table 3).

The positive effect of an increase in the ratio between the reflux and the starting ethylene oxide on the course of the process of ethylene glycol synthesis in a reaction–rectification column becomes largely negative because of the pronounced rise in the energy expenditure for heating of the bottom part of the column and heat removal from the condenser.

A possible way to diminish the energy expenditure for the process under consideration is to replace discrete feed into a single reaction plate with a distributed input into several plates in that zone of the column in which the quality of the reflux and vapor flows remains virtually unchanged (Table 3). Cardoso et al. believe [9] that this can provide a considerably lower expenditure at the same ratio between the reflux and starting ethylene oxide in the column. For example, discrete feed of 100 mol of ethylene oxide requires a reflux in an amount of 10 000 mol for providing a 100 : 1 ratio between the reflux and starting

Table 3. ethylene oxide. At the same time, at distributed feeding of 100 mol into two plates, 50 mol for each plate, the expenditure of the reflux in the plates will decrease to 5000 mol at the same (100 : 1) ratio between the reflux and starting ethylene oxide, i.e., the energy expenditure will decrease by a factor of 2. However, the concepts reported in [9] were not substantiated by calculations or experimental data. Therefore, we considered a problem in which the results of operation of a reaction–rectification column with discrete and distributed feeding of the column are compared (Fig. 1b). Table 4 lists the results of calculation of the column for two alternative solutions of the problem.

In the first alternative, we compared the results of calculation of a column with eight theoretical plates and feeding in the following modes: (i) discrete input into third plate at a 30 : 1 ratio between the reflux and the starting ethylene oxide; (ii) uniform distribution of the feed over three plates (third–fifth), which actually provides a ratio of 90 : 1; and (iii) discrete input into third plate at a 90 : 1 ratio between the reflux and the starting ethylene oxide, as a control. Thus, a potential threefold energy saving would be expected in the first alternative of calculation. In the second alternative, we calculated a column with eight theoretical plates and feeding in the following modes: (i) discrete

input into third plate at a 10 : 1 ratio between the reflux and the starting ethylene oxide; (ii) uniform distribution of the feed over five plates (third–seventh), which actually provides a ratio of 50 : 1; and (iii) discrete input into third plate at a 50 : 1 ratio between the reflux and the starting ethylene oxide, as a control. This had to provide a possibility of a fivefold energy saving in the second alternative of calculation.

The results of these calculations demonstrated (Table 4) that distributed feeding fails to provide the expected energy saving, because the purity of the residue in ethylene glycol is somewhat decreased, compared with the distributed input, at the same actual ratio between the reflux and the starting ethylene oxide. For example, the content of ethylene glycol in the residue is 98.20 mol % at an actual 90 : 1 ratio between the reflux and the starting ethylene oxide and 95.07 mol % in the case of a uniform feed distribution among third, fourth, and fifth plates, which only slightly exceeds the performance parameters at a discrete feed and a 30 : 1 ratio between the reflux and the starting ethylene oxide. In the case of a uniform feed distribution among third to seventh plates at a 50 : 1 ratio between the reflux and the starting ethylene oxide, the composition of the residue (86.1 mol %) was worse than not only that in the case of a discrete input and a 50 : 1 ratio (96.83 mol %), but also that with discrete input and a 10 : 1 ratio between the

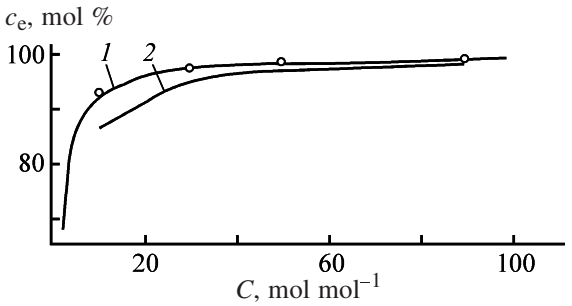

Fig. 3. Content of ethylene glycol in the residue, c_e, vs. the reflux : ethylene oxide ratio C at a pressure of 1.0 MPa. Content of ethylene oxide in the residue: (*1*) potential, according to the compositions of the reaction mixture on the discrete-feeding plate (C is water : ethylene oxide ratio); (*2*) calculated, upon fractionation of the reaction mixture on eight theoretical plates; points: potential, as a result of distinct fractionation of the reaction mixture for curve *2*.

reflux and the starting ethylene oxide. This occurs because, in the case of a distributed feed, ethylene oxide arriving at a next, except the first, plate of the feed zone (this is third plate according to the calculation) comes in contact with the reaction medium in this plate. This medium already contains a considerable amount of ethylene glycol, which enters into a reaction with ethylene oxide to give a diethylene glycol as by-product. This makes lower the yield of ethylene glycol in fourth, fifth, etc., plates. As follows from Table 4, the content of diethylene glycol in the residue is 2–4 times higher with distributed feeding as compared to the discrete input, all other conditions being the same. The potentially possible concentrations of ethylene glycol in the residue (i.e., in the case of a complete evaporation of water from the residue) coincide in evaluation of the residue composition by calculation of the process in the reaction–rectification column and by calculation from the composition of the reaction mixture in the reaction plate (Fig. 3).

Thus, the quality of the residue in fractionation of the reaction mixture primarily depends on the completeness and quality of the chemical process in the reaction zone of the apparatus.

CONCLUSIONS

(1) A study of various operation modes of a reaction–rectification column in a wide range of pressures and ratios between the reflux and starting ethylene oxide demonstrated that, if the column works in the total reflux mode, the quality of the resulting residue is virtually independent of the number of theoretical plates between the feeding and residue discharge zones, with a region of constant process concentrations formed in the middle part of the column.

(2) Alternatives of the point-like (discrete) and distributed feeding of the reaction–rectification column for synthesis of ethylene glycol were analyzed. The distributed feeding cannot provide energy saving because the residue quality in the fractionation of the reaction mixture primarily depends on the completeness and quality of the chemical process in the reaction zone of an apparatus, and the concentration of ethylene glycol in the residue is lower in distributed feeding, compared with the discrete input mode.

Abstract—Liquid-phase oxidation of H_2S in centrifugal-bubbling apparatus in the presence of catalysts [manganese(II) chloride, cobalt phthalocyanine disulfonic acid, and a catalytic system including cobalt phthalocyanine disulfonic acid and $MnCl_2$] was studied.

DOI: 10.1134/S1070427207090194

Sulfides, and hydrogen sulfide in particular, widely occur in nature, being present in water of many natural mineral springs and in volcanic gases, and are obtained in production of oil and natural gas and in mining of coal and ores of heavy and nonferrous metals. Sulfides (in particular, H_2S) are formed in anaerobic decomposition of natural sulfur-containing organic substances, fungicides, pesticides, and fertilizers and are discharged in large amounts into the natural environment with wastewater from plants of pulp-and-paper, oil-refining, chemical, and tanning industries.

The content of sulfides in wastewater formed in chrome tanning at tanneries may be as high as 1000 mg l^{-1}. One of methods for their detoxication is oxidation to nontoxic sulfur-containing compounds with atmospheric oxygen in aqueous–alkaline solutions, which is commonly performed in bubble columns. In this case, the oxidation of sulfides is rather slow even in the presence of highly active catalysts because of the low rate of oxygen dissolution in a solution. Mn(II) compounds are most frequently used as catalysts. For example, wastewater from tanneries, with an initial concentration of sulfides in the range 700–1400 mg l^{-1}, are oxidized to a residual content of 0.5–1.5 mg l^{-1} in bubble columns in the course of 6–12 h. In this case, the specific air expenditure is 30–35 $m^3\ m^{-3}$ [1]. The considerable expenditure of the catalyst (Mn^{2+}/HS^- mass ratio may be as high as 0.4–0.5) is due both to the high concentration of sulfides and to the presence in wastewater of a large amount of suspended and colloidal substances. These substances adsorb on their surface insoluble manganese compounds formed in oxidation of sulfides and thereby make lower the activity of the catalyst.

The oxidation of sulfides can be intensified and the expenditure of the catalyst can be lowered by changing the processing technology of spent solutions and wastewater.

Because more than a half of all the contaminants and more than 90% of sulfides (COD 15–35 g l^{-1}, HS^- 4–6 g l^{-1}, pH 8–12) is discharged into the wastewater disposal system from the liming process, it is advisable to collect and purify separately spent solutions and the most concentrated wastewater. The suspended and colloidal substances are removed by coagulation precipitation from a liming wastewater acidified to pH 4–4.5, and hydrogen sulfide formed in acidification is removed by bubbling of air through the solution. Then, H_2S-containing air is purified to remove H_2S in a centrifugal-bubbling apparatus (CBA) with a circulating aqueous–alkaline solution containing a dissolved catalyst, with simultaneous catalytic oxidation of the caught hydrogen sulfide to nontoxic products, sulfates and thiosulfates.

As catalysts were suggested Mn(II) salts [1], frequently used at tanneries, and also cobalt phthalocyanine disulfonic acid (CPDA) and a catalytic system constituted by a mixture of a Mn(II) salt and CPDA [2].

In an absorbing aqueous solution containing sodium carbonate, the CPDA catalyst is converted to a disodium cobalt phthalocyanine disulfonate, $\{CoPc(SO_3Na)_2\}$, a macrocyclic complex having the form of a planar symmetric 18-π-electron aromatic macroring with a cobalt atom situated in the central cavity and retained there by chemical bonds formed by unoccupied orbitals of the cobalt atom and lone-pair electrons of central nitrogen atoms [3]. In complexes of this kind, the metal plays the role of a redox center.

Previously, an attempt has been made to use CBA for oxidation with atmospheric oxygen of aqueous–alkaline solutions of sodium sulfide in the presence of a catalyst, tetrasodium cobalt phthalocyanine tetrasulfonate, $CoPc(SO_3Na)_4$ [4]. With CBA, a sharp increase in the oxidation rate of hydrosulfide ions by oxygen was observed, compared with oxidation of the same aqueous–alkaline solution in a rocking static "duck" reactor and in a bubbling reactor. According to [4], HS^- ions are oxidized by oxygen in both the "duck" and bubbling reactors under diffusion control. The product formed in CBA in oxidation of aqueous–alkaline solutions of hydrogen sulfide in the presence of $CoPc(SO_3Na)_4$ is sulfur. It should be noted that oxidation of sulfides in CBA to pure sulfur has a significant disadvantage: in prolonged operation, finely dispersed sulfur that accumulated in the absorbing solution settles on the walls of the swirling chamber of the reactor, altering the operation parameters of the apparatus and thus making its work impossible. Therefore, hydrogen sulfide removed from a spent liming solution was oxidized in CBA so as to prevent formation of elemental sulfur and obtain soluble salts, thiosulfates and sulfates, as a result of oxidation.

In weakly alkaline and alkaline aqueous solutions, oxidation of soluble sulfides by atmospheric oxygen may occur to give S^0, $S_2O_3^{2-}$, SO_3^{2-}, and SO_4^{2-}. The extent and rate of oxidation depend on the pH value, concentration ratio of HS^- ions and dissolved oxygen, temperature, and ionic strength of the solutions.

The oxidation of HS^- ions is strongly affected by the choice of a catalyst. The liquid-phase oxidation of H_2S by atmospheric oxygen in the presence of soluble salts of Mn(II) occurs at a high rate to give mainly $S_2O_3^{2-}$ and SO_4^{2-} ions. It should be noted that, at *Eh* of 0.3–0.4 V and pH 8–12, Mn(II) is rather easily oxidized to MnO_2 [5], whose activity in oxidation of sulfur compounds is substantially lower. In addition, it is to be taken into account that soluble salts of manganese are unstable in the presence of hydrosulfide ions and can coagulate to give manganese sulfides.

It has been found in an analysis of oxidation of HS^- ions with dissolved oxygen in the presence of cobalt phthalocyanine sulfonates $\{CoPc(SO_3Na)_n\}$ that there exist various redox forms of $CoPc(SO_3Na)_n$, containing cobalt in oxidation states I–III [6].

In a strongly alkaline medium (pH ≥ 11), hydrosulfide ions are oxidized with oxygen by the mechanism [7, 8] involving formation of a paramagnetic superoxocomplex $[Co(III)Pc(SO_3Na)_n \cdot O_2^-]$ and its subsequent interaction with the substrate:

$$[Co(III)Pc(SO_3Na)_n \cdot O_2^-] + HS^- \rightarrow [HS^- \cdot Co(III)Pc(SO_3Na)_n \cdot O_2^-]. \quad (1)$$

Further, this complex decomposes:

$$[HS^- \cdot Co(III)Pc(SO_3Na)_n \cdot O_2^-] \rightarrow Co(II)Pc(SO_3Na)_n + HSO_2^-, \quad (2)$$

and then HSO_2^- undergoes noncatalytic transformations to give thiosulfate, sulfite, and sulfate ions.

At pH 7.3–8.0, sulfides contained in a solution as hydrosulfide ions are oxidized with oxygen in the presence of $CoPc(SO_3Na)_n$ at a high rate mostly by the polysulfide mechanism [6]. The main oxidation product is elemental sulfur. HS^- ions are oxidized at the expense of redox transitions $Co(II)Pc(SO_3Na)_n \rightleftarrows Co(I)Pc(SO_3Na)_n$.

A transition from one oxidation mechanism of sulfides to another can occur upon a comparatively slight change in the reaction conditions (pH value; concentration ratio of hydrosulfides and dissolved O_2; catalyst concentration; presence in a solution of hydrosulfide oxidation products that favor or hinder accumulation of polysulfides in the reaction mixture [6, 9]). Changing the reaction conditions and choosing cobalt phthalocyanine disulfonate as the most appropriate catalyst make it possible to achieve the required hydrosulfide oxidation intensity and composition of the products obtained.

EXPERIMENTAL

Figure 1 schematically shows a laboratory rig for studying the kinetics of liquid-phase catalytic oxidation of easily volatile compounds, with hydrogen sulfide as example. A Na_2S solution or a spent liming solution is delivered by a pump from tank *1* to bubbling column *2*, to be acidified there by an H_2SO_4

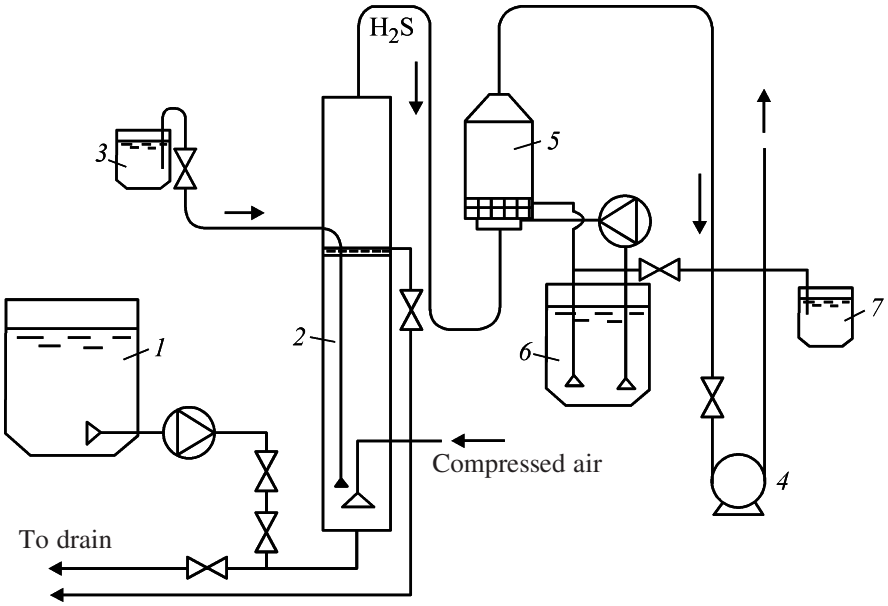

Fig. 1. Laboratory rig for liquid-phase oxidation of volatile compounds in CBA: (*1*) tank with an absorbing solution, (*2*) bubbling column, (*3*) vessel with H_2SO_4, (*4*) ventilator, (*5*) CBA, (*6*) vessel with an absorbing solution, and (*7*) vessel with a catalyst solution.

solution from vessel *3*. The forming hydrogen sulfide is removed from the column and is supplied, together with air, by sucking-in ventilator *4* into CBA *5* and is absorbed there by the circulating aqueous–alkaline solution *6* and rapidly oxidized upon delivery of the catalyst from vessel *7*.

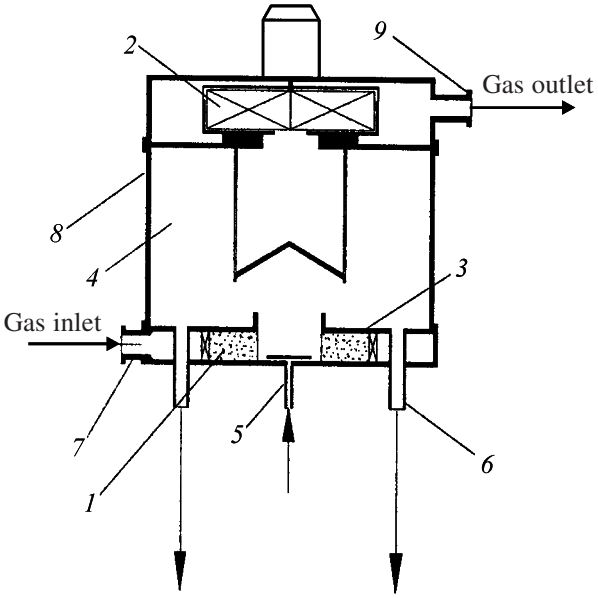

Fig. 2. Schematic of a centrifugal-bubbling apparatus: (*1*) rotating gas–liquid layer, (*2*) ventilator, (*3*) swirler, (*4*) separation zone, (*5, 6*) pipes for liquid delivery and discharge, (*7*) gas supply pipe, (*8*) cylindrical case, and (*9*) gas discharge pipe.

The operation principle of CBA (Fig. 2) is based on passing a gas through a rotating liquid layer *1*, which is retained within the swirling chamber by the gas flow. After ventilator *2* is switched on, gas passes through swirler slits, acquires a rotary motion, and involves the liquid in this motion. As a result, a gas–liquid layer with a developed and instantaneously renewed phase contact layer is formed within the apparatus. The gas and liquid are delivered from the swirling chamber into separator *4* and then discharged from the reactor. The air expenditure in the CBA is 100 $Sm^3\ h^{-1}$ (Sm^3 is m^3 under normal conditions). The circulation rate of the absorbing solution in the CBA is 50 $dm^3\ h^{-1}$.

In the stage of desorption, in contact of an acidified spent liming solution with air, hydrogen sulfide is virtually not oxidized at all. This occurs because the rate of noncatalytic oxidation of dissolved hydrogen sulfide is very low. The caught hydrogen sulfide is oxidized at a very high rate in CBA, because the absorbing solution contains catalysts that can diminish the time of oxidation of the forming hydrosulfide ions at room temperature and atmospheric pressure from several hours or even days to several seconds.

Hydrogen sulfide mixed with air was delivered into the CBA at rates of 2.8×10^{-2}, 5.3×10^{-2}, and 1×10^{-1} mol min^{-1} counting on H_2S. The presence of hydrosulfide ions in the solution discharged from the CBA and of hydrogen sulfide in the purified air at

** Operation time of the installation until appearance (breakthrough) of HS^- in the absorbing solution.

the CBA outlet was checked using lead indicator paper. The concentrations of hydrosulfide, thiosulfate, and sulfite ions were found by iodometric titration [10]. The concentration of sulfate ions in this absorbing solution was determined by complexometry [10] and gravimetry [11]. UV/Vis spectra of absorbing solutions containing CPDA and the catalytic system CPDA + $MnCl_2$ were recorded with an Agilent 8453 spectrophotometer.

An aqueous solution containing sodium carbonate, into which catalysts were introduced, served as an absorbing solution. In the case of a CPDA catalyst and a catalytic system containing CPDA and $MnCl_2$, a 0.001 M aqueous solution of Na_2CO_3 (pH 8.2–8.3) was used. With $MnCl_2$ serving as a catalyst, a 0.1 M Na_2CO_3 solution was used (pH 11.5).

The results of the experiments performed demonstrated (see table) that acidification of sulfide-containing wastewater to pH 4–4.5 and subsequent evaporation of H_2S in CBA enables virtually complete removal of sulfides from spent liming solutions. Hydrogen sulfide is completely caught by the absorbing solution and oxidized (oxidation of HS^- ions) in this apparatus at a high rate and low catalyst expenditure.

The main products formed in catalytic oxidation of hydrosulfide ions by atmospheric oxygen were sodium sulfate and thiosulfate.

The experiments demonstrated that the time during which the $MnCl_2$ catalyst remains in the working state (until appearance of HS^- ions) strongly depends on the method of its introduction into the absorbing solution. In the case of fractional batching of $MnCl_2$ into the reaction zone of the CBA, the amount of oxidized H_2S is 28–56% higher than that in a single-portion introduction of the same amount of $MnCl_2$ into the absorbing solution before the beginning of H_2S delivery into the CBA. Apparently, if the whole amount of the catalyst is introduced in a single portion, excess Mn^{2+} favors fast formation of a precipitate of low-active MnO_2.

The UV/Vis spectra of CPDA and Mn(II) solutions (Fig. 3) show that no chemical interaction occurs between these substances.

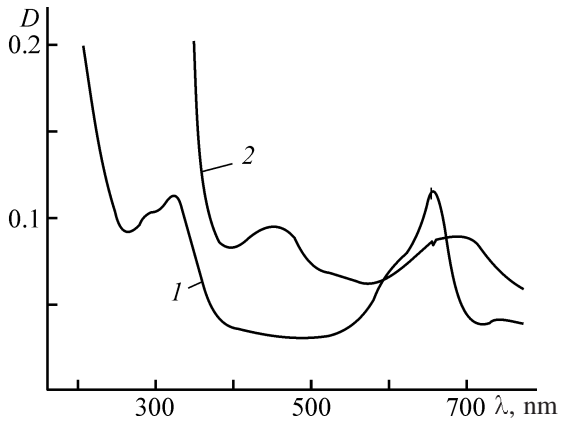

Fig. 3. UV/Vis spectra of CPDA. (*D*) Optical density and (λ) wavelength. Solution: (*1*) absorbing with CPDA + $MnCl_2$, 1.28×10^{-6} M each, after run no. 8 (see table); (*2*) Na_2S (0.45 M) with CPDA (0.86×10^{-6} M) after 60 min of oxidation in a bubbling column.

The spectrum of a CPDA solution obtained upon oxidation of H_2S in a CBA in run no. 8 contains two strong absorption bands at 655 and 320 nm, associated with π–π^* transitions from the ground state to the first excited singlet state. The additional bands appearing in the absorption spectrum of cobalt phthalocyanine disulfonate can be attributed to metal $\rightleftarrows$ ligand charge transfer or to appearance of weak π bonds between molecules of the complex to give dimers [12]. Oxidation of a sodium sulfide solution in the bubbling column in the presence of CPDA gives rise to a weak band at 450 nm in the absorption spectrum, associated with Co(I) $\rightleftarrows$ Co(II) transitions [6]. In oxidation of caught H_2S by atmospheric oxygen in a CBA under conditions of a developed phase contact area in a CPDA-containing absorbing solution both with and without $MnCl_2$, no absorption band at 450 nm is observed in the absorption spectrum of CPDA. In this case, the intensity of the absorption band at 320 nm, associated with Co(II) $\rightleftarrows$ Co(III) transitions, sharply increases.

CONCLUSIONS

(1) Liquid-phase oxidation of H_2S in centrifugal-bubbling apparatus in the presence of catalysts ($MnCl_2$, cobalt phthalocyanine disulfonic acid, and a catalytic system consisting of cobalt phthalocyanine disulfonic acid and $MnCl_2$) occurs at a high rate. The oxidation of hydrosulfide ions is not controlled by dissolution of oxygen in the contacting absorbing solution because of the large, and rapidly changing, area of the gas–liquid mass-exchange surface.

(2) Sulfates are the main oxidation products.

(3) It is recommended to use these catalysts in oxidation of hydrogen sulfide formed in acidified liming solutions from plants manufacturing half-finished leather articles by chrome tanning.

Abstract—Formation of a composite from Se^0 nanoparticles stabilized with polyvinylpyrrolidone and *Acetobacter xylinum* cellulose gel films was studied. The optimal sorption parameters at which the amorphous form of the selenium complex is preserved in the composite were suggested.

DOI: 10.1134/S1070427207090200

Studies of physicochemical properties of bacterial cellulose synthesized by surface cultivation of *Acetobacter xylinum*, strain VKM V-880, showed that an *Acetobacter xylinum* cellulose gel film (AXC GF) fairly readily takes up from aqueous solutions (0.01–0.3 wt %) nanoparticles of zero-valent silver or selenium, stabilized with polyvinylpyrrolidone (PVP-nano-Ag^0 and PVP-nano-Se^0, respectively) [1, 2].

A study of the kinetics of this process shows that silver clusters of size 2–10 nm and larger selenium clusters (20–60 nm) penetrated into AXC GFs [2]. It was also noted that, when AXC GFs dried at 50°C were kept in 3% aqueous solutions of the nanocomplexes, large silver clusters (100–200 nm) or selenium crystals (up to 200–300 nm) were formed on the film surfaces [2]. Structural studies of such specimens allowed the crystalline formations of selenium observed in the electron micrographs to be assigned to trigonal [3] or α-monoclinic [4] modification.

It is well known that, owing to features of the electronic structure, selenium exists in numerous allotropic forms: amorphous, α- and β-monoclinic, trigonal, hexagonal, and others [3, 4]. The most stable is the hexagonal form built of helical selenium chains arranged parallel. These chains form a unit cell with the parameters $a = b = 0.436$ nm, $c = 0.495$ nm, and $\gamma = 120°$ [5].

Of particular interest are sorption and desorption interactions of PVP-stabilized amorphous selenium with AXC GF. The AXC GF structure is a network formed by highly crystalline fibrillar ribbons of nanometric size, surrounded by a large amount of water molecules [6, 7].

Data on sorption on, and desorption from AXC GFs of nanocomplexes PVP-nano-Ag^0 or PVP-nano-Se^0 are important for medical applications of these composite materials as a wound coating bearing PVP-stabilized clusters of Ag^0 or Se^0 [8]. Particular attention should be given to determination of the optimal modes of sorption of PVP-nano-Se^0 nanocomplexes on AXC GF and on their desorption from the film, which is necessary for evaluating the safe concentration of amorphous selenium in the medinicals to be used [9].

The goal of this study is determination of conditions for PVP-nano-Se^0 sorption taking into account structural features of AXC GF. Specimens of the composite materials AXC GF–PVP-nano-Se^0 were prepared by sorption for varied time from PVP-nano-Se^0 solutions of varied concentration on AXC gel films dehydrated at 20–50°C. The specimens were examined by X-ray and electron diffraction and by electron and atomic-force microscopy. Particular attention was given to study of structural changes that occur in

AXC specimens subjected after sorption and drying to desorption with water for 24 h.

EXPERIMENTAL

Biosynthesis of AXC GFs with VKM V-880 was described previously [1, 6]. After removing 80–90% of water by squeezing, film specimens were placed in aqueous solutions with different concentrations of PVP-stabilized selenium nanoparticles.

Selenium nanoparticles were prepared by chemical reduction of selenious acid with ascorbic acid in aqueous PVP solutions under conditions ensuring formation of PVP-nano-Se^0 nanocomposites with the weight ratio PVP : Se = 10 : 1 [10]. The amount of the complex sorbed in the AXC GF matrix was varied by varying the solution concentration (0.01–3 wt %) and the exposure time.

The variation of the PVP-nano-Se^0 concentration in aqueous solution in the course of contact with AXC GF was monitored with a Specord M40 spectrophotometer. The optical density *D* of 0.01% solutions was recorded in the range 200–600 nm.

The time of keeping the gel films in 0.01–3% aqueous solutions was varied from 15 min to 48 h. Then the specimens were dried at room temperature or at 50°C and immersed in a definite volume of distilled water for 0.5–24 h. The desorption kinetics was evaluated by measuring *D* of the solutions. The process was considered to be complete when the optical density decreased to zero.

X-ray studies of dry specimens of the starting AXC GFs and of gel films dried after sorption or desorption of nanoclusters were performed with DRON-2 (Russia) and XRD-3003 TT (Germany) diffractometers in the transmission and reflection modes, using Ni-filtered CuK_α radiation (λ = 1.54 Å). Electron-microscopic studies were performed with a JEM-7A microscope (Japan) at an accelerating voltage of 80 kV. Ultrathin sections of dry starting AXC GFs and of AXC GF–PVP-nano-Se^0 composites dried at 50°C and then cast into Araldite, or of speciments dried at 20°C and cast into Epon resin, were obtained with an LKB-III microtome (Sweden). The magnification was from 1500 to 21 000.

The surface topography of the AXC GFs dried after sorption or desorption of PVP-nano-Se^0 complexes with different content of Se nanoparticles was examined by atomic-force microscopy (AFM) in the tapping mode with a Nanotop NT-206 device (Mikrotestmashiny Limited Liability Company, Belarus). The AFM images were obtained in the constant amplitude mode.

The kinetics of the reaction occurring in the course of preparation of aqueous solutions of PVP-nano-Se (or -Ag^0) nanocomplexes and the morphological characteristics of these complexes were studied by light scattering and spectrophotometry [2, 10, 11]. According to data of static and dynamic light scattering, synthesis of selenium nanoparticles in aqueous PVP solutions at the ratio PVP : Se^0 = 10 : 1 yields aggregation-stable clusters of amorphous selenium with a hydrodynamic radius of about 57 nm. In these estimations, it is assumed that the hydrophobic interaction of PVP with Se^0 is the main driving force of PVP adsorption on selenium nanoparticles and that it leads to the formation of PVP-nano-Se^0 nanocomplexes of approximately spherical shape [2, 10, 11].

The optical density *D* of a 3% solution of the nanocomplexes in the range 245–260 nm noticeably decreases on keeping the gel film for 1 h, after which it increases to the initial value and remains constant for 48 h. On the contrary, with a 0.1% solution of the complex *D* increases during a period of 1 h. Thus, the most pronounced changes in the optical density of the PVP-nano-Se^0 solution on contact with AXC GF occur within the first 2 h.

To examine the sorption of the selenium nanocomplex on AXC GF, we also studied the desorption of this complex with water from the specimens dried at room temperature. The spectra of the solutions obtained (Fig. 1, curves *1'–3'*) differ essentially from the

spectra recorded in the course of sorption (curves *1*–*4*): A well-defined band with a maximum at 300 nm appears, and with increasing time of keeping the film in water its intensity decreases to zero. Presumably, the morphological characteristics of nanocomplexes released in the course of desorption with distilled water from dry films differ from those of the nanocomplexes in the solutions used for the sorption. Such changes in the initial characteristics of the nanocomplexes in the course of their intercalation into the gel film can be attributed to the appearance of new competing interactions of the cellulose matrix with fragments of the complex, i.e., of PVP with the matrix or of Se^0 with the matrix. Such interactions can alter not only the morphological characteristics of the complex, but also the structural parameters of the cellulose film.

Figure 2 shows the diffraction patterns of dried (20°C) specimens of the starting AXC GF (curves *1*, *3*) and the film kept in 1% solution of PVP-nano-Se^0 for 15 min (curves *2*, *4*) or 20 h (curve *5*), at perpendicular (Fig. 2a) or parallel (Fig. 2b) incidence of the X-ray beam relative to the film plane. It can be seen that the intensity of the reflections at 2θ 15°, 17°, and 35° from the ($\bar{1}$10), (110), and (004) planes, respectively, of the monoclinic lattice of cellulose I_β with interplanar spacings *d* 0.610, 0.523, and 0.256 ± 0.005 nm increases by a factor of 1.5–2.0, whereas the (200) reflection characteristic of the parallel-layer packing of hydrogen-bonded cellulose chains in crystallites (*d* = 0.389–0.392 nm; 2θ = 23°) undergoes no appreciable changes. With an increase in the time of sorption from the 1% solution (0.25, 0.5, 1, 4, 8, and 20 h), the most significant changes in the relative intensities of the (–100), (110), and (004) reflections were observed in the initial period (0.25–1 h), with no appreciable changes observed on further keeping the specimens in the initial solution (2–48 h). After 20-h exposure in 1% solution, along with appreciable increase in the intensity of the (110) and (004) reflections, an increase in the diffuse background in the range 2θ = 13°–25° was observed, attributable to the higher content of the complex sorbed in pores of the gel film or on its surface.

Using electron microscopy and X-ray diffraction, we examined how the concentration of aqueous PVP-nano-Se^0 solutions in the range 0.01–0.1 wt % affects the intercalation of nanostructures into AXC GFs at a constant sorption time of 0.5 h (see table; Fig. 3). Upon sorption from a very dilute solution (0.01 wt %), noticeable redistribution of the crystalline cellulose reflections was observed in the diffraction patterns of the dry specimens, similar to the trend observed in

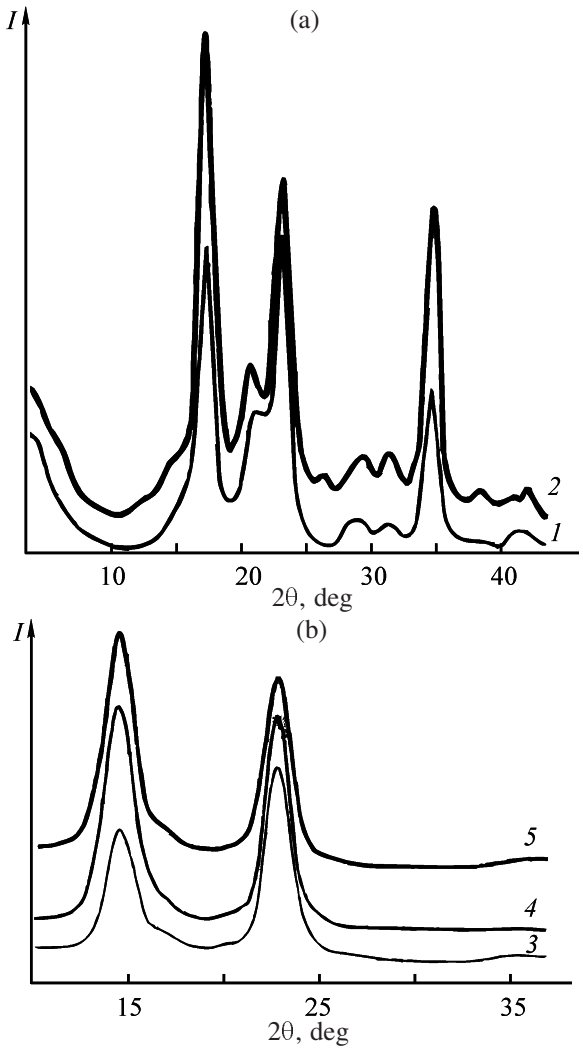

Fig. 2. Diffraction patterns obtained at (a) perpendicular and (b) parallel incidence of the X-ray beam relative to the plane of dried films: (*1*, *3*) starting AXC gel film, (*2*, *4*) AXC GF–PVP-nano-Se^0 composite after keeping in 1% aqueous PVP-nano-Se^0 solution for 15 min, and (*5*) the same, after keeping in this solution for 20 h. (*I*) Intensity and (2θ) Bragg angle; the same for Fig. 6.

going from curve *1* to curve *2* in Fig. 2: The intensities of the (110) and (004) reflections increased by a factor of 2, whereas the intensity of the (200) reflection did not change. The X-ray diffraction data for the specimens kept for 0.5 h in 0.01–1% solutions, dried at 20°C, and subjected to desorption with distilled water for 24 h are given in the table. It is seen that the desorption caused no significant changes in the relative intensities of the crystal reflections compared to the AXC GF–PVP-nano-Se^0 composites before desorption.

Figure 3 shows the electron micrographs of a transverse section of an AXC GF specimen modified in a

Relative changes in the intensity of reflections of the monoclinic lattice of dry AXC GF specimens after sorption (0.5 h) from PVP-nano-Se^0 solutions and subsequent desorption (24 h) with distilled water

Specimen no.	Concentration of aqueous PVP-nano-Se^0 solution, %	Reflection intensity					
		sorption			desorption		
		(110)	(200)	(004)	(110)	(200)	(004)
1	0	0.9	1	0.5	0.9	1	0.5
2	0.01	2.0	1	1.0	2.0	1	1.0
3	0.1	1.9	1	1.2	1.8	1	1.0
4	0.5	1.67	1	0.8	2.0	1	1.3
5	1.0	1.6	1	0.9	1.5	1	0.8

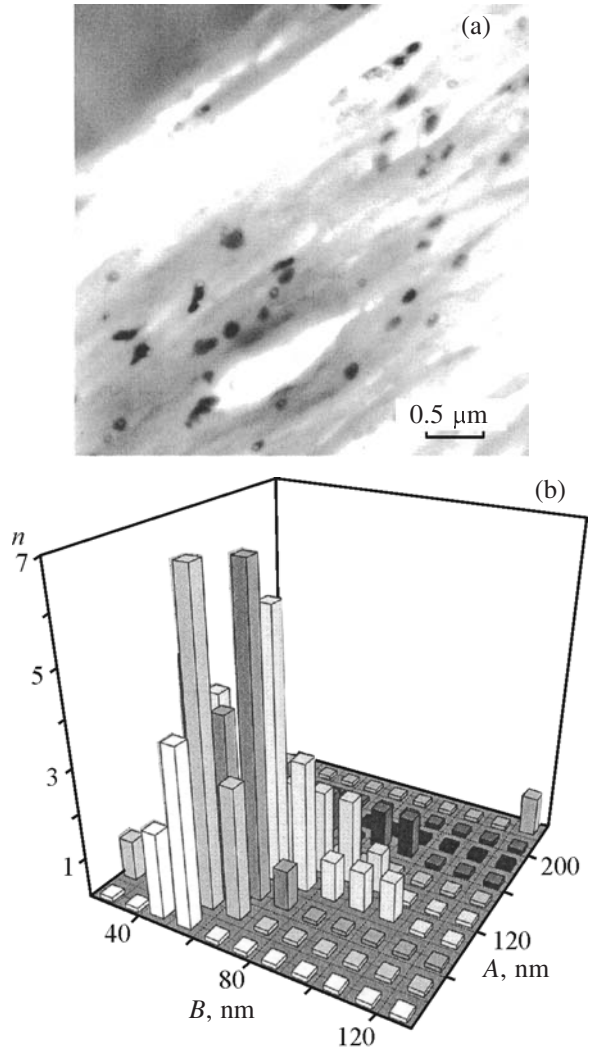

Fig. 3. (a) Electron micrograph and (b) histogram of sections of a dry AXC GF–PVP-nano-Se^0 specimen prepared by exposure of GF for 30 min in 0.01% solution of the complex, followed by drying at 20°C and desorption with water for 24 h. (*n*) Number of nanoparticles, (*B*) minor diameter, and (*A*) major diameter; the same for Fig. 4.

0.01% solution of PVP-nano-Se^0 for 30 min, dried at 20°C, subjected to desorption with water for 24 h, and finally dried at room temperature. The micrographs taken at different magnifications (5000–11 000) show that the distribution of selenium nanoparticles at the film surface is determined by the film arrangement in the course of the biosynthesis under the conditions of static cultivation of AXC: the upper surface contacting with air in the course of the biosynthesis and the lower surface immersed in the cultural medium are distinguished.

After the sorption from the 0.01% solution, ellipsoidal selenium nanoparticles with the major diameter ranging from 50 to 250 nm and the minor diameter, from 30 to 130 nm were detected in the bulk of the film. It can be clearly seen from the histogram that the majority of nanoparticles have an elliptical shape with major and minor diameters of approximately 80 and 60 nm, respectively.

Experiments on sorption on AXC GFs from more concentrated (0.1–1 or 3%) solutions (Fig. 4) showed that, along with nanoparticles detected in the bulk of the film, selenium crystals whose polymorphous modification and size depended on the dehydration temperature were formed on the specimen surface.

Figures 5a and 5c–5e show the AFM images of the upper surface, and Figs. 5b and 5f, those of the lower surface of dried AXC GF after intercalation with a 1% solution of the complex for (a, b) 15, (c) 30, and (d) 60 min, and (e, f) after intercalation for 30 min followed by desorption. It is seen that the lower and upper surfaces of the composite films after drying at 20°C essentially differ in the topography. On the upper surface of the composite, after the sorption for 15 min, there are numerous clusters of approximately spherical shape and size ranging from 50 to 290 nm, arranged on microfibrillar ribbons of AXC GF. On the

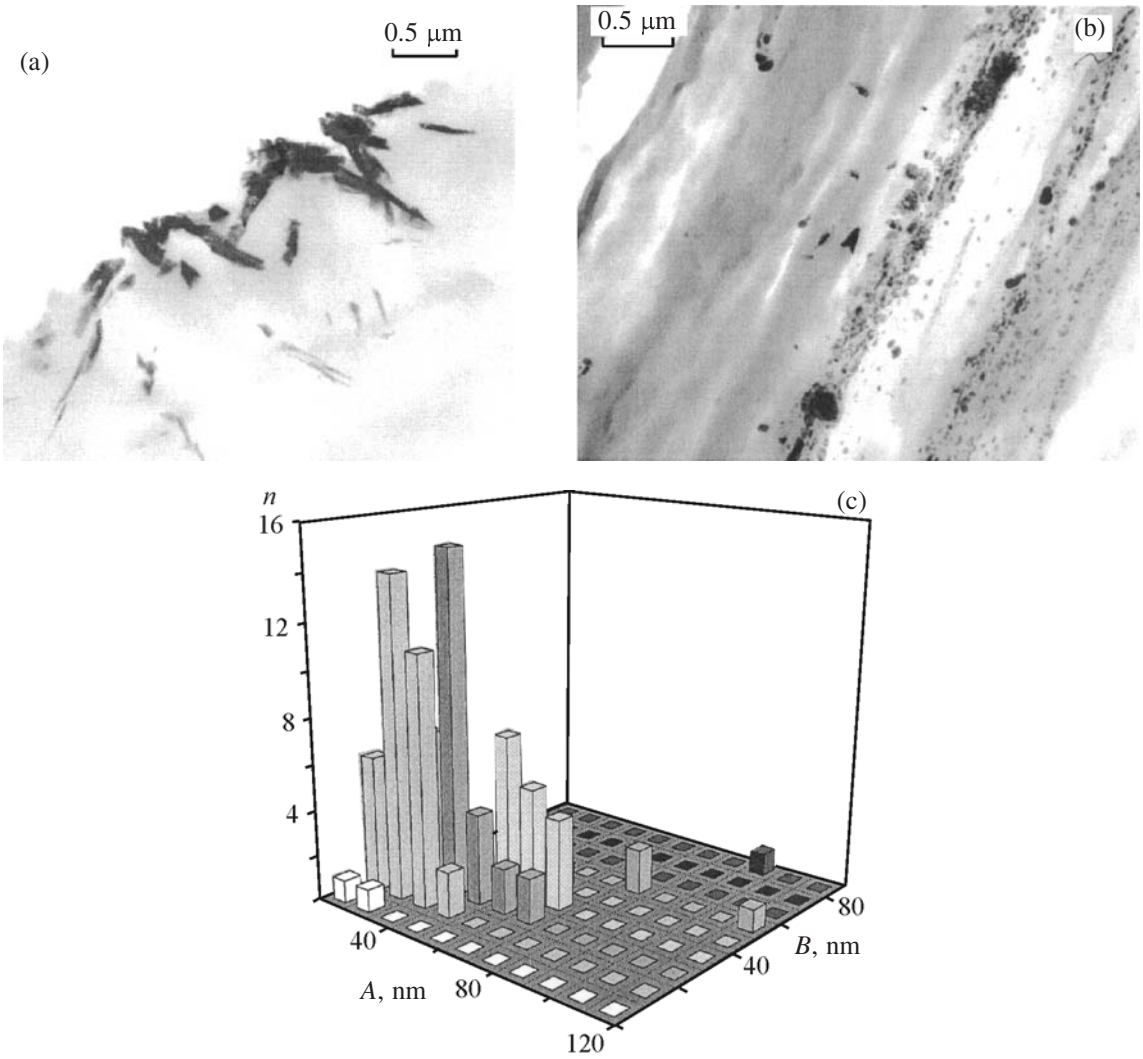

Fig. 4. (a, b) Electron micrographs and (c) histogram of sections of a dry AXC GF–PVP-nano-Se^0 specimen prepared by exposure of GF for 3 h in a 3% solution of the complex, followed by drying at 50°C. Distribution of (a) selenium crystals on the surface and (b) selenium particles in the bulk of the film.

lower surface of the same specimens, there are oval clusters with the minor diamter ranging from 100 to 420 nm, and the major diameter, from 150 to 800 nm.

After the sorption for 30 min (Fig. 5c), both spherical and strongly elongated oval particles were detected on the AXC GF surface. The size of the spherical particles varied in the same range as after the sorption for 15 min (from 55 to 290 nm). In this case, both surfaces of AXC GF have similar topography.

An increase in the sorption time to 60 min led to significant changes in the shape and size of the clusters: coarser aggregates up to 320 nm thick and up to 1000 nm long were observed. Apparently, at this sorption time separate clusters agglutinate to form elongated aggregates.

After the desorption for 24 h followed by drying, the topography of the upper surface changed insignificantly (Fig. 5e), whereas the other surface was "cleaned": microfibrillar ribbons were observed, with only a minor amount of clusters remaining in pores between them.

The AFM data indicate that, when an AXC GF is kept in a PVP-nano-Se^0 solution, the complex is irreversibly adsorbed on the upper surface already in the first 15 min of exposure. After the sorption for 30 min, both surfaces are virtually fully occupied by the clusters, and further increase in the sorption time (to 60 min and over) leads to the formation of microaggregates by agglutination of separate clusters.

In our previous study [12], on the surface of AXC

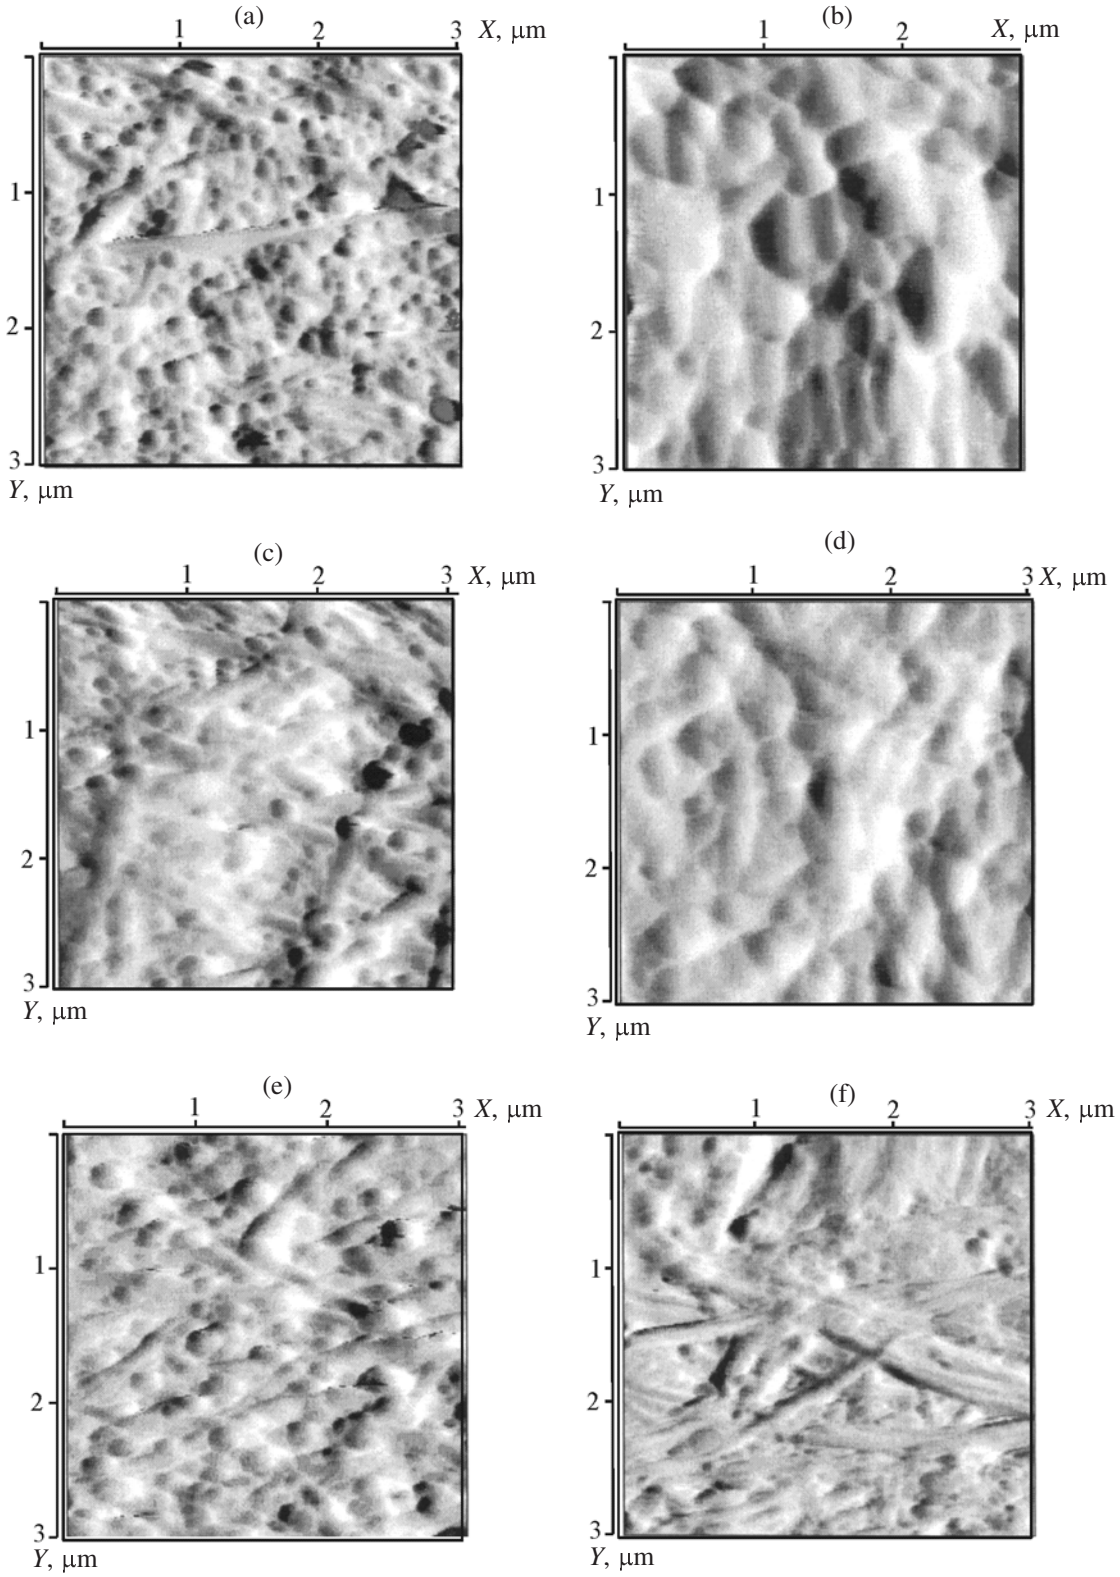

Fig. 5. AFM images, obtained in the constant amplitude mode, of regions of (a, c–e) upper and (b, f) lower surfaces of gel films after intercalation in a 1% aqueous solution of PVP-nano-Se^0 for (a, b) 15, (c, e, f) 30, and (d) 60 min, followed by (a–d) drying at 20°C and (e, f) desorption with water for 24 h and drying at 20°C. Scanning matrix size: (a, c–f) 256 × 256 and (b) 238 × 255. (*X*, *Y*) Coordinates.

GF–PVP-nano-Se^0 specimens prepared by sorption from a 3% aqueous solution of the complex and dehydrated at 40–50°C we detected two types of particles: spherical and rodlike. In the micrographs of sections of such a composite, one can see selenium crystals on the specimen surface (Fig. 4a) and elongated selenium particles with the ratio of major (*A*) and minor (*B*) diameters of 1.5–2 in the bulk of the film (Figs. 4b, 4c). The major diameter *A* varies from 20 to 60 nm, and the minor diameter *B*, from 10 to 40 nm.

In the diffraction pattern of such samples, there are reflections characteristic of trigonal selenium (Fig. 6, curve *1*). Figure 6 shows also the diffraction patterns of the samples dried at room temperature after sorption by the AXC matrix from a 1% solution of PVP-nano-Se^0 for 30 min (curve *2*). In this case, the selenium sorbed in AXC GF remains in the amorphous state. However, if such an AXC film after the sorption from a 1% PVP-nano-Se^0 solution for 30 min is immediately immersed in water for 24 h, additional reflections appear in the diffraction pattern of the specimen after drying at room temperature along with the reflections belonging to AXC GF. These additional reflections at 2θ 23°30′, 30°, 40°21′, 43°40′, and 45°20′ (Fig. 6, curve *3*) can be assigned, like the reflections in curve *1*, to the trigonal selenium cell with the parameters $a = b = 0.436$ nm, $c = 0.495$ nm, and $\gamma = 120°$ [4]. Figure 6 also shows the diffraction pattern of a dry powdered sample of PVP-nano-Se^0 (curve *4*), indicative of its amorphous structure. The presence of this complex in the composite will affect the diffuse background of the diffraction patterns.

It was shown previously [1, 6] that AXC GFs of VKM V-880 strain, dried at room temperature, exhibit axial-planar texture so that the crystallographic plane ($\bar{1}10$) of the monoclinic cellulose I_β cell ($d = 0.61$ nm) is arranged parallel to the specimen plane. In this case, the microfibrillar ribbons oriented in the gel film plane play the role not only of a reinforcing network but also of hydrophilic layers capable to sorb on their surface a large amount of water molecules, PVP, and water-soluble complexes PVP-nano-Ag^0 [1, 13].

According to Fink's model [7], nanofibrils or subunits from which AXC GF ribbons are formed in the course of biosynthesis have a rectangular cross section, 13×7 nm, and the crystallographic plane ($\bar{1}10$) is arranged parallel to the wide face. It was also noted in [14, 15] that the ($\bar{1}10$) face is highly hydrophilic because it incorporates primary hydroxy groups.

Based on the results of this study and previous data for AXC GF–VPV-nano-Ag^0 composites [1], using the Brown's [16] and Fink's models of the supramolecular structure of the intact (before drying) AXC film, we can suggest the scheme of intercalation of Se^0 nanoparticles in AXC GF shown in Fig. 7.

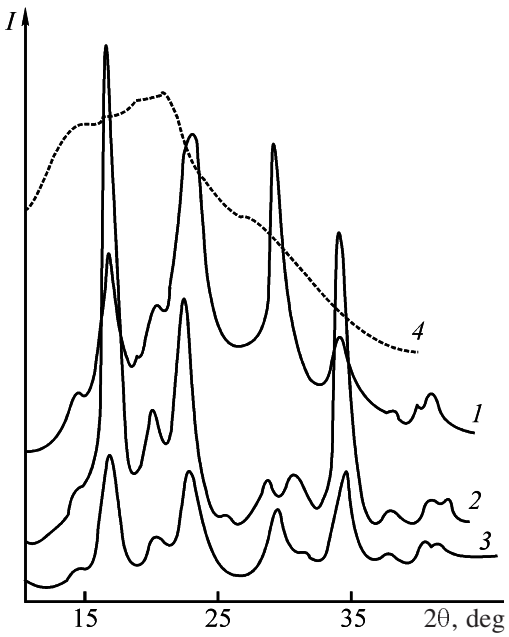

Fig. 6. Diffraction patterns of (*1*, *2*) AXC GF–PVP-nano-Se^0 composites prepared by sorption from 3 and 1% aqueous solution followed by drying at 50 and 20°C, respectively, (*3*) AXC GF specimen intercalated for 30 min in 1% PVP-nano-Se^0 solution with subsequent desorption for 24 h in water (without intermediate drying) followed by drying at 20°C, and (*4*) freeze-dried PVP-nano-Se^0 sample.

Examination of fine details of the biosynthesis and structure of AXC [2, 12] allows us to suggest that in the starting gel film the microfibrillar ribbon consists of numerous crystalline nanofibrils bounded by ($\bar{1}10$) and (110) faces (Fig. 7). The distances between these nanofibrils within the ribbon and between the adjacent ribbons are determined by the AXC strain used, synthesis conditions, and extent of squeezing of the gel film before sorption of water-soluble nanostructures. Nanochannels bounded by (110) faces of crystallites of adjacent nanofibrils build up a specific structure participating as a base in intercalation of nanocomplexes. Because of high surface energy of the ($\bar{1}10$) and (110) faces incorporating primary OH groups, nanosized selenium complexes can very rapidly (within 15–30 min) penetrate into the nanochannels or be accommodated on nanofibrils parallel to the wide face, without forming large clusters.

The deposition of selenium on these faces is proved by an appreciable (by a factor of 2) increase in the intensity of the ($\bar{1}10$) and (110) reflections in the dif-

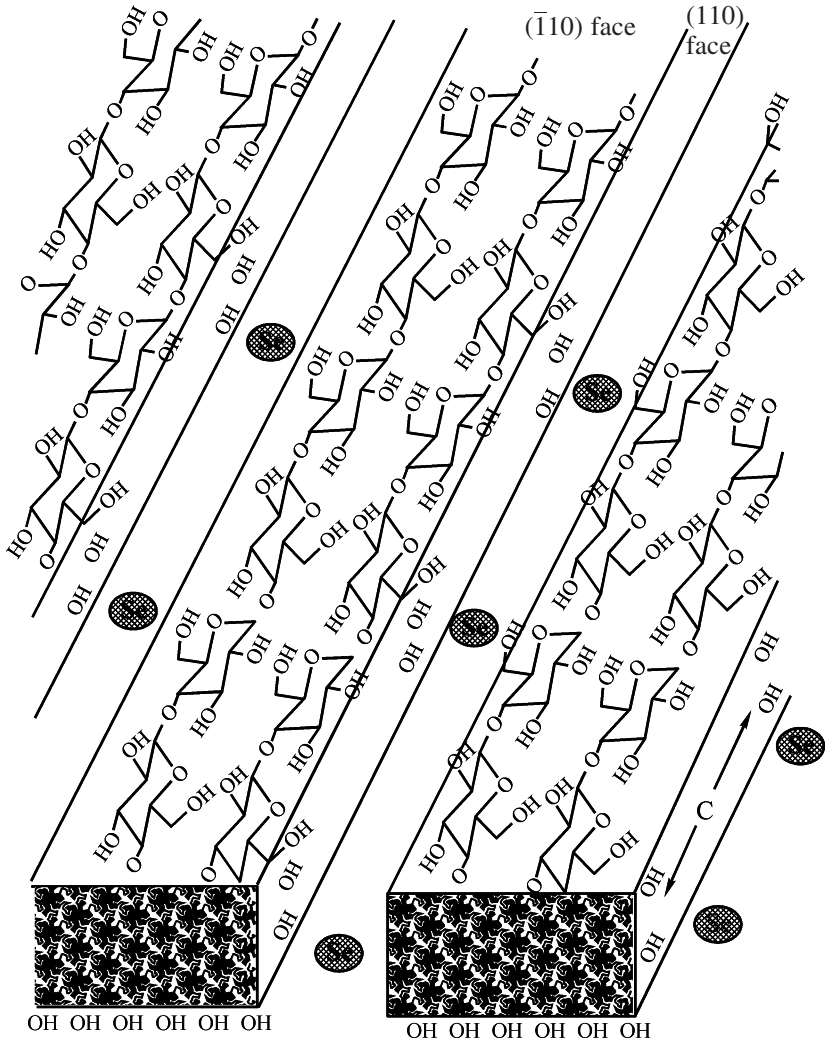

Fig. 7. Scheme of the sorption of PVP-nano-Se^0 by AXC gel film according to Fink's model [7].

fraction patterns of dry AXC GFs after their contact with aqueous PVP-nano-Se^0 solutions (see table; Fig. 2). The same trend is observed with the (004) reflections associated with the fixed periodicity of the deposition of Se^0 along the polymer chain (Fig. 7). Presumably, in this case enhancement of the intensity of the reflections is associated with an increase in the contrast from the ($\bar{1}$10), (110), and (004) planes. Indeed, the cellulose I_β reflections (200), (102), (012), and some other reflections do not change in intensity, because selenium nanocomplexes do not penetrate into nanofibril crystallites and do not alter the AXC structure, but only replace water molecules sorbed on primary OH groups of the crystallite walls.

Upon longer contact of AXC GFs with a 1% aqueous solution of PVP-nano-Se^0 (2–48 h) or with a more concentrated (e.g., 3%) solution, the relative intensities of the (110), (200), and (004) reflections do not change (Fig. 6). In this case, the observed noticeable increase in the total diffuse background and enhancement of the specimen color are due to localization on the specimen surface of coarse selenium clusters capable of crystallization (Figs. 5, 6). Presumably, both nanochannels and developed interribon internal and external surface of the gel films participate in the formation of the composite. Keeping such specimens in water for 24 h after drying at room temperature leads to no significant changes in the reflection intensities, and the specimen color and diffuse background in the diffraction patterns are preserved.

Thus, sorption of PVP-nano-Se^0 complexes from aqueous solutions on AXC GF having extremely developed internal surface can yield three types of composite materials with structure and properties depend-

ing on the concentration of the starting complex and on the sorption time.

(1) In AXC GF–PVP-nano-Se^0 specimens prepared at short sorption times (15–30 min) and low sorbate concentrations (0.01–0.1%), selenium particles are incorporated in the gel film in the amorphous state. Hence, the selenium sorption involves hydroxy groups of the nanochannels.

(2) In AXC GF–PVP-nano-Se^0 specimens prepared at short sorption times (15–30 min) but from more concentrated solutions (0.1–1%), both nanochannels and the developed interribbon surface with hydroxy groups located on the ($\bar{1}10$) faces of microfibrillar ribbons participate in the intercalation.

(3) In AXC GF–PVP-nano-Se^0 specimens prepared at long sorption times (2–48 h) and high sorbate concentrations (2–3% aqueous solutions of PVP-nano-Se^0), fairly large amount of clusters is sorbed on the surface of the gel film and in free volumes of the microfibrillar cellulose network. Specifically in these volumes heating to 30–50°C induces fairly easy crystallization of selenium.

CONCLUSIONS

(1) Differences in the distribution density and size of polyvinylpyrrolidone–nano-Se^0 clusters in their sorption in the bulk and on the surface of *Acetobacter xylinum* cellulose gel film were revealed. These differences may be due to orientation of microfibrillar ribbons and large number of channels between them, and also to high surface energy of the ($\bar{1}10$) and (110) crystal faces bearing primary OH groups.

(2) A scheme based on Fink's model was suggested for the predominant sorption of the polyvinylpyrrolidone–nano-Se^0 complex in channels between nanofibrils and microfibrillar ribbons at the ($\bar{1}10$) and (110) faces.

(3) Optimal conditions were suggested for stabilization of the amorphous form of selenium in a cellulose gel film: sorption from a 0.01–0.1% aqueous solution of the polyvinylpyrrolidone–nano-Se^0 complex in narrow ranges of temperature (20–25°C) and time (30–40 min).

NANOTECHNOLOGIES AND NANOMATERIALS

Relationship between Size of Cadmium Sulfide Nanoparticles and Water Pool Diameter in Reverse Micelles

Abstract—Preparation of CdS nanoparticles in water–sodium bis(2-ethylhexyl) sulfosuccinate–isooctane reverse micelles with various water contents is studied. A direct correlation between the water pool diameter in the reverse micelles and the mean size of CdS nanoparticles is found.

DOI: 10.1134/S1070427207090212

Recently a great interest has been attracted to preparation and characterization of nanomaterials [1]. Reverse micelles in hydrocarbon solvents proved to be appropriate systems for nucleation and growth of nanoparticles. Water droplets (pools) in surfactant-based micelles act not only as microreactors, but also as steric inhibitors of aggregation of atoms and molecules. Micellar synthesis was used to prepare various nanomaterials, among them CdS (see review [2]). Cadmium sulfide is a semiconductor used as a working medium in lasers and also as a material for fabrication of photoresistors, photodiodes, and solar batteries. The advantages of the synthesis of nanoparticles in reverse micelles are, first, in mild conditions of the process (no high temperature and pressure is required) and, second, in that the size and shape of nanoparticles can be controlled by the micelle structure and dynamics.

Presently, in this research field, the major focus is on preparation and characterization of nanoparticles, but not on properties of the dispersions. Particularly, it remains to be understood whether the properties of the micelles and microemulsions are different in the course of synthesis of nanoparticles.

Subdivision into micelles and microemulsions can be made by the microphase sizes in the system water–sodium bis(2-ethylhexyl) sulfosuccinate (AOT)–isooctane, as dependent on the temperature at various $[H_2O]/[AOT]$ ratios w [3]. At 50–60°C, these dependences are different: at $w = 15$ there is a descending curve, and at $w = 18$, an ascending one, suggesting formation of micelles and microemulsions at $w < 15$ and $w > 18$, respectively. According to [2, 3], over the range $0 < w < 15$–18, water occurs in the bound state, and with further increasing w, the structure of water is the same as in straight water. This hypothesis is supported by the trends in various physicochemical properties of water. For example, in the former case, the activity of emulsified water increases with increasing w, reaching saturation at $w = 15$. Similar trend is observed for the chemical shifts of protons of water, and the lifetime of hydrated electrons produced by radiolysis decreases, flattening out at $w = 15$ [2].

Here we report on synthesis of CdS nanoparticles in micelles and microemulsions at $w = 5$–18. Particularly, we analyzed the interrelation between the water pool diameter and nanoparticle size.

EXPERIMENTAL

In synthesis we used $CdCl_2$, Na_2S, $C_{20}H_{37}NaO_7S$ (AOT), and isooctane from Sigma–Aldrich. Water was distilled from potassium permanganate. The projected area of the AOT molecule was measured in a monomolecular layer. The surface tension of the aqueous AOT solution was determined by the plate method. The area of the AOT molecule in the adsorption layer was estimated from the surface tension isotherm obtained at 298 K (Fig. 1) at the water/air interface, assuming that the resulting area does not differ from that at the water/hydrocarbon interface. There are two features in the isotherm: one corresponding to the critical micelle concentration, and the second one, to the concentration at which the maximal adsorption G_m is attained. The quantity G_m was estimated by the Gibbs equation [4]:

$$G_m = -\frac{1}{RT}\frac{\partial\sigma}{\partial\log c}, \quad (1)$$

where σ is the surface tension of the solution

Table 1. Parameters* (nm) characterizing the microphases at various w, and standard deviations σ

w	d_m [3]	d_p [2]	d_p [5]	$d_m - 3.4$	$\overline{d}_p$	$\sigma_{\overline{d}_p}$	$\overline{d}_{CdS}$	$\sigma_{\overline{d}_{CdS}}$
5	6.1	1.8	2.7	2.7	2.4	0.5	2.2	0.2

18	9.4	5.4	7.4	6.0	6.3	0.9	4.5	0.5

* (d_m) Microphase diameter, (d_p) water pool diameter, ($\overline{d}_p$) mean diameter of water pools, and ($\overline{d}_{CdS}$) mean diameter of CdS nanoparticles; σ was estimated as $\sigma = \sum_{i=1}^{N}(d_i - \overline{d}_p)/(N-1)$, $N = 100$ for $\overline{d}_{CdS}$ and $N = 3$ for $\overline{d}_p$.

(mJ m^{-2}); R, gas constant (J mol^{-1} K^{-1}); T, temperature (K); and c, concentration (M).

The derivative was taken at the linear part of the curve. From G_m, the limiting area occupied by the AOT molecule on the water/hydrocarbon interface was estimated by Eq. (2):

$$S_0 = 1/(G_m N_A), \quad (2)$$

where N_A is the Avogadro number.

As a result, we obtain $G_m = 6.6 \times 10^{-6}$ mol m^{-2} and $S_0 = 0.25$ nm^2. The radius of the hydrophilic fragment of AOT was estimated from these values to be 0.28 nm.

The diameters of microphases at various w were taken from [2, 3, 5] (Table 1). According to data from [3], at $w = 0$, $d_m = 3.4$ nm. Therefore, this value corresponds to the size of "dry" micelles. Pileni [2] has demonstrated that the dependence of the water pool diameter of micelles d_p (nm) on w in the system water–AOT–isooctane is described by Eq. (3):

$$d_p = 0.3w. \quad (3)$$

As seen from Eq. (3), at $w = 0$, $d_p = 0$, which corresponds to such condition of the system when in the absence of water there is no apparent void volume in the pool. Bagwe and Khilar [5] suggested another equation for this dependence:

$$d_p = 0.36w + 0.9. \quad (4)$$

Subtraction of the micelle diameter (3.4 nm) from the microphase diameter gives us the water pool diameter of the micelle [2], whose value is well consistent with published data. By averaging data on the water pool diameters of micelles d_p, taken from three sources, we obtain the following correlation equation:

$$\overline{d}_p = 0.28w + 0.9. \quad (5)$$

It follows from Eq. (5) and Fig. 2 that, at $w = 0$, $d_p = 0.9$ nm, as in Eq. (4).

Determination of the relationship between d_p and d_{CdS} in the form similar to Eq. (5) should allow prediction of the size of CdS nanoparticles at a given w, which is practically significant.

CdS nanoparticles were prepared at room temperature as follows (Table 2). First, 1.3×10^{-4} M $CdCl_2$ and 1×10^{-4} M Na_2S solutions were prepared [6]. Then, to each solution, we added AOT to obtain w

18	5.00	7.10	121.00

ranging from 5 to 18 and isooctane (1 : 10). The systems were mixed with a low-frequency ultrasonic disperser until formation of dispersions. Finally, two dispersions with $CdCl_2$ and Na_2S were combined. In 0.5 h, CdS nanoparticles were formed in water pools of the micelles or microemulsions. The dispersion exhibited yellowish-orange opalescence. The nanoparticles were separated by adding DMF until yellow

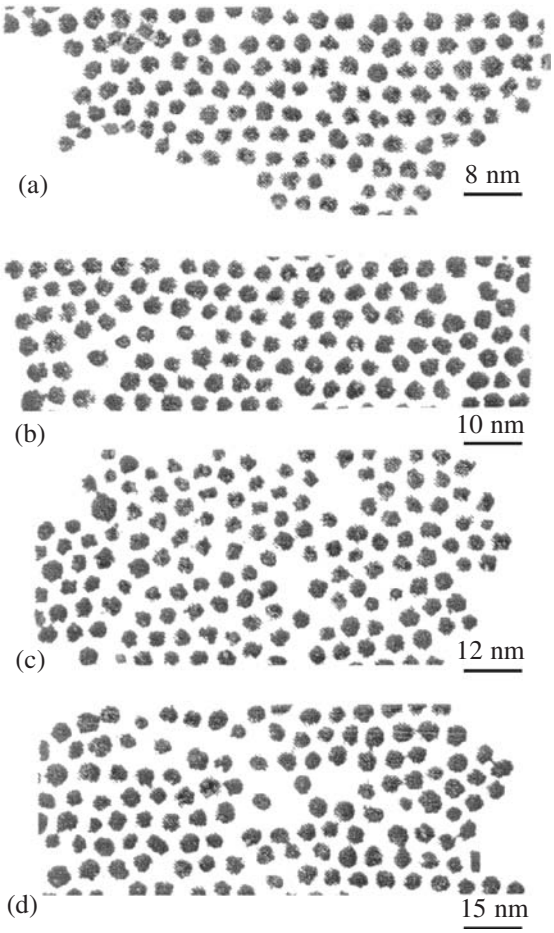

Fig. 3. TEM micrographs of CdS nanoparticles obtained at various w: (a) 5, (b) 9, (c) 15, and (d) 18; the same for Fig. 4.

floccules still remained at the interface between isooctane and aqueous DMF. Isooctane was then removed using a separating funnel. The CdS floccules were separated by centrifugation. The aqueous dispersion was removed by decanting. The precipitate was dispersed in distilled water; the nanoparticles were applied onto a carbon film, and their size was determined by TEM.

Carbon was sputtered onto a thin mica plate using an Edvards auto 306 vacuum evaporator. Along the edges of the plate, scratches were made to separate the carbon film from the mica film. Then one side of the mica film was immersed in water. The carbon film was detached by a needle from the mica film and remained to stand on the water surface. Then the carbon film was covered with a copper grid. Under this covered film, a sheet of waterproof paper was arranged, and after the grid and film were fastened onto the paper, it was withdrawn. The carbon film was cut along the perimeter of each grid, and a drop of the nanodispersion was applied onto it. After water was removed by evaporation, TEM micrographs were obtained with a Hitachi model H-600 transmission electron microscope. In determination of the size distribution of the nanoparticles, the diameters of each of 100 nanoparticles were averaged by the major and minor sizes. The averaged diameter of the particles at each w was determined as an arithmetic mean (Table 1). At $w = 9$, it was found to be 2.9 nm, which is in satisfactory agreement with that obtained in [7] at $w = 8$ for CdS nanoparticles containing adsorbed pyridine (3–4 nm). The micrographs of the nanoparticles are given in Fig. 3 for various w, and the size distribution, in Fig. 4. All the synthesized CdS particles are nearly spherical in shape. In the microphases, at $w = 5$, 81% of the clusters are from 2 to 2.5 nm in diameter; at $w = 9$, 89% of the clusters are from 2 to 3 nm in diameter; at $w = 15$, 71% of the clusters are from 2.5 to 3.5 nm in diameter; and at $w = 18$, 63% of the clusters are from 4 to 5 nm in diameter.

The dependence between the size of CdS nanoparticles and the mean water pool diameter (Fig. 5) is described by Eq. (6):

$$d_{CdS} = 0.74\bar{d}_p. \quad (6)$$

The water pool diameter in the microphases is approximately 26% larger than the size of CdS nanoparticles.

Let us then determine the minimal w at which CdS nanoparticles start to form in the micelles. As demonstrated above, at $w = 0$, $d_p = 0.9$. Let us in-

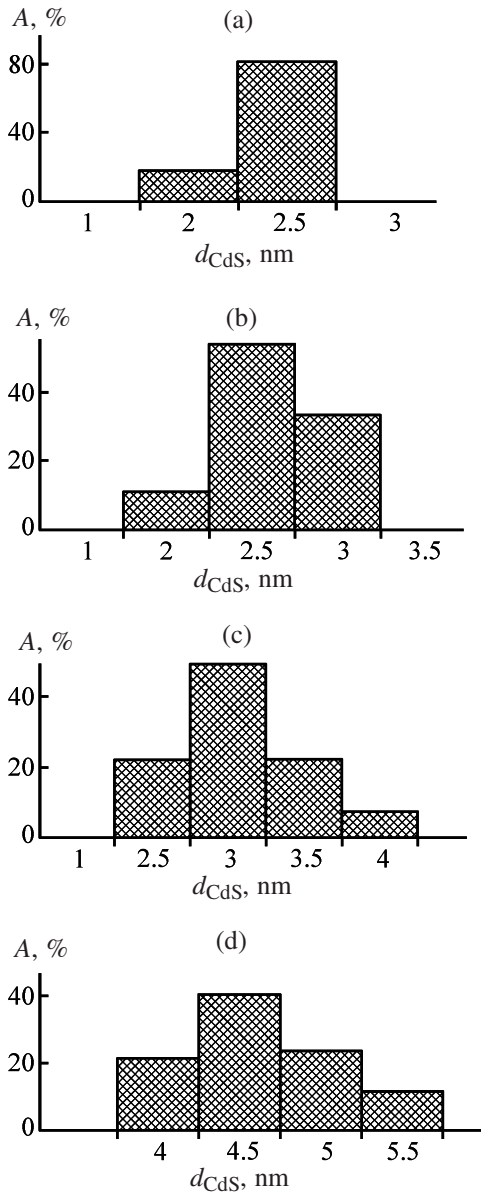

Fig. 4. CdS particle size distribution at various w. (A) Percentage and (d_{CdS}) diameter of CdS nanoparticles.

crease this diameter by 26% (this is the smallest diameter of water pools in which nanoparticles can be formed) to obtain d_p = 1.1 nm. The volume of a pool of such a diameter is 0.7 nm^3. Assuming the volume of the water molecule equal to 0.03 nm^3 [6], we obtain that the number of water molecules in the pool is about 23. The surface area of the water pool is 0.94 nm^2. On this area, four AOT molecules can be arranged, since, as demonstrated above, the projected area of the hydrophilic fragment of AOT is 0.28 nm^2. Hence, in this case, w = 6. Therefore, it is inadvisable to synthesize CdS nanoparticles at w < 6, despite

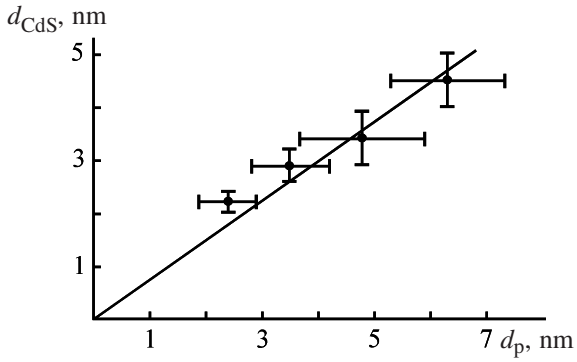

Fig. 5. Correlation between the diameter of CdS nanoparticles d_{CdS} and the water pool diameter d_p.

the fact that in this study we obtained them even at w = 5.

CONCLUSIONS

(1) CdS nanoparticles are synthesized at 25°C in microphases of the systems water–sodium bis(2-ethylhexyl) sulfosuccinate–isooctane at w 5, 9, 15, and 18. The surface tension isotherm of aqueous sodium bis(2-ethylhexyl) sulfosuccinate at 25°C and size distribution of the nanoparticles are determined.

(2) In the range of micelle formation at w = 15, there are linear relationships between w, the mean diameter of nanoparticles, and the mean water pool diameter, suggesting similar structures for reverse micelles and microemulsions in the investigated systems.

Abstract—A procedure was developed for preparing perfluoroethanesulfonyl fluoride by synthesis of hexafluoropropane-2-β-sultone from sulfuric anhydride and perfluoropropene, followed by hydrolysis of the sultone to α-tetrafluoroethanesulfonyl fluoride and fluorination of the latter with elemental fluorine.

DOI: 10.1134/S1070427207090224

Perfluoroalkanesulfonyl halides (PFASHs), including sulfonyl fluorides, are starting compounds for preparing perfluoroalkanesulfonic acids and their salts. They are also used as sources of perfluoroalkanesulfonyl groups in the synthesis of surfactants, dyes, antioxidants, UV stabilizers, and materials for chemical power cells [1–6]. Among PFASHs, of particular interest are lower homologs with 1–3 carbon atoms. However, application of PFASHs is limited by their high cost, caused by the lack of an efficient synthesis process. There are a number of procedures for preparing PFASHs, each having certain features and shortcomings. The best studied process is electrochemical fluorination (ECF), i.e., electrolysis of solutions of alkanesulfonyl halides in hydrogen fluoride [7, 8]:

$$RSO_2Hal \xrightarrow{HF,\ e} R_fSO_2F,$$

where Hal is F or Cl, R is alkyl, and R_f is perfluoroalkyl.

In Russia, the method is implemented at the Angarsk Electrochemical Plant for the production of trifluoromethanesulfonyl fluoride from methanesulfonyl chloride; the yield is 80–85%. Methanesulfonyl chloride, like other lower alkanesulfonyl chlorides, is not produced in Russia. Commercial electrochemical synthesis of perfluoroethanesulfonyl fluoride (PFESF) from ethanesulfonyl fluoride appeared to be unfeasible because of the low yield, which did not exceed 45%. The electrolysis is accompanied by formation of a large amount of impurities with boiling points close to that of PFESF; furthermore, a part of PFESF is mixed with hydrogen fluoride, and its significant fraction (up to 30%) remains dissolved in the electrolyte. Intermediate conversion of ethanesulfonyl chloride into ethanesulfonyl fluoride by the reaction with HF in the presence of a chromium–magnesium catalyst [9] allowed the PFESF yield to be increased to 70%, but its isolation appeared to be difficult. In electrolysis of higher alkanesulfonyl chlorides, the PFASH yields are as low as 25–30%. Another route to PFASHs is the reaction of perfluoroalkyl iodides or bromides with sodium dithionite, followed by chlorination of the resulting sodium perfluoroalkanesulfinate [10–12]:

$$R_fHal + Na_2S_2O_4 \rightarrow R_fSO_2Na,$$

$$R_fSO_2Na + Cl_2 \rightarrow R_fSO_2Cl + NaCl,$$

where R_f is perfluoroalkyl, and Hal is Br or I.

The reaction was performed in a water–acetonitrile mixture. The yield of perfluoroalkylsulfonyl chlorides reached 80%. We reproduced this procedure with perfluoroethyl iodide and obtained perfluoroethanesulfonyl chloride in 76% yield. Despite reasonable yield of PFASH, this procedure has significant drawbacks:

(1) use of expensive perfluoroalkyl iodides and bromides, which are in short supply, as starting compounds;

(2) use of sodium dithionite, which is not produced in Russia, and instability of this salt in storage, which gives rise to additional problems;

(3) strong corrosion of apparatus and pipelines, caused by chlorination of sodium perfluoroalkanesulfinates in aqueous solutions;

(4) overall complexity of the process: It involves steps of extraction, filtration, and regeneration of solvents. Implementation of the process requires a

large set of equipment, and many operations are performed manually;

(4) large amount of wastes: 1.5 t of solid and 2.5 t of liquid wastes are formed per ton of the finished product. The wastes mainly consist of toxic fluorinated compounds, and their regeneration and detoxication require additional chemicals, equipment, time, and energy.

Another procedure suggested for preparing PFASHs is based on the reaction of perfluoroolefins with sulfuryl fluoride or sulfuryl fluorochloride in the presence of cesium fluoride [13, 14]:

$$R_fCF{=}CF_2 + SO_2Hal_2 \xrightarrow{CsF} HalCF(R_f){-}CF_2SO_2Hal,$$

where Hal is Cl or F.

We checked this procedure and found that CsF, olefins, and solvents should be thoroughly dried. The water content should not exceed 0.001 wt %. However, even with such precautions the reaction mainly yielded a mixture of olefin oligomers and polymeric sulfonyl halides $Hal(R_fCF{-}CF_2)_nSO_2Hal$, $(R_fCF{-}CF_2)_n$, n = 1–50. The yield of monomeric PFASHs did not exceed 20%. It should be noted that polymeric sulfonyl halides are used as surfactants, lubricants, and components of impregnating formulations, ion-exchange membranes, and film materials.

The drawbacks of the above-considered procedures for preparing PFASHs make it necessary to search for a simple procedure for their synthesis involving chemicals commercially produced in Russia and to develop an efficient technology based on this procedure. Among possible routes to PFASHs, we chose conversion of sultones. In accordance with [15–17], polyfluorinated alkanesulfonyl fluorides are formed by hydrolysis of perfluorinated sultones which, in turn, are prepared by the reaction of sulfuric anhydride with perfluoroolefins. According to data reported by Knunyants [15, 16] and results of our experiments, the yield of hexafluoropropane-2-β-sultone is as high as 96–98%. The impurities (0.5–2%) are the linear isomer $CF_3{-}CF(SO_2F){-}COF$, six- and eight-membered sultones, and perfluoroallyl sulfate $CF_2{=}CF{-}CF_2O{\cdot}SO_2F$. Sultones are hydrolyzed to α-hydroperfluoroalkanesulfonyl fluorides (HPFSFs), which, as we expected, can be fluorinated to perfluoroalkanesulfonyl florides:

$$R_fCF{=}CF_2 + SO_3 \longrightarrow R_fCF(O_2S){-}CF_2{-}O$$

$$\xrightarrow{H_2O} R_fCFHSO_2F \xrightarrow{F_2} R_fCF_2SO_2F.$$

Experiments on optimization of the sultone synthesis showed that sulfuric anhydride should contain as low amounts of the monohydrate as possible: At 0.2% content of the monohydrate, the yield of the sultone is 98%. An increase in the monohydrate content leads to an increase in the content of impurities: monohydroperfluorocarboxylic acids $R_fCFH{-}COOH$, perfluoroalkenyl fluorosulfonates $R_fCF{=}CF{-}OSO_2F$, sulfuryl fluoride, and carbonyl fluoride. At 2% content of the monohydrate in sulfuric anhydride, the content of impurities reaches 15%.

The optimal temperature of sultone synthesis is 105°C. Above this temperature, the sultone starts to decompose, and its yield decreases. At temperatures below 100°C, the reaction becomes slower. At 50°C, the yield is 53%.

The monomer should be taken in 5–7% excess relative to the stoichiometry, to ensure complete binding of sulfuric anhydride. Free sulfuric anhydride promotes the subsequent acid hydrolysis of the sultone, with polyfluoroalkanoic and sulfonic acids becoming the major products.

Hydrolysis of hexafluoropropane-2-β-sultone involves two successive reactions: formation of (fluorosulfonyl)perfluoropropionic acid and its spontaneous decarboxylation with the formation of α-hydrotetrafluoroethanesulfonyl fluoride (TFESF):

$$CF_3{-}CF(O_2S){-}CF_2 + H_2O \longrightarrow CF_3{-}CF(SO_2F){-}COOH + HF,$$

$$CF_3{-}CF(SO_2F){-}COOH \longrightarrow CF_3CFH{-}SO_2F + CO_2.$$

The formation of hydrogen fluoride in the course of hydrolysis leads to the formation of tetrafluoropropionic acid:

$$CF_3{-}CF(SO_2F){-}COOH + H_2O \xrightarrow{HF} CF_3CFH{-}COOH + H_2SO_4 + HF.$$

The optimal hydrolysis temperature is 0–2°C. At this temperature, the yield of TFESF is 90%. TFESF contained up to 1% water. The content of other impurities did not exceed 0.03 wt %. After drying, the product was used for fluorination without additional purification.

Fluorination of polyfluorinated paraffins, ethers, tertiary amines, and their heterocyclic analogs by various procedures, including that with elemental fluorine, is a fairly well studied process, and high yields of the target products can be attained [18]. Fluorination of compounds containing an S–C bond is

much less studied. The energy of S–C bonds (about 270 kJ mol^{-1}) is appreciably lower than that of C–C (480 kJ mol^{-1}), C–O (360 kJ mol^{-1}), and even C–N (305 kJ mol^{-1}) bonds, which gives rise to certain problems in fluorination, because the cleavage of the C–S bond and formation of C–F and S–F bonds (energy 480 and 290 kJ mol^{-1}, respectively) is thermodynamically favorable. Kornilov et al. [19] studied fluorination of mercaptans with cobalt trifluoride. The major products were SF_6 and polyfluorinated paraffins. In our experiments on fluorination of TFESF with cobalt trifluoride, the yield of PFESF was 19%; the other products were SF_6, SO_2F_2, CF_4, and C_2F_6.

Fluorination of TFESF with elemental fluorine appeared to be more successful. Under static conditions, with slow supply of fluorine (0.5–0.7 ml s^{-1}) at 0–20°C into a reactor containing TFESF and packed with copper chips, the yield of PFESF was 92%. In dynamic experiments with a tubular reactor (nickel tube packed with copper chips), we sometimes observed plops when the rates of feeding the reactants changed or even without any apparent causes. In this case, SO_2F_2, SF_6, C_2F_6, CF_4, and carbon black became the major products. This result is attributable to inefficient removal of excess energy released in the course of fluorination. To remove this energy, it is recommended to use solvating solvents in combination with a heat-removing packing [20]. Among the examined compounds, the best results were obtained with HF and somewhat worse results, with TFESF and N_2. At the molar ratio F_2 : TFESF : HF = 1 : 1 : 1, 97% conversion and 95% selectivity were attained. If we consider the reactants as a donor–acceptor system [21] in which an electron is transferred from the donor (TFESF) to the acceptor (F_2)

$$CF_3CFHSO_2F + F_2 \longrightarrow CF_3\overset{\displaystyle CSO_2F}{\overset{\displaystyle |}{\underset{\displaystyle +\delta H\cdots}{\underset{\displaystyle |}{}}}}\ ,F^{-\delta}\!-\!F$$

$$\longrightarrow CF_3CFSO_2F + F + HF$$

with the formation of a radical pair, a diluent is required for stabilization of this pair and absorption of excess energy. This leads to temporary stabilization of the transition state, so that the radicals have time to recombine before escape into the reaction volume:

$$CF_3CFHSO_2F + F_2\cdots,HF \longrightarrow CF_3\overset{\displaystyle CFSO_2F}{\overset{\displaystyle |}{\underset{\displaystyle +\delta H\cdots}{\underset{\displaystyle |}{}}}}\ ,F^{-\delta}\!-\!F\cdots HF$$

$$\longrightarrow CF_3CFSO_2F + F\cdots HF + HF,$$

$$CF_3CFSO_2F + F\cdots HF \longrightarrow HF + CF_3CF_2SO_2F.$$

Apparently, the amount of HF correlates with the amount of supplied F_2. According to the theory of one-electron transfer, the optimal HF : F_2 ratio should be 1 : 1, i.e., the molar ratio of the components should correspond to the stoichiometric ratio. Indeed, as the HF concentration is decreased to 0.71 mol per mole of F_2, the selectivity decreases by 15–20%, and when it is increased to 1.5 mol per mole of F_2, the conversion of the starting reactants decreases, apparently due to the inhibiting effect of HF and a decrease in the fluorination rate.

Another major factor affecting the reaction is temperature. We found that 120–130°C is the optimal temperature of PFESF synthesis. Based on the results obtained, a pilot plant for PFESF synthesis was constructed at the Galogen Open Joint-Stock Company. The installation consists of units for distillation of sulfuric anhydride, synthesis of sultone, hydrolysis of sultone, fluorination of TFESF, neutralization of crude PFESF with alkalis, its drying with zeolites, and fractional distillation of PFESF to obtain the 99.9% pure products. The results of studies on fluorination of polyfluorinated alkanesulfonyl fluorides were protected with RF patents [22, 23].

EXPERIMENTAL

The reaction products were analyzed by gas chromatography [LKhM-80 chromatograph, thermal conductivity detector, 2-m column packed with Silokhrom + 20% 1,1,1-tris(β-cyanoethyl)acetophenone] and gas chromatography–mass spectrometry (Aligent-5973N, DB-5ms capillary column 60 m long).

Hexafluoropropane-2-β-sultone was prepared as described in [15]. Optimal conditions: hexafluoropropene : SO_3 ratio (1.05–1.08) : 1, 105–107°C, 12–14 h. α-Tetrafluoroethanesulfonyl fluoride was prepared by the procedure described in [15] with some modifications. Namely, the sultone was fed into water, which allowed us to increase the TFESF yield to 92%.

Fluorination of tetrafluoroethanesulfonyl fluoride with cobalt trifluoride. Into a nickel tube 800 mm long and 38 mm in diameter, packed with controllable heating, TFESF was fed from a batcher at a rate of 1–3 ml min^{-1}. The best results were obtained at 260–290°C. According to the gas-chromatographic analysis, the reaction mixture (after neutralization with aqueous NaOH) contained 23% SO_2F_2, 15% SF_6, 35% C_2F_6, 8% CF_4, and 19% $C_2F_5SO_2F$.

Fluorination with elemental fluorine under static conditions. A 2.0-l 12Cr18Ni10Ti stainless steel

vessel packed with copper chips and cooled to 0°C was charged with 18.5 g of TFESF, and fluorine was fed at a rate of 0.5–0.7 ml s^{-1} for 1 h (the procedure was performed in a steel box). After 24 h, the reaction mixture was condensed in a 12Cr18Ni10Ti stainless steel trap cooled with liquid nitrogen. After warming, it was neutralized with aqueous NaOH, dried over CaA zeolite, and collected in a trap cooled to –30°C. The product (yield 20 g) contained 95% PFESF and 5% impurities (CF_3SO_2F, SO_2F_2, C_2F_6, CF_4, SF_6).

Fluorination under dynamic conditions. A solution containing 92 g of TFESF and 10 g of HF was fed at a rate of 0.8–1.0 g min^{-1} from a batcher to a vaporizer (nickel tube 38 mm in diameter and 500 mm long, heated to 80–100°C). Fluorine was also fed to this tube at a rate of 120–130 ml min^{-1}. Then the mixture of the components came into a reactor (nickel tube 38 mm in diameter and 900 mm long, packed with copper chips and heated to 130–140°C). The reaction products were collected in a 12Cr18Ni10Ti stainless steel trap cooled to –120°C. After the reaction completion, the condensate was worked up as described above. The product (yield 90 g) contained 96.5% PFESF and 3.5% impurities (CF_3SO_2F, SO_2F_2, C_2F_6, CF_4, SF_6).

CONCLUSIONS

(1) A procedure was developed for preparing perfluoroethanesulfonyl fluoride by fluorination of tetrafluoroethanesulfonyl fluoride.

(2) The steps of perfluoroethanesulfonyl fluoride synthesis were optimized, and its pilot production was set up at the Galogen Open Joint-Stock Company.

ACKNOWLEDGMENTS

The authors are sincerely grateful to N.V. Baranov and G.G. Furin for the assistance in the work.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

In Situ Version of Radical-Chain Substitution Reactions

A. M. Kurdyukov

Volgograd State Technical University, Volgograd, Russia

Received April 27, 2007

Abstract—Peroxy acetals derived from an ether and a hydroperoxide can be prepared in situ and used without isolation to effect sulfochlorination of *n*-alkanes or chlorination of toluene to benzyl chloride.

DOI: 10.1134/S1070427207090236

The feasibility of initiated radical processes using activators prepared in situ in the reaction volume is obvious. The interest in such way of initiating chain reactions is particularly pronounced in production of polymers, e.g., of suspension PVC [1]. Acyl peroxides prepared in a polymerizer from a hydrogen peroxide salt and an acyl chloride in the monomer–water system are fairly effective. Peroxydicarbonates and sulfonyl peroxides are also used.

Common liquid-phase radical-chain reactions involving C–H substitution, such as chlorination and sulfochlorination of hydrocarbons, are performed in the bulk of a hydrocarbon or in a nonpolar solvent. The components of the chemical initiating system should be readily soluble or uniformly distributed in the hydrocarbon (RH). The majority of organic peroxides described in the literature are used in both polymerization and substitution reactions [2]. However, there are virtually no data in the literature on the use of a reaction mixture of initiator synthesis (without its isolation) for initiating a chain substitution reaction. In a sulfochlorinator or a chlorinator, the presence of oxygen and water, which are frequently used components in syntheses of peroxides, is inadmissible.

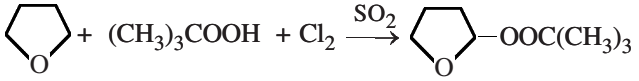
Here we consider a version of initiator synthesis in situ in the reaction volume, followed by an initiated substitution reaction. As investigation objects we chose well-known aldehyde derivatives, peroxy acetals.

Of particular practical value is the procedure for preparing mono- and diperoxy acetals from ethers and hydroperoxides in the presence of sulfuryl chloride SO_2Cl_2 or evaporated Cl_2 (taken separately or in a mixture with SO_2), described in [3]. It was demonstrated by numerous examples that aliphatic and cyclic (unstrained) ethers can be vigorously oxidized with *tert*-butyl hydroperoxide (TBHP) at the α-H atom relative to the ether bond. For example, 1,1-di-*tert*-butylperoxyethane (DTBPE) is rapidly formed in a good yield at the molar ratio Et_2O : TBHP : SO_2Cl_2 = (10–5) : (3–2.3) : 1 by the reaction

$$CH_3–CH_2–O–C_2H_5 + 2(CH_3)_3COOH + SO_2Cl_2 \xrightarrow{0\pm5^\circ C} (CH_3)_3COO–\underset{\displaystyle CH_3}{\underset{|}{CH}}–OOC(CH_3)_3 + C_2H_5OH + 2HCl + SO_2.$$

There is certain evidence that the reaction occurs via formation of the monoperoxy acetal, 1-ethoxy-1-*tert*-butylperoxyethane.

High yield was attained with a 1 : (1–0.2) mixture of Cl_2 and SO_2 taken instead of SO_2Cl_2. For example, 2-*tert*-butylperoxytetrahydrofuran (TBPTHF) is prepared in >90% yield on the standard equipment of chlorine plants [3] by passing Cl_2 and SO_2 evaporated from cylinders through a solution of TBHP in THF at 5–10°C for 20 min:



The procedure of synthesis of peroxy acetals fortunately matches the substitution reactions with respect to reagents, equipment, temperature, and reaction rate, which opens real prospects for simplifying the step of chemical initiation of chlorination and sulfochlorination of hydrocarbons. Indeed, under the conditions typical for the formation of an alkanesulfonyl chloride from a liquid alkane and a mixture of SO_2 and Cl_2 at 30–35°C,

$$R–H + SO_2 + Cl_2 \rightarrow RSO_2Cl + HCl,$$

it is absolutely unnecessary to prepare an initiator (e.g., TBPTHF, an effective sulfochlorination initiator [4]) in a separate step.

Before feeding the gases, it is sufficient to add a solution of TBHP in THF to the hydrocarbon and make sure that the initiator has formed in situ in the sulfochlorinator and affected the parameters of the reaction mixture.

The most important reaction parameter is the rate of accumulation of hydrolyzable chlorine Cl_h after Volhard. The figure shows the results of experiments under similar conditions with TBPTHF prepared beforehand (curve *3*) and in situ (curve *4*), and also with TBHP (curve *2*). These data show that the degree of sulfochlorination, and also the conversion of Cl_2 and RH (evaluated by various procedures) are higher when the initiator is prepared in situ, compared to the separate preparation of the initiator or UV initiation [4].

The idea put forward [4] was indirectly supported by experiments on revealing effective chemical initiators of toluene chlorination with sulfuryl chloride:

$$C_6H_5CH_3 + SO_2Cl_2 \longrightarrow C_6H_5CH_2Cl + SO_2 + HCl.$$

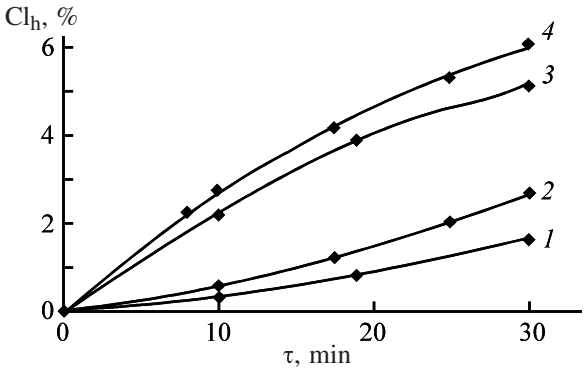
Benzyl chloride is obtained in a high yield only in the presence of benzoyl and lauryl peroxides and AIBN in amounts of 0.001–0.005 mol per mole of toluene, including experiments with 1 : 1 reactant ratio and heating for 20–30 min [5]. Without initiators, toluene does not react with SO_2Cl_2 even under refluxing for 6 h. In many books, this transformation is considered as a particular reaction: The reaction is selective owing to formation of the $^{\bullet}SO_2Cl$ radical in the initiation [2] and chain propagation steps. The reaction

$$Inc^{\bullet} + SO_2Cl_2 \longrightarrow IncCl + {}^{\bullet}SO_2Cl$$

is probable owing to fragmentation of the initially formed acyloxy radicals $R"COO^{\bullet}$ to $R"^{\bullet}$, followed by the reaction of $R"^{\bullet}$ with the reagent.

The results of experiments on preparation of benzyl chloride showed that in situ synthesis of peroxy acetals in the chlorinator ensures higher yield of the final product compared to the synthesis with the ready initiator (52±2°C, 30 min; see table). For comparison we used a protocol of the synthesis of benzyl chloride by the reaction of RH with SO_2Cl_2 at the molar ratio of the reactants of 1 : 0.5 in the presence of AIBN [5].

Under these conditions (run no. 1), the reaction is essentially incomplete. By distillation under reduced pressure, we isolated from the reaction mixture, along



Accumulation of Cl_h with time τ in a dark vessel. (*1*) No initiator, (*2*) ~0.005 M TBHP, (*3*) ~0.005 M TBPTHF, and (*4*) 0.07 g of TBHP (72%) in 1.2 ml of THF (~0.005 M peroxide in reaction mixture). Gas supply rate 0.3 g min^{-1} each. RH weight, g: (*1*, *3*) 73 and (*2*, *4*) 72.

with benzyl chloride, also the unchanged reactants: toluene (63.4%) and SO_2Cl_2 (23.8%). Despite considerable differences in the boiling points of the mixture components, pure benzyl chloride cannot be isolated by single distillation; repeated distillation, desirably with a dephlegmator, is required.

When the peroxy acetal is prepared in the chlorinator in situ (run nos. 4–6), 98.7% pure (GLC data) benzyl chloride can be readily isolated by single distillation (run no. 4).

In the suggested procedure for preparing benzyl chloride [6], it is possible to attain almost quantitative conversion of the reactants with 85–90% product yield. The order of mixing the components exerts a noticeable influence. When a solution of TBHP in an ether is added to toluene before adding SO_2Cl_2, the

Yield of benzyl chloride with various initiators

2	92% TBHP	0.118	1.25	Traces
3	96% TBPTHF	0.387	2.35	50.4
4	TBPTHF, in situ**	0.122	1.10	71.5
5	The same, from 92% TBHP	0.343	4.36	88.2
6	The same, from 92% TBHP	0.398	5.06	77.8

* Per mole toluene. Toluene amount: 92 g in run nos. 1–4, 74 g in run nos. 5 and 6.

** From 85% TBHP.

product yield is always 5–10% higher than when a solution of TBHP in an ether is added to the reactant mixture (run no. 6, as in run no. 1).

Thus, the mechanism of the effect of peroxides prepared in situ in the reaction vessel should not differ from the mechanism of the effect of pure peroxides (as sources of alkoxy radicals) on the system with predominance of RH:

$$0.5R''OOR'' + RH \longrightarrow R''OH + R^{\bullet}.$$

The dissociation of the O–O bond in mono- or diperoxy acetals should not be considered separately from the escape ot the resulting radicals into the bulk of solution. It is improbable, e.g., that the *tert*-butoxy radical would react with a chlorinating agent (including SO_2Cl_2) in the presence of RH (irrespective of whether RH is toluene or *n*-alkane).

The procedure suggested in [6] for preparing benzyl chloride is also very selective (the content of benzal chloride is as low as 0.25%), compared to chlorination of toluene with elemental Cl_2 in the presence of known initiators [2]. Presumably, the considerable differences between the results obtained with different chlorinating agents (Cl_2 or SO_2Cl_2) are associated with the structure and energy of the transition state in the chain propagation step involving these agents, at least provided that the benzyl radical $C_6H_5CH_2^{\bullet}$ is formed in the chain initiation step under the action of peroxides as generators of alkoxy radicals.

The initial component of the initiating system we suggest is TBHP, one of the most readily available organic peroxides whose commercial production is well mastered. At 30–50°C, the O–O bond in TBHP in hydrocarbon solutions does not noticeably dissociate. Experiments (figure, curve *2*; table, run no. 2) show that straight TBHP, irrespective of purity (chemically pure or technical grade), shows no promise for intensification of radical substitution reactions. The hydroxy derivative may react with SO_2Cl_2 as acid chloride or be reduced with SO_2. The latter process (at a high SO_2Cl_2 concentration) is, apparently, responsible for the low yield of the product when the chlorination is performed in the presence of TBPTHF (table, run no. 3) or when the initiating system is added to the reactants mixed beforehand (run no. 6).

Activation of the hydroperoxide with an ether or, more precisely, use of a mixture of TBHP with an ether for in situ preparation of a peroxy acetal (without its isolation) in the reaction volume is a simple way of effective initiation of substitution reactions.

EXPERIMENTAL

Freshly prepared peroxides with a high content of available oxygen (O_a; iodometric titration) were used. In all the cases the initiator was added into the hydrocarbon, after which the chlorinating agents were added. The initiator concentration is given counting on 100% purity.

Sulfochlorination of a liquid paraffin was performed in a round-bottomed vessel equipped with a bubbler for feeding gases, a stirrer, a reflux condenser, and a thermometer. The chlorinating mixture components, SO_2 and Cl_2, were evaporated from cylinders, dried, and fed in 1.1 : 1 ratio, using rheometers, to the reaction mixture at 30±2°C. As alkane we used synthine, TU (Technical Specification) 602-953–77, used in production of ionic surfactants, alkanesulfonates.

Synthine (synthetic paraffin) is a mixture of C_{12}–C_{18} *n*-alkanes with the mean molecular weight of 198; d_4^{20} 0.764–0.768, flash point 85°C, bp 290±65°C.

With TBPTHF prepared in situ from TBHP and THF in the sulfochlorinator, the reaction mixture parameters (figure, curve *4*) after blowing-off are as follows: d_4^{20} 0.8627, n_D^{20} 1.4458, Cl_h 5.65%, weight gain 1.15 g per gram of RH. The conversion evaluated from Cl_h is ~100% for Cl_2 and 34.89% for RH. In experiments described by curves *1–3*, the conversion and weight gain were lower.

Chlorination of Toluene with Sulfuryl Chloride in the Presence of Initiator Prepared in situ in the Chlorinator

Synthesis of benzyl chloride using TBPTHF prepared in situ from TBHP and THF (table, run no. 5). A reactor equipped with a stirrer, a reflux condenser, and a thermometer was charged with 74.0 g (0.8 mol) of toluene [analytically pure grade, GOST (State Standard) 5789–78], after which a solution of 0.343 g of TBHP (92% pure according to iodometric titration data) in 1.8 ml of THF was added. This amount corresponds to 0.004359 mol of TBPTHF per mole of toluene. Then 54.0 g (0.4 mol) of SO_2Cl_2 (bp 69°C, d_4^{20} 1.667) was added. The mixture warmed up to spontaneously to 37°C, and, before the temperature started to decrease, it was heated to 54±4°C and kept at this temperature for 30 min. The resulting mixture (89.0 g) was distilled from a Claisen flask. The following fractions were obtained: unchanged toluene (46.7 g, bp 54–56°C/100 mm Hg, n_D^{20} 1.4963, d_4^{20} 0.864) and benzyl chloride (33.1 g, bp 92–93°C/

43 mm Hg, n_D^{20} 1.5392, d_4^{20} 1.102, in agreement with reference data). According to GLC, the benzyl chloride was 99.35% pure (which is similar to the purity of a commercial sample after fractional distillation [6]). The residue was a dark tar (1.4 g). The yield of benzyl chloride was 88.24% (based on converted toluene, without taking into account the residue).

Synthesis of benzyl chloride with DTBPE prepared in situ from TBHP and diethyl ether. A stirred reactor was charged in succession with 46.1 g (0.5 mol) of toluene, a solution of 0.22 g of 85% TBHP in 1.5 ml of diethyl ether (which corresponds to 0.00206 mol of DTBPE per mole of toluene), and 27.1 g (0.2 mol) of sulfuryl chloride. The mixture warmed up virtually immediately, and vigorous gas evolution started. Although at 52 ± 2°C visually observed gas evolution practically ceased 15 min after the start of the reaction, the reaction was performed for 30 min. By simple distillation of the mixture (55.3 g), 29.0 g (33.5 ml) of unchanged toluene (bp 60–62°C/96 mm Hg) was obtained. Further distillation gave 20.1 g of a product with d_4^{20} 1.104, bp 71–74°C/17–18 mm Hg, n_D^{15} 1.5411, which agrees with the reference data for pure benzyl chloride. Yield of benzyl chloride 85% based on converted toluene or 79.5% based on converted sulfuryl chloride. This is good agreement taking into account possible loss of low-boiling SO_2Cl_2.

CONCLUSION

A mixture of *tert*-butyl hydroperoxide with an aliphatic or cyclic ether was suggested for in situ generation of peroxy acetals in a chlorinator or a sulfochlorinator with the aim of effective initiation of radical-chain C–H substitution reactions in hydrocarbons.

Abstract—The mechanism of processes occurring when a low-molecular-weight compound interacts with a block copolymer is considered. The anomalous results obtained with the butadiene–styrene stationary phase are accounted for. The effect of modifying additives on the sorption properties of the polymer is examined.

DOI: 10.1134/S1070427207090248

Previously we reported on a relationship between the nanoscopic structure of a polymer used as a stationary chromatoghraphic phase and the shape of the retention diagram, with a newly synthesized multiblock polyester–polysiloxane copolymer as example [1]. We demonstrated the potentialities of reverse gas chromatography (RGC) furnishing important information on the internal structure of a polymer and its solubility (or swellability) in various low-molecular-weight substances, using only small amounts of a polymer sample and simple and cheap equipment. This information allows a conclusion on whether the given polymer is suitable for preparing items contacting in the course of operation with a given solvent.

However, an attempt to confirm by RGC the existence of a complex domain nanostructure in a polymer (butadiene–styrene) failed. The retention diagrams of six different sorbates (*n*-alkanes C_5–C_9, chloroform, methylene chloride, carbon tetrachloride) were strictly linear, which, at first glance, contradicts the conlusions made in [1], because specifically for butadiene–styrene copolymer the existence of such structure was confirmed previously in numerous studies [2]. Here we attempt to rationalize this paradox.

EXPERIMENTAL

We used an installation based on an LKhM-8MD chromatograph, described in detail previously [1]. As the stationary phase we used multiblock copolymers of phenolphthalein terephthalate and polydimethylsiloxane with varied ratio of the rigid and flexible blocks, both straight and modified with low-molecular-weight compounds nonvolatile under the experimental conditions, as well as commercially available butadiene–styrene copolymers DST-20 and DSSK-20. The polyester–polysiloxane copolymers were prepared by the procedure described in [3], somewhat adapted to the available solvents. A photomicrograph of the synthesized block copolymer was obtained with a JEOL-S microscope.

To clarify the situation, we compared the retention diagrams of the same sorbate by stationary phases of the butadiene–styrene block copolymer and the random copolymer with the same ratio of the butadiene and styrene units (Fig. 1). It can be readily seen that both dependences are strictly linear, and at any temperature the retention volume for the random copolymer is larger than for the block copolymer.

To a first approximation, the sorption of a low-molecular-weight probe by block copolymers, which have a complex structure formed by nanosized domains of rigid blocks distributed in a continuous medium, can be represented as a sum of two independent processes occurring simultaneously: dissolution of a low-molecular-weight probe in the interdomain dispersion medium and its adsorption on the surface of domains of the "rigid" phase. Then the specific retention volume of a sorbate on the stationary phase V_g^0 ($cm^3\ g^{-1}$) is equal to [4]

$$V_g^0 = S + A, \quad (1)$$

where S is the contribution made by dissolution of sorbate molecules in the dispersion medium, and A, adsorption contribuition, $A = K_A S_A$, where K_A is the

constant of adsorption interaction of sorbate molecules with the surface of rigid vitrified domains, and S_A is the adsorption surface area.

However, Eq. (1) fails to fully explain some experimental results. For example, an assumption that the phases in polymers fully separate is inconsistent with the results of calculating partial contributions of the dissolution. The retention caused by this process is larger than it should be observed on the pure phase of the flexible block [1]. In addition, the fact that the nature of the flexible block strongly affects the chromatographic behavior of the polymer also contradicts the additive scheme [5]. This leads to a conclusion that the sorption of low-molecular-weight compounds is complicated by interaction of the components of the disperse polymer system with each other.

An important component of such interaction is adsorption of molecular segments of a flexible block on the surface of the rigid phase domain [6]. As a result, the mobility of the molecular chains of the flexible block is restricted not only by chemical bonds between the rigid and flexible segments of the macromolecule, but also by the adsorption interaction. Naturally, the adsorption of flexible chain segments on the surface of rigid block domains may affect the sorption properties of the copolymer with respect to low-molecular-weight sorbates.

When the surface of rigid phase domains is occupied by adsorbed segments of flexible block chains, low-molecular-weight sorbate molecules compete with the already adsorbed segments of the flexible phase, which can be represented as a quasi-chemical equation

$$A + MD \rightleftarrows AD + M, \qquad (2)$$

where M is a flexible block segment: D, adsorption center of a rigid block domain; and A, a low-molecular-weight sorbate.

The equilibrium constant of such a process, K_e, is

$$K_e = \frac{c_n^0[AD]}{[A][MD]} = \frac{(c_n^0 + x)x}{[A][N_0 - x]}, \qquad (3)$$

where c_n^0 is the concentration of flexible block segments in the interphase layer at the adsorption surface (mol cm^{-3}); x, concentration of sorbed molecules A (mol cm^{-2}): N_0, surface concentration of adsorbed flexible block segments (mol cm^{-2}); and [A], sorbate concentration in the dispersion medium (mol cm^{-3}).

Thus, the specific retention volume of a sorbate on a stationary phase consisting of a block copolymer is

$$V_g^0 = K_L\theta_L + (dq/dc)S, \qquad (4)$$

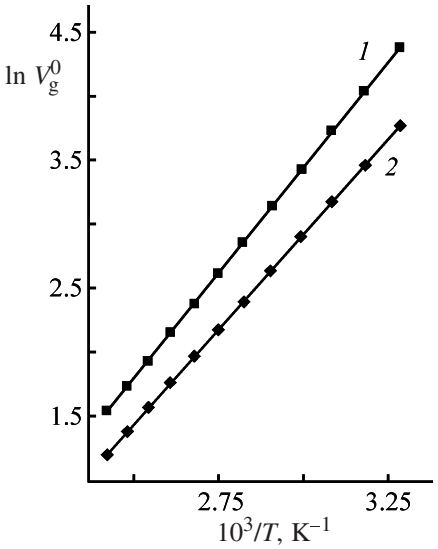

Fig. 1. Retention diagrams of *n*-pentane on (*1*) random and (*2*) block poly(butadiene–styrene). (*T*) Temperature; the same for Fig. 5.

where $K_L\theta_L$ is the contribution from sorbate dissolution in the dispersion medium; θ_L, specific volume of the dispersion medium; K_L, distribution coefficient of the sorbate, characterizing the dissolution process; $(dq/dc)S$, contribution from the adsorption interaction; S, surface area of rigid block domains in unit volume of the polymer; q, surface concentration of sorbate molecules (mol cm^{-2}); and c, concentration of sorbate molecules in the gas phase (mol cm^{-3}).

In our case, $q = [AD] = x$; therefore, solving Eq. (3) for x, we take into account that the contribution of the adsorption to the retention volume is

$$\frac{dq}{dx} = \frac{dx}{dc} = \frac{dx}{d[A]}\frac{d[A]}{dc} = K\frac{dx}{d[A]}. \qquad (5)$$

Then, substituting x in Eqs. (5) and (4), we obtain the following expression for calculating V_g^0:

$$V_g^0 = K_L\theta_L + K_L\{(-K_e/2) + (K_e/2)[1 + N_0(c_0^n + K_e k'h)] \times [1 + 4K_e k'hN_0/(c_n^0 + K_e k'h)^2]^{-1/2}\}S_A, \qquad (6)$$

where h is the peak area (mm); k', detector sensitivity (mol cm^{-2} mm^{-1}); and S_A, surface area of rigid phase domains in 1 cm^3 of the dispersion medium.

It can be readily seen that, with infinitely small samples ($h \to 0$), the expression for the specific retention volume takes the form

$$V_g^0 = K_L\theta_L + K_L K_e(N_0/c_n^0)S_A, \qquad (7)$$

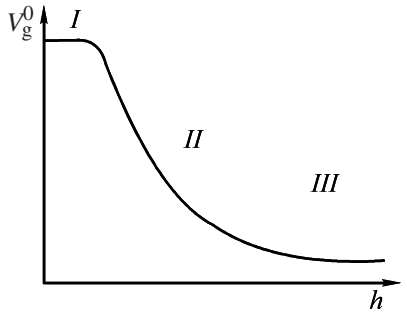

Fig. 2. Theoretical shape of the dependence of the retention volume V_g^0 on height h of the sample peak.

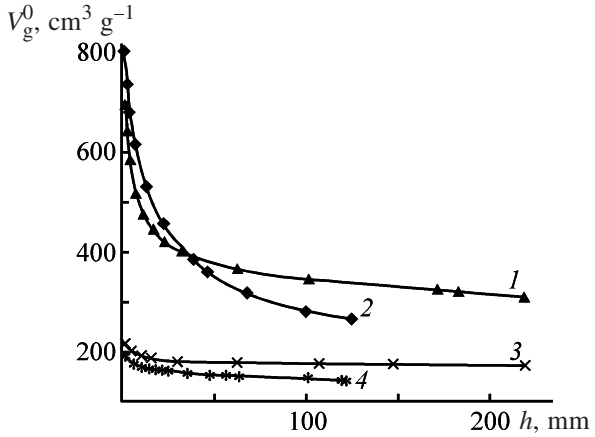

Fig. 3. Retention volume V_g^0 as a function of the height of the sample peak h at 30°C: (*1*) *n*-heptane on straight copolymer of phenolphthalein terephthalate with dimethylsiloxane; (*2*) methylene chloride on straight copolymer of phenolphthalein terephthalate with dimethylsiloxane: (*3*) *n*-heptane on butadiene–styrene block copolymer; and (*4*) methylene chloride on copolymer of phenolphthalein terephthalate with dimethylsiloxane, modified with 2 wt % dinonyl phthalate.

i.e., the retention volume becomes independent of the amount of the sample, and the shape of the chromatographic peak should be symmetrical. Comparing Eqs. (1) and (7), we obtain

$$K_A = K_L K_e (N_0/c_n^0). \quad (8)$$

Thus, K_A, adsorption interaction constant, depends on the ratio of the concentrations of flexible block segments adsorbed on the surface of rigid domains (N_0) and in the interphase layer (c_n^0). Hence, strictly speaking, the constants K_A for the block copolymer and homopolymer of the rigid block do not coincide.

For very large samples ($h \to \infty$), the retention volume described by Eq. (6) decreases, tending to $V_g^0 = K_L\theta_L$, i.e., to the contribution from dissolution of the sorbate in the dispersion medium.

Three portions can be distinguished in the plot of the retention volume vs. sample amount (Fig. 2, *I–III*). It is clear that the retention volume depends on the sample amount only in region *II*, and in regions *I* and *III*, as shown above, it is virtually constant.

It should be noted that actually attempts to construct the dependence $V_g^0 = f(h)$ do not always lead to a plot of the shape shown in Fig. 2. The experimental $V_g^0 = f(h)$ plots are largely determined by the apparatus parameters, primarily by the sensitivity of the chromatographic detector. A highly sensitive detector will give data for regions *I* ($V_{g,h\to 0}^0$), but even in region *II* the device response will become nonlinear.

On the other hand, with a low-sensitivity detector it will be impossible to detect a signal in region *I*.

The experimental dependences of the retention volumes on the sample amount for certain sorbates are shown in Fig. 3. Whereas for the polyester–polysiloxane stationary phase the dependence $V_g^0 = f(h)$ is well pronounced (curves *1*, *2*), for the butadiene–styrene copolymer the retention volume V_g^0 is almost constant, only slightly increasing at small h.

Another important feature of the chromatographic behavior of this polymer is virtually ideally symmetrical shape of the chromatographic peaks, whereas with the polyester–polysiloxane stationary phase the chromatographic peaks are essentially asymmetric (steep front and gently sloping rear wings). It follows from Eq. (6) that the $V_g^0 = f(h)$ dependence should be pronounced if c_n^0 is commensurable with $K_e K' h$. In our study we used the thermal conductivity detector of an LKhM-8MD chromatograph, for which $K' \approx 10^{-10}$ mol cm^{-3} mm^{-1}. Presumably, different block copolymer–sorbate pairs will have different K_e, and in the case of the poly(butadiene–styrene) stationary chromatographic pahse the equilibrium of the process described by Eq. (2) will be virtually fully shifted toward adsorption of flexible block segments on the surface of rigid block domains. In this case, the commensurability condition will not be fulfilled, and region *II* in the $V_g^0 = f(h)$ plot will become extremely narrow, degenerating into a jump, and in the retention diagram the dependence will be linear (because of the lack of the adsorption contribution).

To reveal the influence of the constant on the dependence $V_g^0 = f(h)$, this dependence was calculated by Eq. (6) at $c_n^0 = 5 \times 10^{-9}$ mol cm^{-3} and K_e 1.2, 0.7, 0.4, and 0.1 (Fig. 4). It seems possible to predict the extent of "shielding" of rigid block domains by flexible block chains in one or another copolymer by eval-

uating the compatibility of the homopolymers consisting of the same units as the blocks of the given copolymer. A convenient measure of the mutual compatibility of different polymers is the parameter Δ [7]: $\Delta = (\delta_1 - \delta_2)^2$, where δ_1 and δ_2 are the solubility parameters of the rigid and flexible blocks of the copolymer [(MJ m^{-3})$^{1/2}$]. The solubility parameters are related to the cohesion energy density as $\delta^2 = C$, where C is the cohesion energy density (MJ m^{-3}), $C = N_A w/V$, N_A is the Avogadro number, w is the potential energy of a single molecule, and V is the molar volume [8].

In this case, we proceeded from the assumption that the parameters δ for the rigid and flexible blocks of a copolymer differ from those of the corresponding homopolymer insignificantly. The smaller Δ, the more thermodynamically favorable is the mixing and the higher c_n^0. In particular, for phenolphthalein terephthalate, polydimethylsiloxane, polystyrene, and polybutadiene, δ = 21.4, 14.6, 18.2, and 16.9 (MJ m^{-3})$^{1/2}$, respectively.

It can be readily seen that Δ is the smallest in the polybutadiene–polystyrene pair. In view of this fact, the chromatographic behavior of butadiene–styrene copolymers can be accounted for as follows. As already noted, competing adsorption described by Eq. (2) occurs on the surface of polystyrene domains of the block copolymer. Because of small Δ, the equilibrium is virtually fully shifted toward adsorption of flexible polybutadiene segments rather than sorbate molecules. Actually, all the polystyrene fragments of the macromolecules, incorporated in rigid domains, do not take part in the chromatographic process. As for the random copolymer, it consists of macromolecules of averaged composition in which polystyrene units are uniformly distributed among polybutadiene units, and the formation of rigid nanosized domains is virtually impossible. Under the conditions of our chromatographic experiment (30–140°C), such copolymer is elastic, and the only operative mechanism of the sorbate retention is the dissolution, as in homopolybutadiene.

To finally confirm our hypothesis, we decided to simulate the effect of disappearance of the adsorption mechanism of retention on a polymer for which the occurrence of this mechanism was confirmed previously by RGC. For this purpose, we used the copolymer of phenolphthalein terephthalate and polydimethylsiloxane, whose chromatographic behavior was described in [1]. It was modified with an additive nonvolatile under the experimental conditions and was taken as a stationary chromatographic phase. The

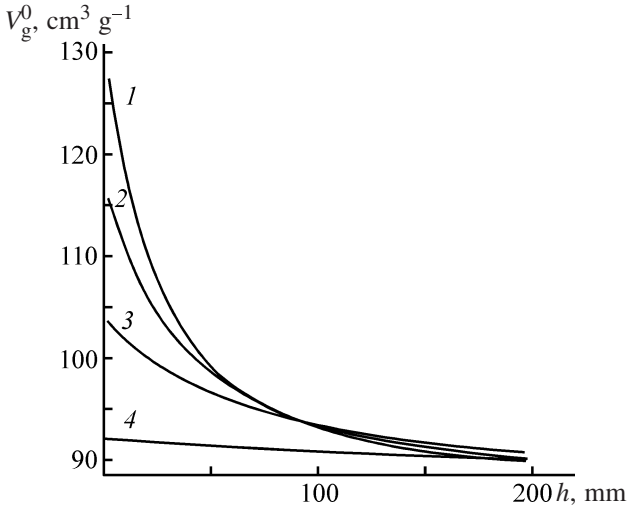

Fig. 4. Calculated dependences of the retention volume V_g^0 on the sample peak height h. $c_n^0 = 5 \times 10^{-9}$ mol cm^{-3}. K_e: (*1*) 1.2, (*2*) 0.7, (*3*) 0.4, and (*4*) 0.1.

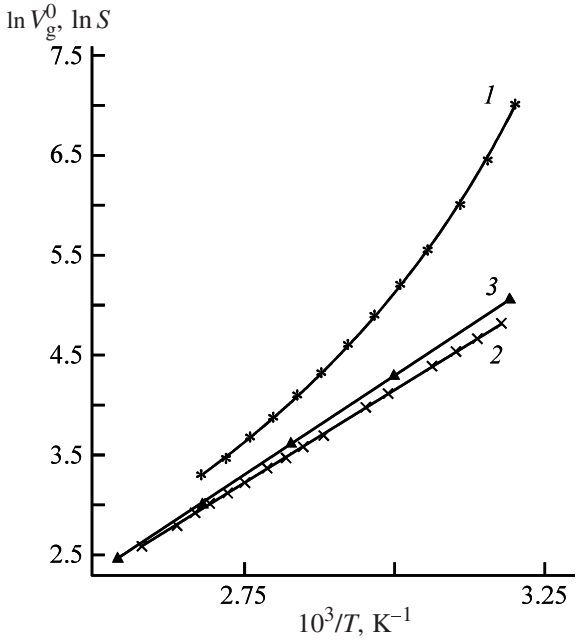

Fig. 5. Retention diagrams of *n*-pentane on (*1*) straight copolymer of phenolphthalein terephthalate with dimethylsiloxane and (*2*) the same copolymer modified with 2% squalene; (*3*) contribution from the dissolution of *n*-pentane in the straight copolymer as a function of reciprocal temperature.

results of the experiment are shown in Fig. 5. Linearization of the retention diagram after modification of the polyester–polysiloxane stationary phase with dinonyl phthalate or squalene indicates that in this case molecules of the additive, being sorbed on rigid block domains, fully shield them from the sorbate molecules, similarly to fragments of polybutadiene chains in butadiene–styrene block copolymer. Previously the

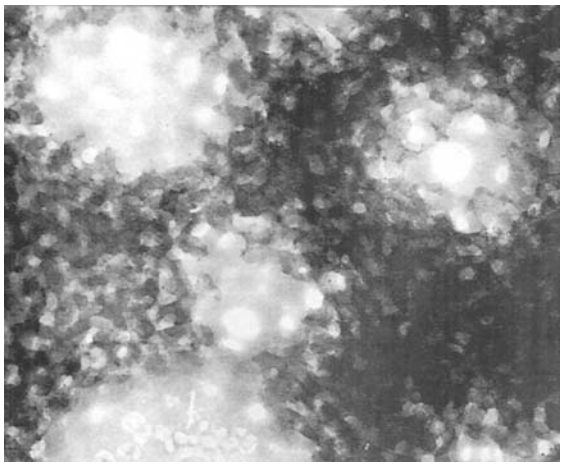

Fig. 6. Micrograph of a nanoscopic structure of a specimen of phenolphthalein terephthalate–dimethylsiloxane copolymer. Magnification 70×10^3.

dependence $\ln S = f(1/T)$ was obtained by calculation from the retention diagram [1]. This dependence almost coincides with the retention diagram for polyester–polysiloxane treated with dinonyl phthalate or squalene (Fig. 5). It should also be noted that modification of the block copolymer with these additives makes the chromatographic peaks less asymmetric.

Electron microscopy, a direct method for studying nanostructured objects, is used widely and for a long time for studying polymers [2]. However, often a minor difference between the optical densities of different blocks of a copolymer makes it impossible to obtain images of high quality with good resolution of details. The problem becomes much simpler if one of the components contains double bonds. High quality of micrographs of these speciments can be attained after their treatment with osmium tetroxide vapor [9, 10]. The OsO_4 molecules add across double bonds in macromolecules and thus increase the optical density of areas rich in an unsaturated component.

According to [11], it is possible to introduce low-molecular-weight unsaturated additives into the polymer, which allows the use of OsO_4 for staining a specimen for electron microscopy. As squalene is an unsaturated compound, this procedure appeared to be suitable for obtaining a micrograph of the phenolphthalein terephthalate copolymer (Fig. 6) demonstrating its nanoscopic structure.

CONCLUSIONS

(1) Factors responsible for the anomalous behavior of butadiene–styrene block copolymer as a stationary phase in a study of its structure by reverse gas chromatography were analyzed. The observed effect was accounted for in terms of the concept of competing adsorption.

(2) The effect of disappearance of the adsorption contribution, observed with butadiene–styrene block copolymer, was simulated with phenolphthalein terephthalate–polydimethylsiloxane copolymer by modification of this copolymer with low-molecular-weight additives.

(3) The conclusions concerning the structure of phenolphthalein terephthalate–polydimethylsiloxane copolymer, made in the previous paper, were confirmed by electron microscopy.

(4) The gas permeability of polymers can be controlled within wide limits by their modification with low-molecular-weight additives, which can be used in the development of membranes of selective gas permeability.

Abstract—Emulsifier-free emulsion polymerization of methyl methacrylate in the presence of potassium persulfate initiator, taken in several different concentrations, at various pH values was studied with the aim to obtain colloidal crystals. The thermal properties of poly(methyl methacrylate) prepared by emulsifier-free emulsion polymerization, as the starting material for fabrication of photonic crystals, were examined in relation to the synthesis conditions.

DOI: 10.1134/S107042720709025X

An important feature of emulsifier-free emulsion polymerization is the possibility of preparing monodisperse polymeric particles with strictly ordered packing, which can serve as a basis for forming colloidal crystals [1, 2]. In turn, from colloidal crystals it is possible to prepare various kinds of photonic crystals opening wide prospects for the development of photonics [3] and showing promise for applications in medicine and optics, as materials for light guides and chemical sensors.

It appeared possible to control the properties of colloidal crystals by using various monomers. In particular, polymeric colloidal crystals based on poly(methyl methacrylate) (PMMA) were studied [2]. It was found [2] that the size of particles formed by emulsifier-free polymerization of methyl methacrylate (MMA) depends on the polymerization conditions and composition of the reaction medium.

At the same time, thermal properties of latex particle powders and of colloidal crystals prepared from these particles have been studied inadequately.

The degradation mechanism of poly(methyl methacrylate) at elevated temperatures has been studied in sufficient detail [4]. Thermal degradation of PMMA occurs by the mechanism of radical unbranched chain reactions. Thermal oxidative degradation of PMMA occurs by the mechanism of branched chain reactions with degenerate chain branching. The main degradation process is depolymerization. The monomer is virtually the only product of PMMA degradation (99% in thermal and 95% in thermal oxidative degradation) [5].

It was shown by mass spectrometry [6] that thermal degradation of atactic PMMA prepared by radical polymerization occurs in three steps. Shibaev et al. [6] assumed that the first degradation step occurring at 120–200°C involves a chain reaction initiated by the decomposition of head-to-head structures in macromolecules. In the second step, at 200–300°C, the degradation is initiated by decomposition of terminal double bonds. The major fraction of the polymer degrades at 300–420°C; the process is initiated by random scission of the macromolecule with the formation of macroradicals which subsequently undergo depolymerization.

It was interesting to examine the thermal properties of PMMA prepared by emulsifier-free emulsion polymerization, as this polymer is a raw material for preparing colloidal crystals. In this study, using DSC and TGA, we examined how the polymerization conditions (initiator concentration, pH) affect the thermal properties of emulsion PMMA.

EXPERIMENTAL

Emulsion polymerization of MMA was performed in an aqueous medium with vigorous stirring at a rate of 1200 rpm. The pH of the medium was adjusted using a pH meter, by adding to double-distilled water the required amount of 0.1 N NaOH or HCl. Water with the adjusted pH was heated to 80°C with continuous

argon bubbling. Then the monomer purified by vacuum distillation was added in an amount of 10 wt % relative to the total weight of the mixture. The mixture was heated for 5 min, after which the required amount of potassium persulfate (analytically pure grade) dissolved in 1 ml of water was added. The reaction was performed at 80°C for 3–5 h depending on the initiator concentration. In the first 10 min the mixture was purged with argon, after which the argon supply was stopped to avoid foaming. The conditions of preparing polymer samples are given in Table 1.

The polymer obtained was filtered off on a membrane filter with a pore size of 0.2 μm under slightly reduced pressure (200–400 mm Hg) and dried in a vacuum oven to constant weight at 60–80°C.

The thermal properties of the samples obtained were studied by DSC and TGA. The DSC studies were performed with a DSK 204 F1 Phoenix differential scanning calorimeter (Netzsch, Germany) in an argon flow (flow rate 20 ml min^{-1}), with linear heating from 20 to 450°C at a rate of 2 or 10 deg min^{-1}. The sample (powder or film) weight was 2.4–6.5 mg. The onset temperatures of particular processes were determined with an accuracy of ±1°C. The glass transition point T_g was determined as an inflection point on the baseline in the region of glass transition (Fig. 1) and was averaged over three replicate measurements (repeatability ±1°C).

The rate of thermal oxidative degradation (TOD) at a constant temperature (302°C) was determined from

* Films prepared from the corresponding powders.

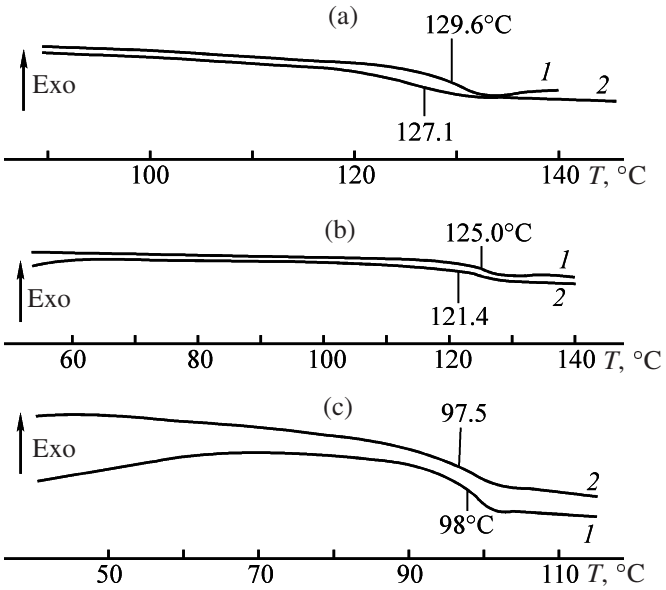

Fig. 2. DSC curves of emulsion PMMA in the form of (a, b) powder and (c) film. Heating rate, deg min^{-1}: (a) 10 and (b, c) 2. Heating run: (*1*) first and (*2*) second, after cooling to room temperature.

the weight loss in an atmosphere with oxygen partial pressure of 200 mm Hg. Samples in the form of ~100-μm-thick films were prepared from a 7–8 wt % solution of emulsion PMMA powder in methylene chloride by casting onto a glass surface followed by vacuum drying at 60–80°C.

The DSC curve (Fig. 1) exhibits the glass transition region and three endothermic peaks corresponding to the degradation of different structures in the PMMA macromolecule. The glass transition points are important characteristics of the emulsion PMMA samples. They appreciably exceed the glass transition points of films cast from powder solutions, and the highest glass transition point is exhibited by samples prepared at the lowest initiator content (Table 2, run nos. 1–3).

The glass transition points of the films are appreciably lower than those of the powders from which these films were prepared. Additional examination of the glass transition region (repeated heating after cooling of powder no. 1 from room temperature to 140°C at a rate of 10 deg min^{-1}) revealed a decrease in the temperature of the inflection point in the DSC curve from 129.6 to 127.1°C (Fig. 2a). The decrease is still more pronounced (from 125.0 to 121.4°C) at a heating rate of 2 deg min^{-1} (Fig. 2b). At the same time, in film sample no. 7a, on repeated heating at a rate of 2 deg min^{-1} after cooling, the glass transition point (97.5 and 98.0°C) remains essentially unchanged (Fig. 2c). This fact indicates that the high glass transition point of the powdered samples may be caused by the ordered structure of the emulsion PMMA in which the macromolecular motion is hindered. These structures are partially broken on heating. In the film samples, the polymer occurs in the glassy state and has no ordered structure, and therefore T_g of the films is considerably lower than that of the powders.

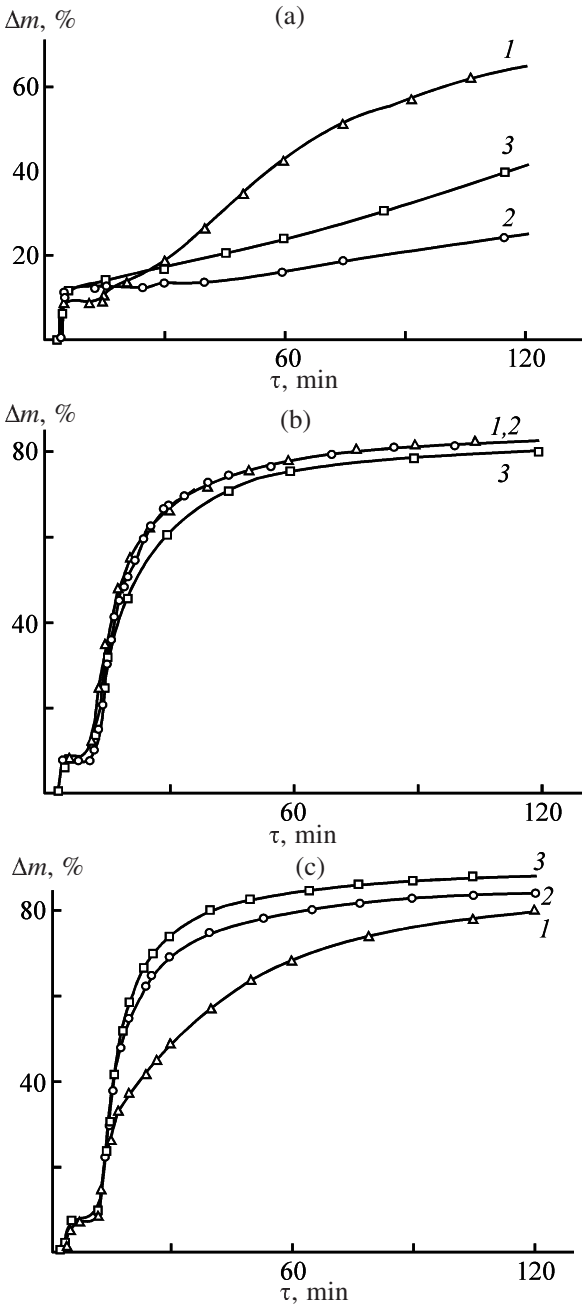

Fig. 3. Curves of weight loss Δm in the course of thermal oxidation degradation of PMMA film. 302°C, oxygen pressure 200 mm Hg. Samples prepared at initiator concentrations of (a) 1.0, (b) 0.5, and (c) 0.1%. (τ) Time. pH: (*1*) 3, (*2*) 7, and (*3*) 10.

As for the endothermic peaks, the temperature ranges of their occurrence suggest that they belong to three steps of thermal degradation of PMMA [6]. The peak areas *S* are proportional to the total thermal effects of the processes occurring in the polymer on heating.

The first DSC peak corresponds to the thermal effect of macromolecule degradation initiated by scission of weak bonds formed by head-to-head recombination of macroradicals. For the samples prepared in neutral medium, the peak area linearly grows with an increase in the initiator concentration. At the minimal initiator concentration (0.1%), the peak area is minimal at all pH values. This fact indicates that under these conditions the rate of macroradical recombination is low.

The second peak in the DSC curve corresponds to initiation of the degradation by cleavage of the terminal double bonds. For the samples prepared at the maximal initiator concentration (1.0%), the peak area grows with decreasing pH. Under these conditions of the polymerization, the disproportionation responsible for the formation of terminal double bonds plays a significant role.

The largest thermal effect is associated with the last step of the degradation, corresponding to random scission of the macromolecules. It is proportional to the area of the third peak. Its intensity grows with a decrease in the catalyst concentration.

A TGA study of thermal oxidative degradation of emulsion PMMA films showed (Figs. 3a–3c) that the polymer samples prepared at the highest initiator concentration (1%, Fig. 3a) were the most heat-resistant, with the highest degradation rate observed with the sample prepared at pH 3 (Fig. 3a, curve *1*). At 0.1% initiator concentration, the dependence of the PMMA heat resistance on pH of the polymerization medium is inverse.

CONCLUSIONS

(1) Increased glass transition points of poly(methyl methacrylate) samples prepared by emulsifier-free emulsion polymerization, compared to the film samples, are consistent with the ordered structure of the latex particles.

(2) Endothermic processes of degradation of emulsion poly(methyl methacrylate) in DSC analysis in an inert medium occur in three steps. Their temperature ranges correspond to the degradation of macromolecules initiated by terminal defective structures and random scission of the backbone.

(3) Thermal oxidative degradation of poly(methyl methacrylate) prepared by emulsifier-free emulsion polymerization occurs more slowly in samples prepared at a higher initiator concentration, which may be due to stabilization of the polymer by terminal sulfate groups of the macromolecules.

Abstract—Complexation of a cationic polyelectrolyte, poly-*N*-benzyl-*N*,*N*-dimethyl-*N*-methacryloyloxyethylammonium chloride, with an anionic surfactant, sodium dodecyl sulfate, in aqueous solutions is studied. The effect of the molecular weight of the polymer on phase separation in the system and on the stability, conformation, and surface activity of the polyelectrolyte–surfactant complexes is examined.

DOI: 10.1134/S1070427207090261

Steadily increasing demand for polyelectrolyte-based materials for production of paints, electrophoretic coatings, cosmetics, and surfactants for oil production and transportation stimulate research in physical chemistry of polyelectrolytes [1–3]. Polyelectrolytes are of particular interest also as active components of drugs [4] and as models for studying the behavior of biopolymers in aqueous and aqueous salt solutions [5]. Practically significant are cationic polyelectrolytes, which are widely used as flocculants [6, 7], additives reducing the hydraulic resistance of turbulent flows of fluids [8], catalysts, ion-exchange resins, sorbents, emulsifiers, and stabilizers.

The presence of reactive functional groups in polyelectrolyte macromolecules is responsible for their ability to form complexes with various high- and low-molecular-weight compounds. Interaction of polyelectrolytes with oppositely charged ions of micelle-forming surfactants results in formation of new amphiphilic polymers with variable lyophilic–lyophobic balance, known as polymer–colloid complexes (PCCs) [9]. Wide use of sorption for recovery of surfactants from process solutions in solving different environmental tasks stimulates interest in studying complexing properties of polyelectrolytes. In the general problem of recovery of surfactants from mixed solutions, of particular significance is such aspect as effects of different factors on the formation, stability, and conformation of polyelectrolyte–surfactant complexes. Polymer–colloid complexes can also be used for synthesis of efficient flocculants selective with respect to some emulsified organic compounds [10].

The formation, structure, and properties of PCCs are strongly influenced by the molecular weight of the polyelectrolyte, the effect being ambiguous and hardly predictable [11–13].

In this study we examined the effect of molecular weight of a cationic polyelectrolyte (CPE), poly-*N*-benzyl-*N*,*N*-dimethyl-*N*-methacryloyloxyethylammonium chloride, on its complexation with an anionic surfactant, sodium dodecyl sulfate (SDS), in aqueous solutions.

EXPERIMENTAL

The CPE samples of various molecular weights MW were prepared from the starting polymer (MW 2.41×10^6) by the ultrasonic degradation (USD) method [14] using a UZDN-1 ultrasonic disintegrator (working frequency 22 kHz; power 4.4 W cm^{-2}) at varied exposure time.

Mild conditions that were selected for USD allowed broad variation of MW and elimination of depolymerization and interchain interactions of functional groups, the latter condition being critical for this study [15]. The molecular weights of the samples were estimated from the viscometric data by the Mark–Houwink equation: $[\eta] = KM^a$, where $[\eta]$ is the intrinsic viscosity (m^3 kg^{-1}), and K and a are con-

Table 1. Characteristics of poly-*N*-benzyl-*N,N*-dimethyl-*N*-methacryloyloxyethylammonium chloride (CPE) samples

Sample no.	Exposure time, min	$[\eta]$, $m^3\ kg^{-1}$	$M \times 10^{-6}$
1	0	0.375	2.41
2	1.5	0.270	1.60
3	3	0.172	0.91
4	20	0.036	0.13

stants (according to [10], $K = 2.94 \times 10^{-4}$ and $a = 0.8$; solvent 0.05 N KBr). The basic characteristics of the samples studied are given in Table 1.

Sodium dodecyl sulfate was purified by threefold recrystallization from ethanol. The purity of SDS was controlled by the critical micelle concentration (CMC) in water using conductometry and tensiometry; CMC was determined to be 8.4×10^{-3} M, which is consistent with the reference data [16].

Solutions were prepared with double-distilled water (conductivity 1×10^{-5} S cm^{-1}).

The phase separation conditions in mixed solutions of the polyelectrolyte and surfactant were studied turbidimetrically. The optical density D was measured on a Specol-10 instrument (Carl Zeiss, Jena, Germany) at $\lambda = 490$ nm against distilled water.

The PCC solutions were prepared by adding dropwise an SDS solution of a fixed concentration to a CPE solution with vigorous stirring. The critical aggregation concentration (CAC) of SDS in the presence of the polymer was determined from data on the solubilization of the organosoluble dye Sudan III. To 5 ml of mixed polymer–surfactant solutions of various compositions, 5 mg of the dye was added, and the system was allowed to stand for a week with intermittent shaking. Finally, excess of the dye was removed by centrifugation at 10000 rpm for 15 min, and the optical density of the solutions at 490 nm was measured. The critical aggregation concentration was determined from the concentration dependence of the optical density of the PCC solutions (as an inflection point of the curve).

The composition of the reaction mixture Z was expressed as the ratio of the molar surfactant concentration to the concentration of the polyelectrolyte units in the solution: $Z = c_{SUR}/c_{PE}$. The polyelectrolyte concentration c_{PE} was 1×10^{-3} (base mol) l^{-1} throughout the experiments with SDS. The surfactant concentration was varied from 1×10^{-6} to 1×10^{-2} M.

The equilibrium SDS concentration was determined potentiometrically with an EM-Br-01 modified commercial dodecyl sulfate selective heterogeneous membrane electrode and a CRYTUR Type 102 calomel reference electrode. The measurements were carried out in a temperature-controlled cell specially designed so to simultaneously obtain potentiometric (on a MICROTECHNA M-120 instrument to within 1 mV) and viscometric data. The electrode function was linear over a wide SDS concentration range. Performance characteristics of the electrodes and the analytical procedure were described in detail previously [17].

The degree of association of the polyelectrolyte with SDS θ was estimated by Eq. (1):

$$\theta = \frac{c_{SUR} - c_{SUR}^{eq}}{c_{PE}}, \quad (1)$$

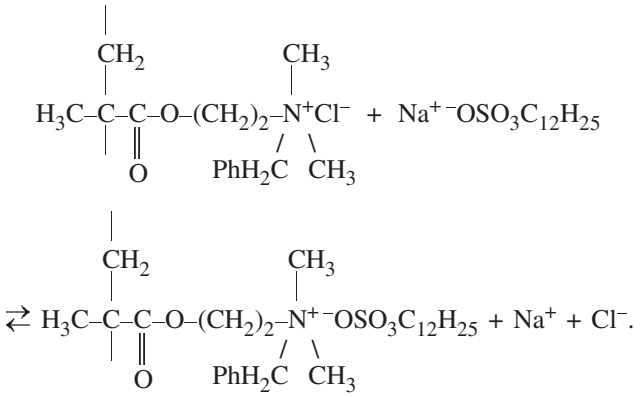
where c_{SUR} and c_{SUR}^{eq} are the total and equilibrium concentrations of the surfactant in solution.

The stability of the PE–surfactant complexes was characterized by the apparent dissociation constant K_d:

$$K_d = \frac{c_{PE}(Z - \theta)(1 - \theta)}{\theta}. \quad (2)$$

Viscometric measurements were carried out at 25°C with a VPZh-1 Ubbelohde viscometer (capillary diameter 0.54 mm) to within 2%.

Polyelectrolytes bind oppositely charged ions of surfactants through both electrostatic interaction of charged groups and hydrophobic interaction of hydrocarbon radicals of surfactants with hydrophobic fragments of the polymer chain [3, 18]. The electrostatic mechanism may be represented by the following scheme:



The use of surfactant-selective electrodes allows us to obtain SDS association isotherms (dependences of

the degree of association θ on the equilibrium SDS concentration) (Fig. 1). The initial section of the isotherm corresponds to the formation of intramolecular SDS micelles inside the macromolecular globule ("microreactor"). Figure 1 shows that, for all the curves, this section is S-shaped, which is typical of cooperative association. The CPE–SDS complex starts to form in an aqueous solution even at extremely low SDS concentrations. The critical aggregation concentration of SDS corresponding to the onset of cooperative association of the surfactant with the polyelectrolyte is near $c_{SUR} = 5 \times 10^{-5}$ M for all the CPE samples. This result is consistent with the published data [1], according to which surfactants start to bind to oppositely charged polyelectrolytes just at surfactant concentrations lower than CMC by 1–3 orders of magnitude. Saturation of the isotherms corresponds to the saturation of the polyelectrolyte macromolecules with the SDS ions. It should be pointed out that, with increasing molecular weight of the polymer, the limiting degree of association of the polyelectrolyte with SDS (θ_{max}) decreases (Table 2). Further increase in the SDS concentration results in degradation of the intramolecular micelles, i.e., in decreasing θ, and also in release of a considerable part of the SDS ions from the complex to the solution. The indicated structural transformation of the polyelectrolyte–surfactant complex was observed for the first time by Bilyalov et al. [19] in studying complexation of poly-4-vinyl-*N*-butylpyridinium bromide and attributed to collapse of the macrochains during coil–globule transition.

The change in the binding mode of SDS to cationic polyelectrolytes is more clearly demonstrated by the dependence of the degree of association θ on the composition of the reaction mixture *Z* (Fig. 2). Up to $Z = 0.7$, SDS is entirely associated with the polymer, which is reflected in a considerable increase in θ. As seen from Fig. 2, over the indicated range of *Z*, the run of the curves is practically independent of the molecular weight of the polyelectrolyte. However, the stability of the complexes increases with increasing molecular weight of the polymer samples, reaching a maximum at MW 2.41×10^6 (Table 2). At $Z > 0.8$, θ starts to abruptly decrease, which, as indicated above, is due to collapse of the macrochains during coil–globule conformation transition. For PCCs containing CPEs of lower molecular weights, the effect of dissociation of the complex is more clearly pronounced (Fig. 2, curves *3, 4*), being observed at lower θ.

To improve the efficiency of the use of polyelectrolyte–surfactant complexes as flocculants in waste-

water treatment to remove surfactants, it is important to examine the effects of factors controlling the phase conditions of the complexes. Depending on the component ratio in mixed polyelectrolyte–surfactant solutions, both water-soluble nonstoichiometric and insoluble stoichiometric complexes can be formed. According to [20], three regions can be distinguished. The first one corresponds to $Z < Z_0$. In the zero solution, water-soluble PE–surfactant complexes are formed. In this case, free PE molecules coexist with PCC particles of the composition $\varphi = \varphi_0$. In the second region, at $Z_0 < Z < Z_1$, the zero solution contains only PCC particles whose composition φ practically coincides with the composition of the reaction mixture Z. Further hydrophobization of the complex ($Z \geq Z_1$) gives the third composition range, in which the remaining free fragments of the polymer chains cannot keep the complex particles in solution, and the system undergoes phase separation at the macroscopic level. In this case, practically stoichiometric complex ($\varphi \sim 1$) is separated as a precipitate.

To identify the existence ranges of the water-soluble and insoluble stoichiometric PCCs, we used turbidimetric titration. Figure 3 shows the concentration (by surfactant) dependences of the optical density of solutions of the cationic polyelectrolytes of various molecular weights. On adding relatively small amounts of SDS to the CPE solutions, we visually observed opalescence and an abrupt increase in the solution turbidity. No soluble polyelectrolyte–SDS complexes were formed. The PCC particles are strongly associated species forming colloid dispersions in aqueous solutions. At $Z = 0.7$, i.e., at the limiting Z_1, we observed the maximum of the optical density, which corresponds to the maximal hydrophobization of the macromolecular coil and to the highest degree of association in the isotherms $\theta = f(\log c^{eq}_{SUR})$. The position of the maximum in the turbidimetric titration curves is practically independent of the molecular weight of CPE. As the surfactant concentration in the reaction mixture increases, the optical density in the titration curves remarkably decreases as a result of precipitation of the stoichiometric complex. In the same composition range of the CPE–SDS mixtures, the degree of association of SDS decreases (Fig. 2). The height of the maximum in the turbidimetric titration curves strongly depends on the molecular weight of the polymer. With increasing MW, the optical density of the PCC solutions decreases, suggesting a decrease in the interaction strength in the CPE–SDS mixtures.

Based on the above experimental data, a preliminary finding is that the conformation and size of the macromolecular coils considerably affect the complexation between the cationic polyelectrolyte and SDS in aqueous solutions. The dependence of the reduced viscosity η_{sp}/c on Z (Fig. 4) provides additional evidence in favor of this suggestion, since a direct correlation occurs between the mean-square size of macromolecules $(\bar{R}^2)^{1.5}$ and η_{sp}/c [21–23]. The points on the ordinate ($Z = 0$) characterize the conformation state of the CPE samples in the aqueous solution without addition of SDS. According to the experimental data, with increasing MW, the hydrodynamic size of the macromolecular coils increases, and the maximal $(\bar{R}^2)^{1.5}$ was obtained for sample no. 1 with the maximal MW. Addition of SDS to solutions of all the polymer samples with various molecular weights results in regular decrease in the reduced viscosity, suggesting that the PE macromolecules become more compact as a result of screening of their charges by the SDS ions and hydrophobic interaction of the macroions with the alkyl radicals of SDS. Transformation to the globular conformation in

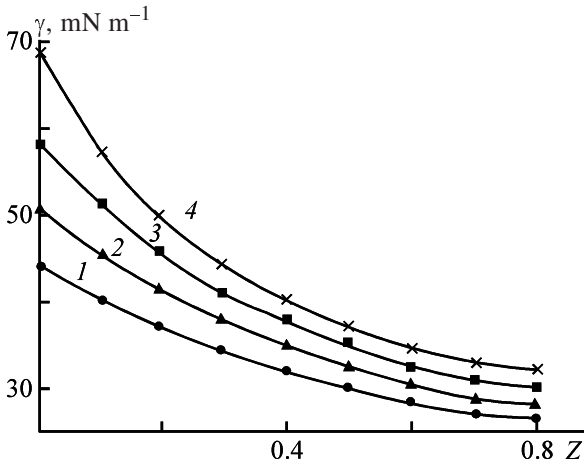

Fig. 5. Surface tension γ of CPE–SDS solutions at the solution/air interface as a function of *Z*.

the polymer macromolecules causes the maximal decrease in the solution viscosity to the value close to that of the pure solvent ($\eta_{sp} \to 0$). As seen from Fig. 4, the molecular weight of the polymer noticeably affects the dependence of the reduced viscosity on *Z*. First, the slope of the viscosity isotherms, characterizing the degree of compaction of the macromolecular coil, increases with increasing molecular weight of CPE. Second, the higher the molecular weight of the polymer, i.e., the larger the initial size of the macromolecular coil, the larger amount of SDS is required for the coil–globule conformation transition to occur. Sample nos. 1 and 2 (MW 2.41×10^6 and 1.60×10^6) take the globular conformation in the phase separation range ($Z = 0.7$); sample no. 3 (MW 0.91×10^6), at $Z = 0.5$; and sample no. 4 with the lowest MW, at $Z = 0.2$, i.e., just on introduction of very small amount of SDS.

Structure and properties of PCCs, as well as the prospects for their use as flocculants considerably depend on the component ratio. Particularly, the adsorption of PE–surfactant complexes is controlled by the ionization and conformation conditions of macromolecules in both the bulk of the phase and in the surface layers. Figure 5 shows the tensiometric titration curves of aqueous CPE solutions with an SDS solution at the solution/air interface. The surface tension of the PCC solutions decreases with increasing *Z*, i.e., as the SDS ions are associated, reaching a minimum for all the samples at $Z = 0.8$ corresponding to the phase separation with precipitation of the stoichiometric complex. With increasing MW, the slope of the surface tension isotherms of the cationic polyelectrolytes decreases, and the surface activity of PCC at the solution/air interface decreases as well. The highest surface activity is typical of the CPE–surfactant complex obtained with the lowest-molecular-weight polymer.

CONCLUSIONS

(1) The molecular weight of the cationic polyelectrolyte has a complex effect on its complexation with an anionic surfactant, sodium dodecyl sulfate, in aqueous solutions. Electrostatic interaction between anions of the surfactant and cationic groups of the polyelectrolyte starts at a surfactant concentration lower by two orders of magnitude than the critical micelle concentration, and the stability of the resulting complexes increases with increasing molecular weight of the polyelectrolyte.

(2) The effect of the molecular weight of the polyelectrolyte on structural transformations of polyelectrolyte–surfactant complexes was analyzed. The complexes exhibit high surface activity at the water/air interface, which decreases with increasing molecular weight of the polymer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Viscosity of Melts and Solutions of Polyolefins Modified with Binary Mixtures of 2,4-Toluylene Diisocyanate and Lactams of Various Structrues

Abstract—The influence of binary mixtures of 2,4-toluylene diisocyanate and lactams of various structures on the viscosity of melts and solutions of polyolefin formulations was examined.

DOI: 10.1134/S1070427207090273

The progress of science and engineering requires the development of new types of polymeric materials with the properties that are not provided by the existing plastics. There are two ways to solve this problem: synthesis of new polymers with the required properties and modification of the existing polymers to impart to them the required characteristics. The second approach is more promising because of a wide set of commercially available polymers, among which polyolefins (POs) occupy a particular place because of availability of the raw materials and good performance [1].

Modification of polymers with individual compounds allows improvement of many processing and service characterustics. However, in many cases the use of binary mixtures gives an effect that considerably exceeds the effect of separate components (synergic effect), and the results attained with mixtures of modifying agents cannot be attained with individual compounds. From this viewpoint, modification with binary systems opens wide prospects for improving the properties of polymeric materials. On the other hand, it may be difficult to find components that enhance the effect of each other.

Of great interest is modification with binary mixtures of compounds that are capable of copolymerization under the conditions of PO processing. Among such compounds are isocyanates and lactams, which copolymerized under the conditions of anionic initiation at temperatures above 140°C to give copolymers whose macro- and supramolecular characteristics vary in a wide range depending on the composition of the starting monomer mixture and structure of the reactants.

In [2] we described chemical reactions occurring between components of the modifying mixture and between them and the modification substrate. The goal of this study was to find how the components of binary mixtures of 2,4-toluylene diisocyanate (TDI) with lactams of various structures affect the viscosity of melts and solutions of PO formulations, and also to reveal the relationship between the lactam structure and the rheological properties of the resulting polymeric compounds.

EXPERIMENTAL

The modification substrates were polypropylene (PP) of Balen 01 030 grade [TU (Technical Specification) 2211-020-00 203 521–96] produced by Polipropilen Private Company and high-density polyethylene (HDPE) of 277-73 grade [GOST (State Standard) 16 338–85] produced by the Kazan'orgsintez Open Joint-Stock Company.

As components of the binary mixture we used TDI, ε-caprolactam (ε-CLM), α-pyrrolidone (α-pyr), and laurolactam (LL). Their choice was governed by the following facts. Early studies of the influence exerted by the structure of isocyanates on the effect of PO modification showed that TDI as a PO modifier is more effective than 4,4'-diphenylmethane diisocyanate and SKU-PFL urethane prepolymer [3]. Therefore, it seems appropriate to use specifically this polymer as one of the components of the modifying mixture. As second component of the binary mixtures we used lac-

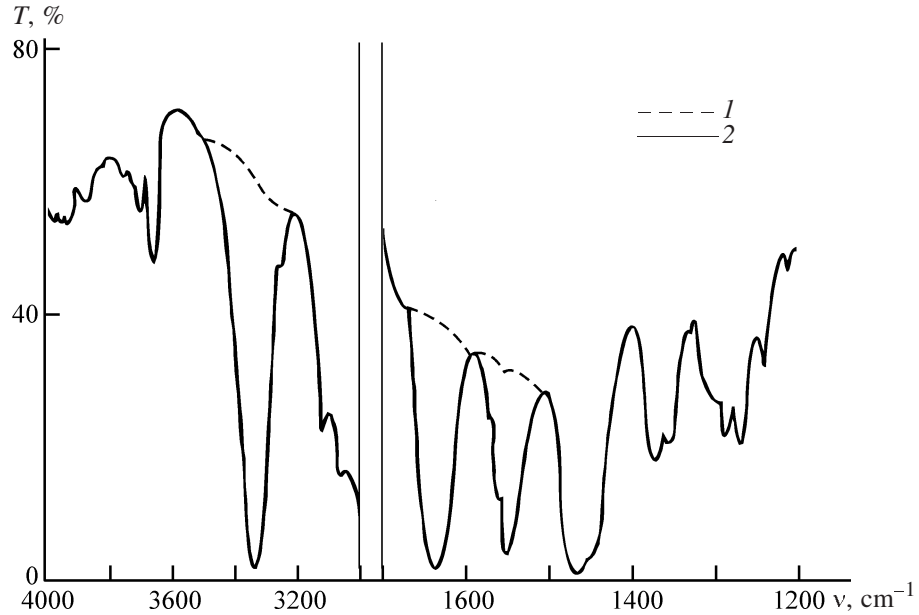

Fig. 1. IR spectra of (*1*) initial HDPE and (*2*) that modified with 12 wt % TDI + LL.

tams of various structures, differing in the ring strain and hence in the reactivity toward TDI.

To optimize the search for effective modifier formulations, we used the simplex–lattice experimental design [4]. As approximating polynomials we used third- and fourth-order Scheffe models.

The PO modification was performed in a melt on rollers for 5 min at 185°C for PP and 165°C for HDPE. The components of the modifying mixture were introduced simultaneously in the presence of 0.1 wt % catalyst, sodium caprolactamate.

The middle-IR spectra of the interaction products of the polyolefin and binary mixtures were taken on a Perkin–Elmer PC-16 spectrophotometer from the samples prepared as films. Quantitative IR analysis was performed with an internal reference [5].

The melt flow index (MFI) was determined according to GOST 11645–83 on an IIRT-type capillary viscometer at a capillary diameter of 0.2095 ± 0.0005 cm under the following conditions: 230°C, 2.16 kg load for PP; 190°C, 5 kg load for HDPE.

The intrinsic viscosity [η] in *o*-xylene at 25°C was determined with an Ubbelohde viscometer with a capillary diameter of 0.054 cm. The sample was preliminarily dissolved in an organic solvent. Then the solution was placed in a viscometer arranged in a thermostat (135°C for PP, 125°C for HDPE). After thermostating for 15 min, the outflow time was measured.

It should be noted that lactams added to PO are capable of copolymerization with TDI. In particular, in the IR spectrum of HDPE modified with a TDI : LL = 50 : 50 mixture (Fig. 1), there are new absorption bands at 1630–1680 and 1530–1550 cm^{-1}, corresponding to the C=O stretching, C–N stretching, and N–H bending vibrations in secondary amides, and at 3200–3400 cm^{-1}, corresponding to N–H stretching vibrations in secondary amides.

To examine changes that occur in PO on the macromolecular level, we measured the viscosities of melts and solutions of the compounds obtained.

The melt viscosities were evaluated by MFI, which is one of the most important processing characteristics determining the feasibility of polymer processing by plastic deformation methods.

We found that introduction into PP (MFI 2.6 g in 10 min) of 3 wt % LL or 3 wt % α-pyr increases MFI to 2.6 and 3.8 g/10 min, respectively (Figs. 2a, 2b).

Introduction of 3 wt % TDI into PP increases MFI to 3.5 g/10 min. The similar effect is attained on adding ε-CLM (Fig. 3a).

It should be noted that the highest MFI is attained when the components are taken in combination (Fig. 3a), which suggests that they interact not only with PP, but also with each other.

The composition–property diagrams for the ternary systems show that the optimum is shifted toward mixed formulations. Therefore, we performed chemical modification of PO with binary mixtures taken in an amount of up to 12 wt %. As the concentration

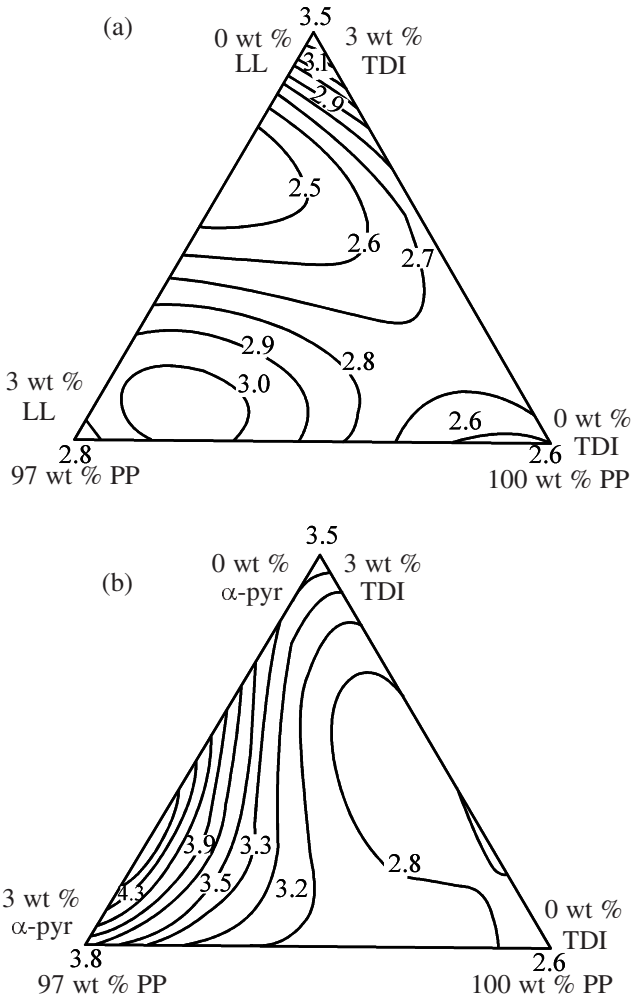

Fig. 2. Composition–property (MFI) diagrams of the systems (a) PP + TDI + LL and (b) PP + TDI + α-pyr.

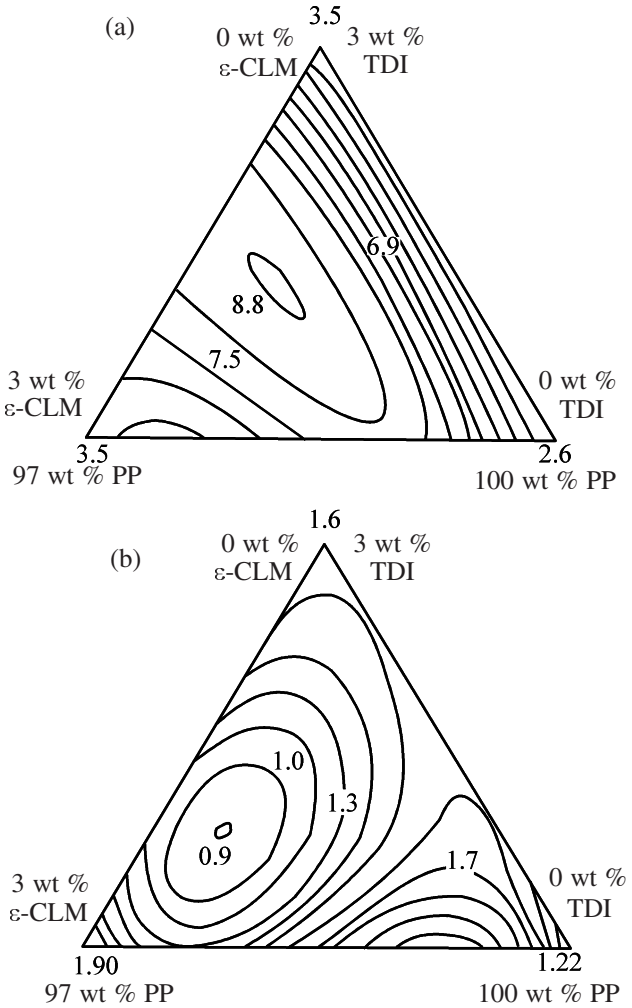

Fig. 3. Composition–property {(a) MFI, (b) [η]} diagrams of the system PP + TDI + ε-CLM.

interval is relatively wide, we used the fourth-order Scheffe model, which describes the real system more adequately because of the larger number of the experimental points. Data on the variation of MFI of PO formulations are given in Table 1.

Introduction of LL into PO does not noticeably alter MFI. Apparently, being capable of polymerization under the conditions of PO processing, LL forms

* (σ) Breaking tensile stress and (ε) relative breaking elongation.

polyamide structures, with the effect being dependent on the processing temperature and more pronounced with PP. Presumably, under real conditions only the isocyanate component can react with PO in the presence of anionic catalysts.

On adding to PP other lactams, in particular, α-pyr, in a mixture with TDI, MFI reaches 5.8 g/10 min. With ε-CLM taken instead of α-pyr, MFI does not increase appreciably. However, ε-CLM added to PP without TDI increases MFI of PP considerably (to 19.2 g/10 min).

A different pattern is observed when binary mixtures of α-CLM and TDI are added to HDPE. In this case, the chemical structure of lactam affects MFI less significantly. The viscosity of HDPE decreases only at high (>9 wt %) concentrations of lactams, and the highest MFI is attained with ε-CLM as modifier (Table 2).

It should be noted that MFI regularly increases when mixtures of TDI and lactams, rather than the individual components, are used. Comparison of the effects of the additives on MFI of the polymeric compounds based on PP and HDPE shows that a decrease in the melt viscosity is observed in approximately the same concentration regions, i.e., the effect of the modifying mixture is only slightly dependent on the nature of the polyolefin.

Table 4. Intrinsic viscosities [η] of PP modified with TDI–lactam mixtures

Composition, wt %			[η], $cm^3\ g^{-1}$	
HDPE	TDI	lactam	α-pyr	LL
100	–	–	1.95	1.95
88	–	12	1.42	2.30
88	12	–	1.56	1.56
91	–	9	2.40	1.41
91	9	–	2.01	2.01
94	–	6	2.08	2.05
94	6	–	2.28	2.28
91	6	3	1.50	1.95
94	3	3	2.51	2.13

Introduction of lactams into POs alters the physicomechanical properties of the polymeric compounds. For example, introduction of α-pyr and ε-CLM into PO in most cases led to an increase in the relative elongation with increasing lactam content, especially with five-membered α-pyr (Table 3).

It is known [6] that the intrinsic viscosity [η] characterizes the behavior of an isolated macromolecule in an infinitely dilute solution. Therefore, a study of the behavior of macromolecules in a solution, where the distance to the adjacent macromolecule is long, is of certain interest.

Figure 3b shows that TDI and ε-CLM, when added to PP, exert effects of different signs. At low concentrations, there is a well-defined maximum of [η], apparently due to grafting of the copolyamide fragment to PO macromolecules, causing their branching. At high concentrations, formation of copolyamides may occur along with such interaction. Introduction of LL into PO does not appreciably affect [η]. This is apparently associated with the fact that the large length of the LL aliphatic radical levels off the difference in the sign of the effects exerted by the mixtures in different concentration ranges (Table 4).

CONCLUSION

The use of binary systems consisting of isocyanates and lactams allows significant improvement of the rheological properties of polyolefins. There are two

concentration ranges in which these effects are maximal. The first optimum, at small additions, is due to improvement of the structure of the polyolefins, caused by deactivation of the residual unsaturated bonds. The second optimum, at large additions, is apparently due to appearance of a copolyamide constituent, which is not chemicall bound to the polyolefin macromolecule and can form a separate phase.

Abstract—The sorption of polyionene 1,4-MePh on the silica gel surface was studied. The silica gel modified with polyionene sorbed was used for sorption preconcentration of MoO_4^{2-}, WO_4^{2-}, $Cr_2O_7^{2-}$, and VO_3^- anions from aqueous solutions. The sorption isotherms of these anions on the initial and modified silica gels were obtained and analyzed.

DOI: 10.1134/S1070427207090285

Polymeric anion exchangers are widely used for sorption preconcentration and separation of Mo(VI) [1–3], Cr(VI) [4, 5], W(VI) [6], and V(V) [3, 5] anions. Although these polymeric sorbents are characterized by high sorption capacity, their drawbacks are large swelling and low sorption rate. In contrast to polymeric resins, modified silica gels and other inorganic sorbents do not swell and exhibit good kinetic characteristics. However, these sorbents have lower sorption capacity for oxoanions of polyvalent metals [7–10].

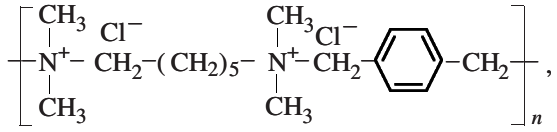
It is known [11, 12] that immobilization of polymers containing a quaternary nitrogen atom on the silica gel surface exhibiting weak cation-exchange properties allows preparation of inorganic anion exchangers. We can expect that such modified silica gels will combine useful properties of both an inorganic sorbent (no swelling) and anion-exchange resin (high sorption capaciity).

In this study silica gel was modified with a water-soluble polyionene containing a quaternary nitrogen atom in the polymer backbone. The most effective method for preparing such polymers is based on the Menshutkin reaction between substituted tertiary diamines and dihalides [13]. The reaction yields no low-molecular-weight products, and the backbone of the resulting polymer consists of regularly alternating quaternary ammonium groups in the backbone (onium polymerization). However, properties of silica gels modified with polyionenes have not yet been studied.

In this study we examined the sorption of Mo(VI), Cr(VI), W(VI), and V(V) from aqueous solutions on silica gels modified with polyionenes.

EXPERIMENTAL

The polyionene 1,4-MePh was prepared by the method reported in [14]. Its monomeric unit has the following structure:



$n \leq 6$.

Silica gel (Merck, fraction 0.06 – 0.16 mm, specific surface area 256 $m^2\ g^{-1}$) was used as a support. The polyionene amount immobilized on the silica gel surface was determined spectrophotometrically from the light absorption of the polyionene–Bromophenol Blue complex at 600 nm.

The sorption of metals on the silica gel modified with immobilized polyionene was studied under static conditions. The sorption was carried out on the contact of the sorbent (0.1 g) with aqueous $(NH_4)_2MoO_4$, $(NH_4)_2Cr_2O_7$, Na_2WO_4, and $NaVO_3$ (25 ml). The equilibrium content of these anions before and after sorption was determined spectrophotometrically from the light absorption of their colored complexes:

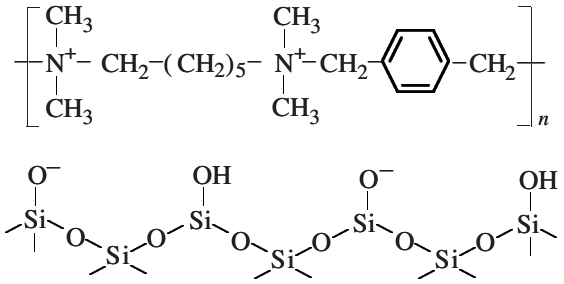
molybdate anions, in the form of a red complex with SCN^- anions [15]; tungstate anions, in the form of tungstic–molybdic heteropoly blue formed in the presence of molybdenum salts [16]; bichromate anions, in the form of a violet complex with diphenylcarbazide in acidic solution [15]; and polyvanadate anions, in the form of a red-orange peroxide complex [17]. The spectrophotometric measurements were carried out on an SF-46 spectrophotometer (LOMO, Russia) in a 1-cm optical cell at the following wavelengths: molybdenum(VI) 470 nm, chromium(VI) 540 nm, tungsten(VI) 610 nm, and vanadium(V) 490 nm.

The degree of metal sorption was calculated by the formula

$$R = (m_{ads}/m_0) \times 100\% = (m_3 - m)/m_0 \times 100\%,$$

where m_0 is the metal content of the initial solution; m, metal content of the equilibrium solution after sorption ($m = cV$, where c is the equilibrium metal concentration in the solution, and V, solution volume).

It is known that, due to partial dissociation of the surface silanol groups, the silica gel surface is negatively charged. Therefore, polyionene can be immobilized on the silica gel surface by electrostatic intermolecular interactions according to the following scheme:



The sorption of polyionene on silica gel (Fig. 1) is described by the Langmuir sorption isotherm typical of chemisorption. The maximal sorption capacity of silica gel for polyionene is 100 mg g^{-1}.

The influence of pH on degree of sorption of aqueous Mo(VI), W(VI), Cr(VI), and V(V) anions on the silica gel modified with immobilized polyionene is illustrated by the table.

It is seen that W(VI) and Cr(VI) are sorbed most efficiently (to 95 and 65%, respectively) from acidic solutions (pH 2–4) where these metals are present in the form of polytungstate and polychromate anions [18]. The degree of sorption of polyvanadate anions is approximately 70–80% and is weakly dependent on

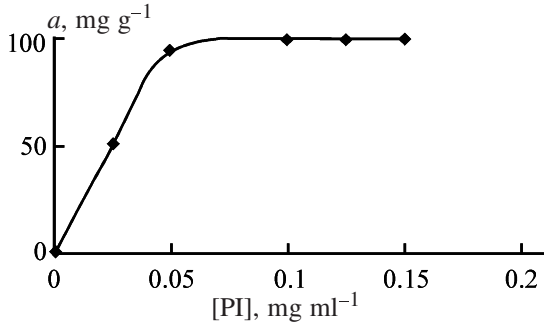


Fig. 1. Sorption isotherm of polyionene on silica gel: (a) polyionene sorption and [PI] equilibrium polyionene concentration in the solution.

pH variations. This means that the sorption of V(V) on the modified silica gel is insensitive to the kind of its soluble species varying from $V_3O_9^{3-}$ in a strongly alkaline medium to $V_{10}O_{28}^{6-}$ at pH 1 [18]. The molybdate anions are efficiently sorbed (to 95%) from acidic solutions where they are present in the form of iso-

Degree of adsorption of molybdate, bichromate, tungstate, and vanadate anions on silica gel modified with polyionene at different pH values. Static sorption; sorbent weight 0.1 g, sorption time 10 min

pH	Degree of adsorption, %			
	Mo(VI)	W(VI)	Cr(VI)	V(V)
1.0	88.0	67.0	8.9	66.6
1.7	95.2	74.0	64.9	50.5

6.8	88.1	0	11.2	70.6
7.0	88.0	0	10.2	67.6
8.0	67.7	0	25.0	70.6
9.2	67.0	55.6	0	70.6

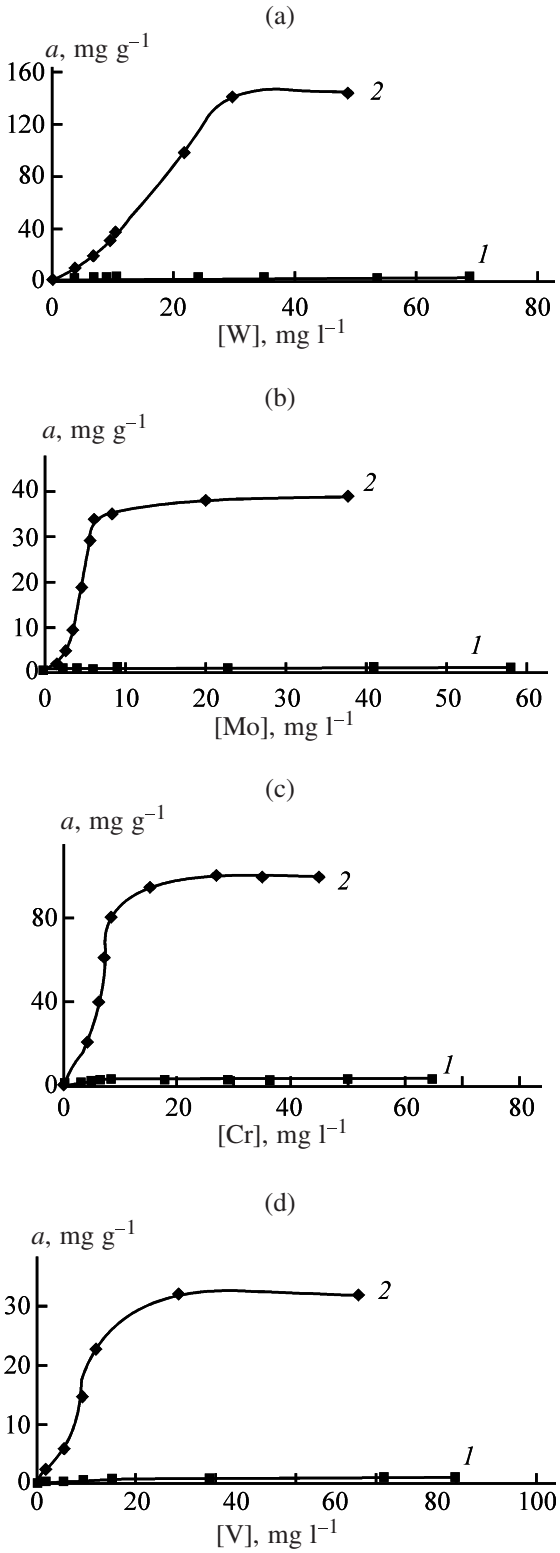

Fig. 3. Adsorption isotherms of (a) tungsten(VI), (b) molybdenum(VI), (c) chromium(VI), and (d) vanadium(V) on the (*1*) initial and (*2*) modified silica gel. (*a*) Adsorption; ([W], [Mo], [Cr], [V]) equilibrium metal concentrations in the solution. pH: (a, d) 4 and (b, c) 2.

poly acids. In going to alkaline media, where Mo(VI) occurs in the form of MoO_4^{2-}, its sorption decreases to 67% [18].

Figure 2 shows the adsorption kinetic curves for the metal-containing anions on silica gel modified with polyionene at optimal pH values for particular metals. It was found that the maximal sorption recovery of metals under consideration is attained within several minutes. Thus, silica gel modified with immobilized polyionene exhibits fairly fast sorption kinetics typical of the initial silica gel. Therefore, this modified sorbent can be used for recovering the metal concerned from aqueous solutions under dynamic conditions.

The comparison of the adsorption isotherms of molybdate, bichromate, tungstate, and vanadate anions (Figs. 3a–3d) on (*1*) initial silica gel and (*2*) initial silica gel modified with polyionene shows that the modified sorbent exhibits pronounced selectivity to these metal-containing anions. Their distribution ratios between modified silica gel and aqueous phase are as follows: Mo(VI), close to 2500; W(VI), 2800; Cr(VI), 4400; and V(V), 2500 ml g^{-1}. The limiting sorption of these metals (mg g^{-1}) calculated from their sorption isotherms is as follows: molybdenum, up to 38; chromium, up to 110; tungsten, up to 158; and vanadium, up to 32. These data show that the sorption power of the modified sorbent for the metal-containing anions exceeds that of the initial silica gel by a factor of 60–100. Thus, silica gel modified with polyionene can be used for efficient preconcentration of Mo(VI), Cr(VI), W(VI), and V(V) anions from aqueous solutions.

CONCLUSIONS

(1) Silica gel modified with immobilized polyionene efficiently sorbs MoO_4^{2-}, $Cr_2O_7^{2-}$, WO_4^{2-}, and VO_3^- anions from aqueous solutions. The sorption of molybdenum(VI) and chromium(VI) is the strongest in the pH range from 2 to 4 in which these metals are present in the form of polymolybdate and polychromate. The efficient sorption of tungsten(VI) and vanadium(V) is observed at pH > 4 favorable for formation of polytungstate(VI) and polyvanadate(V) anions.

(2) The characteristics of silica gel modified with polyionene combine useful properties of an inorganic sorbent (silica gel) and an anion-exchange resin (polyionene). This sorbent does not swell and has good kinetic characteristics and fairly high sorption capacity for Mo(VI), Cr(VI), Mo(VI), and V(V)

anions. Therefore, the modified silica gel can be used for recovery of these anions from wastewater and their preconcentration.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Model of Thermodynamic Compatibility of the Filler with the Polymeric Matrix in a Composite

S. S. Glazkov

Voronezh State Architecture and Building University, Voronezh, Russia

Received December 28, 2006; in final form, July 2007

Abstract—A thermodynamic approach to predicting the compatibility of the binder with the filler by calculating the nonpolar and acid–base parameters of the filler and polymeric matrix was considered. The calculated adhesion stabilities of the composite systems are consistent with the structural and functional features of their ingredients.

DOI: 10.1134/S1070427207090297

At present, the mutual compatibility of polymeric materials, in particular, ingredients of composites, is mostly estimated qualitatively and empirically. This approach does not adequately disclose the nature of interphase interactions of the binder with the filler, the main ingredients of composite materials (CMs). At the same time, specifically the interface is the main source of defects in CMs [1].

Bormotov et al. [2] believe that the binder in CMs provides simultaneous operation under load of all the filler particles via sticking them together into a conglomerate as a single whole. Therefore, a major role in strengthening of CMs belongs to adhesion at the polymer–filler interface. However, the nature of the polymer–filler interaction is very complicated and is not adequately understood [2].

As the starting point in elucidating the criteria of thermodynamic compatibility of the CM ingredients we will take the fundamental principle of thermodynamics postulating a negative free Gibbs energy, or the isobaric–isothermal potential, as the precondition to a spontaneous process [3].

Let us consider the expression suggested by van Oss [3] for the adhesion energy ΔG_{ij}^{a} (equal to the adhesion work W_{ij}^{a} with the opposite sign) of the ingredients i and j constituting the CM:

$$\Delta G_{ij}^{a} = \gamma_{ij} - \gamma_i - \gamma_j = -2[(\gamma_i^{LW}\gamma_i^{LW})^{1/2} + (\gamma_i^{+}\gamma_j^{-})^{1/2} + (\gamma_i^{-}\gamma_j^{+})^{1/2}]. \quad (1)$$

The free surface energy (FSE) of the CM ingredients is determined by the equation

$$\gamma = \gamma^{LW} + \gamma^{AB} = \gamma^{LW} + 2(\gamma_i^{+}\gamma_j^{-})^{1/2}, \quad (2)$$

where γ^{LW} are Livshits–van der Waals nonpolar terms, and γ^{AB}, acid–base interaction parameters (γ^{+} are parameters of Lewis acids, and γ^{-}, of Lewis bases).

Analysis of Eqs. (1) and (2) for highly compatible ingredients of CMs yields an expression determining the tendency of the system to a decrease in the free interphase adhesion energy:

$$\Delta G_{ij}^{a} = -2(\gamma_i^{+}\gamma_j^{-})^{1/2}. \quad (3)$$

Analysis of relationship (3) with account of Eqs. (1) and (2) gives preconditions for the tendency of the system to the maximal thermodynamic stability.

(1) $\Delta G_{ij}^{a} < 0$, if $\gamma_{ij} < (\gamma_i + \gamma_j)$ and $|\gamma_{ij}| \to 0$. Formal analysis of the first necessary and sufficient condition of thermodynamic compatibility suggests that, according to (3), the maximal decrease in the free interphase surface energy is always negative. However, the system will tend to the maximal thermodynamic stability via reduction of the interphase boundary until its disappearance at the maximal decrease of the interphase surface energy (tendency of its module to zero). The more prominent this tendency in interphase interaction, the more stable the composite.

(2) $\gamma_{ij}^{LW} \gg \gamma_{ij}^{AB}$. In this case, the surfaces of the interacting phases are mostly hydrophobic, and, being similar, they are well compatible. However, we will

demonstrate below that this applies mostly to the case of a hydrophobic nonpolar phase surface only. The ingredients are well compatible and form a stable composite.

(3) $\gamma_i^{LW} \gg \gamma_j^{AB}$, $\gamma_i^{AB} \ll \gamma_j^{AB}$. Composite materials in which the hydrophobic phase surface of one ingredient is poorly compatible with the hydrophilic phase surface of the other. The thermodynamic stability of such CMs is extremely low, and under exploitation the ingredient with a lower content migrates to the surface of the article. Technologists call this phenomenon the "sweating" of poorly compatible ingredients on the CM surface, accompanied by deterioration of its properties.

(4) $\gamma_{ij}^{LW} \ll \gamma_{ij}^{AB}$, $\gamma_i^{AB} \approx \gamma_j^{AB}$. The ingredients are hydrophilic and compatible, and the stability increases in the case when the acid component of one of the interacting phases is close in the parameter value to the base component of the other contacting phase, and vice versa, which can be expressed as follows:

$$\gamma_i^+ \approx \gamma_j^-,$$

$$\gamma_i^- \approx \gamma_j^+.$$

Thus, the best compatibility of the ingredients of a composite material is achieved in cases 2 and 4, provided that condition 1 is satisfied. For nonpolar, hydrophobic materials, characterized by the Livshits–van der Waals terms of FSE, the compatibility of the materials is obvious, while that for polar, hydrophilic materials is not unambiguous, as follows from condition 4. For these materials the compatibility tends to grow with leveling of the parameters of the acid and base components of the two contacting phases. In the simplified form, this can be formulated as the plus of one phase should be equal in magnitude to the minus of the other phase. This provides the maximal adhesion contact accompanied by the maximal decrease of the free interphase surface energy.

Methods for estimation of the surface tension of liquids are well known, while those for the free surface energy of solids are lacking. There exist several methods for indirect estimation of γ_s parameters. Based on the concept of additive contribution of the dispersion and polar terms, Owens and Wendt [4] and Good and van Oss [5] measured the contact wetting angle of a solid using a number of test liquids. The polar term is attributed [5] to short-range, basically donor–acceptor, interactions.

To determine the acid–base and nonpolar parameters, we measured the wettability of the examined surfaces of the materials with test liquids whose thermodynamic FSEs parameters can be found in reference books [nonpolar test (diiodomethane) and two polar (water and formamide) liquids]. We measured the contact wetting angles S on the solid surface being examined, substituted them in the system of Eqs. (4)–(6) with three variables, and obtained the acid–base (γ_s^+ and γ_s^-) and nonpolar (γ_s^{LW}) parameters of FSE of this solid:

Table 1. Surface energy terms of test liquids

Liquid	γ	γ^{LW}	γ^{AB}	γ^+	γ^-	γ^{AB}/γ, %
	mJ m^{-1}					
Water	72.80	21.80	51.00	25.50	25.50	70.06
Diiodomethane	50.80	50.80	0.00	0.00	0.00	0.00
Formamide	58.00	39.00	19.00	2.28	39.60	32.76

$$\gamma_s^{LW} = 0.25\gamma_{test}(1 + \cos\theta_{test})^2 + 0.25\gamma_{test}^{LW}(1 + \cos\theta_{test})^2, \quad (4)$$

$$\gamma_{11} = (1 + \cos\theta_1)^2 = (\gamma_s^{LW}\gamma_{11}^{LW})^{1/2} + 2(\gamma_s^+\gamma_{11}^-)^{1/2} + 2(\gamma_s^-\gamma_{11}^+)^{1/2}, \quad (5)$$

$$\gamma_{11} = (1 + \cos\theta_2)^2 = (\gamma_s^{LW}\gamma_{12}^{LW})^{1/2} + 2(\gamma_s^+\gamma_{12}^-)^{1/2} + 2(\gamma_s^-\gamma_{12}^+)^{1/2}, \quad (6)$$

where γ is FSE (for liquids, surface tension of liquids, mJ m^{-2}); superscript LW refers to physical nonpolar (Livshits–van der Waals) terms of FSE, mJ m^{-2}); θ is contact angle, deg, of wetting of the solid surface with the test liquid; subscript test characterizes the test nonpolar or inert liquid, i.e., diiodomethane; subscripts s and l refer to solid and liquid, respectively; subscripts 1 and 2 refer to the first and second of the two polar test liquids, respectively; and superscripts + and – refer to the Lewis acid and base terms of the surface tension, respectively.

For the liquids chosen, the values of the parameters γ, γ^{LW}, γ^{AB}, γ^+, and γ^- are known (Table 1).

EXPERIMENTAL

To combine nonpolar polyethylene waste with polar particles of a wood filler and improve the mechanical characteristics of the manufactured wood–polymeric materials (WPMs), we suggested treatment of the filler surface with modifiers based on synthetic

Table 2. Surface energy terms (mJ m^{-2}) of various solid materials

ethylene–propylene rubber, SKEPT-40TN [TU (Technical Specification) 2294-022-05766-801-014] and a solution of a copolymer of 4-vinylcyclohexene with maleic anhydride (OBMA-6). We used sawdust with particles having a thickness of 1.0–1.5 mm, width of 1.0–2.0 mm, and length of 5.0 mm and recycled polyethylene (RPE) with the particle size of 3.0 mm.

Specimens for measurements of FSE of the WPM components were prepared as follows. Recycled polymer specimens were prepared as plates. To this end, an agglomerate of recycled polymers was heated in a mold under pressure to a temperature exceeding by 10–20°C the melting point and then was cooled. To determine FSE of the sawdust, a block of pine from which it was obtained was cut at 20°C and 65% humidity into $1000 \times 100 \times 15$-mm cleats, whose tangential surfaces were planed. From the treated cleats we cut out ten specimens of a smaller size, $180 \times 12 \times 6$ mm. To prevent physicochemical modification of the wood surface, we used just prepared specimens to be tested only once. To determine FSE of the modified sawdust, the pine cleats of the same shape were treated with OBMA-6 by impregnation with a 80% aqueous solution of the copolymer (4% of the weight of the wood specimens). Next, the cleats were treated in an oven with programmed temperature rise from room temperature to 170°C.

Table 2 presents the calculated FSE, γ_s, of solids (standard absolute error ≤1%; correlation coefficient for graphic determination of FSE is ≥0.995), its three terms, γ^{LW}, γ^+, and γ^-, and the fraction of the polar term of FSE, γ^{AB}/γ.

Comparative analysis of the discussed approaches to assessment of the surface energy terms (Table 2) suggests that the van Oss method [5] has a number of advantages. In particular, it provides a better convergence of the experimental values of the surface energy terms and the wetting angles calculated therefrom.

The above-mentioned criteria of good compatibility of the CM ingredients imply either hydrophobic or monopolar ingredients, of which one should be a Lewis acid, and the other, a Lewis base. To combine hydrophilic sawdust with hydrophobic plastics, wood was treated with 6% OBMA-6 copolymer [6]. The fraction of the acid–base term of FSE of wood decreased from 17 to 3.6% (Table 2).

We found that a polymeric modifier with the structure of a surfactant modifies the surface by reducing its acid component, rather than simply reduces the interphase tension. A minor increase in basicity (Table 2) can be associated with an increase in the number of oxygen atoms in wood due to formation of ester bonds between the hydroxy groups in wood and carboxy groups in the copolymer and incorporation of the double bonds of the copolymer. Increase in the Livshits–van der Waals term is due both to a decrease in the acid–base term and appearance of a nonpolar hydrocarbon radical of the copolymer on the wood surface.

CONCLUSIONS

(1) The thermodynamic compatibility of filler, unmodified pine sawdust and that treated with the 4-vinylcyclohexene–maleic acid anhydride copolymer, with the binder based on recycled polyethylene was tentatively estimated from calculations and analysis of the experimental data.

(2) A low-molecular-weight polyelectrolyte is capable of directed modification of a wood-based filler.

(3) This fact reasonably agrees with the calculational and statistical data for the terms of the free surface energy, as well as with the compatibility criteria proposed on their basis and the structural and functional features of the ingredients of the composite materials.

Abstract—A procedure was developed for purification of concentrated hemoglobin solutions from hemolyzate of human erythrocytes to remove soluble cellular impurities using a frontal chromatographic process on an anion exchanger under conditions of selective absorption of impurities and the absence of sorption of the target product, hemoglobin.

DOI: 10.1134/S1070427207090303

Hemoglobin (Hb), the main respiratory blood protein, is contained in specific cells, erythrocytes, serving the most important function of blood, reversible transfer of oxygen from lungs to tissues [1].

An Hb solution is obtained by breakdown of erythrocytes using the osmotic hemolysis with the subsequent removal of insoluble cellular fragments (stroma) by centrifugation. The resulting solution of hemolyzate contains Hb in a high concentration. Along with Hb, soluble components of erythrocyte membranes, the products of cellular metabolism, having no definite functional and molecular characteristics, pass into the solution. Typically, these are phospholipids and other phosphorus-containing components of a cell and also intracellular proteins and enzymes, the residues of plasma and membrane proteins.

One of serious problems arising in using Hb solutions as a basis for the development of blood substitutes, oxygen carriers [2], is the possibility of toxic reactions caused by the impurities, soluble stroma components. In this connection, it becomes necessary to develop procedures for hemolyzate purification to remove side cellular components. There are published data on procedures of Hb purification to remove impurities by affinity chromatography [3], displacement preparative HPLC [4], and ion-exchange chromatography using cationic and anionic systems [5]. The chromatographic methods suggested usually involved presorption of Hb from the hemolyzate solution with subsequent desorption in a gradient of pH or salt concentration in the eluting solution.

To be suitable as a base for a blood substitute (oxygen carrier), Hb (MW 64 500) should practically fully preserve the physiological activity, which poses stringent requirements upon operation with its solutions, such as narrow range of ionic strength, pH, temperature, and the shortest contact time with the sorbent. In this connection, as a method for purifying Hb from hemolyzate solutions containing Hb in high concentrations we suggested and studied the frontal version of anion-exchange liquid chromatography under such conditions when the main protein, Hb, is not sorbed but foreign soluble components are selectively absorbed from the hemolyzate.

EXPERIMENTAL

We used an EDE-10p anion exchanger (Plastics Plant, Nizhni Tagil, Sverdlovsk oblast, Russia). The sorption experiments were performed with the anion exchanger (grain size 0.1–0.2 mm) in the mixed OH–Cl form, prepared by titration of the OH form of the anion exchanger with 0.2 N HCl in 0.15 N NaCl to the corresponding equilibrium pH value.

Removal of impurities from the hemolyzate was studied in two modes: static (sorption with stirring for 2 h at 20°C) and dynamic (column size 6.5 × 1.2 cm, anion exchanger volume 6 ml, which corresponds to 2 g of dry sorbent, solution flow velocity 25 ml h^{-1} cm^{-2}). Approximately 80 ml of concentrated Hb solution (hemolyzate) was passed through the column; 5-ml fractions were collected and analyzed.

Hemoglobin was prepared from erythrocytes of human blood by osmotic hemolysis of cells. The erythrocytes were separated from blood serum by centrifugation (3000 rpm, 4°C, 20 min) and carefully

Table 1. Sorption of N- and P-containing components from hemolyzate on anion exchanger under dynamic conditions

Initial hemolyzate					Sorption			
Hb, mg ml^{-1}	pH	content, mg per gram of Hb		procedure of Hb precipitation	pH_{eq} of anion exchanger	sorbed, mg per gram of anion exchanger		% of initial
		N	P			N	P	
58	6.6	1.08	–	TCAA	7.4–7.6	0.92	–	29
50	6.8	3.30	–	$ZnSO_4$	6.8	1.25	–	25
50	6.8	2.20	–	$ZnSO_4$	7.9	1.10	–	20
50	6.8	–	1.04	TCAA	6.8	–	1.13	78
50	6.8	–	1.06	$ZnSO_4$	7.9	–	1.15	80

washed several times with 0.15 N NaCl solution. Washing solutions were removed by centrifugation. The osmotic hemolysis of the resulting erythrocyte mass was performed by addition of ice-cold distilled water in a volume ratio erythrocytes : water = 1 : 3 for 1 h in the cold with intermittent stirring. Then, insoluble degraded shells of erythrocytes (stroma) were separated by centrifugation (6000 rpm, 4°C, 20 min), the hemolyzate solution was withdrawn; pH was measured, and the concentration of Hb in the form of its stable cyano derivative was determined spectrophotometrically at a wavelength of 540 nm [6].

The presence of soluble stroma components in the hemolyzate and purified Hb solutions were determined visually from the turbidity of the solution (precipitation) appearing upon addition of a saturated ammonium sulfate solution in 1 : 1 volume ratio. The presence of soluble phospholipids was estimated qualitatively with hydroxylamine and iron chloride [7] from the appearance of a purple color of the samples applied to paper (against the background of Hb). The sensitivity of the procedure was 0.5 μg of phosphorus.

For quantitative determination of a low content of impurities, Hb was precipitated from the hemolyzate solution with 15% trichloroacetic acid (TCAA) to the final concentration of 3%. The mixture was thoroughly stirred, and the precipitate was separated by centrifugation and discarded.

In precipitation of Hb with zinc salts, pH 8.4 of the solution was adjusted with a saturated sodium tetraborate solution. An 0.03 M $ZnSO_4$ solution was added in a ratio $ZnSO_4$: Hb = 12 mol mol^{-1} with stirring. The precipitate of the resulting complex was separated by centrifugation. In transparent colorless solution, supernatant, the content of total nitrogen and phosphorus was determined.

Nitrogen-containing protein components were analyzed for total nitrogen by the modified Kjeldahl micromethod [8] by combustion of the sample in sulfuric acid with the catalyst (K_2SO_4 + $CuSO_4$). The ammonia formed was removed with water vapor and absorbed by 0.01 N H_2SO_4, after which the nitrogen content was determined by titration.

Phosphorus-containing components were determined by the Fiske–Subbarow method [9] using Eikonogen as a reducing agent. The phosphorus amount was determined spectrophotometrically using the calibration dependence at a wavelength of 720 nm.

The immunoassay of stroma impurities was based on the procedure of preparation of membrane specimens [10].

Hemoglobin is an extremely labile protein and in aqueous solutions with variation of pH it is readily subjected to autooxidation (irreversible oxidation of heme iron) to form biologically inactive methemoglobin. Therefore, outside erythrocyte Hb can occur in a solution in the functionally active state only in a narrow pH range from 6.3 to 7.8 in the vicinity of the isoelectric point of Hb (6.8–7.0) and in solutions with ionic strength close to the physiological value (approximately 0.15).

Since the content of impurity components in the hemolyzate is insignificant (from 0.5 to 2–3% of the content of the main protein, Hb), high concentrations of Hb (5–7%) hamper their quantitative estimation. The impurity phosphorus- and nitrogen-containing components were analyzed before and after sorption after precipitation of Hb from the solution with TCAA or $ZnSO_4$. The phosphorus amount in the supernatant did not depend on the procedure of Hb removal and was 1.0–1.1 mg of P per gram of Hb, and after precipitation of Hb with zinc sulfate the supernatant contained the largest amount of nitrogen-containing impurities, up to 3.3 mg of N per gram of Hb (Table 1).

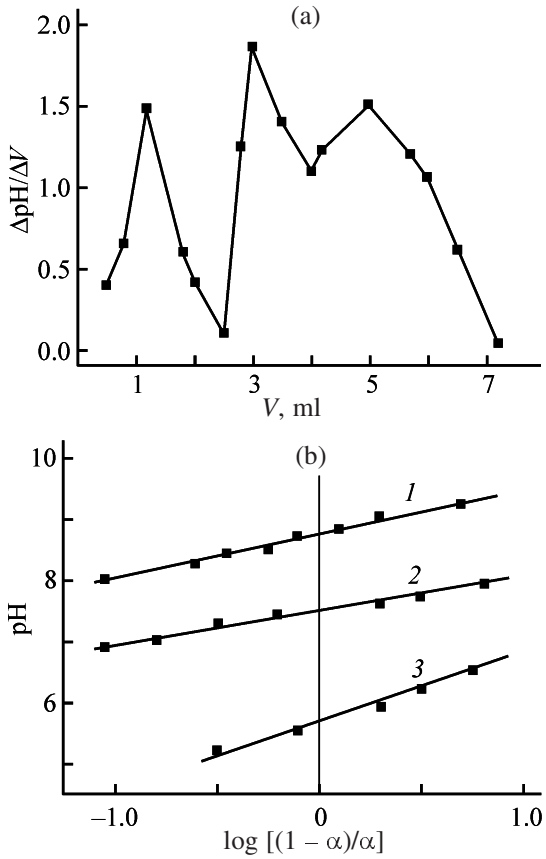

Fig. 1. Results of titration of EDE-10p anion exchanger plotted in (a) $\Delta pH/\Delta V$–V coordinates and (b) Henderson–Hasselbach coordinates. (a) Titrant 0.2 N solution of HCl in 0.15 N NaCl, weighed portion of anion exchanger 0.2 g, OH form. ($\Delta pH/\Delta V$) Variation of pH of the equilibrium solution as a result of addition of ΔV ml of titrant. (b) (*1*) Quaternary ammonium groups, (*2*) tertiary amino groups, and (*3*) secondary amino groups.

It is well known that many impurity proteins have isoelectric points in acidic medium [11], and phosphorus-containing components of cellular shells are mainly negatively charged. Therefore, for sorption of a wide set of impurity components from concentrated solutions of Hb we used polyfunctional anion exchanger EDE-10p, the product of polycondensation of polyethylenepolyamines with epichlorohydrin containing positively charged groups of various basicities.

Table 2. Characteristic of titrated groups of anion exchanger

Functional groups	TEC, mg-equiv per gram of anion exchanger	Titration pH	$pK_{\alpha=0.5}$
Quaternary ammonium	2.8	10.6–8.0	8.8
Tertiary amino	1.7	8.0–6.7	7.5
Secondary amino	1.7	6.7–4.3	5.7

To evaluate the basicity of the anion exchanger and its total exchange capacity (TEC), we performed potentiometric titration of functional groups by the method of individual weighed portions. For the polyfunctional anion exchanger, we considered the completion of titration of each type of functional groups from the differential titration curves plotted in the $\Delta pH/\Delta V$–V coordinates (V is the titrant volume, Fig. 1a). The basicity of three types of anion-exchange groups of the sorbent was determined by expressing the titration results in the Henderson–Hasselbach coordinates (Fig. 1b), pH vs. $\log[(1 - \alpha)/\alpha]$, where α is the degree of ionization. At $(1 - \alpha)/\alpha = 1$, the $pK_{\alpha=0.5}$ value corresponds to the pH value at which groups of a certain type are 50% ionized. The results are presented in Table 2. We determined that titration of the anion exchanger in the OH form is complete at pH 4.2–4.3, and for Cl form, at pH 10.5–10.6, i.e., the pH range of ionization of anion exchange groups of the sorbent is from 10.6 to 4.3. This range is suitable for sorption of soluble stroma components of uncertain nature from a hemolyzate solution.

In the vicinity of the isoelectric point of Hb, its molecule has zero total electric charge balanced with respect to positively and negatively charged functional groups. In this range, strongly basic groups of the anion exchanger are ionized completely, tertiary amino groups are half-ionized, and secondary amino groups able to form hydrogen bonds and participate in weaker interactions are very weakly ionized.

It should be noted that at pH > 8.5 Hb is significantly sorbed from the hemolyzate with the anion exchanger, since under these conditions Hb molecules have significant negative charge. It was shown in preliminary experiments that in the vicinity of the isoelectric point Hb is not sorbed on the anion exchanger, whereas stroma impurities are absorbed from the hemolyzate solution.

The optimum composition of the mixed OH–Cl form of the anion exchanger for absorption of stroma impurities was determined under static conditions. The anion exchanger was titrated until a certain pH of the equilibrium solution, pH_{eq}, was attained, after which the solution was removed by centrifugation. The impurities were sorbed from the hemolyzate under static conditions with stirring for 2 h at the weight ratio anion exchanger : Hb = 1 : 1. After re-

moval of the anion exchanger by centrifugation and precipitation of Hb, we determined the content of impurity phosphorus-containing components in the supernatant. The amount of impurities absorbed by the sorbent was estimated from the difference of the concentrations before and after sorption. The results are shown in Fig. 2.

The maximum absorption of phosphorus-containing impurities was observed for the anion-exchanger sample titrated to pH 5.5–5.7, when all three types of anion-exchange groups are ionized. However, we chose pH 6.5–7.7, which is the optimal range of equilibrium pH values of anion exchanger for preservation of the biological activity of Hb, when Hb undergoes autooxidation to a lesser extent and absorption of impurities remains significant even under static conditions of sorption.

The influence of the degree of ionization of functional groups in the range of pH_{eq} 6.8–7.9 on absorption of impurities from the hemolyzate is presented in Table 1. Absorption of phosphorus-containing impurity components in the dynamic frontal process reached 78–80% of the initial amount, and absorption of nitrogen-containing stroma impurities was 20–30% in the absence of Hb sorption.

The breakthrough curves of frontal chromatography of hemolyzate on anion exchanger (pH_{eq} 7.3) are shown in Fig. 3. The solution corresponding to the free column volume (6 ml) before appearance of colored solution at the outlet of the column was discarded, and in the subsequently collected fractions the hemoglobin and phosphorus concentrations c_{Hb} and c_P were determined. In the initial hemolyzate solution c_{Hb} = 58 mg ml^{-1} and c_P = 62 μg ml^{-1}. As follows from Fig. 3, in the first eight fractions (approximately 40 ml) phosphorus-containing components are practically absent, while Hb concentration remains essentially at the initial level. In this experiment 2.3 g of purified Hb was obtained.

Variation of pH of the initial hemolyzate solutions from 6.3 to 7.7 insignificantly affects the degree of chromatographic purification of Hb (with respect to absorption of phosphorus-containing components), but the absorption somewhat increased in the pH range equal to isoelectric point of Hb (pH 6.8) (Table 3).

In all sorption chromatographic experiments, the qualitative reactions for soluble stroma elements and for phospholipids gave negative results.

To make sure that the obtained degree of purification of concentrated Hb solutions is sufficient for

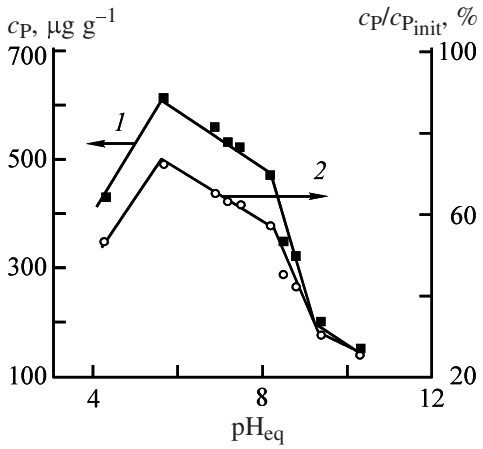

Fig. 2. Sorption of phosphorus-containing components from the hemolyzate of erythrocytes under static conditions as a function of pH_{eq} of the anion exchanger. elimination of undesirable side reactions caused by stroma impurities in the hemolyzate, we used a highly sensitive immunological test for formation of antigen complex (in solutions of purified Hb and initial hemolyzate) with antibodies (in the antiserum). Formation of antigen–antibody complex was monitored from the ring precipitation reaction. For this purpose we used the solutions of the initial hemolyzate and purified 5% solution of Hb obtained after sorption of soluble stroma impurities under static conditions with variation of the Hb : anion exchanger weight ratio (Table 4).

Table 3. Sorption of phosphorus-containing components from hemolyzate solutions on anion exchanger (pH_{eq} 7.7) under dynamic conditions. c_{Hb} = 58 mg ml^{-1}

$pH_{hemolyzate}$	Phosphorus concentration in supernatant, mg per gram of Hb	After sorption on anion exchanger		
		pH of Hb solution in fractions	sorbed P*	
			mg per gram of anion exchanger	% of initial
6.3	1.09	7.7–7.0	2.1	60
6.7–6.8	1.05	7.9–7.4	1.8–2.0	66–70
7.4	1.05	8.0–7.8	1.6	57

Table 4. Results of immunoassay of the initial hemolyzate of erythrocytes and hemoglobin solution purified on anion exchanger under static conditions with stirring. 20°C, sorption duration 2 h, c_{Hb} 52 mg ml^{-1}, pH 6.8

Sample	Amount of anion exchanger in sorption, g	Anion exchanger : Hb, g g^{-1}	Value of immunological reaction, points*
Initial hemolyzate	–	–	2+
1	0.10	0.2	1+
2	0.50	1.0	0
3	0.75	1.5	0
4	1.00	2.0	0
5	1.50	3.0	0
6	2.00	4.0	0
Homogenate of erythrocyte membranes (stroma)	–	–	4+

* Points from 0 to 4+ at 1 : 2 dilution.

Immunoassay shows (Table 4) that solutions of Hb purified on anion exchanger under static conditions with variation of the anion exchanger : Hb weight ratio from 1.0 to 4.0 contain no stroma impurities. At the ratio of 0.2, the presence of impurities can be attributed to insufficient amount of the sorbent.

Thus, the possibility of selectively absorbing undesirable toxic impurities with an anion exchanger in the frontal chromatographic process without loss of the target protein, Hb, provided complete recovery of purified Hb and allowed us to find the conditions at which Hb molecules remain essentially intact and to scale the process.

The chromatographic purification of Hb to remove stroma impurities was scaled on a column containing 1.2 l of anion exchanger (420 g of dry sorbent). As a result of frontal chromatographic purification of the hemolyzate, approximately 9 l of a solution of purified Hb (approximately 5%) was obtained.

It should be emphasized that after purification Hb preserves its biological activity, first of all, the ability to reversibly bind oxygen. With respect to all functional parameters analyzed on the basis of the dissociation curves of oxyhemoglobin obtained on a Hem-O-Scan equipment (Aminco, the United States), the solutions of purified Hb were similar to Hb in the initial hemolyzate. The amount of methemoglobin in chromatographically purified HB was 2–4% of the total content of Hb at its initial content in the hemolyzate of 0.5–1.0%.

CONCLUSIONS

(1) The developed frontal chromatographic procedure of purification of concentrated hemoglobin solutions from hemolyzate of erythrocytes to remove soluble cell components on a polyfunctional anion exchanger provides complete recovery of hemoglobin with preservation of its biological activity and functional characteristics.

(2) The conditions of selective sorption of nitrogen- and phosphorus-containing stroma impurities, excluding sorption of the target protein, hemoglobin, were found.

Received: October 9, 2006; in final form, March 2007

Abstract—A water softening method was saggested. The optimal parameters of the external electric field were determined and apparatus for the implementation of the suggested method was described. The mechanism of the coagulation of hardness salts was studied.

DOI: 10.1134/S1070427207090315

The hardness determined by the concentration of dissolved calcium and magnesium salts is one of important quantitative characteristics of quality of natural water. Thermal, chemical, and ion-exchange methods are used for water softening, i.e., for removal of hardness salts from it [1]. The thermal method of water softening does not remove magnesium salts and converts a half of dissolved calcium salts into insoluble compounds. The chemical and ion-exchange methods involve ion-exchange processes to substitute cations of dissolved calcium and magnesium salts by the cations of chemical reagents used for water softening. The above methods of water softening lead to secondary chemical contamination of water.

The known methods of electromagnetic softening do not provide the necessary technical result and require considerable energy expenditure per unit volume of treated water.

A softening method involving treatment of water with a pulsed electric field was developed [2]. In this method the energy expenditure per unit volume of treated water is minimal, with no chemical contamination of water.

In this study, the optimal parameters of the external electric field ensuring the necessary degree of softening of natural water were determined.

EXPERIMENTAL

It was found that the exposure of water, irrespective of its volume, to a low-frequency electric field causes hardness salts to convert into insoluble compounds which form a precipitate containing 75% calcium salts and 25% magnesium salts on the average. The necessary degree of water softening is obtained at a frequency of ac electric field varying from 1 to 5 Hz, intensity of the external electric field in the treatment zone of 2–2.5 units, and a treatment time of 10–15 s. As a result of this exposure, the hardness of natural water is half as large on the average. The second stage of the treatment performed under the same conditions (i.e., time and parameters of the external electric field are the same) causes the content of calcium and magnesium salts to decrease by 25% of their initial content on the average. The necessary content of hardness salts is obtained after multistage treatment. The choice of the parameters of the external electric field is determined by the technical result. When treatment is performed at a frequency of less than 0.5 Hz or more than 5 Hz, the hardness of natural water decreases by 10% on the average and the chemical contamination of water owing to the electrolysis takes place. The water softening method that we developed provides water treatment in both closed- and flow-type cells.

The developed method uses two flow-through electrolytic cells connected in series to decrease the energy expenditure per unit volume of treated water. Each cell has alternating ground and feeding electrodes. The number of the electrodes in the cells is determined by a water flow (average flow velocity in the interelectrode space $v \le 0.1$ m s^{-1}). This value of the flow velocity provides the necessary technical result on water softening. To the feeding electrodes of each cell, connected in a series, ac electric field with a frequency varying from 1 to 5 Hz was applied from one source.

The voltage diagram measured across the resistor (R = 5.86 Ω) connected in a series with the cell and used for the determination of the current strength passed through the treatment circuit was obtained for the natural water treated in a 13.5 cm^3 cell by ac elec-

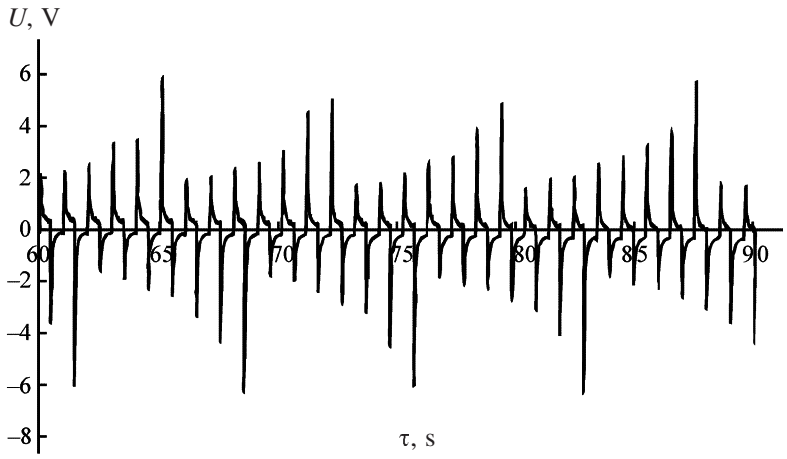

Fig. 1. Voltage U across the resistor measured under the exposure of natural water to ac electric field (frequency 1 Hz, voltage 3 V). (τ) Time; the same for Fig. 2.

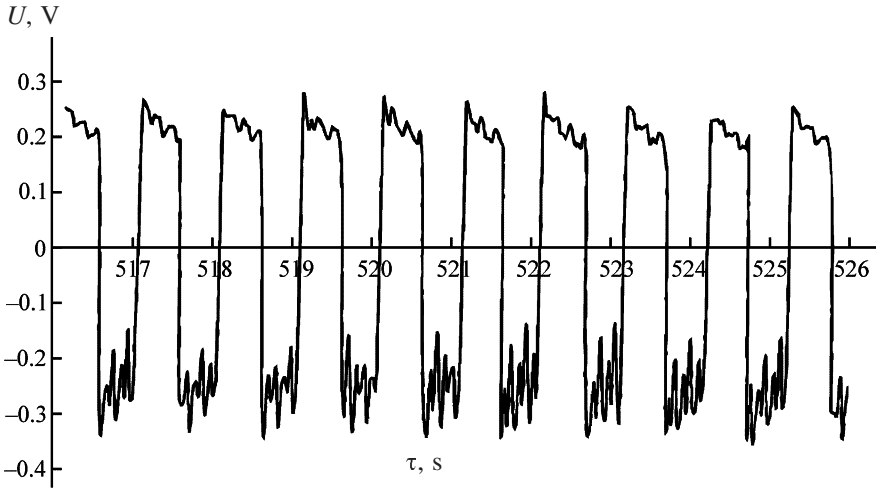

Fig. 2. Voltage U across the resistor measured under the exposure of distilled water to ac electric field.

tric field with a frequency of 1 Hz and a supply voltage of 3 V (Fig. 1). The voltage was measured using a Real Lab system for data collection and control, having an 8-channel analog collection unit with an interval of channel interrogation of 2 ms. A potential drop across the resistor was recorded by one channel of the measuring system. The analysis of the results showed that the potential drop and, consequently, the current passed through the resistor at any time of the measurements depend on the concentration of dissolved salts in the water [3].

We used distilled water to study the effect exerted by dissolved salts on the electrical properties of natural water. The voltage diagram measured across the resistor under the exposure of ac electric field (frequency 1 Hz, supply voltage 4.6 V) to distilled water ($V = 13.5$ cm^2) is presented in Fig. 2. The analysis of the results shows that, when the concentration of dissolved salts in distilled water is minimal, a voltage drop across the resistor remains virtually constant during the exposure time.

CONCLUSIONS

A pulsed method of water softening, causing no chemical contamination of water and ensuring minimum energy expenditure, was suggested.

Abstract—A new procedure was suggested for modification of by-product coke phenols with the aim to eliminate drawbacks revealed in the course of their long-term use as inhibitors of thermal polymerization of unsaturated pyrocondensate components, namely, low inhibiting activity, high water solubility, and unpleasant odor. These drawbacks are eliminated by phenol–formaldehyde polycondensation of total phenols, similar to Novolac production.

DOI: 10.1134/S1070427207090327

Inhibitors of undesirable polymerization are widely used at modern pyrolysis plants [1, 2]. In particular, a wide set of individual substances and formulations are used in ethylene–propylene and benzene production in the step of distillation of liquid pyrolysis intermediates. In Russia, the cheapest and the most available are phenolic fractions from thermal processing of coal and wood [3, 4]. Despite relatively high inhibiting effect of total by-product coke phenols, studies have been pursued in the past two decades with the aim to enhance the inhibiting efficiency by distillation recovery of the most active fractions, e.g., of the pyrocatechol fraction (PCF), which is the fraction of dihydric phenols [5–7]. The PCF composition (see table) determined with a Hewlett–Packard chromatograph–mass spectrometer using the available database [8] shows that the major components are pyrocatechols, resorcinols, and hydroquinones, with a low (about 5–6%) content of various monohydric phenols.

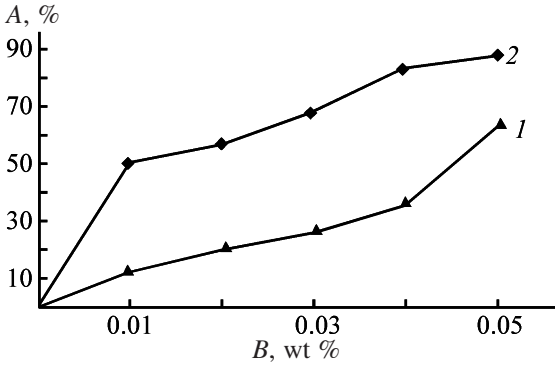
However, the fractionation of by-product coke phenols, solving the problem of enhancement of the inhibiting activity, fails to solve the environmental problem associated with the high water solubility of these compounds, namely, the hazard of ingress of these compounds into the industrial wastewater. Therefore, within the past 5–7 years this class of inhibitors was essentially displaced from the market by inhibitors of other classes.

Analysis of total phenols shows that they consist to ~60% of monohydric phenols and to ~30% of various dihydric phenols (see table), with the remainder being tar.

Attempts to use polymeric inhibitors of polymerization have been reported [9, 10], but prospects for their application were considered doubtful [4], because, along with certain advantages (high heat resistance, nonvolatility), they have significant drawbacks, being less effective and less soluble in the monomers. At the same time, various phenol–formaldehyde oligomers (PFRs) derived from monohydric alkyl(C_9–C_{20})-

Composition of pyrocatechol fraction

Components	Content, wt %
Phenol	2.5
Cresols	2.7
Xylenols + ethylphenols	0.9
Pyrocatechol	11.3
3-Methylpyrocatechol	7.6
4-Methylpyrocatechol	13.8
Resorcinol + hydroquinone	8.6
Dimethylhydroquinone isomers	4.3
Methylresorcinol isomers	14.8
Dimethyl- and ethylresorcinols	13.7



Inhibition efficiency *A* of (*1*) initial and (*2*) modified by-product coke phenols as a function of their concentration *B*.

phenols [11, 12] are widely used as components of so-called antifouling formulations and act as surfactants preventing deposition of polymeric products on the equipment surfaces.

It is well known [13] that the solubility of phenols can be suppressed by involving them in phenol–formaldehyde condensation as in Novolac production. The oligomer formed in the process remains soluble in organic solvents, e.g., in alcohols.

Indeed, standard Novolac PPR derived from monohydric phenol, when tested as a phenolic inhibitor in a concentration of 0.03 wt %, showed ~30% inhibiting effect. The Novolac polycondensate prepared from total by-product coke phenols showed in the same concentration 67% effect, and unmodified total by-product coke phenols showed 24% effect (see figure).

The inhibiting performance was determined as the per cent ratio of the difference between the polymer yields in the absence and in the presence of the inhibitor to the polymer yield without inhibitor. It should also be noted that PFRs synthesized from fractions of mono- or dihydric phenols recovered from total phenols showed appreciably lower inhibiting activity (30–35% at 0.03 wt % concentration) than PFR from the initial nonfractionated phenols. The optimal ratio of mono- and dihydric phenols in the starting mixture of by-product coke phenols taken for modification is (1–2) : 1. An increase in the content of monohydric phenols over the optimum leads to a decrease in the inhibitor performance.

Thus, the procedure suggested for modification of by-product coke phenols yields a product with enhanced inhibiting activity. The oligomeric product obtained is virtually fully soluble in butyl alcohols, which allows the inhibitor to be readily dosed to the reaction mixture. Butyl alcohols are among solvents permitted for use in petrochemical industry [14]. Phenol–formaldehyde oligomers derived from by-product coke phenols meet also other requirements to inhibitos, i.e., the inhibitor obtained does not precipitate from the solutionin the course of heat treatment of the pyrocondensates.

Furthermore, involving by-product coke phenols into phenol–formaldehyde polycondensation strongly reduces the intensity of specific odor of by-product coke phenols, making them more acceptable for industrial applications. The suggested procedure for chemical modification of by-product coke phenols was protected by an RF patent [15], and a project was developed for the production of the modified phenols in an amount of 5–10 t annually.

CONCLUSION

Chemical modification of by-product coke phenols, phenol–formaldehyde Novolac polycondensation, yields an inhibitor of thermal polymerization of unsaturated pyrocondensate components with improved performance and environmental characteristics.

OBITUARIES

Boris Veniaminovich Gidaspov (1933–2007)

DOI: 10.1134/S1070427207090339

On August 15, 2007, in Moscow suddenly died Boris Veniaminovich Gidaspov, a corresponding member of the Russian Academy of Sciences, doctor of chemical science, professor, laureate of Lenin Prize (1976) and State Prize (1981) in science and technology, an outstanding scientist in the field of technical chemistry and technology of highly energetic products, and founder and head of a world-renown scientific school.

B.V. Gidaspov was born on April 16, 1933, in Kuibyshev (now Samara). In 1955, he graduated from the Kuibyshev Industrial Institute and was left to work there as assistant at the chair of explosives. In 1959, he became a postgraduate student at Lensovet Institute of Technology in Leningrad and, having successfully defended his dissertation, made his way up from junior researcher to head of a chair and dean of a faculty. There, Boris Veniaminovich exhibited his remarkable talent of a pedagogue and scientist, combined with his outstanding organizational capacities. Under his supervision, both the chair and the faculty always demonstrated a high level of educational and research work, and the out-of-city research facilities of the chair became Tekhnolog (Technologist) Special Design Office and, headed by chief designer Gidaspov, occupied one of leading positions in the development of highly energetic formulations and special-purpose materials, most important for the country. For example, extensive studies aimed to develop original techniques for synthesis of nitro and polynitro compounds of aliphatic, aromatic, and heterocyclic series were carried out under Gidaspov's supervision and their structure, physicochemical properties, and reactivity were analyzed. The mechanism of the reactions of nitroaminoalkylation, transaminomethylation, N-nitration, and alkylation of tri- and tetrazoles was identified. For these and a number of other reactions, foundations of a quantitative theory were created and a general approach was developed, which enabled prediction of the chemical structure of the reaction products and the rate and equilibrium constants of reversible processes in relation to properties of the starting reactants and characteristics of the reaction medium.

Boris Veniaminovich's activities have been highly appraised; he was awarded Lenin and State Prizes and received a number of Government awards.

Boris Veniaminovich also exhibited his organizational capacity and scientist's talent when being the director general of the State Institute of Applied Chemistry, a most prominent scientific institution specialized in defense chemistry. His indefatigable nature manifested itself in a search for, and development of new methods for managing the chemical industry. On his initiative, a Tekhnokhim multibranch state association was created for the first time in the USSR to improve the working efficiency. Tekhnokhim included 16 institutes and pilot plants and shops, which were removed from the control of Lenneftekhim association and placed under control of the Council of Ministers of the USSR.

From 1989 till 1992, Gidaspov was the first secretary of the Leningrad Regional Committee of the Soviet Communist Party.

Gidaspov became chairman of the council of directors of Aviatsionnoe Vooruzhenie (Aircraft Armament) corporation in 1993 and chairman of the council of directors of Interkhimprom in 1996. From 2004 till 2006 he was director general of Prikladnaya Khimiya Russian Scientific Center, Federal State Unitary Enterprise, and in 2006, he became director general of SVL Proektnoe Upravlenie (SVL Design Control) Private Company and an advisor of the head of the Federal Agency for Science and Innovation.

Under the fundamentally changed economic conditions, Gidaspov organized reforms of the scientific and technological sphere in order to preserve and develop the scientific-industrial and defense potential of the country.

The rich legacy left by Boris Veniaminovich is in his scientific works, implemented technologies, practical recommendations, and the unique Russia's scientific school of broad-profile chemists-technologists.

Gidaspov has trained a large pleiad of specialists working in various fields of science and technology. Among his disciples are candidates and doctors of science and heads of enterprises, with all of whom he shared his ideas, professional experience, and knowledge.

We all sincerely grieve over the loss of a remarkable talented man and present our deep condolences to his relatives, colleagues, and friends. The memory of Boris Veniaminovich Gidaspov will forever remain in our hearts.

BOOK REVIEWS

Pogosyan, A.A., Besser, A.D., and Sorokina, V.S., *Pererabotka ispol'sovannykh akkumulyatorov – osnova retsiklinga svintsa* (Processing of Worked-out Batteries as a Basis for Lead Recycling)

Moscow: TsNIIATOMINFORM, 2005, 256 pp.

DOI: 10.1134/S1070427207090340

The monograph by A.A. Pogosyan and co-authors discusses evidence concerning the modern state of manufacture of secondary lead, based on utilization of worked-out lead batteries. According to the available statistical data, the share of refined lead smelted from secondary lead raw materials was 53.9% of the total world production of the metal. In some countries, the share of secondary lead in the total lead manufacture balance was 65–85%. All the evidence presented in the book is of technological nature. The authors analyze in ample detail the world's practice of collection, transportation, and processing of battery scrap and refining of secondary lead. Particular attention is paid to lead recycling in Russia.

The book comprises an introduction, seven chapters, conclusions and recommendations, and bibliographic list. The introduction (pp. 3–11) notes specific features of processing of secondary raw materials, which are primarily associated with the toxicity of lead and its compounds. In processing of secondary lead raw materials, it is necessary to monitor the environment contamination and minimize the amount of wastes formed. Chapter 1 (pp. 12–26) discusses the modern state of manufacture and consumption of lead, as well as lead recycling. At present, most part of lead output is consumed by the battery industry. In 2000, 74% of world's smelted lead was spent for manufacture of batteries, with this parameter markedly exceeding the average in some countries. In 2000, the fraction of lead used in the United Sates for battery fabrication was 86%. At present, there is no sound alternative to use of lead batteries in vehicles. The depletion of deposits of high-quality ores, decline in production of lead ore raw materials for environmental or economical reasons, necessity for utilization of all kinds of lead waste, and growing demand for lead, all lead to intensification of lead recycling and, in the first place, to utilization of lead battery scrap. In developed countries, more than 90% of worked-out batteries are subjected to processing.

Very brief chapter 2 (pp. 27–34) is devoted to the modern state of, and prospects for lead manufacture in Russia. Before the disintegration of the USSR, lead was mostly produced by processing of ore concentrates, and only 20% of lead was obtained from secondary raw materials and industrial waste. The main plants for manufacture of lead were situated in Kazakhstan and Ukraine. To provide lead for the seven battery plants on the territory of Russia and other consumers, it is necessary to primarily use secondary raw materials, with lead battery scrap collected and processed. Chapter 3 (pp. 35–48) discusses the situation with collection and transportation of worked-out lead batteries in other countries and in Russia. In quite a number of developed countries in the world (the United States, Germany, Japan, France, the United Kingdom, Sweden, Switzerland, etc.), the extent of lead recycling by processing of batteries is 80–100%, which is accounted for by a sufficiently perfect system for collection and utilization of the already accumulated and newly formed raw materials, existence of appropriate regulations, and state support of the activities of this kind. On the whole, present-day Russia's system for collection and transportation of worked-out lead batteries fails to satisfy modern world's standards. According to the available experts' estimates, the amount of battery scrap formed in Russia yearly increases by 150–200 thousand tons because of the rapidly increasing number of vehicles. The regulations of the Russian Federation, concerning the management of lead battery scrap, have become outdated and fail to satisfy modern environmental requirements.

Chapter 4 (pp. 49–77) considers the existing methods for preparation of worked-out batteries for metallurgical processing. In most countries (Russia not in-

cluded), worked-out batteries are included in the list of dangerous wastes because of their content of lead, sulfuric acid electrolyte, and lead-contaminated organic components. Hence follows the requirement that these dangerous kinds of waste should be processed to give the minimum amount of unutilizable materials. The regulations concerning the environment protection, storage of the solid waste, effluent gases, and industrial wastewater are steadily becoming increasingly stringent. The chapter discusses utilization of the electrolyte, battery cropping, desulfation of the active paste, and utilization of organic components.

Chapter 5 (pp. 78–183) analyzing modern methods for manufacture of secondary lead occupies the central place in the monograph. At present, worked-out lead batteries are processed exclusively by pyrometallurgical methods. According to the official statistical data for the year 2003, 68 plants in the world worked totally or partly on primary ores, and 190 plants processed only secondary raw materials. In Europe, plants with an annual output capacity of 30 to 50 thousand tons of lead are most widely used; in the United States, there are plants with an annual output capacity exceeding 100 thousand tons of lead; and in developing countries, the annual output capacity of many plants is less than 10 thousand tons.

The authors note that, recently, a tendency is observed in the world's practice of battery scrap processing toward separate smelting of the metallic fraction, desulfation, and subsequent reducing smelting of the active paste. Among the large number of flowsheets analyzed in the monograph, the authors should have been, in reviewer's opinion, more critical to use of electric furnaces in processing of secondary lead raw materials, the more so as the monograph considers it advisable to create, under the conditions of Russia, regional plants with low output capacity, up to 3–5 thousand tons of lead per year, depending on the amount of worked-out batteries collected in a region. This concept has been more than once substantiated by the reviewer. It should be kept in mind in this case that, for the toxic and comparatively volatile lead, the reducing process should be carried out at as low temperature as possible (720–740°C).

Chapter 6 (pp. 184–214) discusses processes of refining of secondary raw lead. The emphasis is on various pyrometalurgical procedures; any new or promising techniques are not considered by the authors. Chapter 7 (pp. 215–228) contains evidence about hydrometallurgical methods for processing of lead battery scrap. The true efficiency of these techniques cannot be estimated so far.

Of particular interest are the conclusions and recommendations in the final part of the monograph (pp. 229–240). The authors justly emphasize that, taking into account the vast territory of Russia, the problem of environment protection from contamination with various kinds of lead waste can be only solved by State policy on stimulation, by regional tax-reduction, of lead recycling, with heavy fines for discharge of lead-containing materials. It is necessary to bring the system for collection, transportation, and storage of worked-out batteries to the modern level to satisfy the requirements of international environmental regulations. Preliminary cropping of batteries before their metallurgical processing enables utilization of virtually all the battery components.

The bibliographic list (pp. 241–252) contains references to 217 publications of domestic and foreign authors, but, still, seems to be insufficient.

The monograph in question is undoubtedly useful and timely, and it is written by experienced specialists. Works by A.D. Besser and V.S. Sorokina on processing of secondary lead raw materials are widely known. The book makes quite a favorable impression and gives to a reader an exhaustive notion of the modern state of technologies for processing of worked-out lead batteries in Russia and other countries.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Physicochemical Processes in Mechanical Activation of Titanium- and Calcium-containing Minerals

A. M. Kalinkin

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received June 27, 2006; in final form, July 2007

Abstract—A comparative study of processes occurring in mechanical activation of perovskite, sphene, and vollastonite in air and in the atmosphere of carbon dioxide was made. Data on the effect of mechanical activation on the degree of perovskite and sphene decomposition by a 20% nitric acid solution under the standard conditions are presented.

DOI: 10.1134/S1070427207100011

A possible way to intensify processes in the technology of mineral raw materials is mechanical activation (MA) [1–4]. In [5–8], the effect of MA of natural and synthetic titanium-containing minerals, such as ilmenite, leucoxene, rutile, and anatase, on their reactivity toward sulfuric acid was studied. These minerals were mechanically activated with a vibrational grinder and centrifugal and ball mills. Commonly, titanium-containing raw materials are decomposed with concentrated sulfuric acid at temperatures higher than 180°C [9–11]. According to the data obtained in [5–7], the MA of the above-mentioned minerals raises their reactivity and makes it possible to achieve a high degree of titanium recovery under less "severe" decomposition conditions: with 75–85% H_2SO_4 at 140–180°C. A prolonged (for 100 h) grinding in a laboratory vertical ball mill enables a more than 80% dissolution of ilmenite with 50% H_2SO_4 at 120°C [8].

Natural minerals sphene (titanite) $CaTiSiO_5$ and perovskite $CaTiO_3$, which are promising sources of titanium dioxide in the Kola industrial region, are also difficult to decompose [9–11]. Sphene and perovskite differ from the titanium minerals studied in [5–8] in that they contain calcium. It was shown in [12] that preliminary MA of sphene in a centrifugal-planetary mill leads to virtually complete transfer of titanium into solution with a 20–25% solution of nitric acid at room temperature. No data on the effect of MA of perovskite on its acid decomposition could be found in the literature. The increase in the reactivity of titanium minerals difficultly decomposed in acids has been attributed to the higher crystal lattice defectiveness upon MA [5–8]. Apparently, changes in reactivity under MA depend, for different types of titanium-containing minerals, on the composition and structural features of a starting mineral. It should also be noted that the gas medium in which the grinding is carried out may be of particular importance [13]. It has been found that, when subjected to a strong mechanical treatment, a number of calcium- and magnesium-containing silicate minerals can absorb CO_2 from the ambient atmosphere in amounts comparable with the mass of a sample being ground [14, 15]. In the process, the physicochemical properties of activated substances may substantially change.

It was of interest to compare specific features of structural-chemical transformations and extents to which the reactivity of perovskite and sphene increase upon MA under identical conditions in air and atmosphere of CO_2. As an additional object of study was chosen a nonore silicate, vollastonite $CaSiO_3$. Perovskite, sphene, and vollastonite constitute a series: $CaTiO_3$ (calcium titanate), $CaTiSiO_5$ (calcium compound with a complex polyanion, titanosilicate), and $CaSiO_3$ (calcium silicate). It has been shown previously that the nature of a cation (Ca, Mg) and its share in the chemical formula of a mineral are of considerable importance in mechanochemical transformations of silicates [12, 14]. A study of processes occurring in the MA of the compounds that belong to the above series will provide a better understanding of the effect of the anion on their properties and reactivity toward carbon dioxide.

Table 1. Degree of carbonization of perovskite, sphene, and vollastonite after 30 min of MA in AGO-2 in the atmosphere of CO_2 and after 36 h of grinding in a mechanical mortar in air

Mineral	CaO content of a mineral, wt %	$\Delta_r G^0$ of reactions (1)–(3), kJ	Degree of carbonization, wt % CO_2	
			after 30 min of MA in AGO-2	after 36 h of MA in a mechanical mortar
Perovskite	41.3	–(48.0 ± 3.0)	11.6 ± 0.5	10.4 ± 0.5
Sphene	28.6	–(20.1 ± 4.8)	4.8 ± 0.2	6.9 ± 0.3
Vollastonite	48.3	–(41.1 ± 4.6)	11.8 ± 0.5	11.0 ± 0.5

EXPERIMENTAL

To exclude any influence of impurity minerals present in ore concentrates, the experiments were performed with synthetic minerals. The silicate $CaSiO_3$ in the form of a high-temperature pseudovollastonite was synthesized by sintering analytically pure $CaCO_3$ and amorphous SiO_2 of the same grade (calcined to remove water at 1000°C for 12 h), taken in the stoichiometric proportion. The sintering was done at 1200°C in the course of 10 h. Prior to sintering, the mixture was thoroughly ground and compacted into pellets. To provide the full extent of the reaction, the sintering with preliminary grinding and compaction was carried out three times. According to the results of chemical and X-ray phase (XPA) analyses, the substance obtained was a single-phase product, high-temperature pseudovollastonite. Perovskite and sphene were synthesized by the same scheme, with analytically pure $CaCO_3$, amorphous SiO_2 of the same grade, and chemically pure TiO_2 used as starting reagents.

The samples were mechanically activated in an AGO-2 planetary mill [2] in air and in the atmosphere of CO_2 and in a Fritsch mechanical agate mortar (model 2) in air at room temperature and relative air humidity of 30–40%. The weighed portion of a sample in the case of grinding in a mortar was 5 g. In the case of MA in the AGO-2 mill, the ratio between the mass of balls (5 mm in diameter) and samples was 20 : 1. Prior to activation in CO_2, the drum with balls and a sample was purged for 2–3 min with a weak jet of CO_2 from a cylinder to displace air, whose density is 1.5 times lower than that of CO_2. The filling of the drum with CO_2 was repeated after every 2 min of MA.

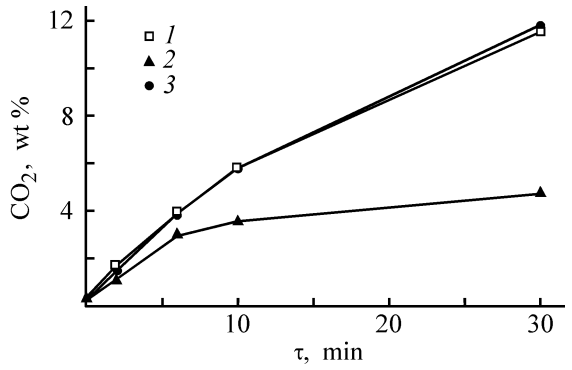

Fig. 1. Degree of carbonization with CO_2 of (*1*) perovskite, (*2*) sphene, and (*3*) vollastonite samples vs. MA duration τ in AGO-2 in the atmosphere of CO_2.

The XPA was carried out on a DRON-2 diffractometer (Cu_{K_α} radiation). IR spectra were measured in pellets with KBr on a UR-20 spectrometer. A thermal analysis was performed on an MOM derivatograph (Hungary). The weighed portion of a sample was 0.5 g, and the heating rate, 10 deg min^{-1}. The sensitivities of TG, DTA, and DTG were 200 mg, 1/5, and 1/10, respectively. The content of CO_2 in the samples was determined by the volumetric method [16] with an AN-7529 express analyzer. A weighed portion of a sample was calcined in a furnace at 1200°C, with the evolving CO_2 absorbed by a titrated solution of $Ba(OH)_2$. The amount of absorbed CO_2 was determined potentiometrically. The specific surface area of the samples was measured by the method of thermal desorption on a Flowsorb II 2300 installation (Micromeritics). Perovskite and sphene samples were decomposed with a 20% solution of HNO_3 at a temperature of 20 ± 2°C at s : l = 1 : 25 under continuous agitation in the course of 24 h.

As can be seen in Fig. 1, perovskite and vollastonite absorb CO_2 substantially more actively under mechanical activation, compared with sphene. In this case, the degrees of carbonization of perovskite and vollastonite virtually coincide (Table 1). On the whole, the result obtained confirms the previously observations [12, 14] according to which the capacity of a mineral for CO_2 absorption under MA increases with the CaO fraction in its chemical formula (Table 1). It

should be noted that, upon grinding of minerals in a mechanical agate mortar in air for 36 h, the degrees of their carbonization via absorption of atmospheric CO_2 are close to the values corresponding to 30 min of MA in pure CO_2 in a centrifugal-planetary mill (Table 1). It is noteworthy that, in the case of grinding in a mortar, the whole amount of CO_2 is absorbed by minerals directly from the atmosphere. Taking into account the amounts of the carbonate contained in the samples after 36 h of grinding, it can be stated that the selectivity of mechanically stimulated extraction of CO_2 from air, in which its content is as low as 0.03 vol %, is exceedingly high.

At the same time, it has been found previously that the degree of mechanically induced carbonization of Ca and Mg silicates is the higher, the more negative the change in the Gibbs energy of the reaction in which carbonates are formed from silicates [12]. For perovskite, sphene, and vollastonite, these reactions are written as

$$CaTiO_3 + CO_2 = CaCO_3(\text{calcite}) + TiO_2(\text{rutile}), \quad (1)$$

$$CaTiSiO_5 + CO_2 = CaCO_3 + TiO_2 + SiO_2(\alpha\text{-quartz}), \quad (2)$$

$$CaSiO_3 + CO_2 = CaCO_3 + SiO_2. \quad (3)$$

The changes in the Gibbs energy, $\Delta_r G^0$, under the standard conditions ($P^0 = 0.1$ MPa, $T = 298.15$ K), calculated for these reactions from reference data [17], are listed in Table 1. Comparison of the values of $\Delta_r G^0$ for reactions (1)–(3) with the other data in Table 1 shows that the previously found tendency is also observed for the series of minerals under consideration.

It is noteworthy that reactions (1)–(3) reflect the real process of CO_2 absorption by minerals under MA rather conditionally. It has been shown for the example of calcium- and magnesium-containing silicates that the mechanically induced sorption of CO_2 is accompanied by extensive incorporation of CO_2 molecules into the structurally disordered silicate matrix to give CO_3^{2-} groups and does not lead to formation of individual carbonate or other phases [12, 14, 15]. As shown below, XPA data demonstrate that the phases represented in the right-hand parts of Eqs. (1)–(3) are not formed, either, in the MA of perovskite, sphene, and vollastonite. Because the carbonate groups in MA minerals are supposedly associated with cations of doubly charged metals [14], the analogy between the mechanochemical processes under study and reactions similar to (1)–(3) is justified and can be used for modeling purposes. This conclusion is confirmed by the correlation between the Gibbs energies of the reactions and the extents of CO_2 absorption in the case of MA [12].

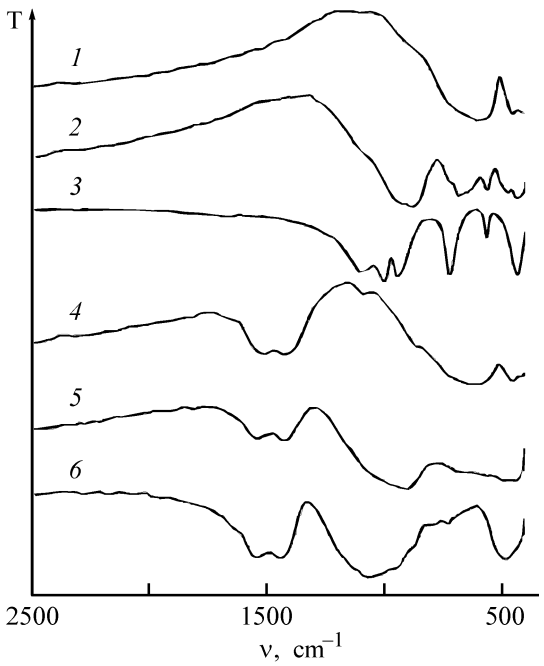

Fig. 2. IR spectra of (*1*, *4*) perovskite, (*2*, *5*) sphene, and (*3*, *6*) vollastonite samples. (T) Transmission and (ν) wave number. (*1*–*3*) Starting samples and (*4*–*6*) those after 30 min of MA in AGO-2 in the atmosphere of CO_2.

Thus, as regards the capacity of the compounds under study for CO_2 absorption under MA, two tendencies previously established for Ca and Mg silicates were confirmed. These tendencies are as follows: (i) the mechanically induced sorption capacity for CO_2 increases with the Ca(II) content and (ii) the degree of carbonization is related to the energy parameters of the reactions in which compounds are converted into carbonates. With account of the previously obtained results [12, 14], a conclusion can be made that the composition of a compound affects the amount of CO_2 absorbed by this compound under MA. The nature of the anion exerts a substantially weaker influence on the mechanochemical sorption of CO_2, compared with the nature of the cation, which is dependent on the position of a metal in the Periodic Table and on its content in the chemical formula of a mineral.

Carbon dioxide is present in activated samples in the form of carbonate ions with distorted configuration. This is indicated by the presence in the IR spectra of activated samples of a split band associated with stretching vibrations of the carbonate group at 1500 cm^{-1}, whose intensity grows with the activation time (Fig. 2). A similar band is present in the IR spec-

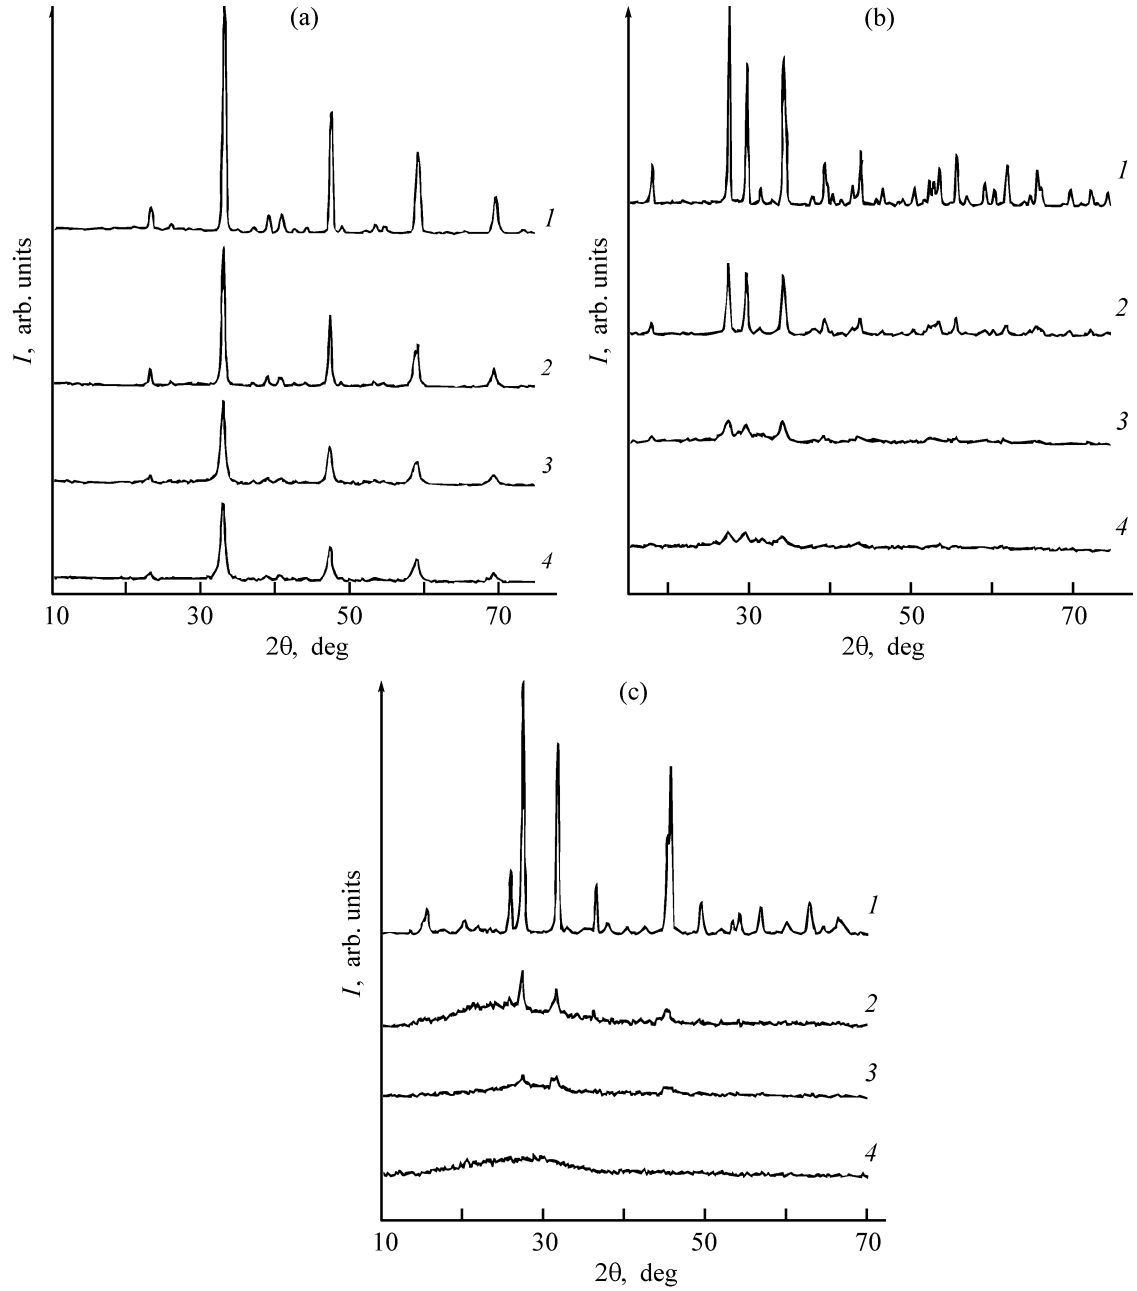

Fig. 3. X-ray diffraction patterns of (a) perovskite, (b) sphene, and (c) vollastonite samples. (*I*) Intensity and (2θ) Bragg angle. (*1*) Starting sample and (*2*, *3*, *4*) samples after MA in AGO-2 in air for 2, 10, and 30 min, respectively.

tra of MA samples of Ca and Mg silicates [12, 14, 15]. As already mentioned, the absorption of CO_2 under MA is accompanied by amorphization of a mineral and incorporation of CO_2 molecules into the disordered silicate matrix. The amorphous substance formed as a result of a mechanical treatment of the mineral in the presence of CO_2 is similar in nature to carbonate-containing glasses obtained by cooling of silicate melts of analogous composition, in which CO_2 is dissolved at high temperatures and pressures [14, 15, 18].

According to XPA data, mechanical activation of perovskite in a centrifugal-planetary mill in air for 30 min leads to a substantial decrease in the intensities of all the reflections, but no complete amorphization is observed (Fig. 3a). Structural changes in sphene and vollastonite in similar experiments are much more pronounced. After 30 min of MA in the centrifugal-planetary mill, vollastonite samples (Fig. 3c) and, to a lesser extent, those of sphene (Fig. 3b) become virtually X-ray-amorphous.

The changes occurring in minerals in the course of MA are presumably determined by specific features of their crystal chemistry. A distinctive feature of the atomic structure of perovskite is the 3D skeleton of vertex-bound Ti-octahedra, which corresponds to the $[TiO_3]^{2-}$ anion. The structure of perovskite is characterized by a cubic close-packed arrangement of oxygen atoms, with two kinds of voids, octahedral and tetrahedral. A cubooctahedral void is formed within each set of eight neighboring Ti-octahedra, in which cations may be situated [19]. A specific feature of the structure of titanium silicates, represented by sphene, consists in combinations of associations constituted by Ti-octahedra and silica tetrahedra. In the sphene structure, infinite associations of Ti-octahedra have SiO_4 orthotetrahedra as neighbors. This 3*D* structure constituted by Si-tetrahedra and Ti-octahedra with common vertices is very open-worked and contains a large number of voids and through channels. The volume of these voids is sufficiently large to accommodate big additional cations [19]. The vollastonite structure is based on an infinite narrow block constituted by three columns of Ca-octahedra. This block bears a "vollastonite" chain of Si-tetrahedra [20].

As is known, the Si–O bond in silicates is so strong that silicon and the nearest four oxygen atoms have virtually the same relative spatial arrangement in various types of structures and form a nearly regular tetrahedron. The bonds connecting structures formed by silica tetrahedra are less stable. As already noted, the perovskite structure is, in contrast to sphene and vollastonite, a very crystallochemically stable 3*D* skeleton of vertex-bound Ti-octahedra situated at sites of a cubic cell characterized by the densest packing of oxygen atoms. Presumably, it is these factors that are responsible for the noticeably higher stability of perovskite against disintegration under mechanical treatments. Under the same conditions, sphene and vollastonite exhibit substantial structural changes, with long-range order disrupted, but the primary structural unit (SiO_4 tetrahedron) remaining unchanged.

Comparison of X-ray diffraction patterns of perovskite samples activated in the AGO-2 mill in air (Fig. 3a) and in the atmosphere of CO_2 shows that the decrease in the intensity of reflections and their broadening as a result of MA in CO_2 are more pronounced, but no complete amorphization occurs under the experimental conditions. According to XPA data, the effect of the atmosphere in which grinding is performed on the degree of amorphization is not important for sphene and vollastonite. Being chemisorbed on a freshly formed surface and penetrating into the outer layers of particles to give carbonate ions, carbon dioxide can stabilize the defects forming in MA and prevent recrystallization by making faster the amorphization of a sample [21]. In the case of the perovskite lattice, which is more stable against mechanical impacts, this effect is rather clearly pronounced. Under the action of an energy-intensive mechanical treatment, the structures of sphene and vollastonite disintegrate to a very large extent and the contribution to defect stabilization via CO_2 absorption remains virtually unnoticeable for these minerals.

It should be noted that, according to XPA data, there are no reflections associated with calcium carbonates in X-ray diffraction patterns of samples of the minerals under study after MA in CO_2. At the same time, the content of the carbonate, in terms of $CaCO_3$, in perovskite and vollastonite samples subjected to 30 min of MA in a centrifugal-planetary mill in the atmosphere of CO_2 exceeds 25% according to the analytical data (Fig. 1, Table 1). Formation of amorphous calcium carbonate as a result of mechanically induced absorption of CO_2 by the minerals is hardly probable, because heating of amorphous $CaCO_3$ (produced by precipitation from aqueous solutions) is accompanied by a pronounced exothermic effect in the temperature range 200–350°C, associated with calcite crystallization [22]. According to the results of thermal (Fig. 4) and X-ray phase analyses, crystallization of calcite does not occur upon heating of mineral samples mechanically activated for 30 min in CO_2. This confirms the assumption that absorption of CO_2 molecules is accompanied by their introduction into the bulk of a structurally disordered mineral to give CO_3^{2-} ions and does not lead to formation of a carbonate as an independent phase [12, 14].

According to the thermal analysis data (Fig. 4) heating of samples subjected to 36 h of MA in a mechanical mortar first leads to removal of water present in the samples because of the absorption of atmospheric moisture in grinding. As temperature is raised further, the carbonate decomposes to give CO_2. For vollastonite and sphene, most part of CO_2 is removed in the interval 600–800°C (Figs. 4a, 4b). For perovskite, this interval is shifted by approximately 100°C to lower temperatures (Fig. 4c). The DTA curves of MA samples of vollastonite and sphene show exothermic peaks at 790 and 740°C, respectively, which correspond, according to XPA data, to crystallization of the starting material. To these temperatures also correspond, according to DTG, extrema in the rate of CO_2 removal (Figs. 4a, 4b). In contrast to sphene and vollastonite samples, the carbonate decomposes in the case of an MA perovskite a clearly

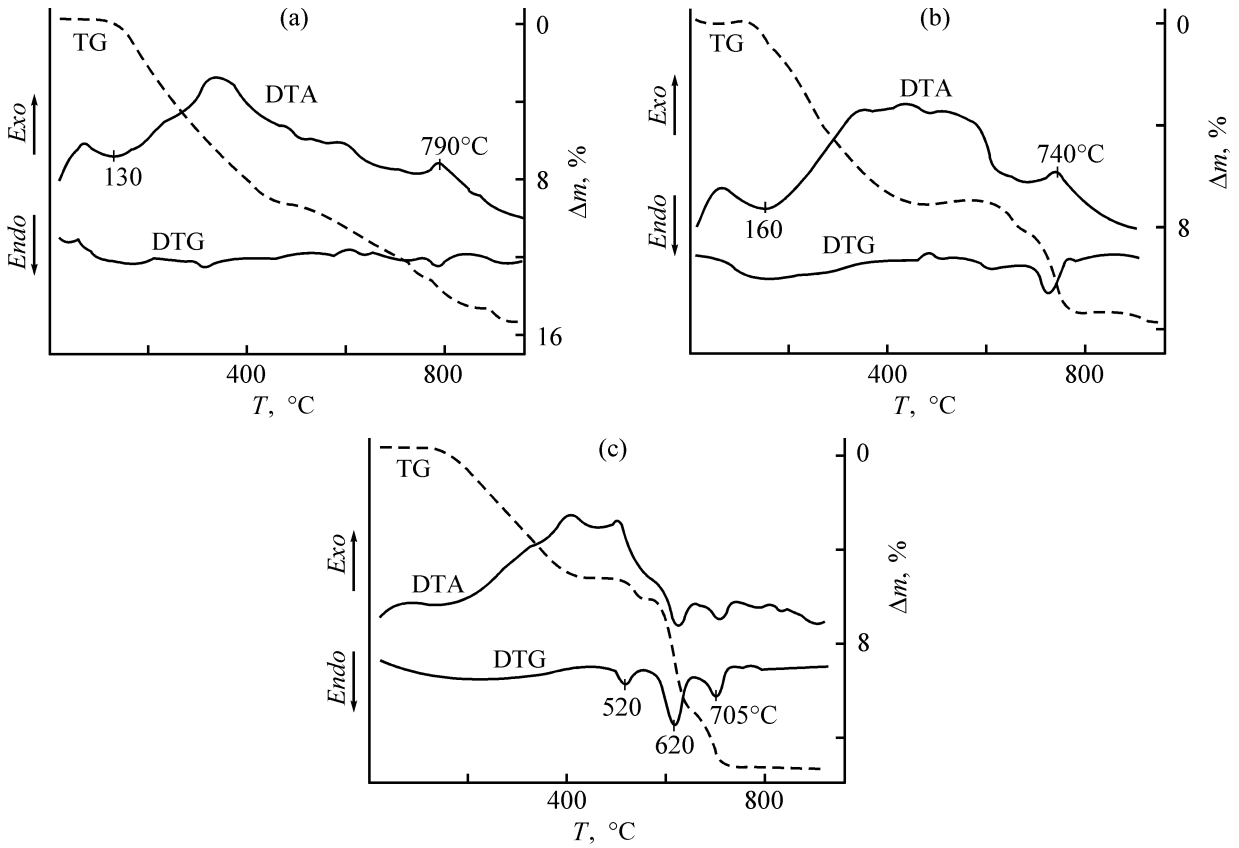

Fig. 4. Thermal analysis data for (a) vollastonite, (b) sphene, and (c) perovskite samples after 36 h of grinding in a mechanical mortar in air. (T) Temperature and (Δm) change in mass.

pronounced step-like nature. The position of the peaks and dips in the DTA and DTG curves indicates that the structure of the sample probably contains three types of CO_3^{2-} groups (Fig. 4c). According to the XPA data, heating of an MA perovskite sample in the temperature range 700–1000°C is accompanied by a gradual increase in the intensity of the reflections associated with the mineral and by a decrease in their halfwidth, but the reflection intensity is not restored completely.

Table 2. Specific surface area of perovskite, sphene, and vollastonite at different MA durations in AGO-2 in air (numerator) and in the atmosphere of CO_2 (denominator)

Mineral	S_{sp}, $m^2\ g^{-1}$, at indicated MA duration, min				
	0	2	6	10	30
Perovskite	0.4	4.9 / 4.9	5.8 / 4.8	7.7 / 5.0	16.0 / 3.4
Sphene	0.3	4.6 / 5.4	4.5 / 5.7	3.7 / 5.0	4.8 / 4.2
Vollastonite	0.3	4.9 / 5.5	4.4 / 5.1	2.2 / 2.5	2.8 / 3.2

The specific surface area of perovskite subjected to MA in air exceeds that obtained upon MA in CO_2, and this difference increases with the MA duration (Table 2). After 30 min of MA in air, S_{sp} of a perovskite sample exceeds a similar value after MA in CO_2 by a factor of 5. The dependence of the specific surface area on the MA duration for sphene and vollastonite (Table 2) is more complex, with the degree of dispersion less sensitive to the grinding atmosphere.

The physicochemical changes in perovskite and sphene upon MA are in agreement with the degree of decomposition of these minerals by a 20% solution of HNO_3 under ambient conditions. The degree of decomposition was defined as a percentage ratio of the amount of Ti(IV) that passed into solution to its content in the MA sample. It was found that the MA atmosphere does not exert any noticeable influence on the extent to which Ti(IV) passes into solution in acid treatment of mechanically activated perovskite and sphene. It is known that, at constant mass-transfer rate and temperature, the rate of heterogeneous chem-

ical processes depends both on the degree of structural distortions, which can markedly lower the activation energy, and on the phase boundary area. For sphene, both the parameters comparatively weakly depend on the type of MA atmosphere. In the case of perovskite, dispersion occurs more effectively in air (Table 2). At the same time, the degree of $CaTiO_3$ amorphization in MA in CO_2 exceeds that for MA in air. Thus, the dispersion and structural distortion factors neutralize each other in MA of perovskite in air and CO_2. As a result, the degree of acid decomposition of perovskite does not depend strongly on the MA medium.

As the time during which perovskite is activated in air increases, the degree of its acid decomposition grows from 1.6% for the starting mineral to 67% for a sample activated in a centrifugal-planetary mill for 30 min. Making the MA duration still longer (50 min) does not lead to any increase in the degree of decomposition. In the case of activation in CO_2, the situation is similar, although the degree of decomposition after 30 min of MA is somewhat lower (63%) than that after MA in air. Treatment of a sphene sample after 30 min of MA in AGO-2 with a nitric acid solution at room temperature provides a 95–98% recovery of Ti(IV) into solution. The solid residue formed upon interaction of a mechanically activated sphene with an HNO_3 solution is composed of virtually pure amorphous silica. These data are in agreement with the substantially stronger amorphization of sphene, compared with that of perovskite, in the course of MA (Figs. 3a, 3b).

CONCLUSIONS

(1) Among the minerals studied (titanate, titanosilicate, silicate), the nature of the anion exerts a considerably lesser influence on the pattern of CO_2 mechanosorption, compared with the nature of the cation, determined by the position of a metal in the Periodic Table and by its content in the chemical formula of the mineral.

(2) Structural distortions in sphene and vollastonite in mechanical activation are much more pronounced, compared with perovskite, which is due to crystallochemical features of the minerals. The medium in which the mechanical activation is performed (air or CO_2) has no effect on the degree of amorphization of sphene and vollastonite.

(3) The specific surface area of perovskite grows much faster in mechanical activation in air, compared with carbon dioxide. For sphene and vollastonite, S_{sp} is less sensitive to the dispersion atmosphere.

(4) The degree of decomposition of activated sphene and perovskite samples by nitric acid weakly depends on the type of the medium in mechanical activation. Treatment of a sphene sample after 30 min of activation in a centrifugal-planetary mill with a 20% solution of HNO_3 at room temperature provides a 95–98% recovery of Ti(IV) into solution. For a similar perovskite sample, the degree of recovery is 63–67%.

Abstract—Effect of the composition of carbonate minerals on the precipitation of iron from Fe(III) sulfate solutions under conditions of their partial neutralization with calcite and dolomite was studied.

DOI: 10.1134/S1070427207100023

Iron is the most important component of the geochemical migration of elements both in undisturbed geological systems and in regions of technologically induced abnormalities. Its sedimentary and originally sedimentary ores, as well as precipitates in the weathering crust, sedimentary rocks, and soils, are largely represented by oxide compounds. Processes of iron concentration, which formed its largest industrially important deposits, had occurred in the hypergenesis zone [1]. Data on the origin and transformation of hypergene iron oxides as possible collectors of heavy metals are of considerable interest for preventing contamination of natural water by heavy-metal compounds contained in acid drainage waters from tailing dumps, mines, and open pits by creating geochemical barriers from carbonate-containing materials [2].

Neutralization is the main method for water purification to remove metal cations forming insoluble hydroxo compounds from water. Among natural materials, calcite is the most widely used for water treatment. A large number of publications describe various methods for water treatment: multistage techniques [3], those with a solid reagent charged into a column, and a technique using a complex agent containing lime and chalk [4]. The high selectivity of calcite in removal of heavy metals has been noted [5]. Such a natural material as dolomite is used to prepare coagulants for surface water treatment. Acid wastewater can be neutralized by its filtration through a lime or dolomite filter or by addition of a finely ground reagent [6].

Because treatment of water from polluted sources and reactions of acid drainage solutions with neutralizing reagents are carried out in climatic conditions of rock weathering, the available data on the formation of iron-containing precipitates in the hypergenesis zone were analyzed. It has been noted [1] that ferrihydrite, which is a widespread hypergene mineral from the Fe(III) oxide group, plays an important part in the geochemical history of iron. It can be regarded as a typical product formed in oxidation of Fe^{2+} from underground water flowing-out at the surface, because the main condition for ferrihydryte formation is fast oxidation of Fe(II), which is rather characteristic of the Earth surface. For iron to be precipitated as ferrihydrite, a high rate of iron removal from a solution is required, and the appropriate conditions occur in reactions of dissolved Fe(III) salts with bases. The conversion of ferrihydrite to goethite in solutions of acids and alkalis consists in dissolution of an unstable phase, followed by precipitation of a substance stable under the same conditions from solution. In solutions with pH < 3, ferrihydrite is converted to goethite at room temperature.

Previously, a series of experiments on iron precipitation with calcite and dolomite from iron(II) sulfate solutions have been performed [7]. It was found that the composition and properties of iron oxohydroxides depend on numerous factors, the main of which are the reagent nature, final solution pH, and reaction duration.

Numerous studies have been devoted to the formation of Fe(III) hydrolytic precipitates. The publications earlier than 1990 were reviewed in the monograph [8]. It is commonly accepted that iron(III) exists in dilute strongly acidic solutions as $Fe(H_2O)_6^{3+}$.

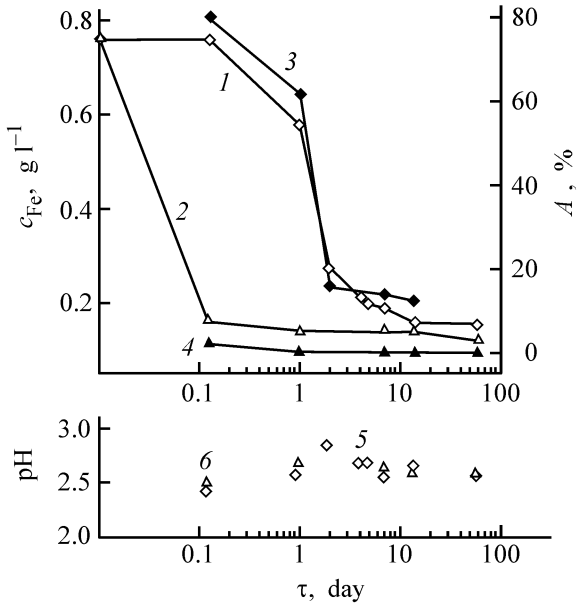

Fig. 1. (*1*, *2*) Iron concentration in solution c_{Fe}, (*3*, *4*) relative content of undissolved minerals *A*, and (*5*, *6*) pH of the suspension vs. the duration τ of reactions of (*1*, *3*, *5*) dolomite and (*2*, *4*, *6*) calcite with the $Fe_2(SO_4)_3$ solution.

The scheme of hydrolysis of Fe(III) hexaaqua complexes includes several stages: formation of equilibrium hydrolysis products, mono- and binuclear hydroxo complexes; formation of polynuclear hydrolysis products, aging of polymers with final conversion to oxide phases; and precipitation of oxide phases directly from equilibrium hydrolysis products. It is convenient to study these stages of hydrolysis in partly neutralized iron(III) solutions [9]. In the present study, we used the same methodological approach. The experiments were carried out using reagent/solution ratios smaller than necessary for complete transformation of iron aqua complexes to hydroxo species.

The aim of the study was to examine the effect of the composition of neutralizing minerals on the iron precipitation from iron(III) sulfate solutions. Such process is not observed in real conditions, but its experimental study will allow us to distinguish two parallel processes, Fe(II) → Fe(III) oxidation and formation of oxohydroxides.

EXPERIMENTAL

Marbled calcite $CaCO_3$ from the Koelga deposit (Chelyabinsk oblast) and dolomite $CaMg(CO_3)_2$ from the Titan deposit (Murmansk oblast) were used in the study. Rock samples were crushed in a porcelain mortar, and a fraction with particle size smaller than 70 μm was taken for the experiments. Source solutions with an iron concentration of 0.76 g l^{-1} were prepared from chemically pure $Fe_2(SO_4)_3 \cdot 7H_2O$ and distilled water. The experiments were carried out with agitation by a magnetic stirrer under conditions of easy air access.

Changes in the iron concentration in solution in reactions with neutralizing reagents were determined by the method of separate weighed samples. The dissolution of minerals was monitored by X-ray analysis of the precipitates composed of iron compounds and the undissolved part of a reagent. The extent of reagent dissolution was calculated from the results of a chemical analysis of the solutions. The properties of the precipitated phase were studied by crystal-optical, X-ray, and electron microscopic (SEM LEO 420 microscope) analyses.

The dependences of the iron concentration in solutions on the reaction duration in the systems with calcite and dolomite are shown in Fig. 1. Despite that the pH values of the suspensions formed are virtually equal, the kinetic curves of iron precipitation by various carbonate-containing reagents are strongly different. In the presence of calcite, the degree of solution purification in 3 h is 82% and changes only slightly as the precipitation duration increases, whereas an induction period is observed in the experiments with dolomite. After 14 days, the residual iron concentrations obtained in reactions of the source solution reactions with calcite and dolomite differ only slightly. The degree of iron precipitation varies in parallel with that of reagent dissolution.

The experimental data obtained demonstrate that the chemical composition of a reagent exerts strong influence on the formation of an iron-containing precipitate, with the main factor that affects the iron precipitation being the dissolution rate of minerals. Let us consider calcite and dolomite properties that are related to their reactivity.

First, it is necessary to note that calcite and dolomite have different crystal structures. As shown by morphological studies, calcite is characterized by a high polydispersity of samples, caused by the presence of small pebbles of the mineral, and a friable branched surface of particles (Figs. 2a and 2b), whereas dolomite particles are dense and smooth with a cleaved surface in the form of a conchoidal fracture (Figs. 2c and 2d). These features of the minerals should lead to a larger specific surface area and higher porosity of calcite, compared with dolomite, which is confirmed by the following data. The results obtained in determining the porosity of dolomite and calcite samples used in this study are presented in the mono-

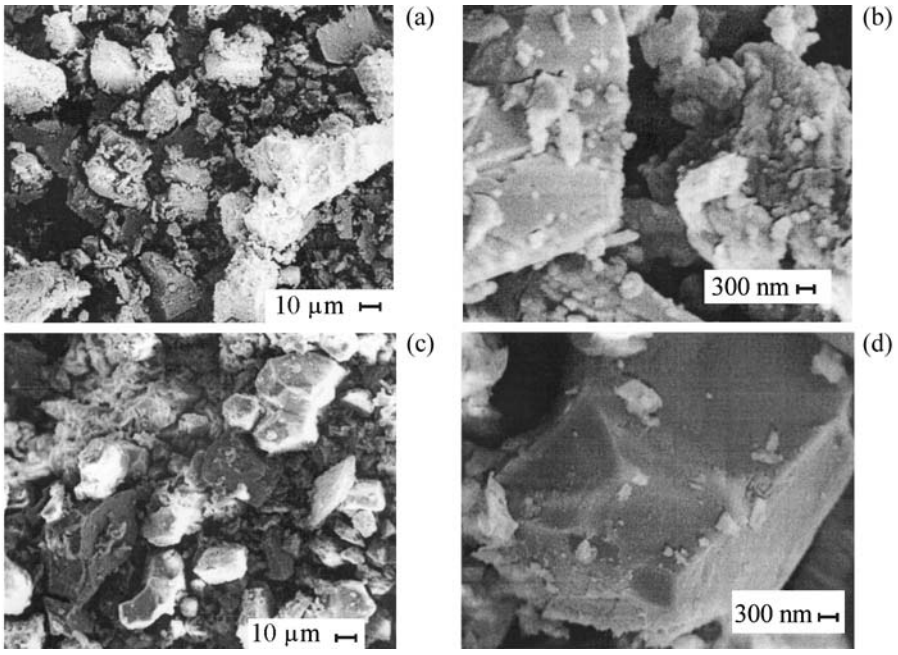

Fig. 2. Micrographs of the initial surface of (a, b) calcite and (c, d) dolomite particles.

graph [10]. The Koelga marble is distinguished by large average pore size (7.1 μm). The porosity of the dolomite marble is mainly associated with pores 0.01–0.03 μm in size. A high short-term water adsorption was also noted for calcite marble, which is due to its mesocrystalline structure. The specific surface area of mineral samples used in the study was determined by the method of low-temperature nitrogen adsorption. The specific surface area of calcite (1.57 $m^2 g^{-1}$) is almost five times that of dolomite (0.34 $m^2 g^{-1}$).

Thus, calcite is dissolved more rapidly, primarily because of its more developed surface area. It can be assumed that the difference in reactivity between the minerals may also be of certain importance. Dolomite is known to be less chemically active than calcite. In particular, dolomite is poorly dissolved in cold dilute acids and does not foam. In addition, when a solution of copper nitrate is used, calcite turns intense light blue due to azurite formation, whereas dolomite does not enter in the reaction, and its color remains unchanged [11].

To understand why the calcite and dolomite properties are strongly different, we examined the results of quantum-mechanical calculations reported in [12]. An estimation of the surface energy of crystal faces of minerals demonstrated that the energy characteristics of the $10\bar{1}1$, $10\bar{1}4$, and 0001 faces are comparable, whereas for the $10\bar{1}1$ and $11\bar{2}0$ faces, the surface energy of dolomite crystals is 5–9 times lower than that of calcite crystals. These specific features of the minerals result in that calcite has a higher reactivity than dolomite in chemical reactions accompanied by dissolution of the starting solid phase.

The data in Table 1 confirm that calcite is dissolved more rapidly than dolomite. It follows from these data that dolomite neutralizes the acid to markedly lesser extent than calcite does. It also follows from the experimental data that hydroxide ions formed in dissolution of minerals are almost completely bound in the $Fe_2(SO_4)_3$ solution to form hydroxo complexes of iron.

A calculation of the OH/Fe ratio in the experiments with calcite demonstrated that, for the systems under consideration, its value is substantially lower than 0.5. In this range of OH/Fe ratios, the time elapsed before precipitation onset rapidly decreases as this ratio increases [13]. Because the instant of time when minerals are added is characterized by a more intense neu-

tralization of the $Fe_2(SO_4)_3$ acid solution by calcite, compared with dolomite, this results in a shorter time before the beginning of iron precipitation in presence of calcite.

The data obtained can be explained by using the model of iron hydrolysis in partly neutralized solutions at OH/Fe < 0.5 [9, 13, 14]. A slow hydrolysis of the originally formed species occurs to give protons, whose neutralization shifts, owing to the dissolution of carbonates, the equilibrium toward the precipitate formation, and proceeds to complete dissolution of the active part of the reagents.

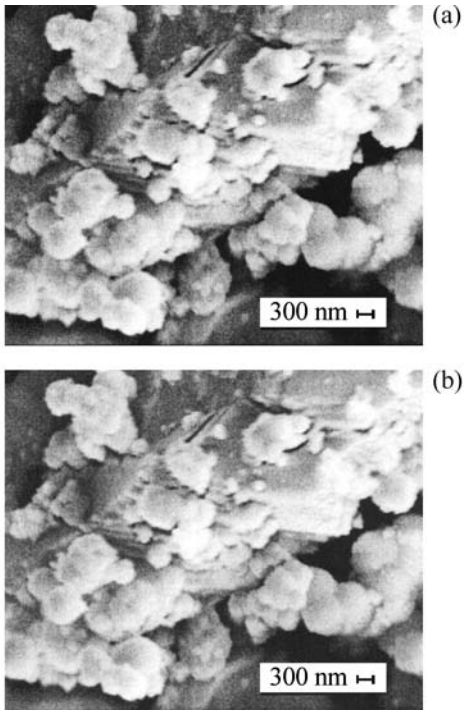

Fig. 3. Micrographs of particles of oxohydroxides precipitated from an iron(III) sulfate solution in the presence of dolomite at a reaction duration of (a) 24 h and (b) 5 days.

Dolomite contains magnesium, whose presence in solution can affect the formation of an iron-containing precipitate. Magnesium is known to have an inhibiting effect on crystallization of, e.g., calcite. As a rule, various mechanisms of the influence of magnesium are considered [15]. We can assume that magnesium cations can be adsorbed on faces of a calcite crystal thereby hindering its growth, or can be incorporated into the crystal lattice of calcite, which yields a more soluble magnesian calcite.

To elucidate the mechanism of the influence exerted by magnesium on the iron precipitation, we performed two series of experiments. In the first of these, calcite was added to a $Fe_2(SO_4)_3$ solution, and in the second, calcite and magnesium sulfate (Table 2). It can be seen from Table 2 shows that magnesium exerts significant influence neither on the rate of iron precipitation, nor on the dependence of the residual iron concentration on pH.

The morphologies of particles of the precipitates obtained in the reactions of iron(III) sulfate solution with calcite and dolomite do not differ from each other, being identical to that of ferrihydrite [1]. Micrographs of precipitates with particle size ranging from several hundred nanometers to 1–2 μm, obtained in the system with dolomite, are shown in Fig. 3. After a one-day reaction, ferrihydrite particles have a spherical shape with a smooth surface, being predominantly precipitated on active nonuniform areas of the mineral crystals. Unreacted dolomite particles with continuous and discontinuous fringes of a newly formed phase along their contour were detected by crystal-optical analysis. As the keeping duration increases to five days, very fine crystals are formed on the surface of the spheres, and elongated crystals are observed in the bulk of the precipitate.

A similar process was observed in [1], where it was found that ferrihydrite is slowly transformed to goethite in moderately acidic iron(II) solutions, and faster, in iron(III)-containing solutions at pH < 3, which is accounted for by the difference in the existence forms of iron. The conversion of ferrihydrite to goethite is a process in which the unstable phase formed upon incorporation of additional iron ions into the lattice of the starting ferrihydrite is dissolved, with the subsequent precipitation of a substance stable under the same conditions [1]. The transformation of the amorphous phase transformation becomes slower in solutions that contain no free iron cations [16]. Because free Fe(III) cations exist only in strongly

acidic solutions, the crystalline phase can be formed from ferrihydrite at pH < 3, which is also observed in partial neutralization of a $Fe_2(SO_4)_3$ solution with carbonate minerals.

CONCLUSIONS

(1) It was found that, upon addition of carbonate minerals to a $Fe_2(SO_4)_3$ solution, neutralization of the acid solution with calcite is faster than that with dolomite. This results in a shorter time before the onset of iron precipitation in the presence of calcite. The slow hydrolysis of the originally formed particles is accompanied by release of H^+ ions, whose neutralization due to the dissolution of carbonates shifts the equilibrium toward precipitate formation, and continues to complete dissolution of the active part of the reagents.

(2) The presence of magnesium in solutions exerts strong influence neither on the rate of iron precipitation, nor on the dependence of residual iron concentration on pH.

(3) Under the conditions of neutralization of $Fe_2(SO_4)_3$ solutions with carbonate minerals, iron precipitates in the form of amorphous compounds. As the reaction duration increases, a crystalline phase is formed in the systems studied.

Abstract—Dehydration of solutions of aluminophosphate binders in a microwave field to obtain aluminophosphate powders of various compositions is considered. The effect of drying conditions and of the chemical composition of aluminophosphate binders on the phase composition and solubility of the products obtained is analyzed.

DOI: 10.1134/S1070427207100035

Aluminophosphate binders (APB) are aqueous solutions of aluminum phosphates with various degrees of substitution, being inorganic polymers in the systems Al_2O_3–P_2O_5–H_2O and Al_2O_3–M_2O_3–P_2O_5–H_2O (where M_2O_3 = Cr_2O_3, B_2O_3) [1, 2]. Aluminophosphate binders are produced by reacting H_3PO_4, $Al(OH)_3$, and modifying additives, Cr_2O_3 and B_2O_3, and used in manufacture of high-temperature materials (refractory and heat-resistant concretes, glues, and sealing compounds) and coatings [3] and electrically insulating formulations [4].

A disadvantage of APB is their low stability in storage. Development of crystallization processes entails a comparatively fast formation (in several months) of a precipitate of insoluble aluminum phosphates. This impairs the properties of materials produced with APB and occasionally makes their use impossible [1].

A possible way to improve the stability of APB is their manufacture in the form of water-soluble powders. For this purpose, it is necessary to dry the binder immediately after its synthesis, to obtain a product with moisture content providing a reversible dissolution. The partly dehydrated state of a binder can provide stability of its properties in the course of time [1].

Examples are known ob obtaining powdered APB by spraying drying [1, 5, 6]. However, use of a heat carrier with high temperature (up to 700°C) [7, 8] may change the properties of APB because of its excessive dehydration.

In this study, the method of microwave drying was employed to dry aluminophosphate solutions. The use of microwave electromagnetic radiation to heat a solution being dehydrated can create milder, compared with those in spraying drying, conditions of the process at comparatively low temperatures (up to 200–300°C) and minimum process duration. In particular, it has been shown that this method is efficient in production of hydrated sodium silicates by dehydration of liquid-glass binder solutions [9, 10].

EXPERIMENTAL

Aluminophosphate binders were produced by dissolution of $Al(OH)_3$ [analytically pure grade, GOST (State Standard) 11841–76] with heating and agitation in a 55–60% solution of H_3PO_4 (GOST 6552–80) in accordance with the recommendations made in [1, 11]. The resulting aluminophosphate solutions were modified by introduction of B_2O_3 in the form of H_3BO_3 [analytically pure grade, TU (Technical Specification) 6-09-17-263–89] and Cr_2O_3 in the form of CrO_3 (analytically pure grade, GOST 3776–78), with the subsequent reduction of CrO_3 with a stoichiometric amount of H_2O_2 (GOST 10929–76) in accordance with the equation

$$4CrO_3 + 8H_2O_2 + 12H^+ \rightarrow 4Cr^{3+} + 14H_2O + 7O_2\uparrow. \quad (1)$$

Chemical composition of aluminophosphate solutions

Run no.	Content of indicated components in a binder solution, wt %					$P_2O_5/(Al_2O_3+Me_2O_3)$, mol/mol	$Al_2O_3/(Al_2O_3+Me_2O_3)$, mol/mol
	P_2O_5	Al_2O_3	Cr_2O_3	B_2O_3	$P_2O_5 + Al_2O_3 + Me_2O_3$		
1	37.12	10.67	–	–	47.79	2.5	1.0
2	38.63	8.67	–	–	47.30	3.2	1.0
3	35.48	7.28	–	–	42.76	3.5	1.0
4	35.90	7.37	2.74	–	46.01	2.8	0.8
5	38.02	7.80	–	1.33	47.15	2.8	0.8

The parameters of the thus prepared aluminophosphate solutions are listed in the table.

A Sanyo household microwave oven operating at a frequency of 2450 MHz served as a source of microwave radiation. The solutions were dehydrated at a fixed output power of about 450 W.

A solution to be dried (weighed portion 100 h) in a $88 \times 62 \times 28$-mm fluoroplastic cuvette (solution layer thickness not exceeding 5 mm) was placed in the chamber of a microwave oven. The drying process was controlled by varying the duration of sample heating in the microwave field. Then, the cuvette with a sample was removed from the microwave oven and cooled in air at room temperature (20°C). The cooling rate was about 15–20 deg min^{-1}.

The residual moisture content of the drying products was found from the calcination loss at 800°C.

Because the aluminophosphate solutions synthesized contained different amounts of moisture, it was appropriate to consider, in order to compare the moisture removal rates, the dehydration curves in dimensionless variables: relative mass of removed water, w_{red}, and reduced drying time τ_{red} [10]:

$$w_{red} = \frac{w_\tau(H_2O)[1 - w(H_2O)_{in}]}{w(H_2O)_{in}[1 - w_\tau H_2O]}, \quad (2)$$

where $w_\tau(H_2O)$ is the moisture content of the product at instant of time τ (wt %) and $w(H_2O)_{in}$ is the moisture content of the starting solution (wt %).

The quantity w_{red} characterizes the amount of evaporated water relative to the initial amount of H_2O in the system.

$$\tau_{red} = \tau P/[mrw(H_2O)_{in}], \quad (3)$$

where τ is the drying time (s); m, solution mass (kg); r, specific heat of water evaporation (2256 kJ kg^{-1}); and P, microwave power (W).

For potentiometric measurements, 10% solutions were prepared from the dehydration products. The measurements were made with a laboratory pH-meter of the 673M type with a glass electrode at 20°C.

X-ray diffraction patterns of powder samples were recorded with a DRON-1 X-ray diffractometer (Cu_{K_α}). IR spectra were measured in KBr pellets on a UR-20 spectrophotometer.

A microwave treatment of aluminophosphate solutions for 4–5 min yielded a transparent melt that solidifies upon cooling as a brittle solid glassy mass. In some cases, a white nontransparent glassy mass was formed after a thermal treatment. If the drying duration was raised to more than 5–6 min, the mass swelled, with its volume becoming 2–3 times larger.

In the course of a microwave treatment of aluminophosphate solutions, the sample temperature increased to 250–280°C. This points to a strong absorption of the microwave radiation by aluminophosphate solutions, which is apparently due to the mostly orientational polarization of water molecules and to the ionic conduction by hydrated aluminum ions and phosphate ions, with the contribution of the ionic conductivity increasing as the system is dehydrated and its temperature increases [12].

Figures 1a and 1b show the kinetics of dehydration of aluminophosphate solutions in a microwave field. It follows from the data obtained that the dehydration curves have a rather typical shape: the rate is constant during the initial period; beginning with a certain value, the dehydration rate decreases and w_{red} tends to a constant value (~0.9).

The chemical composition of aluminophosphate solutions affects the dehydration process. For example, an increase in the content of aluminum oxide (a decrease in the P_2O_5/Al_2O_3 ratio) in a solution leads to a rise in the dehydration rate (Fig. 1a). The lowest dehydration rate is observed for a solution of H_3PO_4

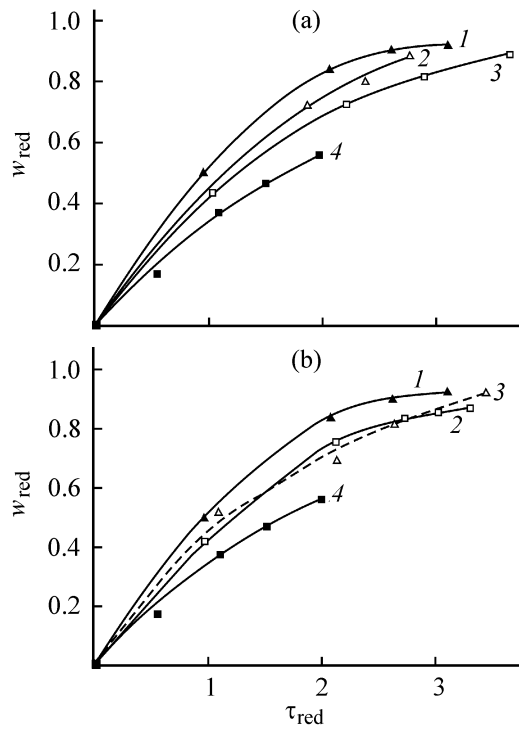

Fig. 1. Dehydration kinetics of solutions of aluminophosphate binders of various compositions and orthophosphoric acid, plotted in dimensionless variables. (w_{red}) Relative mass of removed water and (τ_{red}) reduced drying duration. (a) (*1*) $2.5P_2O_5 \cdot Al_2O_3$, (*2*) $3.2P_2O_5 \cdot Al_2O_3$, (*3*) $3.5P_2O_5 \cdot Al_2O_3$, and (*4*) 47% solution of H_3PO_4. (b) (*1*) $2.5P_2O_5 \cdot Al_2O_3$, (*2*) $2.8P_2O_5 \cdot 0.8Al_2O_3 \cdot 0.2B_2O_3$, (*3*) $2.8P_2O_5 \cdot 0.8Al_2O_3 \cdot 0.2Cr_2O_3$, and (*4*) 47% solution of H_3PO_4.

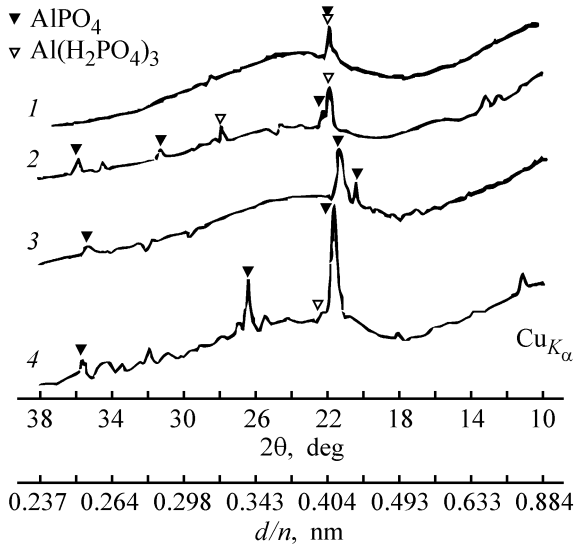

Fig. 2. X-ray diffraction patterns of powdered aluminophosphate binders. (2θ) Bragg angle and (*d*/*n*) interplanar spacing. Sample composition, w_{H_2O} (wt %), and drying time (min), respectively: (*1*) $3.5P_2O_5 \cdot Al_2O_3$, 21, 6; (*2*) $3.2P_2O_5 \cdot Al_2O_3$, 20.8, 5; (*3*) $3.2P_2O_5 \cdot Al_2O_3$, 10.5, 6.5; and (*4*) $2.5P_2O_5 \cdot Al_2O_3$, 7.0, 7.

(Fig. 1a, curve *4*). If Al_2O_3 is partly replaced with Cr_2O_3, the dehydration curve is virtually identical in its initial portion to that for an aluminophosphate solutions of a similar composition (Fig. 1b; curves *1*, *3*); further, the rate becomes somewhat lower. However, the final moisture contents of both products are virtually the same. Introduction of an equivalent amount B_2O_3 into the solution (aluminoborophosphate binder) makes the entire drying process slower (Fig. 1b, curve *2*).

This run of the dehydration curves can be attributed to differences in the acid-base properties of the oxides contained in APB. The presence of B_2O_3 in the system is equivalent to an increase in the P_2O_5 ratio and makes lower the basicity of the solution: the dehydration curve of a aluminophosphate solution modified with B_2O_3 (Fig. 1b, curve *2*) approaches the curve for orthophosphoric acid (curve *4*). Probably, a factor leading to the increase in the acidity of the system in this case is the possibility of formation of complex acids in a reaction between boric and phosphoric acids [13]. In addition, a stronger amorphization of the product formed in thermal treatment of aluminophosphates is observed in the presence of B_2O_3 [14], which may also make lower the rate of moisture removal from the solution.

The effect of chromium(III) oxide on the course of dehydration is comparable with that of aluminum oxide, because the rate of moisture removal from the aluminochromophosphate binder is rather high and approaches that for aluminophosphate solutions (Fig. 1b; curves *1*, *3*). Chromuim(III) oxide contained in an aluminophosphate binder manifests itself as a basic oxide and is analogous in this regard to aluminum oxide, whose higher content in a solution makes the dehydration faster.

Figure 2 shows the results of an X-ray phase analysis of the dehydration products, according to which the composition of all the samples is mostly represented by an amorphous phase, which follows from the clearly pronounced halo, characteristic of glassy materials. However, depending on the thermal treatment duration and chemical composition of the starting solution, samples contain different amounts of crystalline phases corresponding to aluminum phosphates with various degrees of substitution. As the drying duration increases and the P_2O_5/Al_2O_3 molar ratio decreases, the content of crystalline phases in the samples grows.

The X-ray diffraction patterns (Fig. 2) of products obtained at short drying duration (5 min) are dominated by lines corresponding to aluminum dihydro-

phosphates (0.408, 0.321 nm). As the drying duration increases, there appear or become markedly stronger lines characteristic of aluminum orthophosphate (0.428, 0.417, 0.402, 0.331, 0.251 nm) and the analytical lines in the X-ray diffraction patterns change their position. The intensities of the lines corresponding to aluminum dihydrophosphate decrease and they are gradually replaced by lines associated with various modifications of aluminum orthophosphate. This indicates that aluminum dihydrophosphate decomposes in the course of thermal treatment and the fraction of aluminum orthophosphate in the product being dried gradually increases, in agreement with the pattern of phase transformations of aluminophosphates, described in [4, 14, 15].

The change in the phase composition of the products formed in drying of aluminophosphate solutions affects the solubility in water of the products obtained. An increase in the drying duration, accompanied by crystallization processes in the bulk of the product being dried, impairs its solubility in water. This is presumably because, in contrast to aluminum dihydrophosphate readily soluble in water, aluminum orthophosphate is virtually water-insoluble. The powders obtained at drying durations of up to 5 min are rather easily and virtually completely soluble in water. As the drying duration increases, only partial solubility is observed and an insoluble crystalline precipitate is present in a solution even upon a prolonged heating.

In the experiments, the variation of the pH value of the liquid phase was recorded in the course of dissolution of the aluminophosphate powder in water. The deviation from the pH value corresponding to the starting solution of the binder and the kinetics of pH variation indicate a reversible solubility of the product in water [1] i.e., the regenerated binder solution (obtained by dissolution of an aluminophosphate powder) and the starting solution not subjected to dehydration are identical.

Figure 3 shows the kinetics of variation of the pH value in the course of dissolution of aluminophosphate powders in water. According to these data, the product obtained by drying an APB solution for 5 min, with a water content of 20.8 wt % (w_{red} = 0.72), rather rapidly passes into a solution. In the process, the intensive hydrolysis of the solid phase in the initial period results in that the pH value approaches (curve *1*) the pH of a H_3PO_4 solution of equivalent concentration (1.85, curve *4*). The complete dissolution of the product is only achieved on heating the solution, with the pH value of the regenerated aluminophosphate solution equal to 2.1 (curve *3*). In may be noted,

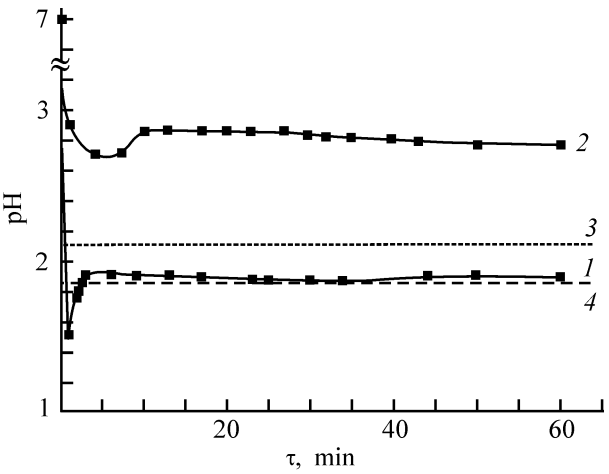

Fig. 3. Kinetics of pH variation in the course of dissolution of powder-like aluminophosphate binders (APB) in water. (τ) Time. APB composition, w_{H_2O} (wt %), and drying time (min), respectively: (*1*) $3.2P_2O_5 \cdot Al_2O_3$, 20.8, 5; (*2*) $3.2P_2O_5 \cdot Al_2O_3$, 10.5, 6.5. pH value: (*3*) ABP solution after complete dissolution of the $3.2P_2O_5 \cdot Al_2O_3$ powder, w_{H_2O} = 20.8 wt %, drying time 5 min; (*4*) 10% solution of orthophosphoric acid.

for comparison, that the pH of the starting binder solution of an equivalent concentration is 2.25.

The pH value of a solution of an aluminophosphate powder with a moisture content of 10.5 wt % (w_{red} = 0.88), produced by drying for 6.5 min, is substantially higher, 2.7–2.9, and shows a certain tendency to decrease (Fig. 3, curve *2*). However, complete dissolution is not achieved even upon prolonged drying and an insoluble precipitate is present in the solution.

These differences in solubility indicate that the dissolution of the products obtained is incongruent because of the hydrolysis of aluminophosphate in the initial stage of dissolution. The occurrence of this process is manifested in a clearly pronounced decrease in the pH value in the initial period (5–10 min) of contact between the liquid and solid phases (Fig. 3; curves *1*, *2*). In this case, a strong opalescence of the solution is visually observed, which disappears after several minutes of contact between the solution and the powder (the process is accelerated by heating and agitation.

The hydrolysis of aluminophosphates (analyzed for the example of aluminum dihydrophosphate) occurs in stages and is reversible:

$$Al(H_2PO_4)_3 + 6H_2O \rightleftarrows [Al(H_2O)_6]^{3+} + 3H_2PO_4^-, \quad (4)$$

$$[Al(H_2O)_6]^{3+} \rightleftarrows [AlOH(H_2O)_5]^{2+} + H^+, \quad (5)$$

$$[AlOH(H_2O)_5]^{2+} \rightleftarrows [Al(OH)_2(H_2O)_4]^+ + H^+. \quad (6)$$

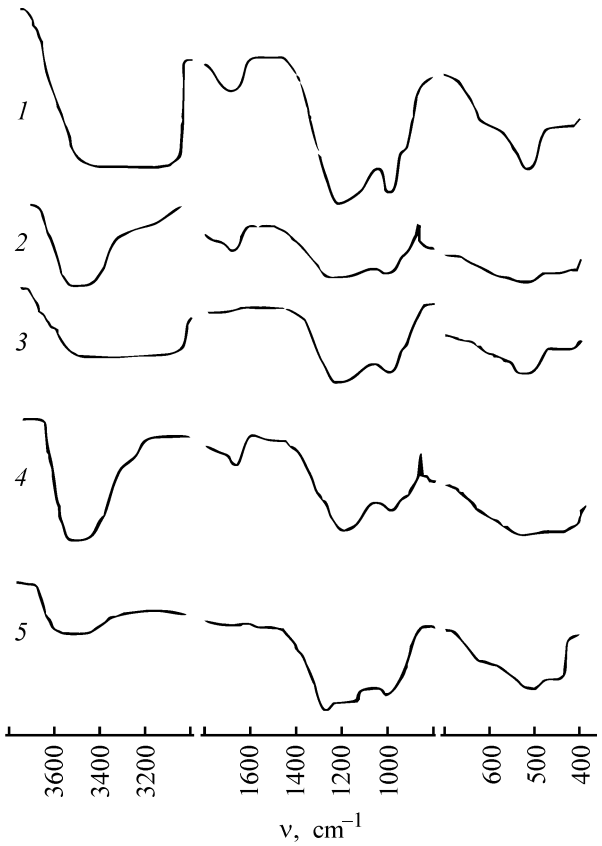

Fig. 4. IR transmission spectra of aluminophosphate solutions and powders. (ν) Wave number. APB: (*1*, *4*) starting solution, (*2*, *5*) powder, and (*3*) APB solution obtained by dissolution of the powder (sample no. 2). Composition: (*1*, *2*) $3.5P_2O_5 \cdot Al_2O_3$ and (*4*, *5*) $2.5P_2O_5 \cdot Al_2O_3$. w_{H_2O} (wt %): (*1*) 55; (*2*) 25.4, drying time 5 min; (*4*) 50; and (*5*) 7.0, drying time 7 min.

The occurrence of reactions (5) and (6) leads to a decrease in the solution pH, observed in the initial stage of dissolution of aluminophosphates. Subsequent keeping of a solution, and especially its heating, lead to occurrence of these reactions in the reverse direction, which is reflected in that the pH increases to values corresponding to the starting binder solution (Fig. 3).

When considering the influence exerted by the composition of aluminophosphates on their solubility, it should be noted that the solution formed in dissolution of products with a P_2O_5/Al_2O_3 ratio smaller than 3.5 is virtually always turbid and contains a crystalline precipitate. A decrease in the P_2O_5/Al_2O_3 molar ratio leads to an increase in the amount of the undissolved precipitate. The powders whose composition corresponds to a P_2O_5/Al_2O_3 ratio of 3.5 and more are completely dissolved to give transparent solutions without any precipitate.

This behavior is correlated with the dependence of the structure of the starting aluminophosphate solutions on their chemical composition, and primarily on the molar ratio between P_2O_5 and Al_2O_3. For example, it was noted in [16] that, at P_2O_5/Al_2O_3 molar ratios exceeding 3.4, aluminophosphate solutions are true solutions. At P_2O_5/Al_2O_3 smaller than 3.4, colloid formations appear in solutions.

If it is assumed that glass formation occurs in drying of an aluminophosphate binder because of the "freezing" of the structure of the starting solution [17], then dehydration of true aluminophosphate solutions ($P_2O_5/Al_2O_3 \geq 3.4$) will give glassy water-soluble products. Presence of colloid formations (at $P_2O_5/Al_2O_3 < 3.4$) that can serve as crystallization nuclei should enhance crystallization processes and favor an increase in the content of crystalline phases in the products formed in dehydration of binder solutions, just which is confirmed by the data obtained.

An IR spectroscopic study of the aluminophosphate products demonstrated (Fig. 4) that the IR spectra of both solutions and powders contain a number of broad bands in the region of stretching vibrations of hydroxyl groups (3580, 3300 cm^{-1}) and deformation vibrations of OH groups (1650, 1680 cm^{-1}), in agreement with the data of [4]. The positions of lines in the spectra of the starting solution (curve *1*) with a P_2O_5/Al_2O_3 ratio of 3.5 and a regenerated solution (curve *3*) are rather close (with the exception of the band at 1650 cm^{-1}, absent in the spectrum of the regenerated solution).

In the spectra of powdered aluminophosphates, the absorption intensity at 3000–3600 and 1650–1680 cm^{-1} decreases, compared with that in solutions, which is due to the removal of molecular water and hydroxyl groups in the course of dehydration (Fig. 4; curves *2*, *5*). Simultaneously, the region associated with absorption by hydroxyl groups and water becomes narrower (3000–3600 cm^{-1}) and lines in the region of stretching and deformation vibrations of P–O bonds (400–1400 cm^{-1}) are noticeably broadened.

In the spectrum of the aluminophosphate powder obtained upon drying of a solution with a P_2O_5/Al_2O_3 molar ratio of 2.5 (curve *4*), a diffuse broadening of the lines is observed, accompanied by their shift to higher frequencies. This points to noticeable structural changes occurring as a result of the intensive development of condensation and crystallization processes in thermal treatment of aluminophosphate solutions whose composition is characterized by P_2O_5/Al_2O_3 molar ratios smaller than 3.5.

CONCLUSIONS

(1) Kinetic dependences of moisture removal from aluminophosphate binder solutions in a microwave field were obtained. The influence exerted by their chemical composition and, in particular, by their modification with chromium and boron oxides on the dehydration process was considered. It was shown that the dehydration process is accelerated on raising the content of basic oxides (Al_2O_3, Cr_2O_3) in solution and decelerated in the case of acid oxides (P_2O_5, B_2O_3).

(2) An X-ray phase analysis demonstrated that mostly amorphous phases well soluble in water are formed in the initial stage of drying. As the drying is made longer, the content of crystalline products in the products obtained increases, which makes lower their solubility in water.

(3) The processes occurring in dissolution of aluminophosphates powders of various compositions in water were considered. The parameters of the chemical composition of powder-like aluminophosphate products that provide their complete solubility in water were suggested and substantiated: P_2O_5/Al_2O_3 ratio not lower than 3.5 and moisture content of no less than 18–20 wt %. The IR data obtained demonstrate that solutions prepared by dissolution of powders having the optimal chemical composition are identical to the starting aluminophosphate binders.

Abstract—Mechanism of interaction of copper sulfate with natural calcium carbonates, responsible for low residual copper concentrations in solutions and for the behavior of open and closed systems in storage is considered.

DOI: 10.1134/S1070427207100047

Natural calcium carbonates (limestone, marble, and dolomite) are used in wastewater treatment mainly as neutralizing reagents included in formulations [1, 2]. The use of calcium carbonates for acidity neutralization is widely known and has been repeatedly implemented in practice. The possibility of fixing toxic admixtures, including copper(II) ions, has been reported [2–6]. The interaction of solutions with a solid phase is usually regarded in this case as exchange of calcium and magnesium ions for ions of heavy nonferrous metals in solution [5, 6] or as sorption of products of their hydrolysis by carbonates [3–5]. Accordingly, the sorption or exchange capacity of a precipitator should be in the range from one hundredth of a milligram to tens of milligrams per gram, which restricts the application field of natural calcium carbonates for treatment of wastewater with low concentrations of metals and complicates analysis of the resulting compounds [2, 3].

Hydrolytic purification of solutions to remove copper requires that they should be alkalized to pH 8–12 [7], whereas precipitation of copper on carbonates occurs at pH 4–7 and the pH rarely reaches a value of 7.5–8 in real flow-through systems [5, 8]. When cakes are subjected to X-ray and microscopic analyses, independent copper-containing mineral phases are occasionally identified (mostly poorly soluble basic salts) [3, 5, 8]. The capacity of a precipitator reaches 0.83 g g^{-1} [5], which corresponds to reagent (but not sorption) precipitation methods and is close in stoichiometry to complete decomposition of the carbonate matrix.

The precipitation of basic salts of heavy metals has been studied in sufficient detail for the case of crystallization from solutions [9]. The formation of basic salts in a heterogeneous system constituted by a sulfate solution and solid calcium carbonate has virtually not been considered, despite the discovery of a number of natural associates of the corresponding composition in deposits of oxidized copper ores [10, 11]. An attempts to synthesize their artificial analogues from malachite or in the $CuO–SO_3–H_2O$ system failed [12]. It was shown in [8] that a wide range of minerals of basic copper sulfates (brochantite, posnjakite, and devilline) can be formed, depending on conditions of precipitation on natural calcium carbonates (initial concentration, temperature, and precipitator grain size).

This study is devoted to analysis of the mechanism of copper sulfate interaction with natural calcium carbonates.

EXPERIMENTAL

In the experiments, we used model solutions of copper sulfate with copper concentrations of up to 1 g l^{-1}, prepared from pure-grade reactive copper sulfate pentahydrate. To 1 l of the solution was added 1, 2, or 5 g of a precipitator. The experiments were carried out in glass beakers under static and dynamic conditions at room temperature.

The pH of the pulp was measured at regular intervals of time and 5-ml liquid-phase samples were taken

Mineral phase: G, gypsum ($CaSO_4 \cdot 2H_2O$); B, brochantite [$CuSO_4 \cdot 3Cu(OH)_2$]; P, posnjakite [$CuSO_4 \cdot 3Cu(OH)_2 \cdot H_2O$]; C, calcite ($CaCO_3$); D, devilline [$CaCu_4(SO_4)_2(OH)_6 \cdot 2H_2O$]; and M, malachite [$Cu_2(OH)_2CO_3$].

for determining the copper content of a solution on an AAS-30 atomic absorption spectrometer (Carl Zeiss, Jena, Germany).

The X-ray phase analysis of the precipitates was carried out on a DRON-3 X-ray diffractometer (Cu_{K_α} radiation, scanning at 0.02° intervals, accumulation time at a point 1 s). The X-ray diffraction patterns obtained were interpreted by the standard method, using the JCPDS file of reference spectra.

Compact colored precipitates (cyan to light green) readily separable from the liquid phase in settling or filtration were obtained in all the experiments. According to published data, copper precipitation upon contact with natural carbonates proceeds by an exchange reaction to give basic copper carbonates: malachite or azurite [11], in accordance with the overall equation

$$2CaCO_3 + 2CuSO_4 + 3H_2O = CuCO_3 \cdot Cu(OH)_2 + 2CaSO_4 \cdot 2H_2O + CO_2. \quad (1)$$

The solubility product of malachite (1.7×10^{-34}) [13] is sufficiently low for deep purification of solutions; however, the calculation formula (2) for this open system contains equilibrium concentrations of carbonate and hydroxide ions, resulting from the solubility of poorly soluble calcium carbonate (SP = 3.8×10^{-9}) [13] and from partial hydrolysis of carbonate ions, respectively, which leads to a pronounced increase in the threshold concentration of copper precipitation.

$$SP_{malachite} < [OH^-]^2 [CO_3^{2-}] a_{Cu^{2+}}^2. \quad (2)$$

The appearance of gypsum in the system reduces the equilibrium concentrations to an even greater extent and raises the residual copper concentrations to tens of parts per million.

In the experiments on solution purification, we obtained well-crystallized copper minerals, which can be readily identified. The X-ray diffraction patterns of typical products of copper precipitation on natural calcium carbonates are shown in Fig. 1. The key factor in copper fixation is the content and form of calcite ($CaCO_3$, JCPDS, 47-1743, d = 3.03 Å). Gypsum ($CaSO_4 \cdot 2H_2O$, JCPDS, 6-46, d 7.56, 4.27, 3.79 Å) was crystallized in all the experiments, except those with the most dilute solutions. In all cases, the precipitates are a mixture of basic copper sulfates with

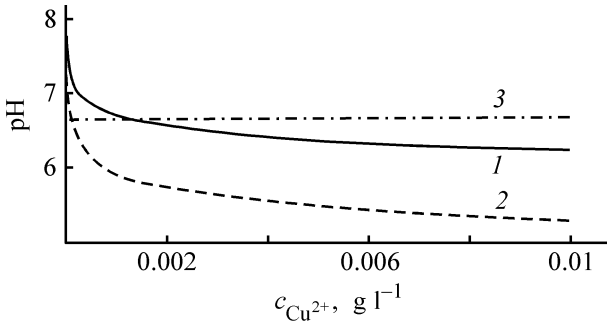

Fig. 2. Dependence of residual copper concentration $c_{Cu^{2+}}$ on the solution acidity. (*1*) Hydrolytic precipitation, (*2*) precipitation in the form of basic salts, and (*3*) pH of gypsum-carbonate buffer solution at 20°C.

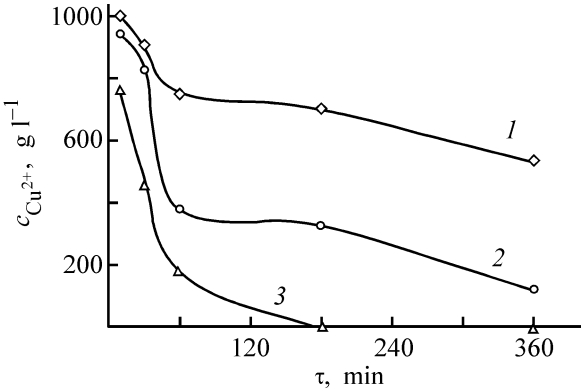

Fig. 3. Kinetics of copper precipitation on marbled limestone with 100% of particles less than 0.16 mm in size at various precipitator-to-copper ratios in solution. gypsum and residues of the starting calcium carbonate [brochantite, $Cu_4SO_4(OH)_6$, *d* 2.52, 6.38, 5.36 Å; posnjakite, $Cu_4SO_4(OH)_6 \cdot H_2O$, JCPDS, 20-364, *d* 6.94, 3.47, 2.70 Å; and devilline, $CaCu_4(SO_4)_2 \cdot (OH)_6 \cdot 3H_2O$, JCPDS, 13-285, *d* 10.22, 5.05, 3.37 Å]. Despite the diversity of mineral forms, the mechanism of copper precipitation on calcite reduces to the following scheme:

$$\underset{\text{Calcite}}{CuSO_4 + CaCO_3} \rightarrow Cu(OH)_2$$

$$\rightarrow \underset{\text{Brochantite}}{CuSO_4 \cdot 3Cu(OH)_2} + \underset{\text{Gypsum}}{CaSO_4 \cdot 2H_2O} + CO_2$$

$$\rightarrow \underset{\text{Posnjakite}}{CuSO_4 \cdot 3Cu(OH)_2 \cdot H_2O}$$

$$\rightarrow \underset{\text{Devilline}}{CaSO_3 \cdot CuSO_4 \cdot 3Cu(OH)_2 \cdot 3H_2O}$$

The results of our study and the existing theoretical concepts of formation of crystalline precipitates [9] suggest the following scheme for describing the interaction of aqueous copper sulfate solutions with calcium carbonate. First, copper hydroxide is formed when pH increases due to CO_3^{2-} hydrolysis in a solution layer close to the carbonate surface. This is a fast stage, but the given mineral phase is not identified by X-ray diffraction analysis, because it further coprecipitates with the excess of copper sulfate in the form of brochantite. The precipitates are formed with hexagonal lattices of the CdI_2 type in such a manner that each layer of metal ions is covered on both sides by similarly built layers of hydroxide groups. In sulfate solutions, the hydroxide groups of the intermediate disordered layers are replaced by sulfate anions, so that a SO_4^{2-} layer is situated between two OH^- layers. The formation of crystal hydrates in storage or in slow precipitate formation does not contradict the mechanism suggested and causes transfer from brochantite to posnjakite. In the case of a low concentration of sulfate ions (or a high gypsum concentration in the reaction zone), a layer of Ca^{2+} ions is further introduced via changed intermediate layers of SO_4^{2-} anions to give devilline.

If copper precipitates as a basic sulfate in contact of wastewater with calcium carbonate in accordance with the overall equation

$$3CaCO_3 + 4CuSO_4 + 5H_2O = Cu_4SO_4(OH)_6 + 3CaSO_4 \cdot 2H_2O + 3CO_2, \quad (3)$$

the threshold concentration of precipitation formation is determined mainly by the activity of sulfate anions

$$SP_{\text{Brochantite}} < [OH^-]^6 a_{SO_4^{2-}} a_{Cu^{2+}}^4$$

present in macroscopic concentrations in terms of hydroxide ions. On the whole, the resulting residual copper concentration is several orders of magnitude lower than that for the system corresponding to Eq. (2). In the case of univalent anions (Cl^- and NO_3^-), the dependence of the threshold concentration on the squared activity of the balance anion makes formation of malachite during the precipitation even less probable.

Furthermore, the formation of a large amount of gypsum and the presence of an excess of calcite result in that copper precipitates under the conditions of a gypsum-carbonate buffer solution maintaining pH at 6.3–6.5 [14]. A self-regulation of the fine precipitation mechanism takes place, because the concentration

of carbonate ions in solution is always lower than that of the salt-balance anions (in most cases, these are sulfates, but chlorides, nitrates, etc. are also possible) and there is no excess of hydroxide ions. In these conditions, no hydroxides and basic carbonates are formed, and heavy nonferrous metals precipitate in the form of basic salts. The described precipitation mechanism is made operative by the low solubility of calcium carbonates. Calculated dependences of the degree of copper precipitation as a hydroxide (curve *1*) and a basic salt (curve *2*) on the solution pH [15] are shown in Fig. 2. The straight line corresponds to the pH of the gypsum-carbonate buffer solution at 20°C. The precipitation of basic salts at this pH results in that the residual copper concentration in solution is nearly an order of magnitude lower than that for hydrolytic methods. The kinetics of copper precipitation on marbled limestone with 100% of particles smaller than 0.16 mm in size is shown in Fig. 3. With an excess of the precipitator (5 g of limestone per 1 g of copper in solution), the residual concentration of copper less than 0.1 ppm is reached in 3 h, with more than one day required at smaller ratios. The excess is necessary because calcite is partly consumed for neutralization of the starting weakly acid solution (as a result of Cu^{2+} hydrolysis, pH is ~5.5). In purification of solutions to remove copper, pH increased to 6.5–6.7, which indirectly confirms that the gypsum-carbonate buffer solution is formed. The pH level reached is apparently insufficient for deep hydrolytic precipitation [7] (Fig. 2).

Nevertheless, malachite can be formed under such conditions in view of (2) upon a sharp increase in the CO_3^{2-}-concentration, e.g., on adding concentrated Na_2CO_3 solutions, which is widely used in preparative syntheses of malachite and basic carbonates of other heavy nonferrous metals [9]. Alternatively, the process can be carried out in closed systems, which precludes fast removal of carbon dioxide (as it occurs under geological conditions). We also performed such a process in the study and obtained a well-crystallized malachite easily identified by X-ray diffraction analysis. However, the malachite formation is of clearly secondary nature, because brochantite is always formed in the first stage (which is readily indicated by the bright blue color of grains) and further reacts with carbon dioxide. This process also partly occurs as a result of saturation of solutions with atmospheric carbon dioxide in keeping, which causes the corresponding increase in the residual concentration of copper in the liquid phase in storage, as described in [3, 5].

CONCLUSIONS

(1) Copper precipitates from sulfate solutions on solid calcium carbonates in the form of basic sulfates. Basic carbonates can be formed in systems of this kind via secondary reactions of basic sulfates with carbon dioxide. The formation of a gypsum-carbonate buffer solution plays an essential role.

(2) The suggested scheme of formation and mutual transformations of basic sulfates can explain specific features of wastewater purification to remove copper and describe technological and geochemical processes in oxidized copper deposits.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Palladium Recovery with Thiourea from Nitric Acid Solutions

V. I. Tikhomirova, T. A. Desyatova, and V. A. Suvorova

Institute of Experimental Mineralogy, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received September 22, 2006

Abstract—Interaction in the system Pd(II)–HNO_3–$SC(NH_2)_2$ was studied. It was shown that the precipitates formed, which have various compositions and solubilities, contain palladium(II) and thiourea conversion products. Elemental, X-ray diffraction, and atomic-adsorption analyses and IR and electronic absorption spectroscopies were applied to demonstrate the possibility of virtually quantitative precipitation of palladium(II) under certain conditions in the form of a poorly soluble precipitate $Pd_2(CN)_4 \cdot H_2O$.

DOI: 10.1134/S1070427207100059

The study was carried out in view of the necessity for development of a technology for utilization of spent nuclear fuel (SNF) temporarily stored in the form of 3–6 M nitric acid solutions. The problem of palladium(II) recovery from products of SNF processing was discussed in the review [1]. It was emphasized that it is necessary to isolate the fraction of noble metals, which create certain difficulties because of the formation of a metallic phase in SNF vitrification. It is important to adapt the recovery of the platinum group fraction to the existing processing technology. The difficulty is in that poorly soluble precipitates containing considerable amounts of platinum group metals, together with Mo, Zr, U, Pu, etc., are formed in different stages of the process. There exist various approaches to, and methods of, Pd recovery from a nitric acid medium: adsorption on anion-exchange resins or activated carbon; extraction with organic phosphates, macromolecular amines, and quaternary ammonium bases; electrochemical deposition of Pd onto electrodes; and precipitation with the use of complexation. However, none of the approaches and methods could be brought to the industrial level. Further search for effective reagents and studies of their interaction with SNF components in a nitric acid medium are necessary.

Previously, up to 10 mg of metallic Pd per gram of carbon could be precipitated in a study of Pd(II)on activated carbons treated first with a saturated NaOH solution and then with thiourea (Thio) [2]. It has been reported that poorly soluble Pd(II) compounds are formed in interaction of Thio with Pd(II) in a nitric acid medium [3]. However, their formation conditions and composition required further analysis.

The aim of this study was to analyze the conditions of Pd(II) recovery with thiourea from 3–6 M HNO_3 solutions, composition of the compounds obtained, and the process of interaction between Thio and HNO_3.

EXPERIMENTAL

UV-Vis spectrophotometry (Carl Zeiss UV-Vis instrument) was used in the study. X-ray phase, micro X-ray fluorescence (Camebax instrument), and classical elemental analyses served to examine solid compounds. IR spectra were measured with a Perkin-Elmer 983 instrument in the range 200–4000 cm^{-1}, with samples of the solids under study prepared in dispersed form in pellets with KBr or CsI.

Thiourea complexes of Pd(II) in solutions were studied by potentiometric titration in a cell with a platinum indicator electrode and silver chloride reference electrode with a salt bridge (1 M KNO_3) at 25°C. In the process, the solution was uninterruptedly agitated with a magnetic rabble.

Pd(II) solutions with an initial concentration of 1–2 mg ml^{-1} were prepared by dissolving the metal of special purity grade in nitric acid. Thiourea of the same grade was used both as a solid and when dissolved in 0.02–3.00 M HNO_3.

The concentration of Pd(II) in solutions over precipitates was determined by atomic-absorption ana-

lysis with flameless atomization (Shimadzu AA-670G instrument). The atomization procedure in a GFA-4A furnace consisted in stages of drying of a solution aliquot at 120°C, salt dissociation at 650°C, and atomization at 2600°C (λ_{Pd} = 244.8 nm). The sensitivity of the analytical procedure was 0.01 μg per 1 ml of a final-dilution solution in 2 M HNO_3.

Figure 1 shows how the potential of the platinum electrode varies in the processes that occur in a system containing 0.01 M of aqua nitrate Pd(II) complexes, 0.02 M of HNO_3, and thiourea. Previously, it has been demonstrated [3] by the method of isomolar series that, at Pd(II) : Thio molar ratios equal to 3 and 4, the compounds formed have UV absorptions peaks at 345 and 300 nm, respectively.

The initial potential of the system in the absence of thiourea is 0.84 V relative to the silver chloride electrode or 1.062 V relative to the standard hydrogen electrode (s.h.e.). According to the data of [4], the standard potential of the $[Pd(H_2O_4)_4]^{2+}$/Pd pair is 0.99 V, and, consequently, that for a Pf(II) solution with a concentration of 0.01 M would be 0.96 V (s.h.e.), which is lower than the observed value. Presumably, the complexes under consideration also contain acido ligands that make E higher.

Upon addition of first Thio aliquots to a Pd(II)/Thio molar ratio of 1.1 to 1.2, a brown precipitate is rapidly formed. In the process, the potential decreases to the minimum extent, because the interaction of Pd(II) with products formed in conversion of thiourea is fast, its adsorption on the electrode is insignificant, and the HNO_3 concentration remains virtually unchanged, which maintains a high electrode potential (curves *1–3*). Curve 4 [Pd(II) : Thio = 1 : 2.5] shows an abrupt decrease in the potential, which corresponds to its dependence on the concentration of free Thio in solution and its adsorption on the electrode surface in accordance with the equation [5]:

$$E = E^0 + \frac{RT}{2F} \ln [C_2S_2N_4H_6]/[SC(NH_2)_2]^2, \quad (1)$$

where $E^0 = 0.408 - 0.420$ V.

At a Pd(II) : Thio ratio of 1 : 3, the precipitate starts to dissolve and makes the solution bright orange. In this case, the fast decrease in E is replaced with its comparatively slow rise (curves *5–7*). This behavior of Pd(II) complexes is similar to the results of a study of the acid-base properties of Pt(II) aqua complexes, with coordinated water molecules replaced with thiourea in the $[Pt(H_2O)(Thio)_2]^{2+}$ aqua complex [6]. It can be assumed that, first, NO_3^- anions in *trans*-

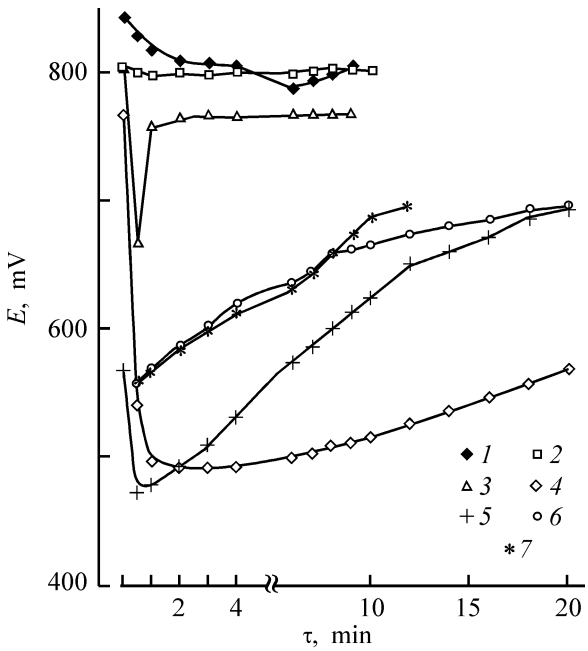

Fig. 1. Potential E of the platinum electrode in a solution of Pd(II) nitrate (10^{-2} M in terms of Pd) vs. time τ elapsed after addition of aliquots of a Thio solution (10^{-2} in a 0.02 M HNO_3 solution). Thio : Pd(II) molar ratio in solution: (*1*) 1.25, (*2*) 1.5, (*3*) 2.0, (*4*) 2.5, (*5*) 3.0, (*6*) 4.0, and (*7*) 4.5.

$[Pd(H_2O)_2(NO_3)_2]$ are substituted, and then water molecules themselves. At Pd(II) : Thio ratio of 1 : 4 (curve *6*), a stable yellow complex is formed (λ_{max} = 300 nm), which enables its use for analytical purposes [7].

As the Thio concentration is raised to Pd(II) : Thio = 1 : 6, the excess Thio is adsorbed on the electrode. This leads to a sharp decrease in the potential to 0.3 V for the Pt electrode and to 0.2 V for the Pd electrode relative to the Ag/AgCl reference electrode at a Thio concentration of 5×10^{-2} M. A calculation by Eq. (1) gives E = 0.25 V, which is close to the potentials obtained in [8] for acid sulfate solutions of Thio.

Further, precipitates formed in 3–6 M HNO_3 solutions with a Pd(II) concentration of 1×10^{-2} M were studied. Upon introduction of solid thiourea into the Pd(II) solutions, variously colored precipitates of Pd(II) compounds with Thio started to be formed. The precipitates were filtered off in 2 days, washed with distilled water to a neutral reaction, and dried in air. The residual content of Pd(II) in the filtrate was determined, and the Pd(II)/S ratio in the precipitates was found by the micro X-ray fluorescence technique (Table 1).

Table 1. Precipitate properties in relation to Pd(II) : Thio molar ratios in 3 and 6 M HNO_3 solutions upon addition of Thio

Pd(II) : Thio molar ratio	c_{HNO_3}, M	Thiourea	Precipitate color	Pd(II) : S in precipitate	Solubility $L \times 10^{-5}$, M, in 2 days
1.0 : 1.5	6	Solid	Brown	1.0 : 1.1	48.00
1.0 : 4.0	6	"	Red	2.1 : 1.0	4.55
1.0 : 6.5	6	"	Orange	1.6 : 1.0	0.13
1.0 : 10.0	6	"	Yellow	2.0 : 1.0	0.70
1.0 : 16.0	3	Dissolved with addition of solid	Yellow	2.1 : 1.0	1.30
1.0 : 4.0	3	Solid	Yellow	2.0 : 1.0	0.05

It can be seen from the data in Table 1 that, depending on the Pd(II) : Thio ratio and HNO_3 concentration, various poorly soluble compounds are formed. Raising the concentration of thiourea in the starting solution does not lead to any increase in the content of sulfur in the precipitates. In all probability, reactions involving products $SC(NH_2)_2$ of interaction with HNO_3 and HNO_2 are important under the experimental conditions. Therefore, accumulation of HNO_2 in the reaction of $SC(NH_2)_2$ with a 3–5 M solution of HNO_3 was studied.

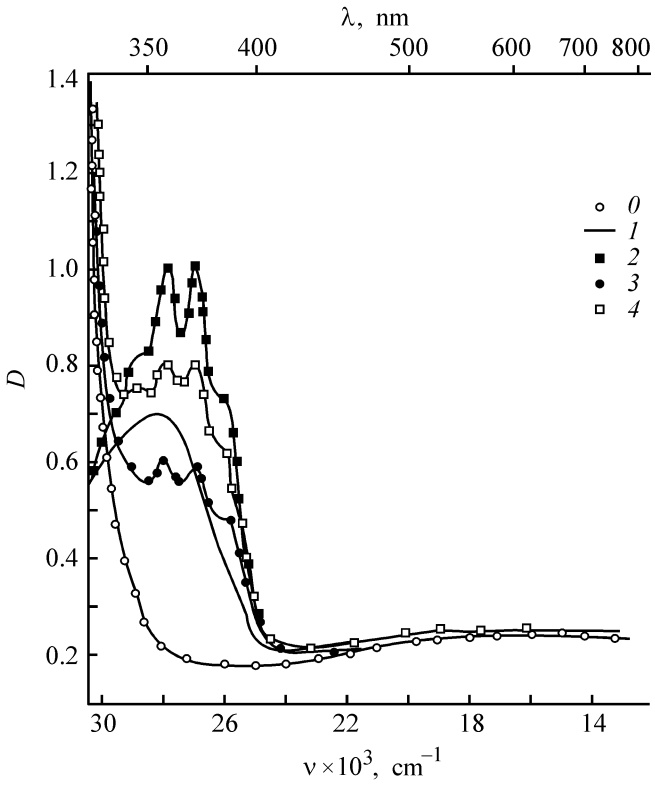

Fig. 2. Electronic absorption spectra of solutions of the starting HNO_3 and HNO_2 appearing as a result of reactions of HNO_3 with various reagents. (λ) Wavelength, (*D*) optical density, and (ν) wave number. Solution composition (M): (*0*) 4 HNO_3, (*1*) 0.05 $NaNO_2$, (*2*) 0.05 $NaNO_2$ + 0.5 HCl, (*3*) 4 HNO_3 + Thio (in 1 h), and (*4*) 4 HNO_3 + Thio (in 3 h).

In 3–6 M solutions of HNO_3, the potentials of the Pt electrode were fixed in the range 0.82–0.99 V (s.h.e.), which is determined by the equilibrium between HNO_3 and nitrogen oxides (for the $2HNO_3/N_2O_4$ pair, E^0 = 0.80 V) [9]. When $SC(NH_2)_2$ was mixed with HNO_3, the solution turned dark brown in 15–20 min and NO_2 was formed. However, the coloration rapidly disappeared, with gas evolution and the solution becoming turbid because of the release of elementary sulfur simultaneously observed. The formation of HNO_2 as a result of the reaction between Thio and a 4 M solution of HNO_3 was indicated by the absorption spectrum, which contained at 350–400 nm four equidistant bands (Fig. 2; curves *3*, *4*), absent in the spectrum of a pure HNO_3 solution (curve *0*). The thickness of the cuvette used was 0.5 cm. Because the same spectrum was observed for esters of HNO_2 [10], it was attributed to absorption by undissociated HNO_2, whose dissociation constant is 5×10^{-4}.

Figure 2 also shows absorption spectra of a 0.05 solution of $NaNO_2$ and of a mixture of 0.05 M of $NaNO_2$ with 0.5 M of HCl (curves *1*, *2*). It can be seen that, upon introduction of hydrogen ions in the form of HCl into the system, the absorption spectrum of NO_2^- ions takes the structure characteristic of HNO_2, which is attributed [11] to transitions in the –O–N=O group. According to the data obtained, the dependence of the absorption associated with HNO_2 on the concentration of NO_2^- ions in a 0.4 solution of HNO_3 is described by the Lambert–Beer law and can be used as a calibration dependence. The value

$\varepsilon = 20.4\ M^{-1}\ cm^{-1}$ obtained at $\lambda = 358$ nm coincides with that reported in [10].

Figure 3 shows dependences of the HNO_2 concentration in 3–5 M solutions of HNO_3 on the duration of their contact with thiourea. The initial concentration of thiourea in all the three sets of experiments was the same, 0.02 M. In the first, comparatively short, stage of HNO_2 accumulation, the rates of HNO_2 formation, found from the slopes of the initial portions of the curves, were 1.0×10^{-5}, 7.5×10^{-6}, and 5.0×10^{-6} mol l^{-1} s^{-1} in 5, 4, and 3 M solutions of HNO_3, respectively. This initial stage gives way to a rather long (22nd to 55th h) steady-state period, in which the rates of HNO_2 formation and expenditure are equal. In this case, the concentration of HNO_2 (0.032 M) is independent of the HNO_3 concentration and exceeds by approximately a factor of 1.6 the initial concentration of thiourea. As the HNO_3 concentration increases, the rates of HNO_2 formation and loss grow to the same extent and the steady-state period becomes shorter. The steady-state period is followed by the third stage, the HNO_2 concentration starts to decrease. This decrease corresponds to a first-order reaction in HNO_2 concentration, i.e., straight lines with slopes of -4.8×10^{-6}, -3.8×10^{-6}, and 2.4×10^{-6} are plotted in the $\ln c_{HNO_2}$–τ coordinates for 5, 4, and 3 M solutions of HNO_3, respectively. Thus, the rates of both expenditure and formation of HNO_2 are approximately proportional to the concentration of HNO_3.

The oxidation of thiourea is complex process; it depends on the solution acidity [6, 8, 12, 13] and occurs via intermediate formation of formamidine disulfide (FADS), which manifests itself in the UV part of the spectrum at 190–240 nm. In acid solutions, FADS is observed at potentials of 0.99–1.4 B (s.h.e.). The formation of FADS is preceded by protonation of Thio, which has been observed both in 1–3 M solutions of H_2SO_4 and in $HClO_4$ [8, 12, 14]. It has been shown, using X-ray photoelectron spectroscopy, that the protonation is associated with conversion of sulfur from the thion to thiol form, i.e., proton is added to a sulfur atom. In HNO_3 solutions with concentrations exceeding 2 M, FADS is also formed from thiourea [10]. Further transformations of FADS yield cyanamide, sulfur, thiocyanic acid, and HCN [15]. The main processes occurring when Thio is brought in contact with HNO_3 can be represented by the following reactions:

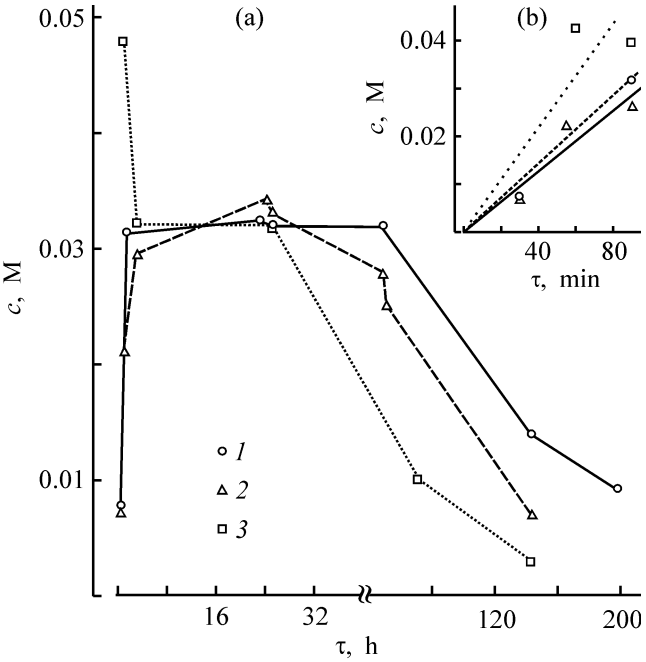

Fig. 3. (a) Dependences of the concentration c of nitrous acid on the time τ of contact between thiourea (2×10^{-2} M) and HNO_3 of various concentrations and (b) the same dependences in the initial 90 min. HNO_3 Concentration (M): (*1*) 3, (*2*) 4, (*3*) 5.

$$SC(NH_2)_2 + HNO_3 \rightleftarrows [H^+SC(NH_2)_2]NO_3, \quad (2)$$

$$2[H^+SC(NH_2)_2]NO_3 \rightarrow S_2C_2N_4H_6 + 2NO_2 + 2H_2O, \quad (3)$$

$$2NO_2 \rightarrow N_2O_4, \quad (4)$$

$$N_2O_4 + H_2O \rightarrow HNO_3 + HNO_2, \quad (5)$$

$$2[HSC(NH_2)_2]NO_3 + 2HNO_2 \rightarrow S_2C_2N_4H_6 + 2NO + 2H_2O + 2HNO_3, \quad (6)$$

$$2NO + HNO_3 + H_2O \rightarrow 3HNO_2 \quad (7)$$

$$S_2C_2N_4H_6 + HNO_2 \rightarrow S + NH_2CN + HNCS + N_2 + 2H_2O, \quad (8)$$

$$S + 2HNO_2 \rightarrow H_2SO_4 + N_2, \quad (9)$$

$$HNCS + 2HNO_3 \rightarrow HCN + H_2SO_4 + 2NO. \quad (10)$$

In the steady-state portion

$$[HNO_2] = \frac{K_2[HSC(NH_2)_2NO_3]^2}{K_7[S_2C_2N_4H_6]} = 3.2 \times 10^{-2}\ M. \quad (11)$$

It was shown in [16–18] that, in aqueous solutions of such acids as H_2SO_4, HCl, $HClO_4$, CF_3COOH,

Table 2. Formation conditions of Pd(II) compounds with RThio (white color) at an initial Pd(II) : Thio ratio of 1 : 6 in 3 and 4 M solutions of HNO_3

c_{HNO_3}, M	Duration of contact of Thio with HNO_3, h	Properties of precipitates		
		Pd(II) : S	duration of precipitate formation, days	solubility $L \times 10^{-5}$, M
3	90	45 : 1	3	1.40
			7	0.02
3	24	45 : 1	5	0.05
4	24	45 : 1	7	0.01

and in *n*-toluenesulfonic acid, the concentration of solvated protons is proportional to the acid concentration and independent of the nature of anions. According to [8], the protonation constant K_p of Thio in aqueous solutions of H_2SO_4 is 31.7, i.e., the basicity constant $K_b = 0.0315$. According to [19], the Hammett acidities $H_o = -\log h_o$ in 3, 4, and 5 M solutions of HNO_3 are –1.02, –1.32, and –1.57, respectively. In accordance with [20],

$$K_{eff} = K\alpha = \frac{K}{1 + 1/K_o h_o}. \quad (12)$$

where $\alpha = AH^+/c$, AH^+ is the concentration of protonated molecules, and $AH^+ + A = c$.

Thus, the concentration of $H^+SC(NH_2)_2NO_3$ in the initial stages is 5×10^{-3}, 7.9×10^{-3}, and 9.2×10^{-3} M in 3, 4, and 5 M solutions of HNO_3, respectively, and, accordingly, $K_2 \approx 1.4 \times 10^{-1}$ mol l^{-1} s^{-1} is obtained from the HNO_2 formation rates. After the steady-state portion, it follows from the slopes of the straight lines for the third stage that $K_7[S_2C_2N_4H_6] = 2.4 \times 10^{-6}$, 3.8×10^{-6}, and 4.8×10^{-6} s^{-1} in 3, 4, and 5 M nitric acid solutions. In the steady-state stage, the concentration $[H^+SC(NH_2)_2NO_3]$ is about 7.3×10^{-4}, 9.2×10^{-4}, and 1×10^{-3} M. According to estimates, approximately 25–30% of the initial amount of thiourea is converted by the beginning of the steady-state stage. While the ratio $[H^+SC(NH_2)_2NO_3]^2/[S_2C_2N_4H_6]$ retains a constant value, the concentration of HNO_2 remains at the level of 3.2×10^{-2} M. Lowering the $SC(NH_2)_2$ concentration to virtually zero leads to a decrease in the HNO_2 concentration via reactions (8) and (9). HCN is accumulated in solution.

Products of Thio oxidation in a nitric acid medium (RThio) form with Pd(II) white precipitates, some of whose properties are listed in Table 2.

It can be seen from Table 2 that the atomic content of Pd in the precipitates markedly exceeds that for S. The precipitates are completely formed after 5–7 days.

Taking into account the exceedingly low solubility of the practically important white precipitate, primary attention was given to its analysis. The following results were obtained in an elemental analysis of white precipitates (%): C 14.14 and 14.18, H 0.7 and 0.68, Cl not found, N 16.43 and 16.54, residue 62.55. The content of Pd in a precipitate dehydrated at 150°C is 67.84%. In accordance with the results of analyses, the formula of the compound can be represented as $[Pd_2(CN)_4] \cdot H_2O$. A precipitate with Ag^+, obtained under the same conditions, was identified by X-ray phase analysis (XPA) as AgCN. It can be assumed that a cyanide group is also present in the compound of Pd(II) with RThio. This was confirmed by the IR spectrum of the white precipitate (Fig. 4), which contains an absorption band with a frequency characteristic of the cyanide group (2213 cm^{-1}). Consequently, hydrocyanic acid, weakly dissociated in the acid medium ($K_{dis}HCN = 7.2 \times 10^{-10}$), is accumulated because of the complete destruction of thiourea.

The completeness of palladium precipitation in the form of $[Pd_2(CN)_4] \cdot H_2O$ with a solubility $L = 2 \times 10^{-7}$ M is reached in the course of time in interaction with HCN, which is gradually accumulated in the solution as a result of reaction (10). It was found that, in a solution with a M : Thio ratio of 1 : 10, the products of Thio conversion do not precipitate Fe(III), Ni(II), Mn(II), and Cr(III) ions.

The following results were obtained in an elemental analysis of red precipitates (%): C 12.74 and 12.38, H 1.13 and 1.12, Cl not found, N 20.78 and 20.73, S 7.91 and 8.72, Pd 49.71 and 49.08. The formula of the compound can be assumed to be $Pd_2(CMS) \times$

$(NH_2CN)(CN)_3 \cdot 2H_2O$. An XPA of white and red precipitates demonstrated that these compounds are amorphous. The white compound decomposes upon heating to 500–600°C to give a metallic Pd powder.

Figure 4 shows IR spectra of the white and red precipitates, together with the spectrum of the starting thiourea, which coincides with that reported in [21]. The absorption bands at 2213 cm^{-1} are associated with vibrations of the cyanide group –C=N [21–23]. A certain shift of these vibrations to higher frequencies suggests that bridging structures are formed [22]. The absorption bands peaked at 3421 and 1618 cm^{-1} are attributed to H_2O molecules [22]. The low-intensity bands at 544 and 464 cm^{-1} in the white substance and those at 548, 462, and 430 cm^{-1} in the red substance indicate that coordination bonds are formed between palladium(II) atoms and CN and CNS groups [22]. It was shown in [24] that simultaneous coordination of Pd(II) both with S atoms and with N atoms is possible. At the same time the band peaked at 1415 cm^{-1} for the red precipitate indicates that NH_2 groups are present in this compound, and the absorption band at 3428 cm^{-1} can be regarded as superposition of bands related to NH_2 and H_2O. The bands at 1380 and 730 cm^{-1} for thiourea and at 1340, 1225, and 780 cm^{-1} for the red precipitate are related to C=S vibrations [23].

CONCLUSIONS

(1) In principle, Pd(II) can be effectively recovered from nitric acid solutions as a $[Pd_2(CN)_4] \cdot H_2O$ complex formed in interaction of aqua acido complexes of palladium(II) with products of thiourea decomposition in solutions with an HNO_3 concentration of 3–6 M.

(2) The compound $[Pd_2(CN)_4] \cdot H_2O$ decomposes upon heating to 500–600°C to a pure metallic Pd powder.

Abstract—Possibility of obtaining an energy-saturated metal complex, copper tetrakis[cyclopentamethylenetetrasol] perchlorate, was studied by reacting copper(II) perchlorate hexahydrate with cyclopentamethylenetetrazol. The composition and structure of the complex were confirmed by elemental analysis and UV, IR, ^{1}H NMR, and ESR spectroscopies. The thermal decomposition of the metal complex synthesized was analyzed and its explosive characteristics and combustion law, as well as the combustion law of a model formulation of a composite solid propellant with addition of the complex, were determined.

DOI: 10.1134/S1070427207100060

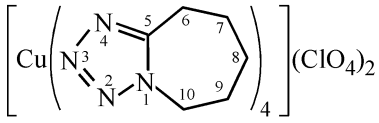
Modern tendencies in the development of rocket technology presume use of fuels with high energy-related characteristics. The specific momentum of the fuels is raised by introduction of energetic components with high heat of combustion, e.g., aluminum. However, this gives rise to the problem of a strong pressure dependence of the combustion velocity of fuels of this kind [1].

This problem can be solved by introduction into fuels of additives that intensify processes occurring in the condensed phase (C-phase).

It is known from the literature that copper complexes containing polynitrous compounds as a ligand can be used as modifiers of composite solid propellants (CSP) [2].

Modifiers based on complex copper perchlorates are use because they not only make weaker the pressure dependence of the combustion velocity of CSP, but also make faster the total combustion velocity of the fuels. In this case, the cation catalyzes the combustion velocity on the molecular level [3, 4].

We studied as a potential modifier of the combustion process of CSP the previously obtained complex copper(II) tetrakis-(1,5-pentamethylenetetrazol) perchlorate [complex (1)]:



Complex (1)

Previously, complex (1) has been prepared in a solution of 2,2-dimethoxypropane in 96% yield [5].

Because of the high cost and deficiency of 2,2-dimethoxypropane, a search was carried out for alternative solvents and, in particular, the possibility of using water and isopropyl alcohol was analyzed.

1,5-Pentamethylenetetrazol (PMT) contains "pyridine nitrogen atoms" and has a high dipole moment (6.14 D). It exhibits both weak basic and weak acid properties [6, 7]. In the spectrochemical series of ligands, it occupies a place between water and ammonia [8]. In view of this circumstance, we can assume that it will replace water in the inner sphere of copper perchlorate hexahydrate, to form compounds with a neutral form of the ligand. The complex was synthesized by the following scheme:

$$Cu(ClO_4)_2 \cdot 6H_2O + 4PMT \rightarrow [Cu(PMT)_4](ClO_4)_2.$$

With water used as a solvent, the product yield is about 60%; with isopropyl alcohol (IPA), a minor amount of ethyl acetate (25% relative to the IPA volume) is to be added to the reaction mass for precipitating the target product. The yield of the product is about 80%.

IR spectra of the complexes synthesized contain absorption bands of all the fragments: coordinated pentamethylene and tetrazol rings, perchlorate anions.

Data furnished by ^{1}H NMR spectroscopy for a free ligand and the copper complex are listed in Table 1.

Table 1. Chemical shifts of protons in PMT and complex (1)

Compound	δ_1	δ_2	δ_3	δ_4	δ_5
	ppm				
PMT	1.68	1.80	1.91	3.07	4.51
$[Co(PMT)_4](ClO_4)_2$	1.57	1.70	1.81	2.92	4.41

As can be seen from Table 1, the methylene group bonded to the carbon atom of the tetrazol ring shows a stronger hypsochromic shift, compared with the methylene group bonded to N^1 nitrogen atom of the ring, which evidences in favor of the coordination of ligands at the N^4 nitrogen atom of the tetrazol ring.

An analysis of the UV spectrum of complex (1) demonstrated that PMT is a monodentate ligand. A single asymmetric absorption band lies in the range 670–800 nm and represents two *d–d* transitions, λ_{max} = 680 nm, ε = 61 (according to published data [9], λ_{max} = 670 nm, ε = 81).

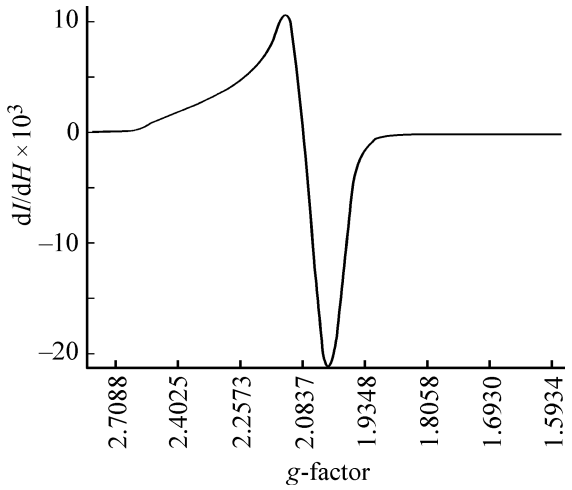


Fig. 1. ESR spectrum of a perchlorate copper complex.

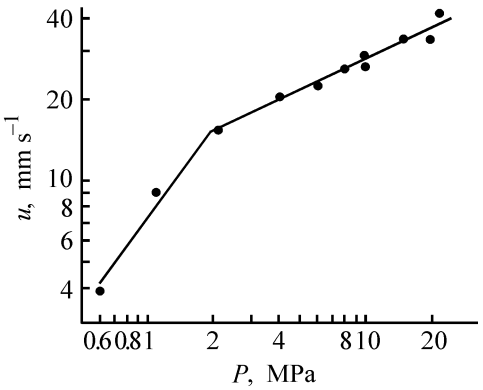

Fig. 2. Combustion velocity *u* of the perchlorate copper complex vs. pressure *P*.

The ESR data for complex (1) demonstrated that the compound obtained has a certain tetragonal symmetry with a distortion along the *Z* axis (Fig. 1).

The whole set of the physicochemical and spectral data we obtained indicates that complexes synthesized in various solvents are identical to the compound reported in the literature [5, 9].

A study of the thermal decomposition of complex (1) under nonisothermal conditions at a heating rate of 5 deg min^{-1} demonstrated its good thermal stability: the onset temperature of fast decomposition exceeds 230°C. In the first stage of decomposition, a 30% decrease in the sample mass is observed in the temperature range 185–235°C, accompanied by an exothermic effect. Probably, one PMT molecule is oxidized in this stage of thermal decomposition by one outer-sphere perchlorate anion. In the second stage of thermal decomposition, in the temperature range 240–305°C, a second PMT molecule is oxidized by the remaining perchlorate anion. The solid residue formed is a copper-containing product of unknown composition and structure.

To assess the possibility of using complex (1) as a catalyst of CSP combustion, we studied the combustion laws of both the complex itself and a model formulation with addition of this complex. A plot describing the pressure dependence of the combustion velocity (combustion law) is shown in Fig. 2.

The perchlorate copper complex we obtained shows two combustion portions with different slopes.

The lower combustion limit of the complex is 0.5 MPa. In the range from 0.5 to 2 MPa, the exponent ν in the combustion velocity law has a value of 1.089, i.e., the combustion process occurs exclusively in the gas phase. Above 2 MPa, the straight line describing the pressure dependence of the combustion velocity has another slope (ν = 0.383) because of the change of the limiting stage of the reaction. At high pressures, the processes occurring in the condensed phase become rate-determining.

The REAL software was used to calculate the combustion temperatures and theoretical composition of the combustion products. As an input parameter for the program we used the enthalpy of formation of the starting metal complex (ΔH_f^0 = 439 kJ kg^{-1}).

The calculated concentrations of the combustion products formed at 10 MPa are listed in Table 2.

The calculated combustion temperature of the complex is 1651 K.

Ballistic tests of model formulations composed of ammonium perchlorate, aluminum, copolymer of 2-methyl-5-vinyltetrazole with methacrylic acid (PMVT) [TU (Technical Specification) 38-403-208–88], and 2% addition of the complex demonstrated the following (Table 3). The exponent ν decreases from 0.71 for the base composition to 0.56, which confirms that the additive exerts positive influence on the processes occurring in the condensed phase.

EXPERIMENTAL

The IR spectra were recorded on a Shimadzu FTIR 8400 spectrophotometer in KBr pellets, and ^{1}H NMR spectra, on a Bruker AC radio spectrometer (working frequency 400 MHz), with DMSO-d_6 as internal standard. The UV spectra were measured with a Perkin–Elmer LAMBDA 40 spectrometer in quartz cuvettes (1 cm). The reaction course was monitored with TLC (UV-254 Silufol plates, 3% aqueous solution of sodium perchlorate as eluent).

A derivatographic analysis was performed on an MOM derivatograph (Hungary) at a heating rate of 5 deg min^{-1}.

The combustion velocity of the model formulation was measured in a BPD-25 bomb at constant pressures of 4 and 10 MPa.

PMT purchased from ACROS ORGANICS (98% purity, mp 58.5°C), copolymer of 2-methyl-5-vinyltetrazole with methacrylic acid (PMVT) (TU 38-403-208–88), and bis-(azidoethyl)-*N*-nitroamine plasticizer were used in the study.

The composition of the model fuel was as follows (%): ammonium perchlorate of C brand (<50 μm) 32, that of A brand (TU 84-942–82, S_{sp} = 12000 cm^2 g^{-1}) 32, aluminum of ASD-6 brand (S_{sp} = 6000 cm^2 g^{-1}) 6, binder and plasticizer 28, and complex (1) 2.

General procedure for synthesis of complex (1). Synthesis in an aqueous medium. To a solution of copper perchlorate (0.91 g) in 30 ml of water was added, under stirring at room temperature, a calculated amount of PMT (1.36 g), and the reaction mass was heated at 60°C for 2 h. The precipitate formed on cooling the mixture to 17°C was filtered off, washed with ethyl acetate (20 ml), and recrystallized from 30 ml of isopropyl alcohol, to give 0.61 g (60%) of a light blue product. IR spectrum, ν (cm^{-1}): 2860 (ν_s CH_2); 1925 (ν_{as} CH_2); 1454 (N=N); 1352, 1337 (C=N); 1282, 1268 (N–N); 1100–800 (Tz). ^{1}H NMR spectrum, δ (ppm): 4.41 (2H, s, CH_2–N), 2.92 (2H, s, CH_2–C), 1.81 (2H, s, C-7), 1.70 (2H, s, C-9), 1.57 (2H, s, C-8).

Found (%): C 34.99, H 5.1, N 27.49.

$C_{24}H_{40}Cl_2CuN_{16}O_8$.

Calculated (%): C 35.4, H 5.95, N 27.5.

Synthesis in isopropyl alcohol. To a solution of copper perchlorate (0.91 g) in 35 ml of isopropyl alcohol was added, under stirring at room temperature, a calculated amount of PMT (1.36 g), and the reaction mass was heated to 60°C and kept at this temperature for 1 h. On cooling the mixture to 17°C, a small amount of ethyl acetate (~5–10 ml) was added and the precipitate formed was filtered off, washed with ethyl acetate (20 ml), and recrystallized from 30 ml of isopropyl alcohol, to give 0.81 g (80%) of a light

CONCLUSIONS

(1) Copper(II) tetrakis-[1,5-pentamethylenetetrasol] perchlorate can be successfully obtained in an aqueous solution or in isopropyl alcohol.

(2) Copper(II) tetrakis-[1,5-pentamethylenetetrasol] perchlorate is a promising catalyst of combustion of solid propellants.

ACKNOWLEDGMENTS

The study was financially supported by the Ministry of Education and Science of the Russian Federation (Program "Development of the Scientific Potential of Higher School Institutions," subprogram II "Applied Research and Development in Priority Areas of Science and Technology") and by State contract no. 02.444.11.7051.

The authors are grateful to V.P. Sidnitskii (Mendeleev Russian University of Chemical Engineering) for assistance in determining the combustion velocity of the complex synthesized.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Production of Foamed Cryogels by Chemical Gas Generation in an Aqueous Solution of Poly(vinyl Alcohol)

Abstract—Foamed cryogels were produced using the gas liberated in a redox reaction in an aqueous solution of poly(vinyl alcohol). The kinetics of the gas-generating reaction was studied. The mechanical and thermal characteristics of the foamed cryogels obtained were determined.

DOI: 10.1134/S1070427207100072

Cryogels formed from aqueous solutions of poly(vinyl alcohol) (PVA) in a freeze–thaw cycle and possessing properties of elastic bodies have found wide use in biotechnologies and medicine and are promising for technological processes used in extraction and transportation of oil [1]. Introduction of a gaseous phase into the solid cryogel matrix gives foamed cryogels, which can be used as heat-insulating materials and blocking screens of hydraulic works.

There exist various methods for formation of foamed cryogels by mechanical frothing of an aqueous solution of poly(vinyl alcohol) [2]. These are, for example, stirring and shaking of a polymer solution or bubbling of air through a Schott filter. Formation of foamed cryogels requires starting foams that are stable in the course of time. The stability of a foam increases with the polymer concentration in the solution. However, the foams formed by the mechanical method even from a concentrated solution (c_{PVA} = 100 kg m^{-3}) have a destruction time shorter than half an hour, which is obviously insufficient for full freezing of a frothed sample [3]. Any further increase in the polymer concentration in a solution is inadvisable because it leads to a sharp rise in the solution viscosity and makes impossible formation of a finely dispersed and stable foam from this solution. Therefore, it seems unlikely that the mechanical method for preparation of gas-saturated systems with large foam ratio could be used in practice. In addition, the foamed cryogels formed by the mechanical method have unstable and poorly reproducible properties. Therefore, to prepare a stable starting foam with a large volume ratio, we used the chemical gas-generation method in which the following reactions occurring in the acid medium were performed in the polymer solution:

$$NH_4Cl + NaNO_2 \rightarrow NaCl + 2H_2O + N_2\uparrow, \quad (1)$$
$$\Delta H = -309 \text{ kJ};$$

$$NH_4NO_3 + NaNO_2 \rightarrow NaNO_3 \cdot 2H_2O + N_2\uparrow, \quad (2)$$
$$\Delta H = -314 \text{ kJ};$$

$$NH_4CNS + 4NaNO_2 + 2H^+ \rightarrow Na_2SO_3 + 2Na^+ + 3H_2O + CO_2\uparrow + 3N_2\uparrow, \quad (3)$$
$$\Delta H = -1486 \text{ kJ};$$

$$(NH_4)_2CO_3 + NaNO_2 + 2H^+ \rightarrow NaNO_2 + 2NH_4^+ + H_2O + CO_2\uparrow, \quad (4)$$
$$\Delta H = -52 \text{ kJ}.$$

The advantage of the first three redox reactions is that they are accompanied by pronounced heat release and warming-up of the reaction mixture (Fig. 1). It

is known that, in storage of a PVA solution at temperatures below 40°C, macromolecules associate and the polymer solution stratifies because of the sedimentation of supramolecular formations that have a somewhat higher density than the solvent [4].

These density fluctuations of the polymeric substance in the starting solution adversely affect the strength of foamed cryogels produced from this solution. The heat released in exothermic reactions homogenizes the starting poly(vinyl alcohol) solution.

The foams have low heat conductivity [5] and, therefore, a certain time is required to freeze them in production of a foamed cryogel. Therefore, only stable frothed systems can be used in practice. The variation of the foam ratio in reactions (1)–(4) in the polymer solutions in which competing processes of foam formation and destruction occur simultaneously is demonstrated in Fig. 2. The foam column increases or settles down, depending on which process dominates at a given instant of time. As follows from Fig. 2, the presence of carbon dioxide adversely affects the foam strength (Fig. 2, curves *3*, *4*); the foam already starts to disintegrate 1 hour after being formed. Consequently, it seems unpromising to use reactions (3) and (4) to produce foamed cryogels.

The most stable foam is formed in systems containing ammonium chloride or nitrate as a reducing agent. In the course of reactions (1) and (2), the volume of finely dispersed foam gradually increases, reaches a maximum in 2 h, and is preserved without any visually observed disintegration during several hours. Reaction (1) also yields, in addition to nitrogen, sodium chloride, whose presence makes the foamed cryogel stronger and improves its thermal stability [3]. Therefore, just the gas-generating reaction (1) was chosen as the optimal way to further formation of foamed cryogels after a freeze–thaw cycle of the frothed system. This reaction is catalyzed by weak acids.

The gaseous product formed by reaction (1) is nitrogen in a weakly acid medium (pH > 5) and nitrogen oxide oxidized to nitrogen dioxide in the presence of atmospheric oxygen at pH < 4 [reaction (1a)]. As a catalyst was chosen aluminum chloride, whose aqueous solutions have pH 3 to 7 at different concentrations of the hydrolyzed salt. Simultaneous reactions occur in these solutions. Depending on the acidity of the medium, the dominant reaction is (1) or disproportionation of the nitrite anion [reaction (1a)]:

$$3NaNO_2 + 2H^+ \rightarrow 2Na^+ + NaNO_3 + H_2O + 2NO, \quad (1a)$$

$$\Delta H = -167 \text{ kJ}.$$

The results obtained in determining the influence exerted by the concentration and catalyst on the volume and chemical nature of the evolving gas are shown in Fig. 3. It can be seen that, at the aluminum chloride concentration $c_{AlCl_3} = 0.3$ M, the rate of the redox reaction (1) is the highest At lower catalyst concentrations ($c_{AlCl_3} = 0.1$ M) the reaction rate is slower and the total amount of nitrogen evolved in a rather long period of time (more than 600 s) tends to a limiting value (curve *1*). At a catalyst concentration raised to 1 M, i.e., in a more acid medium, the reaction occurs in two directions to give both nitrogen and nitrogen oxide. In this case, reaction (1a) is dominant (curve *3*). The total volume of the gas evolved in this reaction is somewhat smaller because only 2/3 mol of nitrogen dioxide is formed in this reaction per mole of the oxidant. To preclude release of a chemically active "brown gas" in further experiments on frothing of a polymer solution, we used

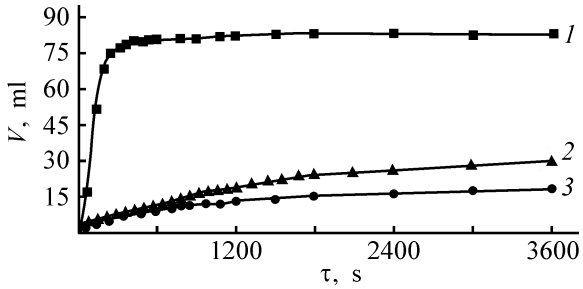

Fig. 4. Volume V of nitrogen evolved in oxidation of ammonium chloride with sodium nitrite vs. the reaction time τ. NH_4Cl, $NaNO_2$ concentration (M): (*1*) 2.5, in water; (*2*) 1.25, in water; (*3*) 1.25, in poly(vinyl alcohol) solution (c_{PVA}).

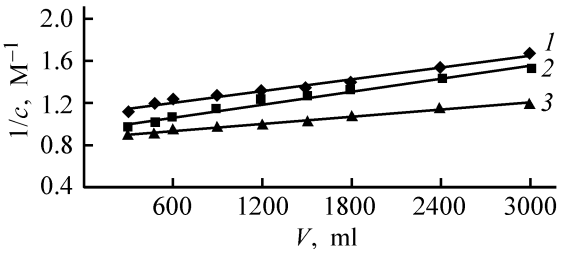

Fig. 5. Inverse concentration c of the reagents vs. the time τ of ammonium chloride oxidation with sodium nitrite in the presence of aluminum chloride. c_{AlCl_3} = 0.05 M. Solution (M): (*1*) aqueous, $c_{NH_4Cl} = c_{NaNO_2}$ = 1.25; (*2*) aqueous, $c_{NH_4Cl} = c_{NaNO_2}$ = 2.5; (*3*) polymer, c_{PVA} = 50, $c_{NH_4Cl} = c_{NaNO_2}$ = 1.25.

aluminum chloride in concentrations lower than 0.1 M, which results in that only nitrogen is released.

To form the foamed cryogel with prescribed foam ratio (gas saturation) at negative temperatures, it is necessary to know kinetic properties of the redox reaction (1) in a pure solvent (water) and in a polymer solution. The reaction of sodium nitrite and ammonium chloride was studied on a gas-meter installation. The concentrations of the reagents (oxidizing and reducing agents) in the solutions were varied, whereas the catalyst concentration was constant (0.05 M). The results of the experiments are shown in Fig. 4.

Based on the empirical data (Fig. 4), which are represented in Fig. 5 as a dependence of the inverse reagent concentrations on time, we found a second order for the reaction described by the kinetic equation

$$1/c = 1/c_0 + k\tau,$$

where τ is the reaction time; k, rate constant of the reaction; c_0, initial concentration of the reagents; and c, running concentration at instant of time τ.

The slopes of the straight lines *1* and *2* in Fig. 5 are the same [$k_w = 0.24 \times 10^{-3}$ l (s mol)$^{-1}$ at 25°C], i.e., the rate constant of reaction (1) in water is independent of the reagent concentrations. The decrease in the slope of the straight line *3* and, consequently, in the rate constant of the redox reaction in the polymer solution (c_{PVA} = 50 g l^{-1}) to a value $k_{PVA} = 0.14 \times 10^{-3}$ l (s mol)$^{-1}$ is due to the diffusion hindrance to motion of reagent molecules in the viscous polymeric medium. The experimentally determined rate constants of the reaction between sodium nitrite and ammonium chloride in water (k_w) and in polymer solution (k_{PVA}) at other temperatures are listed in Table 1. The activation energies of the reaction and the pre-exponential factors of the equation in water and polymer solution (E_w, A_w and E_{PVA}, A_{PVA}, respectively) were calculated using the Arrhenius equation from the empirical data in Table 1: $E_w \approx E_{PVA} \approx$ 60 kJ mol^{-1}, $A_w = 6.76 \times 10^6$ l (s mol)$^{-1}$ and $A_{PVA} = 4.14 \times 10^6$ l (s mol)$^{-1}$.

Using the kinetic pattern of chemical frothing of the polymer solution, elucidated in this study, i.e., varying the concentrations of the gas-generating components and the time of foam formation at positive temperatures (before the freeze stage), we obtained foamed cryogel samples with various compositions and viscosities. To form elastic foamed cryogels, viscous-flow polymer foams were frozen at –22°C for 20 h and thawed at 20°C in the course of 4 h.

Tests of the foam cryogels obtained demonstrated that they retain their stability when in contact with distilled and mineralized water, or with alkaline solutions and hydrocarbon liquids with various polarities. Samples of foamed cryogels are also stable in media with moderate acidity and disintegrate only in concentrated mineral acids.

* λ, heat conductivity coefficient; G, elastic modulus.

The results obtained in the study for the mechanical and thermal properties of the foamed cryogels of various compositions are presented in Table 2.

For run nos. 1 and 2, data for solid cryogels without a gas phase are presented. The foamed cryogel obtained by mechanical bubbling of a gas through a viscous polymer solution has a coarsely cellular structure and small foam ratio (run no. 3). The foamed cryogels formed by chemical frothing of the polymer solution (run nos. 4–9) have a finely dispersed structure and large foam ratio and, therefore, their heat conductivity coefficients are the lowest. To improve the rigidity (elastic modulus) and thermal stability (melting point), technical-grade carbon (carbon black) and sodium chloride were additionally introduced into some of foamed cryogel samples.

CONCLUSIONS

(1) The foam produced by the chemical method is stable and has finely dispersed structure and large foam ratio, which cannot be obtained in a highly viscous polymer solution by the mechanical method.

(2) The product of the reaction suggested for preparation of foamed cryogel is, in addition to nitrogen, sodium chloride, whose presence strengthens the foamed cryogel and makes higher the melting point of the gas-saturated material.

(3) The foamed cryogels formed by the chemical method do not lose elasticity at temperatures of up to –20°C, which enables their use as blocking or heat-insulating materials at negative temperatures without any threat of destruction of technological constructions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of Equilibrium in Anion-Exchange Extractive Systems

V. A. Kovalevich, A. L. Gulevich, and E. M. Rakhman'ko

Belarussian State University, Minsk, Belarus

Received October 23, 2006; in final form, April 2007

Abstract—Anion-exchange extractive systems based on solutions of higher quaternary ammonium salts in the presence of solvating additives, derivatives of trifluoroacetophenone, were considered. A mathematical model of the extractive system was developed and average solvation numbers and constants of solvation of ClO_4^-, SCN^-, Br^-, and NO_3^- ions by variously structured derivatives of trifluoroacetophenone were calculated from experimental data.

DOI: 10.1134/S1070427207100084

At present, the most efficient way to enhance the extraction of anions by higher quaternary ammonium salts (QAS) is modification of the phase of the liquid anion exchanger with solvating additives, derivatives of trifluoroacetophenone [1]. The best-known solvating additive is hexyl ester of *n*-trifluoroacetyl-benzoic acid (HE) [2, 3]. Introduction of this substance into the organic phase can sharply enhance the anion-exchange extraction of doubly charged carbonate and oxalate anions [3–5], and of virtually all organic anions containing a –COOH group [1]. The magnitude of the effect is directly proportional to the HE content of the extractive agent, being equal to 1.5–2 orders of magnitude at its content of 0.01 M. In [1, 6], even more effective solvating additives, nitro and halo derivatives of trifluoroacetophenone, were described.

The main difficulty encountered when studying extractive systems of this kind consists in correct interpretation of the experimental data obtained, specifically, in calculating the stoichiometry of the solvates being formed and anion-exchange extraction constants and solvation constants.

In this communication, a mathematical model of an anion-exchange extractive system and an algorithm for calculation of constants, based on Mathematica 5.0 software, are suggested.

EXPERIMENTAL

Toluene solutions of a trinonyloctadecylammonium picrate salt $(C_9H_{19})_3C_{18}H_{37}N^+Dye^-$(TNODA) were used as an anion exchanger. The starting iodide salt of TNODA, which contained more than 99.7 wt % main substance, was converted to the picrate form by the extraction method [1]. The aqueous phase of the extractive systems was in the form of solutions of sodium perchlorate, rhodanide, bromide, and nitrate. Trifluoroacetophenone derivatives listed in Table 1 were used as solvating additives.

Table 1. Solvating additives used in the study

Solvating additive	Designation	Distribution constant in the toluene–water system, P_s
	S13	102 ± 21
	S14	2.6 ± 0.3
	S17	11.1 ± 0.9
	S18	2.5 ± 0.4

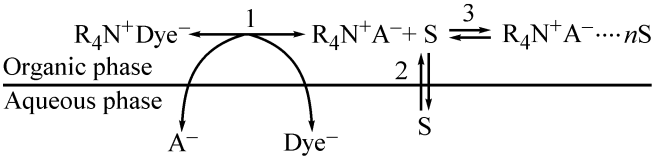

Fig. 1. Scheme of the anion-exchange extractive system. $R_4N^+Dye^-$, extractive agent in the form of a dye; A^-, anion being extracted; S, solvating agent; and *n*, average solvate number.

The extraction was carried out in test tubes with ground-in stoppers at a 1 : 1 phase volume ratio at a temperature of 293 ± 1 K. After the extraction, the aqueous phase was separated and filtered and the content of picrate ions in the aqueous phase was determined on an SF-26 spectrophotometer [7].

The set of equilibria in extractive systems of this kind can be represented by the scheme shown in Fig. 1. Three principal equilibria can be distinguished in this system: (1) anion-exchange equilibrium, (2) equilibrium of a solvating additive distribution among the aqueous and organic phases, and (3) equilibrium of solvate formation in the organic phase:

$$R_4N^+Dye^- + A^- \overset{K_{Dye^-}^{A^-}}{\rightleftarrows} R_4N^+A^- + Dye^-, \quad (1)$$

$$S_{aq} \overset{P_s}{\rightleftarrows} S_{org}, \quad (2)$$

$$R_4N^+A^- + nS_{org} \overset{K_s}{\rightleftarrows} R_4N^+A^-\ldots nS. \quad (3)$$

It has been experimentally confirmed that QAS in the form of a dye is virtually not solvated by S molecules. In addition, the scheme disregards QAS dissociation in the organic phase because of the very low dissociation constants (approximately 10^{-24} [9]).

Equilibria (1)–(3) are described by the exchange constant K_{Dye}^{A}, distribution constant P_s, and solvation constant K_s:

$$K_{Dye^-}^{A^-} = \frac{[R_4N^+A^-][Dye^-]}{[R_4N^+Due^-][A^-]}, \quad (4)$$

$$P_s = \frac{[S]_{org}}{[S]_{aq}}, \quad (5)$$

$$K_s = \frac{[R_4N^+A^-\cdots nS]}{[R_4N^+A^-][S]_{org}^n}. \quad (6)$$

Of the 11 parameters that appear in expressions (4)–(6), only four are known: the exchange constant K_{Dye}^{A} (determined in the absence of a solvating additive), distribution constant P_s (additionally found from experimental results), and equilibrium concentration of the dye in the aqueous phase $[Dye^-]$ (determined spectrophotometrically).

Because the initial concentrations of the extractive agent, anion being extracted, and solvating additive are known, we can write additional four independent equations that reflect the material balances for the anion being extracted (7), dye (8), QAS cation (9), and solvating additive (10):

$$c_{0,A^-} = [A] + [R_4N^+A^-] + [R_4N^+A^-\cdots nS], \quad (7)$$

$$c_{0,R_4Dye^-} = [R_4N^+Dye^-] + [Dye^-], \quad (8)$$

$$c_{0,R_4Dye^-} = [R_4N^+Dye^-] + [R_4N^+A^-] = [R_4N^+A^-\cdots nS], \quad (9)$$

$$c_{0,s} = [S]_{org} + [S]_{aq} + n[R_4N^+A^-\cdots nS]. \quad (10)$$

As a result, the total number of independent equations is seven at eight unknowns. For this reason, the system of equations cannot be directly solved by numerical methods.

To solve this system of nonlinear equations, we employed the linearization method with the use of iteration procedures. For this purpose, the system of equations (4)–(10) was reduced by a number of algebraic transformations to two equations, one of which can be represented as a linear graphical dependence whose slope rate can be used to judge about the average solvation number. Let us briefly consider this derivation.

Summing up expressions (7) and (8) and subtracting (9), we obtain expression (11), which reflects the principle of anion exchange equivalence:

$$c_{0,A^-} = [A^-] + [Kh]. \quad (11)$$

Equating (8) to (9), we obtain

$$[R_4N^+A^-] = [Dye] - [R_4N^+A^-\cdots nS]. \quad (12)$$

At the same time, it follows from (6) that

$$[R_4N^+A^-] = \frac{[R_4N^+A^-\cdots nS]}{K_s[S]_{org}^n}. \quad (13)$$

Then, we obtain from Eqs. (12) and (13)

$$[R_4N^+A^-\cdots nS] = \frac{[Dye^-]}{1 + \dfrac{1}{K_s[S]_{org}^n}}. \quad (14)$$

Now, substituting (14) into (13) we find $[R_4N^+A^-]$:

$$[R_4N^+A^-] = \frac{[Dye^-]}{1 + K_s[S]_{org}^n}. \quad (15)$$

From Eqs. (8) and (11), we have

$$[R_4N^+Dye^-] = c_{0,R_4N^+Dye^-} - [Dye]. \quad (16)$$

$$[A^-] = c_{0,A^-} - [Dye^-]. \quad (17)$$

Then we substitute (15)–(17) into Eq. (4) to obtain the final equation:

$$K_{Dye^-}^{A^-} = \frac{[Dye^-]^2}{(c_{0,R_4N^+Dye^-} - [Dye^-])(c_{0,A^-} - [Dye^-])} \times \frac{1}{1 + K_s[S]_{org}^n}, \quad (18)$$

which can be rewritten in a more compact form

$$K_{Dye^-}^{A^-} = \frac{\tilde{K}_{Dye^-}^{A^-}}{1 + K_s[S]_{org}^n}, \quad (19)$$

where $\tilde{K}_{Dye^-}^{A-}$ is the conditional exchange constant, which can be easily calculated from the known dye concentration in the aqueous phase:

$$K_{Dye^-}^{A^-} = \frac{[Dye^-]^2}{(c_{0,R_4N^+Dye^-} - [Dye^-])(c_{0,A^-} - [Dye^-])}. \quad (20)$$

Having taken logarithm of (19), we obtain a bilogarithmic equation (21), which is the equation of a straight line, whose slope can be used to determine the average solvation number, and the intercept on the ordinate axis, to find the numeric value of the solvation constant:

$$\log\left(\frac{\tilde{K}_{Dye^-}^{A^-}}{\tilde{K}_{Dye^-}^{A^-}} - 1\right) = \log K_s + n\log[S]_{org}. \quad (21)$$

The equilibrium concentration of a solvating additive, necessary for plotting this bilogarithmic straight line, will be determined by the extent of solvation processes and by the distribution of the solvating additive itself and can also be calculated using appropriate interrelation equations.

From Eq. (4), we find

$$[R_4N^+A^-] = K_{Dye^-}^{A^-}\frac{[R_4N^+Dye^-][A^-]}{[Dye]^-}. \quad (22)$$

The material balance equation (9) for the QAS cation gives

$$[R_4N^+A^-\cdots nS] = c_{0,R_4N^+Dye^-} - [R_4N^+Dye^-] - [R_4N^+A^-]. \quad (23)$$

Substituting (22) into (23), we obtain

$$[R_4N^+A^-\cdots nS] = c_{0,R_4N^+Dye^-} - [R_4N^+Dye^-] - K_{Dye^-}^{A^-}\frac{[R_4N^+Dye^-][A^-]}{[Dye^-]}. \quad (24)$$

With account of (16) and (17), expression (24) takes the form

$$[R_4N^+A^-\cdots nS] = [Dye^-] - K_{Dye^-}^{A^-}(c_{0,R_4N^+Dye^-} - [Dye^-]) \times \left(\frac{c_{0,A^-}}{[Dye^-]} - 1\right). \quad (25)$$

Using Eq. (5), we can express the equilibrium concentration of the solvating additive in the aqueous phase:

$$[S]_{aq} = [S]_{org}/P_s. \quad (26)$$

Further, we find from (10) and (26)

$$[S]_{org} = c_{0,s} - \frac{[S]_{org}}{P_s} - n[R_4N^+A^-\cdots nS] \quad (27)$$

and, after certain rearrangements, obtain

$$[S]_{org} = \frac{P_s}{P_s + 1}(c_{0,s} - n[R_4N^+A^-\cdots nS]). \quad (28)$$

Substituting Eq. (25) into 28), we obtain the final variant of the formula for calculating the equilibrium concentration $[S]_{org}$, which takes into account the distribution of a solvating additive among the aqueous and organic phases:

$$[S]_{org} = \frac{P_s}{P_s + 1}\left[c_{0,s} - n\left\{[Dye^-] - K_{Dye^-}^{A^-}(c_{0,R_4N^+Dye^-} - [Dye^-])\left(\frac{c_{0,A^-}}{[Dye^-]} - 1\right)\right\}\right]. \quad (29)$$

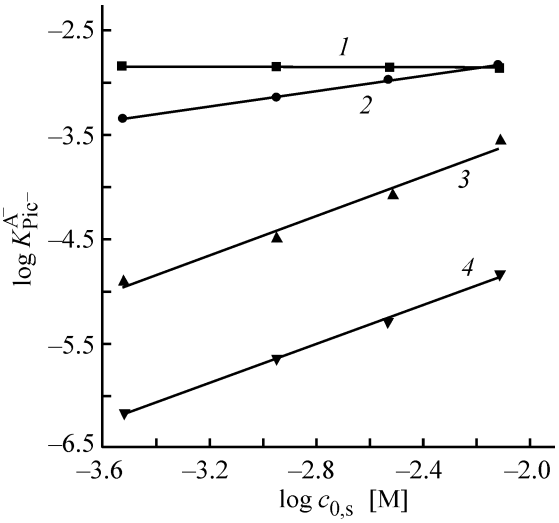

Fig. 2. Effect of the concentration $c_{0,s}$ of solvating additive S18 on the extractability of inorganic anions. ($K^{A^-}_{Pic^-}$) Exchange constant. Anion: (*1*) perchlorate, (*2*) rhodanide, (*3*) nitrate, and (*4*) bromide.

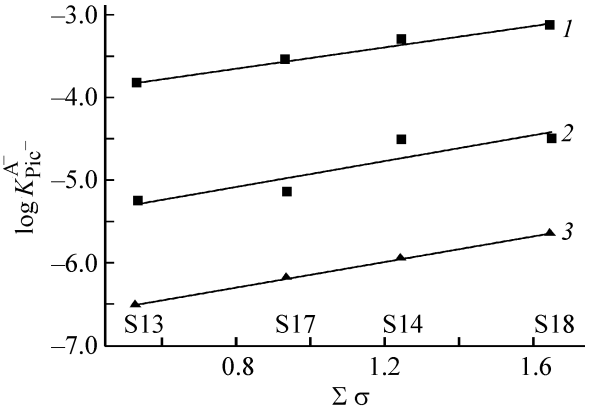

Fig. 3. Dependence of the constants of exchange of anions for the picrate ion, $K^{A^-}_{Pic^-}$, on the sum of the Hammett σ constants of substituents, plotted on the semilog scale. Concentration of solvating additives 1×10^{-4} M. Anion: (*1*) rhodanide, (*2*) nitrate, and (*3*) bromide. Equations of the straight lines: (*1*) $\log K = -4.17 + 0.65\Sigma\sigma$, $r = 0.992$; (*2*) $\log K = -5.72 + 0.79\Sigma\sigma$, $r = 0.922$; and (*3*) $\log K = -6.93 + 0.78\Sigma\sigma$, $r = 0.999$.

Equations (21) and (29) are solved as follows. A zeroth approximation $n_0 = 1$ is set and $[S]_i$ are calculated for each point. Then the log–log dependence (21) is plotted and its slope is used to calculate the first approximation n_1. Further, if the difference $n_1 - n_0$ exceeds a certain prescribed value (commonly 0.01), n_1 is set as zeroth approximation and the cycle is repeated. This procedure was performed using Mathematica 5.0 software.

As can be seen in Fig. 2, the modification of the organic phase with solvating additives differently affects the extraction of the inorganic anions under study. The extractability of bromide and nitrate anions, quantitatively expressed in terms of the conditional exchange constant $\tilde{K}^{A^-}_{Dye^-}$, sharply increases in the presence of solvating additives, with this dependence being directly proportional to the slope, which is close to unity. The effect of solvating additives on the extractability is substantially weaker for rhodanide anions and absent at all for perchlorate anions. This is also confirmed by the calculated values of the average solvation numbers and solvation constants (Table 2).

As can be seen in Table 2, the average solvation numbers for bromide and nitrate anions are close to unity, i.e., solvates of 1 : 1 composition, ($R_4N^+Br^-\cdots S$) and ($R_4N^+NO_3^-\cdots S$), are formed in the organic phase. The average solvation numbers for rhodanide anions are close to 0.5, and those for perchlorate anions could not be determined because the extractability of this anion is independent of the content of a solvating additive. Accordingly vary between these anions the numeric values of the solvation constants. For bromide and nitrate anions, they are substantially larger, compared with rhodanide anions.

Thus, the efficiency of any separate solvating additive is determined by its content in the organic phase. As for the efficiency of a particular anion, it is governed by the type of distribution of the negative charge over its surface. The higher the negative charge density on an anion, the stronger the influence of a solvating additive.

If the efficiency of additives is considered in relation to their structure, then, as can be seen in Fig. 3, there is a linear relationship between the log-

Table 2. Average solvation numbers and logarithms of solvation constants of some inorganic anions by trifluoroacetophenone derivatives

Anion	S13		S14		S17		S18	
	n	log K_s	*n*	log K_s	*n*	log K_s	*n*	log K_s
SCN^-	0.45 ± 0.09	1.43 ± 0.10	0.43 ± 0.03	2.03 ± 0.10	0.57 ± 0.08	2.16 ± 0.10	0.39 ± 0.01	2.16 ± 0.03
Br^-	1.49 ± 0.04	3.68 ± 0.11	0.86 ± 0.07	3.38 ± 0.19	0.99 ± 0.12	3.21 ± 0.10	1.01 ± 0.09	4.18 ± 0.28
NO_3^-	1.09 ± 0.09	3.55 ± 0.16	1.00 ± 0.06	4.33 ± 0.17	1.25 ± 0.19	4.24 ± 0.25	0.96 ± 0.08	4.36 ± 0.23

arithms of the conditional exchange constants and the sum of the Hammett σ constants of substituents in the structure of trifluoroacetophenone. Thus, the Hammett equation is observed for anion-exchange extractive systems:

$$\log K = \log K_0 + \rho\Sigma\sigma. \quad (30)$$

As expected, the maximum effect was obtained for the S18 structure, which has three electron-acceptor substituents: chlorine in the *para*-position and two nitro groups in *meta*-positions. The existence of relation (30) enables prognostication of the efficiency of solvating additives based on trifluoroacetophenone derivatives in relation to the nature and number of substituents.

CONCLUSIONS

(1) A mathematical model of the $R_4N^+Dye^-$ + S/A^- anion-exchange system was suggested and an algorithm for calculating the solvation constants and average solvation numbers was presented.

(2) The anion-exchange extraction of ClO_4^-, SCN^-, Br^-, and NO_3^- anions with toluene solutions of trinonyloctadecylammonium picrate was studied in the presence of solvating additives, trifluoroacetophenone derivatives of varied structure. The extractability of Br^-, NO_3^-, and SCN^- ions linearly increases with the concentration of solvating additives. The extractability of ClO_4^- is independent of the content of solvating additives in the phase of the quaternary ammonium salt.

(3) A linear correlation was found between $\log K_{Dye^-}^{A^-}$ and the sum of the Hammett σ constants, which enables prognostication of the extraction efficiency of solvating additives of varied structure.

Abstract—The kinetics of thorium(IV) and lanthanum(III) extraction from aqueous salt solutions with a composite material based on trialkylamine and a polymeric support at 293.15–333.15 K was studied. The mass transfer coefficients were found, and the apparent activation energy of the extraction reaction was estimated.

DOI: 10.1134/S1070427207100096

The thorium(IV) and lanthanum(III) extraction with a composite material based on trialkylamine (Alamin-336) and a polymeric support in the presence of 0–4 mol dm^{-3} sodium nitrate in the aqueous phase was studied in [1]. The extraction isotherms were described with regard to the formation of compounds $(R_3NH)_2[Th(NO_3)_6]$ and $(R_3NH)_3[La(NO_3)_6]$ in the phase of the composite material (CM).

To use CM in practice, data on both the equilibrium metal distribution [1] and the kinetic features of extraction at various temperatures are required.

In this study, we examined the kinetics of thorium(IV) and lanthanum(III) extraction from aqueous salt solutions with CM at 293.15–333.15 K.

The composite material is produced by Purolite Company in the form of spherical granules 0.5 mm in diameter, consisting of trialkylamine $[(C_7H_{17}–C_9H_{19})_3N]$ and a polymeric support (super-cross-linked polystyrene). The specific volume of CM is 2.50 ± 0.02 dm^3 kg^{-1}, and the extractant content of the CM phase, 0.97 ± 0.01 mol dm^{-3}. Before extraction, CM was treated with 4.0 mol dm^{-3} HNO_3 and then washed with water to obtain the $R_3NH^+NO_3^-$ form of the extractant [1]. Thorium(IV) and lanthanum(III) nitrates of analytically pure grade were used. The experiments were performed with 0.60 and 0.50 mol dm^{-3} Th^{4+} and La^{3+} solutions in the presence of 0.0, 1.0, 2.0, and 4.0 mol dm^{-3} $NaNO_3$. The thorium(IV) and lanthanum(III) concentrations in the aqueous phase were determined by the method described in [1, 2] with an error of ±1–2 rel %. In the kinetic experiments, the Th^{4+} and La^{3+} concentrations in the CM phase $c_{(o),t}$ (mol dm^{-3}) were found from the equation

$$c_{(o),t} = (c_{(aq),0}V_0 - c_{(aq),t}V_t)/(mV_{sp}), \quad (1)$$

where t is time; $c_{(aq),0}$, concentration (mol dm^{-3}) of Th^{4+} and La^{3+} nitrates in aqueous solution at $t = 0$, with the volume of the aqueous phase V_0 (dm^3); $c_{(aq),t}$, concentration (mol dm^{-3}) of Th^{4+} and La^{3+} nitrates in aqueous solution at the instant of time t, with the volume of the aqueous phase V_t (dm^3); m, weight (kg) of CM sample; and V_{sp}, specific volume (dm^3 kg^{-1}) of CM.

Two series of experiments were performed. In the first series, the kinetic experiments on absorption of Th^{4+} and La^{3+} nitrates were performed in a set of vessels from which samples were taken after different intervals of time. In the second series, sampling was performed successively from one vessel, provided that the change of the aqueous phase volume did not exceed 2–4%. The $c_{(o),t}$ values obtained in the two series of experiments agreed to within 2–5 rel %. In the kinetic experiments, aqueous solutions were thermostatically controlled for 60 min with an accuracy of ±0.2 K, and then a CM sample was introduced into the solution. Solutions with CM were stirred with a turbine stirrer with rotation speeds of 3.3, 5, and 6.7 s^{-1}. To determine the Th^{4+} and La^{3+} concentrations in the CM phase under equilibrium conditions, $c_{(o),eq}$ (mol dm^{-3}), aqueous solutions with CM were

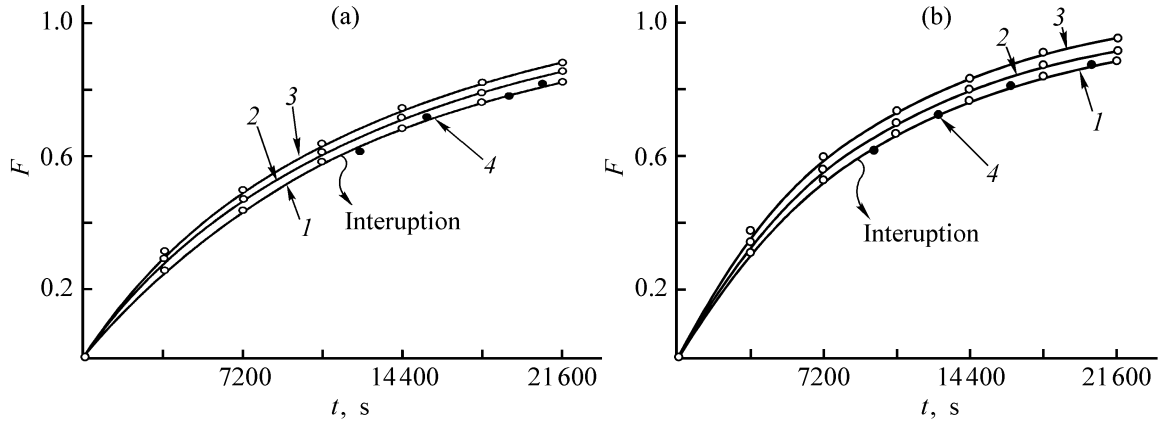

Fig. 2. Dependence of the degree of conversion, F, in extraction on time t at various rates of stirring of aqueous solution-composite material systems and experiments on interruption of metal absorption with the composite material. (a) $Th(NO_3)_4$ aqueous solution, 293.15 K; (b) $La(NO_3)_3$ aqueous solution, 293.15 K, 1 mol dm^{-3} $NaNO_3$, 293.15 K. Speed of rotation (s^{-1}): (*1*) 3.3, (*2*) 5, and (*3*) 6.7; (*4*) experiments with process interruption for 1.5 h.

stored at a given temperature for 3–4 days, then the composition of the aqueous phase was analyzed, and $c_{(o),eq}$ was calculated by Eq (1). In some experiments, absorption of Th^{4+} and La^{3+} nitrates with CM was interrupted on attaining a 40–50% conversion of CM, the CM was separated from the solution by decantation, allowed to stand for 1.5 h, and then the metal ion absorption with CM was resumed at the same temperature and stirring rate.

The dependences of the concentrations of Th^{4+} and La^{3+} nitrates in the CM phase on time at a rotation speed of 3.3 s^{-1} and the equilibrium metal ion concentrations in the CM phase in the absence and presence of sodium nitrate in the aqueous phase are shown in Fig. 1.

The equilibrium concentrations of Th^{4+} and La^{3+} nitrates in the CM phase decrease with increasing temperature at all sodium nitrate concentrations considered and, at a given temperature, increase with the sodium nitrate concentration in the aqueous phase (Fig. 1).

The dependences of the degree of conversion ($F = c_{(o),t}/c_{(o),eq}$) on time at a rotation speed of 3.3, 5, and 6.7 s^{-1} and 293.15 K are shown in Fig. 2. As can be seen, an increase in the rotation speed makes higher the F values at constant time and temperature, which is typical of the film kinetics, when the diffusion across the film at the interface between CM and the aqueous solution phase boundary is the rate-determining stage [3, 4]. Figure 2 also shows the data on

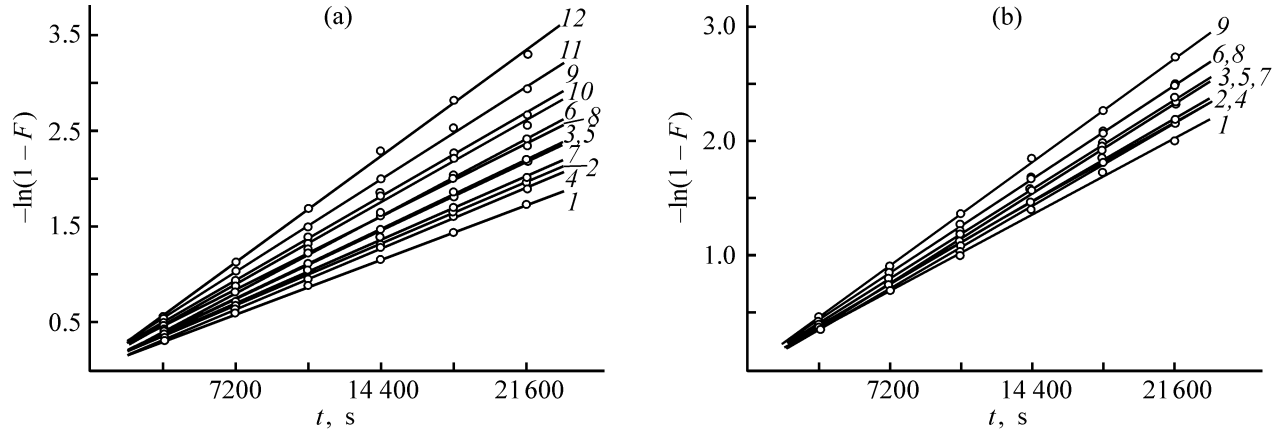

Fig. 3. Dependence of $-\ln(1-F)$ on time t for metal absorption by CM under various conditions.

extraction kinetics in the experiments with interrupted extraction. These data suggest that interruption of extraction for 1.5 h does not noticeably affect the shape of the kinetic curve, i.e., the stage of diffusion within the CM grain is not the rate-determining stage.

The extraction of thorium(IV) and lanthanum(III) nitrates with CM can be represented by the following equation of a heterogeneous reaction [1]:

$$Th^{4+} + 4NO^-_{3(aq)} + 2R_3NHNO_{3(o)} \rightleftarrows (R_3NH)_2[Th(NO_3)_6]_{(o)}, \quad (2)$$

$$La^{3+} + 3NO^-_{3(aq)} + 3R_3NHNO_{3(o)} \rightleftarrows (R_3NH)_3[La(NO_3)_6]_{(o)}, \quad (3)$$

where (aq) is aqueous phase, and (o), CM phase.

In this case, $c_{(o),eq}$ values approach $c_s/2$ and $c_s/3$, where c_s is the extractant concentration in the CM phase (Fig. 1).

To describe the kinetics of extraction of thorium(IV) and lanthanum(III) with CM, we can use the equation [3, 4]

$$dQ/dt = -jS, \quad (4)$$

where Q is the amount of the substance (mol) transferred into the CM phase [$Q = V_{(aq)}(c^0_{(aq)} - c_{(aq),t})$; $V_{(aq)}$, volume of the aqueous phase]; S, surface area (dm^2) involved in the extraction; j, extraction flow (mol s^{-1} dm^{-2}), or specific extraction rate, i.e., the amount of substance extracted in unit time and per unit surface area.

The Q value is numerically equal to the amount of substance in the CM phase at time t [$Q = V_{(o)}c_{(o),t}$; $V_{(o)}$ is CM volume (dm^3)].

The overall equation of the extraction flow, which takes into account the diffusion and chemical resistance [two-film model, presence of thin boundary layers of thickness δ_1 (exhaustive phase is aqueous) and δ_2, dm (extracting phase is CM) at the phase boundary], in the stationary mode is [3, 4]

$$J = \frac{c_{(aq),t} - c_{(aq),eq}}{\frac{\delta_1}{D_1} + \frac{\delta_2}{D_{ex}D_2} + \frac{1}{\vec{K}}}, \quad (5)$$

where D_1 and D_2 are the coefficients of mutual diffusion (dm^2 s^{-1}); $c_{(aq),eq}$, equilibrium concentration (mol dm^{-3}) of Th^{4+} and Ln^{3+} in the aqueous phase; D_{ex}, distribution coefficient, $D_{ex} = c_{(o),eq}/c_{(aq),eq}$; $\vec{K}$, rate constant of the first-order extraction reaction (dm s^{-1}).

Depending on the diffusion and chemical resistances, the extraction process can be controlled by the mass transfer or chemical reaction.

Equations (4) and (5) can be transformed into

$$dc_{(o),t}/dt = S(c_{(o),eq} - c_{(o),t})K/[V_{(o)}D_{ex}]. \quad (6)$$

were K is the mass-transfer constant (dm s^{-1}),

$$\frac{1}{K} = \left(\frac{\delta_1}{D_1} + \frac{\delta_2}{D_{ex}D_2} + \frac{1}{\vec{K}}\right). \quad (7)$$

The mass-transfer coefficient K' (s^{-1}) is equal to

$$K' = SK/[V_{(o)}D_{ex}]. \quad (8)$$

After transformation, Eq. (6) becomes

$$dc_{(o),t}/dt = K'[c_{(o),eq} - c_{(o),t}]. \quad (9)$$

In the semilog form, when $c_{(o),t} = 0$ at $t = 0$, Eq. (6) takes the form

$$\ln(1 - F) = -K't, \quad (10)$$

where F is the degree of conversion.

The dependences of $-\ln(1 - F)$ on t are shown in Fig. 3. In all cases, these dependences are linear at F

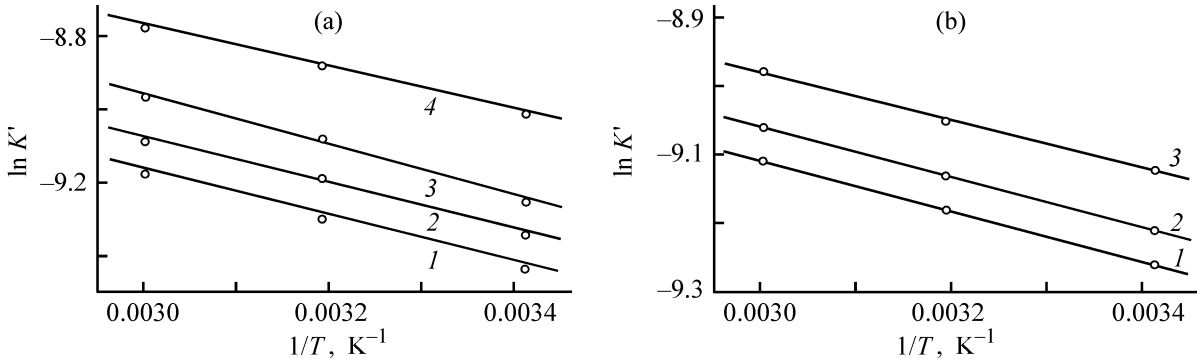

Fig. 4. Dependence of $\ln K'$ on reciprocal temperature T. (a) Thorium(IV) nitrate and (b) lanthanum(III) nitrate. (a) (*1*) Without salting-out agent; $NaNO_3$ (mol dm^{-3}): (*2*) 1, (*3*) 2, and (*4*) 4; (b) (*1*) 1, (*2*) 2, and (*3*) 4.

from 0.1 to 0.8–0.9. This fact indicates that the film kinetics controls the overall process. The calculated $\ln K'$ values under various conditions are shown in Fig. 4. As can be seen, the dependences of $\ln K'$ on reciprocal temperature are linear.

To estimate the apparent activation energy E_a, we used the equation

$$\ln K' = -\frac{E_a}{RT} + \text{const}, \qquad (11)$$

where R is the gas constant.

The E_a values are virtually independent of sodium nitrate concentration (Fig. 4) and amount, on the average, to 5.1 ± 0.3 (Th) and 2.8 ± 0.2 kJ mol^{-1} (La), which is characteristic of diffusion-controlled processes.

The mass transfer coefficients increase with temperature and sodium nitrate concentration in aqueous-salt solution. It follows from Eqs. (5) and (6) that an increase in the distribution coefficient after introducing a salting-out agent should decrease the mass-transfer coefficients. The increase in medium viscosity at increasing electrolyte concentration in the aqueous phase acts in the same direction. At the same time, at constant δ_1, δ_2, D_1, and D_2, the increase in the distribution coefficient decreases the diffusion resistance in the extracting phase and favors an increase in the mass-transfer constant. We believe that the decrease in the diffusion resistance in the extracting phase (decrease in $\delta_2/D_{ex}D_2$), caused by increasing distribution coefficient after introducing a salting-out agent into the aqueous phase, or the possible decrease in δ_1 because of the dehydrating effect of the electrolyte are the major factors causing an increase in the mass-transfer coefficients on raising sodium nitrate content of the aqueous phase (Figs. 3, 4). Differences in $\ln K'$ values between thorium(IV) and lanthanum(III) do not exceed 0.08–0.15 log units (Figs. 3, 4).

The dependence of the mass transfer coefficient on the sodium nitrate concentration in the aqueous phase is described by the equation

$$\ln K' = \ln K'(c_{NaNO_3} = 0) + \theta c_{NaNO_3}, \qquad (12)$$

where parameter θ is virtually independent of temperature and amounts to 0.10 ± 0.01 and 0.043 ± 0.005 for thorium and lanthanum, respectively, i.e., the effect of the supporting electrolyte is stronger for thorium(IV) than for lanthanum(III).

In practice, when using composite materials based on trialkylamine and a polymeric support for thorium(IV) and lanthanum(III) recovery from aqueous salt solutions, the extraction should be performed in the presence of a salting-out agent in the aqueous phase at elevated temperatures. By so doing, the time of the process can be decreased and the maximal equilibrium metal concentration in the CM phase can be attained.

CONCLUSIONS

(1) The diffusion across the phase boundary (film kinetics) is the rate-determining stage of sorption of thorium(IV) and lanthanum(III) nitrates from aqueous salt solutions with a composite material based on trialkylamine and a polymeric support.

(2) The coefficients of mass transfer increase with temperature and the sodium nitrate concentration in the aqueous phase. The E_a values are virtually independent of the sodium nitrate concentration and

amount to 5.1 ± 0.3 (Th) and 2.8 ± 0.2 kJ mol^{-1} (La), which is characteristic of diffusion-controlled processes.

(3) In practice, when using composite materials based on trialkylamine and polymeric support for thorium(IV) and lanthanum(III) recovery from aqueous salt solutions, the extraction should be performed in the presence of a salting-out agent in the aqueous phase at elevated temperatures. By so doing, the time of the process can be decreased and the maximal equilibrium metal concentration in the CM phase can be attained.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Behavior of Ytterbium in an Equimolar Melt of Sodium and Potassium Chlorides

V. V. Smolenskii, A. V. Novoselova, and A. L. Bove

Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received July 30, 2007

Abstract—Electrochemical reduction of Yb(III) ions to Yb(II) was studied in an equimolar NaCl–KCl melt in the temperature range 973–1075 K. Linear, cyclic, and square-wave voltammetry, chronopotentiometry, and potentiostatic electrolysis with tungsten as the working electrode were used in the study.

DOI: 10.1134/S1070427207100102

At present, high-purity rare-earth elements are widely used in various fields of modern technology. Electrochemical recovery and electrorefining in salt melts form a compromise method for production of high-purity rare-earth elements [1–2].

Processing of spent nuclear fuel is another important field of use of salt melts for recovery of rare-earth elements [3]. Lanthanides are present in high-activity wastes as fission products, and, therefore, chemical and electrochemical information about their behavior in regeneration is very important. This is directly associated with calculations of conditional redox potentials of lanthanides and of their principal thermodynamic characteristics [4–14].

There is only scarce published evidence about the behavior of ytterbium compounds in chloride melts. In [15], the redox potential of the Yb(III)/Yb(II) pair in a eutectic LiCl–KCl melt was measured relative to a 1 M Pt(II)/Pt(0) reference electrode and its temperature dependence was presented. The electrochemical behavior of Yb(III) ions at an active electrode (Ni) in an equimolar NaCl–KCl melt was studied at 973 K [16]. It was found that the reaction goes in two stages: Yb(II) ions are formed in the first of these and electrochemical alloying occurs in the second. Transient techniques were used to study the electrochemistry of ytterbium(III) in molten chlorides of alkali metals [17]. The diffusion coefficients of Yb(III) and Yb(II) ions were calculated. Temperature dependences of the conditional standard redox potentials of Yb(III)/Yb(II) were presented and suggestions were made concerning the effect of the cationic composition of the solvent salt on the value of $E^{*}_{\mathrm{Yb(III)/Yb(II)}}$. In [18], the conditional standard redox potentials of Yb(III)/Yb(II) in molten chlorides of alkali metals were estimated using the correlation between aqueous solutions and chloride melts.

The aim of our study was to examine the electrochemical behavior of ytterbium, estimate the conditional standard redox potential of Yb(III)/Yb(II), and calculate the principal thermodynamic characteristics of $YbCl_3$.

EXPERIMENTAL

We paid particular attention to preparation of the starting reagents. Sodium and potassium chlorides of chemically pure grade were used in experiments as solvents. For this purpose, these compounds were dried in a vacuum for a long time, with temperature gradually raised, and then were melted in the atmosphere of an inert gas and after that purified by zone recrystallization [19]. Prior to being used, they were stored in glass ampules filled with argon.

Anhydrous ytterbium trichloride was prepared by chlorination of an appropriate crystal hydrate of the type $YbCl_3 \cdot nH_2O$ (n = 4.5–5.0) by heating in a carbon tetrachloride vapor [20]. The crystal hydrate was produced by dissolving Yb_2O_3 of IbO-L brand [TU (Technical Specification) 48-4-524–90] in hydrochloric acid to pH 1–1.5 and evaporating the solution on a water bath to dryness. The resulting ytterbium chloride had a metal-to-chlorine ratio of 1.0 : 3.01 and did not contain even trace amounts of the oxychloride. The thus prepared $YbCl_3$ was stored in ampules in a box filled with dry nitrogen. The con-

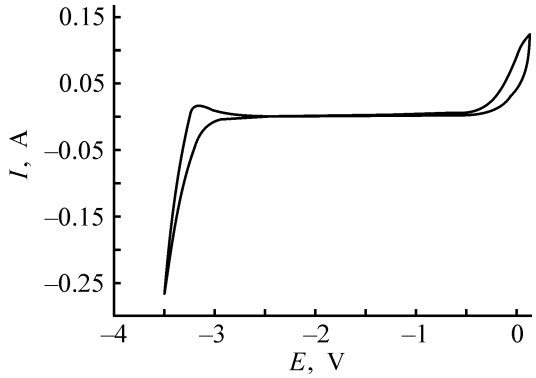

Fig. 1. Cyclic voltammogram of the NaCl–KCl melt at a potential sweep rate of 0.1 V s^{-1} on a W working electrode at 973 K. (*I*) Current strength and (*E*) potential; the same for Figs. 2, 3.

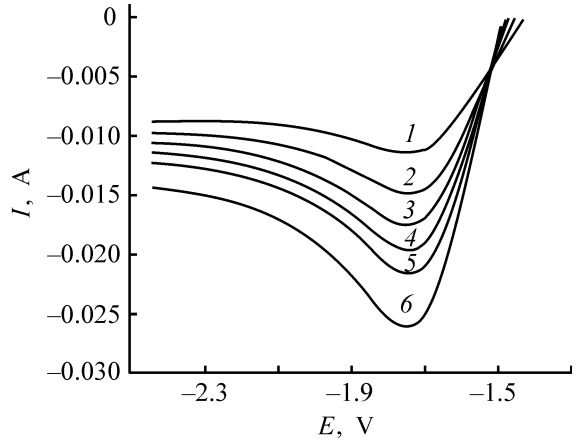

Fig. 2. Linear voltammograms of the NaCl–KCl–$YbCl_3$ melt (m_{YbCl_3} = 3.79×10^{-2} mol kg^{-1}), measured at different potential sweep rates for the reaction Yb(III) + e → Yb(II) on a W working electrode at 973 K. Potential sweep rate (V s^{-1}): (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, (*4*) 0.4, (*5*) 0.6, and (*6*) 0.75.

centration of ytterbium trichloride was 3.9×10^{-2}–1.3×10^{-1} mol kg^{-1} in all the experiments.

We analyzed the electrochemical processes by the following techniques: cyclic, linear, and square-wave voltammetry and chronopotentiometry [21–23]. The measurements were made with an Eco-Chimie Autolab PGSTAT 30 potentiostat-galvanostat with v.4.9 software.

A three-electrode quartz cell with nickel shields was used in the experiments. A tungsten wire of TU 48-9-45–67 brand (diameter 1 mm) with a fixed surface area served as the working electrode. A SU-2000 glassy carbon rod (diameter 3 mm) was used as the counter electrode. The measurements were made relative to a chlorine reference electrode in crucibles made of SU-2000 glassy carbon. The cell was equipped with additional devices for changing the composition of the salt phase at a constant gas phase composition, chlorinating the melt, changing the gas phase composition, and taking samples.

After an experiment, we analyzed the solidified salt cake for the content of Yb^{3+} ions. As shown in [15], when a melt containing ytterbium dichloride is cooled in an inert atmosphere to room temperature, the disproportionation reaction does not occur:

$$3YbCl_2 \rightleftarrows 2YbCl_3 + Yb. \quad (1)$$

Ytterbium was determined in the solidified cake by the atomic-emission method with a Perkin–Elmer Optima 4200 DV optical spectrometer, with inductively coupled plasma as a source of atomization and spectrum excitation [24, 25]. The spectrometer was calibrated against solutions with know ytterbium concentration (100 mg l^{-1}), with a 100-mg l^{-1} chromium solution as internal standard. The concentration in solution samples were measured by determining the intensity ratios of Yb(II) lines at 328.937 or 369.419 nm to those of the internal standard Cr(II) at 267.716 nm. All the solutions used for calibrating the spectrophotometer had an acidity of no less than 2% in terms of hydrochloric acid. The relative measurement error in determining the content of ytterbium did not exceed 3%.

Figure 1 shows a cyclic voltammogram of a NaCl–KCl melt, measured on the tungsten working electrode relative to the chlorine reference electrode at a potential sweep rate of 0.1 V s^{-1} at 973 K. The electrochemical window for the solvent corresponds to reduction of sodium ions and oxidation of chlorine ions.

Upon introduction of ytterbium chloride into the melt, an additional wave appears in the voltammogram (Fig. 2). This wave can be attributed to reduction of trivalent ytterbium ions to the divalent state. Figure 2 shows linear voltammograms of reduction of ytterbium(III) ions, measured relative to the chlorine reference electrode on the tungsten working electrode at different potential sweep rates at 973 K.

A potentiostatic electrolysis at the potentials corresponding to the cathodic current peak did not yield any solid phase on the electrode surface, and the working electrode itself did not undergo any visually observable changes. This means that a soluble product is formed in this stage of the electrochemical process. The wave observed indicates that the electrode reaction occurs in the melt to give Yb(II) ions:

$$Yb(III) + e \rightarrow Yb(II). \quad (2)$$

It was found that the peak current is directly proportional to a square root of the polarization rate in the entire range studied and the potential of the current peak is independent of the logarithm of the potential sweep rate. According to the theory of linear and cyclic voltammetry, the electrode process of reduction of trivalent ytterbium ions to the divalent state is reversible and is controlled by mass transfer. The number n of electrons involved in the electrode reaction was determined by square-wave voltammetry (Fig. 3), by calculating the width of the half-peak ($W_{1/2}$, V) in the range in which the peak current is directly proportional to the square root of the frequency of the signal with the use of the equation [21–23]:

$$W_{1/2} = 3.52\frac{RT}{nF}. \quad (3)$$

Here, $W_{1/2}$ is the half-peak width (V); R, T, n, and F are commonly accepted designations.

Our calculations demonstrated that the number of electrons involved in the reduction of Yb(III) ions to Yb(II) is 0.98 ± 0.1.

To verify the results obtained, we used the method of cyclic voltammetry [21–23]. It was shown that the number of electrons, calculated using the equation

$$E_p^C - E_{p/2}^C = -2.2\frac{RT}{nF}, \quad (4)$$

for the reduction process, is 1.04 ± 0.2 [where E_p^C is the potential of the peak of the cathodic process (V), and $E_{p/2}^C$, the potential of the half-peak of the cathodic process].

It was demonstrated by cyclic voltammetry and chronopotentiometry that the reduction potential of divalent ytterbium ions to the metal in the NaCl–KCl melt is not recorded, because it lies in the range of more negative potentials than the background-decomposition potential.

It is known [26, 27] that tri- and divalent ytterbium ions exist in molten chlorides of alkali metals in the form of complex groups $[YbCl_6]^{3-}$ and $[YbCl_4]^{2-}$. The diffusion coefficients of $[YbCl_6]^{3-}$ ions in the NaCl–KCl melt were calculated by the Randles–Shevchik equation

$$I_p = 0.446(nF)^{3/2}c_0S(Dv/RT)^{1/2}, \quad (5)$$

where I_p is the peak current (A); S, cathode surface area (cm^2); c_0, concentration of electrically active species in the electrolyte bulk (mol cm^{-3}); D, diffusion coefficient (cm^2 s^{-1}); and ν, potential sweep rate (V s^{-1}).

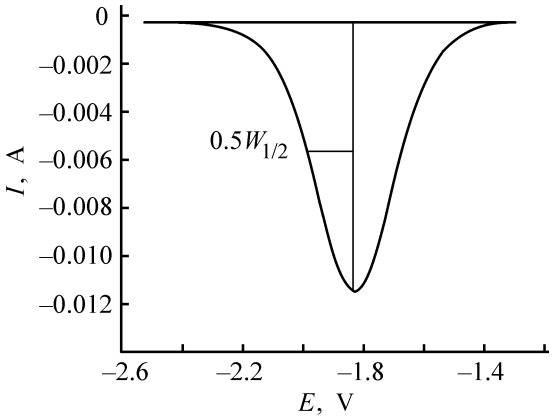

Fig. 3. Square-wave voltammogram of the NaCl–KCl–$YbCl_3$ melt ($m_{YbCl_3} = 3.79 \times 10^{-2}$ mol kg^{-1}) at $\nu = 20$ Hz on a W working electrode at 973 K.

The empirical temperature dependence of the diffusion coefficients of $[YbCl_6]^{3-}$ ions is described by the Arrhenius equation in the coordinates $\log D$–$1/T$:

$$\log D_{[YbCl)_6]^{3-}} = -2.18 - \frac{2377}{T} \pm 0.02. \quad (6)$$

The calculated diffusion coefficients of complex ytterbium(III) ions ($D_{[YbCl_6]^{3-}} = 2.77$ cm^2 s^{-1} at 1000 K) and the activation energies of diffusion (E_A = 45.4 kJ mol^{-1}) are in good agreement with the data obtained in [17] ($D_{[YbCl_6]^{3-}} = 2.34 \times 10^{-5}$ cm^2 s^{-1} at 1000 K and $E_A = 46.4$ kJ mol^{-1}).

According to the theory of voltammetry, the following relations are valid for the reversible electrochemical process between the cathodic (E_p^C) and anodic (E_p^A) potentials of the current peak and the half-wave potential $E_{1/2}$:

$$E_p^C = E_{1/2} - 1.11\frac{RT}{nF}, \quad (7)$$

$$E_p^A = E_{1/2} + 1.11\frac{RT}{nF}, \quad (8)$$

$$\frac{(E_p^C + E_p^A)}{2} = E_{1/2}, \quad (9)$$

$$E_{1/2} = E^0_{Yb(III)/Yb(II)} + \frac{RT}{F}\ln\left(\frac{D_{Yb(II)}}{D_{Yb(III)}}\right)^{1/2} + \frac{RT}{F}\ln\left(\frac{\gamma_{Yb(III)}}{\gamma_{Yb(II)}}\right). \quad (10)$$

For concentrations at which the mole fractions N of depolarizer ions do not exceed $(3–5) \times 10^{-2}$, we can assume that the activity coefficients in molten salts remain virtually constant. Introducing the conditional

standard potential $E^*_{Yb(III)/Yb(II)}$, we can write the following equation [28]:

$$E^*_{Yb(III)/Yb(II)} = E^0_{Yb(III)/Yb(II)} + \frac{RT}{F}\ln\left(\frac{\gamma_{Yb(III)}}{\gamma_{Yb(II)}}\right). \quad (11)$$

Assuming that the diffusion coefficients of tri- and bivalent ytterbium ions are close, $\frac{RT}{F}\ln\left(\frac{D_{Yb(II)}}{D_{Yb(III)}}\right)$ can be considered to be approximately zero.

In view of the aforesaid, we calculated the conditional standard redox potential $E^*_{Yb(III)/Yb(II)}$ by the equations

$$E^*_{Yb(III)/Y(II)} = E^C_p + 1.11\frac{RT}{F}, \quad (12)$$

$$E^*_{Yb(III)/Y(II)} = E^A_p + 1.11\frac{RT}{F}, \quad (13)$$

$$E^*_{Yb(III)/Y(II)} = \frac{(E^C_p + E^A_p)}{2}. \quad (14)$$

The overall temperature dependence of the conditional standard redox potential of the Yb(III)/Yb(II) pair in the NaCl–KCl melt is described by the empirical equation

$$E^*_{Yb(III)/Y(II)} = -(2.031 \pm 0.005) + (3.7 \pm 0.2) \times 10^{-4}T,\ V,\ [973\text{–}1075\ K]. \quad (15)$$

For example, the conditional standard redox potential of ytterbium in an equimolar melt of sodium and potassium chlorides ($E^*_{Yb(III)/Yb(II)} = -1.661$ V at 1000 K), obtained in this study, is in a quite satisfactory agreement with the data of Kuznetsov and Gaune-Escard ($E^*_{Yb(III)/Yb(II)} = -1.670$ V at 1000 K) [17].

The principal thermodynamic characteristics of ytterbium trichloride in the equimolar NaCl–KCl melt are listed in the table. It can be seen that ytterbium ions form stable complexes with chlorine ions in molten salts. A similar behavior has been observed for other polyvalent metals [4, 28–31].

The change in the conditional standard Gibbs energy of the redox reaction

$$YbCl_{2(s)} + 1/2Cl_{2(g)} \rightleftarrows YbCl_{3(s)} \quad (16)$$

is calculated by the formula

$$\Delta G^* = nFE^*. \quad (17)$$

Its temperature dependencies described by the equation

$$\Delta G^*_{YbCl_3} = \Delta H^*_{YbCl_3} - T\Delta S^*_{YbCl_3}. \quad (18)$$

For the molten equimolar mixture NaCl–KCl, this dependence has the following form:

$$\Delta G^*_{YbCl_3} = -195.96 + 0.036T \pm 2.46,\ kJ\ mol^{-1},\ [NaCl\text{–}KCl]. \quad (19)$$

Similar thermodynamic calculations can be made for ytterbium trichloride in a CsCl melt [32]:

$$\Delta G^*_{YbCl_3} = -218.25 + 0.041T \pm 2.46,\ kJ\ mol^{-1},\ [CsCl]. \quad (20)$$

The results of these calculations at different temperatures are listed in the table. It can be seen that the stability of complex ytterbium ions steadily decreases as the cation radius of the solvent salt becomes smaller, and temperature, higher.

The manner in which the thermodynamic parameters of the redox reaction (16) vary with the cation radius of the solvent salt indicates that the Yb–Cl bond in the complex groups $[YbCl_6]^{3-}$ and $[YbCl_4]^{2-}$ becomes stronger on passing to cesium chloride.

In dilute solutions, the stability of the complex species formed depends both on the ionic potential of the complexing agent ($\mu = z/r$, where z is the charge, and r, crystallochemical radius of the ion) [33] and on the cation size of the solvent salt. Based on the available published data on crystallochemical radii of triple- and double-charged ytterbium ions ($r_{Yb^{3+}} = 0.099$ nm and $r_{Yb^{2+}} = 0.102$ nm) [32, 34], we can state that the stability of $[YbCl_6]^{3-}$ complexes ($\mu = 30.30$) substantially exceeds that of $[YbCl_4]^{2+}$ groups ($\mu = 19.61$). At the same time, it is necessary to take into account the counterpolarizing effect of the cation of the solvent salt, which is the stronger, the smaller its radius. As a result, the relative stability of the complex species decreases on going from CsCl to NaCl–KCl. Elevating the temperature also makes weaker the interspecies bonds in the complex groups because of the more intense thermal motion of species in the melt.

Which of the complexes is preferable in a salt medium at a certain temperature can be judged from the conditional equilibrium constants of redox reactions and activity coefficients.

The conditional standard Gibbs energyq of the chemical reaction is related to the conditional equilibrium constant by

$$\Delta G^*_{YbCl_3} = -RT\ln K^*. \quad (21)$$

It follows from the data in the table that the equilibrium constant decreases as temperature becomes higher. Below are presented empirical equations describing the temperature dependence of the conditional equilibrium constants:

$$\log K^* = -1.88 + \frac{10\,239}{T} \pm 0.13, \text{ [NaCl–KCl]}, \quad (22)$$

$$\log K^* = -2.14 + \frac{11\,404}{T} \pm 0.13, \text{ [CsCl]}. \quad (23)$$

CONCLUSIONS

(1) The redox electrode reaction Yb(III) + e $\rightleftarrows$ Yb(II) in the equimolar melt NaCl–KCl was studied in the temperature range 973–1075 K by various electrochemical methods. It was shown that it is reversible and controlled by mass transfer. Its electrochemical parameters were determined and the diffusion coefficients of $[YbCl_6[^{3-}$ ions were calculated.

(2) The temperature dependence of the conditional standard redox potential of Yb(III)/Yb(II) in a molten equimolar mixture of sodium and potassium chlorides relative to a chlorine reference electrode was obtained.

(3) The principal thermodynamic characteristics of $YbCl_3$ in NaCl–KCl and CsCl melts were calculated.

(4) It was shown that the variation of the thermodynamic parameters of the redox reaction $YbCl_{2(s)} + 1/2Cl_{2(g)} \rightleftarrows YbCl_{3(s)}$ with the cation radius of the solvent salt indicates that the srength of the Yb–Cl bond in complex groups increases on passing to cesium chloride.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition and Physicomechanical Properties of Nickel–Chromium Coatings

S. N. Vinogradov and O. K. Sinenkova

Penza State University, Penza, Russia

Received December 25, 2006; in final form, March 2007

Abstract—Technique for deposition of wear- and corrosion-resistant lustrous coatings of a nickel–chromium alloy was developed.

DOI: 10.1134/S1070427207100114

Nickel–chromium coatings are rather hard and corrosion- and wear-resistant. Such coatings can find application in machine building instead of multilayer copper–nickel–chromium and chromium coatings.

A disadvantage is that the electrolyte is aggressive and ecologically unfriendly. Substitution of chromium(III) for chromium(VI) considerably reduces the ecological hazard of the galvanic process, but the electrolyte operation becomes unstable because of chromium oxidation at the anode during electrolysis. The oxidation of chromium not only changes the electrolyte composition, but also affects the coating quality and the process rate.

The main advantages of the technique suggested here are the stabilization of the electrolyte composition via elimination of chromium(III) oxidation to chromium(VI), deposition of lustrous coatings by introduction of brighteners into the electrolyte, improvement of the buffer properties of an electrolyte, and increase in the pH of formation of chromium(III) hydrates upon addition of ammonium sulfate.

The nickel–chromium alloy was electrodeposited from an electrolyte containing chromium sulfate, nickel sulfate, aminoacetic acid, ammonium sulfate, 1,4-butinediol, and saccharin. The electrolyte pH was maintained in the range 2.0–5.0 [1].

To prevent oxidation of chromium(III), an insoluble anode, e.g., made of lead, was placed in a complementary anode cell with a separating MA-40 anion-exchange membrane. The use of a complementary anode cell makes it possible to stabilize the compositions of the electrolyte and the alloy and to obtain lustrous alloy coatings.

The dependence of the chromium content of the alloy on the chromium(III) concentration in the electrolyte is described with a high correlation coefficient by the polynomial equation [2]:

$$[Cr]_{alloy} = 0.0708[Cr^{3+}]^2 + 2.4482[Cr^{3+}] + 0.5268;$$
$$R^2 = 0.9993$$

When the chromium(III) concentration in the electrolyte is raised from 10 to 45 g l^{-1} at current densities of 4 and 6 A dm^{-2}, the current efficiency by the alloy decreases from 22.6 to 10.5 and from 26.1 to 14%, respectively.

Lustrous coatings of the nickel–chromium alloy firmly adhering to the support are deposited on the cathode in the entire range of chromium(III) concentrations in the electrolyte at 40–60°C and current densities of 4 and 6 A dm^{-2}.

As the temperature of the electrolyte is elevated from 20 to 60°C at current densities of 4 or 6 A dm^{-2}, the chromium content of the alloy increases from 9.5 to 13 and from 10.2 to 15%, respectively.

The dependence of the chromium content of the alloys (%) on temperature (°C) is described by the polynomial equation

$$[Cr]_{alloy} = -0.2143[t]^2 + 2.4857[t] + 7.92;$$
$$R^2 = 0.9997.$$

When temperature is elevated from 20 to 60°C at a current density of 4 or 6 A dm^{-2}, the current efficiency by the alloy linearly grows from 10.5 to 16.5 and from 14 to 20%, respectively, i.e., the current

Table 1. Factors affecting the composition of the nickel–chromium alloy and the range of their variation

Design conditions	Factor			
	x_1, %	x_2, A dm^{-2}	x_3, °C	x_4
Main level	35	5.0	45	4.5
Variation range	5	1.0	5	0.5
Top level	40	6.0	50	5.0
Lower layer	30	4.0	40	4.0

efficiency increases with temperature and current density. This is due to the appreciable depolarization in alloy deposition.

Lustrous nickel–chromium coatings are formed at 40 and 60°C and current densities of 4 and 6 A dm^{-2}. At temperatures below 35°C, dull coatings are formed, which is due to deposition of nickel with brighteners.

When the electrolyte pH increases from 4.0 to 5.0, the chromium content of the alloy grows, which is due to a rise in the stability of the ammonia–glycocol complex of nickel. In this case, the chromium content of the alloy increases with the current density.

The dependence of the chromium content of alloys on the electrolyte pH is described by the polynomial equation

$$[Cr]_{alloy} = 0.1286[pH]^2 - 1.6114[pH] + 17.62;$$
$$R^2 = 0.9983.$$

The current efficiency by the alloy virtually linearly increases with the electrolyte pH. Similarly to the preceding dependences, the current efficiency by the alloy increases with the current density, which is due to the chromium behavior.

To optimize the technology of alloy electrodeposition, we derived a multifactorial regression equation that relates the optimization criterion and input parameters affecting the process.

The optimization criterion for the nickel–chromium alloy is the alloy composition, and the input data are the chromium(III) concentration in the electrolyte, current density, temperature, and pH of the electrolyte. As the mathematical model of the process serves the following regression equation, which relates the optimization criterion, alloy composition y, to the input parameters (factors): chromium(III) concentration in electrolyte, x^1; current density x_2; temperature x_3; and pH of the electrolyte, x_4.

$$y = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4 + b_{12}x_1x_2 + b_{13}x_1x_3 + b_{14}x_1x_4 + b_{23}x_2x_3 + b_{24}x_2x_4 + b_{34}x_3x_4 + b_{123}x_1x_2x_3 + b_{134}x_1x_3x_4 + b_{124}x_1x_2x_4 + b_{234}x_2x_3x_4 + b_{1234}x_1x_2x_3x_4.$$

To optimize the electrolyte composition and the deposition mode in order to obtain a nickel–chromium alloy containing 12–13% chromium, we applied a four-factor method of experiment design. The factors affecting the alloy composition and the ranges of their variation are listed in Table 1.

The optimization parameter is the percentage content of chromium in the alloy, y, which should be in the range 12–13%. Data on the percentage content of chromium in the alloy, calculated from the results of a chemical analysis of the resulting alloys, are listed in Table 2, together with regression coefficients calculated on their basis.

On finding the coefficients in the regression equation, we verified their significance by Student's criterion. For this purpose, three parallel experiments were performed at the center of the design on the main level for all the factors. The chemical analyses of the thus prepared nickel–chromium alloys demonstrated that the alloy contains $y_1 = 11.9$, $y_2 = 12.3$, and $y_3 = 12.7$% chromium.

Table 2. Coefficients of the regression equation, calculated from data on the chromium content of an alloy

Chromium content of an alloy, %		Coefficients of the regression equation	
$y_1 = 6.5$	$y_9 = 8.4$	$b_0 = 10.72$	$b_{23} = -0.01$
$y_2 = 8.3$	$y_{10} = 11.6$	$b_1 = 1.48$	$b_{24} = 0.16$
$y_3 = 6.5$	$y_{11} = 10.3$	$b_2 = 0.72$	$b_{34} = 0.18$
$y_4 = 10.5$	$y_{12} = 13.3$	$b_3 = 1.29$	$b_{123} = -0.17$
$y_5 = 8.0$	$y_{13} = 11.5$	$b_4 = 1.66$	$b_{124} = -0.11$
$y_6 = 11.2$	$y_{14} = 14.5$	$b_{12} = 0.08$	$b_{134} = -0.01$
$y_7 = 9.5$	$y_{15} = 13.2$	$b_{13} = -0.02$	$b_{234} = -0.02$
$y_8 = 12.0$	$y_{16} = 16.2$	$b_{14} = 0.04$	$b_{1234} = 0.19$

As a result of the verification, insignificant coefficients b_{13}, b_{23}, b_{134}, and b_{234} of the regression equation were dropped, and the resulting model was tested for adequacy by Fisher's criterion.

The regression equation adequately describing the effect of technological factors on the composition of the nickel–chromium alloy has the form

$$y = 10.72 + 1.48x_1 + 0.72x_2 + 1.29x_3 + 1.66x_4 + 0.08x_1x_2 + 0.04x_1x_4 + 0.16x_2x_4 + 0.18x_3x_4 - 0.17x_1x_2x_3 - 0.11x_1x_2x_4 + 0.19x_1x_2x_3x_4.$$

It is seen from the equation that the alloy composition is strongly affected by the individual factors: chromium(III) concentration in the electrolyte, current density, temperature, and pH of the electrolyte. Less important are the interaction factors: [chromium(III) concentration in the electrolyte]–[current density], [temperature]–[electrolyte pH], and [chromium(III) concentration in the electrolyte]–[pF of the electrolyte]. This influence of the factors on the coating composition makes it possible to maintain the alloy composition within prescribed limits during electrodeposition by varying the deposition mode without adjusting the electrolyte with chromium(III) salts.

The derived single-factor polynomial equations relating the alloy composition to chromium(III) concentration in electrolyte, current density, temperature, and electrolyte pH, and also the four-factor regression equation serve for automatically maintaining and controlling the alloy composition and, hence, the properties of nickel–chromium coatings in their deposition on automated production lines.

Thus, the optimal electrolysis conditions providing lustrous nickel–chromium coatings are as follows: current density 4.0–6.0 A dm^{-2}, temperature 40–50°C, and pH 4.0–5.0.

The microhardness of the nickel–chromium coatings exceeds that of nickel coatings. For example, the microhardness for nickel and nickel–chromium alloy at a 50 g indentor load are 4.5 and 4.95 GPa, respectively. The increase in the microhardness is due to the incorporation of chromium atoms into the crystal lattice of nickel.

It is necessary to note that internal stresses in alloy coatings are considerably lower than those in pure nickel coatings [3]. This is due to the lower hydrogen pickup by nickel–chromium alloy coatings as compared with pure nickel. For example, the internal stresses for nickel and nickel–chromium alloy are 320 and 120 MPa, respectively, i.e., the fraction of hydrogen introduced into a coating and affecting the internal stresses is much greater for nickel as compared with the nickel–chromium alloy. The level of internal stresses arising in a coating during electrodeposition is one of the most important technological characteristics. Coatings with lower internal stresses are less susceptible to microcracking and peeling-off from a support, which should affect the wear resistance of a coating.

The wear resistance of coatings used in friction units is one of the most important characteristics governing the service life of an article. Our studies demonstrated that the wear resistance of nickel–chromium coatings is 30 times that of nickel coatings.

A study of the lattice microstructure demonstrated that the incorporation of chromium atoms into the crystal lattice of nickel results in its distortion and, as a consequence, in a higher coating hardness.

The corrosion tests carried out in the moist chamber for 56 days and in a salt-fog chamber for 7 days showed that the outward appearance of samples with a nickel–chromium alloy remained virtually unchanged after environmental tests, whereas the nickel coating somewhat lost its luster. After the test in the salt-fog chamber, minor corrosion centers were observed on a nickel coating, whereas a nickel–chromium coating remained unchanged.

CONCLUSIONS

(1) A technique for electrochemical deposition of corrosion- and wear-resistant nickel–chromium coatings was developed.

(2) An ecologically safe electrolyte was suggested for obtaining lustrous coatings. It has following composition (g l^{-1}): nickel sulfate (in terms of the metal) 83.47, nickel chloride (in terms of the metal) 20.38, chromium-potassium alum (in terms of the metal) 40, boric acid 30, 1,4-butinediol 0.5, saccharin 1.0, aminoacetic acid 220, and ammonium sulfate 200.

Abstract—Results of a study of a carbon material (carbonizate) obtained in processing of a solid cellulose-containing waste with concentrated sulfuric acid are presented. The mass fractions of water, water-soluble and -insoluble ash, and total pore volume for water were determined. Data furnished by electron microscopy and small-angle neutron scattering were used to analyze the structure of the material and identify factors affecting the cluster organization. Areas in which the carbonizate can be used are suggested.

DOI: 10.1134/S1070427207100126

The problem of processing of a municipal solid waste (MSW) remains topical. Waste of this kind is a large-tonnage heterogeneous mixture with morphological composition varying between different countries. A major part of MSW (up to 50%) is constituted by cellulose-containing components, such as paper, cardboard, and wood [1]. The methods most widely used for MSW utilization are burial (storage at dumping grounds), burning at incinerator plants for production of thermal and electric power, and classification and secondary processing at garbage processing plants. The results of an ecological-economical expertise indicate that all these techniques for MSW processing fail to satisfy the requirements of market economy, ecological safety, and resource saving. In some countries, the problem of MSW utilization is solved by preliminary classification aimed to recover components with consumers' value (metals, plastics, glass, paper, etc.). This approach markedly diminishes the specific expenditure for MSW utilization and improves ecological conditions.

In order to improve the MSW classification efficiency, a method has been suggested [2], which consists in that the whole mass of waste is preliminarily treated with concentrated sulfuric acid. Studies demonstrated that glass (cullet), polymeric materials (polyethylene, polypropylene, polyethylene terephthalate), rubber articles, and natural fancy leather are not subject to the action of the acid and are easily classified after this treatment, whereas perishable cellulose-containing components (paper, cardboard, textile, wood, food waste) are converted into biologically inert substances. The overall chemical reaction of the process can be represented by the equation

$$(C_6H_{10}O_5)_x + xH_2SO_{4(conc.)} = 6xC + xH_2SO_4 \cdot 5H_2O + Q, \quad (1)$$

where x is the number of structural fragments, and Q is the heat effect of the reaction.

The reaction yields a homogeneous black carbon-rich mass. The theoretical yield of pure carbon is about 35% relative to the total mass of the waste. Sulfonic acids are formed as by-products of the reaction.

Presently, products formed in interaction of concentrated sulfuric acid or oleum with carbon-containing materials are known. For example, interaction with coal anthracite) gives sulfo carbon [3, 4] (carbon in which sulfo groups $-SO_3H$ are fixed on the carbon matrix and provide the material with cation-exchange properties). Sulfo carbon is used in water treatment to remove organic substances, odor, and coloration [5, 6] and as a cation exchanger [7, 8]. Carbonization of var-

ious kinds of vegetable waste (including hydrolyzed lignin) with hot concentrated sulfuric acid yields activated carbon, Collactivit [9, 10]. This material is an active adsorbent used to purify syrups in hydrolysis industry. Spent Collactivit is added to polymer-concrete mixture for floors of stock farm buildings [11].

In order to use in various industrial applications the carbonizate obtained by sulfuric acid carbonization of cellulose-containing MSW, we obtained and analyzed its porosity-related structural characteristics. Based on electron-microscopic and small-angle neutron-scattering data, we distinguished structural-organization levels of pores and obtained their dependence on a method used for sulfuric acid removal.

To study the destruction of solid cellulose-containing waste under the action of concentrated sulfuric acid, we took representative samples of cellulose-containing MSW (sample no. 1) with the following component ratio (wt %): paper and cardboard 38.0, food waste[1] 40.0, wood 3.0, leather and rubber 2.5, textile 6.0, bones 2.0, polymeric materials 5.5, ferrous and nonferrous metals 3.0 [1]. The total mass of the representative sample was 427.0 ± 0.5 g, and its moisture content, ≤10%. The calculated content of cellulose did not exceed 75% of the total mass. After being weighed, sample no. 1 was placed in a 3-l glass vessel with a gas-outlet tube and poured over with 0.5 l of sulfuric acid (initial mass fraction of sulfuric acid 94%, density 1831.2 kg m^{-3}), and the mixture agitated for 5 min. At the initial instant of time, the temperature of the mixture increased to 120°C and the reaction proceeded with vigorous evolution of water vapor. In 30 min, the temperature decreased to 90°C and release of water vapor completely ceased. The resulting heterogeneous mixture (sample no. 2) was kept for 20.0 h prior to further studies.

The qualitative and quantitative composition of the heterogeneous mixture was determined by visual inspection of the residues of components and their weighing. The content of the components in sample no. 2 was as follows (wt %): undried carbon material with admixtures 89.5 (bulk density 1.5 g cm^{-3}, found by measuring the mass of a sample and its volume), leather and rubber 2.5, polymeric materials 5.5, rest 2.5; the pH value of the heterogeneous mixture was lower than 0.1 (final mass fraction of sulfuric acid 77%, density 1831.2 kg m^{-3}). The calculated moisture content did not exceed 25%.

[1] The averaged sample contained equal amounts of potato tuber skin, banana skin, bread, yellow corn grains, and white-cabbage stumps.

In the next stage, two methods were used to remove sulfuric acid from sample no. 2. In the first of these, sulfuric acid was extracted with distilled water to obtain the finished product (sample no. 3). The expenditure of distilled water until pH 6.5 of washing water was 1.21 m^3 kg^{-1}. In the second method, sulfuric acid was neutralized with $NaHCO_3$ (sodium hydrocarbonate) to give a carbon material with admixture of salts (sample no. 4). The chemical reaction occurring in the given process can be represented by equation [12]:

$$2NaHCO_3 + H_2SO_4 \cdot 1.7H_2O = Na_2SO_4 \cdot 2.7H_2O + 2CO_{2(gas)} + 1.4 \text{ kJ mol}^{-1}. \quad (2)$$

Most of carbon materials are used as raw materials for production of adsorbents. The size and volume of micropores are the most important parameters in description of adsorption of numerous substances from gaseous and liquid media by activated carbons. The limiting factor determining how the structure of carbon-containing raw materials changes is the treatment temperature of a carbon material [13]. Activated carbons are typically tested by the procedures described in [14–16].

Upon removal of sulfuric acid and drying in air, sample nos. 3 and 4 were analyzed for the content of water (moisture content) and ash and their total pore volume for water was determined.

A direct structural analysis of sample nos. 2–4 was made with a JEOL JSM-840 scanning electron microscope (SEM) at Laboratory of nuclear reactions (Joint Institute of Nuclear Research, Dubna).

Sample nos. 3 and 4 were studied by the method of small-angle scattering of thermal neutrons [17]. The experiments were carried out on a SANS-1 small-angle neutron scattering installation at a stationary reactor of the GKSS research center (Geesthacht, FRG). The samples were poured in a planar quartz cuvette of thickness 1.5 mm. In the experiments, the differential neutron scattering cross-section per unit volume (scattering intensity) was determined as a function of the scattering vector magnitude:

$$q = (4\pi/\lambda)\sin(\theta/2), \quad (3)$$

where λ is the wavelength of neutrons incident on a sample, and θ is the neutron scattering angle.

The wavelength of incident neutrons was 0.81 nm at a monochromatization $\Delta\lambda/\lambda = 10\%$. By varying the sample-to-detector distance within the range 0.7–

9.0 M, small-angle-scattering curves could be obtained in the q-range 0.04–2.7 nm^{-1}. The efficiency calibration of the detector was performed by the standard method of separate measurements of the incoherent scattering for water [18]. The scattering by an empty cuvette was subtracted as the background.

EXPERIMENTAL

According to the experimental data, the equation of reaction (1) has, under the optimal process conditions [moisture content of the representative sample (no. 1) not exceeding 10%; degree of carbonization of the cellulose-containing material, about 99%], the form

$$(C_6H_{10}O_5)\cdot H_2O + 5(H_2SO_4\cdot 0.5H_2O) = 6C + 5(H_2SO_4\cdot 1.7H_2O) + 127.67\ \text{kJ mol}^{-1}. \quad (4)$$

In the first stage of the process, the reaction mixture foams; this stage continues for 4–8 min. In the second stage, the volume of the mixture decreases by a factor of 2 to give a homogeneous black loose mass, the duration of this stage is 30–40 min. Consequently, the dehydration of cellulose and lignin is complete in this interval of time. In the case of a steady supply of the mixture into the reactor, the process temperature should be maintained at about 75°C. Under these conditions, no gases are evolved, including water vapor. The heat of the reaction (kJ) was calculated by the formula

$$Q = \Delta C_p \nu (T_{fin} - T_{in}) K_t, \quad (5)$$

where ΔC_p is the specific heat of a mole of the material (kJ mol^{-1} K^{-1}); ν, amount of mixture components (mol); T_{in} and T_{fin}, initial and final temperatures of the mixture, respectively (K); and K_t, coefficient of mixture heating in the reactor for the first hour of the process, K_t = 1 in the case of a steady supply of the mixture into the reactor during the working time.

The integral heat of dissolution of sulfuric acid (kJ) for Eq. (4) was calculated by the formula

$$\Delta H_r = \Delta H_i \nu_i (H_2SO_4), \quad (6)$$

where ΔH_r = [–41.26 – (–15.73)] × 5 = (–25.53) × 5 = –127.67 kJ [19].

The results of calculations, listed in Table 1, indicate that the released heat Q of the reaction in destruction of 1 mol of cellulose is numerically equal to the integral heat of dissolution of sulfuric acid, ΔH.

Table 2. Summary comparative characterization of carbon half-products and activated carbons [GOST (State Standard) 6217–74]

Parameter	Sample no. 3	Sample no. 4	ACC*
Bulk density, g cm^{-3}	0.9	0.8	–
Moisture content (GOST 12597–67), %	≥10.5	≥25.0	≥10.0
Total pore volume for water (GOST 17219–71), cm^3 g^{-1}	0.7–0.9	0.5–0.7	≤1.4

* ACC, activated charcoal.

The data obtained in determining the moisture content, mass fraction of water-insoluble ash, and total pore volume for water are listed in Table 2.

Figure 1 shows SEM images of the surface of the carbon material. It can be clearly seen that the surface of the carbon material has concentration inhomogeneities. Sample no. 3 (Fig. 1a) has a developed nonuniform surface with spherical and spheroidal inclusions 100–1000 nm in size. In storage, the carbon material (sample no. 3) changes its structure: the developed external surface transforms into a densely packed layered surface (Fig. 1b). Sample no. 4 (Fig. 1c) has a layered surface with inclusions of crystal hydrates.

Figures 2 and 3 show small-angle neutron scattering curves and the results of their processing. It can be seen that there is a fundamental difference in the nature of scattering between sample nos. 3 and 4. Portions in which the intensity decreases by the power law as the scattering vector magnitude increases can be distinguished in the scattering curves [17]:

$$I(q) = B/q^P + C, \quad (7)$$

where B is the free parameter found from the data; the exponent P reflects the internal structure of the scattering units and characterizes the type of their 3D

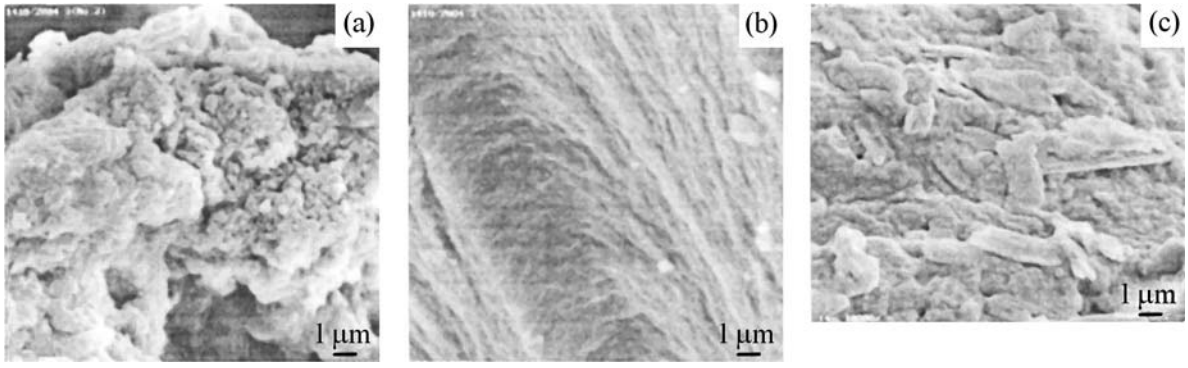

Fig. 1. SEM micrographs of samples. Scale 1 : 10000. Sample: (a) no. 3, freshly prepared; (b) no. 3, after storage for 1 year; and (c) no. 4.

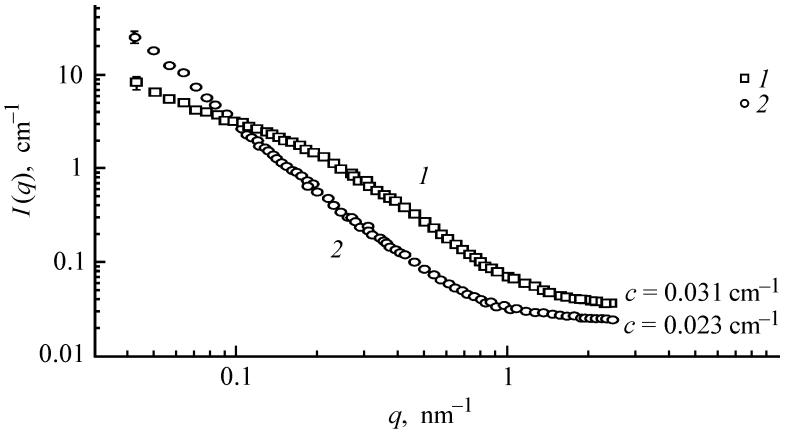

Fig. 2. Experimental small-angle neutron-scattering curves [scattering cross-section $I(q)$ per unit volume vs. the scattering vector magnitude q] reduced to the same bulk density, for sample nos. (*1*) 3 and (*2*) 4.

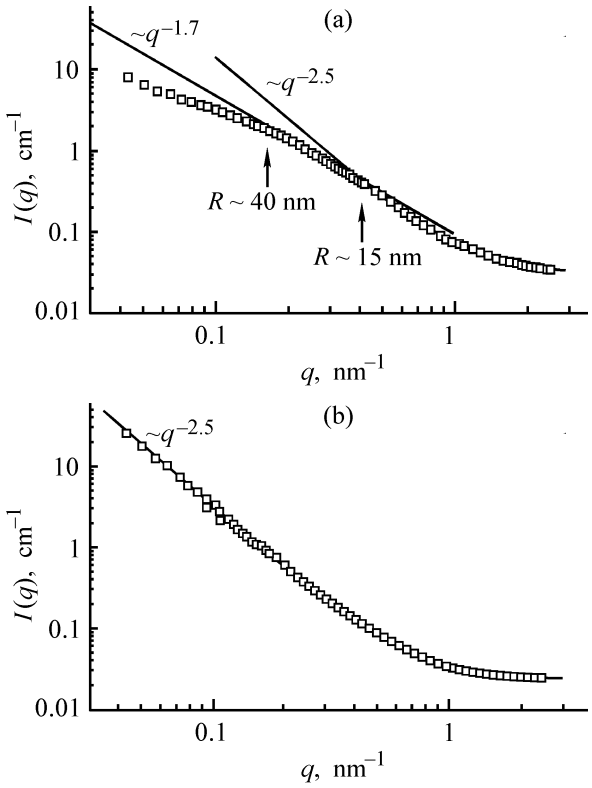

Fig. 3. Power-law portions and evaluation of characteristic radii on small-angle neutron-scattering curves $I(q)$–q for sample nos. (a) 3 and (b) 4.

or surface organization in accordance with the classification [20]:

$$I < P < 3, \tag{8}$$

a mass fractal with a fractal dimension $D = P$;

$$3 > P > 4, \tag{9}$$

a surface fractal with a fractal dimension $D_S = 6 - P$.

The case $P = 4$ corresponds to a smooth boundary surface (Porod's law), so that the dimension $D_S = 2$. Parameter C in Eq. (7) corresponds to the incoherent scattering background, which is proportional to the number of hydrogen atoms in a sample. Deviations from the law described by (7), observed as q decreases, corresponds to the characteristic radius of clusters

$$R \sim 2\pi/q. \tag{10}$$

The exponents and characteristic radii for sample nos. 3 and 4, estimated in accordance with Eqs. (7) and (10), are shown in Fig. 3. For sample no. 3, two scattering modes can be reliably distinguished, which correspond to fractal clusters with dimensions of 2.5 (characteristic radius 15 nm) and 1.7 (characteristic radius 40 nm). The radius of elementary pores constituting the clusters, equal to less than 1 nm, is below the sensitivity limit of the method for systems of this kind. The material has a multilevel organization structure. For sample no. 4, no effect of the final cluster size is observed. In this case, a lower estimate of the cluster radius, q, which is less than 100 nm, can be made by formula (10) from the minimum measured value. The material has a uniform, on this scale, fractal structure.

The method of small-angle neutron scattering confirms the existence of concentration inhomogeneities not only on the surface, but also in the internal structure of the carbon material. Analysis of the scattering curves reveals that the curves for samples nos. 3 and 4 coincide at large q to within a constant factor and the incoherent background, which suggests the common origin of these two materials. It should be noted, however, that the higher incoherent background of sample no. 3 indicates that it contains a larger amount of hydrogen, and consequently, of water as compared with sample no. 4. In addition, use of the neutralization method leads, in contrast to extraction with water, to a sharp increase in the size of the forming clusters and, consequently, makes smaller the total pore volume for water.

Thus, the structural parameters of the carbon material depend on the method used to remove sulfuric acid from sample no. 2.

CONCLUSIONS

(1) The carbon material obtained has, after preliminary treatment of the whole mass of cellulose-containing waste with concentrated sulfuric acid, a developed pore structure with a wide range of pore sizes, 1–1000 nm. Specific features of this structure depend on the method used to remove sulfuric acid from the heterogeneous mixture.

(2) Neutralization of sulfuric acid impairs, compared with the liquid extraction, the properties of the resulting half-product: the amount of impurities in the form of crystal hydrates increases (ash content ≤30%) and the total pore volume for water decreases to 0.5–0.7 cm^3 g^{-1}. At the same time, as also in the case of sulfuric acid extraction with water, the carbon material has an ash content not exceeding 1.5% and a total pore volume for water of up to 0.7–0.9 cm^3 g^{-1}.

(3) The final half-product exhibits good sorption properties and can be used as a sorbent or catalyst support.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of the Longitudinal Agitation Coefficient in Roll Elements of Baromembrane Apparatus

O. A. Abonosimov, S. I. Lazarev, and S. V. Kovalev

Tambov State Technical University, Tambov, Russia

Received December 25, 2006

Abstract—Longitudinal agitation coefficient in industrial baromembrane roll apparatus was studied for two types of separating elements in relation to the motion velocity and pressure of the flow in the apparatus. Dependences of the longitudinal agitation coefficients on hydrodynamic parameters of baromembrane apparatus were analyzed and explained.

DOI: 10.1134/S1070427207100138

The aim of this study was to examine the effect of hydrodynamic parameters of industrial baromembrane apparatus with roll separating elements on the processes of substance transfer across membranes.

The hydrodynamic structure of the flow in a membrane unit strongly affects the mass transfer in baromembrane separation of solutions. In these units, fluid flows, as a rule, occupy an intermediate position in their structure between two idealized limiting cases, piston-flow and complete-mixing modes.

To evaluate the effect of longitudinal agitation on the separating characteristics of a baromembrane unit, it is necessary to have data on longitudinal agitation coefficients. For this purpose, the longitudinal agitation coefficient in baromembrane units was experimentally determined.

EXPERIMENTAL

To determine the longitudinal agitation coefficient, we used the known method of introducing a perturbation in a certain cross-section of the flow and recording the consequences (response of the system) in another cross-section. In experimental studies, we used the method of pulsed introduction of a tracer (20% aqueous solution of NaCl), with the elution curve subsequently recorded at the outlet of the membrane unit. The amount of the tracer introduced was varied, depending on the unit operation mode, and was chosen to use 60% of the scale of the measuring instrument (KSM-4). This was done because the variation of the solution concentration in the unit is small within this range and the displacement of the rheochord slide is proportional to changes in concentration.

The experimental installation used to determine the longitudinal agitation coefficient is shown schematically in Fig. 1.

The installation comprised the following elements: reverse-osmosis separating apparatus *1*; input-solution tank *2*; high-pressure pump *3*; choke *4*; rotameters *5* and *6* for retentate and permeate, respectively; gage *7*;

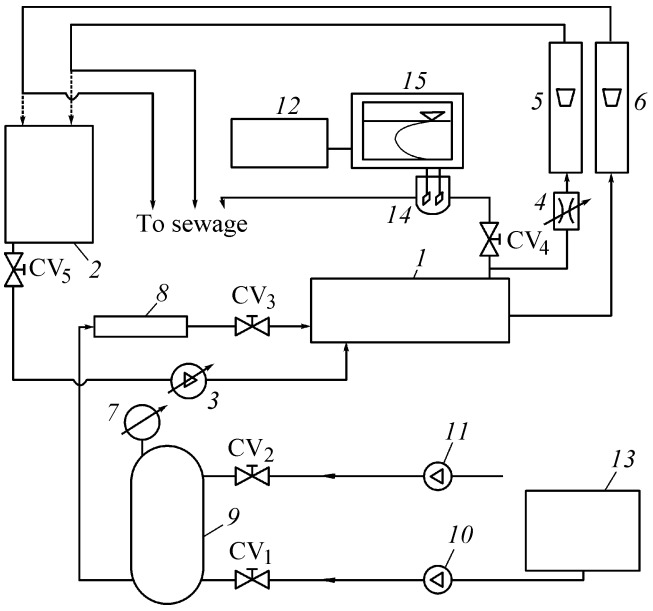

Fig. 1. Schematic of the experimental installation. For explanations, see text.

and tracer injection unit: batching cylinder with a piston, *8*; receiver *9*; high-pressure pump *10*; compressor *11*; resistance box *12*; vessel for solution, *13*; measuring cell *14*, automated bridge *15*; and control valves CV_1–CV_5.

The installation operated as follows. A solution (tap water) was delivered from the input tank by a high-pressure pump into the baromembrane unit, in which the necessary pressure was created. Two roll elements of the ERO-E-6.5/900A type or four of the ERO-K-92-475 type were mounted in the baromembrane unit. The necessary flow rate of the solution was set by adjusting the strokes of pump pistons. Before attaining the steady operation mode, the installation worked in the circulation mode, after which the permeate and retentate were discharged into sewage.

Because of the sufficiently high pressure in the unit (up to 4 MPa), we encountered the problem of fast and accurate introduction of the tracer into the system. It was solved by developing for this purpose an original design.

The tracer injection system operated as follows. The batching cylinder was filled with a required amount of the tracer. The air compressor and high-pressure pump created the required pressure in the receiver connected by a pipeline to the batching cylinder. By opening valve CV_3, the tracer was injected directly at the inlet of the reverse-osmosis unit. The pressure in the cylinder was always set to be somewhat higher than that in the baromembrane unit to provide a fast tracer injection into the unit. The time of tracer injection was 1–2 s.

The response curve was recorded with an electrically conducting cell mounted in parallel to the retentate flow at the unit outlet. The cell comprised two 4×8-mm rectangular parallel planar platinum electrodes spaced by 4 mm (Fig. 2). The cell volume being small, the solution portions between the electrodes rapidly changed.

The cell resistance was measured and recorded with a KSM-4 high-speed automated bridge. Because the electrical conductivity of tap water may somewhat vary, additional adjustment of the null position of the instrument scale was necessary. This adjustment was made by changing the resistance of the MSR-54 resistance box connected in series with the measuring cell. If the electrical conductivity of water increased or decreased, the resistance of the box was changed in the opposite direction, so that the total resistance of the cell and the resistance box remained approximately the same. The temperature of tap water was manually maintained constant because of the high sensitivity of the instrument to changes in its electrical conductivity with temperature.

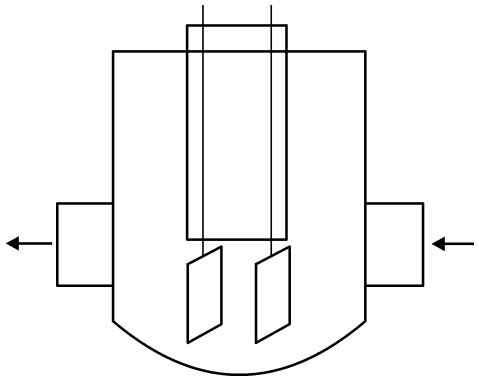

Fig. 2. Measuring cell.

The longitudinal agitation can be evaluated in terms of various theoretical models of the flow structure (cellular, recirculatory, combined, diffusion-type). The calculations were made using the diffusion model, the best applicable to the baromembrane unit under study, which can be classed with apparatus without any noticeably pronounced sectioning [1, 2].

The response C-curves were used to calculate the variance of the solution residence time in the apparatus.

The variance of the dimensionless C-curve was found using the equation [1]

$$\sigma^2 = \frac{1}{\tau_{av}^2}\left[\frac{\Sigma \tau_i^2 c_i}{\Sigma c_i} - \left(\frac{\Sigma \tau_i c_i}{\Sigma c_i}\right)^2\right], \quad (1)$$

where τ_{av} is the average residence time found in relation to the fluid velocity in the intermembrane channel by the formula

$$\tau_{av} = L/U, \quad (2)$$

L, unit length (m); and U, fluid velocity in the intermembrane channel (m s^{-1}).

The parameter of the diffusion model, modified Peclet number (Pe), was found using the known relationship [1] between the Peclet number and the variance of the distribution of the residence time, σ^2, for an infinitely long channel:

$$\sigma^2 = \frac{8}{Pe^2} + \frac{2}{Pe}. \quad (3)$$

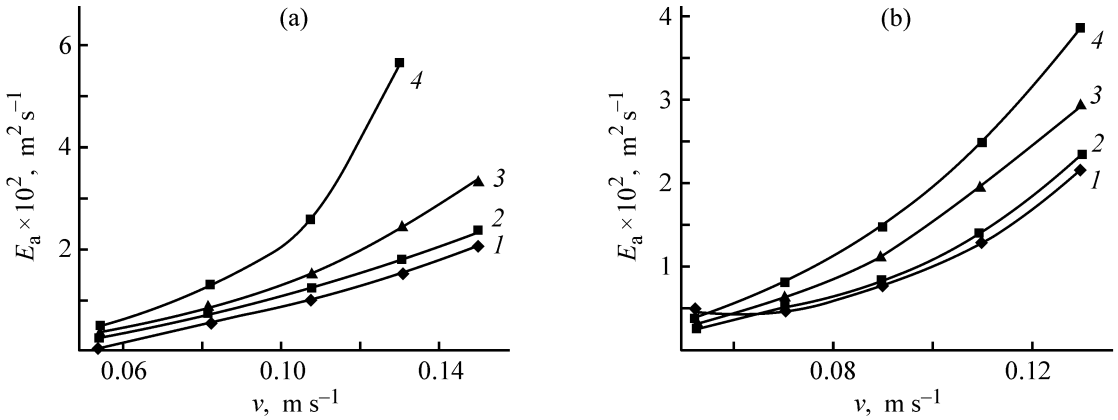

Fig. 3. Longitudinal agitation coefficient E_a vs. the fluid flow velocity v at different pressures in a unit with (a) ERO-E-6.5/900A and (b) ERO-K-92-475 roll elements. P (MPa): (*1*) 0.1, (*2*) 1.0, (*3*) 2.5, and (*4*) 4.0.

The resulting value of Pe was used to calculate the longitudinal agitation coefficient E_a by the formula

$$E_a = LU/\mathrm{Pe}, \quad (4)$$

where U is the solution flow velocity in the channel of the unit (m s^{-1}).

The longitudinal agitation in the baromembrane unit was studied at different solution flow velocities and pressures. The results obtained in experiments aimed to determine the dependence of the longitudinal agitation coefficient on the flow velocity and pressure of the fluid in the unit for both types of elements are shown graphically in Figs. 3a and 3b.

It can be seen that the longitudinal agitation coefficient substantially increases as the fluid flow velocity in the unit becomes higher. For a unit with ERO-K-92-475 elements, the longitudinal agitation coefficient is somewhat higher.

This can be attributed to enhancement of the turbulent agitation in the intermembrane channel of the element at higher fluid flow velocities, which is an important factor related to the intensity of longitudinal agitation. Moreover, additional mixing zones appear between the elements in the unit because of the specific design of element-to-element connections.

Empirical coefficients b, n, m in Eq. (5)

Membrane unit	$b \times 10^6$	n	m
ERO-E-6.5/900A	5.672	2.10	0.16
ERO-K-92-475	1.593	2.55	0.16

In these mixing zones, the flow is also strongly turbulized as the fluid flow velocity increases. The number of these zones is three for a unit with ERO-E-6.5/900A elements and five for that with ERO-K-92-475 elements. Therefore, a more complete agitation occurs in the latter unit, and just this circumstance accounts for the large values of the longitudinal agitation coefficient.

Analysis of the plots of the longitudinal agitation coefficient at different pressures in the unit also shows that the coefficient increases with the pressure in the unit.

The pressure in the unit is an additional factor affecting the longitudinal agitation coefficient. As the pressure in the unit increases, there appears an additional permeate flow, which gradually depletes the main flow along the unit length. The permeate flow is directed from the flow core in the intermembrane channel across the membrane, i.e., perpendicularly to the main flow. Therefore, the permeate flow gives rise to an additional agitation of the fluid flow in the membrane unit. At higher pressures, the permeate flow rate grows, which leads to an increase in the longitudinal agitation coefficient [3, 4]. ERO-K-92-475 membrane elements show a higher throughput in terms of the permeate than ERO-E-6.5/900A and, therefore, have somewhat larger values of the longitudinal agitation coefficient at equal pressures.

We used the experimental data obtained to construct approximation dependences of the longitudinal agitation coefficients on pressure and fluid flow velocity in the baromembrane unit for roll elements of the ERO-E-6.5/900A and ERO-K-92-475 types:

$$E_a = b\mathrm{Re}^n\left(\frac{P}{P_0}\right)^m, \quad (5)$$

where b, n, and m are empirical coefficients; and P and P_0 are the working pressure and pressure taken to be 0.1 MPa, respectively.

Values of the coefficients b, n, and m are listed in the table. The error of the calculated and experimental values of E_a did not exceed ±15%.

CONCLUSION

A strong longitudinal agitation occurs in baromembrane units. The magnitude of this agitation depends on the type of a membrane element, design features of the unit, hydrodynamic situation in the apparatus, and pressure difference.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Model of Separation of Wastewater Containing Vat Dyes

Yu. P. Osadchii and T. E. Nikiforova

Received November 14, 2006; in final form, April 2007

Abstract—Mechanism of fluid separation with capillary-porous polymeric membranes was studied and a mathematical model of separation by ultrafiltration of vat-dye-containing wastewater from finishing shops of textile plants was suggested. The model takes into account the effect of physical parameters on the mechanism and kinetics of the cross-membrane transfer of ingredients, in which a gel layer is formed.

DOI: 10.1134/S107042720710014X

The process of baromembrane separation of industrial wastewater containing dye vats, in which a gel layer is formed on the membrane, is nonstationary. The reason is that changes in the thickness of the gel layer affect the hydrodynamics and mass exchange because of the changing permeability and selectivity of this layer.

The objective in developing a mathematical model of separation of industrial wastewater containing vat dyes (Brilliant Green ZhD, Blue OD, Reddish 2ZhD) used in yarn dyeing in AKDU-6-02 apparatus is to describe the effect of physical parameters on the mechanism and kinetics of the cross-membrane transfer of ingredients, in which a gel layer is formed.

EXPERIMENTAL

The ultrafiltration process was performed under a pressure of 0.3–0.4 MPa, created within membranes by a centrifugal pump, flow velocity of 4–6 m^{-1}, pH 1–12, and temperature of the solution being separated in the range 15–90°C. The tubular membranes have the form of a multilayer tubular fiberglass frame covered from within with a semipermeable polymeric film. The input wastewater is concentrated via permanent circulation through BTU-0.5/2 membrane units comprising a set of tubular membranes [1], with continuous removal of the permeate. The resulting concentrate is delivered at regular intervals of time to a receiver tank for subsequent recirculation.

Apparatus with tubular membranes operate in the piston-flow mode. In the case in question, we have low concentrations of a vat dye (0.2–0.3 g l^{-1}) in water and weak effect of gelation on the permeability and selectivity of membrane durian a certain time. It is assumed that wastewater is separated at a constant pressure along the entire length of membrane units and constant temperature. A schematic of the baromembrane separation process is shown in Fig. 1.

The material balance equation for the flow rates of water and dye has the form

$$Q_1 = Q_2 + Q_3, \quad (1)$$

where Q_1 is the flow rate a substance (water and dye) before a cross-section under consideration (kg s^{-1});

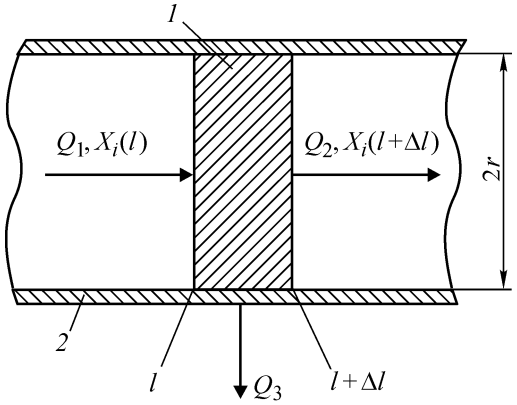

Fig. 1. Schematic of the ultrafiltration separation with a tubular membrane. (*1*) Arbitrary longitudinal cross-section of the flow being separated in the range from l to $l + \Delta l$, where l is an arbitrary coordinate along the tube length and (*2*) separating layer of a polymeric membrane, deposited onto the inner surface of the tube.

Q_2, flow rate of the substance after the cross-section (kg s^{-1}); and Q_3, flow rate of the substance across the membrane (kg s^{-1}).

In the general form, the flow rates are given for each of the components by

$$Q_1 = X_i(l)VS, \quad (2)$$

$$Q_2 = X_i(l + \Delta l)VS, \quad (3)$$

$$Q_3 = G_i \mathrm{d}F = 2G_i \pi r \mathrm{d}l, \quad (4)$$

where X_i is the mass fraction of a component in the flow (kg m^{-3}); V, flow velocity (m s^{-1}); l, coordinate along the apparatus (m); S, cross-section of a membrane tube (m^2); G_i, permeability to the substance (kg m^{-2} s^{-1}); F, separation surface area of the membrane (m^2); and r, membrane tube radius (m).

The mass fraction of the dye passing through the cross-section under consideration has the form

$$X_\mathrm{d}(l)VS = X_\mathrm{d}(l + \Delta l)VS + G_\mathrm{w}(1 - \varphi)2\pi r \mathrm{d}l, \quad (5)$$

$$G_\mathrm{d}\mathrm{d} = G_\mathrm{b}(1 - \varphi), \quad (6)$$

where X_d is the mass fraction of the dye (kg m^{-3}); G_d, membrane permeability to the dye (kg m^{-2} s^{-1}); G_w, membrane permeability to water (kg m^{-2} s^{-1}); and φ, degree of separation by the membrane or selectivity. After certain rearrangements, we obtain the integration constant from the initial conditions $l = 0$, $X_\mathrm{d} = X_{\mathrm{d}0}$ and expression (5) takes the form

$$X_\mathrm{k} = X_{\mathrm{k}0} - \frac{2G_\mathrm{b}(1 - \varphi)}{Vr} l. \quad (7)$$

The change in the mass fraction of the dye after putting wastewater through a single cycle ($l = L$) can be expressed as

$$2X_\mathrm{d} = \frac{GF}{V}[X_{\mathrm{d}0} - (1 - \varphi)]\,\mathrm{d}\tau, \quad (8)$$

where G is the overall permeability of the membrane (kg m^{-2} s^{-1}); V, volume of the permeate obtained in a given time (m^3); and τ, separation process duration (s).

According to the Darcy law [2], the change in the membrane permeability is given by

$$G = \frac{\Delta P \rho}{\mu(R_\mathrm{m} + R_\mathrm{g})}, \quad (9)$$

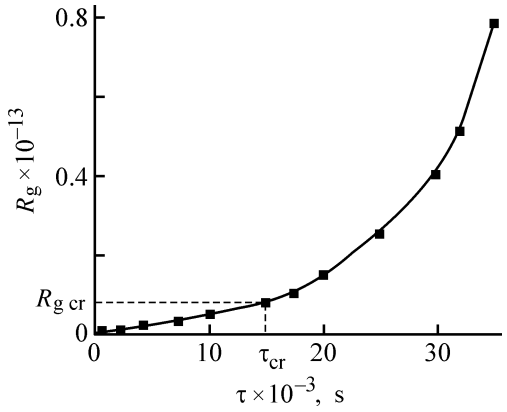

Fig. 2. Variation of the gel layer resistance R_g to the separation process with time τ. ΔP = 0.2 MPa, V = 2 m s^{-1}, T = 293 K.

where ΔP is the pressure difference over the membrane (N m^{-2}); ρ, density of wastewater being purified (kg m^{-3}); μ, dynamic viscosity for wastewater (N s m^{-2}); R_m, membrane resistance (m^{-1}); and R_g, gel layer resistance (m^{-1}).

The membrane resistance is found from the permeability equation for water and is taken to be constant. The gel layer resistance was found from experimental data, using Eq. (9). The plot describing the dependence of R_g on τ is shown in Fig. 2. It can be seen that this resistance starts to change after 7.5–8.5 h. This is the critical time τ_cr, to which corresponds the critical gel layer resistance. Further increase in τ leads to a pronounced rise in R_g and decrease in G.

A mathematical processing of the data yielded the following expression for the dependence of R_g on τ:

$$R_\mathrm{g} = b(e^{n\tau} - 1), \quad (10)$$

where $b = 2.06 \times 10^{10}$ m^{-1} and $n = 1.34 \times 10^{-4}$ s^{-1}.

We tested the adequacy of the calculation relation (10) with a satisfactory convergence at the previously obtained optimal separation process parameters [3]. Solving Eqs. (9) and (10), (8) and (11), we obtained

$$G = \frac{\Delta P \rho}{\mu[R_\mathrm{m} + b(e^{n\tau} - 1)]}, \quad (11)$$

$$\mathrm{d}X_\mathrm{d} = \frac{\Delta P \rho F[X_{\mathrm{d}0} - (1 - \varphi)]}{\mu V[R_\mathrm{m} + b(e^{n\tau} - 1)]}. \quad (12)$$

Having integrated Eq. (12) by the method of undetermined coefficients [4], we obtained an equation that can be used to calculate the mass fraction of a dye in an arbitrary cross-section of the apparatus:

Results of model adequacy tests

$$X_d = X_{d0} + \frac{\Delta P \rho F [X_{d0} - (1 - \varphi)]}{\mu V n [R_m - b]} \left[n\tau + \ln \frac{R_m}{R_m + b(e^{n\tau} - 1)} \right]. \quad (13)$$

Knowing how the mass fraction of the dye in an arbitrary cross-section varies with time, we found the optimal duration and degree of concentration of wastewater containing vat dyes, depending on changes in the resistance of the gel layer over the membrane.

To verify the adequacy of the model, we made a comparative analysis of the experimental and calculated values of X_d in certain intervals of time (see table).

CONCLUSIONS

(1) The model suggested makes it possible to calculate the concentration of vat dyes in a wastewater being separated, depending on the increase in the gel layer resistance.

(2) The calculated value $R_{g.\,cr} = 0.1R_m$ corresponds to a process duration of 8.3 h, which coincides with experimental data. The relative error in X_d is within 2.7–3.1%, which also confirms the validity of the relations used in the calculation. The satisfactory agreement between the experimental and calculated concentrations of vat dyes in wastewater being separated confirms the adequacy of the model suggested.

(3) The model can be used to find the optimal technological mode of the process, determine the main characteristics for both the nonstationary and steady modes, and choose the optimal degree of concentration of the components.

Abstract—Changes in the driving force of the multistage interphase transfer of atmospheric oxygen in the presence of a nonionogenic wetting agent and triethanolamine were assessed by using analytical solutions of the film model of mass exchange at the phase boundary to describe the chemisorption uptake of oxygen by a sodium dithionite solution.

DOI: 10.1134/S1070427207100151

Alkaline treatments are an integral part of processes employed in purification of cellulose-containing materials to remove accompanying impurities in pulp-and-paper and textile industries and in initial processing of bast-fiber cultures to obtain cellulose and fibrous materials from annually renewable vegetable raw materials. In this case, the probability of damaging the main polymer is high because of the pronounced susceptibility of cellulose to oxidative destruction under the action of dissolved oxygen. This predetermines the topicality of studying the fundamental kinetic aspects of aerobic absorption of atmospheric oxygen and the influence exerted on this process by substances used to accelerate the wetting of cellulose materials and emulsify the impurities being removed. This is frequently done using nonionogenic surfactants based on products formed in hydroxyethylation of higher alcohols and alkyl phenols, and triethanolamine salts of their sulfo derivatives. Determining the effect of assistant substances on the chemisorption of oxygen is necessary for substantiating and developing cellulose-preserving techniques for processing of raw materials.

EXPERIMENTAL

In [1, 2], an approach to assessment of the driving force of the multistage process of interphase transfer of atmospheric oxygen into solution from experimental data on sodium dithionite (SDT) oxidation controlled by uptake of the oxidizing agent from the atmosphere was demonstrated. Previously, the adequacy of the method has been confirmed in description of chemisorption-induced oxidation of sodium hydroxymethane sulfinate (rongalite) [3]. Analysis of a concentration set of experimental curves describing the kinetics of dithionite oxidation by surface-absorbed oxygen and extrapolation of the dependences $W_S^{red} = f(c_{red})$ to $c_{red} = 0$ make it possible to characterize the state of an SDT-free solution, i.e., of the medium being analyzed, by analytical solutions obtained in terms of the film model of mass exchange at the phase boundary [4]. In this case, a differentiated assessment is possible of the influence exerted by assistant substances on the successive transfer of a gaseous oxidizing agent first to an adsorbed form and then to a solvated state, followed by its redistribution into the bulk via diffusion (absorption):

$$(O_2)_{atm} \xrightarrow{k_L^0} (O_2)_{ads} \xrightarrow{c_{ox(S)}} (O_2)_{solv} \xrightarrow{D_{ox}} (O_2)_{abs}. \quad (1)$$

As characteristics of stage-by-stage transformations can serve the following: mass-transfer coefficient k_L^0 at the interface (m s^{-1}), oxygen concentration in the surface layer of the solution, $c_{ox(S)}$ (M); and diffusion coefficient of oxygen, D_{ox} (m^2 s^{-1}). These coefficients are related in the model by the expressions

$$k_L^0 = W_S^0(c_{ox(S)} - c_{ox(V)}), \quad (2)$$

$$Y^0 = D_{ox}c_{ox(S)}(W_S^0)^{-1}, \quad (3)$$

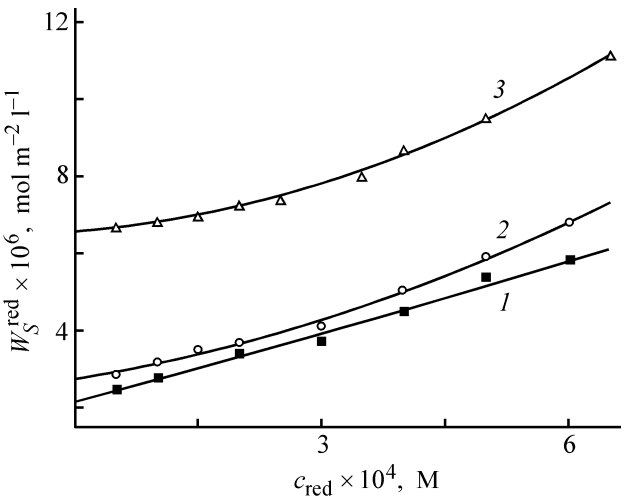

Fig. 1. Effect of the SDT concentration c_{red} on the rate of SDT oxidation by atmospheric oxygen, W_S^{red}, absorbed by aqueous-alkaline solutions (293 K, pH 12.5). (*1*) Without additives; additive (M): (*2*) OEAP (0.005) and (*3*) TEA (0.1).

where $c_{ox(V)}$ is the oxygen concentration in the solution bulk (M); $\{c_{ox(V)} = 0$, oxygen is absent in the solution bulk because of the fast chemical interaction between reagents [5]$\}$; Y^0, depth to which O_2 penetrates and thickness of the layer in which the reaction with SDT occurs (m); and W_S^0, rate of the surface uptake of oxygen by the solution in the absence of a chemical reaction (at $c_{red} = 0$) (mol m^{-2} s^{-1}).

The reaction of SDT with dissolved oxygen at 293 K and pH 12.5 was studied in thermostated (±0.1 K) test tubes with fixed solution volumes and areas of contact between the solution and the atmosphere. The loss of SDT was monitored spectrophotometrically by changes in the absorption associated with the dithionite ion $S_2O_4^{2-}$ (λ_{max} = 315.5 nm, $\varepsilon = 10^4$ l mol^{-1} cm^{-1}) [5]. The initial SDT concentration c_{red}^0 was varied within the range $(0.5–6) \times 10^{-4}$ M. The rate of surface oxygen uptake, W_S^{red} was calculated using the stationary portions of the kinetic curves of SDT oxidation, $c_{red} = f(\tau)$, with the condition $\Delta c_{red} << c_{red}^0$ satisfied.

The content of dissolved oxygen in solvents was determined using Winkler's iodometric method [6]. The diffusion coefficients of oxygen were found using the recommendations of [7] with account of the data on changes in the solvent viscosity, obtained in this study, from the relation

$$D_{ox} = [7.4 \times 10^{-8}(XM)^{0.5}T]/(V_0^{0.6}\eta), \quad (4)$$

where X is the solvent association parameter (for water, X = 2.6); M = 18, molecular weight of water; T, temperature (K); V_0 = 25.6 cm^3 mol^{-1}, molar volume of the solution at the normal boiling point [8]; and η, solvent viscosity (cP).

Viscometric studies were performed on an installation with an Ostwald capillary viscometer, equipped with systems for ultrathermostating and automated recording of the fluid effluence time, which provided viscosity measurements with an rms error not exceeding 0.1×10^{-5} m^2 s^{-1} for ten parallel runs.

The effect of wetting substances on the chemisorption uptake of atmospheric oxygen was studied for the example of two compounds belonging to the conventionally used assortment of textile-assistant substances (TAS); hydroxyethylated alkyl phenol [OEAP; $C_nH_{2n+1}C_6H_5(OCH_2CH_2)_mOH$, n = 10–13, m = 3] and triethanolamine [TEA; $N(CH_2CH_2OH)_3$ or $N(Et)_3$].

The concentration of the additives in the working solutions was 0.005 M for OEAP and 0.1 M for TEA.

Figure 1 shows how addition of the substances under consideration affects the concentration dependences of the calculated rates of SDT oxidation by the oxygen being absorbed. In accordance with the recommendations of [2], the accelerating effect of the chemical reaction on the rate of oxygen uptake upon an increase in the STD concentration can be described with a high reliability of approximation to experimental data (Fig. 1, *points*) by second-order polynomials (*lines*) for a system containing no surfactant (5) and systems with addition of OEAP (6) and TEA (7):

$$W_S^{red} = (2.1597 + 0.5627c_{red} + 0.0067c_{red}^2) \times 10^{-6}, \quad R^2 = 0.9941; \quad (5)$$

$$W_S^{red} = (2.7194 + 0.3541c_{red} + 0.0548c_{red}^2) \times 10^{-6}, \quad R^2 = 0.9990; \quad (6)$$

$$W_S^{red} = (6.5332 + 0.1683c_{red} + 0.0827c_{red}^2) \times 10^{-6}, \quad R^2 = 0.9965. \quad (7)$$

The first term in Eqs. (5)–(7) determines for each of the liquid-phase systems under study the rate of surface absorption of oxygen by a solution containing no sodium dithionite, W_S^0.

The content of oxygen in aqueous-alkaline solutions with addition of wetting substances was measured with account of the possible spatially nonuniform distribution of these latter. For this purpose, the averaged content of dissolved oxygen was first determined, in accordance with the method described in [1], for

the concentration series of assistant substances being introduced, with slow agitation of a solution being analyzed after its equilibration under aerobic conditions. Then, an analysis for the content of oxygen in the surface layer separated from the rest of the liquid with a separatory funnel was made for solutions with TEA and OEAP concentrations of 0.1 and 0.005 M, respectively. The results obtained are shown in Fig. 2.

The increase in the equilibrium concentration of O_2 in the presence of TAS is presumably due to the more effective solvation of gas molecules via formation of hydrogen bonds between atoms of the nonpolar oxygen molecules and unionized alcoholic hydroxy groups of the compounds being introduced. In particular, the micellar state of surfactants, with the hydrophilic moiety of the molecules and alcoholic hydroxyl groups, accessible to interaction, oriented toward the outer shell of a micelle, is characteristic of OEAP solutions in the chosen concentration range. The more considerable increase in c_{ox} for the TEA additive, compared with OEAP, is due not only to the higher concentration of the former and, accordingly, to a large amount of hydroxyl groups involved in solvation processes. Presumably, the incorporation of TEA molecules into the network of hydrogen bonds between water molecules causes substantial changes in the state of the surface layer of the solution, which is manifested in an increase in the size of tetrahedral structures whose cells can retain an additional number of oxygen molecules without formation of H-bonds.

The virtually linear run of the concentration dependences $c_{ox} = f(c_{TAS})$ makes it possible to regard the experimentally recorded increase in the content of oxygen content in the surface layer of the working solution, $c_{ox(S)}$, by Δc_{ox} as a result of concentration of the assistant preparations. To the $c_{ox(S)}$ in Fig. 2 correspond the following concentrations of assistant substances (M): $c_{TEA(S)} = 0.626$ and $c_{OEAP(S)} = 0.0154$. To a first approximation, these values characterize the spatial redistribution of the assistant substances and their content in the surface layer of the aqueous-alcoholic solution.

The dynamic viscosities $\eta_{(S)}$ were determined for these concentrations of the substances subjected to analysis in systems being homogenized. Their values, listed in the table, reflect the rheological properties of the surface layer of the working solutions containing a specified amount of an additive. The table also summarizes the results of analyses of the influence

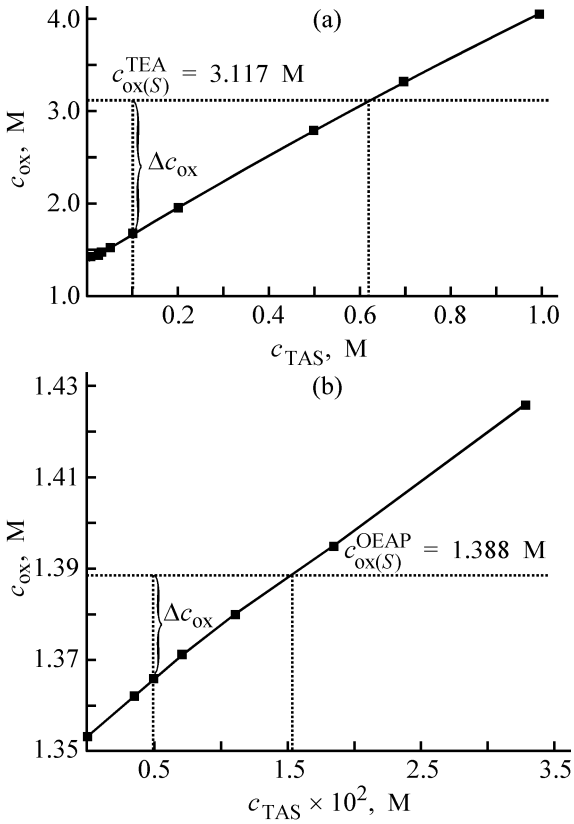

Fig. 2. Oxygen concentration c_{ox} in (a) TEA and (b) OEAP solutions at 293 K and pH 12.5. (c_{TAS}) Additive concentration.

exerted by assistant substances on the parameters of the interphase transfer of oxygen.

Analysis of the kinetic characteristics of the interphase transfer of oxygen into solution shows that the compounds compared intensify to virtually the same extent (by a factor of 1.23–1.31) the mass transfer at the phase boundary, k_L^0. In this case, the rate of surface oxygen uptake becomes more than three times higher owing to the 2.3-fold increase in the equilibrium concentration of oxygen on the surface of a solution with TEA additive, despite the slower inward diffusion. Upon introduction of OEAP into a solution, all stages of the chemisorption process are intensified, including the redistribution of O_2 into the solution bulk via diffusion. The joint effect of these factors provides a 1.26 times faster interphase transfer.

It is highly important in scientific and practical respects to assess the influence exerted by surfactants on the absorption of the oxidizing agent by heated aqueous-alkaline solutions under the real conditions of their application. In view of this circumstance, a set of studies described above was performed in order to determine kinetic parameters of the adsorption-diffusion process at 333 K.

As can be seen from the table, the presence of a wetting agent differently affects the characteristics of the successive stages of the interphase oxygen transfer. The rise in the mass-transfer coefficient at the phase boundary, k_L^0, decreases from 1.23 times at 293 K to 1.11 times at 333 K. At the same time, the temperature-induced decrease in $c_{ox(S)}$ is manifested to a lesser extent in a solution with OEAP additive, and the diffusion coefficient of oxygen, D_{ox} increases in this case more substantially, compared with that without an assistant substance. This manner of variation of the parameters of the adsorption-diffusion process indicates that the intensifying effect of the wetting agent on the rate of oxygen absorption by the solvent is preserved upon a change of the tendency of deviations of the surface layer depth Y^0 to which O_2 molecules penetrate before their complete interaction with sodium dithionite used in the experiment to determine the amount of absorbed oxygen. As applied to the conditions of alkaline treatment of cellulose materials, this means that solutions containing nonionogenic wetting agents based on hydroxyethylated fatty hydrocarbons and their triethanolamine derivatives are more rapidly saturated with oxygen, which makes more probable the oxidative destruction of cellulose.

CONCLUSIONS

(1) The concentration of triethanolamine and a wetting agent based on hydroxyethylated alkyl phenol in the surface layer of the aqueous-alkaline solution was experimentally confirmed. This process provides a steep increase in the solvating power of the liquid toward atmospheric oxygen being adsorbed.

(2) Addition of wetting agents makes lower the surface resistance of the solution and accelerates the mass transfer at the phase boundary by a factor of 1.2–1.3.

(3) Addition of triethanolamine decelerates the inward diffusion of dissolved oxygen, whereas wetting agents based on hydroxyethylated hydrocarbons intensify its diffusion redistribution, with the saturation of the solution with an oxidizing agent additionally accelerated on heating the solution.

(4) The joint effect of these factors intensifies the absorption of the oxidizing agent from the atmosphere 1.3-fold upon introduction of hydroxyethylated alkyl phenol and 3-fold in the presence of triethanolamine.

Abstract—The possibility of synthesis of levulinic acid esters by the reaction of furfuryl alcohol with aliphatic alcohols in the system CCl_4–$Fe(acac)_3$ was studied.

DOI: 10.1134/S1070427207100163

Levulinic, or 4-oxopentanoic, acid has many useful characteristics and has widespresd application [1]. For example, levulinic acid serves as a plant growth regulator and as a modifying additive for resins and Aerosils. Esters and salts of levulinic acid are used in food and pharmaceutical industries as preservatives, stabilizing agents, and odorants.

Levulinic acid is a product of cellulose processing. For example, in acid treatment of a plant material consisting of cellulose and hemicellulose, polysaccharides are first hydrolyzed to form simple sugars and then, under subsequent heating at 110°C for 28 h in the presence of 20% HCl, levulinic acid is formed is 40% yield [1, 2].

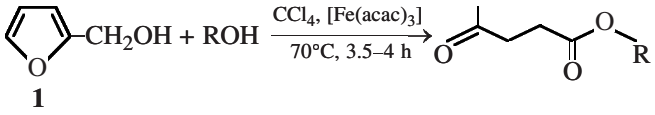
A more convenient procedure for production of levulinic acid is hydration and ring opening of furfuryl alcohol (**1**) in the presence of strong acids. When the reaction is carried out in water, the yield of levulinic acid is 80% [3], and in water-soluble ketones (acetone, 2-butanone), its yield reaches 93% [4].

A modification of this procedure is heating of furfuryl alcohol in the presence of water and HCl acting as a catalyst; in this case, furfuryl alcohol is gradually added to a mixture of concentrated HCl and levulinic acid. The main drawback of this procedure is the necessity for use of a significant amount of levulinic acid (up to 40%) as a solvent [5].

When furfuryl alcohol is involved in the reaction with alcohols under conditions of acid catalyst (concentrated HCl), the direction of its conversion changes to formation of levulinic acid esters. It should be noted that reaction of **1** with alcohols proceeds at a noticeable rate at a large (fourfold) excess of ROH and at slow addition of **1** to boiling alcohol so that its concentration does not exceed 2 vol%; in so doing, the water content should be less than 0.5%. However, even when the above conditions are met, the yields of levulinic acid esters are low, 52 and 67% for methyl and ethyl levulinate, respectively [6].

We found that levulinic acid esters can be synthesized by the reaction of furfuryl alcohol **1** with aliphatic alcohols in the presence of Fe-containing catalysts in CCl_4. Among the iron-containing catalysts [$FeBr_2$, $FeCl_3$, $Fe(OAc)_2$, $Fe(C_7H_{15}CO_2)$, and $Fe(acac)_3$] tested, iron(III) acetylacetonate showed the highest activity: with this catalyst, the yield of levulinic acid esters **2**–**5** was 80–90%. In the presence of other catalysts, the yield of **2**–**5** did not exceed 50%.

For example, the reaction of **1** with methanol occurs at 70°C and continuous stirring within 3.5–4 h with complete conversion of the starting furfuryl alcohol. The yield of methyl levulinate is quantitative (98%). The reaction of furfuryl alcohol with ethanol, propanol, and isopropanol occurs similarly. An attempt to make the yield of *i*-Pr (**4**) and *n*-Pr (**5**) levulinates quantitative by raising the reaction duration to 5 h failed, since a solid oligomeric product (molecular weight determined by the Rast's method 2114 Da) insoluble in water and in most of organic solvents is formed in this case:



1

R = CH_3 (**2**, 98%), R = C_2H_5 (**3**, 95%), R = *i*-C_3H_7 (**4**, 85%), R = *n*-C_3H_7 (**5**, 80%).

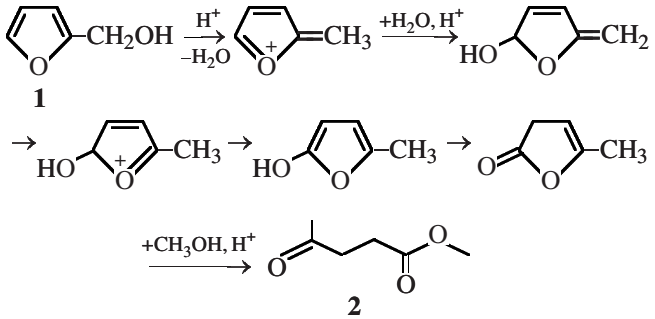
With the aim to identify the actual catalytic species, iron salts or any other compounds, we analyzed the reaction mixture. Titration with NaOH and $AgNO_3$ solutions showed the presence of HCl in the solution in a concentration of 2–2.4 mg ml^{-1} throughout the process. It should be noted that the possibility of HCl formation in the system containing CCl_4, methanol, and iron salts at elevated temperature (140°C) has been found previously [7]. It was shown that generation of HCl from alcohols and CCl_4 under the action of iron compounds follows the scheme

$$RCH_2OH + CCl_4 \xrightarrow{[Fe]} [RCH_2OCl] \rightarrow HCl + RCHO.$$

In the experiments with furfuryl alcohol, carbonyl compounds (formaldehyde from CH_3OH, acetaldehyde from C_2H_5OH, propanal from n-C_3H_7OH, and acetone from *i*-C_3H_7OH) were formed along with HCl.

The presence of HCl in the reaction mixture suggests its possible involvement in the catalysis of formation of **2**–**5**, but in the form of a complex with $Fe(acac)_3$, rather than as free HCl, which causes the higher yield of esters **2**–**5** compared with unbound HCl.

Considering the possible involvement of HCl in the catalysis and taking into account published data [1, 8, 9], we can suggest the following mechanism of formation of esters **2**–**5**:

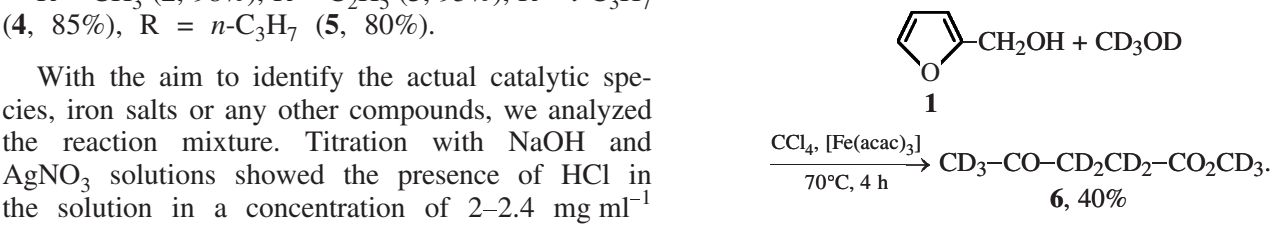


1

2

As further studies showed, the above reaction is also catalyzed by rhodium complexes and, in particular, by $Rh(PPh_3)_3Cl$: in its presence, the process duration decreases to 2–3 h.

The reaction of furfuryl alcohol with deuterated methanol (70°C, 4 h) yielded fully deuterated methyl levulinate, which is not unexpected considering the clearly pronounced capacity of levulinic acid for deuterium exchange in treatment with D_2O [2]:



1

6, 40%

The following optimal ratios of the catalyst and reactants were found experimentally: $[Fe(acac)_3]$: [furfuryl alcohol] : [ROH] : $[CCl_4]$ = 1 : 100 : 400 : 200.

To direct the reaction toward formation of levulinic acid, we performed experiments with water instead of methanol. With iron compounds as catalysts, no noticeable conversion was observed, whereas in the presence of the catalyst $Rh(PPh_3)_3Cl$, furfuryl alcohol reacts with H_2O and CCl_4 to form 2,2'-difurylmethane **7** (yield 80%) and minor amount of difurfuryl ether **8**:
