$$\Delta G^0_{298} = -50.2 \text{ kJ mol}^{-1}; \quad (29)$$

$$[Cu_2S + 2Cu + 7/2O_2 + 3H_2O = CuSO_4 \cdot 3Cu(OH)_2]/21,$$
$$\Delta G^0_{298} = -48.6 \text{ kJ mol}^{-1}. \quad (30)$$

Comparing the changes in the standard Gibbs energies of reactions (24), (29), and (30), we can conclude that the sulfide patination of bronze sculptures favors formation of green patina on the metal surface. Sodium chloride and carbon dioxide contained in atmospheric precipitations can slightly change the composition of the film [reactions (25) and (26)], but presumably do not noticeably affect its protecting properties.

CONCLUSION

Sulfide patination of bronze sculptures favors formation of green patina on the metal surface. Sodium chloride and carbon dioxide contained in atmospheric precipitations can slightly change the composition of the film, but presumably do not noticeably affect its protecting properties.

Abstract—A polythermal study of the solubility of C_{60} and a fullerene mixture (60% C_{60} + 39% C_{70} + 1% C_{76}–C_{90}) in pelargonic and caprylic acids was carried out at 20–80°C. The solubility polytherms are given and discussed.

DOI: 10.1134/S1070427207040076

In this study, we examined the solubility polytherms of individual fullerenes and a fullerene mixture (60% C_{60} + 39% C_{70} + 1% C_{76}–C_{90}) in a series of *n*-alkanoic acids.

Studies of the solubility of fullerenes are of primary importance for developing methods for extraction separation of fullerenes from a fullerene-containing carbon black and for their purification prior to chromatographic isolation [1].

The topicality of this problem is evidenced by the fact that the solubility of C_{60} has been determined in more than 150 solvents, and that of C_{70}, in 20 solvents [2], including those belonging to various classes of organic and inorganic solvents (aromatic solvents, alkanes, cyclohexanes, alkyl halides, and alcohols). Furthermore, much attention has been given to correlations between the solubility and various molecular characteristics of solvents [3–6]. In particular, some of the authors attempted to find correlations between the mole fraction of C_{60} in a saturated solution with such solvent characteristics as the refractive index, molar volume, permittivity, and Hildebrand solubility factor. It appeared that none of the solvent parameters alone can serve as a universal factor controlling the solubility. Nevertheless, it was demonstrated that a set of empirical parameters allows a quite reliable prediction of the solubility. Thus, high solubility of fullerenes should be observed in solvents with high refractive index, dielectric constant of about 4, large molecular volume, Hildebrand solubility factor of about 20 $(J\ cm^{-3})^{1/2}$, and an intermediate nucleophilicity.

It should be pointed out that published data can only be used to describe binary systems, e.g., fullerene (C_{60} or C_{70})–solvent, being rather unsuitable for development of methods for extraction separation of fullerene mixtures because of the strong mutual solubility effects, such as salting-in and salting-out [7].

It is worth noting that there is very limited information in the literature on the mutual solubility of two different fullerenes in one solvent or of an individual fullerene in a mixed solvent. The polythermal dependences of the solubility in the ternary systems like C_{60}–C_{70}–solvent are lacking at all, despite that these data may be significant for optimization of the extraction separation of fullerene mixtures. The only exceptions are the papers [7, 8] dealing with the solid–liquid phase equilibria in ternary systems C_{60}–C_{70}–toluene and C_{60}–C_{70}–*o*-xylene at 25 and 80°C.

No systematic study has been made of the solubility of fullerenes in a series of *n*-alkanoic acids. Individual carboxylic acids and commercial mixtures of higher isomeric carboxylic acids (HICA) show promise because virtually any solution of the fullerene mixture in the indicated solvents is enriched in C_{70}, which considerably increases the efficiency of prechromatographic separation methods based on the solid–liquid, and probably, liquid–liquid phase

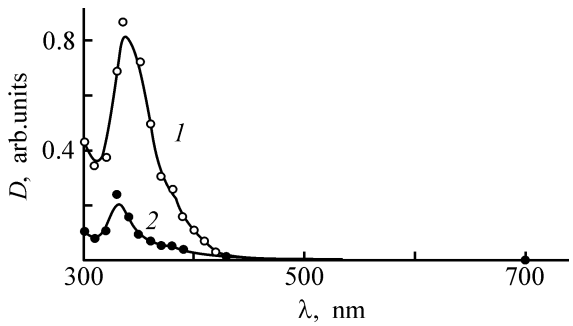

Fig. 1. Electronic absorption spectra of solutions of C_{60} in (*1*) pelargonic acid (c = 177.9 mg l^{-1}) and (*2*) caprylic acid (c = 58.3 mg l^{-1}). Carboxylic acid : *o*-xylene = 1 : 22 (by volume). (*D*) Optical density and (λ) wavelength; the same for Fig. 3.

equilibria. The higher solubility of C_{70} is associated with its higher polarizability (8×10^{-23} cm^3) as compared to C_{60} (6.4×10^{-23} cm^3) [9], which, in turn, is due to the less symmetrical structure of C_{70} (ellipsoid of revolution against a spheroid).

It was demonstrated in the preliminary experiments at 25°C that the most efficient extractants for C_{70} and C_{60} are caprylic and pelargonic acids, respectively. That is why we examined in this study the solubility polytherms of fullerenes just in these solvents.

EXPERIMENTAL

In the experiments we used fullerene C_{60} of 99.9% purity containing about 0.1% C_{70}, a fullerene mixture 60% C_{60} + 39% C_{70} + 1% C_{76}–C_{90} from ILIP Private Company (St. Petersburg), *o*-xylene (analytically pure grade), and pelargonic and caprylic acids (chemically pure grade).

The solubility of individual fullerene C_{60} and fullerene mixture, as influenced by the temperature, was studied by the isothermal saturation method. First, solutions of C_{60} and a fullerene mixture in pelargonic and caprylic acids were prepared (in all cases, fullerenes were taken in a considerable excess: 50 mg of fullerene per 10 ml of solvent). Then the solutions were equilibrated for 8–10 h at each temperature (maintained to within 0.05°C) in a temperature-controlled shaker in the range 20–80°C. Such a long time of the experiments is required for equilibrium to be attained in the systems carboxylic acid–fullerene. Finally, the liquid phase was separated by filtration through a Schott filter no. 16 and analyzed.

Fullerenes C_{60} and C_{70} in the liquid phase saturated at each temperature were determined spectrophotometrically on a Specord-32 instrument at wavelengths of 335.5 and 472.0 nm. The equilibrated solutions taken for analysis were diluted with *o*-xylene. In all determinations, we used as the reference a solution of the respective carboxylic acid in *o*-xylene at the same dilution as in the sample. Such a procedure of analysis is dictated by problems in recovery of fullerenes from high-boiling liquid phases (up to 260°C at 1 atm).

The fullerene concentrations were estimated using empirical relashionships derived for fullerene mixtures [10]:

$$c(C_{60}) = 13.10(D_{335} - 1.808D_{472}), \quad (1)$$

$$c(C_{70}) = 42.51(D_{472} - 0.0081D_{335}), \quad (2)$$

where D_{335} and D_{472} are the optical densities of solutions related to unit path (1 cm); and $c(C_{60})$ and $c(C_{70})$, concentrations of the respective fullerenes (mg l^{-1}).

Here and hereinafter the contribution of higher fullerenes C_n ($n > 70$) is neglected.

The solvent content of crystal solvates was determined as follows. The solid phase just precipitated from a carboxylic acid solution was washed twice with ethanol, dried at 20°C for 30 min, and weighed. Then the resulting solid was refluxed with ethanol in a Soxhlet's apparatus (78°C, 1 atm), vacuum-dried at 200°C (0.1 mm Hg) for 1 h, and weighed again. The solvent content of the initial crystal solvate (or solid solution of fullerenes on its basis) was determined as the weight loss.

Figure 1 shows electronic absorption spectra of the fullerenes and a fullerene mixture in pelargonic acid. Similar spectra were obtained in caprylic acid. It should be pointed out that the spectra in caprylic and pelargonic acids demonstrate no solvatochromic effects, i.e., no strong change in the spectrum induced by insignificant change in the solution concentration or solvent composition, as it was observed in binary solvents, such as acetonitrile–toluene, benzene–methanol, etc. [11–16]. Therefore, there is a full analogy between the spectra we recorded and the corresponding spectra in a series of one-component aromatic solvents (*o*-xylene, benzene, toluene, and *o*-dichlorobenzene), so that the use of empirical relationships (1) and (2) is quite reasonable in our case.

* Equilibrium solid phase at temperatures below 50°C represents C_{60} monosolvate or solid solutions based on monosolvates of light fullerenes C_{60} and C_{70}, and above 50°C, unsolvated C_{60} or solid solutions based on unsolvated light fullerenes C_{60} and C_{70}.

acids. The table lists polythermal data on the solubility of individual C_{60} and of C_{60} and C_{70} from the fullerene mixture in these acids.

The temperature dependences of the solubility of individual fullerene C_{60} and of C_{60} from the fullerene mixture are nonmonotonic in both acids (Figs. 2a, 2b; 3a, 3b), as well as the temperature dependence of the solubility of C_{70} from the fullerene mixture in caprylic acid (Fig. 2c). This kind of temperature dependences is frequently observed in binary water–salt systems, such as $NaF–H_2O$, $CaF_2–H_2O$, $NH_4HF_2–H_2O$, $ZrOCl_2–H_2O$, $MgSO_3–H_2O$, and $CuSO_4–H_2O$ [17].

An analysis of published data revealed that, in the cases of fullerenes C_{60} and C_{70}, such a dependence has been only found in few systems, such as C_{60}–toluene, C_{60}–benzene, $C_{60}–CS_2$, C_{60}–1,2-dimethylbenzene, C_{60}–1,2-dichlorobenzene, C_{60}–tetralin, C_{60}–1,2-diphenylacetone, C_{70}–1,2-dichlorobenzene, C_{70}–tetralin, and C_{70}–1,2-diphenylacetone [2, 16, 17]. Korobov [16, 17] has suggested a thermodynamic model describing this kind of the solubility polytherms. Thermodynamic analysis by Smith et al. [18] revealed that this shape of the solubility diagrams is caused by an unusual relationship between the enthalpy of formation of the crystal solvate and that of the saturated liquid solution.

Our analysis shows that, in all cases when the solubility polytherms demonstrate nonmonotonic temperature dependence for the branch characterized by $(dc/dT)_p > 0$, the fullerene saturated solution is in equilibrium with solid monosolvates of a definite composition $C_{60}–C_nH_{2n-1}COOH$ (in the systems C_{60}–caprylic acid and C_{60}–pelargonic acid) (Figs. 2a, 3a), and also with monosolvates of solid solutions $(C_{60})_x(C_{70})_{1-x} \cdot C_{2n-1}COOH$ (Figs. 2b, 2c, and 3b). At the nonvariant point of the extremum in the solubility diagram (Figs. 2 and 3, points O), incongruent melting of the solid crystal solvate (monosolvate in our case) occurs to give unsolvated individual fullerene C_{60} or unsolvated solid solution (in the case of the fullerene mixture).

Data on the temperature dependence of the C_{60} content of the liquid phase, obtained in dissolution of the fullerene mixture (Figs. 2d and 3d), show that, in the case of pelargonic acid, the maximal enrichment in C_{60} is attained at 20°C (compared to the initial solid phase, the C_{60} content in the solution is higher by 15%). By contrast, in the case of caprylic acid, the liquid phase is enriched in C_{70}, and the maximal fullerene concentration is attained at 50°C (20% enrichment of the liquid phase relative to the initial mixture). It is worth noting that the difference between the fullerene contents of the initial mixture and solution can be used as a basis for development of a method for more or less complete prechromatographic separation of fullerenes.

CONCLUSIONS

(1) Fullerene C_{60} and fullerene mixture (60% C_{60} + 39% C_{70} + 1% C_{76-C90}) are fairly readily soluble in pelargonic and caprylic acids at 20–80°C. The solubility ranges from 50 to 1000 mg l^{-1}.

(2) The solubility polytherms of C_{60} and fullerene mixture in both acids consist of two crystallization branches: a low-temperature branch (C_{60} monosolvates or solid solutions based on fullerene monosolvates) and a high-temperature branch (unsolvated C_{60} or solid solutions based on unsolvated fullerenes).

SORPTION AND ION-EXCHANGE PROCESSES

Specific Features of Sorption of Chromium(VI) Anions by VION Fibrous Chemisorbents

Abstract—Certain fundamental aspects of the process of sorption of chromium(VI) ions from aqueous solutions at pH 6 and 2 by VION fibrous anion-exchangers with varied basicity were revealed.

DOI: 10.1134/S1070427207040088

Sorption of metal anions with variable oxidation state from an aqueous medium by polymeric chemisorbents is accompanied in some cases by redox reacions between ions being recovered from solution and chemically active groups of the sorbent [1, 2]. A study of the role played by the chemical nature of functional groups of an ion exchanger and of the influence exerted by sorption conditions on the recovery of metal anions from solutions, complicated by the occurrence of redox reactions, is of not only theoretical, but also practical interest.

This study makes an attempt to solve this problem, with VION fibrous anion exchangers with varied basicity serving as the sorption material and chromate and dichromate ions as sorbates.

The materials under study contained pyridinium (AN-1, AS-1) and aliphatic (AN-5, AS-2) amino groups. AS-1 fiber was obtained by alkylation with epichlorohydrin of AN-1 fiber, which is alkylated by only 50% because of a steric hindrance. Therefore, AS-1 fiber contains tertiary pyridinium nitrogen in addition to the quaternary pyridinium nitrogen. The fibrous anion-exchangers used are characterized in Table 1, in which the dissociation constants pK_a are taken from the literature [3].

The static exchange capacity (SEC) was determined using a 0.1 N HCl solution for weakly basic anion exchangers (AN-1, AN-5) and a 0.1 N NaCl solution for strongly basic sorbents (AS-1, AS-2), with the experimental error not exceeding 5%. The sorption

Table 1. Parameters of VION fibrous chemisorbents

VION fiber	Chemically active group	pK_a	SEC, mmol g^{-1}	VION fiber	Chemically active group	pK_a	SEC, mmol g^{-1}
AN-1		9–10	2.5	AN-5		6–9	2.5
AS-1		1–2	1.0	AS-2		1–2	1.0

properties of the fibers to saturation were studied under static conditions at a pH value of the medium equal to 2 and 6. HNO_3 was used to acidify the solutions. The hydrogen index was measured with an EV-74 universal ion-meter, the pH value was maintained constant in the course of the experiments to within the device error (≤0.05 pH units). A 0.1-g portion of a fiber was placed in a conical vessel containing 1 dm^3 of an aqueous solution of $K_2Cr_2O_7$ (K_2CrO_4). The initial concentration of Cr(VI) in the form of $Cr_2O_7^{-2}$ or CrO_4^{-2} anions in solution was 0.15 g dm^{-3}. A fiber sample was kept in the solution agitated at regular intervals of time at a temperature of 18–20°C until sorption equilibrium was attained, which was judged from a constant value reached by the amount of sorption in the course of time.

The amount of sorption was calculated from the difference of the Cr(VI) concentrations in the initial solution and that after the study. The content of Cr(VI) in the solution before and after the sorption was monitored photometrically [4], using the reaction with diphenylcarbazide, specific to chromium(VI). The determination was made as follows: 10 cm^3 of a solution of a chromium(VI)-containing salt was diluted with distilled water in a 100-cm^3 volumetric flask, the mixture was agitated, and then three 20-cm^3 samples were taken. One of the samples was neutralized with a 0.1 N NaOH solution, with phenolphthalein as indicator, until a pale pink coloration appeared. To another sample, the same volume of NaOH was added without indicator, 0.5 cm^3 of H_2SO_4 and 0.4 cm^3 of diphenylcarbazide were poured in, and the optical density D of the solution was determined in 10–15 min, in comparison with the third portion of the same water, to which all the reagents except diphenylcarbazide were added. Cuvettes with a layer thickness of 50 mm (wavelength 540 nm) were used in the FEK-56 photoelectrocolorimeter. The measurements were repeated three times and the content of chromium(VI) was found using the average value of D from the calibration plot.

Electronic paramagnetic resonance (EPR) spectra were recorded on a Rubin spectrometer (working frequency ~10 GHz, modulation frequency ~100 kHz). A single crystal of synthetic ruby was used as the side standard; calibration samples of diphenyl picryl hydrazyl (DPPH) and Mn(II) in a solid solution in MgO served as the central standard. The content of paramagnetic Cr(VI) and Cr(III) ions was calculated from EPR spectra by the commonly accepted method [5, 6]. The number of spins in a sample being measured was calculated using the basic formula

$$N = N_{ref} S/S_{ref} h_{ref.st}/h_{st}.$$

Table 2. Sorption of Cr(VI) by fibrous sorbents

Sorbent	Sorption, mmol g^{-1}, at indicated pH	
	6	2
AN-1	0	2.2
AN-5	0.7	3.2
AS-1	1.8	3.2
AS-2	1.2	1.2

Here, N_{ref} is the number of spins in the central standard; S, number under the absorption curve of a sample; S_{ref}, area under the absorption curve of the central standard; $h_{ref.st}$ and h_{st}, amplitudes of the side standard in recording the central standard and a sample under study, respectively.

The $h_{ref.st}/h_{st}$ ratio makes it possible to take into account changes in the spectrometer sensitivity because of changes in the Q-factor of the resonator. To diminish the systematic error, the geometric dimensions of a sample are minimized: the diameter of the ampule for samples is about 2 mm with a filling of about 7 mm. The error in determining the absolute number of spins may be as large as 30–50%. However, this error remains constant if the same measurement mode is used. In the case of an invariable position of a sample in the resonator the scatter in multiple measurements with a set of samples of the same type does not exceed 2%.

IR spectra of the fibers under study before and after the sorption were measured with a Hitachi spectrometer. Samples were prepared in the form of pellets by compaction with KBr preliminarily dried in a desiccator with zero humidity for 48 h. The samples were ground in a ball mill.

The content of fibers in a sample was 1 wt %. The pellets with KBr were formed in a standard annular mold at a compaction pressure of 40 MPa.

Table 2 lists data on catching of Cr(VI) by strongly basic sorbents at pH 6, which markedly exceeds that by weakly basic sorbents. The insignificant amount of Cr(VI) sorption by AN-5 fiber is due to the higher basicity of the aliphatic amine, compared with the pyridinium amine (Table 1).

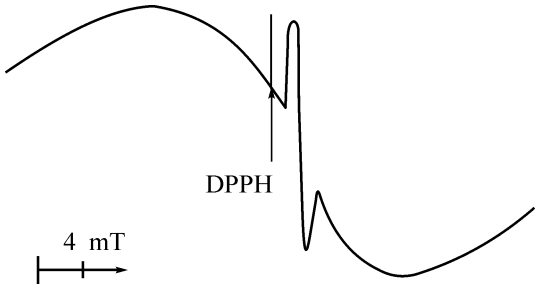
As can be seen from Table 2, the absorption of chromate and dichromate ions by AN-1, AN-5, and

Table 3. Content of paramagnetic ions Cr(V) and Cr(III) in fibrous sorbents after Cr(VI) sorption

Sorbent	pH 6				pH 2			
	Cr(V)		Cr(III)		Cr(V)		Cr(III)	
	$c \times 10^{-18}$, spins g^{-1}	$c \times 10^{2}$, mmol g^{-1}	$c \times 10^{-20}$, spins g^{-1}	c, mmol g^{-1}	$c \times 10^{-18}$, spins g^{-1}	$c \times 10^{-18}$, mmol g^{-1}	$c \times 10^{2}$, spins g^{-1}	$c \times 10^{-20}$, mmol g^{-1}
AN-1	0.0	0.0	0.0	0.0	0.3	0.2	0.8	0.1
AN-5	13.0	2.2	0.0	0.0	5.3	0.9	4.3	0.7
AS-1	14.0	2.3	1.8	0.3	3.4	0.6	8.3	1.4
AS-2	2.7	0.4	3.3	0.6	2.3	0.4	2.6	0.4

AS-1 fibrous sorbents increases at pH 2, which is due to protonation of low-basic pyridinium amines AN-1 and AS-1 and aliphatic amine AN-5. The protonation of the functional groups of the sorbents leads to addition of chromium(VI) anions to these groups to give the salt form, which is confirmed by IR spectral data. For example, absorption bands associated with vibrations of the pyridinium ring (747, 1500, and 1600 cm^{-1}) are characteristic of AN-1 fiber. After the sorption of chromate ions at pH 2, the band of stretching vibrations of the weakly basic group at 1500 cm^{-1} disappears and there appear bands at 774 and 942 cm^{-1}, related to deformation vibrations of chromate ions. Also observed are weak bands at 1350 and 1400 cm^{-1}, associated with the NO_3^- group.

Similar changes in IR spectra were observed for AN-5 and AS-1 fibers after Cr(VI) sorption at pH 2. It should be noted that AN-1 and AN-5 anion exchangers have the same SEC; however, AN-5 fiber sorbs a considerably larger amount of Cr(VI), which is due, as already noted, to the stronger basicity of the aliphatic amine, compared with the pyridinium amine. Probably, the degree of protonation of the active groups of AN-1 at pH 2 does not reach the necessary value.



EPR spectrum of AS-1 sorbent at pH 2 after sorption of Cr(VI) to the maximum value.

As expected, AS-2 sorbent containing only the strongly basic quaternary nitrogen sorbs the same amount of Cr(VI) ions, irrespective of the solution pH.

No EPR spectra of all the fibers studied can recorded before Cr(VI) sorption from $K_2Cr_2O_7$ (K_2CrO_4) solutions. After Cr(VI) sorption, a superposition of EPR spectra is recorded with the sorbents (see figure).

The superposition comprises two EPR signals, a narrow ($\Delta H \approx 0.002$ T) and broad ($\Delta H \approx 0.05$ T). The intensity ratio of these signals depends on the nature of a sorbent and sorption conditions, but the intensity of the narrow signal is always high. The g-factors of the narrow and broad signal are virtually the same and equal to ~1.97. Analysis of the EPR spectra and published data [1] suggests that the narrow signal is associated with Cr(V) paramagnetic ions, and the broad signal, with Cr(III) ions. Consequently, the EPR method shows that redox reactions occur in the chemisorbents under study, which result in that Cr(VI) is reduced to Cr(V) and Cr(III).

Table 3 presents the content of paramagnetic ions in fibrous solvents after absorption of Cr(VI) at pH 6 and 2.

It follows from the data of Table 3 that, irrespective of the solution pH, the strongly basic chemisorbents AS-2 has in its structure virtually equal amounts of reduced ions of penta- and triple-charged chromium and sorbs equal amounts of Cr(VI) (Table 2). Analysis of the data in Tables 2 and 3 for the other sorbents suggests that the capacity for reduction of Cr(VI) depends on the degree of its catching by the sorbents. This is also confirmed by the data on the content of penta- and triple-charged chromium in

relation to the amount of Cr(VI) sorbed at pH 2 for AS-1 VION fiber (Table 4).

Indeed, the larger the amount of Cr(VI) caught by the sorbent, the higher the degree of its reduction, i.e., the amount of Cr(III) increases and the content of Cr(V) decreases.

As shown above, the sorption of Cr(VI) by the chemisorbents under study depends on the pH of the medium and on their basicity, and, therefore, the degree of Cr(VI) reduction to Cr(V) and Cr(III) is related to these factors (Table 3). At the same time, it is necessary to take into account the stability of the chemical groups of the sorbents against oxidation because of the occurrence of redox reactions. Probably, the higher the stability of a sorbent against oxidation, the smaller the amount of the reduced forms of chromium, Cr(V) and Cr(III), formed in sorption. The low content of paramagnetic ions Cr(V) and Cr(III) in AN-1 fiber after sorption of Cr(VI) at pH 2 is to a certain extent due to this circumstance.

Analysis of published data [1, 2] suggests that reduced chromium ions form complex compounds with the functional groups of the sorbents.

CONCLUSIONS

(1) It was shown that the sorption of chromate and dichromate ions by VION anion-exchange fibrous sorbents is determined by their basicity and the pH of the medium.

(2) It was found that, in contrast to strongly basic sorbents, weakly basic sorbents catch chromium(VI) ions when being protonated.

Table 4. Content of paramagnetic ions Cr(V) and Cr(III) in AS-1 VION fiber

Cr(VI) sorption, mmol g^{-1}	Cr(V)		Cr(III)	
	$c \times 10^{-18}$, spins g^{-1}	$c \times 10^{2}$, mmol g^{-1}	$c \times 10^{-20}$, spins g^{-1}	c, mmol g^{-1}
0.5	13.0	2.2	0.5	0.08
1.0	8.7	1.4	1.5	0.25
3.2	3.7	0.6	8.3	1.38

(3) The EPR method demonstrated that sorption of Cr(VI) anions on fibrous anion exchangers is accompanied by partial reduction of chromium(VI) to Cr(III) and Cr(V), whose content is determined by the amount of sorption.

Abstract—The possibility of obtaining smooth homogeneous copper coatings with good adhesion and homogeneous copper coatings with poor adhesion by electrochemical deposition of copper on steel from a solution of nontoxic copper(II) complex with the ligands, 1,3-propylenediamine-*N*,*N*'-*diacetato-N*,*N*'-di-3-propionic acid, was analyzed. For both types of coatings, the optimum composition of the solution and the optimum deposition conditions were determined.

DOI: 10.1134/S107042720704009X

The quality of copper coatings on steel depends on the temperature and composition of the solution, electric current density of deposition, and difference between the equilibrium potential of the copper electrode, E_1, and the steady-state potential of steel electrode, E_2 [1, 2]. At a potential difference $E_1 - E_2 > 0.5$ V, fast cementation occurs. This process yields spongy coatings with poor adhesion and cohesion. In acid solutions of copper(II) sulfate, $E_1 - E_2$ is about 0.8 V, and the quality of copper coatings on steel is, therefore, poor. Smooth homogeneous copper coatings with good adhesion cannot be formed on steel and iron from a solution of copper(II) salts because of the fast cementation [1, 2]. A potential difference of 0.2 to 0.4 V is attained at a certain composition of the solution. At this potential difference the cementation is slow. In this case, smooth homogeneous coatings with weak adhesion, free from inner stresses, can be obtained on steel. These coatings are easily detached from steel, even if the steel was not passivated before coating deposition. Electrochemically produced copper foil free from inner stresses can be used in electrochemical industry for manufacture of printedcircuit boards. In copper foil formed by metal rolling, the inner stresses are considerable. At $E_1 - E_2 < 0.1$ V virtually no cementation occurs. Smooth homogeneous coatings with good adhesion can be electrochemically obtained on steel at an appropriate current density.

Copper coatings are commonly deposited on steel in a cyanide bath. The open-circuit potential of iron in a cyanide solution is more positive than the equilibrium potential of the copper(I) cyanide complex [2]. Therefore, copper can be deposited on steel when no cementation occurs. High-quality copper coatings on steel are deposited in cyanide baths [1].

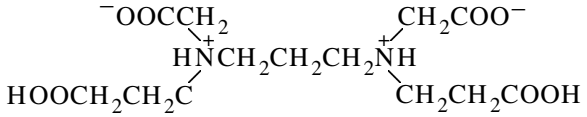
Meanwhile, work with cyanide solutions involves a number of difficultes, primarily because cyanide complexes decompose in an acid medium to give toxic gaseous hydrogen cyanide. Therefore, it is necessary to replace copper(I) cyanide electroplating solutions with solutions of less toxic copper complexes [3].

It has been shown previously [4–8] that EDTA anions affect the electrochemical action of some metals, because they hinder reduction of the surface layer of oxygen compounds or provide dissolution of the surface oxide film being formed. Moreover, these species are involved in anodic dissolution of some metals and in cathodic evolution of hydrogen [4–8].

The goal of this study was to obtain quality copper coating on steel from a solution of diacido-1,3-propylenediamine-*N*,*N*'-diacetato-*N*,*N*'-dipropionate cuprate(II) (CuH_2L), with subsequent deposition of metallic nickel or chromium onto this coating, and to develop a formulation for deposition from this so-

lution of smooth homogeneous coating that are free from inner stresses and can easily detached from steel.

In aqueous solutions, H_4L exists in the ionic form [4]:



The ligand, 1,3-propylenediamide-*N*,*N*'-diacetate-*N*,*N*'-di-3-propionic acid (H_4L), forms with Cu(II) ions complexes of varied composition, depending on pH [9]. With allowance made for the various orientations of carboxylic groups in the Cu(II) complexes, geometric isomers of copper(II) compounds with the ligands under study may be also formed [9, 10].

EXPERIMENTAL

We measured the steady-state potential of the steel electrode and the equilibrium potential of the copper electrode in solutions with varied pH value and different Cu(II) to H_4L ratios. The polarization curves were obtained by the stationary potentiostatic method. We used in the study the standard electrochemical cell of an RDE potentiostat (Pine Instrument Co) and a 7035 BX-Y recording device (Hewlett Packard). A 2 × 2-cm steel (or copper) plate served as the working electrode, and a copper plate, as the counter electrode. A saturated calomel electrode was used as the reference.

The solutions were prepared from triple-distilled water and chemical substances purchased from Merck and used without additional purification.

The pH value of the electrolyte was adjusted in the range from 2.0 to 12.0 with a 2.0 mol dm^{-3} NaOH solution and 25% NH_4OH. The steel electrodes used to study the spontaneous deposition of copper were kept in the solutions for 20 h.

Coatings with a thickness of 1.0, 3.0, 5.0, or 10.0 μm were deposited, depending on the current density. All the experiments were performed at 295 K. The porosity of the coatings was determined by the standard technique [11], and their adhesion, by the cracking method [12].

The equilibrium potential of the copper electrode and the steady-state potential of the steel electrode in solutions of copper(II) complexes with H_4L are complex functions of the pH value (Fig. 1). In strongly acid solutions (2.0 < pH < 3.0) exist $[CuH_2L]$ complexes with $[CuHL]^-$ [9, 10]. At pH in the range from 3.0 to 6.0, the solution predominantly contains $[CuHL]^-$

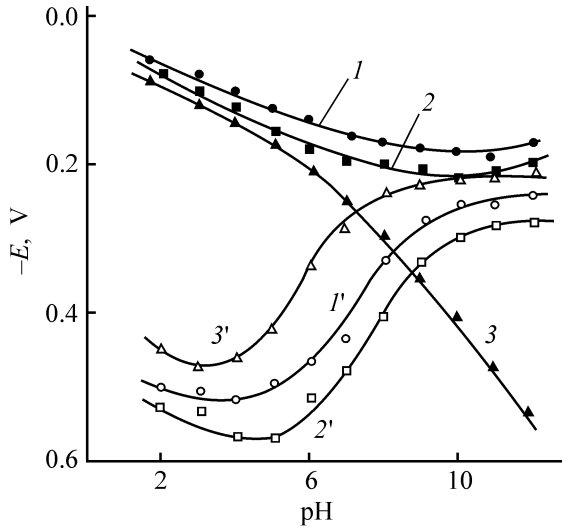


Fig. 1. (*1*–*3*) Equilibrium potential *E* of copper electrode and (*1'*–*3'*) open-circuit potential of steel electrode relative to a saturated calomel electrode vs the pH value and solution composition. Potentials are determined 10 min after submerging the electrodes in a solution. Solution composition (M): (*1*, *1'*) $CuSO_4$ 0.016, H_4L 0.016, Na_2SO_4 0.15, NaOH *x*, (*2*, *2'*) $CuSO_4$ 0.33, H_4L 0.33, Na_2SO_4 0.15, NaOH *x*, and (*3*, *3'*) $CuSO_4$ 0.1, H_4L 0.1, Na_2SO_4 0.15, NH_4Cl 0.1, NH_4OH *x*.

and $[CuL]^{2-}$ ions. The formation of the $[CuL]^{2-}$ complex starts at pH 3.0 and is virtually complete at pH 6.0. At pH 6.0–10.0, only the $[CuL]^{2-}$ complex is formed. At pH higher than 10.0, the complex is hydrolyzed by the reaction [9, 10]:

$$[CuL]^{2-} + H_2O \rightleftarrows [Cu(OH)L]^{3-} + H^+. \quad (1)$$

The hydrolysis reaction (1) is a result of the competition between OH^- ions and carboxy groups for the coordination site. The overall stability constant of a complex depends on its nature [9, 10]. The values of these constants show that the equilibrium concentrations of uncomplexed Cu^{2+} ions decrease as the solution pH becomes higher. This behavior is also confirmed by the run of curves *1* and *2* in Fig. 1. The potential of the copper electrode in a NH_4OH-containing solution is more negative (curve *3*). This is a consequence of the competition between NH_3 and carboxy groups for the coordination site. The open-circuit potential of the steel electrode also depends on pH (Fig. 1) [2, 13] and decreases in the course of time (Fig. 2). Copper is deposited in solutions with lower pH. Immediately after the steel electrodes are placed in solutions containing (mol dm^{-3}): $CuSO_4$ 0.1, H_4L 0.1, NH_4Cl 0.1, Na_2SO_4 0.4, NH_4OH *x* (a); $CuSO_4$ 0.2, NH_4L 0.2, NH_4Cl 0.2, Na_2SO_4 0.8, NH_4OH *x* (b); $CuSO_4$ 0.8, NH_4L 0.3, NH_4Cl 0.3, Na_2SO_4 1.2,

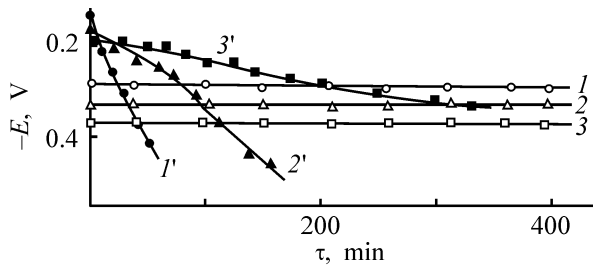

Fig. 2. (*1–3*) Equilibrium potential E of copper electrode and (*1′–3′*) open-circuit potential of steel electrode relative to a saturated calomel electrode in the solution vs. time τ. Fig. 4. Polarization curve of copper deposition. (E) Equilibrium potential and (j) current density; the same for Fig. 5. Solution composition (M): (*1*) $CuSO_4$ 0.04, H_4L 0.04, NH_4Cl 0.04, Na_2SO_4 0.1, NH_4OH x, (*2*) $CuSO_4$ 0.1, H_4L 0.1, NH_4Cl 0.1, Na_2SO_4 0.4, NH_4OH x, (*3*) $CuSO_4$ 0.3, H_4L 0.3, NH_4Cl 0.3, Na_2SO_4 1.2, NH_4OH x, (*4*) $CuSO_4$ 0.4, H_4L 0.4, NH_4Cl 0.4, Na_2SO_4 1.6, NH_4OH x, pH = 9.5, t = 295 K.

NH_4OH x (c); $CuSO_4$ 0.4, NH_4L 0.4, NH_4Cl 0.4, Na_2SO_4 1.6, and NH_4OH x (d), the open-circuit potential is more positive than the potential of the copper electrode (Figs. 2, 3). After a certain time, the open-circuit potentials of the steel electrode become equal to the potential of the copper electrode. When the potential of the steel electrode becomes more negative that that of the copper electrode, spontaneous deposition of copper on steel may occur. The time necessary for the equilibration of the potentials is independent of the concentration of $CuSO_4$ and H_4L, but depends on the solution pH. In 23 min, the open-circuit potential of the steel electrode in solutions (a)–(d) (pH 8.5) becomes equal to the equilibrium potential of the copper electrode (Fig. 2). Only after 2.5 h, a thin transparent copper coating is spontaneously deposited on steel.

At pH 9.0 the potentials become equal after 100 min of contact. A thin copper coating appears on steel in 4.2 h. At pH 9.5 the potentials do not equalize even in 400 min, and no copper coating appears on steel after 18 h of contact. Solutions with pH > 10.0 are unstable and no reliable experimental results can be obtained in this case. At pH < 6.0, spontaneous deposition of spongy copper coatings with poor adhesion to the steel starts immediately.

The optimal pH range for deposition of homogeneous smooth coatings strongly adhering to the steel support is 9.0 < pH < 9.8.

Figure 3 shows the equilibrium potential of the copper electrode (a) and the open-circuit potential of the steel electrode (b) as functions of the $CuSO_4$ and H_4L concentrations and the solution pH. The potentials were recorded 30 s after the electrode was submerged in a solution. The potentials of the copper and steel electrodes decrease as the solution pH increases from 8.5 to 9.5. In the process, the ammonia concentration and, consequently, the concentration of the complexes become higher.

The optimum current density for deposition of smooth homogeneous coatings with good adhesion lies at the beginning of the mixed region of the potentials. In this region, the control over the reaction passes from the charge transfer to diffusion [13–16].

Figure 4 shows polarization curves of copper deposition from solutions of various compositions (arrows indicate current densities corresponding to deposition of 1.0-, 3.0-, 5.0-, and 10.0-μm-thick coatings). The best-quality coatings were obtained at j_{opt} (Fig. 4). At current densities lower than the optimum value, the porosity and roughness of the coatings in-

creases as the current density decreases. The coating roughness also grows with the current density at current densities exceeding the optimum value. The results obtained are well consistent with the data of [13–16].

Figure 5 shows the polarization curve of copper deposition. This curve can be used to accurately determine the limiting diffusion current density j_L.

The optimum current density for deposition of high-quality coatings was found graphically (Fig. 4) as the initial current density corresponding to the onset of deposition in the region of the mixed control (about 0.3 j_L). This optimum current density linearly increases with the CuH_2L concentration (Fig. 6).

The experimentally obtained data confirmed the adequacy of the previously described theoretical approach [2, 14, 15]. The authors derived for the optimum current density j_{opt}, as the end point of the Tafel curve, the equations

$$\frac{j_L}{j_o} = \frac{1}{k}\left(\frac{1}{1-k}\right)^{10}, \quad (2)$$

$$j_{opt} = kj_L, \quad (3)$$

where j_L is the limiting diffusion current density; j_o, exchange current density; and k, proportionality coefficient ($0 < k \leq 1$).

The values of j_{opt} and k were determined for solutions of various compositions on the basis of the experimental data (Figs. 4–6) and Eqs. (2), (3). The coefficient k was found to be 0.3. These values of k and j_{opt} are in good agreement with the graphically determined values (table, Figs. 4, 6).

The data presented show the conditions at which smooth homogeneous copper coatings with good adhesion are formed on steel from a solution of the copper(II) complex with H_4L. Smooth homogeneous coatings with poor adhesion, easily detachable from the steel support, even though the support was not passivated prior to coating deposition, can be deposited from the same solutions.

To obtain coatings of this kind, the steel support should be subjected to "slow cementation" for 7 min before electrochemical deposition of a coating. The slow cementation occurs when the equilibrium potential of the copper electrode is approximately 0.3 V more positive that the open-circuit potential of the steel electrode in solutions of the copper(II) complex with H_4L at a concentration of the latter compound equal to 0.2–0.4 mol dm^{-3} [solutions (b)–(d)].

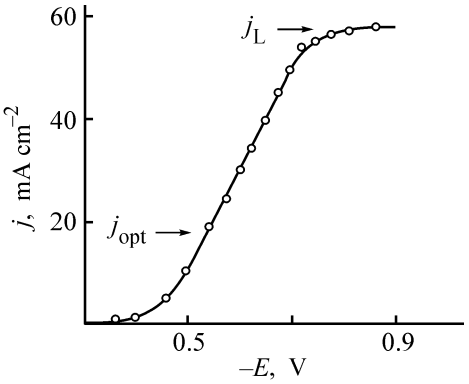

Fig. 5. Polarization curve of copper deposition. Solution composition (M): $CuSO_4$ 0.04, H_4L 0.04, NH_4Cl 0.4, Na_2SO_4 1.6, NH_4OH x; pH 9.5, T = 295 K.

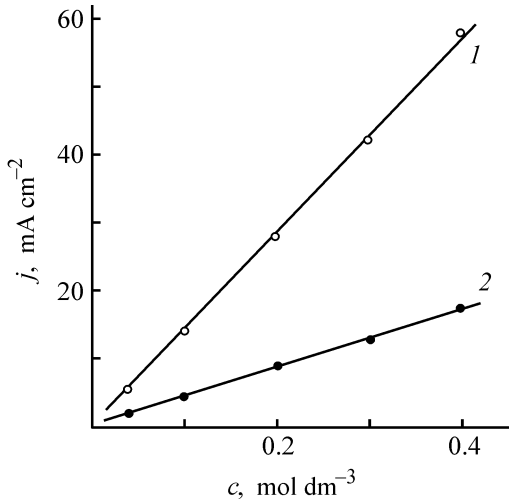

Fig. 6. (*1*) Limiting diffusion current density j and (*2*) optimum current density vs. the CuH_2L concentration c in solution. pH 9.5, T = 295 K.

Thus, high-quality coatings can be obtained at appropriate current densities in electrochemical deposition of copper on steel from a solution of the low-toxic copper(II) complex with the ligand, 1,3-propylene diamine-*N*,*N*'-diacetate-*N*,*N*'-di-3-propionic acid

Limiting diffusion current density j_L, exchange current density j_o, and their ratio at different concentrations of diacyde-1,3-propylenediamine-*N*,*N*'-diacetate-*N*,*N*'-dipropionate cuprate(II)

Parameter	CuH_2L concentration				
	0.4	0.3	0.2	0.1	0.04
j_L, mA cm^{-2}	58	42	28	1.4	5.6
j_{opt}, mA cm^{-2}	18	13	9.0	4.2	1.8
j_{opt}/j_L	0.31	0.31	0.32	0.30	0.33
j_o, mA cm^{-2}	0.44	0.32	0.20	0.10	0.042

(H_4L), as in the case of copper deposition from cyanide electrolytes [1, 2].

CONCLUSIONS

(1) Smooth homogeneous copper coatings can be deposited on steel from a solution of the copper(II) complex with a ligand, 1,3-propylene diamine-*N*,*N*'-diacetate-*N*,*N*'-di-3-propionic acid (H_4L).

(2) The quality of copper coatings depends on the difference between the copper electrode potential E_1 and the open-circuit potential of the steel electrode E_2. At $E_1 - E_2 < 0.1$ V, no cementation occurs, but smooth homogeneous copper coatings with good adhesion can be electrochemically obtained on steel at an appropriate current density.

(3) Smooth homogeneous copper coatings with poor adhesion, easily detachable from the steel support, are obtained if steel is subjected, prior to deposition, to slow cementation for 7 min at the potential $0.2 < E_1 - E_2 < 0.4$ V.

Abstract—A new method for the synthesis of heteroaromatic acids and their derivatives (esters and salts) by carbonylation of the corresponding halides was developed. Hetaryl halides were activated in alcoholic-alkali medium by highly active catalytic systems based on cobalt carbonyl modified with epoxides, developed previously for carbonylation of aryl halides.

DOI: 10.1134/S1070427207040106

Heteroaromatic acids are widely used in preparative organic chemistry and as a raw material in the production of a wide range of substances, mainly biologically active, and first of all of drugs and plant protection agents [1].

The traditional methods for preparing heteroaromatic acids, used today in the industry and laboratory practice, are diverse. They are based on a set of classical reactions of organic chemistry (alkylation, acylation, oxidation, cyanidation) and have a number of serious disadvantages: multistep synthesis, low selectivity, large consumption of raw materials, and complex process flowsheet. Some of these methods are environmentally unfavorable. Recently, the method of carbonylation of the corresponding halides has come into use for selective (one-step) introduction of the carboxy group into an aromatic core, i.e., for the synthesis of aromatic acids. Preparation of arenecarboxylic acids by carbonylation of aryl halides using cobalt carbonyl complex modified with alkyl halides as a catalyst has been known since the mid-1980s [2–6]:

$$\mathrm{ArHal + CO} \xrightarrow[\mathrm{ROH + B}]{\mathrm{Co(CO)_8 + A}} \mathrm{ArCOOR},$$

where A is an activator (alkyl halide) and B, base.

It was found that alkylcobalt carbonyl complexes $\mathrm{R'Co(CO)_4}$ formed in situ by the reaction of alkyl halides R'X, active in nucleophilic substitution (e.g., methyl iodide or methyl monochloroacetate $\mathrm{ClCH_2COOCH_3}$), with cobalt carbonyl in an alcoholic-alkaline medium can activate comparatively inert aryl halides in carbonylation reactions [2]. In the process, alkyl halides act as cocatalysts (activators) of cobalt carbonyl in aryl halide carbonylation. The reaction proceeds under very mild conditions: CO pressure of 1–3 atm and temperature of 60–65°C. We have shown [3, 4] that benzyl chloride forming the catalytic complex $\mathrm{PhCH_2Co(CO)_4}$ is the best activator (A) among alkyl halides.

Miura et al. [7] found that aryl halide carbonylation can proceed at room temperature and atmospheric pressure of CO, with the system cobalt(II) chloride–methyl iodide is used as a catalyst, but the reaction is slow. To accelerate the reaction in this catalytic system, Nindakova et al. [8] used reducing agents and, in particular, sodium borohydride or sodium naphthalenide. Nindakova et al. [8] believe that elimination of the stage of cobalt carbonyl preparation is an advantage of such an approach. However, in spite of the fact that such systems do not differ in activity from the systems studied in [2–6], additional reducing agents complicate the process.

In 1994, we discovered a new catalytic system for carbonylation of bromobenzene and chloronaphtalene, which consists of cobalt carbonyl, potassium carbonate, and olefin oxide (e.g., ethylene oxide or propylene oxide) [9]:

$$ArHal + CO + CHO^- \xrightarrow[\text{CH}_3\text{OH, } K_2CO_3, 60^\circ C, P_{CO} = 1 \text{ atm}]{Co(CO)_4^-,\ \text{epoxide}} ArCOOCH + Hal^-$$

We found that this catalytic system noticeably surpasses in activity the previously used system based on alkyl halides.

The new catalyst was used to prepare various aromatic carboxylic acids: 4-butylbenzoic, 4-acetylbenzoic, 4,4'-diphenyl- and 4,4'-(diphenyl oxide)dicarboxylic, and 2,6-naphtalenedicarboxylic. It was shown that this system can be successfully used for laboratory and commercial synthesis of a wide range of aromatic carboxylic acids of various structures [10].

At the same time, the synthesis, using this catalytic system, of aromatic carboxylic acids with a complex structure containing heterocyclic substituents has not been studied. At the same time, the exclusively high selectivity of the new catalytic system can become especially useful in the case of difficultly available and expensive heterocyclic compounds. Taking into account the fact that a number of various heteroaromatic halides can be prepared comparatively simply (by direct introduction of halogen into the aromatic core or by substitution with halogen of hydroxy group often formed in synthesis of the heterocycle), the use of cobalt carbonyl as an inexpensive and readily available catalyst of oxo synthesis, as applied to carbonylation of hetaryl halides, seemed very attractive from the practical and theoretical viewpoints. At the same time, this question required special consideration, because the majority of the heterocyclic compounds can potentially react as ligands and affect the catalytic properties of the cobalt complex.

First of all, we examined the possibility of using carbonylation to prepare acids derived from a nitrogen-containing heterocycle. It is well known that pyridine can form complexes with cobalt carbonyl, acting as a base ligand [11]. Therefore, it was necessary to check to what extent the catalytic activity of the carbonyl-base-propylene oxide system is preserved in the presence of the pyridine compound. We found that 2-chloropyridine undergoes carbonylation. Some important conclusions follow from this fact: (1) The system preserves the catalytic activity under the above conditions, i.e., in the presence of the potential heterocyclic ligand. (2) Hetaryl halides can undergo carbonylation. (3) As in usual reactions of nucleophilic substitution, halopyridine is more active than the corresponding halobenzene, i.e., the activating effect of the pyridine ring is preserved. This allows preparation of pyridinecarboxylic (and, apparently, also quinolinecarboxylic) acids by carbonylation of the corresponding hetaryl chlorides, which are substantially more readily available than the corresponding hetaryl bromides.

The synthesis of various quinolinecarboxylic acids, which are difficult to prepare by other methods, is of particular practical interest. We studied carbonylation of a series of halides containing tetrahydroquinoline (**I**), quinoline (**IV**, **V**), tetrahydroqiunazoline (**II**), and tetrahydroquinoxaline (**III**) rings:

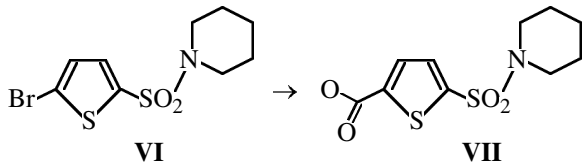
0.34	190 : 1 : 190 : 600	75	71 (95)
0.34	194 : 1 : 400 : 620	68	64 (94)
0.48	200 : 1 : 200 : 600	78	75 (96)

* From ^{1}H NMR data.

The results obtained are listed in Table 1. As seen, all the hetaryl bromides studied readily undergo carbonylation with the catalytic system suggested. Moreover, chlorine derivatives of quinoline can also be, as expected, substrates in carbonylation. With the carbonylation of **I** as an example, we examined the influence of the reactant, catalyst, and activator concentrations on the reaction yield (Table 2).

The data obtained show that the method suggested is suitable for preparing heteroaromatic carboxylic acids.

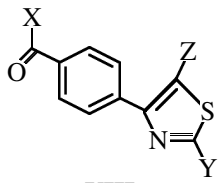
To check whether the activity of the catalytic system is preserved with sulfur-containing heterocycles as substrates, we studied carbonylation of 2-bromo-5-(piperidyl-1-sulfo)thiophene **VI**:



VI **VII**

We found that the substrate conversion in 4 h reached 94%, and the yield of isolated acid **VII** was 79%.

Preparation of 4-(4-carboxyphenyl)thiazoles **VIII**

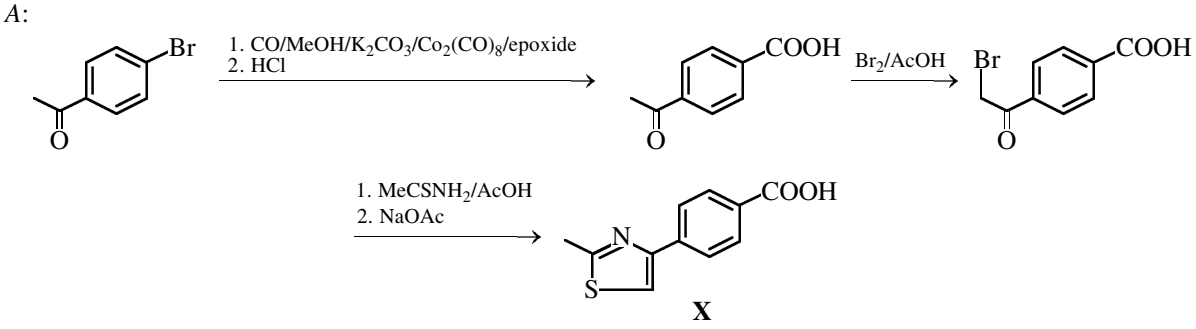


VIII

is of great interest. At present, such derivatives are studied as biologically active substances, e.g., potential COX-2 inhibitors [12]. Preparation of these derivatives involves the use of expensive starting compounds, 4-acylbenzoic acids, whereas carbonylation of aryl halides would allow the use of the substantially less expensive 4-bromoacylbenzenes.

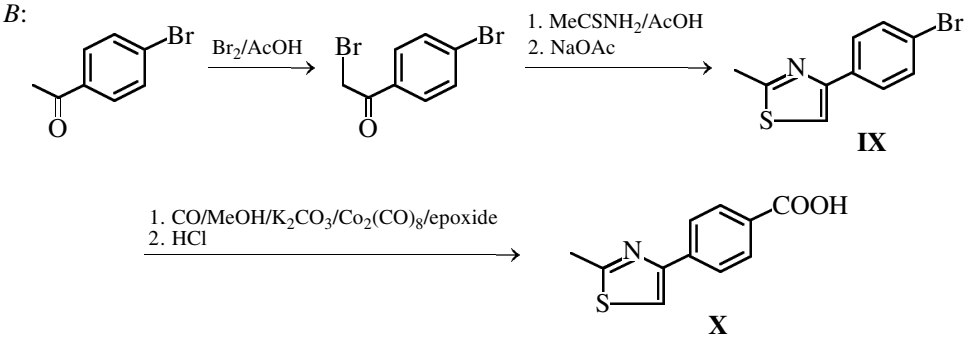
The synthesis of 4-(2-methylthiazol-4-yl)benzoic acid **X** from 4-bromoacetophenone by carbonylation can be performed along two pathways:

A:



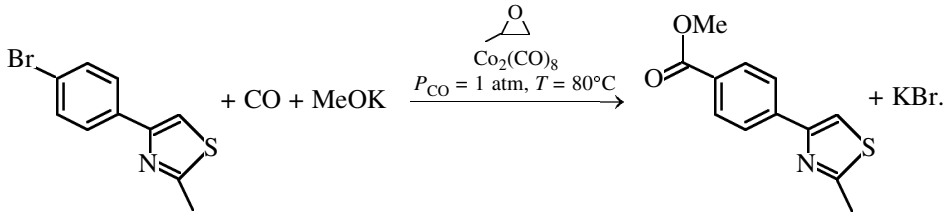
X

B:



Pathway *A* involves carbonylation of aryl halide (4-bromoacetophenone) described in [10]. Pathway *B* includes the stage of carbonylation of halide **IX**, which required preliminary examination.

Carbonylation of 4-(4-bromophenyl)-2-methylthiazole **IX** catalyzed by the cobalt complex readily occurs in methanol with potassium carbonate as a base:



Analysis of the reaction mixture showed a high selectivity of carbonylation of this substrate and good preparation yield (Table 3).

Thus, we can synthesize **X** by two methods (*A* and *B*). The preparation yields are compared in Table 4. The data obtained show that the presence of thiazole fragment in the aryl halide molecule does not prevent carbonylation. Carbonylation after heterocycle formation (but not in the early stage of the synthesis) improves the overall parameters of the process.

As can be seen from the above data, the efficient catalytic system $Co(CO)_4$–propylene oxide–K_2CO_3 in metanol, developed previously for aryl halide carbonylation, can also be successfully used in the selective synthesis of various heteroaromatic carboxylic acids with a good yield and high selectivity under very mild

EXPERIMENTAL

The carbonylation reactions were studied at CO atmospheric pressure in ordinary temperature-controlled glass apparatus with vigorous stirring in a CO atmosphere. The reaction products were analyzed by GLC and ^{1}H NMR. The identification of products was based on data of ^{1}H and ^{13}C NMR spectroscopy and mass spectrometry.

The mass spectra were recorded on an MKh-1321 mass spectrometer using direct sample inlet and ionization by electron impact (70 eV); the temperature of the ionization chamber was 200°C.

GLC analysis was performed on a Chrom-5 chromatograph with a flame ionization detector; the carrier gas was argon, flow rate 20–30 ml min^{-1}. Glass columns, 3 mm in diameter and 2500 mm long, were packed with SF-30 (10%) on Chromaton N-Super (80–100 mesh). The vaporizer and column temperature was 200°C.

The NMR spectra were recorded on a Bruker DPX 300 spectrometer [operating frequency 300.130 (^{1}H) and 75.03 (^{13}C) MHz]; solvent: 2 : 1 (by volume) mixture of CCl_4 with deuterated dimethyl sulfoxide.

A 2-l round-bottomed flask equipped with a power-driven stirrer, reflux condenser, thermometer, gas-feeding tube, and dropping funnel was purged with CO and charged with 200 g (1.4 mol) of K_2CO_3, 1200 ml of methanol, and 0.5 mol of a substrate. The reaction mixture was purged with CO under stirring for 0.5 h. Then, in a CO flow, 2.4 g of octacarbonyldicobalt (7 mmol) was added, and the temperature of the reaction mixture was elevated to 62°C. Then, the required amount of propylene oxide and 15–20 ml of methanol were added from a dropping funnel over a period of 10 min. After that, the temperature of the reaction mixture was elevated to 64°C, and the reaction was performed for 6 h at this temperature. Then the CO flow was stopped, the reaction mixture was cooled, 56 g of KOH (1 mol) was added, and methanol was distilled off at atmospheric pressure with stirring for several hours. After methanol distillation, water and diethyl ether were added into the reaction mixture, the organic phase was separated, and the aqueous phase was acidified with concentrated hydrochloric acid to pH 4–5 and kept until the acids precipitated. The precipitate was filtered off and dried.

CONCLUSIONS

(1) A new method was developed for synthesis of heteroaromatic acids and their derivatives by carbonylation of the corresponding hetaryl halides using highly active catalytic systems based on cobalt carbonyl, modified with epoxides.

(2) It was demonstrated that carbonylation of hetaryl halides proceeds under very mild conditions (CO pressure 1 atm) in alcohols in the presence of bases.

(3) It was shown that hetaryl halides with various structures, containing pyridine, quinoline, tetrahydroquinoline, tetrahydroquinazoline, thiophene, or thiazole fragments can be substrates in the above synthesis.

(4) A series of previously unknown heteroaromatic acids were synthesized.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Inorganic Composite Membranes for Electrodialytic Desaltination

Received November 30, 2006

Abstract—Application of inorganic composite membranes in electrodialytic desaltination of dilute solutions containing Na^+, Ca^{2+}, Mg^{2+}, Cl^-, and SO_4^{2-} ions was studied. The membranes are based on an oxide ceramic containing hydrated zirconium(IV) oxide as an ion-exchange component. The limiting currents were estimated theoretically.

DOI: 10.1134/S1070427207040118

In recent decades, a considerable attention has been given to membrane methods for obtaining high-quality drinking water. A particular place among these methods is occupied by electrodialysis, which enables effective desalination of water containing 1 to 10 g l^{-1} of salts [1–4]. As a rule, ion-exchange membranes based on organic polymers are used for electrodialysis. However, low-soluble substances of organic origin and also colonies of microorganisms are concentrated on the surface of such membranes in the course of exploitation [5, 6]. This leads to gradual reduction of the efficiency of purification by electrodialysis and to an increase in power consumption. Replacement of organic membranes with those made of inorganic materials could solve this problem.

Inorganic ion-exchangers and, in particular, hydrated oxides of Group-IV metals are capable of ion exchange by acid or basic mechanism [7, 8], depending on the pH of the medium. The results reported in [9] show that composite ceramic membranes containing an inorganic cation-exchange component (zirconium hydrophosphate) are promising for electrodialytic extraction of cations from dilute solutions.

The aim of this study was to assess the possibility of using ceramic composite membranes containing an ion-exchange component (hydrated oxide of a Group-IV metal) for electrodialytic desaltination of subsaline water.

A flow of cations $N_{\mathrm{Cat,m}}$ across an ideal selective cation-exchange membrane is determined by their migration in the solution bulk and by diffusion across the near-membrane layer on the side of the desaltination chamber [10]:

$$N_{\mathrm{Cat,m}} = N^{\mathrm{migr}}_{\mathrm{Cat,s}} + N^{\mathrm{dif}}_{\mathrm{Cat,s}}. \quad (1)$$

Here, $N^{\mathrm{migr}}_{\mathrm{Cat,s}}$ and $N^{\mathrm{dif}}_{\mathrm{Cat},s}$ are the migration and diffusion components of the flow, with the subscripts "m" and "s" corresponding to the membrane and solution. In this case, the material balance equation (1) can be represented as

$$\frac{it_{\mathrm{Cat,m}}}{z_{\mathrm{Cat}}F} = \frac{it_{\mathrm{Cat,s}}}{z_{\mathrm{Cat}}F} + k_{\mathrm{Cat}}(c_{\mathrm{Cat,s}} - c^0_{\mathrm{Cat,s}}). \quad (2)$$

Here, i is the current density; $t_{\mathrm{Cat,m}}$ and $t_{\mathrm{Cat,s}}$, ion transport numbers across the membrane and solution, respectively; z_{Cat}, ion charge; F, Faraday constant; $c_{\mathrm{Cat,s}}$ and $c^0_{\mathrm{Cat,s}}$, ion concentrations in the solution bulk and near-membrane solution layer on the side of the desaltination chamber, respectively; and k_{Cat}, mass-transfer coefficient of cations, defined as D_{Cat}/δ, where D_{Cat} is the diffusion coefficient of cations in solution, and δ, the width of the solution layer near the membrane surface.

The diffusion and migration flows are related by

$$N^{\mathrm{dif}}_{\mathrm{Cat,s}} = \frac{|z_{\mathrm{Cat}}|}{|z_{\mathrm{An}}|} N^{\mathrm{migr}}_{\mathrm{Cat,s}}. \quad (3)$$

It follows from Eq. (2) that an increase in the current density should intensify the ion transfer across the membrane. At the same time, the current density has the limiting value $i_{\mathrm{lim,Cat}}$, which corresponds to

$c^0_{\text{Cat, s}} = 0$. If the concentration of the supporting electrolyte is insignificant, the limiting current is determined by both diffusion and migration [11]:

$$i_{\text{lim, Cat}} = z_{\text{Cat}}\left(1 + \frac{|z_{\text{An}}|}{|z_{\text{Cat}}|}\right)Fk_{\text{Cat}}c_{\text{Cat, s}}. \quad (4)$$

In the presence of more than a 10-fold excess of the supporting electrolyte in the solution (in mole ratios), Eq. (4) can be simplified to

$$i_{\text{lim, Cat}} = z_{\text{Cat}}Fk_{\text{Cat}}c_{\text{Cat, s}}, \quad (5)$$

It is necessary to note that the limiting current of transfer across the membrane is an additive quantity and includes the corresponding values of i_{lim} for all the cations. The above relations are also valid for anions.

In the case of a laminar flow along flat parallel membranes (it is assumed that the surface of the membranes is ideally smooth), the mass-transfer coefficient can be found from the correlation equation [12]:

$$\text{Sh} = 1.85\left(\text{Re}\,\text{Sc}\frac{d}{L}\right)^{0.33}. \quad (6)$$

Here, Sh, Re, and Sc are the dimensionless Sherwood, Reynolds, and Schmidt numbers, respectively; d, distance between membranes; and L, height of the working space of the membranes. Because

$$\text{Sh} = \frac{k_{\text{Cat}}d}{D_{\text{Cat, s}}},\ \text{Re} = \frac{du}{\nu},\ \text{Sc} = \frac{\nu}{D_{\text{Cat, s}}}$$

(ν is the kinematic viscosity of a solution), this enables us to calculate the limiting current due to the ion transfer across the membrane.

EXPERIMENTAL

We chose ceramic plates of composition Al_2O_3 (70%) and ZrO_2 (30%) with an average pore diameter of 0.19 μm and specific surface area of 4.5–5 $m^2\ g^{-1}$ as a starting matrix for preparation of ion-selective membranes. The matrix was filled in stages with hydrated zirconium dioxide (HZD). For this purpose, a membrane was impregnated with an HZD sol, kept in ammonia vapor, washed with deionized water, and dried at 423 K [13]. To fill matrix pores to a fuller extent, the ion-exchange component was introduced seven times.

The experimental installation, described in detail in [14, 15], comprised a three-chamber electrodialysis cell, three independent contours for solution feeding, a power source, and measuring devices. Platinum electrodes were placed in side compartments of the cell, and the cathode and anode spaces were separated from the central compartment by ceramic membranes. The effective area of the membranes and electrodes was 16 cm^3 (4 cm × 4 cm), and the distance between the membranes, 1 cm.

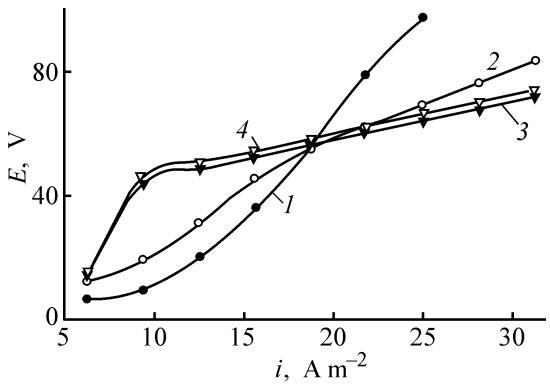

Fig. 1. Voltage E vs. the current density i for the electrodialytic system. Solution flow rate through the middle compartment ($m^3\ s^{-1}$): (*1*) 5×10^{-8}, (*2*) 1×10^{-7}, (*3*) 1.5×10^{-7}, (*4*) 2×10^{-7}; the same for Figs. 2 and 3.

The starting solution, containing (mol m^{-3}) Na_2SO_4 1.8, NaCl 5.9, $CaCl_2$ 3.9, and $MgCl_2$ 3.0, was delivered in a direct-flow mode into the central compartment of the cell (desaltination chamber) at a rate u of 5×10^{-8}, 1×10^{-7}, 1.5×10^{-7}, or 2×10^{-7} $m^3\ s^{-1}$ by SP-311 peristaltic pumps. The electrical conductivity of the solution at the cell output was measured with an HI 9932 conductometer, the pH was recorded wit an EV-40 ion meter. The electrical conductivity of the starting solution was 2.5 $m\Omega^{-1}\ cm^{-1}$, and pH 6.5. A 5 mol m^{-3} solution of H_2SO_4 (anolyte) and a solution with the initial composition corresponding to that of the solution to be purified (catholyte) were circulated through the electrode compartments (concentrating chambers). The initial volume of the solution in each compartment was 200 cm^3.

The experiments were carried out in the galvanostatic mode at current densities 6.2–31.2 A m^{-2}, using an IPPT 65-49 power source. The voltage was measured with an SHCH-1312 voltmeter, and the current, with an SHCH-4311 ammeter. The duration of each experiment at various flow rates and current strengths was about 8 h.

Samples were periodically taken from the compartment containing the catholyte and analyzed for the content of cations with a PYE UNICAM SP 9 atomic-absorption spectrometer (Ca^{2+} and Mg^{2+}) and a PFM-U4.2 flame photometer (Na^+).

Dependences of the voltage E on the current density are shown in Fig. 1. The values of E were re-

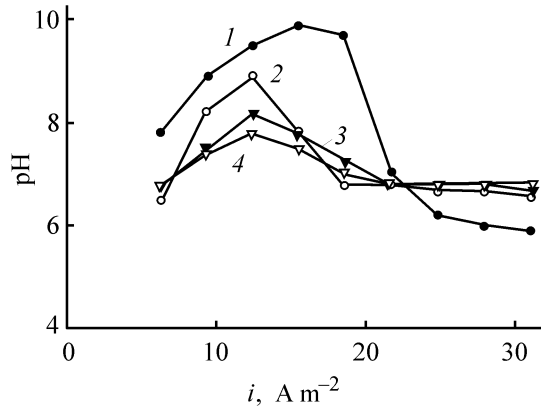

Fig. 2. pH value of the dialyzate vs. the current density i at various solution flow rates through the middle compartment.

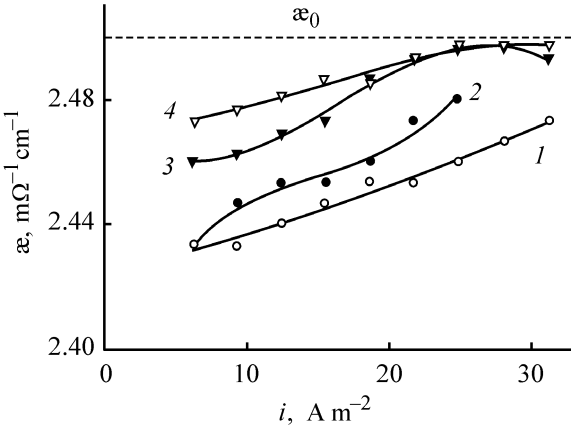

Fig. 3. Electrical conductivity of the dialyzate, æ vs. the current density i at various solution flow rates through the medium compartment.

corded 30 min after the beginning of each experiment. It was found that the current–voltage curve is S-shaped at a solution flow rate through the middle chamber of 5×10^{-8} m^3 s^{-1}. The voltage increases slowly in the range 6.2–9.4 A m^{-2} and sharply at $i > 9.4$ A m^{-2}. In the range 12.5–28.1 A m^{-2} the E–i dependence becomes linear, but tends to deviate from linearity as the current increases further. At a flow rate of 1×10^{-7} m^3 s^{-1}, four portions can be distinguished in the curve E–i: slow (6.2–9.4 A m^{-2}) and steep (9.4–15.6 A m^{-2}) rise in voltage, with the subsequent decrease in the slope of the curve slope (15.6–18.7 A m^{-2}) and a linear region at $i >> 18.7$ A m^{-2}. At flow rates of 1.5 10^{-7} and 2×10^{-7} m^3 s^{-1}, the voltage first sharply increases (6.2–9.4 A m^{-2}), and then decreases (9.4–12.5 A m^{-2}). At $i > 12.5$ A m^{-2} E–i, the curves become linear.

In the course of electrodialysis, the voltage difference tended to decrease at all currents, which is probably due to an increase in the solution concentrations in the electrode compartments because of the transfer of ions across the membranes and generation of H^+ and OH^- ions at the electrodes. The shape of the current–voltage curves in Fig. 1 is undoubtedly related to a change in the solution acidity in the central compartment.

Figure 2 shows how the pH value of the dialyzate depends on the current density (pH was measured 30 min after the beginning of an experiment). It is necessary to note that all the pH-vs.-current density curves exhibit an extremal behavior. At a solution flow rate through the medium chamber of 5×10^{-8} m^3 s^{-1}, the maximal pH value is reached at 15.6 A m^{-2}. Further increase in the current leads to a decrease in the dialyzate pH. At higher flow rates, the pH reaches a limiting value at 12.5 A m^{-2}, sharply decreased (12.5–21.8 A m^{-2}), and then stabilizes at 21.8 A m^{-2}.

Dependences of the electrical conductivity æ of the dialyzate on the current density are shown in Fig. 3. The value æ$_0$ corresponds to the electrical conductivity of the starting solution, with other æ values measured 30 min after the beginning of the experiment. In all the cases, the electrical conductivity of the dialyzate remained unchanged during each experiment. It is seen from Fig. 3 that æ increases with the current density.

It was found that, at a flow rate of 1×10^{-7} m^3 s^{-1} and a current density of 6.25 A m^{-2}, the rate of ion transfer reaches 1.67×10^{-8} (Na^+), 8.33×10^{-9} (Ca^{2+}), and 7.18×10^{-9} mol s^{-1} (Mg^{2+}). When the current density is raised to 25.1 A m^{-2}, these values decreases to 4.12×10^{-9} mol s^{-1} for Ca^{2+} and to 2.65×10^{-9} mol s^{-1} for Mg^{2+}, respectively; the rate of Na^+ transfer somewhat increases (1.8×10^{-8} mol s^{-1}).

We calculated the theoretical values of the limiting current due to transfer of each type of ions. In doing so, we took into consideration that the distance between the membranes was 1 cm, and the height of the central compartment, 4 cm. Because both single- and double-charged cations and anions were present in the solution, we determined the lower and upper bounds on the limiting current. Taking into consideration the concentration of each ion, we carried out the calculations by Eqs. (4) (Na^+ and Cl^-) and (5) (Ca^{2+}, Mg^{2+}, and SO_4^{2-}). In the calculations, we used the diffusion coefficients of ions in solution from

the reference book [16]. The results obtained are listed in the table.

It was found that the total limiting current due to the cation transfer into the cathode compartment is 3.5–4.48, 4.64–5.62, 5.27–6.39, and 5.84–7.07 A m^{-2} at flow rates of 5×10^{-8}, 1×10^{-7}, 1.5×10^{-7}, and 2×10^{-7} m^3 s^{-1}, respectively. The limiting current of anions at the same flow rates is 6.08–7.97, 7.64–9.99, 8.64–11.42, and 9.60–12.57 A m^{-2}. It can be seen that $i_{lim,Cat} < i_{lim,An}$. It is necessary to note that these calculations disregarded the limiting current due to the transfer of OH^- or H^+ ions, because the content of these ions in the dialyzate is very low at low current densities.

The electrodialysis at $i < i_{lim,Cat}$ and $i < i_{lim,An}$ results in that cations and anions enter the cathode and

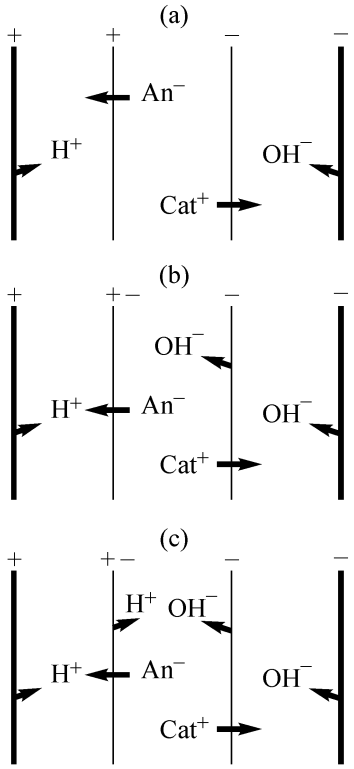

Fig. 4. Schematic of ion transfer across composite inorganic membranes under conditions of (a) sub-limiting current, (b) over-limiting current, and (c) acid leakage from the anolyte across the membrane.

anode chambers in equivalent amounts (Fig. 4a). In the process, equivalent amounts of OH^- and H^+ ions are generated at the cathode and anode; the acidity of the solution being purified remains unchanged. The constancy of the pH value of the dialyzate can serve as an indication that the limiting current is not reached in the system. The neutrality of the solution delivered into the central chamber and the acid character of the anolyte provide that the charge on the surface of the membrane that separates the anode and central compartments is positive and, accordingly, the membrane is permeable to anions. Similarly a neutral dialyzate and an alkaline catholyte favor formation of a negative charge of the membrane on the side of the cathode chamber and, accordingly, provide the selectivity of the membrane with respect to cations.

At flow rates of 1×10^{-7} $m^3\ s^{-1}$ and more, the real value of the total limiting current of cations is apparently higher than the theoretical value. This is demonstrated by the fact that the rate of transfer of Na^+ ions somewhat grows as the current increases from 6.25 to 25.1 A m^{-2}. In addition, the pH of the dialyzate is close to 7. This circumstance may be due to the surface roughness of membranes and, hence, to a certain intensification of the mass transfer. Taking into account that the reaction of the dialyzate is neutral, $u > 1 \times 10^{-7}$ $m^3\ s^{-1}$, and $i = 6.25$ A m^{-2}, we can calculate the current efficiency by cations, Q_{Cat}, from the change in the electrical conductivity of the solution:

$$Q_{Cat} = \frac{æ_0 - æ}{æ_0} u\tau\Sigma z_{Cat} c_{Cat} \frac{F}{Si\tau}. \quad (7)$$

Here u is the volumetric flow rate of the solution; τ, time; and S, membrane area.

The first term in Eq. (7) corresponds to the degree of solution purification, the second, to the dialyzate volume, the third, to the total equivalent concentration of ions in solution, and the fourth, to the amount of transferred ions, calculated by Faraday's law. The current efficiency by anions is determined similarly.

The values of Q_{Cat}, found using Eq. (7), are 68–70% for solution delivery rates of 1×10^{-7}–2×10^{-7} $m^3\ s^{-1}$ at a current not exceeding the limiting value (6.25 A m^{-2}). It is necessary to note that the current efficiency of 100% at $i << i_{lim}$ is, as a rule, not reached, either, in the case of heterogeneous organic membranes because of their polarization [17].

In the case when the current exceeds $i_{lim,Cat}$, an excess of cations is present is a solution being purified. The electroneutrality of the dialyzate is provided by hydroxide ions formed on the membrane surface via water dissociation, which makes the dialyzate more alkaline (Fig. 4b). In this case, the membrane retains the cation-exchange function on the cathode side. At the same time, the surface of the membrane separating the anode and central chambers is charged positively on the anode side and negatively on the side of the desaltination chamber, which hinders penetration of anions into the anolyte. This leads to a sharp rise in voltage. It is believed that, at $i > i_{lim,Cat}$, Ca^{2+} and Mg^{2+} ions are partially precipitated as difficultly soluble compounds on the surface of the membrane separating the cathode and central chambers. This assumption is confirmed by the decrease in the rates of transfer of Ca^{2+} and Mg^{2+} ions at high current densities.

After the limiting current for anions is reached, water starts to dissociate at the membrane separating the anode and central spaces, with H^+ ions generated on the membrane surface on the central chamber side, and the dialyzate pH decreasing to 7. The membrane acquires a positive charge on the anode side. The slope of the E–i curve decreases, which points to a decrease in the resistance of the electrodialytic system.

It is possible that the acid formed in the anolyte penetrates into the central chamber at high current densities (Fig. 4c). This is confirmed by the gradual increase in the electrical conductivity of the dialyzate, observed as the current becomes higher. The dialyzate is slightly acidified at high current densities, although an increase in pH would be expected in view of the inequality $i_{\mathrm{lim,Cat}} < i_{\mathrm{lim,An}}$. Thus, H^+ ions that penetrate from the anode chamber into the central chamber owing to an acid leakage are partly neutralized by OH^- ions generated on the membrane separating the central and cathode chambers. At the same time, the excess of acid anions is compensated by an excess of cations in the dialyzate.

CONCLUSIONS

(1) It was shown that inorganic composite membranes containing an ion-exchange component, hydrated zirconium dioxide introduced into a ceramic matrix, can be used for electrodialytic desaltination of dilute solutions containing Na^+, Ca^{2+}, Mg^{2+}, Cl^-, and SO_4^{2-} ions.

(2) The limiting currents were theoretically estimated for both cations and anions. For currents lower than the limiting value, the degree of desaltination was estimated by a change in the electrical conductivity of the solution.

(3) It was found that the current efficiency in the electrodialytic desaltination is 68–70%.

Abstract—A procedure for concentration of trace amounts of butyl alcohol, butyl acrylate, and acrylic acid from water by joint distillation with ethanol is suggested.

DOI: 10.1134/S107042720704012X

Measurement of the concentration of noxious impurities is one of the most important tasks of sanitary-chemical monitoring of natural and waste water. For most of organic compounds subject to regulations, the maximum permissible concentrations (MPC)) are below 1 mg l^{-1}, and, therefore, they cannot be always determined by the most versatile gas-chromatographic method.

The new requirements to wastewater treatment and the increasingly stringent parameters subject to regulations necessitate development of new high-sensitivity analytical procedures for determination of toxic substances. Presently, the production and consumption of acrylic monomers and polymers and formulations based on them is widely developing, which makes it necessary to monitor discharges from these industries. The wastewater from butyl acrylate (BAc) production contains toxic admixtures of butyl alcohol (BA), butyl acrylate, and acrylic acid (AA), whose MPC in potable water are 0.1, 0.01, and 0.5 mg l^{-1}, respectively [1]. Direct gas-chromatographic analysis of wastewater containing these impurities in amount of 0.5–10.0 MPC fails to provide the required detection limit. Therefore, it is necessary to preconcentrate the impurities in order to improve the determination sensitivity. Published data show that a limited number of methods are being used to concentrate trace amounts of organic substances in water. These include the following: sorption concentration on hydrophobic sorbents; liquid extraction; gas extraction, which is a variety of the vapor-phase concentration of volatile impurities contained in liquids [vapor-phase analysis (VPA)]; and distillation.

The compounds to be monitored are reactive, belong to different classes of organic compounds, and differ significantly in the MPC values. Therefore, application of any of these methods meets certain difficulties. In the case of the sorption concentration, it is necessary to remove water or to eliminate its interference in thermal desorption of impurities into a chromatographic column. The difference in polarity between the above compounds limits the choice and availability of effective sorbents. The liquid extraction is intended for removal of low-volatile substances with limited solubility in water. Therefore, its application is complicated by the need to work with large volumes of wastewater and organic substances because the distribution coefficients of BA and, especially AC, in the known extracting agents are low even upon salting-out and acidification. The main purpose of VPA is to determine readily volatile compounds with poor solubility in water. The method has high sensitivity and can provide the necessary detection limit of BA and BA impurities without any special concentrating procedures [2]. However, it is inefficient for analysis for AC a compound well soluble in water [3], at the MPC level.

Thus, development of a concentration procedure to provide chromatographic determination of BA, BAc, and AA impurities at the MPC level in the case of their simultaneous presence in water is a topical task.

EXPERIMENTAL

We chose for concentration the method of joint distillation of impurities from water with another solvent. The procedure consists in that a solvent with a comparatively low boiling point is added to water. Then, distillation of the solvent will involve simulta-

Table 1. Physicochemical characteristics of substances being analyzed

Compound	MPC, mg l^{-1}	T_b °C	Polarity	Solubility, g l^{-1} at 20°C		
				Water	Ethanol	Acetone*
BA	0.1	117.2	Polar	90	∞	w.s.
BAc	0.01	147.4	Low-Polarity	1.3	∞	s.
AA	0.5	141.6	High-Polarity	∞	∞	s.

* w.s., well soluble; s., soluble.

neous evaporation of trace components. The necessary condition for applicability of this procedure is that the components to be determined should be stable at the distillation temperature [4].

All the analyses were performed by the gas-chromatographic method on an LKhM-80 chromatograph with a flame-ionization detector. A 100 × 0.3-cm steel column preliminarily deactivated with concentrated orthophosphoric acid was packed with Chromaton N-AW-NMDS (0.020–0.025 cm), onto which 15% (by mass) of the stationary phase, polyehtylene glycol adipate (PEGA), was deposited. The chromatographic conditions were as follows. Temperature (°C): evaporator, 190; detector, 170; columns, isotherm at 53 for 16 min, rise in temperature from 53 to 170 at a rate of 25 deg min^{-1}, and then again isotherm for 10 min. Carrier gas: nitrogen at a flow rate of 30 cm^3 min^{-1}. To suppress the irreversible sorption of AA in the column, the carrier gas was mixed with a formic acid vapor in a flask connected to the carrier gas line, or 3 μml of 40% formic acid was introduced into the column prior to analysis. The quantitative determination was performed by the absolute calibration method. The calibrating solutions were prepared from accurately weighed portions of chemically pure BA, BAc, and AA by successive dilution. The detection limit on the scale 50×10^{-12} A (with a 10 μml sample introduced into the column) was 0.01, 0.01, and 0.03 mg ml^{-1} for BA, BAc, and AA, respectively. The analysis time was 30 min and the relative error did not exceed 20%.

The conditions of concentration were chosen using model wastewater solutions containing BA, BAc, and AA in an amount of 0.5–100 MPC.

Concentration by distillation: to wastewater were added sodium chloride (up to 20 wt %), orthophosphoric acid to pH 1–2 as indicated by universal indicator paper, and a low-boiling solvent. Then, the solvent with a vapor temperature equal to the boiling point of the solvent was evaporated into volumetric test tubes by rectification in a glass column packed with a glass pipe cut in pieces. This operation should be performed with great care, because the temperature of the water–alcohol mixture should be raised slowly to provide the vapor rectification mode. The concentration coefficient was calculated as a ratio of the wastewater volume to the volume of the distillate obtained.

Concentration by evaporation: into a test tube with a distillate was introduced a weighed portion of polyethylene glycol (0.01–0.025%), the test tube was connected to a refluxer through a Kuderny–Danishe evaporator, and the solvent was distilled-off. The concentration coefficient was calculated as a ratio of the distillate volume to the volume of the evaporated concentrate.

As solvent was chosen ethanol, because all three impurities have unlimited solubility in this alcohol and its boiling point is 40°C lower than that of the lowest-boiling impurity, BA (Table 1).

To provide complete evaporation of BA and AA from water, we used, by analogy with extraction, the effect of salting-out with an inorganic salt and acidification with a nonvolatile acid, thereby reducing the solubility of organic impurities in water and facilitating their transfer to the alcohol. Preliminarily, we determined that no acid hydrolysis of BA occurs under the experimental conditions. The salting-out also reduces the solubility of ethanol in water and facilitates its evaporation. We used as the salting-out agent the least expensive and readily available sodium chloride. Several explanations for the salting-out capacity of salts have been suggested in the literature, the principal of which is that the hydration of a salt diminishes the amount of unbound water, with the hydration of the organic substance, and, as consequence, its solubility in water, decreasing. This capacity of the ions of a salting-out agent is associated with their radii. Ions with a small radius have a large charge density and are better hydrated. The salting-out capacity of a salt is an additive sum of the effects of cations and anions, with anions having a higher salting-out capacity than cations, all other conditions being the same. This ability of ions of a dissolved salt to interact with water molecules of a solution is quantitatively characterized by the number of water

Table 2. Characteristics of concentration of BA, BAc, and AA from water

Solvent	Degree of extraction into distillate, rel %			Loss in evaporation, rel %		
	BAc	BA	AA	BAc	BA	AA
Methanol	None	99.8	30.5	–	–	–
Acetone		95–98		≤5	≤1	1–2
Ethanol		95–98		40–50	1–2	≤5
				With polyethylene glycol		
				≤5	≤1	1–2

molecules bound to the ion, or by the hydration number. Salts with small ions with a large charge, e.g., aluminum and iron salts, are stronger salting-out agents, but they are not easily available [5, 6]. In this case, a 95–98% extraction of components and the maximum concentration coefficient (100) are achieved (Table 2). However, analysis for BA, BAc, and AA at their concentrations in water in the range 0.5–10 MPC requires higher concentration coefficients.

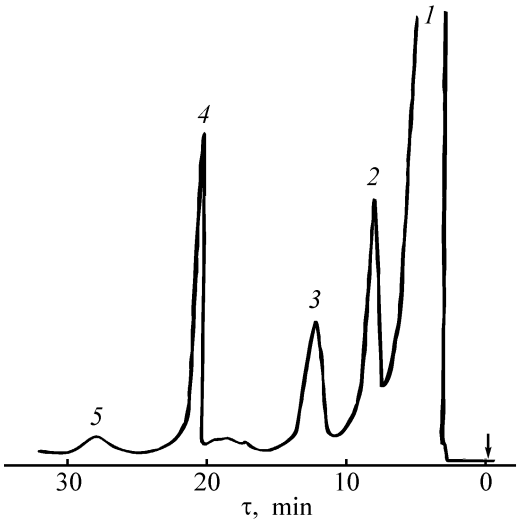
To raise the concentration coefficients, we used a simple procedure of evaporation of organic solvents containing impurities. In some cases, evaporation results in loss of compounds with boiling points 30–50°C higher than that of the solvent (BA, AA) or in those with a high vapor pressure (BAc). To decrease the concentration loss, the alcohol distillate was evaporated using a Kuderny–Danishe evaporator, to which a refluxer was connected in series [7, 8]. The loss of BA in this evaporation process was the largest (Table 2), which is due to its volatility. In addition, the water–alcohol azeotrope (bp 78.4°C) is subject to evaporation together with the impurities and is distilled-off. Because BA is virtually insoluble in water, it is displaced from water and carried away by the alcohol vapor.

To diminish the BA loss in alcohol evaporation, ethanol was replaced with solvents having lower boiling points and forming no azeotropes with water (acetone and methanol). A single run was carried out with methanol, with a 100-fold concentration followed by evaporation. An analysis of the evaporated alcohol distillate demonstrated that virtually the whole amount of BA (99.8%) and 30.5% of AA were preserved, with BAc absent. This result can be accounted for by the possibility of transesterification of BAc into methyl acrylate (MAc) in an acid medium, with simultaneous esterification of AA and methyl alcohol, which also yields MAc. Because the boiling point of MAc (80.5°C) and its concentration are low, its peak in a chromatogram may be masked by that of the solvent (methanol). It can be carried away, similarly to the volatile ester, by the alcohol vapor in distillation. This result and the high toxicity of methanol make inadvisable its use as a solvent.

Experiments with acetone demonstrated that, to provide a 95–98% extraction of BA, BAc, and AA, it is necessary to add this solvent to wastewater in a 1 : 6–1 : 8 ratio (maximum concentration coefficient is 8). This is due to the lower solubility of BA, BAc, and AA in acetone, compared with their unlimited solubility in ethanol. Evaporation of the acetone distillate shows satisfactory results, with the loss of BAc not exceeding 5%. However, the need to use order of magnitude larger amounts of acetone for the distillation and the following concentration of impurities, compared with that of alcohol, leads to a considerable increase in the process time and makes this method inefficient.

Thus, ethanol is the most effective in extraction of all the three impurities. To minimize the loss of the extracted impurities in evaporation of the alcohol distillate, we introduced an additional solvent or compounds that facilitate retention of the trace component in the solution in the evaporation of the main solvent. Difficultly volatile polar compounds are commonly used for this purpose, whose interaction with molecules of the compound being analyzed makes lower the equilibrium concentration of the components being determined in the solution, i.e., diminishes their partial vapor pressures. The vapor pressure of the additive itself should be sufficiently low [8]. As additives were used ethylene glycol and polyethylene glycol (PEG-M-1500 brand, molecular weight 1500), which, being polar compounds, also have a salting-out effect. The best result was provided by polyethylene glycol added in an amount of 0.025–0.05% to the alcohol distillate in evaporation in a Kuderny–Danishe evaporator and a refluxer, with the loss of BAc not exceeding 5%.

To simplify measurements of the concentrate volume in evaporation of the alcohol distillate, we used



Chromatogram of impurities in wastewater from butyl acrylate production shops. (*1*) Ethanol (solvent), (*2*) BA, (*3*) BAc, (*4*) AA, and (*5*) butyl-β-butoxy propionate. (τ) Time.

graduated volumetric tubes or flasks with a volumetric finger-like arm of certain, calibrated volume. The concentration coefficient was calculated as the ratio of the volume of the initial wastewater, V_{ww}, to the that of the concentrate, V_c. The total time of concentration did not exceed 2 h.

The procedure we suggested was tested with real wastewater samples from butyl acrylate production shops (see figure).

CONCLUSIONS

(1) The procedure developed involves extraction of butanol, butyl acrylate, and acrylic acid from water by joint distillation with ethanol added to water being water in a 1 : 50–1 : 100 ratio.

(2) The procedure developed provides a 1000-fold concentration of butanol, butyl acrylate, and acrylic acid for gas-chromatographic determination in the range 0.5–10 MPC.

(3) The concentration coefficient is 500–1000.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Use of Titanium Dioxide for Surface Modification of Polymeric Membranes to Diminish Their Biological Contamination

Abstract—Adhesion of microorganisms to the surface of polymeric membranes and the efficiency of modification of the membrane surface by deposition of titanium dioxide to diminish biological overgrowth were studied.

DOI: 10.1134/S1070427207040131

Use of membrane techniques in water purification [1] involves a number of problems associated with accumulation of various substances (organic, inorganic, colloid, or suspended particles) or microorganisms on their surface. The contamination of membranes with microorganisms and products of their life activity leads to biological overgrowth (colonization of the membrane surface and formation of a biological film) [2]. Microorganisms can rapidly manyfold increase in abundance under favorable conditions, which makes the problem in question even more severe [3].

The process of biological overgrowth is primarily governed by the adhesion of microorganisms to the membrane surface. The key role is played by charges of the surface of microorganisms and functional groups of the working layer of a membrane; at opposite charges the electrostatic attraction makes the adhesion stronger.

To solve the biological contamination problem, thermal or chemical methods for disinfection of membranes can be used, but they failed to find wide application. For the thermal methods, the reason was that the thermal stability of most of the commercial brands of polymeric back-osmosis, ultra-, and nanofiltration membranes is low. In turn, use of chemical disinfectants, which are for the most part toxic and corrosive, changes the barrier layer of membranes and thereby impairs their selectivity [4].

Another approach to the problem of biological contamination of membranes consists in modification of their surface [4, 5] to improve their biological resistance [6] or in deposition of biocide substances, which exert by themselves or under the action of additional factors a disinfecting influence [7, 8]. As a rule, organic substances with a bactericide effect are used as modifying agents.

This paper reports on a study of the adhesion of various kinds of microorganisms to the surface of polymeric membranes of varied nature. Particular attention was given to the decrease in the membrane throughput upon adhesion of microorganisms and to analysis of the disinfecting action of a finely dispersed powder of titanium dioxide deposited onto the membrane surface, under exposure to UV light.

EXPERIMENTAL

Membranes of varied chemical nature: polysulfonic, PS-100H (Millipore) and 4F-PS-100H (Nadir); polysetersulfonic, P005F (Nadir); cellulose, C100F (Nadir); polyvinylidene fluoride, PVDF (Millipore); nylon, Nylon (Millipore); and cellulose acetate, MFA-Ma no. 3 (Vladipor).

The adhesion of microorganisms to the membranes was evaluated using a modified method [9, 10]. To obtain a comparatively size-uniform suspension of bacterial cells, cultures of one-day bacteria grown on a meat-peptone nutritive agar (NA) were placed in 3 cm^3 of a meat-peptone broth (MPB) and *Escherichia coli 1257* (*E. coli*) were cultivated at 37°C, and

Pseudomonas putida (*P. putida*) and *Acinetobacter calcoaceticus* (*A. calcoaceticus*), at 28°C for 24 h.

A 24-h-old broth culture was transferred into 200 cm^3 of MPB and grown at an appropriate temperature until the stationary growth phase commenced. After centrifugation at 2500 g for 10 min (K 26 D centrifuge), the cultures were three times washed with sterile distilled water and resuspended to a density of 10^8 CFU (colony-forming units) per cubic centimeter, as judged by the optical density measured on a KFK-2 photocolorimeter (λ = 540 nm, l = 0.5 cm). In filtration experiments, the initial suspension was diluted to a required density.

Membrane samples of area 1 cm^2 were submerged in 50 cm^3 of a bacterial suspension and kept for 4 h with agitation. When studying the effect of the time of contact on the number of adhered cells, membrane samples were removed from the suspension after a varied time of contact elapsed. The membrane samples removed from the suspension were two times washed, during 15 min, with 50 cm^3 of sterile distilled water on a rocker under mild agitation. Further, the membranes were placed in test tubes with 10 cm^3 of sterile distilled water and three specimens from each sample were treated with ultrasound for 15 min on a UM-4 installation, and three other speciments, shaken on a rocker for 15 min. The number of bacteria removed from the membrane in solution was calculated from the number of CFU on seeding *E. coli* on an *Endo's medium*, and other bacteria on a nutritive agar, and cultivation of *E. coli* at 37°C for 24 h and other bacteria at 28°C for 1–2 days. As the number of adhered bacteria on the membranes was taken the difference between the numbers of bacteria removed in ultrasonic treatment and in agitation.

To study the effect of biological overgrowth on the throughput of membranes, the *P. putida* microorganism was used as the test culture. River water preliminary inoculated with microorganisms was filtered across the membranes. The membranes were placed in Petri dishes and poured-over with sterile river water. After that the membranes were extracted from the solution at certain intervals of time and their throughput was measured. In parallel, the number of *P. putida* cells on the membrane surface was measured using the procedure described above. Additionally, a control run was performed without introduction of bacteria and with bacteria subjected to a lethal dose of UV irradiation (conditionally designated as "dead" bacteria). The extermination of microorganisms was effected by their exposure to light from an SVD-120A ultrahigh-pressure UV lamp (200–400 nm). The incident light power density was 1.89 W cm^{-2}, and the irradiation duration 0.5 h.

Membranes with bacteria were kept in river water or in a nutritive medium. The river water (Nivka river) had the following characteristics: color index 42–45°; content of phosphates, nitrates, and ammonium nitrogen 4–13, 0.5–0.7, and 0.12–0.3 mg dm^{-3}. The synthetic nutritive medium for *P. putida* contained (g dm^{-3}): glucose 3, NH_4Cl 1, KH_2PO_4 2.77, $Na_2HPO_4 \cdot 2H_2O$ 3.49; and 1 cm^3 dm^{-3} of a microelement solution; pH 6.8 [11]. The bacteria attached to the membranes under study were shaken-off by ultrasonic treatment for 15 min on a UM-4 installation.

To obtain modified samples, a PS-100H (Millipore) membrane was preliminarily kept in a suspension of titanium dioxide until its particles were deposited on the membrane surface. A TiO_2 suspension (Sigma-Aldrich, 5 μm) with a concentration of 2 g dm^{-3} was used. After the membrane surface was covered with titanium dioxide particles, a suspension of *P. putida* microorganisms (1.6×10^4 CFU cm^{-3}) was passed across the membrane. Membranes with and without deposited TiO_2 with living cells on their surface were irradiated with an SVD-120A UV lamp with UFS 6-3 and BS-7 light filters to select the wavelength of 365 nm. The irradiation power density was 153 μW cm^{-2}. For control, some of the membranes were not subjected to irradiation.

The number of *P. putida* colonies on the surface of control membranes and membranes subjected to irradiation was determined. When measuring the time dependence of the membrane throughput, samples were daily irradiated for 4 h, using the light filters mentioned above. The throughput of the membrane samples was measured every 24 h.

To photograph membranes with microorganisms, a TiO_2 powder was deposited on the surface of some of the membranes, with the surface of the rest of the membranes (control samples) remaining clean. *P. putida* suspensions with initial concentrations of 10 and 10^2 CFU cm^{-3} were passed across all the membranes. After that the membranes were irradiated with UV light for 4 h. Then the membranes were placed on NA and kept there until visible colonies were formed on their surface. The colonies were stained dark blue with a reagent used to stain oxidase-positive bacteria (dimethyl-*n*-phenylenediamine) [12]. The stained preparations were photographed with a digital camera.

In a study of the adhesion, the maximum time of contact was 4 h, and the concentration of bacteria in the suspension, $(1–6) \times 10^8$ CFU cm^{-3}. As can be seen

in Fig. 1, the test cultures studied can be arranged in order of increasing capacity for attachment to the MFA-Ma no. 3 and C100F membranes as follows: *E. coli* < *A. calcoaceticus* < *P. putida*. With respect to the P005F membrane, *A. calcoaceticus* and *P. putida* have approximately the same adhesion capacity. However, *P. putida* attached to the 4F-PS-100H membrane to a lesser extent than *A. calcoaceticus*, which adhered to this membrane and P005F in approximately equal amounts. *E. coli* bacteria exhibited the lowest adhesion capacity among the test cultured studied to all the membranes. Presumably, this is due to dissimilarities in the hydrophilic-hydrophobic nature of the surface between different bacteria. *P. putida* has a comparatively large wetting angle (38.5°), which indicates that the surface of its cells is hydrophobic. At the same time, this parameter varies for *E. coli* (different strains) within the range 16.7–24.7° [13]. With another method used to measure the hydrophobicity, from the adsorption of bacterial cells on the surface of a hydrophobic liquid (e.g., hexadecane), the K-12 strain of *E. coli* has a zero hydrophobicity index, and the *A. calcoaceticus* microorganism, 91.1% [13].

These data indicate that the capacity of cells for adhesion to the surface grows as the hydrophobicity of the cell surface becomes stronger. Because *P. putida* more widely occurs in natural water than *A. calcoaceticus*, just the former microorganism was used in further studies.

It was found in a study of the biological overgrowth of membranes by *P. putida* that the throughput of the membranes depends on the presence and state of bacteria on their surface. The most pronounced drop in throughput was observed for membranes with living cells (85% in 7 days); with dead bacteria present on the membrane surface, the drop was by 69%. The throughput of membranes that had no microorganisms on their surface decreased by 60% (Fig. 2).

The significant drop in the throughput of the membranes with living cells is due to an increase in the concentration of microorganisms and formation of various life-activity by-products. The change in the throughput of membranes without microorganisms points to a possible colonization of the membrane surface by other microorganism species coming from the environment. A layer of dead cells gave rise to an additional hydrodynamic resistance to the flow of water, which also adversely affected the throughput of membranes on which dead cells were deposited.

As can be seen in Fig. 3, filtration of water containing *P. putida* across membrane samples leads to a significant biological overgrowth of the surface

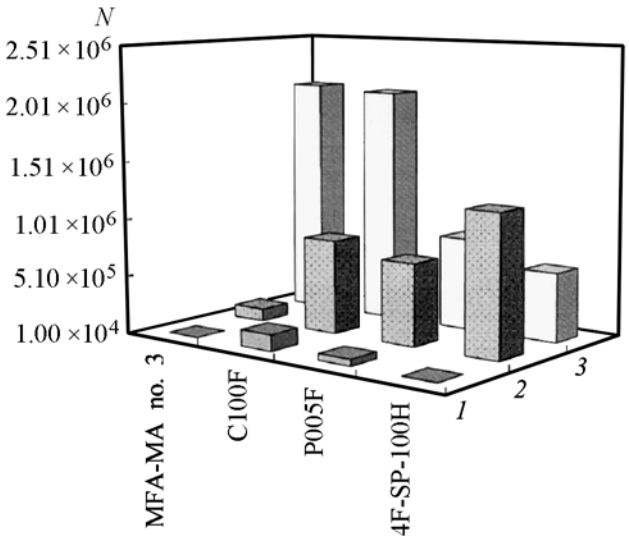

Fig. 1. Adhesion of test microorganisms to various membranes. Suspension density 1×10^8 CFU cm^{-3}, time of contact 4 h. (*N*) Number of bacteria per 1 cm^2 of membrane surface. (*1*) *E. coli*, (*2*) *A. calcoaceticus*, and (*3*) *P. putida*.

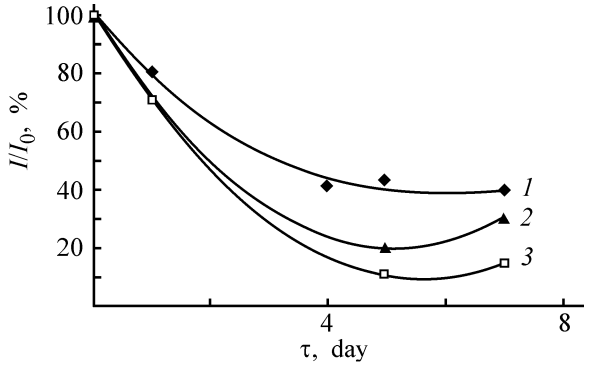

Fig. 2. Throughput of Nylon membranes covered with *P. putida* in contact with river water. (I/I_0) Relative throughput and (τ) process duration. Membrane: (*1*) without cells, (*2*) with dead cells, and (*3*) with living cells.

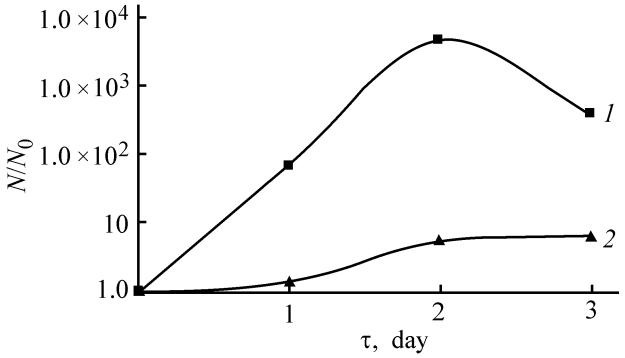

Fig. 3. Concentration of *P. putida* cells on (*1*) PVDF and (*2*) Nylon membranes vs. time τ of contact with river water. (N/N_0) Relative number of cells.

by these microorganisms. For example, the concentration of bacteria on Nylon and PVDF membranes increased in 3 days from 8.8×10^5 to 5.8×10^6 and from 1.4×10^4 to 5.5×10^6 CFU/membrane, respectively. These data indicate that the PVDF membrane is more susceptible to biological contamination than the Nylon membrane. As is known [14], the polyvinylidene fluoride membrane PVDF has a high hydrophobicity, in contrast to the Nylon membrane, which is more hydrophilic. The surface of a *P. putida* cell is also rather hydrophobic. Apparently, it is the hydrophobic interactions between the membrane and a cell that favor an increased adhesion of the microorganisms to the surface of the PVDF membrane.

To preclude biological overgrowth of membranes, experiments with deposition of a titanium dioxide powder on the surface were carried out. As can be seen in Fig. 4 (curves *1–3*), deposition of TiO_2 onto membrane samples without subsequent irradiation or irradiation of the initial membrane samples without deposition of TiO_2 on their surface has virtually no effect on the throughput of membranes. By contrast, a significant increase in the throughput was observed for membrane samples with deposited TiO_2 upon UV irradiation (Fig. 4, curve *4*). In particular, the throughput of modified irradiated membranes was 1.7–2 and 1.9–2.3 times higher in 1 and 2 days, respectively, than that of the other membranes. This is due to a significant decrease in the concentration of *P. putida* bacteria on the surface of membranes with TiO_2 upon UV irradiation: from 7.0×10^4 to 1.3×10^2 CFU/membrane in 4 days (Fig. 5). At the same time, the concentration of cells on the surface of other membranes remained virtually unchanged. These results indicate that the surface of modified membranes exhibits strong bactericide properties (the loss of microorganisms is about 99.8%).

The most vulnerable, to the biocide effect of substances, parts of bacterial cells are the cell wall, cytoplasmatic membrane, and cytoplasm [15]. Presumably, the mechanism of the bactericide action of TiO_2 under UV irradiation consists in the following. TiO_2 is excited by UV light and, as a result, electrons are generated in the conduction band, and holes, in the valence band. In the presence of water molecules, $OH^{\cdot}$, $O_2^{\cdot}$, and $HO_2^{\cdot}$ radicals are formed in the system [16]. Hydrophobic interactions and presence of a cell charge favor adhesion of bacterial cells to TiO_2 particles and enable active oxygen-containing radicals to reach the cell wall and to interact with it. Thus, the cell membrane is damaged in the presence of TiO_2 and the wall of the cell is disintegrated, which leads to its extinction [16].

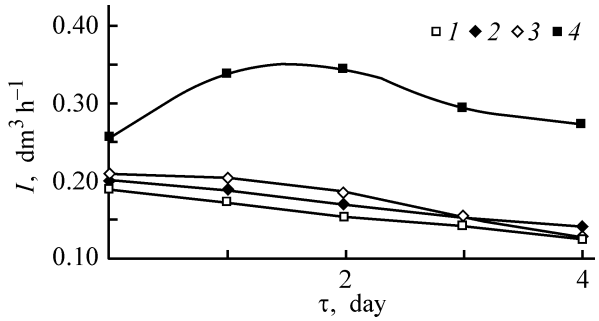

Fig. 4. Throughput *I* of PSSS-100H membrane samples with *P. putida* deposited on their surface vs. the time τ of contact with river water (ΔP = 0.3 MPa). Membrane samples: (*1*) without TiO_2 in the dark, (*2*) with TiO_2 in the dark, (*3*) without TiO_2 with UV, and (*4*) with TiO_2 with UV; the same for Fig. 5.

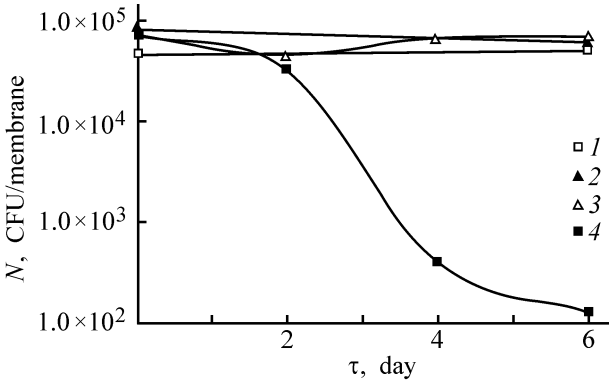

Fig. 5. Effect of TiO_2 deposition and UV irradiation on the concentration of *P. putida* cells on the PS-100H membrane. (*N*) Concentration of *P. putida* and (τ) process duration.

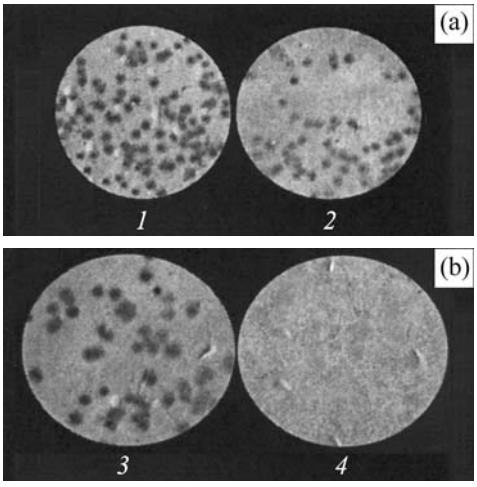

Fig. 6. Photograph of the surface of (*1*, *3*) initial PS-100H membrane and (*2*, *4*) its samples after deposition of TiO_2. *P. putida* suspensions with initial concentrations of (a) 10^2 and (b) 10 CFU cm^{-3} was filtered across the membranes, the samples were irradiated with UV light for 4 h.

Photographs of the surface of membranes across which *P. putida* suspensions with concentrations of 10^2 (Fig. 6a) and 10 CFU cm^{-3} (Fig. 6b) were passed demonstrate the efficiency of surface modification of polymeric membranes with a finely dispersed titanium dioxide powder. In each pair of samples, one membrane was covered with TiO_2 and irradiated with UV light for 4 h, and the other remained unchanged. The difference in the number of colonies on modified and untreated membranes is well noticeable even under visual inspection.

A calculation of the number of colonies gave the following values (FCU/membrane): (a) initial membrane 85, irradiated sample with TiO_2 43; (b) initial membrane 37, irradiated sample with TiO_2 0. Thus, in the case of filtration across membranes of a suspension of *P. putida* with an initial concentration of 10^2 CFU cm^{-3}, the number of bacteria on the membrane decreased because of the bactericide effect of TiO_2 and UV irradiation by 49.4%; at a concentration of 10 CFU cm^{-3}, the decrease was by 100%.

CONCLUSIONS

(1) The tendency of microorganisms to adhere to the surface of membranes becomes more pronounced as the hydrophobicity of the cell surface increases. In particular, the comparatively hydrophilic cells of *E. coli* show a considerably lower adhesion, compared with the more hydrophobic *A. calcoaceticus* and *P. putida*.

(2) The throughput of membranes with microorganisms deposited on their surface decreases in the course of their contact with river water because of the biological overgrowth of the membranes.

(3) Upon deposition of a finely dispersed TiO_2 powder and UV irradiation, the number of microorganisms on the membrane surface markedly decreases and the throughput of the thus treated membrane samples considerably increases, which indicates that the method described can be used to modify the surface of membranes to diminish their biological contamination.

ACKNOWLEDGMENTS

Abstract—Results are presented of a seven-stage counterflow extraction of C_6–C_8 aromatic hydrocarbons from the reformate of the gasoline fraction with a mixed extracting agent composed of triethylene glycol, sulfolane, and water, containing 37.6–57.6 wt % sulfolane.

DOI: 10.1134/S1070427207040143

A process for extraction of aromatic hydrocarbons from the reformate of the 62–105°C fraction with a mixed extractive agent composed of triethylene glycol (TEG) and sulfolane has been developed at St. Petersburg State Technological Institute in cooperation with OOO "Pa Kirishinefteorgsintez" [1–4]. The process developed was implemented on an LG-35-8/300B installation [5].

The use of a mixed selective solvent containing 15 wt % sulfolane, instead of aqueous TEG, made it possible to reduce the ratio of the extracting agent and recycle to the feed by 20% or, in another operation mode, raise the degree of recovery of arenes by 2.1%. In 2002, the use of the mixed extracting agent allowed additional isolation of 2.2 thousand tons of arenes, with an economic effect of about 18 million roubles, resulting from additional sales of products and a decrease in the energy expenditure [6].

With the content of sulfolane in the mixed extractive agent further raised to 25–30 wt %, it became possible, as a result of a decrease in the necessary ratio of the extractive agent to the feed, to use an additional source of raw material for the extracting unit, a part of the prexylene fraction from the installation for total xylenes, with recovery of an additional amount of toluene and benzene. The resulting economic effect obtained by OOO "Pa Kirishinefteorgsintez" was 34 million roubles in 2004 and 32.6 million roubles in the first eight months of 2005 [7].

Transfer of the installation from operation with a mixed solvent to that with pure sulfolane would require a substantial reconstruction of the extracting unit, which is due to the need to regenerate sulfolane from the extract phase by vacuum distillation, with the diameter of the stripping tower increasing.

The aim of this study was to determine the optimal conditions of extraction of C_6–C_8 arenes from the reformate with TEG–sulfolane mixtures containing 37.6–57.6 wt % sulfolane. The increased content of sulfolane in the mixed selective solvent should lead to an increase in its selectivity and dissolving power with respect to arenes and to the resulting possible decrease in the ratios of both the extractive agent and the recycle to the feed of extractor. Further decrease in the expenditure of the recycle and in the total flows in the extractor seems to be possible on replacing the recycle containing C_6–C_8 hydrocarbons with the pentane recycle. Because of the increased solubility of pentane in polar solvents, compared with C_6–C_8, the content of these alkanes in the extract phase should decrease. In addition, the higher relative volatility coefficients of pentane, with respect to benzene and toluene, will lead to a decrease in the content of these aromatic hydrocarbons in the recycle, which will also make lower the recycle expenditure and will improve the throughput of the extractor in terms of the raw material.

Table 1. Parameters of the raw material (reformate) and recycle from the LG-35-8/300B installation

EXPERIMENTAL

A reformate sample from the LG-35-8/300B installation at OOO "Pa Kirishinefteorgsintez," combine with the prexylene fraction from the installation of total xylenes. The reformate is characterized in Table 1. The same table lists parameters of a factory sample of the recycle: recirculating flow returned into the extractor, in which saturated hydrocarbons remaining in the extract phase are concentrated.

The recycle contains a large amount of benzene, with toluene also present. The fact that even toluene finds its way into the recycle is due to a single-stage equilibrium in the single-evaporation chamber and to the low relative volatility coefficients of saturated hydrocarbons C_7–C_8, with respect to toluene, in the presence of a mixed TEG–sulfolane extractive agent.

The multistage extraction was performed in a set of thermostated separating funnels by the scheme of a counterflow process simulating the operation of the extraction column [9] (see Table 2).

The composition of the equilibrium phases was analyzed by means of gas-liquid chromatography using as fixed phases polyphenyl methyl siloxane and Carbowax-20M on a Chromaton-N-AW-HMDS inert solid support.

The raffinate phase was washed with water to complete removal of admixtures of selective solvents. The recycle was evaporated by rectification of the extract phase on a column with an efficiency of 15 theoretical plates, and then the aromatic extract was obtained by distillation with steam.

The parameters of the raffinates and extracts obtained are listed in Table 3, and the degrees of recovery of arenes, in Table 4.

As follows from the data in Tables 3 and 4 and previously published results [5], raising the content of sulfolane in the mixed extractive agent from 15 to 57.6 wt % makes it possible to reduce the mass ratio of the extractive agent to feed from 6.5 : 1 to 3 : 1, i.e., by more than a factor of 2 at a close degree of recovery and quality of aromatic hydrocarbons. The increased content of sulfolane (selective solvent with a high dissolving power and viscosity lower than that of TEG) makes it possible to lower the temperature of the extraction process, which leads to an additional increase in the separation selectivity and reduction of the recycle expenditure.

Use of a pentane recycle (run no. 4), instead of C_6–C_8 hydrocarbons results in that toluene is excluded from its composition and the recycle contains a con-

xylenes	92.0	90.0	93.7	92.0

siderably smaller amount of benzene, 15–30 wt %. The expenditure of the recycle decreases in this case to 23 wt % relative to the feed.

The considerable reduction of the recirculating flows of a mixed extracting agent with increased content of sulfolane and of the recycle makes it possible to improve the output capacity of the existing extractors in terms of the raw material. As an additional source of feed for the extractor of LG-35-8/300B installations can serve not only the prexylene fraction from the installation for total xylenes, but also the benzene fraction of the reformate of the broad gasoline fraction, which will solve the topical ecological problem of reducing the content of benzene in automotive gasolines.

Use of a mixed TEG–sulfolane–water extractive agent with increased content of sulfolane, instead of a switchover of the installation to pure sulfolane as selective solvent, does not require any significant reconstruction of the existing installations. The stripping of the extract to remove the mixed extractive agent does not require vacuum distillation, which is due to the absence of strong intermolecular interactions in the TEG–sulfolane system [2]. The weak hydrogen bonds in this system are due to the low basicity of sulfolane, compared with sulfoxides, amines, ketones, and amides [10]. In accordance with the conditions for azeotrope formation [11], the close saturated vapor pressures of TEG and sulfolane and positive deviations from Raoult law for the TEG–sulfolane system lead to formation of an azeotropic mixture with the minimum boiling point, which facilitates the regeneration of the mixed extractive agent.

CONCLUSIONS

(1) Raising the content of sulfolane in the mixed extractive agent composed of triethylene glycol and sulfolane from 15 to 57 wt % makes it possible to reduce the mass ratio of the extractive agent to the raw material by more than a factor of 2 and the expenditure of the recycle from 80–100 to 30 wt % relative to the raw material.

(2) Use of a pentane recycle instead of C_6–C_8 hydrocarbons results in that toluene is excluded from its composition, the content of benzene in the recycle

becomes considerably lower, and the expenditure of the recycle additionally decreases.

Abstract—Seven-stage counterflow extraction of aromatic hydrocarbons from the toluene–xylene fraction of the reforming catalysate with sulfolane and its mixtures with triethylene glycol was studied. A liquid–liquid phase equilibrium diagram is presented for a pseudoternary system that includes saturated and aromatic hydrocarbons of the toluene–xylene fraction of the reformate and a mixed extractive agent composed of triethylene glycol, sulfolane, and water (48.1 : 48.1 : 3.8 wt %).

DOI: 10.1134/S1070427207040155

It has been suggested to use a mixed selective solvent composed of triethylene glycol, sulfolane, and water as an agent for extraction of arenes C_6–C_8 from the reformate of the 62–105°C fraction [1–4]. In 2000, this method for extraction of arenes was implemented on an LG-35-8/300B installation at OOO "PA Kirishinefteorgsintez" [5].

In view of modern ecological requirements to the quality of automotive gasolines, the maximum permissible content of benzene in the gasolines is limited by 1 vol % [6]. Benzene can be effectively removed from the benzene fraction of the reformate by extractive distillation. For example, an installation for extractive distillation with a Tectiv-100 mixed extractive agent composed of industrially available selective solvents [7] is to be constructed at OOO "PA Kirishinefteorgsintez" under license from Glitsch Technology Co. After the new installation is put in operation, the extracting unit of the working LG-35-8/300B installation can be used to obtain toluene and total xylenes. In doing so, there will be no need to change the technological scheme of the installation, provided that the TEG–sulfolane mixed extractive agent will be used.

However, the activity coefficients and critical solution temperatures (CST) of xylene isomers in polar solvents markedly exceed those for benzene. For example, a mixed TEG–sulfolane extractive agent of 70 : 30 wt % composition forms a homogeneous system with benzene at 25°C, the CST with toluene is 58.3°C and those with C_8 arenes are even higher [2]. Therefore, it is desirable to extract xylenes with a mixed solvent with higher dissolving power, increased content of sulfolane.

The aim of this study was to compare the efficiencies of extraction of arenes from the toluene–xylene fraction with mixed TEG–sulfolane–water solvents of various compositions.

EXPERIMENTAL

Stable reformates from the LG-35-8/300B and LCh-35-11/600 installations of catalytic reforming of the benzene–toluene and xylene fractions at OOO "PA Kirishinefteorgsintez" were used as the starting raw material. A benzene fraction with IBP 90°C was distilled-off on a rectification column with an efficiency of 15 theoretical plates in yield of 64.0 and 11.5 wt %, respectively.

water	4.9	3.8	0.5
Mass ratio:			
extractive agent : feed	5.0 : 1	5.0 : 1	5.0 : 1
recycle : feed	0.5 : 1	0.3 : 1	0.3 : 1

Still bottoms containing no benzene according to chromatographic data were combined in accordance with the output capacity of the installations and yield of toluene–xylene fractions after rectification, i.e., in a 1 : 4.9 mass ratio.

The parameters of the combined toluene–xylene fraction are listed in Table 1.

Multistage counterflow extraction of arenes was performed with a mixed extractive agent in the presence of a recycle (recirculating hydrocarbon flow distilled-off from the extract phase) in a set of thermostated separating funnels by the classical scheme [8]. The conditions of the extraction experiments are listed in Table 2. In run no. 1, a TEG–sulfolane–water mixture circulating in the LG-35-8/300B installation was used as the extractive agent. An addition of technical-grade sulfolane to this extractive agent yielded a mixed selective solvent with equal contents of TEG and sulfolane, used in run no. 2. A technical-grade sulfolane containing 0.5 wt % water was used in run no. 3.

The composition of the equilibrium raffinate and extract phases was analyzed by GLC: Carbowax and PFMS-4 on a Chromaton-N-AW-HMDS solid support as fixed phases; 3-m-long chromatographic columns with inner diameter of 3 mm; carrier gas helium; temperature (°C): columns 70–190, evaporator 280, detector (katharometer) 250. The following calibration coefficients were used: saturated hydrocarbons 0.80, benzene 1.00, toluene 1.02, C_8 arenes 1.04, C_9 arenes 1.06, sulfolane 1.3, TEG 1.6.

The extractive agent was many times re-extracted from the raffinate phase with water. The recycle was evaporated from the extract phase on a rectification column with an efficiency of 15 theoretical plates and then the extract was isolated from the still bottoms by steam distillation.

Table 3 present as an example the material balance of extraction run no. 2, calculated using the yields of the raffinate and extract phases and their composition. The characteristics of the raffinates and extracts obtained are listed in Table 4.

The liquid–liquid equilibrium in the pseudoternary system constituted by saturated hydrocarbons, arenes from the toluene–xylene fraction of the reformate, and TEG–sulfolane–water mixed extractive agent (48.1 : 48.1 : 3.8 wt %) was examined at 60°C by an analytical method: single-stage extractions of arenes

Liquid–liquid phase equilibrium diagram for a pseudo-ternary system constituted by saturated hydrocarbons, arenes from the toluene–xylene fraction of the reformate, and TEG–sulfolane–water mixed extractive agent (48.1 : 48.1 : 3.8 wt %) at 60°C.

were carried out in a hermetically sealed thermostated vessel with a magnetic rabble at various ratios between the extractive agent and feed (see figure, Table 5). Table 5 also lists the distribution coefficients of arenes, calculated as ratios of their concentrations in the extract and raffinate phases, and separation coefficients found as the ratio of the distribution coefficients of aromatic and saturated hydrocarbons.

The results of run no. 1 are inferior to the operation parameters of the LG-35-8/300B installation in extraction of arenes from the reformate of the 62–105°C fraction: the content of arenes in the raffinate is considerably higher, and the degree of extraction of toluene and xylene is lower. This occurs for the following reasons: the considerably higher content of arenes in the feed (>70 wt %); lower degree of extraction of toluene and xylenes, compared with benzene, in extraction with any extractive agent; and smaller ratio between the extractive agent and the combined reformate.

The best way to improve the degree of extraction of toluene and xylenes is to make higher the content of sulfolane in the mixed selective solvent.

Raising the sulfolane : TEG ratio in the mixed extracting agent from 34.5 : 65.5 wt % to 50 : 50 wt % at a smaller recycle : feed ratio and all other extraction conditions being the same makes it possible to reduce the content of arenes in the raffinate by a factor of 1.72 and to raise the degree of extraction by 2.1 wt %.

It follows from the phase equilibrium diagram that the maximum content of arenes in the extract, which can be achieved without use of the recycle at 60°C, is about 87 wt %. This value is in agreement with the material balance of run no. 2 (Table 3), according to which the content of arenes in seven-stage counterflow extraction, in terms of the hydrocarbon part of the extract phase, is as high as 85 wt %.

As demonstrated by capillary GLC, minor admixtures of saturated hydrocarbons, which remain in the extract after rectification removal of the recycle from the extract phase, are represented by octane and higher-boiling alkanes and cycloalkanes C_{8+}.

The extractive recovery of xylenes, used instead of the rectification method presently employed at OOO "PA Kirishinefteorgsintez," will extend the boiling limits of the raw material in catalytic reforming and raise the output of xylenes.

Even higher is the degree of extraction of arenes from the toluene–xylene fraction of the reformate in run no. 3, with sulfolane containing no TEG used as the extractive agent (Table 4). The overall degree of extraction of arenes increases by 0.75 wt %, compared with run no. 2. However, replacement of the mixed extractive agent with neat sulfolane would involve a substantial reconstruction of the extracting unit of the LG-35-8/300B installation because it would be necessary to create vacuum in the stripping column and to replace it with a larger-diameter column [9].

CONCLUSIONS

(1) Seven-stage counterflow extraction of arenes from the toluene–xylene fraction of the reformate with a mixed extractive agent composed of triethylene glycol, sulfolane, and water (48.1 : 48.1 : 3.8 wt %) at a 5 : 1 mass ratio between the extractive agent and the feed will provide a >97% degree of extraction of toluene and xylenes without reconstruction of the extracting unit of the working LG-35-8/300B installation.

(2) The maximum content of arenes in the extract, achieved in extraction from the toluene–xylene fraction of the reformate at 60°C with a mixed extractive agent of the composition specified, without use of the recycle, is as high as 87 wt %.

Received July 5, 2006

Abstract—Recovery of arenes C_7–C_9 from the reformate of the gasoline fraction by a combined method was studied. The method consists in extraction with a mixed extractive agent composed of triethylene glycol, sulfolane, and water, followed by removal of saturated hydrocarbons from the extract phase by azeotropic distillation with ethanol.

DOI: 10.1134/S1070427207040167

In accordance with modern ecological requirements to the quality of automotive gasoline, the total content of aromatic hydrocarbons in the fuel should not exceed 30 vol %, and that of benzene, 1 vol % [1]. Previously, a combined method has been suggested for removal of excess benzene and its homologues from reformed gasoline by extraction with sulfolane, followed by removal of admixtures of nonaromatic hydrocarbons by extractive-azeotropic distillation with sulfolane and ethanol [2, 3]. As a result, a reformulated component of gasoline, which satisfies the requirements to the permissible content of benzene and total arenes, can be obtained. In this component, the decrease in the octane number is compensated for by the presence of a high-octane azeotrope-forming component, ethanol, which requires no regeneration. Simultaneously, commercial benzene, toluene, xylenes can be recovered with a low overall ratio of sulfolane to the feedstock in both stages of the process and, consequently, with a low specific energy expenditure.

To solve the priority problem, to diminish the benzene content of gasolines, it has been suggested to extract benzene from the benzene fraction of the reformate by extraction with sulfolane [4] or by extractive distillation with *N*-formylmorpholine [5]. It is planned by OOO "Pa Kirishinefteorgsintez" to extract benzene by extractive distillation with the use of a mixed selective solvent by the process developed by GTC Co. [6].

After a new installation for extractive distillation is put in operation, the already functioning LG-35-8/300B installation can be used for extractive lowering of the total content of arenes in automotive gasolines and simultaneous recovery of toluene and xylenes. OOO "Pa Kirishinefteorgsintez" employs a mixed extractive agent composed of triethylene glycol (TEG), sulfolane, and water is used for extraction of benzene and toluene. Therefore, it is appropriate to use the same extractive agent for extraction of arenes from a higher-boiling fraction of the reformate.

The aim of this study was to determine the efficiency of extractive removal of the excess amount of C_7–C_9 arenes from the reformed 95–180°C gasoline fraction with TEG–sulfolane–water mixtures with varied content of sulfolane, with the subsequent azeotropic distillation of the extract phase with ethanol.

EXPERIMENTAL

Reforming catalyzates produced in LG-35-8/300B, LCh-35-11/600, and LCh-35-11/1000 installation for catalytic reforming at OOO "Pa Kirishinefteorgsintez" were used as the starting raw material. The benzene fraction with IBP of 90°C was distilled-off from the catalyzates on a rectification column with an efficiency of 15 theoretical plates in 64, 11.5, and 20 wt % yields, respectively. The still bottoms

hydrocarbons of about 2.5 : 1 and the resulting azeotropic mixtures were distilled-off on a rectification column with an efficiency of 15 theoretical plates. Table 4 presents the material balance of the azeotropic distillation with ethanol of the extract phase produced in run no. 2. The distillate was combined with the raffinate obtained from the raffinate phase after washing with water to remove the extractive agent. An aromatic concentrate was removed by distillation with steam from the still bottoms formed in azeotropic distillation. The composition of the products obtained was analyzed by GLC [8].

The products isolated in run nos. 1–3 are characterized in Table 5.

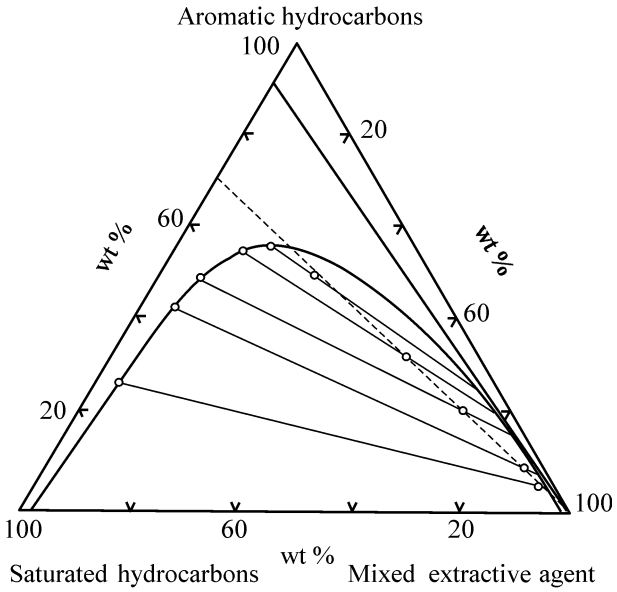
The liquid–liquid phase equilibria in the pseudoternary system constituted by saturated hydrocarbons, C_7–C_9 arenes, and a mixed extractive agent (TEG–sulfolane–water, 48.1 : 48.1 : 3.8 wt %) were studied at 60°C by the analytical method [8] (Table 6, see figure).

It follows from the data in Table 5 that, under the conditions of run no. 1, a reformulated gasoline component satisfying the requirements of Euro-3 can be obtained at a sulfolane : TEG ratio of 34.5 : 65.5 wt % in the mixed solvent. According to these requirements, the total content of arenes in automotive gasolines should not exceed 42% [9]. Because deep rearomatization of the reformate is unnecessary in this case, the ratio between the extractive agent and the feed is as low as 2.5 : 1 (by mass) or 1.7 : 1 (by volume), which is markedly lower than that in industrial extraction processes used in manufacture of benzene and its homologues [10].

Run no. 2, at a sulfolane : TEG ratio of 50 : 50 wt % in the mixed solvent and the same ratio between the extractive agent and the feed yields a reformulated gasoline component satisfying with a safety margin the requirements of Euro-4 and Euro-5 to the total content of aromatic hydrocarbons.

As follows from the figure, the maximum concentration of arenes in the extract, which can be achieved at 60°C without recycling, is 91.5 wt %, in agreement with the results presented in Table 5.

An even deeper dearomatization of the reformate occurs under the conditions of run no. 3, with sulfolane used as the extractive agent. The combined ethanol-containing raffinate obtained in run nos. 2 and 3 can be compounded with the reformate of the gasoline fraction, which is not subject to extractive dearomatization.



Liquid–liquid phase equilibrium diagram for the pseudoternary system constituted by saturated hydrocarbons, arenes from the C_7–C_9 fraction of the reformate, and a mixed solvent (TEG–sulfolane–water, 48.1 : 48.1 : 3.8 wt %) at 60°C.

The compounding of the combined raffinate with the reformate of the gasoline fraction as well as with alkylates and isomerizates, can be performed with account of the GOST (State Standard) 52 201–2004 in force in Russia, according to which the ethanol motor fuel should not contain more than 10% ethanol [11]. In order to homogenize the system, high-octane alcohols C_3–C_4 and, in particular, isobutyl alcohol, which exhibits a synergistic effect in mixtures with ethanol [12], can be added to fuel gasoline formulations.

The aromatic concentrates obtained contain a minor admixture of saturated hydrocarbons, mostly C_8–C_9. For example, according to capillary GLC, the contents of saturated hydrocarbons with different numbers of carbon atoms, which remain in the aromatic concentrate produced in run no. 2, are as follows (wt %): C_7 0.08, C_8 0.33, C_9 0.09. A fractionation of the aromatic concentrate yielded high-quality toluene, a minor amount of the prexylene fraction (about 0.5 wt %), in which admixtures of isooctanes and *n*-octane are concentrated, and C_8 arenes; C_9 arenes remain the still bottoms.

The advantages of the process suggested for diminishing the total content of arenes in automotive gasolines, with simultaneous recovery of toluene and xylenes, consist in the low ratio between the extractive agent and feed and in the absence of recycling flows impairing the output capacity of extraction apparatus.

CONCLUSIONS

(1) A combined method was suggested for extraction of C_7–C_9 arenes from the reformate of the gasoline fraction with a mixed solvent composed of triethylene glycol and sulfolane (50 : 50 wt %), with the subsequent removal of admixtures of saturated hydrocarbons from the extract phase by azeotropic distillation with ethanol, without regeneration of the alcohol. The method can produce a reformulated gasoline component satisfying the Euro-4 and Euro-5 requirements to the total content of arenes.

(2) Commercial toluene and total xylenes were recovered by distillation from the resulting aromatic concentrate. The process is characterized by low extractant-to-raw material ratio and absence of recycling flows.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

A Study of Effect of Agitation Intensification on the Size and External Shape of Silver Bromide Crystals Produced by Controlled Ostwald Growth in the Presence of Dimethyl Sulfoxide

A. Dionizy, P. Nowak, and C. Mora

Institute of Physical and Theoretical Chemistry, Wroclaw University of Technology, Wroclaw, Poland

Received September 26, 2006

Abstract—Results obtained in a study of the effect of agitation intensification on the granulometric properties of silver bromide crystals contained in photographic emulsions and produced by controlled Ostwald growth are presented.

DOI: 10.1134/S1070427207040179

Published and patent data of recent years point to the possibility of technological use of silver halide crystals produced in the form of strongly flattened plates by crystallization from solutions containing polar aprotic solvents [1–7]. The still presently used methods for production of silver halide crystals use aqueous-gelatin solutions as the reaction medium [8–10]. Planar crystals of silver halides (tabular crystals, T-crystals) are also obtained in an aqueous medium, but, in this case, complex organic compounds, the so-called growth directors or modifiers are most frequently used. Owing to the high sensitometric and structuremetric parameters of light-sensitive layers formed by tabular crystals, they are presently used in the technology of light-sensitive materials of nearly all types, especially in highly sensitive materials intended for diagnostics in medicine and industrial defectoscopy. However, wide use of these methods to obtain prescribed granulometric and crystallographic properties is exceedingly difficult because exhaustive data on the mechanism of formation of crystals of this kind in the presence of growth modifiers are still lacking [11–13].

Recently, several methods have been suggested for crystallization of silver halides in nonaqueous media, mostly with use of polar aprotic solvents (or mixtures of these) or aqueous media with other organic solvents, to give silver halide crystals with desirable crystalline shape and granulometric parameters [14–17]. Of particular interest are techniques for synthesis of tabular crystals [11, 13, 18–22]. The tabular silver halide crystals obtained under these conditions are characterized by presence of two or several twinning planes and a comparatively large number of crystal lattice defects. Presence of these defects is necessary for formation, in the course of chemical sensitization, of impurity sensitivity centers with precisely defined topography in the bulk of the crystal. They also act as the so-called sensitivity centers, which are highly efficient traps for holes and electrons.

Of certain importance is the high efficiency of the process of chemical sensitization of tabular silver halide crystals; it appears via formation of comparatively large dye aggregates on large undistorted {111} faces of the crystals. For example, high efficiency of the spectral sensitization is not observed in the case of compact (spherical) crystals. The advantage of the tabular crystals has aroused researchers' interest in methods for synthesis of crystals of this kind, despite the intensively developing technology of digital photography.

Recently, interesting experimental data have been published on synthesis of silver halide light-sensitive emulsions obtained in aqueous-gelatin solutions of aprotic polar solvents or mixtures of these and(or) protic solvents whose dissociation constant is lower than that of water. These results indicate that the efficiency of light-sensitive layers containing light detectors in the form of strongly flattened hexagonal or trigonal crystals of silver halides can be improved [1, 4–7, 23–25].

The results reported in these papers formed the basis for the present study, whose main goal was

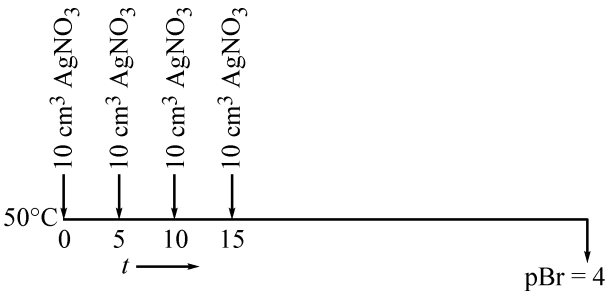

Fig. 1. Scheme of synthesis of the Lippmann emulsion.

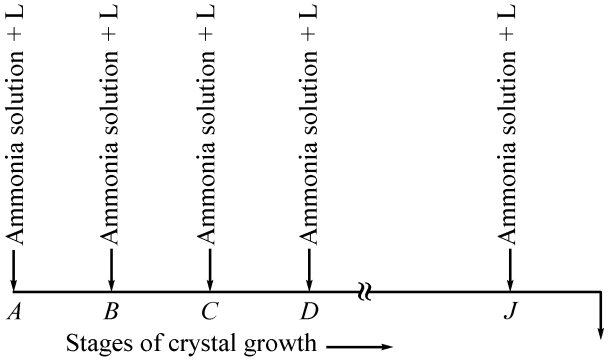

Fig. 2. Synthesis stages of the model emulsion by the COR method.

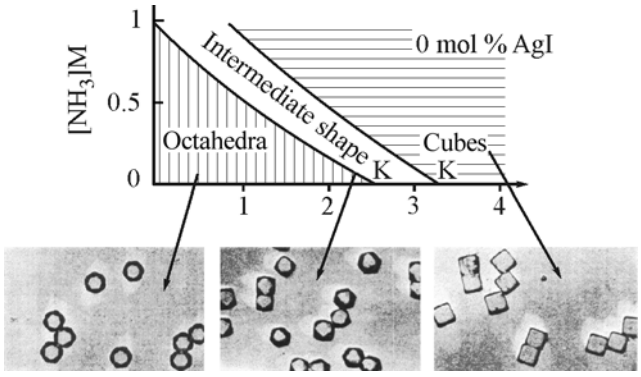

Fig. 3. Scheme of stability of the 3*D* shapes of silver bromide crystals obtained by the COR method in relation to the excess concentration of bromide ions and ammonia [26].

to determine whether or not dimethyl sulfoxide (DMSO) can be used to synthesize light-sensitive emulsions containing tabular crystals of silver bromides by controlled Ostwald ripening (COR). Particular attention was given to the influence exerted by the intensity of agitation of the reaction mixture on the growth rate of silver halide crystals and, consequently, on their size, polydispersity, and shape.

The COR method is a way to fabricate silver-halide model emulsions. It was developed by Romer and Markocki in 1962 [25]. This method is based on production of a certain ensemble of silver halide crystals in an aqueous solution of gelatin at a comparatively low supersaturation and permanent addition of combined ions necessary for crystal growth. Uniform ensembles of silver halide crystals are obtained at a certain constant excess of halide ions, whose concentration, as well as that of other ingredients that form complexes with silver halides, predetermines the shape of the growing crystals.

First, a Lippmann emulsion (L) containing AgHal crystals about 0.01–0.05 μm in size is synthesized at a final concentration of excess bromide ions c = 0.0001 M (pBr 4) (Fig. 1).

In the next stage, a nucleation emulsion with crystals about 0.1–0.3 μm in size is prepared from the Lippmann emulsion (Fig. 2). To this emulsion are successively added (Fig. 2, crystal growth stages *A*, B, *C*, ...) in certain proportions the Lippmann emulsion and solutions of ammonia and potassium bromide. In the presence of substances that enhance the solubility of silver chlorides, fine crystals of the Lippmann emulsion rapidly dissolve and are then precipitated on the surface of large, compared with thee crystals, growing crystals of the nucleation emulsion. The end of the successive stages of crystal growth, as well as that of the whole process of emulsion synthesis, is monitored with a microscope. This method can be used to rapidly obtain comparatively large silver halide crystals with properties similar to those of crystals produced by the double-jet technique.

The COR method can be used to obtain, using the stability conditions of certain forms of AgHal, known from the literature [26], model emulsions containing desired crystals by varying the concentration of ammonia and excess bromide ions. The stability scheme of the shapes of silver halide crystals [26] is shown in Fig. 3. The most recent published data indicate that the COR method can be used, which is considerably simpler than the conventional techniques for synthesis of tabular AgHal crystals with aprotic solvents, e.g., DMSO [27].

Several emulsions were synthesized at a constant excess concentration of bromide ions [c = 0.3 M (pBr 0.5)], constant ionic strength I = 0.54, and constant content of DMSO in the reaction mixture (50 vol %). These emulsions were synthesized in the same reaction vessel under constant topochemical conditions at a varied rotation rate of the rabble, without changes in its configuration. In contrast to the conventional methods for emulsion synthesis by

the COR method, the ammonia solution was replaced with an appropriate amount of DMSO. The scheme of emulsion synthesis is shown in Fig. 4. The next stages of emulsion synthesis were preceded by taking a 40-ml sample of the reaction mixture to maintain constant the liquid level in the conical reaction vessel (level height fluctuations of up to 6.7%; Fig. 5) and preserve to the maximum possible extent the exchange conditions in the entire volume of the reaction mixture. The agitation intensity was changed by varying the rotation rate of the two-blade impeller of the rabble. Three rabble rotation rates were used in the experiments: 430, 650, and 1050 rpm. After each synthesis stage (*A*, *B*, *C*, ...) the emulsion was sampled and preparations for inspection under a microscope were produced. Micrographs of AgBr crystals formed in a certain growth stage under various agitation conditions are shown in Fig. 6. Analysis of changes in the shape and size of the crystals demonstrates that the average size of silver bromide crystals grows and their shape changes as the agitation rate increases and in the course of recrystallization.

The emulsions obtained at the slowest rotation rate of the rabble (430 rpm) contain nearly exclusively planar hexagonal silver bromide crystals with well defined faces and vertices. This indicates that, under the given conditions, there occurs an exceedingly uniform recrystallization process leading to the formation of a nearly uniform ensemble of crystals. The average size of the AgBr crystals obtained under these conditions was about 40 μm. The crystals obtained under the identical conditions, but at a high rotation rate of the rabble (650 rpm), also grow as well-defined hexagonal plates. The average size of these crystals is about 55 μm, with the forming ensembles exhibiting a considerably higher polydispersity, compared with crystals obtained at a lower rotation rate of the rabble (430 rpm). Further increase in the rotation rate to 1050 rpm results in that the AgBr crystals become larger (up to 65 μm) and their polydispersity grows. In addition, undesirable changes of the shape of the crystals occur under the conditions of such an intensive mass exchange, which is manifested in rounding of the faces and vertices of the tabular AgBr crystals. Also observed is a mechanical damage to large tabular crystals, which occurs as a result of mutual friction of mostly large crystals; very thin tabular crystals are most easily mechanically deformed under the conditions of vigorous agitation.

An analysis of changes in the granulometric parameters of photographic emulsions produced by the COR method in the presence of DMSO at a variable rotation rate of the rabble demonstrated that an increase in the rotation rate, on which the rate of mass exchange in the reactor depends, affects the rate of recrystallization of tabular silver bromide crystals. This effect causes the following: (1) the average size of the crystals increases in each stage of the synthesis process; (2) the polydispersity of the crystals becomes more pronounced and noticeably grows with the recrystallization time; and (3) the crystallographic shape of the crystals is more distorted, which is manifested in rounding of the faces and vertices of tabular crystals and, in the final stage of the emulsion synthesis, in mechanical damage to the largest crystals and formation of bulk crystals.

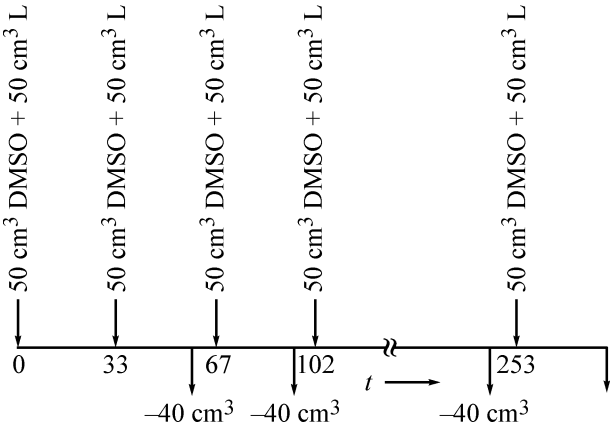

Fig. 4. Scheme of emulsion synthesis by the COR method with 50% DMSO.

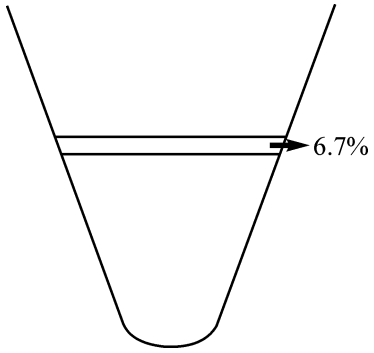

Fig. 5. Change in the level of the reaction mixture in the conical reactor during emulsion synthesis by the COR method by the scheme in Fig. 4. A change in the liquid volume by 30% at an initial volume of 120 cm^3 leads to a change in the height of the liquid level in the reactor by 6.7%.

In the course of emulsion synthesis and, consequently, during the occurring recrystallization, the size of tabular silver bromide crystals steadily grows at each agitation rate. The course of these changes is

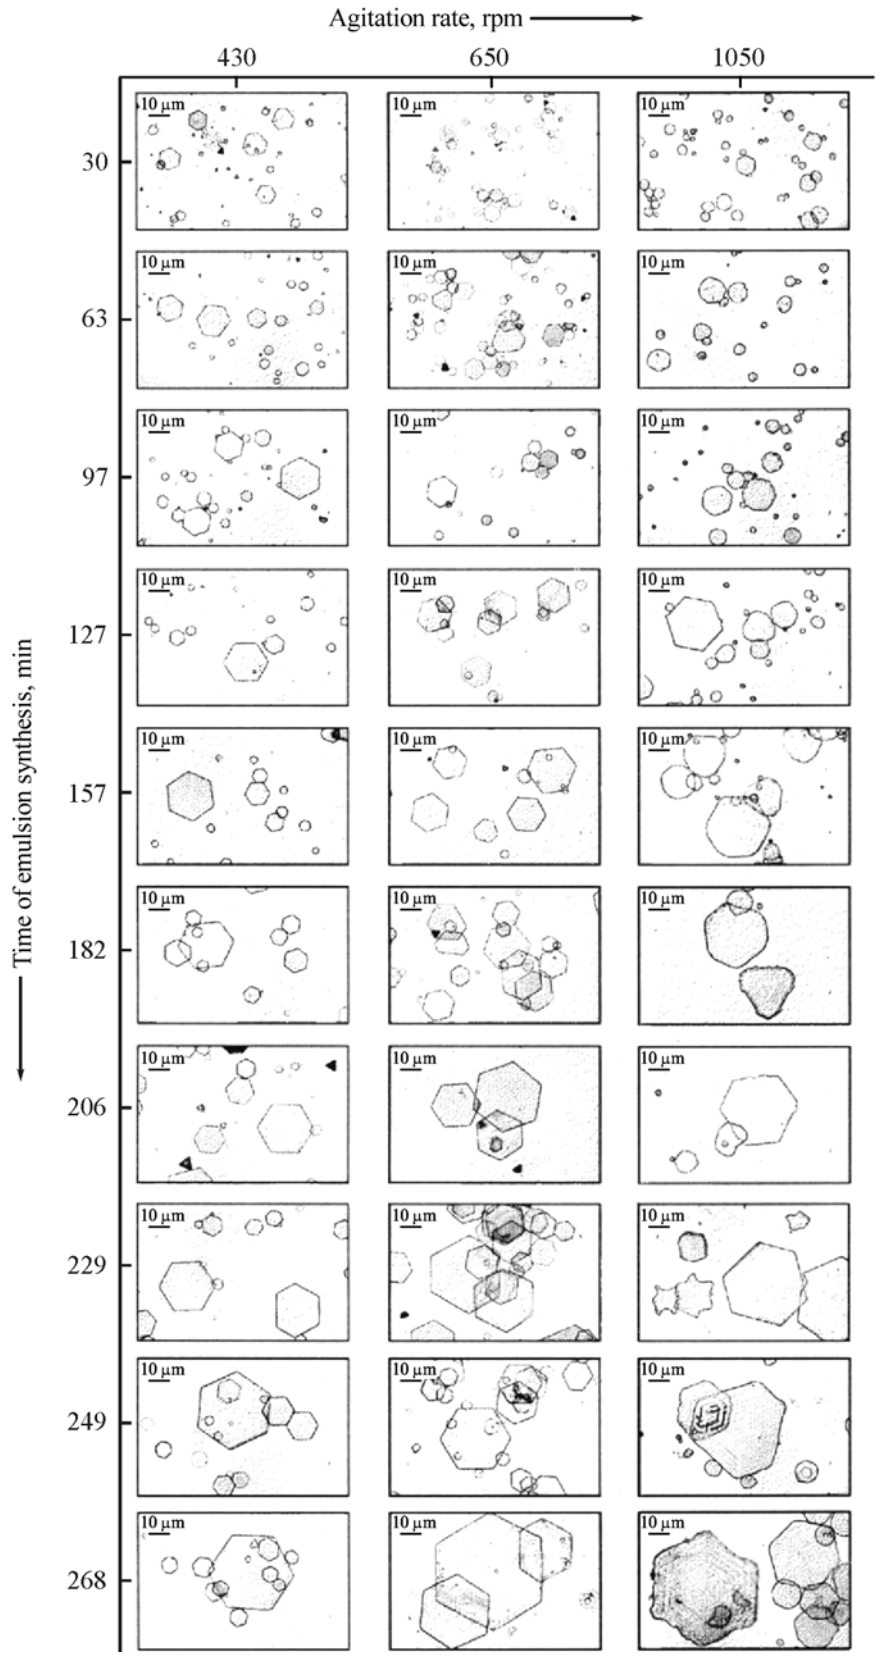

Fig. 6. Microphotographs of silver bromide crystals obtained in synthesis of photographic emulsions by the COR method in the presence of DMSO at various agitation intensities.

shown in Fig. 7. At an agitation rate of 1050 rpm, the crystals grow in size the most rapidly. It should, however, be remembered that, under these conditions, the shape of the crystals undergoes undesirable transformations and their polydispersity increases. Mostly rounded crystal shapes, frequently mechanically damaged and of the bulk type, are for the most part represented in the ensemble of crystals of thus prepared emulsions, with well-defined hexagonal tabular AgBr crystals contained in a minor amount. Making longer the recrystallization time at a vigorous agitation of the reaction mass also leads to a decrease in the shape factor, i.e., leads to formation of bulk-type crystals.

Analysis of the shape of tabular AgBr crystals formed in the final stage of synthesis of some emulsions prepared at different agitation rates (Fig. 6, 268 min of synthesis) shows that the finest, mostly hexagonal, tabular silver bromide crystals of the best shape are produced at a comparatively slow agitation. Intense mass-exchange during synthesis of photographic emulsions by the COR method in the presence of DMSO does not favor formation of tabular silver bromide crystals with well-pronounced granulometric properties, but results in an increase in the average size of the crystals.

No uniform, so-called monodisperse, emulsions were produced in the study. However, ensembles of hexagonal tabular crystals containing more than one twinning plane were obtained. The formation of tabular hexagonal crystals of silver bromide is due to the presence in the reaction mixture of molecular complexes of silver salts, stabilized by DMSO. Complexes of this kind favor formation of first a single type (trigonal crystals), and then a succession of twin crystals, which, in the end, promotes lateral growth of a crystal in the form of a hexagonal plate. Probably, during successive introduction of silver bromide portions in the form of a Lippmann emulsion, there occurs, in parallel with the Ostwald crystallization leading to growth of the already existing crystals, nucleation of a new ensemble of crystals. Under the conditions of emulsion synthesis, these latter are formed in the twin form and further grow via recrystallization and next twinning. Thus, presence of DMSO not only leads to an increase in the solubility of silver halides in the reaction medium and to lateral growth of tabular, but also, and above all, promotes constant twinning of AgBr crystals in each stage of their growth, despite that twinning planes are already present in the crystal. Just this circumstance hinders synthesis of monodisperse emulsions with hexagonal silver

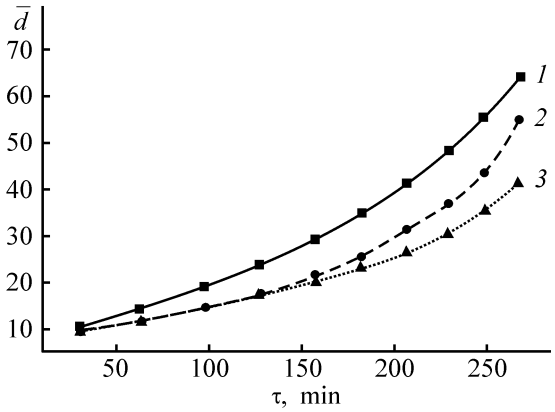

Fig. 7. Variation of the average size $\bar{d}$ of tabular silver bromide crystals, recorded in different stages of emulsion synthesis at three rotation rates of the rabble. (τ) Time of synthesis. ω (rpm): (*1*) 1050, (*2*) 650, and (*3*) 430.

halide crystals by controlled Ostwald growth in the presence of DMSO.

Undoubtedly, the method suggested for synthesis of photographic emulsions by controlled Ostwald growth in the presence of dimethyl sulfoxide opens up new opportunities in the technology of silver halide light-sensitive materials containing crystals having the shape of hexagonal plates.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of 2-Methoxy-3,6-dichloropropenylbenzene with Ozone

R. L. Safiullin and L. R. Enikeeva

Institute of Organic Chemistry, Ufa Scientific Center, Ufa, Bashkortostan, Russia

Received June 27, 2006

Abstract—Oxidation of 2-methoxy-3,6-dichloropropenylbenzene with ozone in acetic acid and carbon tetrachloride was studied.

DOI: 10.1134/S1070427207040180

Ozonolysis is one of the most promising methods for oxidation of hydrocarbons containing double bonds. In this study, we examined the formation of 2-methoxy-3,6-dichlorobenzaldehyde by ozonation of 2-methoxy-3,6-dichloropropenylbenzene (DCPB). 2-Methoxy-3,6-dichlorobenzaldehyde can serve as a starting compound for preparing 2-methoxy-3,6-dichlorobenzoic acid and its derivatives used in agriculture as herbicides [1–3]. It is known that the efficiency of ozonolytic conversion of olefins is determined by the decomposition of intermediate ozonolysis products, ozonides. In this study, we examined the thermal stability of ozonides formed by ozonation of 2-methoxy-3,6-dichloropropenylbenzene and the effect of acidity on their decomposition.

EXPERIMENTAL

2-Methoxy-3,6-dichloropropenylbenzene was purified by vacuum distillation under argon. Carbon tetrachloride (CCl_4) was successively treated with ozone, dried over $CaCl_2$, and distilled in argon. Methanesulfonic acid (CH_3SO_3H) and *p*-toluenesulfonic acid (*p*-$TolSO_3H$) of chemically pure grade were used without purification. Ozone was prepared from oxygen in a ozonizer with an output capacity of 0.5 g of ozone per hour at an oxygen consumption of 4 l h^{-1}.

The ozonation of DCPB and isolation of products of its conversion were carried out as follows. A solution of the olefin in acetic acid or CCl4 was purged with an ozone–oxygen mixture fed into the lower part of a reactor. The ozone content at the inlet and outlet of the reactor was determined spectrophotometrically at λ = 300 nm (ozone extinction coefficient 95 l mol^{-1} cm^{-1}) [4]. After the breakthrough of ozone through the reactor, the ozonation was stopped.

The intermediate compounds containing peroxy groups were determined by spectrophotometric iodometric titration [5]. The concentration of intermediates containing peroxy groups (–O–O–) was calculated by the equation

$$[–O–O–] = AV_{as}/(\varepsilon l V_s),$$

The extinction coefficient of I_3^- at λ = 360 nm is ε = 28 000 l mol^{-1} cm^{-1}, the optical cell width is 1 cm, the volume of the solution being analyzed V_{as} = 2.5–3.0 ml, and the introduced sample volume V_s = 2–10 μl.

The decomposition products of ozonized compounds were examined by ^1H and ^{13}C NMR, IR, and UV spectroscopies, and also by GLC. The ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker AM-300 NMR spectrometer (300 and 75 MHz, respectively).

Ozonation of the olefin in acetic acid solutions. 2-Methoxy-3,6-dichloropropenylbenzene (27.4 mol, 6.06 g) was dissolved in glacial acetic acid (50 ml) and ozonized at 315 K. In the course of the ozonation, the reaction mixture was sampled at regular intervals and the samples were titrated iodometrically. The reaction mixture was ozonized for 3 h . After the ozonation was complete, the ozonide concentration in the reaction mixture was 0.12 M.

Ozonation of the olefin in acetic acid containing water and *p*-toluenesulfonic acid. The initial mix-

ture to be ozonized (50 ml) contained olefin (6.06 g) dissolved in an acetic acid solution containing *p*-TolSO_3H (0.1 g) and H_2O (3.2 g). The ozonation was carried out at 315 K. After a lapse of 2 h 35 min, the ozonide concentration in the reaction mixture reached 0.2 M.

Ozonation of the olefin in CCl_4. In these experiments, solutions of the olefin in CCl_4 (50 ml) containing 6.06 g of the olefin were ozonized at 295 K. Although the ozone breakthrough occurred 40 min after the start of the reaction, the ozonation was continued for 3 h. Under these conditions, the ozonide content in the reaction mixture did not exceed 0.1 M.

* In CCl_4.

The thermal stability of ozonides formed by ozonation of the olefin was examined as follows. A portion of the reaction mixture was taken from the reactor and dissolved in acetic acid. This solution was placed in a temperature-controlled reactor equipped with a water-cooled reflux condenser and a stirrer. At certain intervals, the reaction mixture was sampled drawn and the concentration of the peroxy groups in was determined iodometrically. This experiment was continued until the degree of decomposition of the ozonide reached no less than 70%. To elucidate how the acidity affects the kinetics of acid-catalyzed decomposition of ozonides, weighed portions of the sulfonic acid were added to the reaction mixture.

Thermal stability of 2-methoxy-3,6-dichloropropenylbenzene ozonide. The thermal decomposition of the ozonide was examined in acetic acid solutions at 288–347 K. As can be seen from Fig. 1, 2-methoxy-3,6-dichloropropenylbenzene ozonide is stable at room temperature for several hours. We found that the addition of water (3.3 M) does not affect the kinetics of degradation of the ozonide. With increasing temperature, the ozonide stability decreases. Noticeable decomposition of the ozonide begins at 347 K. The kinetic curve of thermal decomposition of the ozonide is linear in the coordinates of equation of a first-order reaction, which allows calculation of the effective rate constant k_{eff} of the ozonide decomposition (see table). These data show that this rate constant is independent of both the initial ozonide concentration and solvent type, and its value is close to that of decomposition of 1-hexene ozonide [4].

Acid-catalyzed decomposition of ozonide. We found that addition of methane and *p*-toluenesulfonic acids (RSO_3H) accelerates the decomposition of the ozonide. Acetic acid used as the solvent (pK_a 4.75) [6] is weaker than methane- and *p*-toluenesulfonic acids (pK_a 0 and 0.7, respectively) [7]. The table shows that the ozonide decomposition is noticeably accelerated in the presence of methanesulfonic acid. The kinetic curve of ozonide decomposition in the presence of methanesulfonic acid is linear in the coordinates of equation of a first-order reaction, which allows calculation of the effective rate constant k_{eff} of ozonide decomposition. The effective rate constants k_{eff} of ozonide decomposition in the presence of sulfonic acids at varied temperature are listed in the table. Thus, with the content of sulfonic acid in acetic acid solutions increasing within the entire concentration

range, the stability of ozonides decreases, with k_{eff} weakly dependent on the initial ozonide concentration. Figure 2 shows that k_{eff} linearly depends on the sulfonic acid concentration. These correlations suggest that the rate of ozonide decomposition is described by the linear equation

$$W = k_{eff}[\text{ozonide}] = (k_0 + k_c[RSO_3])[\text{ozonide}]_0,$$

where k_0 is the rate constant of ozonide decomposition in the absence of sulfonic acid, and k_c, the rate constant of ozonide decomposition catalyzed by sulfonic acid.

The rate constants of ozonide decomposition in acetic acid containing a sulfonic acid were calculated from our experimental data for $[\text{ozonide}]_0 = 0.16$–$0.03$ M and are as follows: in the presence of *p*-toluenesulfonic acid, $k_0 = (3.5 \pm 1.5) \times 10^{-5}$ s^{-1}, $k_c = (1.5 \pm 0.3) \times 10^{-3}$ l mol^{-1} s^{-1}; and in the presence of methanesulfonic acid, $k_0 = (2.8 \pm 1{,}5) \times 10^{-5}$ s^{-1} and $k_c = (1.5 \pm 1.3) \times 10^{-3}$ l mol^{-1} s^{-1}.

It should be noted that the rate constant of acid-catalyzed decomposition of 2-methoxy-3,6-dichloropropenylbenzene ozonide determined in this study reasonably agrees with the rate constant of decomposition of 1-hexene ozonide catalyzed by *p*-toluenesulfonic acid in the presence of the accumulated aldehyde, 7.4×10^{-4} s^{-1} [8].

After the completion of the ozonide decomposition, the products of oxidative conversion of DCPB were isolated by two different methods. In the first method, water was added to the reaction mixture and the resulting yellow oily precipitate was treated with saturated aqueous Na_2SO_4 and cooled to 273 K. A grayish precipitate formed under these conditions was filtered off, washed with benzene, and dried. The ^{1}H and ^{13}C NMR spectra of this product formed in a yield of 98% were found to be identical to those of 2-methoxy-3,6-dichlorobenzaldehyde.

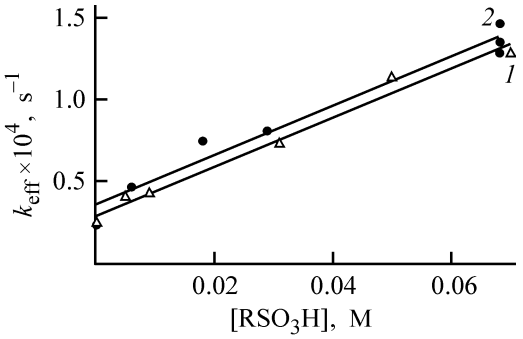

Fig. 2. Plot of k_{eff} vs. RSO_3H concentration at 347 K. (*1*) CH_3SO_3H and (*2*) *p*-TolSO_3H.

In the second method, acetic acid was distilled off from the reaction mixture, and the resulting precipitate was dissolved in CCl_4. This solution was filtered and CCl_4 was distilled off. The ^{1}H NMR spectrum of the resulting product formed in 96% yield contains a signal at 10.4 ppm belonging to the aldehyde group. The ^{13}C NMR spectra show that the product of oxidation of DCPB is 2-methoxy-3,6-dichlorobenzaldehyde.

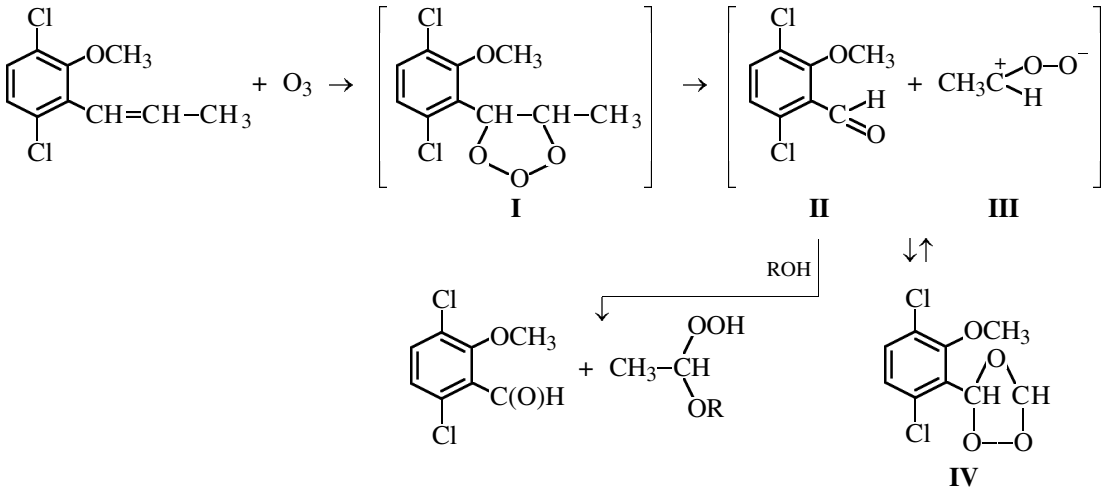
Our experimental results can be adequately described within the framework of the known mechanism of ozonation of unsaturated compounds [4]:



Chemical scheme of ozonation.

In this scheme, molozonide **I** formed by the reaction of ozone with the double bond is very unstable and decomposes to yield aldehyde **II** and carbonyl oxide **III**. Owing to the cell effect, some portion of carbonyl oxide has no time to escape into the bulk and reacts with the aldehyde to form more stable ozonide **IV**. This is evident from the fact that, if the components of the reaction mixture containing active oxygen are not decomposed, the aldehyde yield does not exceed 70%. At the same time, the yield of the product containing the –O–O– group increases in the course of ozonation and, after the reaction is complete, it is approximately 20% of the initial olefin amount.

Thus, the main part of aldehyde is formed by direct ozonation of 2-methoxy-3,6-dichlorobenzene. A small portion of the aldehyde (up to 20% of the initial olefin) is converted to ozonide by the reaction with the simultaneously formed carbonyl oxide. After decomposition of the ozonide in the presence of *p*-toluenesulfonic acid, 2-methoxy-3,6-dichlorobenzaldehyde is formed in a yield of up to 98%.

CONCLUSIONS

(1) The ozonation of 2-methoxy-3,6-dichloropropenylbenzene yields 2-methoxy-3,6-dichlorobenzaldehyde (up to 70%) and the corresponding ozonide.

(2) Strong acids catalyze the ozonide decomposition.

(3) The main ozonation product in acetic acid, formed in 98% yield after completion of decomposition of the ozonide, is 2-methoxy-3,6-dichlorobenzaldehyde.

Abstract—The possibility of preparation of nanocomposite materials with improved physicomechanical properties by polycondensation of spirocyclic silicates and diisocyanates was elucidated. The thermomechanical, spectral, and thermogravimetric properties of the resulting materials were examined.

DOI: 10.1134/S1070427207040192

Polymer-based nanocomposite materials are today a subject of intensive research because particles <200 nm in size are promising as fillers for preparation of items with novel properties [1]. Owing to the large surface area of nanosized filler particles, the interaction between the polymeric matrix and the inorganic component is enhanced. This, in turn, substantially improves the mechanical characteristics of articles, compared to those prepared using conventional micron-sized fillers [2].

Nancomposites are typically prepared by (1) mechanically mixing or exfoliating an inorganic material in the polymer [3, 4]; (2) polymerization of a vinyl type monomer in a mixture with finely ground inorganic material [5]; or (3) formation of filler nanoparticles by sol–gel technique within a the polymeric matrix [6].

All the above-mentioned approaches have both advantages and major drawbacks. For example, mechanical mixing of the components and polymerization in the presence of a filler suspension typically makes problematic a uniform distribution of the particles in the bulk of the composite, which markedly affects the strain-strength characteristics of the articles, namely, the relative elongation and the tensile stress decrease [1]. An alternative approach utilizing the sol–gel technique for generation of nanoparticles of SiO_2 [7] or other oxides, e.g., TiO_2 [8], allows preparation of items with uniform distribution of the particles within the polymeric matrix. In this case, the most widely used synthetic procedure consists in dissolution of a polymer or oligomer, prepared in advance, in a solvent common to the macromolecular compound and tetraalkoxylsilane, with the subsequent initiation of hydrolysis of the orthosilicate [7]. Despite the mild reaction conditions, this method of preparation of nanocomposites also has major drawbacks. For example, its application is substantially restricted by the insolubility of most of polymers in aqueous-organic media required for sol–gel processes. Also, the very high shrinkage (typically 50–75%) results in disintegration of articles prepared from composites obtained by this method [9]. To avoid these difficulties, Ellsworth and Novak [9, 10] suggested to prepare the composites from monomers to be involved in concurrent sol–gel and polymerization processes when exposed simultaneously to radical initiators and water. This made it possible to reduce the shrinkage to 15–20% owing to the lack of volatiles. However, such an approach does not allow use of the polycondensation reaction, whereas a large number of plastics widely used in industry belong to polycondensation polymers.

In this study, we elucidated the possibility of preparing nanocomposite materials via two concurrent polycondensation processes: preparation of SiO_2 by hydrolysis of spirocyclic orthosilicates and synthesis of the polymeric matrix by the reaction of the diol being eliminated with diisocyanate.

As the model system we chose commercially available 1,6-hexamethylene diisocyanate and spirocyclic 2,2-dimethylpropane-1,3-diol orthosilicate [11]. The choice of this system was dictated by the facts that (1) the polycondensation of diols with diisocyanates is not accompanied by release of by-products and (2) the synthesis of polyurethanes and formation of silica gel particles by sol–gel technique proceed at close temperatures (80–100°C). This decreases the prob-

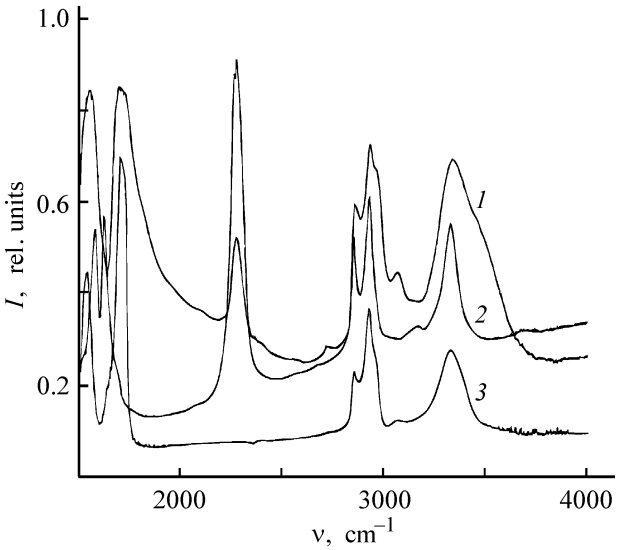

Fig. 1. IR spectra (KBr, IFS88 (Bruker) spectrometer). (*I*) Intensity and (ν) wavenumber. (*1*) Model polyurethane [poly-(2,2-dimethyl-1,3-propylene 1,6-hexamethylenecarbamate]; (*2*) model polyurea [poly(1,3-propylene-1,6-hexamethyleneurea]; and (*3*) nanocomposite.

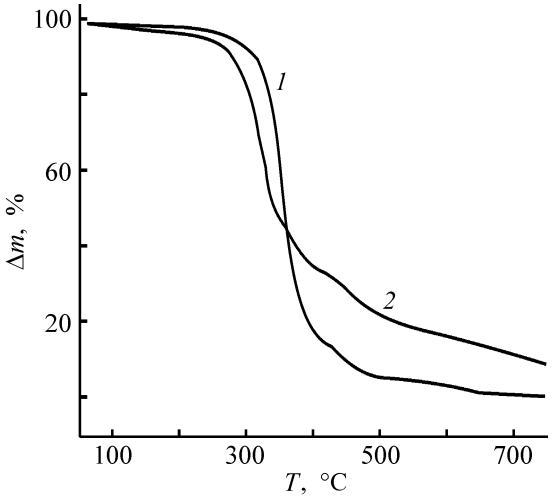

Fig. 2. Thermal gravimetric analysis curves. TGA-7 derivatograph (Perkin–Elmer); air; heating rate 10 K min^{-1}. (Δ*m*) mass loss and (*T*) temperature. (*1*) Model polyurethane [poly-(2,2-dimethyl-1,3-propylene 1,6-hexamethylenecarbamate] and (*2*) nanocomposite.

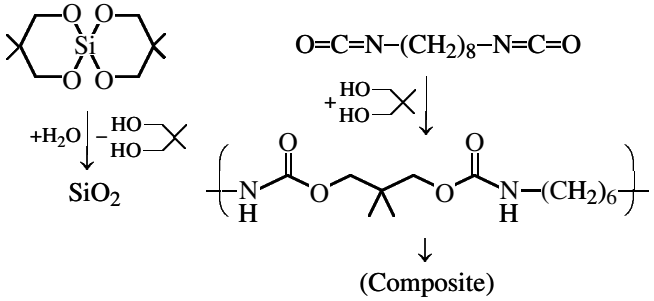
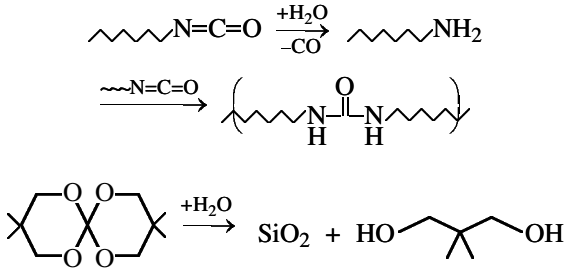
ability that the SiO_2 particles will grow in size because of an increase in the viscosity of the system and the diffusion limitations that preclude dehydration of the silanol groups on the filler surface.

Introduction of a controlled amount of water causes hydrolysis of the Si–O bonds of spirosilane and release of the diol, which further reacts with the diisocyanate. Heating the components at 100–120°C for 2–2.5 h yields a composite material suitable for preparation, under the reactive molding conditions, of transparent films and solid items. It should be noted that the shrinkage of the item being formed does not exceed 8–10%. Combined with strong adhesion to metal and glass, this makes the system of interest suitable for preparation of coatings.



General reaction scheme.

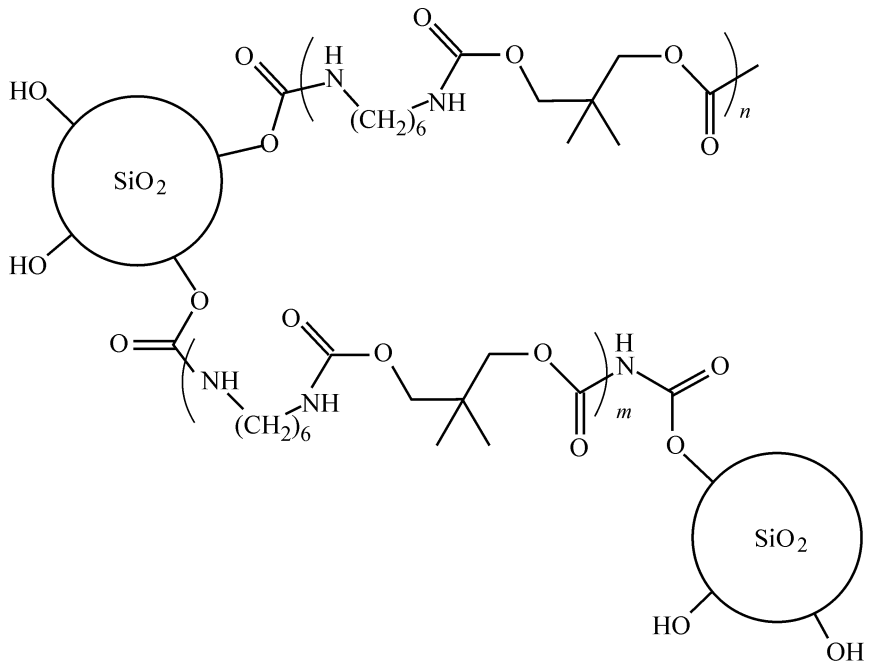
Clearly, introduction of water into the reaction mixture containing hydrolyzable isocyanate groups can result in formation of urea and cyanurate fragments in the polymeric part of the composite. The IR spectra of the composite (Fig. 1) do not contain bands at 1620 and 2250 cm^{-1} corresponding to vibrations of the carbonyl from the urea and isocyanate fragments, respectively. At the same time, the spectrum of unfilled poly(2,2-dimethyl-1,3-propylene 1,6- hexamethylenecarbamate) contains a rather intense absorption band with a maximum at 2250 cm^{-1}. This suggests that, under the actual conditions, the rate of hydrolysis of the Si–O bonds and formation of urethane bonds is much higher than that of hydrolysis of the isocyanate groups. Thus, the resulting polyurethane matrix is virtually free of the ureide and cyanurate fragments:



Comparison of the thermal properties of the model polymer and composite (Fig. 2) suggests that they are close in heat resistance. In both cases, upon heating in air, a 5% mass loss is observed near 295°C. However, upon further increase in temperature, the unfilled polymer virtually breaks down (mass loss 80%) at 345°C, while the composite loses 50% of its mass. In the latter case, the organic component completely disappears near 500°C, the residual mass being ~12%,

which approximately corresponds to the calculated amount of SiO_2 in the material.

Figure 3 presents a cross-sectional micrograph of the nanocomposite film, obtained by scanning electron microscopy. It is seen that the filler nanoparticles have a size of 50–100 nm and a spherical shape. Notably, the SiO_2 particles have blurred boundaries, evidently, due to the reaction between the surface silica gel groups with diisocyanate and formation of partially cross-linked or branched organic/inorganic hybrid structures:



This is also evidenced by the results of an examination by polarization optical microscopy: The flow point of the composite material exceeds 260°C, while the model polymer prepared from hexamethylene diisocyanate and 2,2-dimethyl-1,3-propanediol transforms to the viscous-flow state already at 210°C.

The mechanical properties of the composite material significantly differ from those of the model polyurethane. As already noted, under the reactive molding conditions, optically transparent self-supporting films and solid items can be obtained from the nanocomposite, whose strain-strength characteristics are fairly high for this polymer type. In particular, the modulus of elasticity of the films was estimated at 1.0 GPa, tensile strength, at 35 MPa, and relative elongation, at 22%. Under analogous conditions, only brittle non-self-supporting films were prepared from the model polymer, whose mechanical properties could not be determined. However, we failed to prepare items by molding from the composite melt, whereas solid items can be prepared by this method from the model polyurethane. This observation also confirms the assumption that the nanocomposite has a branched and/or partially cross-linked nature.

Thus, the approach we suggest, which combines synthesis of SiO_2 by sol–gel technique with polycondensation of the released diol with diisocyanate, allows preparation of nanocomposite materials with filler

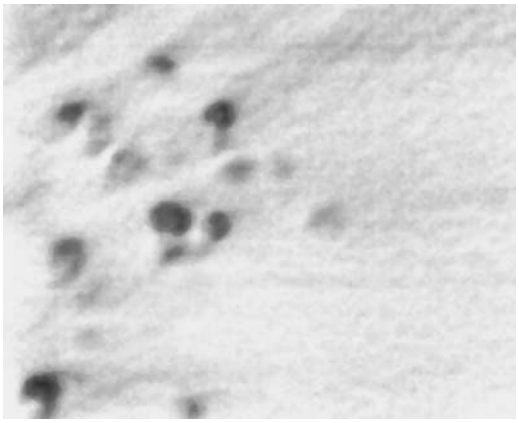


Fig. 3. Electron micrograph of the nanocomposite film cross section [S4800 field emission scanning electron microscope (Hitachi), 1 kV].

particles up to 100 nm in size, which greatly surpass materials based on unfilled polymer in the strain-strength characteristics.

EXPERIMENTAL

Synthesis of 3,3,9,9-tetramethyl-1,5,7,11-tetraoxa-6-silaspiro[5.5]undecane. To a solution of 20.8 g (0.2 mol) of 2,2-dimethyl-1,3-propanediol in 100 ml of absolute toluene, a solution of 11.5 g (0.1 mol) of silicon tetrachloride in 20 ml of absolute toluene was added with stirring. The mixture was refluxed in an argon stream for 4 h, then cooled to 5°C, kept for 3 h, and filtered. After the solvent was distilled off, 18.2 g (76%) of the target product was obtained as a colorless solid substance. Since the product polymerizes in storage, it was kept as a 20% solution in toluene at 5°C.

Found, %: C 58.49, H 8.20.

Calculated, % C 59.69, H 8.68.

^{1}H NMR (Bruker, DRX 500, $CDCl_3$, 25°C, δ, ppm: 0.85 (s, 12H, CH_3) and 3.45 (s, 8H, CH_2).

Synthesis of poly(2,2-dimethyl-1,3-propylene 1,6-hexamethylenecarbamate)-SiO_2 composite. To 1.15 g (0.005 M) of 3,3,9,9,-tetramethyl-1,5,7,11-tetraoxa-6-silaspiro[5.5]undecane, 1.62 g (0.01 M) of 1,6-hexamethylene diisocyanate was added, and the resulting mixture was heated to 80°C. Next, an equivalent amount of water was added, whereupon the mixture was left at 80°C for 3 h. To prepare a film, a viscous transparent melt was poured onto a glass substrate and kept at 80°C for 12 h. A uniform transparent composite film was detached from the substrate and subjected to mechanical tests.

Synthesis of poly(2,2-dimethyl-1,3-propylene 1,6-hexamethylenecarbamate) (model polymer). Hexamethylene diisocyanate [1.62 g (0.01 mol)] was mixed with 1.04 g (0.01 mol) of 2,2-dimethyl-1,3-propanediol, and the mixture was heated to 80°C. After 3 h, a viscous transparent melt was poured onto a glass substrate and kept at 80°C for 12 h. This yielded a transparent brittle polymer.

CONCLUSIONS

(1) A new method was suggested for preparation of transparent film-forming nanocomposites containing highly dispersed silicon dioxide.

(2) It was demonstrated that simultaneous sol–gel process yielding silica gel particles and polycondensation of the released diol with diisocyante yields a composite material with the filler particle size under 100 nm. The mechanical properties of items thereof significantly surpass those prepared from unfilled polyurethane.

Abstract—The boundary and parameters of the thermochemical reaction of lignin and polyacrylonitrile were determined by dynamic and isothermal thermal analysis. The time, temperature, and concentration effects of formation of composites, allowing preparation of new carbonizates with enhanced heat resistance and noticeably higher carbon residue, were studied.

DOI: 10.1134/S1070427207040209

In our previous papers concerned with the possibility of preparing new composite materials (CMs) based on polyacrylonitrile (PAN) and other synthetic polymers we noted the positive influence of PAN on the characteristics of the resulting CMs. However, we encountered in this line of investigation some technological and economical problems [1–3]. To avoid these difficulties, we made an attempt to prepare CMs with PAN on the basis of natural macromolecular compounds [4–6]. The possibility of preparing CMs based on binary mixtures of PAN with cellulose ethers, chitin, and chitosan with high heat resistance, mechanical strength, and ability to carbonization, has been shown. The results obtained allowed formulation of basic principles for preparation of carbon composites by thermochemical cocarbonization of polymers [7].

In this study, we used lignin (LG) as a component in combination with PAN. It is well known that LG is a component of wood (25–30 wt %) and is a complex aromatic substance with uncertain chemical structure [8–10] and molecular weight of $(2–6) \times 10^4$. This structure is based on various phenol derivatives randomly bound by oxymethylene bonds. As regards the reactivity, LG reacts with many organic substances along the pathways of electrophilic and nucleophilic substitution [8]. As regards polymers, there are some publications on modification of a series of thermosetting polymers, such as phenol–formaldehyde, melamine, urea, and epoxy resins and also rubbers. These data are concentrated in special literature (patents, technical reports, processing regulations) and mainly refer to description of the blending procedure and characteristics of the resulting CMs [11–13]. However, these data are insufficient for making certain conclusions on features of polymer-analogous transformations involving LG. Since there are no data on the reaction of PAN with LG, we studied thermochemical reactions of PAN with LG under the conditions of dynamic and isothermal heating of a blend of these polymers in order to elucidate the possibility of preparing CMs based on these substances with account of principles of cocarbonization of polymers [7].

EXPERIMENTAL

As the initial compounds we used PAN synthesized by the radical polymerization mechanism [14] and LG powder recovered using acid hydrolysis [15]. Dynamic thermal analysis was performed on an MOM derivatograph (model C, Hungary) at a heating rate of 10 deg min^{-1} in air; weighed portions 50–100 mg, ceramic crucibles. Dynamic and isothermal analyses of PAN, LG, and their mechanical mixtures in the form of powders at a PAN : LG ratio equal to 25 : 75, 50 : 50, and 75 : 25 were performed on an installation for thermovolumetric analysis (TVA) [16] in a nitrogen medium and in a vacuum.

The first stage of studying thermochemical reactions of LG, PAN, and their mixture was identification of the main thermal parameters characterizing the behavior of the samples during their heating from room temperature to the temperature of complete decomposition and evaporation of thermal degradation products or to a certain temperature limit. The TG curves of the integral weight loss in heating of the samples at a constant rate to 1000°C are shown in Fig. 1a.

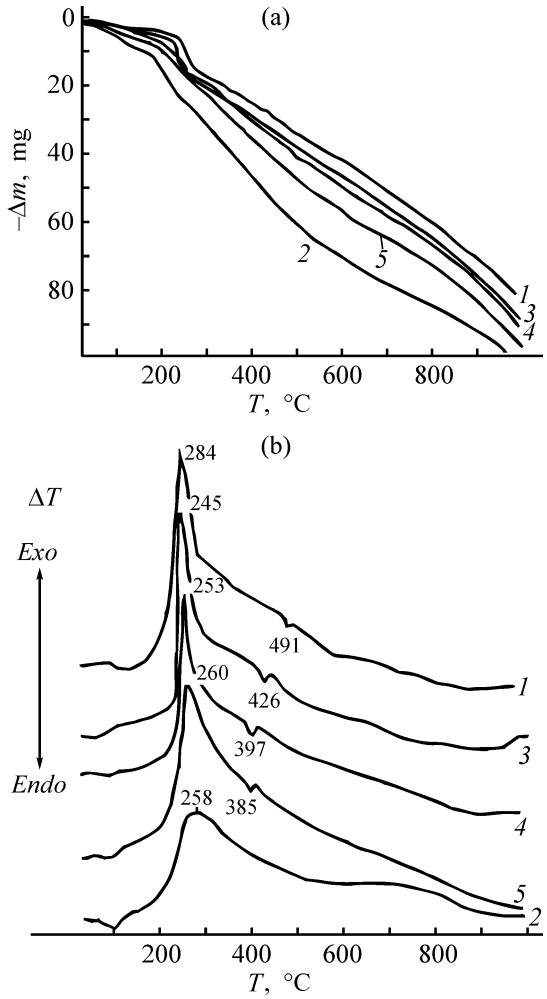

Fig. 1. (a) TG and (b) DTA curves of LG and PAN samples and their powder blends under dynamic heating at a rate of 10 deg min^{-1} in air. (Δm) Weight loss, and (T) temperature; the same for Fig. 3. (*1*) PAN, (*2*) LG; LG : PAN: (*3*) 25 : 75, (*4*) 50 : 50, and (*5*) 75 : 25.

The thermal effects accompanying thermochemical transformations of the samples in the same temperature range, recorded simultaneously with the TG curve, are presented in Fig. 1b (DTA curves). Comparison of the TG curves of the initial products and their blends shows that decomposition of the blend samples proceeds in the temperature range limited by the TG curves of LG and PAN; the curve shapes vary smoothly with the ratio of the initial reactants. The absence of abrupt changes in the kinetics of the weight loss during the entire period of thermal degradation suggests only a weak reaction of LG with PAN even in the period of the maximum thermal activity of both components in the temperature range 200–300°C. The DTA curves furnish more information; comparison of these curves reveals the occurrence of a certain chemical reaction of PAN with LG. The presence of LG in the mixture shifts the exothermic effect to lower temperatures; in this case, the temperature of the exothermic effect of PAN cyclization becomes lower as the concentration of LG decreases. It is likely that phenols formed by thermal decomposition of LG exert a catalytic effect on the cyclization of PAN; however, the possibility of these reactions is limited by the spatial arrangement of the components. For example, the dominating effect at high concentrations of LG is thermal degradation of LG, which is confirmed by broadening of the exothermic peak similar to degradation of pure LG (Fig. 1b, curve *5*). It is evident that, at low concentration of LG, the catalytic cyclization of PAN due to phenols released in degradation of LGs predominates. In this case, the peak of the exothermic effect of PAN cyclization is shifted to low temperatures by 39°C (Fig. 1b, curve *3*).

In addition, the temperature of the endothermic effect in the range 491–385°C decreases as the concentration of PAN becomes lower. The nature of this effect remains to be elucidated; however, it was assumed [17] that some ordered structure is formed in carbonization of PAN and this structure melts in the above temperature range. This phenomenon can be confirmed in an independent structural study using spectral analysis.

The shapes of TG and DTA curves in the initial stage of weight loss up to 230°C suggest that the removal of volatile products from LG–PAN mixtures proceeds due to thermal degradation of LG and the composition of these products (acidic water, traces of phenol and its substituted derivatives) confirms the prevalence of LG degradation. It is likely that the presence of phenols initiates cyclization of PAN at a lower temperature and thus shifts the equilibrium of feasible concurrent reactions of PAN thermal degradation toward cyclization, in comparison with the reactions of PAN with the products of thermal degradation of LG. Such a development of thermochemical reactions in the LG–PAN blend hampers realization of the first principle of cocarbonization: coincidence of temperature ranges of high thermal reactivity for both reacting components. To avoid the activation of low-temperature products of thermal degradation of LG, we performed experiments on isothermal storage of LG and its blends with PAN at different temperatures and compositions of the surrounding medium. These experiments also allowed determination of the limits of thermal stability of the samples with the aim to provide complete homogenization required for reliable contact of the reacting compounds under conditions of heterogeneous synthesis. Preliminary measurements of the thermal stability of LG in isothermal storage for 3 h at 150°C

showed that LG is fairly stable in air. During this period, with the 7% weight loss during heating to 150°C disregarded, the weighed portion of LG loses no more than 5% of its weight and this occurs only in the first hour of heating. Thus, this treatment allows removal of the major part of low-molecular-weight products of the initial thermal treatment of LG. Furthermore, with the aim to make the limits of LG thermal stability closer to the temperature range of a high thermal reactivity of both LG and PAN, we performed stepwise isothermal heating of the samples in a nitrogen medium. The results of this series of experiments (Fig. 2) show that, upon isothermal heating for 6 h at 200°C, LG losses approximately 17% of its weight without stabilization of this process. With further heating, thermal degradation proceeds at the same rate in isothermal and dynamic modes of heating of the sample (Fig. 2, curve *2*).

Addition of PAN powder to LG results in some thermal stabilization of LG, which is seen from a comparison of the curves of weight loss in the isothermal mode at 200 and 300°C for the LG–PAN mixtures at various concentrations of the initial polymers. It should be noted that, at the PAN content in the blend equal to 25%, the weight loss of LG at 200°C due to removal of low-molecular-weight products of thermal degradation is minimal. The effect of PAN is also noticeable at a heating temperature elevated to 300°C (Fig. 2, curve *5*). Thus, we can conclude that the influence of PAN on thermal stabilization of LG and the kinetics of thermochemical reactions of PAN with LG is positive. Further increase in the PAN concentration in the blend results in a gradual approach of the thermal characteristics of the blends to the characteristics of the pure PAN powder.

Typical curves of dynamic TG–DTA in air, which characterize the influence of isothermal heating of the blend LG : PAN = 75 : 25, are shown in Fig. 3. Comparison of these curves with those presented in Fig. 1 reveals a certain increase in the thermal stability of the blend in air and an insignificant variation of the kinetics of thermochemical reactions caused by preliminary removal of low-molecular products of LG degradation and partial cyclization of PAN. Isothermal heating results in a noticeable increase in the carbon residue (CR) to 62% at 600°C; for unheated samples this value is 43%, and at 1000°C the CR values are 15 and 0%, respectively. Figure 3 also shows the TG and TDA curves of the same blend with a large weighed portion (curves 7). A noticeable increase in all the thermal parameters of this sample suggests a significant influence of the "diffusion factor" on the kinetics of carbonization of the LG–PAN blend.

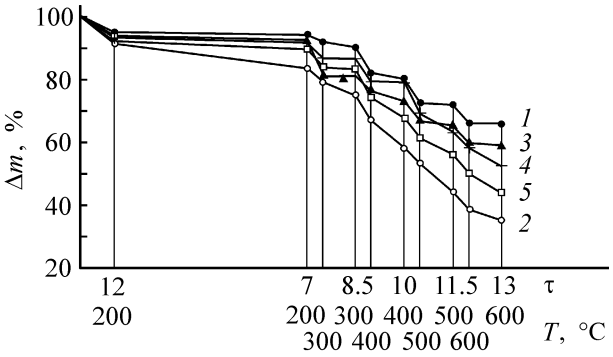

Fig. 2. TG curves in stepwise isothermal heating of (*1*) PAN, (*2*) LG, (*3*) LG : PAN = 25 : 75, (*4*) LG : PAN = 50 : 50, and (*5*) LG : PAN = 75 : 25 in a nitrogen medium. Heating rate in the transition stage 3 deg min^{-1}. (Δm) Weight residue, (T) temperature, and (τ) time of stepwise heating of the samples.

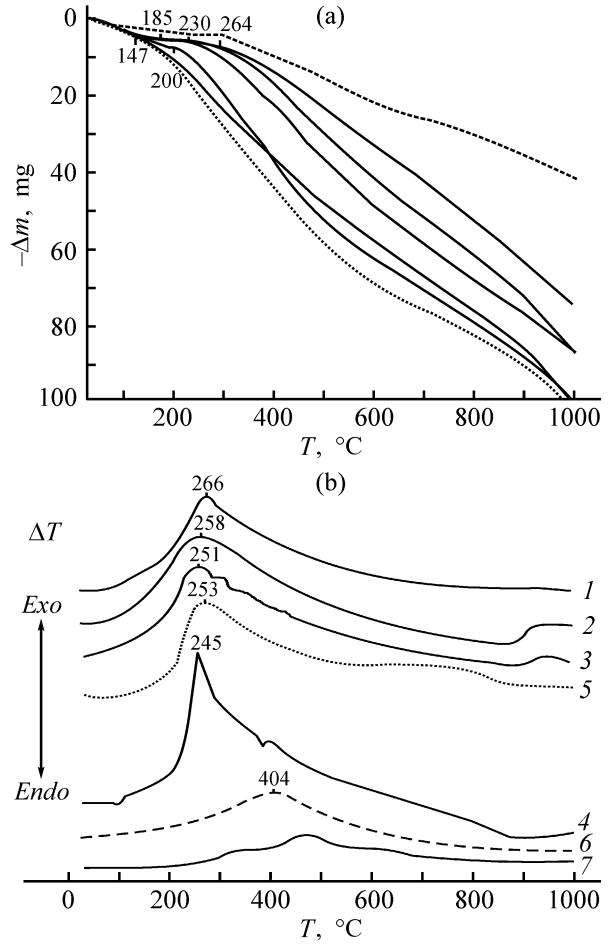

Fig. 3. (a) TG and (b) DTA curves of (*5*) LG and (*6*) PAN samples heated at 300°C for 6 h in N_2: (*1*) blend LG : PAN = 75 : 25, (*2*) blend LG : PAN = 75 : 25 heated at 400°C for 6 h in N_2, (*3*) LG heated at 200°C for 6 h in N_2, (*4*) unheated blen LG : PAN = 75 : 25, and (*7*) blend LG : PAN = 75 : 25 heated at 400°C for 6 h in N_2, weighed portion 500 mg.

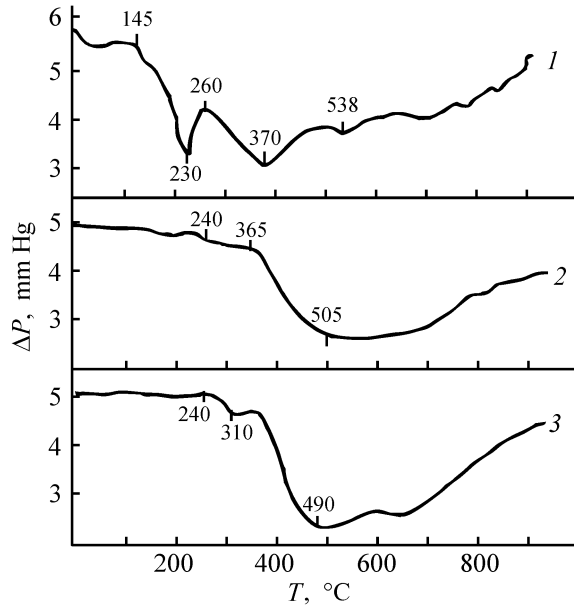

Fig. 4. TVA curves of the LG samples and LG : PAN = 75 : 25 blend, weighed portion 50 mg. (ΔP) Pressure differential and (T) temperature. (*1*) LG (weighed portion 50 mg), heating rate 3 deg min^{-1}, (*2*) LG + PAN after isothermal heating at 400°C for 1 h in N_2, and (*3*) LG + PAN after isothermal heating at 400°C for 6 h in N_2, weighed portion 600 mg.

It also demonstrates that procedures hindering diffusion of low-molecular-weight products of thermal decomposition from the blend samples are efficient in shifting the thermochemical reactions toward intermolecular structuring of the blend components.

This assumption is confirmed by the experiments on dynamic thermal analysis by the TVA method (Fig. 4). These data show that gas evolution in heating of the samples of the same LG–PAN blend noticeable decreases in comparison with pure LG both after additional isothermal heating and on making larger the weighed portion of the sample; accordingly, the CR increases from 15 for LG to 64% for the heated blend with a large weighed portion.

CONCLUSIONS

(1) A study of the thermochemical reaction of lignin with polyacrylonitrile in the temperature range 20–1000°C showed that the cyclization temperature of polyacrylonitrile decreases due to a catalytic effect of the products of thermal degradation of lignin.

(2) The thermal stability of lignin increases upon addition of limited amounts of polyacrylonitrile in isothermal heating of the composites in an inert medium at 200–300°C.

(3) Lignin–polyacrylonitrile carbonizates differing in their characteristics from those obtained from the initial polymers were prepared.

ACKNOWLEDGMENTS

The authors are grateful to the A.M. Bochek's laboratory for submitting the lignin samples.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Acid-Catalyzed Oligomerization of Aromatic Ethers (Rolivsans) with Terminal Styrene and Methacrylate Groups

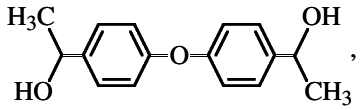
Received December 14, 2006

Abstract—Cationic mechanism of transformation of unsaturated aromatic monomers contained in Rolivsans into thermosetting aromatic oligoethers with increased molecular weight was analyzed. The composition and chemical structure of Rolivsans as influenced by catalytic systems with various donor-acceptor properties were studied.

DOI: 10.1134/S1070427207040210

Rolivsans are low-viscosity thermosetting resins of new type, formed by reactions of secondary aromatic diols, such as di-[4-(1-hydroxyethyl)phenyl] ether (**I**)



with methacrylic acid catalyzed by strong acids [1–5]. Their thermal treatment yields heat-resistant glassy network polymers [6–10] which are used in (micro)-electronics and electrical engineering.

It has been found previously that Rolivsans contain the following monomer aromatic ethers: 4,4'–CH_2=CH–PhOPh–CH=CH_2 (M1), 4,4'–CH_2=CH–PhOPh–CH(CH_3)OCO–C(CH_3)=CH_2 (M2), 4,4'–CH_2=C(CH_3)–COO(CH_3)CH–PhOPh–CH(CH_3)OCO–C(CH_3)=CH_2 (M3), and oligoethers (OL) with terminal styrene-like and methacrylate groups.

The monomer-oligomer composition and properties of Rolivsans can be varied in a wide range depending on the synthesis conditions [3–5]. Low-viscosity compositions (500–1500 mPa s^{-1}) containing no solvents and predominantly consisting of monomers M1, M2, and M3 and small amounts (15–30%) of low-molecular-weight unsaturated oligomers (dimers and trimers) can be used as heat-resistant insulating casting and impregnating compounds.

In this study, we examined the formation of monomer–oligomer formulations with molecular weight of components increased due to higher content of aromatic oligoethers with terminal unsaturated groups. These formulations yield thermosetting polymers with controlled network density and can be used to prepare heat-resistant coatings and binders [11–12].

EXPERIMENTAL

The IR spectra were recorded on a Specord 75-IR device (thin films or $CHCl_3$ solutions). The exclusion liquid chromatography (ELC) of Rolivsans was performed on a GPC Waters chromatograph equipped with Ultrastyrogel (500 Å) columns at 20°C, using toluene as eluent. The number-average molecular weights of oligomers $\overline{M}_n$ were determined with a Hitachi–Perkin–Elmer 115 vapor osmometer. The sample unsaturation was studied on a ADS-4 ozonizer at 0°C (CCl_4 solvent). The viscosity and viscoelastic properties of Rolivsan MV-1 and of the products of its oligomerization were studied on a PIRSP-1 rheogoniometer with a cone-plate working unit (cone diameter 2 cm, cone angle 1°). The velocity gradients were varied from 2×10^{-2} to 4×10^{2} s^{-1}, and circular frequencies, from 2×10^{-2} to 10 s^{-1}.

Samples of Rolivsan MV-1 (series I and II) were prepared in accordance with TU (Technical Specifications) 6-36-57-0–91 by condensation of di-[4-(1-hydroxyethyl)phenyl] ether (**I**) with methacrylic acid in the presence of *p*-toluenesulfonic acid monohydrate (TSA-M) [3–5]; their compositions and properties are listed in Table 1.

Oligomer no. 1 was isolated from the initial reaction mixture (Rolivsan VM-1, series I) after its dilution with chloroform and subsequent precipitation

Table 1. Properties of Rolivsan MV-1*

Series	Composition, wt %				>C=C<, mol g^{-1}	$\bar{M}_n$	n_D^{20}	η^{25}, mPa s^{-1}	d^{20}, g cm^{-3}	τ^{140}, h
	M1	M2	M3	OL						
I	13	31	23	33	0.0058	400	1.585	1500	1.09	1.5
II	13	26	18	43	0.0056	420	1.590	1800	1.09	2.5

* >C=C< is the degree of unsaturation of oligomer, mole of double bonds per gram of product; $\bar{M}_n$, number-average molecular weight; and τ^{140}, time of gelation at 140°C.

with ethanol. The efficiency of oligomer isolation was monitored chromatographically (ELC) by the absence of peaks belonging to monomers M1, M2, and M3 in the product isolated. After a fourfold reprecipitation, the oligomer contained insignificant amounts (2–4%) of the initial monomers; the monomer-free product was obtained only after an eightfold reprecipitation. The properties of oligomer no. 1 were as follows: mp ~80°C, $\bar{M}_n$ ~ 1650, content of dimers with $\bar{M}_n$ ~500 (ELC data) 2–4%; found (%): C 79.6, H 6.5.

The degree of unsaturation of oligomer no. 1 was 0.37 mole of double bonds per 100 g of the product.

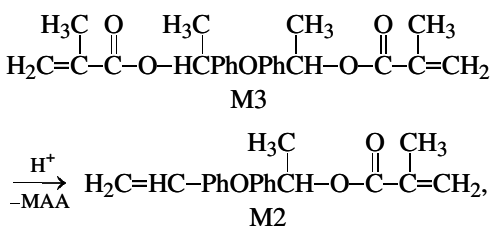
Two catalytic systems (CS A and CS B) were tested in oligomerization of Rolivsans catalyzed by TSA-M. Catalytic system A [solution of TSA-M (19.80 wt %) in polyphenyl ether (PPE, *m*-$C_{30}H_{22}O_4$, analytically pure grade, 5F 4E brand, mp 28°C] was prepared by through trituration of TSA-M (8.7841 g, 99% main compound) with liquid PPE (35.1365 g). Catalytic system B is a glycerol-like solution of TSA-M (23.63 wt %) in Cellosolve.

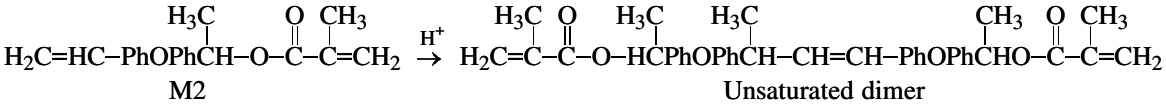
The acid-catalyzed oligomerization was performed by thorough mixing of Rolivsan with CS and storage of the homogenized composition at room temperature or at elevated temperature for a given time; then the composition and properties of the resulting compound were analyzed (Table 2).

To prepare oligomer nos. 2 and 3, CS A (1.05 g) was added with stirring to Rolivsan MV-1, series I (98.95 g), the homogenized composition was heated at 80°c for 1 h 35 min, and a sample was taken for isolation of OL no. 2. The process was continued for 2 h 40 min, and OL no. 3 was isolated from the reaction mixture. The product compositions were studied by ELC and IR spectroscopy. The composition of the sample containing OL no. 2 before isolation was as follows, wt %: 9 M1, 18 M2, 17 M3, and 56 OL. The sample was diluted with chloroform; the oligomer was precipitated with ethanol and dried at 20°C at reduced pressure. The precipitated product contained (wt %): 3 M1, 4 M2, 6 M3, and 87 OL no. 2, it is soluble in acetone and chloroform, $\bar{M}_n$ 1000. Oligomer no. 3 isolated by the similar procedure contained (wt %): 1 M1, 2 M2, 4 M3, and 93 OL; $\bar{M}_n$ 1220.

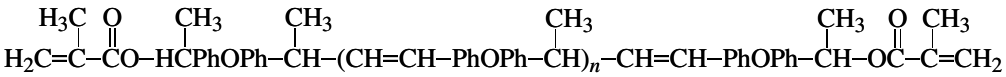
To prepare oligomer nos. 4 and 5, CS B (0.80 g) was added with stirring to Rolivsan MV-1, series I (99.20 g), and then one portion (50 g) of the homogenized composition was heated at 80°C for 2 h 10 min, and another portion (50 g) was stored at 20°C for 21 days. The compositions of the resulting products were analyzed as described above. The composition of the sample containing OL no. 4 before isolation was as follows, wt %: 3 M1, 6 M2, 4 M3, and 87 OL. No monomers were found in OL no. 4 after an eightfold reprecipitation; mp 90–110°C; found (%): C 79.60, H 6.70; 0.0030 mol of double bonds per gram of product, $\bar{M}_n$ 3375. The composition of the sample containing OL no. 5 before isolation was as follows, wt %: 2 M1, 5 M2, 3 M3, and 90 OL (no. 5). After precipitation and drying, we obtained oligomer no. 5 as a light brown resin with mp 95–115°C. After reprecipitation in the presence of hydroquinone (1%), the melting point of OL no. 5 increased to 125–135°C; found (%): C 81.20, H 6.70; 0.0037 mol of double bonds per gram of product, $\bar{M}_n$ 2700.

As shown previously, cleavage of esters (such as methacrylates) [1–5] and cationic addition polymerization of divinyl aromatic monomers with proton transfer [13–18] are of particular importance in catalyzed reactions of aromatic ethers containing secondary alcohol groups with carboxylic acids, such as methacrylic acid (MAA). The cleavage of dimethacrylate of aromatic diol (**I**), which is the main component of Rolivsan M3, and subsequent dimerization of the resulting vinyl aromatic monomer M2 are typical examples of such transformations [19]:





These data suggest that the intensified cleavage of methacrylates (M2, M3, and related compounds: dimers, trimers, etc.) and cationic addition polymerization of vinyl and divinyl aromatic compounds can yield linear unsaturated oligomers of the following type:



Oligomerization was studied using two series of Rolivsans with different compositions and properties (Table 1). It should be noted that homogenization (dissolution) of TSA-M powder by direct stirring with a resin was rather difficult, because a high local concentration of the catalyst sharply accelerates oligomerization in situ and causes encapsulation of the TSA-M particles with the oligomer formed. To improve the homogenization conditions, we suggested two catalytic systems (CS A and CS B) based on PPE and Cellosolve solvents with different donor-acceptor properties.

The conditions of the acid-catalyzed process and the composition and characteristics of the oligomerized compositions and oligomers are listed in Table 2. The oligomers were isolated by dilution of the compositions with chloroform and subsequent precipitation with ethanol. Changes in the monomer-oligomer composition under different conditions of oligomerization of Rolivsans were studied by ELC (Fig. 1), IR spectroscopy (Figs. 2, 3), and rheokinetics (Fig. 4).

Gel chromatograms (Fig. 1) show that the content of the monomers decreases with time, with a simultaneous increase in the content of oligomers (especially, dimers and trimers) with number-average molecular weights of 500 – 800. Oligomerization was performed at a fixed content of catalysts both at 20 ± 2°C and at elevated temperatures. With the temperature increasing from 60 to 80°C, the process rate grows by more than a factor of 4, which corresponds to the known empirical van't Hoff rule.

It should be noted that the characteristics of unsaturation, content of carbon (Table 2), and ^{1}H NMR spectra are not fully consistent with the chemical structure of the oligomers, given above. The calculated degrees of unsaturation and carbon content are slightly higher than the experimental values. This is probably due to formation of small amounts of saturated structures (e.g., 1-methyl-3-phenylindan), along with the main structure of 1,3-diphenyl-1-butene (*trans*) type, in the course of acid-catalyzed dimerization of styrene. We also cannot rule out the side

reactions of oxidation on heating of unsaturated compounds in the presence of strong acids and of an addition of an aromatic solvent (toluene) and an inhibitor of the radical polymerization (hydroquinone) to the internal double bonds of the oligomer of Ar–CH(CH_3)–CH=CH–Ar type [16].

Similarly to the gel chromatograms, the IR spectra strongly change in the course of oligomerization. The initial IR spectrum of Rolivsan (Fig. 2, spectrum *1*) exhibits the absorption bands of the unsaturated and aromatic groups at 3080, 3060, 3030, 2975, 1630, 1600, 1500, 985, 965, 940, and 905 cm^{-1}, methyl and methylene groups at 2960, 2925, 2870, and 2850 cm^{-1}, methine group at 2900 cm^{-1}, and strong bands of the stretching vibrations of the carbonyl group in methacrylates at 1715 cm^{-1} and of aromatic ethers at 1240 cm^{-1} [4]. The IR spectrum of oligomer no. 3 (Fig. 2 spectrum *2*) isolated from the oligomerized composition (Table 2) shows the expected decrease in the intensity of the bands of the carbonyl groups at 1715 cm^{-1} and of out-of-plane bending vibrations H–C= at ~902 and 940 cm^{-1} belonging to the *p*–CH_2=CH–Ph–O–Ph and CH_2=C(CH_3)COO groups, respectively. Simultaneously, the band of H–C= out-of-plane bending vibrations of the –CH=CH– (*trans*) groups, whose concentration increases in the course of the stepwise dimerization reactions (cationic addition polymerization) of vinyl aromatic compounds [4, 19], grows in intensity.

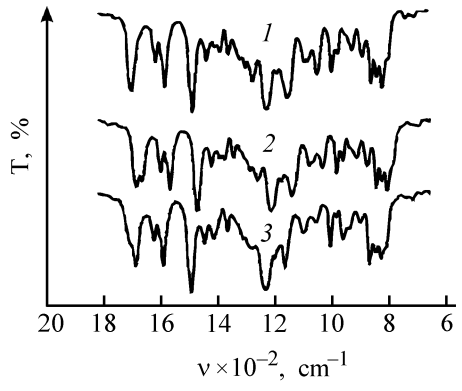

Fig. 3. IR spectra (20°C) of the monomer–oligomer composition Rolivsan MV-1 (series I) after its heating with CS B at a TSA-M content of 2.22×10^{-2} M. (*1*) 20°C (initial composition); (*2*) heated from 20 to 110°C over a period of 1 h and kept at 110°C for 2 h; (*3*) the same plus heating to 130°C over a period of 2 h.

Oligomerization was also performed at higher temperatures (110–180°C), at which the above reactions of addition polymerization are accompanied by crosslinking and cyclization. With heating, the intensity of the absorption bands of the terminal unsaturated groups at 1630, 940, and 905 cm^{-1} strongly decreases (Fig. 3, spectra *2*, *3*) owing to their consumption in copolymerization.

Another process of the cationic type, namely, cleavage of methacrylates to form vinyl aromatic compounds, methacrylic acid, and its copolymers, and also cationic addition polymerization of divinyl aromatic compounds occur simultaneously in the course of

oligomerization. With heating, the band of the stretching vibrations of the carbonyl group >C=O of the methacrylic ester at 1715 cm^{-1} splits, and a new band of the MAA carboxy group appears at 1700–1685 cm^{-1} (Fig. 3, spectra *2*, *3*) [19].

Since the viscosity and gelation time (viability) are the most important process characteristics of the thermosetting plastics, which determine the possibility of their processing into a polymeric material, we studied the rheological properties of Rolivsans in the course of their catalytic oligomerization.

As can be seen from Fig. 4, each curve can be divided into two portions: that with comparatively slowly increasing viscosity, corresponding to the initial stage of the process, and that with rapidly increasing viscosity at the final stage of oligomerization (gelation). The intersection point of the tangents to these portions characterizes the gelation onset time τ_r. Table 3 we present the comparative data on τ_r and gelation time τ_g, determined visually from the loss of fluidity.

The fact that τ_g appreciably exceeds τ_r can be explained as follows: The rheokinetic method allows determination of the start of formation of 3*D* structures (microgel) from a sharp increase in the viscosity more precisely than does the visual determination of the fluidity loss observed at higher microgel concentrations.

Comparison of curves *2* and *4* (Fig. 4) shows that the rate of viscosity growth owing to oligomerization at 60°C is significantly higher in the experiment with addition of CS B (1.5 wt %), although the concentration of TSA-M (2.02×10^{-2} M) is lower in this case in this case than that in the experiment with addition of CS A (2 wt %) and TSA-M concentration of 2.26×10^{-2} M. The effect of the donor-acceptor complexes PPE–TSA–M and Cellosolve–TSA–M on the acidity of CS A and CS B and, thus, on their catalytic activity in the course of the Rolivsan oligomerization is illustrated in Fig. 5.

As can be seen, CS B containing Cellosolve is more reactive than CS A, other oligomerization conditions being equal. This is probably due to the higher basicity of Cellosolve as compared to PPE in which the lone electron pair of the ether oxygen is delocalized and interacts with the electron-acceptor phenyl groups, whereas in Cellosolve it is localized and interacts with the electron-donor alkyl groups. Thus, the electron-acceptor properties of PPE and Cellosolve interacting with TSA-M are strongly different. The electron density on the protonation centers in Cellosolve is higher owing to the lone electron pairs of the oxygen atoms.

ing temperature from 60 to 80°C (Fig. 3, curves *3*, *4*) which is also consistent with the van't Hoff rule.

CONCLUSIONS

(1) A procedure was developed for altering the composition and properties of Rolivsans by conversion of the monomer components [4,4'-divinyldiphenyl ether, 4-vinyl-4'-(1-methacryloyloxyethyl)diphenyl ether, and bis[4-(1-methacryloyloxyethyl)phenyl] ether] into linear unsaturated aromatic oligoethers with the terminal methacrylate groups .

(2) Under the conditions of the homogeneous catalytic oligomerization of Rolivsans at moderate temperatures (60–80°C), successive-parallel reactions of cleavage of methacrylates, formation of (di)vinylaromatic compounds, and addition polymerization of the latter with the proton transfer occur in 1–3 h.

(3) The catalytic systems with different donor-acceptor properties were developed, allowing variation of the rate Rolivsan oligomerization in a wide range.

(4) Low-melting oligoethers with the terminal methacrylate groups containing unsaturated and diphenyl oxide groups in the backbone were prepared and characterized.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of the Molecular Organization of Solutions of Ethylene–Perfluorinated Ether Copolymers

Abstract—Dilute and maximally concentrated solutions of ethylene–perfluorinated vinyl ether copolymers were studied.

DOI: 10.1134/S1070427207040222

Film-forming materials based on polyfluorinated elastomers can be successfully used in aggressive media at elevated temperatures. Depending on the supramolecular structure of polymer solutions, which is closely associated with the chemical structure of a macromolecular unit, such polymers can be used in diverse fields. An example is the use of polyfluorinated elastomers as protective coatings [1] or selectively permeable membranes.

In this study, we examined solutions of ethylene–perfluoroalkyl trifluorovinyl ether copolymers by dynamic light scattering and inverse gas chromatography.

EXPERIMENTAL

We studied copolymers of ethylene with perfluorinated vinyl ethers (EPFEs) of the general formula

$$[(CH_2{-}CH_2){-}(\underset{\displaystyle R}{\underset{|}{CF}}{-}CF_2)]$$

where R = O–CF_2–CF_2–CF_3 (EPFE-1), CF_2–O–CF_2–CF_2–CF_3 (EPFE-2), and CF_2O–$(CF_2)_2(OCF_2)_4OCF_3$ (EPFE-3).

The polymers were prepared by emulsion polymerization, using potassium persulfate as initiator. The majority of experiments were performed with EPFE-1.

According to the ^1H and ^{19}F NMR data, the EPFEs under consideration are alternating copolymers. However, about 15% of ethylene units form diads, and less than 0.01%, triads.

The structure of dilute solutions was studied by dynamic light scattering [2]. The specific features of the chemical structure of the EPFEs prepared sharply restrict the range of potential solvents. Whereas fluorinated elastomers derived from vinylidene fluoride show unlimited swelling in polar solvents (e.g., in acetone) [3], for EPFEs the degree of swelling does not exceed 15–20 wt %. The most suitable solvents for EPFEs are low-molecular-weight fluorinated compounds. For further experiments we chose 1,1,2-trifluorotrichloroethane. This solvent is more readily available than other related compounds and, therefore, is of greater interest for commercial production of film materials.

It should be noted that attaining the molecular solubility of fluorinated elastomers is a nontrivial problem. For example, only 30–60 wt % fraction of commercial fluorinated elastomers derived from vinylidene fluoride forms true solutions [4]. The remaining fraction of the polymer is the so-called globular fraction and consists of microgel particles formed by chemical bonds, including hydrogen bonds.

The structure of EPFE solutions was studied by dynamic light scattering. The distribution of the weight fractions of structural units of an EPFE polymer in 1,1,2-trifluorotrichloroethane solution, determined by this method, is shown in Fig. 1. The curves were obtained at polymer concentrations of 0.07, 0.15, and 0.5 wt %. Figure 1 shows that all the three curves have a bimodal distribution with the components separated by a large distance on the size scale. The fine fraction has a maximum at a size of ~30 nm. We identify this fraction with coils of individual polymer

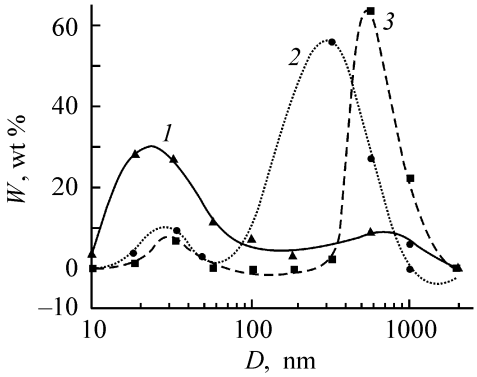

Fig. 1. Distribution of the weight fractions W of EPFE-1 structural units with respect to size D in 1,1,2-trifluorotrichloroethane at a polymer concentration c of (*1*) 0.07, (*2*) 0.15, and (*3*) 0.50 wt %.

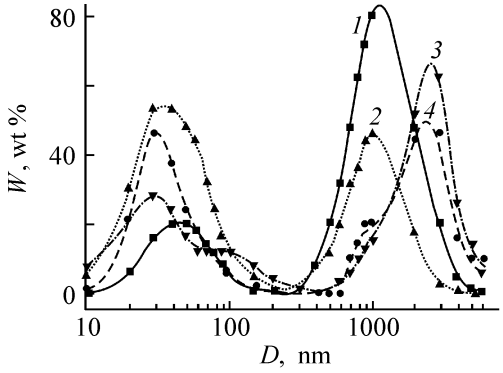

Fig. 2. Distribution of the weight fractions W of EPFE-1 structural units with respect to size D in 1,1,2-trifluorotrichloroethane with addition of (*1*) 5, (*2*) 1, (*3*) 0.5, and (*4*) 0.25 wt % acetone.

molecules. The coarse fraction corresponding to associates of macromolecules has a maximum at a size of the order of 1 μm. The mean size in this fraction is approximately 0.55 μm. The characteristics of the polymer fractions are listed in Table 1. These data show that a decrease in the polymer concentration in solution causes a decrease in the relative content of associated polymer coils and an increase in that of the nonassociated molecules. Figure 1 and Table 1 also show that the hydrodynamic sizes of the molecular coils and associates do not noticeably vary with the polymer concentration in solution.

The curves in Fig. 1 also demonstrate the tendency of EPFE molecules to associate. The weight fraction of associated polymer molecules is 90% in 0.5 wt % solution and only 22% in 0.07 wt % solution.

A dynamic light scattering study showed that a significant content of EPFE associates remains in 1,1,2-trifluorotrichloroethane solution even at low copolymer concentrations.

To determine what forces are responsible for the formation of EPFE associates, we examined the dispersion composition of this polymer in 1,1,2-trifluorotrichloroethane solutions modified with various low-molecular-weight substances (acetone, hexafluorobenzene, nitromethane, benzene). The choice of these additives was governed by our intention to reveal the donor–acceptor mechanism of solvation of EPFE molecules. The thermodynamic quality of the additives as EPFE solvents was estimated by inverse gas chromatography (IGC). Hexafluorobenzene appeared to be a good solvent (weight activity coefficient $\Omega_W < 4$). Benzene, acetone, and nitromethane do not noticeably dissolve EPFE ($\Omega_W \geq 20$; only low-molecular-weight substances with $\Omega_W < 10$ are regarded as solvents [5]). Benzene, acetone, and nitromethane show a tendency toward donor–acceptor interaction with hydrocarbon macrochains. Therefore, it can be expected that addition of small amounts of a modifier can raise the solubility of EPFE molecules in 1,1,2-trifluorotrichloroethylene. Figure 2 shows how the dispersion composition of EPFE molecules changes upon addition of various amounts of acetone.

Figure 2 shows that the general pattern of EPFE particle distribution in solution remained unchanged. However, the mean size of associates in the coarse fraction, equal to 2 μm in the solvent without acetone additions, decreases on adding minor amounts of acetone. The characteristics of the polymer fractions

* Hexafluorobenzene.

are given in Table 2. It is seen that addition of acetone causes, along with a decrease in the size of associates, also a small increase in the hydrodynamic size of the nonassociated coils (from 40 to 49 nm) and an increase in the amount of these species relative to associates. These trends are apparently due to the fact that acetone molecules solvate hydrocarbon units, thereby improving the solubility of EPFE as a whole. Furthermore, a part of molecules pass in this case from associates into the solution. In the process, the mean size of the associates decreases by a factor of approximately 2 at 1 wt % concentration of acetone.

As follows from the results of dynamic light scattering measurements, EPFE macromolecules show a strong tendency toward association. Modification of a solvent by addition of low-molecular-weight substances capable of specific interaction considerably increases the extent of molecular dispersity of the solutions, but does not fully suppress the tendency of EPFE molecules to associate. Nevertheless, the distribution of EPFE structural units in the modified solvent is considerably more uniform, which allows preparation of self-supporting EPFE films, i.e., of films exhibiting satisfactory strength characteristics without application onto a support. Modified EPFE solutions were used for preparing ultrathin films whose supramolecular structure was studied by IGC.

The supramolecular organization in maximally concentrated solutions was studied by IGC [6]. The possibilities of the method were used for characterizing the thermodynamics of sorption of low-molecular-weight EPFE associates and for calculating the thermodynamic parameters of mixing: $\Delta\overline{H}_1^{E\infty}$ and $\Delta\overline{S}_1^{E\infty}$ (excess partial molar enthalpy and entropy, respectively).

The excess partial molar enthalpy $\Delta\overline{H}_1^{E\infty}$ is the resultant of all intramolecular interactions in the infinitely dilute solutions formed [7]. It can be represented as a sum

$$\Delta\overline{H}_1^{E\infty} = \Delta H_{break} + \Delta H_{cav} + \Delta H_{disp} + \Delta H_{sp}, \quad (1)$$

where ΔH_{break} is the enthalpy of breaking of the bonds between the solute molecules; ΔH_{cav}, enthalpy of cavity formation in the structure of the pure solvent (polymer in the case of IGC); ΔH_{disp}, enthalpy of van der Waals interaction; and ΔH_{sp}, enthalpy of the specific interaction.

To calculate the thermodynamic functions of mixing in the systems EPFE–low-molecular-weight substance, we obtained the equations of the temperature dependences of the weight activity coefficients Ω_1^{∞} and the coefficients of these equations [8, 9].

$$\ln \Omega_1 = C \ln T + D/T + E.$$

where C, D, and E are constants.

The values of $\Delta\overline{H}_1^{E\infty}$ calculated on substituting the coefficients obtained in Eq. (1) are listed in Table 3. It is seen that all these quantities are positive

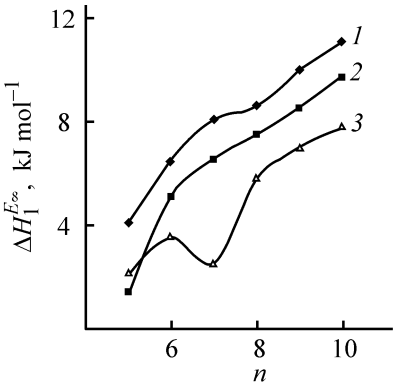

Fig. 3. Excess partial molar enthalpy $\Delta\bar{H}_1^{E\infty}$ vs. the number n of carbon atoms in the chain of a normal alkane: (*1*) EPFE-1, (*2*) EPFE-2, and (*3*) EPFE-3.

and appreciably larger than unity for all the sorbates except HFB.

As far as the solvating properties of HFB toward EPFE are concerned, it should be noted that HFB shows a tendency toward electrophilic addition, which is due to the considerably higher, compared to benzene, density of the π-electron system [10]. At the same time, HFB, like other perfluoroaromatic compounds, is active toward nucleophiles. Thus, HFB can solvate both methylene groups with a partial positive charge on the H atom and the perfluoromethylene groups of the linear chain. In turn, the alternating microstructure of the polymer and the self-organization processes leading to the formation of hydrocarbon clusters in the bulk of the polymer give rise to steric hindrance to solvation of methylene sequences with HFB (shielding with adjacent perfluorinated groups). Such a supramolecular organization should make the copolymers stable in polar solvents. According to our experiments, the polymers under consideration show only limited swelling in polar solvents, in contrast to copolymers derived from vinylidene fluoride, whose solubility in polar solvents is well known [3].

We studied how $\Delta\bar{H}_1^{E\infty}$ varies with increasing molecular mass of *n*-alkane (Fig. 3). The plot obtained for EPFE-1 is characterized by the ascending initial portion (from *n*-C_5 to *n*-C_7), followed by plateau (from *n*-C_7 to *n*-C_8) and second ascending portion (from *n*-C_8 to *n*-C_{10}). With an increase in the molecular mass of *n*-alkane, its absorption by the polymer becomes more difficult, which is reflected in an increase in $\Delta\bar{H}_1^{E\infty}$ (the contribution of ΔH_{cav} grows). At the same time, the dispersion forces acting in the solvation of macrochains increase, which partially compensates for the increase in ΔH_{cav} (plateau in the plot). As the molecular mass of an alkane is raised further, an increase in the dispersion forces no longer compensates for the increase in ΔH_{cav} (second ascending portion).

It could be expected that an increase in the length of the side substituent in EPFE-2, with incorporation of a flexible –OCF_2– unit, would lead to a considerable increase in the free volume and, correspondingly, to a considerable decrease in $\Delta\bar{H}_1^{E\infty}$ of sorbates. However, the absolute values of $\Delta\bar{H}_1^{E\infty}$ of sorbates on EPFE-2 appeared to be only slightly lower than those on EPFE-1. It should be noted that there is no pronounced plateau in the $\Delta\bar{H}_1^{E\infty} = f(n_C)$ curve for EPFE-2. Thus, the difference between EPFE-1 and EPFE-2 in the side substituents, though leading to an increase in the free fluctuation volume in EPFE-2, does not appreciably affect the supramolecular organization of the fluorinated elastomers.

A sharp increase in the length of the side substituent chain in EPFE-3, relative to EPFE-1 and EPFE-2, with alternation of rigid (–CF_2–CF_2–) and flexible (–OCF_2–) segments, apparently leads to an increase in the free volume and correspodingly to a decrease in $\Delta\bar{H}_1^{E\infty}$ of the sorbates. Also, a minimum (at $n_C = 7$) is observed in the curve $\Delta\bar{H}_1^{E\infty} = f(n_C)$. The first fact can be apparently attributed to a relative (compared to EPFE-1) increase in the fluctuation free volume, caused by differences in the geometry of side substituents in the EPFEs, namely, to a decrease in the contribution of ΔH_{cav} to $\Delta\bar{H}_1^{E\infty}$ and the corresponding decrease of the latter quantity. The local minimum in the $\Delta\bar{H}_1^{E\infty} = f(n_C)$ curve suggests that the mean size of elements of the free volume in EPFE-3 corresponds to the molecular size of *n*-heptane.

In the Flory–Huggins thermodynamics, the expression for the partial molar excess entropy of alkanes has the form [11]

$$\Delta\bar{S}_1^{E\infty} = R[\ln m - (m - 1)/m]. \quad (2)$$

where m is the ratio of the solid-core volumes of the polymer and low-molecular-weight substance. The equation is valid if there are no intermolecular interactions and the free volume remains constant on mixing. With these restrictions, Eq. (2) predicts a decrease in $\Delta\bar{S}_1^{E\infty}$ with an increase in the molecular volume of *n*-alkane. The $\Delta\bar{S}_1^{E\infty}$ values obtained are listed in Table 3. Table 3 shows that, with all the examined EPFEs, the $\Delta\bar{S}_1^{E\infty}$ values of *n*-alkanes do decrease with an increase in their molecular volume. It should be noted that Eq. (2) does not hold true for many elastomers [12], and more typical is independence of $\Delta\bar{S}_1^{E\infty}$ from the molecular volume of the al-

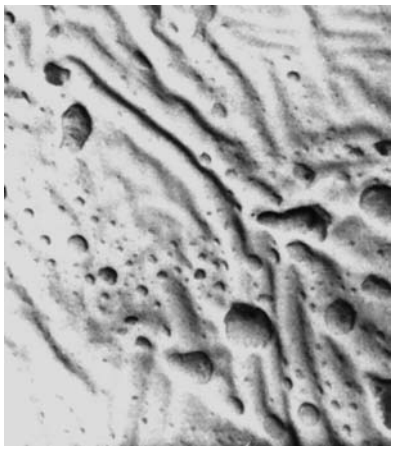

Fig. 4. Supramolecular organization of EPFE-1.

kane. A decrease in $\Delta\overline{S}_1^{E\infty}$ with the molecular volume of the alkane in the case of EPFEs may be due to the sorption mechanism involving accommodation of alkane molecules in the intraassociate voids (free volume elements) of the elastomer, which is characteristic of sorption with associated liquids [13].

We examined the supramolecular organization of thin polymer films. A SEM micrograph of EPFE-1 is shown as example in Fig. 4. The supramolecular organization of the polymer is characterized by the lamellar structure; the alternating microstructure of the chain does not prevent its formation.

CONCLUSIONS

(1) Macromolecules show a strong tendency toward aggregation in dilute solutions of ethylene–perfluorinated ether copolymers.

(2) Self-organization processes occurring in solutions of perfluorinated vinyl ethers directly affect the supramolecular organization of thin copolymer films.

(3) The driving force of self-organization is thermodynamic incompatibility of the hydrocarbon and perfluorinated constituents of perfluorinated vinyl ethers, leading to the formation of hydrocarbon clusters of methylene sequences in the prefluorinated matrix and of free volume elements.

(4) The structure of perfluorinated vinyl ethers, combinated with the specific features of the chain microstructure, ensures high stability of the films derived from these ethers in aggressive polar media, including alkaline solutions.

(5) The presence of free volume elements is a prerequisite for the development of selectively permeable membranes based on these copolymers.

Abstract—The results of physicochemical studies of promising prolonging agents for Tilan antibiotic: polyvinylpyrrolidone and vinylpyrrolidone copolymers, are reported. The optimal component ratios of the drug formulation were determined by viscometry and conductometric titration. As determined by IR spectroscopy, the components are associated mainly via intermolecular hydrogen bonds.

DOI: 10.1134/S1070427207040234

As a continuation of our previous studies of prolonging agents for water-soluble antibiotics for veterinary purposes [1–4], we examined in this study polyvinylpyrrolidone (PVP) and various copolymers of vinylpyrrolidone (VP) with salts of 2-acrylamido-2-methylpropanesulfonic acid. Tilan, a broad-spectrum macrolide antibiotic [5], was used as the pharmaceutical.

The simplest way to prolong the action of pharmaceuticals is covalent and noncovalent binding of a pharmaceutical with hydrophilic polymers. For this purpose, a complex of a pharmaceutical with an auxiliary compound is mainly prepared by mechanical dispersion or mechanical activation of a solution of pharmaceuticals with macromolecular compounds (MMCs). Under these conditions, inter- and intramolecular bonds in polymer macromolecules are ruptured and their reactivity increases. Then, the activated macromolecules react with the pharmaceutical to form inclusion complexes or grafted complexes, depending on the polymer structure [6].

The association in the antibiotic-MMC systems was studied by viscometry, conductometric titration, and IR spectroscopy. These studies allowed more correct estimation of the binding strength in these systems and gave an insight into the mechanism and conditions of formation of polycomplexes of Tilan with PVP and vinylpyrrolidone copolymer.

The choice of vinylpyrrolidone copolymers as promising auxiliary compounds is caused by the fact that, among water-soluble synthetic polymers, PVP and its copolymers are the most widely used in pharmacy. The reason is that PVP is slowly taken in from the injection place, thus decelerating the intake of the pharmaceutical forming a complex with it.This effect is the most pronounced in the case of intramuscular injection of a pharmaceutical [7, 8].

We studied PVP and vinylpyrrolidone copolymers with calcium and sodium salts of 2-acrylamido-2-propanesulfonic acid, prepared by copolymerization of calcium 2-acrylamido-2-propanesulfonate and sodium 2-acrylamido-2-propanesulfonate (Ca-APS and Na-APS) with vinylpyrrolidone in concentrated alkaline aqueous solutions of the monomers at 50°C. The weight ratio of VP and Na-APS was 2 : 98, 6.2 : 93.8, and 12 : 88, and that of VP and Ca-APS, 85.2 : 14.8 [9].

Since the auxiliary compounds should be nontoxic, we performed a preliminary toxicological study of the vinylpyrrolidone copolymers.

EXPERIMENTAL

The complexation of Tilan with MMC was studied by viscometry and conductometric titration of isomolar series. The viscosity of by 0.2 mg ml^{-1} (0.02%)

88 : 12	5–0.02	(97–99) : (3–1)	0.48	0.1–0.1	(17–83) : (83 : 17)	0.864
Ca-APS : VP = 14.8 : 85.2	5–0.02	(97–99) : (3–1)	0.51	0.1–0.1	–	–

aqueous solution of the polymers and a 50 mg ml^{-1} (5%) aqueous solution of the antibiotic (these concentrations are determined by features of the system examined) were measured on an Ubbelohde viscometer with a capillary diameter of 0.73 mm. In the case of the Tilan-PVP system, the initial monomer concentrations were 5 and 3%, respectively.

The electrical conductivity was measured with an R-5021 ac bridge using an Impul's high-sensitivity device as a zero gage and a cell with platinum electrodes. The concentration of Tilan, c_a, and vinylpyrrolidone copolymers in solutions was 1 mg ml^{-1} (0.1 wt %).

All measurements were performed at 25°C. We used both direct and back titration.

The IR spectra of the individual substances and their complexes were recorded on a Specord 75-IR spectrometer. The samples were prepared by uniform application of a paste obtained from solutions of the pure compounds and 4 : 1 antibiotic–VP copolymer mixtures (at this ratio the yield of the complex is maximal) onto a KRS-5 window, followed by prolonged drying at 40°C.

To determine the concentration range of association and to estimate the strength of the complexes between the antibiotic and the auxiliary compound, we used the procedure described in [10].

Our experimental data show that polycomplexes of the antibiotic and PVP and VP copolymers are formed in all the mixtures examined and in a wide range of weight ratios of the components (Table 1).

The substantial deviation of the reduced viscosity and conductometric parameters from unity suggests that strong and compact associates are formed. The results of viscometric measurements are well consistent with those of direct and back conductometric titration.

As can be seen from Table 1, the strength of the intermolecular interaction decreases with increasing fraction of vinylpyrrolidone units in the copolymers. The weakest complexes are formed in the Tilan–PVP system. Apparently, as the content of VP units in the copolymers increases, the contact between the antibiotic molecules and MMC becomes sterically hindered, thus weakening the association of the components. As expected, the reduced conductivity parameters decrease with an increase in the VP fraction, since the degree of dissociation of macromolecules decreases.

Unfortunately, the role of the metal cation in the structuring in the systems examined is difficult to estimate correctly, since the ratios of the monomer units in VP copolymers with calcium 2-acrylamido-2-propanesulfonate and sodium 2-acrylamido-2-propanesulfonate substantially differ.

The nature of intermolecular bonds in molecular complexes is of great significance. Since both proton-donor and proton-acceptor groups are present in the Tilan–PVP system (i.e., carbonyl and hydroxy groups of Tilan and amide and sulfonic groups of the copolymer), intermolecular hydrogen bonds should substantially contribute to the formation of Tilan–PVP polycomplexes. The contribution of the carbonyl groups of the pyrrolidone ring to the structuring is probably less significant since the binding of the antibiotic with PVP gets considerably weakened with an increase in the fraction of VP units.

To elucidate the complexation mechanism in the binary systems, we studied the IR spectra of Tilan,

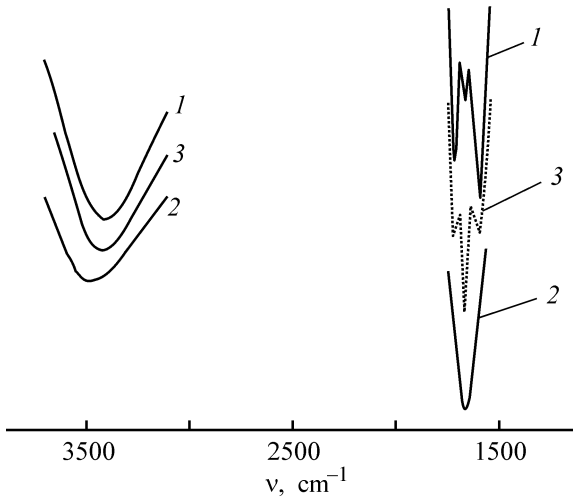
PVP, VP copolymers, and 4 : 1 Tilan–Na-APS : VP mixture (Table 2).

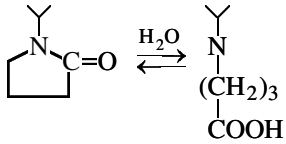
The absorption in the range of stretching vibrations of hydroxy and amino groups (4000–2800 cm^{-1}), which characterizes the presence and type of hydrogen bonding, is of particular interest. A strong band at 3428 cm^{-1} in the Tilan spectrum in this range suggests association of this antibiotic in solutions through a system of hydrogen bonds. The band of carbonyl groups involved in the complexation appears at 1673 cm^{-1}. The band of the –C=C bond conjugated with this group is observed at 1595 cm^{-1}. The strong band at 1720 cm^{-1} is due to C=O vibrations in the aldehyde group.

The IR spectra of the binary systems and corresponding auxiliary compounds have the following features.



Fragment of IR spectra of (*1*) Tilan, (*2*) polyvinylpyrrolidone, and (*3*) Tilan–polyvinylpyrrolidone mixture. (ν) Wavenumber.

Tilan–PVP system. The band at 3478 cm^{-1} is present, along with the characteristic bands, in the spectrum of PVP. This band is mainly due to water impurities absorbed by hygroscopic PVP [11] or to the hydrolysis product of the amide bond in the pyrrolidone ring.



It is known that this product contains carboxy groups having characteristic $\nu_{C=O}$ absorption in the range 1760–1720 cm^{-1}. The intensity of this band is substantially higher than that of $\nu_{OH.}$ The absence of this band in the spectrum indicates that the main impurity is absorbed water.

THe strong difference between the spectrum of the associate and those of the pure components suggests a change in the state of their functional groups (see figure). The frequency of the OH stretching band in the spectrum of the complex is similar to that of Tilan (3428 cm^{-1}), but the intensity of this band in the spectrum of the complex is substantially higher. This suggests formation of a new H-bond network whose strength is higher than that of the hydrogen bonding between adsorbed water and PVP and comparable with that of the intermolecular hydrogen bond in the associates formed in aqueous solutions.

A significant increase in the intensity of the absorption of the carbonyl group in the associate, especially at 1670 cm^{-1}, as compared to that in the spectrum of Tilan not only confirms the formation of the antibiotic-auxiliary compound complex but also suggests the prevailing contribution of the –C=C–C=O group of Tilan

to the complexation. Such an increase in the intensity of the carbonyl band can be only due to an increase in the dipole moment of the C=O bond, caused by intermolecular bonding. The decrease in the intensity of the band of the –C=C bond confirms this assumption [7].

A slight high-frequency shift of the band of the carbonyl groups of PVP (1670 cm^{-1}) suggests its involvement in the complexation.

Thus, the results of this study are consistent with the previously published data [11] and show that complexation of hydrated PVP with various substances occurs via bound water. In this case, water can stabilize the intermolecular complexes.

Tilan–Na-APS : VP system. We studied the IR spectra of two samples of this system with component ratios of 2 : 98 and 6.2 : 93.8. The spectra were similar. The broad asymmetric band in the range 3600–3200 cm^{-1} can be assigned to both stretching vibrations of the NH bond of the secondary amide and to stretching OH vibrations of absorbed water, which causes its complex shape. In the range of absorption of the carbonyl groups, there are two bands: Amide I and Amide II. The first band is strong and is observed at 1664 cm^{-1}; the second band at 1540 cm^{-1} is assigned to bending vibrations of the NH group. The strong band at 1664 cm^{-1} is probably due to vibrations of the C=O bond in the pyrrolidone ring.

The symmetric and asymmetric stretching vibrations of the SO_2 group in the ranges 1260–1150 cm^{-1} and 1080–1010 cm^{-1} are typical of salts of sulfonic acids. In the spectrum of Na-APS : VP, these bands are observed at 1210 and 1040 cm^{-1}, respectively.

The IR spectra of the copolymer and Tilan substantially change after their association in the mixtures. The low-frequency shift of the stretching bands of OH and NH groups suggests the formation of a new stronger (especially as compared to Na-APS : VP) system of hydrogen bonds. The change in the intensity and insignificant shift of the C=O band to low frequencies as compared to the spectrum of the initial components of the system confirm the formation of the complexes. A strong (by 30 cm^{-1}) long-wave shift of the band of symmetrical stretching vibrations of the SO_2 group at 1180 cm^{-1} in the IR spectrum of the complex shows that the contribution of sulfonic groups of the copolymer to hydrogen bonding is maximal.

CONCLUSIONS

(1) It was found that comparatively strong and compact associates of Tilan with polyvinylpyrrolidone and VP copolymers are formed in a wide range of the component ratios.

(2) The optimal Tilan-prolonging agent ratios were determined.

(3) Significant contribution of intermolecular hydrogen bonds to structure formation in Tilan–macromolecular compound system was demonstrated.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Development of Principles of Controlled Synthesis of Monolithic Polymeric Sorbents for Ion Chromatography

Abstract—A series of monolithic macroporous sorbents based on glycidyl methacrylate and ethylene glycol dimethacrylate were prepared by free radical copolymerization. The effect of polymerization conditions and composition of reaction mixture on the pore structure of the monolithic material was studied by IR spectroscopy, intrusion mercury porosimetry, and scanning electron microscopy.

DOI: 10.1134/S1070427207040246

The idea of preparing macroporous copolymers as rigid monoliths, put forward in the late 1980s–early 1990s [1–5], has become a powerful tool in production of modern high-performance sorbents. At present, monolithic stationary phases are widely used in high-speed chromatographic separation of biological (macro)molecules, in modern enzyme reactors, and in other processes based on the dynamic interphase distribution of various compounds [6].

As compared to common chromatographic separation procedures using packed columns, the new separation method has certain significant advantages [6]. These advantages are primarily related to features of the mechanism of intraporous mass transfer controlled by the flow convection, rather than by molecular diffusion typical of chromatography and controlling the rate of the separation process. In the case of monolithic stationary phases, it is possible to use high rates of the eluent flow, which noticeably shortens the process time and significantly increases the separation performance at adsorption capacity and resolution that are comparable with HPLC. Despite the significant progress in application of monolithic sorbents to separation of various biological objects, this stage of development of this method requires improvement of its potential. For example, preparation and optimization of such stationary phases are necessary for development of efficient and highly selective procedures of separation of organic and inorganic ions [7–10]. Obviously, solution of this problem primarily requires an essential rearrangement of the pore structure of the known materials to provide controlled changes in the pore size and adsorption surface. It should be noted that, despite the significant number of papers on this question, there are almost no published data on the algorithm of changes in the pore structure as influenced by the conditions of the sorbent preparation.

In this study, we developed principles of controlled formation of the homogeneous pore structure of monolithic materials for the example of a known copolymer of 2,3-epoxypropyl methacrylate (glycidyl methacrylate, GMA) and ethylene glycol dimethacrylate (EDMA), using thermally initiated free-radical polymerization. For this purpose, we prepared a series of monolithic rods (HPLC columns) characterized by various morphologies and topographies of the sorbent surface, with the aim of finding a compromise sorbent with a high permeability to the liquid phase at relatively low pressure and large area of intraporous adsorption-active surface.

EXPERIMENTAL

In our study we used glycidyl methacrylate (Sigma-Aldrich GmbH, Germany), ethylene glycol dimethacrylate (Sigma-Aldrich GmbH, Germany), 2,2-azobis(isobutyronitrile) (AIBN) (Merck-Schuchard, Germany), dodecanol (D) (Reakhim, Russia), cyclohexanol (C) (Sigma-Aldrich GmbH, Germany), ethanol (Reakhim, Russia), acetonitrile (AN) (Sigma-Aldrich GmbH, Germany), bovine serum albumin (BSA) (Reakhim, Russia), acetone (Reakhim, Russia), *L*-tyrosine (Sigma-Aldrich GmbH, Germany), 25% aque-

ous ammonia (Reakhim, Russia), and sodium chloride (Reakhim, Russia).

The experiments on variation of the polymerization conditions were performed in special vessels (1-ml plastic syringes). The sorbents were prepared using a reaction mixture consisting of an initiator of the free-radical polymerization (AIBN, 1 wt %), a mixture of GMA and EDMA (0.4 ml) with varied volume ratios of these monomers, and a mixture of dodecanol and cyclohexanol (0.6 ml) as pore-forming solvents, with varied ratio of these solvents in the organic phase. Before polymerization, the mixture was purged with a nitrogen flow to remove oxygen acting as polymerization inhibitor. The polymerization was performed at 55–70°C for 12 h (constant time for all the experiments). After the reaction completion, the resulting polymer was washed several times with ethanol and dried at reduced pressure to constant weight. The morphological structure of the copolymer was studied by scanning electron microscopy (JSM-6700F microscope, Japan) and by intrusion mercury porosimetry (PASCAL 440 porosimeter, Thermoquest, Italia). The content of the epoxy groups was determined using a Bruker Tensor 27 IR Fourier spectrometer.

The monoliths prepared directly in stainless steel columns (60 × 2 mm) were washed with ethanol for 15 h on a Milikhrom 4 microcolumn liquid chromatograph (Russia) to remove unchanged monomers and inert porophores. Removal of porophores from the resulting polymer yields a macroporous polymeric material with a volume fraction of pores corresponding to the content of these agents in the initial reaction mixture.

The dependence of the pressure on the eluent flow rate was studied on an Akvilon liquid chromatograph (Russia). The fraction of pores accessible to various compounds was determined chromatographically using a Milikhrom 4 microcolumn liquid chromatograph equipped with a UV spectrophotometric detector (λ 254 nm); 0.05 M NaCl solution was used as a mobile phase. The pore fraction in the sorbents was calculated from the following equation:

$$V_{pore} = (V_R - V_m)/V_{rod},$$

where V_{pore} is the pore fraction in the sorbents (ml ml^{-1}); V_R, eluate volume required to remove the compound from the column; V_m, eluate volume required to remove the compound from the chromatographic system without the column (33 μl); and V_{rod}, volume of the monolithic rod (0.188 ml).

The adsorption amino groups were introduced by treatment of the monolithic porous stationary phases with 25% ammonia solution at 40°C for 5 h.

Table 1. Parameters varied in the course of the polymer synthesis

Monolith*	Content, wt %				Content of epoxy groups, mmol g^{-1}

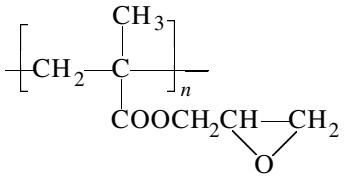
G-60-50	24	16	30	30	4.2

* G means glycidyl methacrylate; the first figure is its percentage in the monomer mixture, and the second, the percentage of dodecanol in the mixture of porophores.

The morphology (namely, the homogeneity of the pore structure, surface quality, total pore surface area depending on then pore size, and size distribution of the pores) is an important characteristic of a monolithic macroporous material [11–14]. In this study, we examined the effect of the polymerization conditions (e.g., ratio of monomers and porophores in the reaction mixture and temperature) on the pore structure of the GMA–EDMA model polymer in order to develop an algorithm for preparing a chromatographic sorbent with controllable properties.

The chemical structure of the GMA-EDMA copolymer is as follows:



The resulting polymeric material has a microglobular texture and contains pores forming a network of interolaced channels with a bimodal pore size distribution. In accordance with the accepted classification of pores, the total pore space is subdivided into macropores [holes between microglobule clusters (>0.05 μm)], mesopores [gaps between microglobules (0.002–0.050 μm)], and micropores [gaps between the nuclei (<0.002 μm)] [15].

A comparative study of the formation of the pore structure in the monolith was performed by scanning electron microscopy (SEM). The parameters varied in the course of preparation of the initial polymeric mixture are listed in Table 1. As can be seen, raising

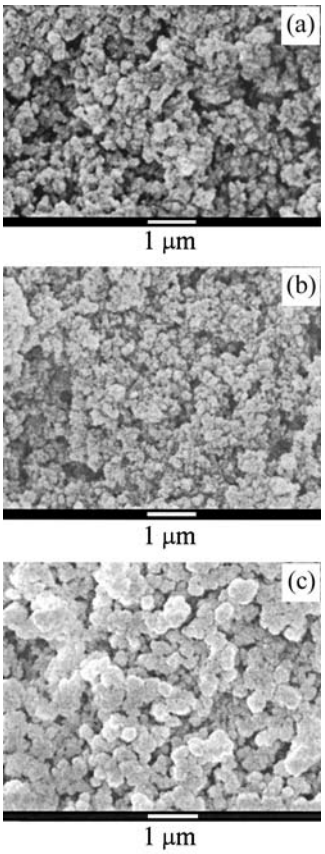


Fig. 1. Electron micrographs of chips of monoliths (a) G-60-10, (b) G-50-10, and (c) G-25-10 prepared by polymerization at 70°C, polymerization time 7 h.

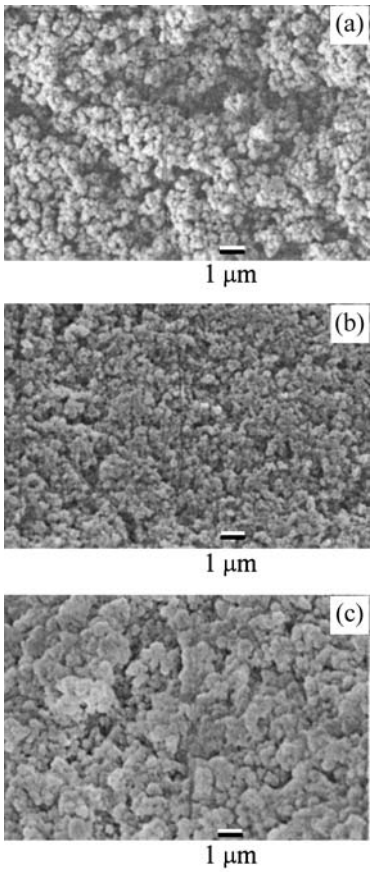

Fig. 2. Electron micrographs of chips of GMA–EDMA monolith (a) G-60-17, (b) G-60-10, and (c) G-60-0 prepared are varied porophore ratio in the reaction mixture.

the content of the cross-linking agent (EDMA) leads to an increase in the "density" of the resulting polymeric products and, thus, in the sorbent surface area and to a decrease in the average pore size (Fig. 1). At the same time, the high degree of cross-linking causes formation of almost impermeable areas on the surface of the porous polymer, which deteriorates its hydrodynamic properties.

It is known that formation of the structure of a monolithic polymer (in particular, GMA–EDMA copolymer) strongly depends on the nature and ratio of the thermodynamically poor solvents (porophores) in the organic phase [16]. We found that, with a mixture of cyclohexanol and dodecanol (C–D) used as the porophore, an increase in the cyclohexanol fraction up to complete substitution of dodecanol leads to a considerable decrease in the size of macropores, with the corresponding increase in the internal surface area of the monolith (Fig. 2).

Table 2. Properties of G-60-10 sorbent prepared at different polymerization temperatures

T, °C	τ, h	Surface area, $m^2 g^{-1}$	Pore size, μm
55	12	23.7	0.6
60	9	32.6	0.3
70	7	70.5	0.1

The polymerization temperature is an important parameter affecting the final morphology of the solid copolymer. Examination by intrusion mercury porosimetry quantitatively showed that the average pore size decreases as the process temperature is elevated (Table 2). It was found that gradient variation of the polymerization temperature, i.e., gradual linear heating from room temperature over a period of 1 h to a given temperature corresponding to the temperature of the initiator decomposition, makes the average pore size larger and the pore size distribution narrower as compared to the sorbents prepared at the same temperature, which was attained by quick

heating and then kept constant (Fig. 3). This phenomenon can be accounted for by the mechanism of radical polymerization: the higher the polymerization rate, the higher the rate of nucleus formation and the greater the number of these nuclei in the unit volume. As a result, the matrix formed is characterized by a higher structure density and, thus, by a smaller average pore size. The random distribution of the growing globules, associated with the high polymerization rate, also broadens the pore size distribution.

Based on the experimental data, we chose the polymerization conditions required to prepare a material with boundary properties, i.e., with the pore size providing unhindered liquid flow at low pressures and high specific surface area of pores. In this case, the GMA : EDMA monomer ratio was 6 : 4, and the porophore ratio C : D = 9 : 1. The polymerization was carried with linear heating from 20 to 55°C over a period of 1 h; the polymerization time was 12 h. The resulting monolith had high mechanical strength and chemical stability. The rigid structure of the monolithic sorbent allowed chromatographic experiments to be performed at a pressure of up to 200 bar in the mobile phase flow. The chemical stability of the stationary phase was confirmed by passing various organic solvents, inorganic and organic acids, buffer solutions, and other eluents through the column. The IR spectroscopic and SEM data showed no degradation of the monolith matrix.

The dependence of the pressure on the linear flow velocity of the mobile phase (water) (Fig. 4) was determined using the (60 × 2 mm) column packed with monolithic GMA–EDMA polymer prepared in situ. It can be seen that, at a water flow velocity of 2.0 ml min^{-1} (corresponding to F = 10.5 ml min^{-1} for a standard column 4.6 mm in diameter), the pressure was only 40 bar, whereas columns of the same size packed with a granular sorbent are characterized by a pressure drop of about 100 bar at an eluent flow rate of 1–2 ml min^{-1}.

The relative porosity of the monolithic stationary phases can be determined chromatographically from the elution of nonsorbable compounds [17]. Markers with different molecular sizes allow determination of the fraction of pores accessible to a given compound in the course of chromatographic separation. The results for the above column, determined from the elution volumes of low-molecular-weight (acetone, *L*-tyrosine) and high-molecular-weight (bovine serum albumin) compounds, are listed in Table 3.

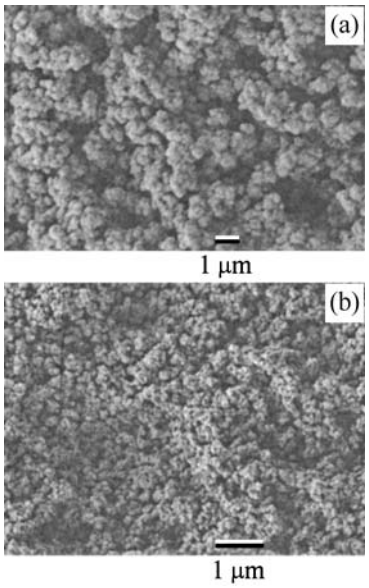

Fig. 3. Electron micrographs of chips of GMA–EDMA monolith prepared at a polymerization temperature of 55°C; (a) constant temperature and (b) temperature gradient.

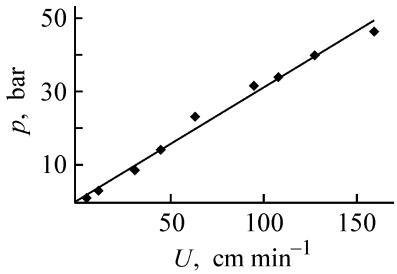

Fig. 4. Pressure P vs. the linear flow velocity U of the eluent (water).

Table 3. Fraction of accessible sorbent pores, calculated from the elution volumes of low-molecular-weight (acetone, *L*-tyrosine) and high-molecular-weight compounds (bovine serum albumin, BSA)

Compounds	Molecular weight	Elution volume V_R			Corrected elution volume V_R^*			Pore fraction V_{por}, ml ml^{-1}
		μl at indicated elution rate, μl $μl^{-1}$						
		20	100	200	20	100	200	
Acetone	58	120	120	120	87	87	87	0.46
L-Tyrosine	181	115	115	115	82	82	82	0.44
BSA	67 000	87	87	87	54	54	54	0.29

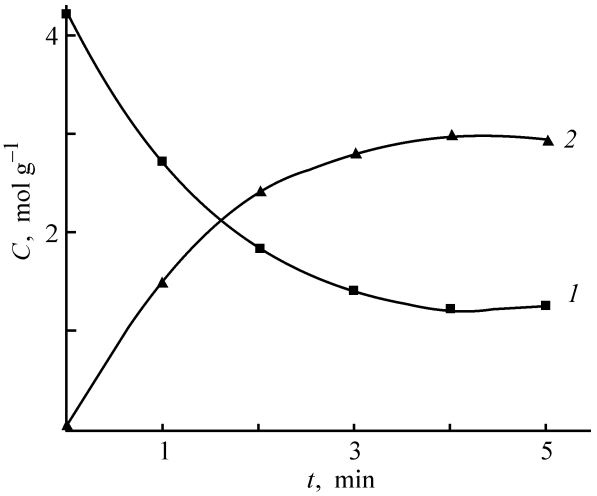

Fig. 5. Kinetic curve of conversion of epoxy groups by ammonia: (*t*) time of modification of the polymer with an ammonia solution and (*C*) conversion of epoxy groups by ammonia. Content, mmol g^{-1}: (*1*) epoxy groups and (*2*) nitrogen.

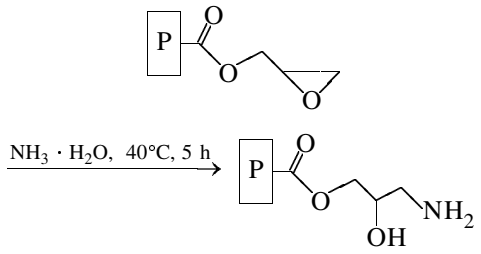
A significantly smaller pore volume was calculated for high-molecular-weight BSA, because it cannot occupy smaller pores. The chromatographic patterns recorded at various elution rates are typical of monolithic stationary phases; they are symmetric and independent of the elution rate.

To make the sorbents suitable for ion chromatography, we introduced a controlled amount of adsorption centers into the sorbent structure by chemical modification of the monolith with amino groups:



We found that the conversion of the epoxy groups upon polymer modification with 25% ammonia solution at 40°C for 5 h reaches 70–75%. The IR spectra showed that, under the static conditions, the kinetic curve of conversion of the epoxy groups by ammonia levels off in 4 h (Fig. 5). This kinetic dependence allows preparation of sorbents with various (even small) densities of the adsorption ligands, which is of particular importance for preparing stationary phases for ion chromatography.

CONCLUSIONS

(1) Matrices of a macroporous copolymer based on glycidyl methacrylate and ethylene glycol dimethacrylate exhibit rigid macroporous morphology controlled in the stage of synthesis and characterized by a large total surface area, chemical stability, mechanical strength, and unique hydrodynamic parameters.

(2) Direct tests in columns showed the efficiency of these materials as fixed phases for high-speed liquid chromatography.

Abstract—A method was developed for synthesis of highly permeable polyelectrolytes through the reaction of polyvinyloxyethylamine with various glycidyl derivatives of dihydroxybenzenes, aminophenols, and aromatic diamines. The physicochemical and sorption properties of the resulting polymers were examined.

DOI: 10.1134/S1070427207040258

Soluble and cross-linked ion exchangers produced on the basis of polyvinyloxyethylamine (PVOEA, monoethanolamine polyvinyl ether) demonstrate unique performance characteristics as sorbents, exhibiting high chemical, thermal, and radiation resistance. They are widely used in solving diverse problems of chemical technology, e.g., for recovery of noble, rare, and nonferrous metals and purification of medical products [1–7].

In this study, we synthesized polyfunctional ion-exchange resins by the reaction of di-, tri-, and tetraglycidyl derivatives of dihydroxybenzenes, *m*- and *p*-aminophenols, and aromatic diamines with VOEA homo- and copolymers and characterized their properties.

EXPERIMENTAL

Epoxy compounds (ECs): diglycidyl derivatives of resorcinol (DGR), hydroquinone (DGH), and aniline (DGA); triglycidyl derivatives of *m*- and *p*-aminophenols (TGmAP, TGpAP); and tetraglycidyl derivative of diaminodiphenylmethane (TGDADPM) were prepared as in [8].

VOEA-based polymers: homopolymer (PVOEA) and VOEA copolymers with *N*-vinylpyrrolidone (VOEA–NVP) and 2-methyl-5-vinylpyridine (VOEA–MVP) were synthesized at a monomer molar ratio of VOEA : vinylpyridine = 25 : 75 by the procedure described in [9].

The ion exchangers were synthesized by polycondensation of homo- and copolymers of VOEA with ECs [10] in isobutanol at 60–120°C for 8–10 h. The reaction mixture was poured on a tray and concentrated at 80°C. The resulting product was crushed and screened to obtain the 0.25-mm fraction by the standard procedure [11, 12].

The chemical resistance of the resins against acids and alkalis was studied according to [11, 13]. Two 1-g samples were placed in 250-ml round-bottomed flasks. One sample was poured over with 100 ml of 5 M H_2SO_4 and the other sample, with 100 ml of 5 M NaOH. The contents were heated for 30 min (water bath) with a reflux condenser and then cooled to room temperature. The sample was filtered off and, if needed, converted into the OH form. Finally, the sample was washed with distilled water and analyzed for the static exchange capacity (SEC). The chemical resistance of the resin X (%) was estimated as

$$x = \frac{\mathrm{SEC}}{\mathrm{SEC}_0} \times 100,$$

where SEC_0 and SEC are the static exchange capacities of the resin before and after treatment, respectively.

To determine the chemical resistance of the resins against oxidants [11, 13], a 1-g resin sample was poured over with 100 ml of 10% H_2O_2 and allowed to stand for 48 h at room temperature with intermittent stirring. Then the resin was filtered off, converted into the OH form, washed with distilled water, and analyzed for $\mathrm{SEC}_{\mathrm{HCl}}$. The chemical resistance was estimated by Eq. (1).

The kinetics of the reaction of DGEA with PVOEA was studied IR-spectroscopically on a Spec-

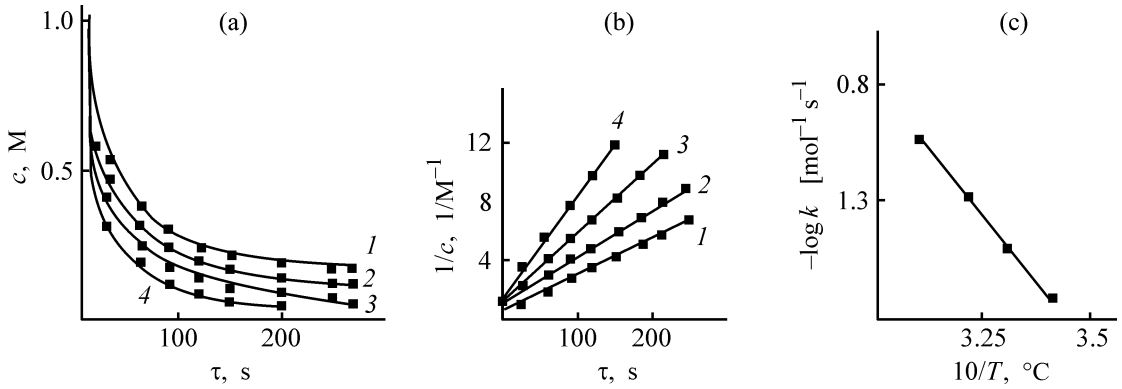

Fig. 1. (a) Kinetic curves for the decrease in the epoxy group content c, (b) their linearized forms, and (c) Arrhenius plot for the reaction of DGEA with PVOEA. (k) Rate constant and (τ) time. T (°C): (*1*) 20, (*2*) 30, (*3*) 40, and (*4*) 50.

ord M80 instrument (Carl Zeiss) with 0.04-mm cells [14, 15]. The reaction was monitored by the decrease in the intensity of the band at 917–920 cm^{-1} (asymmetric stretching vibrations of the DGA epoxy groups). The resulting transmission-vs.-time curves were converted to the curves of epoxy concentration against time.

It follows from Fig. 1 that, under ambient conditions, epoxy groups readily react with the primary amino groups of PVOEA. The linear dependence in the coordinates $1/c$ vs. τ suggests a second-order kinetics.

The activation energies of the reactions of DGA with PVOEA (Fig. 1), VOEA–MVP, and VOEA–NVP were estimated to be 28.04, 31.90, and 35.01 kJ mol^{-1}, respectively, which is well consistent with published data [16, 17]. Data on the influence of the starting reagent ratio, curing time, and temperature on SEC_{HCl} (0.1 M HCl) of the resulting resins, obtained in this study show (Table 1) that, in all cases, SEC grows as

* (SEC) Static exchange capacity (0.1 HCl) after treatment with 5 N H_2SO_4, 5 N NaOH, and 10% H_2O_2; (V) swellability of the resin in water; and (W) moisture content.

the VOEA to EC ratio increses from 1 : 1 to 4 : 1. The anion exchangers based on *m*- and *p*-dihydroxybenzenes are characterized by low SEC, since, in contrast to aromatic mono- and diamines, they contain no titratable amino groups. Introduction of the *N*-vinylpyrrolidone units into the copolymer considerably decreases SEC.

It is known that the properties of ion exchangers are strongly influenced by the prepolymer curing mode. Our results show (Tables 2 and 3) that the products should be cured for 8–10 h at 80–100°C, depending on the condensation temperature and nature of VOEA polymers.

The SEC of the resins prepared under optimal conditions ranges from 2.3 to 7.7 mg-equiv g^{-1}. These products demonstrate a limited swellability (Table 4). In this case, the yield of the target products is 88–95%. The SEC loss caused by treatment of the resins with 5 N H_2SO_4, 5 N NaOH, and 10% H_2O_2 was within 5%.

The polyelectrolytes obtained selectively extract Au ions from hydrochloric acid solutions over a wide concentration range (Fig. 2).

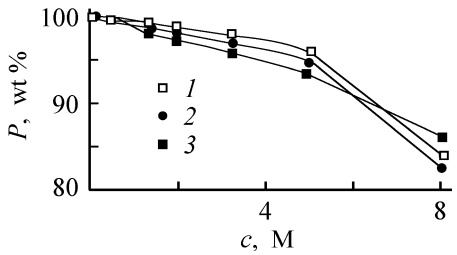

Fig. 2. Sorption P of Au ions on anion-exchange resins based on (*1*) PVOEA, (*2*) VOEA–MVP, and (*3*) VOEA–NVP vs. the HCl concentration c.

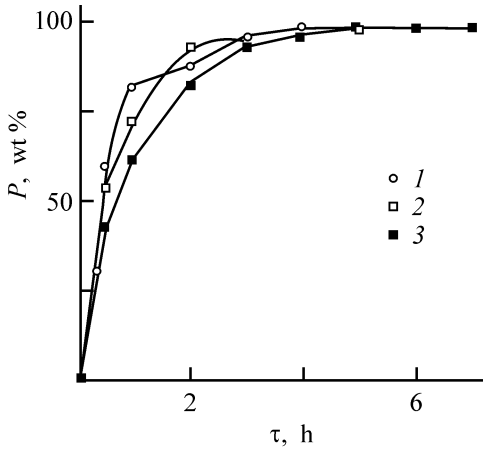

Fig. 3. Kinetic curves of Au sorption on anion-exchange resins based on (*1*) PVOEA, (*2*) VOEA–MVP, and (*3*) VOEA–NVP. (*P*) Degree of sorption and (τ) time.

Kinetic data on the sorption of anionic Au species on the anion-exchange resins show (Fig. 3) that the nature of the epoxy compound has no effect on the sorption rate. For the resins based on TGDADPM, the maximal sorption was attained in 3 h. In this case, a 50% sorption was attained in 0.5 h.

To conclude, anion exchangers based on VOEA polymers and various ECs are highly efficient sorbents for recovery of Au from hydrochloric acid solutions. The resins recover 98–99.9% of Au over a wide HCl concentration range, which points to their high selectivity and chemical resistance.

CONCLUSIONS

(1) Condensation of di-, tri-, and tetraglycidyl derivatives of dihydroxybenzenes, aminophenols, and aromatic mono- and diamines with homo- and copolymers of β-vinyloxyethylamine were studied.

(2) The activation energies of the reactions of aniline diglycidyl derivative with β-vinyloxyethylamine homopolymer and its copolymers with 2-methyl-5-vinylpyridine and *N*-vinylpyrrolidone were estimated to be 28.04, 31.90, and 35.01 kJ mol^{-1}, respectively, which is well consistent with the published data.

(3) It was found that the chemical resistance of ion exchangers synthesized on the basis of di-, tri-, and tetraglycidyl derivatives of aromatic compounds and β-vinyloxyethylamine polymers in 5 N sulfuric acid, 5 N NaOH, and 10% H_2O_2 is 98–100%.

(4) It was demonstrated that the polyelectrolytes obtained selectively recover Au from hydrochloric acid solutions over a wide HCl concentration range. The degree of sorption is as high as 98–99%.

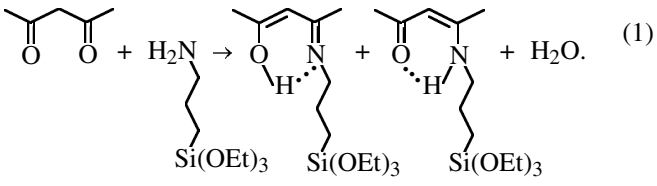
Abstract—A mixture of two isomers of organosilicon carbofunctional compounds, 4-(3'-triethoxysilylpropylimino)pent-2-en-2-ol $(EtO)_3Si–CH_2CH_2CH_2–N=C(Me)–CH=C(Me)–OH$ (**Ia**, 83%) and 4-(3'-triethoxysilylpropylamino)pent-3-en-2-one $(EtO)_3–CH_2CH_2CH_2–NH–C(Me)=CH–C(O)Me$ (**Ib**, 17%) was prepared by reaction of 3-aminopropyltriethoxysilane with acetylacetone. The use of trimethylsilyl ether of acetylacetone instead of acetylacetone yields **Ia** (84%) and silylated derivatives $(Me_3SiO)_n(EtO)_{3-n}Si–CH_2CH_2CH_2–N=C(Me)CH=C(Me)OH$ (**II**) (16%). Solid, liquid, or resinous products were prepared by hydrolytic condensation of **I** and **II**. Compositions for preparing transparent sol-gel films were developed.

DOI: 10.1134/S107042720704026X

β-Diketones and their nitrogen derivatives (keto imines, enamino ketones, and imino enoles) [1] are conventional chelating ligands. Numerous complexes of *d* and *f* elements with these ligands have been prepared [2–5]. Organic polymers and mineral sorbents with grafted chelate groups are used for concentration, separation, and purification of metals [6–8]. In this study, we developed a procedure for preparing a silicon-containing imino enol from 3-aminopropyltriethoxysilane (APTES) and acetylacetone. The presence of triethoxysilyl groups in the product allows its use for hydrolytic polycondensation and grafting of a ligand to hydrated metal oxides and for preparation of organosilicon polymers, transparent films, and functionalized adsorbents.

A mixture of two isomers, 4-(3'-triethoxysilylpropylimino)pent-2-en-2-ol **Ia** and 4-(3'-triethoxysilylpropylamino)pent-3-en-2-one **Ib**, can be prepared by reaction of APTES with acetylacetone or its trimethylsilyl ether.



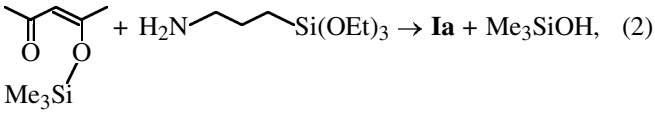
(1)

Ia **Ib**

Ia : **Ib** = 83 : 17

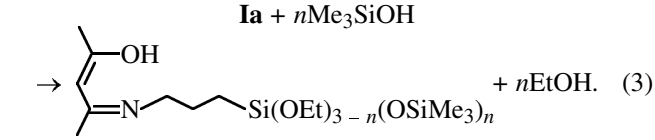
Water released in the course of the reaction reacts with APTES and compound **I**, thus decreasing the yield of **I** and increasing the yield of the oligomers.

The use of trimethylsilyl ether of acetylacetone for this purpose substantially increases the yield of the products distillable in a vacuum. However, preparation of pure compound **I** by this method is complicated by the reaction of the released trimethylsilanol with **I** to form products of substitution of one, two, and three EtO groups at the silicon atom by Me_3SiO: compounds **IIa**–**IIc**, respectively:



(2)

Ia + $n$$Me_3SiOH$



(3)

where n = 1 (**IIa**), n = 2 (**IIb**), n = 3 (**IIc**).

The **I** : **II** ratio calculated from the ^1H NMR data is 84 : 16.

The IR spectrum of compound **I** contains the stretching (2974, 2933, 2888 cm^{-1}) and bending (1441, 1391,

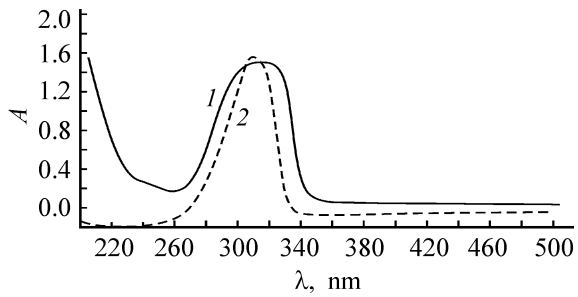


Fig. 1. UV spectrum of (*1*) compound **I** (film on a quartz support, λ_{max} = 310 nm) and (*2*) mixture **I/II** (1.82×10^{-4} M solution in EtOH, λ_{max} = 311 nm, ε = 17200 l mol^{-1} cm^{-1}). (*A*) Optical density and (λ) wavelength.

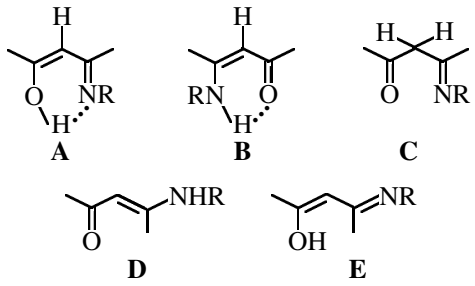
1355 cm^{-1}) bands of C–H bonds. A strong doublet at 1613 and 1583 cm^{-1} and the band at 1517 cm^{-1} are assigned to vibrations of the imino enol (HO–C=CH–C=N–) and enamino ketone (O=C–CH=C–N–) fragments. The strong bands of the triethoxysilyl group are observed at 1168, 1097, 961, and 784 cm^{-1}. The spectra of **I** and **II** are, on the whole, similar. The difference is that the spectrum of **II** contains two additional bands at 1254 and 845 cm^{-1}, typical of the trimethylsilyl group. The IR and NMR data show that compound **I** prepared by the reaction of acetylacetone with APTES mainly consists of imino enol **A** (83%) and enamino ketone **B** (17%). Synthesis via trimethylsilyl ether yield compounds **I** and **II** in the form of pure imino enols. The keto imine form **C** is not typical of compounds **I** and **II**



The IR spectrum of compound **I** contains a broad band of ν(O–H) in the range 3400–2600 cm^{-1}, which is superimposed by three strong ν(C–H) bands. The shape of the ν(O–H) band is typical of the hydrogen-bonded chelate ring. The ^{1}H NMR signals of the protons bound with oxygen and nitrogen atoms are observed in the low field (10.84 ppm for OH and 8.38 ppm for NH), with the signal of the OH group being stronger than that of NH. The signal of the methine hydrogen in the imino enol fragment is observed at 4.91 ppm and has a high-field shoulder due to impurity of tautomer **B**. The intensity ratio of the signal of the methine proton, hydrogen atoms of the methylene bridge $Si(CH_2)_3N$, and ethoxy groups $SiOCH_2CH_3$ is 1 : 2 : 6 : 9, which confirms the presence of tautomers **A** and **B** and the absence of the keto imine form **C** containing two protons at the central carbon atoms. The signals of the $CH_3C(O)$ and CH_3CN groups are observed in the form of two singlets of equal intensity at 1.97 and 1.89 ppm. The ^{1}H NMR spectrum of compound **I** contains similar signals and additional signals at –0.039, –0.021, and +0.003 ppm assigned to the Me_3Si group in $–CH_2–Si(OSiMe_3)_3$, $–CH_2–Si(OSiMe_3)_2(OEt)$, and $–CH_2–Si(OSiMe_3)(OEt)_2$. The electron-withdrawing power of the Me_3SiO substituent (σ_J = +0.05) is lower than that of EtO (σ_J = +0.26) [9]. The signals of the protons of the Me_3SiO groups were assigned on the assumption that they should be shifted upfield in going from **IIa** to **IIb** and then to **IIc**. The molar ratio of the products **IIa** : **IIb** : **IIc** = 31 : 24 : 45, calculated from the ^{1}HNMR spectrum, suggests that the nucleophilic substitution at the silicon atom is nonselective.

The ^{13}C NMR and DEPT spectra confirm the structure of compounds **IIa**–**IIc**. The signals of carbon atoms of the *C*H$_3$Si, *C*H$_3$CH$_2$O, *C*H$_3$CN, and *C*H$_3$C(O) groups and of the *CH* group of the central carbon atom of imino enol are observed at 1.99, 18.56, 19.03, 28.95, and 95.33 ppm, respectively; and the signals of the CH_2Si, CH_2CH_2N, and CH_2O groups, at 7.80, 24.28, 45.73, and 58.77 ppm, respectively. The two lowest-field signals of equal intensity at 162.96 and 194.31 ppm are assigned to the carbon atoms of the imino enol fragment bound to the oxygen and nitrogen atoms. The absence of splitting of these signals suggests the formation of a strong chelate ring. The ring closure through the OH···N hydrogen bond rules out formation of *trans* isomers **D** and **E**. The presence of these isomers should result in splitting of these signals. The results are, on the whole, consistent with the data of monograph [10], in which the imine–enamine tautomerism of the N derivatives of β-dicarbonyl compounds is considered in detail.

The UV spectra of compound **I** and **I/II** mixture (Fig. 1) contain a strong band at 310 nm and a very weak band at 230–240 nm. It is known that β-diketones also have two absorption bands: a short-wavelength band due to the $\pi \rightarrow \pi^*$ transition and a long-wavelength band assigned to the $n \rightarrow \pi^*$ transition. Two bands at 227 and 290 nm are observed in the spectrum of the triethoxysilyl derivative $(EtO)_3SiCH_2CH_2CH_2C[C(O)Me]_2$. The presence of the strong absorption band at 310 nm, which is red-shifted as compared to the band of the β-diketone, suggests the delocalization of π and *n* electrons in the hydrogen-bonded chelate ring. The weak band in the short-

Time of curing τ_{cur} and weight loss of films in the course of their cross-lonking in air and subsequent heating

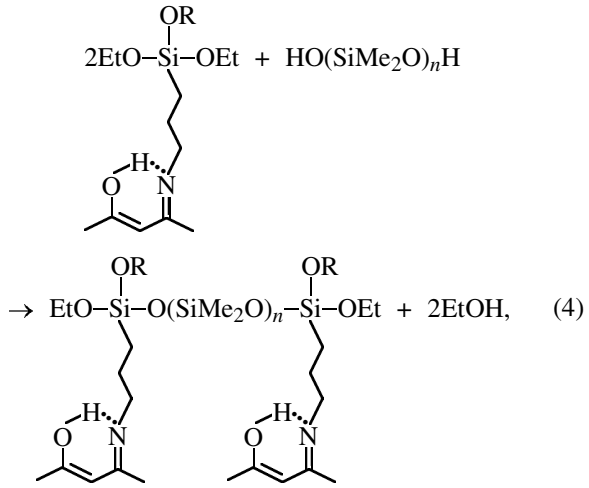
Composition of initial mixture, wt %			τ_{cur}, h	Weight loss, %		
I/II	APTES	Oligodimethyl-siloxanediols		curing in air	heating for 0.5 h	
					100°C	150°C
15	31	54	12	25	28	30
39	31	30	20	8	13	21
49	25	26	28	25	31	40

wavelength range is due to the presence of a small amount of acyclic imino enol and enamino ketone.

Pure compound **I** and a **I/II** mixture prepared by reactions 2 and 3, respectively, are relatively stable with respect to atmospheric moisture. When thin films of these compounds were aged on a glass support for 48 h, no solid films were formed. Transparent 20–50-μm solid films were obtained from compositions containing **I** (or **I/II**), oligodimethylsiloxanediols $HO(SiMe_2O)_nH$ (n = 2–5), and APTES. The time of spontaneous curing at room temperature in air ranges from 15 to 30 h, depending on the composition of the initial liquid mixture. Turbid or strongly opalescent films were formed in 15–20 h in the absence of siloxanediols at **I** : APTES [(**I/II**) : APTES] weight ratio from 0.5 : 2 to 2 : 1. At the weight ratio of 4 : 1, the mixture is cured in 48 h incompletely; however, the viscosity of the liquid layer strongly increases.

The curing time and weigh loss of the films in the course of cross-linking in air and subsequent heating to 100 (0.5 h) and 150°C (0.5 h) are listed in the table. It is seen that the cross-linking duration grows from 12 to 28 h with an increase in the fraction of **I/II** in the initial mixture from 15 to 49 wt %. The weight loss in the course of curing and heat treatment is minimal at the **I/II** content of about 40 wt %. The films withstand heating to 100°C. At 150°C they become yellow, but remain transparent. The maximal weigh loss can reach 40%.

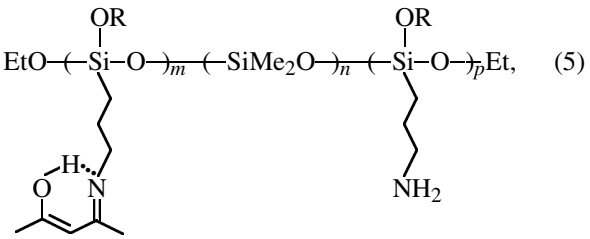
The presence of nonhydrolyzable Me_3SiO groups in compounds **IIa**–**IIc** should result in an increase in the fraction of linear polysiloxane fragments and a decrease in the degree of cross-linking in the course of curing in air as compared to the films prepared from **I**. Siloxanediols act as plasticizers and agents cross-linking tri- and bifunctional molecules of silylated imino enols **I** and **II** by the condensation mechanism. Molecules of APTES containing primary amino groups act as both a base catalyst and a trifunctional component along with **I**:



(4)

where R = Et, $SiMe_3$.

The structure of the solid film can be described as follows:



(5)

where R = Et, $SiMe_3$, –Si≡.

The IR spectra of the film prepared by curing a mixture containing 15 wt % **I/II**, 54 wt % siloxanediols, and 31 wt % APTES in air, followed by heating to 100 and 150°C, are shown in Fig. 2. The IR data can give insight into the curing mechanism. The spectrum of the initial liquid mixture (Fig. 2, curve *1*) contains weak bands at 3449, 3373, 3297, and 3171 cm^{-1} assigned to the O–H and NH vibrations in siloxanediols, compounds **I** and **II**, and APTES. A strong doublet at 1613, 1578 cm^{-1} is assigned to the imino enol group. The bands of $Si(OEt)_3$

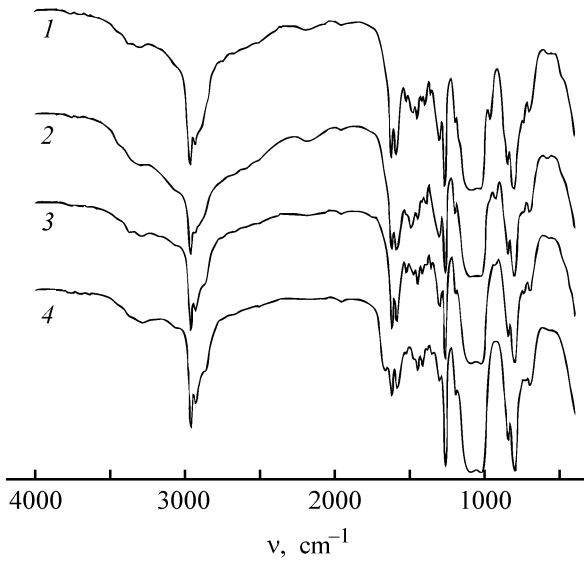


Fig. 2. IR spectra of a film prepared from a mixture of compounds **I/II**, APTES, and oligodimethylsiloxanediols taken in a weight ratio of 15 : 31 : 52. (ν) Wavenumber; the same for Fig. 3. Film: (*1*) initial, (*2*) cured in air for 15 h, (*3*) heated at 100°C for 30 min, and (*4*) heated at 150°C for 30 min.

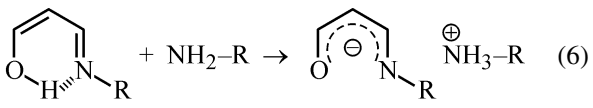
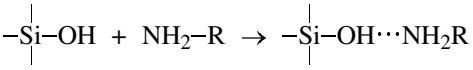
and $Si(OEt)_{3-n}(OSiMe_3)_n$ are observed at 1260, 1168, 1098, 1027, 961, 845, and 804 cm^{-1}.

When a liquid film in kept in air for 15 h at room temperature (until curing) (Fig. 2, curve *2*), the bands in the range 3500–2700 cm^{-1} are broadened and become stronger. At the same time, the spectrum in the range 1150–840 cm^{-1} (SiOEt, $SiOSiMe_3$) changes insignificantly. The bands are broadened owing to the formation of quaternary ammonium cations giving broad N–H bands in the range 3000–2200 cm^{-1}. The spectrum in the range of vibrations of imino enol group and N–H bending vibrations (1700–1450 cm^{-1}) also changes substantially. The bands at 1583 and 1472 cm^{-1} are broadened and shifted toward low (the first band) and high (the second band) frequencies owing to superposition with the bending vibrations of the N–H bond in the ammonium cation. The intensity of the second band (1482 cm^{-1}, NH_3^+) substantially increases. Compounds **I** and **II** are weak protonic acids, whereas APTES is a base. The changes in the IR spectrum in the range 2900–2200 cm^{-1} can be described by the reaction

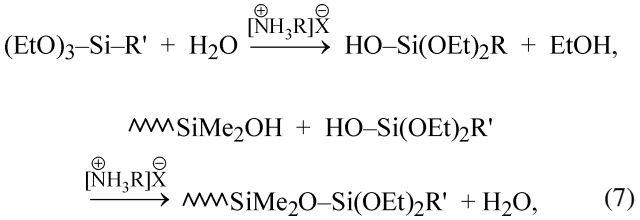


R = ∧∧Si(OEt)$_n$(OSiMe$_3$)$_{3-n}$

The broadening of the absorption bands in the range 3400–3050 cm^{-1} and an increase in their intensities can be due to association of the silanol groups with APTES:



Thus, a quaternary ammonium salt is formed in the composition after introduction of APTES. These compounds are effective catalysts of hydrolysis of triethoxysilyl groups and condensation of silanol groups [11]:



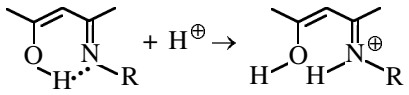
where R = ∧∧Si(OEt)$_3$, R' = ∧∧N=C(Me)CH=C(Me)OH, X = MeC(O)CHC(NR)Me.

Heating of the sample at 100°C for 1 h restores the initial shape of the spectrum (Fig. 2, curve *3*), with the transformation in the range 3500–2700 cm^{-1} being the most pronounced. This is due to decomposition of unstable ammonium derivatives shown in schemes (6) and (7). The main distinction between the spectrum of the film heated to 100°C and that of the initial liquid mixture is the lower intensity of the stretching (3000–2800 cm^{-1}) and bending (1400–1300 cm^{-1}) C–H bands after heating. The shape of the bands in the range 1200–950 cm^{-1} also changes due to a decrease in the content of the SiOEt fragments and an increase in the number of the SiOSi bonds. The intensity of the C–H bands decreases further after heating to 150°C (Fig. 2, curve *4*). The spectrum in the range 1660–1550 cm^{-1} noticeably changes owing to the reaction of the enamino ketone fragment with the primary amino group of APTES.

Thus, the following reactions occur in the course of film curing: formation of imino enol–APTES complex catalyzing the curing; condensation of the silanol groups with the ethoxysilyl groups of compound **I** and APTES; formation of polysiloxane fragments; and release of ethanol.

Organosilicon imino enols **I** and **I/II** were hydrolyzed in an ethanol solution with hydrochloric acid, ammonia, and water in the presence of Bu_4NF. The concentration of hydrochloric acid and ammonia

was 1 mol per mole of the compound. Tetrabutylammonium fluoride was introduced in catalytic amounts. An insoluble powdered polyorganosiloxane, transparent colorless resin, and transparent colorless oil were obtained from **I/II** in the presence of HCl, NH_4OH, and Bu_4NF, respectively. The IR spectra of the products are shown in Fig. 3. The strongest spectral transformations were observed in the spectrum of the samples prepared in the presence of hydrochloric acid (Fig. 3, curve *1*). The appearance of a strong broad band at 3408 cm^{-1} (CO–H) and a number of broadened bands in the range 2730–2400 cm^{-1} (N–H) and transformation of a doublet at 1613 and 1583 cm^{-1} (O–C=C–C=N) into a singlet at 1608 cm^{-1} suggest the protonation of the nitrogen atom and formation of a quaternary iminium cation, with cleavage of the intramolecular hydrogen bond:



(8)

These substantial structural transformations of the chelate ring change the shape of the absorption band of the O–C=C–C=N fragment at 1600 cm^{-1}. The spectral changes in the range 1200–750 cm^{-1} suggest the conversion of the ethoxysilyl groups into disiloxane groups. The band at 1093 cm^{-1} is broadened and split into a doublet; the intensity of the bands at 1168, 956, and 774 cm^{-1} strongly decreases. It is known that organic silanols readily condense to form disiloxanes in the presence of an acid. The band 3408 cm^{-1} is assigned to the alcoholic group. The results of elemental analysis show that the carbon content of the hydrolysis product is underestimated by a factor of 1.5–1.7 and the silicon content is overestimated with respect to those calculated for organosilsesquioxane $O_{1.5}Si–CH_2CH_2CH_2–N=C(Me)–CH=C(Me)–OH \cdot HCl$ and found in the products of hydrolysis in neural and alkaline solutions. This can be due to partial defragmentation of organosilicon imino enol in the presence of a strong acid, formation of acetylacetone, and its removal from the solid products on drying in a vacuum.

Hydrolysis with ammonia and water in the presence of Bu_4NF results in less substantial transformation of the IR spectrum. The shape and intensity of the absorption bands in the range 1650–1200 cm^{-1} remain the same, which suggests the preservation of the chelate ring. The maximal amount of associated silanol groups is formed in hydrolysis of a **I/II** mixture and compound **I** by water in the presence of Bu_4NF (Fig. 3, curve *3*), which is confirmed by the presence of a strong and broad band at 3373 cm^{-1}

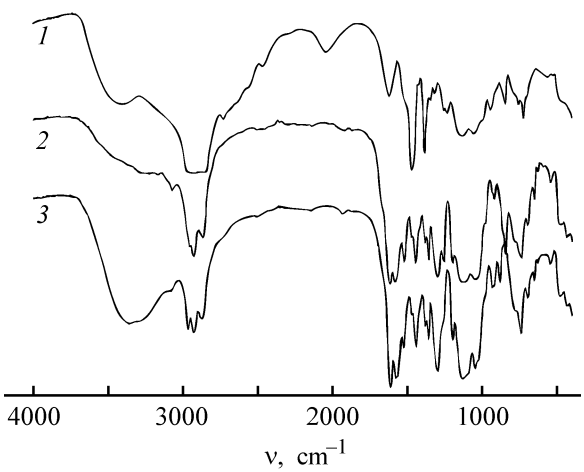


Fig. 3. IR spectra of products formed by hydrolysis of a **I/II** mixture with (*1*) HCl (Nujol mull) and (*2*) NH_4OH solution (liquid film) and (*3*) of compound **I** with water in the presence of Bu_4NF (liquid film).

with a shoulder at 3282 cm^{-1}. The lower intensity of the absorption in the range 3500–3150 cm^{-1} and the stronger broadening of the doublet at 1128 and 1047 cm^{-1} suggest the condensation of a significant number of the SiOH fragments in the presence of NH_4OH to form a high-molecular-weight polysiloxane with terminal silanol groups (Fig. 3, curve *2*).

Thus, solid, resinous, and liquid hydrolysis products with different contents of disiloxane and silanol groups can be prepared by hydrolysis of a **I/II** mixture and pure compound **I** under different conditions.

EXPERIMENTAL

The IR spectra of the samples in the form of a liquid film of Nujol mull between KBr or CaF_2 windows were recorded on an FSM 1201 Fourier IR spectrometer. The electronic absorption spectra were recorded on a Perkin–Elmer Lambda 25 spectrophotometer. The ^1H NMR spectra were recorded in $CDCl_3$ on a Bruker Avance DPX-200 (200 MHz) spectrometer at 25°C using Me_4Si as an internal reference.

Compounds **I** and **II** were analyzed on a Tsvet 530 chromatograph (0.3 × 200 cm stainless steel column, 5% SE-30 on Chromaton N-Super). Acetylacetone was distilled under reduced pressure and was analyzed on a 0.3 × 300-cm column packed with 15% Reoplex-400 on Chezasorb AW-HMDS. 3-Aminopropyltriethoxysilane (Altaikhimprom Production Association, Slavgorod, Altai krai, Russia) was distilled on a 1 × 50 cm column packed with Nichrome spirals and was analyzed on a 0.3 × 200 cm column packed with 5% XC-2-1 silicone on Chromaton-N-AW-DMCS.

The content of isomeric 2-aminopropyltriethoxysilane isomer was 2.0%. Glass (1 × 25 × 40 mm) and quartz (3 × 12 × 40 mm) supports used for film preparation were treated with a saturated NaOH solution in isopropanol for 10 h and then with a chromic acid mixture for 10 h, washed with water, and dried at 150–170°C.

Reaction of acetylacetone with APTES. To a solution of acetylacetone (5.1 g, 0.05 mol) in toluene (25 ml), a solution of APTES (13.3 g, 0.06 mol) in toluene (10 ml) was added. The mixture was refluxed for 4 h. The solvent was distilled off and the residue was subjected to fractional distillation in a vacuum. Compound **I** (5.8 g, 38%) was isolated in the form of a transparent liquid, bp 115–118°C (2 mm Hg), n_D^{20} = 1.4712. IR spectrum, ν, cm^{-1}: 3070 w (H–C=C), 2974 vs (CH), 2933 vs (CH), 2766 w (H–CN), 2736 w (H–CN), 1613 vs, 1583 vs, 1517 m, 1441 s (O–C=C–C=N), 1391 m (CH), 1355 m (CH), 1295 vs, 1194 m, 1168 s (SiOEt), 1097 vs (SiOEt), 1027 m, 961 vs (SiOEt), 784 vs (SiOEt), 648 w, 541 w, 491 m, 445 m. ^{1}H NMR spectrum, $CDCl_3$, δ, ppm (*J*, Hz): 0.63 t (2H, CH_2Si, *J* = 7.8), 1.18 t (9H, CH_3CH2O, *J* = 7.0), 1.59–1.74 quintet (2H, CH_2, *J* = 7.8), 1.89 s [3H, $CH_3C(N)$], 1.97 s [3H, $CH_3C(O)$], 3.15–3.26 q (2H, CH_2N, *J* = 7.0), 3.73–3.83 q (6H, CH_2O, *J* = 7.0), 4.91 s (1H, HC=C), 8.38 s (1H, NH, 17%), 10.84 s (1H, OH, 83%).

Reaction of 4-(trimethylsiloxy)pent-3-en-2-one with APTES. To a solution of (9.3 g, 0.054 mol) of 4-(trimethylsiloxy)pent-3-en-2-one in hexane (20 ml), APTES (12.0 g, 0.054 mol) was added. The mixture was refluxed for 5 h. The solvent was distilled off, and the residue was subjected to fractional distillation in a vacuum. A **I/II** mixture (84/16) was obtained (7.9 g, 49%); bp 110–112°C (1 mm Hg). IR spectrum, ν, cm^{-1}: 3226 vw, 3171 vw (OH), 3070 w (H–C=C), 2974 vs (CH), 2928 vs (CH), 2888 vs (CH), 2766 w (H–CN), 2736 w (H–CN), 1613 vs, 1583 vs, 1512 s, 1441 s (O–C=C–C=N), 1386 m (CH), 1355 s (CH), 1295 vs, 1254 s (CH_3Si), 1194 m, 1168 s (SiOEt), 1093 vs, br (SiOEt, SiOSi), 956 vs (SiOEt), 845 s (CH_3Si), 774 vs (SiOEt), 648 w, 592 vw, 514 w, 486 m, 430 m. ^{1}H NMR spectrum, $CDCl_3$, δ, ppm (*J*, Hz): –0.04 s (27H, CH_3Si), –0.02 s (18H, CH_3Si), 0.03 s (9H, CH_3Si), 0.49–0.57 t (2H, CH_2Si, *J* = 7.8), 1.08 t (9H, CH_3CH_2O, *J* = 7.0), 1.48–1.64 quintet (2H, CH_2, *J* = 7.5), 1.78 m [3H, $CH_3C(N)$], 1.85 s [3H, $CH_3C(O)$], 3.05–3.15 q (2H, CH_2N, *J* = 6.8), 3.62–3.73 q (6H, CH_2O, *J* = 7.0), 4.81 s (1H, HC=C), 10.73 br.s (1H, OH). ^{13}C NMR spectrum, DEPT, $CDCl_3$, δ, ppm: 1.6 (CH_3Si), 7.5 (CH_2Si), 18.2 (CH_3CH_2O), 18.6 (CH_3CH_2O), 23.7 (CH_2), 28.5 [$CH_3C(O)$], 45.3 (CH_2N), 58.3 (CH_2O), 94.9 [*HC*(=C)(C=N)], 163.0 (C=N), 194.3 (C=*C*–OH).

Found, %: C 50.03, H 9.72, Si 20.81.
$C_{16}H_{37}N_1O_4Si_3$.
Calculated, %: C 49.06, H 9.52; Si 21.51.

A typical procedure for preparation and heat treatment of the films was as follows. Compound **I/II** (0.1482 g), APTES (0.1158 g), and oligodimethylsiloxanediol (0.1135 g) were mixed. A weighed portion of this mixture was applied in the form of a thin film onto a weighed glass support. A solid transparent film was formed in 12 h. The film on the support was placed between two Petri dishes and heated in an air thermostat at 100°C for 30 min and then at 150°C for 30 min. The weight loss on curing and heating was determined by weighing the supported film. The results are listed in the table.

Hydrolysis of compounds I/II and I. (a) To a mixture of compounds **I/II** (1.20 g) in EtOH (3 ml), water (0.5 ml) and concentrated HCl (0.4 ml) were added. The mixture was stirred for 7 h and filtered. The filtrate was evaporated. The residue was heated in a vacuum for 30 min at 150°C. Light yellow powder of polyorganosiloxane (0.34 g) was obtained. Its IR spectrum is shown in Fig. 3.

Found, %: C 23.81, H 7.60, Si 19.00, Cl 16.38.

(b) To a mixture of compounds **I/II** (1.95 g) in EtOH (3 ml), H_2O (0.5 ml) and concentrated NH_4OH (0.97 ml) were added. The mixture was stirred for 7 h and filtered; the filtrate was evaporated, and the residue was heated for 30 min at 100°C. Polyorganosiloxane was obtained in the form of a yellow transparent resin; yield 0.30 g. Its IR spectrum is shown in Fig. 3.

(c) To a mixture of compounds **I/II** (0.71 g) in EtOH (10 ml), H_2O (0.2 ml) and Bu_4NF (0.0007 g) were added. The mixture was stirred for 7 h, kept at room temperature for 7 days, and filtered; the filtrate was evaporated at 40–50°C in a vacuum. A transparent colorless oily liquid (0.33 g) was obtained. The viscosity of this liquid increased with time.

Found, %: C 46.67, H 8.72, Si 17.13.

(d) To a solution of compound **I** (1.13 g) in EtOH (10 ml), H_2O (0.4 ml) and Bu_4NF (0.0007 g) were added. The mixture was stirred for 7 h and filtered; the filtrate was evaporated at 40–50°C in a vacuum. A transparent light-yellow viscous liquid (0.37 g) was obtained. The IR spectrum of this liquid is shown in Fig. 3.

Found, %: C 46.73, H 7.61, Si 16.15.

Elemental analyses were performed at the Analytical Center of the Razuvaev Institute of Organometallic Chemistry, Russian Academy of Sciences.

CONCLUSIONS

(1) Acetylacetone reacts with 3-aminopropyltriethoxysilane to form 4-(3'-triethoxysilylpropylimino)-pent-2-en-2-ol (**Ia**, 83%) and 4-(3'-triethoxysilylpropylamino)pent-3-en-2-one (**Ib**, 17%).

(2) Trimethylsilyl ether of acetylacetone reacts with 3-aminopropyltriethoxysilane to form **Ia** and compounds **II** in which the EtO groups at the silicon atom are substituted with Me_3SiO groups.

(3) Compositions containing compound **I**, **I/II** mixture, 3-aminopropyltriethoxysilane, and oligodimethylsiloxanediols can be used for preparing transparent sol–gel films.

(4) Hydrolysis of compounds **I/II** and **I** in ethanol solutions yields solid, liquid, or resinous products, depending of the hydrolysis conditions (HCl, NH_4OH, Bu_4NF).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Features of Oxidative Degradation of Hydroxyethyl Cellulose

V. I. Chursin

Research Institute of Leather-Shoe Industry, Joint-Stock Company, Moscow, Russia

Received October 30, 2006; in final form, December 2006

Abstract—The kinetics of degradation of hydroxyethyl cellulose in its oxidation with hydrogen peroxide, sodium periodate, and potassium persulfate was studied. The effect of oxidation time and oxidant concentration on the properties of the oxidation products was analyzed.

DOI: 10.1134/S1070427207040271

The stringent requirements to the environmental safety of industries, including the leather-shoe industry, make it necessary to reject some of the traditionally used chemicals and processes. Therefore, one of the main trends in the development of modern techniques for treatment of leather raw materials is replacement of toxic chemicals with natural compounds and, in particular, with plant tanning extracts, polysaccharides, and other nontoxic tanning compounds.

A promising approach to synthesis of environmentally safe tanning agents from renewable plant raw materials is based on oxidative transformation of polysaccharides into their dialdehyde derivatives [1–3]. The tanning capacity of starch dialdehyde prepared by oxidation of starch with periodate was reported in [4]. It has been found, however, that polysaccharides (with polygalacturonic acid as an example) are resistant to oxidation at 20°C [5]. Their oxidative degradation occurs only in the presence of a catalyst or on heating to 95°C [6]. At the same time, it has been found [7] that chitosan polysaccharide macromolecules are oxidized with hydrogen peroxide at 30°C and their molecular weight decreases in the course of oxidation in proportion to the oxidant concentration. The possibility of oxidation of arabinogalactan with potassium persulfate with the formation of carboxy groups was reported in [2]. No data have been reported on oxidation of hydroxyethyl cellulose (HEC) with potassium persulfate.

The aim of the study was to analyze the kinetics of HEC oxidation and to obtain oxidation products with a tanning capacity for collagen.

EXPERIMENTAL

Hydroxyethyl cellulose (HEC) produced by the Politsell Private Company [TU (Technical Specifications) 2231-013-32957739–01] was used in our experiments in the form of a 4% aqueous solution. Sodium periodate, hydrogen peroxide (50%), and potassium persulfate were used as oxidants. The optical density of HEC solutions treated with sodium periodate was measured on an SF-46 spectrophotometer at a wavelength of 222 nm corresponding to the maximal absorption of periodate anions. The dynamic viscosity of solutions was measured on a Brookfield viscometer at a shear rate of 20 s^{-1}. The electrical conductivity of solutions was measured on a Hanna Instruments conductometer. The refractive index was measured on a URL-1 refractometer.

The oxidation of HEC was studied in the dark at room temperature. At regular intervals, an aliquot of the reaction mixture was taken and its viscosity, refractive index, and electrical conductivity were measured. The carboxy group content of solutions of oxidized HEC was determined by addition of aqueous barium acetate (0.2 N), followed by titration of the released acetic acid with NaOH (0.02 N). The spectroscopic characteristics of films prepared from oxidized HEC were measured by Fourier spectroscopy.

The variation of characteristics of HEC solutions in the course of oxidation is illustrated by Table 1. These data show that, with the sodium periodate concentration increasing over 0.5 wt %, the oxidative conversion of HEC sharply increases and viscosity

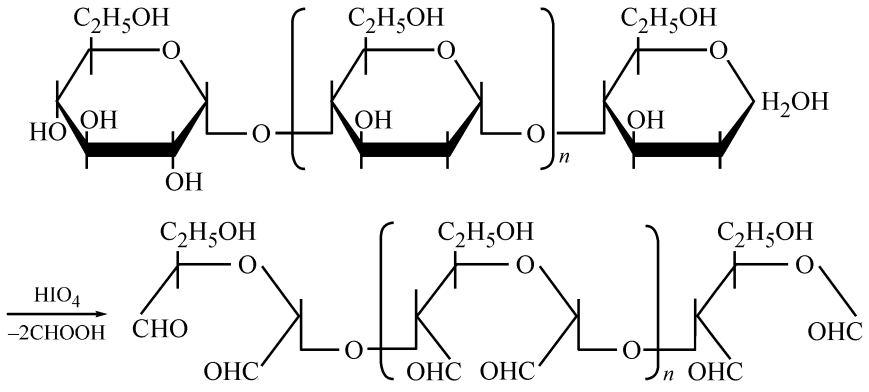
0.5	879	853	791	1.543	1.545	1.547	77	86	163

of its aqueous solutions decreases by a factor of 2.5. It is also seen that, in treatment of HEC with 0.5 wt % and more concentrated sodium periodate, the viscosity first decreases for 30 min and then remains virtually constant.

It is known [1] that periodate breaks carbohydrate chains containing two or more hydroxy groups. This process is accompanied by an increase in the refractive index of the reaction mixture, caused by oxidative conversion of polysaccharide hydroxy groups into other groups. These groups are, most likely, carboxy groups [5], because it is known that the refractive index increases in oxidation of aldehyde groups to carboxy groups [8]. The dependence of the refractive index on the oxidation time is step-like, which is especially pronounced in oxidation with 1% aqueous sodium periodate. We believe that, in the first step of this process, the hydroxy groups of HEC are oxidized to aldehyde groups, which are then converted to carboxy groups. The first reaction step was complete within 60 min after introduction of the oxidant and the second step continued for 3.5 h until complete consumption of the oxidant (1%). At a lower oxidant concentration, the second step is not complete. The oxidative transformation of HEC can be represented by the following reaction scheme:



The variation of the electrical conductivity of HEC solutions, caused by HEC oxidation (Table 1), shows that the oxidation of HEC is a multifactor process involving breakdown of the polysaccharide polymeric chain, formation of new functional groups differing in χ, and also chemical conversion of the oxidant. At decreased sodium periodate concentrations, the electrical conductivity decreases in the course of the reaction. Furthermore, as the oxidant concentration decreases, a minimum in dependence of the electrical

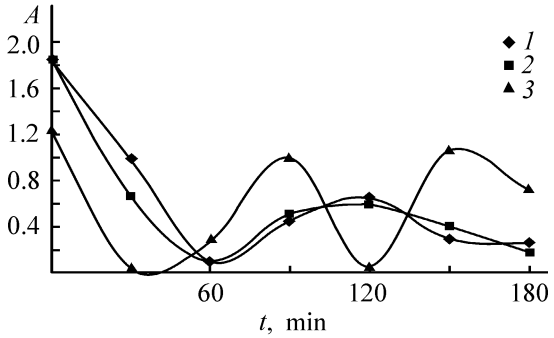


Fig. 1. Dependence of the optical density A of aqueous solutions of HEC on time t of oxidation with sodium periodate at its varied consumption. Sodium periodate consumption, wt %: (*1*) 1, (*2*) 0.5, and (*3*) 0.25.

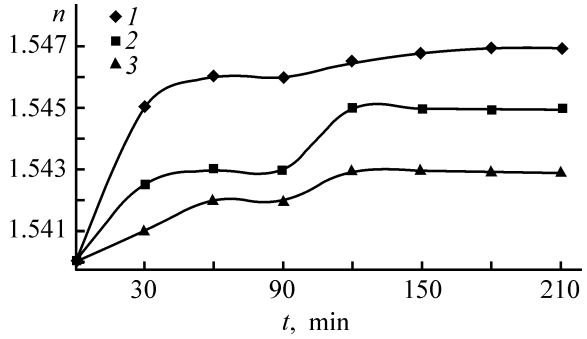

Fig. 2. Variation with time t of the refractive index n of aqueous HEC solutions HEC in the course of oxidation with hydrogen peroxide at its varied consumption. Hydrogen peroxide consumption, wt %: (*1*) 2, (*2*) 1, and (*3*) 0.5.

conductivity on the oxidation time shifts from 130 to 90 and 60 min. We believe that this effect is caused by reduction of periodate to iodide. The decrease in the electrical conductivity of the reaction mixture in the first oxidation step can be caused by formation of an unstable complex of periodate anions with oxygen atoms of the carbohydrate chain. The further increase in the electrical conductivity is apparently caused by decomposition of this complex, with the release of iodide.

Figure 1 shows that the trends in variation of the optical density of reaction mixtures in the course of oxidation of HEC with sodium periodate are similar to those observed for the electrical conductivity. In the first step of this process, the optical density sharply decreases owing to the formation of an intermediate complex between HEC and periodate anions. In the second step of HEC oxidation, this complex is broken down to yield iodide, which is manifested as an increase in the optical density of the reaction mixture.

Table 2 shows that the appearance and features of films prepared from aqueous solutions of HEC oxidized with sodium periodate are dependent on both the oxidation time and sodium periodate consumption.

In contrast to sodium periodate, hydrogen peroxide can oxidize the hydroxy groups bound to the second and third carbon atoms in the cellulose chain to form both the aldehyde and keto groups. Table 1 reveals the following trends in the variation of the viscosity of HEC solutions in the course of their treatment with hydrogen peroxide of various concentrations. First of all, there is an unexpected increase in the viscosity of the reaction mixture in the first oxidation step. At a hydrogen peroxide consumption of 0.5%, the largest increase in viscosity is observed 30 min after addition of hydrogen peroxide, and then the viscosity somewhat decreases. At a hydrogen peroxide concentration of 2%, the viscosity of solutions varies with time in the course of oxidation as follows: decreases within first 30 min, reaches a maximum, as in the case of lower oxidant consumption, and then gradually decreases.

These results suggest that, in oxidation of HEC with concentrated hydrogen peroxide, this biopolymer is subjected to oxidative degradation.

At hydrogen peroxide consumption of 0.5 and 1%, hydroxy groups in HEC are oxidized to carboxy groups only. This transformation increases the viscosity of aqueous HEC due to hydrogen bonding. A certain delay in the oxidation of HEC at a hydrogen peroxide concentration of 2% is caused by the accumulation of peroxy derivatives of HEC [2], which are subsequently consumed for the oxidation of HEC. The aldehyde groups formed in the first oxidation step are converted into carboxy groups.

Table 2. Appearance and features of films prepared from HEC oxidized with sodium periodate

Oxidant consumption, %	Film appearance at indicated oxidation time, h		
	1	2	4
0.25	Flexible transparent	Less flexible transparent	Not formed
0.5	Less flexible whitish	Rigid with frosty pattern	The same
1.0	Brittle with rod-like structure	Brittle with frosty pattern	Rigid and dull

Figure 2 shows how the refractive index of aqueous HEC varies in the course of its oxidation at various hydrogen peroxide consumptions. These curves consist of two portions corresponding to two different steps of HEC oxidation. The first and second steps are complete within 90 and 150–180 min, respectively. In the first step, the hydroxy groups are oxidized to aldehyde groups, and in the second step the aldehyde groups are oxidized to carboxy groups.

The dependence of the electrical conductivity of aqueous HEC solutions on the time of oxidation by hydrogen peroxide is qualitatively consistent with the trends observed for the viscosity and refractive index. The influence of the oxidation time and oxidant consumption on the electrical conductivity of aqueous HEC solutions is determined by the following processes: sequential oxidation of hydroxy and aldehyde groups, formation of complicated oxidation products of HEC, and their involvement in decomposition of hydrogen peroxide [2]. It was found that, at a low initial hydrogen peroxide content of the reaction mixture, the oxidation processes prevail and the degradation of HEC macromolecules is minor. With an increase in the hydrogen peroxide concentration to 2%, the polysaccharide degradation is intensified. The variation of the chemical composition of the reaction mixture in the course of oxidation is manifested as a considerable increase in the refractive index.

In oxidation of aqueous HEC with potassium persulfate, there is no distinct correlation between the oxidant consumption and the reaction mixture viscosity. However, at a persulfate consumption of 2%, an increase in the viscosity occurs, caused by oxidation of hydroxy groups to carboxy groups. With increasing oxidation time, the oxidative degradation of HEC prevails. The prevalence of the degradation processes is typical of systems with low persulfate consumption (0.5 and 1%).

The largest increase in the electrical conductivity of aqueous HEC solution is observed at the potassium persufate consumption of 2%, and this parameter changes insignificantly at lower persulfate concentrations. On treatment of aqueous HEC with persulfate, the refractive index somewhat increases, it does not show a steplike trend typical of the other oxidants. Thus, our results show that potassium persulfate oxidizes HEC and breaks its macromolecules in aqueous solutions to a lesser extent than do other oxidants under consideration. The effect of various oxidants on the dynamic viscosity of solutions of HEC at the same oxidant consumption (1%), shown in Fig. 3,

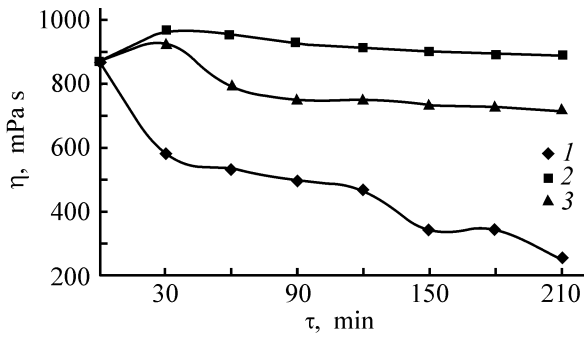

Fig. 3. Influence of the oxidant type on variation of the dynamic viscosity η of aqueous HEC solutions with oxidation time. (τ) Time. (*1*) Sodium periodate, (*2*) hydrogen peroxide, and (*3*) potassium persulfate.

allows comparison of their oxidative powers with respect to hydroxyethyl cellulose.

Based on our experimental kinetic data, the rate coefficients of degradation and oxidation of HEC were calculated by the equation

$$C = b/at,$$

where $b = 1/\eta_t(d_t) - 1/\eta_0(d_0)$; a, oxidant amount (g); and t, oxidation time (min).

Table 3 shows that, in treatment of aqueous HEC with sodium periodate, the rate of oxidative conversion of functional groups of HEC exceeds the rate of degradation of HEC macromolecules by an order of magnitude. In oxidation of HEC with hydrogen peroxide, the formation of aldehyde and carboxy groups

Table 3. Rate parameters of HEC degradation and oxidation with various oxidants

Table 4. Major absorption bands in the IR spectra of HEC before and after oxidation

Wavelength, cm^{-1}	Oxidant consumption, %				
	sodium periodate			hydrogen peroxide	potassium persulfate
	0.25	0.5	1.0	2.0	2.0
1020	1070	1070	–	1070	1070
1260	–	1300	–	–	1300
1350	–	–	–	–	1500
1650	1650	1650	1630	1650	1650

also prevails, whereas the oxidative degradation of polymeric chains is minor. In going to oxidation with potassium persulfate, the conversion of the hydroxy groups is virtually the same as that for hydrogen peroxide, but the degree of oxidative degradation of the carbohydrate polymer increases.

The appearance of protonated carboxy groups in oxidized HEC was confirmed by its back-titration with aqueous sodium hydroxide. The maximal content of carboxy groups was found in HEC treated with 0.25 wt % aqueous sodium periodate. Thus, sodium periodate is the most efficient oxidant for HEC. The high degree of formation of oxidized functional groups in HEC is also reached with the other oxidants at their low concentrations.

The additional information on oxidation of HEC by the oxidants under consideration was obtained from an IR study of the initial HEC and its oxidation products. The IR spectra of celluloses oxidized with periodic acid were published in [9]. Their analysis show that, even at a high degree of oxidative conversion of HEC into cellulose dialdehyde, the oxidation product contains no strong C=O absorption bands. These spectra contain ill-resolved bands at 1370, 1360, 1340, and 1320 cm^{-1} and a strong absorption band at 900 cm^{-1}. The major absorption bands in the Fourier IR spectra of the initial and oxidized HEC are listed in Table 4.

The IR spectrum of the initial HEC contains a broad absorption band of the stretching vibrations of the hydrogen-bonded hydroxy groups at 3000–3600 cm^{-1}, the absorption bands of internal bending vibrations of the CH, CH_2, and CH_2O groups (1350 cm^{-1}), the bands of the C–O–C stretching vibrations (1260 cm^{-1}) and the bands of the CH and CH_2 rocking vibrations (1020 cm^{-1}). The most noticeable changes in the IR spectra of oxidized HEC are observed in the range of the absorption bands at 1020–1070, 1260–1300, and 1350–1500 cm^{-1} (Table 4). The oxidized HEC shows an increased intensity of the absorption band of water of crystallization at 1650 cm^{-1}, and the absorption bands at 1260–1350 cm^{-1} change their shape and intensity, apparently due to oxidation of the CH_2OH groups. The cleavage of the C–C bonds in the carbohydrate chains caused by oxidative degradation of HEC is manifested as a shift of the absorption band at 1020 cm^{-1}, typical of the initial HEC, to 1070 cm^{-1}.

Our experiments showed that, on treatment of leather raw materials with products of oxidative transformation of HEC, the temperature of derma welding increases by 8–10°C, suggesting a strong intermolecular cross-linking in the collagen structure [4]. Thus, oxidative treatment of HEC allows substantial modification of its functionality and broadens the range of its application. The oxidized HEC can be used as an environmentally safe tanning agent and filler in production of leathers and furs.

CONCLUSIONS

(1) Oxidation of hydroxyethyl cellulose with sodium periodate, hydrogen peroxide, and potassium persulfate is accompanied by opening of the polysaccharide cyclic structure and formation of aldehyde and carboxy groups.

(2) Addition of oxidants to aqueous hydroxyethyl cellulose causes degradation of its polymeric structure. The strongest decrease in the molecular weight of polysaccharides occurs in their oxidation with sodium periodate at its concentration of 0.5% and higher.

(3) The maximal rate of oxidative transformation of hydroxyethyl cellulose occurs within the first hour of its oxidation. Depending on the type of oxidant and its concentration, either oxidation or degradation of polysaccharide prevails.

Abstract—Formation conditions and structural and rheological properties of rapeseed oil-based emulsions in the presence of sodium laurate and sodium palmitate were examined.

DOI: 10.1134/S1070427207040283

Formation of emulsions requires introduction into the water–oil system of an emulsifier to promote creation of a strong adsorption layer at the interface and to increase their stability. As oil phase can serve vegetable oils (linseed, hempseed, sunflower, rapeseed, etc.). In recent years, especially wide application has been enjoyed by rapeseed oil and emulsions thereof. We have elucidated previously [1] how the stability and structural and rheological properties of rapeseed oil-based emulsions is influenced by inorganic electrolytes. To prepare stable emulsions, emulsifiers (various surfactants) are typically introduced into the emulsion. The most widely used for these purposes are sodium carboxylates (soaps). Therefore, it was of interest to examine how the stability and structural and rheological properties of rapeseed oil-based emulsions are influenced by soaps. The increased interest in soaps is also due to the fact that they are components of wastes in many chemical productions. For example, adipates are alkaline waste from caprolactam production, and spent lye, the waste from soap manufacture; they can also serve as emulsifiers in preparation of emulsions. As is known [2], only high-molecular-weight soaps (alkaline salts of lauric and fatty acids with higher molecular weights) are used as emulsifiers.

EXPERIMENTAL

In this study, we used as emulsifiers chemically pure-grade sodium laurate and sodium palmitate, as well as rapeseed oil produced according to GOST (State Standard) 8988–77.

Emulsions were prepared by the procedure from [3]. After 15-min dispersing, a portion of the resulting emulsion was placed in calibrated test tubes, and the phase separation in the systems of interest was monitored visually. As the measure of stability we took the percentage ratio of the volume of the separated aqueous or oil phase to that of the entire initially prepared emulsion. The remaining emulsion was used for examining the structural and rheological properties and electrical conductivity. The structural and rheological examinations were carried out on a Rheotest 2 rotary viscometer in the coaxial-cylinder system at the strain rate within 3.0–1312 s^{-1}. Based on the measured data, we calculated, for each velocity gradient D, by standard procedures [4] the shear stress τ_r and the effective viscosity η. The examination of the equilibrium shear stress in relation to the strain rate yielded full rheological curves.

We found that the stability of the emulsions depends on the concentration of the oil phase and emulsifiers, as well as on the nature of the latter. The results are presented in Table 1. It is seen that sodium laurate stabilizes only the water–rapeseed oil system containing 75% oil phase. The stabilizing effect of sodium laurate is manifested even at low concentrations. For example, upon introduction of 0.4×10^{-3} and 0.8×10^{-3} M of the emulsifier, 36 and 40%, respectively, of the oil phase separates within 1 day from the resulting emulsion, whereas without the emulsifier, the emulsion completely separates within this time into the oil and aqueous phases. Upon increasing the sodium laurate concentration to $(8.0–56) \times 10^{-3}$ M, the emulsion preserves stability even for 10 days. Evidently, at these concentrations, the adsorption layer formation at the liquid–liquid interface is complete, which ensures high stability of the emulsions. Introduction of sodium laurate into the system containing 25, 50, and 90% oil phase leaves the emulsion stability virtually unaffected.

* P_{k2} Ultimate shear stress.

With sodium palmitate as the emulsifier, the stabilizing effect was attained only for the system containing 50 wt % rapeseed oil. Upon introduction of 2.1×10^{-3} M of the emulsifier, the stability of the resulting emulsion is preserved for 1 day, while without the emulsifier it breaks down within this period by 25%. Table 1 shows that, with increasing chain length of the soap molecule, the soap concentration corresponding to formation of a stable emulsion tends to decrease. For example, it was estimated at 8×10^{-3} M for sodium laurate and 2.1×10^{-3} M for sodium palmitate.

The rheological curves obtained for rapeseed oil based emulsions in the presence of different concentrations of sodium laurate and sodium palmitate (Figs. 1, 2) show that the emulsions exhibit properties of non-Newtonian fluids. Introduction of sodium laurate into the emulsions containing 50% rapeseed oil

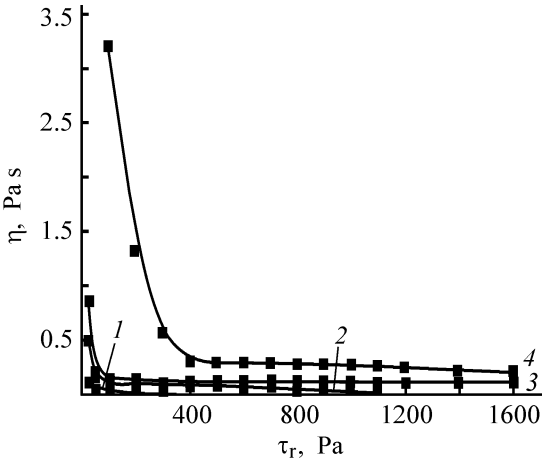

Fig. 3. Effective viscosity η vs. shear stress τ_r for rapeseed oil-based emulsions in the presence of (*3*) sodium laurate and (*4*) sodium palmitate. Rapeseed oil concentration, wt %: (*1*, *4*) 50 and (*2*, *3*) 75. Surfactant concentration, M: (*1*, *2*) 0, (*3*) 0.0284, and (*4*) 0.021.

leaves the rheological properties virtually unaffected. However, for the emulsions containing 75% oil phase in the presence of sodium laurate, the ultimate strength P_{k2} tends to increase with the sodium laurate concentration. This suggests strengthening of the emulsion structure. For example, at the sodium laurate content of 0.4×10^{-3} and 5.6×10^{-2} M, P_{k2} was estimated at 65 and 225 Pa, respectively, against 40 Pa without sodium laurate. Analysis of the rheological curves (Fig. 2) suggests that sodium palmitate strengthens the structure of the resulting emulsions containing 50% rapeseed oil. Upon introduction into the system of 2.1×10^{-3} and 3.2×10^{-3} M of this emulsifier the ultimate shear stress increases to 370 and 400 Pa, respectively, against 25 Pa without the emulsifier (Table 1). When 2.1×10^{-3} M of sodium palmitate is introduced into the system containing 75 and 90 wt % oil phase, the ultimate shear stress is 60 and 40 Pa, respectively. Thus, depending on their concentration and oil phase content, sodium carboxylates (laurate and palmitate) can act both as stabilizers and thinners of the water–rapeseed oil system. This is also confirmed by the growth of the initial effective viscosity of the emulsions stabilized by sodium salts of fatty acids against the initial rapeseed oil emulsion. The dependence of the initial effective viscosity on the sodium laurate concentration in the water–rapeseed oil system (Table 1) has a maximum at a concentration of 2.84×10^{-2} M and was estimated at 1.35 Pa s against 0.5 Pa s without sodium laurate (oil phase concentration 75 wt %). Evidently, at this concentration of sodium laurate its content in the interphase layer increases, thereby making higher the effective viscosity. Further increase in its concentration in the system of interest causes separation of the emulsifier from the interface layer, thereby leading to a decrease in the effective viscosity.

Similar results were obtained upon introduction of sodium palmitate into the water–rapeseed oil system. It should be noted that, in the presence of sodium palmitate, the initial effective viscosity is significantly higher than that in the presence of sodium laurate. For example, upon introduction of 2.1×10^{-3} M of sodium palmitate into the system containing 50% rapeseed oil the largest effective viscosity was 3.2 Pa s. At the same time, upon introduction into this system of 2.84×10^{-2} M of sodium laurate, this parameter was as low as 0.1 Pa s.

Figure 3 shows how the effective viscosity calculated from the flow rheograms varies with the shear stress for the emulsions prepared from rapeseed oil both in the presence of sodium laurate and sodium palmitate and in their absence. The $\eta = f(\tau_r)$ curves also suggest that these emulsions are non-Newtonian fluids, since their viscosity tends to decrease with increasing shear stress in the system. Figure 3 shows that, in the presence of sodium palmitate (curve *4*) and sodium laurate (curve *3*), both the initial and final viscosity tend to increase relative to those of the emulsions containing no emulsifiers. For example, at the sodium palmitate concentration of 2.1×10^{-3} M the former parameter was estimated at 3.2, and the latter, at 0.25 Pa s against 0.05 and 0.01 Pa s, respectively, without the emulsifier (50% rapeseed oil in the system). In the case of sodium laurate ($c = 2.84 \times 10^{-2}$ M), these parameters were as low as 1.35 and 0.15 Pa s, respectively, against 0.5 and 0.05 Pa s without the emulsifier (75% rapeseed oil in the system). These data suggest that sodium palmitate forms a stronger structure in the water–rapeseed oil system than does sodium laurate.

Since many of the emulsification processes occur in the presence of inorganic electrolytes, it was of interest to elucidate how the latter influence the stability and the structural and rheological properties of the rapeseed oil-based systems. As known, inorganic electrolytes as such do not act as emulsion stabilizers because of insufficient adsorption of their ions on the nonpolar hydrocarbon–water interface. However, in the presence of emulsifiers, their adsorption at the liquid–liquid interface can be enhanced. The object of our examinations was the emulsion containing 75% rapeseed oil at different concentrations of sodium laurate, 4.5×10^{-3} and 2.84×10^{-2} M. As inorganic salt we used sodium carbonate (Table 2).

Table 2. Stability and structural and rheological properties of rapeseed oil-based emulsions in relation to the concentrations of sodium laurate *s* and of sodium carbonate *c* (rapeseed oil concentration 75 wt %)

Table 2 shows that, when Na_2CO_3 is introduced into the water–rapeseed oil system in minor concentrations, the stability of the resulting emulsions increases. For example, at the Na_2CO_3 concentration of $(0.8–11.0) \times 10^{-2}$ M, the emulsion preserves stability for 1 day, while without Na_2CO_3 it breaks down completely within this period. The reason is that, in the presence of Na_2CO_3, rapeseed oil undergoes saponification into sodium salts of high-molecular-weight acids that are emulsifiers themselves, which favors formation of stable emulsions. With increasing concentration of the electrolyte, the salting-out of the emulsifier from the interface surface is intensified, which leads to breakdown of the emulsion. For example, upon introducing 0.23 M of sodium carbonate into the water–rapeseed oil system, the emulsion breaks down within 1 day by 75%, and at the sodium carbonate content of 0.28 and 0.34 M it breaks down completely within this period.

When Na_2CO_3 is introduced into the water–rapeseed oil–sodium laurate system at the sodium laurate concentrations below CMC, specifically, 4.5×10^{-3} M, the stability of the resulting emulsions is virtually unaffected by the content of the inorganic electrolyte. Even at the electrolyte concentration of 0.7 M the emulsion preserves stability for 1 day, like without the electrolyte. However, the structural and rheological properties somewhat change, as evidenced by an increase in the ultimate shear stress. For example, at the Na_2CO_3 concentration of 0.23 M, P_{k2} was estimated at 190 Pa, and without it, at 70 Pa.

It should be noted that, in the presence of sodium laurate, the range of inorganic electrolyte concentrations corresponding to formation of stable emulsions extends. For example, with 0.28 M Na_2CO_3 in the absence of sodium laurate, the emulsion breaks down within 1 day (Table 2), while in the presence of sodium laurate ($c = 4.5 \times 10^{-3}$ M) even with 1.4 M Na_2CO_3 the emulsion remains stable. In this case, sodium laurate favors creation of a more stable adsorption layer at the liquid–liquid interface, which increases the aggregation stability of the emulsion.

At the sodium laurate concentration equal to CMC (2.84×10^{-2} M), the emulsion undergoes phase separation only when large amounts of Na_2CO_3 are used. For example, up to the salt concentration of 0.23 M, the emulsions preserve stability for 1 day, while at the salt concentration of ≥0.3 M the emulsion begins to break down. With 1.9 M of the salt it breaks down

by 80%, while without emulsifier even with 0.28 M Na_2CO_3 the emulsion breaks down completely. A possible reason is that, in the presence of electrolytes, saturation of the adsorption layer is achieved at lower bulk concentrations of the surfactant [5, 6]. In this case, sodium laurate separates from the surface layer at the liquid–liquid interface, thereby breaking down the emulsion.

We identified the type of the resulting emulsions from the electrical conductivity and solubility in water. As known, the oil-in-water emulsions can be diluted with water and have a comparatively high electrical conductivity. Water-in-oil emulsions cannot be diluted with water and do not exhibit noticeable electrical conductivity. Tables 1 and 2 show that phases invert depending on the rapeseed oil, surfactant, and Na_2CO_3 concentrations in the system. At minor concentrations of sodium laurate, $(0.4–0.8) \times 10^{-3}$ M, in the system with 75% rapeseed oil (Table 1) the emulsion does not dissolve in water, and the electrical conductivity is not high and remains equal to that of rapeseed oil, 1.3×10^{-7} S cm^{-1}. In this case, a water-in-oil emulsion is formed. At high concentrations of sodium laurate, $(8–56) \times 10^{-3}$ M, the emulsion dissolves in water, and the electrical conductivity increases to 0.8×10^{-4} S cm^{-1}. In this case, an oil-in-water emulsion is formed. With increasing sodium palmitate concentration the phases invert as well. The emulsion type changes in the water–rapeseed oil–sodium laurate–sodium carbonate system depending on the composition as well (Table 2).

Thus, introduction into the water–rapeseed oil system of sodium laurate or sodium palmitate, as well as of sodium carbonate, opens up opportunities for raising its thickening power, with the amount of rapeseed oil to be spent for production of emulsions thereof reduced and the quality of structured dispersed systems improved.

CONCLUSIONS

(1) The rapeseed oil-based emulsions exhibit the highest stability upon introduction of sodium laurate and sodium palmitate into the system containing 75 and 50% oil phase, respectively.

(2) In the presence of sodium soaps, the structural and rheological properties of the water–rapeseed oil system, characterized by the ultimate shear stress P_{k2} and effective viscosity η, are enhanced; sodium palmitate forms in the water–rapeseed oil system a stronger structure than does sodium laurate.

(3) Sodium carbonate introduced into the water–rapeseed oil system exerts a stabilizing effect both in the presence and absence of sodium laurate.

(4) Phases invert in the water–rapeseed oil system. Depending on the oil phase, surfactant, and sodium carbonate concentrations in the system, oil-in-water and water-in-oil systems are formed.

Abstract—A series of nitrogen-containing compounds was synthesized by Mannich condensation of allyl-substituted derivatives of phenol and *o*- and *p*-cresols with formaldehyde and secondary amines. These compounds were studied as antimicrobial additives to motor oil (at a content of 1–2 wt %).

DOI: 10.1134/S1070427207040295

Nitrogen-containing derivatives of phenols, and in particular Mannich's bases are the subject of systematic studies and, despite numerous papers in this field, still attract researchers' interest, which is caused by their useful functional characteristics [1–5].

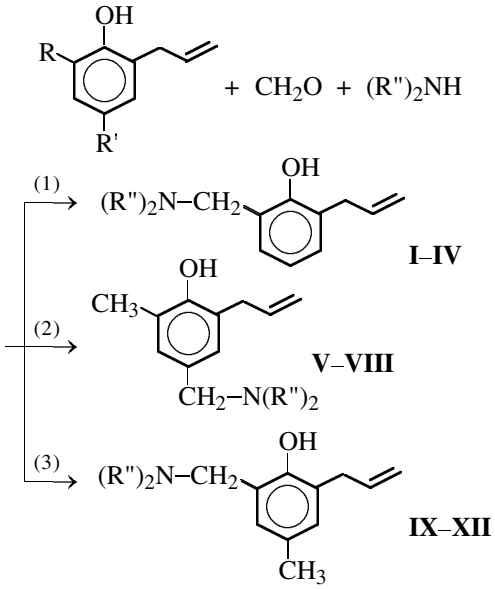
With the aim to synthesize new nitrogen-containing phenols in whole structure an allyl fragment is present, along with aminomethyl group, we examined in this study the reactions of ternary Mannich condensation of 2-allyl-substituted derivatives of phenol and also *o*- and *p*-cresols with formaldehyde and secondary amines.

As can be suggested, the presence of the above substituents in the aromatic core of phenols should impart additional functional properties and, in particular, antimicrobial properties to phenols. Biological protection of oils, fuels, polymers, and other materials is topical problem, since the microbial corrosion of the above materials adversely affects the national economy [6].

EXPERIMENTAL

With the aim to synthesize phenol compounds simultaneously containing an allyl group and amine fragment, we carried out ternary condensation of allyl-substituted derivatives of phenol and *o*- and *p*-cresols with formaldehyde and secondary amines (under the conditions of Mannich's reaction).

Formaldehyde was used in the form of a 37% aqueous solution (Formalin). It was found that the above reaction proceeds well at the equimolar ratio of reactants at 70–75° and duration of 4–5 h to give the corresponding aminomethylated allyl-containing phenols. The target compounds were isolated from the reaction mixture by vacuum distillation. The reaction scheme is as follows:



where (1) at R and R' = H; R" = $-CH_3$ (**I**), $-C_2H_5$ (**II**); $NR"_2$ = –N⟨⟩ (**III**), –N⟨⟩O (**IV**); (2) at R = $-CH_3$; R' = H; R" = $-CH_3$ (**V**), $-C_2H_5$ (**VI**); $NR"_2$ = –N⟨⟩ (**VII**), –N⟨⟩O (**VIII**); (3) at R = H; R' = CH_3; R' = CH_3; R" = $-CH_3$ (**IX**), $-C_2H_5$ (**X**); $NR"_2$ = –N⟨⟩ (**XI**), –N⟨⟩O (**XII**).

The initial allylphenols were synthesized by the well-known procedure [7], Claisen thermal rearrangement of allyl ethers of phenol and *o*- and *p*-cresols, within 3–6 h and were isolated from the reaction mixture by distillation in a high vacuum.

The characteristics of the compounds synthesized are listed in Table 1. Their yield varies from 48.0 to 70.6%, depending on the nature of amine and initial phenol compound. All these compounds, except 4-methyl-2-morpholinomethyl-6-allylphenol (**XII**), are

M-12 motor oil (**XIV**) (without additive)	–	+ +	+ +

viscous liquid substances colored from light yellow to brown and readily soluble in aromatic solvents. 4-Methyl-2-morpholinomethyl-6-allylphenol is a light-straw-colored crystalline substance with mp 43°C.

The structures of all the synthesized aminomethylated derivatives of allylphenols were confirmed by the IR and NMR data.

All the compounds were tested as antimicrobial additives to the M-12 motor oil at a content of 1 and 2 wt %. The operations were performed according to GOSTs (State Standards) 9.082–77 and 9.052–88. The nutrient medium for growing the bacterial culture was meat-extract agar (MEA), and for growing the fungus culture, wort agar (WA). The comparison was performed with 8-quinolinol (reference). The results of the tests are presented in Table 2.

As can be seen from Table 2, all the studied aminomethylated derivatives of allylphenols exhibit a fungicidal activity. The diameter of the area of depression of fungus growth, depending on the compound structure and its concentration, is, on the average, 0.8–1.0 (at a content of 1 wt %) and 1.4–2.0 cm (at a content of 2 wt %).

Morpholine-substituted allylphenols also have bactericidial properties and are second in these properties only to 8-quinolinol (reference). As can be seen from Table 2, the latter has no fungicidal activity and the fungus growth was not suppressed in its presence even at a content of 2 wt %. As regards spent M-12 oil, it shows no resistance to fungi and bacteria. The results of comparison tests show that the aminomethylated derivatives of allylphenols are of practical interest and can find application as antimicrobial additives to lubricating oils.

CONCLUSION

Aminomethylated derivatives of allylphenols synthesized by ternary Mannich condensation of allyl-substituted derivatives of phenol and *o*- and *p*-cresols with formaldehyde and secondary amines, when added at a content of 1–2 wt %, have high fungicidal activity with respect to mold fungi. Compounds **IV** and **XII** containing cyclic amine fragment in their structures have also high bactericidal properties (in comparison with the reference, 8-quinolinol).

BRIEF COMMUNICATIONS

Activity of Components of Binary Chloride Melts

B. V. Patrov and E. S. Chupina

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received February 14, 2007

Abstract—Activities of components of the systems NaCl–AgCl, KCl–AgCl, NaCl–$FeCl_2$, and NaCl–$CoCl_2$ were calculated using the model of regular solutions and data on the enthalpies of mixing of binary chloride melts.

DOI: 10.1134/S1070427207040301

A calculation of the activities of components of melts of binary systems with a common anion from the enthalpies of mixing has been described earlier [1]. It has been shown that, in terms of the regular solution model [2], the activity coefficients of components of binary systems can be represented as

$$\ln \gamma_1 = \frac{A}{RT} x_2^2, \quad (1)$$

$$\ln \gamma_2 = \frac{A}{RT} x_1^2. \quad (2)$$

Here, A is an interaction parameter, and x_1 and x_2 are the mole fractions of the components.

Let us express the interaction parameter A in these equations through molar enthalpy of mixing of the components, ΔH^{M} (J mol^{-1}):

$$A = \frac{\Delta H^{\mathrm{M}}}{x_1 x_2}. \quad (3)$$

As is known, the activities of the components are related to the activity coefficients and mole fraction:

$$a_1 = \gamma_1 x_1, \quad (4)$$

$$a_2 = \gamma_2 x_2. \quad (5)$$

The validity of these equations for the melts under study was verified using Burylev's equation for regular solutions [3]

$$\sigma = \sigma_1 x_1 + \sigma_2 x_2 + C x_1 x_2. \quad (6)$$

Here, σ_1, σ_2 and x_1, x_2 are the surface tension and mole fractions of the components of the binary systems; C is the constant of Burylev's equation.

For the binary chloride melts NaCl–AgCl, KCl–AgCl, NaCl–$FeCl_2$, and NaCl–$CoCl_2$, experimental data on the surface tension [4] and enthalpies of mixing [5] are available, their phase diagrams correspond to simple solutions with an eutectic and to solid solutions [6].

The average values of the constant C in Burylev's equation and of the interaction parameter A of the systems under study are as follows:

System	T, K	$-C$, mJ m^{-2}	$-A$, J mol^{-1}
NaCl–AgCl	1083	57.0	–5496
KCl–AgCl	1083	97.3	8716
NaCl–$FeCl_2$	1083	90.6	25984
NaCl–$CoCl_2$	1083	38.8	28034

A comparison of the experimental values of the surface tension and those calculated by Burylev's equation demonstrated that the difference does not exceed the measurement error (2%). A stronger difference was found for two compositions of the system of potassium and silver chlorides. Hence, the melts under study are regular solutions and Eqs. (1)–(6) are applicable to them.

The activities of the melt components, calculated from the enthalpy of mixing, are listed in Table 1.

The choice of the systems NaCl–AgCl and KCl–AgCl for the study was based on the fact that the partial Gibbs energy of melt formation from the components is known for these systems [5]. It was determined by measuring the electromotive force of galvanic cells. As is known, the partial Gibbs energy is related to activities a_1 and a_2 of components by

Table 1. Enthalpy of mixing and activities of components of the systems under study at 1083 K

$$\Delta\overline{G}_1 = RT\ln a_1, \quad (7)$$

$$\Delta\overline{G}_2 = RT\ln a_2. \quad (8)$$

The activities of the components, calculated using the partial Gibbs energy, are listed in Table 2 for comparison with those found from the data on mixing enthalpies.

It is seen that, for NaCl–AgCl melts with a positive enthalpy of mixing and positive deviations from ideal solutions, the activity of the components, calculated from the enthalpy of mixing, coincides with that calculated from the partial Gibbs energy of melt formation. The difference in the activity values does not exceed 0.002. For the melts of potassium and silver chlorides with a negative enthalpy of mixing, the values of the activity of the components, calculated from the partial Gibbs energies or from the enthalpy of mixing, differ more widely (up to 0.02), presumably owing to the small number of studies concerned with this system.

CONCLUSIONS

(1) It was shown that the binary chloride melts studied are regular solutions.

(2) The activities of the components of chloride melts were calculated using data on the surface tension and enthalpy of mixing.

(3) It was demonstrated that the activities of the components, calculated from the enthalpies of mixing, satisfactorily coincide with those calculated from the partial Gibbs energy of melt formation.

Abstract—Extraction of Re(VII) from sulfuric acid solutions with isomers of octanol was studied.

DOI: 10.1134/S1070427207040313

In their physicochemical characteristics, aliphatic alcohols C_8–C_{10} meet the basic requirements to industrial extractants. Furthermore, with these alcohols, there is no need to use some diluents and modifiers, which simplifies extraction systems. That is why intensive research is being conducted on extraction of inorganic acids and some chemical elements with alcohols, primarily with various isomers of octanol [1–8].

Despite that octanols differ in their physicochemical characteristics, in most of these studies no comparison has been made of the extraction capacity of the isomers. At the same time, Karamushko et al. [8] demonstrated that alcohols can differ significantly in their extraction capacity for Nb(V), depending on their structure, and they recommended 2-octanol for extraction processing of fluorometallate solutions.

The goal of this study was to examine the effect of the structure of octanols on their extraction capacity and to search for efficient extractants for Re(VII). For this purpose, we studied the extraction of Re(VII) from sulfuric acid solutions with isomers of octanol. The possibility of use of octanols for extraction of Re has been reported previously [5–7]. However, in these studies, the results were obtained under different experimental conditions and, generally, without control over the equilibrium concentration of sulfuric acid.

EXPERIMENTAL

In the experiments on extraction of Re(VII), we used 1-octanol and DL-2-octanol from Vekton Private Company, and 3-octanol (synthetic grade, Merck). To prepare the initial solutions, we used chemically pure grade NH_4ReO_4 and H_2SO_4. The extraction experiments were carried out at room temperature in 50-ml volumetric cylinders for 5 min at 1 : 1 organic to aqueous phase ratio. Rhenium in the raffinates was determined spectrophotometrically from the band of the thiourea complex of Re(IV), which is formed in the presence of Sn(II) as a reducing agent. The measurements were performed at λ = 390 nm on a KFK-3 photoelectric colorimeter [7]. The sulfuric acid concentration in the aqueous phase was determined by titration. The Re(VII) concentration in the organic phase was estimated as the difference between its concentrations in the initial solution and raffinate, with account taken of changing phase volumes.

The dependence of the Re(VII) distribution ratio D_{Re} on the H_2SO_4 concentration in the initial solution is shown in Fig. 1 for three octanol isomers. With increasing acid concentration, D_{Re} initially grows, passes through a maximum at 4–7 M H_2SO_4, depending on the isomer, and then decreases. The increase in the extraction capacity of the alcohols with the acid concentration is due to the fact that hydrogen ions are involved in the extraction by the hydration-solvation mechanism [7]:

$$ReO_4^- + H^+ + (n + 1)H_2O + qS \rightleftarrows [H_3O \cdot (H_2O)_n \cdot qS]ReO_4.$$

The subsequent decrease in the distribution coefficients can be attributed to a concurrent extraction of

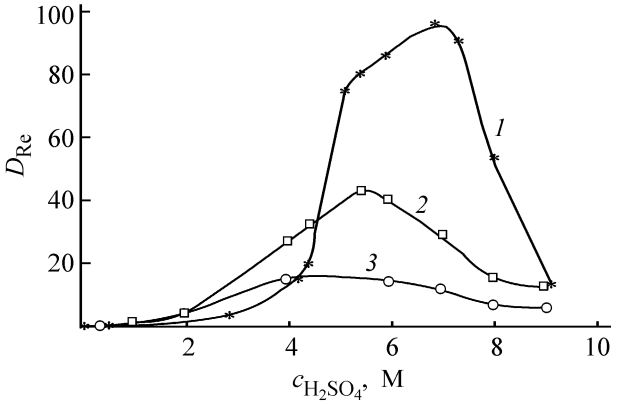

Fig. 1. Rhenium(VII) distribution ratio D_{Re} vs. the equilibrium concentration of H_2SO_4 in extraction with octanols: (*1*) 3-octanol, (*2*) DL-2-octanol, and (*3*) 1-octanol; the same for Fig. 2. ($c_{H_2SO_4}$) Initial H_2SO_4 concentration in the aqueous phase; the same for Fig. 2.

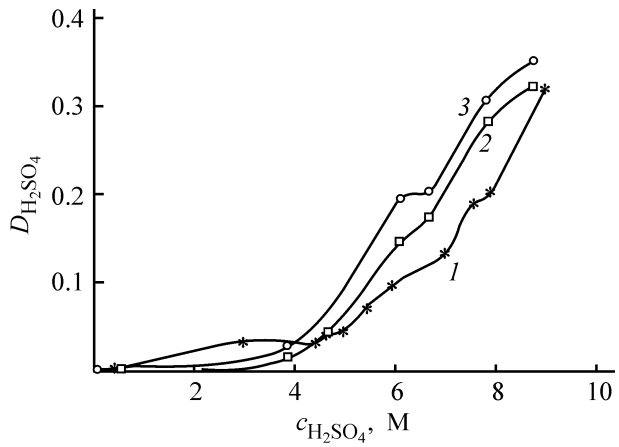

Fig. 2. H_2SO_4 distribution ratio $D_{H_2SO_4}$ vs. its concentration in the aqueous phase in extraction with octanols.

H_2SO_4, which increases with the acid concentration in the solution (Fig. 2). At high acid concentrations in the aqueous phase, the decrease in the extraction of ReO_4^- may be associated with the formation in the extractant phase of sulfuric acid esters [9] which virtually cannot extract Re(VII) [7].

Furthermore, the decrease in D_{Re} at $c_{H_2SO_4}$ above 7 M is caused by the formation of the sulfate complex $H[ReO_2(SO_4)_2]$ [10] which is considerably worse extracted to the organic phase, as we have shown previously for extraction of Re(VII) with triisooctylamine [11]. Evidently, this fact is responsible for the observed abrupt decrease in D_{Re} of 3-octanol at $c_{H_2SO_4} > 7$ M.

Figure 1 shows that the extraction capacity of the octanols depends not only on the H_2SO concentration, but it also strongly affected by their structure. This is clearly illustrated by the fact that the maximal D_{Re} for secondary 3-octanol is above 90, which is higher by about a factor of 5 that that for 1-octanol of the normal structure. Such effect of the structure can be attributed to different basicities of the isomers, which decrease in the order 1-octanol > 2-octanol > 3-octanol as a result of induction effects [12]. The higher D_{Re} values obtained for the secondary alcohols are also associated with the less pronounced effect of the concurrent extraction of sulfuric acid on the extraction of Re(VII) (Fig. 2). The inverse order of the extraction capacity of the alcohols for sulfuric acid is probably due to predominance of the steric factor in the secondary alcohols over the basicity factor.

CONCLUSIONS

(1) The extraction capacity of octanols for rhenium(VII) and sulfuric acid depends on the alcohol structure. It increases for Re(VII), but decreases for H_2SO_4 on passing from 1-octanol to 3-octanol.

(2) The dependences of D_{Re} on the acid concentration have maxima at 4–7 M, which are most clearly pronounced for the secondary alcohols.

(3) The abrupt decrease in the extraction capacity of octanols with increasing H_2SO_4 concentration above 7 M is caused by changes in the extractant composition and Re(VII) speciation in the solution.

BRIEF COMMUNICATIONS

1-Phenacylmethyl-2-(acylaminothiocarbonylamino)pyridinium Bromides as Protectors of Steel Acid Corrosion

R. I. Yurchenko, I. S. Pogrebova, and T. N. Pilipenko

Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received May 11, 2006; in final form, August 2006

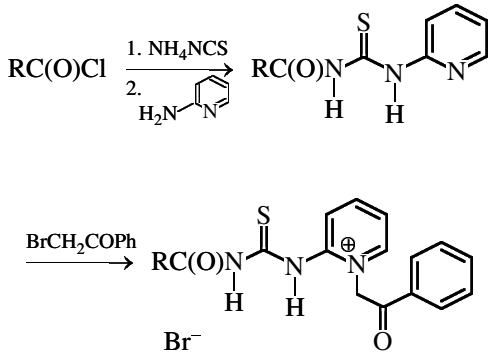
Abstract—Inhibiting effect of 1-phenacylmethylpyridinium bromides containing acylthiourea substituents in the pyridine ring on corrosion of mild steel in sulfuric acid (3 M) was studied.

DOI: 10.1134/S1070427207040325

The inhibiting properties of 1-phenacylmethylpyridinium bromides containing, in the 2-position of the pyridine ring, the $–NH_2$ [1], –NH(C)OR [2], –NHC(O)NHR, and –NHC(S)NHR [3] groups have been studied previously. The thiourea derivatives were found to be the most active. In this study, we examined ureides **I**–**VIII** as a logical continuation of the above studies: 1-(2-oxo-2-phenylethyl)-2-(3-phenylureido)pyridinium bromide **I**, 1-(2-oxo-2-phenylethyl)-2-[3-(4-methylphenyl)ureido]pyridinium bromide **II**, 1-(2-oxo-2-phenylethyl)-2-[3-(4-methoxyphenyl)-ureido]pyridinium bromide **III**, 1-(2-oxo-2-phenylethyl)-2-[3-(4-bromomethylphenyl)ureido]pyridinium bromide **IV**, 1-(2-oxo-2-phenylethyl)-2-[3-(4-chloromethylphenyl)ureido]pyridinium bromide **V**, 1-(2-oxo-2-phenylethyl)-2-[3-(2-furyl)ureido]pyridinium bromide **VI**, 1-(2-oxo-2-phenylethyl)-2-[3-(adamant-1-yl)ureido]pyridinium bromide **VII**, and 1-(2-oxo-2-phenylethyl)-2-[3-(undec-1-yl)ureido]pyridinium bromide **VIII**.

These compounds are acyl derivatives of thiourea and contain RC(O)NHC(S)NH groups in the 2-position of the pyridine ring. It is known that β-dicarbonyl compounds are often used in organic chemistry as complexing agents. Therefore, we can expect that the structure of substituents taken will be favorable for the protective properties of the compounds studied.

Compounds **I**–**VIII** were synthesized by the reaction of acyl chlorides, ammonium thiocyanate, and 2-aminopyridine, followed by treatment of the compounds obtained with ω-bromoacetophenone:



where R is Ph (**I**), 4-$CH_3C_6H_4$ (**II**), 4-$CH_3OC_6H_4$ (**III**), 4-BrC_6H_4 (**IV**), 4-ClC_6H_4 (**V**), 2-furyl (**VI**), 1-adamantyl (**VII**), and 1-undecyl (**VIII**).

The composition of the compounds obtained was confirmed by IR and ^1H NMR spectra.

EXPERIMENTAL

A mixture of an appropriate acid chloride prepared by reaction of the acid with thionyl chloride (2×10^{-2} mol), ammonium thiocyanate (2.5×10^{-2} mol), and anhydrous acetone (15 ml) was stirred for 30 min, after which 2-aminopyridine (2×10^{-2} mol) was added, and stirring was continued for an additional 1 h. The reaction mixture was treated with a small portion of water, and, the next day, the precipitate was separated. Equimolar amounts (1.5×10^{-3} mol) of the compound prepared and ω-bromoacetophenone were refluxed in 15 ml of ethyl acetate for 3 h, and the precipitate was separated. The yields (%) and

Corrosion inhibition coefficient γ and degree of protection, *Z*, for 08KP steel in 3 M H_2SO_4 in the presence of 1-phenacylmethylpyridinium bromides **I**–**VIII**

Compound	R	40°C		60°C		80°C

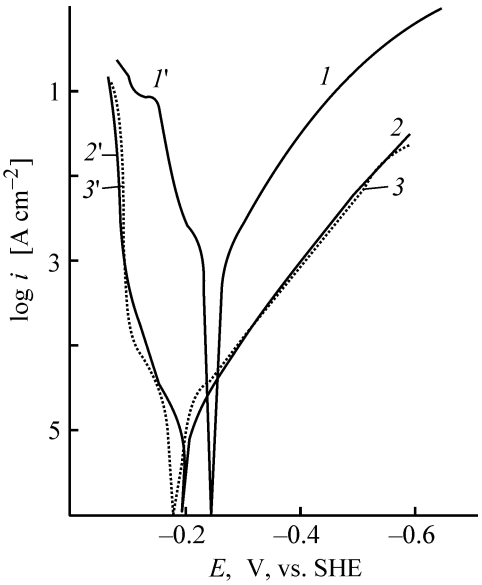
III	4-$CH_3OC_6H_4$	36.70	97.27	396.42	99.75	125.10	99.22
IV	4-BrC_6H_4	22.76	95.60	103.40	99.03	56.55	98.23
V	4-ClC_6H_4	22.76	95.60	121.20	99.17	103.60	99.03
VI	2-Furyl	41.56	97.59	218.70	99.54	119.00	99.16
VII	1-Adamantyl	39.80	97.48	380.56	99.73	192.75	99.48
VIII	1-Undecyl	38.24	97.38	328.10	99.69	102.90	99.02

melting points (°C) of **I**–**VIII** are as follows: **I**, 40, 229–232; **II**, 50, 198–200; **III**, 75, 195–205; **IV**, 70, 210–212; **V**, 71, 196–203; **VI**, 69, 218–220; **VII**, 35, 227–229; and **VIII**, 70, 212–215.

The corrosion-protective properties **I**–**VIII** were evaluated gravimetrically at 20, 40, 60, and 80°C by the inhibition coefficient γ and degree of protection, *Z*, of a 08KP steel in 3 M sulfuric acid [1]. Unfortunately, the poor solubility of the compounds obtained in 3 M H_2SO_4 prevented attaining the same concentration as for the previously studied 1-phenacylmethylpyridinium bromides.



(*1*–*3*) Cathodic and (*1'*–*3'*) anodic polarization curves recorded at 20°C on 08 KP steel in 3 M H_2SO_4 and in solutions saturated with **VI** and **VII**. (*i*) Current density and (*E*) potential. Solution: (*1*, *1'*) supporting electrolyte, (*2*, *2'*) with **VI**, and (*3*, *3'*) with **VII**.

Nevertheless, the tests performed showed that compounds **I**–**VIII** are fairly efficient inhibitors of steel acid corrosion (see table). The corrosion inhibition coefficients found for saturated solutions in 3 M H_2SO_4 vary within the ranges 15.79–26.47 at 20°C, 22.76–41.56 at 40°C, 103.40–396.42 at 60°C, and 41.70–192.80 at 80°C. Voltammetric measurements on steel with **VI** and **VII** at 20°C showed that these compounds behave as mixed-type inhibitors affecting the rate of both anodic and cathodic processes (see figure). Calculations based on the "formal theory" of inhibition [4] indicate that corrosion is inhibited by these compounds at 40°C by the energy-blocking mechanism.

Introduction of MeO group into the *p*-position of the benzene ring in **I** or replacement of the phenyl substituent with a furyl group enhances the protective properties, which is in accordance with the chemical nature of the substituents introduced, but the extent of enhancement is substantially lower than that in the series of the previously studied compounds [2, 3]. At 60°C, the corrosion inhibition coefficient for ureide **III** is only three times higher, and for **VI**, two times higher than that for **I**.

CONCLUSIONS

(1) It was found that the steel corrosion inhibition coefficients for saturated solutions of 1-phenacylmethyl-2-(acylaminothiocarbonlylamino)pyridinium bromides in 3 M sulfuric acid vary within the ranges 15.79–26.47 at 20°C, 22.76–41.56 at 40°C, 103.40–

396.42 at 60°C, and 41.70–192.80 at 80°C; the degree of metal surface protection is 95.6–99.7%.

(2) Voltammetric measurements showed that the compounds studied behave as mixed-type inhibitors affecting the rates of both anodic and cathodic processes. Corrosion is inhibited by these compounds by the energy-blocking mechanism.

INFORMATION

Prospects for Chemical Processing of Fossil Fuels

DOI: 10.1134/S1070427207040337

The International Conference "Prospects for Chemical Processing of Fossil Fuels" was held from September 12 to 15, 2006 in St. Petersburg. The conference was timed with the 135th anniversary of foundation of the Department of Technology of Petro- and Coal-Chemical Works at the Russian's oldest institution for higher technological education, St. Petersburg State Technological Institute (Technical University).

There were presented more than 100 plenary reports and oral lectures, and their abstracts were published. The Conference organizers were the Ministry of Education and Science of the Russian Federation; Division of Chemistry and Materials Science, Russian Academy of Sciences; Joint Scientific Council for Chemistry of Oil, Gas, and Solid Fuels; Scientific Council for Chemistry of Solid Fossil Fuels; Mendeleev Russian Chemical Society; and St. Petersburg State Technological Institute (Technical University).

More than 500 scientists from Russia and other countries were conference participants. They represented 46 institutes of higher-school institutions, more than 90 firms and joint-stock companies from 6 countries, and 23 oil- and coal-processing enterprises.

The Conference included three sessions: (1) Chemical Processing of Oil and Gas, (2) Processing of Solid Fossil Fuels, and (3) Environmental Aspects of Fossil Fuel Processing. A roundtable "Training of Engineering and Scientific Specialists" was organized. The poster session included 98 presentations. Finally, abstracts of 72 correspondence participants were also published in the Proceedings.

In the opening session, Academician G.F. Tereshchenko and Professors A.S. Dudyrev and V.M. Potekhin outlined the great significance of the fuel and energy complex for the world and Russian economy and the contribution of a pleiad of researchers to organization and development of one of the oldest chairs of the St. Petersburg State Technological Institute, the chair of technology of petro- and coal-chemical industries.

Plenary lectures were delivered by such distinguished specialists in the field of processing of natural energy carriers as S.N. Khadzhiev, A.L. Lapidus, V.M. Potekhin, M.I. Levinbuk, A.S. Noskov, A.S. Dykman, V.M. Zakoshanskii, M.G. Rudin, V.M. Strakhov, and J. Soone.

The lecture presented by S.N. Khadzhiev was devoted to the use of promising nanotechnologies in oil refining, including their cost efficiency in relation to secondary processing of the oil stock.

A.L. Lapidus analyzed in his lecture the general processes for making hydrocarbon mixtures from synthesis gas by the Fischer-Tropsch method with cobalt catalysts. The process mechanism was considered as well as the relationships between the activity and selectivity of catalysts and their physicochemical characteristics. The hardware implementation was discussed. Finally, the lecturer reported methods for production of synthetic liquid fuel from alternative raw materials (shale, coal, biomass).

M.I. Levinbuk analyzed the strategy of development of the Russian oil and gas complex, including the changeover from sales of raw materials to sales of high-quality oil and gas processing products and up-to-date technologies, which is extremely topical today.

A.S. Noskov reported recent developments of the Institute of Catalysis, Siberian Division, Russian Academy of Sciences in design of catalysts and processes for deep desulfurization of crude oil, processing of oil gas into arenes, utilization of methane-containing rejects of coal mines for energy production, and catalytic combustion of low-concentrated carbon-containing wastes.

V.M. Zakoshanskii overwieved in his lecture the history and progress of the cumene process for production of phenol and acetone. New chemical and related environmental aspects of the formation and decomposition of cumyl hydroperoxide were considered. The great contribution of Soviet researchers and their priority in the development of this significant process of the basic organic synthesis were underlined.

A.S. Dykman analyzed the prospects for production of monomers for synthetic rubber, which is topi-

cal in the context of modernization of domestic synthetic rubber plants.

M.G. Rudin made an overview of the current status and prospects for oil processing in Russia. He clearly demonstrated the need to modernize domestic oil refineries and emphasized the increasing significance of such processes as catalytic cracking, hydrocracking, low-temperature isomerization, and heat-contact carbonization. The lecturer also reported the specific features of oil processing in the United States. He outlined the necessity for application of promising processes developed by US companies to modernization of domestic refineries.

J. Soone, Director, Oil Shale Research Institute, Tallinn Polytechnical Institute, reported the potentialities of his institute for training students in chemistry and technology of fuels. He demonstrated the need for close collaboration with Russian institutes in this area.

THe session "Chemical Processing of Oil and Gas" included 19 oral lectures, including those presented by professors and lecturers of the department whose anniversary was celebrated: A.A. Gaile, A.M. Syroezhko, Yu.V. Pokonova, D.A. Rozental', V.A. Proskuryakov, and V.V. Gromova.

E.A. Chernysheva (Moscow) considered the problem of exchange-resonance effect of the electromagnetic field on oil dispersions and the prospects for application of this effect to oil processing in both primary distillation and processing of black stock.

The lecture delivered by S.A. Akhmetov (Ufa, Bashkortostan) was devoted to analog simulation and search for physicochemical constants of individual hydrocarbons and oil fractions (these data are necessary for technologists and developers).

A.M. Syroezhko (St. Petersburg) considered features of processing of heavy oil residue in the presence of oil shales, to obtain top fractions and residual stock for production of modified bitumens, pitches, and water-fuel emulsions.

A.A. Gaile (St. Petersburg) devoted his presentation to development of extraction and combined processes for oil product refining.

V.V. Vasil'ev (St. Petersburg) reported the results of analysis of the commercial fraction of shale naphtha by chromatography-mass spectrometry. Out of 225 identified compounds, 69 were detected for the first time.

The problems of petrochemical industry of Algeria were overviewed by Professor Hamada Boudjema (Algeria).

The fundamental aspects of formation of carbon nanofibers and carbon black in the course of electrocracking of organic raw materials were reported by B.V. Peshnev (Moscow).

The lecture presented by D.L. Astanovskii (Moscow) was devoted to selection of the hardware implementation in processing of natural gas into petrol.

The experience gained at four refineries in use of new highly selective naphtha reforming catalysts (RB series), developed at the Olkat Research and Production Company, Limited Liability Company (St. Petersburg), was analyzed by V.B. Maryshev.

V.Z. Mordkovich (Moscow) shared his experience in use of reactors with high-performance composite membranes in production of synthetic liquid fuel.

V.Yu. Dolmatov (St. Petersburg) prospects for using nanodiamonds produced by explosion in oil and gas technology.

A many-year experience gained in utilization of oil residues was summarized by Yu.V. Pokonova (St. Petersburg).

New methods for processing of oil residues such as hydroviscosity breaking, hydrocarbonization, thermal deasphalting, tested at the State Petroleum Technical University (Ufa, Bashkortostan), were reported by A.F. Ishkal'din.

Formation of a carbon fiber by thermal treatment of petroleum pitches under an inert atmosphere in reactors made from various materials was reported by R.N. Gimaev (Ufa).

An interesting lecture delivered by T.E. Zhesko (St. Petersburg) was devoted to use of carbon oxide for carbonylation of aryl halides to obtain aromatic acids and their derivatives.

In other oral, poster, and correspondence presentations, such important problems of oil and gas processing were considered as oil preparation for processing; use of the membrane technology in oil processing; hydrofining; demetallization and dewaxing of various oil fractions; processing of oil gas; processes for petrol improvement; hydroisomerization and isomerization catalysts; dehydrogenation, hydrofining, and reforming catalysts; wax accumulation inhibitors and combined-action antioxidants; high-performance thermocatalytic processing of residual gas condensate and oil fractions; improvement of bitumens and polymer bitumastics; combined processing of peats and bitumen; production of refined petroleum coke; cutting fluids; addidives to gasoline and diesel oil; desul-

furization; oxidation and conversion of natural gas; Fischer-Tropsch production of a synthetic liquid fuel; production of hydrogen by catalytic pyrolysis of methane; improvement of the gas condensate processing technology; catalytic purification of phenol; synthesis of alkylphenols and cyclohexanones; aqueous bitumen and fuel emulsions; etc.

The session "Processing of Solid Fossil Fuels" also included 19 oral presentations. They covered such topics as the prospects for further development of coal fuel chemistry and shale chemistry [gasification in melts (V.N. Vorob'ev)], thermal solvolysis of coals (E.I. Andreikov), integrated processing of shale oils (Yu.A. Strizhakova), non-fuel use of coals (A.A. Knyazev), and transformation of coal under high-rate heating (V.D. Glyanchenko). The problems associated with the production of semicoke in Russia were discussed by V.M. Strakhov (Novokuznetsk) and S.G. Stepanov (Krasnoyarsk).

At the Institute of Fossil Fuels (Moscow), G.S. Golovin and coworkers have developed a concept of multidimensional supramolecular structure and also a model of average statistical structural unit of the organic matter of coal. Combined with quantum-chemical calculations of the electronic structure of model compounds (A.M. Gyul'maliev), this approach allows simulation of the decomposition of coal matter.

Among the Conference participants were coal fuel chemists from Ukraine: A.F. Dmitruk, V.I. Saranchuk, A.F. Popov, T.G. Shendrik, L.V. Pashchenko, I.B. Frolova, L.F. Butuzova, and I.G. Krut'ko (Donetsk). They all made interesting presentations on chemistry and technology of coal. The abstracts of these contributions have been published.

The problems of processing of mixtures of coals with oil products were considered in the presentations given by T.G. Shendrik, E.I. Andreikov, and E.A. Khukhrin. V.A. Proskuryakov with coworkers and I.L. Glezina reported on nonresiduum processing of oil shales.

The section also included 26 poster presentations. Their abstracts have been published.

The composition of alcohol-benzene extracts of coals, heated under high pressure, and transition of coals into the plastic state was considered by V.D. Glyanchenko (Yekaterinburg), with the theoretical concepts of the coal-sintering and carbonization mechanisms extended.

The rest of the oral, poster, and correspondent contributions covered such significant aspects of solid fuel processing as the prospects for development of novel technologies; low-temperature coking and high-temperature pyrolysis of coals; hydrogenation and thermal dissolution of coals and oil shales; gasification, liquation, and oxidation of coals; granulation and briquetting; carbonization of coals, wood, and oil-slime; chemical processing of coals; combined processing of coal, oil shale, and oil-slime; non-fuel coal processing; nonwaste oil shale processing; binders; pitches; carbonaceous reducing agents; sorbents and synthetic fuel from coal; wastewater treatment at by-product coke plants and utilization of wood-chemical resins and mining and coal-cleaning wastes; resource saving; exposure of coal and its processing products to microwave, cavitation-wave, and other treatments; NMR spectroscopy of coal resins; effect of sulfur on coke formation; and so on.

In particular, A.Ya. Eremin and coworkers devoted their presentation to a promising coke quenching technique. A combined process for thermal preparation of coal charges and coke cooling was reported by V.I. Sukhorukov and coworkers (Yekaterinburg).

Oxidative desulfurization of fiery coal was considered by Kh.V. Shevchuk (Lviv, Ukraine).

Microwave breakage of coal, followed by its briquetting with iron-ore concentrate, was reported by A.A. Khaidurov (Irkutsk). Thermal dissolution of younger coal of the Irkutsk coal fields was considered by G.G. Shevchenko (Irkutsk).

R.Sh. Mirzoev (Baku, Azerbaijan) and Dangaa Oyuunbold (postgraduate student from St. Petersburg) devoted their presentation to the development of fuel pressing technology. Dangaa Oyuunbold also reported specific features of fast pyrolysis of Kansk-Achinsk, Kirgiz, and Mongolian brown coals and oil shale.

The problems of coal slack and coal cleaning wastes were analyzed by V.S. Beletskii and I.A. Arovin (Donetsk, Ukraine). A.S. Torgashin (Novosibirsk) and M.I. Baikenov (Karaganda) reported features of hydrogenation of coal organic matter.

Dangaa Oyuunbold reported on a study of the structure and bioactivity of humic acids separated from Mongolian brown coals. She underlined that non-fuel aspects of brown coal processing (production of various humics) are very topical for Mongolia, where most of soils are poor in humus.

Properties of carbonaceous sorbents and reducing agents produced from coal and wood-chemical raw materials were considered by I.L. Glezin (St. Petersburg), Yu.O. Lesishina (Donetsk), and E.V. Veselovskaya (Novocherkassk).

The session "Environmental Aspects of Fossil Fuel Processing" included 14 oral presentations. They covered such problems as utilization of aerosol releases from heat-electric generating plants and mining wastes; refining of hydrocarbon raw materials to remove hydrogen sulfide, mercaptans, carbonyl sulfide, and carbon disulfide; remediation of areas contaminated with oil (L.P. Zaichenko); and monitoring of air and water in territories under the impact of oil and gas production complexes. The environmental problems of by-product coke works and ways to their solution were considered by V.I. Sukhorukov (Yekaterinburg).

The "Training of Engineering and Scientific Specialists" roundtable (chairman V.M. Potekhin) included three presentations.

The Conference's decisions were as follows:

(1) To hold the conference "Prospects for Chemical Processing of Fossil Fuels" every three years on the basis of the St. Petersburg State Technological Institute or related departments of other institutes.

(2) To promote application of nanoprocesses to oil refining and petro-, gas-, and coal- chemical syntheses.

(3) To promote more intensively utilization of alternative raw materials (coal, oil shale, natural gas, plant raw materials, biomass, and oil, gas, and oil shale processing wastes), to produce competitive and environmentally friendly high-performance petrol.

(4) To practice international specialist exchange programs, to train students and postgraduates in fossil fuel processing.

BOOK REVIEWS

Sergeev, G.B., *Nanokhimiya: Uchebnoe posobie* (Nanochemistry: Textbook),

Moscow: University Book Publishing House (KDU), 2006, 336 pp.

DOI: 10.1134/S1070427207040349

In 2003, G.B. Sergeev, a professor of Lomonosov State University in Moscow and a known specialist in low-temperature chemistry, published the, in fact, first domestic monograph devoted to the new, rapidly developing area of research in modern science, nanochemistry [Sergeev, G.B., *Nanokhimiya* (Nanochemistry), Moscow: Mosk. Gos. Univ, 2003]. The textbook with the same title, brought to readers' notice, was for the most part written by the same author on the basis of this monograph, with account of very recent original studies (2003–2005) and lectures delivered by Sergeev at the chemical and materials science faculties of Moscow State University.

The book comprises a preface, eight chapters, conclusion, and extensive bibliography. The brief preface (pp. 6, 7) notes that the world's scientific community has recognized the development of nanotechnologies as the most promising area of research in science and technology of the XXI century. A new interdisciplinary area has formed: nanoscience, regarded as a body of knowledge about the fundamental properties of matter on the nanometer scale. The advances of this science are implemented in nanotechnologies by development of new materials, functional devices, and structures on the atomic, molecular, and nanometer levels. The author emphasizes that nanochemistry is now one of the leading areas of nanoscience.

The introduction (pp. 8–10) reminds that nanosize particles have started to attract researches' attention in various fields of science only in the last 15–20 years. Nevertheless, the sections "nanoparticles," "nanoclusters," and "nanocomposites" are already included to some extent in curricula, not to say about the congresses, conferences, and symposia devoted to this issue. The author convincingly substantiates the chemists' interest in nanoparticles and specially notes that particles less than one nanometer in size deserve special attention. The unusual chemical properties of particles composed of several atoms or several tens of atoms require a profound modification of the concepts previously developed for systems including thousands and millions of atoms. The textbook by Sergeev can be regarded, on the one hand, as an interestingly and lively written introduction to a novel field of chemistry, and on the other, as a thorough, and composed by a skilled author, guide to the vast material accumulated by nanochemistry by the year of 2005.

The first chapter (pp. 11–20) gives a general notion of the nanoscience developing at the intersection of physics, chemistry, and biology. The rapid advance of the nanoscience in the last decade is primarily due to the development of new methods for synthesis, study, and modification of nanoparticles and nanostructures. A considerable attention is given by the author in the first chapter to notions and terms used by the nanoscience and, in particular, by nanochemistry. A classification of nanoparticles by their size, number of atoms in a particle, and number ratio of surface to bulk atoms is given. The author believes that the key issue is to determine the influence exerted by the size of particles on their chemical activity. In conclusion of the chapter, Sergeev notes that he is convinced that the importance of nanochemistry in the development of nanotechnology will steadily increase in the nearest 5–10 years.

The second chapter (pp. 21–61) considers methods for synthesis and stabilization of nanoparticles. Most of elements of the Periodic table are metals, and, therefore, the primary attention in further presentation is given to metals. Methods for synthesis of nanoparticles are analyzed in detail and classified, and processes of their stabilization are discussed.

The third chapter (pp. 62–75) describes methods for analysis of the size and properties of nanoparticles in the gas phase, on a surface, in the bulk, or in a host. The following techniques are considered: transmission and scanning electron microscopy, probe microscopy, diffraction analysis, etc. The potentialities, advantages, and disadvantages of various methods of analysis are compared.

The fourth chapter (pp. 76–150) discusses problems of the cryochemistry of nanosize metal particles (nanocryochemistry). The author of the textbook,

Sergeev, has made a major contribution to the development of this field of nanochemistry. In most detail have been studied reactions of magnesium, silver, and rare-earth metal particles at low (77 K) and ultralow (4–7 K) temperatures. The possibility of modeling of the physicochemical properties and reactivity of metal nanoparticles is considered.

The fifth chapter of the textbook (pp. 151–215), named "chemical nanoreactors," mostly includes evidence concerning methods for stabilization of nanoparticles. The activity of metal clusters and particles is primarily due to uncompensated surface bonds. Systems of this kind can be regarded as chemical nanoreactors possessing a significant store of energy. The author considers in detail the method of matrix isolation, which enables stabilization of active particles. The sixth chapter (pp. 216–226) is devoted to the role of carbon in nanochemistry. The discovery of fullerenes and carbon nanotubes has been an important contribution to the development of the nanochemistry of nonmetals. This chapter also presents information about silicon clusters.

The seventh chapter (pp. 227–250) summarizes the evidence concerning dimension effects in nanochemistry. By the dimension effect is understood a fundamental change in the physicochemical properties and reactivity of particles of a substance, which occurs as the number of atoms or molecules in a particle decreases to less than about 100 atomic-molecular diameters. It can be regarded confirmed that the manifestation of dimension effects is one of the main distinctions of nanochemistry from chemical transformations under ordinary reaction conditions. A notion of the internal, external, and quantum dimension effects is given. It is once again emphasized in the final part of the chapter that analysis of the dimension effects and establishment of a relationship between the number of atoms involved in a reaction and the resulting fundamental changes is the primary goal of nanochemistry. The size, shape, and structure of metal particles in the nanosize range exert direct influence on the chemical activity of systems, stability and properties of the materials obtained, and opportunity of their application in nanotechnology.

The eighth chapter (pp. 251–297) discusses, on the basis of the most recent publications (2000–2005), the application of nanoparticles in various fields of science and technology: catalysis on nanoparticles, use of nanocrystalline oxides in various syntheses, nanoparticles in semiconductors and sensors, photochemistry (nanophotonics), carbon nanotubes, and nanoparticles in biology and medicine.

In the conclusion (pp. 298–306), the author formulates, based on an analysis of a vast body of diverse experimental data, promising avenues of development of fundamental and applied nanochemistry. The basic research is primarily aimed to establish relationships between the chemical and physical properties, size, and shape of nanoparticles. The goal of applied nanochemistry is to use nanoparticles to develop new materials with unique optical, electrical, magnetic, mechanical, sensor, and catalytic properties. In the context of these global tasks, the author discusses a number of special problems.

Each of the eight chapters of the textbook ends with control questions. The book is provided with a rather informative bibliographic list (pp. 307–333), composed separately for each of the chapters (a total of 335 references). The textbook by Sergeev is close in structure and contents to the already mentioned monograph by the same author. The bibliographic list in the textbook is less extensive than that in the monograph (606 references), but seems to be still exceedingly large for a textbook. A considerable part of foreign periodic publications of recent years, included in the list, are, unfortunately, nearly inaccessible to students who study outside Moscow. The textbook by Sergeev is of interest and can be recommended for students specialized in quite a number of areas, as well as for postgraduate students, research workers, and lecturers. The book luckily combines simplicity and high scientific level of presentation.

REVIEWS

Procedures for Preparing Chitin-Based Fibers

G. M. Mikhailov and M. F. Lebedeva

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received October 4, 2006; in final form, March 2007

Abstract—Data on preparation of chitin threads for the fabrication of absorbable suture materials, dressings, and biodegradable substrates for the growth of human skin cells (keratinocytes and fibroblasts) are analyzed.

DOI: 10.1134/S1070427207050011

Chitin, poly-(1-4)-2-acetamido-2-deoxy-β-*D*-glucopyranose, is contained in shells and exoskeletons of Crustacea and insects. This natural renewable polysaccharide exhibits a set of unique biological properties: it is enzymatically cleaved with lysozyme to form *N*-acetylglucosamine and glucosamine; it shows antimicrobial activity; it is a hemostatic, an immunomodulator, etc. [1–4]. Like cellulose, which is the most widely used polysaccharide, chitin is a fiber-forming polymer.

The use of chitin as suture material was suggested by L.L. Balassa [5]. He noted the capability of chitin to promote wound healing. Studies of chitin-based sutures confirmed that they fix tissues until the wound is completely healed, after which they fully resolve without leaving a trace. The resulting stitches become cosmetic, without cicatrization of tissues [3, 4]. Chitin is resistant to hydrolysis and is therefore stable in prolonged storage. The sutures resolve in a patient's body in a time ensuring complete healing of a wound.

Despite apparent advantages of this polysaccharide, there is still no commercial production of chitin-based absorbable suture materials in the world because of insufficient elasticity of chitin threads and certain problems in the production process.

The information considered in this review concerns preparation of chitin threads for the fabrication of absorbable suture materials, wound textiles, and biodegradable substrates for the growth of human skin cells (keratinocytes and fibroblasts).

The first attempts to prepare chitin solutions to make fibers from them were made in the beginning of the XX century. In 1926, Kunike [6] reported on the first studies of chitin fibers. He dissolved chitin in cold concentrated sulfuric acid and obtained 6–10% solutions. He used a wet procedure for thread forming, with water, alcohols, or alkali as coagulants. After drying the filament,[1] he obtained chitin fibers with a density of 1.4 g cm^{-3} and a tensile strength of about 35 kg mm^{-2}.

Knecht and Hibbert [7] prepared films from a solution of chitin in concentrated HCl.

It is known that concentrated acids slowly dissolve chitin with the simultaneous hydrolysis of the polysaccharide to oligomers and monomers. Orthophosphoric acid containing 15% water dissolves chitin mildly, and in some cases brittle films can be prepared from the solution [8].

Saturated solutions of salts capable of intense hydration ($LiCNS > Ca(CNS)_2 > CaI_2 > CaBr_2 > CaCl_2$) were tested as chitin solvents. With these solvents, chitin was converted to a strongly swollen plastic paste from which a fiber-like material was prepared [9].

In 1936, Clark and Smith [10], using LiCNS as chitin solvent and aqueous acetone as coagulant, prepared a fiber; its characteristics, however, were not reported. Further search for a chitin solvent led to systems containing acids and organic solvents. Solutions of chitin in a mixture of chloroethanol and H_2SO_4 were used for forming fibers, with the precipitation into water, methanol, or aqueous ammonia [11].

Attempts were made to dissolve chitin in solutions of mono- and dichloroacetic acids; however, the resulting threads showed poor strain and strength characteristics because of strong hydrolyzing power of these acids.

In 1975, Brine and Austin suggested trichloroacetic

[1] Filament is the amount of fibers corresponding to the number of holes in a spinneret used for fiber forming; monofilament is a fiber prepared using a single-hole spinneret, and polyfilament, a thread prepared by twisting several filaments together.

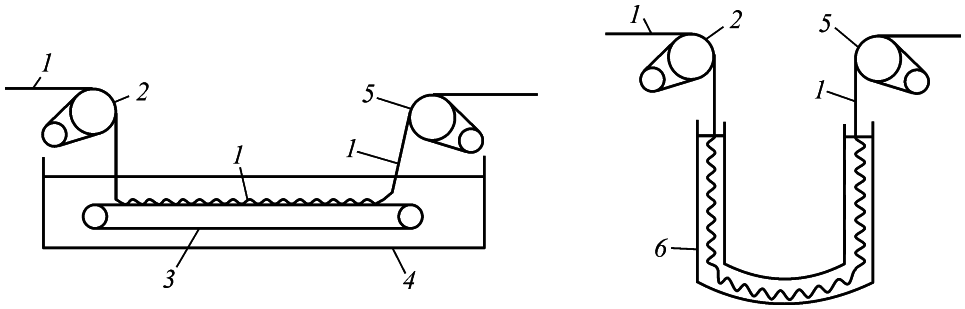

Fig. 1. Scheme of a unit for preparing chitin fibers: (*1*) chitin fiber, (*2*) feed roller, (*3*) belt conveyor, (*4*) second spinning bath, (*5*) transfer roller, and (*6*) U-shaped tube.

acid (TCA) for chitin dissolution. Because TCA is a very strong acid promoting hydrolysis of polysaccharides and has a high melting point (57°C), it becomes necessary to use it as solution and to dissolve chitin at low temperatures at which the hydrolysis is slow. A 2% chitin solution was prepared on adding to TCA 40% chloral hydrate and 20% methylene chloride. Acetone was used as coagulant. The precipitated fiber was neutralized with a solution of KOH in isopropanol and was washed with water. The fiber strength σ was 63 kg mm^{-2} (618 MPa), and elongation ε, 13%. It was claimed that the mechanical characteristics of threads could be substantially improved by controlling the extrusion rate and choosing appropriate coagulant [13].

In 1977, Austin and Brine [14] patented chitin films and fibers suggested for use for foodstuff protection and suture fabrication. In this case, they used for dissolving chitin TCA and chlorinated solvents like chloral or chloral hydrate. The spinning solutions obtained were used in chitin reclaiming for forming fibers and films. The strength of the fibers they obtained was 63 kg mm^{-2}, and breaking elongation, 13%; however, the filament contained 5.03% N and 9.455% Cl.

Preparation of high-strength chitin fibers for absorbable sutures was described by Inoue et al. [15]. To dissolve chitin, they used a 25 : 75 to 75 : 25 mixture of TCA with methylene chloride. The claimed chitin concentration in the spinning solution was from 1 to 10%; the setting bath was filled with acetone. The fiber draw ratio was from 0.4 to 1.4 (preferably from 0.6 to 1.1). Under these forming conditions, the strength of the dry fiber was 255 MPa and over. Kifune et al. [16] suggested a procedure for preparing chitin fiber intended for use as suture. To prepare chitin solutions, they used TCA in a mixture with chlorinated hydrocarbons (chloromethane, dichloromethane, chloroform, etc.). The fiber was characterized by a linear density of the filament of 0.5–20 denier[2] and a dry strength exceeding 384 MPa.

To prepare a spinning solution of chitin, Kifune et al. [17] used TCA solutions, with anhydrous acetone or anhydrous methanol as coagulant; the fibers were formed by adding the chitin solution to a setting bath with a coagulant temperature of 10–25°C and keeping in the bath for approximately 1 min. Since the fiber contained the solvent, it was fed with a belt conveyor to a second spinning bath where the solvent was removed. The residence time of the fiber in the second bath was ≥10 min. Then the fiber was fed to a U-shaped tube for more complete neutralization of the acid that had been the chitin solvent. The fiber was washed with distilled water and dried. The scheme of the equipment used is shown in Fig. 1.

Filament *1*, which was extruded to the first spinning bath from a spinneret with 40 holes 0.04–0.06 mm in diameter, from feed roller *2* was fed to conveyor *3* of the second spinning bath *4*, from which it was loaded through transfer roller *5* into U-shaped tube *6* containing a coagulant with an alkali. From this tube, the filament was withdrawn with a transfer roller and taken up by a reel at a tension of 64 or 38 MPa, or at a lower tension. The resulting fiber had a linear density of 0.5 to 20 denier. The fiber could be extended by 20–80%. The tensile strength of the fiber exceed 255 MPa.

Later a process for producing chitin fibers for suture materials was patented. The chitin fibers were plaited; the plait size met the US Pharmacopoeia standard for catgut sutures. A solution of TCA in chlorinated hydrocarbons (chloromethane, dichloromethane, 1,2-dichloroethane, 1,1,1-trichloroethane, 1,1,2-trichloroethane) was used as chitin solvent; the TCA concentration in solutions was 25–75 wt %. The dissolution of chitin was performed at a low tempera-

[2] 1 denier = 1 g/9000 m of fiber.

ture (5°C); the solution was filtered through a steel gauze (1480 mesh) under a pressure of 4 kg mm^{-2} and degassed in a vacuum to obtain 1–10% spinning solutions of chitin.

The equipment used for forming fibers is shown in Fig. 1. A spinneret with 40 holes 0.04–0.08 mm in diameter was used; the coagulant was acetone at 14°C (first setting bath). The temperature of the spinning solution before feeding to the spinneret was raised to 20°C. The spinning solution was fed at a rate of 2.3 ml min^{-1}. Then the filament was fed to a conveyor and washed in the second bath with methanol containing 0.3 g l^{-1} KOH, after which it was kept in a U-shaped tube filled with the same methanolic solution of KOH. Then the fiber was washed with distilled water and dried. The strength of the dried fiber was 215–400 MPa, and the breaking elongation, 8.7–20.0%. After keeping the fiber in 0.5% KOH solution, the fiber strength increased to 290–412 MPa, and the breaking elongation, to 19.2–27.3%. From the filaments thus prepared, plaited sutures were fabricated, and their knot strength and variation of the tensile strength in vivo were evaluated.

The characteristics of chitin fibers (polyfilament and monofilament) prepared under various conditions are listed in Table 1. It is seen that all the samples have good mechanical properties. The best of them is sample A exhibiting the highest values of the tensile strength (396 MPa) and breaking elongation (20.0%).

Twelve polyfilaments of each of these four samples were plaited to obtain sutures no. 3-0 (0.31 mm in diameter) in accordance with the US Pharmacopoeia standard (20th edition). The knot strengths of these materials are given in Table 2.

All the four samples were tested as sutures. Sample A showed good absorption properties in vivo.

A filament prepared similarly to sample A (Table 1) was subjected to an additional 1.4-fold extension (Table 3, sample 1). Its tensile strength was 523 MPa. The fibers were plaited to obtain suture material no. 4-0. Experiments with suture materials made of polyglycolic acid (sample 2) and chromic catgut (sample 3) were made for comparison. The results of a comparative study of the absorption properties of these materials in vivo are given in Table 3.

Table 3 shows that, with polyglycolic (sample 2) and catgut (sample 3) suture materials, the absorption is too fast. The chitin material (sample 1) resolves slowly in the first 10 days, after which the process accelerates; just such a behavior is required of an absorbable suture material.

Table 1. Characteristics of chitin fibers

Sample	Linear density, denier		Dry strength, MPa	Elongation, %
	polyfilament	monofilament		
A	72	1.80	396	20.0
B	68	1.70	211	8.7
C	66	1.65	213	8.8
D	71	35.5	370	18.0

Table 2. Strength characteristics of suture materials

A	1.87	235
B	0.80	106
C	0.79	107
D	1.97	222

* According to the Japanese Pharmacopoeia standard, the breaking load in knot should exceed 1.25 kg.

In 1990, Kifune et al. [19] took out a patent for chitin fibers and their fabrication procedure. They claimed that chitin fibers are intended for the production of chitin suture materials exhibiting high strength, elasticity, and good absorption properties.

With a reference to the previous patent [18], Kifune et al. reported that fabrication of sutures by the previously suggested procedures was complicated by large thickness of filaments. Patent [19] concerns production of threads with a dry filament strength exceeding 255 MPa at a linear density from 0.5 to 20 denier. The authors claimed that chitin fibers with such characteristics can be prepared by an additional treatment of filaments with a coagulant solution in a unit (Fig. 1) described as a second spinning bath with a belt conveyor, in which the fiber is in the free state.

In [19], Kifune et al. specified the parameters for preparing chitin fibers, in particular, for the fabrication of sutures of all sizes, from no. 1 to no. 9-0 in accordance with the US Pharmacopoeia standard for catgut; the characteristics of these threads in a knot were given. As chitin solvent Kifune et al. used TCA solutions. To minimize hydrolysis of chitin macromolecules, the spinning solution of chitin was prepared and used immediately before forming the fiber.

The above procedures for preparing spinning solutions of chitin involve the use of TCA with its solvents. This is a very aggressive medium causing not only corrosion of the equipment, but also, what is

Table 3. Strength of suture materials

Sample no.	Knot strength, kg	Residual knot strength, %				Tissue reaction (in 30 days)
		5 days	10 days	20 days	30 days	
1	1.31	76	52	13	0	Complete recovery
2	0.97	54	32	4	0	Complete recovery
3	0.79	25	12	0	0	Damage of capillaries in the area of suture resorption

more important, depolymerization of chitin in spinning solutions both during their preparation and in the course of storage and processing of a chitin solution into a thread. Furthermore, the fiber contains a large amount of chlorine, up to 9.455 wt %, which cannot be removed by washing the freshly formed fiber [14]. The chlorine content of threads can be reduced to 1% only by prolonged refluxing in *n*-propanol containing 1% NaOH.

The results of the above-mentioned studies suggest that the supramolecular organization and morphology of the fibers became nonuniform, as indicated by the large breaking elongation of the fiber (up to 20%). Presumably, TCA reacts directly with chitin, because washing with various solvents and even refluxing with an alkali do not ensure complete removal of chlorine from the target product.

To recover chitin from shells, the shells are heated with aqueous solutions of alkalis to remove protein. In so doing, chitin undergoes partial deacetylation with the formation of amino groups, which can react with TCA to form both salts and chlorinated amide groups. The latter groups can also be formed by displacement of the weaker acetic acid from acetamide groups with the stronger trichloroacetic acid. In contrast to Austin and Brine [14], Kifune did not determine the chlorine content of the fiber. These procedures have not yet found industrial application.

Thor and Henderson [20, 21] prepared chitin xanthates. The following protocol is given as example: 150 g of purified chitin was mixed at room temperature with a 31–40% NaOH solution. The mixture was allowed to stand for 2 h. After squeezing, approximately 450 g of alkali chitin was obtained; it was mixed in a sealed vessel with 60 ml of CS_2. The mixture was stirred at 25°C for 4 h and transferred into a vacuum flask. Crushed ice (1.6 kg) was added; the mixture was stirred for 1 h and allowed to stand for 12–16 h. Then it was filtered and degassed, and a spinning solution subsequently used for forming fibers was obtained.

The same method for preparing fibers was used by Balassa and Prudden [22]. A solution of chitin xanthate was fed to a precipitation bath containing 8% sulfuric acid, 25% sodium sulfate, 3% zinc sulfate, and water at 40°C. The filament was collected in skeins; its strength ranged from 77 to 128 MPa.

The fibers obtained were tested as dressings in studies of wound healing, performed on animals and humans. The authors claimed that the matherials efficiently promote wound healing.

The strength properties of chitin fibers were somewhat improved by Noguchi et al. [23]. The viscosity of a chitin xanthate solution aged for 14–18 h was 130 P. Addition of an equimolar amount of urea with respect to the *N*-acetylglucosamine group decreased the solution viscosity to 100 P. After filtration and degassing, a spinning solution was obtained. Forming was performed at room temperature into a spinning bath containing 10% sulfuric acid, 25% sodium sulfate, and 1% zinc sulfate. Ethanol was used in a stretch bath; after that, the fibers were washed with water and then, before drying, with ethanol and were dried on a roller at 110°C.

In patent [24], Yoshikawa et al. claimed preparation of chitin fibers and films to be used for fabrication of clothes, hygienic materials, fibers with antimicrobial activity, and items for everyday life. The authors treated chitin with a NaOH solution and obtained chitin containing 10–48% NaOH; after removing excess alkali by squeezing, this material was treated with a CS_2 solution to obtain a solution of chitin xanthate, similar to solutions of cellulose xanthate. From this solution, Yoshikawa et al. prepared by wet forming, as it is commonly done in production of viscose silk, "chitin" fibers with excellent antimicrobial characteristics. By mixing a solution with chitin xanthate with a solution of cellulose xanthate in various ratios, Yoshikawa et al. prepared composite fibers consisting of "chitin" and cellulose. These fibers exhibited a tensile strength of 240–304 MPa at

a breaking elongation of 24.3–16.7%. The chitin-to-cellulose ratio was varied from 5 : 95 to 95 : 5.

One of key factors governing the properties of chitin and its derivative chitosan (solubility, biological activity, etc.) is the degree of acetylation (DA). Treatment of chitin with a concentrated NaOH solution results not only in formation of alkali chitin, but also in elimination of acetate froups from acetamide fragments of glucopyranose units of the polysaccharide macromolecules, i.e., the degree of acetylation of chitin decreases. At 50% decrease in DA, the properties change so drastically that the product is no longer termed chitin and is termed chitosan. The chitin fibers prepared in [24] were not characterized by the degree of acetylation. Chitosan exhibits higher antimicrobial activity than chitin. Since the degree of acetylation is not indicated in these patents, it can be concluded that actually the fibers obtained in these studies were formed by chitosan (copolymer of glucosamine with *N*-acetylglucosamine) rather than chitin.

Since chitosan is cleaved by lysozyme more difficultly, and at high degrees of deacetylation is not cleaved by lysozyme at all, it is impossible to prepare absorbable suture materials from these fibers. The fibers should be tested for the cleavage with lysozyme.

It was discovered later that chitin forms stable solutions in *N*,*N*-dimethylacetamide (DMAA) and *N*-methylpyrrolidone (MP).

In 1977, Austin patented new chitin solvents [25] and their use for purification and reclaiming of chitin in the form of fibers or films [26]. The solvent was a solution of 2–5% LiCl in DMAA, MP, or their mixture. The dissolution of chitin was peformed at room temperature or at moderate heating (50°C). It was noted that the amount of the dissolved chitin depended on its molecular weight. Concentrations as high as 15% can be attained, but in this case the solution becomes so viscous that forming of fibers and films becomes impossible. Therefore, it is advisable to use 2–5% chitin solutions. Acetone was used as coagulant. However, in studies concerning chitin reclaiming, only films were prepared and characterized.

Rutherford and Austin [27] reported on forming of chitin fibers from solutions of chitin in aprotic solvents. The fiber forming procedure was not described; only the film preparation was reported in detail. The films were cut into strips which could be subjected to 75% extension.

Kibune et al. [28], with a reference to [25], reported on the preparation of fibers and films from solutions of chitin in dimethylacetamide or *N*-methylpyrrolidone containing LiCl; the chitin concentration in the spinning solution was 2–10 wt %.

Crab shells thoroughly washed and dried at 40°C were ground and sieved through a 180-mesh sieve. One portion (220 g of chitin powder) was treated with 2 l of 2 N HCl at room temperature for 5 h, and another portion (91 g), with 500 ml of 2 N HCl for 2 days. Both portions were subsequently washed with water and treated with 500 ml of 1 N NaOH at 100°C for 12 h, washed again with water, and dried. The resulting chitin was dissolved in a mixture of 92% DMAA (23 g) and 8% LiCl (2 g). The solution containing 0.2 g of chitin per 100 g of DMAA had a viscosity of 985 cP at 30°C. After additional treatment of chitin at 40°C with 1 N HCl for 1 h, the solution viscosity decreased to 305 cP. This chitin was dissolved at room temperature in a 20 : 1 mixture of DMAA with LiCl, taken in an amount required to obtain a 3 wt % chitin solution. The mixture was degassed, and the solution was used for spinning. The fibers were obtained using a 50/0.08 spinneret (50 holes 0.08 mm in diameter). The spinning bath contained isobutanol; the wind-up speed was 10 m min^{-1}. The fiber obtained had a linear density of 61 denier; the dry strength was 483 MPa. From a chitin sample whose solution had a viscosity of 985 cP, at a wind-up speed of 3 m min^{-1}, the fiber with a strength of 408 MPa was obtained. After an additional treatment of chitin with 1 N HCl for 1 h, the viscosity of the spinning solution was 24 cP, and the fiber prepared had a linear density of 63 denier and a strength of 331 MPa. LiCl was not removed from the fibers. Medical applications of the fibers were not considered.

Kibune et al. [29] used for dissolving chitin both DMAA and MP, both containing more than 5.5% LiCl. The reported chitin concentration in the spinning solution ranges from 0.5 to 10 wt % relative to DMAA or MP. The fiber forming procedure is similar to that given in [28]. The fibers have a linear density of 58 denier and a strength of 542 MPa.

As in the previously discussed patent, crab shells were washed with water, dried, and ground. The sieved chitin was treated with 1 N HCl at 40°C to control the molecular weight. The control system, a solution of 2 g of LiCl and 0.2 g of chitin in 25 g of DMAA, had a viscosity of 350 cP at 30°C. A 50/0.08 spinneret was used. The solution was fed at a pressure of 2 kg cm^{-2}. The spinning bath contained isobutanol at 25°C. The fiber wind-up speed was 10 m min^{-1}. The fiber had a linear density of 65 denier and a strength of 529.8 MPa. With MP + 5% LiCl used as chitin solvent, the dissolution was performed at 25°C.

The solution was filtered through a stainless steel gauze (1480 mesh), degassed, and formed as described above. The linear density of the fiber obtained was 62 denier, and the strength, 390 MPa. The drying conditions were not reported. Lithium chloride was not removed.

Kibune [30] patented a chitin spinning solution containing chitin, LiCl, and MP or DMAA; the LiCl weight exceeded that of chitin. The chitin amount relative to MP or DMAA containing LiCl was 0.5–10 wt %. Chitin was dissolved at 25°C in LiCl-saturated MP or DMAA. The fiber was formed using a 50/0.08 spinneret. The solution at 25°C was fed with a pump to a spinning bath (isobutanol, 70°C, contact time 2 min, wind-up speed 10 m min^{-1}). The fiber obtained had a linear density of 65 denier and a strength of 530 MPa. With DMAA replaced with MP, other conditions being the same, the linear density of the fiber was 65 denier, and the dry strength, 456 MPa. LiCl was not removed from the fibers. The breaking elongation and the degree of acetylation of the reclaimed chitin were not reported.

According to [31], crab shells were treated for 3 h with 5% aqueous NaOH at 80°C and for 3 h with 6% HCl at 60°C, after which they were washed with water and dried. Chitin flakes were ground and sieved through a 30-mesh sieve. The chitin powder was dissolved in DMAA + 8% LiCl; the viscosity of the 0.2% chitin solution was 31 cP at 30°C. From this chitin powder, 7% chitin solutions in DMAA + 8% LiCl were prepared. After degassing, the highly viscous spinning solution was extruded at 70°C through a spinneret with 6000 holes 0.1 mm in diameter into a spinning bath with a coagulant temperature of 70°C. The fiber was spooled at a speed of 5 m min^{-1} and then was treated for 8 h with hot (90°C) water, apparently, to remove LiCl. After drying, the linear density of the single fiber obtained was 2.0 denier. Fibers were cut into 5-mm pieces which were blended with a cut fibrous binder. The blend was dispersed in water, and sheets were formed as in paper production. The samples were calendered, and a 0.08-mm-thick nonwoven material was obtained. After sterilization with gaseous ethylene oxide, the nonwoven material was used for treatment of skin wounds after heavy thermal burns. Within 15 days, the damaged area of the skin was recovered and had an even surface.

In another procedure, a fiber was prepared by extrusion of a spinning chitin solution through a spinneret with 6000 holes 0.07 mm in diameter into water at 80°C. The fiber wind-up speed was 8 m min^{-1}. The fiber was washed with water at 90°C for 6 h to remove LiCl. The filament had a lustrous surface; the linear density was 1.8 denier. The fiber was cut into pieces 6 cm long, which were processed into a 5-mm-thick nonwoven material using a carding machine and a needle stem. The material was cut into 10 × 10-cm pieces which, after bactericidal treatment, were used for treating bedsores (removing the fluid, draining the wound).

However, the strain and strength characteristics of fibers were not reported in the patents. Probably, the fibers were too brittle to be used for preparing sutures.

Virtually 1 month after taking out patent [18], Kifune et al. patented a nonwoven dressing material [32] formed by chitin fibers with a linear density less than 1 denier and a strength of no less than 255 MPa, with a fibrous binder. As chitin solvents, along with TCA solutions, Kifune et al. claimed solutions of LiCl in DMAA and MP.

A chitin powder (100 mesh) was treated to remove calcium and protein with 1 N HCl for 1 h at 4°C and with 3% NaOH for 3 h at 90°C, after which it was washed and dried. A 0.2% solution of purified chitin in DMAA + 8% LiCl had a viscosity of 256 cP at 30°C.

Chitin was dissolved in DMAA containing 7% LiCl. The spinning solution contained 7% chitin. The solution was fed at a rate of 2.2 ml min^{-1} through a spinneret (200 holes 0.06 mm in diameter) to a spinning bath (butanol, 60°C). The precipitated chitin was wound up at a speed of 10 m min^{-1}. The filament was washed with water and dried. It had a linear density of 0.68 denier and a strength of 393 MPa; it was used for preparing nonwoven materials.

Agboh and Qin [33] prepared chitin solutions using DMAA + 7% LiCl. Prior to dissolution, chitin was treated with *p*-toluenesulfonic acid in isopropanol. As noted in [33], this pretreatment substantially facilitates the subsequent dissolution of chitin and preparation of a spinning solution. It leads to a decrease in the molecular weight of chitin from 2×10^6 to 1.5×10^5 Da. They found that the best composition of the spinning bath is H_2O + DMAA in 75 : 25 ratio, at a bath temperature of 40–75°C. The fibers had the following characteristics: diameter 8–20 μm, strength 97–306 MPa, and elongation 7–7.5%.

Examination of the forming conditions showed that the formability was improved with increasing temperature of the spinning bath and on adding a properly chosen plasticizer to the spinning solution. However, the content of chitin derivatives and toluenesulfonic acid in the spinning solution and ready fiber was not

reported. Treatment of chitin-containing raw materials to remove proteins results in formation of a certain amount of amino groups which, when reacting with toluenesulfonic acid, can form not only salts but also amides. These structures are inadmissible if the material is intended for use in surgery as suture material, because the release of free toluenesulfonic acid in patient's body can cause a pain shock.

Using DMAA + LiCl as solvent, Nakajima [34] prepared chitin fiber with a tensile strength of 496 MPa. Thin filaments ~5 μm in diameter were formed using a spinneret with a hole diameter of 0.05 mm. Butanol was used as coagulant.

The strain and strength characteristics of chitin fibers prepared in various periods using vaious solvents are listed in Table 4. In cases when the breaking elongation was not reported, the fibers, apparently, exhibited high crystallinity and were very brittle [29]. The high brittleness is commonly observed at high orientation stretching under the conditions when the chitin fiber acquired a highly crystalline structure [35].

Using DMAA and MP aprotic solvents with dissolved LiCl (up to 9%), we prepared stable chitin solutions. In these systems, chitin hydrolysis does not occur. We found that the chitin solution, if protected from the contact with atmospheric moisture, preserved its properties for more than 5 years, and the strain and strength properties of fibers prepared during this period were reproducible. In contrast to the previously used chitin solvent systems containing acids and causing hydrolysis of the polysaccharide, solutions in DMAA or MP containing LiCl are stable.

When studying the fiber-forming ability of chitin, we found that the high brittleness of chitin fibers is caused by its strong tendency to crystallize [35]. An increase in the structural heterogeneity of the system upon partialy heterogeneous deacetylation of chitin hinders crystallization of the polymer in the course of fiber preparation and allows the fiber elasticity to be enhanced. At a degree of chitin deacetylation of 0.30 and less, the fiber can be tied in a knot and preserves 40% of the initial elasticity [36]. Heterogeneous deacetylation involves severe treatment with a concentrated alkali (30–50%) at a high temperature and often yields products with poorly reproducible characteristics. Therefore, inclusion of this step in the production process is undesirable because of unstable characteristics of the resulting copolymer (solubility, gelation), complicating or even making impossible preparation of spinning solutions and fiber forming.

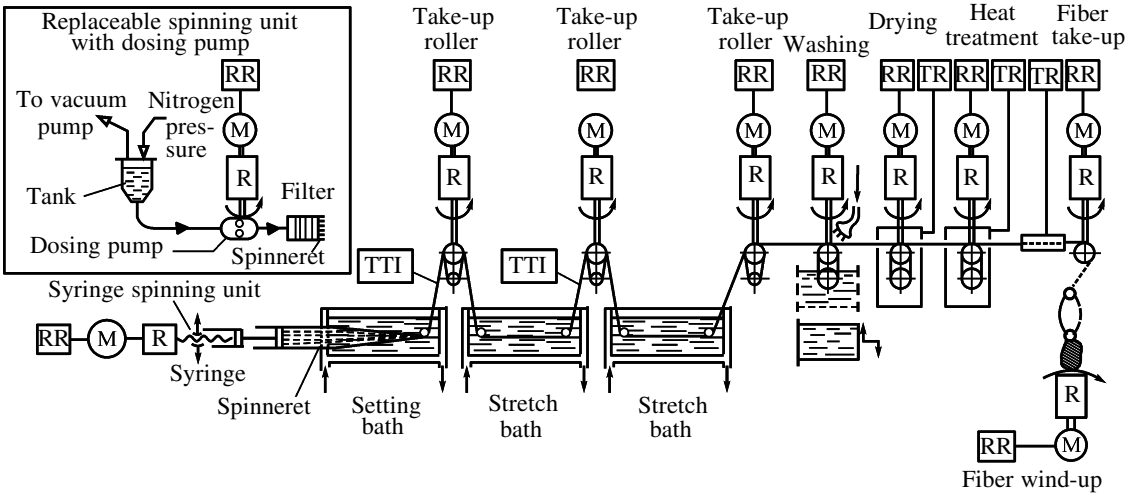

Fig. 2. Functional scheme of an installation for studying orientation forming of fibers from polymer solutions (PIFV-01): (RR) rotation speed regulator, (M) motor, (R) rotor, (TR) temperature regulator, and (TTI) thread tension indicator.

The forming of chitin fibers starts with the chitin recovery from shells of crabs, shrimps, and krill. To obtain strong fibers, it is necessary to use the high-molecular-weight polysaccharide from crab shells.

The chitin purification process should not significantly alter the molecular weight of the polymer. Therefore, removal of calcium and other ash components should be performed at low temperatures, preferably at 4–5°C. Shells of Far-Eastern crabs, thoroughly washed and dried at 60°C in a vacuum oven, were ground and sieved through a 180-mesh sieve. Then the powder was treated with 1 N HCl for 0.5 h at 4–10°C and solid-to-liquid ratio of 1 : 10 to remove ash elements. The liquid was removed by vacuum filtration, and the treatment was repeated under the same conditions. Then the chitin was washed with distilled water until the absence of Cl^- ions in the wash water.

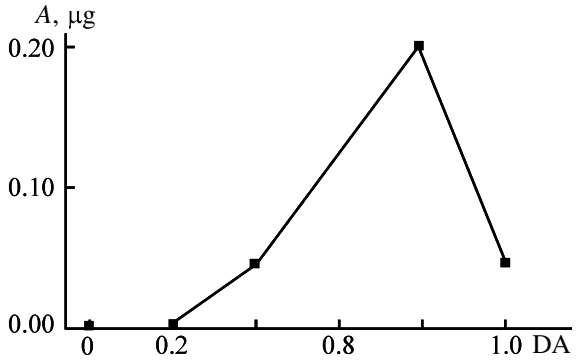

Fig. 3. Rate of enzymatic cleavage of chitosan with hen egg lysozyme as a function of the degree of *N*-acetylation of chitosan: (*A*) amount of reducing sugars (*N*-acetyl-*D*-glucosamine) and (DA) degree of chitosan *N*-acetylation.

To remove protein, chitin was subsequently treated with 1 N NaOH for 1 h at 40°C and solid-to-liquid ratio of 1 : 5, washed with distilled water, and again treated with 0.5% HCl for 30 min at 4–10°C and solid-to-liquid ratio of 1 : 5. After removing the liquid phase, the chitin was again washed with distilled water until the absence of Cl^- ions in the wash water and treated with a detergent solution (pH 11) with continuous stirring for 1 h at 40°C and solid-to-liquid ratio of 1 : 5. The solution was removed by vacuum filtration, and the chitin was washed with distilled water until pH of the wash water became neutral. After dehydration to the maximal extent, the chitin was washed two times with anhydrous acetone, with 10-min standing, and then was vacuum-dried at 60°C to constant weight.

After such treatment, chitin contained no protein and ash; its molecular weight was 170 kDa, and the degree of deacetylation, 5%.

LiCl was dissolved in DMAA on heating to 80°C with continuous stirring. A chitin sample was poured over with a solution of LiCl in DMAA. The mixture was stirred for 5 h with natural cooling to room temperature. After standing for 10–12 h, the solution was filtered under pressure through a filter made of a nonwoven material. The filtration was easy, and a colorless transparent solution was obtained. The solution was degassed in a vacuum, and the fiber was formed on the PIFV-01 installation (Fig. 2).

Dosing, take-up, and winding units were equipped with stroboscopic sensors interfaced with control units and a digital recorder.

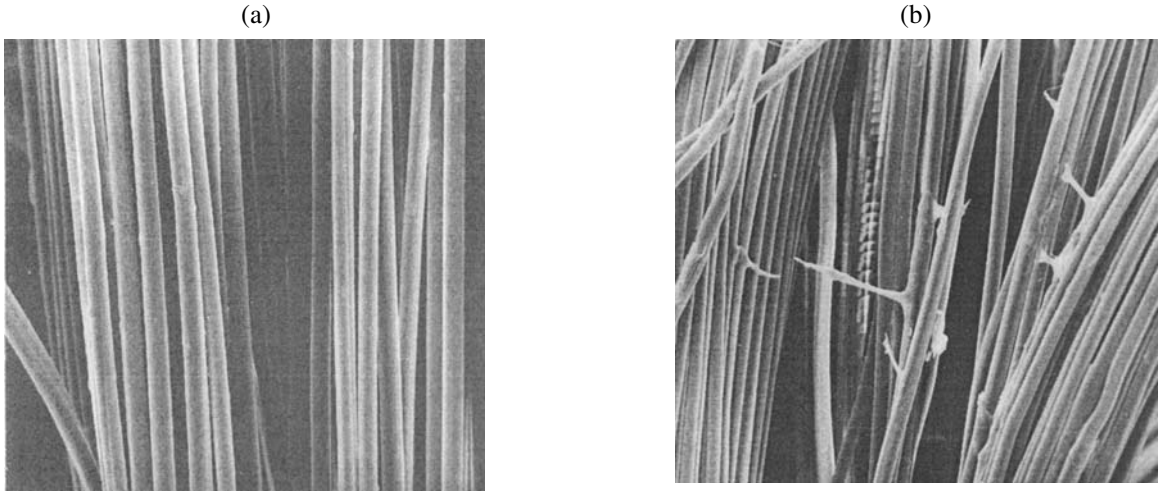

Fig. 4. (a) Initial chitin fibers without cells and (b) cultivation of fibroblasts for 5 days.

A spinning solution containing 3.2% chitin and 6.5% LiCl was extruded into an isopropanol bath through a 300/0.08 spinneret. The coagulant temperature was 18°C, and the temperature of the stretch and washing baths, 50°C. The fiber wind-up speed was 3 m min^{-1}. The filament was washed with hot (80–90°C) water, treated with acetone, and dried at room temperature.

The filament has the following characteristics: linear density 17.9 tex, strength 237 MPa, relative knot strength 70%, and breaking elongation 7.5%.

After keeping for 24 h in a desiccator over a concentrated solution of sodium acetate (relative humidity 65%), the fibers were tested with an Instron-110 device. The extension diagrams were obtained with a 50-mm specimen at a loading rate of 5 mm min^{-1}.

The material proved to be resistant to radiation sterilization at doses accepted for polypropylene and catgut (Table 5).

Figure 3 characterizes the enzymatic cleavage of chitin to the monomers with lysozyme isolated from egg white [39]. These results show that, by varying the degree of deacetylation of chitin from which the fiber was prepared, it is possible to control the rate of enzymatic cleavage of sutures and thus the time of their absorption. To this end, it is necessary to develop a procedure for homogeneous deacetylation of chitin and to determine the conditions of thread forming.

Another socially significant application field of chitin threads is production of woven fabrics (Fig. 4) on which human skin cells can be grown. These fabrics can be used for treating extensive burns and other skin damages that previously led to lethal outcome.

The above features make chitin thread very promising for production of absorbable materials for medicine.

Abstract—Nitric acid solutions (c_{Pd} up to 3.2 M) with variable HNO_3 concentration were studied by electronic spectroscopy, ^{14}N and ^{17}O NMR, acid-base titration, gravimetry, and other methods. Solid phases that precipitated on storing these solutions were studied by X-ray phase analysis, thermogravimetry, and IR spectroscopy. The conditions for stability of particular Pd(II) species were determined, and specific features of aging of such highly concentrated palladium solutions were revealed. A procedure for palladium isolation as $[Pd(NH_3)_4](NO_3)_2$ from nitric acid solutions in 98% yield was developed.

DOI: 10.1134/S1070427207050023

The main body of the data on speciation of platinum group metals (PGMs) in media unconventional for their refining, in particular, in nitrate, sulfate, and phosphate solutions, were obtained by the middle of the 1970s. The results of these studies are summarized in reviews cited in [1]. According to the data obtained, PGMs in these acid solutions exist in the form of polynuclear or oligomeric species, and chemical processes occurring in the systems are extremely complicated and variable. It should be noted that the data obtained concerned solutions with low PGM concentrations (of the order of mM). In the subsequent decades, studies in this direction were not systematic.

At present, interest in such studies, mainly concerning the speciation and stability of PGM complexes in solutions other than hydrochloric acid, increased. It is caused by the need for expanding the assortment of commercially produced PGM compounds and catalytic systems based on them. Special attention is given to highly concentrated or saturated PGM solutions. The progress in this direction is limited by the lack of experimental data on the PGM behavior in such media.

The aim of this study was to examine the processes occurring in solutions maximally concentrated with respect to platinum metal, using the system Pd–HNO_3 as an example, to reveal the state of Pd and changes in the macrocomponents of the systems, and to evaluate the stability of solutions in their storage under various experimental conditions.

EXPERIMENTAL

The electronic absorption spectra (EAS) of all solutions without dilution were recorded on a Hewlett–Packard Vectra instrument in cells of 0.0019 cm thickness, and the NMR spectra, on a Bruker CXP-300 spectrometer with a working frequency of 21.865 MHz for ^{14}N and 40.700 MHz for ^{17}O, at natural abundance of the isotopes in solutions. The chemical shifts, which are positive in a weak field, are given in the δ scale and measured relative to conventional standards. The error in determining chemical shifts did not exceed ±0.05 ppm. Thermogravimetric studies were carried out on a Q-1000 device modified for operating in various gaseous media with numeralization of an analog signal. The other data were obtained using standard modern devices and equipment.

The starting nitric acid palladium solutions (NAPSs) were prepared as follows. A powder of metallic palladium containing no less than 99.97% Pd was dissolved at 90–95°C within 1 h in 40 ml of HNO_3 (ultrapure grade, density d = 1.419 g cm^{-3}) with addition of 0.02 ml HCl (chemically pure grade, d = 1.165 g cm^{-3}) per 10 g of Pd. Then the solution

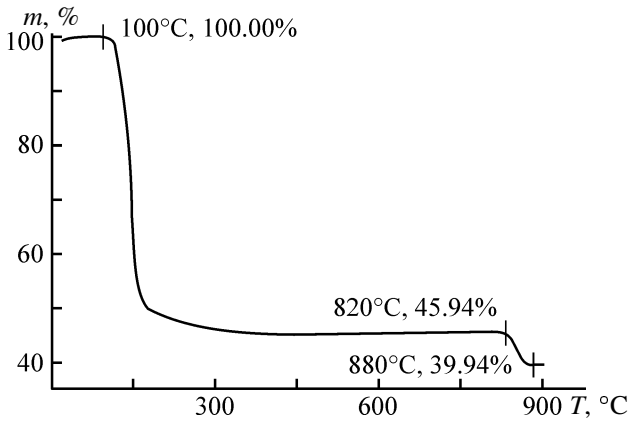

Fig. 1. Curve of $[Pd(NO_3)_2(H_2O)_2]$ weight loss in air. The weight of the starting sample is taken as 100%. (*m*) Sample weight and (*T*) temperature.

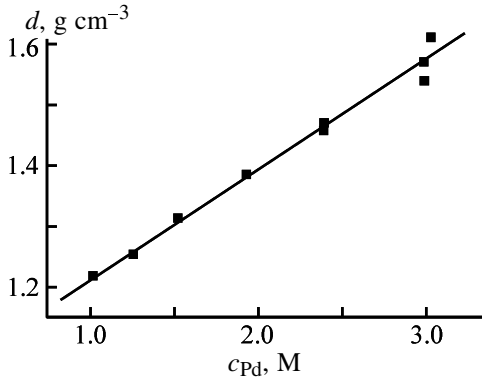

Fig. 2. Dependence of the density *d* of Pd(II) nitric acid solutions on the Pd(II) concentration c_{Pd}. Concentration of free nitric acid in solutions varied from 1.5 to 2.6 M.

was evaporated at the same temperature and diluted with water to c_{Pd} = 2–3 M; the concentration of free HNO_3 was varied from 3.8 to 5.6 M.

In certain experiments the starting substance for obtaining NAPS was crystalline $[Pd(NO_3)_2(H_2O)_2]$. It was prepared from NAPS by concentrating in air to wet crystals. Then the dish with the wet precipitate was placed for 1–2 days in a desiccator over KOH to complete removal of liquid phase traces, after which it was kept in a desiccator without a desiccant. The compound was identified by elemental analysis, IR spectroscopy, X-ray phase analysis, and thermogravimetry.

The curve of the weight loss of the synthesized $[Pd(NO_3)_2(H_2O)_2]$ on heating is shown in Fig. 1. It agrees well with the data [2]. Furthermore, the Pd(II) content in the crystalline product (39.9 wt %) determined from this curve corresponds to its content in $[Pd(NO_3)_2(H_2O)_2]$ (calculated 39.94 wt % Pd). Two endothermic effects are clearly detected in the DTA curves (in air) at 160 and 817°C. The first of them is caused by the reaction

$$[Pd(NO_3)_2(H_2O)_2] \rightarrow PdO + H_2O + 2HNO_3. \quad (1)$$

The theoretical weight loss for this reaction is 54.06, and the observed loss, 53.8%. The second effect is caused by PdO decomposition to the metal, as follows from the correspondence between the theoretical and experimental weight losses.

The data on the crystal structure of $[Pd(NO_3)_2 \cdot (H_2O)_2]$ obtained from the powder X-ray patterns by ab initio method were published in [3]. The starting substance was synthesized by dissolution of metallic palladium in concentrated HNO_3 with the subsequent evaporation of the solution. It is a light brown powder, relatively stable in air depending on atmospheric conditions. Dinitratodiaquapalladium(II) has an orthorhombic lattice, space group *Pbca*, $Z = 4$. Unit cell parameters: $a = 5.0036(3)$, $b = 10.6073(7)$, and $c = 11.7223(8)$ Å. The coordination surrounding of Pd(II) is square planar, and nitrato groups are monodentate. It is interesting that in the previous studies concerning the synthesis and properties of $[Pd(NO_2)_2(H_2O)_2]$ its geometric configuration was not discussed. Indirect data about its *trans* structure are known [4], and in [3] its *trans* configuration was clearly determined.

We have obtained EAS of $[Pd(NO_3)_2(H_2O)_2]$ solutions in 2–2.5 M HNO_3. The concentration of Pd(II) was varied from 0.00123 to 0.184 M. The spectrum of this compound has a very broad absorption band; therefore, accurate determination of its maximum is difficult: its position varies from 397 to 404 nm, and the extinction coefficient, from 138 to 145 $1\,mol^{-1}\,cm^{-1}$.

Determination of acidity. To determine c_{Pd} and acidity of NAPS, aliquots of solutions containing from 100 to 200 mg of Pd(II) were weighed. To obtain correct data, it was necessary to measure the densities of these solutions. The results of such measurements are shown in Fig. 2.

It is seen from Fig. 2 that the dependence of NAPS density on Pd(II) concentration is linear and is expressed by the equation $d = 1.03 \pm 0.18 c_{Pd}$. These data make it possible to determine accurately the palladium concentration. The measurement of NAPS density is also the simplest and the most effective method of estimating the state of solutions in their storage. The relatively low reproducibility of the data at c_{Pd} of about 3 M will be discussed below. It should be noted that the insignificant scatter of the experimental

data is caused by two reasons. The first of them is the fact that the concentration of free HNO_3 in solutions varied from 1.5 to 2.6 M. However, it is possible to estimate these deviations. In particular, it follows from the reference data on the HNO_3 density that its change is no more than 3.3 rel. % in this interval of concentrations, which is the maximal error of the measurements. The second reason consists in the fact that the NAPS density was measured at room temperature, which varied within the range 20–28°C. It was experimentally found that the density variation under these conditions was about 1.5%.

Several techniques were tested for the acidity determination. The first (method no. 1) consisted in that a NAPS aliquot diluted by a factor of 12.5 was treated with a tenfold amount of solid $NaNO_2$ relative to Pd(II) for quantitative binding of Pd(II) in the tetranitro complex, with the subsequent pH-metric titration to pH 6.8–7.0. Unreliability of this technique consisted, firstly, in the formation of small amounts of nitrogen oxides. Secondly, the titration curves of free HNO_3 and of the same amount of HNO_3 with an addition of $Na_2[Pd(NO_2)_4]$ and of the required excess of $NaNO_2$ differed essentially.

The second technique (method no. 2) was based on the results of [5–7] where it was proved that Pd(II) is quantitatively extracted as compounds $[Pd(NO_3)_2L_2]$ with sulfides according to Eq. (2), with the concentration of free HNO_3 remaining unchanged during the process:

$$\{Pd^{2+} + 2NO_3^-\}(aq) + 2L(org) \rightarrow [PdL_2(NO_3)_2](org), \quad (2)$$

where L designates a molecule of coordinated sulfide. Then the raffinate containing only HNO_3 was titrated with a standard alkali solution. This technique of the acidity determination could be close to ideal if it were possible to determine precisely the volume of the raffinate after the separation of Pd(II) by extraction. It appeared to be extremely difficult; therefore, for calculations we used eight parameters and six equations, which resulted in the accumulation of errors and low reproducibility.

The third technique (method no. 3) allowed us to determine simultaneously the content of free HNO_3 and also c_{Pd} during NAPS storage. Using the data of Fig. 2, we took NAPS weighed portions, diluted them with water approximately to 50 ml, and precipitated Pd(II) with dimethylglyoxime (DMG) by the standard procedure [8]. The difference from the technique [8] consisted in that the separated precipitate was washed only with hot water without its acidification. The main difference was that the excess of the precipitant did not exceed 10% of the Pd(II) : DMG = 1 : 2 stoichiometry. The mother liquor and the whole amount of the washing liquid were transferred to a 200-ml volumetric flask, and 50-ml aliquots were titrated with a standard NaOH solution, using a mixture of Phenol Red and Bromocresol Green indicators [9]. According to the data of [9], its color changes at pH 7.2 ± 0.2. It was found experimentally that the use of indicators with a higher pT results in regular overestimation of results. When calculating the concentration of free HNO_3, $2c_{Pd}$ was subtracted from the found total acidity, as two H^+ ions are released into solution upon Pd(II) precipitation with DMG.

Finally, a direct pH-metric titration of freshly prepared NAPS solutions resulted in the formation of dark brown precipitates. In this case, it was necessary to wait for no less than 1 h for reaching a stable potential; therefore, this technique is unacceptable.

To check the correctness of techniques for the acidity determination, we have carried out introduced–found experiments using model solutions. They were prepared by the dissolving accurately weighed portions of crystalline $[Pd(NO_3)_2(H_2O)_2]$ in a fixed volume of HNO_3 of precisely known concentration. The final volume of such solutions was always higher than the initial HNO_3 volume; therefore, to express concentrations in the M scale, we determined the densities of the model solutions.

Method no. 3 gives the maximum discrepancy of 1.5% between the found and introduced amounts. However, it is rather labor-consuming, and a DMG excess larger than 10%, as well as wrong choice of an indicator, result in the substantial overestimation of the NAPS acidity. These drawbacks are compensated by the possibility of the exact determination of both c_{Pd} and the concentration of free HNO_3 from a single NAPS sample. The causes of regular errors in the results obtained by method nos. 1 and 2 were considered above. For the other methods, the deviation of acidity from that of model solutions did not exceed –5.6 (no. 2) and +9.4% (no. 1).

NMR studies of NAPSs. The in situ determination of the concentration of components in nearly saturated solutions, like NAPSs under study, is a difficult problem. The NMR method seems to be the most informative in these cases. To elucidate its possibilities, we have carried out several series of experiments in which we varied the following parameters of solutions: concentrations of nitric acid and nitrate ions and the nature of a nitrate salt cation (Na^+ or Zn^{2+}). Taking

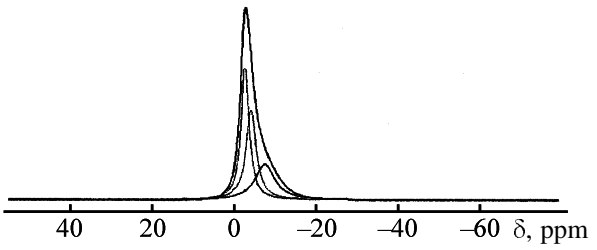

Fig. 3. Experimental ^{14}N NMR spectrum of NAPS-1 diluted by a factor of 2.5 with water and components of its resolution by the Simplex method. (δ) Chemical shift.

into account the facts that the ionic radii of palladium and zinc are close to each other and the Zn(II) complex formation with nitrate ions is, presumably, very weak, we chose zinc as a model simulating aqueous solutions of Pd(II) nitrate. The following regular trends were revealed. In 0.5–7 M solutions of $Na^{14}NO_3$, the factor defining $^{14}NO_3^-$ chemical shifts is the solution acidity. Further, as the acidity of solutions increases, the concentration dependence of the $Na^{14}NO_3$ chemical shift is displaced upfield and becomes linear with a slope of 0.70. However, the linear dependence of the chemical shift on the concentration of $Zn(NO_3)_2$ has a slope of 1.15 when the HNO_3 concentration is varied. Hence, the dependences of the chemical shift of free nitrate ions both on their concentration and on the acidity are individual for each specific cation. Thus, the determination of the concentration of nitrate ions based on the analysis of regular trends in variation of ^{14}N chemical shifts in nitrate solutions shows little promise.

The presence of nitrite ions in NAPSs is of a principle importance in their analysis. The identification of nitrite ions in concentrated nitric acid Pd(II) solutions can be rather simple when using the NMR method. It was found experimentally that, when the number of scans of the ^{14}N resonance is about 10^4 (experiment duration about 6000 s), a signal of nitrite ions can be readily seen at their content of 0.01 M. Such a detection limit of nitro groups is sufficient for determination of their content in the systems under consideration. In any case, when the content of nitro groups in NAPSs with a Pd(II) content of about 3.0 M is monitored by ^{14}N NMR, the contribution Pd(II) nitro complexes to the material balance is negligible.

To elucidate the nature of Pd(II) complex species and to determine the concentrations of certain NAP macrocomponents, we also used NMR. The overwhelming majority of such experiments were carried out with a sample hereinafter designated as NAPS-1. The content of Pd(II) in it is 20.07 wt % counting on the metal (or 3.042 M), and the density of this solution at 20°C is 1.613 g cm^{-3}.

In the ^{14}N NMR spectrum of NAPS-1 taken in the range from +460 to –560 ppm, only a symmetric signal with a chemical shift of –8.93 ppm is detected. This range essentially exceeds the range of 48–88 ppm characteristic of nitrite ins coordinated to Pd(II) in various amounts [10]. This fact confirms our earlier conclusion that Pd(II) nitrite complexes make a negligible contribution to the material balance of the NAPS system and allows us to rule out the presence of noticeable amounts of nitrite ions or nitrous acid (CS ~200 ppm [10]) in Pd(II) nitric acid solutions.

The spectrum of the same solution diluted by a factor of 2.5 with water, taken immediately after the dilution, is shown in Fig. 3. After the dilution of the starting NAPS-1 solution, a shoulder appears in the high field in all the spectra, and it is the more pronounced, the more diluted is the NAPS-1 solution (by a factor of 10 at most). This is apparently due to changes in the Pd(II) speciation. In this case, lines of irregular and unsymmetric shapes were resolved into a number of components specified by an operator. Then, using the Simplex method, we carried out the optimization of the following parameters of each component: position in the spectrum (chemical shift), amplitude, half-width, and Gaussian line contribution to the shape of the signal resolved after Lorentz. The optimization continued until the best fit of the experimental spectrum with the total envelope of all the components was attained. It should be noted that the line of undiluted NAPS-1 was resolved neither into two nor into three components, unlike the lines of diluted solutions. The correctness of this approach is illustrated by the fact that the experimental and optimized spectra of undiluted NAP-1 coincide to within 1%. This is a very good result for NMR spectroscopy.

The presence of a single symmetric line in the NMR spectrum of undiluted NAPS-1, which is not resolved into any number of signals, can be, in principle, associated with the closeness of the chemical shifts of Pd(II) species present in solution and of nitric acid, or with a high rate of exchange of coordinated and free nitrate ions, or with the fact that the ^{14}N NMR signals of NAPSs are considerably broader than those of nitrate ions. In our case, the line width is 95.8 Hz. To compare, the line width of the signal of ~3 M nitric acid is 9 Hz, and that of a nitric acid solution with a total concentration of nitrate ions of 7.0 M is 13.9 Hz. The presence of Pd(II) in a concentration of about 3 M in NAPS can affect the viscosity and

other parameters of solutions, but the comparison of the above-given data shows that it would hardly lead to an increase in the line width in the NAPS-1 spectrum by an order of magnitude.

This fact, together with the asymmetry of lines of NAP solutions diluted with water, was the reason why we attempted to resolve the NMR spectra of dilute solutions into components.

The change in the symmetry of lines in the spectra of solutions diluted with water and the presence of three resolved components of these spectra adequately describing the experimental spectra suggest either the appearance of hydrolyzed Pd(II) species upon lowering the acidity or the dissociation of complex Pd(II) nitrates resulting in an increase in the concentration of NO_3^- ions. These reasons are supported by the data on the stability Pd(II) nitratoaqua complexes and by the constants of $[Pd(H_2O)_4]^{2+}$ acid dissociation.

Stability constants of Pd(II) nitratoaqua complexes. There are only three publications [11–13] in which the constants of formation of Pd(II) nitratoaqua complexes are given. Shoittsov [11] reported that a bathochromic shift in EAS of Pd(II) aqua complexes with λ_{max} = 390 nm is observed at 2.1 : 1 ratio of concentrations of nitrate ions and Pd(II) at c_{Pd} = 0.008 M. In that study, the formation of Pd(II) nitrato complexes was examined spectrophotometrically up to 3.6 M NO_3^- concentration at a total ionic strength of 4.0 M. It was found that only the mononitrato complex $[Pd(H_2O)_3(NO_3)]^+$ with a stability constant $\beta_1 = 1.6 \pm 0.3$ is formed in the examined concentration range. The calculated EAS parameters of this species are as follows: λ_{max} = 415 nm and ε_{max} = 155 l mol^{-1} cm^{-1}. The formation constant of the mononitrato complex $\beta_1 = 1.2 \pm 0.4$ was also determined spectrophotometrically in [12]. Note that the β_1 values from [11, 12] completely agree with each other within the limits of the errors given in these papers. The parameters of $[Pd(H_2O)_3NO_3]^+$ EAS in these two papers also practically coincide. It was shown in [12] that the position of the maximum and its intensity in EAS of $[Pd(H_2O)_3NO_3]^+$ noticeably decrease both on replacement of HNO_3 by $NaNO_3$ and with a decrease in HNO_3 concentration. The procedures for preparing the nitrate solutions in [11, 12] are the same and are based on the dissolution of Pd powder in concentrated HNO_3 with the subsequent boiling to eliminate possible sources of NO_2 generation. The range of working Pd(II) concentrations in these studies was 0.001–0.01 M.

The stability constants of Pd(II) nitrato complexes determined from the extraction data sharply differ from the results of [11, 12]. This question is discussed in [13]. The approach to the estimation of the constants is based on the examination of the dependences of the Pd(II) distribution coefficient D_{Pd} on the concentration of HNO_3 in the aqueous phase in the case of the extraction from nitric acid media with neutral phosphoryl-containing compounds, nitrates of amines, and salts of quarternary ammonium bases. In so doing, it was postulated that the nonideality of the aqueous phase is caused solely by the formation of Pd(II) nitrato complexes. Such approach gives the β_1 value lying in the range 14–20. Moreover, the constants of formation of di- and trinitrato complexes were estimated at 2 and 6, respectively. However, Shmidt et al. [13] consider these estimates of β_i only as empirical parameters in the dependences of D_{Pd} on HNO_3 concentration in the aqueous phase, as there are no quantitative approaches to the determination of the activity coefficients in a wide range of conditions.

The first paper on the hydrolysis of Pd(II) aqua ions was published in 1967 [14]. In that paper, solutions of palladium aqua ions (c_{Pd} = 0.001–0.006 M) were prepared by dissolving in perchloric acid the palladium hydroxide precipitated from nitric acid solutions. Hydrolysis constants were determined both from the data of pH-metric titration and by spectrophotometry, and then extrapolated to zero ionic strength. Reaching constant pH values took about 5 h in each point of the titration curve. The constants $\beta_1 = [PdOH^+(aq)]/[Pd^{2+}(aq)][OH^-]$ and $\beta_2 = [Pd(OH)_2(aq)]/[Pd^{2+}(aq)][OH^-]^2$ were determined. The values of $\log\beta_1$ and $\log\beta_2$ at 25°C averaged by both methods are 12.7 ± 0.6 and 26.2 ± 0.7, respectively. The logarithm of the constant K_s of the equilibrium $[Pd(OH)_2(s)] = [Pd(OH)_2(s)]$ is –2.7. Combining this value with $\log\beta_2^{-1}$, we obtain the solubility product $Pd(OH)_2(s)$ equal to $10^{-28.9}$. The constant β_1 found for the reaction

$$[Pd(H_2O)_4]^{2+} + OH^- = [Pd(H_2O)_3OH]^+ + H_2O \quad (3)$$

can be readily converted to the constant K_d of $[Pd(H_2O)_4]^{2+}$ dissociation by the equation

$$[Pd(H_2O)_4]^{2+} = [Pd(H_2O)_3OH]^+ + H^+. \quad (4)$$

In this case, $K_d = \beta_1 K_w$. The values of pK_d calculated in such a way from the data of [11, 14] are 1.2 ± 0.1, which shows that the acid dissociation constants calculated using data from two independent sources actually coincide. It remains unclear why such an important quantity as the dissociation constant of

Pd(II) aqua ion has not been calculated previously. It follows from the value cited above that, first, the Pd(II) aqua ion is in fact a strong acid, and, second, in solutions without complexing ligands (e.g., perchlorate) at $[H]^+ = 1$ M approximately 10% of Pd(II) will be in the monohydroxo form, and at $[H]^+ = 10$ M this fraction will be about 1%. In the specified acidity range, the fraction of hydrolyzed Pd(II) will always be several percents.

The dissociation processes are very fast; hence, the subsequent slow changes in properties of solutions, mainly precipitation, are probably associated with slow polymerization of the hydrolyzed species. The presence of ligands capable of forming complexes with Pd(II) will lead to a decrease in the strength of acids such as $[Pd(H_2O)_3L]$; therefore, the degree of hydrolysis decreases. Hence, the contribution of polymerization processes to the common patztern of the occurring reactions also decreases.

Speciation of Pd(II) in nitric acid solutions. In view of the considered data on the stability of nitrate complexes and acid properties of Pd(II) aqua ions, using the NMR data for solutions, we can obtain the information on the nature of species present in NAPS. The regular trends in variation of the ^{14}N NMR spectra of NAPS-1 solutions on their 2.5-, 5-, and 10-fold dilution with water are as follows. For the species giving the lowest-field signal, the shift changes from –2.4 to –0.8 upon dilution, with the fraction of the species increasing by a factor of almost 2 with dilution. We can readily assign this signal to free NO_3^- ions on the basis of the previously obtained data on the resonance of concentrated $NaNO_3 + HNO_3$ solutions. Hence, on dilution nitrate ions are accumulated in solutions, which can be caused only by decomposition of the Pd(II) nitrate complex. The chemical shift of the next signal varies from –4.2 to –1.6 ppm, with the fraction of this species, 0.31 ± 0.05, remaining approximately constant. This signal presumably corresponds to the Pd(II) nitratotriaqua complex, which should be the most stable complex species at these concentrations. The highest-field signal has a stable chemical shift (-7.6 ± 0.1 ppm), with the fraction of the species decreasing from 0.24 to 0.12. It should be noted that the ratio of the concentration of coordinated nitrate ions to c_{Pd}, calculated from the integral intensities of lines, decreases on dilution from 1.9 to 1.4.

To confirm the absence of hydrolytic processes and the prevalence of dissociation reactions of complex Pd(II) nitrates, as indicated by all experimental data, we have carried our two series of experiments. The idea of the first series consisted in the following. In the NAPS material balance, only hydroxide and nitrate ions can be anions. To check it, we have taken the ^{14}N NMR spectrum of one of NAPSs with an internal reference, nitromethane (0.124 M) in NAPS with the initial concentration $c_{Pd} = 21.05$ wt %, diluted by a factor of 3. As a result, the difference between the calculated concentration of nitrate ions and the concentration found from the integral intensities of the total nitrate lines and the internal reference line appeared to be 3.5%, which is a very accurate result for the method in use. The second series of experiments consisted in measuring pH of freshly prepared solutions of the same NAPS with a dilution by a factor from 12.5 to 193. An important result is the fact that the measured pH values for the first solution were 0.56 ± 0.04, which agrees well with the concentration of hydrogen ions calculated on the basis of the acid dissociation constant of Pd(II) aqua ions.

The ^{17}O NMR spectra of both the starting NAPS-1 solution and solution after its dilution (at most tenfold) contain only two lines with chemical shifts of 412 ± 1 ppm and from –121 to –128 (variation with increasing dilution). The first signal exactly coincides with the spectrum of 3.12 M nitric acid. The comparison of the second signal with the data of [15] shows that it corresponds to the Pd(II) aqua ion with a good accuracy. It confirms the fact that the exchange of free nitrate ions with the nitrate groups coordinated to Pd(II) is very fast, and the difference between these ions cannot be detected by NMR.

Thus, the above-discussed results allow the following conclusion. The undiluted NAPS solution has a symmetric signal in the ^{14}N NMR spectrum (δ –8.9 ppm, half-width about 96 Hz), contains the dominating form $[Pd(NO_3)_2(H_2O)_2]$, and approximately equal low concentrations of $[Pd(NO_3)(H_2O)_3]^+$ and $[Pd(NO_3)_3(H_2O)]^-$ providing the line symmetry. The following processes occur on dilution of the solutions with water:

$$[(PdNO_3)_3(H_2O)]^- + H_2O \rightarrow [Pd(NO_3)_3(H_2O)_2] + NO_3^-, \quad (5)$$

$$[Pd(NO_3)_2(H_2O)_2] + H_2O \rightarrow [Pd(NO_3)(H_2O)_3]^+ + NO_3^-, \quad (6)$$

$$[Pd(NO_3)(H_2O)_3]^+ + H_2O \rightarrow [Pd(H_2O)_4]^{2+} + NO_3^-, \quad (7)$$

$$[Pd(H_2O)_4]^{2+} \rightarrow [Pd(OH)(H_2O)_3]^+ + H^+. \quad (8)$$

Reactions (5)–(7) result in increasing concentration of nitrate ions in solutions, which accounts for the

essence of the occurring processes. The occurrence of process (8) is proved without controversy by the fact that, in all NAPSs diluted with water, dark brown fine precipitates are formed within 5–7 days after the dilution. The data of IR spectroscopy, X-ray diffraction, and elemental analysis suggest that the precipitate is hydrated palladium oxide $Pd(OH)_2 \cdot xH_2O$, where x varies within the range 1.20–1.45. The greater the dilution, the higher x. The maximal dilution corresponded to the 25-fold decrease in c_{Pd}. Dilute acid HCl did not dissolve these precipitates, and concentrated HCl, only on boiling. This agrees completely with the data of [16].

Isolation of Pd(II) from NAPS in the form of $[Pd(NH_3)_4](NO_3)_2$. It should be noted that we were able to reach a nearly quantitative yield of $[Pd(NO_3)_2 \cdot (H_2O)_2]$ crystals. The $[Pd(NO_3)_2(H_2O)_2]$ obtained can be used as the starting compound in the synthesis of a very important product, $[Pd(NH_3)_4](NO_3)_2$. Owing to its high solubility, the compound can find use in the production of supported palladium catalysts or precursors of polymetallic powders. Furthermore, the use of $[Pd(NH_3)_4](NO_3)_2$ makes it possible to carry out syntheses in the presence of small amounts of HCl, in contrast to $[Pd(NH_3)_4]Cl_2$ whose application inevitably leads to the formation of *trans*-$[Pd(NH_3)_2 \cdot Cl_2]$. The complex $[Pd(NH_3)_4](NO_3)_2$ was obtained from $[Pd(NO_3)_2(H_2O)_2]$ in the presence of an excess of concentrated ammonia, after which the resulting reaction mixture was evaporated. As a result, $[Pd(NH_3)_4](NO_3)_2$ was obtained in a high yield:

$$[Pd(NO_3)_2(H_2O)_2] + 4NH_3 \rightarrow [Pd(NH_3)_4]^{2+} + 2NO_3^- + 2H_2O. \quad (9)$$

To optimize the synthesis procedure, a series of experiments with various starting conditions have been carried out. The reaction of solid $[Pd(NO_3)_2 \cdot (H_2O)_2]$ (~0.01 mol) with an excess of concentrated aqueous solution of ammonia (~0.5 mol) at room temperature or at 50–60°C yields a light brown solution containing a small amount of a voluminous brown precipitate. On further heating of the reaction mixture with the added ammonia, the color becomes lighter within several hours, and the solid practically completely precipitates on the bottom. Then the reaction mixture is filtered through a porous glass filter, and the mother liquor is evaporated to dryness. The target product $[Pd(NH_3)_4](NO_3)_2$ represents crystals in the form of colorless or slightly yellowish plates. The yield reaches 97%. The recrystallization of the substance from water allows us to obtain a high-purity product.

The reaction of 5 ml of $Pd(NO_3)_2 \cdot 2H_2O$ aqueous solution (~1 M) with an excess of concentrated aqueous solution of ammonia at room temperature yielded a light brown solution containing a small amount of a voluminous brown precipitate. The reaction mixture was heated with excess ammonia, the precipitate was filtered off, and the resulting solution was evaporated to dryness on a water bath. Yield 98%.

The reaction of 10 ml of an aqueous solution containing 0.8 M $Pd(NO_3)_2$ and 1.6 M free HNO_3 with an excess of concentrated aqueous solution of ammonia at room temperature proceeds as follows. At the first moment after the addition of the ammonia solution, a light yellow voluminous flocculent precipitate is formed, which completely dissolves on further adding ammonia. The resulting solution has a light brown color. No clear precipitate is observed. Then the solution is evaporated up to the formation of a film of crystals and is cooled. The precipitated crystals are separated by filtration. To remove an NH_4NO_3 impurity, the product is recrystallized from aqueous solution. Yield 70%. The reaction at room temperature with a solution containing 2.5 g of NH_4HCO_3 in concentrated ammonia proceeds similary.

Our experiments show that small amounts of a precipitate contaminating the target product are formed during the synthesis. In the synthesis from $Pd(NO_3)_2 \cdot 2H_2O$ solutions containing free HNO_3, such precipitate is not formed. We failed to determine the composition of the precipitate. However, data of IR spectroscopy and of X-ray phase and thermal analysis suggest that the precipitate composition can be expressed by the general formula $PdO(NH_3)_x(H_2O)_y$. In particular, this assumption is supported by the fact that the dried precipitates of this phase readily dissolve in dilute HCl without heating, which is quite uncharacteristic of dried $PdO(H_2O)_x$.

Variation of NAPS properties in time. We have obtained the following experimental data on the NAPS stability in time. First of all, it should be noted that freshly prepared NAPSs can contain solutions oversaturated with respect to Pd(II), which are fairly stable for a certain time. Depending on the Pd(II) concentration in solution, they remain homogeneous for a period from 2 to 24 h, but after that a crystalline phase of $[Pd(NO_3)_2(H_2O)_2]$ precipitates. We have obtained NAPS containing up to 26.22% Pd(II). If the precipitate is separated from it and the solution is stored further, crystalline $[Pd(NO_3)_2(H_2O)_2]$ precipitates again from the solution. It is most likely that the crystalline precipitates are formed due to limited solubility of $[Pd(NO_3)_2(H_2O)_2]$ in nitric acid.

* Molar extinction coefficients.
** Solutions A, B, C, D, and E were prepared using the technique of acidity correction.
*** Prepared by dissoluving crystalline $[Pd(NO_3)_2(H_2O)_2]$ in HNO_3.

From the experimental data we concluded that NAPSs are the most stable if the Pd(II) content is 21–22%, or close to 3.0 M. Higher Pd(II) content results in the precipitation of crystalline products of the composition $[Pd(NO_3)_2(H_2O)_2]$. This fact is responsible for the above-mentioned low reproducibility of the data on the NAPS density in the region of c_{Pd} 3 M (Fig. 2). The most important conclusion from our experiments is the fact that NAPSs are stable in time if c_{Pd} does not exceed 21 wt % and the molar ratio of free HNO_3 and c_{Pd} is no less than 1 : 1.

This conclusion on the Pd(II) and HNO_3 concentrations ensuring the stability of NAPS solutions was supplemented by a series of other measurements. We have monitored the dynamics of variations of such solution parameters as palladium(II) concentration, acidity, and EAS taken in situ without dilution. These observations were carried out during a period of 3–9 months. The weight fraction of Pd(II) in the solutions studied was in the range 15.0–20.7 wt %, or 2.07–3.17 M. The content of free HNO_3 was from 172 to 316 g l^{-1}. All the solutions were prepared according to the technique described above, but after the evaporation to the necessary volume the acidity was corrected by adding certain amounts of concentrated HNO_3 to ensure the molar ratio of Pd(II) and free HNO_3 required for the NAPS stability.

It was found that the concentration of Pd(II) in solutions prepared in such a way remains unchanged in time within 0.1–0.6 rel. % and practically does not depend on the fact whether these solutions were held in the dark or in a scattered laboratory light. The latter conclusion was confirmed by an experiment on laser flash photolysis, carried out as follows. A solution was irradiated at a wavelength of 308 nm (the average position of the maximum of NAPS absorption) by 100 pulses of 20 mJ each, which corresponds to approximately a week storage under usual laboratory illumination. No difference was observed between the spectra of the irradiated and initial solutions.

The characteristics of the absorption spectra of the NAPSs under study are given in the table. All the solutions were kept in the dark, except for solution no. 2. The solutions designated by letters A, B, C, D, and E were prepared using the acidity correction. It should be noted that the contribution of nitric acid to the absorption in its fairly concentrated solutions does not give rise to an appreciable fixed error at wavelengths longer than 350 nm, which is very favorable for characterizing EAS of Pd(II) nitric acid solutions. Typical spectra of undiluted Pd(II) nitric acid solutions are shown in Fig. 4.

It is interesting that the EAS of the solutions are of two types. The spectra of NAPS-1 and solution A have a maximum at approximately 400 nm, which coincides in position with the maximum of $[Pd(NO_3)_2 \cdot (H_2O)_2]$, but these spectra are much more intensive. At the same time, solutions B, C, D, and E are characterized by a maximum at 425 ± 4 nm, and EAS are apparently superpositions of at least two spectra of different Pd(II) species in NAPS. Furthermore, the difference in the molar extinction coefficients of the spectra under consideration is about 30%. The comparison of the spectra of solutions C and E is especially characteristic, as they noticeably differ in c_{Pd}, but have almost the same shape.

It should be noted that the characteristics of EAS of Pd(II) nitric acid solutions depend, as follows from the published data [11–13, 17], on the concentration

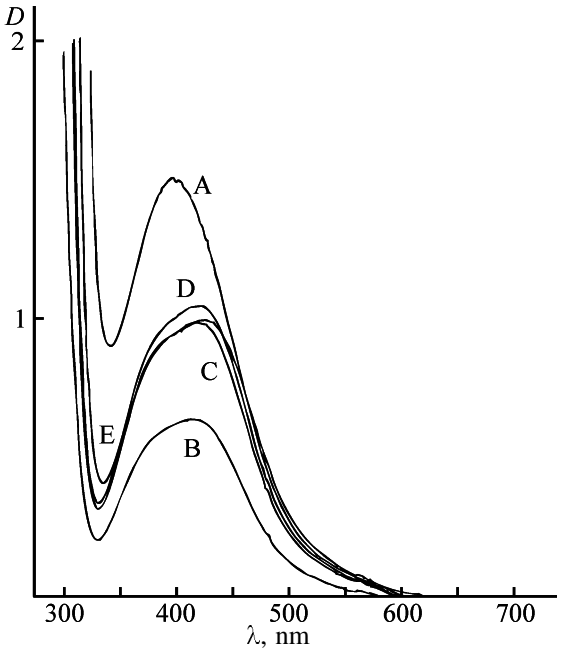

Fig. 4. EAS of Pd(II) nitric acid solutions. (*D*) Optical density and (λ) wavelength. (A–E) Solutions (see text).

of free nitric acid, which noticeably varied in different NAPSs. Solutions A, B, and C have almost equal acidity, but their spectra essentially differ in the shape. It is probable that differences in the NAPS spectra somehow depend on fine details of the solution preparation and acidity correction.

The most important conclusion consists in the fact that, when solutions are kept for three months, the positions and intensities of maxima in EAS remain constant within the limits of measurement errors, which first of all depend on the thickness of the absorbing layer of the cell in use and on specific features of its filling with solutions. This conclusion is also proved by the measurements of the solution densities, which, in spite of appreciable temperature variation during monitoring, were nevertheless more accurate and remained constant within 2%.

Along with recording EAS of solutions, we measured the acidity of solutions using NAPS-1 as an example of the most aged solution. This monitoring was carried out during a period of 10 months. In this period, the acidity remained constant and was 198 ± 3 g l^{-1} HNO_3 (confidence level 95%).

CONCLUSIONS

(1) The nature of solid phases precipitating from Pd(II) nitric acid solutions with c_{Pd} of up to 20.67 wt % (or 3.181 M) and the concentration of free HNO_3 of 3.7–5.6 M during their storage both in light and in the dark under various conditions was determined.

(2) At Pd(II) content higher than 21 wt %, the crystalline phase $[Pd(NO_3)_2(H_2O)_2]$ precipitates from solutions. It is hygroscopic and unstable to the action of light on storage. The technique of the preparation of $[Pd(NH_3)_4](NO_3)_2$ from this substance with a yield close to quantitative was suggested. Thanks to its specific properties, the product can be used for preparing supported palladium catalysts.

(3) The ratio of concentrations of palladium(II) and free nitric acid is important for the stability of Pd nitric acid solutions in storage. Solutions with c_{Pd} about 20 wt % can be stored for indefinitely long time if the ratio of concentrations of free HNO_3 and Pd(II) is no less than 1 : 1 (i.e., no less than 3 M HNO_3, or about 200 g l^{-1}).

(4) According to the data obtained, the Pd nitric acid solutions contain a mixture of palladium(II) nitroaqua compounds in the presence of free nitric acid. Nitrite ions or nitrous acid are present in negligible amounts or absent at all. One of the main conditions of the safe storage of nitric acid solutions containing about 20% Pd and about 3 M free HNO_3 is the exclusion of their dilution by water. Otherwise Pd(II) hydroxides precipitate from the solutions within several days.

(5) The comparison of properties of solutions kept in the light and in the dark shows that they are almost inert photochemically.

(6) To diagnose properties of nitric acid solutions in the course of their storage, it is suggested to use a combination of visual observation and measurement of solutions density. In this case, using calibration dependences of the density of nitric acid solutions on the Pd(II) concentration in them, it is possible to determine palladium concentration accurate to 3% without analytical measurements.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Specific Features of the Kinetics of Autocatalytic Combustion of Sodium Chlorate with Polyethylene in a Manometric Bomb

O. N. Kirsanov

Prikladnaya Khimiya Russian Scientific Center, Federal State Unitary Enterprise, St. Petersburg, Russia

Received March 24, 2006; in final form, March 2007

Abstract—Velocities of combustion and outflow of combustion products from the surface of formulations based on sodium chlorate and polyethylene in a constant-volume bomb were evaluated in relation to the aggregative state of polyethylene.

DOI: 10.1134/S1070427207050035

This study is a continuation of [1]. The principal goal of the study was to examine the kinetics of the combustion of sodium chlorate (SC) with polyethylene (PE) and to determine, on the basis of the previously derived analytical dependences, to what extent the combustion process is close to the critical conditions (to detonation). Good agreement of the results obtained in a calculation of the pressure in the bomb by equations of autocatalytic reactions with experimental data has been attained previously [1] for the combustion of SC with PE, with the coefficient of correlation between the calculation and experiment no less than 0.98.

EXPERIMENTAL

To make the previously obtained data more reliable, we carried out additional studies of formulations based on SC and PE in a constant-volume bomb by the method described in [1]. Polyethylene was used both as a powder (conventional scheme for explosives) and in the form of tubules (layered system). We also tested a layered system with addition of 9.1 wt % sodium chloride. As before [1], the measurement error was ±10% for pressure and ±0.001 s for time (time marker of an N117/1 loop oscilloscope). The formulations studied were charged into textolite cups with an inner diameter of 38 mm, and the cups were placed on the bomb bottom. The ignition was done with a weighed portion (2 g) of black powder. Table 1 lists the following parameters: charge mass M; oxidant excess factor α; induction time t_{ind}; combustion time t_{com}; fuel density ρ; combustion chamber volume V; maximum pressure P_m in combustion of the formulations; and specific strength of combustion products, RT, in comparison with the energy efficiency θ of the process. The process efficiency was evaluated by comparing the RT value found from experimental data with the calculation [1].

Analysis of these experimental data confirms the previously obtained results: the higher dynamic (t_{ind} and t_{com}) and energetic (RT and θ) process parameters of the powder system, compared with layered systems (with or without sodium chloride). In accordance with the aforesaid, we use the equations of autocatalytic reactions to describe the combustion process in the bomb. We assume that the final pressure in the bomb is determined by the mass of gaseous products of charge combustion (initial concentration [A] and "primer" concentration [B]). Then the starting expression for the autocatalytic reaction can be expressed in a modified form in terms of the process completeness as

$$d\alpha/dt = k_1(1 - \alpha)(\beta - \alpha), \quad (1)$$

where α is the completeness of the process (reduced pressure in the bomb); $\beta = [A]/[B]$, share of the primer in the total mass; and $k_1 = k[A]$.

Solution to differential equation (1) has the form

$$\alpha(t) = \frac{\beta[\exp(\beta + 1)k_1 t - 1]}{1 + \beta\exp(\beta + 1)k_1 t}. \quad (2)$$

For the powder system, oscillograms of the combustion processes in the bomb can be processed with the Mathcad software package, using the reduced equation because of the rapidity of the process. For

the layered system (with or without sodium chloride), we use an equation that accounts for thermal loss (by Ya.B. Zel'dovich):

$$\alpha(t) = \frac{\beta[\exp(\beta + 1)k_1(t)t - 1]}{1 + \beta\exp(\beta + 1)k_1(t)t}, \quad (3)$$

$$k_1(t) = 1/(a/T_0 + bt), \quad (4)$$

where T_0 is the initial (calculated adiabatic) temperature of the system; t, time; and a and b, coefficients to be determined.

It was shown in [1] that the amount of primer was not determined for the powder system, although it was taken for the simple layered system as the limiting in accordance with GOST (State Standard). As a result, the coefficients of Eq. (1) may take different paired values at a virtually complete coincidence of the calculated curve with the experiment. Table 2 lists calculated values of the coefficients of Eqs. (2)–(4).

We use the equation parameters obtained to determine how the combustion velocity varies in the systems under consideration and to find, based on these results and on the mass conservation law, the outflow velocity of combustion products from the burning surface. The gas outflow velocity can be used to judge whether the subsonic combustion can pass to detonation. Let us make the following assumptions: the combustion products are described by equations for ideal gases, combustion occurs in the layer-by-layer mode (this is justified for atmospheric conditions [2]), diameter d_{com} of the combustion chamber of the bomb is equal to the charge diameter (d_{ch} = 38 mm), and RT = const during the process (further alternatives in which RT increases with time will be considered).

Table 2. Coefficients of Eqs. (2)–(4)

Formulation	β	k_1	a	b
SC + PEP	10^{-6}	1900		
	10^{-8}	2500		
	10^{-10}	3100		
SC + PET	0.003	52	33	0.06
SC + PETC	0.091	43	55	0.10

The pressure (Pa) developed in fuel combustion can be found, with account of the assumptions made, using the formula

$$P(t) = \frac{m(t)RT}{V(t)}, \quad (5)$$

where $m(t) = \rho\pi d^2 h(t)/4$ is the mass of the burnt fuel (kg), and $V(t) = V_{com} + V_f$ is the combustion chamber volume (m^3), equal to the initial volume plus that of the burnt fuel.

With account of the assumptions made, the total volume is given by

$$V(t) = \pi d^2[h_1 + h(t)]/4,$$

where h_1 is the height of the initial volume of the bomb, related by the charge diameter, and $h(t)$ is the height of the burnt fuel (m) (varies with time).

We substitute in Eq. (5) expressions for the mass and volume and, after cancellations, obtain

$$P(t) = \frac{\rho RT h(t)}{h_1 + h(t)}. \quad (6)$$

From expression (6) we find how the height of the burnt fuel bed depends on pressure:

$$h(t) = \frac{P(t)h_1}{\rho RT - P(t)}. \quad (7)$$

However, $P(t) = P_m\alpha(t)$ [1], where P_m is the maximum pressure developed in combustion of the whole amount of fuel in the bomb. This pressure can be, in turn, calculated by formula (6), with the initial charge height h_2 substituted instead of $h(t)$. Then, we obtain after simple rearrangements the dependence of the height $h(t)$ of burnt fuel as

$$h(t) = [h_1h_2\alpha(t)]/[h_1 + h_2 - h_2\alpha(t)]. \quad (8)$$

The derivative of $h(t)$ with respect to time is just the linear combustion velocity, i.e.,

$$u(t) = \mathrm{d}h(t)/\mathrm{d}t. \quad (9)$$

Now we calculate, using the data listed in Table 1, the reduced height of the initial volume of the bomb and the initial height of the fuel bed (Table 3).

Carrying out a single differentiation of Eq. (8), we obtain the dependence (9) of the linear velocity on the combustion time, and upon a double differentiation, we find the instant of time at which the maximum combustion velocity is reached, t_u. Figure 1a shows, as a typical example, how the combustion velocity of the powder system varies for the second pair of parameters from Table 2. Numerical values for all the three cases are given below. Figure 1b shows similar kinetic curves for the layered system with and without sodium chloride added. Numerical values of the maximum combustion velocities and instants of time at which these velocities are reached are listed in Table 4.

It follows from Fig. 1 that (i) all the curves of variation of linear combustion velocities are bell-shaped, (ii) linear combustion velocity of the powder system is 1–1.5 orders of magnitude higher than that of layered systems, (iii) the time in which the maximum combustion velocity is reached is an order of magnitude shorter than that of layered systems, (iv) combustion velocity of a layered system with NaCl additive somewhat exceeds that without the additive, and the time in which the maximum velocity is reached is two time shorter, and (v) initial combustion velocity for the layered system with a NaCl additive exceeds that without the additive. Autocatalytic reactions [2] are characterized by an extent of reaction at the initial instant of time that is dependent on the primer concentration [Eq. (1)]. It should be noted that Eq. (3) well describes the development of the process in the bomb with a correlation coefficient not lower than 0.98.

A characteristic feature of autocatalytic reactions is the position of the inflection point on the conversion vs. time curve [3]. At this instant of time, the rate of the chemical reaction reaches its maximum value. For example, in the case when the rate equation of the reaction is first-order with respect to the product and starting substance, the inflection point approximately corresponds to 50% conversion of the starting substance into reaction products. When the rate equation is second-order with respect to the conversion product and first-order with respect to the starting substance,

Table 3. Initial heights of the original volume of the bomb and of the fuel bed

Formulation	h_1, m	h_2, m

10^{-6}	1900	16.6	0.0073	17.5	0.5	41.3
10^{-8}	2500	21.9	0.0074	17.5	0.5	55.8
10^{-10}	3100	27.1	0.0075	17.5	0.5	69.1
0.003	52	0.39	0.08	14.1	0.4	1

the inflection point corresponds to consumption of approximately two thirds of the starting substance. In the opposite situation with the reaction orders, the inflection point will correspond to consumption of an approximately one third of the starting product. It should be noted that the smaller the amount of primer, the closer the position of the inflection point on the kinetic curve to the limiting values (0.5, 0.66, and 0.33). Let us consider from this standpoint the combustion of a mixture of SC with PE powder for

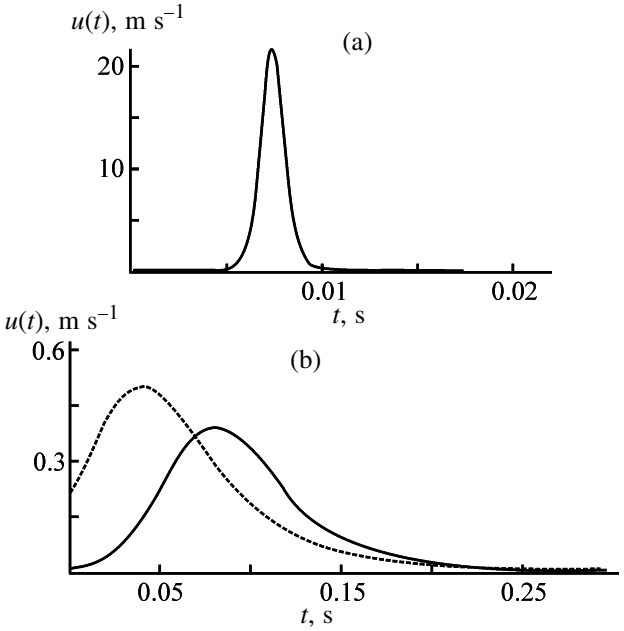

Fig. 1. Kinetic curves of variation of the linear combustion velocity $u(t)$ for (a) powder formulation (β = 10^{-8}, k_1 = 2500) and (b) layered system (*1*) without and (*2*) with addition of sodium chloride. (*t*) Time; the same for Fig. 2.

the three values of the equation parameters in Table 2, in comparison with the layered system. We determine the numerical values of the maximum linear combustion velocities and the instants of time at which these velocities are reached, using Eq. (8). To find the reaction order, it is necessary to calculate the fraction of fuel burnt by the instant of time when the maximum combustion velocity is reached. For this purpose, we integrate the expression for the linear combustion velocity from 0 to t_u, the time corresponding to the maximum combustion velocity:

$$h = \int_0^t u(t)\mathrm{d}t. \quad (10)$$

We divide the resulting value of the height of the burnt bed by the initial value of h_2 to obtain the degree of conversion:

$$\varphi = h/h_2. \quad (11)$$

Table 4 lists the results of these calculations and, in addition, the ratios z between this linear combustion velocity and the linear velocity for the layered system.

Analyzing the data in Table 4 and, primarily, those related to the powder system, we see that a decrease in the share β of the primer leads to an increase in the linear combustion velocity, although the inflection point on the kinetic curve remains constant and corresponds to 50% conversion of the fuel. Based on this circumstance, we can assume that this is the case in which the reaction equation is first-order with respect to both the starting substance and the reaction product (sodium chloride). Apparently, this assumption is also valid for the layered system, despite the difference in the degree of half-conversion (0.4 instead of 0.5), because it is rather improbable that the reaction mechanism would change because of differences in the aggregative state of polyethylene. This difference is probably accounted for by introduction of corrections for thermal loss introduced into Eq. (2) [Eq. (3)]. For the layered system with addition of NaCl, the degree of conversion is even lower (0.3) than that for the system without NaCl because of the even larger thermal loss (Table 1).

As shown previously [4], the combustion of the powder formulation of SC with PE occurs under kinetic control (activation energy E_p = 141 700 J mol^{-1}), and that of the layered system, under mixed (but closer to diffusion) control (activation energy E_s = 38 000 J mol^{-1}). If the preexponential factor is considered the same for these cases, the calculated ratio of the reaction rates (linear combustion velocities) can be expressed as

$$z_1 \approx \exp(E_p/R_\mu T_a)/\exp(E_s/R_\mu T_a), \quad (12)$$

where T_a is the adiabatic temperature of formulation combustion [3], and R_μ, the universal gas constant. Substituting the corresponding values of R_μ and T_a into expression (12), we obtain z_1 = 41.3. This value virtually coincides with the value of z in the first row of Table 4. Consequently, the first pair of parameters of Eq. (2) in Table 2 can be regarded as more appropriate for description of the combustion process of the powder system. Thus, the different linear combustion velocities are due to differences in the activation energies.

Knowing the law by which the linear combustion velocity varies with time and having made several additional assumptions, we can pass to determining the velocity of the gas outflow from the burning surface of the fuel. Let us first consider the case of the powder system (for the second pair of parameters in Table 2), whose tests by the UN-approved procedure demonstrated that such a system belongs to the class of explosives. Let us assess for this system to what extent the combustion process is close under our experimental conditions to transition to detonation. To find the outflow velocities, we use the mass conservation law

$$w(t)\rho_1(t) = u(t)\rho, \quad (13)$$

$$\rho_1(t) = p(t)/RT, \quad (14)$$

$$p(t) = p_k\alpha(t) + 101\,325, \quad (15)$$

where $\rho_1(t)$ is the density of the combustion products, and $p(t)$ is the absolute pressure in the bomb.

Let us assume that the specific strength of the combustion products, RT, is established instantaneously upon the onset of combustion and does not vary with time and, specifically, during the time shorter than, or equal to the induction period (t_{ind} = 0.005 s) to be RT = 785.50 kJ kg^{-1} (specific strength of air in the gas generator at the initial instant of time), otherwise RT = 646.500 kJ kg^{-1}. Figure 2a (curve *1*) shows how the outflow velocity of the combustion products from the burning surface (or, more precisely, from the combustion front) varies with time in this case.

It follows from an analysis of Eqs. (13)–(15) and Fig. 2a (curve *1*) that the maximum gas outflow velocity is 581.5 m s^{-1} 0.006 s after the onset of the combustion process.

Table 5. Velocity parameters of the combustion process

Formulation	β	k_1	u, m s^{-1}	t_u, s	w_{lin}, m s^{-1}	t_{lin}, s	w_v, m s^{-1}	t_v, s
SC + PEP	10^{-6}	1900	16.6	0.0073	413	0.006	442	0.006
	10^{-8}	2500	21.9	0.0074	573	0.007	582	0.006
	10^{-10}	3100	27.1	0.0075	720	0.007	721	0.0062
SC + PET	0.003	52	0.39	0.08	13.1	0.043	19.2	0.021
SC + PETC	0.091	43	0.48	0.039	23.9	0.011	24.2	0.011

Let us consider another case, when RT varies gradually (e.g., by a linear law) and reaches a steady value after half the combustion time, i.e., 0.005 s, elapses. We represent the linear dependence as $s(t) = 90\,000\,000t + 78\,550$. Figure 2a (curve *2*) shows the dependence obtained under these conditions.

It can be seen from Fig. 2a that the maximum outflow velocities and the instants of time at which the maximum values are reached are virtually only slightly different for these cases: 581.5 m s^{-1} at $t = 0.006$ s and 572.6 m s^{-1} at $t = 0.007$ s. It is interesting that the outflow velocity was 332.2 m s^{-1} at the instant of time at which the maximum combustion velocity is reached, $t_u = 0.0074$ s.

We now perform similar calculations for outflow velocities for the layered system. Let us first consider the case when RT is established immediately after the onset of combustion, or, more precisely, 0.001 s after the induction period (Fig. 2b, curve *1*).

In the case of a linear rise in RT as $f(t) = 10\,000\,000t + 78\,550$, we obtain a somewhat different value of the outflow velocity (Fig. 2b, curve *2*).

Analysis of the graphical dependences of the outflow velocities for the layered system shows that the absolute values of the velocities are only slightly different, and the difference is mostly determined by the adopted law of RT variation. The variation of the outflow velocities for the layered system with 9.1% NaCl is similar to that without this additive.

It follows from Table 5 that the linear combustion velocity of the powder systems exceeds by more than an order of magnitude that for the layered systems and reaches these values in an order of magnitude shorter time. For this reason, the combustion of the powder system occurs under virtually adiabatic conditions with a higher energetic completeness θ of the process and larger RT (Table 1). The outflow velocities of the combustion products of the powder system also exceed by 1.5–2 orders of magnitude those for the layered system and approach the critical velocity (equal to 940 m s^{-1} according to preliminary calculations) beyond which transition from the subsonic combustion mode to detonation is possible. Because the powder system belongs to explosives, the absence of detonation in the experiment under consideration is possibly accounted for by the small height of the fuel bed, low bulk density of the fuel, and its granulometric composition, or by all these factors taken together [5, 6]. It is known [3] that the kinetics of autocatalytic and branching chain reactions may be rather similar. Therefore, it is difficult to distinguish these reactions, although they differ in nature. Our attempt to describe the combustion of the powder system with a typical equation for branching chain reactions

$$U(t) = Ae^{\varphi t} \qquad (16)$$

failed to give any encouraging result: the total coef-

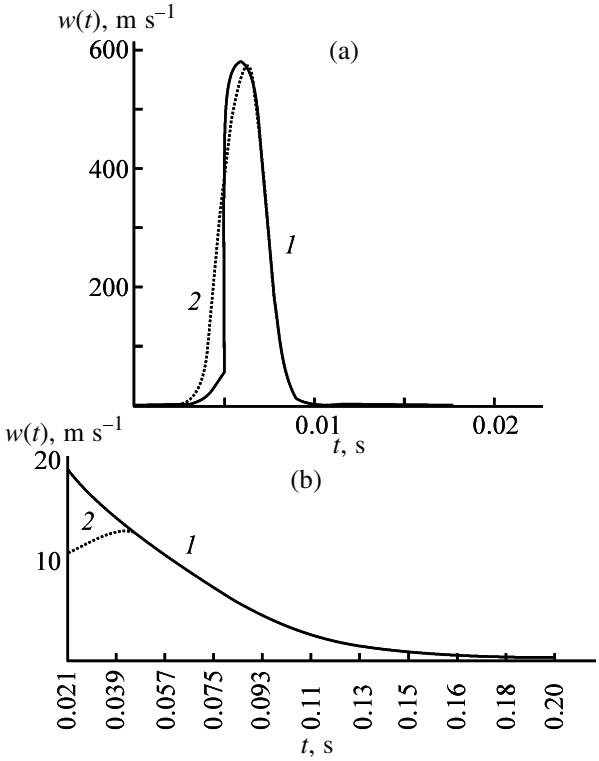

Fig. 2. Variation of the velocity $w(t)$ of gas outflow from the burning surface (reaction front) for (a) powder system and (b) layered system, with (*1*) instantaneous establishment of RT and (*2*) linear rise in RT.

ficient of correlation between the experiment and calculation does not exceed 0.8. Moreover, the exponential dependence well describes only the beginning of the process and disregards the burning-out of the substance in the course of the reaction, and, therefore, no graphical dependence by Eq. (16) is given here.

Because only the layered system can be considered for practical purposes, the fact that introduction of 9.1 wt % NaCl into the formulation not only does not impair the dynamic parameters of the process, but even somewhat improves them makes this fuel promising as being less expensive and having a lower hygroscopicity [7].

CONCLUSIONS

(1) The experiments performed in a constant-volume bomb and calculations demonstrate that the combustion of sodium chlorate with polyethylene in a closed volume is described by an equation of autocatalytic reactions of first-order with respect to both the starting substance and the reaction products.

(2) The linear combustion velocity in the powder system exceeds by more than an order of magnitude the combustion velocity of the layered system. This is attributed to difference in activation energies (reaction control modes).

(3) The outflow velocity of combustion products in the powder system approaches, under the given experimental conditions, the critical value, beyond which transition to detonation is possible.

(4) The layered systems are far from the critical conditions in both the maximum combustion velocities and outflow velocities of the combustion products from the burning surface (reaction front).

(5) Of practical interest is the layered system with a sodium chloride additive, which, not impairing the dynamic parameters of the process, is less expensive and has lower hygroscopicity.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calorimetric Study of Dissolution of Amino Carboxylic Acids in Water at 298.15 K

Abstract—The enthalpies of solution of glycine, *DL*-alanine, *D*-valine, and *L*-serine in water at 298.15 K were measured on a special ampule calorimeter equipped with an isothermal shell. The enthalpies of hydration of 12 α-amino acids differing in the steric configurations of the side radical were estimated using the measured values and the published data on the heats of solution and sublimation for biologically active substances. The influence of hydrophobicity of the substances on their dissolution and hydration was considered.

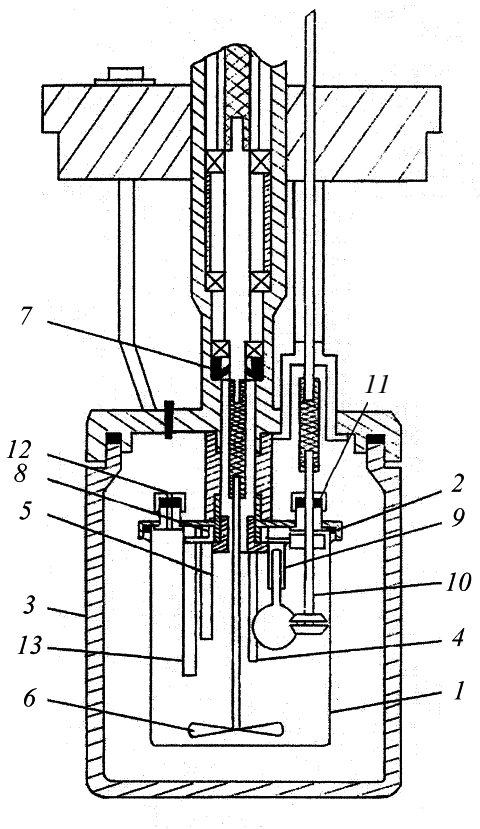
DOI: 10.1134/S1070427207050047

It is known that water plays the key role in structurization and functioning of proteins in a liquid medium [1, 2]. Therefore, study of interactions of protein model compounds with water is extremely important for the estimation of functional capabilities of active groups in biological and medicinal compounds (enzymes, pharmacological receptors), in genetic engineering, and for the development of remedies, new analytical and diagnostic procedures, and molecular sensors [3, 4]. Recently the development of new medicines advantageous in that they are identical to compounds inherent in human body became an important direction in pharmacology. Model protein compounds, such as amino acids, peptides, and their derivatives, can be classed with the above medicines. To develop the optimal processes of the synthesis of such substances and construct the thermodynamic cycles of formation of intermediates, it is necessary to know their thermodynamic constants, including enthalpies of sublimation and solution.

Here we report the experimental values obtained in a thermochemical study and the calculated enthalpies of solution, sublimation, and hydration for some amino carboxylic acids, which are used as remedies (glycine) or model catalytic or substrate centers of enzymes (alanine, *L*-phenylaniline, etc.). Each protein molecule involves the specific number of amino acids. Amino acids can be arranged in the following order with respect to abundance in the living nature: leucine, alanine, and serine [5]. Therefore, the above acids were chosen as objects of study. Note that amino acid molecules, in both solutions and crystals, are in the bipolar or zwitterionic form, NH_3^+–CH(R)–COO^- [5, 6]. Along with the NH_3^+ and COO^- groups bearing effective charges, different polar and hydrophobic groups are present in the amino acid structure. The chemical properties of amino acids in the proteins, i.e., their capability to enter into a particular reaction, are determined by the properties of a side radical –R. It was of interest to estimate how their hydrophobicity affects the energies of solution and hydration. In this respect, calorimetric methods are particularly important for studying thermodynamic properties of such systems [6].

EXPERIMENTAL

Isothermal calorimetry has been recommended as one of efficient methods providing direct thermodynamic information about interactions of various amino acids with water. The enthalpies of solution of glycine (Gly), *DL*-alanine (*DL*-Ala), *D*-valine (*D*-Val), and *L*-serine (Ser) were measured with a special four-ampule calorimeter with an isothermal shell. A series of thermal effects that occurred in dissolution of several weighed portions of a substance were measured in the same volume of the solvent without recharging the calorimetric cell. The reactor and all inner parts of the calorimeter in contact with the solution were made of VT-1 titanium alloy. A thin-walled calorimetric beaker *1* about 110 ml in volume, sealed with a silicone rubber gasket *2*, was placed into a massive brass shell *3* with insulated surface (see figure). Inertia-free heater *4* made of manganin wire and placed into a cylindrical thin-walled case, heat exchanger *5*, and a propeller stirrer *6* were



Scheme of a calorimetric cell: (*1*) Thin-walled beaker (V = 110 cm^3), (*2*) silicone gasket, (*3*) brass shell, (*4*) heater, (*5*) heat exchanger, (*6*) stirrer, (*7, 11*) stuffing boxes, (*8*) cogged bushing, (*9*) holder of ampules with a substance, (*10*) ampule breaker, (*12*) valve for filling the beaker with a solvent, and (*13*) temperature sensor (KMT-14).

located inside the calorimetric beaker. The inlet of the stirrer was sealed with a self-packing stuffing box *7*. The calorimeter was calculated for four ampules that are fixed to a cogged bushing *8* with holders *9*. A stuffing box *11* ensured tightness of the system in the course of rotation of ampule breaker *10*. The solvent was added to the calorimetric vessel through valve *12*. As temperature sensor was used a KMT-14 thyristor placed into case *13*. The Wood's alloy ensured secure heat contact between the thermistor and the walls of the case. The assembled massive unit was placed into a water bath of 16 l volume. In the course of the calorimetric measurement, the stability of the temperature-control system was maintained constant to within 10^{-3} K. The sensitivity of the calorimeter in measuring the temperature and energy was 2×10^{-4} K mm^{-1} and 1×10^{-3} J mm^{-1}, respectively, of the scale of the measuring device. The thermal effect was compensated by the electric current.

Each weighed portion of the substance examined was ground in an agate mortar to decrease the dissolution time and dried to constant mass. All ampules used for measuring the thermal effect of solution were weighed on a VLR-200 balance with an accuracy of 5×10^{-5} g. In the general case, the integral heat of solution was estimated in successive dilutions by the equation:

$$\Delta_{sol}H^m = \frac{\sum_1^n \Delta m_i/\Delta_{sol}H(m_{i-1} \to m_i)}{\sum_1^n \Delta m_i}, \quad (1)$$

where Δm_i is change in the molal concentration in ith measurement; $\Sigma \Delta m_i = m$, final molal concentration of the solution; and n, number of successive measurements.

The accuracy and reliability of operation of the calorimetric installation was estimated by measuring the thermal effect of solution of KCl at 298.15 K. Using 10 independently measured enthalpies of solution of KCl in water and the values from [7], we obtained the standard enthalpy of solution $\Delta_{sol}H^0$ = 17.23 ± 0.06 kJ mol^{-1}, in good agreement with the generally accepted value of 17.22 ± 0.33 kJ mol^{-1}.

The chromatographically homogeneous amino acids, Gly, *DL*-Ala, *D*-Val, and Ser (Reanal, Hungary) used in the study were dried in a vacuum oven at 343 K for 48 h immediately before use. Water was subjected to deionization and double distillation. The maximum error in determining the enthalpies of solution of amino acids was 0.5% at a confidence level of 0.95. In the concentration range studied, 0.003–0.012 mol kg^{-1}, $\Delta_{sol}H^m$ of all systems is concentration-independent within the experimental error. Therefore, the enthalpies of solution $\Delta_{sol}H^0$ were found as weighted averages of seven independent measurements.

Table 1 generalizes the measured values and the published data for the amino acids studied, which are used to compare the enthalpies of solution in water of amino acids differing in the structures of the side radical. As objects of study we chose linear and branched aliphatic amino acids (Gly, *L*-Ala, *DL*-Ala, Abu, *DL*-Nva, *DL*-Nle, *L*-Val, *D*-Val, and *L*-Leu), amino acids with a polar side chain (*L*-Ser, *L*-Thr), and those containing benzene ring (*L*-Phe). As follows from Table 1, the dissolution of amino acids in water is an endothermic reaction, which may be due to the fact that the energy spent for breaking a network of hydrogen bonds in water and crystal structure of

Table 1. Standard enthalpies of solution $\Delta_{sol}H^0$ in water and standard enthalpies of sublimation $\Delta_{subl}H$ of α-amino acids at 298.15 K

2-Aminohexanoic acid (norleucine, Nle)	$CH_3(CH_2)_4$–	–6.1 ± 0.2 [11]	114.4 ± 0.4 [13]

the substances is large and is not compensated by exothermic hydration effects. As the length of the side radical increases, the enthalpy of solution of amino acids becomes more negative. On passing from linear acids (Abu, Nva, Nle) to the more branched acids (Val, Leu), $\Delta_{sol}H^0$ increases. The heats of solution of the isomers (*DL*- and *L*-alanine, *D*- and *L*-valine) differ by 1.73 and 3.18 kJ mol^{-1}, respectively. The enthalpies of solution of Ser and Thr are more positive than the heats of solution of aliphatic amino acids, despite possible formation of hydrogen bonds between the OH polar group and water molecules. Introduction of the benzene ring into Ala (passing to Phe) affects the heat of solution only slightly.

It should be noted that, for all the amino acids, the nature of the reactive charged groups (COO^-, NH_3^+) is the same and, in all probability, the changes in the thermodynamic properties may be caused by the specific solvation and by the change in the molecule hydrophobicity. The logarithm of the coefficient of the substance distribution between two immiscible phases (in the *n*-octanol–water model system) $\pi = \log P$ [5] was accepted as the hydrophobicity coefficient. The π values calculated for the amino acids by the AM1 method [14] are listed in Table 2. The hydrophobicity coefficients π vary in the orders Gly < Ala < Val < Leu, Phe > Ala > Ser < Thr, and Ala < Abu < Nva < Nle. In other words, π grows with increasing length of side alkyl chains and with introducing additional CH_3 (Thr) or C_6H_5 (Phe) group. Note that, among the amino acids studied, Phe is the most hydrophobic. The π value is somewhat higher for linear compounds than for branched ones (Nvl > Val, Nle > Leu). Considerably less hydrophobic are Ser, Thr, and Gly, which is due to the influence of OH group on the interaction energy of Ser and Thr molecules with water (formation of hydrogen bonds) and to the electrostatic interaction of Gly zwitterions with water dipoles.

The variation of the hydrophobicity of amino acid molecules is reflected in the enthalpies of solution. An increase in the hydrophobicity makes the dissolution of biosubstances less endothermic and enhances the exothermic contribution, first of all, of hydrophobic

Table 2. Enthalpies of hydration $\Delta_{hydr}H^0$, specific volume enthalpies of hydration $\Delta_{hydr}H^0/V_2^0$, and coefficients of molecule hydrophobicity π and molecule packing D_{aq} in aqueous solutions of α-amino acids

hydration. However, correct estimation of the hydration contributions to the thermal effects of solution of amino acids can be done solely by taking into account the energies of their crystal lattices. As a measure of the interaction of a dissolved substance with water molecules we used the heat of hydration $\Delta_{hydr}H^0$ [15]:

$$\Delta_{hydr}H^0 = \Delta_{sol}H^0 - \Delta_{subl}H, \quad (2)$$

where $\Delta_{subl}H$ is the enthalpy of sublimation of amino acid (Table 1).

The calculated heats of hydration, $\Delta_{hydr}H^0$, of amino acids are presented in Table 2.

In model amino acid crystals, $\Delta_{subl}H$ decreases in a series of linear amino acids (Ala > Abu > Nva > Nle) and increases in a series of aliphatic acids (Leu < Val < Ala < Gly) with increasing length of the side alkyl chain. At the same number of carbon atoms, $\Delta_{subl}H$ is considerably higher for amino acids with branched side radicals than for linear acids. This may be due to the change in the degree of braking of the internal rotation about the C_α–N bond and to the contribution from the side radical. Introduction of the benzene ring into the side chain of alanine decreases, and the introduction of OH groups increases the specific volume enthalpy of sublimation, which is defined as $\Delta_{subl}H/V_w$ ratio and characterizes the "rigidity" of the crystal structure [16].

Tables 1 and 2 show that, along with electrostriction of the water molecules arranged close to effective charges on NH_3^+ and COO^- groups of amino acids, the complementary influence of the specific interaction of water with polar functional groups of biomolecules and the interaction of water with a nonpolar hydrophobic radical determine the enthalpies of solution and hydration of amino acids. Using the values of [17–19] for the partial molar volume V_2^0 of amino acids in water at infinite dilution at 298.15 K, we calculated the specific volume enthalpies of hydration, $\Delta_{hydr}H^0/V_2^0$ [20], of the compounds studied. The packing coefficients of amino acid molecules in water were calculated from the relation $D_{aq} = NV_w/V_2^0$ (where V_w is the van der Waals volume of molecule and N, number of molecules present in a cell, equal to the Avogadro number) [8, 21]. The results obtained are collected in Table 2. The relative error in calculating $\Delta_{hydr}H^0/V_2^0$ does not exceed 3.5%. The lower the $\Delta_{hydr}H^0/V_2^0$ of amino acids, the higher the coefficient D_{aq} and the degree of structurization of the aqueous solutions [8].

In a series of aliphatic amino acids having nonpolar side chains, the strongest electrostriction effect on the surrounding water is exerted by Gly. The fact that the effect of Thr is weaker than that of Ser is due to the presence of a methyl group. The ratio $\Delta_{hydr}H^0/V_2^0$ tends to increase with increasing π (Table 2). Increasing the nonpolar moiety of the molecule makes it more hydrophobic, with $\Delta_{hydr}H^0$ decreasing for branched amino acids and becoming less negative for linear acids. Apparently, this is accounted for by the state of molecules in the solid phase and by the contribution of the crystal lattice energy in dissolution of a compound in water. The introduction of the OH polar fragment into a nonpolar side chain of Ala decreases its hydrophobicity and is accompanied by a decrease in $\Delta_{hydr}H^0$ for Ser. In comparison with Ser, the presence of an additional methyl group in Thr increases the hydrophobicity and makes the hydration more exothermic. In some cases, the difference in the $\Delta_{hydr}H^0$ values of zwitterions is obscured by the difference in their $\Delta_{subl}H$ values. For example, in the case of *L*-Ala and *L*-Phe, the enthalpies of solution are virtually the same, whereas $\Delta_{hydr}H^0$ for Phe is more exothermic by 15.7 kJ mol^{-1}.

CONCLUSIONS

(1) The heats of solution of glycine, *DL*-alanine, *D*-valine, and *L*-serine in water at 298.15 K were determined experimentally on a special calorimeter equipped with an isothermal shell. The enthalpies of solution and hydration were determined for 12 α-amino carboxylic acids, containing linear or branched alkyl radicals, polar OH groups, or a benzene ring in a side chain, which simulate the properties of active centers of enzymes or remedies.

(2) The parameter $\Delta_{hydr}H^0/V_2^0$ can be used as a measure of the stabilizing effect exerted by amino acid on the aqueous solution. The lower its value, the more structured is the solution examined.

(3) The electrostriction compression of water in the vicinity of charge centers (NH_3^+, COO^-) in the molecules of different amino acids is the same. The hydrophobic interaction with water is accompanied by a decrease in $\Delta_{hydr}H^0$ (it becomes more negative) in a series of branched acids (from Ala to Leu) and by only slight its variation in a series of linear acids (Abu, Nva, Nle).

(4) From the energy standpoint, the thermal effects of solution of various amino acids in water can simulate the denaturation, which is considered as transfer of amino acid residues from the inner region of the

protein into water. In this case, balance between the hydrophobic and specific interactions and between the specific interactions and dehydration of amino acid is of great importance. It was demonstrated that hydrophobic hydration plays the key role in interaction of amino acids with water and is larger for more complex biomolecules.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Technology of Vapor-Phase Extraction of Water-Soluble Organic Substances

Abstract—A method of vapor-phase extraction has been suggested for recovery of organic substances from an aqueous medium. The appropriate apparatus have been developed. The method enables use of both hydrophobic and hydrophilic organic liquids. The results of vapor-phase extraction of low-molecular-weight organic acids are discussed in terms of the kinetic model of the process mechanism.

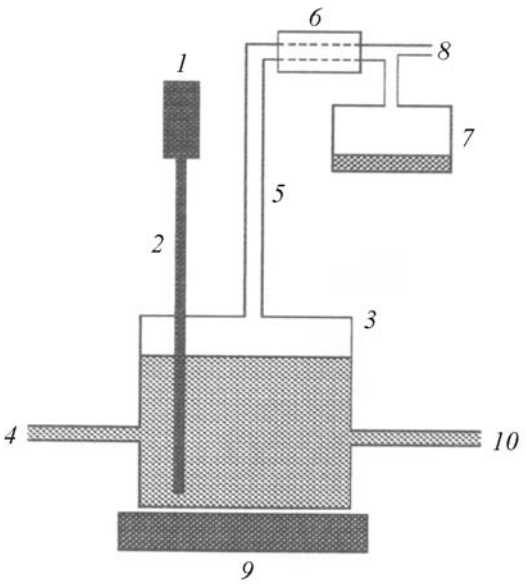
DOI: 10.1134/S1070427207050059

Numerous technologies are based on extraction of target products. A considerable experience has been accumulated in liquid extraction of organic compounds, and theoretical foundations of the process have been developed, which enables prediction of the efficiency of extraction systems. At the same time, the distribution ratios ($K_d = c_{org} : c_{aq}$) of well soluble organic compounds do not exceed 50 even in the best solvent–water systems [1]. The use of hydrophobic alcohols (pentyl, decyl alcohols), acetic acid esters (butyl acetate, heptyl acetate) has shown that the extractive activity of solvents-homologs steadily grows as the number of carbon atoms in their molecules decreases. However, this leads to an increase in the solubility of an extractive agent in water, which does not allow (and even rules out) the use of low-molecular-weight homologs without a special "salting-out" procedure: introduction of large amounts of neutral salts into a water sample. A risk of side chemical processes arises, numerous technological difficulties are encountered, etc.

Here we suggest a possible solution to the problem of use of hydrophilic organic liquids for recovery of water-soluble organic substances: vapor-phase extraction (VPE). Aqueous solutions of low-molecular-weight carboxylic acids served as objects of study.

EXPERIMENTAL

To implement the method of vapor-phase extraction of dissolved organic substances from aqueous objects, we developed the device described in [2]. It served as a basis for creating the extraction unit schematically shown in the figure [3]. The extraction unit comprises, in addition to the necessary, but not shown in the figure, instrumentation for measuring



Device for vapor-phase extraction of organic substances (VPE unit): (*1*) liquid batching pump for delivery of the extractive agent, (*2*) pipeline for supply of the extractive agent, (*3*) distillation vessel, (*4*) pipeline for feed, (*5*) steam line, (*6*) condenser for condensing the vapor of the extractive agent with target components, (*7*) vessel for collection of the extract, (*8*) pipe for connecting a compressor or a vacuum pump, (*9*) heater, and (*10*) discharge pipe.

process parameters (temperature, pressure, level and feeding rate of liquids, etc.), the following basic units and parts: liquid batching pump *1* (NNR-5001, former Czechoslovakia), which delivers the extractive agent via pipeline *2* into a liquid sample in the distillation vessel *3*; steam line *5* for discharge of the extractive agent vapor with organic substances being recovered and its delivery to condenser *6* for condensing the vapor and obtaining an extract collected in vessel *7*; pipe *8* for connecting a compressor or a vacuum pump; heater *9*; and pipe *10*, through which the spent liquid is delivered to the next stage of the overall production scheme. At an industrial plant this may be discharge or a further stage in the process chain, as well as delivery to the input of a next VPE unit with another extractive agent.

To perform vapor-phase extraction, the extractive agent used should have a boiling point lower than that of the sample. The sample is heated to the boiling (distillation) point of the extractive agent added. When necessary, for recovery of thermally unstable substances, the distillation temperature can be lowered by reducing the pressure with a vacuum pump via pipe *8*. In the case of vapor-phase extraction under elevated pressure, the vacuum pump is replaced with a compressor.

The vapor-phase extraction can be carried out in the above-described installation in the static mode. In this case, a hydrophilic organic liquid or an immiscible extractive agent with a density exceeding that of the sample is delivered by batcher *1* into the sample volume *3*. Then the sample is heated and the extract-condensate is collected. The extraction may be single-stage or steplike multistage successive, when, before adding the next portion of the extractive agent, the sample is cooled below the boiling point of the extractive agent. A series of successive vapor-phase extracts is obtained, which makes it possible to raise the degree of recovery.

The temperature of the steplike successive VPE, i.e., the boiling point of a sample after addition of a hydrophilic solvent, was gradually raised in the course of the extraction procedure as the solvent evaporated from the sample. The recovery was terminated when the volume of the cocondensate exceeded that of the solvent added by approximately 50%. This corresponded to a VPE temperature of 96 ± 2°C.

The vapor-phase extraction in the dynamic mode involves continuous delivery of the extractive agent by a liquid pump *1* into a sample preliminarily heated to the boiling point of the extractive agent, with this temperature further maintained by heater *9*. Continuous feeding of the starting sample can also be additionally carried out in this mode.

The content of organic acids in the samples being analyzed was found by gas chromatography on an M-3700 chromatograph with a flame-ionization detector and glass column with a length of 1.25 m and inner diameter of 4 mm, packed with Chromaton N-AW-DMCS (0.16 – 0.20) with 15% Carbowax 20M, and a Meta-Khrom analog-digital signal processing system.

We found in the course of the experiment that the degree of recovery depends on individual physicochemical characteristics of dissolved organic substances, amount of the extractive agent used, etc. To explain the results obtained, we suggested a theoretical model that regards the phenomenon under study as a process of distribution of the target substance among two phases: liquid (water) and vapor of the organic extractive agent added.

Gas extraction, in which a target component is transferred into a gas medium (nitrogen, argon, etc.) in contact with a liquid, is widely used in chemical analysis [4, 5]. It should, however, be noted that the vapor-phase extraction as extraction with a vapor of an organic liquid differs from gas extraction (extraction with a gas, blowing-out, bubbling with a gas). The vapor is the gaseous state of a substance, into which it passes upon evaporation, but, in contrast to a gas, it is below the so-called critical temperature. This circumstance indicates that the vapor and the condensed phase have a number of common physicochemical properties. It is known, in particular, that the vapor of individual organic substances and mixtures of these is composed of separate molecules and various associates of these molecules. The critical temperatures of the organic extractive agents used in this study substantially exceed the experimental temperatures. With account of the established terminology and commonly accepted classification, the aforesaid makes it possible to name the extraction of target components from water with a vapor of an organic liquid the vapor-phase extraction (VPE).

As a direct confirmation that the vapor of a solvent added to a sample is involved in recovery of organic substances from an aqueous medium can serve the experimental results listed in Table 1. Experiments on vapor-phase extraction with ethanol, i.e., in the presence of ethanol in an aqueous solution of organic acids, showed that, all other conditions being the same, their equilibrium concentrations in the vapor-and-gas phase noticeably increase, compared with those in gas extraction. Collecting and condensing in

a separate vessel the vapor of the organic solvent added, formed in evaporation from the sample, i.e., by performing VPE, we can obtain the extract-cocondensate containing the target substances.

In our opinion, the PVE mechanism is as follows. In evaporation of the organic solvent (alcohol) added to the aqueous solution from this solution, it forms a separate phase, the vapor in the bulk of the sample (bubbles) and over the solution in the distillation vessel, to give a heterogeneous liquid–vapor system.

Molecules of the organic substances dissolved in water permanently pass from one phase into another and back. In our case, the vapor of the organic solvent is an extractive agent with respect to water.

The rates of migration of the substances from one phase into another are proportional to the concentrations of the component being recovered in these phases. Accordingly, the following expression is valid for the rates of transfer of molecules from the liquid phase to vapor (v_L) and back (v_V):

$$v_L = k_L c_L, \quad (1)$$

$$v_V = k_V c_V, \quad (2)$$

where k_L and k_V are the corresponding rate constants, determined by the physicochemical parameters of a component and the heterogeneous system under consideration; c_L, concentration of the component in the liquid phase; and c_V, that in the vapor phase.

Under the dynamic equilibrium conditions, the number of substance molecules that passed from the liquid into the vapor in unit time is equal to the number of its molecules returning from the vapor to the liquid:

$$v_L = v_V, \quad (3)$$

$$k_L c_L = k_V c_V, \quad (4)$$

$$c_V/c_L = k_L/k_V = K_{eq}. \quad (5)$$

The validity of the assumption that equilibrium can be attained in VPE is confirmed by the following. It is known that, under the conditions of the dynamic mode of gas extraction, the equilibrium conditions of liberation of the substances into the gas phase are provided at gas flow rates of up to 0.5 l min^{-1} [4], or, recalculated to the amount of the gaseous extracting agent, 0.5/22.4 = 0.022 mol min^{-1}. In our case, e.g., in dynamic vapor-phase extraction with 95 vol % ethanol fed into the sample at a rate of 1 ml min^{-1}, we have the following rate mode: (0.95 ml × 0.7893 g ml^{-1})/46 g mol^{-1} = 0.016 mol of the extractive agent per minute. Consequently, taking into account a certain analogy between the gas and vapor-phase extraction, we believe that our experiment is performed under equilibrium conditions of transboundary transfer of molecules of the components being recovered.

The equilibrium constant K_{eq} characterizes the extractive properties of the organic solvent added. At $K_{eq} < 1$, the equilibrium concentration of the substance being recovered is higher in the liquid (water), and, conversely, at $K_{eq} > 1$, in the vapor phase.

Taking into account the material balance in the case when the target substance is completely concentrated in water at the beginning of an experiment, we can write

$$m_0 = m_L + m_V, \quad (6)$$

where m_0 is the initial mass of the substance in a sample (water); m_L, mass in the liquid phase (water) after the equilibrium is attained; and m_V, mass in the vapor phase (ethanol vapor) after the equilibrium is attained.

Taking into account (6), we can rewrite (5) as

$$K_{eq} = (m_0 - m_L)V_L/m_L V_V = (m_0/m_L - 1)V_L/V_V, \quad (7)$$

where V_L is the volume of the liquid phase, and V_V, that of the vapor phase.

* V_{org}/V_{aq}, volume ratio of an alcohol and an aqueous solution of organic acids before VPE; n, number of determinations; N/fr, ordinal number of a vapor-phase extract; V_D, volume of the condensate produced in VPE; $c_{ethanol}$, content of alcohol; and $*K_{eq}$, distribution coefficient of an indicated acid between the vapor and liquid.

It is noteworthy that Eq. (7) can be transformed by simple mathematical operations into the expression derived in [4] for calculating the concentration of a substance in the liquid phase in gas extraction.

In VPE, the whole amount of the vapor is condensed and the condensate is collected in a receiving flask, i.e., the mass of the forming vapor (M_V) is equal to that of the distillate obtained (M_D):

$$M_V = M_D, \quad (8)$$

$$V_V\rho_V = V_D\rho_D, \quad (9)$$

$$V_V = (\rho_D/\rho_V)V_D, \quad (10)$$

where ρ_D is the density of the distillate obtained, and V_D, volume of the distillate.

Taking into account (8)–(10), we can write the following expression:

$$K_{eq} = K_{eq}(\rho_D/\rho_V) = V_L/(m_0/m_D - 1)V_D, \quad (11)$$

where m_0 is the mass of the substance being extracted in the condensate, and $m_D = m_V$ because the whole amount of the vapor and, accordingly, the entire mass of the target component is collected in the condensate.

In Eq. (11), the constant quantity ρ_D/ρ_V, because the vapor and the distillate obtained from this vapor are composed in equal proportions of water and an organic extractive agent, is combined with K_{eq}. The content of the components being recovered is incommensurably small and their contribution to the density of the vapor and condensate can be neglected. Expression (11) is a kind of integral characteristic of the VPE procedure, because fluctuations of the composition and density of the vapor and collected condensate are possible in recovery of target components. Nevertheless, the experiment demonstrated (Table 2) that Eq. (11) derived using the above-described theoretical concepts of the VPE mechanism is well observed. The calculated distribution ratio $*K_{eq}$ is a kind of the extraction equilibrium constant and it should depend neither on the concentration of the components being recovered nor on the volumes of the water sample and extractive agent, taken for vapor-phase extraction. A slight decrease in this coefficient in triple succes-

sive VPE with ethanol of C_2–C_4 acids, observed as the volume of the extractive agent grows, is presumably due to a rise in the alcohol concentration remaining in the sample after a VPE procedure.

The coefficient $^*K_{eq}$ is determined by the physicochemical properties of a component being recovered and extractive agent. Indeed, replacement of ethanol with methanol leads, as can be seen from a comparison of the results listed in Table 2, to a pronounced increase in this coefficient. Isopropanol exhibited approximately the same activity as ethanol in VPE. If a hydrophobic solvent, carbon tetrachloride, is chosen for vapor-phase extraction of the aliphatic acids mentioned above, the coefficient of vapor-phase extraction decreases dramatically. On replacing ethanol with CCl_4, the value of $^*K_{eq}$ for butyric acid decreases by a factor of more than 30 to be 0.06 ± 0.009. If we remain within the range of acid concentrations in water, used in this study, determination of $^*K_{eq}$ for acetic and propionic acids is difficult under these conditions because of the low sensitivity of the method (GLC-FID). The constant $^*K_{eq}$ in vapor-phase extraction with CCl_4 is 0.005 ± 0.0014 for acetic acid and 0.013 ± 0.0032 for propionic acid. In our opinion, these data open up prospects for the development of a method for selective vapor-phase extraction of target products for technological purposes.

The vapor-phase extraction in the dynamic mode involves continuous feed of the extractive agent by a liquid pump *1* (see figure) into a sample preliminarily heated to the boiling point of the extractive agent. The results obtained in determining the coefficient $^*K_{eq}$ of vapor-phase extraction of a mixture of low-molecular-weight aliphatic acids with ethanol from water at different alcohol feed rates are listed in Table 3. In the experiment, the collected portion of the extract-condensate was delivered after a certain interval of time (extraction time), without interrupting the process, to GLC to determine $^*K_{eq}$. As follows from the data obtained (Tables 2, 3), the constants of vapor-phase extraction of acetic, propionic, and butyric acids with ethanol from water under static (steplike successive extraction) and dynamic conditions virtually coincide. In other words, the extraction equilibrium in the vapor–liquid system, assumed to exist in the theoretical analysis of the VPE mechanism, presumably has enough time to be attained in the course of dynamic VPE at extractive agent feed rates in the range 1–2 ml min^{-1}.

Thus, the mechanism of vapor-phase extraction can be hypothetically represented, in the case of water-soluble extractive agent, as the classical liquid–liquid extraction from a water volume into that of an organic solvent additive, collected as a cocondensate with target components. Being infinitely miscible with water, the cocondensate in fact forms no interface with water.

Hence, in contrast to the conventional liquid extraction, the vapor-phase extraction makes it possible to recover organic compounds from aqueous solutions with water-soluble organic liquids without any additional treatment of a sample. Moreover, compared with the gas extraction, which can only use a limited number of gaseous extractive agents, the vapor-phase extraction can, with a proper choice of an extractive agent from the extremely wide variety of organic solvents, selectively recover separate classes or groups of organic compounds. This is so because the VPE apparatus and the dynamic mode of VPE make it possible to introduce into the system also hydrophobic water-insoluble organic extractive agents. Successive use of VPE and back extraction can potentially provide selective isolation of separate chemical compounds.

An additional number of advantageous properties of VPE should be noted. In contrast to the case of gas extraction, the apparatus to be used in the VPE experi-

ment is considerably simpler because there is no need to use hermetical sealing, compressed gases, pressure gages, etc. Moreover, the vapor-phase extracts obtained can be used in the production chain virtually without any additional procedures.

CONCLUSIONS

The process suggested for vapor-phase recovery of water-soluble organic substances extends the capacity of extraction techniques by making possible use of hydrophilic solvents. The results obtained for the example of low-molecular-weight organic acids indicate that, in the case in question, the efficiency of recovery from aqueous solutions exceeds that in gas extraction. The kinetic model of the mechanism of vapor-phase extraction, presented here, is in satisfactory agreement with the experiment.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solutions in the Calcium Oxide–Ethylene Glycol–Water System

Abstract—A comprehensive study of solutions formed in dissolution of calcium oxide in ethylene glycol and in its mixtures with water was carried out. The major form of compounds in the solutions was established. The maximum attainable concentration of Ca(II) in solutions was determined in relation to the temperature and composition of the mixed solvent.

DOI: 10.1134/S1070427207050060

Metal alkoxides and their alcoholic solutions find increasing application as intermediate products in fine inorganic synthesis. They are used for the production of simple and complex metal oxides, ceramics, dielectrics, and other substances and materials [1]. Not-too-viscous alkoxide solutions with a reasonably high concentration of base substance are superior to other reagents, in particular, in sol–gel synthesis [2].

Among such calcium-containing compounds, a solution of calcium glycolate in ethylene glycol (EG) shows much promise. It is, for example, successfully used for the production of hydroxylapatite [3, 4]. Ethylene glycol has a higher boiling point compared to other alcohols, which makes it possible to extend the temperature interval of synthesis of various calcium glycolate products. The drawback of the known compound consists in its relatively high cost associated with the use of calcium metal in its synthesis. Therefore, the study of the possibility of using a cheaper and more readily available compound, i.e., calcium oxide, is topical. In this work, the solutions formed by reaction of CaO with EG and with a mixture of EG and water were studied with the aim to substantiate the synthesis conditions.

The reaction of calcium metal with EG, accompanied by hydrogen evolution, yields calcium glycolate solvated with two alcohol molecules [3]:

$$4HOCH_2CH_2OH + Ca \rightarrow Ca(OCH_2CH_2OH)_2 \cdot 2HOCH_2CH_2OH + H_2.$$

The direction and character of reactions proceeding in alkaline-earth metal oxide–alcohol–water systems are still poorly understood. Their study is complicated by the reaction of the above oxides with water, yielding the corresponding hydroxides. For example, preparation of calcium glycolate by dissolution of CaO in anhydrous EG at normal temperature, proceeding with water release,

$$CaO + 2HOCH_2CH_2OH \rightarrow Ca(OCH_2CH_2OH)_2 + H_2O,$$

can be accompanied by the formation of $Ca(OH)_2$. Therefore, it is likely that basic salt, calcium hydroxy glycolate, may be preferentially formed under these conditions:

$$CaO + HOCH_2CH_2OH \rightarrow Ca(OH)(OCH_2CH_2OH).$$

The salt formed can also be solvated with solvent molecules.

The assumption that the second scheme of the process (formation of basic calcium glycolate) is more probable is also supported by the same character of the reactions proceeding in the $CaO–CH_3OH$ [5] and $BaO–CH_3OH$ systems [6]. Also, it may be suggested that, depending on the process temperature and duration, any of the suggested reactions may proceed. In this case, it should be taken into account that EG has low volatility in comparison with water and monohydric alcohols.

The dissolution of CaO in the $EG–H_2O$ mixture containing a fairly large amount of H_2O yields poorly soluble in water $Ca(OH)_2$ as the major product. At the same time, taking into account the behavior of the metal oxide–methanol systems, the reaction of calcium hydroxide with anhydrous EG is likely to yield

other products, i.e., the reaction

$$Ca(OH)_2 + 2HOCH_2CH_2OH \rightleftarrows Ca(OCH_2CH_2OH)_2 + 2H_2O$$

can proceed in both directions depending on the synthesis conditions.

EXPERIMENTAL

We used freshly prepared calcium oxide, EG, and water. Calcium oxide was prepared from analytically pure grade calcium carbonate by calcination at 1000°C for 4 h. The degree of calcination was no less than 99.5%. The concentration of CaO in the compound was no less than 98.5 wt %. Ethylene glycol (analytically pure grade) was dried over sodium sulfate and then distilled in vacuum. Freshly distilled water used for preparing solutions was decarbonated by boiling to remove 1/3 of the initial volume. The specific electrical conductivity of both pure solvents and their mixtures did not exceed 2×10^{-6} S cm^{-1}.

The most promising for use in syntheses are solutions with high concentrations of Ca(II) ions. In this connection, it is appropriate to study in more detail the physicochemical properties of the system under consideration and the interactions in it in the region of the maximal Ca(II) concentration in the liquid phase. Therefore, in the first stage of the study it was necessary to obtain data on the solubility, coexisting equilibrium solid phases, and equilibration time in the CaO–EG–H_2O system. In many cases, determination of the solubility in systems containing organic solvents is known to meet serious difficulties associated with a long time of attainment of the liquid–solid equilibrium. This is especially true for highly viscous solvents, EG in particular. In addition, the true solubility in oxoalkoxide alcoholic solutions is difficult to attain, and their solid phase is mostly a noncrystalline mass [2].

The same characteristic features were revealed in studying the solubility in the CaO–EG–H_2O system. In particular, it was established that, with approaching saturation, the solutions become viscous gel-like systems, and no coexisting equilibrium solid phases can be separated from them by traditional methods. In the context of the above problems, we attempted to determine the maximum attainable concentration of Ca(II) in EG and its aqueous solutions.

The CaO dissolution in EG and its aqueous solutions was performed with vigorous agitation at a preset temperature. We used in the experiments a glass vessel equipped with a thermostating jacket and a stirrer with a liquid seal. The rotation rate of the stirrer was 300 rpm. By gradual addition of CaO we reached the state when the dissolution in the system virtually ceased, which was controlled visually.

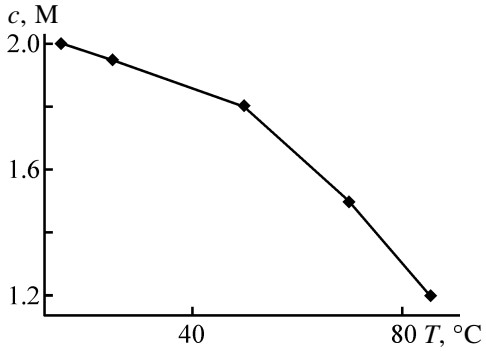

Fig. 1. Maximum attainable Ca(II) concentration c in solutions of the CaO–EG system vs. temperature T.

The CaO dissolution in EG was studied in the 25–90°C range, and that in its aqueous solutions, at 25°C. The calcium(II) concentration in the solutions prepared was determined by complexometric titration [7], with the relative determination error not exceeding 0.5%.

It was established that the Ca(II) concentration in the solution is maximal (about 2 M) at 25°C, the lowest temperature studied (Fig. 1). The Ca(II) concentration in the solution decreases with increasing temperature and attains a value of about 1.2 M at 90°C, i.e., the temperature coefficient of the CaO solubility in EG is negative. It should be noted that the similar properties are exhibited by alkoxides of alkali and alkaline-earth metals, whose solubility in the corresponding alcohols decreases with increasing temperature [8, 9]. The obtained values of the Ca(II) concentration in the solution are higher by two orders of magnitude than those in saturated aqueous solutions of calcium hydroxide at the same temperatures. It was also found that the viscosity suitable for practical use is exhibited by the solutions containing no more than 0.5 M Ca(II), which corresponds to its concentration in solutions prepared from calcium metal and used for inorganic synthesis [3].

In studying the CaO dissolution in aqueous EG solutions at 25°C, we determined the region of existence of solutions in the CaO–EG–H_2O system at the ethylene glycol concentration in the mixed solvent varied from 5 to 100 vol %. As expected, the Ca(II) concentration in the solution increases with increasing concentration of the organic component in the mixed

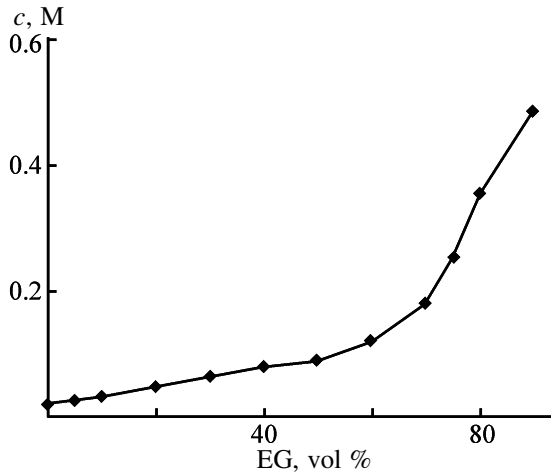

Fig. 2. Maximum attainable Ca(II) concentration c vs. EG concentration in the mixed solvent.

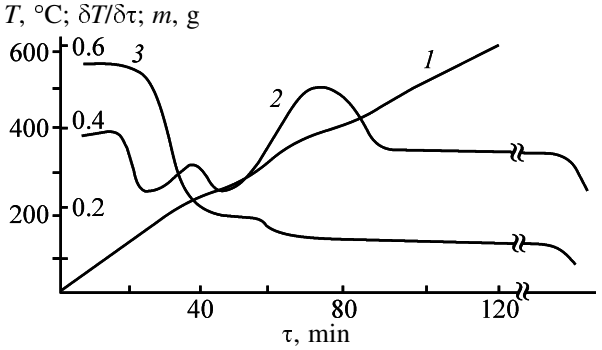

Fig. 3. Curves reflecting variation with time τ of (*1*) temperature T, (*2*) differential change in temperature $\delta t/\delta\tau$, and (*3*) sample weight m.

solvent (Fig. 2). It should be noted that the bend in the plot at 65 vol % concentration of EG approximately corresponds to the composition of the solvate $HOCH_2CH_2OH \cdot 2H_2O$ formed in the EG–H_2O mixture.

The composition of the compounds formed in the CaO–EG system was determined by NMR spectroscopy. The ^1H NMR spectra were recorded on a Tesla BS-467 NMR spectrometer (60 MHz) at 20°C. The chemical shift was determined relative to an external reference (tetramethylsilane). The ^{13}C NMR spectra were recorded on a Bruker WP-200 NMR spectrometer. Deuterated acetone was used as external reference. The Ca(II) concentration in the solutions examined was 0.5 M.

Along with the signal at 64.3 ppm from the CH_2 groups of ethylene glycol, the ^{13}C NMR spectra of the solution formed in the CaO–EG system contain weaker signals at 65.7 and 69.8 ppm, which are probably due to calcium hydroxy glycolate. The ^1H NMR spectrum also confirms the presence of hydroxy glycolate in the solution. In the presence of electrolyte in the solution, the spectral line at 4.3 ppm, assigned to OH groups of the pure solvent, becomes broadened and asymmetrical, which confirms the presence of different types of OH groups. Thus, NMR data show that the main species formed in solutions of the CaO–EG system at ambient temperature is calcium hydroxy glycolate, which is also confirmed by the previous pH-metric studies of these solutions [10]. The presence of hydroxy group in the composition of the dissolved substance should be taken into account in synthesis of calcium-containing compounds based on these solutions. For example, the conditions of the hydroxylapatite preparation may differ from those when calcium glycolate is used as intermediate [3, 4].

As shown above, the fact that the boiling point of ethylene glycol is higher than that of other alcohols makes it possible to considerably extend the temperature interval in which different glycolate products can be synthesized. To get insight into the processes occurring in the CaO–EG system at higher temperature and obtain additional information about the composition and properties of the solutions in this system, a thermogravimetric study was also performed. The dissolved substance was salted-out from concentrated solutions of the CaO–EG system by addition of dioxane. The substrate obtained was analyzed on an OD-102 derivatograph (MOM, Hungary). The derivatograms of the concentrate containing 25 wt % Ca(II) were recorded in the 20–1000°C range.

The DTA curves have endothermic and exothermic peaks (Fig. 3). The endothermic peak at about 190°C is associated with removal of EG molecules of solvation, which is in agreement with the observed weight loss.

As known, above 150°C monosubstituted alkali metal glycolates disproportionate with the formation of disubstituted glycolates and release of EG. In our case, the effect observed corresponds to the transformation of calcium hydroxy glycolate into disubstituted glycolate:

$$Ca(OH)OCH_2CH_2OH \xrightarrow{\Delta} Ca(OCH_2CH_2O) + H_2O.$$

The exothermic effect without weight change is observed at 320°C and is likely due to the oxidation of disubstituted calcium glycolate to calcium carbonate by the reaction

$$Ca(OCH_2CH_2O) + 2.5O_2 \xrightarrow{\Delta} CaCO_3 + CO_2 + 2H_2O,$$

which proceeds without change in the weight of the condensed phase.

Thus, the results of the derivatographic study also show that the solvated basic calcium glycolate exists in solutions of the CaO–EG systems up to 150°C. The transformations occurring in the system at higher temperatures should be taken into account when choosing synthesis conditions of calcium-containing compounds.

CONCLUSIONS

(1) The maximum attainable concentration of Ca(II) in solutions of the CaO–EG system was determined. With increasing temperature from 25 to 90°C, it decreases from 2 to 1.2 M.

(2) The maximum attainable concentration of Ca(II) in solutions of the CaO–ethylene glycol–H_2O ternary system at 25°C was determined. The solubility of calcium oxide increases with increasing ethylene glycol concentration in the mixed solvent. The region of the solution concentrations recommended for the use in inorganic synthesis was determined (concentration up to 0.5 M).

(3) The NMR and thermogravimetric analyses show that calcium hydroxy glycolate is the major species in the solutions formed by dissolution of calcium oxide in ethylene glycol.

(4) The transformations in the calcium oxide–ethylene glycol system at elevated temperature were studied. Calcium hydroxy glycolate is preserved in the system up to 150°C. At higher temperatures, disubstituted calcium glycolate is formed, which is then oxidized to calcium carbonate.

SORPTION AND ION-EXCHANGE PROCESSES

A New Method for Production of Composites Consisting of Expanded Graphite and Amorphous Carbon

Abstract—A new method was developed for production of composites constituted by expanded graphite and amorphous carbon from residual graphite hydrosulfate and a precursor of amorphous carbon, sucrose.

DOI: 10.1134/S1070427207050072

At present, the problem of water treatment to remove contaminants is exceedingly topical [1]. It is frequently solved using sorption methods. Floating carbon–carbon sorbents based on expanded graphite (EG) and amorphous carbon (AmC) are among the most promising sorbents because they combine the valuable properties of the individual components: large surface area and high sorption activity of amorphous carbon with the buoyancy of expanded graphite. The methods for production of EG–AmC composites, described in the literature, are multistage processes performed in an inert atmosphere (He, Ar) and employ expensive raw materials, organic solvents, and a binder for combining the components of the composite [3, 4]. Procedures of this kind are laborious and energy-intensive and have an increased impact on the environment. Consequently, industrial manufacture of EG–AmC composite sorbents requires that methods for their production should be improved and simplified.

Rather attractive in this regard is a single-stage process for production of EG–AmC composites, in which expansion of a graphite intercalation compound, its impregnation with a precursor of amorphous carbon, and carbonization of the precursor would occur simultaneously, in the same process stage, without organic solvents and inert atmosphere. Until now, a process of this kind could not be performed because the commonly used graphite intercalation compounds are effectively expanded only at 900–1200°C, whereas amorphous carbon is strongly oxidized in air at these temperatures, which leads to irrational utilization of raw materials.

Recently, an industrial method for manufacture of residual graphite hydrosulfate, which can be effectively expanded even at temperatures of about 500°C, has been developed [5]. With this compound, it was possible to perform for the first time a single-stage process for production of EG–AmC composites at comparatively low temperatures and, as a result, to discard the inert atmosphere. A successful choice of a precursor of amorphous carbon, sucrose, also made it possible to avoid use of an additional binder for combining the components of a composite.

EXPERIMENTAL

To obtain EG–AmC composites, we used residual graphite hydrosulfate [TU (Technical Specification) U 26.8-20 372 011-001–2002] produced from a GSM-1 flake graphite from Zaval'evskoe deposit (Ukraine) and sucrose (Merck) with an ash residue of 0 wt % as a precursor of amorphous carbon. Sucrose was ground into a fine powder and mixed in the course of several minutes with residual graphite hydrosulfate in a glass vessel on an MPW-300 stirrer. After that, distilled water was added in an amount equal to the mass of graphite and agitation was continued for an additional 10 min. The content of components of the mixture was varied, but its total mass remained constant (25 g). After the mixing stage, the composite was kept at 105°C for 2 h for partial caramelization of sucrose. After that, the mixture was transferred in 3-g portions to cold stainless steel cells placed for 4 min in a Fisher Scientific Isotemp® Model 650 programmable muffle furnace heated to 650°C. The thermal treat-

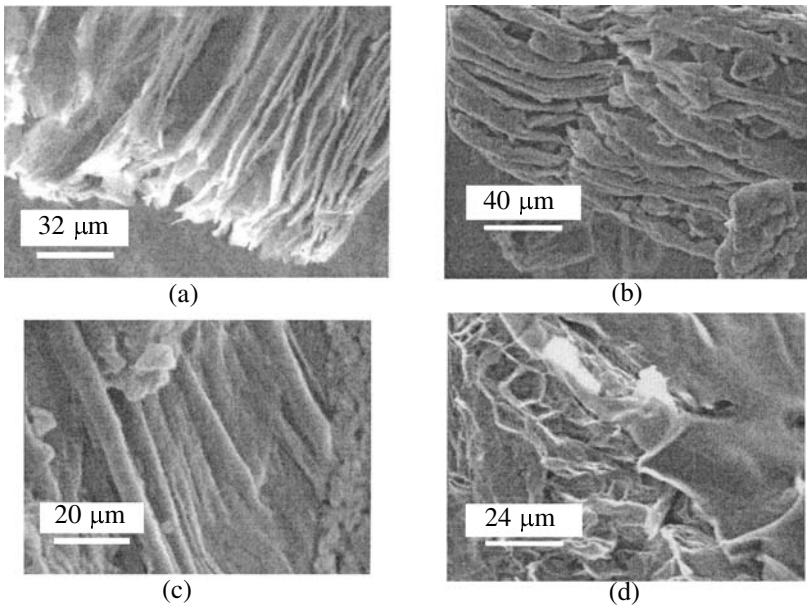

Fig. 1. SEM micrographs of products formed in different stages of synthesis of the EG–AmC composite material. RGH: (a) starting, (b) after mixing with sucrose, (c) after keeping in an oven at 105°C for 2 h; (d) EG–AmC composite.

ment yielded a finished product in 25 to 70% yield, depending on the composition of the starting mixture. The specific surface area was found by the method of low-temperature adsorption of argon (BET) in accordance with GOST (State Standard) 13 144–79. The composites obtained were studied by scanning electron microscopy (SEM) on a JEOL JSM-T300 instrument.

The sorption of phenol from its aqueous solutions with a concentration of 10–50 mg l^{-1} by composite samples was studied in a temperature-controlled (25°C) glass vessel with a ground-in glass cover and a magnetic stirrer. A 500-ml portion of a phenol solution was poured into the reactor, 0.35–0.40 g of a composite (1–2-mm grains) was placed on the surface of the solution, and agitation was switched on. The liquid phase was sampled at regular intervals of time and the content of phenol in the samples was determined by the standard photoelectrocolorimetric method with 4-aminoantipyrine [6]. The experiment was carried out in the course of 12–48 h until the sorption equilibrium was attained, which was indicated by the fact that the phenol concentration in the solution ceased to vary.

Figure 1a shows a micrograph of the starting residual graphite hydrosulfate (RGH) produced by the method described in [5]. It can be seen that, in contrast to other graphite intercalation compounds [7], the RGH used shows a considerable separation into layers. This results in that the second component of the composite easily penetrates, even under simple mechanical agitation, into spaces between graphite stacks. As a result, graphite flakes are homogeneously and densely filled with particles of the second component, precursor of amorphous carbon (sucrose particles in the given case) (Fig. 1b).

Further keeping in an oven at 105°C for 2 h leads to partial caramelization of sucrose and spreading of the melt to give a uniform thin layer over the surface of RGH flakes (Fig. 1c).

The caramelization of sucrose under mild conditions is accompanied by polycondensation reactions, which favors an increase in the yield of amorphous carbon in the course of its subsequent carbonization [8, 9].

The material obtained upon caramelization of sucrose is subjected to heat treatment at 300–900°C, which leads to swelling of the graphite intercalation compound, which is conjugated in space and time with the progressing melting and caramelization of sucrose, impregnation of the cellular structure of swollen graphite with molten caramel, and carbonization of the precursor of amorphous carbon, to give the final product, EG–AmC composite. The heat treatment parameters (in particular, temperature and time of treatment) exert a strong influence on the properties of the material obtained. In special-purpose experiments, we determined the optimal values of these parameters, with production of composite materials

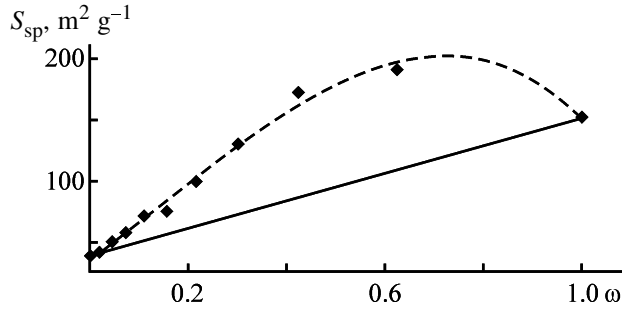

Fig. 2. Specific surface area S_{sp} of EG–AmC composites vs. their composition ω (mass fraction of amorphous carbon in a composite). Straight line, calculation in terms of the additive model with account of the yield of amorphous carbon.

having the most developed surface used as the target condition. Values of the specific surface area of EG–AmC composites in relation to the temperature and time of treatment are listed below.

Specific surface area S_{sp} of an EG–AmC composite with 16 wt % amorphous carbon in relation to the temperature and time of swelling

T, °C	300	400	450	500	550	600
S_{sp}, m^2 g^{-1}	0.4	2	8	29	50	29
T, °C	650	700	750	800	850	900
S_{sp}, m^2 g^{-1}	27	27	27	31	21	19

S_{sp}, m^2 g^{-1}	22	70	89	90	66	53	52
τ, min	2	3	4	5	7	10	30

The maximum surface area is obtained at 550°C, with keeping at this temperature for 4 min. Any further increase in the temperature or time of treatment is inadvisable. Moreover, it follows from the data presented here that this leads to burning-out of the amorphous carbon phase. The yield of the composite at the optimal composition and time and temperature of treatment is about 50%.

Figure 1d shows a SEM micrograph of one of the EG–AmC composites obtained. The micrograph well shows the macroporous structure of the composite with coarse mouth-like pores belonging to the graphite matrix and the amorphous carbon phase coating the vermicules of expanded graphite. The texture of the material in Fig. 1d is typical of composites produced from expanded graphite and in situ prepared activated carbon [10, 11].

The partial melting of sucrose in the production of the composite, accompanied by spreading of the melt over the surface of the graphite substrate, provides an intimate contact between the two phases in the product obtained. This structure imparts a sufficient mechanical strength to the EG–AmC composite. An EG–AmC composite with an AmC content of 16 wt %, placed on the surface of water, remained intact for a month.

Figure 2 compares specific surface areas of the EG–AmC composites obtained, measured by the method of low-temperature sorption–desorption of argon, with those calculated in terms of the additive model. The additive model presumes that the specific surface area of the composite is the sum of the specific surface areas of its individual components:

$$S_{sp} = \omega_{AmC} S_{sp.AmC} + \omega_{EG} S_{sp.EG}, \quad (1)$$

where S_{sp} is the specific surface area of an EG–AmC composite of composition $\omega_{AmC} : \omega_{EG}$ (m^2 g^{-1}); ω_{AmC} and ω_{EG}, mass fractions of AmC and EG in a composite; and $S_{sp.AmC}$ and $S_{sp.EG}$, specific surface areas of the individual components (m^2 g^{-1}).

In the entire range of sucrose concentrations, except at the end points corresponding to the individual components, the measured specific surface areas of the composites obtained markedly exceed the values calculated by Eq. (1). The deviations grow as the content of amorphous carbon in the composite increases. This behavior can be attributed to a concerted effect of two factors: (i) acid catalysis of condensation reactions that occur upon heating of sucrose and (ii) activation of the forming amorphous carbon by gaseous components (H_2SO_4, SO_2, SO_3, etc.) and water, liberated in expansion of residual graphite hydrosulfate.

Because the composites obtained were intended from the very beginning for use as high-efficiency floating sorbents for purification of natural and waste water, we studied their behavior in sorption of a real contaminant, phenol, from aqueous solutions. The measured values of the limiting sorption of the composites for phenol grow as the fraction of amorphous carbon increases (Fig. 3) to reach a maximum at an AmC content of the composite equal to 63 wt %. A clearly pronounced correlation is observed between the limiting sorption capacities of the composites for phenol and their specific surface areas, with a correlation coefficient ρ = 0.953 (Fig. 3). In this case, despite the small specific surface area of the composite with 63 wt % AmC (S_{sp} = 192 m^2 g^{-1}), it shows a rather high limiting sorption capacity for phenol (A = 23.7 mg g^{-1}), i.e., it is virtually as good in this regard as commercial samples of granulated activated carbons [12]. At the same time, the EG–AmC composite, in contrast to activated carbon, has buoyancy, which

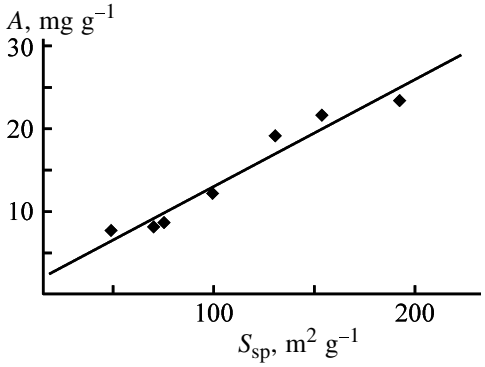

Fig. 3. Sorption capacity A of the EG–AmC composite for phenol vs. the specific surface area S_{sp} of the composite.

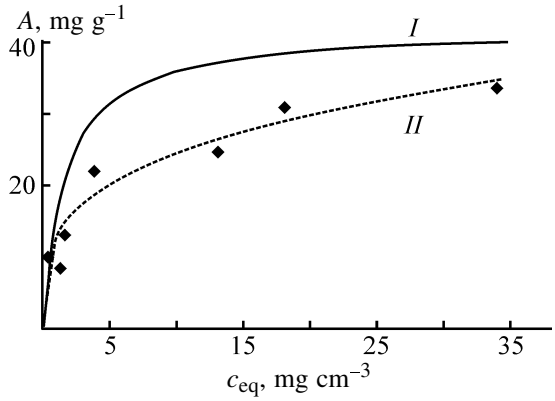

Fig. 4. Isotherm of phenol sorption A by a composite containing 63 wt % amorphous carbon. (c_{eq}) Equilibrium concentration of phenol. Points, experimental data; calculation: (*I*) by Langmuir equation and (*II*) by Freundlich equation.

markedly facilitates purification of large open aquatic surfaces and, in particular, natural water basins.

Figure 4 shows an isotherm of phenol sorption at 25°C by a composite containing 63 wt % amorphous carbon. The Langmuir and Freundlich equations were used as models in experimental data processing. The data obtained are better described by the Freundlich isotherm, which is characteristic of adsorption on surfaces with an exponential energy distribution of active centers. This indicates that, in all probability, there occur both chemical (chemisorption involving surface functional groups) and physical types of adsorption [13].

CONCLUSIONS

(1) A new method for production of composite materials composed of expanded graphite and amorphous carbon from residual graphite hydrosulfate and sucrose was suggested. The method is distinguished from the presently existing techniques by lower time and energy expenditure and better availability of raw materials.

(2) It was shown by scanning electron microscopy that the products obtained are indeed composite materials composed of expanded graphite and amorphous carbon, in which an intimate contact between the solid phases of graphite and amorphous carbon is provided by specific features of the synthesis of the composite. This yields a sufficient mechanical strength of the materials obtained.

(3) Synthesis of composites by the method suggested leads to an additional increase in their surface area, compared with the additive value. This increase is provided by acid catalysis of the condensation reactions occurring in heating of sucrose and activation of the forming amorphous carbon by gaseous acid products evolved in expansion of residual graphite hydrosulfate.

(4) The sorption activity of the materials obtained in absorption of phenol from its aqueous solutions is comparable with that of commercial activated carbons. The composites obtained are favorably distinguished from activated carbons by their capacity to remain on the surface of a liquid for a long time.

Abstract—Halide–ammonium electrolytes were developed for electrochemical production of high-purity manganese.

DOI: 10.1134/S1070427207050084

Metallic manganese of purity 99.7–99.8% [GOST (State Standard) 6008–90] is produced by electrolysis, as a rule, from sulfate–ammonium solutions with the use of insoluble lead cathodes [1]. A major disadvantage of this technique is that cathode deposits of manganese contain inclusions of sulfur (0.03–0.1%) and alloying components of lead anodes: tin, antimony, and cobalt [1, 2].

High-purity manganese is necessary for obtaining new semimagnetic semiconductors, single- and polycrystalline ferrites, materials with magnetooptical properties and luminophores, high-purity metal oxide catalysts and inorganic sorbents, and precision alloys. High-purity manganese can be obtained by electrolysis on replacing sulfate–ammonium electrolytes with those of halide–ammonium composition [3, 4]. Development of promising electrolyte compositions requires detailed information about the electrochemical behavior of manganese in these electrolytes, including that concerning the kinetics and mechanism of anodic dissolution of manganese and cathodic reduction of manganese ions. Published data on fundamental aspects of these electrode processes are rather contradictory.

The standard electrode potential of manganese is –1.185 V [5]. Therefore, it is necessary to take into account corrosion processes in cathodic deposition of manganese, which may govern the current efficiency by the metal. At low current densities, the rate of electroreduction of Mn^{2+} ions may be comparable with the rate of corrosion dissolution of cathode deposits of manganese.

The aim of this study was to determine cathode current efficiencies by manganese in its deposition from chloride–bromide–ammonium electrolytes on various cathode supports and to analyze the kinetics and mechanism of discharge–ionization of manganese.

The cathode current efficiencies by manganese were found from changes in the mass of cathodes thoroughly washed after electrolysis and dried with ethanol and diethyl ether and from the theoretical amounts of manganese that would be deposited on the cathodes at a 100% current efficiency by manganese. Polarization curves were measured on a smooth rotating disc electrode (RDE) made of electrolytic manganese, with a PI-50-1 potentiostat and PR-8 programmable unit at a potential sweep rate of 4 mV s^{-1} and electrode rotation rate of 980 rpm. The cathode and anode spaces of a glass cell were separated by a glass filter. The atmospheric oxygen dissolved in the electrolyte was removed with a flow of high-purity nitrogen. The electrolyte temperature was maintained with a U-4 thermostat. The potentials of the working electrode were measured relative to a saturated silver chloride reference electrode. A plate of electrolytic manganese served as the auxiliary electrode. The electrolytes were prepared from $MnCl_2$ of chemically pure grade, NH_4Br of ultrapure grade, and water double-distilled in a quartz apparatus. In the electrolytes studied, the exchange equilibrium with the electrode was attained in the course of 3–5 min, after which the pH value of the solution was 5.5 ± 0.1.

Figure 1 shows the dependences of the current efficiency by manganese, η (%), on the cathode current density, measured at 25°C in $MnCl_2$ + NH_4Br solutions of various quantitative compositions on several metals used as cathode supports. It can be seen that the current efficiency by manganese depends on the

electrolyte composition. Changing the NH_4Br concentration within the range 0–0.5 M only slightly affects the value of η, which is as high as 40% in a solution composed of 1.0 M $MnCl_2$ + 0.5 M NH_4Br. As the NH_4Br concentration is raised to 2.0 (curve *5*) and 3.0 M (curve *6*) in a solution containing 1.0 M $MnCl_2$, the value of η on a titanium support increased to 70 and 73%, respectively.

Gamali et al. [6] found that η depends on the atomic radius of the metal of a cathode support. Manganese is deposited with a high current efficiency on metals whose atomic radii are close to that of manganese (1.30 Å). From this standpoint, the most promising metals for use as cathode supports are Ni (1.24 Å), Co (1.25 Å), Fe (1.26 Å), Cu (1.28 Å), Ir (1.35 Å), Pt (1.38 Å), and Zn (1.39 Å), as well as Cr (1.27 Å) and Rh (1.34 Å) [7]. It is known that titanium has a high chemical resistance in electrolyte solutions, but its atomic radius (1.46 Å) [7] is markedly different from that of manganese. In this study we compare the values of η obtained in an electrolyte of the composition 2 M $MnCl_2$ + 2 M NH_4Br on titanium (Fig. 1, curve *7*) and nickel (Fig. 1, curve *8*) supports at various current densities. In the current density range 160–300 mA cm^{-2}, these values were 83–86% on titanium and 94–96% on nickel, despite that the overvoltage of hydrogen evolution on titanium (0.97 V) exceeds that on nickel (0.62 V) [8]. The overvoltage of hydrogen evolution on mercury is very high (1.40 V) [8], and, therefore, η values as high as 99.5–100% were obtained on a manganese amalgam cathode (Fig. 1, curve *9*).

Figure 2 shows experimental anodic and cathodic polarization curves measured on a manganese RDE in an electrolyte composed of 2.0 M $MnCl_2$ + 2.0 M NH_4Br at pH 5.5±0.1 and temperatures of 18, 40, and 60°C (Fig. 2a) and the same curve in the semilog coordinates. It can be seen that the anodic polarization curves are smooth, whereas the cathodic curves have inflections indicating that the cathodic process is hindered in certain range of potentials. As the temperature is elevated, the rates of the anodic and cathodic processes grow and the regions of current delay on the cathodic curves are shifted to more negative potentials and higher current densities.

Inflections in the cathodic polarization curves of manganese are attributed in the literature to attainment of limiting currents of kinetic or diffusion nature [9, 10] or to occurrence of corrosion processes [11]. However, beyond the region of limiting currents, the rate-determining electrode reaction responsible for the limiting current should change. For example,

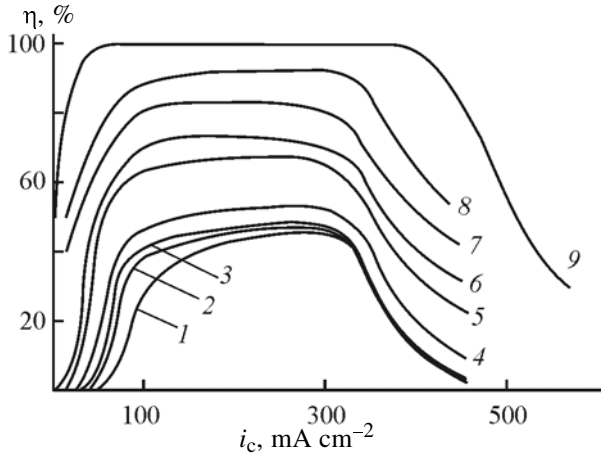

Fig. 1. Current efficiency by manganese η vs. the cathode current density i_c in (*1–6*) 1.0 M $MnCl_2$ and (*7–9*) 2.0 M $MnCl_2$ solutions at various NH_4Br concentrations (25°C). the discharge of Mn^{2+} ions can be replaced with hydrogen liberation from water, or discharge of high-ligand complexes $[MnCl_4]^{2-}$ may occur instead of the discharge of low-ligand complexes [$MnCl^-$] or [$MnCl_2$] [12]. Such changes of the mechanism of the electrode process at the manganese cathode have not been confirmed experimentally, despite being postulated by numerous authors for explaining the "anomalous" run of polarization curves [1, 9–11].

Inflections in the cathodic polarization curves of manganese are attributed in the literature to attainment of limiting currents of kinetic or diffusion nature

[9, 10] or to occurrence of corrosion processes [11]. However, beyond the region of limiting currents, the rate-determining electrode reaction responsible for the limiting current should change. For example, the discharge of Mn^{2+} ions can be replaced with hydrogen liberation from water, or discharge of high-ligand complexes $[MnCl_4]^{2-}$ may occur instead of the discharge of low-ligand complexes $[MnCl^-]$ or $[MnCl_2]$ [12]. Such changes of the mechanism of the electrode process at the manganese cathode have not been confirmed experimentally, despite being postulated by numerous authors for explaining the "anomalous" run of polarization curves [1, 9–11].

Probably, the occurrence of an inflection in the cathodic polarization curves of manganese in solutions of its salts is due to a change in the surface charge of the electrode after the attainment of the zero-charge potential E_{zc}. As can be seen in Fig. 2, the potential of the onset of the inflection in the polarization curve obtained at 18°C is –1.332 V (relative to silver chloride electrode), which corresponds to the reference value of E_{zc} for manganese (–1.11 V relative to standard hydrogen electrode [13]). As the temperature is raised, the potential of the onset of the inflection shifts in the negative direction to –1.349 V relative to silver chloride electrode at 40°C and –1.398 V at 60°C.

It should be noted that inflections in the cathodic polarization curves at a potential of an uncharged electrode surface were first observed by Kolotyrkin and co-workers in a study of the hydrogen evolution on a lead electrode, and later also on thallium and cadmium electrodes, in a sulfuric acid solution [14].

Clearly pronounced linear portions are seen in the polarization curves plotted in the semilog coordinates (Fig. 2b), with portions of this kind present in the cathodic curves both before and after the inflections. The only electrode process occurring on manganese anodes in the region of linear portions of the polarization curves is ionization of manganese. The slope of the linear portion of the anodic curve obtained at 18°C is 0.116 V per $\log i$ unit; on raising temperature to 60°C, this parameter slightly increases. The linear portions of the anodic polarization curves shown in Fig. 2b can be regarded as Tafel portions, because it is apparent that the anodic ionization of the manganese RDE (980 rpm) in the region of these portions occurs with kinetic hindrance.

The theoretical values of the slope of the Tafel portions of the anodic polarization curves were calculated by the formula

$$b_a = 2.303RT/\beta zF, \quad (1)$$

where R is the universal gas constant; T, absolute temperature; β, transport coefficient of the anodic process; z, number of electrons involved in an elementary event of the rate-determining step of the electrode process; and F, Faraday number.

At 18°C, the theoretical value of b_a is 0.1156 V at $z = 1$ and $\beta = 0.5$. Such a value of b_a is virtually equal to its experimental value and, consequently, a single electron is involved in the elementary event of the rate-determining step of anodic ionization of manganese, and the electrode process occurs in steps:

$$Mn^0 \rightarrow Mn^+_{ads} + e, \quad (2)$$

$$Mn^+_{ads} \rightleftarrows Mn^{2+} + e. \quad (3)$$

Intermediate ions Mn^+_{ads} formed by reaction (2) can be further oxidized by reaction (3) or interact with each other within the electrical double layer (disproportionation reaction):

$$2Mn^+_{ads} \rightleftarrows Mn^0 + Mn^{2+}. \quad (4)$$

The rate of the anodic ionization of manganese is determined by the rate of the slow step of abstraction of the first electron from surface manganese atoms and is described by the equation

$$i_a = k_a \exp(\beta FE/RT), \quad (5)$$

where k_a is the rate constant of the anodic process, and E is the electrode potential.

The adsorbed intermediate species Mn^+_{ads} are rather unstable and are rapidly consumed by concurrent reactions (3) and (4). The high chemical activity of the Mn^+_{ads} species points to their high energy capacity. The formation of just these species is, in all probability, the slowest step of the electrode process and the reason for the electrode polarization.

As shown above, the current efficiency by manganese on various cathode supports, except that composed of an amalgam, from an electrolyte of composition 2.0 M $MnCl_2$ + 2.0 M NH_4Br is lower than 100%. A possible reason may be both corrosion-induced dissolution of manganese cathode deposits and hydrogen evolution at the cathode, concurrent with manganese deposition. According to data of various authors, the pH value of the electrolyte solution near the surface of the manganese electrode differs from that in the bulk of the electrolyte and falls within the range 8.1–10.5 [9]. At these pH values, the concentration of hydroxonium ions in solution is negligibly low. Being a salt of a weak base and strong acid, ammonium chloride is hydrolyzed in solution to give ammonia hydrates whose dissociation constant is

1.81×10^{-5} at 25°C [15]. Consequently, the content of ammonium ions in the solution is also exceedingly low. Under these conditions, the only possible source of hydrogen ions that discharge at the cathode is water, whose decomposition requires high values of the cathodic polarization of manganese. Therefore, it may be considered that only manganese ions are discharged at the cathodes at low polarization values and the corresponding linear portions of the cathodic polarization curves reflect only this process.

The slope of the initial linear portion of the cathodic polarization curve measured at 18°C and shown in Fig. 2b is 0.117 V per $\log i$ unit. As the temperature is raised, the slope of these linear portions changes only slightly. Such a value of the slope of the Tafel portion of the polarization curve indicates that a single electron is involved in an elementary event of the rate-determining step of discharge of manganese ions.

The reasoning behind the above analysis of the anodic ionization of manganese suggests that the discharge of manganese ions also occurs in steps

$$Mn^{2+} + e \rightarrow Mn^{+}_{ads}, \quad (6)$$

$$Mn^{+}_{ads} + e \rightleftarrows Mn^{0} \quad (7)$$

by a branched mechanism, because chemical disproportionation (4) may proceed in parallel with reaction (7). The rate of the electrode process, determined by the rate of formation of unstable intermediate species Mn^{+}_{ads}, is given by

$$i_c = k_c a_{Mn^{2+}} \exp(-\alpha FE/RT), \quad (8)$$

where k_c and α are the rate constant and transport coefficient of the cathodic process, respectively; and $a_{Mn^{2+}}$ is the activity of manganese ions.

It should be noted, however, that the real mechanisms of the anodic and cathodic processes are apparently more complex because it is quite probable that other components of the electrolyte solution are involved in these processes.

CONCLUSIONS

(1) Manganese can be cathodically recovered from chloride–bromide–ammonium electrolytes with high current efficiency, especially in those cases when metals whose atomic radii are close to that of manganese are used as cathode supports.

(2) The most probable reason for the appearance of inflections in the polarization curves describing the discharge of manganese ions is that the charge of the electrode surface changes after the zero-charge potential is reached.

(3) The mechanisms of the anodic ionization of manganese and cathodic discharge of manganese ions are multistep and branching: the chemical reaction of disproportionation of intermediate species Mn^{+}_{ads} can occur in parallel with the single-electron electrochemical reactions of discharge–ionization. The rate-determining step for both the anodic and cathodic processes is that in which Mn^{+}_{ads} species are formed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetic Parameters of Electroextraction of Cobalt from Aqueous Solutions of Cobalt and Manganese Sulfates

L. A. Voropanova and L. P. Khomenko

North-Caucasian Institute of Mining and Metallurgy (State Technological University), Vladikavkaz, North Ossetia, Russia

Received March 24, 2006; in final form, September 2006

Abstract—The effect exerted by cobalt(II) concentration in the initial solution and temperature on the kinetics of cobalt(II) electroextraction from cobalt(II) and manganese(II) sulfate solutions was studied. The kinetic parameters of the process were determined.

DOI: 10.1134/S1070427207050096

The known methods of treatment of sulfate and chloride–sulfate solutions of cobalt(II) to remove manganese(II) are manganese(II) oxidation with gaseous chlorine and sorption of cobalt(II) on an anion exchanger followed by its desorption with an acid solution [1, 2]. One of promising methods is the electrochemical treatment [3]. Cathodic cobalt obtained from sulfate and chloride–sulfate solutions of cobalt(II) and manganese(II) using this method has high purity, lustrous smooth surface, and, according to the spectral and X-ray phase analyses, contains virtually no manganese.

This study is concerned with the effect exerted by cobalt concentration in the initial solution and electroextraction temperature on the kinetic parameters of cobalt electroextraction from the sulfate solutions of cobalt(II) and manganese(II).

The electrolytic separation of cobalt(II) from solution is known. According to reference data of [4], the standard electrode potential of the reaction E^0 is

$$Co^{2+} + 2e \rightarrow Co,\ E^0 = -0.277\ V.$$

The manganese anions move toward the anode and are separated on the lead anode with the anodic sludge. According to the reference data of [4],

$$MnO_2 + 4H^+ + 2e \rightarrow Mn^{2+} + 2H_2O,\ E^0 = +1.23\ V;$$

$$MnO_4^- + 8H^+ + 5e \rightarrow Mn^{2+} + 4H_2O,\ E^0 = +1.51\ V;$$

$$MnO_4^- + 2H_2O + 3e \rightarrow MnO_2 + 4OH^-,\ E^0 = +0.588\ V.$$

Thus, the Mn^{2+} cation is oxidized on the anode by the reactions

$$Mn^{2+} - 2e + 6H_2O = MnO_2 + 4H_3O^+,$$

$$Mn^{2+} - 5e + 2O_2 = MnO_4^-.$$

The MnO_4^- ion is reduced on the cathode by the reaction

$$MnO_4^- + 5e + 8H_3O^+ = Mn^{2+} + 12H_2O; \quad (1)$$

however, the Mn^{2+} ion is not reduced on the cathode, because $E^0(Mn^{2+}/Mn^0) = -1.18$ V.

The scheme of the electrolyzer is shown in Fig. 1. The solution was fed into the anode cell and removed from the cathode space. The anode was made of lead containing 1% silver, and the cathode was made of

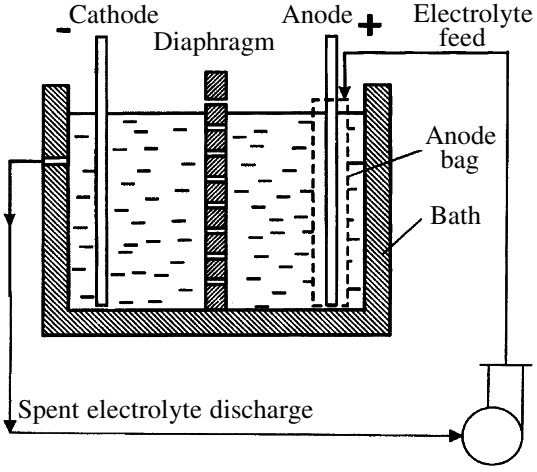

Fig. 1. Scheme of the electrolyzer.

aluminum. The supply and removal of the electrolyte were performed in a closed loop using a pump.

In such method of the electroextraction, MnO_4^- anions forming on the anode are unlikely to appear in the cathode space, because, for example, Mn^{2+} ions present in the initial solution and MnO_4^- ions can react with each other:

$$3Mn^{2+} + 2MnO_4^- + 2H_2O = 5\ MnO_2 + 4H^+. \quad (2)$$

Thus, the manganese(II) ion is removed to the anodic sludge in the form of MnO_2 by reaction (2) or in the form of other difficultly soluble compounds. This makes penetration of MnO_4^- anions into the cathode space and, consequently, their recovery on the cathode by reaction (1) impossible. Difficultly soluble manganese compounds incorporated into anodic sludge are accumulated on a dense filter cloth, anode bag, and do no not enter the cathode space. Passage of the anodic sludge particles toward the cathode is also impeded with a porous diaphragm.

This method for feeding initial solution into an electrolyzer and removing spent electrolyte makes quality of the cathodic cobalt surface better and decreases the concentration of manganese in it. In this method, the concentration of manganese(II) ions is not limited, especially if, according to reaction (2), the molar ratio of Mn^{2+} ions in the initial solution to MnO_4^- ions in the anolyte $Mn^{2+}/MnO_4^- \geq 3/2$.

At many plants for the electrolytic production of cobalt, the electroextraction is performed at pH 1.1–1.4 or 4.6–6.5 [2]. The studies show that the mechanism of the cathodic process is different in the following pH ranges: 0.5–2.2, 2.5–4.0, and from pH 4.0 to a value corresponding to the onset of cobalt hydr°lysis [2]. At pH 0.5–2.2, Co^{2+} ions are discharged on a negatively charged surface of the cathode by addition of two electrons to a discharging simple Co^{2+} ion [2].

We studied the cobalt electroextraction at pH 1 (Tables 1, 2).

As follows from these data, at a constant current density and the same concentration of manganese(II) ions in the initial solution, the results of the electrolysis depend on the concentration of the initial solution, temperature, electrolyte flow rate, voltage, time, and other electrolysis parameters (Tables 1, 2). The current

Table 3. Phase composition of anodic sludges according to X-ray phase analysis

Electro-extraction time, h	Content, vol %								
	$PbSO_4$	PbO_2	PbO	$CoSO_4$	$MnSO_4$	$Mn(OH)_4$	$(Co, Mn)(CoMn)_2O_4$	$MnPbMn_6O_{14}$	others
6	19	22	11	10	10	4	12	–	12
12	17	28	10	14	7	9	11	4	0
18	16	22	14	13	10	8	8	9	0

efficiency by cathodic cobalt increases, whereas the specific consumption of the electric power decreases with increasing concentration of the cobalt(II) ions in the electrolyte and temperature. The loss of cobalt in the anodic sludge is 9.62, 11.77, 1.08, and 5.78% in run nos. 1, 2, 3, and 4, respectively (Table 2). The loss increases with decreasing temperature and significantly decreases as the number of strippings of the anodic sludge and cathodic cobalt decreases. In runs of Table 1 and in run nos. 1 and 2 of Table 2, the interval at which the cathode and anode were stripped was 6 h; in run no. 3 (Table 2), it was 18 h for the cathode and 6 h for the anode; and in in run no. 4 (Table 2), it was 18 h for the cathode and 12 and 6 h for the anode. Decreasing the number of anodic sludge strippings increases the bath voltage.

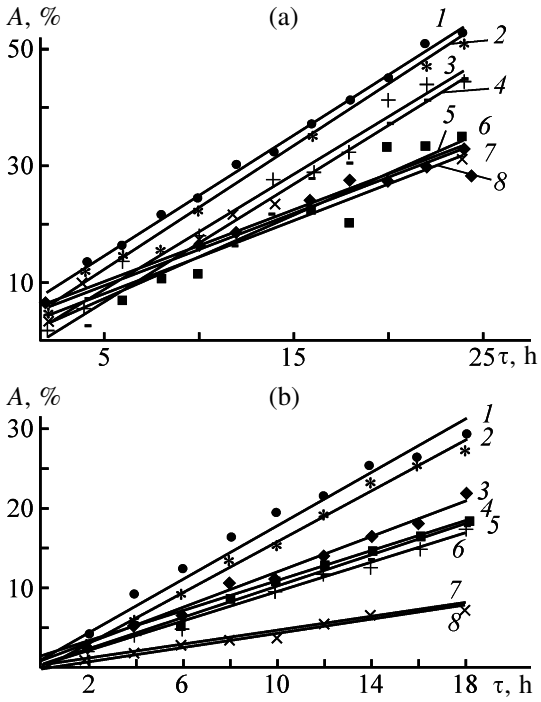

Fig. 2. Dependence of the degree of extraction A of cobalt and manganese on the electrolysis time τ in runs of Table 2: (a) nos. 1 (27°C) and 2 (22°C); (b) nos. 3 (20°C) and 4 (15°C). (a) (*1*) Mn-22a, (*2*) Mn-22c, (*3*) Mn-27c, (*4*) Mn-27a, (*5*) Co-22a, (*6*) Co-27a, (*7*) Co-22c, and (*8*) Co-27c; (b) (*1*) Mn-20a, (*2*) Mn-20c, (*3*) Co-20c, (*4*) Co-20a, (*5*) Mn-15a, (*6*) Mn-15c, (*7*) Co-15c, and (*8*) Co-15a.

The spectral analysis revealed no more than 0.01 wt % manganese in the cathodic cobalt. Unlike a box-type batch electrolyzer, the given electrolyzer, suitable for continuous electroextraction, also ensures decrease in the concentration of manganese impurity in the cathodic cobalt by more than an order of magnitude.

According to the X-ray phase analysis, anodic sludges obtained by electrolysis in aqueous solutions of cobalt(II) and manganese(II) sulfates in runs indicated in Table 1 contain compounds of lead, cobalt, and manganese and their double salts (Table 3).

Figure 2 shows how the cobalt(II) and manganese(II) extraction depends on the electrolysis time under the conditions of (a) runs no. 1 (27°C), 2 (22°C), and (b) run nos. 3 (20°C) and 4 (15°C) (Table 2).

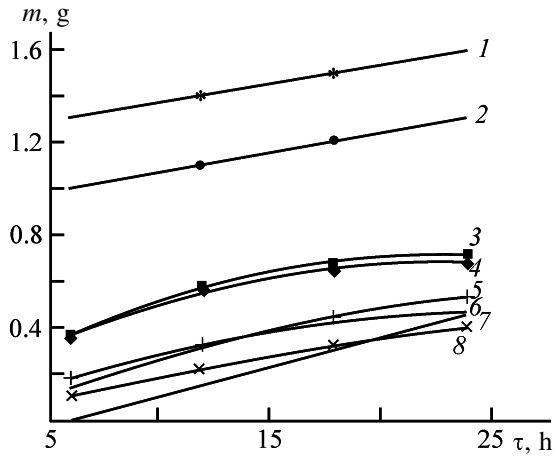

Fig. 3. Variation with time τ of the mass *m* of cathodic cobalt and anodic sludge (as) formed during the electroextraction: (*1*) Co-20, (*2*) Co-15, (*3*) Co-27, (*4*) Co-22, (*5*) as-27, (*6*) as-22, (*7*) as-20, and (*8*) as-15.

equation adequate to the dependences of Figs. 2a and 2b. Figures 2a and 2b and Table 4 show that the degree of manganese and cobalt extraction increases with increasing electrolyte temperature and the increase in the cobalt(II) concentration facilitates its extraction on the cathode.

Variation with time of the masses of the electroextracted cathodic cobalt and anodic sludge is shown in Fig. 3. As seen, the masses increase as the concentration of cobalt(II) ions in the electrolyte and the temperature increase.

The electroextraction of manganese ions can be considered in terms of equations of formal kinetics by taking into account that, in the course of the process, the pH and electrolyte volume are constant, the cobalt concentration varies only slightly, the concentrations of manganese ions are far from saturation, and the concentration of manganese ions is lower by an order of magnitude than the cobalt(II) concentration during the whole process.

Table 5 shows how the residual concentration of manganese(II) ions varies with time and temperature in run nos. 1–4 (Table 2).

The data of Table 6 characterize the $c = f(\tau)$, $\ln(c_{in}/c) = f(\tau)$, $c^{-1} = f(\tau)$, and $c^{-2} = f(\tau)$ dependences obtained for manganese ions from data of Table 5.

As follows from the data obtained, under the conditions of run nos. 1 and 2 the $c = f(\tau)$ functions are linear and have the form

$$c = a_1\tau + b_1. \quad (3)$$

For run nos. 3 and 4, the $c^{-1} = f(\tau)$ functions are linear and have the form

$$c^{-1} = a_2\tau + b_2. \quad (4)$$

The coefficients of the linear regression equations (3) and (4), calculated by the least-squares method, are listed in Tables 7 and 8. It is seen that the correlation coefficients are close to unity, i.e., functions (3) and (4) are adequate to the experimental data.

A slight difference in temperatures did not result in the change in the process mechanism, and, consequently, in the order of the electroextraction reaction. Under these conditions, the rate with respect to the extracted manganese can be expressed by the equation

$$V = -dc/d\tau = kc^n, \quad (5)$$

Table 6. Correlation coefficients for the concentration vs. time dependences obtained for manganese ions from data of Table 5

	Mn-a	00006	0.0555	0.9869

Table 9. Coefficients of Eq. (6)

T, °C	Mn	c_{in}, mmol dm^{-3}	k, mmol dm^{-3} h^{-1}
27	Mn-c	18.324	0.4092
	Mn-a	18.026	0.4050
22	Mn-c	18.971	0.3534
	Mn-a	19.322	0.3521

where k is the rate constant; τ, electroextraction duration; and c, residual concentration of manganese ions to a time moment τ.

The solution of differential equation (5) at $n = 0$ is the relationship

$$c = c_{in} - k\tau, \quad (6)$$

and at $n = 2$, the relationship

$$c^{-1} = c_{in}^{-1} + k\tau. \quad (7)$$

From Eqs. (3) and (6) we obtain the relationships $a_1 = -k$, $b_1 = c_{in}$, and from Eqs. (4) and (7), the relationships $a_2 = k$ and $b_2 = c_{in}^{-1}$. The results are given in Tables 9 and 10.

Table 10. Coefficients of Eq. (7)

T, °C	Mn	c_{in}^{-1}, dm^3 mmol^{-1}	k, dm^{-3} mmol^{-1} h^{-1}
20	Mn-c	0.0545	0.0012
	Mn-a	0.0550	0.0013
15	Mn-c	0.0545	0.0006
	Mn-a	0,0555	0.0006

The reaction order ($n = 0.15$) (Table 2, run nos. 1, 2) was also calculated by the half-conversion method.

The reaction order $n \approx 0$ shows that the manganese electroextraction depends only slightly on the initial concentration of manganese ions (Table 2, run nos. 1, 2), whereas the reaction order $n = 2$ confirms the existence of the above dependence (Table 2, runs nos. 3, 4).

The activation energy E can be calculated by the Arrhenius equation

$$\ln k = \ln k^0 - ER^{-1}T^{-1},$$

where T is temperature (K).

The activation energies of the manganese electroextraction, as estimated from the experimental data (Table 10) obtained within 15–20°C, are $E_c = 97.3$ kJ on the cathode and $E_a = 108.5$ kJ on the anode.

The reaction order $n \approx 0$ and the activation energy $E = 20.6$–21.6 kJ suggest that the manganese electroextraction under the conditions of run nos. 1, 2 (Table 2) is controlled by internal diffusion.

The reaction order ($n = 2$) and the activation energy $E = 97.3$–108.5 kJ suggest that the manganese electroextraction in run nos. 3, 4 (Table 2) is controlled by the chemical redox reactions.

CONCLUSIONS

(1) In production of metallic cobalt, the electrochemical treatment of cobalt solutions to remove

manganese has a number of advantages such as high degree of purification, good quality of the surface of cathodic cobalt, the possibility of utilizing anodic sludge, i.e., developing wasteless technology, and environmental safety of the process.

(2) The degree of manganese and cobalt extraction increases with increasing electrolyte temperature. The increase in the cobalt concentration facilitates its extraction on the cathode.

(3) With increasing concentration of the cobalt ions in the electrolyte, the processes associated with the extraction of manganese ions pass from the diffusion to kinetic control.

Abstract—Effect of modification conditions on the electrochemical and structural properties of fibrous carbon materials was studied.

DOI: 10.1134/S1070427207050102

Having a well-developed surface, large porosity, and high electrical conductivity, fibrous carbon materials find wide use in widely diverse processes of chemical technology [1, 2]. A promising application of carbon fibers is that as electrodes and sorption materials [3]. Activated fibrous carbon (AFC) is used as electrodes in high-sensitivity electrochemical analytical methods [4], electrochemical treatment of wastewater, and manufacture of supercapacitors [5]. The efficiency of use of fibrous materials in sorption processes is due not only to their large surface area and high adsorption rate, but also to the possibility of carrying out a process at a prescribed polarization potential. The possibility of implementation of liquid-phase adsorption methods based on use of carbon materials under electrochemical polarization conditions largely depends on the efficiency of charging of porous carbon electrodes whose structure strongly affects the course of an electrochemical process.

Structural characteristics of fibers can be changed by various kinds of modification by electrochemical or chemical methods. For example, the size of the existing pores can be adjusted by electrochemical treatment of fibers to make larger the specific volume of mesopores [6]. A developed system of pores in activated carbon fibers and their surface groups can be formed by steam-and-gas activation or by deposition of metal oxides and hydroxides or various polymers [2, 3]. Modification of the surface of carbon materials with, e.g., titanium hydroxide, which forms mechanically strong and biologically inert coatings and is stable in a wide range of pH values, makes it possible to vary the surface properties and the pore structure of AFC. These latter, in turn, affect the conditions of carbon fiber charging [8].

The electrochemical properties of a carbon material brought in contact with an electrolyte solution allow evaluation of changes in its structural and surface characteristics [9]. Structural changes in AFC can be directly examined by atomic-force and electron microscopy [10].

The aim of this study was to determine by the electrochemical method how the surface characteristics of activated carbon fibers vary with the conditions of their modification and to supplement these measurements with analysis by atomic-force and electron microscopies.

EXPERIMENTAL

We used as electrode materials Aktilen B bundle fibers (AFC-B) and 709-P granulated mesoporous carbon, whose specific surface area, pore volume, and average pore radius are, respectively, 700 and 200 $m^2 g^{-1}$, 0.4 and 0.4 $cm^3 g^{-1}$, and 4 and 100 Å. In addition, we used modified carbon fibers obtained by chemical [11] and electrochemical [7] deposition of titanium hydroxide. We used as electrolytes saline (0.9% NaCl) and a universal buffer solution (sodium phosphate–acetate–borate). The choice of the electrolytes was due to further use of composite materials in sorption and electrosorption of protein molecules.

Electrochemical measurements were made using cyclic voltammetry [8, 9]. A sample of a carbon material was placed on a gold grid serving as a current lead. A silver chloride electrode was used as reference. The auxiliary electrode, made of a porous carbon material, was separated from the working electrode by an MB-2 bipolar membrane. Cyclic voltam-

metric curves were measured at potentials of ±50 mV [8] relative to the immersion potential of the working electrode at potential sweep rates of 4×10^{-5}–1×10^{-3} V s^{-1}. The electrode capacitance C (F g^{-1}) was calculated by the formula [12]

$$C = (I_a + I_c)/2mv, \quad (1)$$

where I_a and I_c are the anode and cathode polarization currents (A): m, mass of the carbon material (g); and v, potential sweep rate (V s^{-1}).

The degree (fraction) α of utilization of the electrode surface in the electrochemical process was calculated using the relation

$$\alpha = C/C_{max}, \quad (2)$$

where C and C_{max} are the electrode capacitances at a given and minimum potential sweep rates.

In processing the potentiodynamic curves by the least-squares method, we calculated the characteristic charging time τ and ohmic resistance R of the electrolyte in pores ($R = \tau/C$) by the formula [13]

$$I = Cv\{1 - (2/\pi^2)\sum_{n=0}(n + 1/2)^{-1}\exp[-\pi^2(n + 1/2)^2(t/\tau)]\}, \quad (3)$$

where I is current (A g^{-1}); v, potential sweep rate (V s^{-1}); t, time; and n, summation index.

The structure of the fibers was studied on an LEO430 scanning electron microscope (Germany) and an atomic-force microscope (AFM) (Zelenograd, Russia). The AFM measurements were made in contact and tapping modes, with images chosen in the most representative presentations.

For effective use of AFC as an electrode material in various processes, it is necessary to reveal specific features of the influence exerted by their pore structure on the electrochemical properties of fibers. Carbon, including fibrous, electrodes with a well-developed system of pores have a large-area interface between the carbon matrix and the electrolyte solution. However, the polarization of porous electrodes may lead to hindrance associated with a slow supply of ions (diffusion hindrance) and changes in potential in pores (ohmic hindrance). As a result, not the whole internal surface is equally accessible to the electrochemical process. For microporous materials, in which the pore radius is smaller than 1.5–2.0 nm, there may also occur difficulties in formation of the electrical double layer (EDL) in pores [8, 9], which hinders polarization of the internal space and impairs the efficiency of operation of the porous electrode. Modification of the carbon matrix can also change its surface properties and structure and, as a result, also alter the accessibility of the surface to the electrochemical process.

A basic characteristic of an electrode is the capacitance of the electrical double layer, whose value depends on conditions of its formation in the pore structure of a carbon material, including a modified material. Use of data on the EDL capacitance of porous electrodes makes it possible to calculate their charging conditions [14] determining the efficiency of application of AFC and AFC-based composite materials as electrodes in various processes occurring under polarization conditions.

One of methods used to determine the EDL capacitance of porous carbon and fibrous electrodes is cyclic voltammetry [8], because it makes it possible to assess the effect of structural and surface properties of carbon materials on the conditions of their charging. Figure 1 shows as an example voltammograms measured at different electrode polarization rates in saline (0.9% NaCl) and buffer solutions. The voltammograms obtained at the minimum potential sweep rate (0.4 mV s^{-1}) are virtually rectangular (curves *1* and *2*), which indicates that, in this case, there are no hindered charging processes, which appear upon a significant increase in the electrode polarization rate (curves *3* and *4*). The occurrence of the hindered charging processes may be due to pore structure parameters of the fiber, phase-boundary phenomena at the electrode–solution interface, and properties of the conduction band of the carbon material [15], which are all dependent on the conditions of its synthesis.

It should be noted that the electrolyte composition affects the process of electrode charging. In polarization in a buffer solution (especially at high potential sweep rates), hindered charging processes are manifested to a greater extent, in contrast to similar processes in polarization of the electrodes in saline. This difference is possibly due to the presence of larger ions in the multicomponent buffer solution, which hinder EDL formation in a porous electrode at high potential sweep rates. It is also not improbable that specific adsorption of phosphate ions on the surface of a titanium-containing fiber is important, which may affect the charging of composite electrodes.

The differences in charging and the specific structural features of carbon materials can be judged from how their capacitance varies with the potential sweep rate. At a slow polarization, when the potential sweep rate corresponds to the supply rate of ions forming

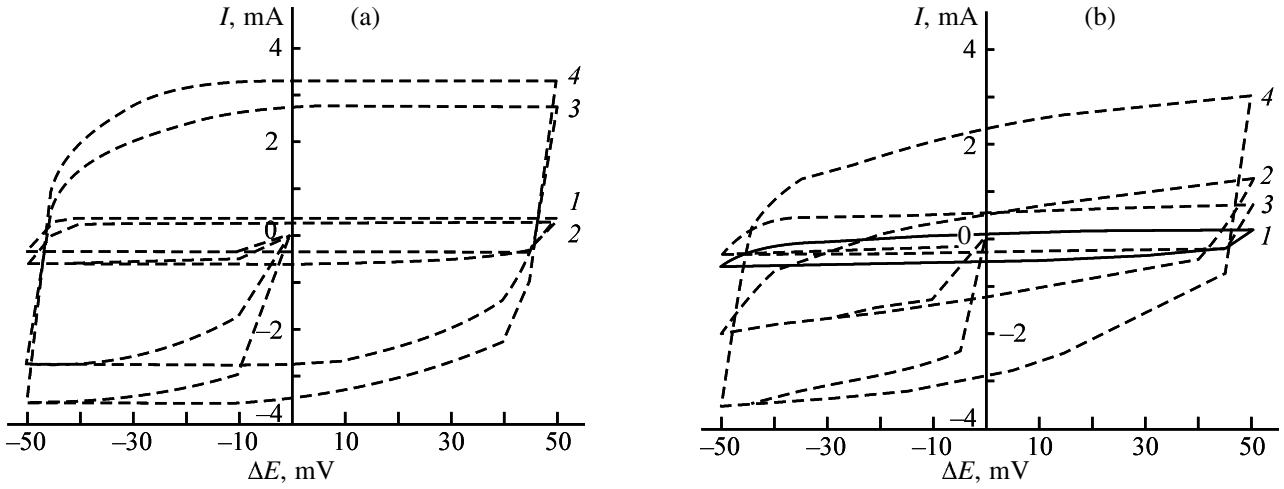

Fig. 1. Cyclic voltammograms measured on carbon electrodes at different potential sweep rates v in (a) saline and (b) buffer solution. (I) Current strength and (ΔE) shift of the potential relative to the steady-state value. v, mV s^{-1}: (*1, 2*) 0.04 and (*3, 4*) 0.4. (*1, 3*) AFC and (*2, 4*) AFC-Ti(ECh).

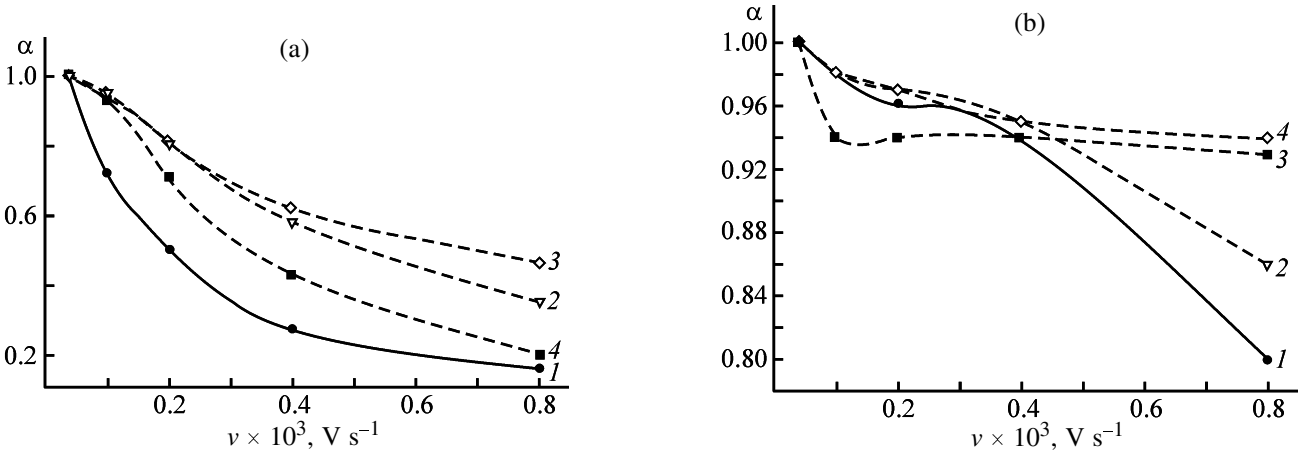

Fig. 2. Surface fraction α involved in the electrochemical process vs. the potential sweep rate v in (a) buffer solution and (b) saline. (*1*) AFC, (*2*) AFC-Ti(Ch), (*3*) AFC-Ti(ECh), and (*4*) 709-P.

the EDL "plate," the capacitance corresponds to the entire surface area that can be involved in charging of the electrode in a given electrolyte. An increase in the rate of polarization of the microporous material makes the ohmic potential drop higher and the diffusion hindrance to the rate of the electrode process stronger. This leads to a decrease in the capacitance, because the value measured corresponds only to the surface area that is involved in the electrochemical process and constitutes a certain fraction of the total surface area.

As follows from the dependences in Fig. 2a, the EDL capacitances (and, consequently, the surface fractions involved in the electrochemical process) of the starting fiber and granulated carbon steeply decrease as the rate of electrode polarization in the buffer solution is raised and reach rather small values, which indicates that the charging process is displaced to the outer surface. However, modification of fibers results in that the capacitances of fibrous electrodes reach higher values in polarization. This indicates that the fiber structure changes in preliminary chemical and electrochemical treatment with titanium hydroxide.

Changing the electrolyte composition (replacing the buffer solution with saline) (Fig. 2b) affects the polarization of carbon materials in the entire range of potential sweep rates. This may be due to the fact that, in a low-component solution (saline), the surface of porous electrodes is more accessible to smaller ions forming the EDL plate. As a result, fibrous electrodes

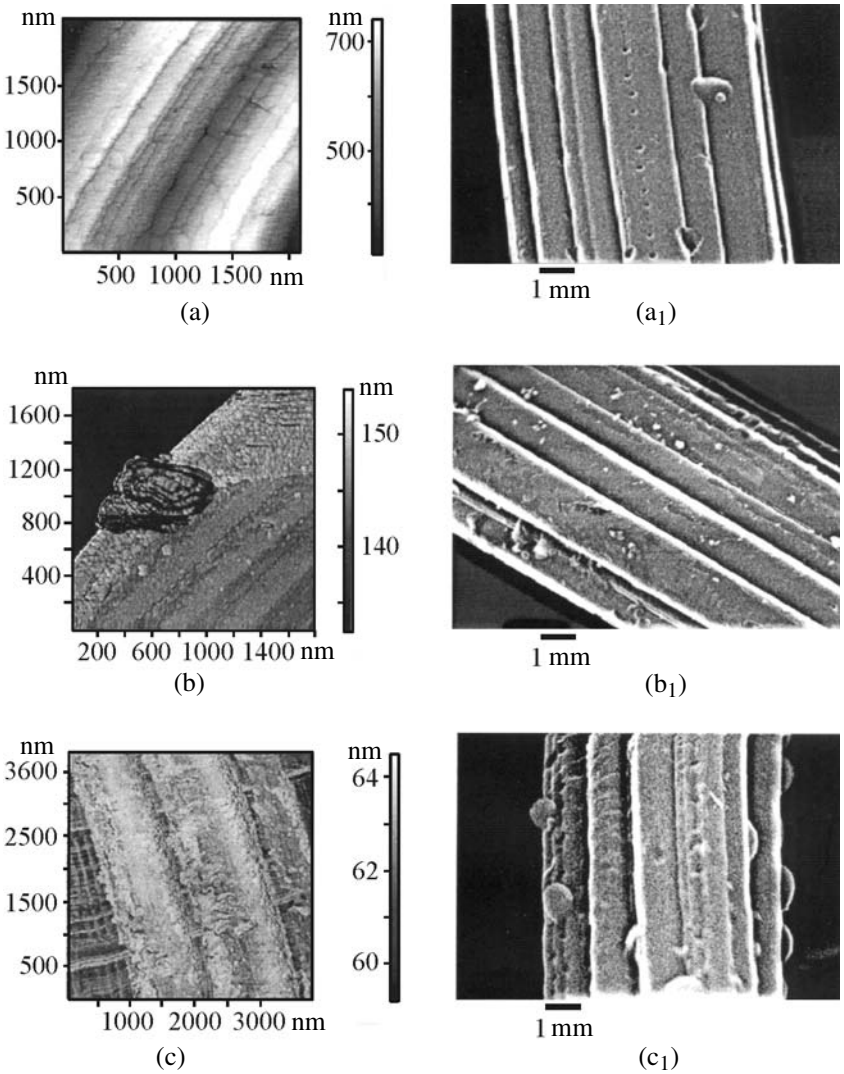

Fig. 3. (a–c) AFM and (a_1–c_1) SEM images of carbon fibers: (a, a_1) AFC, (b, b_1) AFC-Ti(ECh), and (c, c_1) AFC-Ti(Ch).

are polarized similarly to mesoporous granulated carbon. The fact that high values of the AFC capacitance are preserved in the entire range of potential sweep rates may also be due to the lability of the fiber structure under the polarization conditions. The effect of lability of the carbon fiber is manifested in a change in its pore structure upon polarization, which consists in parting of fibrils of the fiber and in an increase in the size of transport pores [6, 14, 16]. The manifestation of this effect results in that the hindering influence exerted by the porous medium on the process of EDL formation is weakened and rather high rates of current and mass transport are preserved. It should be noted that, irrespective of the electrolyte composition, the surface of modified AFC is more accessible to the electrochemical process than the starting fiber. The behavior of this kind is due to structural changes in AFC in the course of its modification.

Figure 3 shows AFM and SEM images of unmodified and titanium-containing AFC. It follows from the AFM data obtained that the unmodified AFC (Fig. 3) is composed of fibers 1000–1500 nm in diameter, which are, in turn, constituted by even thinner microscopic fibrils [2] 100–300 nm in diameter. The carbon fiber is formed by microcrystalline blocks aligned along the fiber axis. Pores of various sizes are present on the surface. Micropores with a transverse size of about 10 nm are formed, according to the AFM data obtained, at joining places of blocks constituting the fiber. The SEM image in Fig. $3a_1$ shows some micropores with sizes of up to 100 nm, formed between microfibrils or at places of their transverse rupture.

Figures 3b and $3b_1$ show AFM and SEM images of an AFC modified by electrochemical deposition of

titanium hydroxide, which forms a coating in the form of separate island-like particles-blocks with a size of up to 300 nm. Possibly, island particles are formed at micropores, which are rather sparsely situated in the starting fiber. Micropores are formed in the titanium-containing fiber among the blocks. It follows from the AFM data that the system of pores constitutes a double sieve in the modified fiber at places in which it is coated with titanium hydroxide. This sieve is formed by pores in the titanium hydroxide film at the top, and by pores in the fiber itself, below.

Figures 3b and $3b_1$ show AFM and SEM images of an AFC modified with titanium hydroxide by chemical modification. As also in the case of the electrochemically produced coating, the images demonstrate particles of about micrometer size. In this case, however, the particles are not of the island type, but adhere to each other so as to form, on large areas, a solid coating with a thickness of up to tenths of a micrometer. According to the AFM data, the chemically deposited coating has a more profiled surface and is composed of conglomerates of about micrometer particles. Thus, comparison of the results obtained shows that different methods of titanium hydroxide deposition can give structurally different composite fibers, which, in turn, leads to dissimilar charging conditions of modified AFCs.

A mathematical processing of the data on variation of the capacitance of the electrodes with the rate of their polarization in terms of Eq. (3) made it possible to calculate the resistance *R* of the electrolyte in the pores and the characteristic electrode charging time τ. The table lists the calculated values, which enabled evaluation of the efficiency of utilization of carbon materials under the polarization conditions. Analysis of the data obtained shows that, in contrast to granulated carbon, both the starting and modified fibers are charged faster and with lower electrolyte resistance. Presumably, this is due to changes in the structure of the fibers both in the course of AFC polarization [6, 14, 16] and in deposition of a modifier onto the carbon matrix. In the process, the radii of pores in the labile AFC structure increase [16], which leads to a decrease in the diffusion and ohmic resistance and makes it possible to achieve a more uniform polarization of fibrous electrodes. Moreover, it should be noted that the AFC modified with titanium hydroxide by electrochemical deposition is among fibers with the lowest electrolyte resistance within pores. Presumably, this is due both to an increase in the size of pores in the fiber itself in the course of polarization and the forming pore structure of the hydroxide being deposited. Thus, a study of the relationship between the structural and electrochemical properties of modified fibrous electrodes can determine the most promising materials to be used in electrochemical processes.

CONCLUSIONS

(1) It was shown by cyclic voltammetry that carbon fibers are polarized more uniformly when electrodes are charged in physiological saline.

(2) Deposition of titanium hydroxide onto a carbon matrix changes its structure and the charging conditions of composite fibers.

(3) The composite material produced by electrochemical deposition of titanium hydroxide onto a carbon fiber is more suitable in its electrochemical characteristics for use in electrodes.

Abstract—Catalytic activity of FeZSM-5 zeolites in oxidative degradation of Rhodamine 6G and Methyl Orange dyes was studied in relation to the nature, localization, and dispersity of active centers and on the reversibility of the oxidation–reduction of iron contained in the zeolites.

DOI: 10.1134/S1070427207050114

Millions of tons of dye-contaminated wastewater formed in textile and paint-and-varnish industries and in manufacture of finishing materials pose a severe environmental problem [1]. Use of adsorptive, biological, electrochemical, and oxidative technologies makes it possible to clarify contaminated water, but only catalytic methods provide complete degradation of dyes [2]. Of particular interest in this regard is the oxidizing system based on the homogeneous Fenton reagent ($Fe^{2+}/Fe^{3+}/H_2O_2$) [3, 4]. However, a number of disadvantages, such as impossible regeneration of the catalyst, narrow range of pH values at which the reaction occurs, and necessity for removal of iron compounds from purified water strongly restrict the possible application field of this system [3–5]. Most of these problems can be resolved by using heterogeneous catalysts and, in particular, zeolites, whose recovery from water and regeneration are not too difficult [6]. Fe-containing zeolites show redox properties because iron can change its oxidation state (Fe^{2+}, Fe^{3+}, Fe^{4+}) [7]. These materials are effective catalysts for oxidative breakdown of phenol [6], a number of carboxylic acids [8], and ethanol [9] in water. Their efficiency in the Fenton reaction may strongly depend on the structural topology, surface chemistry, and preparation method. However, this issue and the question as to whether the FeZSM-5 zeolite can be used as a catalyst for dye degradation in aqueous media have been poorly elucidated.

The aim of this study was to analyze the relationship between the nature of active centers and the catalytic properties of the FeZSM-5 zeolite in oxidative degradation of a diaminoxanthene dye Rhodamine 6G and an azo dye Methyl Orange. The choice of these model objects is due to the presence in their structure of different functional groups and other reactive centers, which can enter into redox reactions.

EXPERIMENTAL

The FeZSM-5(A) zeolite containing Fe^{3+} ions in the zeolite framework (Si^{4+}/Fe^{3+} = 40) was synthesized under hydrothermal conditions by the method described in [10, 11], using the reaction mixture $TEOS : TPAOH : Fe_2O_3 : H_2C_2O_4 = 1.0 : 0.312 : 0.0125 : 0.0823$, where TEOS is tetraethyl orthosilicate, and TPAOH is tetrapropylammonium hydroxide (20% aqueous solution). A [Fe, Al]ZSM-5(B) sample isomorphically substituted with iron and aluminum cations (Si^{4+}/Fe^{3+} = 50, Si^{4+}/Al^{3+} = 200, Fe^{3+}/Al^{3+} = 4.0) was synthesized in a similar way. Composition of the reaction mixture (g): TEOS 10.24, TPAOH 15, $Fe(NO_3)_3 \cdot 9H_2O$ 0.383, $Al(NO_3)_3 \cdot 9H_2O$ 0.089, and $H_2C_2O_4 \cdot 2H_2O$ 0.493. The template (TPAOH) was removed from both the zeolites by calcination in a flow of N_2 for 8 h and then in a flow of dried air at 823 K for 4 h at a heating rate of 1.0 deg min^{-1}. The FeZSM-5(C) catalyst was prepared by ion exchange in the medium of in situ generated Fe^{2+} ions [12, 13] using NH_4ZSM-5 zeolite (atomic ratio Si^{4+}/Al^{3+} = 40, Akzo-Nobel). The FeZSM-5(D) sample was synthesized by modification of the same zeolite with iron acetylacetonate in toluene [14].

The content of iron in the materials under study was determined by the ICP-AES method (Perkin–Elmer Optima, DV-3300, ICP-AES Instrument). Their X-ray diffraction analysis was made on a Rigaku RINT-2000 diffractometer (CuK_α radiation, λ = 1.54178 Å) at Bragg angles 2θ = 5°–50°. Electronic diffuse reflection spectra (EDRS) of the catalysts were measured on a Shimadzu UV 2401 spectrophotometer (spectral range 190–800 nm), with $BaSO_4$ as reference. The IR spectra were recorded on a Nicolet Avatar 360 FT-IR spectrophotometer with pelletized samples prepared by compaction of a material under study with thoroughly dried KBr (taken in 1 : 60 ratio). A thermally programmed reduction of the catalysts with hydrogen (H_2-TPR) in the temperature range 298–1073 K was performed in a flow-through reactor at a heating rate of 10 deg min^{-1} in a flow of a hydrogen–argon mixture (5 vol % H_2) passed through the reactor at a flow rate of 30 cm^3 min^{-1}. The absorption of H_2 was determined using a thermal conductivity detector calibrated against CuO. Prior to experiments, the samples (100 mg, grain size 0.3–1.0 mm) were heated in a flow of Ar at 473 K to remove physically sorbed water. Part of the samples were calcined for 2 h at 623 K in an Ar/N_2O mixture (5 vol % N_2O), cooled to 298 K in a flow of the same mixture, and blown-through with argon for 1 h, and then a TPR experiment was carried out. Isotherms of nitrogen adsorption–desorption at 77 K were recorded with preliminarily vacuum-treated samples (5 h, 673 K) on a Micromeritics ASAP 2010 installation. The isotherms obtained were analyzed using Langmuir and Dubinin–Astakhov equations [15]. This was so done because the BET method based on the polylayer model of N_2 adsorption inadequately describes adsorption processes in zeolite channels owing to the small size of these channels (<0.7 nm) [16].

The oxidative degradation of the dyes (0.1 g dm^{-3}) was performed at a catalyst concentration of 1 g dm^{-3} in isothermal conditions (298–323 K) under permanent agitation in a shaded temperature-controlled glass reactor. Fifteen minutes after the catalyst was introduced into the dye solution, addition of 30% H_2O_2 at a constant rate was started. The degree of decolorization of the dyes was measured colorimetrically (Specord M-40 spectrophotometer or FEK56 colorimeter, λ = 540 nm) with an aliquot from which the catalyst was removed by centrifugation (7000 rpm). To assess the operation stability of the catalysts, they were recovered from the solution after the reaction was complete and their activity was again measured, with the ratio between the catalyst mass and dye concentration remaining the same as that in experiments with a fresh sample. The effect of iron ions leached-out from FeZSM-5 samples on the degradation of the dyes was determined as follows. After the activity was measured, the catalysts were recovered from the reaction mixture by filtration at a temperature equal to the reaction temperature. Then, the dye and H_2O_2 were introduced into the filtrate in the same amounts as those in the heterogeneous catalytic process, after which the reaction was again carried out. The specific activity A_{sp} of the catalysts and the activity A_{Fe} of leached-out iron cations were expressed as the molar ratio of a dye decolorized in unit time to the iron content of the samples. The content of the total organic carbon in water was measured using a Shimadzu TOC-VCSN analyzer, with the reaction preliminarily terminated by addition of a fixed volume of a 10% $NaHSO_3$ solution (pH 9–10). The reaction products were analyzed with a Tsvet 3006 ion chromatograph with an Elsian 6 column.

The FeZSM-5(A) and [Fe,Al]ZSM-5-5(B) catalysts have an MFI (ZSM-5) structure [17], which follows from the presence in their X-ray diffraction patterns of basal reflections characteristic of highly crystalline zeolites of this type (Fig. 1). The IR spectra of these samples show a weak absorption band at around 650 cm^{-1} (stretching vibrations in ≡Si–O–Fe= structural fragments [10, 11]), which indicates that iron(III) is present in the zeolite framework. Introduction of iron cations into channels of the NH_4ZSM-5 zeolite via ion exchange has virtually no effect on its crystallinity (Fig. 1). However, this changes the coordination state and distorts the ligand surrounding of a part of Al^{3+} structural ions, which was revealed by ^{27}Al NMR spectroscopy in preliminary studies. This occurs under the action of a strongly acidic medium used to perform the given process. The adsorption isotherms

of all the samples can be attributed to type I by IUPAC classification [15, 16], which points to their microporous structure characteristic of MFI-type zeolites [18]. The pore structure parameters of the [Fe]ZSM-5(A) and [Fe, Al]ZSM-5(B) catalysts differ only slightly (Table 1) because of the similar conditions of their synthesis. The smaller values of the specific surface area and micropore volume of FeZSM-5(C) and FeZSM-5(D) samples, compared with the starting material (Table 1), can be attributed to the blocking role of iron compounds localized within pores and on the surface of zeolite crystals.

The coordination and oxidation states of iron and the dispersity of its oxides in the catalysts under study were determined by EDRS [11, 19]. The EDR spectra of [Fe]ZSM-5(A) and [Fe, Al]ZSM-5(B) samples (Fig. 2) show a band at around 250 nm, which reflects charge transfer between a ligand and a metal atom [19, 20], tetrahedrally coordinated iron(III) [11, 19], which points to its localization in the zeolite structure. A similar conclusion also follows from an analysis of the spectra in the range of *d–d* transitions (300–500 nm). However, the [Fe, Al]ZSM-5(B) sample contains a smaller number of Fe^{3+} ions in its framework, which follows from the lower intensity of bands at 350 and 415 nm (absorption by isolated Fe^{3+} ions [21]) (Fig. 2). This is a consequence of competition between Al^{3+} and Fe^{3+} in the formation of the crystal lattice of the zeolite, with the result that a larger number of Fe^{3+} ions occupy out-of-framework positions [22]. The FeZSM-5(C) catalyst mostly contains iron(II) because its spectrum contains no clearly pronounced bands in the range of absorption by Fe^{3+} ions (224, 278, 350, and 495 nm) [19]. The spectrum of the FeZSM-5(D) sample shows, together with bands characteristic of dispersed oxide clusters of iron(III) (230, 280, and 335 nm), also absorption by aggregated Fe_2O_3 particles (at 500 nm) [19, 20].

The catalysts were also characterized by their temperature-programmed reduction with hydrogen (H_2-TPR), which can be used to determine the structural localization and dispersity of oxide clusters of iron and the reversibility of its reduction–oxidation [23–25]. The H_2-TPR curves of [Fe]ZSM-5(A) and [Fe, Al] ZSM-5(B) samples contain each two peaks of hydrogen uptake at 640, 670 and 960, 1020 K, respectively (Fig. 3). The first peak reflects the reduction of out-of-framework compounds of the Fe_xO_y and $(Fe_xO_y)_n$ types [23], whereas the higher-temperature peak corresponds to reduction of structural ions of iron(III) [23, 24]. The shift of the peaks to higher temperatures, observed for the [Fe, Al]ZSM-5(B) catalyst, is apparently due to the lower content of iron and to the effect of structural ions of aluminum. Oxidative treatment of these samples in NO_2 leads to an increase in the intensity of the low-temperature peak, its shift, and rise in the H_2/Fe molar ratio from 0.38–0.40 to 0.50–0.53 (Fig. 3). This effect is commonly attributed to the presence of readily oxidizable out-of-framework iron(II), which is formed via the $Fe^{3+} \rightarrow Fe^{2+}$ conversion in thermal degradation of the organic template to give [Fe]ZSM-5 [21, 23]. The presence of two high-temperature peaks in the H_2-TPR curves points to existence of different kinds of the framework iron. For the FeZSM-5(C) catalyst, the temperature of the maximum absorption of H_2 is about 770 K (H_2/Fe $\approx$ 1.0), which corresponds to the $FeO \rightarrow Fe^0$

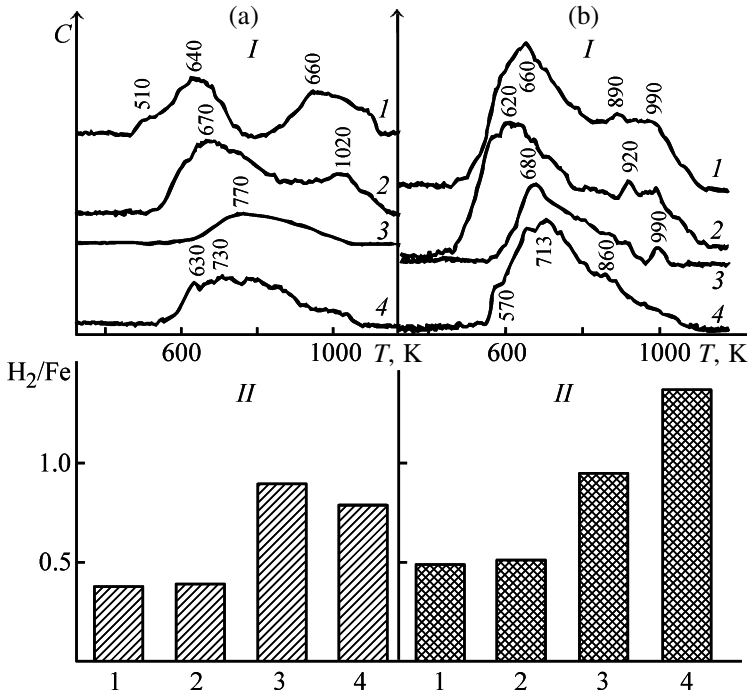

Fig. 3. Temperature-programmed reduction of catalysts: (*C*) H_2 uptake, (*T*) temperature, and (H_2/Fe) hydrogen-to-iron molar ratio. (*I*) TPR curves and (*II*) H_2/Fe molar ratio. (a) Starting samples and (b) N_2O-treated samples.

conversion [25], and decreases by 90 K after its oxidation (Fig. 3). In all probability, the appearance in the process of a peak at about 990 K reflects the reduction of an admixture of the framework iron(III), which is commonly present in industrial zeolites. The reduction of iron(III) in the FeZSM-5(D) sample occurs in a very wide temperature range (Fig. 3), which points to a considerable inhomogeneity of composition and strong nonuniformity of the aggregative state of the oxide phase. This phase is predominantly localized at the external surface of the zeolite, because iron acetylacetonate used in synthesis of the given sample does not penetrate into the channels of ZSM-5 because of the large molecular size (~1.0 nm). This is also confirmed by the adsorption data (Table 1). The shoulder at about 570 K in the H_2-TPR curve of an oxidized [Fe]ZSM-5(D) sample (Fig. 3) can be attributed to the presence of binuclear oxo cations of iron $[OH–Fe–O–Fe–OH]^{2+}$ [25].

The H_2 uptake at 600–1000 K reflects the conversion $Fe_2O_3 \rightarrow Fe_3O_4 \rightarrow FeO \rightarrow Fe^0$ [25], and the weak peak at about 800 K points to existence of aggregated Fe_2O_3 particles, which is consistent with the EDRS data. The noticeable rise in the H_2/Fe ratio, observed for [Fe]ZSM-5(D) after its treatment with N_2O (Fig. 3), also points to a considerable inhomogeneity of the composition of the oxide phase. The results obtained make it possible to assess the capacity of iron for reversible reduction–oxidation [23–25]. For the materials studied, this capacity decreases in the following order: FeZSM-5(C) > [Fe]ZSM-5(A) ≥ [Fe, Al]ZSM-5(B) > FeZSM-5(D).

Thus, the data obtained suggest that the [Fe]ZSM-5(A) and [Fe, Al]ZSM-5(B) catalysts contain iron in framework position and in the form of dispersed Fe_xO_y and $(Fe_xO_y)_n$ clusters mostly localized in zeolite channels. In the FeZSM-5(C) sample, iron is in the cationic form, whereas in FeZSM-5(D), oxo cations, $(Fe_xO_y)_n$ clusters, and Fe_2O_3 particles are mostly situated on the external surface of the zeolite. The so widely diverse nature and composition of

Table 1. Iron content of the catalysts studied and parameters of their pore structure

FeZSM-5(D)	40	0.07	0.23	410	0.128

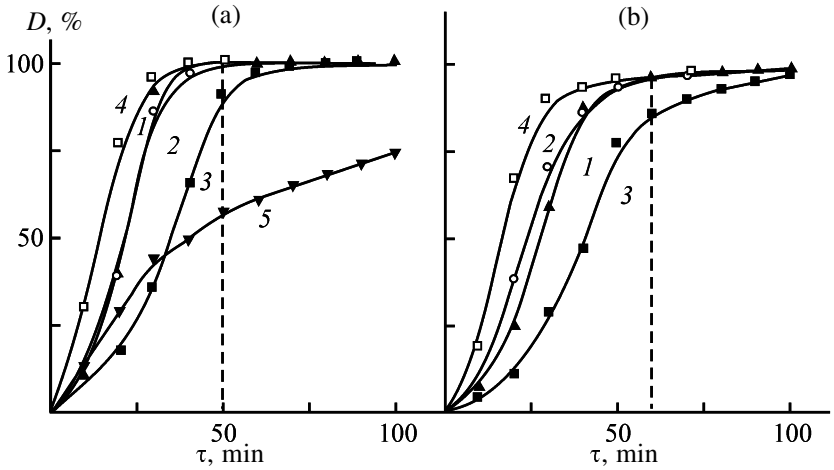

Fig. 4. Kinetics of dye decolorization in the presence of FeZSM-5 catalysts. (*D*) Decolorization and (τ) reaction duration. (a) Rhodamine 6G and (b) Methyl Orange. (*1*) FeZSM-5(A), (*2*) [Fe, Al]ZSM-5(B), (*3*) FeZSM-5(C), (*4*) FeZSM-5(D), and (*5*) 0.3 M $Fe(NO_3)_3$ solution.

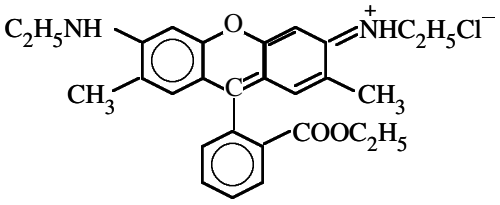
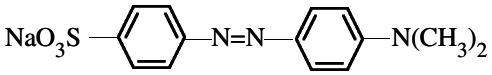
active centers and the surface chemistry may strongly affect the behavior of these catalysts in the reaction under study.

It can be seen from the schematic of the structures that the dyes used differ in the size and shape of the carbon skeleton, as well as in the number of reactive centers and functional groups sensitive to the action of oxidizing agents and pH.



Rhodamine 6G



Methyl Orange

It was found that, irrespective of the iron content and nature of active centers of the catalysts, variation of the initial pH value of the reaction medium within the range 3.0–6.0 has virtually no effect on the rate of their decoloration. This is possible at a considerably higher pH value than the pK_a of organic compounds in water [26]. In the presence of the catalysts under study, the pH of water decreases to 3.5–4.0, depending on the content of iron and aluminum compounds in the catalysts. Hence follows that the acid centers of the zeolites, i.e., bridging hydroxy groups of the structural fragments ≡Si–OH–Al= or ≡Si–OH–Fe= or hydrated exchange cations of iron, can control the pH value. Therefore, further experiments were performed at a pH value natural to the dyes.

The lower activity of the homogeneous catalyst, compared to the heterogeneous analogs (Fig. 4), can be attributed to the absence of Fe^{2+} ions. As is known [27, 28], the initial stage of H_2O_2 decomposition catalyzed by iron(III) is its reduction accompanied by the formation of hydroperoxy radicals $HO_2^{\bullet}$ [5]:

$$Fe^{3+} + H_2O_2 \rightarrow Fe(OOH)^{2+} + H^+, \quad (1)$$

$$Fe(OOH)^{2+} \rightarrow Fe^{2+} + HO_2^{\bullet}. \quad (2)$$

The oxidizing capacity of $HO_2^{\bullet}$ is considerably lower than that of $OH^{\bullet}$ radicals [29] generated by H_2O_2 decomposition in the presence of Fe^{2+}. The higher activity of the heterogeneous catalysts may also be due to the specific structure and composition of their active centers, which depend on the structural topology of a zeolite [23–25]. It should, however, be taken into account that iron cations washed-out in the course of the reaction can contribute to the total activity of the catalysts [9]. This effect is the most pronounced for the FeZSM-5(C) sample (Table 2). This seems to be reasonable because this zeolite contains cations retained within its pores by electrostatic interaction with uncompensated negative charges of the crystalline framework. In the rest of the catalysts, iron is in a more bound state, i.e., is partly localized in the structure or in out-of-framework positions in the form of oxide clusters, which leads to a decrease in its leaching-out rate. Nevertheless, even in the case of the Fe-exchange zeolite, the contribution of this process to its activity does not exceed 9%.

Table 2. Specific activity A_{sp} of the catalysts and the activity A_{Fe} of iron cations leached-out from them

Catalyst	A_{sp}	A_{Fe}	A_{sp}	A_{Fe}
	activity, h^{-1}			
	Rhodamine 6G		Methyl Orange	
FeZSM-5(A)	0.79	0.063	0.66	0.029
FeZSM-5(B)	0.66	0.082	0.70	0.069
FeZSM-5(C)	2.82	0.178	2.71	0.150
FeZSM-5(D)	2.73	0.010	3.0	0.048

The deactivation of the catalysts may also be due to loss of the active phase in the course of the reaction. The activity of samples that were used and then dried at room temperature is markedly lower than that of the fresh samples. However, it is virtually completely restored on washing of the catalysts with methanol, followed by drying at 383 K. Consequently, the decrease in activity is mostly due to blocking of surface centers, rather than to loss of iron cations in the course of the reaction. These results clearly demonstrate the relationship between the catalytic function of the materials under study and the nature of their active centers.

Elevation of the temperature from 298 to 323 K leads to a noticeable increase in the rate of dye decolorization in the presence of the catalysts under study. However, the loss of total organic carbon (TOC) depends on temperature to a lesser extent. This is apparently due to formation of intermediates whose mineralization is hindered [8]. The rate at which H_2O_2 is introduced can strongly affect the degree of degradation of the organic substratum [3, 4]. At H_2O_2 addition rates of 21, 41, and 82 mmol h^{-1}, the dye decolorization in the initial period of time (~20 min) only slightly depends on this parameter (Fig. 5). As the reaction proceeds, their degradation slows down at a less vigorous addition of H_2O_2, which points to an insufficient content of the oxidizing agent in the reaction medium. Only for the FeZSM-5(C) catalyst the loss of total organic carbon grows as the rate of H_2O_2 addition is raised (Fig. 5). In all probability, the reason is that, in the case of H_2O_2 deficiency, the forming $OH^{\bullet}$ radicals [Eq. (3)] are partly consumed for oxidation of Fe^{2+} ions [Eq. (4)] [27, 28]:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^{\bullet} + OH^-, \quad (3)$$

$$Fe^{2+} + OH^{\bullet} \rightarrow Fe^{3+} + OH^-. \quad (4)$$

Therefore, further experiments were performed at an H_2O_2 addition rate of 82 mmol h^{-1}, because the

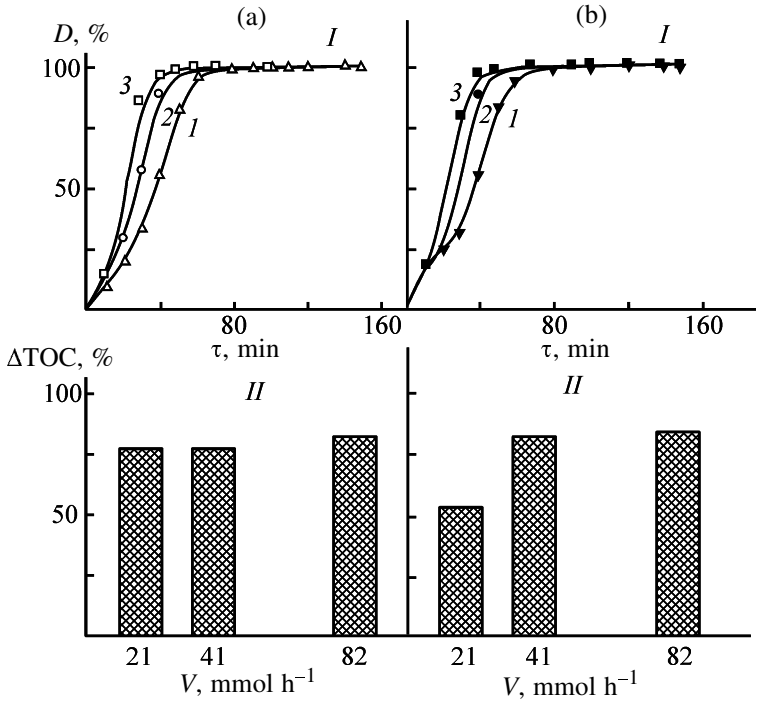


Fig. 5. Effect of the rate V of H_2O_2 addition on the dye decolorization D and TOC loss ΔTOC in the presence of the catalysts under study. (τ) Reaction duration. (*I*) Decoloration curves and (*II*) TOC loss. (a) FeZSM-5(A) and (b) [Fe, Al]ZSM-5(C). V, mmol h^{-1}: (*1*) 21, (*2*) 41, and (*3*) 82.

performance of the catalysts is the highest in this case. Despite the different iron contents (Table 1) and the varied nature of active centers, the total activities of FeZSM-5(C) and FeZSM-5(A) samples are approximately the same (Fig. 5). However, the specific activity of the first of them is considerably higher (Table 2). This can be accounted for by the increased content in this material of Fe^{2+} ions, which catalyze formation of $OH^{\bullet}$ radicals [Eq. (3)] [28], with the result that their concentration in the reaction medium will be high. The [Fe]ZSM-5(A) catalyst contains a larger amount of iron(III) and, therefore, it generates, in addition to $OH^{\bullet}$, the less reactive radicals $HO_2^{\bullet}$ [29], which adversely affects their specific activity. However, the higher concentration of the forming $HO_2^{\bullet}$ radicals compensates for the influence of this factor, and, as a result, the performance of the FeZSM-5(C) and [Fe]ZSM-5(A) samples becomes equal. The dispersity of the active centers may also be a reason for the difference in the catalytic properties of the materials under study. In the FeZSM-5(C) sample, iron is in the highly dispersed cationic form, which leads to an increased reactivity of an individual center. This is reflected in the high specific activity of this catalyst.

The validity of the aforesaid is confirmed by the results obtained with the FeZSM-5(D) catalyst, in whose presence the dye decolorization rate is the highest. However, the loss of TOC is only 40% in this case. This is possibly because the given sample can mostly generate $HO_2^{\bullet}$ radicals and O_2 [28] owing to the fact that the role of its active centers is played by dispersed and aggregated Fe_2O_3 particles. The oxidizing power of these agents was sufficient for decolorization of dyes, but not for their deep degradation. Another important factor is the reversibility of the oxidation–reduction of iron, which is the dominant cycle in the formation of $OH^{\bullet}$ radicals from H_2O_2 [27–29]. According to the H_2-TPR data, the FeZSM-5(D) catalyst contains the smallest amount of active centers exhibiting this property, which totally correlates with its low performance, as indicated by the loss of TOC.

At the optimal rate of H_2O_2 addition (82 mmol h^{-1}) and temperature of 323 K, the deepest degradation (TOC loss of 85%) is observed in the presence of the FeZSM-5(C) and [Fe]ZSM-5(A) catalysts at H_2O_2/dye molar ratios of 860 and 520 for Rhodamine 6G and Methyl Orange, respectively. This result seems to be reasonable because the molecule of Rhodamine 6G has a more branched carbon skeleton and contains a larger number of centers that can enter into reactions involving free radicals. Its degradation catalyzed by FeZSM-5 is more complex, compared to that of Methyl Orange. This process can include a number of competing stages, e.g., degradation of the chromophore and formation of *N*-dealkylation products, which then undergo hydroxylation to give the final products of the reaction, mostly lower carboxylic acids, as indicated by a chromatographic analysis. The change in the oxidation state of iron in the course of the reaction [Eqs. (1)–(4)] and the interaction of the radicals being generated with intermediate products of dye degradation [28] also necessitate use of an excess amount of H_2O_2.

CONCLUSIONS

(1) The nature, localization, and dispersity of active centers predetermine the catalytic behavior of FeZSM-5 zeolites in oxidative degradation of dyes.

(2) Materials containing iron(II) in the cationic form or highly dispersed clusters of the Fe_xO_y and $(Fe_xO_y)_n$ types in zeolite channels have an increased reactivity. The most stable are the catalysts in which iron is localized in both out-of-framework and structural positions.

(3) The catalytic properties of FeZSM-5 strongly depend on the reversibility of the oxidation–reduction of iron forming the active centers. Complete decolorization of Rhodamine 6G and Methyl Orange dyes, accompanied by a 80–85% decrease in the content of total organic carbon, is achieved at a reaction duration of 50–70 min and not-too-high temperature (323 K). The degradation of these compounds can be effected at a nearly neutral pH value, which is an important advantage over the homogeneous system (Fe^{2+}/Fe^{3+} : H_2O_2).

CATALYSIS

New Floating Photocatalysts Based on Expanded Graphite and Anatase

Abstract—A new method for production of composites constituted by expanded graphite, amorphous carbon, and titanium dioxide was suggested. The structure of the materials obtained was studied, and it was demonstrated that they show promise as photocatalysts for water treatment to remove organic contaminants.

DOI: 10.1134/S1070427207050126

Photocatalytic processes of contaminant decomposition involving titanium dioxide are presently regarded as one of the most promising methods for water treatment [1]. This is due to the high photocatalytic activity, longevity, stability in aqueous media, comparatively low cost, and low toxicity of this material [2]. Beginning in the second half of the 1990s, when TiO_2 deposited on expanded graphite (EG) was first described [3, 4], this composite material is of interest because of the unique combination of the photocatalytic activity of TiO_2 and the buoyancy of EG [5]. This combination provides the most complete utilization of UV light by titanium dioxide particles and substantially simplifies the procedure of removal of a spent photocatalyst from the water surface. Recently, it has been reported that EG–TiO_2 composites can effectively decompose such dangerous water contaminants as petroleum [6], heavy oil [7], pesticides [8], and phenols [9].

However, wide-scale use of EG–TiO_2 floating composites is still hindered by the lack of simple and inexpensive methods for their manufacture. The few procedures described in the literature [3, 4, 7] are primarily oriented to laboratory production and are hardly suitable for industrial manufacture because they are complicated and require that expensive and hazardous reagents should be used, including organometallic compounds, organic solvents, and organosilicon binders.

Recently, we have suggested [10] a simple method for production of composites composed of expanded graphite and amorphous carbon (EG–AmC) from inexpensive and readily available starting materials: graphite intercalation compounds (residual graphite hydrosulfate) and a renewable source of amorphous carbon, sucrose. The procedure includes a considerably smaller number of stages and does not require any organometallic and organosilicon compounds, organic solvents, and an inert atmosphere, which enables industrial manufacture of EG–AmC composites with low energy and labor expenditure. In this study, the previously suggested approach is extended and used to obtain new EG–AmC–TiO_2 photocatalysts to be used in water treatment.

EXPERIMENTAL

EG–AmC–TiO_2 composites were produced from residual graphite hydrosulfate [TU (Technical Specification) U 26.8-20372011-001–2002] synthesized by the method described in [11] from GSM-1[1] flake graphite and sucrose (Merck) as a precursor of amorphous carbon. The procedure for synthesis of EG–AmC–TiO_2 composites is similar to that described in [10] with the only difference that a TiO_2 powder (anatase 99.9 wt %, Aldrich, particle size 10 nm) was added to the starting mixture of residual graphite hydrosulfate and sucrose. A detailed description of the methods used to obtain EG–AcM–TiO_2 composites can be found in [12]. The specific surface areas (by BET) of the materials obtained, determined by the method of low-temperature adsorption of argon in conformity with GOST 13144–79, varied from 30 to 200 $m^2 g^{-1}$, depending on the composite composition. The structure and composition of the samples were

[1] Zaval'evskoe deposit (Ukraine).

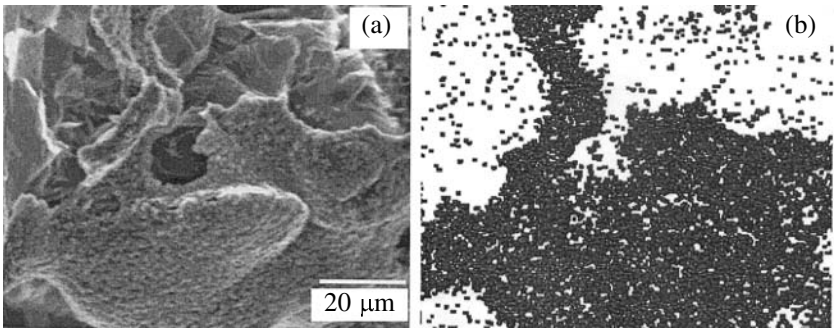

Fig. 1. SEM images of the same part of an EG–AmC–TiO_2 composite, obtained (a) by the conventional method with secondary electrons and (b) with the TiK_α radiation.

analyzed by scanning electron microscopy (SEM) on a JEOL JSM-1300 instrument.

The photocatalytic activity of the EG–AmC-TiO_2 composites in photodegradation of phenol was studied by the method described in [13]. A 100-W DRSh-100-2 high-pressure mercury lamp with a continuous emission spectrum was used as a source of UV light. To preclude photolysis of phenol under the action of absorbed photons, the spectral range 310–410 nm was used [13]. The intensity of light that entered the reactor, found by the standard procedure with a ferrisilicate actinometer [14], was $(3.0 \pm 0.3) \times 10^{-4}$ E s^{-1}.

Kinetic measurements were performed as follows. A freshly prepared aqueous solution of phenol, with a concentration of 50–200 mg l^{-1}, was placed in a thermostated reactor (25°C) and 0.4 g of the EG–AmC–TiO_2 composite was added so that it uniformly covered the entire surface of the solution. To reach sorption equilibrium before the beginning of irradiation, the solution was agitated in the dark for 48–60 h. Then, the UV source was switched on and the loss of phenol in the liquid phase was determined using the standard photoelectrocolorimetric method with 4-aminoantipyrine [15] after prescribed intervals of time under continuous agitation.

SEM micrographs of a sample of the composite synthesized are shown in Figs. 1a and 1b. The image in Fig. 1a clearly demonstrates the multicomponent structure of the material, with a macroporous cellular matrix of expanded graphite, covered with a layer of amorphous carbon formed in situ by carbonization of sucrose. It is noteworthy that a similar structure is also characteristic of previously obtained EG–AmC composites [10]. It can also be well seen in Fig. 1a that the amorphous carbon phase coating particles of expanded graphite has a rough surface. This is due to inclusions of titanium dioxide particles in the layer of amorphous carbon. The image in Fig. 1b confirms that these embedded particles are TiO_2 particles. The same figure shows at the same magnification the same part of the surface of the composite material as that in Fig. 1a, but obtained with TiK_α radiation. The dark spots in Fig. 1b correspond to places of localization of TiO_2 particles on the sample surface, from which photons with energy of the K_α line of titanium are emitted.

Thus, amorphous carbon produced in situ by carbonization of sucrose not only acts as an effective sorbent [10], but also binds together the individual components of the material, which makes unnecessary use of any additional binder. The intimate contact between EG and TiO_2 particles, provided by amorphous carbon, imparts to the composite obtained a disintegration resistance sufficient for its use as a floating photocatalyst. It was found in a separate experiment that particles of the EG–AmC–TiO_2 composite placed on the surface of water retain buoyancy under laboratory conditions and do not disintegrate into individual components, at least during several weeks.

It should be noted that the procedure suggested can give stable floating EG–AmC–TiO_2 composites with high content of TiO_2, in contrast to the previously suggested methods. For example, the technique described in [7], which uses titanium isopropoxide as a TiO_2 precursor without any additional binder, gives no way of making the titanium dioxide content of the composite higher than 14.5 wt %. Ramanathan et al. [3], who were the first to suggest a method for synthesis of EG–TiO_2 materials with an organosilicon binder, reported nothing about composites containing more than 45 wt % TiO_2. The method suggested in this paper allows easy production of EG–AmC–TiO_2 composites with titanium dioxide content of up to 70 wt %.

Preliminary data on the kinetics of photocatalytic

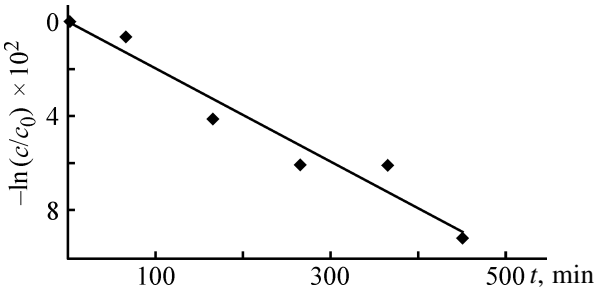

Fig. 2. Photodegradation of phenol in an aqueous solution, catalyzed by an EG–AmC–TiO_2 composite (68 wt % TiO_2). Initial concentration of phenol in solution 195 mg l^{-1}. (c) Phenol concentration and (t) reaction duration.

degradation of phenol in aqueous solutions with the materials obtained is satisfactorily described by pseudo-first-order equations. The apparent rate constant for a composite with TiO_2 content of 68 wt % is $(3.3 \pm 0.4) \times 10^{-6}$ s^{-1} (Fig. 2), which agrees in order of magnitude with published data for AmC–TiO_2 composites [13].

CONCLUSIONS

(1) A new method is suggested for synthesis of composite materials composed of expanded graphite, amorphous carbon, and titanium dioxide from residual graphite hydrosulfate, sucrose, and titanium dioxide in the form of anatase. The method is distinguished from the presently existing techniques by low time and energy consumption, readily available raw materials, and easy scaling-up to industrial manufacture.

(2) The results of a study of the composites by scanning electron microscopy confirm their multicomponent structure and demonstrate that TiO_2 is predominantly localized on the surface of the amorphous carbon phase, which serves not only as a sorbent, but also as a binder of the individual components of the composite material.

(3) Preliminary data on the photocatalytic activity of new composite materials composed of swollen graphite, amorphous carbon, and titanium dioxide, obtained in the study, make it possible to regard these materials as readily available effective floating photocatalysts for water treatment and environment protection.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Surface Activity of Oxyethylated Alkylphenols

V. Z. Kuz'min, I. I. Safarova, T. M. Prokudina, V. A. Shepelin, and R. R. Sharifullin

Nizhnekamskneftekhim Joint-Stock Company, Nizhnekamsk, Tatarstan, Russia

Received June 13, 2006; in final form, January 2007

Abstract—Pilot samples of oxyethylated products derived from octylphenol, isononylphenol, and isododecylphenol were synthesized. Their colloidal characteristics were studied and compared with the characteristics of ethoxylates of higher aliphatic alcohols.

DOI: 10.1134/S1070427207050138

Surfactants are widely used in many modern processes and materials. The assortment of natural and synthetic surfactants is very wide. With respect to the characteristics, structure, and composition, the most diverse are nonionic surfactants, whose share in the whole commercial production of surfactants reaches 20% [1].

Oxyethylated isononylphenols, Neonols, produced by the Nizhnekamskneftekhim Joint-Stock Company are nonionic surfactants. Oxyethylated isononylphenols are mixtures of oligomers-homologs, whose average degree of oxyethylation can vary in a wide range. The fields of application of Neonols are the same as those for oxyethylated aliphatic alcohols, but they are more widely used for technical purposes. Being adsorbed at the phase boundary, surfactants play a significant role in wetting, dispersion, emulsification, foaming, and other phenomena.

One of the main characteristics of surfactant performance is surface tension σ. There are numerous data on surface and interfacial tension of aqueous surfactant solutions, showing that the structure of surfactant molecule significantly affects its ability to decrease the interfacial tension. The other important characteristic of the surfactant performance is the critical micellization concentration C_{cmc}, i.e., concentration at which micelles are formed, causing abrupt changes in other characteristics of surfactant. The C_{cmc} value corresponds to the minimum surface tension. For homologous series of surfactants it was established that, the lower C_{cmc}, the more efficient is the surfactant [2].

The study of the surface tension of aqueous solutions of oxyethylated primary aliphatic alcohols as an example showed [2] that an increase of the length of alkyl chain increases the surface tension. With respect to decreasing surface tension, a branched alkyl group is more preferable than a linear radical. The general regularity of decreasing surface activity with increasing number of oxyethyl groups was elucidated. The individual values of surface tension for some samples of oxyethylated octylphenols and nonylphenols were determined. The influence of the hydrocarbon radical and the length of the polyoxyethylene chain of polyglycol ethers of alkylphenols was studied in [3, 4] for alkylphenols with CH_3, C_4H_9, C_9H_{19}, $C_{12}H_{25}$, and $C_{18}H_{37}$ radicals having normal hydrocarbon chains and degree of oxyethylation from 2 to 28.

This study was aimed to compare of colloidal-chemical characteristics of commercial Neonols produced by the Nizhnekamskneftekhim Joint-Stock Company and specially synthesized pilot samples of oxyethylated isononylphenols with degree of oxyethylation higher than 12 and also oxyethylated products derived from oxyphenol and isododecylphenol (alkylphenol derived from propylene tetramers).

EXPERIMENTAL

Alkylphenols were synthesized on a laboratory installation for alkylation of phenol at 110°C using two- or threefold molar excess of phenol in the presence of Lewatit SPC-108 HG sulfonated ion-exchange resin as a catalyst. α-Olefins C_8 and trimers and tetramers of propylene produced by the Nizhnekamskneftekhim Joint-Stock Company were used as alkylating agents. These products were suited to the require-

Table 1. Composition of alkylphenols used for oxyethylation

Component	Composition, wt %		
	octylphenol	isononylphenol	isododecylphenol

Alkyl phenyl ether	0.44	–	–
Monoalkylphenol	99.48	99.79	99.03
Dialkylphenol	0.01	0.20	0.59

ments of the technical specifications and were used without additional purification. Alkylphenols were recovered from the reaction mixtures by vacuum distillation. The compositions of the resulting alkylphenols used for oxyethylation are presented in Table 1.

Oxyethylene derivatives were synthesized on a laboratory installation for oxyethylation at a temperature of 120–125°C and a pressure of 5–6 kgf cm^{-2}. A 30% aqueous solution of sodium hydroxide [GOST (State Standard) 2263–79] or potassium hydroxide (GOST 24368–80) in an amount of 0.12–0.20% relative to the final product was used as a catalyst. After addition of alkali to the initial alkylphenol, the moisture was removed from the starting system. The starting system was dried for 60–90 min at 80–90°C and residual pressure of 2660–3990 Pa. Polyethylene glycol ethers were neutralized with acetic acid (GOST 19814–74) to pH 6.5–7.5.

Physicochemical characteristics of polyethylene glycol ethers of alkylphenols of the general formula $C_mH_{2m+1}C_6H_4O(CH_2–CH_2–O)_nH$ are presented in Table 2.

For water-soluble samples of the alkylphenols studied, we measured the surface tension at the water–air interface by the ring detachment method on a du Nouy tensiometer at 24 ± 1°C for surfactant concentration in aqueous solution in the range 0.4–10^{-6} wt %. From the experimental data, we plotted the isotherms of surface tension at the interface of aqueous solution of nonionic surfactant and air (Fig. 1), and from the

Isotherms of surface tension $\sigma \times 10^{-3}$ of (a) aqueous solutions of oxyethylated octylphenols, (b) isononylphenols, (c) isododecylphenols, and (d) alkylphenols oxyethylated by 10 mol of ethylene oxide. (*c*) Concentration of nonionic surfactant, g l^{-1}. Product: (a) (*1*) AF_8-8, (*2*) AF_8-10, (*3*) AF_8-12, and (*4*) AF_8-20; (b) (*1*) AF_9-8, (*2*) AF_9-14, (*3*) AF_9-18, and (*4*) AF_9-25; (c) (*1*) AF_{12}-10, (*2*) AF_{12}-12, (*3*) AF_{12}-14, and (*4*) AF_{12}-16; (d) (*1*) AF_8-10, (*2*) AF_9-10, and (*3*) AF_{12}-10.

coordinates of the inflection points of the resulting dependences we determined the C_{cmc} for a series of samples of oxyethylated products.

The results of our experiments showed that the regular trends determined for oxyethylated adducts, including ethoxylates of aliphatic alcohols, are also observed with oxyethylated alkylphenols.

For all the three groups of the alkylphenols in hand, the surface tension increases with increasing degree of oxyethylation (Figs. 1a–1c) and, on the contrary, decreases with increasing length of hydrocarbon chain of alkylphenol (Fig. 1d).

For comparison, we determined the surface characteristics of pilot samples of polyethylene glycol ethers of higher aliphatic alcohols (HAAs, C_{12}–C_{14} fraction) produced by the Procter and Gamble Company and oxyethylated with 2 (AE-2), 3 (AE-3), and 7 (AE-7) mol of ethylene oxide.

The surface tension values determined experimentally and the critical micellization concentration are presented in Table 3.

Some researchers believe that in their surface characteristics ethoxylates of aliphatic alcohols are more efficient than their analogs based on alkylphenols; this, however, is not quite correct. The surface characteristics of oxyethylated adducts based on alkylphenols are governed by the ratio of hydrophilic and hydrophobic parts (hydrophilic-lipophilic balance, HLB) and by the structure of the hydrocarbon substituent of the benzene ring of alkylphenol.

The experimental data showed that polyethylene glycol ethers derived from alkylphenols and HAAs having close values of HLB have also close values of surface tension. Oxyethylated alkylphenols derived from tetramers of propylene and ethoxylates of HAAs have low C_{cmc}, which suggests their higher surfactant performance. For Neonols based on octylphenol and isononylphenol, the C_{cmc} values are lower, and approximately constant, 0.01 wt %. For isododecylphenols oxyethylated with 8 and 10 mol of ethylene oxide and for aliphatic alcohol of C_{12}–C_{14} fraction oxyethylated with 7 mol of ethylene oxide (57.3, 62.7, and 60.6 wt % ethylene oxide, respectively), close values of surface tension were obtained.

CONCLUSIONS

(1) The main physicochemical characteristics of polyethylene glycol ethers of octyl-, isononyl-, and isododecylphenols were determined and variation of the surface tension as a function of the length of the oxyethylene chain at constant alkyl radical and of the radical length at a constant length of oxyethylene chain was studied.

(2) At a certain combination of fractions of alkyl and oxyethyl components in the structure of polyethylene ethers of alkylphenols and depending on the structure of alkyl substituent in the aromatic ring, adducts based on alkylphenols, well competing in the performance with ethoxylates of higher aliphatic alcohols, can be synthesized.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Hydrolysis of 2-Substituted and 1,2-Disubstituted Imidazolines

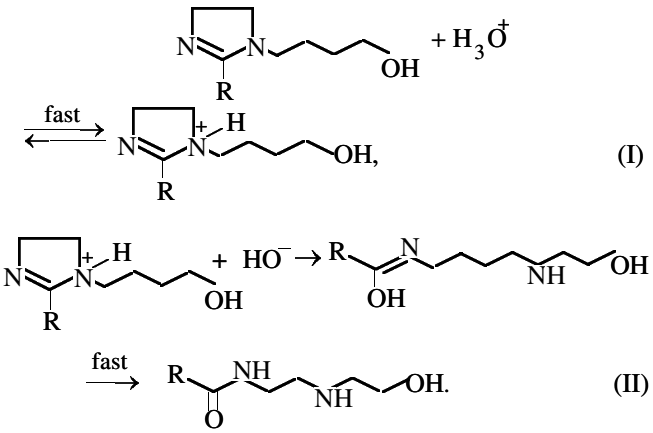
Abstract—The mechanism and kinetics of hydrolysis of 2-substituted and 1,2-disubstituted imidazolines in acid, neutral, and alkaline solutions were studied. The influence of the substituents at the 1- and 2-positions of the imidazoline ring on the hydrolytic resistance of these compounds was demonstrated.

DOI: 10.1134/S107042720705014X

2-Substituted and 1,2-disubstituted imidazolines are widely used for preparing cationic and ampholytic surfactants [1–6] and as corrosion inhibitors in production, transportation, and refining of oil [1, 7–13]. The possibility and advisability of industrial application of imidazolines depend significantly on their hydrolytic resistance.

Since preparation of ampholytic surfactants from imidazolines is performed in aqueous solutions at a high excess of alkali metal hydroxide [1–5], hydrolysis of 2-substituted and 1,2-disubstituted imidazolines in alkali solutions was studied most extensively [1, 14–24]. The kinetics of base hydrolysis of 1-hydroxyethyl-2-nonyl-2-imidazoline at 40–90°C was studied in [16–18, 24]. The content of 1,2-disubstituted imidazoline in the hydrolysis products was estimated by IR and UV spectroscopy. Taking into account a large water excess, the experimental results were treated by the pseudo-first-order rate equation. The calculated rate constants of hydrolysis show that hydrolysis of 1-oxyethyl-2-nonyl-2-imidazoline is extremely temperature-sensitive. For examples, at 40°C $K_{hydr} = 1.22 \times 10^{-4}$ and at 90°C $K_{hydr} = 8.42 \times 10^{-4}$ s^{-1} [16]. The apparent activation energy of hydrolysis in the temperature range 40–90°C is very low (5.73 kJ mol^{-1}). The hydrolysis rate constant of 1-hydroxyethyl-2-nonyl-2-imidazoline is almost independent of its concentration. The hydrolysis rate constant varies within the limits of the experimental error when the molar excess of water ranges from 11- to 50-fold and in the presence of *N*-capryl-*N*'-(β-hydroxyethyl)ethylenediamine (hydrolysis product of 1-hydroxyethyl-2-nonyl-2-imidazoline, up to 10 wt %) [16].

The influence of the pH of the solution on the hydrolysis rate is stronger than that of temperature [17–19, 24]. The hydrolysis rate constant at 50°C increases by a factor of more than 40 (from 0.078×10^{-4} to 3.14×10^{-4}) with increasing pH from 8.05 to 12.5. The dependence of $\log K_{hydr}$ on pH is linear and has a bend at pH 9.7. The linearity of the $\log K_{hydr}$–pH dependence suggests that the rate-determining step of the process is nucleophilic attack of OH^- ions on protonated 1-hydroxyethyl-2-nonyl-2-imidazoline:



At pH 9.7, equilibrium (I) is shifted to formation of the neutral product, the fraction of protonated imidazoline decreases, and hence the relative hydrolysis rate decreases [17]. The hydrolysis rate constant decreases also with an increase in the ionic strength of the solution.

A study of the influence of OH^- and imidazoline concentrations on the hydrolysis rate constant showed that the reaction was of the first order with respect to

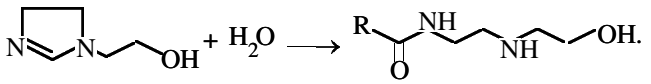
OH^- and imidazoline. Hence, the overall reaction order of 1-hydroxyethyl-2-nonyl-2-imidazoline hydrolysis is second [17].

Savignac et al. [19] studied, with 1-aminoethyl-2-decyl-2-imidazoline and 2-nonyl-2-imidazoline as examples, the influence of the substituent at position 1 of the imidazoline ring on the kinetics of base hydrolysis at 25–50°C. As determined by UV spectroscopy, an increase in the concentration of hydroxide ions in the reaction mixture accelerates substantially hydrolysis of 1,2-disubstituted imizazoline and has virtually no effect on the hydrolysis rate of the 2-substituted imidazoline, irrespective of the temperature. It should be noted that the apparent rate constants of hydrolysis at similar pH differ by approximately an order of magnitude, especially in strongly alkaline solutions (pH > 10) [19]. Substantially lower stability of 1,2-disubstituted imidazoline as compared to that of 2-substituted imidazoline is confirmed by the activation energies of base hydrolysis of these compounds: for 1-aminoethyl-2-decyl-2-imidozaline E_{act} = 69.5 kJ mol^{-1}, and for 2-nonyl-2-imidazoline E_{act} = 75.2 kJ mol^{-1}.

The experimental results show that the amphoteric surfactants prepared by alkylation of 1,2-disubstituted imidazolines with monochlorinated aliphatic carboxylic acids in aqueous alkali solutions (pH 9.5–13.5) at 40–100°C are the reaction products of hydrolyzed imidazolines rather than substituted imidazolines [1–6].

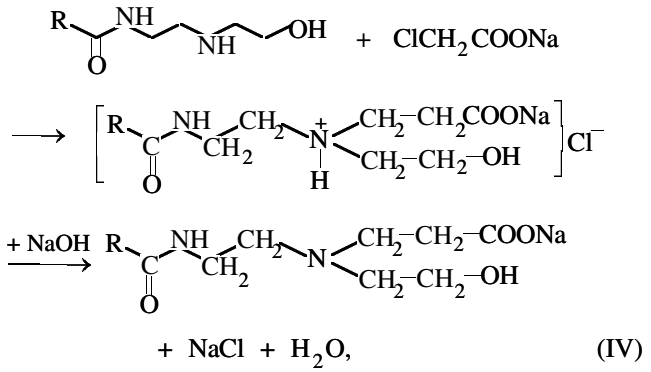
Experiments on alkylation of 1-hydroxyethyl-2-alkyl-2-imidazolines show that at pH ~13.5 their base hydrolysis products but not the initial compounds are alkylated [18, 24].

The absorption at 230 nm completely disappears and a new band at 206 nm appears after reaction of 1-hydroxyethyl-2-nonyl-2-imidazoline with sodium monochloroacetate in the presence of sodium hydroxide. The IR spectrum of the reaction product contains a band of bending vibrations of the N–H bond of secondary amides at 1565 cm^{-1} and the C=O band of the amide group at 1645 cm^{-1}. The bands at 1605 and 1415 cm^{-1} are due to symmetric and antisymmetric vibrations of the carboxy group (COO^-), respectively [18]. The results of elemental analysis, the aggregation state, and the physicochemical and colloidal properties of the products prove the absence of imidazoline ring in the amphoteric surfactants prepared in aqueous alkali solutions and the linear structure of these products. Thus, the first step of alkylation of 1-hydroxyethyl-2-nonyl-2-imidazoline with sodium monochloroacetate is hydrolysis of imidazoline [18, 24] to form acyclic *N*-acyl-(β-hydroxyethyl)ethylenediamine:

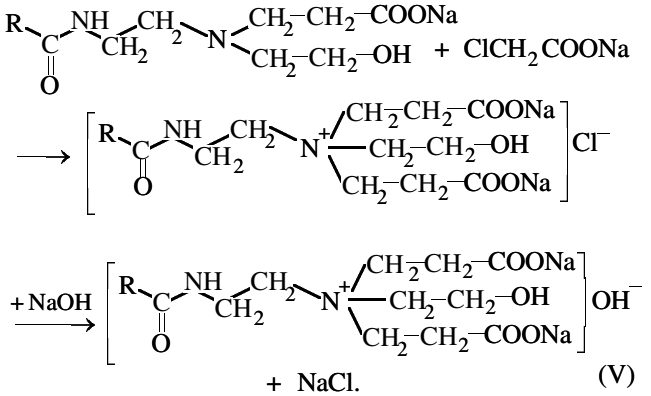


(III)

This is followed by consecutive reactions of nucleophilic substitution in sodium monochloroacetate



(IV)



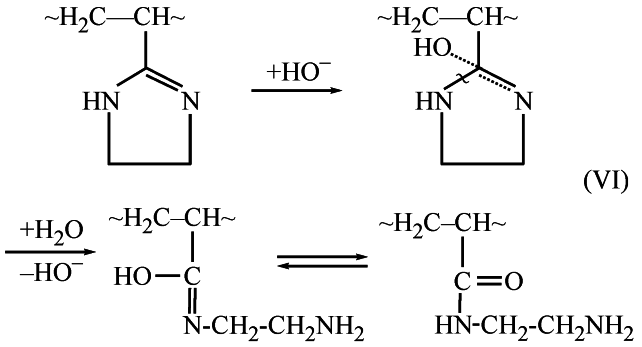
(V)

The main reactions (III)–(V) are accompanied by side hydrolysis of sodium monochloroacetate to form sodium glycolate [24]:

$$ClCH_2COONa + NaOH \rightarrow HOCH_2COONa + NaCl.$$

Since the rate of this reaction is close to that of hydrolysis of 1-hydroxyethyl-2-nonyl-2-imidazoline, these reactions are competitive. The experimental results show that the content of sodium glycolate in the reaction products increases with an increase in pH of the solution [24].

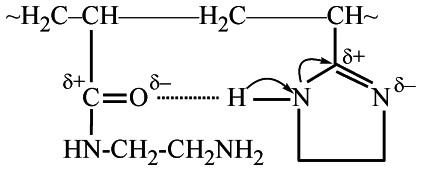
Poly(2-vinyl-2-imidazoline) is more stable in an alkaline solution and is hydrolyzed by the mechanism similar to that of 1-hydroxyethyl-2-alkyl-2-imidazoline [20]:



(VI)

The UV and IR spectra of aqueous solutions of poly(2-vinyl-2-imidazoline) show that this compound is completely hydrolyzed in an alkaline solution within 2 months. The apparent activation energy of hydrolysis at pH 10.7 and 12.0 is 65.2 and 68.6 kJ mol^{-1}, respectively.

It should also be noted that, in the course of hydrolysis, the reactivity of the imidazoline units in the polymer decreases owing to formation of amido amine units in the macromolecules. The amido amine units contain highly polarized carbonyl groups, which promotes shielding and decrease in the positive charge on the second carbon atom of the imidazoline ring:



(VII)

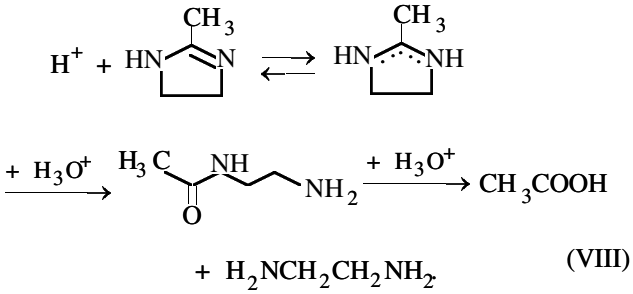
Introduction of a branched substituent at the α-position of the reaction site noticeably complicates addition of hydroxide ion, which can significantly decrease the imidazoline hydrolysis [23].

The apparent hydrolysis rate constant of 1-(2-aminoethyl)-2-(1-ethylpentyl)-2-imidazoline at 50°C and pH 12.4 [$K_{hydr} = (2.8 \pm 0.1) \times 10^{-5}$ s^{-1}] is approximately one order of magnitude lower than that of 1-hydroxyethyl-2-nonyl-2-imidazoline ($K_{hydr} = 30 \times 10^{-5}$ s^{-1}). At 90°C, the apparent hydrolysis rate constant of the imidazoline increases by a factor of approximately 7.5. However, the hydrolysis rate at this temperature is lower by a factor of 25 than that of imidazolines with linear alkyl substituents [21, 23]. The activation parameters of hydrolysis of 1,2-disubstituted imidazolines containing branched substituent at the position 2 of the imidazoline ring were determined from the temperature dependence of $\ln K_{hydr}$. At pH 12, E_{act} for imidazoline with branched alkyl substituents is noticeably higher (53.8 kJ mol^{-1}) than that for imidazolines with linear substituents (44.6 kJ mol^{-1}), with the preexponential factor A being the same ($\log A = 4.1$). As determined by ^{13}C NMR and IR spectroscopy and gas–liquid chromatography, the hydrolysis product of 1-(2-aminoethyl)2-(1-ethylpentyl)-2-imidazoline is *N*-(5-amino-3-azapentyl)-2-ethylhexanamide [23].

The published data on the stability of the imidazoline ring in neutral and acid solutions are rather contradictory [1, 22, 23, 25–29]. Belov et al. [1] state that higher 1,2-disubstitued imidazolines are stable in acid solutions (pH ≤ 7) at elevated temperatures. At the same time, it was shown [14, 15] that in acid solutions the imidazoline ring underwent slow hydrolysis to form the initial acid and the amine.

We studied the stability of the imidazoline ring with 1-hydroxyethyl-2-nonyl-2-imidazoline as example in acid and neutral solutions at 50 and 140°C [26]. The products of hydrolysis at pH ≤ 7 were analyzed by UV spectroscopy and physicochemical methods. At relatively low temperatures (50°C), hydrolysis is noticeably accelerated with increasing acidity, and at high temperatures (140°C) 1-hydroxyethyl-2-nonyl-2-imidazoline is hydrolyzed almost completely to form capric acid and β-hydroxyethylethylendiamine hydrochloride. The experimental data on acid hydrolysis of 2-methylimidazoline at 99.9°C in the presence of 0.1–6.0 M HCl and 4.0–16.0 M H_2SO_4 [27] show that the apparent hydrolysis rate constant increases by a factors of tens with decreasing pH of the solution irrespective of the chemical structure of the acid. An increase in the ionic strength of the solution also decreases the resistance of 2-methylimidazoline to hydrolysis [27].

It should also be noted that the hydrolysis is accelerated with increasing concentration of H_2SO_4 from 4.0 to 11–12 M. In more acidic solutions, the hydrolysis rate decreases, with the final hydrolysis products being acetic acid and ethylenediamine. Haake and Watson [27] suggested a mechanism of acid hydrolysis of 2-methylimidazoline via protonation of the nitrogen atom, followed by rupture of the C–N bond of the imidazoline ring:



(VIII)

The kinetics of acid hydrolysis of 1-aryl-2-phenyl-2-imidazoline and the influence of electron-acceptor substituents on the hydrolysis rate were studied in [28]. It was found that the hydrolysis was accelerated with decreasing pH of the solution (increasing H_2SO_4 concentration). At the H_2SO_4 concentration lower than 1 M, the reaction is of the first order with respect to both imidazoline and H^+. In solutions with higher acid concentration, the hydrolysis rate does not increase.

The basicity of the substituents at position 1 of the imidazoline ring also affects the acid hydrolysis rate of 1,2-disubstituted imidazolines. The acid hydrolysis rate of imidazolines containing benzene substituents with electron-acceptor groups at position 1 of the imidazoline ring is higher by two orders of magnitude that that of imidazolines with electron-donor substituents, which agrees with the Hammett equation [28]

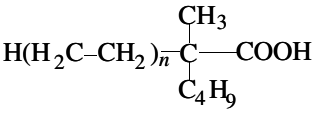
$$\log K_{hydr} = -1.14pK - 6.56.$$

Introduction of an alkyl substituent at the α-position relative to the reaction site enhances, as in the case of base hydrolysis [23], the hydrolytic resistance of the imidazoline ring in neutral and acid solutions. A study of hydrolysis of 1-(2-aminoethyl)-2-(1-ethylpentyl)-2-imidazoline in the pH range 2.0–12.7 showed that the $\log K_{hydr}$ vs. pH dependence measured at 90°C consisted of two linear portions and a bend at pH 10 [23]. At pH 10, the content of imidazoline with protonated primary amino group is the highest. At pH < 6, 1-(2-aminoethyl)-2-(1-ethylpentyl)-2-imidazoline is not noticeably hydrolyzed, although the content of 1,2-disubstituted imidazoline with protonated tertiary nitrogen atom of the imidazoline ring is the highest [23]. Probably, the positive charge on the tertiary nitrogen atom prevents hydrolysis, since no positive charge is formed on the carbon atom in this case.

EXPERIMENTAL

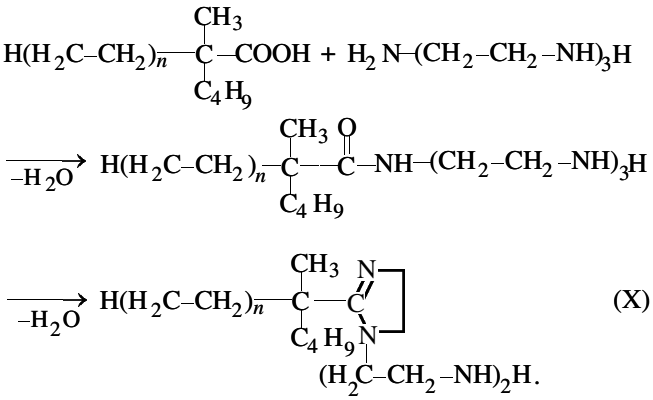
1-[2-(2-Aminoethyl)aminoethyl]-2-alkyl(C_8–C_{18})-2-imidazoline was prepared by condensation of triethylenetetramine with α,α'-branched C_{10}–C_{19} monocarboxylic acids at 250–280°C in a nitrogen atmosphere. The imidazoline content in the condensation products in the course of hydrolysis was estimated by the intensity of the $\pi \rightarrow \pi^*$ band of the C=N bond in the heterocycle at 230–235 nm [23]. The pH of the solutions was measured with an OR211/1 pH meter with a combined glass electrode. The pH of the solution was adjusted with 0.1 N HCl or 0.1 N NaOH.

The facts that the =C–N= bond in 1,2-disubstituted imidazolines prepared from α,α'-branched C_9–C_{19} monocarboxylic acids



(IX)

(n = 1–6) and triethylenetetramine is strongly shielded and the rate of cyclocondensation of the corresponding 1-*N*-monoacyltriethylenetetramine into imidazoline is lower by an order of magnitude than that of linear 1-*N*-monoacylpolyethylenepolyamines [23, 25] suggest that the hydrolytic resistance of 1,2-disubstituted imidazoline prepared from α,α'-branched acids should be higher than that of 1,2-disubstituted imidazolines prepared from linear acids [25]:



(X)

The kinetic curves of hydrolysis of 1-[2-(2-aminoethyl)aminoethyl]-2-alkyl(C_8–C_{18})-2-imidazoline in alkaline solutions (pH 10) are shown in Fig. 1. Analysis for the 1-[2-(2-aminoethyl)aminoethyl]-2-alkyl-(C_{10}–C_{18})-2-imidazoline content in the course of base hydrolysis of 30 wt % solutions containing 2.0 and 1.0 M imidazoline shows no hydrolysis in a period of 30 days. Thus, the imidazoline ring containing branched alkyl radicals at the α-position shows high hydrolytic resistance. An insignificant decrease in the imidazoline content during the first days of storage is probably due to the presence in the condensation products of imidazolines with short (C_2–C_9) linear alkly substituents which are always present in 1-[2-(2-aminoethyl)aminoethyl]-2-alkyl(C_8–C_{18})-2-imidazoline (Fig. 1). The hydrolytic resistance of shielded 1,2-disubstitued imidazolines X in neutral and acid solutions is still higher.

The kinetic curves of acid hydrolysis of 1,2-disubstituted imidazolines are similar (Fig. 2). These compounds are stable at pH 2.

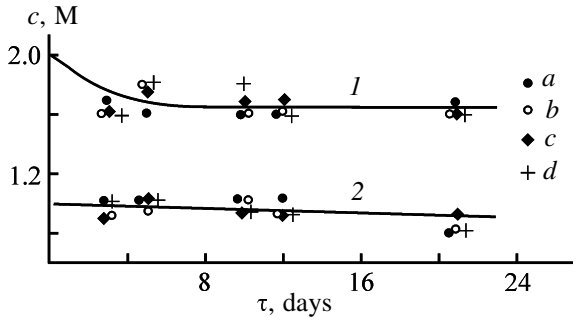


Fig. 1. Kinetic curves of hydrolysis of cyclocondensation products containing (*1*) 65.0 and (*2*) 35.0 wt % of appropriate 1-[2-(2-aminoethyl)aminoethyl]-2-alkyl(C_{10}–C_{18})-2-imidazoline in alkaline solutions (pH 10). (*c*) Concentration and (τ) time; the same for Fig. 2. Water content, %: (*a*) 0–3, (*b*) 0–5, (*c*) 0–10, and (*d*) 0–2; the same for Fig. 2.

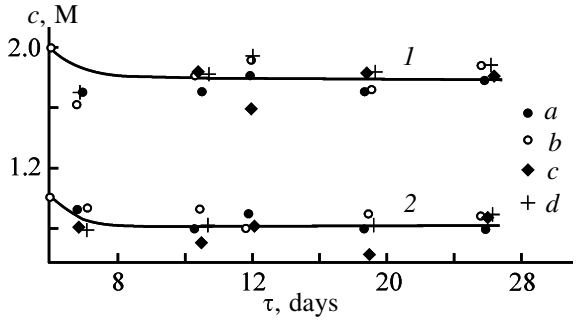

Fig. 2. Kinetic curves of hydrolysis of cyclocondensation products containing (*1*) 65.0 and (*2*) 35.0 wt % of appropriate 1-[2-(2-aminoethyl)aminoethyl]-2-alkyl(C_{10}–C_{18})-2-imidazoline in acid solutions (pH 2).

Thus, comparison of the apparent hydrolysis rate constants in alkaline (~10^{-3} s^{-1}) [17, 19, 23] and acid solutions shows that hydrolysis of the imidazoline ring in acid solutions even at 90–100°C is substantially slower than that in alkaline solutions. The hydrolytic resistance of 1,2-disubstituted imidazolines depends on the type and chemical structure of the substituents at the first and especially second position of the imidazoline ring. Significant shielding of the C–N bond in the condensation products of α,α'-branched saturated monocarboxylic acids with polyethylenediamines sharply enhances the hydrolytic resistance of the imidazoline ring, which is hydrolyzed neither in acidic or neutral nor in alkaline solutions.

CONCLUSION

Shielded 1,2-disubstituted imidazolines prepared by condensation of α,α'-branched saturated monocarboxylic acids with polyethylenepolyamines are resistant to hydrolysis and can be used as effective corrosion inhibitors in production, transportation, and refining of oil and in preparation of cationic and ampholytic surfactants.

Abstract—With the aim of widening the applications of 1,1-dimethyl-1-alkylhydrazinium chlorides, the physicochemical properties (solubility, hygroscopicity, thermal and chemical stability, distribution between aqueous and organic phases) of their homologs with the alkyl radicals $C_{10}H_{21}$–$C_{18}H_{37}$ were studied.

DOI: 10.1134/S1070427207050151

Quaternary hydrazinium salts (QHSs) are known for a long time [1, 2]. The increased current interest in them is caused both by urgency of problem of utilization of 1,1-dimethylhydrazine DMG used as a component of rocket propellant [3] and useful properties of QHS (in particular, 1,1-dimethyl-1-alkylhydrazinium chlorides DMAHCs which can be readily prepared from DMG) [4]. These compounds are cationic surfactants, bactericides [1, 2, 5], and polyfunctional [3, 6] and flotation [7] reagents. The wide application of DMAHCs stimulates study of their physicochemical properties. In available literature we found only data on surface-active properties of a few DMAHCs [1, 2, 5, 7, 8].

In this study we examined the physicochemical characteristics of DMAHC homologs with the alkyl radicals $C_{10}H_{21}$–$C_{18}H_{37}$.

EXPERIMENTAL

1,1-Dimethyl-1-alkylhydrazinium chlorides of the general formula $[C_nH_{2n+1}(CH_3)_2NNH_2]Cl$, where n = 10, 12, 14, 16, 18, and 12 + 14 mixture, were prepared by quaternization of DMH by the reaction with primary chloroalkanes [9]

$$C_nH_{2n+1}Cl + (CH_3)_2NNH_2 \rightleftarrows \underset{\mathbf{I}}{[C_nH_{2n+1}(CH_3)_2NNH_2]Cl}, \quad (1)$$

The product of reaction (1) was doubly or triply recrystallized from acetone, and the main compound content in the final product was determined by the modified volumetric method as follows [10]. A weighed portion of the product to be analyzed (about 0.05 g) was dissolved in 0.1 N HCl and then chloroform (20 ml), and 1–2 drops of a mixed indicator (0.1% alcoholic solution of Dimethyl Yellow + 0.1% alcoholic solution of Methylene Blue in their volume ratio of 2 : 1) were added; the resulting mixture was titrated at stirring with 0.015 M aqueous sodium lauryl sulfate until the color of the chloroform layer changed from yellow-green to pink-violet. The DMAHC content c_{DMAHC} was calculated by the equation

$$c_{DMAHC} = \frac{V_{ls}N_{ls}M_{DMAHC}}{m_w 1000} \times 100, \quad (2)$$

where V_{ls} is the volume of aqueous lauryl sulfate consumed for titration (cm^3); N_{ls}, lauryl sulfate concentration in the titrant (g-equiv l^{-1}); M_{DMAHC}, DMAHC molecular weight; and m_w, DMAHC weighed portion.

The hygroscopicity of DMAHCs was determined as follows. A DMAHC portion was dried at 80°C and then weighed (P_0, g). This weighed sample was kept at room temperature (20°C) at controlled humidity and then weighed again. The relative increase in the moisture content of DMAHCs, ΔH_2O (%), was calculated by the equation

$$\Delta H_2O = \frac{P - P_0}{P_0} \times 100. \quad (3)$$

The solubility of DMAHCs in water and organic solvents was determined gravimetrically. To do this, an aliquot of a saturated solution of DMAHC was heated to evaporate the solvent and the resulting residue was kept in an oven at 105–110°C to constant weight.

The thermal stability of DMAHCs was examined thermogravimetrically on a Q-1500D derivatograph (MOM, Hungary) in air (weighed portion 190–200 mg, temperature range 20–500°C, heating rate 10 deg min^{-1}).

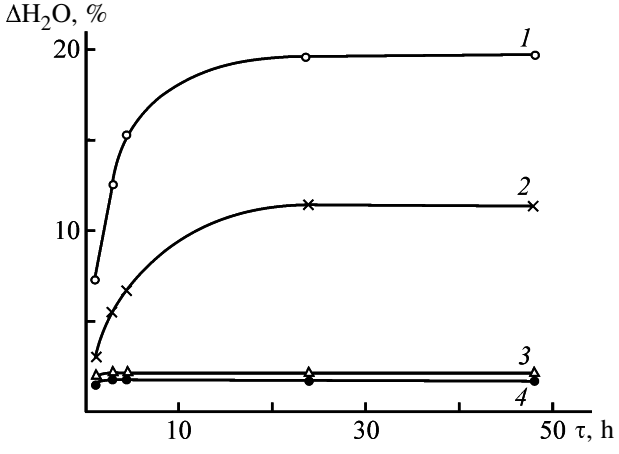

Fig. 1. Water content ΔH_2O in DMAHCs $[(CH_3)_2RNNH_2]Cl$ vs. the time of keeping in air of 96% humidity. (τ) time. R: (*1*) C_{10}, (*2*) $C_{12} + C_{14}$, (*3*) C_{12}, and (*4*) C_{16}.

The IR spectra of DMAHCs (mull in Vaseline oil) were recorded on a UR-20 spectrophotometer.

The chemical stability was determined by two different techniques. In the first method, a weighed portion of DMAHC was dissolved in 1 M aqueous HCl or NaOH, and the DMAHC content was determined by titration with aqueous sodium lauryl sulfate. In the second method, DMAHC was dissolved in water and its content was determined at regular intervals during a period of 154 days.

The distribution of DMAHCs between aqueous and organic phases was determined as follows. A 0.072–0.100 M DMAHC in an organic solvent (5 ml) was shaken with 0.1 N aqueous H_2SO_4 at $V_o : V_{aq} = 1 : 10$ for 3 min. Upon standing for 30 min, an aliquot of the aqueous phase (10 ml) was sampled and analyzed for DMAHC by microvolumetric titration with aqueous sodium lauryl sulfate. The distribution ratio of DMAHCs between the aqueous and organic phases *D* was calculated by the equation

$$D = [c_0 - c_{aq}(V_{aq}/V_o)]c_{aq}^{-1}, \quad (4)$$

where c_0 is the initial DMAHC concentration in the organic phase (M); c_{aq}, equilibrium DMAHC concentration in the aqueous phase (M); and V_{aq} and V_o, volumes (cm^3) of the aqueous and organic phases, respectively.

The average distribution ratios D_{av} of DMAHCs under consideration were determined from five successive contacts of the initial organic solution with fresh portions of water after complete removal of the previous aqueous phase equilibrated with the organic phase.

The DMAHCs under consideration (Table 1) are white crystalline compounds. The lower homolog (n = 10) deliquesces in air. Figure 1 shows the kinetics of absorption of water with various DMAHCs from air at a relative humidity of 96%.

Figure 1 shows that the hygroscopicity of individual DMAHCs strongly depends on the radical length and sharply decreases in going from DMAHC with $R = C_{10}H_{21}$ to that with $R = C_{18}H_{37}$. The commercial DMAHC ($C_{12} + C_{14}$) has relatively high hygroscopicity: after 48-h keeping in air, its weight increased by 9%.

Table 2 shows the solubility of DMAHCs in various solvents. It is seen that DMAHCs with $R = C_{10}$,

C_{12}, and C_{14} readily dissolve in water. However, with further lengthening radicals, the solubility sharply decreases. The solubility of DMAHC with R = C_{18} is as low as 2.0 g l^{-1}. The dependence of the solubility of DMAHCs in 2-ethylhexanol on the radical length is similar. In toluene and hexane all the DMAHCs are poorly soluble.

Three DMAHC samples (individual DMAHCs with R = C_{12} and R = C_{14} and a commercial mixture with R = C_{12} + C_{14}) were tested for their thermal stability in air. Figure 2 shows as an example the thermogravimetric diagram of DMAHC with R = C_{14}. The other individual DMACHs show similar thermal behavior.

We observed no weight loss of individual DMAHCs on their heating up to 190°C, i.e., within this temperature range these compounds are thermally stable. At the same time, the mixed DMAHC with R = C_{12} + C_{14} slowly loses its weight (by 10% in heating from 20 to 190°C). On heating above 200°C, all the DMAHCs begin to decompose, and this process is accompanied by heat evolution, formation of white gaseous products, and considerable weight loss.

The IR spectra of DMAHCs with R = C_{12} and C_{14} and of their commercial mixture contain absorption bands of medium intensity of the ν_{NH_2} vibrations (3200–3190, 3080–3065 cm^{-1}), δ_{NH_2} bands (1635–1630 cm^{-1}), the ν_{NN} bands (1100–1090 cm^{-1}) and a weak absorption band of the ν_{N^+C} vibrations (1400–1410 cm^{-1}). These spectroscopic characteristics of DMAHCs agree with those reported in [11].

Table 3 illustrates the stability of 26.7 and 29.3% aqueous solutions of DMAHCs in their storage in a polyethylene flask for 154 days. Two samples of mixed commercial DMAHC with R = C_{12} + C_{14} were tested. In the course of these experiments, the solution of DMAHCs was sampled at regular intervals and analyzed for the DMAHC content. Table 3 shows that throughout the storage time the main compound content remains constant within the determination error (5 rel. %).

The DMAHCs with R = C_{10} and R = C_{16} were tested for their chemical stability. To do this, the first compound was kept at a constant temperature of 60°C for 4 h, and the second DMAHC was refluxed in 1 M aqueous HCl and NaOH for 2 h. We found that such a treatment did not alter the chemical composition of the compounds under consideration. These results disagree with the data reported in [11] which show that under identical conditions DMAHC with R = C_{12} decomposes to give dodecylmethylamine and dodecene.

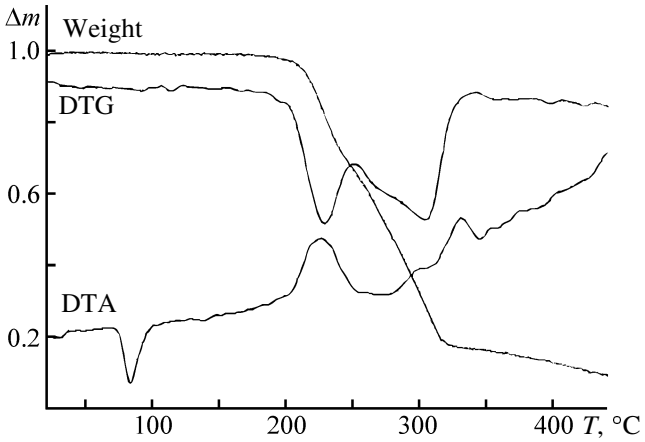

Fig. 2. Thermogravimetric diagram of DMAHC (R = C_{14}). (Δm) Weight loss and (T) temperature.

It is possible that this difference is caused by higher alkali concentration used in [11].

Table 4 shows the distribution ratios of DMAHCs between 0.1 M aqueous H_2SO_4 and 2-ethylhexanol

Table 3. Stability of aqueous DMAHC (R = C_{12} + C_{14}) in prolonged storage at room temperature*

Storage time, days	Main compound content, wt %	
	sample no. 1	sample no. 2
0	26.7	29.3
7	26.4	28.5
56	26.8	29.2
84	26.5	29.3
140	26.7	29.0
154	26.6	29.2

* Evaluated as the average from results of two determinations; the main compound content was determined by potentiometric titration of ~0.3–0.5-ml aliquots with 0.01 M aqueous $AgNO_3$ in 0.01 M aqueous HNO_3 using silver and silver chloride electrodes.

Table 4. Average distribution ratios D_x of DMAHCs between 0.1 M aqueous H_2SO_4 and 2-ethylhexanol (2-EG). $V_0 : V_{aq} = 1 : 10$

R	M	DMAHC concentration, M		D_x*
		initial in 2-EG, $c_0 \times 10^2$	after phase separation, $c_{aq} \times 10^3$	
$C_{14}H_{29}$	292.5	10.0	1.42	60
$C_{16}H_{33}$	320.5	9.3	0.44	201
$C_{18}H_{37}$	348.5	7.20	0.106	659

* Average from five experiments.

(2-EG). It is seen that, with lengthening radicals from C_{14} to C_{18}, the distribution ratio increases from 60 to 659.

It is known [12] that the distribution ratio of homologous extractable organic species correlates with their radical length:

$$\log D_x = \log D_0 + hn, \quad (5)$$

where D_0 and D_x are the distribution ratios of the reference and tested extractable species depending on particular organic solvent; n, number of methylene groups in homologous extractable species; and h, contribution of the CH_2 group to the distribution ratio.

The factor h calculated from the experimental data listed in Table 4 was found to be 0.26. This value is smaller than h ~0.52 reported in [12] for homologous series of aliphatic amines.

With the mixed solvent 2-EG-xylene (2-EG to xylene ratio 1 : 1), D_x of DMAHC with R = $C_{18}H_{37}$ was found to be 1150, i.e., the loss of the reagent with the aqueous phase is smaller than in the system with straight 2-EG.

CONCLUSIONS

(1) In homologous series of 1,1-dimethyl-1-alkylhyldrazinium chlorides $[(CH_3)_2NNH_2]Cl$, the relatively high hygroscopicity is shown only by homologs with R = C_{10} and commercial mixture with R = C_{12} + C_{14}, and the hygroscopicity sharply decreases in going to longer alkyl substituents.

(2) Among the solvents tested, 1,1-dimethyl-1-alkylhydrazinium chlorides readily dissolve in 2-ethylhexanol and especially in water; the solubility rapidly decreases with increasing length of radical.

(3) 1,1-Dimethyl-1-alkylhydrazinium chlorides are stable in 1 M aqueous NaOH and HCl and are thermally stable on heating to 190 °C. Their aqueous solutions remain stable in the course of no less than 6-month storage.

(4) The distribution ratio of 1,1-dimethyl-1-alkylhydrazinium chlorides between aqueous and 2-ethylhexanol phases increases from 60 to 659 with increasing length of the alkyl radical (going from $C_{14}H_{25}$ to $C_{18}H_{37}$).

(5) The physicochemical properties of 1,1-dimethyl-1-alkylhydrazinium chlorides obtained in this study allow their wider applications.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of the Methyl Cellulose–Polyvinylpyrrolidone Binary System in Solution and in the Solid State

Abstract—Rheological properties of dilute and moderately concentrated aqueous solutions of methyl cellulose–polyvinylpyrrolidone blends, as well as the conditions of gelation in them, were studied. Films were obtained from solutions of the polymer blends, and their physicomechanical properties were examined. The range of the compositions corresponding to thermodynamic compatibility of methyl cellulose with polyvinylpyrrolidone was identified by the solvent vapor sorption method and by thermomechanical examinations of the films.

DOI: 10.1134/S1070427207050163

Preparation of cellulose materials with novel or improved properties through combining cellulose ethers with synthetic polymers is of scientific and practical interest. Structural modification of polymers by combining two polymers of different chemical structures in a common solvent allows preparation of polymer blends with controllable properties. Depending on the chemical composition, rigidity of the macromolecular chain, degree of polymerization, and kind of solvent, the blended polymers can form in solution structures of different organization and stability.

Increased attention is given today to self-associated polymer systems based on environmentally safe and biodegradable natural polymers [1]. Among these polymers are water-soluble compounds of cellulose: sodium salt of carboxymethyl cellulose (NaCMC), methyl cellulose (MC), and other ethers [2, 3]. Methyl cellulose is widely used as thickener of muds in oil extraction, as well as in textile, pulp and paper, food, and pharmaceutical industries [4]. The rheological properties of MC solutions and conditions of gelation in them, as well as the physicomechanical properties of the films obtained from solutions, can also be varied by introducing a different water-soluble polymer into solutions [5–7].

Polyvinylpyrrolidone (PVP) is used in production of tableted medicines and also serves as blood substitute and blood detoxifier. It is used for preparing prolonged-action agents with a wide activity spectrum [8].

In this study we examined the rheological properties of dilute and moderately concentrated solutions of MC–PVP blends, as well as the thermodynamic compatibility of these polymers and the physicomechanical and thermomechanical properties of the films obtained from their solutions.

Examination of the properties of MC–PVP blends was motivated by a search for new modifiers of methyl cellulose intended for encapsulation of medicines, as well as by the possibility for preparing film materials containing PVP which, in turn, is suitable as the basis for medicines.

EXPERIMENTAL

The objects of our study were commercial samples of MC with the degree of substitution of 1.7 and molecular weight (MW) of 150000 and PVP with MW of 14200. The solutions of the MC–PVP blends were prepared by mixing equiconcentrated solutions of the two polymers at different component ratios. Distilled water served as the solvent. The viscosity of the dilute solutions was measured on an Ubbelohde capillary viscometer at 20°C.

The rheological properties of moderately concentrated solutions (2 wt %) were studied on a Rheotest-2.1 rheoviscometer at shear stresses within 3–600 Pa at 20–50°C. The gelation onset temperature T_{gel} in solutions was determined from the change of the viscosity of the solutions on a Hoeppler viscometer.

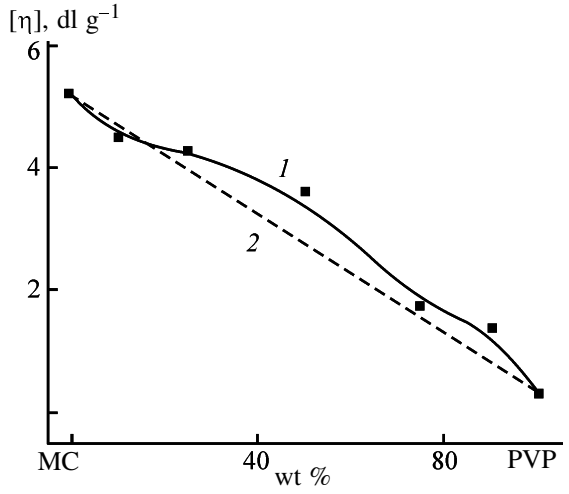

Fig. 1. (*1*) Experimental $[\eta]_e$ and (*2*) calculated $[\eta]_c$ intrinsic viscosities $[\eta]$ of the MC–PVP blends as functions of the composition at 20°C.

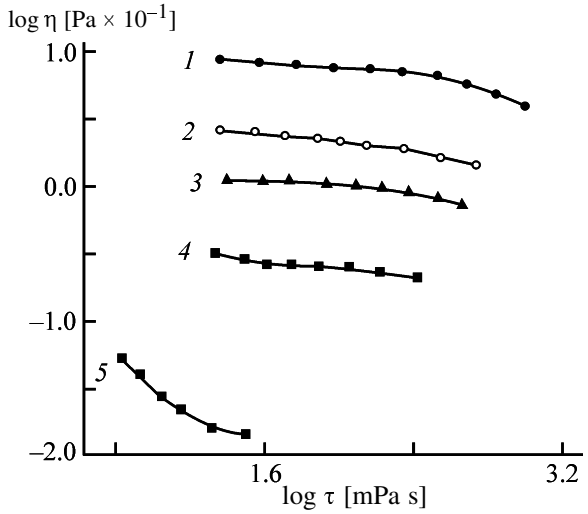

Fig. 2. Flow curves of 2% solutions of (*1*) MC, (*2–4*) MC–PVP blends, and (*5*) PVP at 20°C. (η) Viscosity and (τ) shear stress. PVP content, wt %: (*2*) 30, (*3*) 50, and (*4*) 70.

The compatibility of the polymers, depending on the blend composition, was determined by the solvent vapor sorption on films formed from 2% solutions, as well as from the change in the glass transition points of the polymers T_g in films. The films from the polymer blend solutions were formed by the dry method using a laboratory draw plate with controlled slit.

The mechanical characteristics of the films formed from blends were determined at room temperature in the uniaxial stretching mode on a UTS 10 (UTS-testsysteme, Germany) universal setup for mechanical tests. The samples were stretched at a rate of 20 mm min^{-1} (100% of the initial length of the sample per minute). We recorded the sample stretching diagram, which allowed estimation of the modulus of elasticity E, elastic limit σ_e, tensile strength σ_t, and breaking elongation ε_b.

The glass transition point T_g was determined by a thermomechanical method on a UMIV-3 setup; the sample heating rate was 50 deg min^{-1} at a constant stretching load of 0.5 MPa.

To characterize the mutual influence of the MC and PVP macromolecules in solutions, we examined variation of the intrinsic viscosity $[\eta]_e$ of blends of different compositions. We recorded deviation of $[\eta]_e$ of the blends from the calculated ideal values $[\eta]_c$. This deviation can be treated as a measure of intermolecular interactions of different kinds of polymers [9].

The ideal $[\eta]_c$ values were calculated by the formula

$$[\eta]_c = [\eta]_1 W_1 + [\eta]_2 W_2, \quad (1)$$

where $[\eta]_1$ and $[\eta]_2$ are the experimental intrinsic viscosities of the first and second components of the blend, and W_1 and W_2, their mass fractions, respectively.

Figure 1 shows how the experimental $[\eta]_e$ and calculated $[\eta]_c$ intrinsic viscosities vary with the MC–PVP blend composition. For all the compositions, except for the blend containing 10 wt % PVP, the experimental viscosity exhibits a positive deviation from the calculated viscosity.

A positive deviation of the experimental viscosity of the blends of dilute solutions from the calculated viscosity suggests predominance in the solution of intermolecular interactions of the different kinds of macromolecules, yielding structures whose hydrodynamic volume exceeds the weighted-average hydrodynamic volumes of the two components taken separately. A negative deviation of the $[\eta]_e$ parameters of the blends from the additive values can be due both to compaction of the polymer macromolecules in the case of their incompatibility and to formation of mixed complexes whose hydrodynamic volume is smaller than those of the macromolecules of the two polymeric components taken separately.

The intermolecular interactions in moderately concentrated solutions were analyzed through examination of the rheological properties of the 2% solutions of MC–PVP blends at 20–50°C. Figure 2 presents as an example the flow curves for the solutions of MC and PVP and their blends of different compositions at 20°C. The flow curves of the solutions of MC, PVP, and their blends are partial flow curves of non-

Table 1. Amount of the water sorbed Q, volume fractions of the solvent φ_1 and polymer φ_2, and polymer–solvent χ_1 and polymer–polymer χ_{23} interaction parameters

Newtonian fluids. The structural viscosity branch for the MC solution becomes prominent at shear stresses over $\log\tau = 2.4$ ($\tau > 250$ Pa $\times 10^{-1}$). The viscosity of the PVP solution is much lower than that of the MC solution because of a lower molecular weight of the synthetic polymer.

The temperature dependences of the viscosities of the solutions of the blends (20–45°C) were used for calculating the heat of activation of viscous flow of solutions E_a. Figure 3 shows how the viscosity of concentrated solutions of the blends, heat of activation of viscous flow E_a, and gelation onset temperature T_{gel} vary with the composition of the 2% solutions. It is seen that the viscosity of the concentrated solutions of the blends exceeds the additive value; the same is true of E_a. The observed positive deviations of the viscosity and E_a can be due to formation in solutions of the blends of a new three-dimensional system of hydrogen bonds and of new mixed structural units due to interaction of different kinds of polymer macromolecules.

With increasing PVP fraction, the gelation onset temperature T_{gel} tends to increase, presumably due to a decrease in the fraction of the gel-forming polymer, MC. At the PVP content over 90 wt %, no gelation is observed in solutions.

To estimate the thermodynamic compatibility of MC with PVP, as well as the affinity of the polymer for the solvent, we used the solvent vapor sorption method [10]. Samples of films prepared from the solutions were vacuum-dried to constant weight, placed into a closed vessel containing water, and kept in the atmosphere of saturated vapor at 20°C until the equilibrium was attained, whereupon the samples were weighed, and the degree of swelling of the films was determined.

Table 1 presents data on the water vapor sorption by the films. Based on the experimental degrees of swelling of the films we calculated the polymer–solvent interaction parameter χ_1 and the polymer–polymer interaction parameter χ_{23}; χ_1 was calculated by the Flory–Huggins equation [11]

$$\ln a_1 = \ln(P_1/P_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \quad (2)$$

where a_1 is the solvent activity, and P_1/P_1^0, relative pressure of the solvent vapor.

The experiments were performed at the saturated solvent vapor pressure, i.e., at $a_1 = P_1/P_1^0 = 1$, $\ln a_1 = 0$. The volume proportion of the polymer was calculated by the expression

$$\varphi_2 = 1/[1 + (d_2/d_1)W], \quad (3)$$

where d_1 is the solvent density; d_2, polymer density; and W, amount of the solvent sorbed, g g^{-1}.

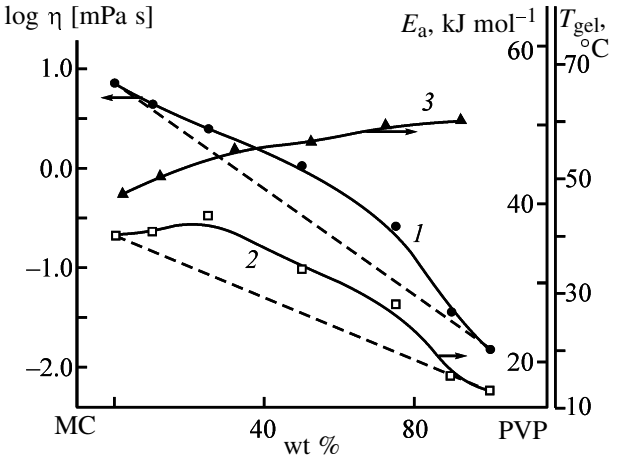

Fig. 3. (*1*) Viscosity η, (*2*) viscous flow activation energy E_a, and (*3*) gelation onset temperature T_{gel}, °C, as functions of the composition of 2% MC–PVP solutions.

The density of the samples was determined by hydrostatic weighing in heptane.

The polymer–polymer interaction parameter χ_{23} was calculated by the Patterson relationship [12]:

$$\chi_{23} = \chi_{12}\varphi_a + \chi_{13}\varphi_b - \chi_{1(23)}/\varphi_a\varphi_b, \quad (4)$$

where χ_{12}, χ_{13}, and $\chi_{1(23)}$ are the Flory–Huggins parameters of interaction with water of individual polymers MC and PVP and their blends, respectively, and φ_a and φ_b, volume proportions of MC and PVP in the blend, respectively. For blends of compatible polymers $\chi_{23} < 0$ [13].

Table 1 shows that, in the solid state (films), MC is compatible with PVP in the polymer blends containing up to 40% PVP. At the PVP content above 60% the polymers are incompatible.

It should be noted that the data on the compatibility of MC with PVP, derived from water vapor sorption experiments, do not always correlate with the measured viscosities of dilute solutions of polymer blends (Fig. 1) As mentioned above, in the case of compatibility of different kinds of polymers in dilute solutions (in our case, with up to 10 wt % PVP), negative deviations of $[\eta]_e$ from $[\eta]_c$ can be due to formation of mixed structural units whose hydrodynamic volume is smaller than those of the macromolecules of both polymeric components taken separately. With over 10% PVP in the solutions, the experimental viscosity exhibits a positive deviation from the calculated data. This is also due to formation of mixed structural units whose hydrodynamic volume exceeds the weighted-average hydrodynamic volumes of the two components taken separately because of the predominance of intermolecular interactions of different kinds of macromolecules. In the case of the polymer blends in the solid state, the polymers are compatible only in films with up to 40–50 wt % PVP. These contradictions between the data on the compatibility of the same polymers, obtained by two different methods, are due to changes in the affinity of the different kinds of polymers, observed with variation of the total concentration of the polymers in solution. As known, the compatibility of polymers can decrease with increasing concentration of solutions. Presumably, in dilute solutions, MC and PVP are compatible throughout the composition range examined. During formation of the films, the solvent evaporates, and the range of the compositions of the polymers within which they are compatible tends to decrease with increasing concentration of the solution.

It was of interest to examine the physicomechanical properties and characteristics of the relaxation transitions of the MC–PVP blend films. As known, PVP, though exhibiting a biological activity, is not a film-forming polymer. However, film materials (films, coatings) can be prepared from blends of PVP with other polymers having film-forming properties. Methyl cellulose is suitable for these purposes because its films exhibit a high strength, are elastic, and do not exert harmful or irritating effect on human body [14].

In mechanical tests we used MC films and films of blends with up to 50% PVP. It should be noted that, throughout the composition range examined, we obtained uniform transparent films. Further increase of the PVP concentration in the blends resulted in formation of turbid nonuniform films whose appearance suggested the onset of phase segregation in the material. The results of the tests are summarized in Table 2.

Analysis of the trends in variation of the modulus of elasticity E with the composition of the composite films revealed a marked decrease in the film rigidity with increasing PVP fraction in the blends: The Young modulus decreases by 25% with increasing

PVP fraction from 0 to 0.50. Similar, through less prominent, trend is exhibited by the elastic limit σ_e.

The dependences of the mechanical characteristics of the films on their composition are determined by the combined action of several factors. On the one hand, the deformability of the films does not decrease with increasing PVP content in the blend to 50%. By contrast, the breaking elongation clearly grows with increasing PVP fraction in the blend to 0.40. It should be emphasized that, even at a fairly high content of PVP in the blend (up to 50%), we obtained nonbrittle elastic films suitable for practical application. At the same time, increase in the PVP content in the blend within the limits mentioned causes the strength of films to decrease by 1/3 of that of films of pure MC. Combined with an increase in the tensile strain and the slightly varying elastic limit, this decrease can be attributed only to the change in the nature of the deformation processes in films with increasing PVP content. Indeed, this is suggested by the change in the appearance of the deformation curves of the film in changing from MC to blends with a substantial content of PVP (Fig. 4).

The MC film exhibits a stretching diagram typical for rigid-chain polymers with initially stretched unfolded chains, while, upon introducing PVP, the deformation of the film after passing through the elastic limit (at 5–10% strain) acquires a prominently plastic nature. The diagram contains a prominent section in which the film deformation proceeds without marked increase in the force, i.e., orientation and unfolding of the macromolecular chains are observed. This section is not long, i.e., introduction of PVP into the material causes only a small growth of the folding of the supporting macrochains, but this growth is specifically responsible for deterioration of the strength characteristics of the films of the blends.

Examination of the characteristics of the relaxation transitions in the films of blends is a very important stage of the study, since specifically these data furnish information on the compatibility of the components of the MC–PVP blends in the condensed state. These characteristics were determined by the thermomechanical method (Fig. 5). The temperatures of the transitions recorded during thermomechanical tests of the films of different compositions are presented in Table 2.

It is seen that no individual temperatures of phase transitions characterizing each of the blend components can be identified in the thermomechanical curves of the blends.

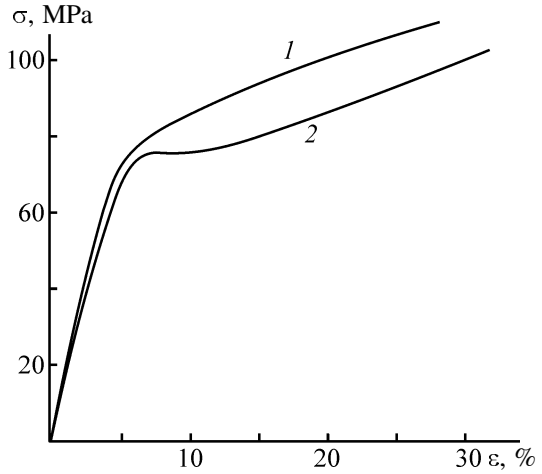

Fig. 4. Stretching diagrams of the (*1*) MC films and (*2*) films of MC–PVP blends with 50% PVP. (σ) Stretching stress and (ε) relative elongation.

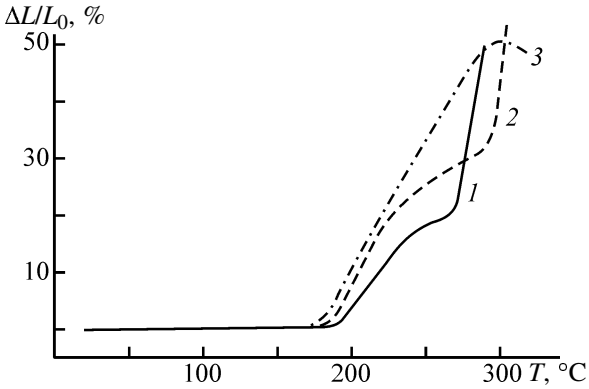

Fig. 5. Thermomechanical curves of the (*1*) MC films and (*2, 3*) films of MC–PVP blends with (*2*) 30% and (*3*) 50 wt % PVP. ($\Delta L/L_0$) Relative strain and (*T*) temperature.

The MC films exhibit two temperature transitions: The mobility of the macrochains sharply increases near 190°C (glass transition point of MC) and, upon further increase of temperature, the mobility increases once again near 270°C (Fig. 5). Evidently, this high-temperature transition reflects melting of the ordered domains in MC; the temperature range within which it is observed agrees well with the melting points of MC, reported in [15]. Further heating leads to degradation of the MC film virtually immediately after this transition.

Upon changing from MC to MC–PVP blends, no additional transitions appear in the thermomechanical curves in the range of temperatures corresponding to the glass transition point of PVP, near 150°C [8]. At the same time, the glass transition gradually shifts to lower temperatures with increasing PVP content in the blend (increase in the PVP content in the blend

to 50% causes the glass transition point to shift by over 15°C). These features of thermal behavior is indicative of both a high compatibility of the blend components throughout the composition range examined, i.e., of blends with the PVP content of up to 50% (the polymers do not form individual phases and exist as a solid molecular solution) and of strong intermolecular interaction. Thus, the range of the MC–PVP compositions in which the polymers are compatible, determined by thermomechanical method, is identical to that revealed by the solvent vapor sorption method.

CONCLUSIONS

(1) Viscous properties of dilute and moderately concentrated aqueous solutions of methyl cellulose, polyvinylpyrrolidone, and their blends of different compositions were examined. For moderately concentrated solutions of the polymer blends, the viscosity of the solutions and the heat of activation of viscous flow exhibit positive deviations from the additive values. This can be due to intermolecular interaction of the polymers, resulting in formation of mixed structures with a new hydrogen bond system.

(2) The gelation onset temperature in the solutions increases with increasing PVP fraction in the blends.

(3) The compatibility of methyl cellulose with polyvinylpyrrolidone in films was examined by the solvent vapor sorption method. In composite films with up to 50% polyvinylpyrrolidone, the polymers are thermodynamically compatible.

(4) Transparent uniform composite films of methyl cellulose with polyvinylpyrrolidone, containing up to 50% of the latter and exhibiting high deformation and strength properties, were obtained. Thermomechanical tests of the resulting films showed that, by varying the quantitative composition over a wide range, from pure methyl cellulose to blends with up to 50% polyvinylpyrrolidone, it is possible to obtain polymeric composite materials with a high degree of dispersion of the components forming solid molecular solutions.

Abstract—Random 50 : 50 *N*-methacryloylglucosamine–*N*-vinylformamide copolymers were synthesized, and their hydrodynamic and molecular characteristics were examined. For the copolymers with the molecular weight $70 < M \times 10^{-3}$ g mol^{-1} < 570 in 0.2 M NaCl, the Kuhn–Mark–Houwink–Sakurada equations were obtained, which relate the intrinsic viscosity and the translational diffusion and centrifugal sedimentation coefficients, on the one hand, to the molecular weight, on the other. The length of the statistical segment of the copolymer chains was estimated.

DOI: 10.1134/S1070427207050175

Interaction of biopolymer macromolecules plays an important role in biological processes, in particular, in intercellular recognition. In these interactions, of key importance are glycoprotein molecules containing both the peptide and carbohydrate moieties. The mechanisms of intercellular recognition are examined for various model polymeric systems of a simpler chemical structure than glycoproteins, whose structure can be controlled. Possible models of glycoproteins include, e.g., carbon-chain polymers containing in their side chain the characteristic functional groups, carbohydrate moieties and amide groups. Examples of such model systems are vinylsaccharide–vinylamide copolymers, e.g., *N*-vinylformamide (VFA)–*N*-methacryloylglucosamine (MAG) copolymers [1]. The presence of carbohydrate moieties and amide groups in the same macromolecule, able of forming hydrogen bonds under intra- and interchain contacts, can substantially affect their conformational properties. We examined earlier the conformational properties of homopolymers, poly-*N*-methacryloylglucose (PMAG) [2, 3] and poly-*N*-vinylformamide (PVFA) [4]. We found that both belong to flexible-chain polymers and revealed a difference between them, consisting in a slightly larger equilibrium rigidity of the PMAG chains. The potential tendency of the PMAG and PVFA macromolecules to intrachain interactions with hydrogen bonding between the –CO–NH– and OH– groups makes of interest elucidation of how the intrachain hydrogen bonds can affect the conformational properties of the MAG–VFA copolymers simulating glycoproteins.

In this study we synthesized 50 : 50 MAG–VFA copolymers with different molecular weights and examined their molecular and conformational characteristics by the molecular hydrodynamics methods.

EXPERIMENTAL

The MAG–VFA copolymers were synthesized as described earlier [1]. To obtain the copolymers with a wide range of molecular weights, we varied the nature of the initiator and its content in the polymerization medium and the concentrations of the comonomers, and also used various solvents. The synthesis conditions for the copolymers are presented in Table 1.

The hydrodynamic characteristics of the copolymers were studied in 0.2 M NaCl with the following

Table 1. MAG : VFA = 50 : 50 copolymerization at T = 60°C

characteristics at 20°C: density $\rho_0 = 1.007\ g\ cm^{-3}$ and dynamic viscosity $\eta_0 = 1.0 \times 10^{-2}$ P. The translational diffusion was studied on a Tsvetkov diffusometer [5] in a glass cell, 3 cm in length along the beam path. The solution with the concentration no higher than $c = 0.10 \times 10^{-2}\ g\ cm^{-3}$ was introduced under the solvent layer. The variance of the diffusion boundary σ^2 was calculated from the area and the maximal ordinate of the symmetrical diffusion curve. From the variance vs. diffusion time t plot we estimated the translational diffusion coefficient D (Fig. 1) by the relationship

$$\delta^2 = \sigma_0^2 + 2Dt. \quad (1)$$

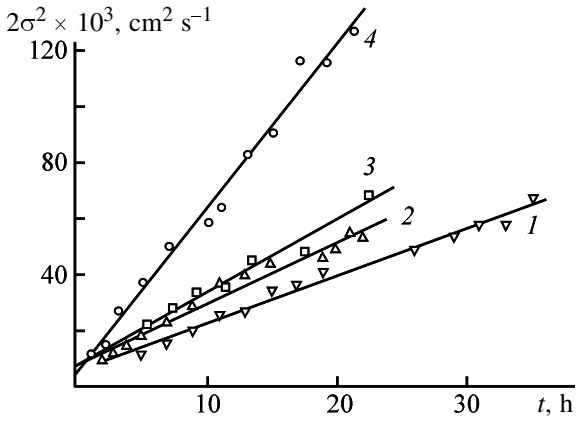

Fig. 1. Diffusion boundary variance σ^2 vs. the diffusion time t. Digits at straight lines correspond to the copolymer sample nos. in Table 2; the same for Fig. 3.

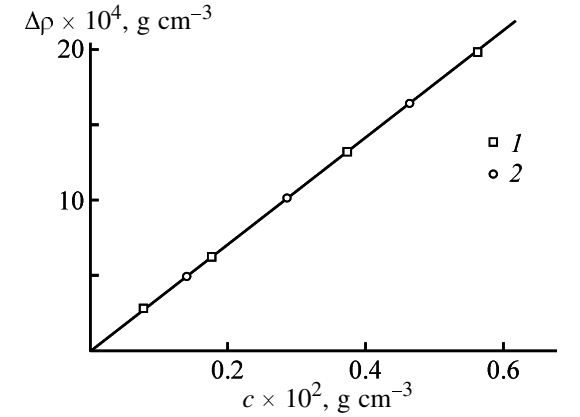

Fig. 2. Difference in density between the solution and solvent $\Delta\rho$ vs. the concentration c of the aqueous solution for sample no. (*2*) 1 and (*1*) 3 (Table 2).

The solutions were diluted and satisfied the condition of virtually limiting dilution $c[\eta] \ll 0.1$, where $[\eta]$ is the intrinsic viscosity. Hence, we took the parameter D equal to that corresponding to the limiting dilution D_0, which was further used for calculating the molecular weight.

The density increment $\Delta\rho/\Delta c$ or the buoyancy factor $(1 - v\rho_0)$ of the copolymer solutions in straight water was determined from the concentration dependence of the density (Fig. 2). The density of the solutions was measured on a Kratky densitometer (A. Paar, Austria) at 20°C [6]. Based on the $\Delta\rho/\Delta c = (1 - v\rho_0)$ parameter, we estimated the partial specific volume v of the copolymer at $0.651 \pm 0.003\ cm^3\ g^{-1}$.

The viscometric measurements were carried out on an Ostwald viscometer (Fig. 3). The intrinsic viscosities $[\eta]$ and Huggins parameters k' are listed in Table 2.

The sedimentation experiments were carried out on a Beckman XLI analytical ultracentrifuge at the rotor rotation rate of 57 000 rpm in two-sector cells (12 mm in length along the beam path), placed into a four-cell rotor. The sedimentation boundary was monitored using interference optical devices (a Rayleigh interferometer). The sedimentograms were processed using a Sedfit routine [7]. We preliminarily selected in the framework of the routine the parameter f/f_0 [where f and f_0 are the coefficients of translational friction of the macromolecule (particle) and a rigid sphere of the identical molecular weight, respectively], which minimizes the divergence between the calculated and experimental sedimentation profiles (Fig. 4). The

sedimentation coefficients were determined for each sample at three concentrations from within $0.10 < c \times 10^2$ g cm^{-3} < 0.65, which yielded reliable coefficients s_0 and k_s from the linear approximation

$$s^{-1} = s_0^{-1}(1 - k_s c + ...). \quad (2)$$

The experimental hydrodynamic characteristics are listed in Table 2.

Analysis of the s_0 and k_s parameters showed that they are correlated as $k_s = Ks_0^{\gamma} = 3.55s_0^{(1.7\pm0.2)}$. The exponent γ is related to the corresponding exponent b_s in the Kuhn–Mark–Houwink–Sakurda (KMHS) relationships [8] as $\gamma = (2 - 3b_s)/b_s$; the parameter b_s can be estimated at (0.43 ± 0.02). Also, we compared the parameters k_s with parameters [η] having identical dimensionalities. The average $k_s/[\eta]$ was estimated at 2.3 ± 0.3, which exceeds ~1.7 typical for flexible-chain homopolymers [9]. Further analysis of the system of the hydrodynamic data involves estimation of the hydrodynamic invariant A_0 [5, 10] and the sedimentation parameter β_s [11, 12]. These hydrodynamic invariants were calculated using the following relationships:

$$A_0 = (R[D]^2[s][\eta])^{1/3}, \quad (3)$$

$$\beta_s = N_A(R^{-2}[D]^2[s]k_s)^{1/3}, \quad (4)$$

where R is the universal gas constant; N_A, Avogadro number; $[D] \equiv \eta_0 D_0/T$; and $[s] \equiv s_0\eta_0(1 - v\rho_0)$.

The parameters A_0 and β_s for each sample and their average values are presented in Table 2. The fact that these parameters fluctuate around a certain average value suggests that the hydrodynamic characteristics are consistent. It should be noted, however, that A_0 is smaller than the parameter typical for flexible-chain homopolymers, $(3.2\pm0.2)\times10^{-10}$ g cm^2 s^{-2} deg^{-1} × mol$^{-1/3}$ [10]. At the same time, the average β_s agrees well with the parameters characteristic for flexible-chain homopolymers [12].

The molecular weights M were estimated on the basis of the sedimentation and diffusion analysis using the Svedberg formula

$$M_{sD} = R[s]/[D]). \quad (5)$$

By comparing the molecular weights and hydrodynamic characteristics, we established a complete set of KMHS relationships $C_i = K_i M^{b_i}$, where $C_i \equiv [\eta]$, D_0, or s_0 (Fig. 5). The coefficients K_η–b_η, K_D–b_D, and K_s–b_s are listed in Table 3.

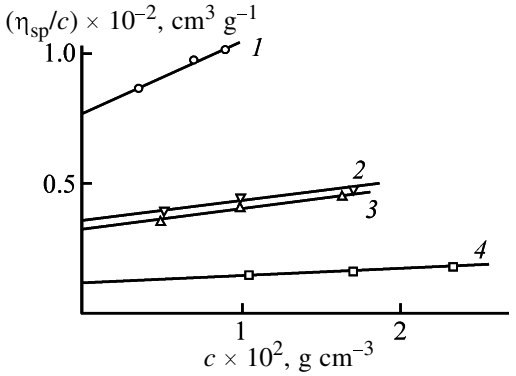

Fig. 3. To determination of the intrinsic viscosity η_{sp}/c of the MAG : VFA = 50 : 50 copolymers in 0.2 M NaCl. (*c*) Concentration.

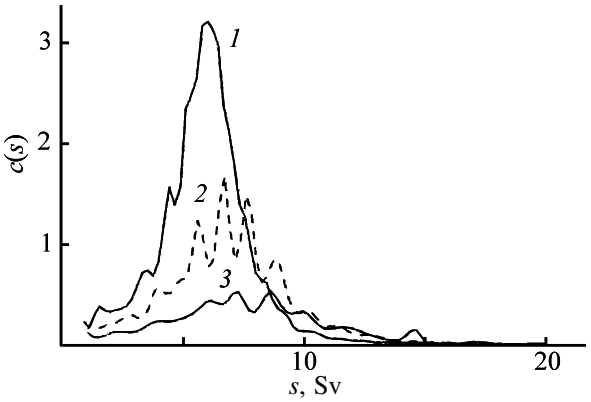

Fig. 4. Distribution with respect to the sedimentation coefficients, $c(s)$ vs. s, for sample no. 1 at concentrations of (*1*) 0.351, (*2*) 0.210, and (*3*) 0.106×10^{-2} g cm^{-3}.

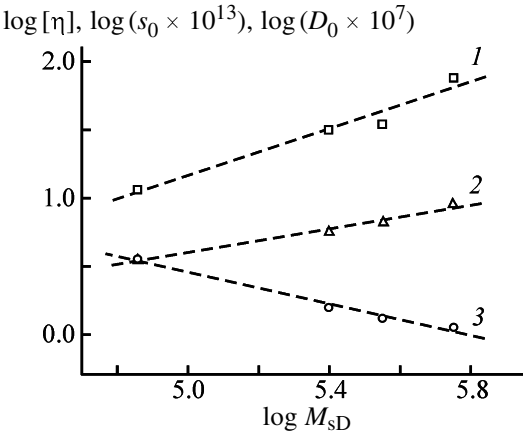

Fig. 5. Kuhn–Mark–Houwink–Sakurada plots for MGA : VFA = 50 : 50 copolymers in 0.2 M NaCl: (*1*) intrinsic viscosity, (*2*) sedimentation coefficient, and (*3*) translational diffusion coefficient.

The errors in determination of the b_i parameters, especially of b_η, are fairly high. Within the accuracy of determination holds a relationship between b_η and b_D module, derived assuming the equivalence of

Table 3. Parameters of the Kuhn–Mark–Houwink–Sakurada relationships obtained for the MAG : VFDA = 50 : 50 copolymers in 0.2 M NaCl at 20°C

Parameter	b_i	K_i	r_i
$[\eta]$–M	$0.86 \pm 0.1_2$	7.10×10^{-4}	0.9808
D_0–M	$-(0.56 \pm 0.04_6)$	1.85×10^{-4}	–0.9933
s_0–M	$0.44 \pm 0.04_6$	2.57×10^{-15}	0.9892

the chain dimensions in translational and rotational frictions in solutions [13, 14]:

$$|\beta_D| = (b_\eta + 1)/3. \quad (6)$$

Expression (6) was used for correcting the KMHS relationships. Within the accuracy, we selected such b_i values at which relationship (6) strictly holds. It should be noted that, when the molecular weight is determined by the Svedberg formula, the b_s and b_D parameters are unambiguously related as $b_s + |b_D| = 1$. By rocking the straight lines around the middle points we estimated further the parameters K_i, which yielded

$$[\eta] = 2.25 \times 10^{-3} M^{0.77},$$

$$D_0 = 2.61 \times 10^{-4} M^{-0.59},$$

$$s_0 = 3.69 \times 10^{-15} M^{0.41}.$$

In view of the carbon-chain structure of the backbone of the copolymer and the molecular properties of the corresponding homopolymers [2–4], we can suggest that the deviation of the parameters b_i from 0.50 is due to the occurrence of volume interactions in the copolymer macromolecules. The parameter characterizing the thermodynamic quality of the solvent was estimated as $\varepsilon = (2b_\eta - 1)/3 = (2|b_D| - 1) = 0.18 \pm 0.06$ [15].

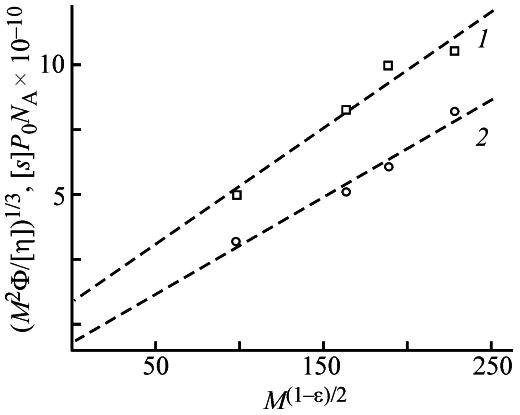

Fig. 6. To determination of the statistical Kuhn segment A of the MAG : VFA = 50 : 50 copolymer macromolecules: (*1*) intrinsic viscosity and (*2*) translational friction.

The hydrodynamic data were further interpreted using the relationships that can be derived from the Gray–Bloomfield–Hearst theory [16] taking into account both the volume interaction and the intramolecular permeation in the macromolecules [17]:

$$[s]P_0N_A = (M^2\Phi_0/[\eta])^{1/3} = [3/(1 - \varepsilon)(3 - \varepsilon)]M_L^{(1+\varepsilon)/2} \times M/A^{(1-\varepsilon)/2} + (M_L P_0/3\pi)[\ln A/d - (3A/d)^{-1} - \varphi(\varepsilon)], \quad (7)$$

where $P_0 = 5.11$ and $\Phi_0 = 2.87 \times 10^{23}$ are the hydrodynamic Flory parameters; M_L, linear density of the polymer chain; A, statistical Kuhn segment length; d, hydrodynamic cross section of the macromolecule; and $\varphi(\varepsilon) = 1.431 + 2.64\varepsilon + 4.71\varepsilon^2$.

Relationships (7) were used for estimating the statistical Kuhn segment of the chains simulating the macromolecules of the random copolymer. Figure 6 presents the corresponding plots, and Table 4, the coefficients characterizing the linear approximations of the experimental points: $y = ax + b$, where $x = M^{(1-\varepsilon)/2}$; a, section cut in the ordinate; and b, slope of the straight line. The latter parameter allows estimation of the Kuhn segment length characterizing the equilibrium rigidity of the chain:

$$b = d([s]P_0N_A)/d(M^{(1-\varepsilon)/2}) = d\{(M^2\Phi_0/[\eta])^{1/3}\}/d\{M^{(1-\varepsilon)/2}\} = [3/(1 - \varepsilon)(3 - \varepsilon)]M_L^{(1+\varepsilon)/2}A^{-(1-\varepsilon)/2}. \quad (8)$$

Based on the copolymer composition, we estimated the average linear density of the chains $M_L = 629$ g nm^{-1} mol^{-1} to be used in estimating the parameters A from Table 4.

The section cut in the ordinate corresponds to the second term in the right-hand part of Eq. (7); it describes the intramolecular permeation in the chains and, in principle, allows estimation of the hydrodynamic cross section of the macromolecule. However, Table 4 shows that, in our case, a limited number of the samples and possible heterogeneity of their composition, as well as a limited range of the molecular weights, are responsible for the fact that the error in determining the parameter exceeds the parameter itself, and, hence, the hydrodynamic diameter remains uncertain.

We compared the equilibrium rigidity of the chains of the random MAG–VFA copolymers, estimated in this study, with those for the corresponding homo-

Table 4. To estimation of the equilibrium rigidity of the chains of the MAG : VFA = 50 : 50 random copolymer

Parameter	$(b \pm \Delta b) \times 10^{-8}$	$(a \pm \Delta a) \times 10^{-10}$	r	$A \pm \Delta A$, nm
Translational friction	$3.75 \pm 0.4_5$	$-(0.72 \pm 0.7_9)$	0.9859	3.1 ± 0.9
Intrinsic viscosity	$4.50 \pm 0.6_5$	$0.83 \pm 1.1_5$	0.9797	2.0 ± 0.7

polymers [2–4] on the basis of the concept of normalized KMHS relationships [18]. The translational friction was plotted as $\log [s]/M_L$ vs. $\log L$, and the intrinsic viscosity, as $\log [\eta]M_L$ vs. $\log L$, where L is the contour chain length $L = M/M_L$ (Fig. 7). It is seen that the hydrodynamic dimensions of the copolymer macromolecules are intermediate between those of the initial homopolymers with the corresponding contour lengths.

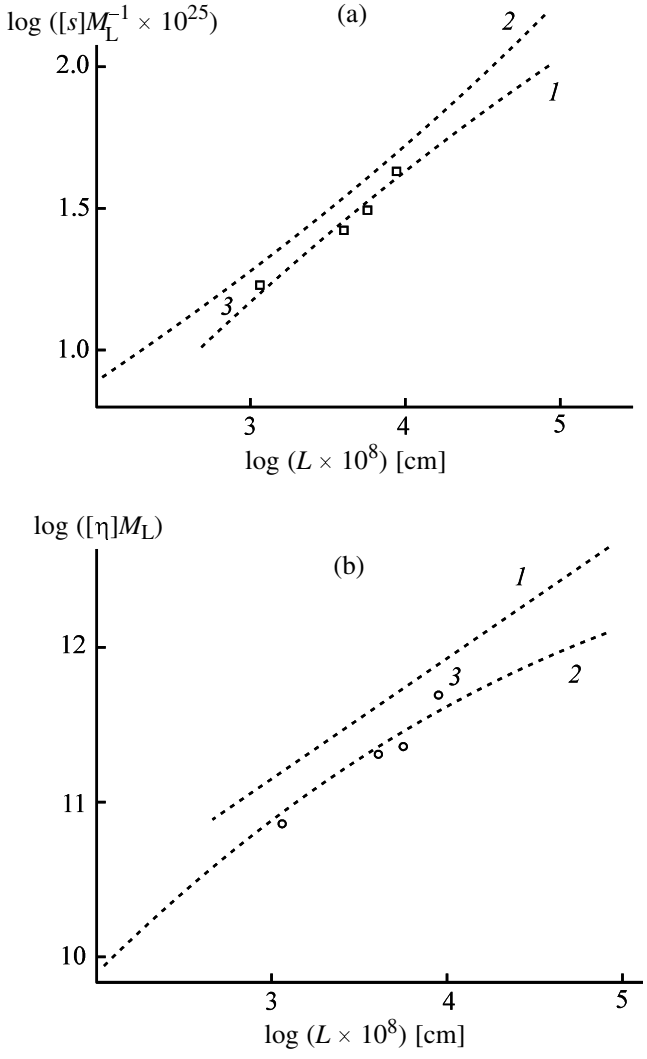

Fig. 7. Log–log plots of the (a) centrifugal sedimentation coefficient and (b) intrinsic viscosity, normalized to the linear density, vs. the contour length of the macromolecules L. (*1*) Poly-*N*-methacryloylglucose [2, 3]; (*2*) poly-*N*-vinylformamide [4]; and (*3*) points corresponding to the MAG : VFA = 50 : 50 copolymer, according to Table 2.

CONCLUSIONS

(1) Random 50 : 50 *N*-methacryloylglucosamine–*N*-vinylformamide copolymers were synthesized by radical polymerization.

(2) The diffusion and sedimentation analysis allowed estimation of the molecular weights of the copolymers and determination of the parameters of the Kuhn–Mark–Houwink–Sakurada relationships.

(3) The length of the statistical segment of the copolymer chains lies within $2.0 < A < 3.1$ nm and is actually intermediate between the values of the corresponding homopolymers.

ACKNOWLEDGMENTS

This study was financially supported in part by the Russian Foundation for Basic Research (project no. 05-0333210).

The authors are grateful to C. Ebel (Institut de Biologie Structurale, Grenoble, France) for the opportunity to carry out the sedimentation experiments in the Laboratoire de Biophysique Moleculaire.

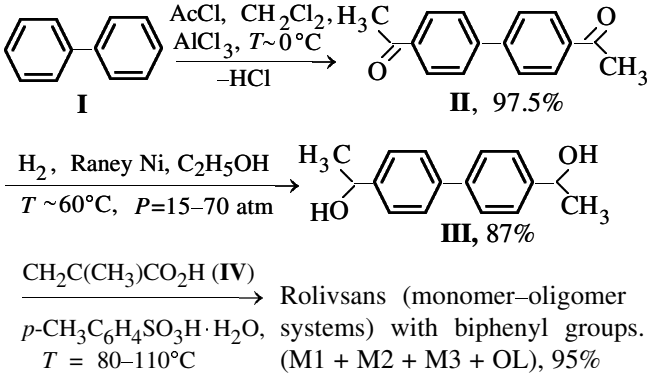
Abstract—The mechanism and kinetics of formation, and also the structure, composition, and properties of thermosetting resins of a new class, Rolivsans with biphenyl units, were studied.

DOI: 10.1134/S1070427207050187

Rolivsans are thermosetting polyfunctional resins exhibiting high thermal and chemical resistance and containing diphenyl ether units with terminal vinyl and methacrylate groups. They are used as insulating materials operating under extreme conditions [1–4]. Rolivsans are prepared from various aromatic compounds and unsaturated carboxylic acids [5–8]. Rolivsan MV-1 resin has been developed and has found practical application. Its synthesis is based on transformations of methacrylic acid and bis[4-(1-hydroxyethyl)phenyl] ether, catalyzed by strong acids. The starting ether, in turn, is prepared from diphenyl ether [9, 10].

The goal of this study is detailed examination of the conditions of synthesis, structure, and properties of unsaturated biphenyl compounds and of compositions and resins of Rolivsan type based on them.

It is known that biphenyl is a readily available starting compound and that biphenyl units incorporated in some heat-resistant polymers are characterized by high resistance to thermal oxidation and hydrolysis; they also tend to form mesomorphic structures. The synthesis and molecular design of Rolivsans [6–8] determine in this case the choice of 4,4'-di(1-hydroxyethyl)biphenyl as the starting compound. This compound is prepared in two steps. The first step is Friedel–Crafts acetylation of biphenyl **I**, giving 4,4'-diacetylbiphenyl **II** in quantitative yield [8, 11]. In the second step, compound **II** is subjected to catalytic hydrogenation on Raney nickel to obtain 4,4'-di(1-hydroxyethyl)biphenyl, also in quantitative yield. Rolivsans with bifunctional units were prepared by heating of bisecondary diol **III** with methacrylic acid **IV** in an aromatic solvent in the presence of *p*-toluenesulfonic acid monohydrate **V** and polymerization inhibitors:



Previously we studied in detail acid-catalyzed dehydration of di[4-(1-hydroxyethyl)phenyl] ether **VI** both in the presence of carboxylic acids (mainly methacrylic acid) and without them. The reaction was performed with refluxing in an aromatic solvent, with azeotropic distillation of the released water [6–10]. Comprehensive studies showed that the process involves consecutive-parallel reactions: polycondensation of the bisecondary diol, its esterification with methacrylic acid, dehydration of this diol and its polycondensation products, cleavage of (di)methacrylates with the formation of a (di)vinylaromatic compound and methacrylic acid, and dimerization of (di)vinylaromatic compounds by the polyaddition mechanism with the proton transfer (oligomerization) [12–16].

However, first we studied a simpler process, polycondensation of 4,4'-di(1-hydroxyethyl)biphenyl (**III**) itself without a carboxylic acid. Based on the previ-

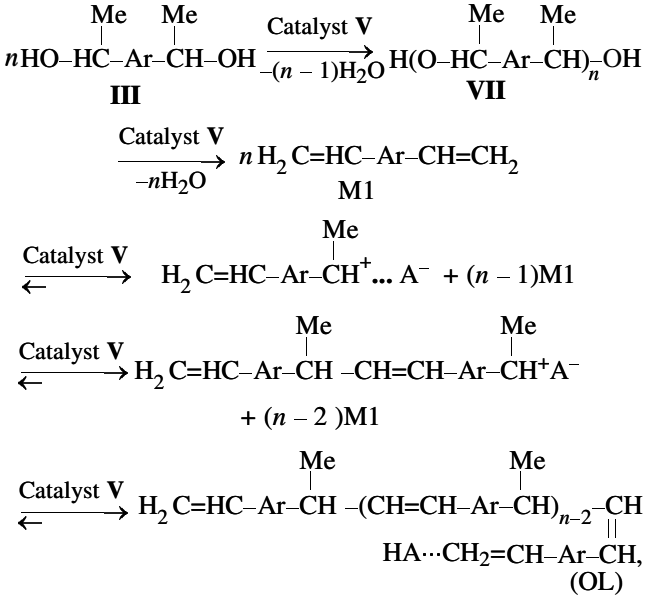
* Refluxing in toluene (111°C) or *o*-xylene (144°C).
** $(m_1)_2$, $(m_1)_3$, and $(m_1)_{n>3}$ refer to dimers, trimers, and higher oligomers, respectively.
*** The degree of unsaturation of the product (run no. 3), determined by ozonolysis, is 0.00773 mol of double bonds per gram.
**** Mixture of unsaturated oligoethers (OL) and produtcs of imcomplete dehydration (cleavage) of oligoerthers described previously [6, 7, 13].

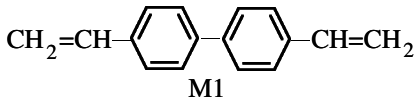
ously suggested mechanism [6, 7, 8, 11–16], after the polycondensation of bisecondary aromatic diols [13] catalyzed by strong acids and the subsequent dehydration of oligoethers **VII** [12], formation of divinylbiphenyl monomer–oligomer systems of various compositions could be expected:



where Ar = 4,4'-Ph–Ph; n = 0, 1, 2, 3, etc.; HA is catalyst **V**.

Indeed, as seen from Table 1 and Fig. 1, acid-catalytic transformations of diol **III** lead to compositions consisting of 4,4'-divinylbiphenyl (M1), its unsaturated dimer, trimer, tetramer, and oligomers of higher molecular weights. The product composition strongly depends on the synthesis conditions. For example, refluxing of diol **III** in *o*-xylene at a relatively high temperature (run no. 7) and low c_{cat} results in the formation of 4,4'-divinylbiphenyl (M1) in almost quantitative yield. This monomer, like low-melting divinylarene compositions listed in Table 1, is readily miscible with the known thermosetting resins and is of interest as a heat-resistant and chemically stable cross-linking agent. Pure divinylbiphenyl monomer M1 (melting point 152–154°C) can be readily separated from such compositions by sublimation.

In accordance with the established mechanism, in the case of similar "polycondensation" of biphenyl diol **III** with carboxylic acid **IV** we could expect formation of divinylarene monomer–oligomer systems of the following compositions:



M1

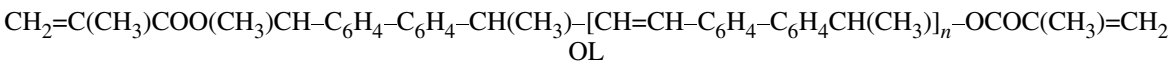
M3



OL

The results of these transformations are given in Tables 2 and 3. The composition and structure of Rolivsans containing biphenyl units were examined by exclusion liquid chromatography, IR spectroscopy, elemental analysis, and analysis for functional groups (ester numbers, ozonolysis). As seen from Fig. 2, the initial rates of the dehydration of aromatic diols with biphenyl (**III**) and diphenyl ether (**VI**) groups on heating with methacrylic acid are essentially different. Despite the fact that the concentration of acid catalyst **V** in the system with biphenyl diol **III** is approximately 2.5 times higher, the initial dehydration rate in this system is considerably lower. To compare the rates of both processes, the kinetic data can be reduced to the same synthesis conditions, taking into account the fact that the initial dehydration rate is proportional to the concentration of the acid catalyst [6–8, 17]. Calculation shows that in this case the rate of water release from the start of the process to 70–80% conversion is approximately five times higher for the system with diphenyl ether diol **VI**. This effect, apparently, cannot be assigned to the influence of the chemical structure of diols **III** and **VI** on the reactivity of terminal hydroxy groups in the dehydration. The difference in the electronic effects seems to be insignificant in this case. The difference in the catalyst acidity in these media is considerably more pronounced. The acidity of catalyst **V** in the medium of diphenyl ether diol **VI** is considerably higher, because it forms a protonated species with the lone electron pair of the ether oxygen atom [17].

It should be noted that monomer M1 can also be prepared by sublimation from methacrylate compositions; however, in this case it contains an impurity of jointly subliming methacrylate M2 (Fig. 3).

As seen from Tables 2 and 3, and from Figs. 4 and 5, the composition and properties of products formed by reaction of diol **III** with carboxylic acid **IV** regularly vary in accordance with the established mechan-

ism and kinetics of the process. In the initial and middle steps of the process, primary oligoethers undergo dehydration, and the maximal amounts of vinyl- and divinylaromatic monomers (M1, M2) and of methacrylates (M2, M3) are formed. Further steps involve consecutive-parallel cleavage of methacrylates (M2, M3) to form again monomers M1 and M2, which, in turn, enter into stepwise dimerization reactions (cationic polyaddition with the proton transfer), etc. The final products of these transformations are oligomers (OL) of type m_2–$(m_1)_n$–m_2, where m_1 and m_2 are units of monomers M1 and M2, respectively.

The IR spectra of unsaturated biphenyl compounds containing terminal vinyl and methacrylate groups and internal double bonds (Fig. 6) exhibit bands of unsaturated and aromatic groups at 1630, 1600, 1495, 990,

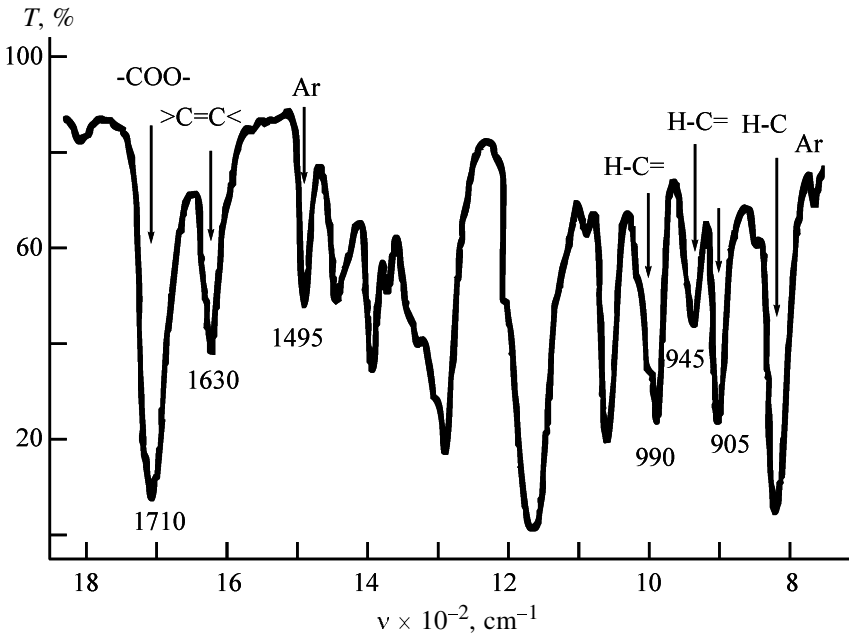

Fig. 6. IR spectrum of the monomer–oligomer composition [Table 3, run no. 11 (2)]. (*T*) Transmission and (ν) wavenumber.

965, 945, and 905 cm^{-1}, bands of methyl and methylene groups at 2960, 2925, 2870, and 2850 cm^{-1}, bands of methine groups at 2900 cm^{-1}, and also strong bands of stretching vibrations of the carbonyl group, characteristic of methacrylates, at 1710 cm^{-1} [18, 19]. With the progress of the reaction, the carbonyl band at 1710 cm^{-1} and of the out-of-plane vibration bands of the H–C= group in *p*-CH_2=CH–Ph–Ph– and CH_2=C(CH_3)COO fragments at ~902 and 940 cm^{-1}, respectively, decrease in the intensity, whereas the band at 965 cm^{-1}, belonging to the out-of-plane vibrations of the H–C= group in *trans*-–CH=CH– fragments, increases; the concentration of these fragments grows in the course of stepwise dimerization (cationic polyaddition) of vinylaromatic compounds [14–16, 20]. The unsaturated compositions obtained are pasty or low-melting compounds curing on heating and forming monolithic network polymers and plastics with a high softening point (Table 4).

EXPERIMENTAL

4,4'-Di(1-hydroxyethyl)biphenyl III was prepared by Friedel–Crafts acetylation of biphenyl **I** [8, 11] followed by catalytic hydrogenation or reduction of the resulting aromatic diketone **II**. Diketone **II** was prepared as follows. To a mixture of 80 ml of CH_2Cl_2 and 133.2 g (1.0 mol) of anhydrous $AlCl_3$, cooled to approximately 0°C, 85.2 ml (94.2 g, 1.20 mol) of acetyl chloride was added with stirring over a period

of 15–20 min. To the resulting acetylating complex, a solution of 61.6 g of biphenyl **I** in 80 ml of CH_2Cl_2 was added over a period of 1 h at 0±5°C with vigorous stirring; the released HCl was absorbed by an alkaline solution. The resulting complex of the acetylated product with $AlCl_3$ in methylene chloride was stirred for 0.5 h at ~0°C and for an additional 3 h at ~40°C. Diketone **II** was isolated by decomposing the complex with a mixture of 900 g of finely crushed ice, 2 l of distilled water, and 1.2 l of 20% HCl, which was followed by washing with water and drying at 60–70°C. The yield of dry diketone **II** was 95.8 g (97.5%), mp 165–170°C; after recrystallization from ethanol and repeated recrystallization from toluene, the melting point of **II** increased to 185–190 and 193–195°C, respectively (published data [21]: 190–192°C). The content of acetyl groups in **II** was determined by oximation.

Found, %: >C=O 24.1.
$C_{16}H_{14}O_2$.
Calculated, %: 23.5.

4,4'-Di(1-hydroxyethyl)biphenyl III was prepared by two procedures: (*A*) hydrogenation of **II** on Raney nickel and (*B*) reduction of **II** with sodium borohydride. In procedure *A*, a mixture of 250 ml of ethanol, 5.0 g of Raney nickel (Merck–Schuchardt) containing about 88% Ni and 12% Al, and 30.0 g (0.126 mol) of **II** was stirred in a pressure vessel at 60–70°C at initial hydrogen pressure of 50–70°C for approximately 1 h. Then the catalyst was separated by decanting and centrifugation of the solution of the hydrogenated product in ethanol; the alcohol was distilled off at reduced pressure, and the residue was recrystallized from toluene. Yield of aromatic diol **III** 26.5 g (87%), mp 158–159.5°C (published data [21]: 159–161°C).

Found, %: C 79.2; H 7.4.
$C_{16}H_{18}O_2$.
Calculated, %: C 79.3; H 7.5.

The content of hydroxy groups was determined by acetylation.

Found, %: OH 13.7.
$C_{16}H_{18}O_2$.
Calculated, %: OH 14.

In procedure *B*, a mixture of 200 ml of absolute ethanol, 5.0 g (0.13 mol) of sodium borohydride, and 25.8 g (0.11 mol) of diketone **II** was heated at 60°C for 2 h. The reaction mixture was treated with 50 ml of water, the precipitated hydroxides were filtered off, the solvent was distilled off at reduced pressure, and the residue was recrystallized from toluene. Yield 18.6 g (70%), mp 160–161°C.

4,4'-Divinylbiphenyl (M1). A mixture of 5.0020 g (0.02064 mol) of diol **III**, 0.0500 g of *tert*-butylcatechol, 0.0742 g of catalyst **V**, and 75 ml of *o*-xylene was refluxed (~144°C) for 50 min with azeotropic distillation of the released water. Then the mixture was worked up as described above. Yield of unsaturated monomer–oligomer composition containing about 75% monomer M1 (data of exclusion liquid chromatography) 3.8 g, mp 135–145°C. Sublimation of 0.500 g of the composition at a bath temperature of 160°C and residual pressure of 1–2 mm Hg for 7–10 min gave 0.33 g of pure monomer M1, mp 152–154°C (published data [21, 22]: 152.5–153°C).

Biphenyl compounds with terminal vinyl and methacrylate groups, and also their oligomerization products containing unsaturated dimers, trimers, tetramers, and higher oligomers were prepared as follows. A solution of biphenyl diol **III** in an aromatic solvent (benzene, toluene, *o*-xylene), containing inhibitors of radical polymerization (hydroquinone, CuCl) and a catalyst (*p*-toluenesulfonic acid monohydrate, **V**) was refluxed in the presence of methacrylic acid **VI** or without it in a flask equipped with a Dean–Stark trap. Water formed by polycondensation, esterification, and dehydration was removed by azeotropic distillation. Then the mixture was cooled and, after filtering CuCl off, washed successively with water, 5% $NaHCO_3$ solution, and again water, after which it was dried over $CaCl_2$ and passed through a 2–3-cm Al_2O_3 bed; the solvent was distilled off at reduced pressure. The conditions of synthesis, composition, and properties of the unsaturated biphenyl compounds [4,4'-divinylbiphenyl (M1), dimethacrylate of diol **III** (M3), 4-vinyl-4'-(1-hydroxyethyl)biphenyl methacrylate (M2)] and of unsaturated aromatic monomer–oligomer systems containing Rolivsans with biphenyl-containing units are listed in Tables 1–3. The IR spectra were recorded on a Specord 75-IR device from thin films or solutions in $CHCl_3$. Exclusion liquid chromatography was performed on a KhZh-1307 chromatograph at 20°C; the column was packed with Ultrastyrogel sorbent (500 Å); the eluent was toluene; the product concentration was 0.20–0.50 g in 100 ml of a solvent. The degree of unsaturation was determined on an ADS-4 ozonizer at 0°C (solvent CCl_4). The ester number was determined by dissolving a resin sample in dioxane purified by distillation from KOH and Na, which was followed by adding a 0.1 N solution of KOH in ethanol–dioxane, refluxing the mixture for 7 h (in so doing, the reflux condenser was equipped with a soda

lime tube), and titrating with 0.1 N HCl. Samples of glass fiber laminates in the form of 1.6–2.0-mm-thick plates were prepared by hot pressing of prepregs (eight sheets of T-10-80 glass fiber fabric impregnated with a melt of the unsaturated composition) in a mold at a pressure of 1 kgf cm^{-2}, followed by thermal curing of the stack at 120–250°C (heating rate 10 deg h^{-1}). The ultimate bending stress at three-point bending was determined with 3–4-mm-wide samples at a support spacing of 15 min and a loading rate of 15 mm min^{-1}. Dynamic thermogravimetric analysis (DTGA) was performed in air on a C derivatograph (MOM, Hungary) at a heating rate of 4.5 deg min^{-1}. The softening point was determined on a Vicat-type device designed at the Institute of Macromolecular Compounds, Russian Academy of Sciences at an indenter load of 1 kg and an indenter cross section of 1 mm^2.

CONCLUSIONS

(1) The previously suggested method for preparing polyfunctional aromatic compounds, divinylaromatic monomer–oligomer compositions, and heat-resistant thermosetting resins of a new type (Rolivsans), based on acid-catalyzed transformations of bisecondary aromatic diols, was applied to biphenyl derivatives.

(2) Previously unknown unsaturated monomeric and oligomeric compounds with biphenyl groups, e.g., 4,4'-di(1-hydroxyethyl)biphenyl dimethacrylate, 4-vinyl-4'-(1-hydroxyethyl)biphenyl methacrylate, and difficultly accessible 4,4'-divinylbiphenyl, and their compositions can be prepared in high yield by a one-pot process: dehydration of 4,4'-(1-hydroxyethyl)biphenyl and of the system 4,4'-di(1-hydroxyethyl)biphenyl–methacrylic acid.

(3) Rolivsans containing biphenyl units and based on the above (di)vinylbiphenyl compounds and methacrylates of secondary alcohols form heat-resistant network polymers and plastics on curing.

Abstract—Transport properties and structural features of a number of already known and new types of polymeric membranes in desalination of aqueous salt solutions by membrane distillation and pervaporation were studied. The possibility of obtaining distilled water in a single stage by pervaporation from dilute or concentrated aqueous salt solutions was examined for the example of membranes fabricated from celluloses of varied origin (wood, cotton, bacterial).

DOI: 10.1134/S1070427207050199

In view of the steadily increasing deficit in fresh water, development of new methods and improvement of the already existing ones for water desalination and treatment to remove other undesirable impurities is a topical scientific and applied task. An important place in solving the problem is occupied by membrane technologies using mostly porous polymeric membranes (of micro-, ultra-, or nanofiltration type, as well as reverse-osmotic and ion-exchange membranes). Depending on the initial salt content and required degree of water treatment, multistage process schemes are commonly used, which include various combinations of the above-mentioned types of membranes and sorptive treatment to remove organic impurities.

Of interest in this context are alternative single-stage methods for deep desalination of water, based on evaporation of polymeric membranes. To these methods belong membrane distillation (water evaporation through porous membranes based on hydrophobic polymers) and pervaporation (evaporation of liquid substances through nonporous membranes of the diffusion type). The membrane distillation has been used for production of distilled water from aqueous salt solutions [2] and concentration of alcohols or organic acids from dilute aqueous solutions [3, 4]. The pervaporation method is more versatile and can be used for separation or concentration of mixtures of aqueous–organic or organic liquids, including those of azeotropic composition [5–7]. At the same time, there is virtually no published information about application of this method to water desalination. Previously, the possibility of application of the membrane technique to production of distilled water from aqueous salt solutions has been demonstrated for the example of a methanol-selective multilayer composite pervaporation membrane [8].

This paper presents a comparative analysis of specific features of the mass-transfer mechanism, structure, and transport characteristics of the already known and new types of membranes in water desalination by pervaporation and membrane distillation. Also, the possibility of pervaporation concentration of aqueous-salt dispersions of proteins in the over-membrane space under mild temperature conditions was examined.

EXPERIMENTAL

We performed the membrane distillation with industrial ultrafiltrates of MFFK brand, based on Ftoroplast-42 (analog of Teflon) manufactured by Vladipor Private Co. (Vladimir), with average pore diameter on the surface equal to 0.05, 0.1, or 0.2 μm.

The pervaporation was done with nonporous films of hydrated cellulose (HC) produced from plant cellulose (wood or cotton) of thickness 30 ± 5 μm and bacterial cellulose (BC) synthesized in surface cultivation of *Acetobacter xylinum* of VKM V-880 strain.

We studied samples of gel films of BC, containing 10% residual water (GFBC-10) or dried to constant weight (BC-D), with thicknesses of 240 and 40 μm, respectively [9]. Also, we used composite membranes produced by forming a thin layer (3–5 μm) of cellulose diacetate (CDA) on the surface of substrates composed of MFFK or UPM-20 (based on aromatic polyamide manufactured by Vladipor Private Co.), with the subsequent saponification of the coating layer in a 1 : 1 NaOH–CH_3COONa buffer solution at 50°C.

The degree of equilibrium swelling (%) of film membranes was found from the difference of masses of swollen and dry membranes, related to the mass of a dry membrane (measurement error ±7%).

An X-ray diffraction analysis of the film membranes was made on a DRON-2 diffractometer (CuK_α radiation).

The membranes were tested in a laboratory cell of the flange type with a useful membrane surface area of 7×10^{-4} m^2.

The permeability was evaluated at 20–40°C after a steady-state mode of mass transfer across the membrane was attained at a pressure below the membrane equal to 0.2 mbar. We used solutions of NaCl or sea salt in distilled water, with an initial salt content of 4–20 wt %, and aqueous-salt protein dispersions with initial concentrations of 10–100 g l^{-1}. All experiments with aqueous-salt solutions or dispersions were performed with their agitation over the membrane in order to minimize the undesirable effect of concentration polarization [5].

The water vapor passed through the membranes was condensed in a vacuum in a glass receiver with liquid nitrogen and weighed, with the flow rate subsequently calculated (kg m^{-2} h^{-1}).

The salt content of the water obtained was evaluated using a refractometer or by electrical resistance.

After each experiment, the absence of a salt in the submembrane space was determined, because the salt that passes across the membrane virtually does not reach the receiver and is accumulated in the bottom part of the cell.

1. MEMBRANE DISTILLATION

As noted above, this method can be implemented using porous membranes based on hydrophobic polymers, such as polypropylene, polytetrafluoroethylene, or polyvinylidene fluoride, with average pore size on the membrane surface of 0.1–0.45 μm [2]. As a result of the poor wetting, water forms menisci on the surface of pores in these membranes. On application of a driving force (temperature or pressure gradient), mass transfer of water occurs via evaporation across the menisci, with its intensity controlled by the equilibrium between the liquid and vapor phases, similarly to the distillation process. There are no published examples of application of MFFK membranes to membrane distillation, and, therefore, the membranes were tested in desalination of water from 4–10 wt % NaCl solutions, with the membranes operating in the pressure-gradient mode. The results obtained are listed in Table 1.

Table 1. Permeability of MFFK membranes in desalination of aqueous NaCl solutions in relation to the average pore size (37°C)

Membrane no.	Average pore diameter, μm	Initial salt concentration, wt %	Flow rate, kg m^{-2} h^{-1}	Salt content, %
1	0.05	4	4.2	100
2	0.1	4	5.6	100
3	0.1	10	5.4	100
4	0.2	4	7.3	Trace amounts*

* Trace amounts of the salt in the bottom part of the cell.

Table 1 shows that the permeability increases with the average pore size of the membranes and somewhat decreases as the salt content of the starting solution is raised to 10 wt %. The latter may be of practical interest for desalination of more concentrated aqueous salt solutions, which cannot be done with reverse-osmosis membranes.

A membrane with an average pore size of 0.1 μm was also tested in concentration of a 10% aqueous solution of ethanol at 20°C. Under these conditions, a stable permeability (3.8 kg m^{-2} h^{-1}) was observed during a 10-day experiment, with the degree of enrichment with ethanol of the flow that passed through the membrane being 39%. This value is somewhat lower that the content of ethanol in the vapor phase (45.1%) in distillation of a mixture of the same initial composition [10].

At the same time, the membrane distillation failed to find wide use in the applications considered above, which is due to the narrow variety of industrial membranes of this type, gross loss of heat in mass transfer, and comparatively high cost of these membranes [2]. In addition, the surface tension forces of water may be insufficient, in the case of a broad pore size distribution, for menisci to be formed in coarser pores. For this reason, the mass transfer in this zone will occur

Table 2. Transport characteristics of film HC membranes in desalination of aqueous salt solutions (40°C)

Membrane no.	Type of cellulose	Pretreatment and experimental conditions	Initial salt concentration, %	Flow rate, kg m^{-2} h^{-1}	Salt retention, %
1	CDA*	Without activation	4	0.91	100
2	WC	Without activation	4	1.7	100
2.1	WC	Without activation	0	1.8	–
3	CC	Without activation	0	1.95**	–

by flow through pores. Apparently, such an effect partly takes place in membrane no. 4 (Table 1) and occurs in concentration of an aqueous–alcoholic solution. In operation of these membranes, periodic rupture of the menisci formed can also be favored by the presence of mechanical impurities in the starting solution and by intense turbulization of the solution over the membrane surface. The mass-transfer process can also be complicated by capillary condensation of water vapor in transverse pores in the membranes. This undesirable effect becomes more probable as the temperature gradient increases or the pressure gradient across the opposite sides of a membrane decreases. The transport parameters of the MFFK membranes (Table 1) will be used for comparison with those for the membranes fabricated in this study in pervaporation desalination of water, which was our basic goal.

2. PERVAPORATION

The mechanism of mass transfer of liquids across diffusion-type (nonporous) polymeric membranes is more complex and includes successive stages of sorption of a liquid and its diffusion through the free volume of the polymeric material. In the process, the phase state of the liquid changes to a vapor. This mechanism indicates that the physicochemical properties of membrane-forming polymers and of components of liquid mixtures exert a decisive influence on the selectivity of membranes and intensity of mass transfer. Apparently, a higher water permeability in pervaporation desalination should be observed for membranes based on hydrophilic polymers, to which hydrated cellulose also belongs. The pervaporation of an aqueous salt solution can be regarded as separation of a pseudo-liquid mixture containing free water molecules and bulkier hydrated ions formed in solution upon dissociation of the salt in water. The possibility of selective separation of such a mixture depends on the competitive diffusion of its constituent components through unit elements of the free volume. Apparently, for high-selectivity separation to be possible, the size of these elements should be very small and comparable with the kinetic diameter of water molecules (2.7 Å). For this reason, it is preferable that the membrane-forming polymer should be highly structurally ordered on the supramolecular level. In the case of HC, this is favored by the dense packing of polymer chains, provided by the network of intermolecular hydrogen bonds. It should also be noted that any possibility of transport of bacteria, viruses, and other pathogenic species across diffusion membranes is completely ruled out by the very small size of free-volume elements.

2.1. Transport characteristics of film membranes fabricated from hydrated cellulose. Table 2

lists transport parameters of two HC films based on wood (WC) and cotton (CC) cellulose and films of bacterial cellulose, GFBC-10 and BC-D. We tested membranes fabricated from HC of varied origin for distilled water and aqueous salt solutions under various experimental conditions. Irrespective of their origin, membranes of all the types, except GFBC-10 (Table 2, no. 12), demonstrated 100% salt retention at significant differences in their water permeability. Among the membranes studied, those based on WC and its CDA derivative had lower permeability. A possible reason for the difference in permeability between these membranes (Table 2, nos. 2 and 1) may be the lower hydrophilicity of CDA, compared with WC, evaluated by the equilibrium swelling of the corresponding membranes at 20°C (6.5 and 28 wt %, respectively).

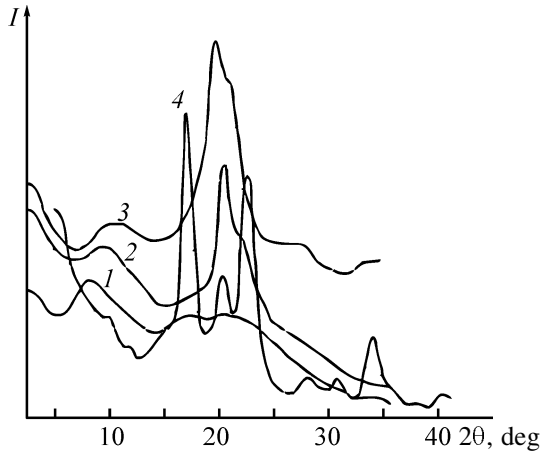
The equilibrium swelling in water of the CC-based membrane is 44 wt %, and, as a result, it has higher water permeability. All other experimental conditions being the same, the permeability of the CC membrane is 2.6 times that of the WC membrane (Table 2, nos. 4 and 2.1). The significant difference between the permeabilities of HC membranes of varied origin may also be due to their structural features on the supramolecular level.

It is known that the permeation of gases or liquids across diffusion-type polymeric membranes increases with temperature. This can also be seen in comparison of the water permeabilities of membrane nos. 3 and 4 (Table 2) at 20 and 40°C. It was found that the permeability of CC-based membranes can be raised to an even greater extent if samples are preliminarily activated in contact in water directly in the cell without applying the driving force of the mass transfer (Table 2, nos. 5 and 6). Under these conditions, the water permeability was as high as 8.2–8.7 kg m^{-2} h^{-1} in the initial stage of the pervaporation experiment and then decreased with time to stabilize at a flow rate of 6.4–6.5 kg m^{-2} h^{-1} in approximately 1.5 h. It can be seen from Table 2 that the stabilized flow rate for membrane nos. 5 and 6 markedly exceeds that for membrane no. 4 (4.7 kg m^{-2} h^{-1}). For membrane no. 4, which operated from the very beginning with a driving force applied, the flow, by contrast, steadily increased with time and stabilized approximately 30 min after the beginning of an experiment, after the steady-state mass-transfer mode was attained.

In all probability, the strong difference in the stabilized flow rates is due to the position of the lower boundary of the concentration gradient of water vapor relative to the cross section of membranes activated and nonactivated with water. The vapor concentration decreases in the direction of mass transfer, and, therefore, the working surface of the membrane is always plasticized with water to a greater extent in the course of pervaporation, compared with its back, "drier" side. This suggests that, under conditions of preliminary activation with water, the lower boundary of the concentration gradient for membrane nos. 5 and 6 lies, after the steady-state mass-transfer mode is attained, closer to their backside, compared with membrane no. 4, which is plasticized to a smaller depth in accordance with the experimental conditions. Thus, preliminary activation of HC membranes with water can be used to intensify the mass transfer. A similar effect can also be obtained by making the membranes thinner, which will be demonstrated below for the example of composite membranes.

It should be noted that the permeability markedly decreased in an experiment without agitation (Table 2, no. 7) because of the well-known effect of temperature-related polarization at the interface between the membrane and water, caused by a decrease in temperature at this interface upon a change in the aggregative state of water to a vapor [5]. For this reason, we carried out the rest of the experiments with vigorous agitation of solutions over the membranes.

Comparison of the permeabilities of CC membrane nos. 4 and 8, and also 5 and 10 (Table 2), confirms that the nature of the process of water mass transfer is the same in pervaporation of distilled water and aqueous salt solutions. It should be noted that, in the latter case, the water permeability of membrane no. 8 (not activated with water) somewhat decreases to 4.55 kg m^{-2} h^{-1}, and that of membrane no. 10 (activated with water), to 6.05 kg m^{-2} h^{-1}, compared with membrane nos. 4 and 5, respectively. The decrease in permeability can be primarily attributed to introduction into the starting mixture of a component (salt) that cannot penetrate across the membrane and to the known effect of concentration-related polarization near the membrane surface. The effect of the concentration- and temperature-related polarizations can be minimized by turbulization of the salt solution over the membrane surface. Apparently, the influence of all the above-mentioned effects is manifested to a greater extent in separation of a more concentrated aqueous salt solution of NaCl (Table 2, no. 11), when the permeability decreases to 3.7 kg m^{-2} h^{-1}. It should also be noted that quantitative desalination of an aqueous solution of sea salt is also possible (Table 2, no. 9). This seems to be reasonable on the background of the positive results obtained in desalination of aqueous solutions of NaCl, because the size of hydrated



X-ray diffraction patterns of film membranes made of (*1*) WC-based CDA, (*2*) saponified CDA, (*3*) CC, and (*4*) BC. (*I*) Intensity and (2θ) Bragg angle.

Ca^{2+} and Mg^{2+} ions markedly exceeds that of not only water molecules, but also hydrated Na^{+} ions.

The positive, as regards the salt retention, results were obtained for BC membranes only with completely dried samples (Table 2, nos. 13–15). The bacterial cellulose produced in biosynthesis is a bulky gel film containing 99 g of water per gram of the polymer. Most part of water can be removed from the gel film by squeezing under a press. The thus obtained GFBC-10 membrane contains 10% residual water, has a thickness of about 240 μm, and shows a very high water permeability (21.9 kg m^{-2} h^{-1}) at a total absence of salt retention (Table 2, no. 12). Apparently, this is due to its exceedingly loose structure even at so low content of water. At the same time, complete removal of water in further drying of GFBC-10 results in 100% salt retention for BC-D membrane at a comparatively low permeability (Table 2, no. 14) comparable with that of the WC-based membrane. Preliminary activation of the BC-D membrane with water does not lead to any increase in its water permeability (Table 2, no. 15). Apparently, this is due to the fact that, in contrast to WC and CC membranes, it virtually does not sorb water, which is due to the specific supramolecular structural organization of bacterial cellulose, formed in the stage of its synthesis [9], and to compaction of the starting gel film of BC in drying. The latter is confirmed by the significant difference between the thicknesses of the GFBC-10 and BC-D membranes (240 and 40 μm, respectively).

Comparative analysis of the data in Tables 1 and 2 shows that the permeabilities of CC-based membranes and those of the MFFK type are of the same order of magnitude. At the same time, the pervaporation mode of desalination seems to be preferable as regards the stability of the selectivity parameter, because, for porous hydrophobic membranes, several above-mentioned factors (broad pore size distribution, possible partial absence or menisci or their being damaged) may lead to a decrease in, or loss of, selectivity.

2.2. Structural features of hydrated cellulose membranes of varied origin. The figure shows X-ray diffraction patterns of film membranes fabricated from WC-based CDA (curve *1*) and saponified form of CDA (curve *2*) and a WC membrane (curve *3*). On the whole, the structure of WC- and CC-based membranes can be classed on the basis of the diffraction patterns as mesomorphic. A strong difference in the structural organization of cellulose chains on passing from CDA (curve *1*) to its saponified form (curve *2*) is seen when comparing the corresponding diffraction patterns. It is manifested in the appearance of a clearly pronounced reflection peaked at 2θ = 21°20′ in curve *2*. The positions and intensities of the reflections at 2θ = 19°–23° for WC- and CC-based membranes are close (curves *2* and *3*, respectively). At the same time, the decrease in the intensity of the reflection at 2θ = 8°–14°, demonstrated by comparison of curves *1–3*, and the tendency toward its shift to a reflection angle characteristic of the CC membrane can be attributed to transformation of acetate groups into hydroxy groups in the course of CDA saponification. Comparison of the reflection intensities in curves *1–3* in this range of Bragg angles shows that the content of OH groups in the CC-based membrane is higher. This is quantitatively confirmed by the data on the water permeability and equilibrium swelling in water for CC membranes, compared with those for the membranes made of CDA and its saponified form. This comparison is justified because the water affinity of cellulose of varied origin and their derivatives primarily depends on the content of hydroxy groups [11]. At the same time, it is known that the supramolecular structure of CC is close to that of cellulose II characterized by a more disordered 3D structure and the resulting weakened hydrogen bonding. According to IR data, cellulose II has a wide variety of intermolecular hydrogen bonds in which the distances between oxygen atoms in the O–H···O bonds are larger than those in the crystal structure of cellulose I. The positions of OH groups are not strictly fixed and easily change in interaction with water or water vapor, accompanied by partial rupture of hydrogen bonds.

This suggests that the supramolecular organization of HC-based membranes and their transport properties

not only depend on the origin of a cellulose material, but also can change for membranes of the same type in their interaction with water. For the series of the membranes studied, this conclusion is confirmed by the strong difference in their water permeabilities and by the increase in the permeability of the CC membrane after its preliminary activation with water, with this effect not observed for BC-D membranes.

The figure also shows an X-ray diffraction pattern of the BC-D membrane (curve *4*). Comparison of the diffraction patterns in the figure points to a particular supramolecular organization of BC-D. The presence of distinct reflections at $2\theta = 17°$, 21°, 23°, and 35° is an indication of the highly crystalline structure of BC-D, similar to that of cellulose I [9]. According to [9, 11, 12], BC is composed of nanosize crystalline microfibrillar ribbons with an axial-planar texture, with the microfibrils having a 13×7 nm rectangular cross section. The formation of GFBC with very high water content in the stage of BC synthesis is determined by the presence of a large number of primary OH groups on the surface of the ribbons and on their lateral faces. This creates conditions for interaction of the initial crystalline nanofibrillar BC ribbons with water, which can be sorbed by GFBC and be contained in it both in the free and hydrogen-bonded states [13].

Apparently, even upon removal of about 90% of water from the starting gel film of BC by squeezing, the structure of the GFBC-10 film remains rather loose. This is confirmed by the high water permeability of the latter at a totally lacking salt retention (Table 2, no. 12) and by the possibility of introduction into a matrix of this kind of silver or selenium nanoparticles stabilized by polyvinyl pyrrolidone by sorption from aqueous solutions [12]. Because of the crystallinity of the BC microfibrils, their cross section cannot be a zone of mass transfer for water molecules. Probably, the free volume is constituted in BC by voids formed in the textured network of microfibrillar ribbons. Comparison of the salt retention data for the GFBC-10 and BC-C membranes (Table 2) and of their thicknesses suggests that, only for the latter, in which the packing density of microfibrils is considerably higher, the size of free-volume elements is comparable with the kinetic diameter of free water molecules. As a consequence, only the BC-D membrane can provide 100% salt retention.

At the same time, the close flow rates for WC and BC-D membranes indicate that their free volumes in mass transfer are comparable. It should be noted in this context that, for HC membranes of plant origin, the manner in which the free volume varies fundamentally differs from that for BC membranes. In the first case, the free volume of the starting dry samples grows via swelling in preliminary activation of membranes with water or in the initial stage of their operation, before the steady-state mode of mass transfer is attained. In this case, reversible changes of the free volume are possible, after drying of the membranes and a repeated pervaporation experiment. By contrast, in the second case, the free volume irreversibly decreases already in the stage of GFBC-10 drying (in air on the surface of a glass plate) and remains unchanged under the conditions of a pervaporation experiment for the BC-D membrane. It can be assumed that the morphology and free volume of the GFBC-1-membrane can be additionally varied by changing the method of its drying (squeezing, drying in air in the free state or upon successive treatments with organic liquids).

2.3. Composite membranes. Problems of membrane separation are, as a rule, solved using composite membranes (CM) composed of a microporous polymeric or inorganic substrate and thin (0.1–0.5 μm) diffusion cover layers formed by polymers of another chemical nature, which show selectivity for accomplishing a specific separation task. Minimization of the thickness of the selective layer diminishes its resistance to mass transfer, which makes it possible to considerably raise the permeability of membranes. To obtain CM on the above-mentioned two types of substrates, we used as a selective layer WC-based CDA and its saponified form. Table 3 lists transport characteristics of the corresponding CM in pervaporation of distilled water or aqueous salt solutions.

Data for membrane nos. 1 and 2 (Table 3) with selective layers composed of CDA and its saponified form show that the water permeability of CM on an MFFK substrate is low and comparable with that for the corresponding film membranes (Table 2). This indicates that a CDA layer is formed not only on the surface of the MFFK substrate, but also within pores of its cross section. For this reason, the total thickness of the CDA layer in CM approaches the thickness of the films whose properties were considered above (Table 2), which makes higher the overall resistance of CM to mass transfer. In addition, an increase in the resistance to mass transfer can also be favored by the possibly hindered saponification of that part of the CDA layer which lies within the substrate pores. In this case, mass transfer will occur successively via the saponified and nonsaponified forms of CDA, which have different water permeabilities

Table 3. Transport properties of composite membranes at 40°C

Membrane no.	Type of cellulose	Pretreatment and experimental conditions	Initial salt concentration, %	Flow rate, kg m^{-2} h^{-1}	Salt retention, %
1	MFFK* (0.2 μm)	Without saponification of CDA layer and activation	0	1.05	–
2	MFFK	After saponification of CDA layer, without activation	0	2.0	–
3	UPM-20*	Without saponification of CDA layer and activation	0	2.9	–
4	UPM-20	After saponification of CDA layer, without activation	0	6.8	–

9	UPM-20	After saponification of CDA layer, without activation	4	4.1	100
10	UPM-20	After saponification of CDA layer, activation with water or 4% aqueous solution of NaCl for 20 min	4	5.1	Trace amount of the salt in the bottom part of the cell

* Formation of a cover layer from a 6% solution of CDA.
** Formation of a cover layer from a 4% solution of CDA.

(Table 2). The results obtained with a CM based on an MFFK substrate are also markedly inferior to those of MFFK membranes in membrane distillation (Table 1). The best results were obtained for CM on UPM-20 substrates. The smaller average size of pores on the surface of these substrates makes it possible, all other conditions of cover layer formation (concentration of the CDA solution) being the same, to produce a thinner selective layer because of its formation mostly on the substrate surface. This leads to a considerable increase in the permeability of CM with cover layers composed of both CDA and its saponified form (Table 3; nos. 3 and 4, respectively). Preliminary activation of the selective cover layer of CM leads, as in the case of film membranes, to a sharp increase in the water permeability in the initial stage of a pervaporation experiment, with its subsequent decrease (Table 3, no. 5). However, the stabilized flow rate is close in this case to that for membrane not activated with water (Table 3, no. 4). It should also be noted that the CM nonactivated with water provides a 100% salt retention at a permeability of 5.1 kg m^{-2} h^{-1} (Table 3, no. 6) This value is three times that for the film WC membrane (Table 2, no. 2) and is comparable with the flow rate across the film version of the CC membrane (Table 2, no. 8). A decrease in the CDA concentration in formation of a cover layer on the UPM-20 substrate does not lead to any increase in the permeability of CM. It is apparent that an undesirable effect of filling of substrate pores by the cover polymer, also observed in the case of the MFFK substrate, but to a greater extent, is manifested in this case, accompanied by hindrance to saponification of the polymer. This is confirmed by comparison of the permeabilities of membrane nos. 4 and 8 (Table 3). It should be noted separately that the small thickness of the selective layer in CM (3–5 μm) gives no way of achieving 100% salt retention under the conditions of a preliminary activation of their selective layer with water or a NaCl solution (Table 3, no. 10). In so thin films, activation can lead to a nearly equilibrium swelling across the entire thickness of the selective layer, with partial transport of the salt across the activated membrane probably occurring only in the initial stage of the pervaporation experiment (before the steady-state mode of mass transfer is reached), when the flow rate across the CM is at a maximum.

2.4. Concentration of aqueous-salt protein dis-

Table 4. Transport properties of a film CC membrane in concentration of aqueous–salt protein dispersions

Initial concentration, g l^{-1}	T, °C	Experiment duration, min	Flow rate, kg m^{-2} h^{-1}		Final concentration, g l^{-1}
			beginning of experiment	end of experiment	
0	40	120	6.4	6.4	0

persions. The sufficiently high water permeability of the membranes studied in desalting of aqueous salt solutions justified a test of the pervaporation method for concentration of aqueous-salt (NaCl) protein dispersions in the over-membrane space. Commonly, solutions or dispersions of various substances, including proteins, are concentrated with microporous membranes. However, this method is unacceptable, similarly to the evaporation technique, for achieving a sufficiently high degree of concentration because of the rapid decrease in the permeability of membranes, caused by blocking of pores or by thermal degradation of proteins. The undesirable effect of pore blocking is totally ruled out for diffusion-type membranes because of the absence of physical pores in the selective layer of such membranes. An example is known of use of a polysulfone pervaporation membrane fabricated for concentration of a liquid radioactive waste [14].

As shown above, CC-based membranes exhibit a fairly high water permeability under mild conditions. The properties of a film version of such a membrane in concentration of aqueous-salt protein dispersions with various total initial concentrations of dry substance are listed in Table 4. The results obtained confirm the possibility of achieving high degrees of concentration (up to 194 g l^{-1}). In this case, the permeability decreases both in the course of time and on raising the initial concentration of the dispersion. This occurs because of an increase of the fraction of the component that cannot penetrate across the membrane in the starting mixture and as a result of concentration- and temperature-related polarization effects. The concentrates can be brought to the dry-residue state in a shorter time with a rotary evaporator. It should be noted that, in all the experiments on dispersion concentration, the permeate was composed of distilled water. In addition, the adsorption of proteins on the membrane surface was insignificant, as indicated by visual inspection.

The study we performed demonstrated the possibility of using the pervaporation method for deep single-stage desalination of dilute or concentrated aqueous salt solutions to give distilled water. Owing to their high hydrophilicity, HC-based membranes have a throughput that is sufficiently high for the pervaporation method (up to 6–7 kg m^{-2} h^{-1} at 40°C). This value substantially exceeds that of the known analog for the same purpose [15], for which the throughput in pervaporation treatment of water from underground sources to remove dissolved salts is 2.35 kg m^{-2} h^{-1} at 82°C. At the same time, it should be noted that all the desalination experiments were carried out under model conditions with salt solutions in distilled water. Under real conditions, water can contain, in addition to salts, impurities of organic substances and various pathogenic species. Permeation of these latter via diffusion through nanosize free-volume elements of pervaporation membranes is totally ruled out. A qualitative prognosis can be made regarding noxious impurities of organic liquids. The most probable is mass transfer of molecules, close in polarity and size to water, of organic substances, such as aliphatic alcohols (methanol), aldehydes (acetaldehyde), acetonitrile, and some others. At the same time, joint mass transfer with water of weakly polar or high-boiling substances, or those having bulky molecules, such as phenol, chlorophenol, chloroform, and aromatic and aliphatic hydrocarbons, is hardly possible. Additional studies in this area require high-sensitivity methods for analysis of permeates.

CONCLUSIONS

(1) A comparative study was carried out of desalination of aqueous salt solutions with microporous hydrophobic fluoroplastic membranes in membrane distillation and with film or composite membranes fabricated from celluloses of varied origin in pervaporation processes.

(2) High efficiency of both the methods as regards the quality (distilled water) and throughput of desali-

nation (up to 6–7 kg m^{-2} h^{-1} at 40°C) was demonstrated.

(3) The possibility of controlling the throughput by varying the structural organization of cellulose, type of membranes, and experimental conditions, including preliminary activation of the membranes with water, was demonstrated for the example of film and composite membrane based on celluloses of varied origin.

(4) The possibility of pervaporation concentration of aqueous-salt protein dispersions in the over-membrane space to high concentrations under mild temperature conditions was shown.

ACKNOWLEDGMENTS

The study was financially supported by the Russian Foundation for Basic Research (project no. 06-03-32493).

The authors are grateful to P.A. Vdovin for provision of microporous fluoroplastic membranes.

Received March 13, 2007

Abstract—New polymeric electrochemical sensors based on various neutral and charged organic ionophores were suggested. The new sensors have a high sensitivity to anions of various organic acids (acetic, oxalic, lactic, malic, succinic, tartaric, and citric) in a wide concentration range. The selectivity and the detection limit of the developed sensors with respect to anions of the acids were studied.

DOI: 10.1134/S1070427207050205

Rapid development of such branches as pharmaceutics, food-processing industry, and various biotechnological productions both in Russia and abroad pose a number of new problems in the fields of industrial and environmental analytical chemistry. One of the most important tasks is the development of fast, convenient, and reliable methods of monitoring industrial processes on-line and of monitoring various industrial emissions. The problem of the determination of organic components of various solutions and mixtures, in particular, organic acids is of prime importance. Available methods of the determination of these organic compounds, such as high-performance liquid chromatography, some kinds of ionic chromatography, etc., are characterized by high prices of equipment, complexity of the analyses, and are insufficiently quick. An attractive solution of the problem is the use of chemical sensors, for example, ion-selective electrodes and(or) arrays of selective and nonselective chemical sensors ("electronic tongue"), measurements with which are simple and fast, do not require complicated equipment and highly skilled staff, and can be readily automated. This brings up a problem of searching for new active components of sensory membranes which would ensure a high reproducible sensitivity to various organic acids and selectivity in the presence of inorganic and organic anions.

Published compositions of polymeric sensory membranes for the determination of anions of organic acids are limited in number. The majority of the studies are devoted to the determination of salicylate, benzoate, and citrate anions. Metal porphyrins with various central atoms were used as membrane-active compounds in sensors for salicylate ions [1, 2]. To determine benzoate ions, sensors based on derivatives of trifluoroacetylbenzoic acid were applied [3]. Citrate ions in aqueous solutions were determined using sensors with membranes containing various dibenzyltin derivatives [4]. Sensors with membranes containing phenylporphyrins and uranyl salophen complexes were used as acetate-sensitive electrodes [5, 6]. It should be noted that the determination of salicylate, for example, is of a low practical value, and more often it is used as an illustration of sensitivity and selectivity of sensors to this ion. At the same time, in real media organic acids, as a rule, are present in complicated mixtures both with each other and with inorganic ions.

The aim of this study was to develop compositions and to study properties, in particular, sensitivity and selectivity, of a wide set of solid-contact potentiometric polymeric anion sensors based on various metal porphyrins, quarternary ammonium bases, and derivatives of trifluoroacetylbenzoic acid for the determination of several practically most important organic acids, namely, acetic, citric, oxalic, lactic, malic, succinic, and tartaric, which in various combinations and proportions are contained in the overwhelming majority of drinks, foodstuffs, process liquids of food and pharmaceutical productions, and other important real objects. As the organic acids under study dissociate in aqueous solutions, at least partially, for the determination of organic residues of these acids in liquids it is appropriate to develop and study potentiometric chemical sensors sensitive to anions.

The final aim of such studies is the development of not one, but a number of chemical sensors with reproducible sensitivity to several organic acids (cross sensitivity), and also with various selectivity toward anions of organic acids and widespread inorganic anions, such as, e.g., chloride, bromide, and nitrate. Combination and use of such sensors in multisensory systems like "electronic tongue" will make it possible to solve the problem of simultaneous quantitative determination of several organic acids in mixtures and in a number of real media.

EXPERIMENTAL

All the components for making sensory membranes were purchased from Fluka (Switzerland). We also used Merck (Germany) analytical grade organic acids, chemically pure grade inorganic salts and organic solvents from Reaktiv (St. Petersburg), and double-distilled water.

The polymeric sensory membranes studied (a total of more than 15 different compositions) contained various membrane-active components: metal porphyrins differing in the nature of the central metal atom, quarternary ammonium bases with various length of alkyl radicals, and derivatives of trifluoroacetylbenzoic acid. Seven of them are the most promising for the analysis of anions of organic acids, namely: types 1–3 based on metal porphyrins with manganese and rhodium central atoms and substituents in the porphyrin ring; types 4 and 5 based on quarternary ammonium salts; types 6 and 7 based on neutral organic complexing agents, structural analogs of trifluoroacetylbenzoic acid.

Sensory membranes were prepared by a standard technique. Weighed samples of membrane components were poured over with tetrahydrofuran (THF) and mixed using a magnetic stirrer until the dissolution was complete. The resulting cocktail was poured in a Teflon weighing bottle with a flat bottom and allows to stand until THF evaporated completely (~48 h). Disks 7 mm in diameter were cut out from the resulting membrane, and a solid contact (a composite conducting material) was deposited onto one of disk sides. Depositing the composite material results in the formation on the membrane surface of a layer with a mixed conductivity: ionic due to the membrane composition and electronic due to the composite. A current lead (a copper wire) was immersed into the deposited composition. The structure was allowed to stand until the composite conducting material dried completely; then the membrane was pasted in a plastic electrode case. We have made at least three sensors with membranes of each type. The numerical characteristics of electrodes given below are averaged values for sensors of the same type.

Potentiometric measurements were carried out in the voltaic cell

Cu	Ag	AgCl, KCl_{sat}	Test solution	Membrane	Solid contact	Cu.

Readings were taken using a multichannel electronic digital voltmeter with a high input resistance connected to a personal computer for data collection and processing. An EVL 1M 3.1 silver chloride reference electrode was used.

The sensitivity of sensors was studied by the method of calibration measurements in the range of concentrations of organic acids 10^{-6}–10^{-2} M. The slopes of the linear portions of the electrode functions were calculated for the concentration range 10^{-5}–10^{-2} M.

The pH values of all the calibrating solutions for all the organic acids were fixed by adding sodium hydroxide to pH 6 to eliminate the effect of acidity variation on the electrode functions. The selectivity coefficients were determined by the method of mixed solutions (MMS). The pH values of solutions were monitored with a standard ESL 43-07 pH glass electrode.

To check whether the sensors under study are sensitive to anions of organic acids, we made a series of calibrations with respect to solutions of the following acids: oxalic, acetic, citric, lactic, malic, succinic, and tartaric. The calibrations were carried out over the range of organic acid concentrations 10^{-6}–10^{-2} M at a constant pH 6 in all solutions, which was adjusted with sodium hydroxide solution.

A typical shape of calibrating plots for various sensors in tartaric acid solutions is shown in Fig. 1.

Experimental data on the slopes of the linear portions of the electrode functions of sensors in solutions of organic acids are given in the table.

The above data show that the majority of sensors under study have a high sensitivity to anions of organic acids. The slopes of the electrode functions of the majority of the sensors towards anions of oxalic, succinic, malic, and tartaric acids are in the range 24 ± 3 mV decade^{-1}, which agrees well with the theoretical value for double-charged anions. The sensitivity of sensors of types 1 and 2 in solutions of acetic acid also approaches the theoretical value of

Slopes of the electrode functions of sensors in solutions of organic acids. Average error of the determination of the electrode function slope ±2 mV

Sensor type	Slope of electrode function for indicated acid						
	acetic	citric	lactic	malic	oxalic	succinic	tartaric
1	–53	–38	–33	–26	–23	–26	–27
2	–53	–40	–34	–28	–24	–27	–28
3	–50	–39	–33	–28	–24	–27	–28
4	–31	–24	–23	–20	–18	–20	–20
5	–32	–20	–23	–20	–20	–20	–21
6	–43	–25	–27	–22	–21	–22	–23
7	–35	–22	–25	–22	–21	–22	–22

59 mV decade^{-1} for single-charged anions. As a whole, the sensitivity of the sensors based on metal porphyrins to anions of organic acids is slightly higher as compared to other types of sensors. All the types of sensors under consideration are the least sensitive to oxalic acid anions, which is apparently due to high hydrophilicity of oxalate anions ($\log K_{o/w} = -0.7$). On the whole, sensors of types 4 and 5 based on quarternary ammonium salts of various structures show the lowest electrode sensitivity, as their response is of the ion-exchange nature and is not connected with specific complex formation.

The selectivity of sensors was determined by the method of mixed solutions. The results obtained are presented in Fig. 2.

The sensors studied show the highest selectivity toward citric acid anions. For all the types of sensors, the values of $\log K_{sel}$(Acetate/Citrate) are less than –1.0, and in case of sensors of type 6, $\log K_{sel}$(Acetate/Citrate) = -4.3 ± 0.1, i.e., sensors of type 6 are capable of determining citrate in the presence of 10000-fold excess of acetate anions.

The selectivity to anions of tartaric and succinic acids in the presence of acetate is also fairly high, and the corresponding values of $\log K_{sel}$(Acetate/X) lie in the range 0.5–1.

The selectivity of sensors with respect to lactate and oxalate in the presence of acetate is low, and the logarithms of the corresponding selectivity coefficients of the majority of sensors are close to zero.

For several structurally related acids, succinic, malic, and tartaric, differing only in the number of hydroxy groups at atoms in the carbon skeleton, we have carried out a special experiment on studying their selectivity. The selectivity coefficients were determined by the MMS method at a fixed tartaric acid concentration. The experimental data are given in Fig. 2b.

Sensors of types 4 and 5 based on quarternary ammonium bases do not exhibit significant selectivity to any of the three acids. A similar pattern takes place for sensors of type 7 based on a neutral transporting agent.

The selectivity of the sensors based on metal porphyrins (types 1–3) clearly increases as the number of hydroxy groups in the carbon skeleton of an acid molecule decreases. These sensors exhibit the highest selectivity to succinic acid anions, which have no hydroxy groups in the carbon chain; then the selectivity decreases to malate (one hydroxy group in the carbon skeleton) and then to tartaric acid anions (two hydroxy

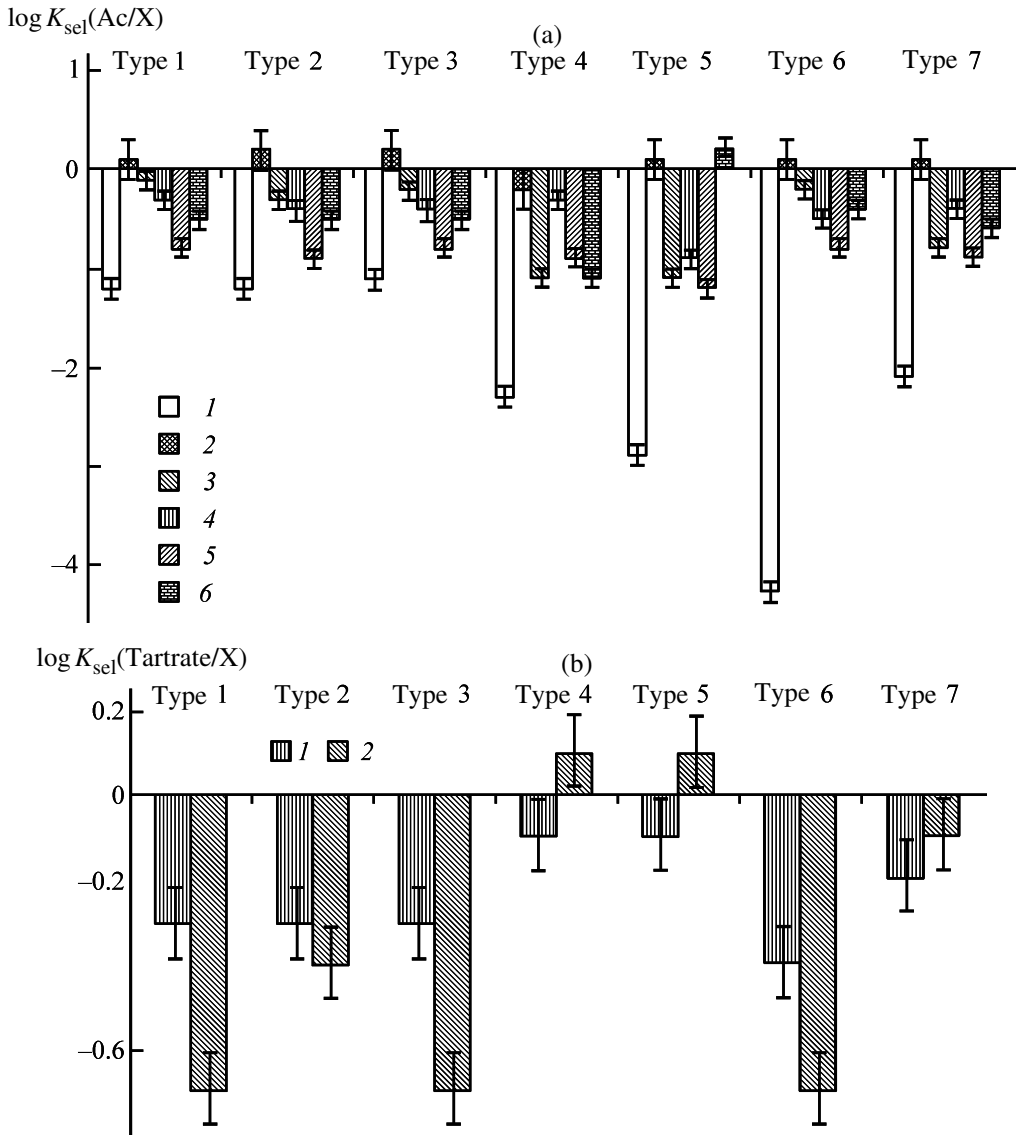

Fig. 2. Logarithms of selectivity coefficients K_{sel} of sensors (MMS, constant pH 6). Fixed concentration of (a) acetate, (b) tartrate, (c) chloride, and (d) nitrate. (a) (*1*) citrate, (*2*) lactate, (*3*) oxalate, (*4*) malate, (*5*) succinate, and (*6*) tartrate; (b) (*1*) malate and (*2*) succinate; (c, d) (*1*) acetate, (*2*) citrate, and (*3*) oxalate.

groups). Sensors of type 6 based on a neutral complexing agent behave similarly. The membranes containing quarternary ammonium salts show no selectivity to any of structurally related acids.

It is known that inorganic anions, in particular, chloride and nitrate, can be present in many real analytical objects in noticeable concentrations along with anions of organic acids. Their influence on the electrode function can hinder the determination of organic acids in real solutions. To estimate this influence, we have carried out a series of experiments on studying the selectivity toward the most wide-spread organic acids (acetic, citric, oxalic) in the presence of inorganic anions. The data obtained are shown in Figs. 2c and 2d.

Sensors based on quarternary ammonium bases and neutral transporting agents (types 4–7) allow citrate ions to be determined in the presence of a tenfold excess of chloride [$\log K_{sel}(Cl^- : \text{citrate}) \approx -1$]. In the case of sensors based on metal porphyrins (types 1–3), chloride ions exert a very strong interfering effect on the determination of organic acids, and the logarithms of the corresponding selectivity coefficients are either positive or close to zero (sensors of types 2 and 3, in a citrate–chloride pair).

The interfering effect of nitrate ions (Fig. 2e) is

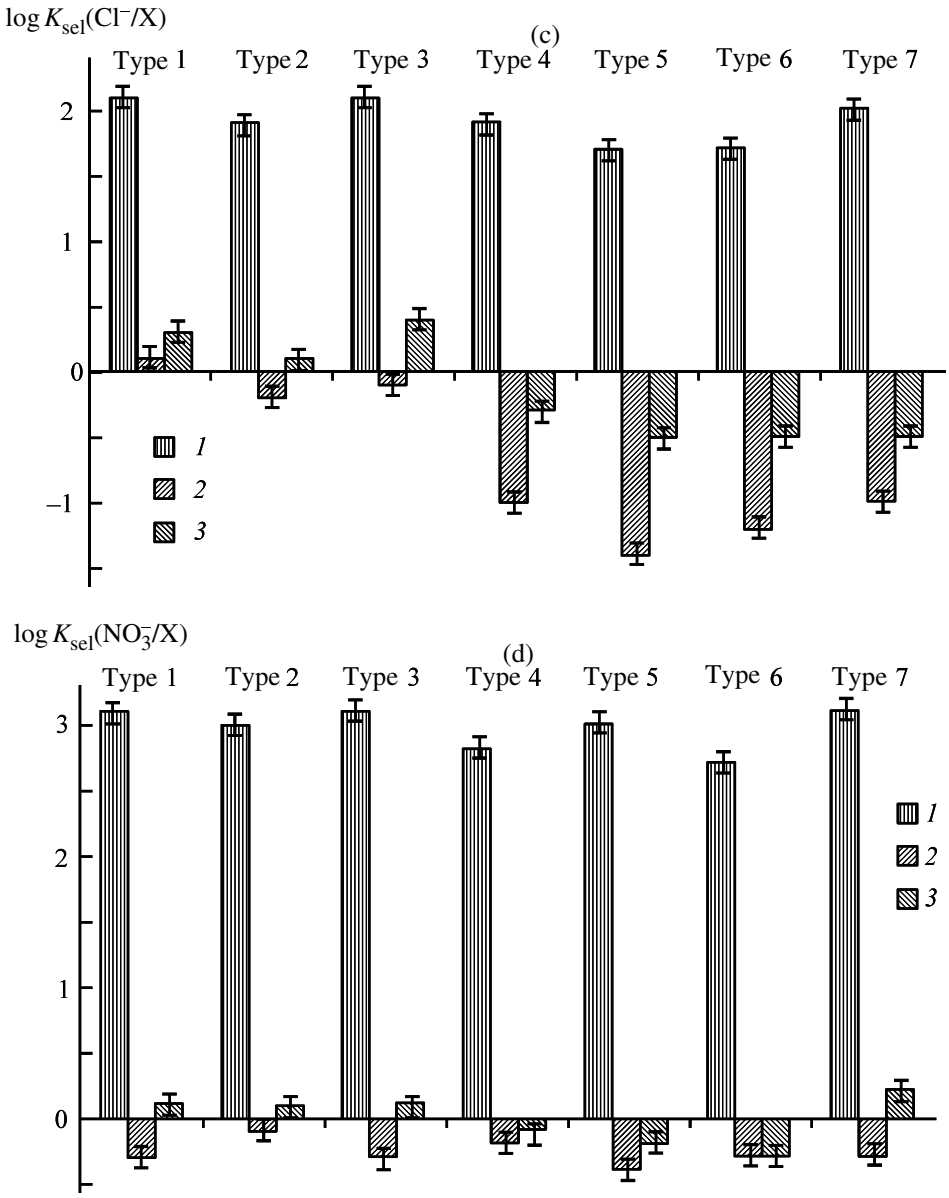

Fig. 2. (Contd.)

stronger than that of chloride ions, which is evidently due to the higher lipophilicity of nitrate. However, the determination of citrate (sensors of types 1, 3–7) and oxalate (type 6) in the presence of a small (2–3-fold) excess of nitrate ions is possible.

It should be particularly noted that essentially different selectivities of sensors with different compositions open prospects for their successful and differentiated analytical applications, and also for effective use of a set of such sensors with different sensitivities and selectivities (cross sensitivity) in the composition of multisensor systems like "electronic tongue."

CONCLUSIONS

(1) New polymeric sensors based on membrane-active components of various nature have been developed.

(2) The new sensors have a high sensitivity to anions of widespread organic acids (acetic, citric, oxalic, lactic, malic, succinic, and tartaric) over a wide concentration range at pH 6.

(3) The slope of the linear portion of the electrode function of the sensors, e.g., those based on metal porphyrins, in solutions of singly charged anions, in particular acetate, is 53–54 mV decade^{-1}, and for

anions of dibasic acids it is 24 ± 3 mV decade^{-1} for the majority of sensors.

(4) The selectivity of sensors both in solutions of organic acids and in solutions containing inorganic anions (chloride and nitrate) has been studied. The selectivities of sensors of various composition toward the same ion differ essentially (by a factor of more than 100), which opens prospects for their successful analytical application in various conditions, and also for the use of a set of such sensors in the composition of multisensor systems.

Abstract—Using photosedimentation procedure, the sedimentation stability of 60% suspension of calcium carbonate was studied in relation to the concentration, molecular weight, chemical composition, and conformation of macromolecules of cationic Praestol and to the concentration and nature of mineral coagulants (NaCl and $CaCl_2$).

DOI: 10.1134/S1070427207050217

Suspensions of calcium carbonate are used in production of paper, ceramics, soda, and sugar. The stability of suspensions can be controlled by water-soluble polymers, whose performance is determined by molecular and adsorption characteristics of polymers and by the nature of the disperse phase particles and solvent [1–3]. The data on the behavior of $CaCO_3$ suspensions, presented in reviews [4–6], are ambiguous. The effect of cationic Praestols on sedimentation stability of dilute suspensions of sodium carbonate was studied previously in [7].

Here we report on the sedimentation stability of 60% $CaCO_3$ suspension as influenced by the concentration, molecular weight, chemical composition, and conformation of macromolecules of cationic Praestol and by mineral coagulants (NaCl and $CaCl_2$).

EXPERIMENTAL

We used cationic Praestols [copolymer of acrylamide (AA) with *N*-acrylamidopropyl-*N,N,N*-trimethylammonium chloride (AAPTMAC)] purchased from Moscow–Stockhausen–Perm Private Company (Perm, Russia). The properties of Praestols studied are listed in the table. In the experiments we also used pure grade $CaCO_3$, chemically pure grade NaCl and $K_2S_2O_8$, and distilled water.

The samples of cationic Praestol with intrinsic viscosities [η] of 100, 68, 57, 46, and 25 $cm^3\ g^{-1}$ and constant chemical composition were prepared according to [8] by radical degradation of Praestol 655 in 0.1% aqueous solutions at 50°C in the presence of potassium persulfate (PP) radical degradation agent ([PP]/[polymer] = 0.6). The content of ionic units in cationic Praestol macromolecule was evaluated from the content of chloride ions, determined by mercurimetric titration [9].

The molecular weight *M* of cationic Praestols was calculated from the intrinsic viscosities using the Mark–Houwink equation. The intrinsic viscosity [η]

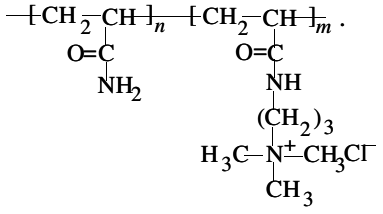
* Structure of the macromolecule unit:



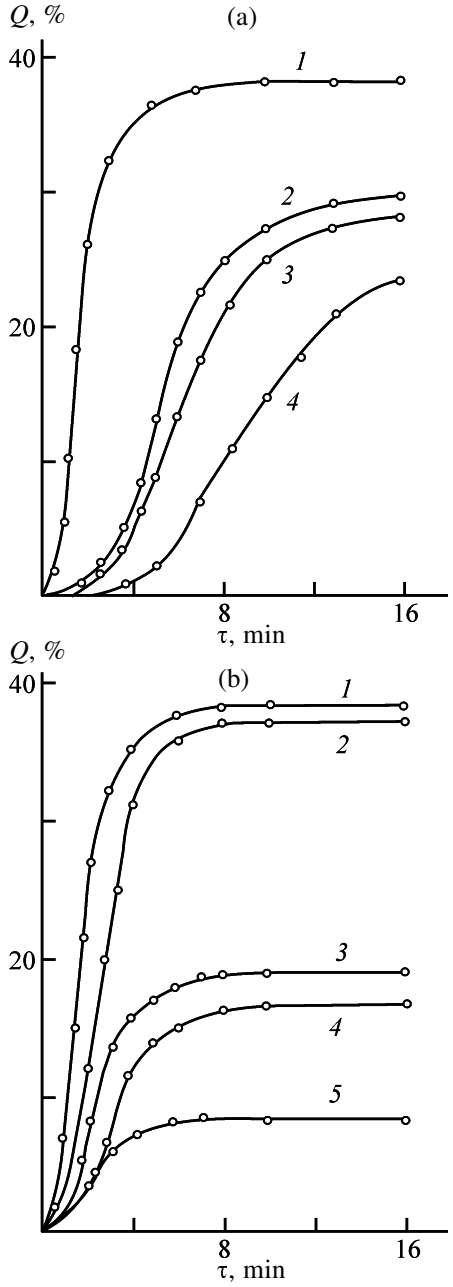


Fig. 1. Degree of clarification of calcium carbonate suspension Q at various concentrations of (a) dispersed phase c_d and (b) cationic Praestol 650, as a function of time τ. (a) c_d, %: (*1*) 40, (*2*) 50, (*3*) 55, and (*4*) 60. (b) c_d = 60%; $c_p \times 10^3$, %: (*1*) 0, (*2*) 1, (*3*) 2, (*4*) 3, and (*5*) 5.

of copolymer solutions was measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 viscometer (d_c = 0.56 mm). The [η] values were determined from the experimental linear dependence of the reduced viscosity $\eta_{sp}/c_p = f(c_p)$, where c_p is the copolymer concentration:

$$[\eta] = \lim(\eta_{sp}/c_p) \text{ at } c_p \to 0.$$

The effective size of the macromolecule globules $(\bar{r}^2)^{1/2}$ of cationic Praestol in aqueous solutions was evaluated from the reduced viscosity η_{sp}/c_p, because at small c_p $(\bar{r}^2)^{3/2} \sim \eta_{sp}/c_p$ in accordance with the Flory–Fox equation.

The sedimentation tests were out carried using 60% $CaCO_3$ suspensions at 20°C in a 150 cm^3 cylinder. After addition of all the reagents, the system was mixed for 1 min with a perforated stirrer (ten back-and forth movements), and variation in the optical density of the resulting suspension with time was recorded. The measurements were carried out in the upper section of the cylinder at a depth of 60 mm from the surface and thickness of the absorption layer of 40 mm using an FS-1 photosedimentometer.

The ζ potential of the $CaCO_3$ particles was determined by electrophoretic procedure and calculated from the Smoluchowski equation.

First we determined the stability of the $CaCO_3$ suspension as influenced by the concentration of the dispersed phase c_d. The tests were performed in the c_d range from 40 to 60% in the absence of polymer additives (Fig. 1a). As seen, in the entire concentration range studied the degree of clarification Q increases with time, which suggests that the concentrated suspensions are unstable and the sedimentation rate v_0, which was determined from the curve slopes, decreases with increasing c_d. This is obviously due to the enhancement of sedimentation hindrance with increasing c_d. All the further tests were performed at c_d = 60%.

To evaluate the effect of the cationic Praestol concentration c_p on the $CaCO_3$ suspension stability, the sedimentation tests were performed at c_p $(1–5) \times 10^{-3}$. Several kinetic curves of $CaCO_3$ suspension clarification are shown in Fig. 1b. Using these data, we calculated the rates of sedimentation in the presence of polymer and the flocculation activity of cationic Praestols D:

$$D = (v - v_0)/v_0,$$

where v and v_0 are the sedimentation rates of the $CaCO_3$ suspension in the presence of the polymer and without it.

The increase in D values indicates an increase in the flocculation activity of the polymer, whereas their decrease suggests enhancement of the stabilizing effect on the suspension sedimentation stability.

The dependence of the flocculation effect D of cationic Praestol 655 on the polymer concentration c_p

is shown in Fig. 2 (curve *2*). As seen, this dependence passes through a maximum. First, with increasing c_p the flocculation effect increases (ascending branch), which is due to the enhanced adsorption of the polymer on $CaCO_3$ particles owing to charge neutralization. With addition of positively charged polymer to negatively charged $CaCO_3$ particles, the overall particle charge decreases and their recharging is observed. This is confirmed by the data on changes in ζ potential of the particles (Fig. 3). As a result, the electrostatic repulsion between the $CaCO_3$ particles decreases, which improves binding between the particles. Increase in the polymer adsorption on the $CaCO_3$ particles with increasing c_p makes higher the concentration of macromolecular bridges between the $CaCO_3$ particles, providing formation of coarse floccules and thus accelerating their sedimentation. Further increase in c_p (after passing a maximum) causes saturation of the particle surface with the polymer, hinders mobility of the dispersed particles and, thus, stabilizes $CaCO_3$ suspension (descending branch, Fig. 2). As seen from Fig. 2, at $c_p > 1 \times 10^{-3}$% D decreases for both Praestol 644 (curve *1*) and Praestol 611 (curve *3*).

The dependence of the flocculation parameter D on the chemical composition of cationic Praestol macromolecules is also illustrated in Fig. 2. Comparison of experimental data at c_p = const shows nonmonotonic variation of D: Praestol 655 < Praestol 644 > Praestol 611. Our experimental results are probably due to the fact that $(\bar{r}^2)^{1/2}$ varies in the same direction as β (content of the ionic units in cationic Praestols). This fact is indirectly confirmed by the dependence $\eta_{sp}/c_p = f(\beta)$ at c_p = const. (Fig. 4). The viscosity data obtained at various c_p well agree with each other (Fig. 4, curves *1* and *2*). The maximal flocculation effect D is observed at β 27 mol% (Fig. 2, curves *1* in comparison with curves *2, 3*). We assumed that in this case the macromolecules are characterized by the optimal ratio of the charge density and chain flexibility, providing the highest $(\bar{r}^2)^{1/2}$ values. As a result, binding of two and more $CaCO_3$ particles with macromolecular bridges makes the globules coarser and accelerates their sedimentation.

The effect of the molecular weight M of polymers on the flocculation effect D was evaluated using the samples (see table) with [η] changing in the 25–555 $cm^3\ g^{-1}$ range and constant chemical composition of macromolecules prepared by radical degradation of Praestol 655. The results of these experiments are shown in Fig. 5. As seen, all the dependences $D = f([\eta])$ determined at various c_p pass through a mini-

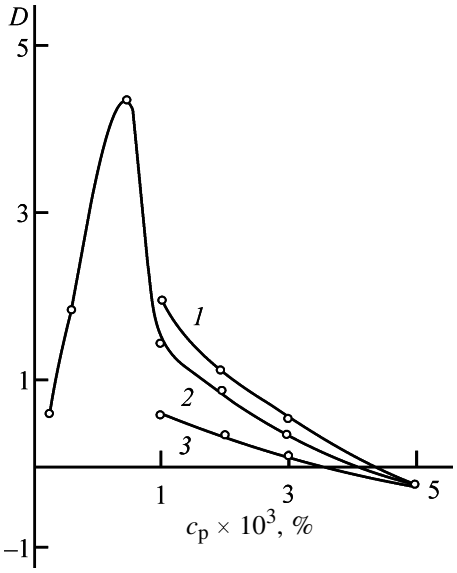

Fig. 2. Flocculation parameter D as a function of the concentration c_p of cationic Praestol (c_d = 60%). Praestol: (*1*) 644, (*2*) 655, and (*3*) 611.

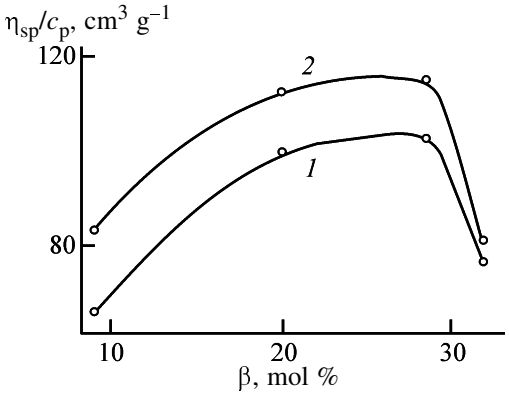

Fig. 4. Reduced viscosity η_{sp}/c_p as a function of the content of ionic units β in the cationic Praestol macromolecules. c_p, %: (*1*) 0.002 and (*2*) 0.004.

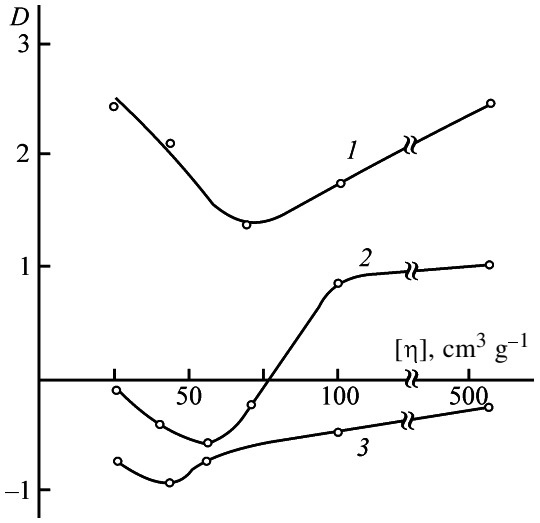

Fig. 5. Flocculation parameter D as a function of intrinsic viscosity [η] of cationic Praestol (c_d = 60%). $c_p \times 10^3$, %: (*1*) 0.8, (*2*) 2, and (*3*) 5.

mum (Fig. 5). This suggests changes in the nature of interaction of the $CaCO_3$ particles with polymer. First, D decreases with increasing [η] (descending branches of the curves). This phenomenon is obviously due to an increase in the number of contacts between macromolecules and $CaCO_3$ particles, when separate macromolecules are adsorbed on the particle surface owing to the charge neutralization. Adsorption layers arising in this case make weaker the contacts between particles and improve the suspension stability. After passing through a minimum of the dependence $D = f([\eta])$, D increases with increasing [η] (ascending branches of the curves). This is probably due to the adsorption of not only separate macromolecules on the particle surface but also of their aggregates, which are formed under the given experimental conditions [10]. In this case, macromolecules unrolling over the particle surface form greater number of contacts with $CaCO_3$ particles. As a result, owing to charge neutralization and formation of bridges between the suspension particles, globules become coarser and precipitate, which is confirmed by the increase in the flocculation parameter D.

As seen from Fig. 5, at [η] = const D decreases with increasing c_p at all the M values, This is due to an increase in the sedimentation stability of $CaCO_3$ suspension (passing from curve *1* to curve *3*) owing to a decrease in the particle charge and probable formation of bridges between the $CaCO_3$ particles through adsorbed macromolecular ions.

The effect of salt additions on sedimentation of $CaCO_3$ suspension was evaluated using the sample of

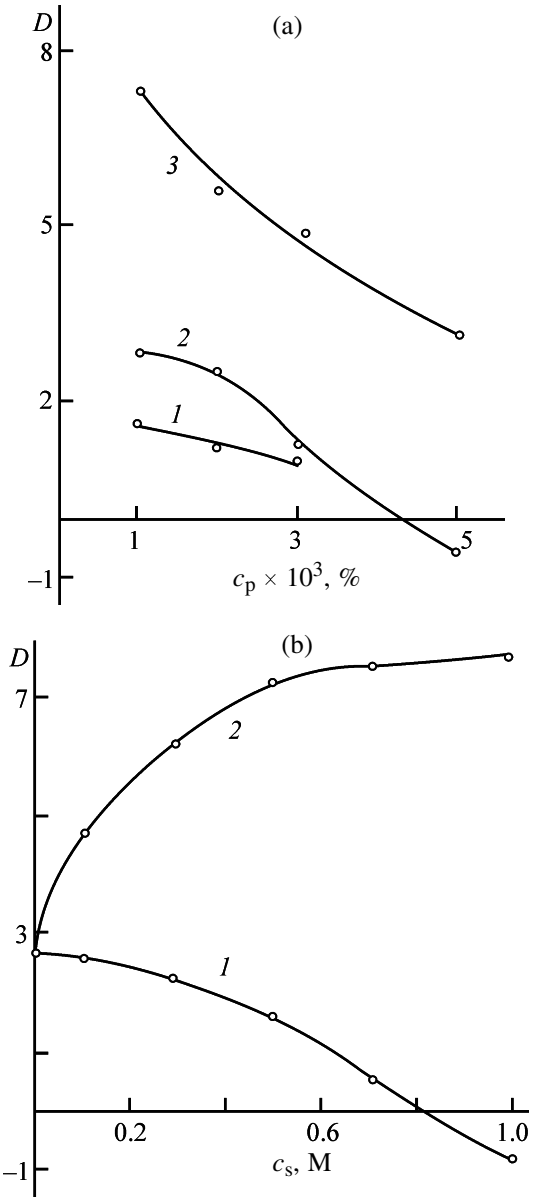

Fig. 6. Flocculation parameter D as a function of (a) concentration c_p of cationic Praestol 650 and (b) concentration c_s of (*1*) NaCl and (*2*) $CaCl_2$. (a) c_d = 60%; 0.5 M salt added: (*1*) NaCl and (*2*) $CaCl_2$; (*3*) no salt added. (b) c_d = 60%, $c_p = 1 \times 10^{-3}$%.

cationic Praestol 655 in the presence of NaCl and $CaCl_2$. In this case, D was determined taking into account changes in v_0 determined in sedimentation of the polymer-free suspension in the presence of these salts. The effect of salt additions on D is shown in Fig. 6. As seen, with (a) addition of NaCl and (b) increase in its concentration D decreases (Fig. 6, curves *1*). This is obviously due to the compression of the electrical double layer around the $CaCO_3$ particle, which decreases the distance between the particles

owing to strengthening of the van der Waals interaction, causes their aggregation, and decreases the sedimentation stability of the $CaCO_3$ suspension. As seen, with (a) addition of $CaCl_2$ and (b) increase in its concentration D increases (Fig. 6, curves *2*). This is obviously due to the hydrolysis of $CaCl_2$ in aqueous solutions to form the hydroxide poorly soluble in water. Positively charged hydroxy complexes neutralize negatively charged $CaCO_3$ particles, which then form aggregates and precipitate. In the presence of the polymer, formation of complex bridges (such as particle–macromolecular ion–Ca^{2+}) also causes aggregation and sedimentation of the dispersed particles. The effect of NaCl and $CaCl_2$ additions on the behavior of $CaCO_3$ suspension in the presence of cationic Praestol was observed at various c_p (Fig. 6a).

Our experimental data suggest that the above relationships of the $CaCO_3$ suspension sedimentation in the presence of cationic Praestol can be used not only to promote the flocculation but also to stabilize the suspension.

CONCLUSIONS

(1) The data on sedimentation stability of 60% suspension of calcium carbonate in the presence of cationic Praestol showed that at polymer concentration $c_p > 1 \times 10^{-3}$% D decreases with increasing c_p upon addition of NaCl and increases upon addition of $CaCl_2$, and the dependence of D on the intrinsic viscosity $[\eta]$ of the polymer passes through a minimum with minimal value at $[\eta] = 50–75$ cm^3 g^{-1}.

(2) The dependences of the flocculation parameter D and reduced viscosity η_{sp}/c_p on the content of the ionic units β in the macromolecule of cationic Praestol pass through a maximum at $\beta = 27$ mol %, which is due to the parallel variation of $(\bar{r}^{-2})^{1/2}$.

Abstract—Effect of the history of chitosan films on their transport characteristics in relation to elimination of drugs from the body is studied.

DOI: 10.1134/S1070427207050229

Unique properties of the natural polysaccharide chitosan (Cht), which is produced from renewable natural raw materials, such as its compatibility with human body tissues, biodegradability, moisture permeability, etc. [1, 2], make this polymeric product suitable for medical use. The above useful properties of Cht, on the one hand, and the possibility of modifying its structure and, therefore, the structure of its derivatives, on the other hand, suggest that Cht can be used as a polymer matrix for systems with controlled elimination of drugs. The elimination of a drug associated with a polymer film is controlled primarily by the supramolecular structure of the polymer, which is preset even in the course of film preparation by, e.g., varying the thermodynamic quality of the solvent. Therefore, the film preparation procedure may considerably influence the elimination rate of drugs from the film. The goal of this study was to prepare chitosan films with controllable transport characteristics.

EXPERIMENTAL

In the study we used chitosan [TU (Technical Specifications) 6-09-05-296–76] from the Khimmed Company (Russia), prepared by alkaline deacetylation of crab chitin (degree of deacetylation ~75%, M_η 120 000); polyvinyl alcohol (PVA) of 16/1 grade [GOST (State Standard) 10 779-78] with M_η 25 000; and antibiotic Levomycetin (LC) as a 3% alcoholic solution. The films of Cht and blends of Cht with PVA in the salt form were prepared by casting a polymer solution in acetic acid (1–70 wt %) onto glass. The weight concentration of the polymers in the initial solution was 2 g dl^{-1}. The solution of LC was added to the solution of Cht just prior to film preparation. The LC concentration was varied from 0.0082 to 0.063 mol mol^{-1} Cht. The film thickness was 0.1 mm in all experiments. The kinetics of elimination of LC from the films was studied UV-spectrophotometrically at λ = 270 nm. To prevent dissolution of the Cht salt film in water, it was treated for 15, 30, or 60 min with aqueous sodium dodecyl sulfate (SDS) of 0.5 wt % concentration, which is above CMC [3]. Finally, the film was heat-treated at 120°C. The swellability of the films was determined gravimetrically.

It is known that dissolution of Cht in acetic acid (HAc) is accompanied by the protonation of its amino groups. The degree of protonation and the thermodynamic quality of the solvent depend on the HAc concentration in the solution [4]. The maximal unfolding of the macromolecular chains and the minimal degree of structurization of the solution were observed in the Cht solutions in 10% HAc. Both decrease and increase in the HAc concentration in the solution lead to a decrease in the degree of protonation of the amino groups and, correspondingly, to an increase in the level of structurization. Whereas in more dilute HAc solutions (1–2%) intramolecular bonding dominates, a different situation takes place in concentrated solutions. Taking into account that, according to the published data [5], a 70% HAc solution demonstrates the best thermodynamic quality with respect to Cht, it becomes clear that, in this case, structurization occurs through intermolecular bonding. Evidently, the difference in the structure of the initial solution is reflected in the kinetics of elimination of LC from the film.

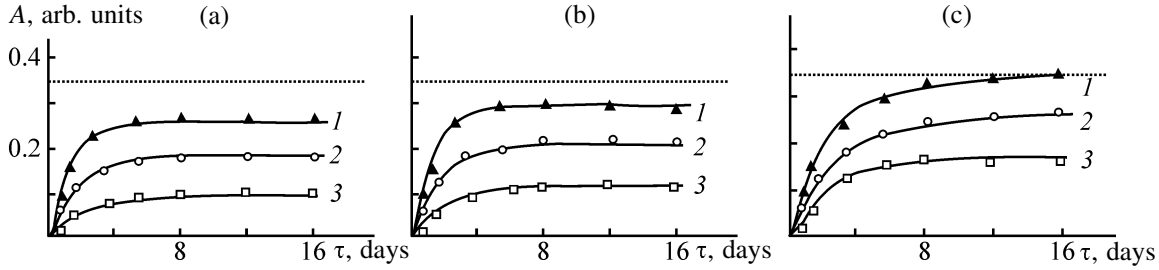

Fig. 1. Kinetics of LC elimination from the film obtained from solution in (a) 1, (b) 10, and (c) 70% HAc. (*A*) Optical density and (τ) time. Treatment time with the SDS solution, min: (*1*) 15, (*2*) 30, and (*3*) 60. LC concentration in the film 0.0163 mol mol^{-1} Cht; the optical density corresponding to this LC concentration is shown as a dotted line.

Table 1. Equilibrium elimination of LC (%) from Cht films

[HAc] in initial solution, wt %	Exposure time in SDS, min	Equilibrium elimination of LC, %, at indicated LC content in film, mol mol^{-1} Cht				
		0.0082	0.0163	0.0314	0.049	0.063
1	15	100	72	60	52	50
	30	75	69	49	40	33
	60	48	33	28	21	17
	Heat-treated films	100	74	71	69	67
10	15	100	78	75	72	70
	30	91	65	54	52	51
	60	54	39	26	24	22
70	15	100	82	78	75	73
	30	98	63	55	53	52
	60	73	51	34	30	25

Figure 1 shows typical dependences of the elimination of LC on the exposure time in water. The features of the elimination curves are as follows. Firstly, the most intensive elimination of LC is observed in the initial 2–3 days. By the 10th–12th day, the elimination of LC reaches its equilibrium value. Secondly, the higher the HAc concentration in the initial solution, the more complete is the elimination of LC from the film. Thirdly, the elimination of LC from the Cht film decreases with increasing time of the film treatment with SDS. For the film prepared from a solution in 70% HAc and treated for 15 min with the SDS solution, we observed practically complete elimination of LC in two weeks. In all other cases, the elimination was incomplete. Furthermore, as seen from Table 1, the lower the LC concentration in the film, the higher the probability of its complete elimination. LC in high concentration (>0.07 mol mol^{-1} Cht) deteriorates mechanical characteristics of the film, making it brittle and decreasing its moisture absorption (Fig. 2).

An additional tool for controlling the degree of elimination of drugs from the polymer matrix is formation of films from polymer blends. Comparison of Tables 1 and 2 shows that the elimination of LC from Cht–PVA film is lower than that from the individual Cht films, evidently, as a result of higher packing density in the polymer blend [4]. Note that the elimination of LC from blend films is an additive function of the blend composition (Fig. 3), and the moisture absorption of Cht–PVA film is considerably lower as compared to individual Cht film. However, treatment

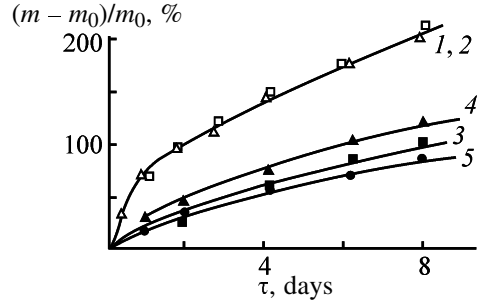

Fig. 2. Swellability $(m - m_0)/m_0$ of films of (*1–4*) Cht and (*5*) Cht–PVA blend (80 : 20), all prepared from solutions in 1% acetic acid, as a function of the swelling time in water vapor τ. Films contain (*1–3, 5*) no LC and (*4*) 0.063 mol LC mol^{-1} Cht; films (*2*) heat-treated or (*3*) treated with the SDS solution for 30 min.

Table 2. Equilibrium elimination of LC from 80 : 20 Cht–PVA films obtained from solutions in 1% acetic acid

Treatment time with SDS, min	Equilibrium elimination of LC, %, at indicated LC/Cht molar ratio			
	0.0163	0.0314	0.049	0.063
15	60	54	48	47
30	40	43	32	26
60	27	25	18	15
Heat-treated films	62	58	55	53

of the films with SDS solution practically eliminates this difference: all the films after treatment swell weakly.

Insolubility of the SDS-treated films in water is without question advantageous, as increasing the durability of the polymer matrix under conditions of medical use. However, the fact that these films demonstrate low moisture absorption is a significant disadvantage. Furthermore, treatment of Cht films with SDS solution strongly deteriorates their mechanical properties, which is reflected in clearly pronounced surface irregularity of the films. At the same time, heat treatment at 120°C for 3 h allows preparation of water-insoluble films demonstrating high moisture absorption well comparable with that of individual Cht (Fig. 2) and satisfactory mechanical characteristics. The elimination of LC from these heat-treated films is only slightly higher as compared to the untreated films.

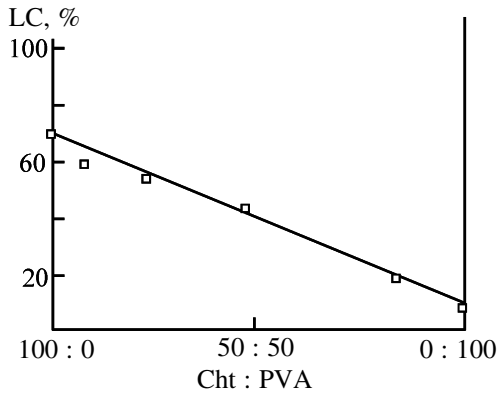

Fig. 3. Equilibrium elimination of LC from the films obtained from solutions in 10% acetic acid as a function of the Cht : PVA ratio in the polymer blend. LC concentration in the film 0.049 mol mol^{-1}; treatment time with the SDS solution 15 min.

Finally, the elimination of a drug from the polymer matrix can be controlled by varying film composition and by using heat treatment or treatment with surfactant solution.

CONCLUSION

The elimination of Levomycetin from chitosan films can be controlled by several ways such as (a) variation of the Levomycetin concentration in the film, (b) variation of the acetic acid concentration in the initial solution for film preparation, (c) introduction of the second polymer into the film, (d) treatment of the film surface with surfactant solution, and (e) heat treatment.

Abstract—Catalytic oligomerization and hydrolytic polymerization of ε-caprolactam in the presence of the system 1,1,5-trihydroperfluoropentanol–acetic acid was studied.

DOI: 10.1134/S1070427207050230

Perfluorinated low-molecular-weight compounds, oligomers, and polymers are widely used to impart water-, oil-, and dust-repellent properties to polymers [1]. Introduction of small amounts of polyfluorinated derivatives of unsaturated polyesters (0.05–1 wt part per 100 wt parts of the formulation) into polyamides improves their tribological properties [2, 3].

It was shown previously that addition of 1,1,5-trihydroperfluoropentanol (TPFP) into polycaproamide (PCA) in the step of granule processing enhances the heat resistance, inhibits UV-induced oxidative degradation, and enhances the resistance of PCA to oxidative degradation in the dark [4–6]. It is also known [7] that acetic acid (AA) catalyzes oligomerization of ε-caprolactam (CL).

N-Acyl derivatives of ε-aminocaproic acid and its oligomers were isolated from the reaction of AA with CL [8–11]. Without a carboxylic acid, polymerization of CL occurs with an induction period [12], which is attributed to accumulation of ε-aminocaproic acid and its subsequent participation in opening of the lactam ring.

Korshak et al. [13] studied the hydrolytic polymerization of CL using $H_2{}^{18}O$ and supportred the opinion [14] that the reaction occurs by an ionic mechanism with the protonation of the NH group of the lactam ring. In this connection, it becomes necessary to study the modification of PCA by adding TPFP in the step of ε-caprolactam polymerization.

In this study we examined the features of oligomerization and polymerization of ε-caprolactam in the presence of the system 1,1,5-trihydroperfluoropentanol–acetic acid and the processing characteristics, heat resistance, and physicomechanical parameters of the resulting PCA.

EXPERIMENTAL

The IR spectra of liquid substances (Specord M82) were recorded from thin films, and the spectra of solid substances, from mulls in mineral oil. The rates of reactant consumption and oligomer formation were estimated by the ampule method. A 8–10 cm^3 glass ampule was charged with 0.02 mol of CL and 0.02 mol of dried acetic acid, after which a catalytic amount (0.001 mol) of a saturated monohydric alcohol (butanol, pentanol) and TPFP was added. The mixture was heated to 200°C. For TPFP, the concentration was varied within 0.025–0.1 mol % (Fig. 1). The ampule was withdrawn from the thermostat after the lapse of the required period (60-min steps) and cooled at room temperature. Then the mixture from the ampule was transferred into a beaker, 15–20 ml of chloroform was added, and the mixture was thoroughly stirred to separate the forming oligomer from the starting compounds. The oligomer was filtered off, washed successively with 5 ml of chloroform and 10 ml of diethyl ether, and dried. The oligomer prepared in 4 h was filtered off and recrystallized from ethanol. The results are given in Tables 1 and 2 and in Fig. 1.

The higher-molecular-weight oligomers remained on the filter and were separated using their different solubilities in hot water and ethanol.

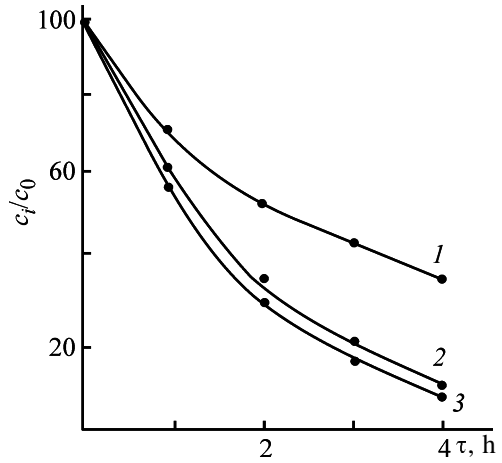

Fig. 1. Consumption of ε-caprolactam in the reaction with acetic acid at different TPFP concentrations. (c_i/c_0) Percent ratio of the running and initial concentrations of ε-caprolactam and (τ) time. TPFP concentration, mol %: (*1*) 0.025, (*2*) 0.05, and (*3*) 0.1.

The molecular weight was determined cryoscopically in glacial acetic acid. In particular, the molecular weight of the oligomer prepared using TPFP, determined in acetic acid, is 2447, which corresponds to 21 monomeric units (calculated: 2443) (Tables 1, 2). Nitrogen content: found 11.98%, calculated for $CH_3C(O)[HN(CH_2)_5C(O)]_{21}OH$ 11.99%.

The structure of the reaction products was proved by IR spectroscopy. The IR spectra contain amide I (1636 cm^{-1}) and amide II (1546 cm^{-1}) absorption bands. The band of hydrogen-bonded NH groups (NH···O=C) is observed at 3292 cm^{-1}. The hydrogen-bonded COOH groups give the bands $\nu_{C=O}$ at 1708 and ν_{OH} at 3112 cm^{-1}. The composition was determined by elemental analysis.

Table 1. Effect of alcohol on the oligomerization parameters, number of monomeric units *n*, and properties of oligomers. Temperature 200°C, thermostating for 4 h

Alcohol	CL conversion, %	Oligomer yield, % based on CL	T_m, °C, of oligomer	*n*
None	40	35	163–165	12
Butanol	65	61	177–180	14
Pentanol	70	68	183–187	15
TPFP	90	82	193–194	21

Table 2. Influence of the TPFP amount on the CL oligomerization parameters

TPFP amount, mol %	Conversion, %		Oligomer yield, %	*n* in 4 h
	CL	AA		
0.025	65	15	61	14
0.05	90	25	82	21
0.1	92	30	82	21

Addition of TPFP in the step of hydrolytic polymerization of CL was performed in an ANP-12 commercial apparatus for continuous polymerization. CL (16 t day^{-1}) and a mixture containing water (1.24–1.32%), AA (0.04–0.05%), thermostabilizer {1,2-di-[4-(*N*-phenylamino)phenoxy]ethane (N1) or 2-hydroxy-1,3-di[4-(*N*-phenylamino)phenoxy]propane (N2), 0.05–0.07%}, and TPFP (0.001 wt %) [15] were continuously fed in a nitrogen flow. The reaction temperature was 265–270°C. The polymer was analyzed for the content of low-molecular-weight compounds, and the relative viscosity of PCA was determined. The heat resistance was evaluated by changes in the thread strength before and after heating for 2 h at 200°C; the heat resistance of the granulate was studied derivatographically [15].

Quantum-chemical calculations were performed by the AM1 method allowing the associative interactions in the system to be taken into account [16, 17].

We studied the hydrolytic polymerization of CL in the presence of the TPFP–AA system. The step of the lactam ring opening (studied also by the AM1 method) and the step of oligomer formation were considered with the CL–AA–TPFP system as model, in comparison with the systems with *n*-butanol and *n*-pentanol. Experiments on hydrolytic polymerization revealed the effect of TPFP on the content of low-molecular-weight compounds (LMC), relative viscosity of the polymer, and amount of thin extrudate (bristle) returned to reprocessing.

First we performed experiments at a minimal concentration of TPFP (8.8×10^{-4} wt %) and as low concentration of thermal stabilizer as possible. As seen from Table 3, a decrease in the concentration of the thermal stabilizer from 7.1×10^{-2} to 5.8×10^{-2} wt % causes a certain decrease in the relative viscosity of the granulate after casting and the amount of thin extrudate (bristle) returned to reprocessing (2.1–2.6%). However, further decrease in the amount of the thermal stabilizer, as well as an increase in the TPFP amount, deteriorate the processing parameters and cause a drastic increase in the amount of bristle returned to reprocessing: with 9.2×10^{-4} wt % TPFP and 1×10^{-2} wt % thermal stabilizer, the amount of thin extrudate (bristle) increases to 6.0%. In the absence of TPFP, the volume of bristle returned to re-

processing increases to 9.4–9.9%. Hence, further decrease in the thermal stabilizer concentration and increase in the TPFP concentration are not appropriate, resulting in worsening of the polymer properties. It should also be noted that the absence of the polyfluorinated alcohol in the polymerization system results in an increase in the LMC content to 11.62% and in the amount of thin extrudate (bristle) returned to reprocessing, to 9.4–9.9%. The relative viscosity of the granulate is also an important parameter. Introduction of TPFP increases the relative viscosity from 2.81–2.84% without TPFP to 2.91–2.95% with TPFP added (8.8×10^{-4} wt %).

To elucidate the character of the reaction of CL with AA and with the AA–TPFP system, we examined the rate of CL oligomerization in these systems in comparison with that in the presence of saturated monohydric alcohols.

We found (Table 1) that the CL conversion in the course of oligomerization strongly depends on the structure of the alcohol added (0.05 mol %) and decreases in the order TPFP > 1-pentanol > 1-butanol.

The highest conversion of CL (temperature 200°C) is attained with TPFP: 90% in 4 h (Table 1). Introduction of TPFP also increases the oligomer yield (to 82%) and the number of monomer units in the oligomer (from 12 without catalyst to 21 with TPFP).

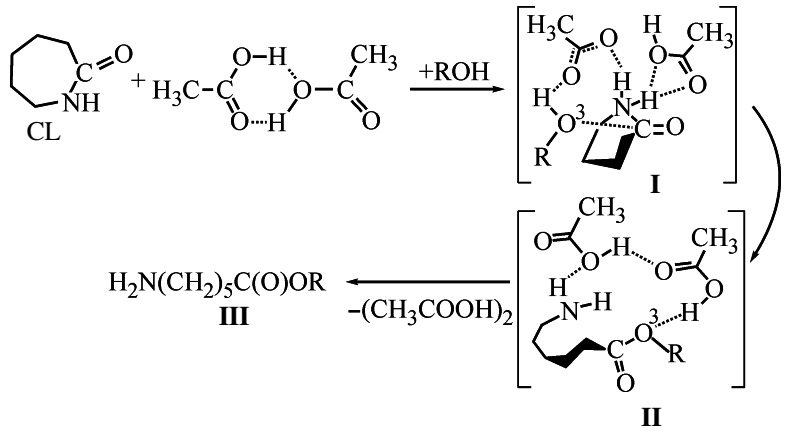
To determine the optimal amount of the most effective catalyst, TPFP, we examined how the TPFP concentration varied in the range 0.025–0.1 mol % affects the CL transformation rate (Fig. 1). Table 2 and Fig. 1 show that the optimal concentration of TPFP is 0.05 mol %: CL conversion 90, AA conversion 25, oligomer yield 82%. Further increase in the TPFP concentration only slightly affects the conversion of CL and AA and the oligomer yield. At the same time, at the catalyst concentration decreased to 0.025 mol %, the CL conversion decreases to 65, AA conversion, to 15, and oligomer yield, to 61%.

Table 3. Effect of the TPFP–AA system on the LMC content, relative viscosity of the granulate, and amount of bristle returned to processing

Run no.	$c_{TPFP} \times 10^4$, wt %	PCA granulate		Thin extrudate (bristle)
		η, %	LMC content, %	
1	8.8(1)*	2.91–2.95	10.56	2.1
2	8.8(2)	2.86–2.89	10.85	2.6
3	9.2(3)	2.85–2.87	10.40	6.0
4	None(1)	2.81–2.83	11.62	9.4
5	None(3)	2.81–2.84	11.25	9.9

* The reaction mixture contained 1,2-di[4-(*N*-phenylamino)-phenoxy]ethane (N1) in an amount of 7.1×10^{-2} (1) or 5.1×10^{-2} (2) wt %, or 2-hydroxy-1,3-di[4-(*N*-phenylamino)phenoxy]-propane in an amount of 5.1×10^{-2} wt % (3).

Simultaneous participation of alcohols and AA in the opening of the lactam ring can be represented by the scheme taking into account the electrophilic properties of the acid protonating the amide nitrogen atom and the acidity and nucleophilicity of the alcohol participating in the interaction with the lactam carbonyl carbon atom and simultaneously in the release of AA from the forming complex:



where R = C_4H_9, C_5H_{11}, or $CH_2(CF_2CF_2)H$.

This scheme was analyzed by the AM1 method. As the reaction coordinate we chose the O^3–C bond formed as the hydroxyl oxygen atom (O^3) of the alcohol approaches the carbonyl carbon atom of the lactam ring. In the first step of the reaction, the anion–cation complex is attacked by another acetic acid mol-

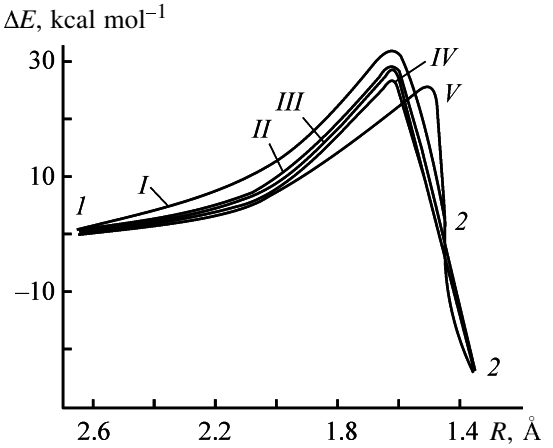


Fig. 2. Variation of the relative energy $\Delta E = E_0 - E_R$ of the systems ε-caprolactam–AA and ε-caprolactam–alcohol along the reaction coordinate R: (*I*) AA, (*II*) C_4H_9OH, (*III*) $C_5H_{11}OH$, (*IV*) $H(CF_2)_2CH_2OH$, and (*V*) $H(CF_2)_4CH_2OH$. (*1*, *2*) Points corresponding to the initial and final states of the reaction system, respectively. The reaction coordinate R is the length of the O^3–C bond.

ecule or by an alcohol molecule (HOR) (structure **I**). This results in the ring opening via structure **II** with the simultaneous formation of ester **III** in the case of participation of ROH and acetic acid dimer.

It is important that, in the case of attack with acetic acid, the energy of the products coincides with that of the reactants (Fig. 1), i.e., a situation arises when the ring opening does not occur completely (N–C bond length about 0.17 nm). Attack with alcohol leads to an appreciable gain in the energy of the final product, with the complete ring opening (N–C bond length about 0.46 nm). The energy barrier of this reaction is about 28 kcal mol^{-1} (Fig. 2).

The experiment and quantum-chemical calculations show that TPFP is more reactive than 1-butanol or 1-pentanol.

The formation of the intermediate polyfluoroalkyl esters of the oligomers was detected by ^1H NMR spectroscopy: The intermediate product, 1,1,5-trihydroperfluoropentyl esters (identified in the initial step of the reaction of CL with AA in the presence of TPFP after recrystallization from water), gives a triplet of triplets of the $H–CF_2CF_2$ proton at $\delta = 6.4$ ppm. Synthesis of polyfluoroalkyl esters of ε-aminocaproic acid oligomers was described in [18, 19].

Table 4. Effect of TPFP on the physicomechanical characteristics and heat resistance of PCA fiber (200°C, 2 h)

Run no.*	Tex	Tensile strength, N	Relative elongation, %	Residual fiber strength, %
1	187	13.4	15.3	85.7
2	185	12.5	16.0	88.8
3	183	12.5	16.1	90.7
4	185	12.5	16.0	80.3
5	183	12.4	16.5	81.0

* The numbering is the same as in Table 3.

In the presence of the polyfluorinated alcohol, the oligomers are formed faster and have a considerably higher molecular weight, compared to the synthesis in the presence of unsubstituted alcohols.

An increase in the oligomer molecular weight and regeneration of the catalyst (alcohol) are due to the reaction of the ester with the amino group of the adjacent molecule:

$$R–C(O)[NH(CH_2)_5C(O)]_nOCH_2(CF_2CF_2)_2H$$

$$+ H_2N(CH_2)_5\sim \rightarrow R–C(O)[NH(CH_2)_5C(O)]_nO(CH_2)_5\sim$$

$$+ H(CF_2CF_2)_2CH_2OH.$$

Introduction of the perfluorinated group into the ester moiety (in the case of TPFP) increases the positive charge on the carbonyl carbon atom, which favors its attack by the lone electron pair of the amine nitrogen atom of the adjacent oligomer molecule, with the regeneration of TPFP.

The reaction between the ester group of the oligomer and the amino group of the PCA macromolecule in the course of hydrolytic polymerization of CL in the presence of TPFP leads to a decrease in the LMC content and to an increase in the viscosity of the granulate melt (Table 3), confirming the occurrence of the above reactions. These transformations lead to a decrease in the content of reactive functional groups in the polymeric system. All these factors favor enhancement of the heat resistance of PCA. The heat resistance of PCA was judged from changes in the residual strength of the PCA fiber and in the granulate weight upon heat treatment [15]. The residual tensile strengths of the PCA fiber samples upon heat treatment for 2 h at 200°C with TPFP introduced into the polymerization system and without it (commercial polymer) are compared in Table 4. It is seen that the residual strength of the PCA sample prepared in the presence of TPFP decreases insignificantly upon heat treatment at 200°C, whereas without TPFP (commercial PCA) it decreases by almost 20% (the variation of the PCA fiber upon heat treatment is the most important parameter for evaluation of the heat resistance of the fiber in the production process). Consistent data were

Table 5. Decrease in the granulate weight in time in the course of heating to 400°C

T, °C	Time of reaching indicated temperature, min	Weight loss of granulate, %	
		commercial	with TPFP added
150	17.8	1.1	0.4
330	34.2	6.0	2.0
355	36.6	7.7	4.0
380	39.0	11.0	6.0
400	41.5	20.2	12.7

also obtained in evaluation of the heat resistance by derivatographic examination of the thermolysis of the PCA granulate (Table 5). For example, on heating to 330°C over a period of 34.2 min, the weight loss of the granulate prepared in the presence of TPFP was three times smaller, compared to the commercial granulate.

Thus, introduction of 1,1,5-trihydroperfluoropentanol in polymerization of ε-caprolactam favors opening of the ε-lactam ring, and participation of the intermediate ester in the chain propagation step leads to an increase in the molecular weight of poly-ε-caprolactam and to the enhancement of the heat resistance of the polymer.

CONCLUSIONS

(1) The system 1,1,5-trihydroperfluoropentanol–acetic acid catalyzes opening of the lactam ring more efficiently than acetic acid or polyfluorinated alcohol.

(2) The mechanism of catalysis of caprolactam oligomerization and polymerization in the steps of ring opening and chain propagation, with the regeneration of 1,1,5-trihydroperfluoropentanol, was considered.

(3) The processing characteristics (decrease in the content of low-molecular-weight compounds and in the amount of bristle returned to reprocessing) and heat resistance of polycaproamide are improved by using the system 1,1,5-trihydroperfluoropentanol–acetic acid.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Features of Polystyrene Synthesis in the Presence of (Diphenylbutadiene)tricarbonylchromium

Abstract—Features of radical polymerization of styrene in the presence of (diphenylbutadiene)tricarbonylchromium were studied.

DOI: 10.1134/S1070427207050242

New approaches to control over the kinetic parameters of synthesis of polymers attract a great attention. These methods involve formation of stable radicals controlling chain propagation by the mechanism of reversible inhibition directly in the polymerization system (in situ) [1–3]. Under these condition, polymerization is faster and the reaction temperature is lower (50–80°C) than those in the presence of stable nitroxyl radicals introduced directly into the polymerizate.

Metal-containing monomers including chromium complexes can be used as chain-terminating agents formed in situ under the conditions of radical initiation [3]. Organochromium compounds react with initiator radicals or with growing macroradicals to form relatively stable metal-containing carbon radicals affecting directly the polymerization rate and the molecular weight of the polymers [3–5].

The aim of this study was to develop a procedure of gel-free polymerization of one of the most practically important monomers, styrene, in the presence of (diphenylbutadiene)tricarbonylchromium (DPB). This complex can accept an initiator radical to form in situ a relatively stable sterically hindered carbon radical stabilized additionally by the arenetricarbonylchromium group.

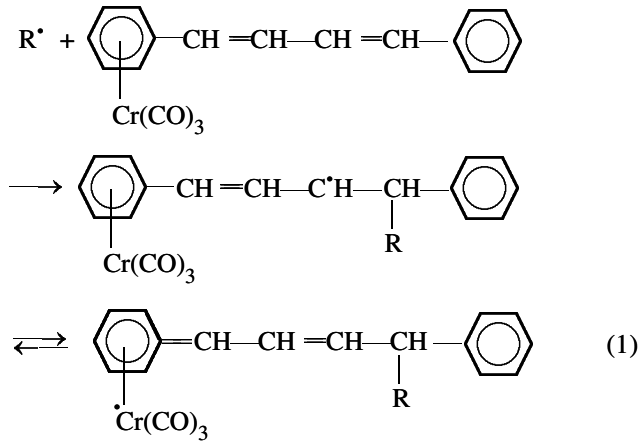
EXPERIMENTAL

(Diphenylbutadiene)tricarbonylchromium was prepared by the procedure described in [6]. Its physicochemical properties were similar to the published data. Styrene was purified by the conventional procedure [7]. Commercial azobis(isobutyronitrile) (AIBN) used as an initiator was recrystallized from methanol. Di-*tert*-butylperoxytriphenylantimony (DPS) was prepared by the procedure described in [8]. Triisobutylboron was a commercial product. Physicochemical properties of all the compounds used in this study were similar to the published data.

Styrene was polymerized in temperature-controlled evacuated ampules. The polymerization kinetics was studied by gravimetric and thermographic methods. To remove unchanged monomer from the polymerization product, the polymers were precipitated with hexane from an ethyl acetate solution under argon. The molecular weight (MW) and molecular weight distribution (MWD) were estimated by gel permeation chromatography (GPC) [10]. Chromatographic analysis was performed on a Knauer liquid chromatograph with a Linear-2 column ("Phenomenex"). An R-2301 Knauer differential refractometer was used as a detector. The eluent was chloroform.

The study of the kinetics of styrene radical polymerization initiated by AIBN in the presence of DPA showed that DPB substantially affected propagation of the polymeric chain and significantly decreased the gel effect (Fig. 1). Autocatalytic polymerization is almost completely suppressed at a DPB concentration of 0.3 mol %. In this case, the time dependence of the styrene conversion is almost linear (Fig. 2, curve *2*), which is typical for controlled radical polymerization [11–13]. Styrene polymerization initiated by the radical initiator in the absence of the chromium complex is characterized by the S-shaped time dependence of the conversion (Fig. 2, curve *1*), which is typical for polymerization with gel effect. In this case the MW increases spontaneously.

Our previous ESR studies [14] showed that DPB reacted with radicals to form a sterically hindered chromium-containing radical with the unpaired electron localized at the carbon atom:



(1)

1,4-Diphenyl-1,3-butadiene, an organic analog of DPB, readily forms diphenylbutadienyl anions in the presence of *sec*-butyllithium in toluene at 70°C [15]. Although diphenylbutadienyl anions are readily formed by the reaction of diphenylbutadiene with *sec*-BuLi, this diene does not polymerize and copolymerize with styrene. As shown by Barson et al. [16], 1,4-diphenyl-1,3-butadiene (organic analog of DPB) is almost inert to 1-cyano-1-methylethyl radical formed by thermolysis of AIBN initiator. Thus, introduction of the bulky tricatbonylchromium group into diphenylbutadiene results in redistribution of the electron density in the molecule so that DPB becomes capable of entering into radical reactions.

Previously we showed [14] that DPB did not polymerize under the conditions of radical-initiated polymerization in a polar solvent (ethyl acetate) at 70°C for 50 h. No poly[(diphenylbutadiene)tricarbonylchromium] was formed when the polymerization was performed for 33 days in the presence of binary organometallic initiator [di-*tert*-butylperoxytriphenylantimony + triisobutylboron]. This initiator was used as an effective initiator of polymerization of various monomers, including dienes, in a wide temperature range [13].

As seen from the table and Fig. 3, the viscosity-average and number-average MW (M_n) linearly increase with the monomer conversion after introduction of the organochromium compound in the amount comparable with the initiator concentration. The dependences of the molecular weight of PS on the conversion with AIBN initiator in the absence of DPB are shown in Fig. 3 for comparison. As seen from these data, in the absence of the organometallic monomer,

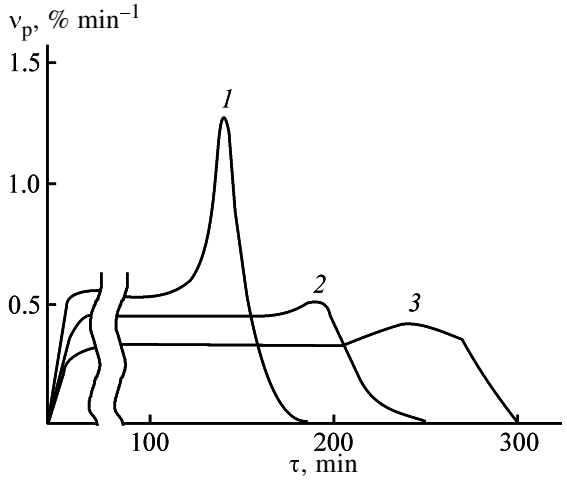


Fig. 1. Differential kinetic curves of ST polymerization in the presence of (*1*) 0, (*2*) 0.2, and (*3*) 0.3 mol % DPB at 80°C. Initiator AIBN (0.8 mol); the same for Fig. 2. (ν_p) Polymerization rate and (τ) time.

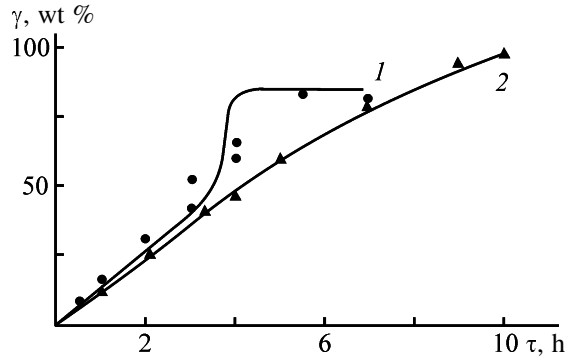

Fig. 2. Integral kinetic curves of ST polymerization in the presence of (*1*) 0 and (*2*) 0.3 mol % DPB at 80°C. (γ) Conversion and (τ) time.

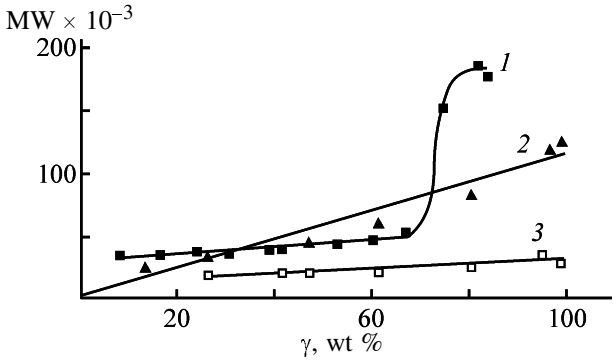

Fig. 3. (*1, 2*) Viscosity-average and (*3*) number-average MW of polystyrene formed in the presence of (*1*) 0, (*2*) 0.2, and (*3*) 0.3 mol % DPB as a function of the conversion γ. Initiator AIBN (0.8 mol). T = 70°C.

MW increases spontaneously in the course of the polymerization.

Introduction of DPB into the polymerizate substantially affects the kinetics of ST polymerization. This is

Molecular-weight parameters of polystyrene prepared at T = 70°C in the presence of (diphenylbutadiene)tricarbonylchromium. Initiator AIBN (0.8 mol %)

DPB, mol %	Monomer conversion, wt %	$M_n \times 10^{-3}$	$M_w^* \times 10^{-3}$	M_w/M_n
0	84	77	246	3.2
0.3	42	20	36	1.8
	48	21	39	1.9
	62	23	45	2.0
	81	27	107	4.1
	95	37	182	4.9

* M_w is weight-average MW.

probably due to reaction of the propagating radical with the chromium-containing monomer to form sterically hindered carbon radical stabilized by the arenetricarbonylchromium group [Eq. (1)]. We suggest that these stabilized radicals formed in the system can affect the kinetic parameters of polymerization and molecular weight parameters of the polymer by the mechanism of reversible inhibition:

$$\sim P_n^{\bullet} + {}^{\bullet}X \rightleftharpoons \sim P_n \cdots X \qquad (2)$$

$$\sim P_n\text{–}X \underset{k_c}{\overset{k_d}{\rightleftharpoons}} \sim P_n^{\bullet} \overset{k_p}{\circlearrowright} + {}^{\bullet}X \qquad (3)$$

where $\sim P_n$ is the propagating radical; X, chromium-containing carbon radical; k_d, dissociation rate constant of the adduct; k_r, recombination rate constant; and k_p, rate constant of chain propagation.

In addition, the shift of MWD curves of PS samples prepared in the presence of DPB to higher MWs with an increase in the monomer conversion suggests

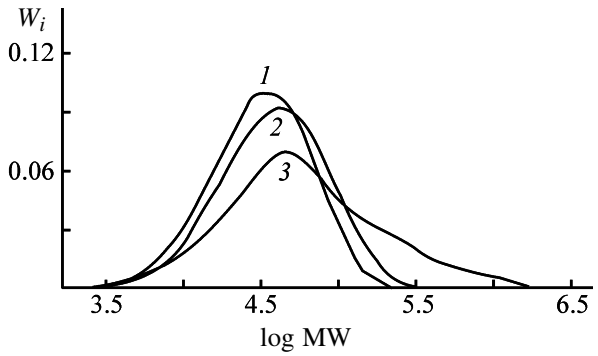

Fig. 4. Molecular weight distribution of PS samples prepared at 70°C in the presence of 0.8 mol % AIBN and 0.3 mol % DPB. (W_i) Weight fraction of molecules with the given MW. Conversion γ, wt %: (*1*) 42, (*2*) 62, and (*3*) 99.

that polymerization of styrene in the presence of DPB occurs by the mechanism of controlled chain propagation [scheme (3)].

Thus, styrene polymerization in the presence of the chromium-containing monomer in the amount comparable with the initiator concentration has features of "living" polymerization, in particular, linear dependence of the molecular weight of the polymer on the conversion. This is an indirect evidence that the molecular weight of the polymer increases continuously in the course of polymerization [13, 17, 18] and hence the MWD shifts to higher MWs with increasing polymer conversion from small conversions owing to fragmentary propagation of the polymeric chain.

It should be noted that the MWD curves are broadened and the polydispersity coefficients of the samples increase (see table) at high conversions, which is atypical for controlled radical polymerization by the mechanism of reversible inhibition. Clearly, this can be due to reactions increasing the polydispersity coefficient (isomerization, disproportionation, and chain transfer to monomer and polymer), i.e., formation in the system of "dead" polymer by bimolecular chain termination. These reactions occur concurrently with the reactions of reversible inhibition.

Similar features of controlled polymerization were observed when sterically hindered (α-methylstyrene)-tricarbonylchromium radical was used as a chain-terminating agent [3].

CONCLUSIONS

(1) Introduction of (diphenylbutadiene)tricarbonylchromium into the polymerization system affects the kinetics parameters of styrene polymerization and molecular-weight properties of the polymer and suppresses the gel effect. Under these conditions, the molecular weight of the polymer increases linearly and the molecular-weight distribution shifts to higher molecular weight with the monomer conversion.

(2) The chain-terminating agent substantially affects the chain propagantion at temperatures of industrial preparation of polystyrene (70–80°C). The disadvantage of this agent under conditions of radical initiation is relatively high polydispersity of the resulting polymer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Copolymerization of the C_9 Hydrocarbon Fraction of Liquid Pyrolysis Products with Maleic Anhydride

V. P. Lesnyak, D. I. Shiman, L. V. Gaponik, S. V. Kostyuk, and F. N. Kaputskii

Research Institute of Physicochemical Problems, Belarussian State University, Minsk, Belarus

Received September 12, 2006; in final form, March 2007

Abstract—Radical copolymerization of the C_9 hydrocarbon fraction of liquid pyrolysis products with maleic anhydride was studied. The influence of reaction conditions on the copolymer yield, its molecular mass, and maleic anhydride content was elucidated. Hydrophilic products showing promise as modifying additives to paper stock, binding agents, dispersants, and compatibilizers were prepared.

DOI: 10.1134/S1070427207050254

Oligomerization of the C_9 fraction, a by-product from production of ethylene and propylene, yields petroleum polymeric resins (PPRs) which are widely used in production of synthetic drying oils and oil varnishes, and also as plasticizing, sizing, and other additives to various composites. The hydrophobicity of PPRs restricts their applications. Chemical modification of PPRs by carboxylation [1–6] and sulfonation allows not only variation of their physicochemical properties but also preparation of hydrophilic products, thus expanding the PPR application area. Maleinization of hydrocarbon resins by the reaction of PPR with maleic anhydride (MA) at a high temperature (≥200°C) with the formation of hydrophilic carboxyl-containing oligomers (MA content c ≥ 15 wt %) has been described in detail [1–5]. We believe that radical copolymerization of the C_9 fraction with MA, allowing preparation of resins with an MA content of up to 50%, is more promising. However, virtually no data on this process are available. On the contrary, copolymerization of binary mixtures of individual vinylaromatic monomers (in particular, styrene and its derivatives) and dicyclopentadiene, present in the C_9 fraction, with MA, maleic acid, or fumaric acid has been extensively studied [8–38].

The goals of this study were to perform copolymerization of the C_9 fraction with MA, examine the effect of reaction conditions (nature and content of initiator and solvent; reaction temperature and time) on the yield and composition of the products, and prepare hydrophilic copolymers promising as additives to stock in paper production, as binders, dispersants, compatibilizers, etc. To prepare the copolymers, we used the C_9 fraction of the composition given in Table 1. It is known that the copolymerization of monomers of the electron-donor (vinylaromatic monomers, DCPD) and electron-acceptor (MA) types in the presence of radical initiators occurs by the radical-complex mechanism with the formation of predominantly alternating copolymers [11].

To determine how the initiator affects the copolymer yield and its MA content, we tested as copolymerization initiators such commonly used agents as benzoyl peroxide (BP), cumyl peroxide, and 2,2'-azobis(isobutyronitrile). Table 2 shows that the most effective initiators of the copolymerization of the C_9

Table 1. Composition of the C_9 fraction (bp 94–175°C)

* 2.5 h at 65°C + 0.5 h at 115°C.

fraction with MA are benzoyl and cumyl peroxides; in their presence, the copolymers are formed in a high yield. In the presence of 2,2'-azobis(isobutyronitrile), even at elevated temperatures, the copolymer yield is lower than in the presence of BP and cumyl peroxide. With BP, at the synthesis temperature increased to 115°C, it is possible to prepare copolymers in a high yield, due to accelerated decomposition of the initiator. Since too high copolymerization temperatures distort the alternation of the monomer units [12, 13], it is not appropriate to heat the reaction mixture above 120°C. Therefore, in the further studies we used BP; furthermore, it ensured the highest, compared to the other initiators tested, content of MA in the resulting copolymers. It is interesting that the nature of the initiator and its content in the reaction mixture do not noticeably affect the molecular mass of the copolymer; the molecular masses show a large scatter in different experiments, and the molecular-mass distribution (MMD) is broad.

When studying the effect of the initiator amount on the copolymer yield and its MA content, we found that the copolymer yield regularly increased with an increase in the initiator concentration. The MA conversion did not noticeably change (64 wt %) with an increase in the BP concentration in the reaction mixture (starting from 1 wt %), and the content of the anhydride in the copolymer was 31 wt %.

A study of how the copolymerization time affects the copolymer yield and its MA content showed that, at a BP concentration of 1 wt %, the highest (for these conditions) yield of the product (85%) is attained in 3 h, whereas in the presence of 0.5 wt % BP the highest yield (76%) is attained in a longer time, 6 h (Fig. 1). The MA content of the copolymer does not noticeably vary with the conversion of the monomers. The number-average molecular mass of the copolymer decreases with an increase in the reaction time (Fig. 2), and the products prepared show very broad

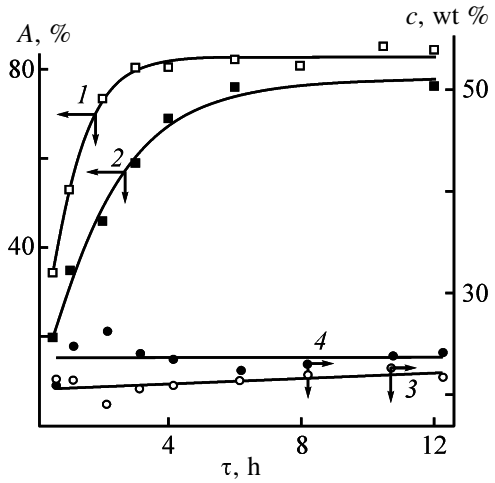

Fig. 1. (*1, 2*) Copolymer yield *A* (% based on monomer) and (*3, 4*) its MA content *c* as functions of the synthesis time τ. Copolymerization conditions: weight ratio of monomers of the C_9 fraction to MA 1 : 1, initiator BP, solvent dioxane, volume ratio of dioxane to the C_9 fraction 2 : 1, temperature 80°C; the same for Fig. 2. BP content, % of monomers: (*1, 3*) 1 and (*2, 4*) 0.5.

Copolymerization conditions: initiator BP, 1% of the monomers; solvent dioxane, volume ratio of dioxane to C_9 fraction 1 : 1; 80°C, 3 h. The figures denote the M_n values; the M_w/M_n ratios are given in parentheses.

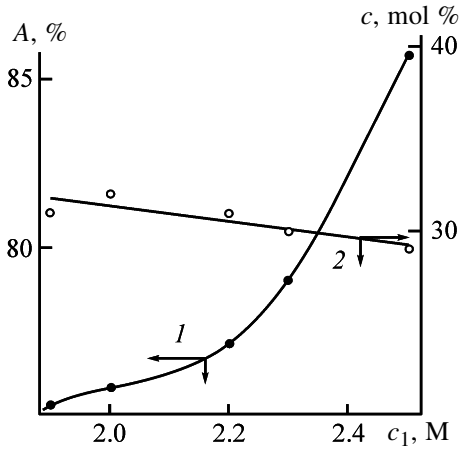

Fig. 4. (*1*) Copolymer yield *A* (% based on monomer) and (*2*) its MA content *c* as functions of the concentration of the monomers in the starting mixture c_1. Copolymerization conditions: initiator BP, 1% of the monomers; weight ratio of the monomers of the C_9 fraction to MA 1 : 1; solvent dioxane; 80°C, 3 h.

MMD even at low conversion of the monomers. This may be due to the presence of a large number of monomers of different activities in the system.

A study of how the ratio of the monomers of the C_9 fraction to MA in the reaction mixture affects the copolymer composition (Fig. 3) showed that the 1 : 1 copolymer can be prepared only from a mixture with a large excess of the anhydride (MA content 84 mol %). At 50 : 50 molar ratio of the monomers, no more than 36 mol % MA is incorporated into the copolymer. On the contrary, the copolymerization of binary mixtures styrene (or styrene derivative)–MA and DCPD–MA (molar ratio 50 : 50) yields copolymers whose composition does not noticeably differ from that of the monomer mixture, i.e., 50 : 50 [14–17]. It should be noted that neither MA nor DCPD homopolymerize under the copolymerization conditions [14].

Despite the fact that the mixture of monomers of the C_9 fraction is complex and multicomponent, a certain tendency to alternation of monomers of different nature in the copolymers is observed. As seen from Fig. 3, this tendency is particularly pronounced in the copolymerization of mixtures with an MA content of up to 35 mol %, from which copolymers with the anhydride content exceeding that in the starting mixture are formed. The copolymer with the relative content of anhydride units equal to the MA content in the starting mixture is formed only from a mixture with 35 mol % MA. When the MA content in the starting mixture exceeds 35 mol %, the resulting copolymers are depleted of the MA units. This trend may be due to exhaustion of the most active electron-donor monomers present in the C_9 fraction (styrene, vinyltoluenes) and increase in the contribution to the chain propagation of separate monomers rather than of relatively stable monomeric donor–acceptor complexes. As a result, the distribution of units in the copolymer becomes random.

The copolymer yield also depends on the composition of the monomer mixture, and the reaction rate is the highest at the molar ratio of the monomers of the C_9 fraction to MA of approximately 50 : 50 (Fig. 3). Apparently, at this monomer ratio the concentration of monomeric donor–acceptor complexes in the system is the highest, and it is well known that the rate of the copolymerization involving complexes is higher than that of the process involving separate monomers [11]. A study of how the concentration of the monomers affects the copolymerization rate showed that the reaction rate increased with the monomer concentration, and the MA content of the copolymer slightly decreased (by approximately 2%) (Fig. 4).

Figure 3 shows that the number-average molecular mass of the copolymers decreases with an increase in the MA content of the starting monomer mixture. From a mixture with 9 mol % MA, we obtained a copolymer with the highest molecular mass (7540). Apparently, an increase in the ratio of MA to monomers of the C_9 fraction in the starting monomer mixture increases the probability of chain transfer. It is interesting that, at both low (9 mol %) and high

Table 3. Effect of solvent on the copolymer yield and its MA content. Copolymerization conditions: weight ratio of the monomers of the C_9 fraction to MA 1 : 1; volume ratio of the solvent to the C_9 fraction 1 : 1; initiator BP, 1 wt % relative to the monomers; 3 h

Solvent	Dielectric permittivity of solvent	Copolymer yield based on monomers, wt %	MA content of copolymer, wt %	M_n	M_w/M_n
1,4-Dioxane	2.2	76	32	1820	15.6
Toluene	2.4	55	21	–	–
1,2-Dichloroethane	10.4	63	34	4670	6.4
Cyclohexanone	18.2	44	21	1200	4.1
Dimethylformamide	36.7	18	34	–	–

(84 mol %) MA content of the reaction mixture, the resulting copolymers have a narrower MMD than those prepared at the intermediate monomer ratios.

The copolymerization of monomers of the electron-donor and electron-acceptor types is strongly influenced by the solvent [9, 10, 18–20]. Some solvents used in the copolymerization of MA with vinylaromatic monomers can form donor–acceptor complexes with the anhydride (tetrahydrofuran, dioxane, etc.), affecting the formation of complex monomer pairs and correspondingly contributing to the overall copolymerization process [9, 10]. For example, in the photopolymerization of a mixture of styrene with MA, the copolymerization rate and molecular mass of the copolymer decrease with an increase in the donor power of the solvent.

Experiments on the copolymerization of MA and C_9 fraction in various solvents showed that the dependence of the copolymer yield (and hence copolymerization rate) on the solvent polarity was common (Table 3). The lowest yield was observed in the most polar solvent, dimethylformamide. This is due to the fact that, among the solvents tested, dimethylformamide has the highest dielectric permittivity and the highest Gutmann donor number (26.6 [22]); therefore, it forms with electron-acceptor MA a stronger complex than do monomers of the C_9 fraction, which leads to suppression of the copolymerization, the more so as the solvent is in excess relative to the electron-donor monomers. With low-polarity toluene, a deviation from the common trend is observed, probably due to the fact that the arising copolymer forms a separate phase. The solvent affects not only the reaction rate but also the copolymer composition. In toluene and cyclohexanone, copolymers with a lower MA content were obtained. However, no clear correlation is observed between the solvent polarity and the MA content of the copolymer. Table 3 also shows that the copolymers formed in various solvents have low M_n and broad MMD.

Thus, our studies of how the copolymer yield and MA content depend on the composition of the starting monomer mixture, nature of the initiator and solvent, and reaction conditions showed that the copolymerization of the C_9 fraction with MA in the presence of radical initiators somewhat differs from the copolymerization of the binary monomer mixtures. No clear dependence of the molecular mass of the copolymers on the reaction conditions (initiator concentration, temperature, solvent) is observed. The copolymers obtained from equimolar monomer mixtures contain considerably less than 50 mol % MA. Apparently, the observed deviations from certain regular trends characteristic of radical copolymerization are primarily associated with the multicomponent composition of the system, leveling off the effect of various reaction parameters on the copolymerization. The copolymers prepared have M_n from 500 to 17 000; they are soluble in acetone, dioxane, tetrahydrofuran, and cyclohexanone, and in the form of ammonium and sodium salts, in water.

EXPERIMENTAL

The copolymerization was performed in a glass reactor equipped with a power-driven stirrer, a thermometer, and a reflux condenser. The reactor was purged with an inert gas, after which it was charged with 10 ml of a solvent (dioxane, cyclohexanone, dichloroethane, toluene, or dimethylformamide), 5.7 g of MA (at 1 : 1 weight ratio of MA to monomers of the C_9 fraction), 10 ml of the C_9 fraction, and 0.114 g (1 wt % relative to monomers) of an initiator [benzoyl peroxide, cumyl peroxide, or 2,2'-azobis(isobutyronitrile)]. The mixture was heated with vigorous stirring to 85 (with BP), 120 (with cumyl peroxide), or 65°C [with 2,2'-azobis(isobutyronitrile)] for a prescribed

time (usually 3 h). The resulting mixture was poured into a four- to fivefold excess of a precipitant (80–100 mol of a mixture of petroleum ether and benzene, 1 : 1 by volume). The precipitated copolymer was separated and dried. The product was dissolved in acetone and reprecipitated, after which it was vacuum-dried (90–100°C, 2 mm Hg) to constant mass.

The number-average and weight-average molecular masses and the molecular-mass distribution of the copolymers prepared were determined by gel permeation chromatography on a Spectra Physics device equipped with two columns (PL gel, length 300 mm, diameter 5 μm, pore size 100 and 500 Å) and an SP8430 differential refractometer as detector. The elution was performed at 30°C with tetrahydrofuran at a rate of 1 ml min^{-1}. The values of M_n and M_w/M_n of the polymer were calculated from the elution curves using the calibration plots obtained with close-cut polystyrene references.

The MA content was determined by back-titration with phenolphthalein as indicator. A copolymer sample (0.1–0.2 g) was dissolved in 10 ml of acetone, and 10 ml of water and 10 ml of 0.2 N KOH were added. After standing for 2–3 h, the resulting solution was titrated with 0.1 N HCl.

The C_9 fraction was analyzed with a Shimadzu GC-17A-QP-5000 gas chromatograph–mass spectrometer equipped with an HP-5ms detector. The fraction was separated on a 50 m × 0.2 mm capillary column coated with a 0.33-μm layer of the stationary phase. Measurement conditions: electron impact (70 eV), column temperature 60–300°C (10 deg min^{-1}), carrier gas He (1 ml s^{-1}).

The C_9 fraction was dried over $CaCl_2$ and distilled under reduced pressure. Maleic anhydride was recrystallized from chloroform and then distilled under reduced pressure. The initiators and solvents were purified by standard procedures.

CONCLUSIONS

(1) Copolymerization of the C_9 fraction of liquid pyrolysis products with maleic anhydride in the presence of various initiators [benzoyl peroxide, cumyl peroxide, 2,2'-azobis(isobutyronitrile)] was performed. The dependence of the copolymer yield and content of maleic anhydride in it on the composition of the starting monomer mixture, nature and concentration of the initiator, solvent, and reaction temperature and time was elucidated. As compared to the copolymerization of binary mixtures of individual electron-donor monomers with electron-acceptor maleic anhydride, copolymerization of the C_9 fraction with maleic anhydride is characterized by weaker tendency to alternation of different units. The copolymers prepared from monomer mixtures containing 50 mol % maleic anhydride contained only 36 mol % anhydride units.

(2) Based on the regular trends revealed, hydrophilic copolymers containing 25–50 mol % maleic anhydride with M_n from 500 to 17 000 and a broad molecular-mass distributoin were prepared.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Immobilization of Cobalt Disulfophthalocyanine Complex on Polypropylene

I. V. Pimkov, O. G. Lutsenko, and O. A. Golubchikov

Received November 20, 2006

Abstract—Procedures were developed for chemical activation of polypropylene materials and subsequent immobilization on them of the cobalt disulfophthalocyanine complex. Factors affecting these processes were examined, and the state of the phthalocyanine on the surface of the polypropylene fiber was determined.

DOI: 10.1134/S1070427207050266

Because of the absence of polar groups on the surface and in the bulk of the polymer, polypropylene materials are very poorly dyed with all the types of dyes, and their coloration is possible only through structural modification [1].

The goals of this study were to develop methods for modification of a nonwoven polypropylene material and for immobilization of the cobalt disulfophthalocyanine complex (CoP) on activated polypropylene, and also to examine how the concentrations of the electrolyte and CoP affect the adsorption of the dye.

EXPERIMENTAL

We used distilled water, *o*-xylene, H_2O_2, NaOH, Br_2 (pure grade), HNO_3 (d = 1.36, chemically pure grade), sodium peroxocarbonate (Khimprom Joint-Stock Company, Novocheboksarsk, Chuvashia, Russia), and CoP (Zavolzhsk Chemical Plant, Joint-Stock Company, Russia). We also used geotextile nonwoven polypropylene material (GPP) produced by the Kamenskvolokno Joint-Stock Company with the surface density of 400 g m^{-2} and thickness of 4 mm, and a 20-μm film of biaxially oriented isotactic polypropylene of molecular mass 400–700 kDa [TU RB (Technical Specifications of Belarus Republic) 00204079.164-97]. The absorption spectra were recorded on a U-2000 spectrophotometer, and the IR MATIR spectra, on an Avatar 360 FT-IR spectrometer. The specific surface area of GPP was determined on a Sorbtometr-M surface area analyzer. The photomicrographs of polypropylene films were obtained with an Axiostar plus microscope. Polypropylene was activated by different procedures.

Activation with hydrogen peroxide. A round-bottomed flask equipped with a reflux condenser was charged with 100 ml of 35% aqueous H_2O_2 and 2 g of GPP (four 0.5-g specimens), after which 5 mg of $FeSO_4$ was added (larger amounts impart a brown color to polypropylene, and smaller amounts do not ensure efficient catalysis of H_2O_2 decomposition). The reaction mixture was heated to boil and refluxed for various periods. The start of boiling was considered as the start of the reaction. After the activation, the specimens were washed with distilled water, dried in air, and analyzed by IR MATIR spectroscopy. The results obtained with different activating agents and at different activation times are listed in Table 1.

Activation with sodium peroxocarbonate. A 500-ml round-bottomed flask equipped with a reflux condenser was charged with 2 g of GLL (four 0.5-g specimens) and 200 ml of 5% NaOH. The mixture was heated to boil, and 10 g of sodium peroxocarbonate was added in small portions over a period of 1 h, so as to ensure continuous evolution of oxygen. The specimens were withdrawn and immersed in a fresh 5% NaOH solution, after which another 10 g of sodium peroxocarbonate was added over a period of 1 h. The thus treated specimens were washed with distilled water.

Activation in NaBrO solution. The activation procedure is based on the NaBrO synthesis protocol [2]. A 250-ml flask equipped with a reflux condenser was charged with 2 g of GPP, and 100 ml of 40% NaOH

and 25 ml of Br_2 were added. The mixture was heated to boil and refluxed for various periods. The start of boiling was considered as the start of the reaction. The activated specimens were washed with distilled water.

Activation by nitration. Nitration is seldom used for the modification of polypropylene and is the least studied [3]. We used a procedure based on data from [4]. A flask equipped with a reflux condenser was charged with 100 ml of HNO_3 (d = 1.36) and 2 g of GPP. The reaction was performed at the boiling point of the acid for various periods.

To perform the immobilization and determine the surface concentration of CoP on geotextile polypropylene, a 1-g specimen of GPP preliminarily wetted in distilled water was placed in a flask equipped with a reflux condenser, and 100 ml of an aqueous solution of CoP and electrolyte was added. The mixture was heated to boil and then left at room temperature for 12 h. Then the specimen was washed (until the wash water became transparent) and dried in air.

The CoP amount on the polypropylene surface was determined similarly to [5]. A dyed 0.5-g specimen was placed in a 100-ml flask equipped with a reflux condenser; 20 ml of 20% aqueous solution of pyridine was added, and the mixture was heated for 30 min on a boiling water bath. The solution was separated, and the dye retained on the fiber was washed out with an additional portion of aqueous pyridine. The solutions were transferred into a 50-ml volumetric flask and brought to the mark with aqueous pyridine, after which the optical density at 670 nm ($\log\varepsilon = 4.82$) was determined. The dependence of the surface concentration of CoP on its and NaCl concentrations in solution is presented in Table 2.

The state of CoP on the GPP surface was examined by spectrophotometry [6]. A dyed specimen was placed in a cell and poured over with *o*-xylene whose refractive index is virtually equal to that of polypropylene. The light scattering in the dispersion of polypropylene in *o*-xylene is absent, which allows correct recording of the electronic absorption spectra.

The procedures used for activation of a polypropylene film and immobilization of CoP on its surface were similar to those described above.

Alkaline treatment of the material was performed as follows. A 150 × 10-mm strip of the geotextile material with immobilized CoP was placed in a cy-

Table 2. Surface concentration of CoP on GPP at various solution compositions

lindrical vessel 350 mm high and 35 mm in diameter and fixed on the bottom, after which 200 ml of 0.2 M NaOH was added. A glass tube reaching the bottom was inserted, and air was passed at a rate of 2 l min^{-1}. The CoP concentraiton of the fiber was determined at the initial moment and after the treatment for 20, 40, 60, and 80 h.

The IR MATIR spectra of the activated polypropylene films and GPP show that the suggested activation procedures result in formation of oxygen-containing groups on the surface. The appearing absorption bands at 1635, 1740, and 1710 cm^{-1} correspond to stretching vibrations of C=O groups in various surroundings, and those at 3200 and 3300 cm^{-1}, to stretching vibrations of OH groups involved in hydrogen bonding [7, 8] (Fig. 1). The IR spectra show that the initial polypropylene film and GPP contain a small amount of oxygen-containing groups. The band at 1555 cm^{-1} in the spectrum of the specimen activated with nitric acid can be unambiguously assigned to the $-NO_2$ stretching vibrations [7].

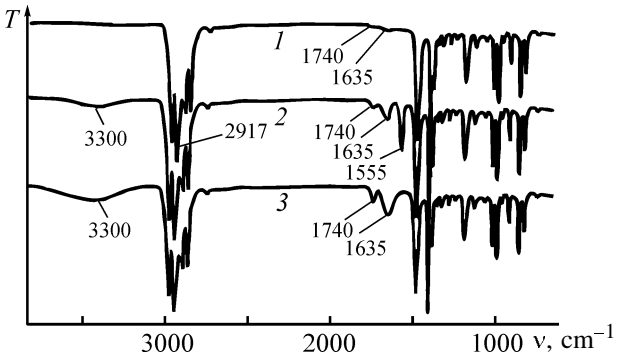

Fig. 1. IR MATIR spectra. Polypropylene film: (*1*) initial, (*2*) activated in HNO_3, and (*3*) activated in NaBrO. (*T*) Transmission amnd (ν) wavenumber.

It is appropriate to estimate the amount of oxygen-containing groups on the polypropylene surface from the relative (reduced), rather than absolute, heights of the corresponding peaks in the IR MATIR spectra (Table 1):

$$h = (T_i/T_{2917}) \times 100,$$

where T_i is the transmission at a given wavenumber and T_{2917}, that at 2917 cm^{-1}.

This peak of the C–H stretching vibrations was chosen as internal reference, because its intensity is affected by any kind of treatment of polypropylene materials to the least extent.

Table 1 shows that GPP undergoes chemical modification somewhat more readily than does the polypropylene film. The degree of modification increases with an increase in the activation time. The most efficient modification procedure for GPP is treatment in a sodium peroxocarbonate solution, and for polypropylene film, activation with NaBrO.

All attempts to immobilize CoP on a polypropylene film activated by one or another procedure failed.

The electronic absorption spectra of films, even after folding in six, demonstrate the presence of only traces of CoP on the surface. However, on GPP (both activated and initial) CoP is adsorbed readily. This difference is caused by the fact that the specific surface area of polypropylene film is considerably lower than that of nonwoven polypropylene: 0.054 $m^2 g^{-1}$ for polypropylene film, 3.84 $m^2 g^{-1}$ for the initial GPP, and 5.11 $m^2 g^{-1}$ for GPP treated with NaBrO.

It should be noted that the presence of oxygen-containing groups (–COOH, –OH, etc.) on the GPP surface promotes the adsorption of CoP. For example, the surface concentration of CoP was 0.056 mg g^{-1} on the initial material and as high as 0.28 $m^2 g^{-1}$ on that activated in H_2O_2. Furthermore, preliminary activation of polypropylene enhances the strength of CoP binding to the surface. This can be judged from the dynamics of variation of the surface concentration of the complex on treatment of the modified GPP with aqueous solutions of alkalis (Fig. 2). Apparently, CoP molecules form intermolecular hydrogen bonds with oxygen-containing centers on the GPP surface.

It is known [9] that the presence of an electrolyte in the solution increases the degree of adsorption of dyes on the fiber surface. Since the suggested procedure of CoP immobilization is similar to dyeing, we examined how the CoP and NaCl concentrations affect the degree of adsorption of cobalt disulfophthalocyanine. Table 2 shows that, with an increase in the electrolyte concentration, the CoP amount on GPP increases by an order of magnitude, reaching a limit at c_{NaCl} = 150 g l^{-1}. With an increase in the CoP concentration in solution, the degree of its immobilization on the fiber also increases (Table 2). The optimal CoP concentration is 2.31 g l^{-1}.

An increase in the temperature also favors the immobilization of the complex on GPP. Apparently, heating causes expansion of microcracks (potential sites for CoP fixation) on the GPP surface [10].

To check this assumption, we made photomicrographs of polypropylene fibers before and after the activation and after the immobilization of the phthalocyanine. We found that oxidative treatments make the fiber surface rough and cause formation of shallow ckacks in which the local concentration of CoP is increased.

Figures 3 and 4 show the CoP spectra recorded under different conditions. In dilute solutions, the complex exists in the monomeric form characterized by the bathochromic shift of the long-wave absorption maximum (Fig. 3): 667 nm in aqueous solution,

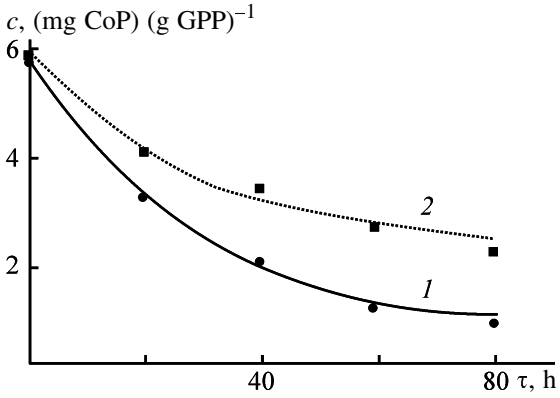

Fig. 2. Variation with time τ of the CoP surface concentration *c*: (*1*) without chemical pretreatment and (*2*) after treatment in NaBrO.

669 nm in DMF, and 670 nm in pyridine–water mixture. With an increase in the CoP concentration or with a decrease in pH, favoring association of sulfo derivatives of phthalocyanines [11], dimeric species

(λ_{max} 628 nm) are accumulated in aqueous solution (Fig. 3). The CoP polycrystals prepared by evaporation of an aqueous solution of the phthalocyanine on glass are characterized by an absorption maximum at 616 nm. The complex immobilized on polypropylene at its surface concentration less than 0.40 mg of Co per gram of GPP, as judged from the spectrum (Fig. 4), occurs to a large extent in the monodisperse form. At the surface concentration on polypropylene exceeding 5.73 mg of Co per gram of GPP, the polycrystalline form of CoP prevals.

Thus, experiments with the cobalt complex of a sulfonated phthalocyanine, chosen as a model, show that chemical activation of polypropylene fibrous materials is a promising pretreatment procedure for the subsequent immobilization of dyes and of catalytically and biologically active substances.

CONCLUSIONS

(1) The best procedure for chemical activation of nonwoven polypropylene is treatment with sodium peroxocarbonate, and in the case of polypropylene film, treatment with a NaBrO solution.

(2) The optimal conditions for immobilization of cobalt disulfophthalocyanine on geotextile polypropylene material are as follows: concentration of the complex in solution 2.31 g l^{-1} and NaCl concentration 300 g l^{-1}.

(3) At a surface concentration of 5.73 mg of CoP per gram of geotextile nonwoven polypropylene material, the phthalocyanine occurs on the fiber mainly in the form of microcrystals, and at a concentration of 0.40 mg of CoP per gram, in the monomeric form.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

New Film Composites Based on Alicyclic Polyimide

Abstract—New film composites based on alicyclic polyimide with polyethylene terephthalate and polycarbonate plasticizers were prepared. The thermodynamic parameters of mixing of film materials were determined by differential scanning calorimetry and thermogravimetry. The structure and composition of the resulting materials were studied by IR spectroscopy and X-ray diffraction analysis.

DOI: 10.1134/S1070427207050278

Polyimides (PIs) are of particular importance owing to the development of nanotechnologies which are widely used in production of light plastics applied in instrument-making industry, e.g., in design of large devices to be unrolled in the outer space [1].

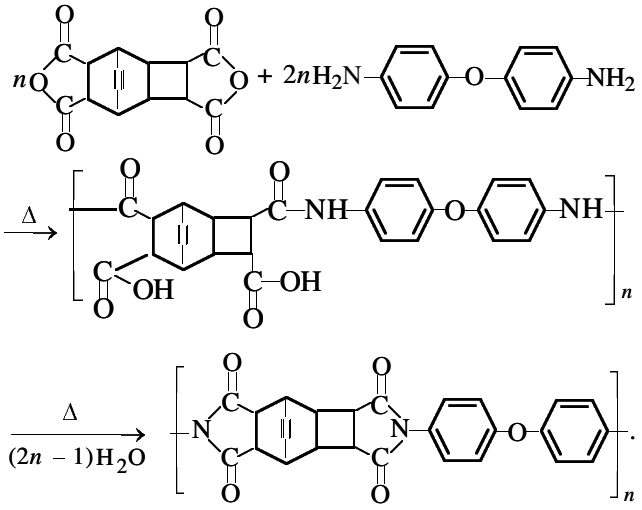
Films based on aromatic polyamides (produced by Du Pont, the United States), which exhibit high thermal and radiation resistance, are most often used as supports for further metal plating of their surface. However, these films do not promote rapid and profound penetration of metal ions into the polymer [2–4]. Therefore, to obtain materials with improved physicochemical properties, new polymeric films were prepared, which are based on alicyclic polyimide prepared by high-temperature single-stage polycondensation of tricyclododecenetetracarboxylic acid dianhydride (adduct of benzene and maleic anhydride) with oxydianiline in *m*-cresol and DMF [5].

The choice of plasticizers is governed by the fact that the degree of crystallinity in polyethylene terephthalate (PET) and polycarbonate (PC) reaches 60 and 40%, respectively, which strongly improves the material strength [6]. Moreover, PET and PC are film-forming, thermally stable, and frost-resistant compounds and can operate in a wide temperature range from –60 to 200°C and from –150 to 200°C, respectively [7].

The aim of this work was to prepare film polymeric composites with improved mechanical properties based on an alicyclic polyimide.

EXPERIMENTAL

Initial PI was prepared by high-temperature single-stage polycondensation of dianhydride of tricyclo-(4.2.2.$0^{2,5}$)dec-7-ene-3,4,9,10-tetracarboxylic acid (adduct of benzene and maleic anhydride) with oxydianiline in *m*-cresol–DMF (40%) solution with pyridine catalyst [8, 9] at gradual heating to 140–170°C over a period of 5 h:



Commercial PET and PC (Aldrich and Bayer Material 5 brand, respectively) stabilized with phosphine (3%) were used. The composites were prepared by reaction and mechanical mixing at various initial component ratios [10, 11].

The viscosities of the polymer solutions in *m*-cresol were determined on an Ubbelohde viscometer at 20°C [12]. The IR spectra were recorded on a Nexus-Nicolet 5700 Fourier spectrometer.

The films on a support were fixed in a holder which was placed in a spinner of a D8 Advance (Bruker AXS) diffractometer (CuK_α radiation, λ 1.5406 Å). When the Kapton films were inelastic or

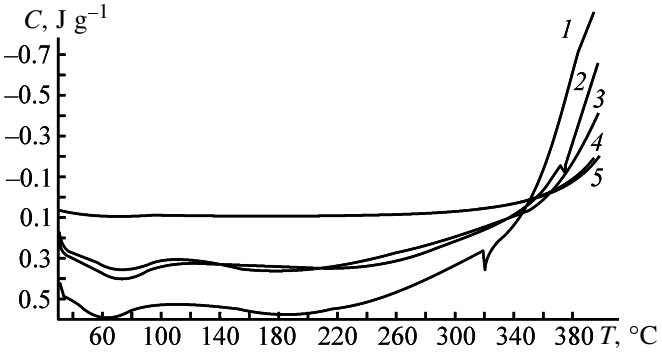


Fig. 1. Heat capacity C of PI–PET composites as a function of temperature T. PI : PET, wt % : wt %: (*1*) 85 : 15, (*2*) 95 : 5, (*3*) 98 : 2, (*4*) 99 : 1, and (*5*) pure PI.

buckled, they were glued to the support using a Ramsay paste invisible in X-ray diffraction.

The thermogravimetric (TGA) analysis and evaluation of the heat capacity of the polymers in question were performed by the procedures of thermal degradation and differential scanning calorimetry (DSC) on a Mettler Toledo TGA/SDTA 851^c and an FP85 TA Cell devices at constant heating rates of 4 and 8 deg min^{-1}, respectively.

The mechanical properties of the film samples (60×10 mm) determined out on a Com-Ten Testing Equipment tensile-testing machine (the United States).

The polymer blends based on PI and PET were prepared in *m*-cresol solutions by the reaction mixing at PET concentration varied from 1 to 20 wt %. The reaction mixing provides preparation of the polymers completely thermodynamically compatible with formation of molecularly homogeneous blends [13]. However, owing to specific smell, *m*-cresol cannot be widely used as high-temperature solvent for mechanical mixing of the initial components.

The polymeric composites based on PI and PC were prepared by mechanical mixing of the components in DMF at PC concentration varied from 0.5 to 2 wt %. Such narrow concentration range is due to relatively low solubility of PC in DMF; moreover, at PC concentration higher than 5 wt % the films become thermodynamically incompatible with PI.

The data on the polymeric compositions of PI and PET showed that the compatible films are formed at a PET concentration of 1–5 wt %; with increasing PET content to 15 wt %, the polymeric material becomes turbid, but its physicomechanical properties remain, on the whole, unchanged.

To evaluate the thermodynamic compatibility of the polymers (films), we determined the heat capacities of PI–PET and PI–PC systems and initial PI in *m*-cresol and DMF. From the temperature dependences of the heat capacities (Fig. 1), the glass transition points T_g were determined (Table 1).

The observed decrease in T_g in the PI–PET system with increasing PET content is probably due to the nature of the plasticizer, which in the presence of water released above 100–120°C in the course of cyclization of the amide groups is partially hydrolyzed with breakdown of the ester group, thus decreasing the degree of crystallinity and glass transition point of the polymer. With increasing PC content in the PI–PC composites, the glass transition point of the polymeric films increases.

This increase in the glass transition temperature T_g with increasing PC content in the PI–PC composites is probably due to the fact that these polymers are characterized by strong interchain interaction through H bonds owing to high polarity of the carbonyl groups in PC [7]. As a result, the crystal structure in the PI–PC polymers is more stable as compared to the PI–PET composites.

It is known [5] that PI is an amorphous polymer whose morphology is described as an ideal melt with irregular supramolecular structure. On transformation from hyperelastic into rigid glassy state, amorphous polymers remain in the disordered glassy state. Mutual transformations of amorphous polymers from one state into another are not phase transitions. In contrast to real phase transitions, these transformations proceed gradually and continuously within a given temperature range and only in the transition area the behavior of the polymer glasses resembles the thermodynamic transition of the second kind when an abrupt change in the thermodynamic properties is observed [13].

Temperature dependences of the heat capacity of the polymer blends given in Fig. 1 involve no breaking points, which corresponds to the thermodynamic transition of the first type, e.g., given polymers are characterized by the short-range ordering.

It should be noted that the heating rate can strongly affect T_g of the amorphous polymers [6], and this is probably typical for their blends when the content of the additive is relatively small. For example, at a heating rate of 4 deg min^{-1} no T_g is observed on the DSC curves for PI in *m*-cresol (Fig. 1), whereas at a heating rate of 8 deg min^{-1} (Fig. 2) certain jump at 114°C in the curve of the weight loss is observed, which corresponds to T_g of PI.

Also, the glass transition point is an important criterion for evaluating the compatibility of the poly-

Table 1. Physicochemical properties of the PI–PET and PI–PC composites

mer blends. If a composite is characterized by two glass transition points corresponding to the polymeric components, then this system is incompatible; and the system is compatible if it is characterized by a single glass transition point.

As seen from experimental results (Fig. 1, Table 1), the polymeric composites based on PI and containing PET (1–15 wt %) or PC (0.5–2.0 wt %) exhibit only one glass transition point, which indicates that all the polymeric films are thermodynamically compatible.

Thus, we succeeded in preparing compatible polymeric films based on PI containing the above amounts of PET and PI plasticizers; T_g of PI–PET composites is lower than that of PI–PC composites. The main parameters affecting T_g are the chain flexibility and the nature of intermolecular packing [6]. With a decrease in the chain flexibility, T_g increases owing to steric hindrance, which is typical for PI–PC systems. The observed decrease in T_g for PI–PET composites is probably due to higher degree of freedom in macromolecules causing higher mobility and flexibility of the polymer sections owing to the plasticizing affect of PET. Based on the resulting thermodynamic parameters we assumed that the composites with PET plasticizer show more promise for further modification of the film material, namely, for implantation of metal ions such as Ag^+, Cu^{2+}, Ni^{2+}, or Co^{2+} [15].

In this work we studied the structure and physicochemical properties of the film materials, because addition of partially crystalline PET and PC into the amorphous PI matrix improves the composite morphology [16] and probably enhances the strength of the polymer film.

The assumption that the packing in PI–PC composites is more rigid than in PI–PET systems is confirmed by X-ray diffraction data, namely, by the presence of PC crystallites in PI halo (Fig. 3). This fact confirms the presence of a crystalline area in the polymer, in contrast to the PI–PET films, for which the crystalline area is rather diffuse.

The presence of the PET ester group in the PI–PET polymers is confirmed by the IR spectra. As seen from Fig. 4a, with increasing content of PET from 1 to 5 wt % the intensity of the stretching vibrations of the ester group ν_{C-O} at 1000 cm^{-1} increases, and at 15 wt % content of the PET plasticizer in the polymer blend the intensity of these vibrations is close to that

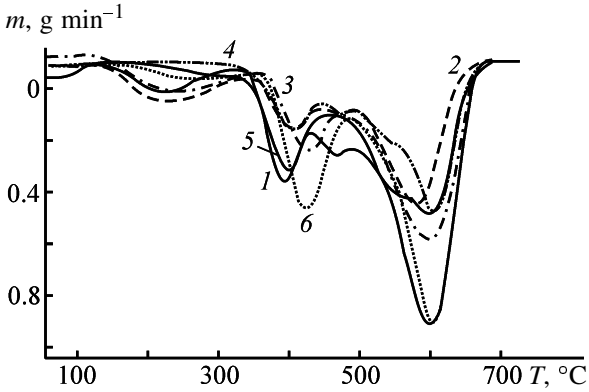

Fig. 2. DTG curves of composites based on (*1*) neat PI and PI–PET with PET content of (*2*) 2, (*3*) 5, (*4*) 10, (*5*) 15, and (*6*) 20 wt %. (*m*) Weight loss rate and (*T*) temperature.

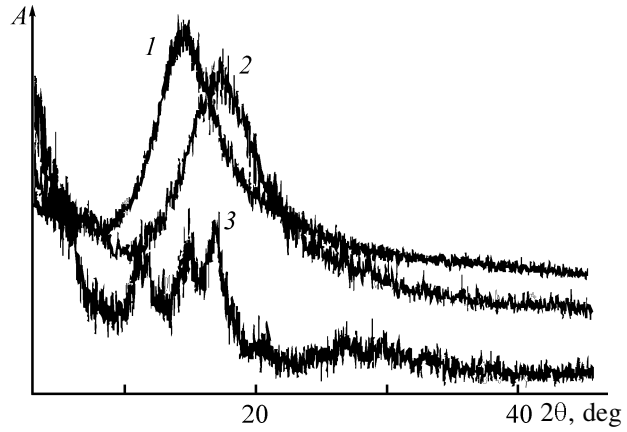

Fig. 3. Diffraction patterns of (*1*) pure PI and its composites containing (*2*) 5 wt % PET and (*3*) 1.5 wt % PC, sliding angle 2 deg. (*A*) Intensity and (2θ) Bragg scattering angle.

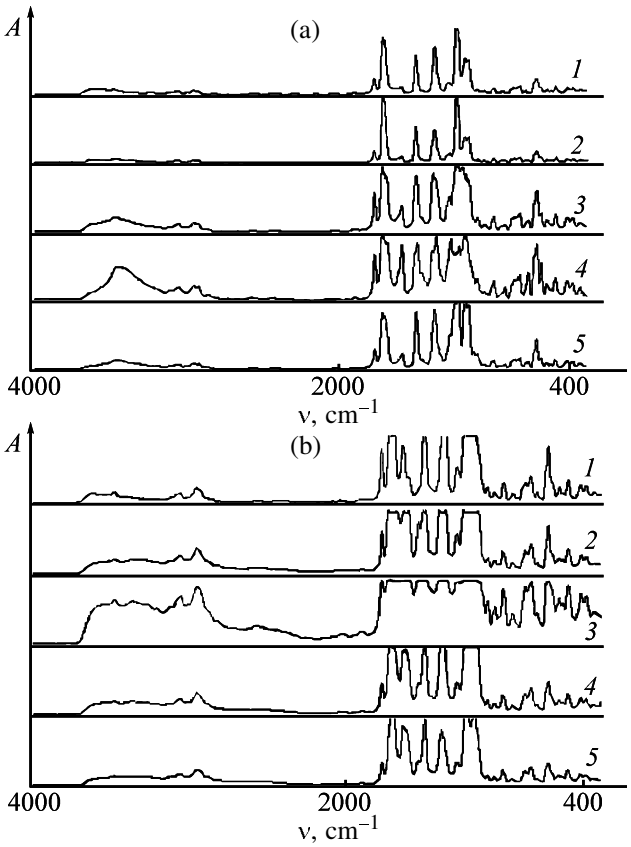

Fig. 4. IR spectra of (*1*) neat PI and (a) PI–PET composites with PET content of (*2*) 1, (*3*) 2, (*4*) 5, and (*5*) 15 wt % and (b) PI–PC with PC content of (*2*) 0.5, (*3*) 1.0, (*4*) 1.5, and (*5*) 2.0 wt %. (*A*) Adsorption and (ν) wavenumber.

in the initial PI. This is probably due to the fact that at 15 wt % content of PET the polymer blend undergoes phase segregation making the polymer film turbid; this corresponds to the second weak peak in the temperature dependence of the heat capacity of the PI–PET composite (Fig. 1). In the IR spectra of the PI–PET composite, the bands of the carbonyl group of the initial PET at 1735 cm^{-1} and of the carbonyl group of PI at 1700 cm^{-1} are shifted by 35 and 20 cm^{-1}, respectively, probably due to the formation of a hydrogen bond between the carbonyl group of PET and hydroxy group of the amido acid fragment [17] formed in the course of PI synthesis. The presence of this acid in the PI–PET systems is confirmed by thermogravimetric analysis. The content of the imide groups and amido acid fragment appearing in the polymer with addition of PET is shown in Table 2. These results correspond to the theoretical ratio of the components.

Table 2. Composition of polyimide systems

Composite	Content, wt %		Content of PET, wt %	
	imide	amido acid	gravimetry	TGA data
PI	89.8	10.2		
PI–PET, PET, %:				
1%	86.1	12.4	1.05	1.15
2%	83.8	12.0	2.1	2.25
5%	80.5	11.8	5.1	7.7
15%	74.0	10.9	15.3	14.9

The above data suggest that there are no chemical interactions in the PI–PET polymer films, which are physical blends associated through hydrogen bonds.

No chemical interactions were observed in the PI–PC composites. The characteristic band belonging to the PC carbonyl group at 1740 cm^{-1} is found in all the IR spectra of PI–PC composites with various component ratios (Fig. 4b). No shifts by more than 200 cm^{-1} were observed. Hence, PI–PC composites are also probably formed due to the hydrogen bonds. This is indirectly confirmed by the fact that after heating at temperatures higher than 50°C the film becomes turbid and brittle.

We also tested the mechanical properties of new PI–PET and PI–PC composites; the data on the tensile strength and relative elongation at constant deformation rate are listed in Table 1. As seen, the tensile strength of the PI–PET composites decreases with increasing PET content (similarly to T_g) but remains significantly higher than that of the individual PET (14–29 MPa). As for PI–PC systems, T_g and δ_t vary in the opposite directions. This is probably due to the

fact that, in contrast to PET with linear polymeric structure and more compact packing, PC contains bulky side groups, which make the polymeric films brittle. Nevertheless, addition of partially crystalline PET and PC polymers improves the strength of the polymer films; upon mixing of PI and PC, δ_t increases from 71 to 100 MPa. For PI–PET (99 : 1) composites δ_t increases from 100 to 106 MPa; at the other component ratios, when the tensile strength of the polymer films slightly decreases, their relative elongation remains fairly high (15.2–17.2%), i.e., all the PI–PET polymer films are characterized by high rupture strength and relative elongation. Since the melting points of the composite materials are 355–393°C at high reduced viscosities of the polymer solutions, these polymers can be classed with thermally stable composites with high physicochemical and mechanical properties.

Thus, polymeric films with thermally controlled and high strength properties were prepared using PI–PET and PI–PC polymer blends with various ratios of the initial components.

CONCLUSIONS

(1) The thermodynamic parameters of mixing of the film materials were determined by differential scanning calorimetry and thermogravimetry; these data show that the films based on polyimide containing polyethylene terephthalate (1.0–15.0 wt %) or polycarbonate (0.5–2.0 wt %) have a single glass transition point, i.e., the resulting polymer films are thermodynamically compatible.

(2) The absence of chemical interaction between polyimide and polyethylene terephthalate or polycarbonate was confirmed by IR spectroscopy.

(3) Addition of polyethylene terephthalate (1.0–15.0 wt %) or polycarbonate (0.5–2.0 wt %) into the polyimide matrix enhances the film strength. Their tensile strength increases from 71 to 100 and from 72 to 106 MPa for PI–PET and PI–PC systems, respectively, whereas the thermal properties of the composites (T_m 355–393°C) remain essentially unchanged.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structure and Composition of Polymer–Bitumen Composites

A. A. Gorbatovskii, D. A. Rozental', and S. V. Dronov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received January 25, 2007

Abstract—Features of the composition and structure of polymer–bitumen composites are examined, including the effects of the amount and quality of the basic components on the characteristics of the final product. The effect of butadiene–styrene thermoplastic elastomer on the properties of the cold applied polymer–bitumen mastic is considered. Typical component mixing schemes are analyzed, and a flowsheet for production of polymer–bitumen mastic is presented.

DOI: 10.1134/S107042720705028X

Polymer–bitumen composites are widely used in production of mastics for various purposes and advanced paving mixes, and in repair of critical sections of highways and airfield paving. Presently, there are a lot of patents on the composition of such materials. However, no general theory substantiating the processes for their production is developed yet, since there is no common view of the behavior of bitumen and polymers in preparation of composites.

It is a common view that heavy oil residues including bitumens are colloid systems: the dispersion medium is represented by oils and resins (so-called malthenes), and the dispersed phase, by solid lamellar-block asphaltene particles. According to the modern views, molecules of practically all components of petroleum bitumens are built on the same principle. Molecules of both hydrocarbons and their hetero derivatives are hybrid compounds with a polycyclic core containing 4–6 rings, mostly six-membered. This polycyclic system may have several methyl and one long-chain (C_3–C_{12}) alkyl substituents. The cyclic part of the molecule may include sulfur- or nitrogen-containing rings, the oxygen-containing functional groups being arranged mostly at the periphery of the molecule [1, 2].

The feature of the structure of asphaltene molecules is that they have three aromatic or heteroaromatic rings. This ensures the practically planar structure of asphaltene molecules; as a result of interaction of π-electron clouds with polar groups, they build associates in the form of stacks of parallel planar molecules. Therefore, asphaltenes of bitumen occur as extremely fine solid particles (1.2–2.5 nm) surrounded by solvate shells, which are spread among oil and resin molecules [2, 3].

The structure of a colloid system controls its characteristics. Therefore, the properties of bitumens are controlled by the concentration of asphaltenes (dispersed phase), component composition of malthenes (dispersion medium), and degree of their aromaticity. This is clearly demonstrated by the dependence of the softening point on the composition of bitumen: the softening point increases with increasing asphaltene concentration.

Depending on the asphaltene content, bitumens form sols, sol–gel structures, and gel-like structures (at the maximal asphaltene content). Different energy is required to destroy these structures. This energy is indirectly characterized by the softening point, which is higher for bitumens having a gel structure. In all the indicated structures, asphaltene particles are surrounded by solvate shells, preventing their adhesion. The higher the asphaltene concentration, the smaller is the dispersion medium space between the particles. At a certain asphaltene content, their solvate shells are brought in contact with each other to form clusters, which, in turn, are surrounded by a solvate shell of the molecules of the dispersion medium. Further increase in the asphaltene content results in adhesion of the clusters with formation of a rigid framework in bitumen (bitumens of structural and some special grades). However, in this case, when practically the entire dispersion medium is converted into a solvation shell, asphaltenes do not form an individual phase. Therefore, it is asphaltenes that most significantly affect the strength and softening point of bitumen [4].

Effects of the composition of bitumen on its brittle point and penetration are more complex, since these parameters depend primarily on the characteristics of the dispersion medium, like such parameters as plasticity, frost resistance, cohesion, viscosity, tendency to exudation, and many others.

To make commercial bitumen suitable for use as a structural material, its properties are modified by adding various polymers (so-called bitumen modifiers). The resulting composites are characterized by a wide plastic temperature range (high softening point and, at the same time, high plasticity at low temperatures). The use of bitumen modifiers also improves the plasticity of the material as well as its capability to withstand periodic stress without damage. The latter properties can be characterized in part by such parameters as the relative and residual elongation.

Thus, upon addition of only 4 wt % of styrene–butadiene–styrene (SBS) thermoplastic elastomer Kraton (Kraton Polymers Co.), the ring-and-ball softening point [GOST (State Standard) 11 506–73] of BND 60/90 viscous paving bitumen increased from 52 to 75°C, and the relative elongation (GOST 2678–87), from 94 to 400%.

As an illustration for the effect of bitumen modifiers on the properties of the composites we may present the results of testing obtained for cold applied mastics with various Kraton polymer contents (see table and Figs. 1–3). Cold applied mastics are distinguished in the lack of the need in warming prior to use, which is attained by adding a special solvent, making it possible to use the viscous-flow composite at relatively low temperatures.

Note that as bitumen modifiers there were tested practically all existing polymers, but the spectrum of applicable polymers appears to be rather limited.

To improve the elastic characteristic of bitumens, styrene–butadiene–styrene (SBS) thermoplastic elastomers are used. Butadiene–styrene rubbers are prepared by bulk polymerization of styrene and butadiene; they are block copolymers with spatial nodes and linear chains with the polybutadiene phase in the center and polystyrene phase at the ends [4]. Addition of the polymer into bitumen alters the structure of the latter, but not its dispersion medium. It is a common view that polymer–bitumen composites are physical blends, although at high temperatures their components can form a small amount of chemical bonds, which has no significant effect on properties of the composite.

It is advisable to consider the polymer–bitumen composites as three-component systems containing a solvent (malthenes) in which more rigid particles of bitumen and polymer are spread. The polymer dissolved in bitumen mostly thickens the dispersion medium, thus increasing the softening point of bitumen. Furthermore, the solutions generally have a lower freezing point than the solvent, thus decreasing the brittle point [4].

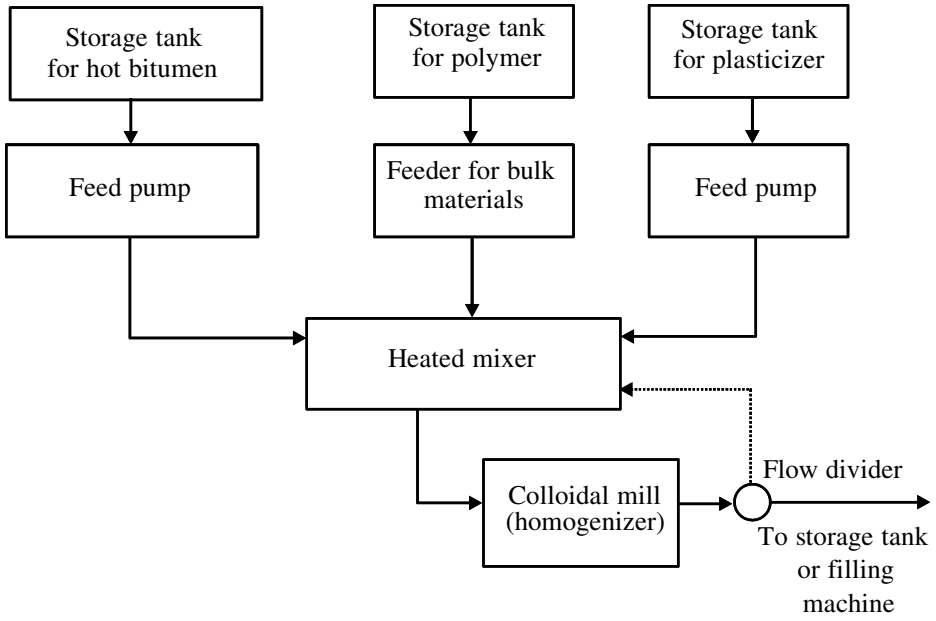
Scheme 1. Flowsheet for production of polymer–bitumen composites.



Depending on the concentration, the polymer first affects the dispersion medium and, through it, bitumen as a whole; then, at higher concentration, the polymer forms a new (the third) phase in the system, becoming a filler for bitumen. At high polymer concentrations, inversion of the phases takes place, and the polymer turns from filler into a material to be filled, and bitumen turns into filler. The phase inversion follows the coexistence state of the two continuous phases of the polymer and bitumen (in this state, the polymer fibers penetrates throughout bitumen, thus reinforcing it).

Since the polymer is dissolved just in the malthene fraction of bitumen, the relative content of this fraction should be taken into account: at an insufficient content of oils in bitumen, the modifier can locally coagulate, thus deteriorating the performance characteristics of the composite. To avoid this, bitumen is additionally modified with so-called plasticizers, which eliminate the shortcomings of the dispersion medium. The decision on the plasticizer should be made taking into account their nature, compatibility with other bitumen components, and the ability to dissolve the polymer. The plasticizer should be aromatic; otherwise, exudation of some of its components from the body of the composite will occur, like that in the case of using machinery oil.

In producing polymer–bitumen composites, of a great importance is to optimize a flow chart (Scheme 1). In the use of three basic components, bitumen, oil, and polymer, the following versions of the process are feasible in principle.

(1) Introduction of the polymer into temperature-stabilized oil, followed by mixing of the resulting mass with heated bitumen. This operation can be performed at 150–160°C, which is below the melting point of the polymer (190–200°C). In this version, it takes shorter time to complete mixing of the polymer with a softener and then with bitumen.

(2) Premixing of heated oil and bitumen, followed by addition of the modifier. Generally, this version is distinguished by longer time of mixing required to attain complete dissolution of the polymer, but it would be the best choice under certain circumstances.

In addition to the above-indicated components, polymer–bitumen composites may include diverse additives for various purposes, e.g., to improve the adhesion, to stabilize the dispersion system, to inhibit oxidation processes, etc. Generally, such additives are quite efficient, but their use considerably increases the cost of the products.

By now, some problems remain to be understood in the area of bitumen composites modified with polymers, including those concerning interaction of the components, aging of the composites, and some properties of bitumen itself.

Nevertheless, polymer–bitumen composites stand well among diverse construction materials, the field of their application being steadily expanding.

CONCLUSIONS

(1) Characteristics of bitumens and, therefore, polymer–bitumen composites depend primarily on the relative content of asphaltenes, which, along with the polymer additive, exert a structuring effect on bitumen.

(2) There is a well-defined limit of the modifier content in the composite, beyond which the performance characteristics of the product deteriorate as a result of phase inversion, when the polymer, initially acting as filler, becomes a material to be filled, and bitumen turns into filler.

(3) In formulation of the polymer–bitumen composite, a special attention should be paid to the nature of a plasticizer and its compatibility with bitumen and polymer additive.

CHEMISTRY OF FOSSIL FUEL

Synthesis and Characterization of Biodiesel Fuel Based of Esters of Tall Oil Fatty Acids

A. V. Kurzin, A. N. Evdokimov, O. S. Pavlova, and V. B. Antipina

Abstract—Synthesis of esters from tall oil fatty acids and lower aliphatic alcohols is studied, and characteristics of the products as substitutes or components of diesel fuel are determined.

DOI: 10.1134/S1070427207050291

Biofuel is a renewable environmentally friendly power source, which could compete with fossil fuel. Liquid biofuel is used in spark-ignition engines (ethanol and methanol) and in diesel engines (vegetable oils and their methyl esters as well as their mixtures and mixtures with conventional diesel fuel). Biodiesel is synthesized from renewable resources by ester interchange of fats and oils with lower aliphatic alcohols using acid, base, or enzymatic catalysis [1–3]. The sources of fatty acids can be vegetable oils, animal oils, and by-products and wastes from production of edible fats and oils [1–6].

Currently, the common view is that the most promising biodiesel, whose characteristics are close to those of hydrocarbon fuel, is a mixture of methyl esters of colza oil fatty acids (COFAs). It is known that even a small addition of biodiesel to the conventional fuel reduces exhaust [1, 2].

Biodiesel produced using the traditional processes has a higher cost (by 10–20%), requiring consumption of common kinds of energy, which pollute the environment. The viscosity of COFA-based biodiesel is twice that of the conventional diesel fuel, resulting in incomplete combustion of fuel aerosols. Another limitation of using oils and their derivatives is high oxygen content (8–10%), causing a decrease in the low heat value of this fuel as compared to hydrocarbon fuel and, correspondingly, an increase in the biodiesel consumption.

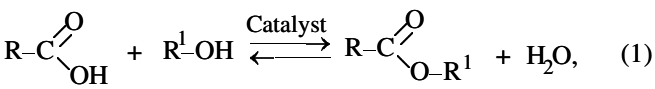
Despite the indicated drawbacks, the biodiesel output steadily increases. Investigators are improving the processes for its production and searching for new raw materials including esters having higher caloric value.

Among the available sources of fatty acids is tall oil, a by-product of craft pulp production. In vacuum distillation of crude tall oil (its yield amounts to 60 kg per ton of bone-dry cellulose), along with other components, fatty acids (TOFAs) constituting 30–60% of tall oil, depending on the kind of wood to be processed, are separated [7]. The fatty-acid composition of tall oil resembles that of vegetable oils, being represented primarily by unsaturated acids C_{16}–C_{18} (oleic, linoleic, linolenic, etc.) [8].

Presently, the conventional application fields of TPFAs are being reduced. Among the ways to their chemical modification is esterification. In their characteristics the resulting esters are well comparable with petroleum gas oil, so that they can be used, like COFAs, as individual fuel or depressor additive to black oil, to improve its performance characteristics [9, 10]. It should be pointed out that tall oil and distilled tall oil was suggested to be used as an additive to low-sulfur fuel for diesel engines [11].

In this study we examined esterification of TPFAs with lower aliphatic alcohols (methanol, ethanol, and isopropanol) in the presence of various catalysts, and also properties of the resulting esters characterizing them as biodiesel.

As known, the reaction can be catalyzed by mineral acids, sulfonic acids, Lewis acids, or solid acid catalysts, among them ion-exchange resins in the H form [3, 12–14]:



where R is the hydrocarbon radical of TOFA and R^1 = Me, Et, *i*-Pr.

Table 1. Influence of the catalyst concentration on the yield of alkyl esters of TOFAs (alcohol : TOFAs = 3 : 1, reaction time 3 h)

TOFA ester	Catalyst	Ester yield, %, at indicated catalyst concentration, wt %			
		0.5	1.0	2.0	4.0
Methyl	Sulfuric acid	54.4	63.6	68.9	70.1
	p-Toluenesulfonic acid	62.8	67.3	83.0	85.5
	Zinc(II) chloride	12.0	17.1	23.2	24.5
	Amberlyst-15	57.0	65.2	75.0	76.0
Ethyl	Sulfuric acid	56.7	64.0	69.2	71.8
	p-Toluenesulfonic acid	64.7	69.2	80.4	83.2
	Zinc(II) chloride	13.2	18.6	24.5	26.3
	Amberlyst-15	60.5	67.2	74.0	75.1
Isopropyl	Sulfuric acid	52.1	57.4	64.7	65.2
	p-Toluenesulfonic acid	62.8	68.6	79.8	81.0
	Zinc(II) chloride	11.9	17.5	22.9	24.1
	Amberlyst-15	58.0	63.8	73.8	74.1

As catalysts we used sulfuric acid, *p*-toluenesulfonic acid, $ZnCl_2$, and Amberlyst-15 ion-exchange resin.

Table 1 shows how the catalyst nature and concentration and also the alcohol structure influence the ester yield. Practically, the decision on the catalyst is made taking into account such parameters as the product yield, catalyst availability and practicability, and regenerability. The catalysts in hand are widely used on commercial scale, being, therefore, available. For reasons of economy, sulfuric acid is most widely used, even though it does not provide the maximal yield. We obtained the best results with *p*-toluenesulfonic acid (2 wt %) and Amberlyst-15. In the case of *p*-toluenesulfonic acid, increase in the catalyst concentration from 1.0 to 2.0 wt % increased the ester yield to 85.5%. Further increase in the catalyst concentration did not increase the conversion. Additionally, the indicated catalysts do not cause dehydration of alcohols and sulfonation of double bonds in fatty acids. At the same time, the catalyst based on an ion-exchange resin is more practicable and regenerable.

Therefore, it is insufficient to only optimize the catalyst to ensure the maximal ester yield. Another way is to remove one of the products from the reaction zone. Performing the reaction with simultaneous azeotropic distillation of water with benzene allowed increase of the product yield by 6%. However, in this case, the hardware implementation of the process becomes more complex.

To increase the yield, we developed a system in which methanol vapor passes through a heated catalyst unit, where it reacts with fatty acids, and the resulting esters stream down to a receiver. The use of this system increased the conversion of TOFAs by 10%.

The composition of the esters, determined by GLC, resembles that of the initial acids, suggesting that their reactivity is similar under the esterification conditions.

In Table 2, a comparison is made of the properties of the esters obtained and commercial diesel fuel (Diesel Motor Fuel Euro, Lukoil). The kinematic viscosity of the TOFA esters is no more than 4.6×10^{-6} $m^2 s^{-1}$, which is lower than the maximal value of 5.0×10^{-6} $m^2 s^{-1}$ fixed in European EN 14214 Standard. On passing from the methyl ester to isopropyl ester, the refractive index increases, and the pour point decreases. The iodine number, acid number, saponification number, sulfur content, flash point (closed cup), cloud point, and filtration termination temperature for the TOFA esters obtained are close to each other. In these parameters (except for sulfur content) the esters meet the requirements of EN 14214 standard.

As known [15], biodiesel additive based on methyl esters of vegetable oils increases the lubricity. We studied the lubricity of the TOFA methyl esters (HFR2, PCS Instruments). The results showed that the wear scar diameter (WSD) decreases from 374 μm for the hydrocarbon fuel to up to 330 μm for diesel fuel containing 10% TOFA esters, which can be attributed to increasing stability of the film on the metal surface.

EXPERIMENTAL

The IR spectra of the esters were recorded in a thin film on an IKS-29 instrument. The final product was characterized by GLC [Chrom-5 chromato-

graph, flame-ionization detector, column 50 m × 0.22 mm (stationary phase BP×70), carrier gas helium (30 $ml\ min^{-1}$)]; solvent hexane.

Characteristics of the final product such as density, refractive index, acid number, saponification number, iodine number, ester content, sulfur content, closed-crucible flash point, flow point, cloud point, lower filtration temperature, and lubricity number were determined by the standard procedures. TOFAs from Segezha Pulp and Paper Combine (FA content 96.5%) were used as received. Alcohols (methanol, ethanol, and 2-propanol) and catalysts [sulfuric acid, *p*-toluenesulfonic acid, zinc(II) chloride, and Amberlyst-15 cation-exchange resin (Rohm & Haas)] were of chemically pure grade. Methyl esters of individual FAs (analytically pure grade) were purchased from Merck, Sigma, Aldrich, and Fluka. All the chemicals were used without additional purification.

In all the experiments, the reaction time was 3 h and the alcohol to TOFAs molar ratio was 3 : 1. The catalysts were added in amount from 0.5 to 4.0 wt % relative to the total weight of reactants.

Alkyl esters of TOFAs were synthesized by refluxing the acids with a threefold excess of an alcohol in the presence of various amounts of catalyst [16, 17].

The esterification was carried out in a 500-ml flask equipped with a reflux condenser and a mechanical stirrer. The flask was charged with 200 g of TOFAs and appropriate amounts of an alcohol and a catalyst. The mixture was vigorously stirred and heated to the boiling point of the alcohol (70, 80, or 85°C). At fixed intervals, a 2-ml portion of the reaction mixture was taken for IR analysis. The amounts of esters formed was determined by the intensity of the absorption band at 1165–1185 cm^{-1}. Additionally, the conversion of TOFAs was characterized by the acid number determined by the standard procedure. After completion of the experiment, the reaction mixture was analyzed for esters by GLC. The mixture was transferred into a separating funnel and washed three

times with 5% $NaHCO_3$ and then with distilled water to pH 7 of the wash water. The resulting esters were dried over $MgSO_4$. Then esters were separated from the unchanged acids by vacuum distillation. The ester content in the resulting product was determined by the IR spectra and GLC analysis. The ester yield was from 12.0 to 85.5%.

The product, TOFA esters, was obtained as a yellowish liquid soluble in nonpolar organic solvents and poorly soluble in water.

CONCLUSIONS

(1) Methyl, ethyl, and isopropyl esters of tall oil fatty acids were synthesized using various acid catalysts. The highest ester yield was obtained with *p*-toluenesulfonic acid.

(2) A specially designed reactor was developed to increase the yield of the methyl esters.

(3) Esters of tall oil fatty acids can be used as a substitute for, or an additive to hydrocarbon diesel fuel.

CHEMISTRY OF FOSSIL FUEL

Effect of Ozonation on the Composition of Crude Coal-Tar Benzene

Abstract—The effect of ozonation on the composition of crude benzene produced by the coal-tar chemical industry was studied.

DOI: 10.1134/S1070427207050308

One of the most urgent problems of coal-tar chemical industry is improvement of crude benzene quality. The main impurities deteriorating characteristics of crude benzene are sulfur-containing, unsaturated, and saturated hydrocarbons. At present, among procedures of benzene purification are conventional sulfuric acid treatment and also fairly expensive catalytic hydrofining [1]. The latter combines in one process hydrogenolysis of sulfur-contaning compounds and hydrogenation of unsaturated hydrocarbons, which allows production of the pure product, an important raw material for synthesis of organic compounds [2].

Difficulties in utilization of wastes formed in sulfuric acid purification and high capital and operation costs of hydrofining processing [3] require development of simple and environmentally safe procedures of purification of crude benzene.

Along with conventional procedures, oxidation (e.g., with hydrogen peroxide) [4], ultrasonic treatment [3], and biotechnologies [6] are also used for purification of oil fractions for which the main detrimental impurities are unsaturated and sulfur-containing compounds.

Ozonation [7, 8] is suggested as one of oxidation procedures of purification of diesel fractions. The feature of ozone is its selective electrophilic addition to both sulfur-containing and unsaturated compounds and polycyclic arenes [9]. Unique chemical activity of ozone allows the reactions to be efficiently performed at moderate temperatures without catalysts.

Considering similar composition of undesirable target products of oil refining and coal-tar chemical industries, ozonation can be one of the feasible procedures of purification of crude coal-tar benzene. In this connection, our study was aimed to determine how ozonolysis affects the composition of crude coal-tar benzene.

EXPERIMENTAL

Crude benzene produced by coal-tar shop at the Novokuznetsk Metallurgic Plant was used as a subject of the study. The characteristics of the initial product are presented in Table 1.

Ozonation was performed at 25°C and atmospheric pressure in a bubbling-type reactor with uninterrupted feeding of ozone–oxygen mixture (1.5 vol % ozone). After the process completion, tar products accumulated at the reactor walls and dissolved in benzene were extracted with 5% KOH. Then, the product purified to remove tar was treated with 50% H_2SO_4 in

Table 1. Characteristics of crude benzene

Index	Characteristic
External appearance	Transparent yellow-orange liquid without suspended particles
Density, g cm^{-3}	0.87
Temperature, at which 97% of the product is distilled, °C	Not higher than 140
Content, wt %:	
benzene	32.3
toluene	37.1
xylene	13.5
carbon disulfide	0.24
Acidity, mg g^{-1}	1.10
Bromine number, %	5.66

the 2 : 1 ratio to remove sulfones and sulfoxides. The samples treated with acid were decanted in a separating funnel and washed with distilled water to neutral reaction.

Alkali-soluble ozonation products were acidified with dilute sulfuric acid. The precipitate containing macromolecular acids (MMAs) was separated on a filter. Low-molecular-weight products were recovered from acidic aqueous solution by extraction with methyl ethyl ketone. The products were dried, and their yield was determined.

The acid number was determined by the reaction of crude benzene with KOH, and the bromine number, by iodometric titration [10]. The elemental analysis of the products was performed by the procedure described in [11]. Chromatographic mass-spectrometric analysis was performed on a Hewlett–Packard device comprised of an HP-5890 gas chromatograph (series II) and an HP-5971 mass-selective detector. Capillary column HP-5MS (5% diphenyl-, 95% dimethylsiloxane) 30 m × 0.25 mm × 0.26 μm. Carrier gas helium, flow rate 1 ml min^{-1}. Heating mode of the column: 2 min at 50°C, from 50 to 300°C at a rate of 10 deg min^{-1}, 30 min at 300°C. The vaporizer temperature was 280°C; temperature of ion source, 175°C. The scanning rate in the range 30–650 amu was 1.2 scan s^{-1}. The IR spectra were recorded on a System-2000 Perkin–Elmer Fourier spectrometer.

Ozonation of crude benzene is accompanied by variation of its total acidity (Fig. 1). The cause of its decrease at the beginning of ozonation can be oxidation of phenolic impurities in the product. An increase in the ozonation duration over 1 h promotes intense formation of oxygen-containing products, which results in increasing acid number of crude benzene. It is likely that, after treatment with ozone for 2 h, the resulting products are subjected to secondary oxidation and the product acidity decreases again. In this case, the product color changes from the initial yellow to bright orange. After base hydrolysis, the acidity of crude benzene decreases from 1.1 to 0.2 mg g^{-1} (Fig. 1a).

The content of unsaturated and sulfur-containing compounds in the product decreases after its ozonation. For example, the bromine number of crude benzene decreased by 60% (Fig. 1b), and the content of carbon disulfide, the main component of sulfur-containing impurities in benzene [1], by 80% (Fig. 2). The effect of treatment corresponds to ozonation for 2 h. Then, the process decelerates due to saturation of crude benzene with oxidation products.

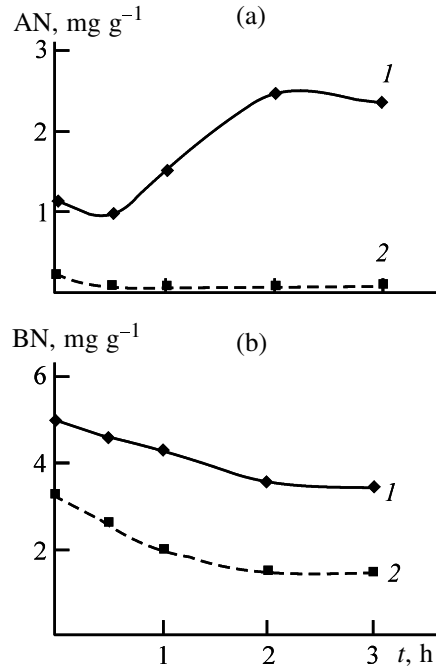

Fig. 1. (a) Acid number AN and (b) bromine number BN of crude benzene (*1*) before and (*2*) after purification, as functions of ozonation time *t*.

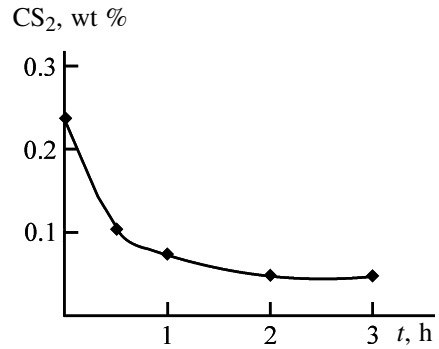

Fig. 2. Content of carbon sulfide CS_2 in crude benzene as a function of ozonation time *t*.

In the initial crude benzene, 46 individual compounds were identified by the chromatography–mass spectroscopy with a probability of identification higher than 90% (Table 2). Among these compounds, for approximately 60% substances the content of each component was more than 0.1 wt %. The content of main components of the product, benzene, toluene, and xylenes, is approximately 83% of the total compounds accessible for chromatographic analysis. The other aromatic hydrocarbons (approximately 1%) include ethyl- and trimethylbenzenes. The content of unsaturated hydrocarbons (linear and cyclic alkenes and alkadienes) is approximately 11.5%. It is likely that the presence of some low-boiling compounds

(1,3-butadiene with bp –4.5°C, 1-pentene with bp 30°C, etc.), present in crude benzene in trace amounts (less than 0.05 wt %), is caused by their solubility in the mixture of higher-boiling components. Linear, cyclic, and structural isomers of paraffins are contained in insignificant amounts (approximately 1.7%). Nitrogen-, sulfur-, and oxygen-containing compounds together account for approximately 2.6%.

It should be noted that successive treatment of crude benzene with alkali and sulfuric acid solutions is favorable to removal of nitrogen-containing compounds, acetonitrile and pyridine, from the product (Table 2). This operation does not significantly affect the content of other substances.

As a result of ozonation, the ratio of individual compounds in the crude product changes. Treatment with ozone exerts the most noticeable influence on the content of unsaturated compounds (Table 2), which is in good agreement with the results of determination of the bromine number (Fig. 2). Their fraction in the initial product decreased to 6.8%. To a greater extent this concerns dienes of linear (butadiene) and cyclic (cyclobutadiene, cyclopentadiene) structures, and to a lesser extent, compounds containing one double bond (pentene, cyclohexene, etc.). Among sulfur-containing components, unsaturated thiophene reacts with ozone more actively than do its methyl derivatives. It is likely that the presence of alkyl substituents poses steric hindrance to ozone molecules, which leads to a decrease in the reaction rate. Paraffin (hexane, heptane, nonane) and naphthene (cyclohexane) hydrocarbons and their isomers are not noticeably involved in the reaction because of low rate constants (k = 0.02–0.03 $1\,ml^{-1}\,s^{-1}$) [9]. It is likely that the increase in the fraction of neutral oxygen-containing compounds not extracted with alkali (formaldehyde, benzaldehyde) is a result of ozonolytic rupture of the C=C bonds in unsaturated hydrocarbons [9]. Removal of by-products from crude benzene results in a relative increase in the content of the main components: benzene, toluene, and xylene.

The results of extraction of oxygen-containing products of ozonolysis of crude benzene are presented in Fig. 3. The most active formation of the extractable products corresponds to ozonation for 2 h. In the extract composition, low-molecular-weight compounds (LMC) soluble in acidic medium predominate. With increasing process duration, the fraction of macromolecular insoluble substances (MMS) increases (Fig. 3).

The fraction of LMC is characterized by higher content of oxygen and higher O/C ratio (Table 3). The fraction of MMS is characterized by increased carbon content and decreased H/C ratio, which suggests prevalence of insoluble oxygen-containing products of aromatic structure.

With increasing ozonation time, the O/C ratio in LMC composition decreases and the amount of acidic groups increases (Table 3). A high content of oxygen

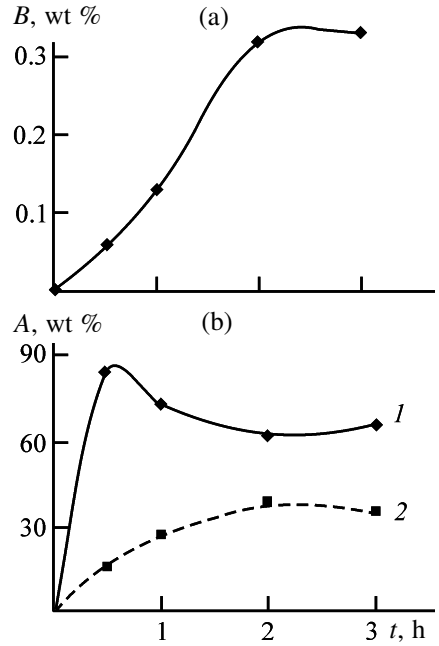

Fig. 3. (a) Yield of extract B and (b) fraction of (*1*) LMC and (*2*) MMS as functions of duration of ozonation of crude benzene t.

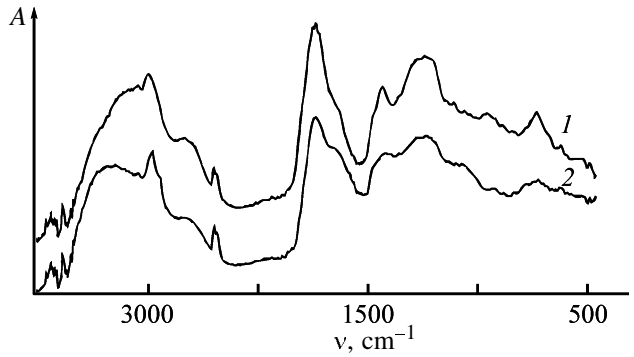

Fig. 4. IR spectra of (*1*) LMC and (*2*) MMS. (*A*) Absorption and (ν) wavenumber.

in soluble products in the initial stage of ozonation can be caused by primary oxidation of diene hydrocarbons with ozone with formation of low-molecular-weight acids and aldehydes as a result of degradation of C=C bonds. It is likely that subsequent increase in the content of carbon and hydrogen in LMC is caused by formation of compounds with longer or branched alkyl chain in the course of ozonation. This is possible due to the reaction of ozone with hydrocarbons of linear and cyclic structure containing one double bond (e.g., 1-pentene, cyclohexene) and also hydrocarbons having bulky substituents at the C=C bond (e.g., 2-methylbicyclo[2.2.1]hept-2-ene).

In the IR spectrum of extracted products (Fig. 4), the strongest absorption bands are those of oxygen-containing groups: for example, in the range 3100–3500 cm^{-1}, the bands corresponding to the OH groups of alcohols and carboxylic acids, involved in formation of hydrogen bonds; in the range 2500–2800 cm^{-1}, the bands corresponding to stretching modes of OH groups of acid dimers bonded with stronger intramolecular hydrogen bonds. The absorption bands in the range 1610–1780 cm^{-1} correspond to the –C=O groups of aromatic and aliphatic acids, aldehydes, and ketones. In the range 1100–1300 cm^{-1}, a broad band with a maximum at 1260 cm^{-1} characterizes in-plane bending vibrations of OH groups and stretching vibrations of the C–O groups of alcohols and acids.

In the spectrum of LMC, the strongest are the bands of oxygen-containing OH– (3400, 2500–2800 cm^{-1}), C=O– (1610–1780 cm^{-1}), and C–O (1100–1300 cm^{-1}) groups and also aliphatic CH_3 groups (2920 and 1380 cm^{-1}). On the contrary, MMS components are characterized by a wide variety of aliphatic bonds (CH_3 at 2920 and 1380 cm^{-1} and CH_2 group at 2920, 2850, and 1460 cm^{-1}) and the presence of aromatic structures (C=C– at 1600 cm^{-1} and CH_{ar} group in the range 690–870 cm^{-1}). These data suggest prevalence of low-molecular-weight saturated mono- and dicarboxylic acids in low-molecular-weight products and more complicated composition of macromolecular substances containing aromatic nuclei with a high degree of substitution.

CONCLUSIONS

(1) Crude coal-tar benzene can be purified by ozonation to remove unsaturated and sulfur-containing hydrocarbons.

(2) In the composition of extractable oxygen-containing substances, low-molecular-weight products prevail. These products can serve as the raw materials for synthesis of individual chemical compounds.

BOOK REVIEWS

Turaev, N.S. and Zherin, I.I., *Khimiya i tekhnologiya urana* (Chemistry and Technology of Uranium)

Moscow: Ruda i Metally, 2006, 396 pp.

DOI: 10.1134/S107042720705031X

The book is based on the course of lectures on chemistry of radioactive elements and technology of uranium, delivered to students of Tomsk Polytechnic University (TPU), supplemented with materials from domestic and foreign monographs, periodic literature, and works of staff members of the chair of chemical technology of rare, scattered, and radioactive elements at TPU. All this makes it possible to regard the book as an extended and in-depth textbook for study of chemistry and technology of uranium.

The book comprises an introduction, twelve chapters, and bibliographic list. The introduction (pp. 3–11) briefly presents historical evidence about studies of uranium and other radioactive elements and development on nuclear power engineering in various countries. Chapter 1 (pp. 12–37) presents a general characterization of the physicochemical properties of uranium and its main compounds: hydride, oxides, fluorides, and a number of other compounds of uranium in various oxidation states. The very small Chapter 2 (pp. 38–40) gives a general scheme of uranium ore processing from mining to production of metallic uranium. Chapter 3 (pp. 41–56) considers formation of uranium deposits, most important uranium-containing minerals, and main uranium ore deposits. It is noted, in particular, that about 19% of reliably surveyed resources is concentrated in Kazakhstan, with 70% of the uranium ore resources suitable for underground leaching.

Chapter 4 (pp. 57–105) summarizes evidence about mechanical treatment of uranium ore raw materials, methods for dressing of uranium ores, and their high-temperature treatment (oxidative calcination, sulfatizing calcination, chlorination of ore concentrates, and sintering with sodium chloride). Chapter 5 (pp. 106–168) is devoted to leaching of uranium ores with acid or carbonate solutions. Together with the conventional technology of leaching of ores, processes of heap, underground, and well-underground leaching are considered. Chapter 6 (pp. 169–184) discusses processes of separation of the solid and liquid phases (thickening, filtration) as applied to processing of uranium ores. Chapter 7 (pp. 185–308) presents in ample detail methods for uranium recovery from solutions: chemical precipitation, ion-exchange processes, extraction.

In Chapter 8 (pp. 309–326), the authors substantiate the limiting content of various groups of impurities in uranium compounds used in nuclear technologies. To the most dangerous impurities having the largest cross sections of thermal neutron capture are attributed boron, cadmium, and lanthanides of the yttrium group. Various methods for refining of uranium compounds are discussed. Chapter 9 (pp. 328–346) contains evidence concerning production of uranium trioxide from various compounds of uranium. Also described are reduction of higher uranium oxides with hydrogen, thermodynamics and kinetics of the processes, and the apparatus used.

One of the most important intermediate products in uranium industry is uranium tetrafluoride UF_4, used to manufacture both metallic uranium and uranium hexafluoride UF_6. Synthesis of UF_4 by reaction of uranium dioxide with hydrogen fluoride is considered in detail in Chapter 10 (pp. 347–365). Chapter 11 (pp. 366–376) is devoted to the theory and technology of manufacture of uranium hexafluoride UF_6. The final Chapter 12 (pp. 377–389) briefly considers methods for manufacture of metallic uranium: electrolysis of chloride–fluoride melts, reduction of uranium oxides with calcium, and reduction of uranium tetrafluoride with magnesium or calcium. Also described is refining melting of raw uranium ingots in vacuum induction furnaces. The bibliographic list contains references to 75 nearly exclusively Russian publications.

The entire technology for processing of uranium-containing raw materials, beginning from ore mining to production of most important uranium compounds and pure metal, has probably been for the first time described in so ample detail and so thoroughly in the domestic literature. A major advantage of the book

is, in our opinion, presentation of examples of some technologies used not only in Australia or Canada, but on the territory of CIS countries as well. Having unquestionable advantages, the book is not devoid of certain shortcomings, which could be eliminated in a close scientific editing. It seems that it was not too successful idea to make a rather detailed presentation of physicochemical issues, to which belong thermodynamics of leaching processes, theoretical foundations of extraction, and thermodynamics of reduction processes.

Long ago, it was a professor of TPU, A.G. Stromberg (1910–2004), who wrote (together with D.P. Semchenko) one of the best domestic textbooks on physical chemistry for students of chemical higher school institutions. Since the time when it was written (1973), the textbook ran into five editions (4th in 2001 and 5th in 2003). The authors of the, on the whole, technological book about uranium should have kept in mind this textbook and followed its terminology and representation of thermodynamic characteristics of processes and reactions under consideration. It is impossible to discuss details of presentation in this brief review of N.S. Turaev and I.I. Zherin's book. We note only that, widely using the terms "activity" and "activity coefficient," the authors never mention that some standard state is to be chosen. The form in which heat effects are written for reactions (12.1)–(12.4) is unacceptable. The aggregative state of the substances involved should be specified for reactions occurring at high temperatures. It is necessary to use the same terminology for thermodynamic functions throughout the text.

The book by Turaev and Zherin is provided with a large number of illustrations. However, the plentiful of details of secondary importance complicates understanding of the operation principles of apparatus. If the book is primarily regarded as a textbook, it seems that schematic representation of apparatus (e.g., Figs. 4.20, 4.25) would be more appropriate than their detailed circuits (Figs. 4.5, 4.6). As regards the polygraphic quality of the book, it is very well published.

Abstract—Effect of mechanochemical activation of mono- and mid-fraction of phosphorites from the Burenkhan deposit was studied by IR and ESR spectroscopies in vibration and planetary mills.

DOI: 10.1134/S1070427207060018

Phosphate raw materials occupy one of the first places among the plentiful mineral resources of Mongolia and are the most important for manufacture of fertilizers [1]. The Burenkhan deposit contains medium-quality ores of a carbonate-siliceous composition: 60–70% apatite minerals, 20% SiO_2, 13.01% $CaCO_3$, and 6.51% $MgCO_3$ [2].

A promising area in decomposition of mineral raw materials is their mechanochemical activation [3, 4]. This way of processing of phosphate ores is ecologically safe and allows use of phosphate raw materials containing 15% P_2O_5 and more. The thus produced activated phosphate fertilizers are not carried away from plow fields into water reservoirs and exhibit a prolonged effect [1]. It is known that treatment of natural phosphorites in power-intensive mills results in amorphization of their structure because of the crystal lattice deformation, defect formation, and intensification of chemical processes, which, in turn, raises the activity of phosphate minerals [3–5]. In this case, the solubility of phosphates in weak acids imitating humic acids increases [6]. The reasons for the high solubility of the Burenkhan phosphates in citric acid solutions are still unclear and may be related to structural changes in mechanical activation. The nature of structural disturbances of natural apatites, which occur as a result of amorphization and rupture of inter- and intramolecular bonds in the course of mechanical activation, may depend on changes in both the functional and radical compositions, as it has been confirmed by numerous studies [7]. Of present interest are studies concerned with the effect of the activator type on the degree of phosphorus conversion to a form assimilable by plants. Introduction into soil of a phosphorite treated in a vibration mill promotes, to a greater extent than that in the case of a planetary mill, an increase in the cellulose-decomposing activity, oats yield (by 28%), and weight of wheat grains (by 8.5%), compared with superphosphate [2].

In this study, we made a comparative analysis of changes in the structural-chemical properties of mono- and mid-fraction of Burenkhan phosphates in their mechanical activation in vibration and planetary mills, by IR and ESR spectroscopies.

Along with medium technological sample (3), we used mono-fraction (I) as an object of study. It was isolated from natural phosphorite (II) by elutriation and centrifugation in a mixture of heavy liquids under an X-ray purity control [2]. According to [8], the mono-fraction can be classed, as regards the $F : H_2O$ weight ratio (Table 1), with the FOH type apatite, and the phosphorite, with the OHF-type apatite. The total content of organic substances in phosphorites is low (0.5–2%). Impurities present in the phosphorite, namely, SiO_2 (20%), K_2O (0.06%), Na_2O (0.04%), MgO (2.02%), Fe_2O_3 (0.55%), Al_2O_3 (0.32%), and S_{total} (0.11%), are contained in the monophosphate in insignificant amounts.

Table 1. Main components of Burenkhan phosphorite and its monophosphate

Sample	Composition, %				
	P_2O_5	CaO	CO_2	F	H_2O
Phosphorite (II)	25.00	40.60	9.16	1.80	0.78
Monophosphate (I)	40.98	52.82	1.72	2.92	0.61

Based on the chemical composition of the monophosphate (Table 1) and on results of X-ray and derivatographic analyses, we found the crystal-chemical formula of Burenkhan phosphorites: $Ca_{9.83}(PO_4)_{5.66} \cdot (CO_3)_{0.41}F_{1.59}(OH)_{0.34}$, which allows us to assign them to fluorocarbonatehydroxoapatites.

The monophosphate with the empirical formula $Ca_{9.9}P_{5.66}O_{24}F_{1.49}$ has F/P_2O_5 and CO_2/P_2O_5 ratios of 0.070 and 0.023, respectively [2].

A qualitative analysis of the IR spectra of phosphorite samples was carried out in the following three spectral ranges most important for the mineral: 4000–3000, 1800–800, and 700–400 cm^{-1} [9]. The quantitative analysis of the IR spectra is based on a comparison of the absorption band intensities measured relative to the baseline line and internal standard: absorption by the P–O–P bond in the range 748–730 cm^{-1} characteristic of fluorohydroxoapatites. This absorption band is related to the crystallinity and is sensitive to various substitutions in the phosphorite [10]. The variation of the intensity of the absorption band at 748–730 cm^{-1} between samples I (0.8), 3 (1.3), 1 (1.0), 2 (0.8), 4 (0.7), and 5 (0.6), relative to the absorption in phosphorite II, indicates that this band is sensitive to external treatments.

The isolation of monophosphate and phosphorite 3 from mother raw materials II and their mechanical activation result in certain changes in the position and relative optical absorption intensities ($ROA\nu/\nu_{748-730}$) of IR bands (Tables 2 and 3). The IR spectra of sam-

ples under study contain a broad absorption band with peaks at 3547–3534 and 3441–3428 cm^{-1}, which are associated with hydrogen bonds with fluorine or oxygen [11]. The variation of the intensity of the absorption by hydrogen bonds with fluorine and oxygen makes it possible to judge about surface disturbances of the phosphorite structure. The peaks of the absorption bands associated with hydrogen bonds in samples I (3547 and 3436 cm^{-1}) and 3 (3537 and 3441 cm^{-1}) are shifted relative to those in the starting sample II (3542 and 3440 cm^{-1}), as well as the peaks of the absorption bands of the products of mechanical activation of monophosphates 1 (3540 and 3429 cm^{-1}) and 2 (3534 and 3440 cm^{-1}), which indicates that some types of hydrogen bonds are ruptured and other types are formed. In the products formed upon treatment of phosphorite 3, the peaks of absorption by hydrogen bonds are not shifted, but the intensity of absorption by the O–H...F bond in sample 4 (3537 cm^{-1}) somewhat decreases upon a vibration mill treatment. After a planetary mill, the intensity of absorption by hydrogen bonds with fluorine and oxygen in sample 5 increases.

It can be seen from Table 3 that hydrogen bonds are ruptured only in the monophosphate upon activation in a planetary mill. The activation of monophosphate in a vibration mill and that of phosphorite in mills of both types favor formation of hydrogen bonds, which may be due to sorption of water on the surface of crushed phosphorite (predominant grain size of 0.5 to 5–10 μm [12]). In the monophosphate and in the products of its treatment in a vibration mill (sample 1), and also in samples 4 and 5 obtained upon both types of treatment of phosphorite 3, the intensity of absorption by methyl and methylene groups (2920 and 2850 cm^{-1}) increases, which may be due to disintegration of organomineral complexes. The decrease in the intensity of absorption by these groups in phosphorite 3 and sample 2 points to destruction of the organic component. The decrease in the intensity of the absorption by C–F bonds (2089–2085 cm^{-1}) upon

treatment of phosphorites in a planetary mill confirms the data of [12], which indicate that the position of fluorine in the fluorapatite structure is more easily affected by mechanical treatment.

The absorption by the functional groups of phosphorite is observed at 1800–800 and 700–400 cm^{-1}. In the same IR spectral ranges, there are absorption bands of minerals entering into the phosphorite composition: quartz (1170, 1090, 795, 770, and 695 cm^{-1}), carbonate (1640, 1520, 1450, 1420, 880, 855, and 700–705 cm^{-1}), and calcite (1425, 875, and 715 cm^{-1}) [9]. The change in the $ROA\nu/\nu_{748-730}$ intensity of the doublet at 799–798 and 777–775 cm^{-1} shows that Si–O– bonds are present in the samples. The presence of quartz and kaolinite is characterized by the absorption near 696 cm^{-1}, and that of calcite, at 878–873 cm^{-1}. According to the electron-microscopic data [12], the mineral component of the Burenkhan phosphorite mainly consists of quartz and fluorapatite.

Mechanical activation of phosphorites leads to an increase in the intensities of absorption by impurities, especially upon a treatment in a vibration mill, whereas their decrease is characteristic only of a monophosphate treated in a planetary mill (Table 3). The absorption by structurally bound carbonates, with peaks of stretching vibrations at about 1450 and 1425 and 880–870 cm^{-1}, is weaker in samples I and 3, compared with the starting phosphorite II. However, treatment in a vibration mill results in that the absorption intensity increases, especially in the phosphorite sample 4 containing a larger amount of bound water. The weaker bands at 1996 and 2000 cm^{-1} can be assigned to vibrations of CO_3^{2-} ions formed upon the absorption of carbon dioxide from air [11], and the band at 1500 cm^{-1} points to a shift of the carbonate group toward fluorapatite (type B) [13]. The strongest bands in the monophosphate and phosphorite samples under study are observed at 1000–1100 cm^{-1}, with peaks at 1095 and 1045 cm^{-1}. These bands are associated with stretching vibrations of P–C-, C–F-, and P–S bonds and PO_4^{3-}-, HPO_4^{2-}-, and H_2PO^--groups. Absorption bands associated with the H–O–P– bonds are observed at 966–961 cm^{-1}; bands related to P–O–P– bonds, at 740 cm^{-1}; and those associated with bending vibrations of P–O– and –P–O–Me, at 600–400 cm^{-1}. It should be noted that the intensities of $ROA\nu/\nu_{748-730}$ of phosphate groups of the monophosphate and of products of its mechanical activation are about the same, and those for products of mechanical activation of sample 3 are 2–3 times higher (Table 2). In the range of vibrations of the complex PO_4^{3-} ion, five absorption bands have been observed [4, 14]. These bands are related to fully symmetric stretching vibrations ν_1 at 966–961 cm^{-1}, asymmetric stretching vibrations ν_3 near 1045 and 1095 cm^{-1}, and bending vibrations ν_4 at 575 and 603 cm^{-1}. The occurrence of the ν_1 vibrations points to a decrease in the symmetry of the PO_4^{3-} anion for sample I upon its isolation and mechanical treatment in a vibration mill, and for sample 3 subjected to both types of activation. The intensity of the ν_3 absorption does not change for sample 1 upon its treatment in a vibration mill, but slightly decreases in sample 2 upon treatment in a planetary mill. The ν_3 range of sample 3 is activated as a result of mechanical treatment, and this occurs to a greater extent after treatment in a vibration mill (sample 4). Similar changes were observed in the vibration intensities of the C–F–, C–S–, and S–P– bonds (1160–1158, 693–696 cm^{-1}) and in the intensities of bending vibrations ν_4 of PO_4^{3-} anions (Table 2, 3). Therefore, the type of mechanical activation strongly affects the type of structural changes in the monophosphate and phosphorite.

The $ROA\nu/\nu_{748-730}$ data on vibrations of the bridging P–O–P bond point to an increase in the content of water, hydrogen bonds, and carbonate and phosphate groups in samples under study upon their treatment in a vibration mill. A more severe treatment in a planetary mill also activates the above-mentioned structures in phosphorite, but does so to a lesser extent, and, according to the changes in the monophosphate absorption, results in a pronounced disintegration of the structure, including phosphate groups. Adsorbed water molecules are involved in the formation of hydrogen bonds, which is confirmed by the identical changes in $ROA\nu/\nu_{748-730}$ at 3547–3534, 3441–3429, and 1649 cm^{-1} (Table 2). An analysis of the monophosphate subjected to mechanical activation in a vibration mill demonstrated that its composition remains virtually unchanged; however, there occurs isomorphous substitution of elements. Various isomorphous impurities (Mn^{2+}, Cu^{2+}, Fe^{3+}, Ti^{3+}, V^{4+}, Au^{3+}, Ag^+, Sr^{2+}, Si^{4+}, C^{4+}, S^{6+}, and O^{2-}) result in a compositional disorder, structural disturbances and distortions (especially of nonisovalent types), and formation of various centers of electron and hole types [12, 15].

The samples studied are paramagnetic and give complex ESR spectra consisting of several superimposed signals related to different paramagnetic centers (Figs. 1 and 2). The content of radicals in the samples is comparatively low, about 10^{16} spins g^{-1}.

Several types of paramagnetic centers were detected in sample II, among which CO_2^-, CO_3^-, and

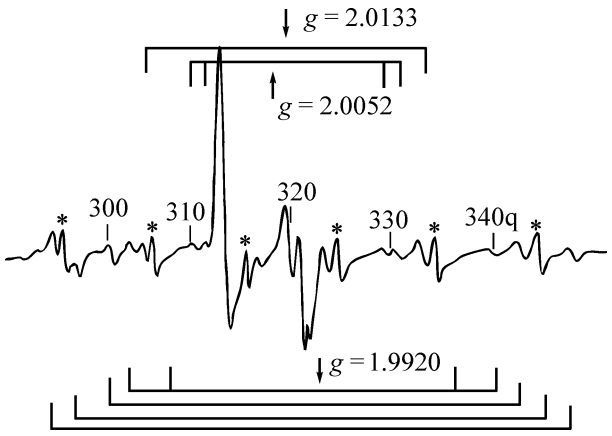

Fig. 1. ESR spectrum of natural phosphorite from the Burenkhan deposit (doublets of phosphorus radicals are shown in the spectrum; $^{55}Mn^{2+}$ lines are marked by asterisks).

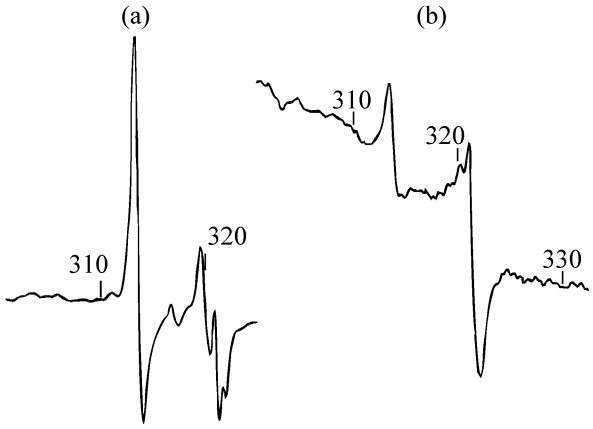

Fig. 2. ESR spectra of phosphorites, recorded in the magnetic field scanning range of 70 mT. (a) mid sample 3, (b) monophosphate I.

CO_3^{2}- centers, oxygen radicals, $^{55}Mn^{2+}$ ions, and phosphorous-containing radicals were identified (Table 4 and Fig. 1). The signals with a *g*-factor of 2.052–2.055 and a noticeable contribution of spin-orbit interactions are associated with oxygen paramagnetic centers OH^-–O^-–HO^- or F^-–O^-–F^- [15, 16]. Lines at *g*-factors of 2.010–1.998 can be assigned to overlapping signals of CO^{2-}-, CO_3^--, and CO_3^{2-}- centers [7, 15–22]. The sextet with a splitting of 9.3 mT and *g*-factor of 2.002(6) is due to interaction of an unpaired electron with the nucleus with a spin 5/2 and can be attributed to $^{55}Mn^{2+}$ ions. In the ESR spectrum of the starting phosphorite II, the signals with *g*-factors of 1.992, 2.005, and 2.013 and with stronger (20 to 50 mT) doublet splittings were also recorded (Fig. 1), related to various types of phosphorus radicals PO_3^{2-} and PO_4^{3-} [22, 23]. The starting phosphorite also contains paramagnetic centers (g = 1.988), which are absent in both mono- and mid-fractions of phosphorite and, apparently, are impurity-related. In addition, a narrow line with ΔH = 0.4 mT and g = 2.028 is present in the ESR spectrum of the starting phosphorite, which may be associated with the presence in apatites of either uranium ions [23] or anion-radicals S_4^- [24].

As a result of production of the mid-fraction phosphorite 3 and isolation of monophosphate I from the natural phosphorite II, the paramagnetic centers responsible for the sextet are lost. This can be accounted for by structural disordering or by ionization of Mn^{2+} to give diamagnetic Mn^{3+} [26]. At the same time, carbon radicals CO_2^-, CO_3^-, CO_3^{2-}, and oxygen radicals OH^-–O–HO^- and F^- –O^-–F^- (g = 2.055) are retained in mono-fraction I, and also a new type of paramagnetic centers appears, which gives a very broad (> 40 mT) absorption line with a *g*-factor of about 2.0 (Fig. 2b).

In the samples subjected to a mechanical treatment, some paramagnetic centers disappear, and new centers appear. In the process, a very high-intensity broad absorption line, absent in the spectrum of the starting phosphorite, appears in the ESR spectrum of the monophosphate. Treatment of monophosphate I in a vibration mill (sample 1) does not lead to changes in the structure of the ESR spectrum. In turn, treatment of I in a planetary mill changes the relative contents of various carbon radicals in sample 2, which is confirmed by the appearance of a signal with g = 1.998 in the ESR spectrum.

By contrast, mechanical activation of the mid-fraction phosphorite 3 in a vibration mill results in that the signal with g = 1.998 (9) (sample 4) disappears from the ESR spectrum, whereas treatment in a planetary mill does not lead to any changes in the spectrum (sample 5). All of the mechanically activated sam-

Sample	O-Radicals	C-Radicals		
	g_1 (ΔH = 0.27–0.93 mT)	g_2 (ΔH = 0.67–0.90 mT)	g_3 (ΔH = 0.32–0.98 mT)	g_4 (ΔH = 0.25 mT
II	2.055(0)	2.010(2)	2.004(9)	1.998(3)
3	2.055(2)	2.008(3)	2.002(7)	1.998(9)
I	2.055(0)	2.008(9)	2.003(3)	
1	2.053(0)	2.011(0)	2.003(9)	
2	2.054(0)	2.008(0)	2.003(8)	1.998(0)
4	2.051(5)	2.008(5)	2.003(6)	
5	2.055(2)	2.008(2)	2.003(9)	1.997(0)

ples contain, similarly to the monophosphate, paramagnetic centers responsible for a broad absorption line in the ESR spectra at a *g*-factor of 2.0, which are, presumably, defects or vacancies that captured an electron.

Thus, according to the IR and ESR spectral data, mechanical activation in mills of different types leads to unequal changes in the phosphorite structure, although spectral changes are observed already in the stage of isolation of the mono- and mid-fractions from the starting phosphorite. A strong activation of phosphates is observed upon a mechanical treatment in a vibration mill, which is accompanied by a breakdown of the symmetry of the PO_4^{3-} anion and does not lead to disintegration of the monofraction, as is the case of treatment in a planetary mill.

EXPERIMENTAL

Phosphorite was treated in a DRM-75T vibration mill in steel cups with balls with a weight of 500 g for 30 min. The activation of phosphorite in an EI-2 × 150 planetary mill was performed in steel drums with steel balls 3 mm in diameter with a total weight of 200 g for 15 min. The treatment time was chosen experimentally so as to obtain approximately equal degrees of amorphization (64% of particles smaller than 20 μm in size). In this way, we obtained monophosphate (1 and 2) and phosphorite (4 and 5) samples, respectively.

The IR spectra were measured in the spectral range 400–4000 cm^{-1} on an IFS 25 instrument in KBr pellets containing 2 wt % phosphorite. The inaccuracy in the positions of absorption bands was ±1 cm^{-1}.

The ESR spectra were measured on an SE/X-2547 Radiopan spectrometer (Poland) equipped with a magnetometer and a high-frequency meter at room temperature in the magnetic field scanning range 10–300 mT. The amplitude of HF modulation was 100 kHz. The content of paramagnetic centers was calculated using the known techniques with diphenylpicrylhydrazyl (DPPH) and ultramarine as calibrated standards [20, 21].

CONCLUSIONS

(1) Mechanical treatment of phosphorite in a vibration mill favors an increase in the relative content of phosphate groups.

(2) In the more severe conditions of a planetary mill, the activation of phosphate groups is less effective because of the destruction of the monophosphate.

(3) Irrespective of the type of a mechanical treatment, the relative content of carbon and oxygen radicals is 2 : 1 for monophosphate and 1 : 2 for phosphorites.

Abstract—Methods of crystal-optic, X-ray phase, chemical, and IR spectroscopic analyses were used to study the interaction of sphene and fluorapatite concentrates with dilute mineral acid solutions. The conditions under which the sphene concentrate can be purified to remove admixtures of phosphorus-containing compounds were found.

DOI: 10.1134/S107042720706002X

Sphene ($CaTiSiO_5$) is a rock-forming mineral in apatite-nepheline ores of the Khibiny deposits. The sphene concentrate obtained in dressing of these ores is regarded as a promising raw material for production of titanium pigments and for use in coatings of welding electrodes [1]. Presence of phosphorus in the concentrate intended for manufacture of the titanium dioxide pigment leads to a pronounced decrease in the yield of titanium into the final product [2] and precludes direct use of the concentrate in coatings of welding electrodes. According to technical specifications for the sphene concentrate for welding electrodes [TU (Technical specification) 1715-069-00203938–2000], the content of phosphorus should not exceed 0.1% in terms of P_2O_5. The presence of phosphorus is due to the fact that the sphene concentrate contains an admixture of a fluorapatite mineral, $Ca_5(PO_4)_3F$, both as aggregations with sphene and separately.

Phosphorus compounds cannot be removed to the required extent in the dressing stage. Therefore, chemical purification methods based on decomposition of fluorapatite with dilute solutions of mineral acids (sulfuric acid, for the most part) have been suggested [3]. In this process, sphene remains unchanged.

The content of phosphorus in the initial sample of the sphene concentrate used to develop the purification procedure was 1.88% in terms of P_2O_5.

The conditions of the given process require an additional study to substantiate the choice of an acid and minimize its expenditure at satisfactory purification parameters. The mineralogical[1] and chemical compositions of the starting sphene and fluorapatite concentrates used in this study are listed in Tables 1 and 2, respectively.

Chemical purification to remove fluorapatite can be performed not only with sulfuric acid, but also with hydrochloric and nitric acids [3]. With H_2SO_4 used,

Table 1. Mineralogical composition of sphene and fluorapatite concentrates

Mineral	Sphene concentrate	Apatite concentrate
	content, wt %	
Sphene	86.0	0.4
Fluorapatite	4.5	95.1
Nepheline	3.2	1.8
Aegirine	4.5	0.8
Feldspars	1.5	
Microcline		0.1
Hydromicas	0.5	0.1
Titanomagnetite		0.1

[1] Mineralogical analysis was made by V.F. Fedchenko at the Central laboratory of Apatit Open Joint-Stock Company.

Table 2. Chemical composition of sphene and apatite concentrates

Concentrate	Content, wt %							
	TiO_2	SiO_2	CaO	Fe_2O_3	P_2O_5	MgO	Na_2O	F
Sphene	35.9	30.4	25.1	1.7	1.88	0.6	0.7	0.4
Fluorapatite	0.4	2.3	49.6	0.4	39.2	0.2	0.2	3.1

the purified sphene concentrate is contaminated with an additional impurity to be controlled, sulfur. Nevertheless, use of this acid can be justified by the simpler utilization of spent sulfuric acid solutions, compared with those of hydrochloric and nitric acids. To choose rational purification conditions, the behavior of fluorapatite and sphene concentrates in their interaction with dilute mineral acids was studied.

Samples of apatite and sphene concentrates, taken from the dressing stage, were treated with acids of various concentrations and subjected to chemical, crystal-optic, X-ray phase, and IR spectroscopic analyses. The behavior of aegirine, feldspars, and nepheline was not studied because they contain no phosphorus. In addition, the first two of these minerals are stable against dilute acids and the decomposition of nepheline has been studied in sufficient detail [4].

Because it is fluorapatite that is the source of phosphorus impurity limited in the sphene concentrate, its interaction with mineral acids was studied separately.

To determine the behavior of fluorapatite under sphene concentrate purification conditions, experiments on fluorapatite decomposition with dilute sulfuric, hydrochloric, and nitric acids were performed at room temperature and s : l = 1 : 3. The chosen expenditure of the acids was lower than the stoichiometric value even for 5% solutions. The interaction of fluorapatite with dilute mostly occurs under the chosen conditions by the reactions

$$2Ca_5(PO_4)_3F + 3H_2SO_4 = 6CaHPO_4 + 3CaSO_4 + CaF_2,$$

$$2Ca_5(PO_4)_3F + 6HCl = 6CaHPO_4 + 3CaCl_2 + CaF_2,$$

$$2Ca_5(PO_4)_3F + 6HNO_3 = 6CaHPO_4 + 3Ca(NO_3)_2 + CaF_2.$$

The degree of apatite decomposition was judged from the increase in the phosphorus concentration in solutions in the course of time. The results obtained (Table 3) characterize the kinetics of fluorapatite decomposition. It follows from these data that the decomposition of fluorapatite by sulfuric and hydrochloric acids occurs at approximately equal rates exceeding that for nitric acid. The choice of nitric acid is also undesirable because of the more difficult utilization on nitrate waste solutions.

The data furnished by chemical, crystal-optic, X-ray phase, and IR spectroscopic analyses of precipitates formed in decomposition of fluorapatite with dilute H_2SO_4 at an acid expenditure exceeding the stoichiometric value show that these precipitates are composed of anhydrite, $CaSO_4$. The IR spectra of precipitates not washed to remove the mother liquor and dried at room temperature and at 90°C also coincide with the spectrum of anhydrous calcium sulfate [5] (see figure, curves *1* and *2*).

At the same time, the spectra of the precipitates washed with water and dried at room temperature show that anhydrite is converted into gypsum in the course of washing. The IR spectrum reveals the appearance of a doublet of absorption bands in the ranges of both stretching (3400–3600 cm^{-1}) and deformation vibrations (1630–1690 cm^{-1}) of water molecules (see figure, curve *3*).

In drying of washed precipitate at 90°C, gypsum loses 1.5 molecules of water and is converted into a semihydrate $CaSO_4 \cdot 0.5H_2O$. This is indicated by the disappearance of splitting in the region of deformation vibrations and a shift of the absorption bands

in the range of stretching vibrations of water to higher frequencies (see figure, curve *4*).

The methods used in this study did not reveal any content of calcium phosphate in the precipitates.

Similarly to experiments on apatite decomposition with dilute acid solutions, the purification of the sphene concentrate to remove phosphorus (fluorapatite) was studied. The results obtained are listed in Table 4.

Table 4. Kinetics of purification of the sphene concentrate to remove fluorapatite (s : l = 1 : 3)

Treatment time, h	Residual content of P_2O_5, wt %, upon treatment with indicated acid, wt %

5	0.094		0.081		0.11	

The results of purification of the sphene concentrate to remove the phosphorus impurity confirm the data obtained in fluorapatite decomposition and demonstrate that nitric acid is less effective than hydrochloric and sulfuric acids. The efficiency of the acids decreases in the order HCl > H_2SO_4 > HNO_3. In the same order grows the overstoichiometric expenditure of the acid for fluorapatite decomposition. At equal percentage concentrations of the acids, nitric acid has the lowest concentration in gram-equivalents. Nevertheless, the characteristics obtained with any of the three acids can give a sphene concentrate satisfying the requirements of TU 1715-069-00 203 938–2000 to the content of phosphorus (less than 0.1% in terms of P_2O_5).

From the ecological standpoint, use of nitric acid for purification of the sphene concentrate to remove phosphorus is less attractive because the maximum permissible concentration (MPC) of nitrate ions is lower than that for sulfate and chloride ions. The MPC is most simply provided in purification of waste solutions containing sulfate ions. Use of H_2SO_4 solutions leads to contamination of the concentrate with calcium sulfate having low solubility, and the technical specification for welding materials does not limit the content of sulfur. It is necessary to take into account that the expenditure of water for washing of the purified sphene concentrate to remove mother liquor containing sulfate ions is approximately 2–3 times that for washing to remove chloride ions. The real expenditure of water for purification to remove phosphorus is at a minimum for hydrochloric acid.

It follows from the data in Table 4 that purification to remove fluorapatite is sufficiently effective and the content of phosphorus in the target product decreases to the required level already in 3–5 h, depending on the acid concentration.

Starting from the assumption that there exist aggregations of sphene and fluorapatite [3], it was decided to check the effectiveness of the purification conditions for a finely ground sphene concentrate, in which the content of aggregations is virtually zero. The sphene concentrate was ground in a ball mill to grain size of –28 μm and treated with 2% hydrochloric acid. The choice of the acid was due to its higher efficiency, compared with sulfuric and nitric acids.

The reactivity of sphene in its interaction with the acid grows with the grinding fineness, and the higher the acid concentration, the stronger the interaction. Simultaneous decomposition of sphene and fluorapatite may lead to formation of a poorly soluble

titanium phosphates, i.e., to lower degree of purification to remove phosphorus. Therefore, 2% hydrochloric acid was taken for the treatment in order to reduce the degree of sphene decomposition. The finely ground sphene concentrate was processed using the procedure described above. The results of the experiments are presented below

Treatment time, h	1	2	3
Residual content of P_2O_5, wt %	0.14	0.029	0.024

Comparison with the data in Table 4 shows a considerably higher efficiency of purification to remove phosphorus for the finely ground sphene concentrate.

The final stage in preparation of the sphene concentrate is its washing with water to remove the mother liquor. Because of the low solubility of the precipitated calcium sulfate (~2 g l^{-1}), its removal by washing requires a water volume exceeding that of the acid by a factor of 6–8. At the same time, the expenditure of water to removal of chloride and nitrate ions by washing is 2–3 times smaller than that for calcium sulfate.

The problem of utilization of solutions formed in decomposition of fluorapatite and washing solutions requires an additional analysis. One of suggestions is to purify the sphene concentrate in fluidized-bed apparatus, which will enable fuller consumption of the acid and lower expenditure of water for washing of the purified concentrate. In this case, the acid will be consumed nearly completely. With hydrochloric acid used for purification, the waste solution will be a solution of $CaCl_2$, which can be utilized, e.g., by electrodialysis [6, 7].

With sulfuric acid used for purification to remove phosphorus, the forming finely crystalline $CaSO_4$ will be carried away from the apparatus by the washing solution and then can be separated by hydroclassification, which was confirmed in the stage of pilot industrial tests at Apatit Open Joint-Stock Company.

CONCLUSION

The efficiencies of purification of the sphene concentrate to remove a phosphorus impurity with hydrochloric and sulfuric acids are close, but preference should be given to hydrochloric acid, which rules out any contamination of the concentrate with sulfur impurity and makes it possible to reduce the expenditure of water for washing by a factor of 2–3.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Leaching-out of Biologically Active Elements from Enriched Granulated Phosphogypsum

L. P. Firsova

Moscow State University, Moscow, Russia

Received December 8, 2005

Abstract—Leaching-out of biologically active microelements (Mn^{2+}, Zn^{2+}) from grains of phosphogypsum enriched with macro- and microadditives introduced into its composition before granulation was experimentally studied.

DOI: 10.1134/S1070427207060031

The main product of sulfuric acid processing of phosphorites, with dissolution of mineral raw materials in mixtures of sulfuric and phosphoric acids, is, together with phosphoric acid, calcium sulfate (phosphogypsum) in the form of semihydrate, dihydrate, or anhydrite. The less stable under ordinary conditions is semihydrate, which transforms in the presence of an excess amount of moisture, including that of atmospheric origin, into a dihydrate [1–3]. Under conditions that favor dehydration, the semihydrate transforms into anhydrous calcium sulfate.

As shown in [4, 5], phase transitions between various forms of calcium sulfate also occur in phosphogypsum grains. The forms of phosphogypsum differ not only in stability, but also in other physical and chemical properties and, accordingly, in application methods and areas. Purified dihydrate (gypsum) with low content of phosphorus and fluorine is used in manufacture of building materials, special types of paper, and gypsum board. Unpurified (to remove phosphorus and other impurities) phosphogypsum is mostly used in agriculture as a meliorating agent. To extend the application area of phosphogypsum in plant growing, it seems advisable to enrich it with biologically active macro- and microadditives (phosphorus, nitrogen, boron, manganese, zinc, cobalt, copper, molybdenum, etc.), which make phosphogypsum an integrated mineral fertilizer of prolonged action [6–9]. A necessary condition in this case is development of methods for granulation of phosphogypsum in the presence of specially introduced admixtures imparting to grains such properties as, e.g., sufficient mechanical strength and low dusting, which enable prolonged storage and transportation. Important characteristics of phosphogypsum for agriculture are its stability against moisture and parameters of impurity leaching-out from grains by water and aqueous solutions, including soil moisture.

This study is concerned with leaching-out of biologically active chemical elements, manganese and zinc, from phosphogypsum grains prepared by various methods, including those with specially introduced macro- and microadditives.

EXPERIMENTAL

In the experiments, calcium sulfate semihydrate powders with phase composition stabilized by treating phosphogypsum (industrial waste from phosphoric acid production) with several portions of acetone to remove hygroscopic moisture in order to preclude conversion of $CaSO_4 \cdot 0.5H_2O$ into $CaSO_4 \cdot 2H_2O$. Phosphogypsum washed with acetone was dried in air. The stabilized phosphogypsum contained (wt %): water 6.8 (theoretical value for semihydrate 6.2), CaO 39–40, SO_3 56–57, P_2O_5 0.9–1.1, F 0.3–0.4, SiO_2 0.7–0.8, and oxides of rare-earth elements 0.5–0.6. The content of zinc and manganese was less than 0.1 wt %. The bulk density of the powder was 0.94–1.0 g cm^{-3}. According to the results of a microscopic analysis, the phosphogypsum powder was composed of druses 10 to 300 μm in size, constituted by hexagonal prisms of the semihydrate of lengths in the range from 1 to 30 μm, with their (001) edges for the most part sticking together.

Immediately before granulation, an air-dry powder of the semihydrate was wetted with distilled water or aqueous solutions containing various specially introduced components, including manganese or zinc sulfates in an amount of 1–5 wt %, urea (up to 60–80 wt %), or urea phosphate $m\mathrm{CO(NH_2)_2} \cdot n\mathrm{H_3PO_4}$ (up to 40 wt %). To wet the taken weighed portions of the powder, the amount of a moistening solution was chosen so as to provide production of the maximum amount of grains with diameter in the range 2–6 mm in stock pelletization. The humid powder was transferred to the steel plate of the granulator and the stock was palletized for several minutes. The rotation rate of the granulator plate was varied from 50 to 80 rpm at a plate inclination angle of 20°–40°.

After the pelletization was complete, grains into whose composition no urea or urea phosphate was introduced, which had an initial strength of about 1–2 kg cm^{-2}, were carefully transferred for several hours into a humid atmosphere of a desiccator for "ripening," to be strengthened via a change in the phase composition in the transition from $\mathrm{CaSO_4} \cdot 0.5\mathrm{H_2O}$ to $\mathrm{CaSO_4} \cdot 2\mathrm{H_2O}$. After many hours of ripening the grains were dried in air. The degree of phase transformation of the semihydrate, found from the content of crystallization water, depended on the ripening time and composition of the moistening solution. For example, it was 35–45% if aqueous solutions of manganese or zinc sulfates (1–5 wt %) were used for moistening of the semihydrate, whereas in the case of wetting with solutions of manganese sulfate in 5% sulfuric acid, the degree of transformation increased to 80 ± 3% in about the same ripening time. The degree of phase transformation in ripening correlated with the grain strength. According to the results of measurements on an IPG-1 device (Russia), the strength of ripened air-dry grains (without urea) under uniaxial compression varied from 4 ± 1 to 12 ± 2 kg cm^{-2}, depending on the content of impurity components, manganese ions. Grains obtained from suspensions containing urea or urea phosphate, which have, immediately after pelletization, a considerably higher initial strength than urea-fee grains, were dried in air, without the ripening stage. The air-dry grains with urea sustained load on the order of 20 kg cm^{-2} without disintegration. The bulk density of these grains was 10 ± 2% higher than that of grains containing no urea. A study with an MBI-14 microscope (USSR) demonstrated that grains containing urea or urea phosphate were less friable and had a smaller number of pores than grains with addition of manganese(II) or zinc(II) salt, but without urea. Table 1 lists data on the content of chemical additives in the grains and on their mechanical strength θ.

Table 1. Content of chemical additives in phosphogypsum grains and their mechanical strength

Content, wt %			θ, kg cm^{-2}
$(NH_2)_2CO$	P_2O_5	Mn	
–	1.0	<0.1	11 ± 2
–	1.0	1.8	8 ± 1
22	0.8	1.0	19 ± 2
7.8	7.8	1.5	20 ± 2

X-ray spectra previously obtained [10] on an ARL X*TRA X-ray diffractometer (USA–Switzerland) demonstrated that the phase compositions of grains with and without urea are different. In grains produced in wetting of calcium sulfate semihydrate with aqueous solutions containing urea or urea phosphate, the main form of calcium sulfate is anhydrite. In grains that contained no urea and were ripened in a humid atmosphere, calcium sulfate semihydrate is present.

The leaching-out of impurities (manganese and zinc compounds) from phosphogypsum grains was studied under static or dynamic conditions at a temperature of 19 ± 20°C. Grains of size 2, 4, or 6 mm were taken for experiments. In static experiments, weighed portions of equal-size grains were placed in glass vessels and poured over with distilled water at s : l = 1 : 5. The grains were in contact with water for 24 h. During this time, the vessels were periodically turned upside down. After the time of contact between grains and water was over, the liquid was separated by centrifugation or filtration. The content of manganese or zinc ions in the filtrate was determined spectrophotometrically. In the dynamic experiment, a weighed portion of grains was introduced into a glass column with an inner diameter of 10 mm, the grain layer was densified by tapping and its height was measured. Bidistillate, taken in an amount of up to 30 volumes of the grain layer, was passed at a rate of 8 ± 0.5 ml h^{-1} through the column filled with grains by UNIPAN-335A micropumps (Poland). The solutions collected were filtered and the content of zinc or manganese ions was spectrophotometrically determined. The number of parallel experiments on leaching in static and dynamic modes was 10–12. It was visually noticed that grains containing no urea or urea phosphate are destroyed by water more rapidly under both static and dynamic conditions.

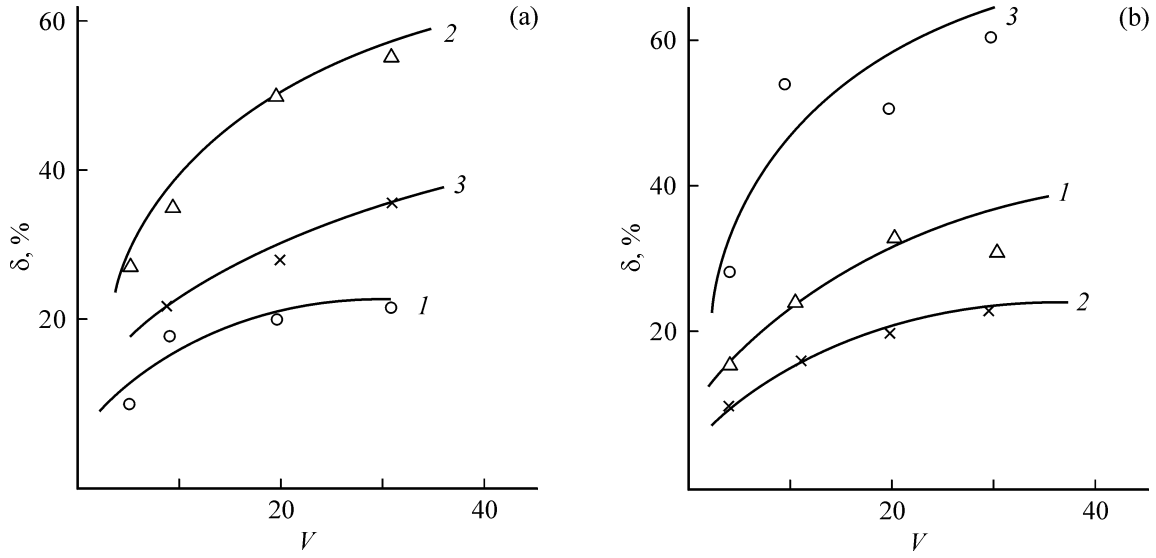

Fig. 1. Fraction δ of manganese(II) and zinc(II) leached-out from phosphogypsum grains produced by moistening with aqueous solutions containing various additives. Additive: (a) (*1*) manganese sulfate, (*2*) manganese sulfate and urea sulfate, and (*3*) manganese sulfate and urea phosphate; (b) (*1*) zinc sulfate, (*2*) zinc sulfate and urea sulfate, and (*3*) zinc sulfate and urea phosphate.

The content of manganese in the filtrates was determined by the peroxodisulfate method, with Mn^{2+} ions converted into permanganate ions, and that of zinc was found by the dithizone technique [10]. The optical densities of the solutions under study and standard colored solutions were compared using a KF–77 (Poland) or FEK-56 M photocolorimeter (USSR). The data obtained were used to calculate the degrees δ of microelement recovery from the solid phase on the assumption that the concentrations of manganese and zinc ions in distilled water can be taken to be zero. The experimental data on the degree of Mn(II) and Zn(II) leaching-out from phosphogypsum grains of various compositions are listed in Table 2 and shown in Fig. 1.

Table 2. Degree of leaching-out of Mn(II) and Zn(II) from phosphogypsum

Additives to $CaSO_4 \cdot 0.5H_2O$	Degree of leaching, δ	
	Mn(II)	Zn(II)
$MnSO_4$	0.74 ± 0.31	–
$MnSO_4$ + urea	0.65 ± 0.28	–
$MnSO_4$ + urea phosphate	0.52 ± 0.24	–
$ZnSO_4$	–	0.71 ± 0.25
$ZnSO_4$ + urea	–	0.64 ± 0.34
$ZnSO_4$ + urea phosphate	–	0.49 ± 0.27

The data in Table 2 demonstrate that Mn(II) and Zn(II) are leached-out from grains enriched in urea or urea phosphate at a considerably slower rate. The slowing-down of Mn(II) and Zn(II) leaching-out from grains with urea or urea phosphate may occur for several reasons. First, the moisture resistance and mechanical strength of grains whose skeleton is formed in the presence of urea by crystals of anhydrous calcium sulfate [10], which also has lower solubility than hydrated forms $CaSO_4 \cdot xH_2O$. Such grains more slowly disintegrate under the action of water or soil moisture. Second, a visual analysis with an MBI-14 microscope and measurements of bulk density demonstrated that grains with urea or urea phosphate have a less friable structure and lower porosity, which may also lead to a decrease in the fraction of impurities washed-out from pores. In addition, the rate of washing-out of Mn(II) and Zn(II) ions from pores may decrease because of the presence in the pore space of ions of orthophosphoric acid and urea forming with sulfates MSO_4 adduct, e.g., of composition $MSO_4 \cdot 2CO(NH_2)_2 \cdot 4H_2O$ [12]. Thus, presence of urea and phosphate ions may lead both to an increase in the mechanical strength and moisture resistance of grains and to a decrease in the rate of leaching-out of bioactive microcomponents, including manganese or zinc ions, from grains.

CONCLUSIONS

A study of the leaching of phosphogypsum grains enriched in various biologically active macro- and microcomponents demonstrated that urea and phosphate ions, including those in the form of urea phosphate, introduced into the composition of the grains can markedly improve the mechanical strength and moisture resistance of the grains. Simultaneously, they make lower the rate of washing-out of manganese(II) and zinc(II) from the grains and prolong the action of integrated fertilizers based on industrial wastes from sulfuric acid processing of phosphorites.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Diluents on the Extractive Capacity of Organophosphoric Acids in Vanadium(V) Recovery from Sulfuric Acid Solutions

Abstract—The extractive capacity of di(2-ethylhexyl)phosphoric and di(2,4,4-trimethylpentyl)phosphinic acids for vanadium(V) in its extraction from individual sulfuric acid solutions with the use of kerosene, a number of aliphatic alcohols, and octanone as diluents was studied. The most effective organic mixtures for extraction of vanadium(V) were determined in relation to the concentration of sulfuric acid.

DOI: 10.1134/S1070427207060043

One of sources of vanadium are sulfuric acid solutions obtained in aqueous or acid leaching of vanadium-containing raw materials [1, 2]. Extraction methods are frequently used for recovery of vanadium from solutions of this kind and its concentration and purification. The extent to which the metal passes into the organic phase depends on its state in aqueous solutions. In contrast to niobium and tantalum, which are present as cations in dilute solutions of the mineral acid and form anionic complexes as the concentration of sulfuric acid increases, vanadium(V) typically forms a wide variety of ion forms at both low and high contents of H_2SO_4 [3–13].

Analysis of published data shows that the ionic state of V(V) in H_2SO_4 solutions is determined by the concentrations of vanadium(V) and H_2SO_4. It was shown in [3] that, in dilute H_2SO_4 solutions, vanadium(V) is in the form of mono- and polynuclear complex ions whose composition depends on the solution pH.

It has been found [4–8] that, at a concentration of less than 10^{-4} g-ion l^{-1}, vanadium exists in the monomeric state, irrespective of the solution pH, and at vanadium concentrations exceeding 1×10^{-4} g-ion l^{-1}, polycondensation of ions occurs in solution, with degrees of polycondensation of 2, 3, 4, and 10 [8]. The structures of the ionic forms of vanadium have been determined in relation to the solution pH. As the pH value increases from 1 to 14, the following species are found in solutions: VO^{2+}, VO^{3-}, $V_2O_7^{4-}$, VO_4^{3-}, $V_3O_9^{3-}$, $V_3O_{10}^{5-}$, $V_4O_{12}^{4-}$, $V_4O_{13}^{6-}$, HVO_4^{2-}, $HV_2O_8^{5-}$, $H_aV_{10}O_{28}^{(6-a)-}$ ($a = 0-6$) [8, 9].

In concentrated H_2SO_4 solutions, the following species have been found: VO^{2+} [8], HVO_3 [3], and VO^{3+} [10]. A decrease in the acidity of the medium, causes conversion of VO^{2+} into other ionic forms, whose formation depends on the vanadium concentration. It was shown in [11] that, at high V(V) concentrations (≥0.12 M) in solutions containing more than 9 M of H_2SO_4, dimeric species are formed, and at H_2SO_4 concentration of 13–16 M, vanadium(V) exists only in the dimeric form [12]. At H_2SO_4 concentrations of 9 M and less, vanadium forms monomeric complexes whose central group is a vanadium(V) dioxocation [13].

The wide variety of forms of vanadium(V) in sulfuric acid solutions poses certain difficulties in preparation of selective extractive systems for separation of vanadium from accompanying impurities.

There is published evidence about use of a wide variety of extractive agents, such as amines [1], ketones [14], tributyl phosphate [15], alcohols [16, 17], di(2- ethylhexyl)phosphoric acid (D2EHPA) [11], and mixtures of extractive agents for recovery of vanadium(V) from sulfuric acid solutions.

Of particular interest among the reagents listed above are polydentate extractive agents having in their composition several extraction-active groups and, in

particular, organophosphoric acids (OPA), to which belongs D2EHPA. Extracting agents of this class contain two functional groups: hydroxy (–OH) and phoshoryl (P=O), which makes it possible to regard these groups as cation-exchange groups, on the one hand, and neutral oxygen-containing extractants, on the other.

Data on extraction of vanadium(V) with OPA are scarce. There have been several reports of extraction of vanadium(V) in the weakly acidic region [18] and in concentrated H_2SO_4 [11], with undiluted purified D2EHPA used as an extractive agent. It is known, however, that OPA are dimerized in pure form and in solutions of inert solvents [19, 20], which is due to the simultaneous presence in their composition of proton-donor and proton-acceptor groups (–OH and P=O). This gives rise to a system of hydrogen bonds and leads to a decrease in the thermodynamic activity of the extractive agent, because, in this case, the access to the functional groups of the extractive agent of particles being distributed is hindered.

In recent years, a considerable attention has been given to the choice of extractant mixtures having synergetic properties with respect to a metal being recovered [1, 21, 22]. It is known that active solvents, to which belong neutral oxygen-containing reagents, such as TBP, sulfoxides. DMSO, ketones and alcohols, make lower the degree of dimerization of organic acids [19, 20, 22], which should raise their extractive power. It was shown in [20] by IR spectroscopy that D2HPA is completely monomerized in methanol because of the formation of H-complexes of D2HPA with the alcohol molecule.

Because extractive systems with alkylphosphoric acids and neutral ligands are commonly regarded as systems that typically exhibit synergism [22], of particular interest is a study of the effect of neutral oxygen-containing reagents as diluents on the extraction characteristics of OPA.

Previously, the extractive properties of two organophosphoric acids, D2EHPA and di(2,4,4-trimethylpentyl)phosphinic acid (Cyanex 272) with respect to titanium, niobium, and tantalum in extraction from hydrochloric solutions have been studied [23–25]. It was found that replacement of an inert diluent with a neutral oxygen-containing reagent positively affects the extractive properties of both organophosphoric acids, whereas the extractive power of OPA with respect to rare-earth elements shows pronounced differences.

The aim of this study was to compare the extractive properties of D2EHPA and Cyanex 272 with respect to vanadium(V) on replacement of inert diluents with neutral oxygen-containing compounds.

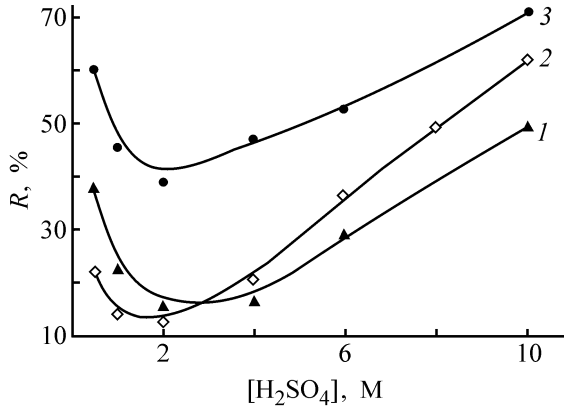

Fig. 1. Effect of H_2SO_4 on the recovery R of vanadium(V) with (*1*) $D2HPA_{techn}$, (*2*) $D2HPA_{pur}$ (manufactured by Bayer), and (*3*) Cyanex 272 in a diluent, kerosene, at a constant concentrations of vanadium in the starting solutions (1.5×10^{-2} M V_2O_5) and of the extractive agent in the diluent (1.2 M).

EXPERIMENTAL

The following OPA were used as extractive agents: D2EHPA manufactured by Bayer (Germany), with 97.3% main substance, technical-grade D2EHPA of domestic manufacture (Volgograd), with the content of the main substance of 65% and more; and Cyanex 272 manufactured by Cytec (Canada), with 85–90% main substance. The following diluents were used: an inert diluent, aviation kerosene; long-chain aliphatic alcohols, octanol, isooctanol, and decanol; and a ketone, octanone-2. All the neutral oxygen-containing reagents were of pure grade.

Vanadium solutions were prepared by dissolution of V_2O_5 of special purity grade in 1–10 M of H_2SO_4 of chemically pure grade. The extraction was performed in calibrated test tubes. After volume measurements, the phases were separated. The concentration of sulfuric acid was determined by titration with NaOH in the presence of Methyl Orange. The concentration of vanadium(V) in the starting solutions and in equilibrium aqueous phases after extraction was found using the phosphorus-tungstate method [26] and also a Plasma-400 ICP spectrometer with inductively coupled plasma. The content of vanadium(V) in extracts was calculated from the difference of the concentrations in aqueous solutions before and after extraction.

Figure 1 shows data on the influence exerted by the concentration of sulfuric acid on vanadium(V)

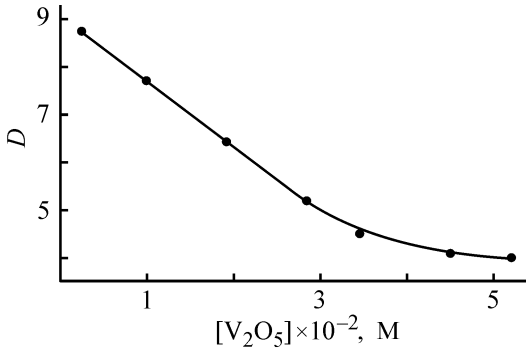

Fig. 2. Vanadium distribution coefficient D vs. the V_2O_5 concentration in the starting solution at $pH_{in} \approx 3$. Extractive agent: 1.2 M $D2EHPA_{techn}$ in kerosene.

recovery with technical-grade (curve *1*) and purified (curve *2*) D2EHPA and with Cyanex 272 (curve *3*) in an inert diluent, kerosene, at concentrations in the range 0.5–10 M. It was found that the dependences of the extraction of vanadium(V) on the H_2SO_4 concentration show minima at 1–4 M (Fig. 1, curves *1–3*). Previously, data on extraction of niobium(V), tantalum(V), and titanium(IV) with D2EHPA of various brands in the same inert diluent have been obtained [27]. The existence of minima was only noticed in recovery of niobium, tantalum, and titanium with purified D2EHPA in kerosene.

The data obtained indicate that the mechanism of extraction of rare-earth elements becomes more complex as the H_2SO_4 concentration increases. This occurs because, in the case of chelating extractive agents of acid nature (to which belong OPA), both the functional groups, –PO and –OH, are involved in coordination and the coordination mechanism, whose contribution increases with the solution acidity, operates in addition to the cation exchange, which complicates the extraction process [28].

Previously, differences in the extraction characteristics of pure and technical-grade D2EHPA with respect to niobium, tantalum, and titanium have been revealed [27]. It was shown that, in contrast to the pure extractive agent, technical-grade D2EHPA extracts rare elements with high distribution coefficients in the entire range of acidities (1.5–10 M H_2SO_4). The high degree of recovery of niobium, tantalum, and titanium with technical-grade D2EHPA has been attributed to the synergic effect [22, 27] appearing in the presence of monoalkylphosphoric acid contained in technical-grade D2EHPA [28]. In the case of vanadium(V) extraction with OPA in inert diluents (Fig. 1, curves *1–3*), no synergic effect of was observed.

Thus, OPA in inert diluents can be arranged in order of increasing capacity for vanadium(V) extraction in acid solutions containing 0.5 M of H_2SO_4 and more as follows: D2EHPA (technical grade) < D2EHPA (purified) < Cyanex 272.

It is known that branching of carbon chains in OPA can affect both the extractive power and the selectivity of extraction of separate elements [29]. The acids D2EHPA and Cyanex 272 possess, respectively, ethyl and methyl radicals in the β-position. In contrast to D2EHPA, phosphonic acid has two more substituents (methyl radicals) at the fourth carbon atom, which suggests a higher selectivity of Cyanex 272 with respect to vanadium, compared with D2EHPA.

An opposite pattern was observed in extraction of vanadium(V) from weakly acidic solutions, in which the cation-exchange mechanism is operative. In recovery of vanadium with technical-grade D2EHPA (pK_a 2.12) in kerosene from solutions with pH 3, the vanadium(V) distribution coefficient was, at vanadium(V) concentration in the aqueous solution equal to 2.8×10^{-2} M, $D = 5.2$ in contrast to $D = 0.08$ for Cyanex 272 (pK_a 6.4). These differences are probably due to the fact that two ester groups (–OR) are present in the structure in the case of D2EHPA [structural formula $(RO)_2POOH$] and absent in the case of Cyanex 272 (structural formula R_2POOH). These groups favor extraction of metals by the cation-exchange mechanism because they withdraw the electron density from the hydroxy group –OH and thereby make higher the proton mobility. The occurrence of the extraction by the cation-exchange mechanism is indicated by a considerable change in the pH value of the aqueous solution in the course of extraction.

Figure 2 shows how the vanadium distribution coefficient depends on the concentration of vanadium in the starting solution in the range $(0.25–5.2) \times 10^{-2}$ M V_2O_5 at pH_{in} 3 in the case of technical-grade D2EHPA in kerosene.

The dependence obtained indicates that the distribution coefficients decrease as the vanadium(V) concentration in the starting solutions becomes higher. This is probably due to polymerization in the aqueous phase and agrees with published data [8, 9], according to which polycondensation of vanadium occurs under these conditions.

Replacement of an inert diluent with a neutral oxygen-containing reagent leads to substantial changes in the extractive properties of organophosphoric acids.

Figures 3 and 4 show how the vanadium(V) distribution coefficients depend on the H_2SO_4 concentration in extraction with OPA in oxygen-containing diluents. The dependences obtained with purified D2EHPA virtually coincide with the results for technical-grade D2EHPA, and, therefore, are not shown here. For comparison, the same figures show data on extraction of vanadium with OPA in inert diluents (Figs. 3 and 4, curves *2*) and with an individual aliphatic alcohol, 100% isooctanol (Fig. 3, curve *5*). The data obtained indicate that oxygen-containing diluents differently affect the extraction of vanadium(V) from dilute and concentrated solutions with alkylphosphoric acids.

In extraction of vanadium(V) with D2EHPA from solutions containing less than 2 M H_2SO_4, the following dependence of the effect of the diluents used on the extractive properties of alkylphosphoric acid was obtained: kerosene > octanol ≈ isooctanol ≈ decanol > octanone. A somewhat different dependence was obtained in vanadium extraction with phosphonic acid Cyanex 272: kerosene > octanone > decanol = isooctanol = octanol.

It follows from the data obtained that is kerosene the best diluent for D2EHPA at H_2SO_4 concentrations of less than 2 M.

The long-chain ketone has a positive effect as a diluent at low H_2SO_4 concentrations only when it is used in a mixture with phosphonic acid (Fig. 4, curve *1*). Because, in contrast to D2EHPA, Cyanex 272 contains no electron-donor ester groups, the acceptor C=O group of the ketone possibly withdraws the electron density from the hydroxy group of OPA and thereby makes higher the mobility of a proton and promotes its exchange for a metal cation.

It was found that, as the H_2SO_4 concentration is raised from 0.5 to 4 M, the distribution coefficient of vanadium in its extraction with 100% isooctanol changes from 0.06 to 0.08 and the degree of vanadium extraction in this range does not exceed 8% (Fig. 3, curve *5*).

In recovery of vanadium from H_2SO_4 solutions concentrated in mineral acid (c > 4 M), a significant increase in the extractive power of OPA was observed in such diluents as aliphatic alcohols, compared with inert diluents. In this case the maximum effect was observed with isooctyl alcohol (2-ethyl-1-hexanol) (Fig. 3, curve *6*; Fig. 4, curve *5*), compared with alcohols of normal structure. The degrees of vanadium(V) recovery in extraction with OPA in mixtures with octanol and decanol virtually coincide (Figs. 3 and 4, curves *3* and *4*).

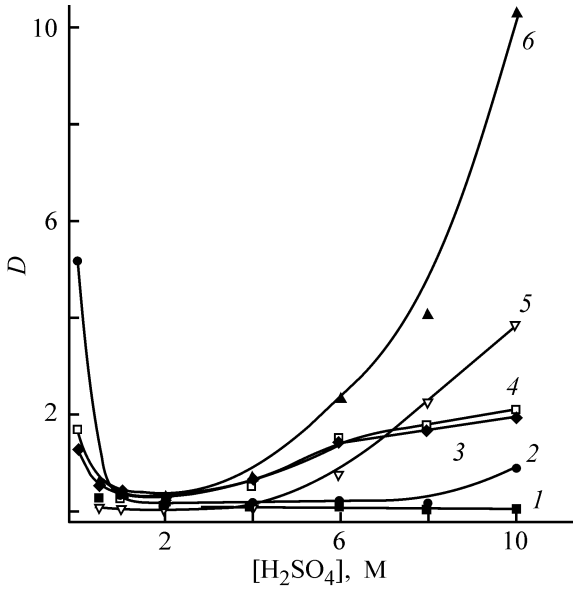

Fig. 3. Vanadium distribution coefficient D vs. H_2SO_4 concentration in the starting solution in extraction with 1.2 M D2EHPA in the following diluents: (*1*) octanone, (*2*) kerosene, (*3*) decanol, (*4*) octanol, and (*6*) isooctanol; and (*5*) in extraction with pure isooctyl alcohol.

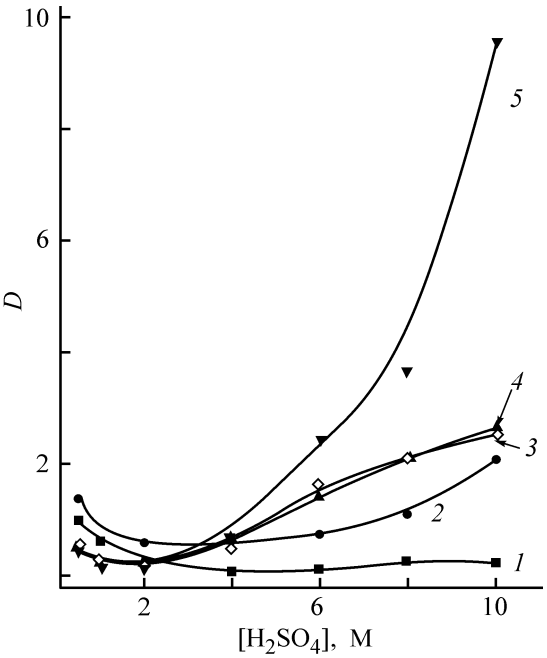

Fig. 4. Vanadium distribution coefficient D vs. H_2SO_4 concentration in the starting solution in extraction with 1.2 M Cyanex 272 in the following diluents: (*1*) octanone, (*2*) kerosene, (*3*) decanol, (*4*) octanol, and (*5*) isooctanol.

With isooctyl alcohol used as diluent for organophosphoric acids, there probably occurs a synergic effect, because the extraction of vanadium with a pure alcohol or OPA in an inert diluent is considerably lower.

CONCLUSIONS

(1) A study of the extractive properties of a number of industrial organophosphoric acids in an inert and neutral oxygen-containing diluents with respect to vanadium(V) in its extraction from individual sulfuric acid solutions revealed differences in the extraction behavior of vanadium(V) and other rare elements: niobium(V), tantalum(V), and titanium(IV).

(2) The influence exerted by the sulfuric acid concentration in the starting solutions on the extraction characteristics of extractive agents was determined. It was found that, at low H_2SO_4 concentrations (<2 M), the most effective diluent for all of the organophosphoric acids under study is kerosene. Use of octanone under these conditions has a positive effect only on the extractive properties of phosphonic acid.

(3) The optimal conditions of vanadium recovery with technical-grade di(2-ethylhexyl)phosphoric acid in kerosene at pH 2.8–3.0 were found. It was shown that use of phosphonic acid under these conditions is inefficient.

(4) Advantages of neutral oxygen-containing reagents as diluents in vanadium(V) recovery with organophosphoric acids from concentrated (in sulfuric acid) solutions were demonstrated. The conditions were found and the composition of extractive mixtures based on organophosphoric acid and isooctanol was suggested for effective recovery of vanadium from solutions containing H_2SO_4 in concentrations of 9 M and more.

Abstract—A scheme for utilization of chloride solutions of complex composition with α- and β-activity of up to 35 and 28 kBq l^{-1}, respectively, is suggested.

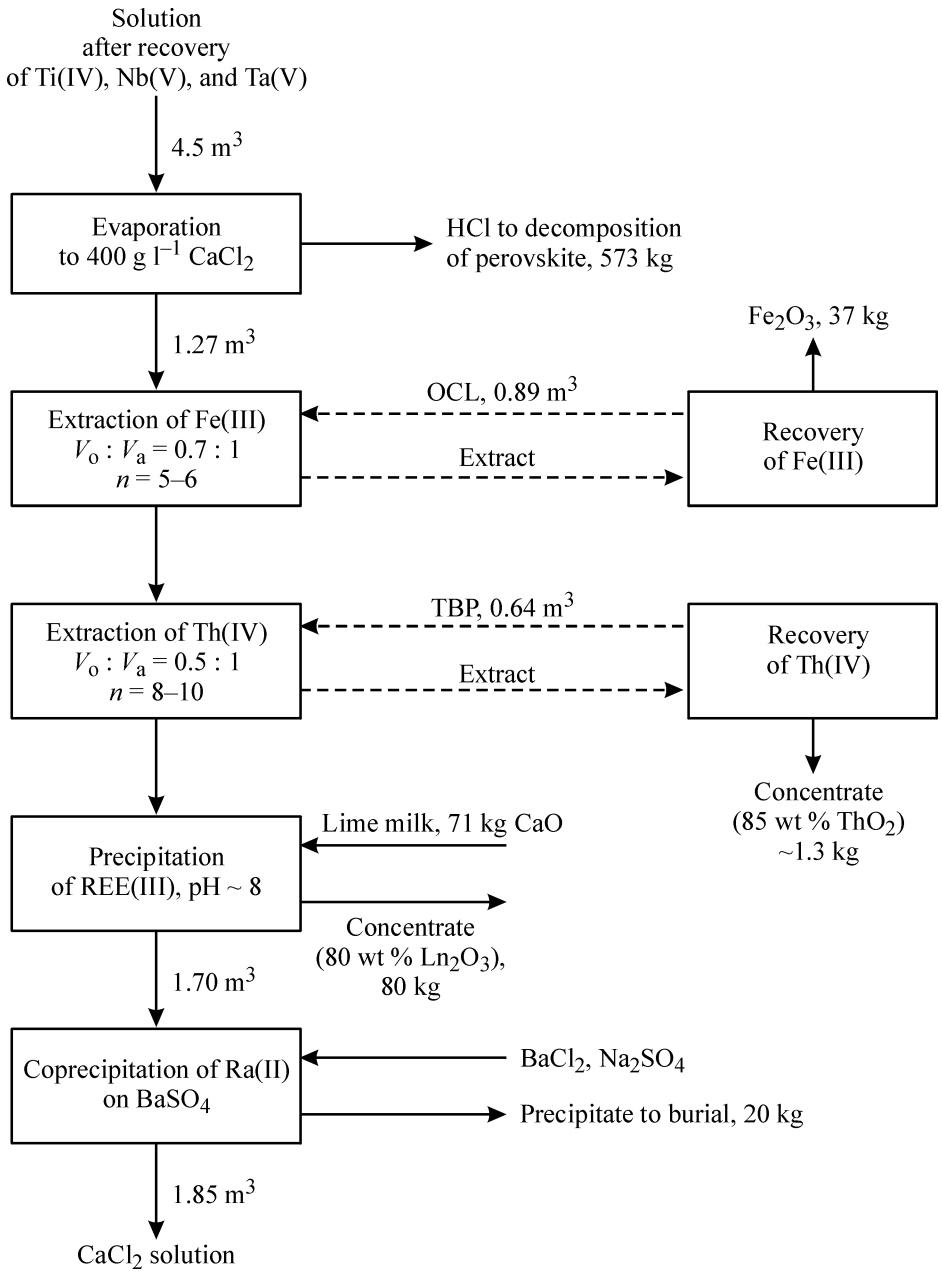
DOI: 10.1134/S1070427207060055

In Russia, there is a stable deficit of titanium(IV), niobium(V), and tantalum(V) compounds, which is due to the lack of a surveyed resources of the conventional raw materials (ilmenite, columbite-tantalite, pyrochlore, and microlite ores). At the same time, Russia possesses a considerable part of world's resources of titanium–rare-earth raw materials, of which the Kola Peninsula has about half of the national resources. The largest stock of titanium–rare-earth materials are concentrated in loparite ores of the Lovozero deposit and perovskite ores of the Afrikand and Vuoriyarvi deposits. The loparite concentrate is manufactured in limited amounts and is the only source of raw materials in the country for manufacture of niobium–tantalum and rare-earth products. Deposits of perovskite ores for manufacture of these deficient products deserve a greater attention.

The total resources of ores at only the Afrikand deposit (best prepared for industrial use) constitute 626.2 million tons (52.2 million tons of TiO_2). A characteristic feature of perovskite is the complex multicomponent composition. For example, perovskite from the Afrikand deposit contains (wt %): $(Nb + Ta)_2O_5$ 0.64–2.50, TiO_2 50.8–56.8, SiO_2 0.12–1.93, Al_2O_3 0.15–1.30, Fe_2O_3 0.43–2.00, FeO up to 1.44, Ln_2O_3 2.18–10.7 (here and hereinafter Ln_2O_3 is a sum of oxides of rare-earth elements, REE), CaO 26.3–38.1, Na_2O 0.10–2.35, and ThO_2 0.07–0.14. Various schemes for integrated processing of perovskite have been developed [1, 2], which are mostly based on decomposition of a concentrate with mineral acids: sulfuric, nitric, or hydrochloric, followed by separation of the main components of the systems by hydro- and pyrometallurgical methods. These technologies can produce 0.41–0.47 ton of pigment titanium dioxide, up to 100 kg of a rare-earth concentrate, 7.7–9.3 kg of Nb_2O_5, and 0.42–0.50 kg of Ta_2O_5 from a ton of the concentrate. A promising technique is decomposition of perovskite with hydrochloric acid, with calcium(II), REE(III), and thorium(IV) transferred to solution, and titanium(IV), niobium(V), and tantalum(V), to a precipitate further processed into commercial products by known techniques [1–3].

A difficult problem in the hydrochloric acid technology of perovskite is posed by utilization of waste solutions containing radionuclides, mostly thorium(IV), and also U(VI) and Ra(II). These solutions have a complex multicomponent composition and contain chemical elements with markedly different properties and a large amount of $CaCl_2$, which strongly affects the recovery and separation of components of the system. The processing of solutions of this kind has virtually not been studied at all. The utilization of these solutions, with their purification to remove radionuclides and to obtain valuable components as commercial products, has been analyzed [4–9]. In this communication, the results of these studies are used when choosing a utilization scheme (see scheme; *n* is the number of stages in the continuous counterflow process) and evaluating the main material flow rates.

The radioactive contamination of the solutions being processed is mainly due to presence of thorium(IV). Th(IV) can be recovered by both extraction and pre-



cipitation methods, which have been tested previously [6–8]. Preference was given to extraction because this technique can more selectively recover Th(IV) from technological solutions to give concentrates rich in this element. It was taken into account that the interest in thorium(IV) as an energy-containing raw material has revived: at a deficiency of natural uranium(VI), thorium(IV) can markedly improve the resource potential of the nuclear power engineering of the future. As the most important source of thorium(IV) is recommended its accompanying recovery in processing of rare-metal ores [10].

Solution obtained upon extraction of Ti(IV), Nb(V), and Ta(V), which contained 100–200 g l^{-1} of HCl and 100–150 g l^{-1} of $CaCl_2$ were preliminarily evaporated to a $CaCl_2$ concentration exceeding 400 g l^{-1} in order to reduce technological flow rates, regenerate HCl (returned to perovskite decomposition), and improve the extraction of thorium(IV). According to published data [11] and results obtained in the present study, the extraction of Th(IV) with tributyl phosphate steeply increases with the $CaCl_2$ concentration, especially at $[CaCl_2] > 400$ g l^{-1}. The scheme shows the solution volumes before and after evaporation and the mass of

regenerated hydrochloric acid (in terms of 100% acid); here and hereinafter the material flow rates were calculated (per ton of the perovskite concentrate) using average values of the composition of perovskite and the starting and intermediate solutions.

After the evaporation, the solutions had the following composition (g l^{-1}): HCl 70–90, $CaCl_2$ 430–470, ThO_2 0.54–1.38, Ln_2O_3 25–30, Fe_2O_3 27–32 [Fe(II) + Fe(III) in terms of Fe_2O_3], TiO_2 1–5, ZnO 0.5–1.5, Al_2O_3 2–6, V_2O_5 0.1–0.4, and MnO 0.5–1.3, with α- and β-activities of up to 35 and 28 kBq l^{-1}, respectively. Preliminarily, prior to recovery of Th(IV), Fe(III) was selectively extracted with octanol-1 (OCL) in order to reduce the mass of the further obtained concentrates of Th(IV) and REE(III) [4, 5]. Because Fe(II) cannot be extracted in the given system [11], it was oxidized to Fe(III) by the known methods. A virtually complete recovery of Fe(III) is achieved at a ratio of organic to aqueous phases $V_o : V_a \approx 0.7 : 1$. Under these conditions, the transfer of titanium(IV), thorium(IV), and REE(III) into the organic phase does not exceed 50, 2, and 0.1%, respectively. After washing and re-extraction of iron(III) with water [at $V_o : V_a$ of 10 : 1 and (2–3) : 1, respectively], neutralization with an ammonia solution yielded pure iron(III) hydroxide. According to the results of an emission spectral analysis, the content of impurities in Fe_2O_3 (after calcination) was as follows (wt %): Cu, Al, and Mn < 0.001; Mg ≤ 0.001; Si and Ti ≤ 0.003; Ca, Ce, La, and Pb < 0.03; Cr ≤ 0.03; and Zn, Sn, and Zr < 0.1. Pure iron(III) compounds are widely used in various fields of technology [12].

In Th(IV) recovery were tested di(2-ethylhexyl)-phosphoric acid, OCL, and TBP, with good results obtained in the case of TBP. In a system with TBP, the influence exerted on the Th(IV) distribution by the content of HCl and $CaCl_2$, and $V_o : V_a$ values in extraction, washing, and re-extraction has been studied. A conclusion was made that a high Th(IV) recovery is favored by an increase in the $CaCl_2$ concentration at a minimum content of HCl in the system. At $[CaCl_2] > 400$ g l^{-1} and $V_o : V_a \approx 1 : 1$, the degree of Th(IV) recovery in a single stage is 92–94%. However, the $V_o : V_a$ ratio was lowered to approximately 0.5 : 1 in order to diminish the co-extraction of impurities (see scheme). Under these conditions, the recovery of Th(IV) decreases to 78%, but the extraction of the main accompanying impurities, Ca(II) and REE(III), decreases to an even greater extent (severalfold), to 5 and 2.6%, respectively. The low recovery of impurities made it possible to eliminate the stage of extract washing. The re-extraction of Th(IV) is performed with a solution of 10 g l^{-1} HCl ($V_o : V_a$ = 1 : 1), with thorium(IV) precipitated from the re-extract at pH 5. The content of ThO_2 in the concentrate is about 85%; the recovery of Th(IV) from the starting solution into the product obtained is about 75% (with recycles disregarded).

Uranium(VI), whose content in perovskite is approximately 0.01 wt % [an order of magnitude lower than that of Th(IV)], is extracted from hydrochloric solutions better than Th(IV) [11, 13] and is concentrated together with Th(IV). In the scheme under consideration, U(VI) can be isolated from the filtrate after precipitation of Th(IV).

After extraction of Th(IV), the activity of the solution, naturally, decreases dramatically, to values of about 7.5 and 9.0 kBq l^{-1} for α- and β-radiation, respectively; however, these values still remain high and considerably exceed the levels specified by sanitary regulations.

The raffinate obtained after extraction of Th(IV) contains Ti(IV), Nb(V), and other elements precipitating in a more acidic medium than do REE(III). To separate these elements from REE(III), neutralization with lime milk (20 wt % CaO) to pH 2–4 is carried out. A precipitate of hydroxides (up to 10 kg per ton of perovskite) is returned to the stage of concentrate decomposition. Further processing of the solution includes recovery of the REE(III) concentrate at pH ~8 and coprecipitation of radium(II) with $BaSO_4$ [6–9, 14]. If purification to remove Ra(II) is performed before precipitation of REE(III), REE(III) are partly precipitated (lost), which presumably occurs because of the formation of poorly soluble double sulfates with Na_2SO_4 [15] introduced into solution in recovery of radium(II).

The REE(III) concentrate is contaminated with radioactive impurities, mostly radium(II) and products of its decay, because of the sorption of radionuclides on REE(III) hydroxides in the course of their precipitation; the α- and β-activities of the product are 6.4 and 21.7 kBq kg^{-1}, respectively; the content of ThO_2 is about 0.1 wt %. According to sanitary regulations, the concentrate does not belong to radioactive solid waste, but its use as a raw material in subsequent processing requires a permission by sanitary control [16]. The concentrate is further processed by the known methods, including (when necessary) an additional purification to remove radionuclides [1, 2, 17–20].

After the precipitation of REE(III), the α- and β-activities of the solution, approximately equal to 3 and 2.2–4 kBq l^{-1}, respectively, are mostly determined by the presence of radium(II) and products of its decay. To remove Ra(II) by coprecipitation with $BaSO_4$, $BaCl_2$ and Na_2SO_4 were successively introduced into

the solution. The conditions of radium(II) recovery: solution acidity, expenditure of $BaCl_2$ and Na_2SO_4, temperature, and other precipitation parameters, were studied in detail. The most complete purification to remove radionuclides is achieved at an expenditure of 0.068 m^3 of a solution containing 170 g l^{-1} of $BaCl_2$ per 1 m^3 of the technological solution and a 180% expenditure (relative to the amount stoichiometrically necessary for $BaSO_4$ formation) of a solution of a 180 g l^{-1} solution of Na_2SO_4, temperature $T \approx 20°C$, and pH 7–9. The expenditure of $BaCl_2$ and Na_2SO_4 per ton of the concentrate is 12 and 14 kg, respectively.

In this stage, the specificity of the technological solutions being processed, with a high content of $CaCl_2$, was manifested the most clearly. It is known [14] that Ra(II) is precipitated the most completely with $BaSO_4$ from acid solutions. In the case in question, however, it is necessary to make the acidity of the system lower. It has been noted [14] that the degree of precipitation of a microcomponent in cocrystallization of isomorphous compounds is the higher, the more complete is the precipitation of a macrocomponent. It can be concluded that the solubility of $BaSO_4$ [and $CaSO_4$ on which Ra(II) also partly coprecipitates] in a system with high $CaCl_2$ concentration is at a minimum at pH 7–9. Accordingly, a higher degree of purification to remove radium(II) is observed just in this region.

After the final purification to remove radionuclides, the α- and β-activities of the solution are less than 0.18 and 0.08 kBq l^{-1}, respectively. The final solution is not dangerous for the environment in radiation regard.[1] Methods for processing of a solution containing virtually only $CaCl_2$ were considered in [1–3, 17]; a possible way is addition of H_2SO_4 to obtain gypsum, with HCl regeneration. The expenditure of H_2SO_4 and the yield of gypsum and HCl (100% acid) per ton of the concentrate are, respectively, 622, 864, and 464 kg.

On the whole, the scheme suggested is virtually waste-free. Among disadvantages of the scheme are the comparatively high flow rate of TBP in Th(IV) recovery and contamination of the REE(III) concentrate with radionuclides.

CONCLUSION

A scheme for utilization of solutions formed in perovskite processing, which have complex composition and high content of $CaCl_2$ and other salts, was suggested. The scheme includes extraction of iron(III) with octanol-1 ($V_o : V_a = 0.7 : 1$) and extraction of thorium(IV) with tributyl phosphate ($V_o : V_a = 0.5 : 1$) to give a Th(IV) concentrate (ThO_2 content of about 85 wt %), neutralization with recovery of a concentrate of rare-earth elements (80–90 wt % Ln_2O_3), and coprecipitation of radium(II) with $BaSO_4$. The final solutions are radiation-safe and suitable for production of gypsum and other calcium(II) compounds.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Porous Inorganic Materials Modified with Pyrolytic Carbon Producted from Polystyrene

Abstract—Microporous materials were obtained by pyrocarbon modification of matrices based on a highly dispersed silicon dioxide. The modification involved polystyrene carbonization at 400 and 700°C in an argon flow. The possibility was elucidated of varying the properties of porous materials (density, porosity, sorption of organic solvents, and compression strength) by varying the way of introduction of polystyrene solutions into the matrix and their concentrations.

DOI: 10.1134/S1070427207060067

Direct carbonization of carbon-containing compounds yields carbonizates with low strengths, which prevents preparation of fairly large articles therefrom. This problem can be solved by carrying out carbonization in an inorganic matrix. Pyrocarbon modification of inorganic porous materials is widely used for preparation of carbon-mineral adsorbents and gas-separation membranes [1–3]. Recently, pyrocarbon modification has been characterized by ever widening use of carbonization of polymers in a solid matrix, yielding porous carbon structures. In solid-phase carbonization, the resulting carbon is concentrated in the volume or on the surface of the pores; its structures are distinguished by high density and microporosity. The structure of the resulting carbonizate depends on the concentration and composition of the polymer and intermediates, carbonization conditions, rate of the process, etc. The difference in the structure of the carbonizates governs their properties: strength, density, total and closed porosities, and sorption properties [4–5].

We examined here the properties of porous materials based on highly dispersed silicon dioxide with a pyrocarbon coating formed from polystyrene carbonization.

EXPERIMENTAL

The structure-forming components were highly dispersed silicon dioxides (particle size 5–80 nm): hydrophilic Aerosils (A-300, S_{sp} = 300 $m^2 g^{-1}$; A-175, S_{sp} = 175 $m^2 g^{-1}$; A-50, S_{sp} = 50 $m^2 g^{-1}$) and hydrophobic Aerosils (AM, with modifying methyl groups on the surface, with S_{sp} = 175 $m^2 g^{-1}$; AO, with trimethylsilyl modifying groups on the surface, with S_{sp} = 195 $m^2 g^{-1}$). In the presence of a liquid dispersion medium, highly dispersed silicon dioxides form gels [6] which, after drying, were used as matrices for preparation of pyrocarbon. The precursor for carbon preparation was polystyrene (PS) with the molecular weight (MW) of 240 000. We used ethyl acetate solutions of PS with various concentrations for impregnation of the matrix obtained from silicon dioxide or as the dispersion medium. The carbonization of PS was carried out at 400 and 750°C in an argon flow. For technique of preparation of matrices and carbonized samples, see [7, 8].

Sorption of organic solvents by the composites was examined under static conditions at room temperature. The true density of the composites was determined pycnometrically, the porosity of the composites, from sorption of carbon tetrachloride [9]; and adsorption of Methylene Blue, by UV spectroscopy. [10]. The compression strength was determined for 1.0 × 1.0 × 0.5 cm samples.

Polystyrene is a virtually noncarbonizable polymer: Heating causes its degradation with breakdown of the backbone of the macromolecule and formation of low-molecular-weight volatiles. However, in carbonization in an inert gas atmosphere, removal of volatiles formed by PS degradation and their diffusion in the bulk of the samples are decelerated to such an extent that they get involved into secondary reac-

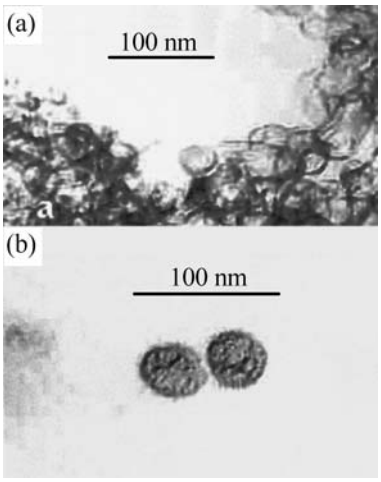

Fig. 1. TEM images of the carbon structures formed from carbonization of polystyrene introduced together with the dispersion medium into the pores of the composite based on A-50 silicon dioxide. Concentration of the polystyrene solutions in ethyl acetate, g per 100 ml: (a) 1.5 and (b) 5.

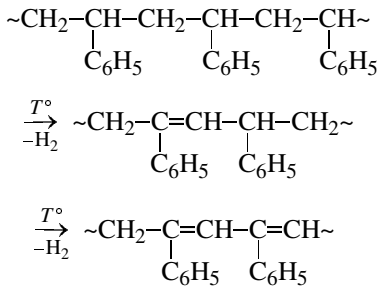
tions. Therefore, a coke residue can remain in the pores of the matrix composite.

The intermediates formed in thermal degradation in a vacuum of PS with MW of 230000 are compounds with MW of 264 at 500°C and 476 at 800°C, which evaporate before degradation. In thermal degradation in an inert gas atmosphere, these compounds decompose mainly to styrene; also formed are benzene, toluene, and minor amounts of other compounds [11]. It can be assumed that, in the composites of interest, the thermal degradation products formed when PS is carbonized at 750°C in an argon atmosphere undergo further transformations into carbon. The resulting samples were black. An elemental analysis confirmed that carbonizate was virtually pure carbon.

Madorsky [11] examined the amount of volatiles as influenced by the thermal degradation time at $T < 400$°C for PS with MW of 230000 and revealed a mass loss of 20–50% within 30 min. Thus, the yellow color of the samples in which PS was carbonized at 400°C is presumably due to formation of structures containing double bonds conjugated with the benzene ring [12]:



An elemental analysis confirmed that the carbonizate consisted of carbon (~95%) and hydrogen (~4 wt %).

As is known [13], the size of aggregates of the PS macromolecules in ethyl acetate at the concentration $c = 0.25$ g per 100 ml is 1000 Å; at $c = 1.5$ g per 100 ml, 4000 Å; and at $c = 5.0$ g per 100 ml, 890 Å, and their number is 0.017×10^9, 0.27×10^9, and 6.88×10^9, respectively. We have found earlier [7, 8] that the pore size of matrices based on A-50 silicon dioxide is such that the PS molecules with the conformation formed in a solution with the concentration of 5.0 g per 100 ml penetrate into these pores without hindrance during impregnation. To obtain composites with other concentrations of PS, its solutions were used as the dispersion medium for formation of polymer-containing gels carbonized after drying. Figure 1 shows TEM images of the carbon nanostructures formed in these composites. These are up to 5-nm-thick spherical segments with a diameter of up to 60 nm (Fig. 1a), or segmented spheres with a diameter of up to 60 nm (Fig. 1b).

Table 1 presents the properties of the carbon-containing composites obtained at 750°C. It is seen that these are highly porous materials, since their apparent

density d_{eff} is much lower than that of amorphous silicon dioxide and graphite (2.20 and 2.27 g cm^{-3}, respectively), and their structure depends on the concentration of PS being introduced into the matrix.

A decrease in the volume of the solvents sorbed v, ml g^{-1}, with increasing size of their molecules can be associated with the molecular sieve effect. An increase in the amount of the solvents sorbed on going from one composite sample to another is indicative of an increase in the porosity for the composites obtained from PS solutions of a higher concentration, and also of a change in the carbon coating structure. This is confirmed by a decrease in the true density of the composites with increasing precursor solution concentration. The adsorption of Methylene Blue by the composite prepared from A-50 silicon dioxide, using ethyl acetate as the dispersion medium was estimated at 17 mg g^{-1}. The fact that Methylene Blue is not sorbed by carbon-containing composites, whose properties are summarized in Table 1, suggests that these are microporous composites with a pore size under 1.3 nm [15].

Water sorption does not provide adequate information on the porosity of hydrophobic composites [14], but is indicative of the presence in the carbon composition of a large number of polar groups.

To prepare carbon-containing composites by introducing a carbonization precursor by the impregnation method, we obtained matrix composites from mixtures of highly dispersed silicon dioxides. Table 2 lists the composition and properties of these composites.

Table 3 summarizes the properties of the carbon-containing materials obtained from these composites. It is seen that these are highly porous materials whose properties vary with the matrix composition and PS solution concentration. A decrease in the PS concentration causes the effective density of the carbon-containing composites to increase. This is due to the change in the structure of the carbon coating, depending on the conformation of the PS macromolecules in the solution and, hence, on their interaction with silicon dioxide [13]. Introduction into the matrix of smaller, compared to A-50, silicon dioxide particles results in a denser packing [13]. On the one hand, this is responsible for an increase in the effective density of the composites, and on the other, the porosity increases due to additional formation of carbon from

the modifying groups when the modified silicon dioxides are introduced during carbonization.

Table 3 shows that the composites prepared by carbonization at 400°C differ only slightly in the properties from those carbonized at 750°C. The practical use of the former should take into account the presence in them of incompletely carbonized PS residues.

Comparison of the properties of the composites into which PS was introduced by impregnation (Table 3) and with the dispersion medium (Table 1) shows that the former have a smaller porosity, sorb smaller volumes of organic solvents, and the molecular-sieve effect is less pronounced or lacking.

The sorption characteristics of the obtained carbon-containing porous composites are by approximately an order of magnitude higher than those of commercial active carbons. The high sorption power and mechanical strength make these composites promising for practical application. A drawback of these composites is that, like commercial active carbons, they burn out at temperatures above 250°C.

CONCLUSIONS

(1) Polystyrene carbonization in matrices based on highly dispersed silicon dioxide yielded monolithic porous composites, which are, essentially, a pyrocarbon-coated silicon dioxide skeleton.

(2) Physicomechanical and sorption properties of the composites can be changed by varying the size and composition of the surface of the SiO_2 particles constituting the matrix, as well as the polystyrene concentration and the way of its introduction into the matrix.

Abstract—The phase diagrams of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–TBP–isooctane in the temperature range 298.15–333.15 K were constructed.

DOI: 10.1134/S1070427207060079

The mutual solubility of components in the binary systems decane (tetradecane)–REM(III) nitrate solvates with tri-*n*-butyl phosphate $[Ln(NO_3)_3(TBP)_3]$ at different temperatures was studied in [1, 2]. The phase diagrams of these systems contain the field of homogeneous solutions and the field of separation into two liquid phases. The upper critical solution temperature of these systems depends on the kind of a rare-earth metal(III).

The phase diagrams of the ternary systems $[Th(NO_3)_4(TBP)_2]$–$[UO_2(NO_3)_2(TBP)_2]$–decane (tetradecane) in the tempetrature range 298.15–333.15 K were constructed in [3, 4]. These diagrams contain a field of homogeneous solutions and a field of separation into two liquid phases (I, II). Phase I is enriched in $[Th(NO_3)_4(TBP)_2]$ and $[UO_2(NO_3)_2(TBP)_2]$, and phase II is enriched in saturated hydrocarbon diluent. In extraction of actinides and lanthanides with organic solutions of TBP, not only saturated hydrocarbon of normal structure, but also their isomeric derivatives, for example isooctane, are of interest as diluents.

No data have been reported on the phase diagram of the system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$-isooctane, which is of interest for extractive separation of thorium and REM.

Before use, TBP was distilled in a vacuum. The densities of TBP and isooctane $\rho_{298.15}$ were 0.9727 and 0.6868 g cm^{-3}, respectively. The solvates $[Th(NO_3)_4(TBP)_2]$ and $[Gd(NO_3)_3(TBP)_3]$ were prepared by three- or fourfold contact of TBP with concentrated aqueous solutions of Th(IV) and Gd(III) nitrates. The molar content of the stoichiometric solvates $[Th(NO_3)_4(TBP)_2]$ and $[Gd(NO_3)_3(TBP)_3]$, c (mol dm^{-3}), was 1.80 ± 0.01 and 1.10 ± 0.01, respectively. Their densities, $\rho_{298.15}$ (g cm^{-3}) were 1.7022 ± 0.0013 and 1.2755 ± 0.015, respectively.

The binodal curves were obtained by Alekseev's visual polythermal technique [1–4]. The content of $[Th(NO_3)_4(TBP)_2]$ and $[Gd(NO_3)_3(TBP)_3]$ in organic solutions was determined by complexometric titration [5, 6]. In preliminary experiments, we found that the volumes of solution of Th(IV) and Gd(III) nitrate solvates in isooctane are additive quantities within the limits of 0.3 vol %. The experimental compositions of the coexisting phases (vol %) were recalculated to the weight fractions, taking into account the solution densities. The binodal curves were approximated with polynomials of third and fourth degrees.

Our experimental results were represented as the phase diagram constructed in the form of the second Roozeboom's triangle in rectangular coordinates with weight fractions of two components along the coordinate axes (the weight fraction of the third component is calculated as the difference $\omega_3 = 1 - \omega_1 - \omega_2$). The determination error of the weight fraction of the components did not exceed $\pm(0.001 - 0.002)$. The determination error of temperature was ± 0.2 K.

The components of the binary system $[Gd(NO_3)_3 \cdot (TBP)_3]$-*iso*-$C_8H_{18}$ have infinite mutual solubility over the entire temperature range studied (298.15–333.15 K). By contrast, the similar system with satu-

Composition of coexisting phases in the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–*iso*-C_8H_{18} at 288.15–333.15 K

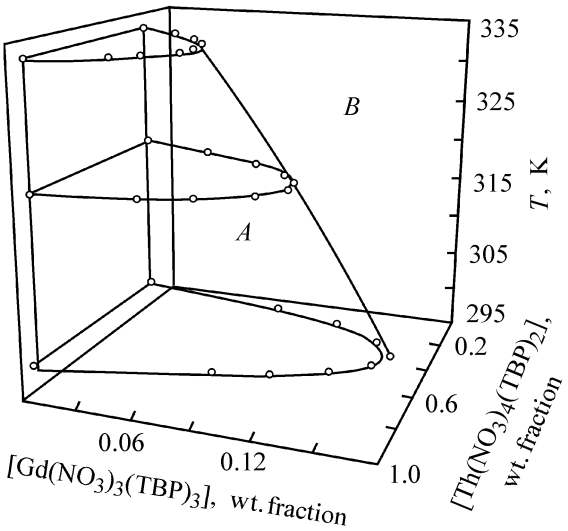

Fig. 1. Phase diagram of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–isooctane at different temperatures. (*A*) Field of separation into two liquid phases and (*B*) field of homogeneous solutions.

rated normal hydrocarbon separate into two phases. The binary system $[Th(NO_3)_4(TBP)_2]$–isooctane is a two-phase system over the entire temperature range studied (see table, Figs. 1, 2). It can be seen that, with increasing temperature, the mutual solubility of components in the binary system $[Th(NO_3)_4(TBP)_2]$–isooctane grows only slightly. We failed to determine the upper critical solution temperature in this binary system since, with the temperature increasing above 353.15 K, the system loses isooctane because of its evaporation.

At all the temperatures studied, the phase diagram of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–*iso*-C_8H_{18} contains a field of homogeneous solutions (*B*) and a two-phase field (*A*). These fields are bounded by binodal curves. With the tem- perature increasing from 298.25 to 333.15 K, the two-phase fields somewhat contract. The nodes in these diagrams show that one of the coexisting phases is enriched in both $[Th(NO_3)_4(TBP)_2]$

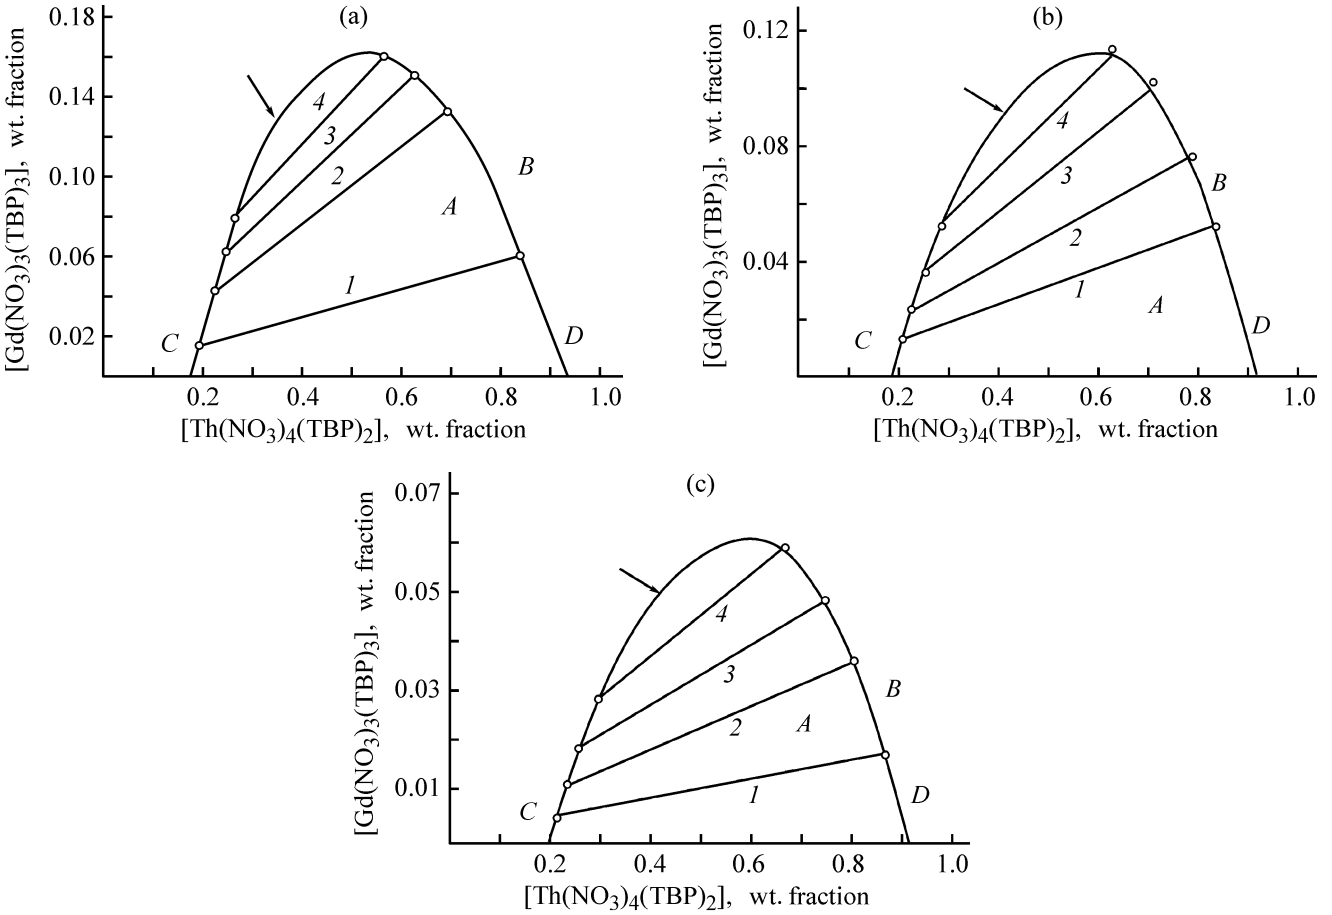

Fig. 2. Isothermal sections of the phase diagram of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–*iso*-C_8H_{18}. (*1*)–(*4*) Nodes of the binodal curves. The arrow shows the critical point in a binodal curve. (*A*) Field of separation into two liquid phases, (*B*) field of homogeneous solutions, and (*CD*) binodal curve. Temperature, K: (a) 298.15, (b) 318,15, and (c) 333.15.

and $[Gd(NO_3)_3(TBP)_3]$ (phase I), and the other is enriched in isooctane (phase II).

Figure 2 shows that, with the temperature increasing from 298.15 to 333.15 K, the $[Th(NO_3)_4(TBP)_2]$ concentration at the critical point grows (from 0.35 to 0.43 wt fraction), the $[Gd(NO_3)_3(TBP)_3]$ concentration decreases (from 0.13 to 0.051 wt fraction), and the isooctane content remains virtually constant (~0.52–0.53 wt fraction). This means that, with increasing temperature, $[Gd(NO_3)_3(TBP)_3]$ and isooctane dissolve in phase I to a greater extent, whereas phase II becomes enriched in $[Th(NO_3)_4(TBP)_2]$.

It should be noted that, whereas the binary systems $[Gd(NO_3)_3(TBP)_3]$–decane (tetradecane) containing normal saturated hydrocarbon separate into two phases, the binary system $[Gd(NO_3)_3(TBP)_3]$-isooctane is homogeneous over the entire composition range.

Addition of $[Gd(NO_3)_3(TBP)_3]$ to the heterogeneous system $[Th(NO_3)_4(TBP)_2]$–isooctane homogenizes the resulting ternary system at the temperature-dependent critical points.

Thus, to prevent formation of the second organic phase in extraction of Th and Gd nitrates with solution of TBP in isooctane in the temperature range 298.15–333.15 K at saturation of the extractant with metals, the content of Th nitrate solvates with TBP in the organic phase should be lower than 0.30, and the content of Gd nitrate solvate, no less than 0.13 wt fraction. Taking into account that REM(III) nitrate solvates and isomeric saturated hydrocarbons have infinite mutual solubility at all the temperatures, these solvents are more preferable in extraction than normal saturated hydrocarbons.

CONCLUSIONS

(1) The binary system $[Gd(NO_3)_3(TBP)_3]$–decane (tetradecane) containing normal saturated hydrocarbon solvents separates into two phases, whereas the binary

system $[Gd(NO_3)_3(TBP)_3]$–isooctane is homogeneous over the entire composition range. The binary system $[Th(NO_3)_4(TBP)_2]$–isooctane separates into two phases over the entire temperature range studied (T = 288.15–333.15 K).

(2) At all the temperatures studied the phase diagram of the ternary system $[Th(NO_3)_4(TBP)_2]$–$[Gd(NO_3)_3(TBP)_3]$–*iso*-C_8H_{18} contains a field of homogeneous solutions (*B*) and a two-phase field (*A*). These fields are bounded by binodal curves. With the temperature increasing from 298.25 to 333.15 K, the two-phase fields slightly contract. The nodes in these diagrams show that one of the coexisting phases is enriched in both $[Th(NO_3)_4(TBP)_2]$ and $[Gd(NO_3)_3(TBP)_3]$ (phase I), and other phase is enriched in isooctane (phase II).

(3) Addition of $[Gd(NO_3)_3(TBP)_3$ to the heterogeneous binary system $[Th(NO_3)_3(TBP)_3]$–isooctane homogenizes the ternary system at the temperature-dependent upper critical points. Thus, to prevent formation of the second organic phase in extraction of Th and Gd nitrates with a solution of TBP in isooctane at saturation of the extractant with metals, the content of Th nitrate solvates with TBP in the organic phase should be lower than 0.30, and the content of Gd nitrate solvate, no less than 0.13 wt. fraction. Taking into account that REM(III) nitrate solvates and saturated isomeric hydrocarbons have infinite mutual solubility at all the temperatures, these solvents are more preferable in extraction than normal saturated hydrocarbons.

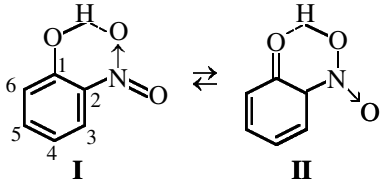
Abstract—The reactions of 2-nitro-, 2-nitro-4,6-dichloro-, 2,4-dinitro-, and 2,4,6-trinitrophenols with aluminum bromide in nitromethane solution were studied by calorimetry and by ^{1}H and ^{13}C NMR.

DOI: 10.1134/S1070427207060080

The reactions of methylated phenols, naphthols, and polyphenols with strong Lewis acids in nonaqueous solutions frequently result in tautomeric transformations [1–4]. Data on the reactions of nitrophenols with Lewis acids are searce. For example, it has been found that the reaction of 4-nitrophenol with $TiCl_4$ in benzene at room temperature yields the salt NO_2–C_6H_4–O–$TiCl_3$ [5]. In dry methanol, iron(III) chloride forms a coordination compound with 4-nitrophenol via OH group [6]. Complexes of 2-nitrophenol with gallium, aluminum, and boron halides in organic solutions were studied in [7, 8]. It was concluded that a coordination bond of metal halides with the nitro group is formed; however, in [9] this conclusion was to questioned.

The most complete data on the structure of complexes of nitrophenols with metal halides can be obtained by NMR spectroscopy. Therefore, we synthesized complexes of *o*-nitrophenols with aluminum bromide and recorded ^{1}H and ^{13}C NMR spectra of these complexes.

It is well known that metal halides are bonded in nonaqueous solutions with aromatic nitro compounds via nitro group [10, 11]. In the presence of other donor groups, such as hydroxy, carbonyl, or amino group, the coordination site may change. In the case of *o*-nitrophenol, nitro-aci tautomerism **I** : **II** is also possible



I **II**

Furthermore, formation of complexes of different compositions is possible; thus, the pattern becomes complicated.

To determine the stoichiometry of complexes of *o*-nitrophenol **I** with aluminum bromide, we performed calorimetric measurements. First, an 0.01 M solution of *o*-nitrophenol in bromobenzene was titrated with an $AlBr_3$ solution at 100°C and then back-titration was performed. The experimental procedure has been repeatedly described in the literature [9, 10]. In the dependence of the enthalpy of reaction on the molar ratio of donor and acceptor $m_D : m_A$, there are two inflections: at the ratios of 1 : 1 and 1 : 2. The heat effects were evaluated by the procedure described in [9], assuming that the enthalpy of reaction is expressed by the equation

$$\Delta H_c = \Delta H_e + 0.5\Delta H Al_2Br_6 - \Delta H_{solv},$$

where ΔH_c is the heat of complexation; ΔH_e, enthalpy determined experimentally; $\Delta H Al_2Br_6$, enthalpy of dimer dissociation; and ΔH_{solv}, enthalpy of solvation [4].

The first portion of the curve corresponds to ΔH_c = 31.5, and the second, to 20.1 kJ mol^{-1}. The total thermal effect is 51.6 1 kJ mol^{-1}.

To estimate the energy of *o*-nitrophenol transformation into an aci tautomer, we performed a quantum-chemical calculation. The molecular configurations of **I** and **II** were optimized using the restricted Hartree–Fock method. The energies were estimated by considering correlation effects in the framework of the Møller–Plesset method (MP-2) [13]. In the cal-

V

To find the structure of the complexes, we recorded their ^{1}H and ^{13}C NMR spectra. The ^{1}H chemical shifts of the initial phenols and complexes are listed in the table. The specific feature of the spectra of free *o*-nitrophenols is that the signals of hydroxylic protons are shifted downfield (10–11 ppm) due to the presence of intramolecular hydrogen bond [10], contrary to phenols associated by intermolecular bonds (4–5 ppm) [2].

Attempts to obtain a complex of 2-nitrophenol with $AlBr_3$ in inert solvents at room temperature failed, since the reaction is complicated by the release of gaseous hydrogen bromide. The most suitable solvent was nitromethane.

The influence of $AlBr_3$ on the chemical shifts of nitro compounds bound into in a complex was demonstrated for nitrobenzene as an example. The ^{1}H NMR spectrum of its complex shows no differences from that of free nitrobenzene, except a certain broadening of the signals. This fact suggests that, in coordination with aluminum bromide, the charge on the nitrogen atom of the nitro group does not noticeably change [11].

In the spectrum of a solution of 2-nitrophenol with $AlBr_3$ the ^{1}H signals are noticeably shifted upfield (not downfield, as it is observed for complexes of methylated phenols and naphthols) relative to the signals of the initial phenol. Hence, it can be assumed that the coordination mode of 2-nitrophenol differs from that of nitrobenzene and phenols. The signals with chemical shifts of 8.37 and 8.13 ppm (approximately 3 : 1) were assigned to hydroxyl protons of complex compounds, since they have integral intensities corresponding to one hydrogen atom each. Accidentally, the chemical shifts of the 1 : 1 and 1 : 2 complexes almost coincide; as a result, all the signals in the spectrum are broadened. The ^{1}H signal of 3-H (8.12 ppm, $J_{3,4}$ 8.55; $J_{3,5}$ 1.64 Hz in the initial phenol) is a doublet at 7.89 ppm; in this case, no Moler remote coupling is observed. The split triplet of 5-H gives broadened signal at 7.75 ppm. The hydrogen atoms 4-H and 6-H appearing in the form of a split doublet at 7.17 and triplet at 7.08 in the initial *o*-nitrophenol in the complex give an unresolved multiplet in the range 6.8–7.1 ppm.

On heating, hydrogen bromide is released from the solution as a result of formation of 2-NO_2–C_6H_4–O–Al_nBr_{3n-1}, and the intensities of the signals at 8.37 and 8.13 ppm decrease. All other signals remain unchanged. This fact indicates that the chemical shifts of the complexes and aluminum salts are close. A similar fact has been noted previously [14]. After recording the spectrum, hydrogen bromide was passed with cooling through the resulting solution until its saturation. As a result, the intensities of signals of hydroxyl protons increased to the initial value. The absence of any other changes in the ^{1}H NMR spectrum after saturation of the solution with HBr suggests that the complex compounds are protonated neither via the ring nor via the functional groups.

To elucidate whether the complexes obtained are actually complexes of aci form **II**, we recorded the ^{13}C NMR spectrum of a solution of 2-nitrophenol with $AlBr_3$. We did not find a signal at 170–190 ppm (coordinated carbonyl group [15]), which suggests the absence of a system of double bonds >C=O and >C=N–. This fact is in good agreement with calculations and calorimetric measurements.

The effect of substituents on the complexation of *o*-nitrophenols was determined in the reactions of 2-nitro-4,6-dichloro-, 2,4-dinitro-, and 2,4,6-trinitrophenols with $AlBr_3$ in nitromethane.

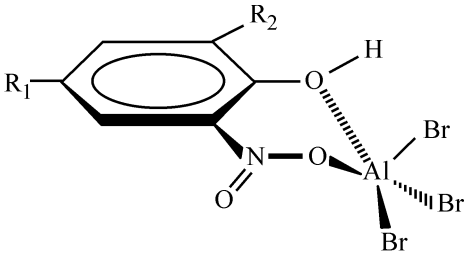
In the spectrum of a solution of 2-nitro-4,6-dichlorophenol with $AlBr_3$, the signal of 3-H protons is shifted upfield from 8.14 to 7.84 ppm, the signal of 5-H proton is split into two (7.81 and 7.80 ppm) but remains virtually at the same place. In addition, instead of the low-field (10.7 ppm) signal of the hydroxyl proton, two signals whose intensity corresponds to one proton appear in higher field at 8.54 and 8.28 ppm (ratio approximately 3 : 1).

The signal of 3-H in the spectrum of a solution of 2,4-dinitrophenol with $AlBr_3$ is shifted upfield from 9.05 to 8.79 ppm. The doublet of 6-H (7.45 ppm) is shifted to 7.25 ppm. The doublet of 5-H (8.49 ppm) transforms into a complex set of signals in the range 8.55–8.62 ppm, suggesting the existence of several complexes in the solution. Two signals of hydroxyl protons appear in the spectrum: at 8.86 ppm and in the range of the 5-H signal at 8.65 ppm. In the ^{13}C NMR spectrum of the 2,4-dinitrophenol complex, there are signals at 162.8 (C_1), 131.0 (C_2), 134.3 (C_3), 137.0 (C_4), 125.3 (C_5) and 125.3 ppm (C_6). As in the preceding case, the signals in the range 170–190 ppm corresponding to the coordinated C=O group [15] were not found.

A similar pattern is observed in the reaction of 2,4,6-trinitrophenol with $AlBr_3$. It is the common opinion that the yellow color of 2,4,6-trinitrophenol solution is caused by appearance of an aci structure (type **II**) [16]. However, both ^{1}H and ^{13}C NMR signals correspond to picric acid in the phenolic form. Upon addition of $AlBr_3$, the color of the solution becomes deeper and the signal of aromatic protons is insignificantly shifted upfield. In parallel, two signals appear at 8.65 and 8.40 ppm, whose intensity corresponds to one proton.

Thus, the NMR spectra show that, irrespective of the structure of *o*-nitrophenols, two complexes in which the aromaticity of the benzene ring is preserved are formed with $AlBr_3$.

The whole set of the results obtained is well accounted for by formation of chelate complexes. When considering a model of chelate complex 1 : 1 **V** (complex 1 : 2 has apparently the same structure excluding the fact that aluminum bromide is dimer), it is seen that $AlBr_3$ should be situated between OH and NO_2 groups. This arrangement of $AlBr_3$ will result in rupture of the intramolecular hydrogen bond. Due to the formation of a chelate, the fractional positive charge on the oxygen atom of the hydroxy group will be lower than that in the oxonium complex; therefore, the shift of hydroxyl proton in the NMR spectra will be intermediate between the shift in free phenols and oxonium complexes, which is actually observed. The upfield shift of aromatic protons in complexes is apparently caused by the anisotropic effect of aluminum atom in the resulting six-membered ring.



V

The model suggested is additionally confirmed by the ^{17}O NMR spectra obtained previously for the complex 2-NO_2–C_6H_4–OH · BCl_3 [8]. In the spectrum of the complex, two signals appear at 560 and 406 ppm, instead of one signal of two oxygen atoms of nitro group (569 ppm). The signal of oxygen atom of the hydroxy group is shifted after coordination from 94 to 144 ppm, i.e., one oxygen atom of nitro group and oxygen atom of hydroxy group are involved in

the coordination. This fact can be explained by assuming that a chelate complex of *o*-nitrophenol with BCl_3 is formed.

EXPERIMENTAL

The phenols used had the following mp (°C): 2-nitrophenol 45.3–45.7, 4-nitrophenol 113–114, 2-nitro-4,6-dichlorophenol 124–125, and 2,4-dinitrophenol 115–116. Nitromethane was dried and distilled at bp 102–103°C. The complexes were prepared by dissolution of aluminum bromide in nitromethane with subsequent addition of nitrophenols in a molar ratio of 2 : 1 to the suspension cooled to –20°C. The enthalpy of the reaction of 2-nitrophenol with aluminum bromide was determined by the procedure described in [12]. The solutions of complexes were saturated with hydrogen bromide at 0°C. The ^1H NMR spectra were recorded on a Bruker Avance 200 spectrometer. In recording the spectra of free nitrophenols, TMS was used as an internal reference; the spectra of complexes were recorded using nitromethane as a reference (4.28 ppm).

CONCLUSIONS

(1) Calorimetric measurements show that *o*-nitrophenol forms 1 : 1 and 1 : 2 complexes with aluminum bromide, with the enthalpy of formation of 31.6 and 20.1 kJ mol^{-1}, respectively.

(2) Quantum-chemical calculation estimates the enthalpy of transition of *o*-nitrophenol into the aci form at 72.7 kJ mol^{-1}.

(3) The experimental data obtained indicate that *o*-nitrophenols in complexes with the chelate structure remains aromatic.

SORPTION AND ION-EXCHANGE PROCESSES

Criteria for Choice of a Brand of Activated Carbon for Hydrometallurgical Recovery of Gold from Ore Pulps in Carbon-in-Leaching and Carbon-in-Pulp Processes

Received January 24, 2007

Abstract—Criteria used to choose activated carbons suitable for sorption recovery of the $[Au(CN)_2]^-$ anion from cyanide ore pulps are considered. Results obtained in the development of authors' own tests for determining the mechanical strength and loss of carbons via their disintegration in this technological process are presented. Changes occurring on the surface of grains of activated carbon in its agitation in abrasive media and specific features of the design of sorption apparatus that can be used for rationally carrying out carbon-in-pulp and carbon-in-leaching processes are discussed.

DOI: 10.1134/S1070427207060092

One of the most important events of the last quarter of the XX century in hydrometallurgy of gold was the introduction of sorption technologies employing activated carbons (AC). These sorbents can be used for recovery of gold from clarified solutions in column apparatus (carbon-in-column, CIC process) or be introduced into the pulp. Depending on the ore composition, AC can be delivered into the pulp together with the leaching agent (carbon-in-leach, CIL process) or after preliminary leaching of gold (carbon-in-pulp, CIP process). As a rule, the CIL process is used in those cases when the ore contains natural sorption-active materials that can adsorb $[Au(CN)_2]^-$ anions from solution. In the second edition of the widely known monograph by Marsden and House [1], the introduction of the CIP technology into the world practice of gold mining in 1972–2000 was named the "CIP revolution." Indeed, more than 50% of world's gold production is presently done with the use of AC [2]. The main advantages of the carbon sorption technologies consist in the economics of the process, which is determined not in the last turn by avoiding the procedures of thickening, counter–current decantation washing of cakes, and filtration. This is particularly important in processing of poorly thickening and poorly filterable pulps and solutions.

In Russia, modern carbon technologies started to be introduced into gold mining practice only in the late 1990s. In the fraction of gold recovered by carbon sorption technologies, Russia occupied, in the end of 2004, 12th place among the 15 largest manufactures of this metal, being only ahead of China, Peru, and Chile [3]. At the same time, the Russian Federation firmly held fifth place in overall manufacture of gold. Presently, use of carbon technologies in domestic gold mining is hindered by a number of objective and subjective factors. Among these is the lack of the relevant literature accessible to most of domestic specialists and insufficient experience in choice and optimal use of AC in CIL and CIP processes. In this communication, we dwell on the last of the problems mentioned above.

When choosing an AC brand for CIL or CIP processes, the following carbon characteristics are commonly taken into account [1, 4]:

kinetic parameters of gold(I) sorption on carbons;

mechanical strength;

adsorptive capacity;

shape and size of adsorbent particles;

bulk density;

content of fine and dust particles in the carbons;

loss of the material in reactivation and conditioning;

ash content after burning of the starting materials;

cost of the adsorbent.

The first two parameters are believed [4] to be the most important and predetermine the choice of an AC brand. The rest are related to the first two, or to conditions of a technological process, or, as shown below, bear no relation to solution of the problem under consideration.

The adsorption kinetics of the $[Au(CN)_2]^-$ anion on AC particles, which governs the principles of process simulation and the choice of an AC brand, are rather difficult in analysis and mathematical description. It is commonly believed [5, 6] that, in the first stage of sorption (far from carbon saturation), gold(I) is adsorbed on the surface of macro- and mesopores in AC at a high rate and the process itself occurs under outer-diffusion control and is described by the film-diffusion mechanism. In this stage, pseudo-equilibrium is attained rather rapidly (in 2–48 h [6, 7]). The rate constant k_1 of $[Au(CN)_2]^-$ ion adsorption on AC corresponds in the case in question to a first-order reaction and is described by the following equation

$$d[Au]_c/dt = k_I[Au]_s, \quad (1)$$

where $[Au]_c$ and $[Au]_s$ are, respectively, the concentrations of gold(I) in the carbon and solution phases.

The adsorption rate constant k_I depends on a multitude of parameters [5, 6]:

pulp agitation intensity (increases to a certain limit with the agitation intensity);

pulp viscosity and density (decreases as either of these increases);

temperature (increases with temperature);

NaCN concentration and pH value (decreases as either of these increases);

AC particle size (inversely proportional to the carbon particle size);

total and relative numbers of macro-, meso-, and micropores in the AC structure;

presence in the liquid phase of the pulp of organic and inorganic compounds and ions that can block sorption centers of the carbon;

ionic strength of the solution (increases with the ionic strength of the solution to a certain limit and then falls).

With account of the parameters listed above, CIL and CIP processes are, as a rule, carried out in the turbulent mode of pulp agitation at pH not exceeding 10.8 and as low sodium cyanide concentration as possible. The last requirement is also due to the fact that, after adsorption cyanidation, the pulp is commonly subjected to detoxication and high concentrations of the residual cyanide in the pulp will lead to an increase in expenditure for detoxication. In addition, AC catalyzes oxidation of the cyanide anion by atmospheric oxygen [8]. This process is the most intense if copper(I) compounds are present in solution [9], which also leads to unjustified loss of sodium cyanide.

In a real industrial sorption process performed in the counter–current mode, the value of k_I is not lower than 80–100 h^{-1} and should remain approximately constant in all tanks of the cascade, irrespective of the concentration of the $[Au(CN)_2]^-$ anion in the liquid phase in each vessel [7].

The most acceptable from the standpoint of adsorption kinetics would be carrying out the process in dilute, as regards the content of the solid phase, pulps. However, the economics of the process, necessity for precluding carbon segregation in too liquid or too thick pulps, and requirements to the sedimentation stability of the pulps themselves result in that sorption is commonly performed with pulps with a content of the solid phase equal to 40–50 wt %.

In the second stage of adsorption, $[Au(CN)_2]^-$ anions slowly diffuse into the micropores of AC. This process occurs under inner-diffusion control. The duration of the adsorption process in the second stage may exceed that of the first stage by a factor of 10 and more. Although the content of gold(I) in the AC phase grows in the second stage of sorption, this stage makes difficult the subsequent desorption of gold(I) from carbon micropores and impairs the economics of the process.

The variation of the gold(I) concentration in the liquid and solid phases of the pulp in adsorption of the $[Au(CN)_2]^-$ anion from solution onto activated carbon can be described by the equations [6]:

$$-d[Au]_s/dt = (kM_c/M_s)(K[Au]_s - [Au]_c), \quad (2)$$

$$d[Au]_c/dt = k(K[Au]_s - [Au]_c). \quad (3)$$

Here, $k = k_s k_c A/(k_c K + k_s)$; k_s and k_c are the mass-transfer coefficients of Au(I) in solution and in carbon pores; K, equilibrium constant; A, surface area of a unit volume of AC; and M_c and M_s, masses of carbon and solution, respectively.

The adsorption rate of Au(I) on AC particles in a stage of the industrial counter–current process is

commonly evaluated using the following simple empirical equation [6]:

$$\Delta[\mathrm{Au}]_c = k''[\mathrm{Au}]_s t^n. \quad (4)$$

Here, $\Delta[\mathrm{Au}]_c$ is the change in the gold(I) concentration on carbon (g ton^{-1}) in a time t (h) elapsed after the transfer of AC from the preceding stage; $[\mathrm{Au}]_s$, gold(I) concentration in solution (mg l^{-1}); and k'' rate constant of the process.

For each industrial plant, the parameters k'' and n take their own values.

In view of the wide diversity of factors affecting the adsorption kinetics of the $[Au(CN)_2]^-$ anion on AC, the suitability of a carbon for use in sorption processes in laboratory is occasionally assessed on the basis of pseudokinetic constants k' [10]. The method for determining k' is based on the test in which an AC sample (0.5 g) is agitated at a certain frequency (100 min^{-1}) in a 0.5-l bottle roll agitator in contact with a solution containing gold(I) in the form of the $[Au(CN)_2]^-$ ion and NaCN in concentrations of 10 and 250 mg l^{-1}, respectively, at pH 10.0. Samples for determining the Au(I) content are taken in 0, 0.5, 1.0, 2.0, and 3.0 h. The value of k' is found from Eq. (4), which is transformed for convenience to

$$\log \Delta[\mathrm{Au}]_c^t/[\mathrm{Au}]_s^t = n\log t + \log k'. \quad (5)$$

Here, $\Delta[\mathrm{Au}]_c^t$ is the change of the Au(I) concentration on the carbon relative to $t = 0$ (g ton^{-1}); $[\mathrm{Au}]_s^t$, Au(I) concentration in solution at a time t (mg l^{-1}); n, experimentally found parameter ($0.6 < n < 1.2$); and t, time (h).

For good-quality AC, the value of k' at 25°C is within the range 800–1300 h^{-1} [10]. Comparison of various AC brands in the value of k' enables choice of the best, among several brands, carbon having the highest adsorption rate under the standard conditions. However, these conditions do not correspond to the real conditions characteristic of industrial CIP or CIL processes. The method considered here may be of use in preliminary screening of ACs. It is convenient to compare the constant k' of an AC under study with that of the reference carbon during the same period of time, e.g., in $t = 1$ h, with the following simple equation used instead of (4) [10]:

$$[\mathrm{Au}]_s^t = 10000/(k' + 1000). \quad (6)$$

The working experience of South-African plants shows that the average time of contact of an AC with the $[Au(CN)_2]^-$ anion in CIP processes commonly does not exceed 24 h in each sorption apparatus [24]. An economical criterion of the necessity for carbon transfer between apparatus in the counterflow scheme is the ratio between the gold(I) concentration in the carbon phase, $[\mathrm{Au}]_c$ (g ton^{-1}), to that in solution, $[\mathrm{Au}]_{aq}$ (mg l^{-1}):

$$[\mathrm{Au}]_c/[\mathrm{Au}]_{aq} = 750–1000. \quad (7)$$

It has been found [7] that mechanical agitation of a pulp with AC is substantially better than pneumatic agitation as regards the effect on the adsorption kinetics of gold(I).

One of the principal disadvantages of the CIL and CIP processes is the accompanying wear of carbon particles, whose part is lost in the form of fine fractions with a particle size of less than 1 mm. Particles of AC disintegrate in all stages of its existence, from transportation to a consumer to carbon reactivation at a gold mining plant (GMP). Among the factors leading to wear of carbon particles and loss of carbon, we can mention the following:

damage to and disintegration of carbon particles upon collisions with impeller blades and other members of adsorptive cyanidation apparatus;

mechanical disintegration of carbon in its transport by pumps and abrasion against pipeline walls and screen grids;

abrasion of AC particles by solid particles of the pulp;

cracking of carbon under sharp temperature changes in autoclave desorption and quenching after reactivation in a kiln;

loss of carbon for oxidation and abrasive wear in the regeneration kiln (5–10%);

abrasion of carbon by carbon particles themselves in preliminary conditioning and subsequent screening of carbon (1.5 to 30%).

It is important to emphasize that the first four reasons for carbon loss are accompanied by removal of fine AC particles containing adsorbed gold(I) from the technological process. This may lead to loss of up to 0.85 kg of Au per ton of carbon fines [2].

The loss of AC at GMPs is directly associated with the strength of AC particles. At present there exist three approaches to determination of the strength properties of AC [10, 11]. Abroad, “dry” methods of abrasion in a rod mill (abrasion index, AI) or on

a vibrating sieve with balls (ball-pan hardness, BPH) are used for this purpose [11, 12].

In Russia, the mechanical strength of AC is evaluated in conformity with GOST (State Standard) 16188–70 [13] by grinding a dry weighed portion in a rod mill for 3 min, followed by sieving of the sorbent and determination of its mechanical strength Π (%) by the formula

$$\Pi = \frac{m}{M} \times 100. \quad (8)$$

Here, M and m are, respectively, the masses (g) of a dry weighed portion of carbon, with preliminarily removed fine fractions, and that after grinding.

This procedure, which is largely similar to the foreign method for determining the abrasion index AI [11], has been developed for evaluating the mechanical strength of catalysts.

For example, it is known that the value of Π is 85% for a domestic carbon of IPI-T brand and 91.5% for a TAIKO CW 814 Japanese carbon. It is clear that the information importance of these figures is rather poor, because they give no way of prognosticating the working life of a sorbent and furnish no evidence concerning the control over the particle comminution process in industrial apparatus with intensive pulp motion under the action of mechanical agitating devices (MAD). These methods for testing of AC samples can only reveal differences in their mechanical properties under the conditions of a particular test. Carbons with good mechanical properties according to tests performed in conformity with GOST 16188–70 have Π exceeding 90%. The parameter Π is commonly several units lower than the AI and BPE parameters obtained using foreign methods [11, 12].

Specialists of a Dutch company Norit introduced into the practice of mechanical testing of AC the so-called "wet" method. This technique is based on mixing of AC grains with a water-sand pulp simulating the CIP or CIL process [10, 11, 15]. Comparison of the results of dry and wet tests for AC shows that the strength of carbon increases with the size of its grains in dry tests and the reverse pattern is observed with the wet method [10]. However, the varieties of wet tests considered in the literature [10, 11, 15] for AC samples, as applied to real industrial hydrometallurgical processes, have similar disadvantages, because the technical characteristics of laboratory apparatus, granulometric parameters of sand, and concentration of AC particles in AC conditioning are taken without regard for specific features of real apparatus in which the test results will be used.

In this communication, we suggest to perform laboratory tests of the adsorbent under conditions that are closer to the real industrial process. This will enable not only correct prognostication of the loss of activated carbon and precious metals, but also control over the abrasion rate of the sorbent by making a rational choice of the design and basic parameters of apparatus for sorption cyanation.

The problems of abrasion (disintegration) of solid materials have been actively studied in recent decades as regards the appearance of secondary particles in crystallizers with stirrers [16] and bead mills in manufacture of pigments [17], erosion wear of stirrer blades [18, 19], specific features of floccule disintegration in microbiological industry [20], etc. The process of particle abrasion in apparatus with stirrers is rather complex and has not been reliably mathematically substantiated so far. However, the already accumulated experimental information indicates that the most important parameters governing the kinetics of particle abrasion are the following:

specific agitation power introduced from the outside into the process under study and the shear stresses dependent on this power [18, 20];

properties of the materials of moving particles and apparatus members interacting with these particles [18, 20];

size and number of solid particles [18–21];

design of the apparatus and its technical characteristics [17–21].

It is noteworthy that this multitude of important parameters should be considered simultaneously with the requirement of complete suspension of precipitated particles of the ore being cyanidated at the so-called determining rotation frequency of the stirrer [22]

$$n_0 = 10.4\frac{D}{d^2}\left[\frac{(\rho_{sol} - \rho_{liq})\delta(1 - \varepsilon_{pr})f\Gamma_D}{\rho_{ss} K_N}\right]^{0.5} \quad (9)$$

at which the power N expended for agitation is calculated using the known formula [23]:

$$N = K_N \rho_{ss} n_0^3 d^5. \quad (10)$$

Here, D and d are the diameters of the apparatus and stirrer, respectively; Γ_D and K_N, simplex of geometric similarity of the stirrer and its power coefficient; f, internal friction coefficient of particles; ρ_{liq}, ρ_{sol}, and ρ_{ss}, density of liquid and solid phases and suspension, respectively; δ, particle size; and ε_{pr}, precipitate porosity.

Simulation studies of the abrasion kinetics of activated carbon particles should be governed by the condition necessary for suspension: the shear stresses in shear of a monolayer of particles of the industrial pulp in model (τ_m) and industrial (τ_{ind}) apparatus should be equal:

$$\tau_m = \tau_{ind} = (\rho_{sol} - \rho_{liq})\delta f g(1 - \varepsilon_{pr}), \quad (11)$$

where g is the acceleration of gravity.

As is known [24], from (11) results formula (9) and the following scaling rules for smooth-wall apparatus with MAD:

$$n_0 D^q = \text{idem}, \quad (12)$$

$$PD^q = \text{idem}, \quad (13)$$

$$T = \text{const}, \quad (14)$$

where $P = N/V$ is the specific power expended for pulp agitation in an apparatus of volume V; $T = [N/(2\pi n_0)]/V$, specific rotational moment of the MAD; and q, constant dependent of the stirrer type and suspension agitation mode [23]. In the case of a three-blade stirrer with a blade angle $\alpha = 24°$, considered here, q is 0.9.

Let us consider as an example of application of relations (9)–(14) to simulation of the process of carbon particle abrasion the apparatus for sorption cyanation, working at one of Russia's GMPs. The sorption apparatus and the pulp in these apparatus have the following parameters: $V_{ind} = 280$ m^3, $D_{ind} = 7$ m, $d_{ind} = 2.8$ m, $n_{ind} = 0.5$ s^{-1}, $x = 0.474$; $\delta = 0.074$ mm, $\rho_{sol} = 2860$ kg m^{-3}, and $\rho_{liq} = 1000$ kg m^{-3}.

The volume concentration of activated carbon is maintained within the range 5%. All the AC samples used at the GMP and in laboratory experiments were of industrial manufacture. An AC sample produced from the coconut shell by its carbonization and activation (henceforth, coconut carbon) had an average particle size d_C 3.35 × 1.70 mm (6 × 12 mesh). Extruded (molded) AC obtained from a complex composite material had cylindrical particles with a diameter $d_C = 1.5$ mm and length equal to two to three diameters. The model laboratory apparatus geometrically similar to the industrial apparatus had the following parameters: $V_m = 0.003$ m^3, $D_m = 0.150$ m, $d_m = 0.060$ m. The chemically active ore was replaced in laboratory experiments on abrasion of AC grains with neutral sand of the corresponding granulometric composition and concentration, and distilled water was used as dispersion phase.

The rotation frequency of MAD on the model stand was calculated in accordance with the scaling rule (12):

$$n_{ind} D_{ind}^{0.9} = n_m D_m^{0.9} \quad (15)$$

to be

$$n_m = 0.5\left(\frac{7}{0.15}\right)^{0.9} = 15.9 \text{ s}^{-1}.$$

In the first stage of the study, only $z = 15$ of coarse grains of the carbon, rather than 5 vol %, was charged into a water-sand pulp with a mass fraction of sand, $x = 0.474$. Such a small number of grains can be readily separated after a certain time, together with the fragments formed, from the pulp with a sieve with a 0.5-mm mesh, washed, dried, and weighed on an analytical balance, after which changes in grains agitated together with the pulp can be visually analyzed. To reveal the main reason for abrasion and comminution of grains, experiments were carried out two times for each carbon brand: with steel stirrer blades in one experiment and rubber-coated blades in the second, with the latter leading to an elastic interaction between a grain and a rotating blade.

The run of the curves in Fig. 1 and the number of coarse grains (number z near the corresponding curve

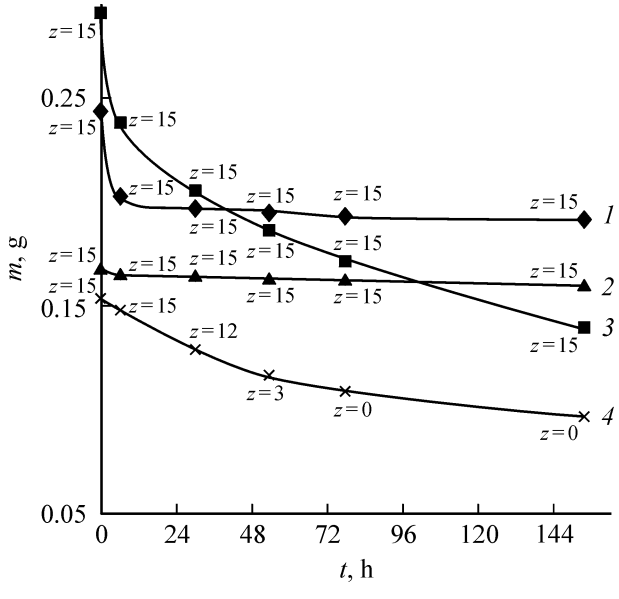

Fig. 1. Mass m of a sample vs. the abrasion time t for abrasion of 15 particles at a clockwise rotation of stirrer blades with $d = 60$ mm. (z) Number of intact grains. Carbon: (*1*) coconut, rubber-coated blades; (*2*) molded, rubber-coated blades; (*3*) coconut, steel blades; and (*4*) molded, steel blades.

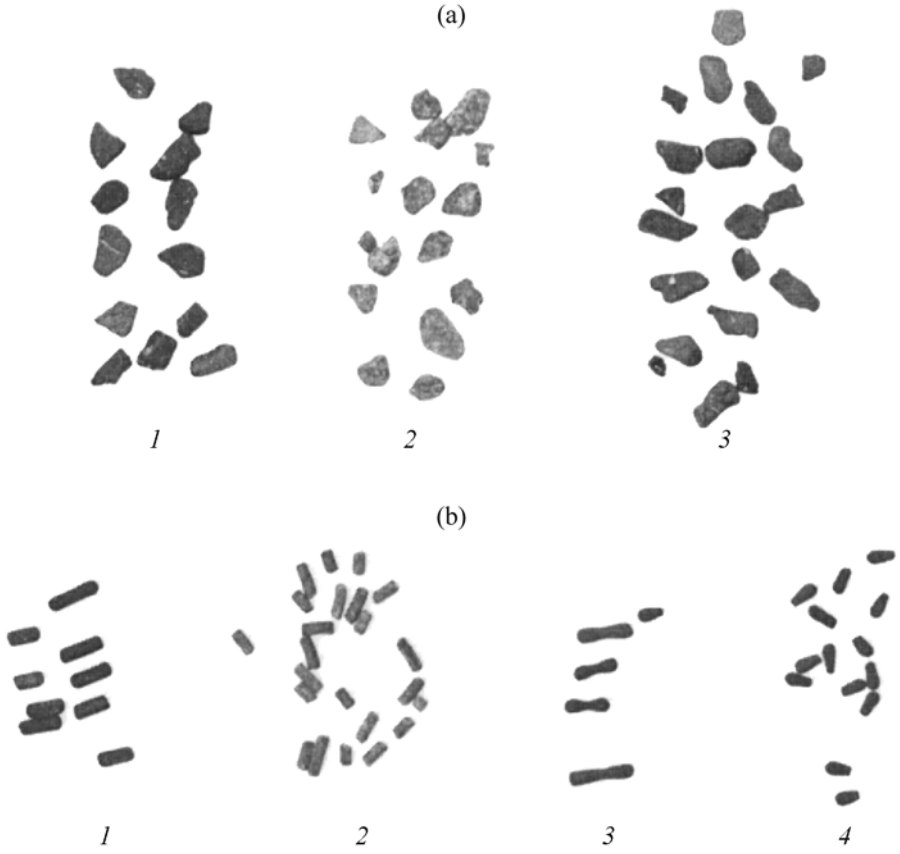

Fig. 2. Photographs of (a) coconut and (b) molded carbons. Carbon: (*1*) starting, (*2*) taken from the technological process, and (*3*, *4*) abraded.

of each curve), as well as their photographs in Fig. 2 before and after experiments, indicate that the mechanisms of disintegration of grains of the two brands of carbon under study are fundamentally different and lead to practical conclusions about how the loss of carbon and, consequently, of precious metals, too, can be diminished. In grains of the coconut carbon, sharp edges are first rounded.

Then the grains slowly delaminate into coarse plates of smaller thickness, which do not pass through a sieve with a 0.5-mm mesh. In the final stage of abrasion, thin flakes are mechanically disintegrated and the resulting fragments form tailings.

The cylindrical grains of the molded carbon first acquire a dumb-bell shape and then disintegrate nearly in two halves. Subsequently, these halves become spheres with a gradually decreasing size, which penetrate through the screen grid and find their way into the waste. These observations are in agreement with previous reports [15].

Comparison of the wear of AC grains with steel and rubber-coated blades indicates that the main reason for wear of carbon particles under the experimental conditions is their strong impact interaction with steel blades of the stirrer, whose circumferential velocity may be as high as 3–5 m s^{-1}. It is of interest to emphasize here that this conclusion is in agreement with numerous publications, according to which a larger part of the agitation power is dissipated in a small volume of the medium, $V_{ag} = \pi/4d^2h$ (h, height of the blade projection onto the diametral plane) near the stirrer blades [25]. As confirmed by the experiments performed in [20], intense disintegration of floccules in agitation in fermenters occurs just in this zone. It is also natural to believe that the most erosion-vulnerable place of MAD is the blade periphery moving at the highest circumferential velocity, which is indicated by the experiments and calculations reported in [18, 19, 26]. It is also reasonable to note the published suggestions that the circumferential velocity of stirrer blades in the CIP process should be limited to a value of 4–5 m s^{-1} [27]. Thus, it is possible to markedly depress a reason for loss of carbon and precious metals and, simultaneously, to make longer the service life of the stirrer by coating blades with rubber, which is typically done with hydrometallurgical equipment.

In the second stage of the study, we analyzed the abrasion of carbon particles with a concentration of 5 vol % in a water-sand pulp. As follows from Figs. 3 and 4, at a considerably higher concentration of carbon grains, too, the influence exerted on their abrasion by an antiabrasive rubber coating of blades, which positively affects the dynamics of interaction between grains and the rapidly rotating stirrer, is still strong. At the same time, even though the difference in wear resistance between carbons of two brands is in favor of molded carbon particles, it is rather insignificant. In this case, the final choice of the carbon brand should be governed by other important criteria, such as kinetic characteristics of adsorption, adsorptive capacity, cost, etc. [2, 10].

The empirical dependence of the loss of mass by an AC sample (Δm) on the time of its agitation with a pulp (t), which can be used to describe the abrasion of carbons in the model experiment, has the form ($t \le 30$ h)

$$\Delta m = at^b, \qquad (16)$$

and the values of the coefficient a and exponent b are shown in Fig. 4 at the corresponding curves.

The abrasion of particles of the extruded carbon of industrial concentration in the water-sand pulp was also studied with other MAD parameters (d = 80 mm, n = 8.33 s^{-1}, rubber-coated blades), at which the energy dissipation decreases by approximately a factor of 2, compared with the previously tested variant. In this case, a slower wear of AC particles would be expected. These MAD parameters approximately conform to requirements (11) and (14), which is important for elucidation of the wear pattern of carbon under model and industrial conditions. Figure 5 compares the results of abrasion of molded carbon particles for two MADs, which confirm the conclusion that, in the case of particle disintegration in apparatus with stirrers, it is necessary to take into account the energy dissipation not only in the total working volume of an apparatus, but also in the conditional volume V_{st} of a cylinder formed in rotation of stirrer blades [20]. Thus, the dependence (16) we obtained can be extended with a large safety margin to prognostication of particle abrasion under industrial conditions, because $P_{ind} \ll P_m$. It is noteworthy that the loss of AC in smooth-wall sorption apparatus must be considerably lower than that in energy-intensive apparatus with a baffles.

We also experimentally studied the influence exerted by the direction of axial rotation on the abrasion of carbon particles by standard three-blade stirrers

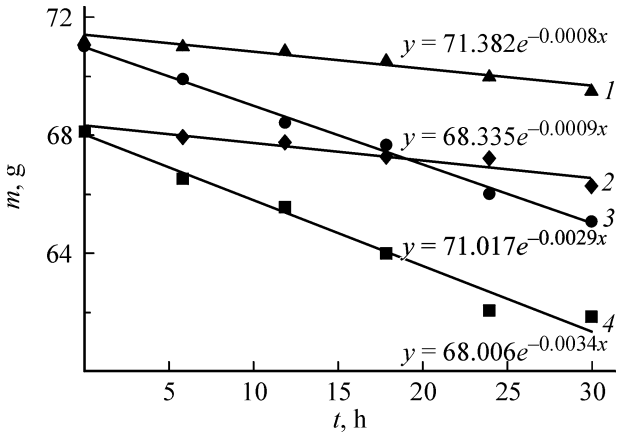

Fig. 3. Sample mass m vs. abrasion time t at a 5 vol % content of activated carbon in the pulp and clockwise rotation of stirrer blades with d = 60 mm. Carbon: (*1*) molded, rubber-coated blades; (*2*) coconut, rubber-coated blades; (*3*) molded, steel blades; and (*4*) coconut, steel blades; the same for Fig. 4.

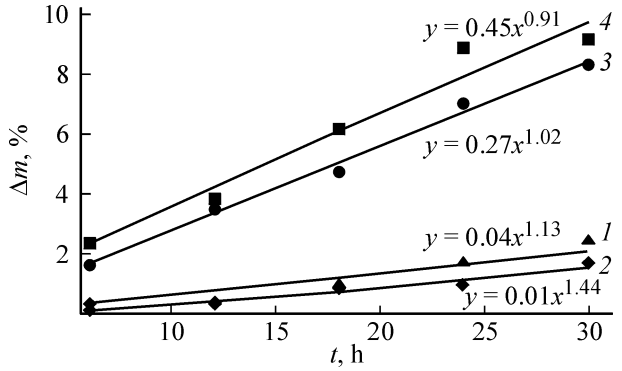

Fig. 4. Relative mass loss $\Delta m = [m_0 - m_t)/m_0] \times 100$ by a sample vs. abrasion time t at a 5 vol % content of activated carbon in the pulp and clockwise rotation of stirrer blades with d = 60 mm. (m_0) Mass of the starting sample and (m_t) that after abrasion for a time t.

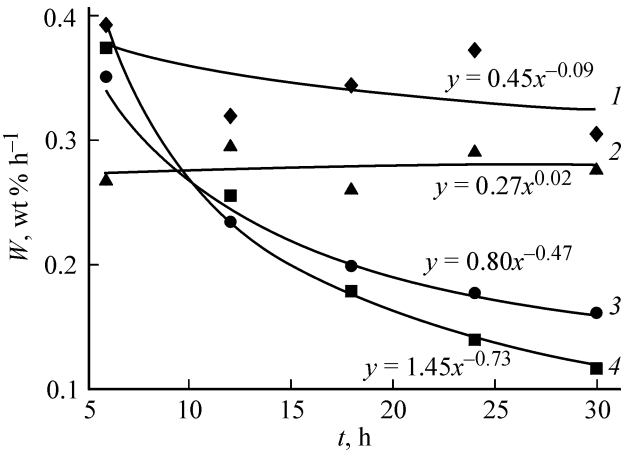

Fig. 5. Rate of mass loss by a sample, $W = (\Delta m/m_0 t) \times 100$ vs. abrasion time in the case of a clockwise rotation of steel blades of various diameters. Carbon, d (mm): (*1*) coconut, 60; (*2*) molded, 60; (*3*) molded, 80; and (*4*) coconut, 80.

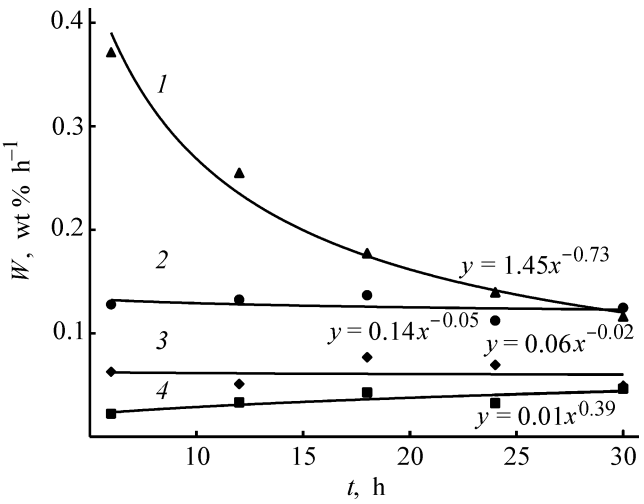

Fig. 6. Rate of mass loss by a sample, *W*, vs. abrasion time *t* for coconut carbon at different directions of meridian circulation of the pulp at d = 80 mm. Blades: (*1*) steel, clockwise; (*2*) steel, anticlockwise; (*3*) rubber-coated, clockwise; and (*4*) rubber-coated, anticlockwise.

with a blade angle with respect to the horizon equal to 24°. As it can be seen from Fig. 6, the upward suspension motion in the central zone of the apparatus (anticlockwise rotation) is accompanied by lower abrasion of sorbent particles, compared with the conventionally taken [28] downward motion of the suspension to the bottom. This preferable upward direction of suspension motion is accompanied, as Japanese researchers have demonstrated [19], by a more uniform distribution of the number of collisions of solid particles with each of the 25 small elements of area, marked out on the working surface of a blade (5 areas across the width of a blade and 5 along its radius). At the same time, in the case of suspension motion in the central zone toward the bottom (on reverting the direction of stirrer rotation), the distribution of collisions among these 25 areas is exceedingly nonuniform. For example, five and more areas adjacent to the stirrer hub do not interact with particles at all, and five peripheral areas having the highest circumferential velocity may experience 50–80% of the total number of collisions with solid particles [19]. Naturally, not only intensive crushing of particles, but also rapid erosion wear of the blade periphery occur in this case [18, 19, 26, 29].

Comparison of the curves describing the loss of mass via mechanical abrasion (Fig. 1) shows that, in the course of time, the rate of carbon loss via mechanical abrasion for coconut carbon markedly decreases to become virtually equal to that for extruded carbon. This indicates that the loss of precious metals with carbon fines can be substantially diminished if each portion of carbon is subjected, before being fed into the sorption process, to mechanical conditioning. This procedure consists in agitation of a concentrated water-carbon suspension in an apparatus with baffles, followed by classification of the resulting mass on a screen. As a result of this conditioning, carbon particles that are predisposed to disintegration because of the presence of pronounced mechanical defects (cracks), as well as long and thin AC fragments, will be separated from coarse and firm particles because of the comminution in this apparatus. This precludes loss of precious metals adsorbed on fine AC fragments in CIL and CIP processes and, as shown below, activates to a certain extent the adsorbent surface.

As shown by studies of agitation of water-carbon suspensions with a mass concentration $X \le 0.25$ (kg of carbon per kg of water), standard apparatus with a conical bottom, baffles, and three-blade stirrer are well suitable for mechanical conditioning of carbon [30].

The apparatus was successively charged, at a working stirrer, first with water and then with a preliminarily weighed portion of carbon. The conditioning time (1–3 h) and the degree of abrasion ($\Delta m \le 10\%$) depended on the brand of carbon and parameters of MAD and the apparatus [24] at the optimal specific agitation power $P = N/V \approx 2$ kW m^{-3}.

The stirrer blades and baffles, near which nearly the whole amount of power is dissipated, should be rubber-coated to preclude excessive crushing of carbon particles. As usual in agitation of suspensions whose solid phase particles markedly differ in shape from the well-studied spherical particles, tests of a geometrically similar model of an industrial apparatus are necessary, with transfer of the experimental data obtained to a full-scale apparatus by means of the known scaling rules [24].

Thus, it is desirable to subject AC to preliminary mechanical conditioning, with sieving and removal of particles of the fine fraction (<1.0–1.2 mm). This will substantially diminish the loss of both carbon itself and gold in apparatus for sorptional cyanidation. With this simple technological method implemented, the difference in mass loss between the two AC brands considered here is largely eliminated.

It should be noted that, as the concentration of AC particles in the pulp increases, the time of their residence in the cascade of counter–current sorption apparatus becomes longer, which, among other things,

enhances the abrasion interaction of carbon particles with each other. Therefore, the reasonable range of volume concentrations of AC in the pulp is commonly 1–5%, but the problem of optimization of this concentration is economical.

A mistake widely occurring among specialists is that the concentration of AC in the last, along the pulp flow, counter–current apparatus for adsorptive cyanidation should exceed that in the others. The studies performed demonstrated that the best results in the CIP process are achieved in the case of a uniform distribution of the carbon concentration along the entire sorption scheme [6].

In addition to the AC characteristics described above, the choice of a carbon brand is occasionally based on such parameter as its adsorptive capacity (SC) for the $[Au(CN)_2]^-$ anion. In real industrial processes, only several percent of this capacity is used, and therefore, it is believed [5, 6, 10] that the value of SC is not a key characteristic in AC choice. The capacity of AC decreases as the concentration of a free CN^- anion in solution, temperature, and pH value grow, and increases with the ionic strength of the solution [6]. The pseudoequilibrium value of SC may exceed 100 mg of Au(I) per gram of carbon [31]. Under industrial conditions, the content of gold(I) on a saturated carbon delivered to desorption is, as a rule, 3 to 10 mg g^{-1}.

At low concentrations of the $[Au(CN)_2]^-$ anion in the liquid phase, characteristic of the CIL and CIP processes, the dependence of the SC of activated carbons on the Au(I) concentration is commonly well described by the Freundlich isotherm equation

$$SC = K'[Au]_{sol}^{1/\beta}, \quad (17)$$

where $[Au]_{sol}$ is the equilibrium concentration of gold(I) in solution (M or mg l^{-1}). The coefficient K' and exponent β in Eq. (17) depend on the state of the AC surface.

Figure 7 shows isotherms of adsorption of the $[Au(CN)_2]^-$ anion on samples of molded and coconut carbons, fresh and taken after 152 h of agitation with a water-sand mixture, and the table lists the corresponding values of K' and β. As follows from the data we obtained, the values of K' and β in the Freundlich isotherm equation decrease upon mechanical abrasion of the adsorbent surface, but the influence exerted by the exponent β on SC is stronger than that of the slope ratio K'. As a result, all other conditions being the same, the capacity of samples of both coconut and extruded carbons subjected to abrasive wear exceeds that of "fresh" samples.

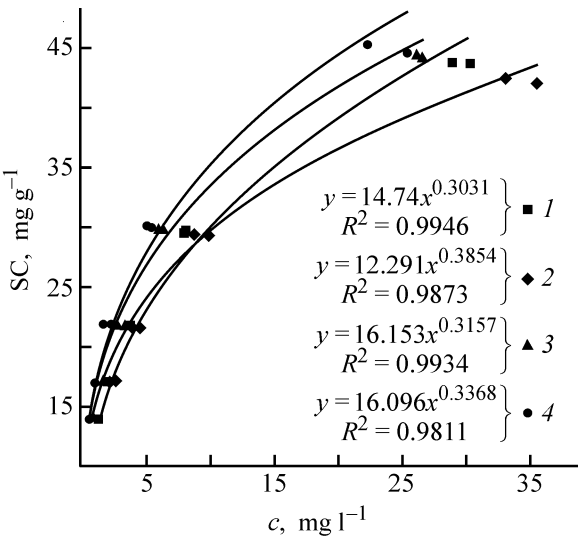

Fig. 7. Isotherms of adsorption of cyanide complexes of Au by various ACs. (SC) Sorption capacity of AC and (*c*) concentration of $[Au(CN)_2]^-$. Carbon: (*1*) coconut fresh, (*2*) coconut abraded, (*3*) molded fresh, and (*4*) molded abraded.

In adsorption of the $[Au(CN)_2]^-$ ion from aqueous solutions and pulps under real conditions, oppositely directed processes occur. Part of these processes lead to a decrease in the adsorptive capacity of the carbon. The following can be distinguished among these processes: (1) deactivation of the AC surface via deposition of organic (flocculants, flotation reagents, combustible and lubricant substances, natural humic acids, etc.) [32–34] and insoluble inorganic [$CaCO_3$, $MgCO_3$, $Fe(OH)_3$, $(MgOH)_2CO_3$, etc.] substances [31] and adhesion of solid ore particles to the surface {the strongest negative influence is exerted on the Au(I) sorption by organic substances, and primarily by flotation reagents [7]}; (2) rapid oxidation of sorption-active centers, which gives rise to surface oxygen complexes of carbon and, to a lesser extent, to nitrogen-containing fragments [35] (the sorption capacity of AC for the $[Au(CN)_2]^-$ ion decreases as the content of oxygen in the carbon adsorbent increases [36]); and (3) saturation of accessible adsorption centers by cyanide complexes of Au(I), Ag(I), and other metals [37].

Values of K' and β in the Freundlich equation at varied abrasion of activated carbon samples

Sample	K'	β
Carbon:		
coconut fresh	14.740	3.3
coconut abraded	12.291	2.6
molded fresh	16.153	3.2
molded abraded	16.096	3.0

At the same time, mechanical contact of carbon particles with each other and solid particles in the pulp, as well as with the stirrer blades and vessel walls, leads to formation of new defects on their surface, and primarily on the basal planes of AC particles. These defects have the form of new macro- and mesopores whose mouths can sorb an additional amount of $[Au(CN)_2]^-$ ions, which leads to an increase in the sorption activity of the surface of AC particles for the cyanide complex anion of gold(I). Such a change in the behavior of AC particles may evidence in favor of a mechanical activation of the sorbent in the course of abrasion, with this referring to a greater extent to the sample produced from the coconut shell. A similar increase in the adsorbent capacity as a result of its mechanical activation has been observed in a study of the sorption of Zn(II) ions on calcite [38].

The positive influence of mechanical abrasion on the adsorption process is nearly eliminated in industrial CIP and CIL processes by loss of gold(I) with carbon, but not completely because a larger part of AC is lost in the form of fine fractions with particles less than 1 mm in size.

It is occasionally recommended to be oriented, when choosing AC samples, to a number of accessible, but indirect characteristics of carbons, such as their specific surface area, capacity for adsorption of some organic or inorganic substances, bulk density of AC, size of AC particles, and ash content [1, 6, 10, 39]. We emphasize that, strictly speaking, these quantities cannot serve as a reliable basis for determining the suitability of a carbon for use in the technological process under consideration.

Commonly, AC samples used for adsorption of gold(I) have a specific surface area S_{sp} of 800 to 1200 $m^2 g^{-1}$, which can be found from the low-temperature sorption of Ar or N_2 by the BET method. If we determine the specific surface area of AC from the adsorption of carbon dioxide by calculation with the Dubinin–Polany equation and subtract from the value obtained the specific surface area furnished by the BET method, the resulting value gives notion of the specific surface area of micropores in the sample [40]. The relative amount of micro-, meso-, and macropores in AC is largely determined by the nature of a material from which the sample is fabricated. The AC fabrication technology affects this amount and, consequently, the possible value of the SC of a carbon for gold(I) to a lesser extent [41]. The specific surface area of AC samples is determined by the content of meso- and micropores in these samples. These same types of pores sorb the main amounts of gold(I). However, it has been demonstrated on the basis of a vast statistical material that, at S_{sp} of 484 to 1861 $m^2 g^{-1}$, the linear correlation coefficient between the equilibrium capacity of a carbon for gold(I) and its specific surface area is as low as 0.137 [42].

In practice, attempts to characterize the quality of AC samples as regards their suitability as sorbents for gold(I) recovery from cyanide pulps are frequently based on such characteristics of these samples as the iodine number and capacity to absorb CCl_4 vapor or organic dyes, e.g., Methylene Blue, from aqueous solutions [10]. For carbons best suitable for the CIL and CIP processes, the published values of the iodine number and activity with respect to CCl_4 vapor are, respectively, 1100–1200 mg g^{-1} [1] and 55–70% [39]. These parameters of carbons are indirectly related to their specific surface area S_{sp}. However, the linear correlation coefficient between the specific surface area of AC samples and their capacity for the $[Au(CN)_2]^-$ anion has, as already noted, a rather low value. Special studies [42] have shown that the linear correlation coefficients between the equilibrium capacities of AC for the $[Au(CN)_2]^-$ anion, on the one hand, and the capacities for Methylene Blue and the iodine number, on the other hand, are negative and equal to -0.133 and -0.393. On the whole, two AC samples having equal specific surface areas or iodine numbers may strongly differ in their capacity for adsorption of Au(I) [39]. The larger the specific surface area of an AC, the lower, at the same particle size, its bulk density and mechanical strength, which should also be taken into account when choosing a carbon. A usual value of the bulk density of activated carbons with a specific surface area in the range 800–1200 $m^2 g^{-1}$ is approximately 420–520 kg m^{-3} at an average AC grain size of 1.7–2.5 mm for coconut carbons and 490–510 kg m^{-3} for extruded carbons [1]. The bulk density of carbons in the range 500 ± 10 kg m^{-3}, as a rule, provides a good combination of kinetic and strength properties of AC and a good segregation stability of a carbon in ore pulps. In this case, the true pycnometric density of various AC samples falls within the range 1800–2100 kg m^{-3}.

The size of AC grains is also important in selection of AC brands suitable for CIL or CIP processes. Naturally, small particles (passing through a sieve with a 1-mm mesh) will have better kinetic characteristics, compared with larger particles. However, their lifetime is shorter because of the mechanical abrasion, and, consequently, the loss of precious metals with these particles substantially exceeds that with coarser particles. As a result, it is advisable to remove small

particles from the process in the stage of carbon reactivation. At the same time, AC particles retained in classification by a sieve with a 3-mm mesh are considerably less active in sorption of the $[Au(CN)_2]^-$ anion than smaller particles [10]. This circumstance will make necessary a longer contact of these particles with the pulp to reach the same degree of gold recovery as that with finer particles. This leads either to an increase in the number and volume of sorption apparatus or to a higher AC concentration in the pulp, which is undesirable. Therefore, the optimal size of AC particles presently used in CIL and CIP processes is 1.5–3.0 mm, and the desirable particle shape is spherical.

The ash content of the best AC samples used for gold recovery from cyanide pulps is 2–4% [1].

Finally, one more characteristic of carbons, which determines their suitability for gold mining, is their capacity for reactivation. Reactivation of ACs primarily restores their kinetic activity with respect to gold(I) adsorption, but involves a noticeable loss of mass by the adsorbents via oxidation and mechanical disintegration. The variation of the adsorptive properties of a carbon with the time of its contact with deactivating impurities and the degree of restoration of the adsorptive activity of the AC upon reactivation can be determined in laboratory. It has been suggested to use for this purpose electrochemical methods [43, 44], thermogravimetry, determination of the specific surface area of ACs [44], and kinetic parameters of adsorption of a saturated or regenerated carbon samples under study in comparison with the similar characteristics of the starting carbon. The last method consists in determining the pseudokinetic rate constant of sorption, k', and was described above.

Comparison of the curves describing the loss of mass by the starting sample and that under study in an inert atmosphere in the temperature range 150–600°C suggests that the ACs are contaminated with various compounds [44].

As the surface of an AC sample is saturated, its steady-state electrochemical potential shifts in the negative direction, compared with that of the starting sample, and its specific surface area decreases. The method of cyclic voltammetry shows that the currents of the cathodic and anodic peaks and the areas under the current peaks in a redox process involving a 0.05 M solution of $Fe(NO_3)_3$ in an acid medium (HNO_3, pH 1) on an AC powder electrode [43] depends on the degree of adsorbent saturation with various impurities of organic and inorganic nature.

EXPERIMENTAL

In simulation of the mechanical disintegration of AC particles, we used a quartz sand with a content of the –0.071-μm fraction of 95 ± 2%, which corresponds to the granulometric composition of the ore. The granulometric composition of the sand was determined on a Fritsch Alalysette 22 Compact laser granulometer (Germany). The water-sand pulp was agitated with an Ekros PE-8000 device (Russia). The stirrer rotation frequency was monitored with a tachometer and maintained constant during the entire experiment (152 h). The parameters of a polypropylene laboratory vessel and a stirrer were specified ented above.

The isotherm of gold(I) adsorption was measured using the method of varied weighed portions. The capacity of a carbon for Au(I), A (mg g^{-1}), was calculated by the formula $A = (c - c_0)V/m'$, where c_0 is the initial concentration of gold(I) in the solution (mg l^{-1}); c, its equilibrium concentration in the solution (mg l^{-1}); V, solution volume; and m', sorbent mass (g).

The concentration of Au(I) in solution was determined on a Varian SpectrAA 110 spectrometer (Australia).

CONCLUSIONS

(1) Direct and indirect characteristics of activated carbons were considered from the standpoint of their choice for use in CIL and CIP processes. The most important characteristics of carbons, which determine their suitability for hydrometallurgical processes, are the pseudokinetic rate constant of adsorption of the dicyanoaurate(I) anion on an activated carbon sample and its mechanical strength in agitation in an abrasive medium.

(2) A procedure for testing carbon sorbents for abrasion, made closer to the conditions of a real pulp process, was developed. The method is based on the assumption of geometrical similarity of the industrial and model smooth-wall apparatus and on the requirement that the shear stresses in these apparatus should be equal for providing an effective agitation of particles of the ore being cyanidated. The method was tested in a study of the abrasion of activated carbons of two brands differing in the fabrication technology, adsorptive capacity, and cost.

(3) Mechanisms of abrasion (comminution) of particles of the coconut and molded sorbents in a compact and energy-saturated volume of the medium, in

which occurs dynamic interaction of grains with rapidly rotating blades, were suggested. It was shown that the detrimental effect of the dynamic interaction on the particle abrasion and, simultaneously, on the blade erosion can be suppressed to a considerable extent by rubber coating of the stirrer blades.

(4) The available published evidence that the dissipation of the suspension agitation energy is the key factor in carbon abrasion was confirmed. As a result, it becomes possible, when designing apparatus of this kind, to make their technical characteristics conform to, among other things, the requirement of the minimum loss of the sorbent. In this case, it is preferable to use smooth-wall apparatus with three-blade stirrers at a simplex $\Gamma_D = D/d = 2–3$, which consume a considerably lower power than apparatus with baffles, more popular abroad and more energy-intensive.

(5) It was shown that the rotation direction of the three-blade stirrer studied affects the degree of abrasion of activated carbon particles. A stirrer rotation causing an ascending central-zone axial flow of a material being agitated is preferable to the descending flow.

(6) A comparison of the results of a simulation model with industrial data on abrasion of carbon particles demonstrated that a kinetic dependence of the type (16) can be used to evaluate the loss of activated carbon with a wide safety margin dependent on the considerable excess of the specific agitation power in a model apparatus over that in its industrial analogue.

(7) A design and technical characteristic of an apparatus for conditioning of activated carbon to diminish the loss of precious metals with carbon fines were suggested.

(8) It was found that mechanical treatment on carbon particles in CIL and CIP processes activates the adsorbent surface because of the formation of new defects on the surface of activated carbon.

SORPTION AND ION-EXCHANGE PROCESSES

Pervaporation Selectivity as a Function of Pressure and Sorption Properties of a Polymeric Film Membrane

Abstract—Results obtained in an experimental study of the pervaporation of binary solutions with a cellulose hydrate (cellophane) nonporous film membrane are discussed. A primary attention is given to the sorption and the effect of the residual pressure of the permeate on the separation characteristics.

DOI: 10.1134/S1070427207060109

Researchers' interest in pervaporation (evaporation across a membrane) is due to the possibility of application of this process in the separation technology in those cases when the conventional methods, such as distillation or rectification, are inapplicable or inefficient [1]. By now, a number of methods for simulation and calculation of pervaporation parameters have been developed, with the dissolution–diffusion model being commonly accepted [1–4]. At the same time, the concepts of the process mechanisms are widely diverse and, occasionally, contradictory [5]. Therefore, the existing methods are insufficiently versatile, which impairs their practical value as compared with the methods of thermodynamics of the liquid–vapor equilibrium, used in the case of distillation and rectification [6]. Development of the pervaporation theory requires that additional physicochemical information about various stages of the process should be invoked.

A study of the sorption as an equilibrium between a feed mixture and a membrane has been the subject of extensive research [7]. In [8], the equilibrium between a liquid ternary mixture of benzene, cyclohexene, and cyclohexane and films of polyurethane and polyetherblockamide was studied. In [9], a study of the sorption of aqueous solutions of ethanol, methanol, and 2-propanol by a film of polyvinyl alcohol was reported. The sorption of gaseous oxygen, carbon dioxide, ethylene, dimethyl sulfide, trichloroethylene, and toluene by a film of polydimethylsiloxane was examined in [10]. These data can be used to calculate the equilibrium solubility factor of a component in a membrane, defined as the ratio of the component concentration in the membrane to the concentration in solution. This factor reflects the pervaporation properties of the membrane material and makes it possible to prognosticate, to a certain extent, the pervaporation selectivity [8]. In the vacuum mode, pervaporation is an open phase process [11], because the forming permeate is continuously removed. In this case, the pervaporation substantially differs from the evaporation of a liquid from a free surface. It is known that direct evaporation from a free surface occurs considerably faster, compared with the subsequent diffusion of the vapor, and just this stage is the rate-determining stage of the process as a whole [12]. Accordingly, the vapor formed is in a prolonged contact with the solution, which favors attainment of a dynamic equilibrium. In the case of pervaporation, the vapor is rapidly removed by evacuation, which precludes attainment of an equilibrium. As the residual pressure increases, the flux of substances across the membrane decreases and the permeate composition changes.

It is noteworthy that the dependence of pervaporation parameters on the residual pressure has been the subject of only a small number of reports. This is due to the practical purpose of the pervaporation: a low permeate pressure is necessary for creating technologically attractive high transmembrane fluxes. In [13], the concept of a vapor–liquid "pseudo-equilibrium" in pervaporation was discussed as the state of the process at a zero transmembrane flux and unequal pressures on the sides of the feed solution and the vapor. However, the concept suggested was verified at a the same permeate pressure in all the exper-

iments and no data on fluxes were reported. Moreover, the initial amount of the feed solution was so small that its composition substantially changed in the course of an experiment because of the loss of substances into the permeate. Therefore, the experimental conditions correspond to a nonsteady-state mode and do not satisfy the requirements of the concept suggested in [13].

In [14], the recovery of isomeric butanols from dilute (~1 wt %) binary aqueous solutions with various membranes was studied. It was shown that, for a polyetherblockamide membrane, an increase in the residual pressure (decrease in the flux) differently affects the content of butanol isomers in the permeate, which partly correlates with their vapor pressures (or boiling points). In the case of *n*-butanol (bp 117.7°C), its content in the permeate moderately decreased as the residual pressure became higher, whereas for tertiary butanol (bp 82.5°C), it steeply increased. It should be noted that evaporation of butanol solutions across the membranes studied leads to a poorer separation, compared with open equilibrium evaporation. Only with a polydimethylsiloxane (PDMS) film the content of alcohols (with the exception of tertiary butanol) in the vapor was somewhat higher than that at the liquid–vapor equilibrium.

A mathematical simulation of the pervaporation process with organophilic membranes in terms of the dissolution–diffusion model was performed in [15]. The model developed makes it possible to take into account the effect of the residual pressure of the permeate on its composition, which must correspond in the limiting case of high pressures to the liquid–vapor equilibrium. To confirm the adequacy of the model, the results of the calculations were compared with experimental data on recovery, from aqueous solutions, of phenol (5 wt % phenol) with an acetate–PDMS membrane [16] and ethanol (5–50 wt % ethanol) with a PDMS membrane [17]. Upon an increase in the residual pressure from nearly zero values to 110 mm Hg, the content of phenol in the permeate decreased from 15 to 4 mol % at $T = 75$°C; for the liquid–vapor equilibrium the content of phenol in the vapor is 1.16 mol % [18]. Upon an increase in the residual pressure to 50 mm Hg in the case of aqueous–ethanolic solutions, the content of the alcohol in the vapor reaches values corresponding to the liquid–vapor equilibrium. Thus, it is confirmed [7] that polydimethylsiloxane, a known hydrophobic polymer, is unsuitable for recovery of such strongly polar compounds as alcohols from aqueous solutions.

This communication reports the results of an experimental study of the sorption properties of a hydrophilic nonporous membrane and of the dependence of the pervaporation selectivity on the permeate pressure in separation of liquid aqueous–organic mixtures.

Pervaporation experiments were carried out with binary systems constituted by water and acetic acid and water and ethanol with the use of a film membrane (thickness 70 μm) made of cellulose hydrate (cellophane manufactured by Tsellofan Open Joint-Stock Company, Balakovo, Saratov oblast), which is a hydrophilic polymer. The setup for pervaporation experiments has been described previously [19]. The fluxes were calculated from gravimetric data with account of the membrane area and experiment duration. The temperature of the liquid mixtures used was 30 ± 0.1°C. The residual pressure in the vacuum chamber was maintained at 1, 20, 30, or 50 mm Hg with an accuracy of ±0.1 mm Hg. The mixtures were prepared from distilled water, ethanol, and acetic acid (chemically pure grade). The equilibrium sorption of a liquid by cellophane was studied at 30 ± 0.1°C, using the procedure described in [8]. For this purpose, cellophane strips with a mass of 0.6–0.7 g were placed in thermostated aqueous-organic solutions. In the course of sorption there occurs swelling of a polymeric film, with its weight, accordingly, increasing. After the mass of a swollen polymer reached a constant value, the compositions of the solution and liquid sorbed by cellophane were considered equilibrium. For the solutions and membranes studied, equilibrium was attained in 10–14 days. Further, the free liquid was removed from the surface of a membrane sample with a filter paper and the sample was placed in a flask thermostated at 60°C. The flask was connected to a vacuum pipeline and a liquid-nitrogen-cooled trap in which a condensate of the desorbed vapor was collected after evacuation. The residual pressure was 1 mm Hg. The completeness of liquid extraction from the polymeric membrane was monitored by comparing its mass before and after the desorption experiment. The liquid was completely removed from the membrane after 2 h of vacuum treatment. The compositions of the solutions and vapor condensates were determined in all the experiments by gas chromatography; changes in the membrane mass were monitored gravimetrically.

The results obtained when studying the pervaporation process and the sorption equilibrium for a mixture of water and acetic acid are presented in Figs. 1–3.

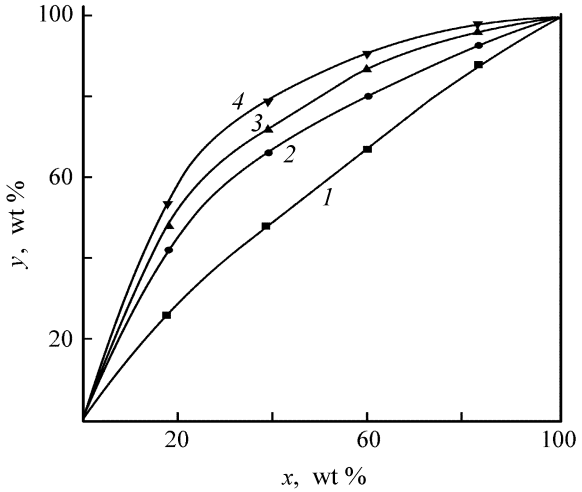

Fig. 1. Water content y of the vapor (permeate) vs. the water content x of the feed solution in pervaporation at residual permeate pressures of (*2*) 1, (*3*) 10, and (*4*) 300 mm Hg. System constituted by water and acetic acid, $T = 30 \pm 0.1$°C; the same for Figs. 2, 3. Line *1* corresponds to the liquid–vapor equilibrium; the same for Fig. 4.

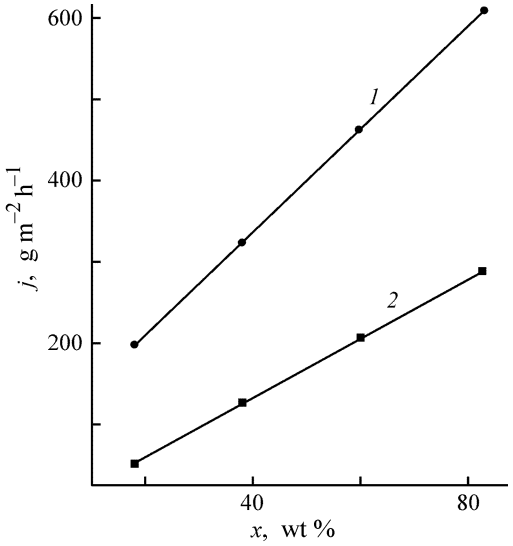

Fig. 2. Flux J in pervaporation vs. the water content x of the solution at residual vapor pressures of (*1*) 1 and (*2*) 10 mm Hg.

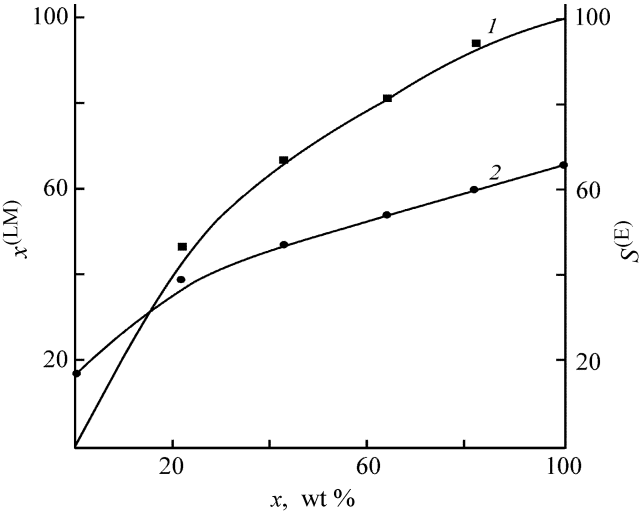

Fig. 3. (*1*) Equilibrium water content $x^{(LM)}$ of the liquid sorbed by a cellophane film membrane and (*2*) degree of membrane swelling, $S^{(E)}$, vs. the water content x of the solution.

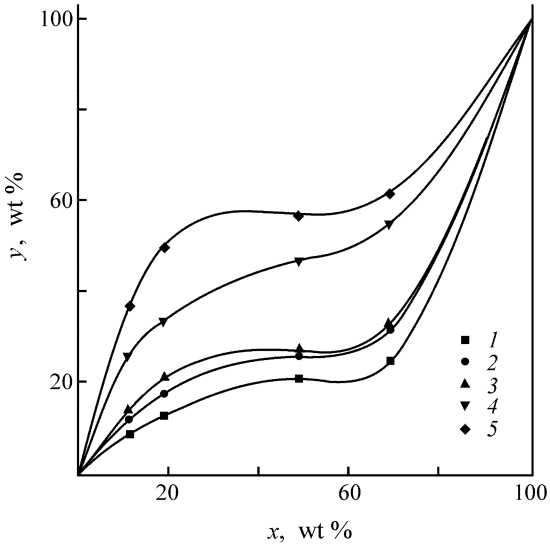

Fig. 4. Water content y of the vapor vs. the water content x of the feed solution in pervaporation at residual permeate pressures of (*5*) 1, (*4*) 10, (*3*) 40, and (*2*) 50 mm Hg. Water–ethanol system, $T = 30 \pm 0.1$°C; the same for Fig. 5.

Figure 1 demonstrates how the water content of the permeate depends on the composition of the liquid at different residual pressures of the permeate. The same figure shows for comparison a curve for the liquid–vapor equilibrium [18]. As the residual pressure increases from 1 to 30 mm Hg for the entire range of compositions of the feed solution, the water content of the permeate grows and differs to an increasingly great extent from the values corresponding to the liquid–vapor equilibrium. As the residual pressure increases further (from 30 to 50 mm Hg), the composition of the permeate remains virtually unchanged. Under the conditions of increasing residual pressure, the transmembrane flux decreases (Fig. 2) to become as low as 2–7 g m^{-2} h^{-1} at 30–50 mm Hg (the last line is not shown in Fig. 2). As equilibrium is attained, the liquid absorbed by the cellophane membrane is strongly enriched in water, compared with the starting solution. This plot is shown in Fig. 3. The same figure presents data on the effect of the solution composition on the degree of swelling $S^{(E)}$. This quantity is defined [7] as the percentage ratio of the mass of liquid ab-

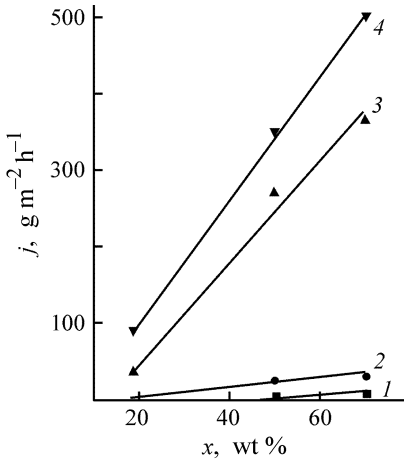

Fig. 5. Flux J in pervaporation vs. the water content x of the solution at residual permeate pressures of (*4*) 1, (*3*) 10, (*2*) 40, and (*1*) 50 mm Hg.

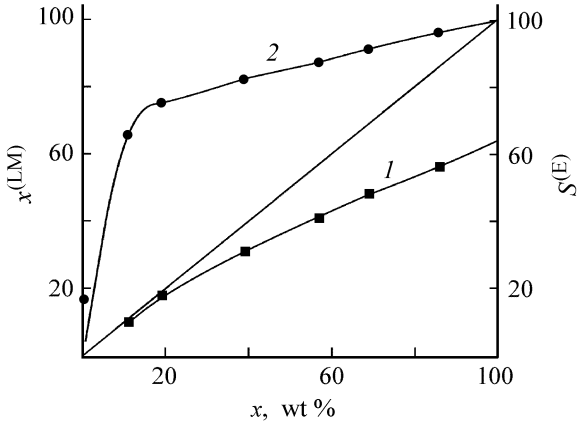

Fig. 6. (*2*) Equilibrium water content $x^{(LM)}$ of the liquid sorbed by a cellophane film membrane and (*1*) degree of membrane swelling, $S^{(E)}$, vs. the water content x of the solution of ethanol.

sorbed by a membrane to the mass of the membrane. As can be seen in Fig. 3, the degree of swelling increases with the content of water, x, in the solution, to reach a value of 64%. This dependence becomes linear at $x > 20$ wt %.

In contrast to the case of aqueous solutions of acetic acid, an increase in the residual pressure in pervaporation separation of water and ethanol leads to a decrease in the water content of the permeate (Fig. 4), and, in the case of low fluxes, the hydrophilic film mainly permeates the alcohol, so that the selectivity of pervaporation falls. As the value of 50 mm Hg is reached, the permeate composition becomes independent of any further increase in pressure; however, it differs from the values corresponding to the liquid–vapor equilibrium (Fig. 4, line *1*). As also in the case of the system constituted by water and acetic acid, the flux of substances increases as the residual pressure becomes lower and the water content of the starting solution of ethanol grows (Fig. 5). As can be seen in Fig. 5, the fluxes in membrane evaporation of a mixture of water and ethanol are substantial and equal to 5–30 g m^{-2} h^{-1} at 40–50 mm Hg. Figure 6 illustrates the dependence of the equilibrium water content $x^{(LM)}$ of the water–ethanol mixture sorbed by the membrane on the water content of the solution. Figure 6 also shows how the degree of film swelling, $S^{(E)}$, depends on the solution composition. The values of $x^{(LM)}$ and $S^{(E)}$ increase as the water content becomes higher, with the water content of the liquid sorbed by the membrane exceeding that in the case of solutions composed of water and acetic acid.

CONCLUSIONS

(1) The sorption characteristics (equilibrium swelling and composition of sorbates) in pervaporation of water–ethanol and water–acetic acid mixtures of various compositions were studied.

(2) It was shown that, in pervaporation of these mixtures at residual under-membrane pressures of 1–50 mm Hg, the membrane exhibits dehydrating properties for the mixture constituted by water and acetic acid at any water content of the starting mixture, and for the water–ethanol mixture, at a water content not exceeding 40 wt %.

(3) It was demonstrated that, as the residual under-membrane pressure increases, the permeability decreases in all cases, with the separation selectivity for acid-containing mixtures increasing and that for ethanol-containing mixtures decreasing because of the difference in the volatilities of acetic acid and ethanol relative to that of water.

SORPTION AND ION-EXCHANGE PROCESSES

A Variation of Circular Thin-Layer Chromatography with Closed Adsorbent Layer

V. G. Berezkin and E. V. Kormishkina

Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow

Received August 18, 2006; in final form, April 2007

Abstract—A new variation of circular thin-layer chromatography with an adsorbent layer closed during the experiment and a simple dismountable device for implementation of this technique are suggested.

DOI: 10.1134/S1070427207060110

Thin-layer chromatography (TLC) is a variation of planar chromatography, in which substances are separated on a planar, commonly open adsorbent layer, which makes a chromatographic experiment simple and convenient.

An efficient variation of TLC is circular TLC (CTLC) [1–3]. In this variant, samples to be analyzed are deposited at a certain distance from the plate center along a circle and an eluent is fed into the central part of the plate. In CTLC, substances with low and moderate mobilities R_f are well separated. At the starting area, the zones of the compounds being separated are more symmetric and compact, whereas closer to the front, these zones contract in the elution direction and are simultaneously elongated along the circumference. Circular chromatography is the simplest variation of planar chromatography. Its most important advantage is the automatic contraction of zones in the motion direction of the mobile phase as a result of the existence of the velocity gradient of the mobile phase in the direction of zone motion.

However, a disadvantage of both this method and the TLC technique in general is the comparatively slow course of the experiment and poor reproducibility. This is mostly due, in the opinion of numerous researchers [4], to the influence exerted on the chromatographic process by the gas phase commonly present in the chromatographic chamber. In this context, it seemed appropriate to suggest and implement a new variation of TLC with a closed sorption layer, in which the adsorbent layer virtually does not come in contact with the gas phase.

It is noteworthy that use of chromatography with a closed layer has been known previously, but only in connection with a single problem, development of a quasi-column thin-layer system operating at high pressures. In [5–7], high-pressure TLC was suggested for the first time. This method is implemented on a special device in which the adsorbent layer of a TLC plate is covered with a polymeric film forced against the plate by a high pressure. Consequently, the system used for development of a TLC plate has no free gas volume. The concept, method, and device suggested in [5–7] have been successfully used in TLC for more than 25 years; the system suggested is actually a planar column. However, some researchers justly note as the principal disadvantage of this interesting, useful, and original system its intricate design and comparatively high cost. Therefore, the main goal of our studies of recent years has been to develop new approaches to design of simple dismountable low-cost devices for performing the process of chromatographic separation on standard plates under conditions of a closed adsorbent layer and to perform an experimental study of the possibility and advisability of carrying out the chromatographic process under the conditions of a new TLC variation with a closed layer.

Previously, a new simple device has been suggested for linear chromatography, in which a TLC plate is compressed between two glass plates, with a layer of Parafilm M polymeric film [8] placed between the adsorbent layer of the TLC plate and the glass plate and no high-pressure system employed. This approach has been successfully used in a variation of the conventional linear chromatography with a closed layer under conditions of ascending elution [8, 9].

The main goal of the present study was to implement the new approach to CTLC with a closed (for

the time of an experiment) adsorption layer and to analyze this concept experimentally.

EXPERIMENTAL

The design of the device (chamber), previously described for the conventional CTLC and used in this study, is shown in Fig. 1 [2].

The CTLC process with an open layer was implemented as follows: a mixture to be chromatographically separated was circularly deposited onto a plate at a distance of 1 cm from the plate center. Then the plate with a flexible substrate was placed on a glass plate (base) and covered with a polymeric funnel into which a glass tube serving to center the capillary was inserted. This capillary was passed through the tube so as to touch the adsorbent layer of the chromatographic plate. A vessel with the mobile phase was situated above the plate level at a height of approximately 15 cm.

Circular chromatography with a closed adsorbent layer (Fig. 2) was performed as follows: a mixture of standard compounds was circularly deposited onto a TLC plate at a distance of 1 cm from the plate center. Then the plate was covered with a Parafilm M sealing polymeric film and pressed between glass plates with special metallic clumps along the entire TLC plate length. Then the mobile phase was delivered to the plate through a fused silica capillary (diameter 0.32 μm) and the separation process was performed.

The chromatographic process under conditions of a closed layer were performed on plates with silica gel on a 100×100 mm aluminum support for high-efficiency TLC with a UV indicator (STKh-1VE silica gel, grain size 8–12 μm, layer thickness 110 μm, UF-254 UV indicator), manufactured by Sorbpolimer Private Company (Krasnodar, Russia).

As a seal served a Parafilm M transparent polymeric film (thickness 0.12 mm), manufactured by Pechiney Plastic Packing, Inc. (Chicago, USA).

Characteristics of the conventional CTLC and of the variation with a closed adsorption layer, suggested here, were studied in separation of a mixture of the following dyes: (i) Brilliant Green, Rhodamine S, and Erythrosine, taken in a ratio of 1 : 1 : 1 (chromatographed with rectified ethanol as mobile phase) and (2) Rhodamine G, Neutral Red, and Methyl Red in a ratio of 1 : 1 : 1 [separated with a mixture of acetonitrile of pure grade, TU (Technical Specification) 6-09-3534–87, with ethanol in a volume ratio of 10 : 1]. The samples were deposited with a microsyringe.

The distance to which the front of the mobile phase moved in the experiments was 35 mm, with this height measured from the starting line at which the samples containing the substances under study were deposited. In parallel with the experiments in the CTLC variation with a closed layer, we carried out experiments in the conventional circular variation by the procedure described above.

On completion of an experiment, the device was disassembled and the TLC plate was dried in air and scanned on a Genius Color Page-Vivid3x flatbed scanner (KYE Systems Corp., China). The scanning was done with Sorbfil Videodensitometr TLC Quantitative Evaluation software (v. 1.7.0.216) developed by Sorbpolimer Private Company (Krasnodar, Russia). The statistical processing of the results obtained was carried using Excel software (Microsoft, USA).

When performing the chromatographic experiments, we used as parameters of the process under study the following chromatographic quantities: (1) dye mobility R_f

$$R_f = l/Z_f, \quad (1)$$

where l is the largest distance traveled by the spot center from the point of sample deposition, and Z_f is the distance (35 mm in our experiments) traveled by the eluent front from the starting line; and (2) height equivalent to a theoretical plate (HETP or H), calculated for each compounds by the equation

$$H = l/N, \quad (2)$$

where N is the number of theoretical plates; N was found using the Sorbfil Videodensitometr TLC Quantitative Evaluation software.

We estimated the reproducibility of the mobilities R_f in variations of the conventional chromatography and TLC with a closed layer with the use of commonly accepted methods [10].

We first estimated the rough deviation (miss). The miss was estimated by the τ-criterion. In this case, we calculated the average $\bar{x}$ and the standard deviation s for the whole set of measurements (including "doubtful" values) and then found the confidence interval

$$\bar{x} \pm \Delta x = \bar{x} \pm \tau s, \quad (3)$$

in which all the values of the set, except misses (τ-coefficient), can be found with a prescribed confidence probability.

The average value of the quantity being measured, R_f, was calculated using the formula

$$\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n}, \quad (4)$$

where x_i is a single random measurement, and n is the number of repeated measurements.

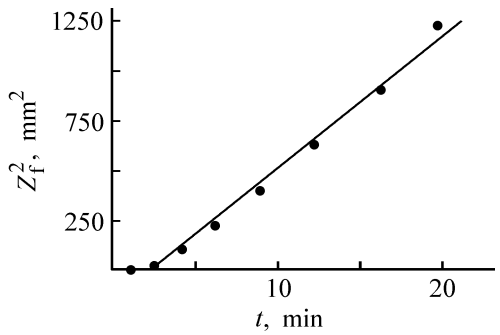

Fig. 3. Z_f^2 for the CTLC variation with a closed sorption layer vs. time t. Mobile phase ethanol.

To evaluate the variance of a random quantity, we used the selected variance s^2, which is a sum of squared deviations of the measurement results from the selected mean, divided by $(n - 1)$:

$$s^2 = \frac{\Sigma(x_i - \bar{x})^2}{n - 1}. \quad (5)$$

The standard deviation s characterizing the scatter of the results in the selected data set was calculated by the formula

$$s = \sqrt{s^2}. \quad (6)$$

The standard deviation is a measure of scatter and characterizes the random error in R_f measurement.

To characterize the reproducibility of the results of our quantitative analysis, we also used the relative determination error

$$\varepsilon = \Delta X/X_{av}. \quad (7)$$

We also studied specific features of the chromatographic process in variations of the conventional CTLC and the CTLC with an adsorption layer covered with a Parafilm M polymeric film. It was found that it is advisable to use, for describing the time dependence of motion of the front of the mobile phase for CTLC with a closed layer, a quadratic equation of motion [3]

$$Z_f^2 = kt + a, \quad (8)$$

where Z_f is the distance from the starting line to the front line of the mobile phase on the plate; k, flow-rate constant; t, time of motion of the mobile phase front from the starting line to a distance $Z_f(t)$; and a, constant.

Figure 3 shows the time dependence of the position of the mobile phase front for a CTLC variation with

Table 1. Front motion distance Z_f in relation to time t for the conventional CTLC and the CTLC with a closed adsorption layer, with a binary acetonitrile : ethanol = 10 : 1 mobile phase (polymeric seal Parafilm M $Z_{f.max}$ = 35 mm)

Distance Z traveled by the binary phase front, mm	Time t, min		Distance Z traveled by the binary phase front, mm	Time t, min	
	conventional CTLC	CTLC with a closed layer		conventional CTLC	CTLC with a closed layer
0	0.43	0.38	20	4.61	3.38
5	1.09	0.84	25	6.02	4.61
10	2.14	1.48	30	7.41	6.05
15	3.27	2.34	35	8.59	7.61

a closed adsorption layer and ethanol used as a mobile phase. It can be seen that the motion time of the mobile phase front is 20 min.

Table 1 lists data on the motion of the front of a binary mobile phase (acetonitrile–ethanol) in the course of time for the conventional CTLC and a CTLC variation with a closed adsorption layer. It can be seen that the motion velocity of a low-viscosity mobile phase in the variation with a closed layer is 10% higher than that in the conventional case.

The smaller difference in the time of the chromatographic process between the conventional CTLC and the CTLC with a closed adsorption layer is due to the use of low-viscosity mobile phases.

If we take into account that, in the case of motion of the mobile phase front along a plate in the conventional CTLC (especially with a volatile mobile phase), there may occur its noticeable evaporation, it seems advisable to use for describing the front motion an equation that accounts for the volatility of the mobile phase. An equation of this type was suggested in [11], whose authors believed that the motion of the front of the liquid mobile phase along the plate is combined with the saturation of the dry adsorption layer of the plate with the mobile phase vapor:

$$Z_f^2 = \chi t + \chi(V_v/\Sigma_0 d)t^2, \quad (9)$$

where Z_f^2 is the position of the mobile phase front; χ, flow rate constant,

$$\chi = 2k_0 d_p \gamma \eta^{-1}, \quad (10)$$

γ, surface tension; η, liquid viscosity; d_p, particle diameter; k_0, permeability parameter dependent of the structure of outer pores; V_v, fraction of the capillary volume, occupied in the preliminarily saturated layer by the liquid phase; $\Sigma_0 = V_m/V_e$; V_m, total pore volume; and V_e, geometric volume of the layer (total).

Then

$$Z_f^2/t = \chi + \chi(V_v/\Sigma_0 d)t = a + bt. \quad (11)$$

In accordance with Eq. (9), we obtained time dependences of the motion of the mobile phase front in the (Z_f^2/t)–t coordinates for the conventional circular chromatography with ethanol or an acetonitrile–ethanol mixture as a mobile phase (Fig. 4). It can be seen that Eq. (9) well describes experimental data for the conventional CTLC.

It also follows from Fig. 4 that the time of motion of the mobile phase in the conventional CTLC is about 35 min for ethanol, which is approximately 40% higher than that in circular chromatography with a closed adsorption layer.

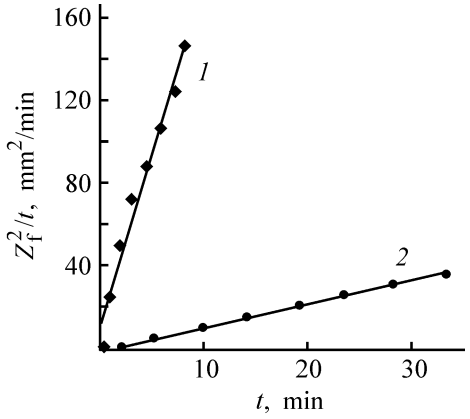

Fig. 4. Z_f^2/t in the conventional CTLC vs. time t. Mobile phase: (*1*) acetonitrile : ethanol = 10 : 1 (by volume) and (*2*) ethanol.

Table 2. Mobilities and efficiencies (R_f and H) for dyed compounds chromatographed by the conventional CTLC and the CTLC with a closed adsorption layer, with ethanol as the mobile phase (polymeric seal Parafilm M, $Z_{f.max}$ = 35 mm, AF-V-UF plates)

	H, μm	32	28	26

Table 4. Statistical estimates of the experimentally measured mobilities in the conventional CTLC and the CTLC with a closed layer (n = 10, p = 0.95)

Sorbate	$\overline{X}$	ΔX	S	S	ε, %
			Conventional CTLC		
Brilliant Green	0.07	0.0001	0.00002	0.005	0.15
Rhodamine S	0.50	0.0004	0.00042	0.021	0.08
Erythrosine	0.81	0.0006	0.00090	0.030	0.07
			CTLC with a closed layer		
Brilliant Green	0.08	0.0002	0.00007	0.008	0.25
Rhodamine S	0.49	0.0007	0.00096	0.031	0.15
Erythrosine	0.94	0.0009	0.00145	0.038	0.10

We also estimated the mobilities and efficiencies in the CTLC with a closed adsorption layer and the conventional CTLC with ethanol as the mobile phase (Table 2). It can be seen that the mobility of compounds is higher in a CTLC variation with a closed adsorption layer and the efficiency is somewhat higher in the conventional method.

Table 3 lists the mobility and efficiency characteristics for the conventional CTLC and a CTLC variation with a closed adsorption layer, with an acetonitrile–ethanol mixture as the mobile phase. It follows from these data that the mobilities are somewhat higher in the conventional CTLC, compared with the variation with a closed layer. The efficiency in CTLC with a closed adsorption layer is, as a rule, somewhat lower, and the selectivity, somewhat higher than those in the conventional CTLC.

Using the data obtained, we estimated the reproducibility of the mobilities R_f and efficiencies (HETP). The statistical estimates of the results obtained, by values of R_f for the conventional CTLC and the CTLC with a closed adsorption layer, are listed in Table 4. It should be noted that the average values of R_f are only slightly different between the two variations of chromatography. A somewhat wider difference between values of R_f for erythrosine are due to the closeness of the zone of this compound to the mobile phase front, i.e., erythrosine is eluted in the region of a vir-

tually nonsteady-state flux of the mobile phase. The standard deviation S and the relative error ε for the CTLC with a closed adsorption layer exceed those for the conventional chromatography. However, the wider scatter of R_f for the circular chromatography variations under study is not a factor leading to a negative assessment of the method we suggested, because the CTLC with a closed adsorption layer is an express technique (the separation duration decreases in the case of this variation by 10–40%).

CONCLUSIONS

(1) Use of a circular thin-layer chromatography with a closed adsorption layer can markedly simplify the chromatographic process at an insignificant change in efficiency, with the device for implementation of the variation suggested being rather simple and convenient in operation.

(2) Implementation of the new variation of circular thin-layer chromatography somewhat reduces the expenditure of the mobile phase and its evaporation into the ambient medium.

ACKNOWLEDGMENTS

The study was supported by a grant of the Department of Chemical Sciences, Russian Academy of Sciences, in the framework of the program "Development of efficient methods for chemical and structural analyses of substances and materials."

SORPTION AND ION-EXCHANGE PROCESSES

Selective Sorption of Water Vapor from Gas Mixtures Containing H_2S, SO_2, NO_2, NO, and CO on KU-2 Sulfonic Styrene Cation Exchanger in Different Ion Forms

Abstract—Sorption of water vapor and some acid gases (H_2S, SO_2, NO_2, NO, and CO) on KU-23-15/100 macroporous sulfonic cation exchanger in different ion forms and on commercial KSM silica gel and NaX artificial zeolite was studied under equilibrium and dynamic conditions. The equilibrium isotherms of water vapor sorption were measured for all the adsorbents examined. The mechanism of water sorption on the sulfonic cation exchanger was discussed.

DOI: 10.1134/S1070427207060122

Adsorption and gas-chromatographic properties of macroporous ion exchangers are due to their high porosity, i.e., to the presence of macro- and mesopores permeable to molecules of gaseous adsorbates [1, 2]. These molecules can be irreversibly sorbed on the internal surface of ion exchanger grains. The sorption is caused by specific interaction of gases with the functional groups of the ion exchanger [3]. Selective sorption of a gas can be provided by introduction of appropriate functional groups into the sorbent. For example, the sorption capacity of particular ion forms of KU-23 sulfonic action exchanger for some gases (e.g., ammonia and amines [4, 5]) is fairly high, with the sorption being mainly determined by the type of the exchangeable cation.

The aim of this study was to examine the possibility of using KU-23 macroporous sulfonic cation exchanger as selective desiccant for gas mixtures containing hydrogen sulfide and oxides of sulfur, nitrogen, and carbon. These substances are the main atmospheric pollutants whose detection on gas-analyzers is complicated by the interfering effect of water vapor present in a gas–air mixture (GAM) [6, 7].

EXPERIMENTAL

We used commercial KU-23-15/100 macroporous sulfonic styrene cation exchanger (Azot Production Association, Cherepovets, Russia) [8]. The static exchange capacity of the sample for 0.1 M NaOH, determined by the procedure described in [9], was 3.8 mg equiv g^{-1}. We studied the sulfonic cation exchanger in the hydrogen, sodium, copper, and cobalt forms. The hydrogen form was prepared by successive washing of the initial sample with 5% solutions of NaOH and HCl to their constant concentration in the filtrate and then with distilled water to the neutral reaction. The salt (sodium, copper, and cobalt) forms were prepared by washing of the hydrogen form of the cation exchanger with a 5% solution of the appropriate metal salt until the concentration of the metal ion in the solution became equal to that in the filtrate. Commercial desiccants of various gases (artificial NaX zeolite and KSM silica gel) [10] were studied for comparison.

We used as adsorbates gaseous H_2S, SO_2, NO_2, NO, and CO prepared from analytically pure grade chemicals and purified by know procedures. Twice distilled water was used to produce the water vapor.

The equilibrium sorption was studied with a vacuum unit equipped with a MacBain–Bakr quartz spring balance [12]. The sorbent was placed in the unit and kept at 293 K and a residual pressure of 0.133 Pa until the sample weight became constant, i.e., the sorption equilibrium was attained. Prior to the experiment, NaX zeolite was kept at 620 K for 2 h, and KSM silica gel at 570 K for 2 h. The measurements were performed with the aid of a cathetometer. The water vapor pressure gradually increased to p/p_s ~0.95.

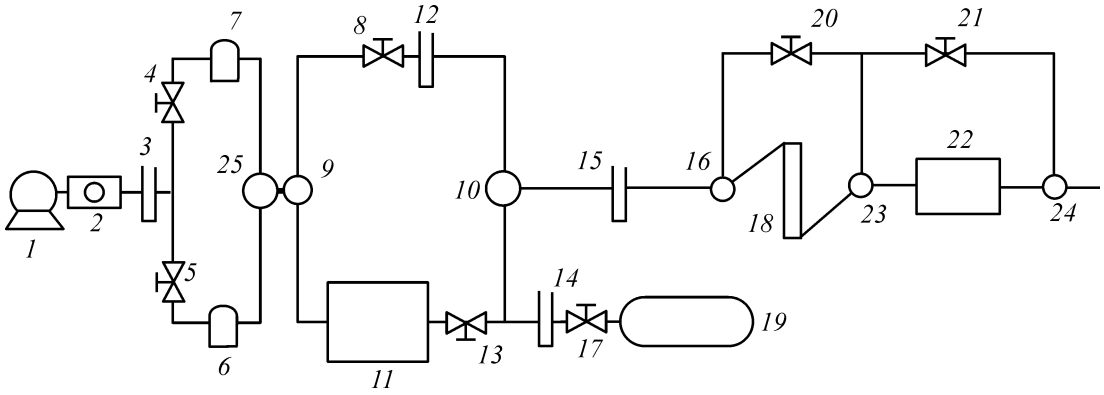

Fig. 1. Scheme of the unit for dynamic sorption: (*1*) pump, (*2*) flow-rate stabilizer, (*3*, *12*, *14*, *15*) flowmeters, (*4*, *5*, *8*, *13*, *17*, *20*, *21*) control valves, (*6*) air humidifier, (*7*) air drier, (*9*) hygrometer, (*10*, *25*) mixers, (*11*) gas mixture generator, (*16*, *23*, *24*) two-way stopcocks, (*18*) filter with adsorbent, (*19*) cylinder with a gas mixture, (*22*) gas analyzer .

The relative determination error of the adsorption, calculated in accordance with the recommendations of [12], did not exceed 6.0% in the whole range of p/p_s.

The dynamic sorption capacity for water vapor and indicated gases was measured with a bench unit schematically shown in Fig. 1. Prior to the measurements, the sorbents were dried at 393 K for 2 h.

To determine the moisture capacity of the gas-vapor mixture with a relative humidity of 20 to 95% at 298 K, it was passed at a flow rate of 60 $dm^3\ h^{-1}$ through a sorbent bed packed in a 25 cm^3 transparent filter body. The water vapor content at the inlet and outlet of the filter was measured with a Volna-5 piezosorption hygrometer (2.5 grade of accuracy). The humidity of more than 1% at the outlet was taken as a breakthrough. The water adsorbtion was determined gravimetrically.

To determine the selectivity of the sorbents, we prepared gas-air mixtures of purified air and a gaseous adsorbate. The adsorbate content was controlled with a Mikrogas diffusion generator of calibrating gases (H_2S, SO_2, NO_2) or with gas cylinders (NO and CO). The experiments were performed at 298 K, flow rate of gas-air of 60 $dm^3\ h^{-1}$, 50% humidity, and weight concentration of the adsorbate of 20 mg m^{-3}. A 100-mm column 15 mm in diameter was packed with sorbents. The gas concentrations at the inlet (c_{in}) and outlet (c_{out}) of the column were measured. The retention time τ defined as the time for which the c_{out} was no less than 0.9 c_{in} was determined. The H_2S and SO_2 concentrations were measured with a GAU-2 electrochemical gas analyzer, and the CO concentration, with Palladii electrochemical gas analyzer. The NO and NO_2 concentrations were determined with a coulometric cell with a working electrode made of a platinum gauze immersed in a KBr solution. The cell was calibrated using conventional colorimetric procedures [13]. To construct the outlet curves, we used in all cases an appropriate gas analyzer measuring continuously the sorbate concentration at the column outlet. The relative determination error of the gas concentrations was no higher than 20%.

The isotherms of water vapor sorption on all of the sorbents examined are shown in Fig. 2. As can be seen from Fig. 2, the relative position of the isotherms substantially changes with increasing p/p_s. The sorption capacity of NaX zeolite is the highest in the p/p_s range from 0 to 0.3. However, at p/p_s = 0.8–0.95, the sorption capacity of the sulfonic cation exchanger

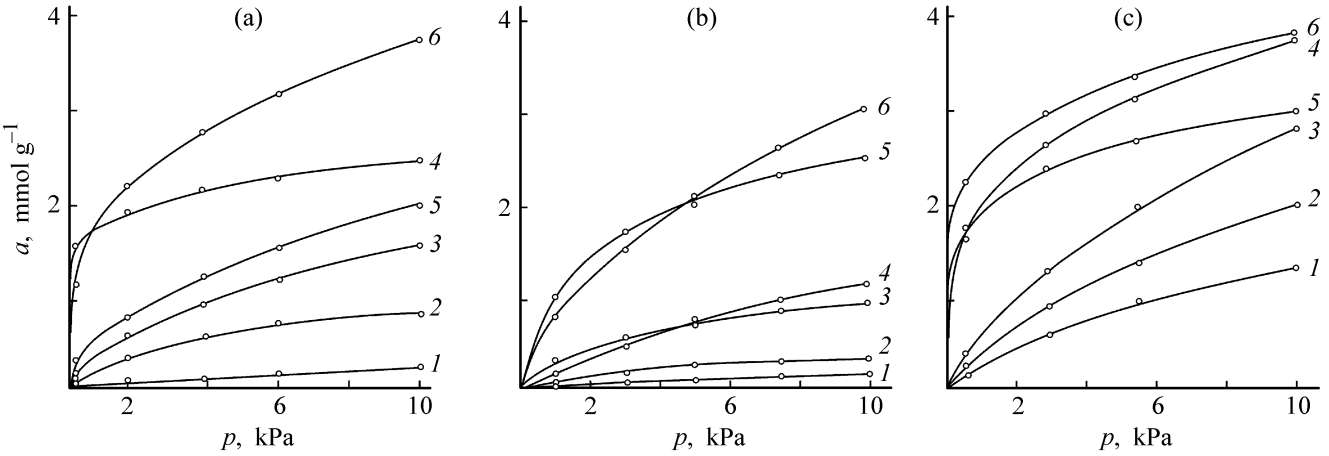

Fig. 3. Sorption isotherm of (a) H_2S, (b) SO_2, and (c) NO_2 on KU-23-15/100 sulfonic cation exchanger in the (*1*) H^+, (*2*) Co^{2+}, (*3*) Na^+, and (*4*) Cu^{2+} form and on (*5*) KSM silicagel and (*6*) NaX zeolite. (*a*) Adsorption and (*p*) pressure.

in the hydrogen and cobalt forms exceeds by a factor of more than 2 that of the other sorbents. The sorption capacity of KSM silica gel at $p/p_s > 0.6$ is higher than that of the zeolite, but significantly lower than that of the sulfonic cation exchanger in the hydrogen and salt forms in the whole range of the partial pressures. These sorption features are due to different mechanisms of water vapor sorption on inorganic sorbents, NaX zeolite, and KSM silica gel. It is known [10] that the microporous zeolite structure is filled even at low p/p_s, whereas the hydrophilic silica gel sorbs water vapor in a wide range of p/p_s.

The isotherms of water vapor sorption on all the ion forms of the sulfonic cation exchanger are S-shaped, which is typical of hydrophilic strongly polar polymers [14]. The fist sorption steps consist in hydration of sulfonic groups to form a monolayer of adsorbed water molecules. Next, some adlayers are formed by binding of water molecules with exchangeable cations. Finally, the sample swells owing to osmotic water absorption caused by capillary condensation of water vapor [15]. Clearly, this multistep mechanism causes high sorption capacity of the cation exchanger, which makes it promising as a desiccant of gas mixtures.

The moisture capacity of the zeolite under the dynamic conditions in the humidity range of 20–40% is the highest. However, as the p/p_s ratio increases, the adsorption of water vapor on the sulfonic cation exchanger and silica gel grows, especially at $p/p_s > 0.9$ (see table).

It should be noted that the dynamic sorption capacities of the zeolite and silica gel are underestimated as compared to published data [16]. This is probably due to the fact that, in small filters, whose length (10–15 cm) is comparable to the height of the working bed of the desiccant, the sorption capacity is saturated incompletely. This is not the case for the cation exchanger whose effective particle size is approximately 0.5 mm, i.e., is an order of magnitude smaller than that of grains of the mineral sorbents. In this case, the height of the working sorbent bed does not exceed 1 cm, so that the sorption occurs in the mode of frontal chromatography and hence the sorption capacity is comparatively high. It should also be noted that the color of the sulfonic cation exchanger in the cobalt form changes layerwise from blue to pink during saturation of the sorbent with water vapor. This is due to formation of cobalt(II) aqua complexes on the surface of the cation exchanger.

To assess the possibility of preparing a selective sorbent for drying of gas mixtures containing H_2S, SO_2, NO_2, NO, and CO, we studied the equilibrium sorption of these compounds on KU-23-15/100 cation exchanger in different ion forms and on KSM silica gel and NaX zeolite. The sorption isotherms of H_2S, SO_2, and NO_2 are shown in Figs. 3a–3c, respectively. As can be seen from Figs. 3a–3c, the sorption capacity

20	96	90	115	70
40	110	106	122	98
60	125	110	125	110
80	143	126	126	115
95	150	130	128	118

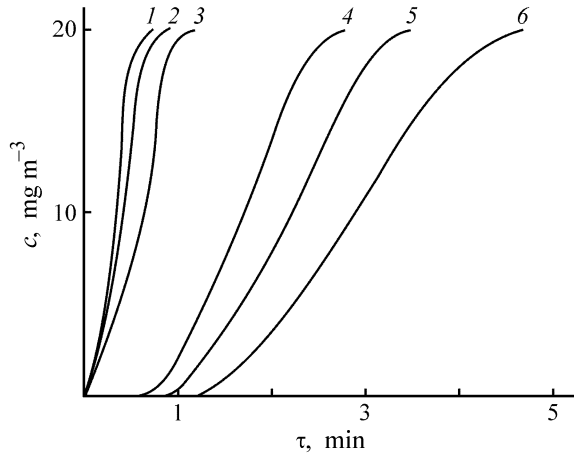

Fig. 4. Breakthrough curves of (*1*, *4*) H_2S, (*2*, *5*) SO_2, and (*3*, *6*) NO_2 on KU-23-15/100 sulfonic cation exchanger in the (*1–3*) hydrogen and (*4–6*) cobalt forms. (*c*) Sorbate concentration and (τ) time.

of the salt form of the cation exchanger for these gases is comparatively high and is comparable to that of the mineral adsorbents. The sorption capacity of the hydrogen form is substantially lower.

It is known [2] that the mechanism of specific interaction of ion exchangers with gases depends on the presence of water in the system. For example, the water content of the cation exchanger samples after attainment of the sorption equilibrium at 293 K and a residual pressure of 0.133 Pa is up to 5% [17]. As a result, the first step of sorption of H_2S, SO_2, and NO_2 on the salt forms of the cation exchanger occurs by the conventional ion-exchange mechanism between the cation of the sulfonic group and the proton of the mineral acid formed. It is clear that this is not the case for the hydrogen form of the sulfonic cation exchanger and hence the sorption capacity of this form for all of the compounds examined is significantly lower. Since NO and CO cannot form strong mineral acids, they are not noticeably sorbed by any of the ion forms of the sulfonic cation exchanger.

Taking into account the results obtained under equilibrium conditions, we studied further KU-23-15/100 sulfonic cation exchanger in the hydrogen and cobalt forms. The breakthrough curves of H_2S, SO_2, and NO_2 on these samples are shown in Fig. 4. It can be seen that the retention time in the case of the hydrogen form of the cation exchanger is as short as 30–50 s. Hence, this sorbent can be used for selective adsorption of water from mixtures of water vapor with H_2S, SO_2, and NO_2. The sorption properties of the spent sorbent are completely restored after heating at 393 K for 2 h. The zeolite and silica gel completely sorb these gases for several hours. The retention time τ_r for the cobalt form of the cation exchanger is 2.5–4.5 min. Thus, these sorbents cannot be used as selective desiccants.

CONCLUSIONS

(1) Macroporous KU-23-15/100 sulfonic cation exchanger in different ion forms was used for the first time as a selective desiccant for analytical pretreatment of gas samples containing water vapor in a mixture with H_2S, SO_2, NO_2, NO or CO. The specific sorption of water vapor on the sulfonic cation exchanger at $p/p_s > 0.5$ (this range is of the most practical interest) is higher than that on commercial desiccants, NaX zeolite and KSM silica gel.

(2) The advantages of KU-23-15/100 sulfonic cation exchanger in the H form as a selective desiccant of gas mixtures containing H_2S, SO_2, NO_2, NO and CO were demonstrated.

(3) It was shown that the cobalt form of KU-23-15/100 sulfonic cation exchanger can be used as indicator selective desiccant for gas mixtures containing NO and CO.

Abstract—Carbonization of birch sawdust modified with zinc chloride and selected properties of the resulting porous carbon materials were studied.

DOI: 10.1134/S1070427207060134

Birch wood is the conventional raw material for manufacture of carbon sorbents. Industrial technologies for production of activated carbon include stages of wood carbonization and subsequent activation of raw carbon with steam. With account of the low yield of activated carbon (5–12% relative to the mass of the starting raw material), a topical task is to raise the yield of activated carbon and to extend the resources of raw materials for manufacture of sorbents by using waste wood.

It is known that modification of plant polymers with various chemical reagents can be used to control the yield of the carbon product and its texture characteristics [1–3]. A promising way to produce carbon materials is modification of plant polymers with compounds of transition metals [1, 3–6]. In pyrolysis of metal-substituted plant materials, carbonization and chemical activation simultaneously occur [3–9]. It is believed that a modifying reagent activates aliphatic groups, with aryl–aryl C–C bond nearly unaffected at all, and leads to selective removal of oxygen, hydrogen, and other heteroatoms, accompanied by carbonization and activation at temperatures that are commonly below 650°C [4–8].

The goal of this study was to analyze fundamental aspects of thermochemical transformations of birch wood (BW) modified with zinc chloride and examine properties of the resulting porous carbon materials.

EXPERIMENTAL

Birch sawdust of the 0.25–0.50-mm fraction was used as object of study. The sawdust was activated by impregnation with an aqueous solution of $ZnCl_2$, followed by drying to constant weight. The content of $ZnCl_2$ in the samples obtained was 5 and 10 wt % (BW-5 and BW-10, respectively).

The samples were carbonized in an installation with a horizontal flow-through reactor in a flow of argon supplied at a rate of 130 $cm^3\ min^{-1}$. The heating was performed in a programmed mode at a rate of 10 deg min^{-1} to a temperature of 800°C, with a 30-min keeping at the final temperature.

The specific surface area of the carbon products was measured by the method of thermal desorption of nitrogen on a Gazometr-1 analyzer. The elemental composition was determined with a Flash EA 1112 instrument. Thermogravimetric studies were carried out on an MOM Q-1500D derivatograph (Hungary) by heating a sample in a flow of helium, delivered at a rate of 1200 $cm^3\ min^{-1}$, at a heating rate of 10 deg min^{-1} to a final temperature of 1000°C. IR spectra of the samples under study were recorded on a Vector 22 IR Fourier spectrometer.

Figure 1 shows how the yield and specific surface area of the carbon product (CP) depend on temperature. Up to a treatment temperature of 200°C, the yield of CP from unmodified sawdust exceeds that from

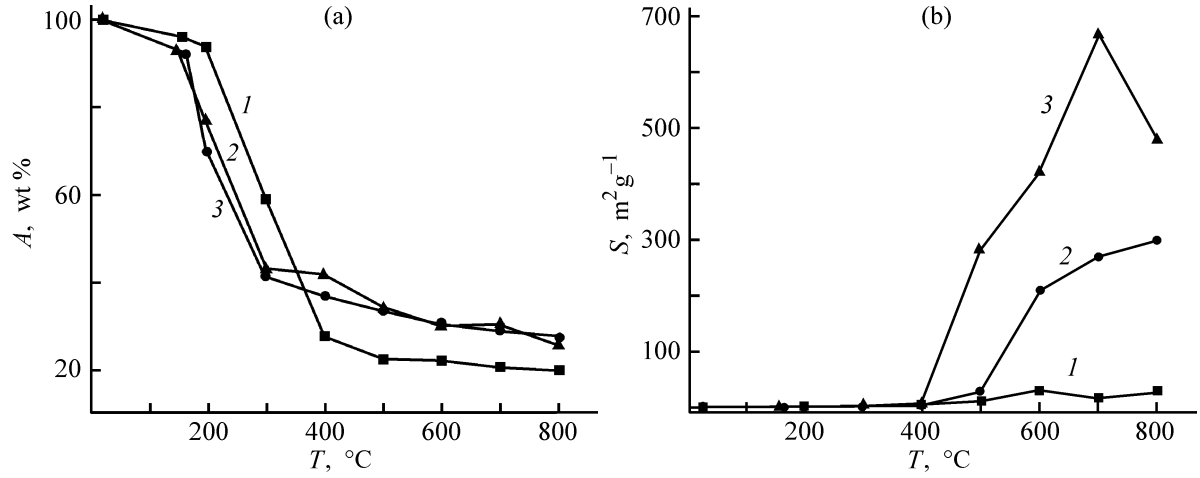

Fig. 1. (a) Yield *A* and (b) specific surface area *S* of the carbon product formed from (*1*) starting birch wood and (*2*, *3*) wood modified with solutions containing (*2*) 5 and (*3*) 10% $ZnCl_2$ vs. the carbonization temperature *T*.

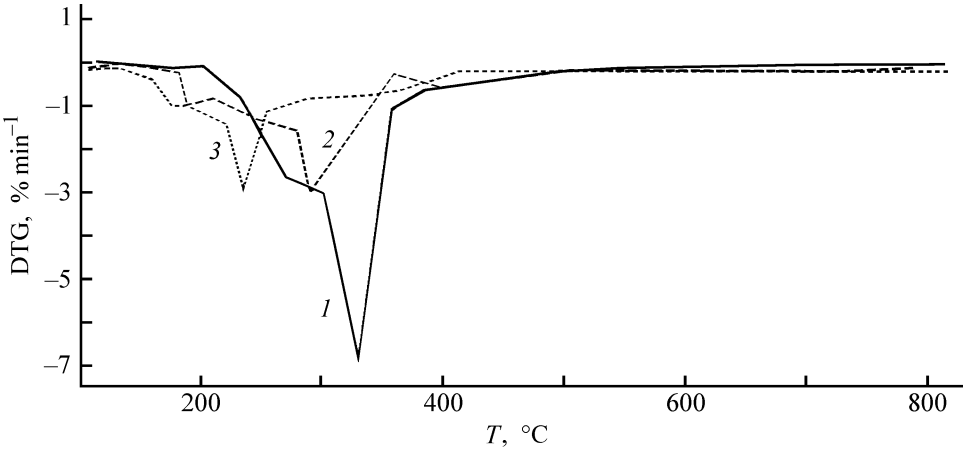

Fig. 2. Differential thermogravimetric (DTG) curves for (*1*) BW, (*2*) BW-5, and (*3*) BW-10 samples, obtained at a heating rate of 10 deg min^{-1}. (*T*) Temperature; the same for Fig. 3.

the samples promoted with $ZnCl_2$ (Fig. 1a). A major decrease in the yield of CP occurs in the range 200–400°C for a sample of the starting birch wood and in narrower range 200–300°C for samples of wood modified with zinc chloride. The yield of the carbon product from zinc-containing wood samples is 5–10 wt % higher than that from unmodified wood, with a change in the content of zinc chloride in the samples from 5 to 10 wt % having virtually no effect of the CP yield.

The specific surface area of the carbon product strongly changes in the course of carbonization of modified samples (Fig. 1b), whereas the specific surface area of the carbon product formed from unmodified birch wood increases with temperature only slightly: from 1.0 $m^2 g^{-1}$ at 25°C to 27.0 $m^2 g^{-1}$ at 800°C. The specific surface area of CP produced from BW-5 sample markedly grows at treatment temperatures exceeding 500°C, to reach a value of 300 $m^2 g^{-1}$ at 800°C. In carbonization of BW-10 sample, the specific surface area starts to grow at lower temperatures (400°C), to reach the maximum value of 670 $m^2 g^{-1}$ at 700°C. Thus, chemical activation of birch wood with $ZnCl_2$ leads to an increase in the yield and specific surface area of the carbon product in the course of carbonization. As the content of zinc chloride in BW increases, the yield of the carbon residue remains virtually unchanged and the specific surface becomes 1.5–2 times larger.

The thermograms in Fig. 2 demonstrate that the onset temperature and rate of thermochemical transformation of birch wood markedly decrease in the presence of $ZnCl_2$. The most intense thermochemical

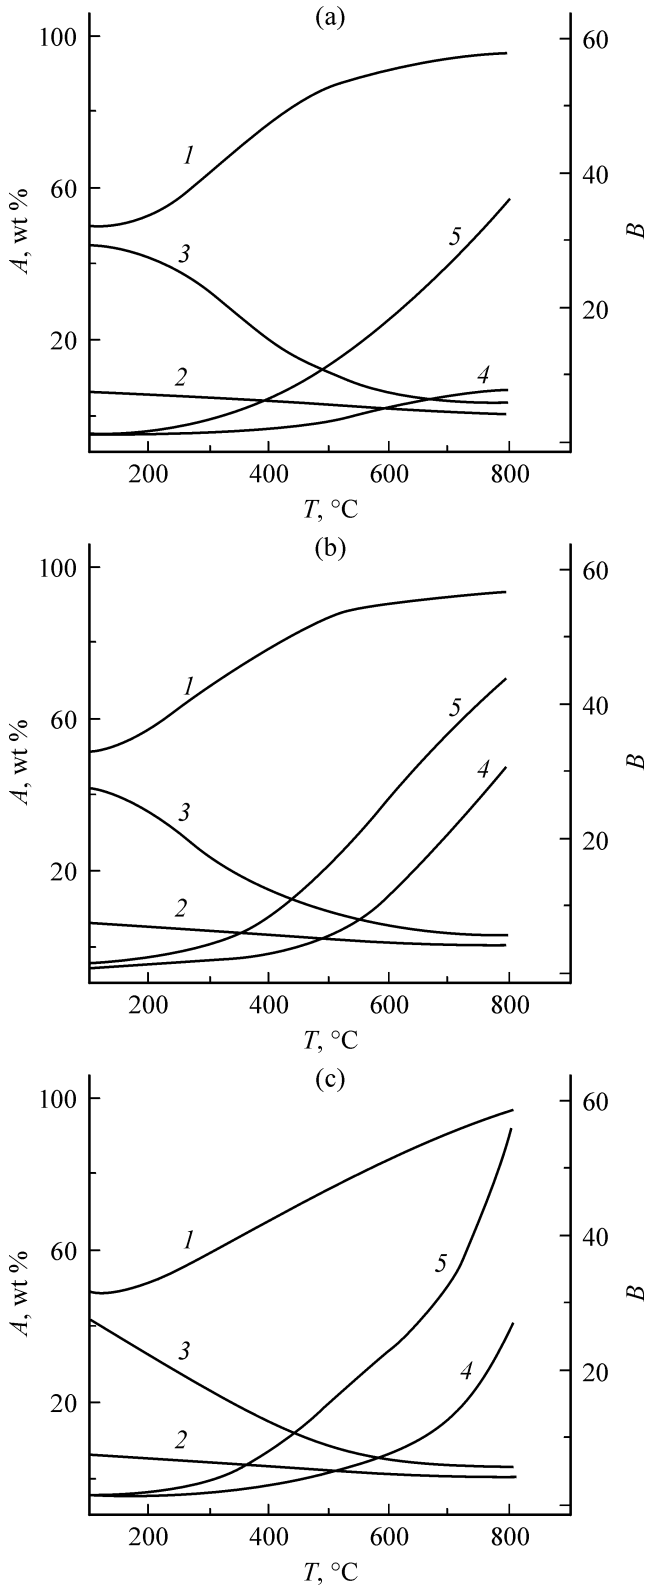

Fig. 3. Variation of the content *A* of (*1*) C, (*2*) H, and (*3*) O and of atomic ratios B (*4*) C/H and (*5*) C/O in the course of carbonization of birch sawdust. Sample: (a) BW, (b) BW-5, and (c) BW-10.

transformations are observed at 330°C for unmodified wood and at 290 and 235°C for BW-5 and BW-10, respectively.

According to the results of an elemental analysis, the content of carbon in carbon products obtained from modified and unmodified wood increases and the content of hydrogen and oxygen decreases as the treatment temperature becomes higher (Fig. 3). At carbonization temperatures exceeding 500°C, the C/O and C/H ratios markedly increase, especially for modified samples (Figs. 3b, 3c). The decarboxylation, decarbonylation, and aromatization processes are presumably intensified at temperatures exceeding 500°C in the presence of $ZnCl_2$ in a sample. This leads to formation of a developed porous structure of the carbon product.

Results of an IR spectral study of BW, BW-5, and BW-10 samples also indicate that the composition of unmodified wood changes at a treatment temperature of 300°C, and that of wood samples modified with $ZnCl_2$, at 200°C. In the process, the content of hydroxy and ester groups increases and an ordered cellulose structure starts to be observed. In the high-temperature region, there probably occur aromatization and condensation processes leading to removal of oxygen and hydrogen and to formation of a porous structure of the carbon product.

CONCLUSIONS

(1) Modification of birch wood with zinc chloride leads to a slight increase in the yield of the carbon product and to a rise in its specific surface area by a factor of 10–25. It is found that $ZnCl_2$ shifts the onset of intense thermochemical transformations of wood to lower temperatures by 100°C.

(2) In the course of pyrolysis, $ZnCl_2$ promotes reactions of deoxygenation and condensation of components of the organic matter of wood and favors development of a porous structure of the carbon product.

Abstract—Relationship between electrochemical, structural, and sorption properties of woven carbon materials modified with chitosan was studied.

DOI: 10.1134/S1070427207060146

Carbon materials, including activated carbon fibers (ACF), are used in technical electrochemistry for fabrication of energy accumulators [1] and as sorbents and electrosorbents in sorption processes for purification of technological solutions, potable water, and biological liquids [2, 3]. Carbon fibers having high electrical conductivity are used in both electrochemical and electrosorption processes [3, 4]. To raise the working surface area, capacity, and selectivity of fibers, they are modified with metal oxides and hydroxides, by chemical and electrochemical oxidation, and by deposition of films of synthetic and natural polymers [5]. A promising modifying agent is chitosan, which can form membranes, has high selective permeability to water, good bioadhesion, high mechanical strength, and is susceptible to chemical modification because of the presence of chemically active amino and hydroxy functional groups [6]. Chitosan can serve as a support or sorbent for biological substances [7]. The maximum unfolded state of the chitosan surface and accessibility of all the active ionogenic groups can be achieved on depositing the biopolymer onto the surface of a porous support [8]. Carbon materials having chemical stability in acid and alkaline media, electrical stability and conductivity, and highly developed porosity and surface, are best suitable for this purpose. The best among various methods for deposition of a modifier onto a solid surface are electrochemical methods, which allow control over the growth and size of particles being deposited onto the support surface [9]. Use of chemical and(or) electrochemical modification methods enables, with account of the properties of chitosan and carbon fibers, targeted synthesis of chitosan–carbon materials with controllable properties [10]. It is necessary, however, when using materials of this kind as electrodes, to primarily take into account the fact that the operation efficiency of an electrode depends on the accessibility of its surface to the electrochemical process. In turn, the course of the electrochemical is strongly affected by the porous structure of the carbon material [11].

The electrochemical properties of a carbon material brought in contact with an electrolyte solution make it possible to assess changes of its structural and surface characteristics [12]. The porous structure of the carbon matrix affects formation at the interface of an electric double layer (EDL), within which charge redistribution and adsorption of ions or molecules occur [13]. Therefore, elucidation of the relationship between the electrochemical, structural, and sorption properties of fibers will enable us to characterize the modified materials under study to a fuller extent.

The aim of this study was to examine the possibility of using woken carbon materials modified with chitosan as electrodes and sorbents.

EXPERIMENTAL

We used as an electrode a Busofit T-055 activated woven carbon fiber, whose specific surface area, pore volume, and average pore radius are 700 $m^2 g^{-1}$, 0.55 $cm^3 g^{-1}$, and 3.5–8 Å, respectively. In addition, we used modified carbon fibers produced by deposition of chitosan onto the surface of the starting Busofit in the absence of polarization [ACF(w/o/p)] and

at potentials of +0.9 V [ACF(900)] and –0.9 V [ACF(900)] [10].

Electrochemical measurements were performed using methods of cyclic voltammetry and charging curves in solutions of 0.9% NaCl (physiological solution) and 3.5% NaCl. The solutions were vigorously agitated and bubbled with inert gas. The choice of the electrolytes was governed by further studies of sorption processes for protein recovery with chitosan–carbon materials (CCM). The fiber samples under study were placed on a gold grid serving as an inert current lead. A silver chloride electrode was used as reference. The auxiliary electrode made of a porous carbon material was separated from the working electrode by an MB-2 bipolar membrane. Potentiodynamic curves were obtained with a P-5848 potentiostat in the double-layer region of potentials in the range ±50 mV relative to the immersion potential of the working electrode [14]. The capacitance of the EDL was calculated by the formula [14, 15]:

$$C = I/mv = (I_c + I_a)/2mv. \quad (1)$$

Here, C is the electrode capacitance (F g^{-1}); I_c and I_a, cathode and anode polarization currents (A); and v, potential sweep rate (mV s^{-1}).

The degree (fraction) α of utilization of the electrode surface in the electrochemical process was calculated using the relation

$$\alpha = C/C_{max}, \quad (2)$$

where C and C_{max} are the electrode capacitances at a given and the minimum potential sweep rates.

When processing the potentiodynamic curves by the least-squares method, we calculated the characteristic charging time of the EDL (τ) and the ohmic resistance of the electrolyte within pores ($R = \tau/c$) by the formula [16]:

$$I = Cv\left[1 - \frac{2}{\pi^2}\sum_{n=0}\frac{1}{\left(n+\frac{1}{2}\right)^2}\right]e^{-\pi^2(n+\frac{1}{2})^2\frac{t}{\tau}}. \quad (3)$$

Here, I is the current (A g^{-1}); v, potential sweep rate (V s^{-1}); t, time; and n, summation index.

In galvanostatic measurements, the polarizing current density was chosen experimentally. In all cases, the charging current density was varied within the range 10^{-11}–10^{-10} A cm^{-2}. The capacitance C (F g^{-1}) was calculated by the formula

$$C = I\Delta t/m\Delta E, \quad (4)$$

where I is the polarization current (A); Δt, electrode charging time (s); m, electrode mass (g); and ΔE, shift of the electrode potential (V).

The sorption properties of the fibers for bovine serum albumin (BSA) was studied in recovery of the protein from a physiological solution (0.9% NaCl) with a BSA concentration of 1 mg ml^{-1} under static conditions in a standard three-electrode cell. The protein was analyzed by HPLC on a Shimadzu LC-10Avp liquid chromatograph (Japan) with a Shimadzu SPD-10Avp UV detector (wavelength 280 nm). The amount Γ of sorbed BSA (mg g^{-1}) was calculated by the formula

$$\Gamma = (c_{in} - c_{eq})V/m,$$

where c_{in} and c_{eq} are the initial and equilibrium concentrations of the protein in a solution (mg cm^{-3}); V, solution volume (ml); and m, sorbent mass (g).

BSA was desorbed by changing the charge of the electrically conducting carbon matrix in the same solution from which the protein was preliminarily recovered at the open-circuit potential. The measurements were made relative to the silver chloride electrode. The potentials at which the BSA desorption was carried out were chosen in the range in which no chemical transformations occurred with the protein. For this purpose, preliminary voltammetric measurements were performed in a system constituted by the protein and carbon fibers.

Microscopic studies were carried out with an EVO-50XVP scanning electron microscope in the secondary-electron mode at accelerating voltages ranging from 20 to 30 kV. The materials to be studied were glued with a conducting silver glue to an aluminum table.

The use of porous carbon electrodes with a highly developed surface markedly improves the efficiency of the electrochemical process. However, the electrode polarization may hinder the charging process. This hindrance is due to slow supply of ions (diffusion hindrance) or to changes in the potential within pores (ohmic hindrance). In addition, presence of micropores less than 1.5–2.0 nm in size, within which EDL formation is difficult [14, 17], can complicate polarization of the intrapore space and impair the operation efficiency of the porous electrode. Also, the modification of the carbon surface can change its structure and, as a result, alter the accessibility of the surface to the electrochemical process.

Effect of ACF modification on the capacitances and charging parameters of the electrodes in various NaCl solutions

Sample	C_1	C_2	R, ohm	τ, s
	F g^{-1}			
0.9% NaCl				
Starting	50.89	51.09	79.2	434
(+900)	64.85	64.97	198.3	1529
(w/o/p)	58.46	58.7	233	1929
(–900)	43.45	43.64	68.5	389
3.5% NaCl				
Starting	50.42	50.32	27	129
(+900)	69.79	69.58	28.3	189
(w/o/p)	60.5	60.18	42.8	255
(–900)	47.37	47.14	28	162

Note. C_1 was found from the results of voltammetric measurements at the minimum potential sweep rate, and C_2, from galvanostatic data.

To find out whether the chitosan film is permeable and the surface is accessible to electrolyte ions forming the EDL plate, we preliminarily determined the capacitances of unmodified and chitosan-coated glassy carbon electrodes. We obtained that the capacitances of such electrodes are the same and equal to 8 μF cm^{-2}. This value is comparable with the data of other researchers who measured the capacitances of glassy carbon electrodes in various solutions [14, 17]. The results obtained suggest that the chitosan film does not prevent electrolyte ions from penetrating to the carbon surface to form an EDL. It was shown in [6] by various methods, including cyclic voltammetry, that a chitosan film deposited on glassy carbon has good permeability and favors fast penetration of electrolyte ions to the surface of the carbon material.

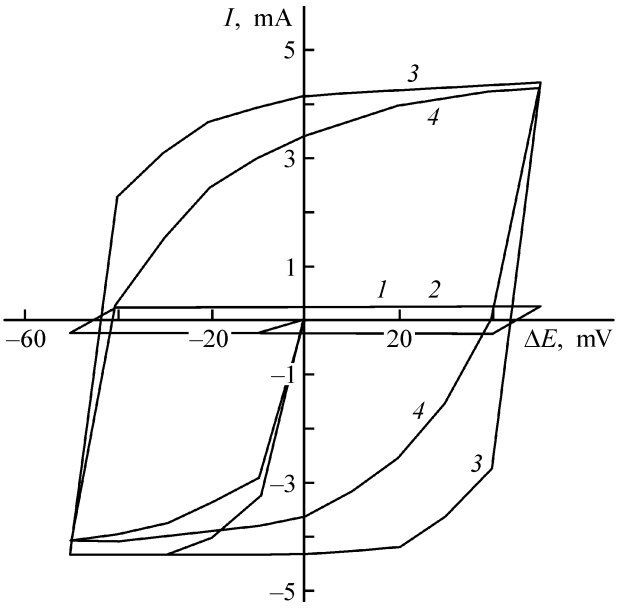

Fig. 1. Cyclic voltammetric curves obtained on (*1*, *3*) initial and (*2*, *4*) modified ACF(–900) in a solution of 0.9% NaCl at various potential sweep rates *v*. (*I*) Current and (Δ*E*) shift of the potential from the steady-state value. *v* (mV s^{-1}): (*1*, *2*) 0.04 and (*3*, *4*) 0.1.

The capacitance of the electric double layer is one of the main electrochemical characteristics of an electrode. The capacitance of EDL depends on the conditions of its formation in the porous structure of carbon materials, including those modified. Data on the EDL capacitance make it possible to calculate the charging conditions of porous fibrous electrodes [18] and to evaluate the efficiency of utilization of ACF and ACF-based composites in processing occurring under polarization.

One of methods for determining the EDL capacitance of porous carbonic and fibrous electrodes is cyclic voltammetry [14], which can evaluate the effect of the structural and surface properties of carbon materials on the conditions of their charging. We compared the electrode capacitances found by cyclic voltammetry and galvanostatic measurements. The values obtained are listed in the table. The good agreement of the results indicates that these two methods can be equally successfully used to determine the capacitance of porous electrodes.

The effect of the porous structure on the charging of carbon materials can be judged from the shape of voltammetric curves. Figure 1 shows as an example voltammograms obtained at different polarization rates in a solution with 0.9% NaCl. The shape of the cyclic curves, with equal areas under the anodic and cathodic portions indicates that no irreversible Faraday processes occur [19]. The voltammograms obtained at the minimum potential sweep rate of 0.04 mV s^{-1} (curves *1*, *2*) have a virtually rectangular shape, which indicates that there are no hindered charging processes, which appear upon a considerable increase in the electrode polarization rate (curves *3*, *4*). The occurrence of hindered charging processes may be due to porous structure parameters of the fiber, surface phenomena at the electrode–solution interface, and properties of the conduction band of the carbon material [20], dependent on the preparation conditions of the carbon fabric. In turn, modification of the carbon fiber predetermines changes of its porous structure, which will affect the charging conditions of chitosan–carbon materials.

The differences in charging and the structural features of modified fibers can be judged from the dependence of the electrode capacitance on the potential sweep rate (Fig. 2). The EDL capacitance calculated at the minimum potential sweep rates is close to that found from galvanostatic measurements (see table). As the load on the electrode increases, the capacitance decreases, which is due to diffusion and ohmic limitations appearing in a structure whose specific features are determined by the modification conditions of the carbon matrix. Deposition of chitosan onto the surface of a porous support in the absence of polarization and under an anodic potential gives CCM in which the capacitance is larger compared with that for an unmodified fabric. The capacitance of the composite material obtained upon chitosan deposition at cathodic potentials is lower than that of the unmodified electrode (see table). However, the CCM obtained at cathodic potentials is polarized more uniformly, compared with the composites produced at anodic potentials. An increase in the charging rate of an electrode does not lead to any sharp decrease in its capacitance and in the fraction of its working area that is involved in the electrochemical process (Figs. 2 and 3, curves *4*). It should be noted that, in the case of polarization in a solution with 3.5% NaCl, the capacitance of the electrodes under study does not decrease considerably and the fraction of the surface involved in the electrochemical process remains rather large. Presumably, this is favored by a substantial increase in the concentration gradient of charged particles promoting faster EDL formation in an electrode subjected to charging.

A mathematical processing by Eq. (3) of the dependences of the capacitance of the electrodes on the rate of their polarization made it possible to calculate the charging time of the electrodes and the electrolyte resistance in the intrapore space. Analysis of the data presented in the table shows that charging of CCM (especially in the 0.9% NaCl solution) depends on the preparation conditions of these materials. A faster charging with a lower electrolyte resistance within pores is observed for modified electrode materials obtained in cathodic deposition of chitosan onto a carbon matrix. Presumably, this method of modifier deposition gives a structure that favors better EDL formation and more uniform charging of the chitosan–carbon electrode.

The use of scanning electron microscopy (SEM) revealed structural differences between the starting and modified carbon matrices. It was found that meso- (~25 to 50 nm) and rounded macropores not exceeding 320 nm in size are present on the surface of the

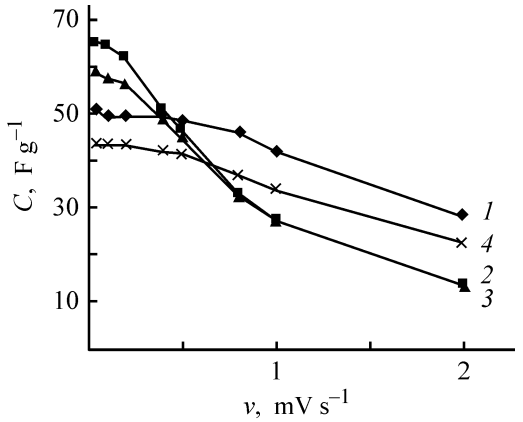

Fig. 2. Capacitance C vs. the potential sweep rate v in polarization in the double-layer range of potentials in a solution with 0.9% NaCl. (*1*) ACF, (*2*) ACF(+900), (*3*) ACF(w/o/p), and (*4*) ACF(–900); the same for Fig. 3.

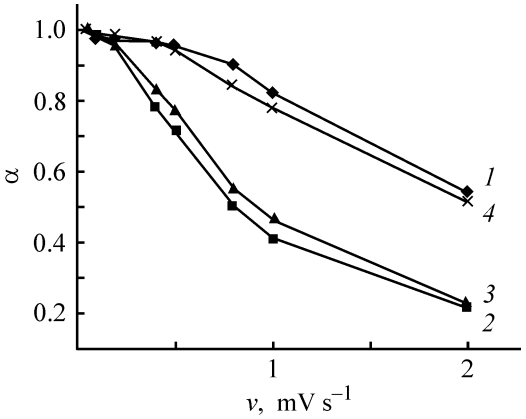

Fig. 3. Surface fraction α vs. the potential sweep rate v for carbon electrodes in a solution of 0.9% NaCl.

starting woven fiber. The surface is mostly covered by mesopores.

Modification of a carbon fiber at cathodic potentials leads to deposition onto the ACF surface of an insoluble chitosan as a result of solution alkalinization in the near-electrode space. In the cathodic polarization, the porous structure of the carbon matrix changes, with the depth of pore penetration into the fiber increasing. Finer pores merge in the course of their development into macropores of complex structure, which have the form of a sieve combining meso- and macropores of size not exceeding 300 nm. Presumably, the formation of just this kind of hierarchic structure across the depth of the porous electrode affects the charging conditions of the modified electrode.

In anodic polarization, a large number of macropores, absent in the starting fiber, are formed in the surface layer of the modified fiber. This is due to

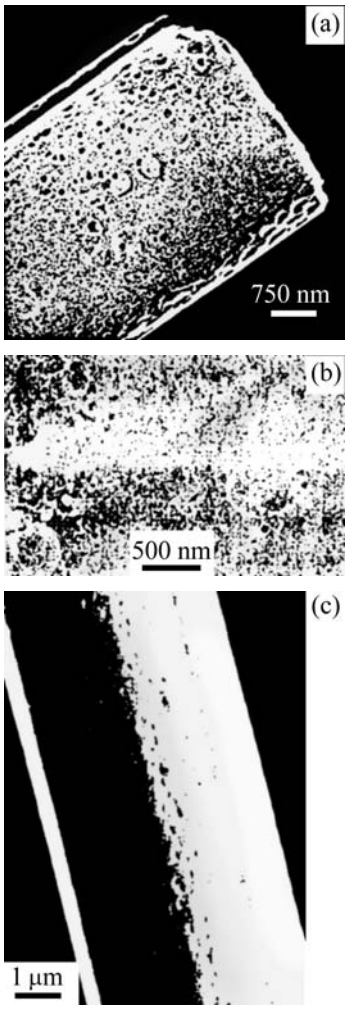

Fig. 4. SEM images of (a) starting and (b, c) modified carbon fibers. (b) ACF(–900) and (c) ACF(+900).

an additional electrochemical oxidation of the surface [21]. Thus, according to SEM data, the morphology of the carbon surface strongly varies with the conditions of ACF treatment.

Figure 4 shows SEM images of the surface of the starting and modified fibers.

Having determined the electrochemical characteristics of CCM, we can judge about changes in the structure of the carbon matrix in modifier deposition, whereas determination of sorption characteristics of CCM allows evaluation of changes in the surface parameters of the carbon fiber upon its modification. We studied the sorption properties of CCM in recovery of BSA from a physiological solution (0.9% NaCl). For the unmodified fiber and chitosan–carbon materials obtained at potentials of –0.9 and +0.9 V, the sorption capacities are 20.4, 73.7, and 36.7 mg g^{-1}, respectively, i.e., the absorption capacity of CCM for albumin depends on the preparation conditions of the sorbents. In chitosan deposition onto a carbon matrix, the chemical nature of the surface significantly changes, with hydrophilic-hydrophobic areas with different densities of ionogenic groups formed as a result of chitosan deposition onto the surface of a charged fiber at different polarization potentials [10]. This, in turn, determines the sorption capacity of the composite materials.

Changing the surface charge of a chitosan–carbon fiber with preliminarily sorbed BSA, with the surface potential shifted into the cathodic region, leads to desorption of the protein from the surface of the carbon material and can serve as a method for sorbent regeneration [22]. By electrodesorption of BSA under cathodic polarization (ΔE = –0.3 V), 42.7, 72.6, and 35.2% of the preliminarily sorbed protein can be removed from the surface of, respectively, unmodified sorbent and chitosan–carbon sorbents obtained at cathodic and anodic potentials. BSA is removed from the surface because of the generation of OH^- ions under the cathodic polarization of the carbon material [14, 17], and these ions substantially change the pH in the nearelectrode layer. This, in turn, leads to ionization of protein molecules and to repulsion of like-charged ions from the sorbent surface. Thus, cathodic polarization of the CCM makes it possible to remove BSA from its surface and to restore the absorption capacity of the sorbent.

We found in a study of the sorption properties of CCM that chitosan is firmly retained on the carbon matrix and is washed into solution neither in protein adsorption nor in sorbent polarization. This was indicated by the results of an analysis by HPLC of solutions formed upon adsorption and desorption of BSA from the CCM surface. The absence of even trace amounts of chitosan in the liquid phase indicates that chitosan is firmly fixed to the fiber surface. In addition, the absence in chromatograms of additional peaks corresponding to appearance of albumin decomposition products suggests that protein molecules do not undergo any destructive changes when in contact with the modified surface.

CONCLUSIONS

(1) It was shown that modification conditions affect the process of charging of chitosan–carbon electrodes. The modified fabric produced in chitosan deposition onto an electrically conducting matrix in the range of cathodic potentials is a promising electrode material and can be successfully used in an electrosorption process.

(2) The adsorption of bovine serum albumin was studied and it was demonstrated that the fiber modification conditions affect both the absorption capacity of the chitosan–carbon sorbent and the removal of albumin from the fiber surface.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Isopropyl Alcohol on Cathodic Deposition of Ultradispersed Copper-containing Powders from Electrolyte Solutions

Abstract—The possibility of cathodic deposition of copper-containing powders of nanosize dispersity from solutions of copper dichloride in a mixed water–isopropanol solvent was studied.

DOI: 10.1134/S1070427207060158

By now, a large number of techniques for production of nanomaterials with prescribed size, shape, and other particle parameters have been developed [1–3]. All methods for synthesis of highly dispersed materials, including ultradispersed powders of metals and metal-containing compounds, can be conditionally subdivided into those of mechanical and condensation types [4, 5]. The former involve comminution of starting raw materials without, as a rule, changes in their chemical composition. In processes of the latter type, both the aggregative state and chemical composition of the starting components change.

Powders of copper and copper oxides are of particular interest for chemical technology and industry. Ultradispersed copper-containing powders can be used as additives to metal-ceramic sealants and to lubricants for various friction units [6].

A promising area of modern technologies is electrochemical cathodic deposition of metal-containing nanosize powders from electrolyte solutions [7–9]. In this technique, a metal and its compounds pass from the dissolved state into a solid state in the form of loose deposits. To important advantages of this method belong the simplicity of the apparatus used and the possibility of controlling the process by changing the electrical modes.

The formation of a cathodic deposit in electrolysis is governed by the occurrence and competition of two parallel processes: nucleation and dynamics of nucleus growth. If the number of nucleation centers formed exceeds that of developing centers, the resulting deposit is finely dispersed. Therefore, an important factor governing the mechanism and kinetics of these reactions is the required balance of the rates of these processes. A high dispersity of electrodeposited particles can be achieved in the presence of surfactants. The effect of surfactants introduced into an electrolyte is primarily manifested in a redistribution of the rates of formation and growth of a new phase via blocking of active centers and change in surface energies at interfaces. Performing an electrochemical synthesis at the limiting current density makes it possible to recover metal-containing products from electrolyte solutions directly as highly dispersed powder.

This study is concerned with the effect of organic additives to an electrolyte on the dispersity of copper-containing powders produced by electrochemical cathodic reduction from copper dichloride solutions with a concentration of 0.1 mol kg^{-1} solvent (m) in mixed water–isopropanol solutions of various compositions.

EXPERIMENTAL

The electrochemical deposition of copper-containing powders was performed in a glass cell. A steel rod served as a cathode. As anodes were used ruthenium-titanium oxide plates. Current was switched on several seconds after the electrodes were submerged in the electrolyte. During this time, a thin homogeneous layer of contact copper was formed, in which the ripening of active centers and the subsequent growth of ultradispersed cathodic deposits were considerably

faster than those in the case of direct deposition onto a steel rod.

The electrocrystallization of copper was performed from solutions without forced agitation and removal of dissolved oxygen. A minor amount of hydrogen evolving in the accompanying process provided natural agitation of the solution in the near-cathode space and favored loosening of the growing deposit. A criterion for termination of the process was vigorous hydrogen evolution, and, therefore, the duration of deposition varied between the experiments. The evolving hydrogen had no effect on the quality of the forming deposit and did not enter into its composition. The electrolytic deposit was formed on the cathode as a sponge at T = 25°C. The deposit formed upon completion of the electrolysis was three times washed with twice-distilled water and then with isopropyl alcohol and dried to a powdered state. The electrolyte was prepared from reagents of chemically pure grade. Isopropyl alcohol i-C_3H_7OH (0.00–0.80 mole fraction) served as an organic component.

To determine the working concentration ranges of copper dichloride and the initial current density corresponding to the limiting mode of diffusion mass transfer, polarization studies were carried out in the potentiodynamic mode with a PI-50-1 potentiostat with a PR-8 programming unit. The potential sweep rate was 5 mV s^{-1}. The working electrode had the form of a cylindrical copper disc embedded in fluoroplastic. A platinum electrode served as auxiliary electrode, and a saturated silver chloride electrode, as reference. The cathodic polarization curves were measured in the model solutions under study. Because of the increase in the cathode surface area in the course of electrolysis, the polarization curves are plotted with currents, rather than current densities.

It can be seen from Fig. 1 that the optimal concentration of copper dichloride for electrochemical synthesis of ultradispersed powders is 0.1 mol kg^{-1}. Carrying out the electrolysis at higher salt concentrations is difficult in view of the instability of the electrolysis mode, because the range of formation of finely dispersed deposits is very narrows. In 0.1 m copper dichloride solutions, the range of potentials in which the rate of ion delivery into the near-cathode space lags behind the rate of their discharge (and just this is one of the main reasons why finely dispersed copper-containing deposits are formed) is sufficient for the formation of crystallization centers and their subsequent growth. At lower salt concentrations, electrochemical deposition is inadvisable for several reasons: low deposition rate, low yield of the product, and increase in the size of particles contained in the cathodic deposits obtained.

Figure 2 shows the results of polarization studies in 0.1 m aqueous-organic solutions of copper dichloride with various concentrations of isopropyl alcohol. The polarization curves have the classical shape characteristic of multistage processes occurring under the diffusion control. This is manifested in the appearance of plateaus corresponding to limiting currents. A steep rise in current, which follows these plateaus

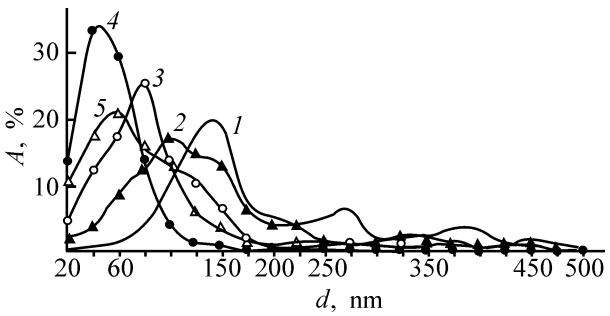

Fig. 3. Size distribution of copper-containing particles obtained in solutions with varied content of i-C_3H_7OH. (*A*) Fraction of particles and (*d*) particle diameter. i-C_3H_7OH content (mole fraction): (*1*) 0.00, (*2*) 0.01, (*3*) 0.03, (*4*) 0.04, and (*5*) 0.08.

in the polarization curves, is due to vigorous evolution of hydrogen.

Analysis of the results of the polarization studies suggests that carrying out electrolysis at isopropanol concentrations exceeding 0.12 mole fraction is inadvisable because of the pronounced coarsening of particles. The peaks observed in the polarization curves are due to formation of difficultly soluble chlorine-containing compounds of copper(I) [10]. As the concentration of the organic component increases, the cathodic polarization curves shift to more electronegative values and the peak heights and cathode currents decrease, which can be attributed to an increase in the viscosity of the aqueous-alcoholic electrolyte [11] and to the resulting decrease in the diffusion coefficients of copper ions.

The data previously obtained in measurements of the surface potentials of organic and aqueous-organic solvents of various classes [12–14] (on reaching a certain concentration of the nonaqueous component in an aqueous-organic mixture, the surface potential changes its sign on passing from water to nonaqueous solvents) suggest that the diffusion layer in the near-electrode space is virtually completely composed of alcohol molecules after an isopropanol content of 0.12 mole fraction is reached. This leads to a decrease in the dielectric constant and the electrical conductivity of this part of the solution, and, as a consequence, in the cathodic currents.

The particle size of the deposited powders was found from micrographs obtained with an EMV-100 L transmission electron microscope in the high-resolution mode at an accelerating voltage of 75 kV [15]. Electron-microscopic measurements were performed for several preparations of each of the samples, immediately after they were made up. For each preparation, several micrographs of its various microscopic areas were taken, which provided a statistical sample sufficient for reliable construction of histograms characterizing the dispersion composition of the powders. Data on the size distribution of electrolytically deposited nanosize copper-containing powders in relation to the composition of the nonaqueous solvent are listed in the table. The distribution curves plotted using these data (Fig. 3) confirm the conclusion that isopropanol additives affect the powder particle size. The maximum amount of 20–100-nm powder particles was obtained at an isopropanol content of 0.04 mole fraction. The maximum lies at around 50 nm. The amount of coarser particles is small and equal to about 10–15% of the total.

CONCLUSIONS

(1) The study performed demonstrated that nanosize copper-containing powders can be produced by electrochemical reduction from aqueous-organic electrolyte solutions.

(2) It was found that the electrochemical crystallization of copper-containing deposits from copper dichloride solutions in water–isopropanol mixtures is strongly affected by the composition of the aqueous-organic solvent.

(3) It was shown that addition of low-molecular-weight surfactants to aqueous electrolyte solutions lead to a decrease in the limiting cathodic currents, which favors formation of finely dispersed deposits and ultradispersed powders.

(4) It was demonstrated that use of organic solvents as additives to water opens up promising opportunities for optimization of the size characteristics of metal-containing powders obtained from electrolyte solutions by cathodic reduction.

CATALYSIS

Electron and Proton Transfer in Acid–Base Catalysis

K. K. Kalnin'sh

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April, 12 2007

Abstract—The role of electron and proton transfer in acid–base catalysis is discussed, with two reactions as examples, in one of which (polymerization of cyclobutenes) an acid, and in another (nitramide decomposition), a base acts as the catalyst.

DOI: 10.1134/S107042720706016X

The conventional theory of acid–base catalysis regards proton transfer as the basic elementary process [1]. These views originate early papers by Brønsted and Pedersen [2, 3], who established the catalytic law in the simple form

$$k_A = G_A K_a^{\alpha} \quad (1a)$$

for an acid and

$$k_B = G_B (1/K_a^{\beta}) \quad (1b)$$

for a base. Here k_A, k_B are the reaction rate constants; K_a, acid dissociation constant; G_A and G_B, constants; and indices A and α refer to the acid, and B and β, to the base.

Equations (1a) and (1b) are usually represented in the linear logarithmic form:

$$\log k_A = -\alpha \, pK_a + \text{const}, \quad (2a)$$

$$\log k_B = \beta \, pK_a + \text{const}. \quad (2b)$$

Linear dependences (2a) and (2b) have been obtained for a number of systems and many acids and bases, but they are not universal. Bell [4, 5] advanced (apparently for the first time) a concept stating that the acid–base catalysis is based on proton transfer. It is believed that the cleavage of a covalent bond is much easier when one of the reacting molecules is protonated [1]. The general acid–base catalysis theory was also applied to enzymatic catalysis, whose extremely high efficiency is attributed to high concentrations of acids and bases in the enzymatic active site and proper orientation of the reacting groups [1].

We have suggested a totally different approach to the mechanism of acid–base catalysis [6–11] and demonstrated that, like any other chemical reaction, a catalytic reaction is based on by electron transfer (excitation), and proton transfer (or hydrogen bonding) facilitates, catalyzes, this process. We believe that proton transfer itself does not cause a structural rearrangement of the molecule, and a chemical bond is actually cleaved only via subsequent electron transfer, yielding chemically active radical species. The proton transfer, combined with transfer of electron in an electronically excited state, underlies the fundamental electron–proton effect [12]. The latter consists in a decrease in the lifetime and a huge decrease in the energy of the electronically excited states of the molecular complexes (associates) down to thermal energies, due to interrelated transfers of the electron and proton.

This paper discusses the mechanism of acid–base catalysis with two reactions as examples, using data of nonempirical quantum-chemical calculation. For the calculation technique, see [13, 14].

Electron-donor–acceptor and proton-donor–acceptor interactions in the reaction complex. Among the elementary stages of acid–base catalysis, electron transfer (excitation) is of special importance, as it immediately precedes the chemical transformation of the molecules. The probability of thermal transfer of an electron depends on the state of the proton-donor–acceptor (PDA) interactions between the molecules of the reactants, and the latter, in turn, are directly exposed to the third species, a catalyst. This requires a combined analysis of the electron-donor–acceptor (EDA) and PDA properties of the molecules of the reactants in the presence of an acid or base catalyst.

There are two important factors governing the catalytic effect of acids and bases in reactions in which the reactants are not identical: one acts as electron donor, and the other, as electron acceptor.

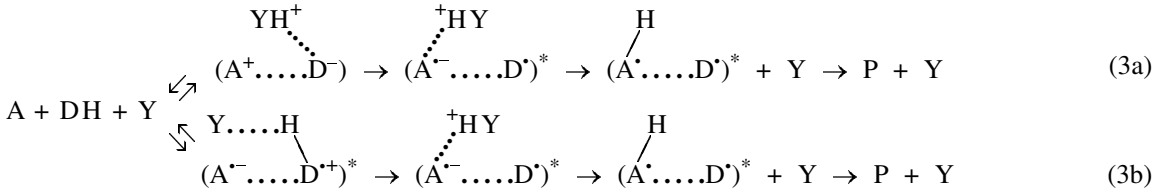
(1) An acid (generally, a proton donor) activates one of the reactants acting as an electron acceptor in such a manner that its electron affinity increases.

(2) A base (generally, a proton acceptor), by contrast, activates the electron donor via hydrogen bonding or deprotonation, thereby making lower its ionization potential.

These effects, taken separately (acid or base catalysis) or in combination (bifunctional catalysis), enhance the EDA power of the molecules of the reactants, thereby lowering (in terms of the approach taken here) the energy of the excited level of the reaction complex and the energy barrier of the reaction. The strength of the interaction of the acid or base with the reactant widely varies from weak hydrogen bond, which can be discussed in terms of the continuum approach, to complete proton transfer: proton addition to (protonation), or detachment from (deprotonation) the reactant molecule. Only the latter case, protonation/deprotonation of reactants, is typically regarded as catalysis, whereas weak interactions are qualified as the influence of the environment. The acid–base catalysis theory being developed considers all these cases from a common standpoint: In all of them the PDA interactions are responsible for the lowering of the energy of the excited level of the reaction complex.

The proton transfer in the DH + Y system, where Y is a proton acceptor, takes place only in the limiting case of strong interactions; a more common case is hydrogen bonding D–H…Y. Importantly, the H bond is stronger and the probability of the proton transfer in the excited state of the complex, much higher, compared to the ground state because of an increase in the acidity of the OH groups in the radical-cation state yielded by the electron transfer. The energy of stabilization of the excited levels via hydrogen bonding is very significant and, according to our data, can exceed 1.5 eV. In the case when proton transfer precedes electron transfer, and, hence, occurs in the ground state, the role of the base catalyst consists in lowering the ionization potential of the reagent, down to 1–3 eV in the case of complete deprotonation of DH.

In base catalysis, the catalyst Y activates the electron and proton donor DH via deprotonation [Eq. (3a)] of DH or hydrogen bonding [Eq. (3b)]

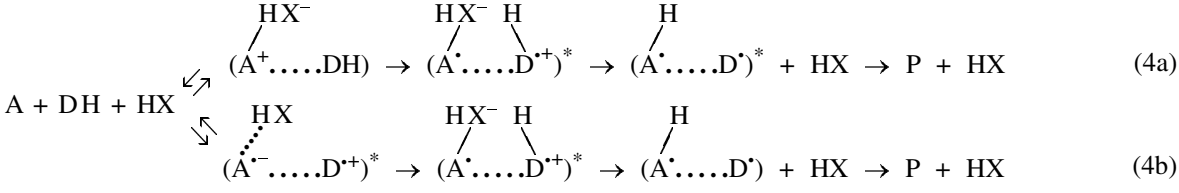


(3a)

(3b)

The resulting enhancement of the electron-donating power of DH makes higher the electron transfer probability. Of key importance in the given context is the formation of excited levels with low energies (<1 eV), as specifically these levels can be thermally populated under ordinary conditions.

In acid catalysis [Eq. (4)], an acid HX that acts as a catalyst (a strong proton donor) interacts with both the electron acceptor A and the electron donor DH. The latter interaction is energetically more favorable, but yields hydrogen-bonded X–H…..DH or protonated $DH_2^+X^-$ species, which are not involved in the reaction, because of the weakening of the electron-donating power in the reaction of DH with acid HX. In acid catalysis, the basic initiating event is the activation of the acceptor A:



(4a)

(4b)

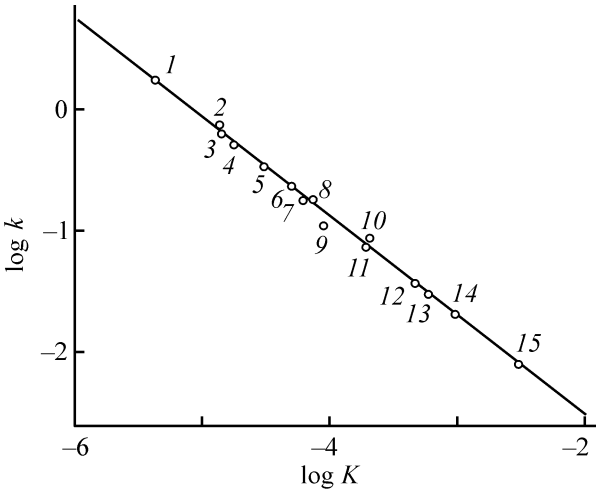


Fig. 1. Brønsted plots for the catalytic reaction of nitramide decomposition [2]: (*1*) succinate II, (*2*) malate II, (*3*) propionate, (*4*) acetate, (*5*) succinate I, (*6*) phenyl acetate, (*7*) benzoate, (*8*) tartrate II, (*9*) oxalate II, (*10*) formate, (*11*) malate I, (*12*) tartrate I, (*13*) phthalate I, (*14*) salicylate, and (*15*) phosphate I.

Formation of the A.....HX hydrogen bond and protonation of the electron acceptor AH^+X^- raise its electron affinity, thereby lowering the energy of the excited level of the reaction complex. According to Kampar [15], the electron affinity E_A of organic cations is 5–7 eV, which is responsible for the low charge-transfer energies. In real systems, the counterion makes lower the electron affinity of the cations, which is to be taken into account in theoretical analysis.

Base catalysis of the nitramide decomposition. The key role of proton transfer in acid–base catalysis is typically confirmed by the reaction of nitramide (NA) decomposition into water and dinitrogen oxide molecules, proceeding in water in the presence of bases:

$$H_2N–NO_2 \rightleftarrows H_2O + N_2O. \quad (5)$$

For this reaction, the logarithm of the rate constant $\log k_r$, shows a linear correlation with the logarithm of the constant of the base added, pK_a (Fig. 1), which is consistent with Eq. (2a). A good linear correlation is observed over three units of pK_a and two decimal orders of the rate constants. The straight line has a slope $\beta = 0.66$. Similar Brønsted dependences were obtained for many other reactions and a much greater number of experimental points than in Fig. 1. At first glance, these data suggest that the chemical catalytic process is controlled by proton transfer, which is easily recorded experimentally and can be described quantitatively.

Presumably, a proton is transferred in the first stage of nitramide decomposition catalyzed by base B from nitramide to the base molecule:

$$H_2N–NO_2 + B \rightleftarrows HN–NO_2^- + BH^+,$$

and the proton transfer is a rate-limiting stage. It is believed that the nitramide anions $HN–NO_2^-$ formed in an aqueous solution have enhanced reactivities and decompose into dinitrogen oxide N_2O and hydroxide ion OH^-, which is easily converted into a water molecule: $OH^- + BH^+ \rightarrow H_2O + B$. The decomposition rate for deprotonated HA molecules is unambiguously determined by the strength of the base, i.e., by pK_a, which is responsible for observed the linear dependence $\log k_r \sim pK_a$.

The above concept does not specially consider the mechanism of decomposition of the deprotonated nitramide molecule. Without discussing the mechanism, it is taken for granted that the nitramide anions, or anions of any other substance, yielded by the reaction with a base, are unstable and acquire a new quality, which is responsible for their decomposition or chemical transformations in subsequent reactions.

A new approach to the mechanism of catalysis, suggested in this paper, implies that, in the specific case of reaction (5), an enhanced chemical activity is exhibited by complexes of the nitramide anions with the initial HA molecules, rather than by nitramide anions proper. In the ground electronic state in solutions, such EDA complexes are in dynamic equilibrium with the reactants and do not exhibit any chemical activity:

$$H_2N–NO_2 + HN–NO_2^- \overset{K_{eq}}{\rightleftarrows} (H_2N–NO_2...HN–NO_2^-). \quad (6)$$

By contrast, excited states of the EDA complex, and above all the lowest singlet S_1 and the lowest triplet T_1 states, are highly reactive. This is due to a specific feature of the excited states of the complexes: These states result from intermolecular electron transfer, which occurs between the anion and the neutral HA molecule in our case. Similar states generate radical (radical ion) species involved in chemical transformations following the nitramide deprotonation events.

We can state that decomposition of an isolated deprotonated nitramide molecule in the ground state is unlikely. This follows from the available data on the nature of the molecular bonding and dissociation curves demonstrating that passing to the dissociation

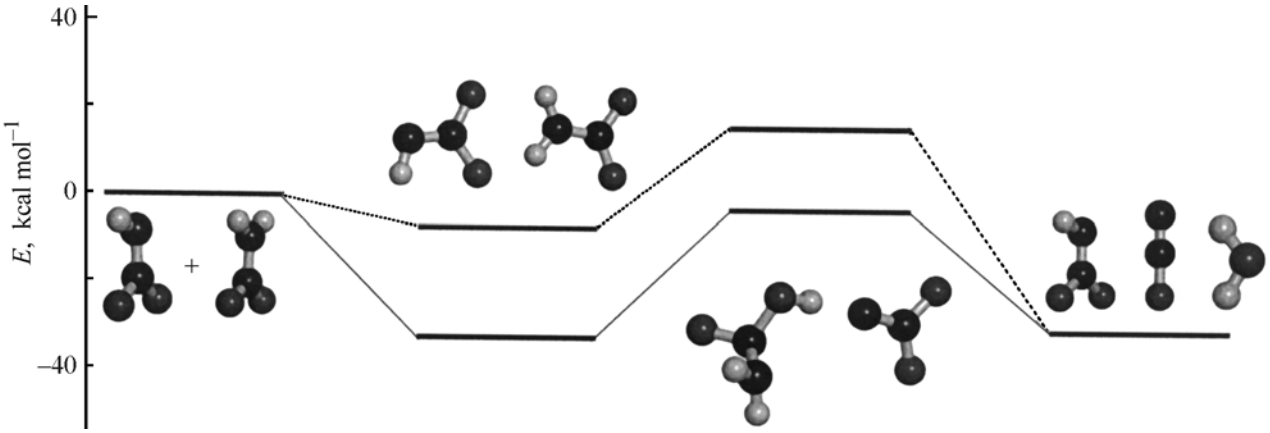

Fig. 2. Energy diagram for *E* of the catalytic reaction of nitramide decomposition, calculated by RHF, ROHF, and MCSCF/DH methods. (*Dashed lines*) Calculation in the PCM approximation for an aqueous medium; insets demonstrate the optimized structures of the molecules and complexes.

potential curve leading to cleavage of the chemical bond can result only from excitation of the molecule. Such an excitation cannot be achieved in thermal experiments because of the high energies of the electronic states (>3 eV). However, it can be observed in a system of two reacting nitramide molecules, one of which turns into a strong electron donor upon deprotonation making it negatively charged, and the other acts as electron acceptor. Intermolecular electronic levels are located much below the intramolecular levels, and specifically in this system of short-lived excited low-lying states, yielded by collision events, thermal reactions can proceed.

The initial nitramide is not a strong electron acceptor: ROHF/6-31G* calculations gave 1.03 eV for its electron affinity (PM3/GAMESS calculations, 0.85 eV). However, in a complex with deprotonated molecule ($HA\ldots HA^-$), electron transfer can take place and an $(N_2O_2H_2^{\cdot -}\ldots N_2O_2H^{\cdot})^*$ radical-ion pair can be formed. In an excited state of the complex, electron transfer transforms the nitramide molecule to the $N_2O_2H_2^{\cdot -}$ radical anion, and the deprotonated molecule, to the $N_2O_2H^{\cdot}$ neutral radical.

In this context, however, of principal importance is the probability of thermal population of the excited state of the complex, which depends on the energy of the state. If these levels are located significantly above 1 eV, their population at room temperature is insignificant. This is responsible for the insignificant rate of the thermal transfer of an electron. Therefore, the excitation energy should be correctly estimated.

Figure 2 shows the energy diagram of the nitramide decomposition reaction, obtained by nonempirical calculations by RHF, ROHF, and MCSCF/DH methods, which adequately describe the structure and properties of excited states of reaction complexes. Calculations were performed for vacuum conditions and in the PCM approximation for a water medium. For convenience of comparison, the energy levels of the reactants for these two cases are superposed. It is seen that the excitation (electron transfer) energy is negative relative to that of the free molecules in a vacuum, –2.45 kcal mol^{-1}, and takes a small positive value of +16.7 kcal mol^{-1} in an aqueous medium. Thus, spontaneous electron transfer in a vacuum is possible. In water, this requires a certain thermal activation, but, because of the low energy, the corresponding T_1 excited level can be populated under ordinary conditions. The heats of reaction (5), calculated from the difference of the total energies of the end reaction products (H_2O and N_2O) and the reactant, nitramide, are identical for these two cases and take a large negative value of –30 kcal mol^{-1}. Hence, nitramide decomposition is thermodynamically favorable.

There can be different arrangements of the molecules in the excited complex $(N_2O_2H_3^{\cdot}\ldots N_2O_2^{\cdot -})^*$, differing in the energy and spin density distribution. The lowest excitation energy of –2.45 kcal mol^{-1} is characteristic of the complex shown in Fig. 2, in which both molecules are linked by a strong hydrogen bond N...H–O ($R_{N\ldots H}$ = 1.82 Å). Along with electron transfer in the excited state of the complex, quantum-chemical optimization implies a proton transfer from the $N_2O_2H^{\cdot}$ radical to the $N_2O_2H_2^{\cdot -}$ radical anion. The resulting new structure is a complex of $N_2O_2H_3^{\cdot}$ radical with $N_2O_2^{\cdot -}$ neutral double-deprotonated radical anion. This chemical transformation can be regarded as reduction of nitramide with a similar,

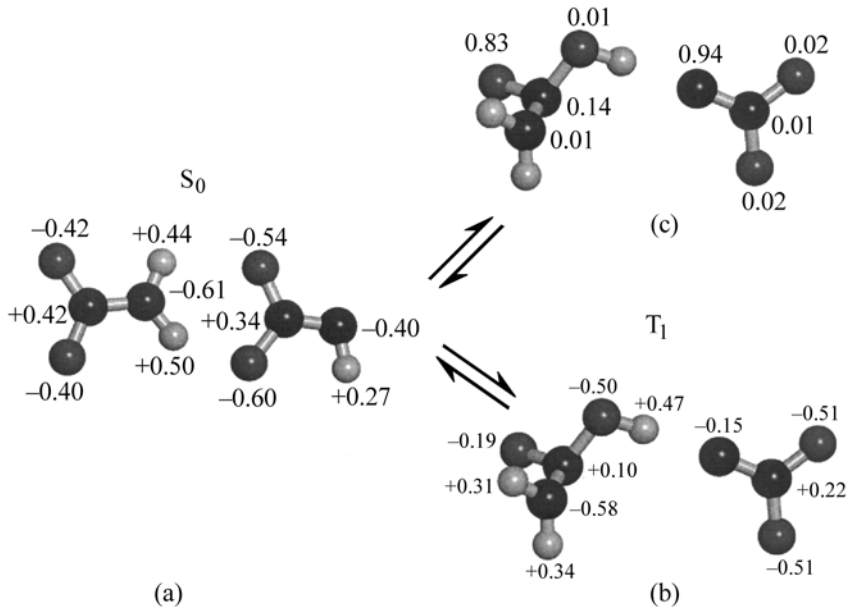

Fig. 3. (a, b) Atomic charges for (a) S_0 ground singlet and (b) T_1 excited triplet state and (c) spin populations for the triplet state.

though deprotonated, molecule, which yields an unstable biradical pair $(N_2O_2H_3^{\cdot}...N_2O_2^{\cdot -})^*$. A probable pathway of its chemical transformations is dissociative decomposition of $N_2O_2H_3^{\cdot}$ radical species, with cleavage of the N–O bond and splitting of a hydroxyl radical, which is further converted to a water molecule.

Of certain interest is analysis of the atomic charge and spin population distributions. Figure 3a shows that, in the ground state of the EDA complex, the electron density is only slightly ($\Delta q = -0.07$) withdrawn from the $N_2O_2H^-$ anion by the nitramide molecule. In the excited state (Fig. 3b), complete electron transfer is accompanied by a proton transfer. As a result, the HA molecule loses two protons and turns into a negatively charged ion $N_2O_2^{\cdot -}$. The spin populations S_p in the triplet state (Fig. 3c) are localized on the oxygen ($S_p = 0.94$) and nitrogen ($S_p = 0.83$) atoms in each of the interacting molecules. These atoms are separated by 4.4 Å and cannot be involved in recombination events to form a chemical bond, but fragmentation of the generated radical species is highly probable.

Our calculations show that, in the above-considered cases, the excited levels of the $(N_2O_2H_3^{\cdot}...N_2O_2^{\cdot -})^*$ complex can be thermally populated under ordinary conditions. The chemical transformations in the excited state of the reaction complex of nitramide are driven by dissociative attachment of the electron, resulting in the fragmentation of the molecule and formation of stable reaction products. Our calculations confirm the original concept stating that base-catalyzed reactions proceed via an electronically excited state of the reaction complex. The excitation energies of such complexes fall within the thermal energy range, which favors their thermal population at room temperature.

Acid catalysis of polymerization of cyclobutenes. The concept of the leading role of proton transfer in acid–base catalysis has been applied in various areas of organic chemistry and, in particular, to cationic polymerization [16]. The conventional theory states that, in reactions initiated by Brønsted (HX) or Friedel–Crafts ($AlCl_3 \cdot HX$) acids, protonation of a monomer molecule enhances its chemical activity and facilitates addition of a new monomer molecule M in the chain propagation event:

$$M \overset{HX}{\rightleftarrows} M\text{–}H^+ \overset{M}{\rightleftarrows} M_2\text{–}H^+, \qquad (7)$$

However, no details concerning the chemical activation are typically provided. A specific feature of polymerization is that an acid promotes formation of a new bond, rather than cleavage of the chemical bond, as is usually indicated for the activating role of protonation of the molecule. In this context, we cannot state that addition of a proton to the molecule weakens the chemical bonds and promotes their cleavage. The cationic polymerization practice suggests that acids activate the propagating polymeric chain in such a manner that a monomer molecule can add to the positively charged chain end.

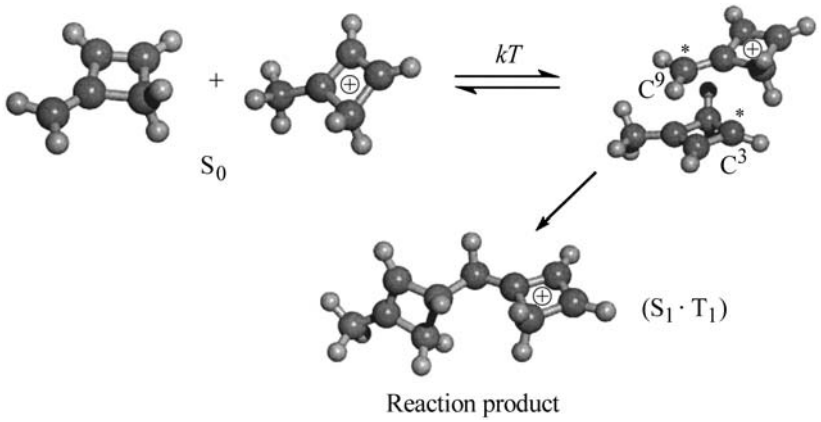

Fig. 4. Molecular scheme of the first stage in addition of methylenecyclobutene to the protonated analog. $(S_1 \cdot T_1)$ Electronically excited complex; asterisks mark atoms with the maximum spin population, involved in chemical bonding.

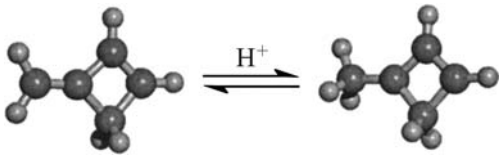
A contradiction is inherent in traditional views, as evident from a consistent application of the concept of the leading role played by proton transfer in catalysis to various chemical reactions. The concept postulating that proton transfer is the basic elementary chemical process, in fact, reflects only one aspect of the chemical reaction, and simply ignores the other aspect, electron transfer (excitation). The latter is not so prominent in ordinary chemical experiments as proton transfer, due to difficulties in observation of short-lived radical species. However, specifically this stage and the subsequent rearrangement of the electronic structure of the molecules are responsible for the actually observed changes of the chemical structure of the substance.

In this context, the nature of the activating role of an acid should be elucidated so as to more comprehensively disclose the mechanism of acid–base catalysis. An illustrative example of the interrelation between the proton and electron transfer stages can be found in cationic polymerization catalyzed by a Brønsted acid.

Hall and Ykman [17] carried out detailed experiments on cationic polymerization of cyclobutenes and demonstrated that it can be catalyzed by both anionic and cationic agents to form different polymeric products from the same monomers. Previously [18], we have carried out quantum-chemical analysis of the mechanism of polymerization of cyclobutenes. In this study, we consider another aspect of this reaction, modeling of acid catalysis.

As in the conventional theory of acid catalysis, it is believed that the first stage of the reaction consists in addition of proton to the 3-methylenecyclobutene (MCB) molecule at the exocyclic carbon atom of the double bond:



(8)

Methylenecyclobutene exhibits a high proton affinity of 220.7 (RHF, ROHF/6-31G* calculations) or 212.5 kcal mol^{-1} (RHF, ROHF/DH calculations) and a rather low ionization potential of 8.9 eV (PM3/GAMESS semiempirical calculation). The positive charge in the MCB–H^+ cation is distributed primarily over the hydrogen atoms; therefore, MCB–H^+ can be regarded as a positive single-charged bulky species. In the second stage, a collision of a strong electron acceptor MCB–H^+ (E_A = 7.9 eV) with the electron donor MCB results in the formation of an electron-donor–acceptor complex which, at a favorable mutual orientation and sufficient energy, passes into an electronically excited state (Fig. 4). Such collision complexes have a short life, but, within this period, the main elementary process, intermolecular electron transfer with formation of chemically active radical species, takes place.

The energy of the excited state is one of the basic factors: Only at low (<1 eV) energies, the population of excited states can be sufficient for providing the experimentally observed reaction rate. According to an ROHF/DH quantum-chemical calculation for vacuum conditions, the excited triplet state energy of the $^3(MCB^{\cdot+}...MCB–H^{\cdot})^*$ reaction complex is 26.6 kcal mol^{-1} relative to the energy level of the free molecules of the reactants. This is close to the thermal energy boundary and, evidently, if the initial geometry and environmental conditions are adequately accounted for, this energy can be lower (<1 eV), which corresponds to the reaction rates observed.

According to Hall and Ykman [17], the reaction product (Fig. 4) is a polymer containing cyclobutene units linked by methylene bridges. A polymer with such a structure is obtained in the case when a bond is formed between the exocyclic carbon atom C^9 of the double bond in the monomer and the carbon atom C^3 of the ring in the terminal moiety (Fig. 4). However, specifically this line of attack of the propagating polymer end of MCB–H^+ species by a monomer molecule is predicted by calculation of the spin densities (or free valence indices), characterizing the chemical activity of atoms in the excited states of the reaction complex.

The calculated atomic charges additionally confirm the original concept of electron transfer in the reaction. A complete electron transfer ($\Delta q = 0.06$) occurs between the MCB monomer molecule and its protonated analogue MCB–H^+ in an excited state: The monomer molecule is converted to the $MCB^{\cdot+}$ radical cation, and the protonated molecule, to the MCB–$H^{\cdot}$ neutral free radical. A stable product is formed in the final stage after recombination events with the radical centers that can be regarded as independent free radicals with all their inherent properties, of which the main is an extremely high chemical activity. In the product molecule, the positive charge is shifted to the terminal unit (Fig. 4), which acts as an electron acceptor in the subsequent stage of the polymerization reaction, whereupon the sequence of elementary events is repeated.

CONCLUSIONS

(1) Deprotonation of the nitramide molecules under the action of bases sharply raises their electron-donating power and favors electron transfer to the initial nitramide molecules. The energies of the excited levels of the complexes fall within the thermal energy range.

(2) Cationic polymerization of cyclobutenes proceeds via protonation of the monomer molecule and subsequent electronic excitation of the complex formed by the resulting cation and the initial cyclobutene molecule.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Performance and Selectivity of Organic Solvents in Extraction of Caprolactam from Lactam Oil

Abstract—The extraction of lactam from lactam oil with benzene, toluene, cyclohexane, and cyclohexane-benzene and cyclohexane-cyclohexanol mixtures, followed by its backwashing with water, was studied. The distribution ratios of caprolactam and main characteristics of the resulting aqueous lactam (permanganate number, content of volatile bases) were determined.

DOI: 10.1134/S1070427207060171

Caprolactam is one of the most marketable chemicals. Approximately 98% of the world production of caprolactam is consumed for manufacture of a polyamide (Nylon-6) [1].

The characteristics of the polyamide are sensitive to the purity of the initial caprolactam. The presence of even minor impurities negatively affects the polymerization. Therefore, the quality of caprolactam must meet stringent requirements [2–4].

The purification of caprolactam to remove impurities involves extraction, ion-exchange treatment, and distillation. In extractive purification step, caprolactam is recovered with an organic solvent from lactam oil prepared by Beckmann rearrangement of cyclohexanone oxime [5]. In the second step, caprolactam is backwashed with water and the resulting aqueous solution is subjected to ion-exchange treatment. The efficiency of extraction is dependent on the kind of organic solvent used as extractant and its physicochemical characteristics: solubility in the aqueous phase and selectivity with respect to caprolactam.

It is known that organic compounds can be recovered from aqueous solutions with organic solvents of various types: alcohols, ethers, esters, ketones, phosphorus-, nitrogen-, and sulfur-containing organic oxides, nitro- and halo-substituted aromatic hydrocarbons [6].

Data on extraction of caprolactam from aqueous media, available from published papers and patents, are insufficiently comprehensive. As a rule, these studies are restricted to determination of the distribution ratios and do not analyze the selectivity of solvents to caprolactam [7, 8].

In the modern chemical industry, caprolactam is extracted from lactam oil with trichloroethylene (TCE). This extractant is characterized by high distribution ratio of caprolactam, good phase separation, and fire safety. However, TCE has the following significant drawbacks: in the course of regeneration, TCE partially decomposes to give corrosion-active hydrogen chloride; in oxidation and also in prolonged storage without protection from light, TCE is converted to phosgene; and, in combustion of trichloroethylene-containing waste at 700 °C, environmentally hazardous dioxins are formed.

In this study, we tested a series of environmentally acceptable chlorine-free organic solvents to choose extractants that would be suitable for effective recovery of caprolactam from aqueous-organic mixtures and have technical and economic characteristics comparable to, or even exceeding those of TCE. This extractant must meet the following requirements: high distribution ratio of caprolactam, high selectivity for caprolactam (evaluated by the permanganate number PN), low solubility in water, commercial availability, and hazard class not worse than 3–4. Furthermore, to simplify the regeneration, this extractant must be involved into existing industrial cycle of caprolactam production.

EXPERIMENTAL

In this study, we examined the extraction of caprolactam from lactam oil with benzene, toluene, cyclo-

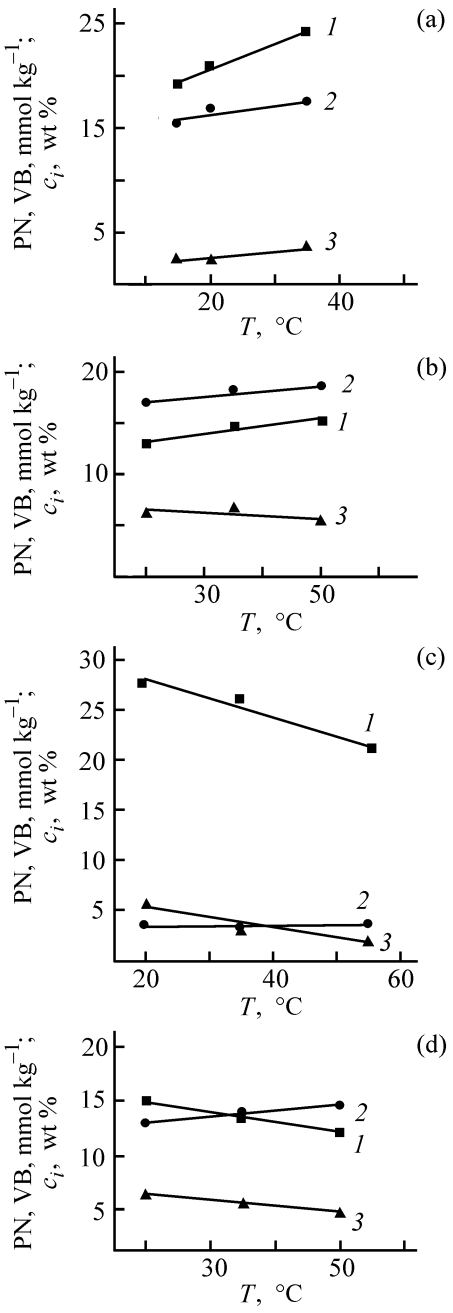

Fig. 1. Influence of the temperature T of caprolactam extraction from lactam oil with (a) trichloroethylene, (b) benzene, (c) cyclohexane, and (d) toluene on the characteristics of the resulting aqueous caprolactam: (*1*) permanganate number PN, (*2*) concentration of caprolactam c_i, and (*3*) concentration of volatile bases VB.

hexene, and also with cyclohexane–benzene and cyclohexane–cyclohexanol mixtures.

The extraction was carried out at a constant weight ratio of organic solvent to lactam oil of 2 : 1. The temperature was varied from 20 to 50°C. The characteristics of lactam oil used in our experiments were as follows: caprolactam content not lower than 70%, PN 153 units, content of volatile bases 149 mmol kg^{-1} caprolactam.

Weighed samples of lactam oil and an immiscible organic solvent were placed in a separating funnel temperature-controlled with an aqueous thermostat. These liquids were vigorously stirred for 30 min and then allowed to settle to complete separation of the extract (solution of caprolactam in organic solvent) from the raffinate (depleted aqueous caprolactam solution). To reach complete recovery of caprolactam from the organic extract, the latter was triply washed with distilled water specially pretreated to remove oxidants (PN no higher than 0.02), with pH from 6.2 to 6.5 [9].

In backwashing caprolactam with water, a portion of the organic solvent inevitably passes to the aqueous phase, and its content in the resulting aqueous solution may reach 3–4%. The presence of an organic solvent in the backwash increases the permanganate number of caprolactam. To remove the organic solvent, the backwash was mixed with an equal volume of distilled water and then the aqueous azeotrope was distilled off under moderate boiling. The residual content of the organic solvent in the purified aqueous phase was monitored on a Kristall-2000 gas chromatograph with an OV-101 capillary column (50 m) equipped with a flame ionization detector. The gas-chromatographic analysis of caprolactam in these solutions was performed at a column temperature of 200°C and vaporizer temperature of 300°C, with helium as carrier gas at a flow rate of 10 ml min^{-1}. In quantitative determination of caprolactam and solvents, the detector was calibrated with respect to substance volume. We found that the residual content of solvents in the resulting aqueous caprolactam did not exceed 0.001 wt %. The content of caprolactam in these solutions was determined refractometrically. The PN and content of volatile bases were found by standard techniques [9, 10].

Figure 1 shows how the main characteristics of the resulting aqueous caprolactam (permanganate number, concentrations of volatile bases, and concentration of caprolactam) depends on the temperature of caprolactam extraction from lactam oil with various organic solvents. It is seen that, with increasing temperature of extraction of caprolactam with cyclohexane and toluene, the PN of aqueous caprolactam containing 3% caprolactam decreases, whereas in extraction of caprolactam with benzene, and especially with trichloroethylene, PN increases. This means that, with increasing temperature of extraction, the selectivity

of caprolactam recovery with benzene and trichloroethylene decreases, whereas the selectivity of caprolactam recovery with cyclohexane and toluene increases. In accordance with the permanganate number, the smallest amounts of oxidizable impurities are present in aqueous backwashes from benzene extracts obtained at 20°C (PN = 12.9 units) and in those from toluene extracts obtained at 50°C (PN = 12 units). These PN values are less by factors of 1.5–2.0 than those of aqueous backwashes from extracts of caprolactam with the other solvents [PN 20–44].

The smallest content of volatile bases in aqueous backwashes (2.3–3.5 mmol kg^{-1}) was found in extraction of caprolactam with trichloroethylene. In extraction with other organic solvents, the content of volatile bases was as follows: benzene 6.2–10.1, toluene 2.7–4.7, cyclohexane 2.3–5.8, cyclohexane–benzene 6.2–6.9, and cyclohexane-cyclohexanol 11.6 mmol kg^{-1}. However, in extraction with trichloroethylene, hydrogen chloride can be liberated. Hydrogen chloride binds volatile amine impurities present in caprolactam [reactions (1) and (2)], which leads to their underestimation.

$$CHCl{=}CCl_2 \rightarrow CCl{\equiv}CCl + HCl, \quad (1)$$

$$RNH_2 + HCl \rightleftarrows [RNH_3]^+Cl^-. \quad (2)$$

The distribution ratio of caprolactam between the organic extract and aqueous raffinate was calculated by the equation

$$K_d = c_e/c_r, \quad (3)$$

where c_e and c_r are the equilibrium concentrations of caprolactam (wt %) in the extract and raffinate, respectively.

Figure 2 shows that the extraction of caprolactam from lactam oil (K_d) with cyclohexane, toluene, trichloroethylene, and benzene only slightly depends on temperature. The highest distribution ratios at 20°C were reached in extraction with trichloroethylene and benzene.

In this study, the binary solvents cyclohexane-cyclohexanol and benzene–cyclohexane were also tested as extractants for caprolactam. These mixed solvents are used in caprolactam production. Straight cyclohexanol cannot be used as extractant because of its high polarity, high boiling point (161°C), and high solubility in water (5.7 g per 100 g of water at 15°C), which causes its large loss with wash waters. This solvent is also difficult to remove from aqueous backwashes.

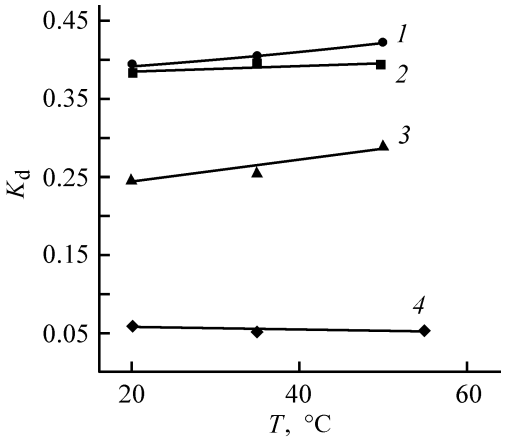

Fig. 2. Effect of temperature T on the extraction (distribution ratio K_d) of caprolactam from lactam oil with (*1*) trichloroethylene, (*2*) benzene, (*3*) toluene, and (*4*) cyclohexane.

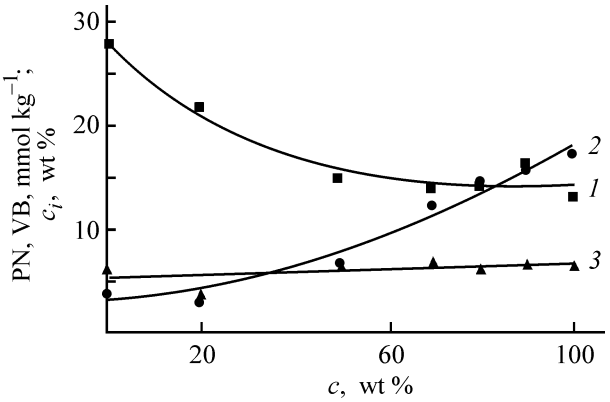

Fig. 3. Effect of benzene concentration c in benzene–cyclohexane mixed solvent on characteristics of final aqueous caprolactam: (*1*) permanganate number PN, (*2*) caprolactam concentration c_i, and (*3*) concentration of volatile bases VB.

The addition of cyclohexanol (10 wt %) to cyclohexane did not improve the recovery of caprolactam. In this case, K_d = 0.13, and the characteristics of aqueous backwash were as follows: PN = 45 units, content of volatile bases 11.6 mmol kg^{-1}, and caprolactam concentration in the resulting aqueous solution 4.43 wt %.

Figure 3 shows the effect of the benzene content of the benzene-cyclohexane extract on the characteristics of the aqueous backwash of caprolactam at 20°C: permanganate index PN, concentration of volatile bases VB (mmol kg^{31}), and caprolactam content c_i (wt %). It is seen that, with increasing benzene content in the mixed extractant, the capolactam content in the final aqueous backwash increases to 17 wt %, the permanganate index decreases to 12.9 units, and the content

Influence of temperature on the distribution ratio of caprolactam in its extraction from lactam oil with various solvents and the main characteristics of the resulting aqueous solutions of caprolactam: permanganate number, concentration of volatile bases, and caprolactam concentration c_i (wt %) (weight ratio of solvent and lactam oil 2 : 1)

* Benzene (cyclohexanol) content of the mixture.

of volatile bases remains approximately constant (6.2–6.8 mmol kg^{-1}). The distribution ratio of caprolactam gradually increases with the benzene content of the mixed cyclohexane–benzene extractant (from pure cyclohexane to pure benzene). Taking into account that benzene is more selective extractant for caprolactam, the extraction of caprolactam with cycloxane-benzene mixtures is unsuitable. The experimental data obtained in this study are listed in the table.

CONCLUSIONS

(1) The extraction powers of benzene and trichloroethylene in extraction of caprolactam from lactam oil at 20–30°C are close, but the extraction with neat benzene allows the extraction selectivity to be increased by a factor of 1.5–2 at a close consumption of the extractant. The extraction of caprolactam with toluene is also feasible, but this solvent is less efficient because of the lower distribution ratio.

(2) Substitution of trichloethylene with chlorine-free benzene in industrial extraction of caprolactam from lactam oil allows improvement of the economic and environmental characteristics of the process by excluding formation of dioxin in waste incineration, decreasing corrosion of equipment, and improving the caprolactam quality.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A Versatile Procedure for Synthesis of Organic Acids by Cobalt Carbonyl Catalyzed Carbonylation of Organic Halides

Abstract—A versatile procedure for synthesis of a broad range of fatty-aromatic and aromatic acids by carbonylation of the corresponding halides under very mild conditions in the presence of cobalt carbonyl as a catalyst was suggested. The main principles of a flexible process for production of practically significant acids and their derivatives were developed.

DOI: 10.1134/S1070427207060183

Aromatic and fatty-aromatic acids and their derivatives (ethers, salts) have a wide application area. They are used in paint and varnish industry and in production of pharmaceuticals, plant-protecting agents, fragrance compounds, lubricants, and corrosion inhibitors. In addition, aromatic carboxylic acids find growing application in production of liquid-crystal materials. Di- and polyarenecarboxylic acids are used in production of liquid crystal thermoplastics, nanomaterials, and electroluminescent compounds applied in development of new kinds of equipment.

The conventional synthesis of these acids is based on classical organic reactions: alkylation, acylation, oxidation, and cyanation and has serous disadvantages. The methods are multistage, low-selective, expensive, and environmentally hazardous.

An alternative method is carbonylation of organic halides, which finds growing application for synthesis of fatty-aromatic and aromatic acids [1]. For example, phenylacetic acid (FAA) can be readily prepared by carbonylation of benzyl chloride under very mild conditions (1–5 atm, 40–80°C) in the presence of the conventional catalyst for oxo synthesis, cobalt carbonyl. The reaction is performed in an alkaline-alcoholic (mainly in methanol) solution, in which the catalyst exists in the salt form $MCo(CO)_4$. Since benzyl chloride readily enters into nucleophilic substitutions, it is activated in the course of carbonylation owing to the substitution of chlorine by the $Co(CO)_4$ anion to form alkylcobalt carbonyl (**1**). Then the CO molecule is inserted to form acylcobalt carbonyl complexes (**2**). The target methyl phenylacetate (**3**) is reductively eliminated under the action of the methylate anion [1]:

$$PhCH_2Cl \xrightarrow{Co(CO)_4^-} \underset{\mathbf{1}}{PhCH_2Co(CO)_4} \xrightarrow{CO} \underset{\mathbf{2}}{PhCH_2COCo(CO)_4}$$

$$\xrightarrow{O(CH)_3^-} \underset{\mathbf{3}}{PhCH_2COO(CH)_3}$$

The optimization of PAA synthesis allowed us to obtain this compound in a yield of no less than 95% [2]. We also developed a procedure for preparing the cobalt catalyst in the form of $Co(CO)_4^-$ in methanol under relatively mild conditions (at pressures of up to 50 atm) [2]. This procedure can be used instead of the reaction of benzyl chloride with highly toxic sodium cyanide. A batch of PAA (~40 kg) was prepared by this method for the first time in Russia and was tested in production of antibiotics. Naphthylacetic acid was prepared similarly. This compound is an intermediate product in production of Naphthizin pharmaceutical, Heteroauxin plant growth stimulant, and a valuable monomer, phenylenediacetic acid (Table 1).

Methyl monochloroacetate enters into this reaction at a higher CO pressure (up to 10 atm) to form malonic acid. Practically significant fatty-aromatic and

Table 1. Acids produced by the versatile process for carbonylation of organic halides

Product	Application
	Fatty-aromatic and aliphatic acids
X-C_6H_4CHRCOOH X, R = Phenylacetic acid	Antibiotic precursor; used in production of dyes, optical brighteners, and fragrance compounds
X = *p*-OH, *o*,*p*,-Cl; R=CH_3	Production of pharmaceuticals

 *p*-Phenylenediacetic acid	Monomer in production of aviation oils and polymers
$PhCH_2COCOOH$ Phenylpyruvic acid	In production of phenylalanine and synthetic sweetener, aspartame
$CH_2(COOH)_2$ Malonic acid $PhCH(COOH)_2$ Phenylmalonic acid	Intermediates in production of pharmaceuticals, vitamins, and dyes
	Aromatic acids
 p-Butylbenzoic acid (X = *p*-C_4H_9) X = R, RO, RCO, R , R	Liquid crystals and components of liquid–crystal systems
 4,4'-Diphenyldicarboxylic acid  X = O, SO_2  2,6-Naphthalenedicarboxylic acid	Monomers in production of highly heat-resistant liquid-crystal thermoplastics used in preparation of modern composites
 5,6-Acenaphthenedicarboxylic acid	Intermediate in synthesis of 1,4,5,8-naphthalenetetracarboxylic acid used in production of high-quality vat dyes (Vat Crimson 2Zh) and highly heat-resistant fibers

aliphatic (malonic) acids prepared by carbonylation of the corresponding halides by the above procedure are represented in Table 1.

Of particular interest is a modification of the method for carbonilation of benzyl chloride with calcium hydroxide in isopropanol serving as a base:

$$PhCH_2Cl + CO \xrightarrow[Ca(OH)_2]{Co_2(CO)_8/Isopropanol} \underset{\mathbf{1}}{(PhCH_2COCOO)_2Ca} + \underset{\mathbf{2}}{(PhCH_2COO)_2Ca}$$

We found [2] that the product of double carbonylation of benzyl chloride (calcium phenylpyruvate) is formed in large amounts along with PAA under mild conditions (atmospheric CO pressure and 30–40°C) (Fig. 1). Phenylpyruvic acid can be used for preparing an important amino acid, phenylalanine, which is a precursor for production of a valuable sweetener, aspartame (Table 1).

Carbonylation of aromatic halides. It is known that, unlike fatty aromatic halides, nonactivated aryl halides do not enter into nucleophilic substitution. That is why, apparently, these compounds are not activated with the $Co(CO)_4^-$ anion by the S_N2 mechanism under the conditions of benzyl chloride carbonylation.

First we activated more reactive aryl bromides and aryl iodides by oxidative addition of low-valent metal complexes [1]. We studied the preparation of acenaphthenedicarboxylic acid by carbonylation of 5,6-dibromoacenaphthene [3] under the conditions of phase-transfer catalysis by palladium halophosphine complexes. As determined by IR spectroscopy, the active catalytic species was the intermediate zero-valent palladium complex $PdCOP_3$ formed in the presence of carbon monoxide. The mechanism of this reaction was described in our previous paper [3]. It should be noted that palladium complexes have also been recently used to catalyze carbonylation of less active aryl chlorides with acceptor substituents. In this case, complex ligands (e.g., cyclohexyl-substituted ferrocenylphosphines) were developed to activate palladium [4]. However, these catalytic systems are difficultly available and expensive and can be used only for fine synthesis of small amounts of expensive compounds.

Although aryl halides are completely inactive in carbonylation catalyzed by cobalt carbonyl under ordinary conditions [in alcohols in the presence of bases (B)], the making possible use of cobalt carbonyl (the cheapest and the most available catalyst of oxo synthesis) in carbonylation of aryl halides is a very attractive practical and theoretical task.

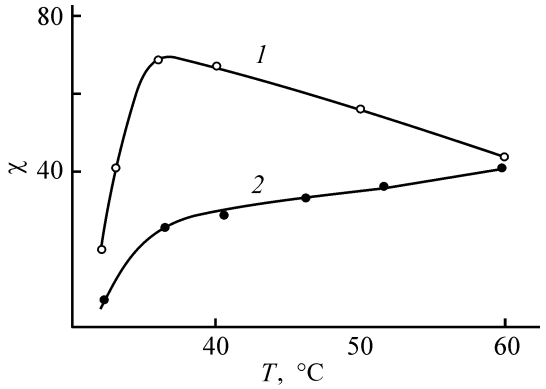

Fig. 1. Yield χ of (*1*) phenylpyruvic and (*2*) phenylacetic acids vs. temperature T (P = 1 atm).

Some alklylcobalt carbonyl complexes $RCo(CO)_4$ formed in situ in the course of carbonylation of alkyl halides RX can catalyze carbonylation of low-active aryl halides [5]. In this case, alkyl halides are cocatalysts (A) (activators) of cobalt carbonyl in carbonylation of aryl halides. The reaction occurs under very mild conditions (CO pressure 1 atm, 60–65°C):

$$ArHal + CO \xrightarrow[ROH + B]{Co_2(CO)_8 + A} ArCOOR \qquad (I)$$

We have shown previously [2, 6] that the most reactive catalytic complex, $PhCH_2Co(CO)_4$, is formed in the reaction with benzyl chloride as a cocatalyst [A, scheme (I)].

The results of a study of the catalytic effect of acceptor substituents on carbonylation of substituted bromobenzenes and of the inhibition of aryl halide carbonylation with one-electron acceptors (nitrobenzene, anthraquinone) [7] suggest the $S_{RN}1$ radical anion mechanism of aryl halide activation. The active catalytic species of carbonylation is the anionic complex $[RCo(CO)_3COOCH_3]^-$ [5, 7] formed by nucleophilic attack of the methylate anion on the carbon atom of the carbonyl group of alkylcobalt carbonyl. The nucleophilic power of this complex is very high. Because benzyl chloride is also carbonylated under these conditions [scheme (I)], we determined the mode and rate of feeding the cocatalyst, benzyl chloride, to maintain the catalyst in the active form, thus providing an almost complete conversion [7]. The catalytic cycle of the reaction in the presence of benzyl chloride as a cocatalyst has been suggested and analyzed [7].

A series of practically significant aromatic acids was prepared for the first time by carbonylation in the presence of a new effective catalytic system, cobalt carbonyl–benzyl chloride–base, in methanol (Table 1). This catalytic system is the most suitable

Table 2. Main process parameters of carbonylation in the presence of benzyl chloride

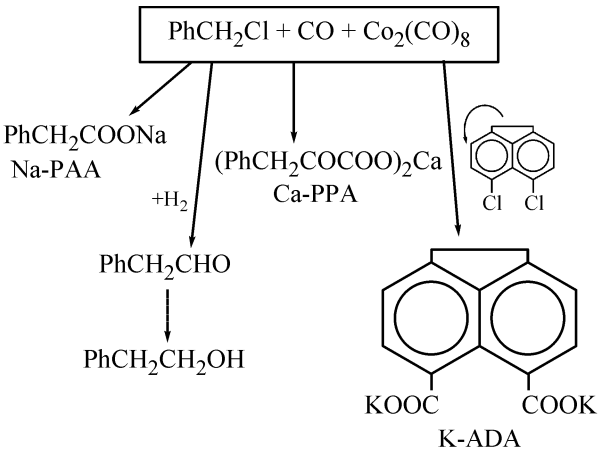
* MBE is methyl benzyl ether.

for synthesis of preparing acenaphthendicarboxylic acid (potassium salt K-ADA) by carbonylation of 5,6-dichloroacenaphthene. This acid is used for production of a valuable commercial product, 1,4,5,8-naphthalenetetracarboxylic acid (Table 1) [2, 8]. The technical documentation for this process was developed. A pilot batch of the product (50 kg) was produced for the first time by the carbonylation procedure and was tested in production of a valuable heat-resistant dye, Vat Crimson 2Zh.

Some implementations of the developed versatile process in carbonylation in the presence of benzyl chloride as both reagent and cocatalyst are shown in the scheme below. The process was tested in practice. The main process parameters are listed in Table 2.

The process for synthesis of a valuable aromatic compound, phenylethanol, an analog of rose oil, by carbonylation (hydroformylation) of benzyl chloride via intermediate formation of phenylacetaldehyde is also shown in the scheme.



Process scheme based on benzyl chloride.

To improve the efficiency of the catalytic system for carbonylation of aryl halides, we studied other cocatalysts of cobalt carbonyl. The main requirements to the cocatalyst are the low self-carbonylation rate and the absence of chlorine in their composition, to decrease the consumption of a base required for halide binding. We developed new catalytic systems [7, 9, 10] containing ethylene chlorohydrin, olefin oxides, and epichlorohydrin as cocatalysts. The catalytic activity of these systems was higher by a factor of approximately 2 that that of the system containing benzyl chloride [7, 9]. These cocatalysts are not carbonylated under the reaction conditions but can undergo methanolysis, which, however, is insignificant in the presence of weak bases (B), alkali metal carbonates.

Epoxy cocatalysts are halogen-free compounds, and, hence, additional consumption of a base for halide binding is not required. The most available, low-cost, and convenient in use cocatalyst is propylene oxide. The mechanism of aryl halide carbonylation catalyzed by a cobalt carbonyl–epoxide system was analyzed in our previous paper [9].

Thus, cobalt carbonyl–epoxide–base system [9, 10] is a highly active and readily available catalytic system for selective carbonylation of aryl halides in a high (frequently quantitative) yield. This system, along with the catalytic system containing benzyl chloride as a cocatalyst, can be used as a highly efficient catalyst for both industrial production of many valuable products (Table 1) and fine laboratory synthesis [9]. This system is the most convenient for low-active substrates such as stable organic pollutants, polychlorobiphenyls [10].

A fundamentally new versatile process for synthesis of valuable industrial products by halide carbonylation was developed, based on the results of a study of new catalytic systems containing cobalt carbonyl. It should be noted that preparation of fatty-aromatic acids by carbonylation of the corresponding halides was described in [1], whereas the synthesis of aromatic acids is our original development.

A technological development of these processes showed that they can be performed using the same equipment. The preparation of the catalyst and carbonylation are performed with common units (Fig. 2). The units for feed preparation and isolation of the reaction products differ (depending on the properties

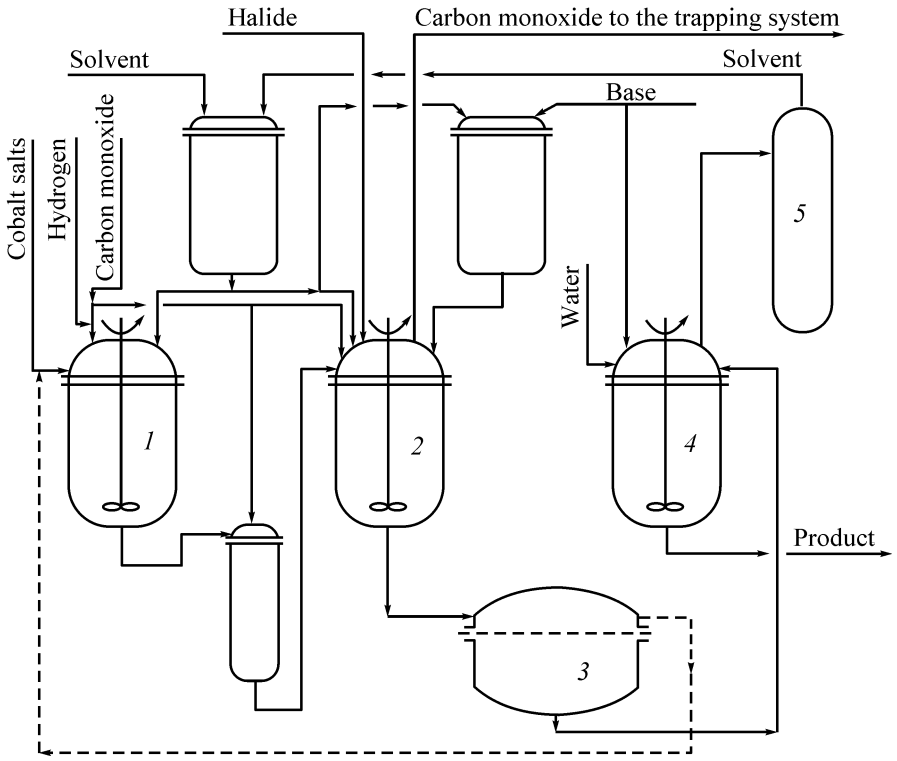


Fig. 2. Schematic of the installation for carbonylation of halides.

and aggregative state). The carbonylation is performed under mild conditions, which can be varied in a narrow range [CO pressure 1–5 atm, 35–70°C, alkali or alkaline-earth metal hydroxides and carbonates as bases, alcohols as solvents (we used methanol as the solvent in all processes except double carbonylation)]. To devise a process for sythesis of key products (fatty-aromatic and aromatic acids, namely, phenylacetic, penylpyruvic, and 5,6-acenaphthendicarboxylic acids) and thus the main units for the versatile process, we developed and fabricated an original pilot installation for carbonylation of halides [2] (Fig. 2). The installation consists of a reactor for preparing catalyst *1* (alcoholic solution of cobalt carbonyl), reactor for carbonylation *2*, pressure filter *3* (product isolation step), reactor for hydrolysis *4*, and collector of the solvent to be recycled *5*. A pilot batch of the product in an amount of 10 to 50 kg was produced on this installation. The reactor volume is 100 l. The design productivity of the unit is 10 tons year^{-1}.

The aim of further studies is to broaden the range of compounds involved in the carbonylation, including, in particular, heteroaromatic compounds [pyridines, furans, thiophenes, polychlorobiphenyls (PCB)] and to develop processes for synthesis of new products and utilization of stable organic pollutants (PCB) [10] as highly heat-resistant industrial insulators and polybromodiphenyl ethers as fire-retardants.

EXPERIMENTAL

All laboratory carbonylation experiments were performed under atmospheric pressure of CO in temperature-controlled glass reactors under vigorous stirring in a CO flow. The experimental procedure was described in detail in [7]. The reaction products were analyzed by GLC, chromatography-mass spectrometry, and NMR spectroscopy, including 2*D* COSY spectroscopy, for identification of complex products.

The industrial process was developed using a 1-l pressure vessel and the pilot unit described above (Fig. 2).

CONCLUSIONS

(1) Fatty-aromatic and aromatic carboxylic acids were prepared by carbonylation of the corresponding halides in alcohols in the presence of cobalt carbonyl as the catalyst and of bases under very mild conditions (CO pressure, up to 3 atm; temperature, up to 65°C).

(2) It was shown that the reaction is highly selective and occurs with a high yield. To carbonylate chemically stable aryl halides, benzyl chloride and epoxides were added as cocatalysts (promoters).

(3) A novel versatile and economically efficient process for producing a wide range of organic acids (mainly aromatic and fatty-aromatic carboxylic acids) and their derivatives by carbonylation of the corresponding organic halides was developed.

Abstract—Regeneration of ceramic aluminosilicate filter cells for water purification by chemical methods and, in particular, by acid dissolution of the deposit formed in filter pores was studied.

DOI: 10.1134/S1070427207060195

Filter cells are regenerated to restore their rated service characteristics. In this case, a filtering body is to be regarded as a combination of two phases: a ceramic and a contaminating substance, i.e., as a specific state associated with the dispersity of particles forming the porous body and with phenomena in pores, caused by their appreciable curvature and by the nature of interactions at interfaces between the material of a filter cell and a contaminant. Specific features of the regeneration are determined in the case under consideration by the specificity of the dispersed state of the contaminant in pores of the ceramic and should be manifested in kinetic dependences of the influence exerted by the regenerating medium on the mechanism of restoration of the service characteristics.

Ceramic aluminosilicate filter cells are used for removal of mechanical admixtures of varied origin and colloid particles of iron hydroxide from drinking and return water. Ceramic filter cells have a multilayer porous structure, with the pore size successively decreasing from layer to layer.

In this communication, we present the results obtained in a study of the process of regeneration of ceramic filter cells for water purification, manufactured in Belarus and used at various plants of the Republic. The chemical composition of deposits filtered-off from drinking and return water was studied, and possibility of regeneration of ceramic filter cells by chemical methods and, in particular, by acid dissolution of the deposit formed in filter pores was demonstrated.

EXPERIMENTAL

The regeneration was experimentally studied on segments of tubular filter cells with an external diameter of 70 mm and height of 50 mm, built in the water supply system of the Institute, using a laboratory bench.

The working capacity of a filter is defined as the volume of water passed before loss of 95% of the initial throughput of filter cells. The ratio of the initial throughput and working capacity after regeneration to the values of these characteristics before regeneration was taken as the degree of regeneration (%).

In the study, we used filter cells selected after tests at industrial plants and at housing and communal facilities, as well as those used in water recycling systems at industrial plants.

The initial throughput and working capacity of starting filter cells before exploitation were measured for a set of witness samples to be, on the average, 0.38 $l\ s^{-1}$ and 960 l, respectively.

In chemical regeneration, a filter cell segment was steeped in a 1–20% hydrochloric acid solution and kept in this solution for 2–24 h. Then the filter cell was washed with water, and its restored initial throughput and working capacity were measured.

Table 1. Results of X-ray fluorescent determination of the mineral composition of the deposit from the filter

Sample no.*	Content of oxides in a sample, wt %										
	K_2O	CaO	Fe_2O_3	SiO_2	P_2O_5	MgO	Al_2O_3	TiO_2	S	Cl	MnO
1	2.5	4.3	24.4	49.1	1.1	1.5	9.4	0.6	0.2	0.1	3.0
2	0.3	15.2	58.1	4.5	3.0	2.0	0.6	0.0	0.1	0.0	0.06

* Sample: no. 1, return water; no. 2, drinking water (typical examples).

To determine the chemical composition of the deposit filtered-off by ceramic filter cells from drinking and return water, it was separated from the filter, dried to constant weight at room temperature in air, thoroughly homogenized, and then its chemical composition was determined by the quantitative X-ray fluorescent analysis on an SRM-18 instrument.

The averaged results of the chemical analysis of the deposits filtered-off from drinking and return water, obtained using the X-ray fluorescent method, are listed in Table 1 in terms of element oxides. As can be seen from Table 1, the main components of the deposit taken from the filter are silicon, iron, calcium, and aluminum. The deposit also contains minor amounts of potassium and manganese, with the total content of their oxides being about 5%. The content of other components is insignificant and does not exceed 1%. The elements represented in Table 1 are contained in water as hydroxides and salts in a colloid-dissolved state, and silicon may be in the form of insoluble silicates and oxides.

The mineral composition of the filtered-off deposit is determined by the composition of underground water used for water supply in a given region and also by the chemical nature of the reagents employed in water treatment. In particular, the presence of such elements as Al, S, Mn, and Cl in the deposit may be due to use of aluminum sulfate $Al_2(SO_4)_3$ as a coagulant and also of permanganate and chlorine oxidants in water treatment.

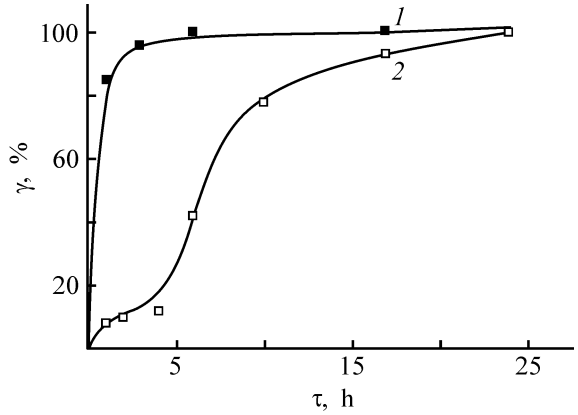

Fig. 1. Degree of filter cell regeneration, γ, with respect to (*1*) initial throughput and (*2*) working capacity vs. time τ.

All the minerals listed in Table 1, except silicon oxide, are readily soluble in inorganic acids and, in particular, hydrochloric acid. Silicon-containing admixtures insoluble in acids (SiO_2) can be separated from the surface of a filter cell in dissolution of other components.

To determine the optimal conditions of dissolution of the oxides represented in Table 1, we used hydrochloric acid in a wide range of concentrations (1–20%), with the treatment time varied from 1–2 to 24 h.

Figure 1 shows curves describing the degree of filter cell regeneration with respect to initial throughput and working capacity by treatment with a 5% HCl solution. It can be seen that these curves strongly differ in shape.

In the first case, the curve steeply rises and, having reached the maximum values of the degree of regeneration, rapidly flattens out to form a plateau. The curve describing the degree of regeneration with respect to the working capacity is markedly different. It has an S-shape characteristic of diffusion-dependent processes.

The process of dissolution of colloid particles of aluminum and iron hydroxides in hydrochloric acid is rather fast and complete in several minutes [1]. However, particles being dissolved are, in this case, within pores of the aluminosilicate ceramic, and, therefore, the diffusion of hydrogen ions requires a certain time.

The influence of the chemical treatment conditions (treatment time and HCl concentration) on the degree

Table 2. Influence of chemical treatment conditions on the degree of filter cell regeneration

20	24	0.42	~100*	960	100

* The degrees of regeneration with respect to the initial throughput exceed 100%, but fall within the range of the initial throughputs measured for a set of witness samples.

of filter cell regeneration is illustrated by Table 2. It can be seen that particles in the coarsest pores of outer layers of a filter cell are dissolved within 1–2 h, which is sufficient for a 85–95% restoration of the initial throughput. In contrast to the initial throughput, the working capacity of the filter cell is not restored so rapidly and requires at least 15 h. Even when the initial throughput of filter cells reached 100% upon a treatment for 1–10 h, the working capacity of the regenerated filter cells did not exceed 50% of the initial value. For example, filters with the initial working capacity of 960 l had, after regeneration in a 10% HCl solution for 5 h, a working capacity of 404–379 l.

The data presented indicate that the key factor in chemical regeneration of filter cells is the kinetics of diffusion of hydrogen ions into pores of deep layers of the filter. Therefore, the process requires a rather long time, and only the working capacity of a filter cell, but not the degree of restoration of the initial throughput, can serve as a measure of regeneration.

It was also of interest to study the capacity of filter cells for multiple regeneration. For this purpose, we carried out the following experiment. A segment of a mullite-quartz filter cell was built in the water supply system of the Institute, using a laboratory bench, and water was passed until the filter was clogged. Then the filter was regenerated, its initial throughput and working capacity were measured, and the filter was again built in the water supply system.

The results obtained are plotted in the form of histograms (Figs. 2a and 2b). It can be seen that the working capacity of a filter cell after three regenerations for 17 h still has sufficiently high values (up to 870 l).

According to the data obtained, a prolonged acid treatment of filter cells has no effect on the strength

properties of ceramic filter cells. Table 3 lists average values of inside-to-outside load gradients leading to breakdown of filter cells after regeneration. The breakdown pressure of aluminosilicate ceramic filter cells not subjected to chemical treatment is 2.9–7.0 atm, depending on the size of initial particles and sample wall thickness. Thus, chemical treatment only slightly affects the strength properties of filter cells.

CONCLUSIONS

(1) The results of the study indicate that the degree of recovery of the working capacity of filter cells, but not the initial throughput, can serve as a measure of the regeneration of aluminosilicate ceramics.

(2) The process of the chemical regeneration of ceramic filter cells based on aluminosilicates is diffusion-dependent. The principal factor governing the degree of filter cell regeneration is the diffusion kinetics of hydrogen ions within pores of inner layers of the aluminosilicate ceramics.

(3) A rather prolonged treatment (for no less than 10–15 h) of filter cells with hydrochloric acid solutions is necessary for the optimal regeneration of the filter cells. The concentration of hydrochloric acid has no significant effect on the regeneration rate, which enables use of dilute acids (1–5%) in this process.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Determination of Formic and Acetic Acids in Air by Piezoelectric Microweighing

Ya. I. Korenman, N. N. Popova, and T. A. Kuchmenko

Voronezh State Technological Academy, Voronezh, Russia

Received August 3, 2006; in final form, February 2007

Abstract—The quantitative and kinetic parameters of sorption of formic and acetic acids on thin films of various modifiers of piezoelectric quartz resonator electrodes are determined. Parameters of film formation on the electrodes (application procedure and thickness) are optimized. Methods for joint and separate determination of formic and acetic acids in air by piezoelectric microweighing with single- and double-sensor devices are developed.

DOI: 10.1134/S1070427207060201

Development of microsensors for determination of toxic compounds in air is a topical problem of modern analytical instrument making. Formic and acetic acid are a health hazard not only when occurring at a level close to the maximum permissible concentration (MPC) (1–5 mg m^{-3}), but also in lower concentrations as a result of the cumulative effect [1–4]. In emergencies, emission sources of carboxylic acid are classified with stable rapid damage sites [2]. Carboxylic acids are to be determined in air in working areas at hazardous works and factory laboratories and for risk assessment. The limitations to use of such common methods as gas and liquid chromatography are caused by large consumption of chemicals (sometimes no less hazardous than the acids to be determined) and by the need in expensive and sophisticated equipment and highly skilled staff. Piezoelectric quartz microbalances [piezoelectric quartz bulk acoustic wave resonators (PQRs) with film-coated electrodes] are widely used for determination of toxic compounds in air. The sensitive films on the PQR electrodes are recyclable, in contrast to dosimeters and indicator tubes, which can be used only once [4, 5].

EXPERIMENTAL

The experiments were carried out on a laboratory setup consisting of electric power unit, detector cell with rigidly mounted PQRs with electrodes preliminarily modified with sorbents, compressor, and F5137 two-channel digital frequency meter connected to a computer. In the study, we used an AT-cut PQR with a resonance frequency of 10–15 MHz. The 5-mm electrodes were fabricated from Al_2O_3 [6].

The sorbents were selected taking into account the selectivity criteria (McReynolds constants, Rohrschneider coefficients) with respect to the acids to be determined, and also the nature of the sorbent and sorbate and their polarities. As sorbents we examined such commonly used chromatographic phases as polystyrene (PS), Triton X-100 (TX-100), poly(ethylene glycol) esters [adipate (PEGA), succinate (PEGS), and sebacate (PEGSb)], pentaerythritol tetrabenzoate (PETB), poly(vinylpyrrolidone) (PVP), Apiezon N (A-N), Apiezon L (A-L), squalane (Sq), and Tween-40 (Tw-40) [7, 8].

In addition to the chromatographic phases, we used for modification of the electrodes β-alanine, glycine, ethylenediaminoazobenzenesulfonic acid sodium salt (EDBSA), dibenzo-18-crown-6 (DB18C6), bee-glue (BG), and beeswax (BW) [7]. These modifiers were selected taking into account the physicochemical properties of the sorbents and acids to be determined.

Films on the PQR electrodes were prepared by the following methods: (I) static evaporation of a drop of a sorbent solution or layer-by-layer application of solutions of two sorbents and (II) immersing of PQR in a sorbent solution or in a mixed solution of two sorbents (III).

* $\bar{X}$, average value of the analytical signal ΔF_f; dash means that a film cannot be formed by this method.

To enhance the analytical response, improve the reproducibility of results, and reduce the measuring error, the modifiers were bound to a polymer support (polystyrene).

In film fabrication by method I, the solution was applied onto the PQR electrode using a microsyringe. The thickness of the films was controlled by the volume of the sorbent solution applied onto the electrode surface. In fabricating the films by method II, the thickness was controlled by varying the solution concentration. As solvents we used distilled water, acetone, and alcohol (analytically pure grade).

The solvents were removed from the films in an oven at 40–50°C for 20–30 min, except for PQRs modified with BW and amino acids. In the case of amino acids, the drying time was 30–50 min, since water is evaporated more slowly than the organic solvents. Beeswax irreversibly degrades above 30°C [8, 9]. The BW-modified resonator was dried in a desiccator over a desiccant bed for 1.0–1.5 h at 20°C. The drying time of the films fabricated by immersing PQRs into sorbent solutions was 10–15 min at 40–50°C.

The film weight m_f (μg) was estimated by the Sauerbrey equation [10]:

$$m_f = \frac{\Delta F_f s}{K_f F_0^2},$$

where $\Delta F_f = (F_0 - F_f)$ is the change in the resonator frequency after coating (Hz); K_f, calibration factor of the piezoelectric microbalance (under normal conditions, $K_f = 2.3 \times 10^{-6}$ cm^2 g^{-1}); F_0, resonance frequency of PQR (Hz); s, surface area of the PQR electrodes (cm^2); and F_f, oscillation frequency of film-coated PQR (Hz).

The sorption efficiency was estimated from the analytical signal (maximum frequency difference of the sensor in sorption) ΔF_s^{max} (Hz) [6, 9, 11–13]. The acid concentration in the detection cell before sorption c_0 (mg m^{-3}) was estimated by the reduced Mendeleev–Clapeyron equation, taking into account the dilution with laboratory air [6, 9, 11–13]. The sensitivity of the piezosensors S_M (Hz dm^3 mol^{-1}) with respect to the acids was calculated as the ratio of the signal of the film-coated PQR sensor (piezosensor) to the acid concentration in the sample [6]. The kinetic parameters of sorption were estimated from the time of establishment of the sorption equilibrium under isothermal conditions (time elapsed from sample injection in the detection cell until the maximum analytical signal was obtained [12]).

The procedure of film application onto PQR electrodes was optimized in the experiments with sorbent solutions of the same concentration by measuring δGF_f (Table 1), using the reproducibility of the film weight and sorption capacity as criteria.

In deposition of the films by method II, the uncertainty in the stage of film application was lower than in method I. Therefore, in all further experiments, the films were deposited by immersing the PQR electrodes in the sorbent solutions, except the films of amino acids, which were dissolved in water. Because of the poor wetting of the quartz plate and PQR electrodes with water, it is impossible to obtain a uniform thin film. The films obtained from the solutions of amino acids, DB18C6, and EDBSA are air-sensitive and the response of an unloaded piezosensor is unstable (drift more than 100 Hz min^{-1}). Therefore, the films were bound to the polymer support (polystyrene film), which is stable and demonstrates the minimal drift of the piezosensor baseline. The films of amino acids and DB18C6 were applied by method I onto a preformed support. To obtain a PS–EDBSA film, the 10 mg cm^{-3} solutions of the modifiers were mixed at a 4 : 1 volume ratio, and the PQR electrodes were immersed in the resulting solution.

The optimal film weight was found to be 20.0 ± 1.5 μg, and the injected sample volume, 3 cm^3 [11–13]. The samples were injected in a closed cell at 20 ± 1°C.

It is known that chromatographic data cannot be used as a unique criterion for characterization of the selectivity of sorbents with respect to the compounds to be determined (or their group). These data are not always consistent with the results obtained by piezoquartz microweighing [11]. Therefore, to make a decision on the films, we determined the quantitative and kinetic parameters of sorption of individual acid vapors. PEGA, PS–β-alanine, PS–glycine, PS–EDBSA, TX-100, and PS–DB18C6 appeared to be the most selective sorbents for formic and acetic acids (Fig. 1).

Virtually all the air samples contained both formic and acetic acids in various proportions, which made necessary experiments on sorption of the acids from their mixtures. In exposure of PQRs with the most sensitive films (Fig. 1), it was demonstrated that the sorption is an additive value, with the calculated analytical responses from the acid mixtures being lower than those obtained experimentally (Fig. 2). Statistical data processing revealed that the difference between the calculated and experimental values is statistically significant. This is due to the fact that, after the sorption sites on the film surface are covered, the molecules of amino acids adsorbed on the film and those occurring in the gas phase form dimers. The total acid concentration in air was determined with the PS– β-alanine film, which is highly sensitive to both acids (Fig. 1); the sorption time was 10 s.

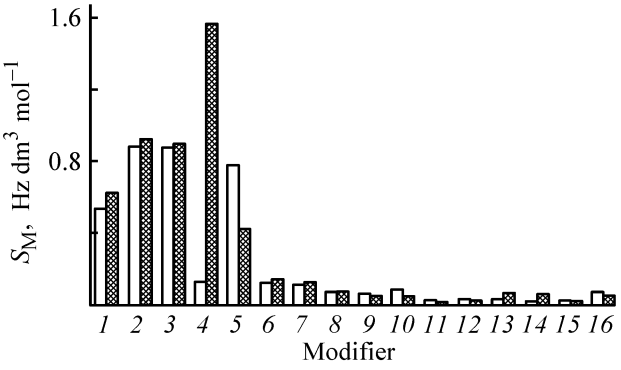

Fig. 1. Molar sensitivity histograms of the modifiers with respect to formic (white bars) and acetic (cross-hatched bars) acids: (*1*) PS–DB18C6 (I), (*2*) PS–β-alanine (I, layer-by-layer), (*3*) PS–glycine (I, layer-by-layer), (*4*) PS–EDBSA (II, mixed sorbent solution), (*5*) TX-100 (II), (*6*) PEGA (II), (*7*) PEGS (II), (*8*) PEGSb (II), (*9*) PETB (II), (*10*) PVP (II), (*11*) BG (II), (*12*) BW (II), (*13*) A-N (II), (*14*) A-L (II), (*15*) Sq (II), and (*16*) Tw-40 (II). (S_M) Sensitivity of the piezosensor.

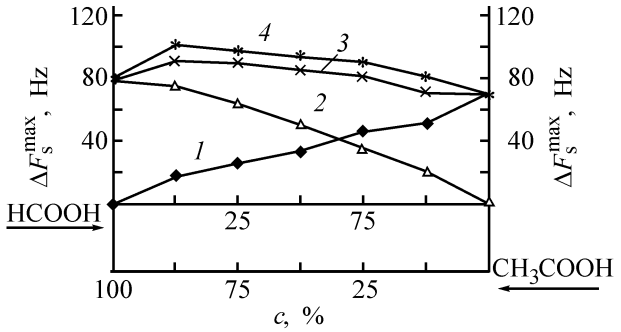

Fig. 2. Analytical signal of the sensor, ΔF_s^{max}, vs. (*1*) formic and (*2*) acetic acid concentration c. (*3*) Theoretical and (*4*) experimental analytical signals obtained in joint sorption of formic and acetic acids (1–10 mg m^{-3}) on the PS–β-alanine film.

When exposed to individual acid vapors, the sensor modified with the PS–β-alanine film demonstrated a linear response over the acid concentration range from 1 to 10 mg m^{-3}. The calibration curves for determination of formic and acetic acid concentrations by microweighing with this sensor are described by Eqs. (1) and (2), respectively:

$$\Delta F_1 = 7.0c_{HCOOH} + 7.2, \quad (1)$$

$$\Delta F_2 = 6.5c_{CH_3COOH} + 4.1, \quad (2)$$

where ΔF_1 and ΔF_2 are the analytical responses (Hz) of the sensor exposed to individual formic and acetic acid vapors, and c_{HCOOH} and c_{CH_3COOH}, the acid concentrations (mg m^{-3}).

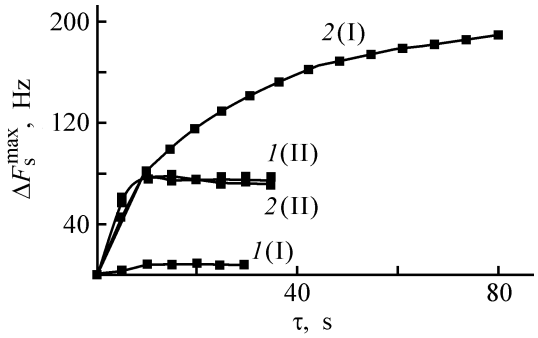

Fig. 3. Analytical signal of the sensor, ΔF_s^{max}, vs. time τ in sorption of (*1*) formic and (*2*) acetic acids on (I) PS–EDBSA and (II) PS–β-alanine films. Acid concentration $c = 10$ mg m^{-3}.

The modifiers used are characterized by cross sensitivity to formic and acetic acids. Therefore, two piezosensors are required for their separate determination, provided that one of them is selective. This condition is met for the sensors with electrodes modified with the PS–EDBSA and PS–β-alanine films (Fig. 1).

It was demonstrated that the sorption time of formic and acetic acids on the PS–EDBSA film should be 20–175 and 40–215 s, respectively, depending on their concentrations. It is seen from the time dependence of the analytical signal (Fig. 3) that, in exposure of the piezosensor modified with the PS–β-alanine film to the acid vapors, the signals are virtually indistinguishable (5–10 s). The detection limits of formic acid with the piezosensors modified with PS–EDBSA and PA–β-alanine films are 10 and 1 mg m^{-3}, and that with both piezosensors, 1 mg m^{-3}. The piezosensor with the PS–EDBSA film is selective with respect to the acetic acid (its molar sensitivity to formic acid is lower by an order of magnitude than for acetic acid [14]).

The calibration curves for determination of formic and acetic acid concentrations by microweighing with a piezosensor with the PS–EDBSA film are described by Eqs. (3) and (4), respectively:

$$\Delta F_1 = 1.6c_{HCOOH} - 0.8, \quad (3)$$

$$\Delta F_2 = 15.8c_{CH_3COOH} + 1.3. \quad (4)$$

The sorption isotherm of acetic acid on the PS–EDBSA film shows two linear sections, one being described by Eq. (4) (over the concentration range 1–15 mg m^{-3}) and another, by Eq. (5) (15–30 mg m^{-3}):

$$\Delta F = 37.4c_{CH_3COOH} - 278.7. \quad (5)$$

Two linear portions were also found in the sorption isotherm of formic acid on the PS–EDBSA film in the region of low concentrations, one being described by Eq. (3) (1–10 mg m^{-3}) and another, by Eq. (6) (10–70 mg m^{-3}):

$$\Delta F = 5.4c_{HCOOH} - 4.8. \quad (6)$$

Therefore, the acids can be determined separately both at the MPC level and at higher concentrations. At concentrations close to MPC, it is quite enough to expose the sensors to the acid vapor for 20 s, and at higher concentrations, for 1.5–2 min, since the sorption time of acetic acid on the PS–EDBSA film increases with the acid concentration.

From regression equations (1)–(4), obtained for PQRs modified with the PS–EDBSA and PS–β-alanine films, we derived equations allowing joint determination of formic and acetic acids in air:

$$c_{HCOOH} = \frac{(b_{2.2} + \Delta F_{tot.2} - b_{2.1})a_{1.1} - (\Delta F_{tot.1} + b_{1.1} + b_{1.2})a_{2.1}}{a_{2.2}a_{1.1} - a_{1.2}a_{2.1}}, \quad (7)$$

$$c_{CH_3COOH} = \frac{(\Delta F_{tot.1} + b_{1.1} + b_{1.2})a_{2.2} - (b_{2.2} + \Delta F_{tot.2} - b_{2.1})a_{1.2}}{a_{2.2}a_{1.1} - a_{1.2}a_{2.1}}, \quad (8)$$

where $a_{1.1}$, $a_{1.2}$, $a_{2.1}$, $a_{2.2}$, $b_{1.1}$, $b_{1.2}$, $b_{2.1}$, and $b_{2.2}$ are the regression coefficients in Eqs. (1)–(4); $\Delta F_{tot.1}$ and $\Delta F_{tot.2}$, integral analytical signals from the sensors with the PS–β-alanine and PS–EDBSA films, respectively, exposed to a mixed acid vapor.

To check the analytical procedure for consistency, the piezosensors were calibrated in individual acid vapors, and the experimental regression coefficients were introduced into Eqs. (7) and (8). Then we prepared gas mixtures with fixed acid concentrations of 1 to 10 mg m^{-3}. A sample of the equilibrium gas phase was injected into the detection cell equipped with two piezosensors. The exposure time was 20 s. Finally, the acid concentrations were estimated

Table 2. Joint and separate determination of (1) formic and (2) acetic acids with the piezoelectric sensor ($n = 3$, $P = 0.95$)

Separate determination					Joint determination

using the above equations. The results are listed in Table 2.

CONCLUSIONS

(1) Based on data on the sorption of formic and acetic acid and their mixtures from the gas phase on thin film-coated electrodes of bulk-acoustic-wave piezoelectric quartz resonators, methods for joint and separate determination of the acids were developed, using single- and double-sensor devices, respectively. The polystyrene–β-alanine film is recommended for joint determination of the acids, and the polystyrene–sodium ethylenediaminoazobenzenesulfonate film for separate determination.

(2) It was shown that the response time of the piezosensors depends on the formic and acetic acid concentrations in the mixed vapor.

(3) Regression equations for determination of formic and acetic acids in air were derived from the linear portions of the sorption isotherms of the acids on the modifier films.

Abstract—The fundamental aspect of the pore structure formation in composite films based on ultra-high-molecular-weight polyethylene and multiwall carbon nanotubes were studied by IR spectroscopy, mercury porosimetry, scanning electron microscopy, and differential scanning calorimetry in relation to the degree of filling.

DOI: 10.1134/S1070427207060213

Preparation, structural studies, and search for new applications fields of polymeric composites (in particular, nanocomposites) are important problems of modern materials science. Nanotubes receive particular attention today as a polymer filler. Such fillers, when added to a polymer, change its structure (often causing its ordering) and, thus, its properties, such as melting point, mechanical and thermoelastic characteristics, diffusion coefficients, etc. Although papers on this problem have been published [1, 2], data on the structure and some properties of the polymer composites with nanotubes in the form of fibers are scarce.

It has been found recently [3, 4] that addition of some fillers (strontium ferrite, vermiculite, etc.) to a solution of ultra-high-molecular-weight polyethylene (UHMWP) increases the porosity of the xerogel structure, which is of particular importance in synthesis of highly absorbing materials. The fraction of pores in a material determines not only its sorption properties, but also its mechanical characteristics (e.g., strength), which are impaired at large free volumes in the composite. This dependence should be taken into account in production of polymeric fibers [5]. Thus, evaluation of the conditions of the pore structure formation in the course of preparation of the final material (e.g., fibers and films with high strength characteristics) is a topical problem.

In this study, we examined the formation of the pore structure in the UHMWP xerogel films in relation to the concentration of multiwall carbon nanotubes as filler.

EXPERIMENTAL

In the experiments, we used films of UHMWP xerogels with a molecular weight M_w 1.7×10^6, filled with multiwall carbon nanotubes (MWCNT) [6]. The average diameter and length of the nanotubes were 20 nm and 5 μm, respectively. The allotropic modification of carbon used was purchased from the Carbon Nano-Material Technology Co., Ltd. (Germany, South Korea). An electron micrograph of MWCNT is shown in Fig. 1. The films were prepared as follows. First, the polymer was dissolved in a solid paraffin and the filler was added to the true solution obtained. The resulting heterogeneous system was slowly cooled

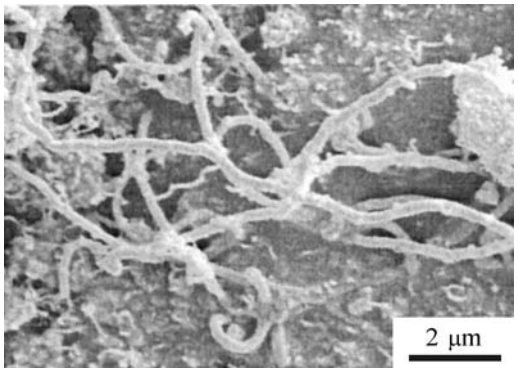

Fig. 1. Electron micrograph of MWCNT.

to room temperature, forming a filled xerogel film. Then, paraffin was washed out with hexane in a Soxhlet apparatus in the course of 24 h. The method used to prepare xerogel films is described in detail elsewhere [3, 4]. As a result, we obtained filled UHMWP xerogel films with a thickness of 20 to 60 μm; the degree of film filling was varied from 0 to 15%. We failed to prepare xerogel films with a higher degree of filling because of their mechanical breakdown in the course of preparation.

The dependences of the pore structure of the composites on the degree of their filling were studied by IR Fourier spectroscopy [7]. The IR spectra were recorded on an Equinox 55 Fourier IR spectrometer (Bruker). The IR evaluation of the porosity parameters, such as total porosity, average pore size, and pore size distribution, was described in [8, 9]. It is known that the overall extinction coefficient (attenuation factor) ε consists of the extinction coefficient related to absorption ε_A and extinction coefficient related to scattering ε_S, i.e., $\varepsilon = \varepsilon_A + \varepsilon_S$. The total porosity of the material α (%), which is the ratio of the total pore volume in the sample to the sample volume, was calculated using the following equation [8, 9]:

$$\alpha = \frac{\varepsilon_A^M - \varepsilon_A}{\varepsilon_A^M} \times 100, \quad (1)$$

where ε_A^M is the absorption-related extinction coefficient (ratio of the optical density at the absorption peak to the sample thickness in centimeters) of the most intense IR band (for polyethylene we used the absorption band at 730 cm^{-1}, associated with rocking vibrations of the CH_2 groups in the monolithic sample) and ε_A is the absorption extinction coefficient of the same band in the porous sample. In other words, ε_A decreases, with increasing pore volume in the material, i.e., the absorption-related extinction coefficient is inversely proportional to the total porosity.

When the sample contains heterogeneities (e.g., pores or filler particles) whose size is comparable with the wavelength of the incident radiation, this radiation is scattered in the system, which is manifested in the transmission or absorption spectra as a typical S-shaped inflection [8, 9]. The scattering-related extinction coefficient ε_S depends on the concentration, size, and shape of the scattering particles [10]. The larger the scattering S in the sample, the lower the light transmission and the greater the inflection curvature. By subtracting the IR spectrum of the monolithic sample of the same thickness, containing no scattering particles, from the IR spectrum of the scattering sample, we can obtain the dependence of scattering S (or directly the dependence of the size of scattering particles) on the wavelength λ. Subsequent differentiation of the resulting dependence of $S(\lambda)$ with respect to λ gives data on the size distribution of the scattering particles (in our case, pores) in the sample [8, 9].

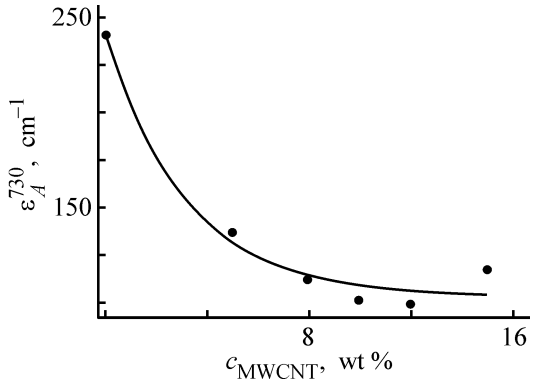

Fig. 2. Absorption-related extinction coefficient ε_A^{730} of UHMWP xerogel film vs. the degree of filling, c_{MWCNT}.

As independent methods for studying the composite pore structure, we used scanning electron microscopy [11] and mercury porosimetry (measurement of the mercury volume penetrating into the material at given pressures and evaluation of the size of pores filled with mercury) [12]. The samples for microscopic studies were prepared as follows. A sample was placed on a support coated with sputtered gold and dried in a vacuum [13]. Micrographs of the composite film surface were obtained with a Zeiss DSM 962 scanning electron microscope. The porosity (average pore diameter and total porosity determined only by micro- and nanopores) of the samples was determined on a Pascal 140 mercury porosimeter (Thermo Electron Corporation). Thermograms of melting of the polymer composites were recorded on a Diamond DSC 700 differential scanning calorimeter (Perkin–Elmer) at a heating rate of 10 deg min^{-1}; the weight of the xerogel film samples was 1.0–1.5 mg. Then, using the above thermal data, we calculated the degree of crystallinity æ (%) from the following equation:

$$æ = (\Delta H_m/\Delta H_m^0) \times 100, \quad (2)$$

where ΔH_m is the specific heat of melting of the given sample, and ΔH_m^0 is the calorific heat of melting of the ideal polyethylene crystal (293 J g^{-1} [10, 11]).

As shown above, the absorption-related extinction coefficient is inversely proportional to the free volume in the sample. The dependence of the extinction coefficient ε_A^{730} (or total porosity) of the composite on the filler concentration is shown in Fig. 2. As can be seen, the total porosity gradually increases with

Table 1. Total porosity α, average pore diameter d_{av}, and pore concentration c_{mac} in relation to the degree of filling, c_{MWCNT}, (based on IR data)

c_{MWCNT}, wt %	α, %	d_{av}, μm	c_{mac}, arb. units
0	8.8	5.7	171
5	48.0	9.9	50
8	57.3	9.9	41
10	61.5	3.1	87
12	62.3	6.1	41
15	55.1	3.4	119

the filler content of the sample. However, the corresponding curve flattens out at a filler concentration of 10–12 wt %, and at filler concentration of 15 wt % the total porosity even slightly decreases. A possible explanation is that the filler first leads to disordering of the polymer system, but, at its content exceeding 12 wt %, the sample becomes more compact owing to filling of the pores with the filler particles added. The results obtained using Eq. (1) are listed in Table 1. With account of the fact that ε_A^{730} for the monolithic polymer is 262.8 cm^{-1}, these data suggest that the total porosity is the highest (~62.0%) at an MWCNT content of 10–12%. Further increase in the filler content causes breakdown of the sample.

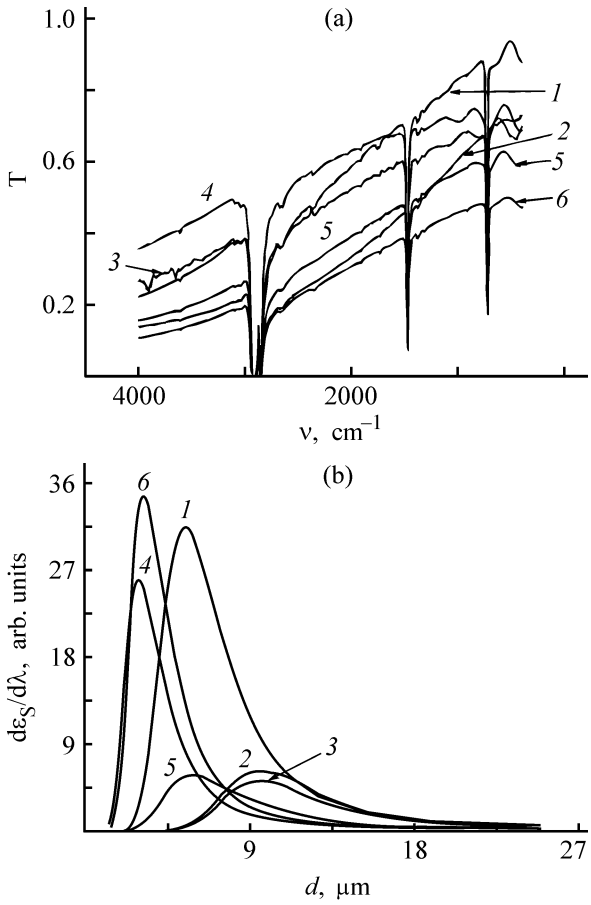

Fig. 3. (a) Transmission IR spectra of the composite UHMWP xerogel films with various degrees of filling and (b) pore size distribution in the composite films vs. the degree of filling. (T) Transmission, (ν) wavenumber, (*d*) pore diameter, and ($d\varepsilon_S/d\lambda$) first derivative of the scattering-related extinction coefficient with respect to the wavelength λ. Degree of filling, c_{MWCNT}, wt %: (*1*) 0, (*2*) 5, (*3*) 8, (*4*) 10, (*5*) 12, and (*6*) 15.

The transmission IR spectra of the composite polyethylene films with various degrees of filling are shown in Fig. 3a. As can be seen, the previously observed trend [3, 4] toward an increase in the pore size with the filler content of UHMWP is preserved. However, at a 8% degree of filling, the average size of the scattering sites (in particular, pores) decreases, which is confirmed by a shift of the characteristic S-shaped bend in the IR spectra toward shorter wavelengths [7, 8] (Table 1).

The size distribution curves of the scattering particles (pores, nanotubes), determined from the IR spectra using the procedure given in [8], are shown in Fig. 3b. As can be seen, a sharp increase in the porosity and a shift of the size distribution toward larger pore diameters are observed at 5 and 8% degrees of filling. With a further increase in the degree of filling, the sample with a smaller pore diameter is formed (10%) and the pore size distribution curves shift toward smaller values.

However, the total content of macropores, i.e., pores of micrometer size, which is determined as the integral of the pore size distribution curves or the area under these curves in Fig. 3b [15]), changes nonmonotonically. As can be seen from Table 1, the concentration of macropores in the xerogel film decreases in the initial stage (5 and 8% filling), as the total porosity of the sample increases. This can be attributed to an increase in the average pore size owing to merging of fine pores in the course of formation of the pore structure, promoted by the filler addition. At a 10% filling, the amount of macropores first grows, and as the degree of filling increases further, it decreases again. Presumably, both the size and concentration of nanopores contributing to the total porosity increase along with changes in macropores. Moreover, with increasing filler content, nanotubes can penetrate in the pore volume, thus changing the number and size of macropores.

Addition of one-wall carbon nanotubes changes such important system parameters as the melting point of the material [16]. It was found that multiwall carbon nanotubes, when added to the xerogel, affect not only the pore structure of the polymer, but also

the degree of polymer crystallinity [4]. In this case, the melting point of the xerogel films changes insignificantly (by 2–3°C). On the whole, the degree of crystallinity of the composite decreases with an increase in the degree of filling of the polymer. Comparison of the data of IR spectroscopy and differential scanning calorimetry (Figs. 3 and 4, respectively) shows that, when the degree of crystallinity in the system decreases, the average size of macropores (5, 8, and 12 wt % filling) increases, and vice versa. This is probably due to deceleration of the polymer crystallization upon addition of a filler. When carbon nanotubes are used as a filler, the composite can be regarded as a polymer layer between two planes formed by nanotubes. In accordance with [17, 18], the volume of the crystalline areas formed upon cooling correlates with the thickness of this polymer layer; it should be noted that this dependence passes through a maximum. If the thickness of the polymer layer is small, then the crystalline phase is formed predominantly on the surface (12, 15%). We assume that, in this case, changes in the crystallization process should leads to a decrease in the fraction of the surface pores At some intermediate layer thickness, corresponding to 10% filling, the volume of the crystalline phase is the largest, which is illustrated by a certain increase in the degree of crystallinity (Fig. 4). Further increase in the polymer layer thickness (5 and 8 wt % filling) accelerates formation of amorphous regions (film bulk), which ultimately leads to an increase in the fraction of pores in the material.

The data of mercury porosimetry are listed in Table 2. As can be seen, a certain decrease in macroporosity is observed at 10 wt % filling, which agrees with IR (Fig. 3a, the IR spectra are less distorted at 10% filling) and calorimetric data. However, as can be seen from Fig. 2, the sample porosity steadily increases with the degree of filling. This suggests that, in this case, the porosity is due to closed pores. The average diameter of macropores, d_1, increases with the degree of filling (Table 2), which also disagrees with Fig. 3b. This can be explained as follows. Mercury porosimetry characterizes only open and through pores in the sample, whereas IR spectroscopy reveals all the pores present in the sample. Along with the pores of micrometer size (1.0–100.0 μm), which can be studied by IR spectroscopy [8, 9], sample also contains nanopores (thinner than 1 μm). Changes in the total nanoporosity α_2 are proportional to changes in the total microporosity α_1 (Table 2). Changes in the average diameter of nanopores are expectable, because especially this fraction of the pore volume should be sensitive to an increase in the degree of crystallinity of the sample. Less porous structures are formed owing to disappearance of nanopores.

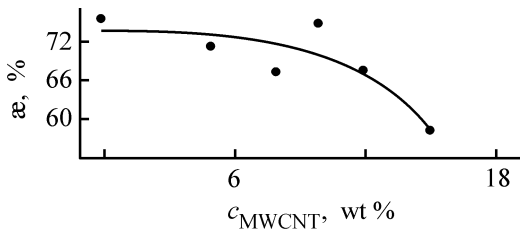

Fig. 4. Degree of crystallinity æ of the UHMWP xerogel films vs. the degree of filling, c_{MWCNT}.

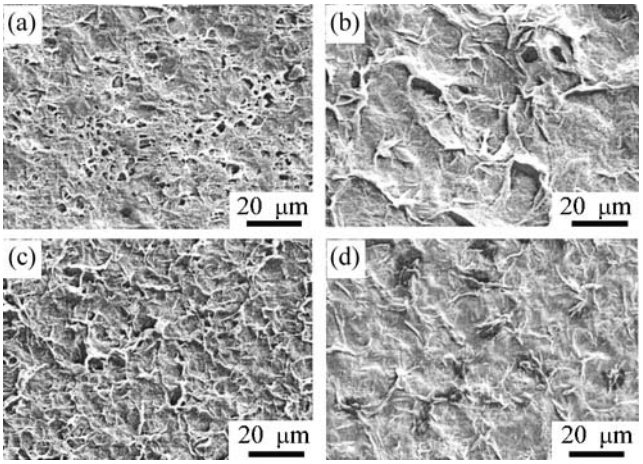

Fig. 5. Electron micrographs of the composite UHMWP xerogel surface at various degrees of filling, c_{MWCNT}, wt %: (a) 0, (b) 5, (c) 10, and (d) 15.

Electron micrographs of the surface of the composites with various degrees of filling are shown in Fig. 5. With increasing content of the filler (Figs. 5a, 5b; 0, 5 wt % filling), the average size of pores on the sample surface grows. When the content of nanotubes reaches 10–15 wt % (Fig. 5c, 5d), the sample

Table 2. Average volume of macro- (d_1) and micropores (d_2), and fraction (relative to total sample volume) of macro- (α_1) and micropores (α_2) in relation to the degree of filling of the composite, c_{MWCNT} (mercury porosimetry data)

c_{MWCNT}, wt %	α_1, %	α_2, %	d_1, μm	d_2, nm
0	13.2	15.2	26.8	39.1
10	2.1	0.8	39.4	25.0
15	44.6	14.8	36.7	87.4

surface becomes smoother and the content of the surface pores decreases, which agrees with the data shown in Fig. 2. The electron-microscopic data confirm that the porosity in the surface polymer layers varies with the degree of filling.

CONCLUSION

The data on the formation of the pore structure in composite xerogel films of ultra-high-molecular-weight polyethylene filled with multiwall carbon nanotubes showed that, with increasing filler content, the porosity of the system grows. As the degree of filling increases to more than 10 wt %, the system becomes more compact owing to the filling of the pores by the carbon nanotubes added.

Abstract—A method for characterization of the adhesion interaction of polymers with the surface of filler nanoparticles is suggested.

DOI: 10.1134/S1070427207060225

Undoubtedly, the adhesion of a polymer to the surface of filler particles is among factors substantially influencing the structure and properties of filled polymers. Therefore, it is important to have a technique allowing characterization of such an adhesion interaction. Numerous papers concerning this problem have been published [1–13]. However, it appeared difficult to develop a sufficiently reliable method for measuring the efficiency of adhesion interaction of a polymer with the surface of filler nanoparticles, because of the extremely small particle size of the filler and the high viscosity of the polymers [1–13].

The existing methods can be subdivided into two groups. The first group includes those based on determination of parameters characterizing the energy of interaction of a polymer with the surface of filler particles (true cohesion energy) [1–6]. Being based on sorption techniques for determination of thermodynamic parameters and on construction of thermodynamic cycles, these methods are very complex.

The second and the most numerous group covers the methods based on direct or indirect determination of the mechanical strength of adhesion of the polymer to the filler particles [8–13]. All the indirect methods allow estimation of only the relative efficiency of the adhesion interaction. The major drawback of the direct mechanical methods is the uncertainty about the adhesive fracture area and, frequently, even about the fracture mode.

Because of the lack of simple and reliable methods for determination of the adhesion strength, published data on the effect of the filler and polymer on the adhesion strength between them are scarce. Therefore, development of new adequate methods for determination of this characteristic appears to be a very topical task.

EXPERIMENTAL

We used in the study the following commercial thermoplastics: 15803-020 grade high-pressure low-density polyethylene (LDPE) [GOST (State Standard) 16337–77]; 11708–1250 grade ethylene/vinyl acetate copolymer (EVA) [TU (Technical Specifications) 6-05-1636–97] containing 28 wt % VA; PSM-115 polystyrene (PS) (GOST 20282–86); D-50 poly(vinyl acetate) (PVA) (GOST 18992–90); and 01 003 grade polypropylene (PP) (GOST 26996–86); and also commercial elastomers: P-118 polyisobutylene (PIB) (GOST 13303–67); 1,4-*cis*-polybutadiene (SKD) (GOST 14924–75); SKN-40m butadiene/acrylonitrile random copolymer (SKN) (GOST 7738–65, Mooney viscosity 54) containing 39 wt % AN; Nairit-M polychloroprene (PCP) (Mooney viscosity 62); SKT poly(dimethylsiloxane) (PDMS) (GOST 14680–79, number-average molecular weight 560000); and Urelan urethane thermoplastic elastomer (UTPE) (TU 38-403-0006–77) based on polyfurite, 4,4'-diphenylmethane diisocyanate, and 1,4-butanediol (0.5 : 1.0 : 0.5 molar ratio).

As fillers we used P267 crude oil furnace carbon black (CB) (GOST 7885–86, specific adsorption surface area S_{sp} = 225 $m^2 g^{-1}$, mean size of primary aggregates 28 nm) and A175 pyrogenetic amorphous silica in the form of Aerosil (GOST 14922–77, S_{sp} = 175 $m^2 g^{-1}$, particle size 10–40 nm). Prior to determination of the heat of wetting, the fillers were vacuum-

dried for 1 h in to remove physisorbed water. Carbon black was dried at 120°C, and Aerosil, at 200°C.

All the solvents used were of chemically or analytically pure grade, and they were additionally distilled before use.

The heats of wetting of the fillers with low-molecular-weight liquids were determined on a DAK1-1A automatic differential calorimeter. A weighed portion (40 mg) of a dried filler was placed in a thin-wall ampule, and the ampule was slowly evacuated and sealed. The ampule, wetting liquid (2 ml), and glass stick for breaking the ampule were placed in both cells of the calorimeter. After the desired temperature in the cells was reached, the ampule in one of them was broken. The liberated heat was recorded with an automatic potentiometer. The specific heat of wetting, ΔH, was estimated as

$$\Delta H = Q/S_{ads},$$

where S_{ads} is the specific adsorption surface of the filler, and Q, heat of wetting, determined from the calorimetric curves by the equation

$$Q = AS,$$

where S is the area under the curve recorded by the potentiometer, and A, calorimeter constant at a fixed sensitivity. The determination error was within 2%.

The specific heat of wetting, ΔH, was determined at 30.2°C, because the thermostat of the calorimeter operates reliably only at temperatures several degrees above the ambient temperature, whereas at higher temperatures, the volatility of the solvents increases.

To determine the peeling resistance of the polymer from the powdered filler, the latter was added to polypropylene by mixing on roll mills at 190 ± 5°C. The resulting filled polymer was compacted into a plate on a hydraulic press at 200 ± 5°C.

A thin polymer layer was then removed from the surface of the filled PP by treatment with an abrasive paper (grain size 50 μm). To avoid warming-up of the plate surface, the abrasive treatment was carried out in a cooling water stream at a very low processing speed. A plate made of unfilled PP was processed similarly.

Finally, the thus prepared plates were covered with a layer of the test polymer from a solution. The coating was carried out step-by-step, with each preceding layer dried. In the course of coating, the polymer layer was reinforced with a cotton fabric. The resulting sample was air-dried at room temperature for 1 day and then in a vacuum oven to final dryness.

The polymer solutions were prepared using the following solvents: toluene for SKD and PS; THF for UTPE; and chloroform for SKN, PCP, EVA, and PVA. A PE layer was applied onto a filled PP plate step-by-step at 160°C for 15 min.

After applying and drying a layer, all the rubber coatings were cured. For this purpose, the standard sulfurous curing agent [14] was added to SKN-40, SKD, and PCP using a roll mill prior to solution preparation. In the case of PDMS, K-18 hardener (5 wt %) was added prior to coating. The filled PP plates coated with the indicated rubbers were cured at 160°C for 20 min in an oven.

The peeling resistance was measured on a tensile-testing machine at a holder speed of 25 mm min^{-1}, temperature of 23°C, and peeling angle of 90°. Three parallel series of tests were performed with five samples in each series.

As mentioned above, the existing methods for determination of the interaction energy of polymers with a solid surface are very complex. At the same time, it is clear that the energy of adsorption interaction of liquids with a solid surface at a fixed temperature mostly depends on the chemical natures of the adsorbent and adsorbate [15–17]. Therefore, the energy of adsorption interaction of low-molecular-weight analogs of polymers with a solid surface should be well comparable with that of the corresponding polymers with the same surface, allowing evaluation of the efficiency of adsorption interaction of polymers with the surface of filler particles from model experiments with low-molecular-weight analogues.

The energy of adsorption of liquids on the surface of filler particles can be estimated from the heat of wetting ΔH. Since the adsorption of a liquid on a solid surface is not accompanied by changes in the aggregative state of the substances, the entropy of the system only slightly changes. Therefore, in this case, the integral heat of wetting is virtually equal to the energy of adhesion of the liquid to the surface [15].

It appeared interesting to measure the heat of wetting of the fillers not only with some low-molecular-weight analogues of the polymers, but also with a broader spectrum of liquids, in order to study the effect of the nature of liquids on ΔH. Our results showed that the ΔH values of carbon black and Aerosil

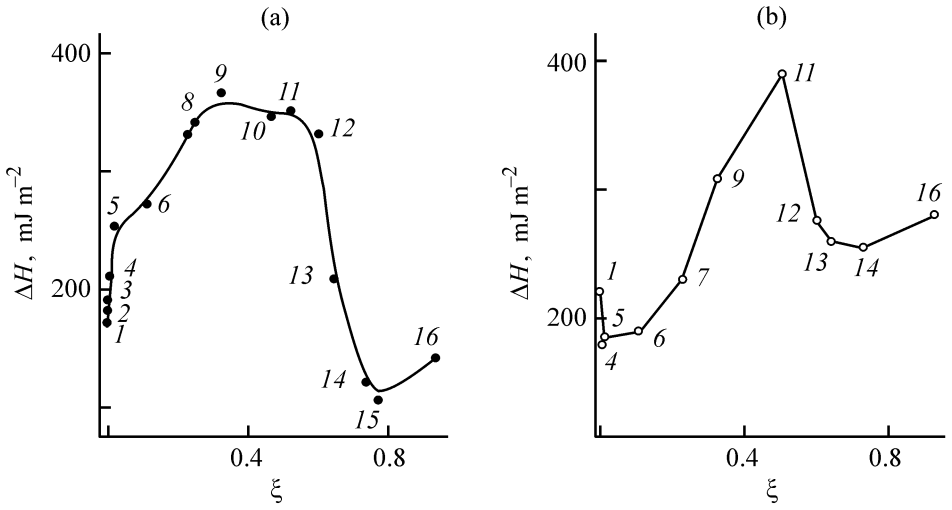

Fig. 1. Heat of wetting, ΔH, of (a) carbon black and (b) Aerosil vs. the polarity ξ of the liquids: (*1*) carbon tetrachloride, (*2*) *n*-hexane, (*3*) 2,2,4-trimethylpentane, (*4*) ethylbenzene, (*5*) toluene, (*6*) 1-chlorobutane, (*7*) MMA, (*8*) THF, (*9*) ethyl acetate, (*10*) 1-hexanol, (*11*) DMF, (*12*) acetonitrile, (*13*) ethanol, (*14*) ethylene glycol, (*15*) glycerol, and (*16*) water.

depend in a certain way on the polarity of liquids ξ (Fig. 1). The polarity of the polymers and liquids was estimated from the polar (δ_p) and hydrogen-bonding (δ_h) terms of the solubility parameter δ [18–21]:

$$\xi = (\delta_p^2 + \delta_h^2)/\delta^2.$$

The results showed that, with increasing polarity of the liquid, ΔH of carbon black and Aerosil passes through a maximum in a certain ξ range. The initial increase in ΔH is caused by the formation of hydrogen and polar bonds on the surface of carbon black with oxygen-containing groups, in addition to dispersion bonds. The increase in ΔH with the polarity of the liquid has been reported for carbon black previously [15, 22]. Furthermore, it was reported that the dependence of the adhesion of organic liquids to the surface of a number of metal oxides on the polarity of the liquids, determined from the soaking rate of the powders, is also nonmonotonic [23].

The maximal ΔH for such a filler as P267-grade carbon black is observed at $\xi \sim 0.33$, which is in satisfactory agreement with published data on the polarity of the surface of two other types of carbon black, determined from data on their dispersibility in liquids (0.43 and 0.38 for gas and furnace carbon blacks, respectively [18, 19]). P267-grade carbon black is distinguished by a relatively low concentration of the carboxy groups on the surface (9 mg-equiv g^{-1} on the average [24]). As a result, it has a slightly lower ξ.

Similar results were obtained for A175-grade Aerosil (pyrogenetic silica). For this material, the maximal ΔH was observed at $\xi = 0.51$ (Fig. 1), suggesting a higher polarity of the Aerosil surface as compared to carbon black, which is well consistent with the chemical structure of the surfaces of the fillers investigated.

Our results show that an increase in the polarity of the polymers to $\xi = 0.33$ enhances their adhesion to carbon black. Similar trend should also be observed for Aerosil with the polarity of the polymer increasing to 0.51.

It was of interest to examine how the above results correlate with the adhesion of the polymers to the fillers. However, the existing methods for determination of the adhesion of polymers to fine powders suffer from significant disadvantages [9]. For example, Yagnyanenskaya and Voyutskii [11] suggested to embed a powder in a polymeric binder, e.g., by mixing the filler power with a solution of polyvinyl alcohol, followed by removal of the solvent, and then to measure the peeling resistance of the surface of the polymeric binder with encapsulated filler particles with respect to the polymer investigated. However, the filler surface is covered in this case with the polymeric binder, so that a change in the peeling resistance could be detected only at a very high degree of filling. Savel'ev et al. [13] suggested to apply filler to the surface of a PS polymeric support pretreated with an organic solvent (chloroform). After the removal of the solvent, a part of the filler was glued to

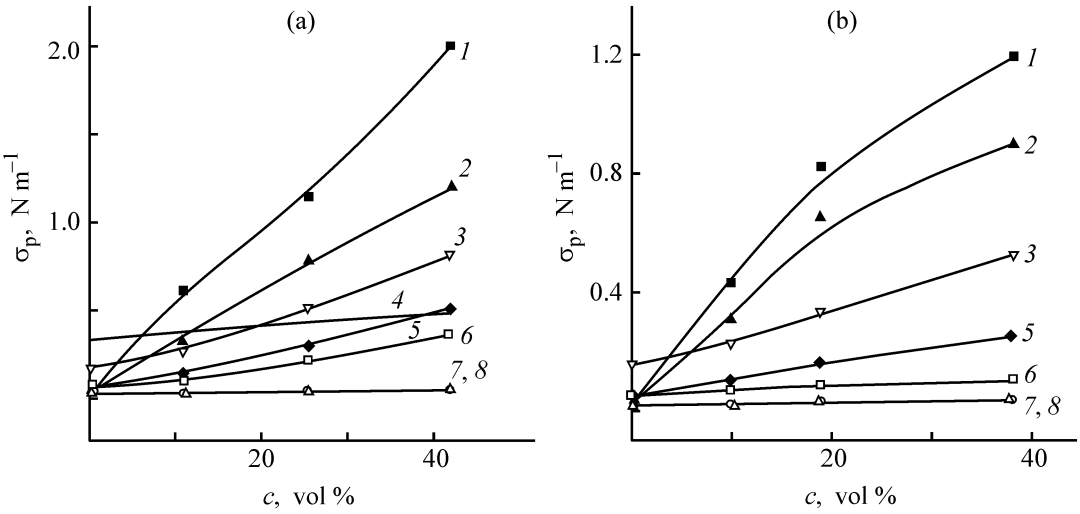

Fig. 2. Peeling resistance σ_p of (a) carbon black and (b) Aerosil fixed in polypropylene with respect to polymers vs. the filler content c: (*1*) PVA, (*2*) UTPE, (*3*) PCP, (*4*) SKD, (*5*) SKN-40m, (*6*) EVA-28, (*7*) PS, and (*8*) LDPE.

the support. The residual filler was removed with a brush. Then the polymer investigated was applied as a melt to the plate by pressing, and the peeling resistance of the filler particles fixed on the support was measured with respect to the polymer investigated. It is noteworthy that, in this method, the filler surface remained partly open. However, some doubt is cast in this case upon the strength of fixation in the matrix of all the remaining filler particles. Furthermore, the surface concentration of the filler is unknown.

To overcome these drawbacks, we suggest in this study a somewhat different technique for fixation of the filler to the polymer matrix. The filler was introduced into a polymer melt and the resulting mixture was compacted into plates. In this case, as mentioned above, the surface of the filler particles appears to be coated with a polymer layer. To strip the surface of the filler particles, a thin layer of the polymer was removed from the plate surface using an abrasive. Then a layer of the polymer investigated was applied to the wafer by spraying, followed by removal of a solvent, and the peeling resistance was measured. Analysis of the experimental results becomes simpler if the polymeric binder used as a matrix for the filler is characterized by very low adhesion to the polymer investigated. In this case, the adhesion of the binder to the polymers can be neglected. In this study, we used polypropylene as a binder, as having a very low adhesion to the most of the investigated polymers and low room-temperature solubility in liquids.

In this sample preparation procedure, the fraction of stripped surface of the filler particles should be in proportion to its volume fraction in the binder, as demonstrated by the almost linear dependence of the peeling resistance σ_p on the filler content (Fig. 2). In the case when the filled polymer plates have not been processed with an abrasive prior to application of the adhesive, σ_p started to increase only at a filler (carbon black or Aerosil) content of about 30 vol %. Evidently, at such a high degree of filling, the surface of carbon black or Aerosil is incompletely wetted with the polymer in the mixture, so that the mixture adsorbs the adhesive.

To adequately characterize the adhesion of the polymer to the filler, it is necessary to know what mode [adhesion (along boundaries) or cohesion (though the bulk of the material)] of peeling occurs in the tests. An optical-microscopic examination of the surfaces of the adhesive and supporting wafer after testing suggested that the filler particles are not transferred from PP to the surface of the polymer film being peeled. Only at the filler content in PP as high as approximately 40 vol %, we observed transfer of small amount of the filler particles onto the adhesive. The microscopic examination revealed no residual adhesive on the plate surface coated with the binder. All these facts allow characterization of the relative efficiency of the adhesion interaction of the polymers with the filler by the increase in the peeling resistance $\Delta\sigma_p$, resulting from a higher filler content of PP.

Data on σ_p (Fig. 2) show that, with increasing polarity of the polymer (see table), its adhesion to the filler grows. Qualitatively, this result is well consistent with data obtained from the heat of wetting

Characteristics of the interaction of polymers and their low-molecular-weight analogues with carbon black and Aerosil

Polymer				Low-molecular-weight analogue			
kind of polymer	ξ [18–21]	$\Delta\sigma_p^*$, kN m^{-1}		compound	ξ [18–21]	ΔH, mJ m^{-2}	
		carbon black	Aerosil A-175			carbon black	Aerosil A-175
PE	0.0	0.02	0.01	*n*-Hexane	0	170	220
PIB	0.0	0.02	0.01	2,2,4-Trimethylpentane	0	175	225
PS	0.012	0.02	0.01	Ethylbenzene	0.01	205	180
SKD	0.003	0.15	0.05	1-Hexene	–	180	–
PDMS	0.041**	0.03	–	Octamethylcyclotetrasiloxane	0.04	200	–
EVA-28	–	0.32	0.05	–	–	–	–
SKN-40	–	0.46	0.21	–	–	–	–
PCP	0.112**	0.65	0.37	1-Chlorobutane	0.11	270	190
UTPE	–	1.17	0.87	–	–	–	–
PVA	0.333	2.12	1.17	Ethyl acetate	0.33	365	308

* ($\Delta\sigma_p$) Increase in σ_p with an increase in the carbon black content of PP from 0 to 42 vol % and in the Aerosil A-175 content of PP from 0 to 38 vol %.

** Estimated from the ratio of the polar and dispersion terms of the surface tension of the polymer [25].

(see table and Fig. 1). Therefore, with increasing fraction of the polar and hydrogen constituents of the solubility parameter of the polymers from 0 to 0.33, their adhesion to carbon black and Aerosil becomes stronger.

Data on ΔH and σ_p show that PE, PIB, SKD, PP, PS, and PDMS have the lowest and close energies of adsorption interaction with the surface of carbon black and Aerosil. The adhesion of the other polymers to carbon black and Aerosil increases in the order EVA-28 < SKN-40 < PCP < UTPE < PVA.

CONCLUSIONS

(1) Data on the efficiency of adsorption interaction of a series of polymers with the surface of finely dispersed fillers, determined from data on the heat of wetting of the fillers with low-molecular-weight analogs, agree well with those obtained by measuring the peeling resistance of the fillers with respect to the polymers.

(2) With the fraction of the polar and hydrogen constituents of the solubility parameter of the polymers increasing from 0 to 0.33, their adhesion to carbon black and Aerosil becomes stronger.

Abstract—Oxidative electrochemical synthesis and formation kinetics of electrically conducting polymeric platinum(II) complexes with 8-quinolinol was studied. Spectroscopic and electrochemical properties of the polymers were characterized.

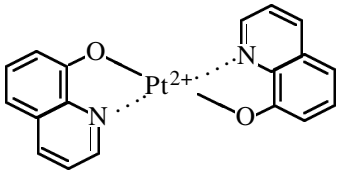
DOI: 10.1134/S1070427207060237

The chemistry of electroactive polymers is rapidly developing. These materials are widely used as corrosion protectors, catalysts, electrochromic materials, materials for chemical sensors and voltaic cells [1].

The so-called redox polymers, which are characterized by regular alternation of oxidized and reduced molecular fragments, occupy a particular place among polymeric materials. Organometallic redox polymers have a number of advantages over organic polymers with uniform electronic structure. Some of them are analogues of biocatalysts, e.g., peroxidase and oxygenase, and are characterized by high efficiency and selectivity. In addition, the properties of these materials can be controlled by varying the nature of metal centers, which opens up new prospects for control over optical properties of polymers by electric signals or protons [2]. Recent studies of production of transparent light-emitting diodes demonstrated the advisability of using electroluminescent polymers based on [Al(qol)$_3$] in LED devices, which are elements of flat-panel display screens of the next generation [3].

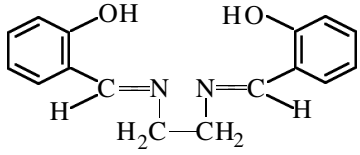
Redox polymers based on transition metal complexes are among the most important polymers of this type [4–10]. Among them, thin-layer electrically conducting, photosensitive, and luminescence-active polymers based on Pt(II) complexes with various polychelate ligands including *N*,*N*'-bis(salicylidene)ethylenediamine (Salen) and its derivatives [11] are of particular interest.

In this study, we used *trans*-[Pt(qol)$_2$] (Hqol is 8-quinolinol) as a monomeric unit in synthesis of multifunctional polymers [12]. The formula of this complex is as follows:

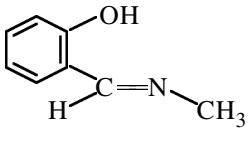


The optical, photophysical, and catalytic properties of [Pt(qol)$_2$] have been well studied [3, 13–16]. However there are no data on electrochemical synthesis of thin electrically conducting polymeric films on its basis.

In contrast to the previously used meSal ligand [17], containing imine nitrogen atom bound with the methyl group, in the qol ligand, the nitrogen atom is incorporated in the pyridine ring of 8-quinolinol. Thus, one of our main goals was to examine the influence of the chelate ring size (five-membered ring in Pt complex with qol in contrast to six-membered cycles with Salen and meSal) on the electropolymerization of the metal complex. The structural formulas of Salen and meSal are as follows:



Salen



meSal

The complex [Pt(qol)$_2$] was synthesized by the modified method [13]. Potassium tetrachloroplatinate(II), K_2PtCl_4 and 8-quinolinol C_9H_7ON (Merck), recrystallized from ethanol, were used.

Potassium tetrachloroplatinate(II) (0.6 g) was dissolved in water (6 ml), and the solution was added

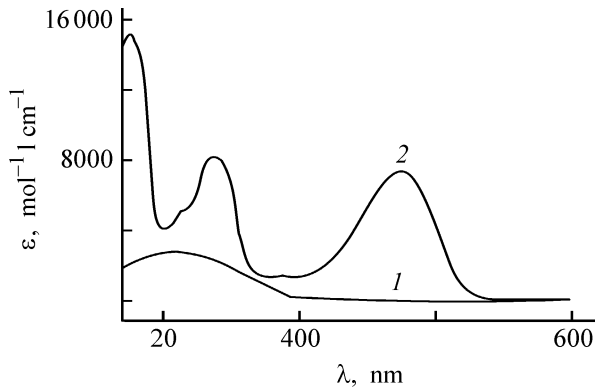


Fig. 1. Electronic absorption spectra of 1×10^{-4} M solutions of (*1*) 8-quinolinol ligand Hqol and (*2*) complex $[Pt(qol)_2]$ in DMF. (ε) Extinction coefficient and (λ) wavelength.

to a solution of 8-quinolinol (1 g) in 10 ml of glacial acetic acid (pH 4). The reaction mixture was stirred for 1 h at 70°C. After cooling, the orange-brown precipitate formed was filtered off, washed with plentiful of dilute acetic acid, then with ethanol, and recrystallized from DMF. The yield was 86%.

Because $[Pt(qol)_2]$ is photochemically labile in the presence of atmospheric oxygen [3, 13], all solutions were prepared in the dark.

The ligand and complex were identified by electronic absorption spectroscopy (EAS) and X-ray photoelectron spectroscopy (XPES).

The electronic absorption spectra of the ligand and complex in DMF (ultra-pure grade) and of the polymer (both oxidized and reduced forms) were recorded on an SF-2000 spectrophotometer at 293 K.

Pt4*f*			73.7	4.07

The absorption spectra of the ligand Hqol and complex $[Pt(qol)_2]$ are shown in Fig. 1. As can be seen, the spectrum of Hqol is characterzed by a strong absorption band at 314 nm (ε = 2630) corresponding to intraligand π–π^* transition [13].

The complexation of $[Pt(qol)_2]$ is accompanied by pronounced changes in the EAS. For instance, the strong π–π^* band shows a batochromic shift to λ_{max} = 345 nm (ε = 8000). In addition, a new strong band at λ_{max} = 478 nm (ε = 6900) appears. This band was assigned, according to published data [3], to intraligand charge transfer (ILCT) from oxygen to nitrogen atom, or from phenolic to pyridine ring. At the same time, the mixed type of this absorption band associated with overlap of the ILCT band with the metal-to-ligand charge transfer (MLCT) band cannot be ruled out.

X-ray photoelectron spectra were recorded on an Axis Ultra (Kratos Alalytical, the United Kingdom) electron spectrometer with excitation by Al_{K_α} (1486.6 eV)[1] radiation. During measurements, the residual pressure in the spectrometer was 5×10^{-7} Pa. The spectra were processed using Vision 2 software, Kratos Analytical. The energy scale was calibrated against the C1*s* line of aromatic carbon as a reference (E_b = 285.0 eV).

The binding energy of photoelectrons and the atomic concentrations of the components (in at.%) for Hqol and $[Pt(qol)_2]$ are listed in Table 1.

The presence of two lines at 531.7 and 532.9 eV in the O1*s* spectrum and of two lines at 399.1 and 400 eV in the N1*s* spectrum for protonated ligand Hqol is probably caused by equilibrium proton transfer from the O atom to the N atom and back, with the equilibrium being shifted to formation of hydroxy groups.

The formation of $[Pt(qol)_2]$ is accompanied by changes in the binding energy of the highest-intensity components of O1*s* and N1*s* spectra as compared to Hqol. The N1*s* energy decreases from 399.3 to 400.9 eV, while the O1*s* energy decreases from 532.9 to 531.9 eV, respectively.

The observed chemical shifts (+1.6 eV for N1*s* and –1.0 eV for O1*s*) show that the binding energy of N1*s* electron increases because of the formation of the σ-donor bond in the complex with the participation of the unshared electron pair of the nitrogen atom belonging to the polycyclic ligand. In the process,

[1] Spectra was obtained by A.V. Shchukarev, St. Petersburg State University.

a part of the electron density shifts to the oxygen atom via the metal center.

In the complex, the platinum atom has the 4*f* electron binding energy of 73.7 eV, which corresponds to Pt(II) [18]. The Pt : N : O ratio is about 1 : 2 : 2, which indicates a virtually complete coordination of the metal center with the ligands via two nitrogen atoms and two oxygen atoms.

The electrochemical properties of the ligand and complex [Pt(qol)$_2$] and the synthesis and the redox properties of polymeric compounds obtained from monomeric [Pt(qol)$_2$] were studied by cyclic voltammetry.

The electrochemical measurements were carried out on an IPC-PRO potentiostat-galvanostat in a hermetic beaker with a common space for the working, auxiliary, and reference electrodes. A platinum wire (99.99% purity) with a surface area of 0.27 cm^2, soldered in a Pyrex holder, platinum plates, and optically transparent quartz plates with a layer of Sn(IV) oxide deposited on their surface served as working electrodes. A platinum grid was an auxiliary electrode. All potentials are given relative to a glass AgCl/Ag reference electrode filled with a NaCl saturated solution. A 0.1 M solution of tetrabutylammonium perchlorate (Bu_4NClO_4) in ultrapure grade dichloromethane (CH_2Cl_2) served as the supporting electrolyte. The concentration of the complex in the solution was 1 mM.

To find the optimal conditions of the synthesis of electrically conducting and photoactive [Pt(qol)$_2$] polymers, polymeric films were formed on an electrode in two modes: potentiodynamic and potentiostatic.

In the potentiodynamic mode, the polymer was accumulated under the conditions of cycling of the working electrode potential within the range 0.0–1.2 ± 0.1 V in the solution of the initial monomeric compound at a sweep rate of 0.05 V s^{-1}. The cycloammogram (CVA curve) obtained by single potential cycling in the solution of the complex [Pt(qol)$_2$] in CH_2Cl_2 is shown in Fig. 2 and is characterized by two oxidation waves with features at potentials of 0.9 (shoulder) and 1.0 V (peak). Two broad unresolved cathode waves with current peaks at 0.75 and 0.15 V appear when sweep direction is changed.

At the same time, only one oxidation wave is observed on a CVA curve of the ligand solution, with a peak at 1.1 V, whereas the back reduction wave is absent. Thus, there is no reversible charge transport, i.e., free ligand (8-quinolinol) in CH_2Cl_2 (and in acetonirile [19]) does not form active polymeric substances on the electrode surface. This was also confirmed visually. The close potentials of the anodic oxidation peak of the ligand and of the second peak of oxidation of the complex suggest that the orbitals of predominantly ligand type participate in the electrooxidation of the complex. At the same time, the first oxidation potential of the complex at E = 0.9 V can be attributed to the transfer of electron predominantly belonging to metal orbitals.

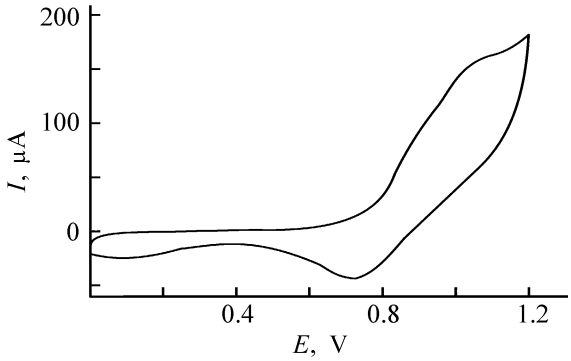

Fig. 2. CVA curve of the first cycle of electrode sweep potential in 1 mM solution of the complex [Pt(qol)$_2$] in 0.1 M solution of Bu_4NClO_4 in CH_2Cl_2. v_p = 0.05 V s^{-1}. (*I*) Current strength and (*E*) potential; the same for Figs. 3 and 6.

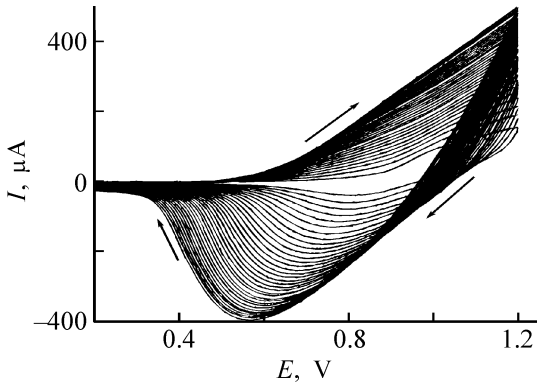

Fig. 3. CVA curves reflecting the dynamics of precipitation of the electroactivesubstance on the electrode surface from 1 mM [Pt(qol)$_2$] in 0.1 M solution of Bu_4NClO_4 in CH_2Cl_2. v_p = 0.05 V s^{-1}; 35 scans.

The subsequent cycling of the potential within the range from 0.0 to +1.2 V at a sweep rate of 0.05 V s^{-1} is accompanied by an increase in the height of the current peaks on both anodic and cathodic branches of the CVA curves, and also by overlap and leveling of the peaks and by the shift of the cathodic peak at E = 0.75 V to the negative region. By the 35th cycle, when an increase in current peak stops, we can note a cathodic peak at E_p = 0.6 V and appearance of an unresolved broad anodic wave with a feature at E = 0.9 V (shoulder) (Fig. 3).

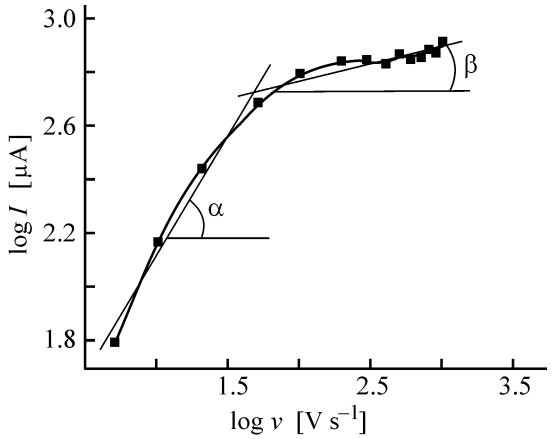

Fig. 4. Dependence of the logarithm of the cathode peak current I on the logarithm of the sweep rate of the potential of the electrode modified with a 1.4 μm layer of $[Pt(qol)_2]$ in 0.1 M solution of Bu_4NClO_4 in CH_2Cl_2.

A red film insoluble in water and organic solvents is detected visually on the electrode surface which confirms the formation of a stable solid product of $[Pt(qol)_2]$ oxidation. The transition from the reduced to oxidized form is accompanied by an electrochromic effect, with the film color changing from red to black. A calculation [20] showed that the polymer film thickness increases by 100 nm after each potential sweep.

To study the electrochemical stability and determine certain quantitative characteristics of polymeric films, we transferred the electrodes with poly$[Pt(qol)_2]$ obtained by polymerization in various potential sweep ranges into a solution of the pure supporting electrolyte and cycled the potential within the range from 0.0 to +1.2 V. It was found that the CVA curves remained unchanged for a long time. This fact confirms the stable character of the reversible charge transport in the bulk of the polymer solid phase.

A study of CVA curves at various sweep rates (from 0.005 to 1.0 V s^{-1}) allowed us to determine such quantitative characteristics of the polymer as thickness h (μm) and diffusion coefficient D_{ct} (cm^2 s^{-1}). As is known [20, 21], at low potential scanning rates, the film function in the mode of thin-layer voltammetry (TVA), which is accompanied by oxidation or reduction of all molecular fragments of the polymer chain. At high rates, only certain fragments of the polymeric chain are active, so that we have the mode of semiinfinite diffusion (SID). Thus, SID allows estimation of the charge transport rate in the polymeric phase, whereas we can approximately estimate by thin-layer voltammetry the thickness of the electrically conducting layer. As can be seen from the dependence of the logarithm of the cathode current peak on the logarithm of the potential sweep rate (Fig. 4), redox processes occur at sweep rates of 0.005 to 0.05 V s^{-1} in the TVA mode, as judged from the slope of the straight line ($\tan\alpha = 1$). The increase in the potential sweep rate for the electrode modified with poly$\{Pt(qol)_2]$ from 0.05 to 1.0 V s^{-1} causes transition to the diffusion mode of the polymer functioning ($\tan\beta = 0.5$).

The thickness of the polymer film and charge diffusion coefficient in the bulk of poly$[Pt(qol)_2]$ were calculated by the known methods [20]. The values obtained in the dynamic mode for films differing in synthesis conditions are listed in Table 2.

It should be noted that widening of the range of the electrode potential sweep in the complex solution to 1.4 V sharply changes the shape of the CVA curve already in the second cycle: the anode and cathode current peaks disappear.

Vilas–Boas et al. [22] suggest that the fact the current peaks cease increase during polymerization can be caused by "overoxidation" due to irreversible ligand oxidation with increasing potential. It was also found that narrowing of the potential sweeping range in oxidation of the complex under the dynamic conditions from 0.1–1.2 to 0.9–1.2 V does not change the quan-

Table 2. Thickness of the polymer film and charge diffusion coefficient in the bulk of poly$[Pt(qol)_2]$ synthesized under the dynamic conditions

Electrode potential, E^*, V	Number of cycles	$D_{ct} \times 10^{-11}$,** cm^2 s^{-1}	h,*** μm
0.0…+1.1	35	4.7	0.8
0.0…+1.2	35	7.3	1.4
0.0…+1.3	35	4.0	1.4

* 1 mM solution of $[Pt(qol)_2]$, supporting electrolyte 0.1 M Bu_4NClO_4 in CH_2Cl_2.

** Calculated from CVA curves obtained by sweeping the potential of the electrode modified with poly$[Pt(qol)_2]$ in pure supporting electrolyte at a sweep rate of 0.05–1.0 V s^{-1}.

*** Calculated from CVA curves in the pure supporting electrolyte at potential sweep rates of 0.005–0.05 V s^{-1}.

titative characteristics of the polymer synthesized, whereas sweeping within the 1.0–1.2 V and 1.1–1.2 V ranges decreases the thickness of the polymeric film. This can be caused by the fact that a sharp change of the direction of the potential sweeping with the corresponding alternation of the redox processes, prevents formation of a homogeneous polymer structure and, hence, increase in the film thickness.

The static mode involves formation of the polymer at a constant accumulation potential E_a. The optimal E_a is that at which the maximal amount of the electrochemically active polymer is deposited on the electrode surface in unit time.

To determine the optimal potential of accumulation and specific features of the poly[Pt(qol)$_2$] formation, we studied the dependence of the polymer layer thickness on E_a and process time τ_a.

The optimal values of E_a were determined as maxima of functions $h = f(E_a)$ and $h = f(\tau_a)$ (Fig. 5). The thickness of the polymer film at various E_a is listed below (accumulation time τ_a is 5 min):

E_a, V	0.8	0.9	1.0	1.1	1.2	1.3	1.4
h, μm	0	0.06	0.8	0.65	0.5	0.25	0.25

The increase in h values on raising the potential from 0.8 to 1.0 V may be due to an increasing rate of electrooxidation of complexes. The decrease in the film thickness after attaining the optimal potential or formation time is probably due to loss of the polymer electroactivity because of the irreversible oxidation and decomposition of the π-conjugation chain in the ligands.

As can be seen from Fig. 5, the extremum of the function $h = f(\tau_a)$ exceeds, under static conditions of synthesis, the extremum of the similar function for dynamic conditions. This indicates that it is economically advisable to prepare films in the static mode, because a larger film thickness can be attained in a shorter time and the synthesis can be performed for a longer time as compared to dynamic conditions.

The CVA curves obtained at a single potential sweep for poly[Pt(qol)$_2$] films with various thicknesses in a solution of pure supporting electrolyte (sweep rate 0.01 V s^{-1}) are shown in Fig. 6. As can be seen, the anodic and cathodic waves characterizing the reversible charge transport in the bulk of the polymer phase are observed in the CVA curves. An increase in the synthesis time to 45 and 60 min is accompanied by termination of the growth and decrease in the reduction wave, respectively, whereas the anodic peaks continue to increase. Alpatova et al. [23] and Vorotyntsev et al. [24] explained the decrease in the polymer redox activity by existence of the residual structural units of the polymer in the oxidized form which act as of electron "traps," or areas with "inhibited core".

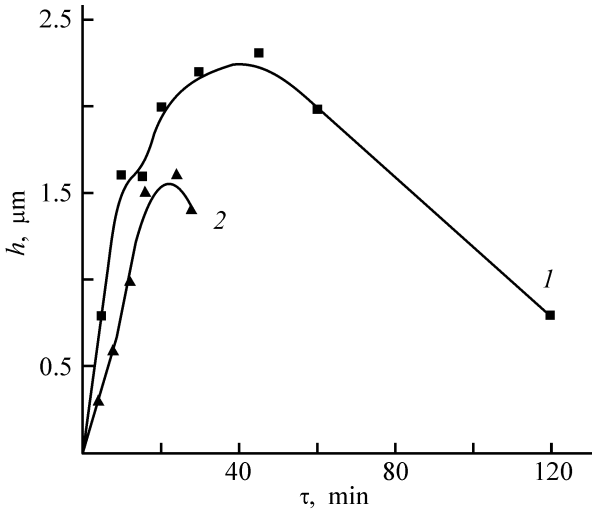

Fig. 5. Thickness h of poly[Pt(qol)$_2$] layer vs. the accumulation time τ in the (*1*) potentiostatic (E_a = 1.0 V) and (*2*) potentiodynamic modes.

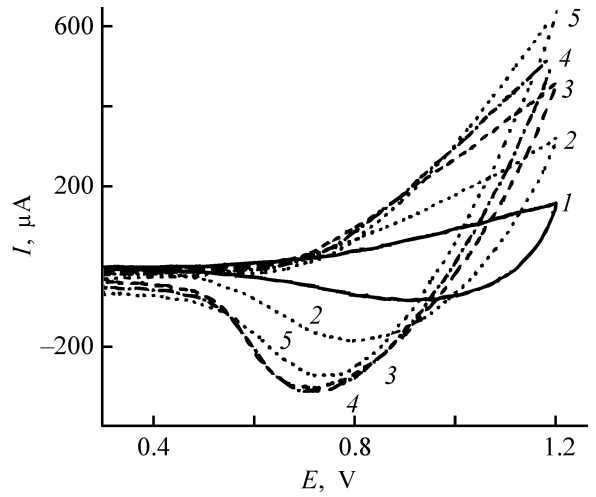

Fig. 6. CVA curves describing solid-phase redox processes in samples of poly[Pt(qol)$_2$] synthesized in the potentiostatic mode at E_a = 1.0 V. 0.1 M solution of Bu_4NClO_4 in CH_2Cl_2, v_p = 0.01 V s^{-1}. Synthesis time, min: (*1*) 5.0, (*2*) 15.0, (*3*) 30.0, (*4*) 45.0, and (*5*) 60.0.

Thus, accumulation in the static mode at E_a = 1.0 V for τ_a = 30–40 min is the optimal condition of synthesis of poly[Pt(qol)$_2$].

As mentioned above, the diffusion coefficient D_{ct} is the most important characteristic of the charge transfer rate in the polymeric matrix. The D_{ct} values

of poly[Pt(qol)$_2$] prepared in the static mode at various times and accumulation potentials are listed in Table 3.

As can be seen, D_{ct} is constant for thin films, but begins to decrease as the film thickness increases. These data are consistent with the concept that the number of the chain cross-links increases with the thickness [25]. The calculated values of D_{ct} suggest that the rate of diffusion of counterions is the rate-determining stage of the charge transport in poly[Pt(qol)$_2$].

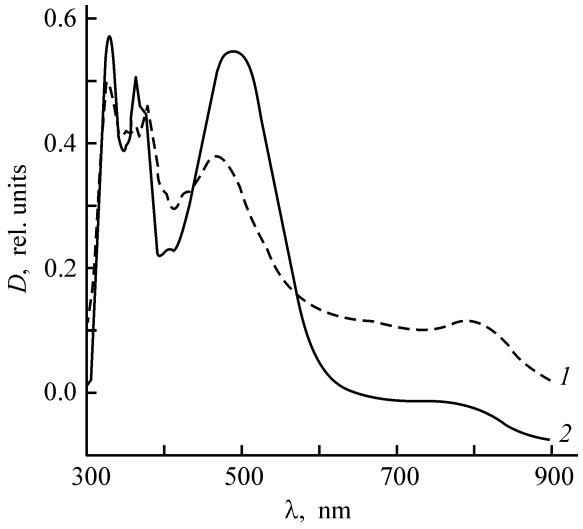

Fig. 7. Electronic absorption spectra of poly[Pt(qol)$_2$] in the (*1*) oxidized (1.0 V) and (*2*) reduced (0.2 V) forms. (*D*) Optical density and (λ) wavelength.

Probably, an increase in the number of cross-links of the polymeric chains with the synthesis time hinders the diffusion of ClO_4^- counterions stabilizing the oxidized form of the polymer, which, in turn, decreases D_{ct}.

A comparative analysis of XPES data for monomeric and polymeric platinum complexes allowed characterization of the poly[Pt(qol)$_2$] composition. In going from monomeric to polymeric compound, a new line with E_b = 75.2 eV appears in the XPES spectrum, which suggest partial oxidation of Pt(II) to Pt(IV) during electropolymerization. The ratio of the atomic concentrations of the corresponding components depends on whether the complex is predominantly in the oxidized or reduced forms.

In the XPES spectrum of the polymer, a Cl2$p^{3/2}$ line at 208.0 eV indicates the presence of the ClO_4^- ion in the film. Thus, the ClO_4^- ion plays the role of a counterion providing the electroneutrality of the polymer. It should be noted that additional lines at 198.5 and 200.6 eV, belonging to the chloride ion, also appear in the XPES spectrum. This fact can be accounted for by partial reduction of the ClO_4^- counterion during recording of the XPES spectrum. The XPES data for the polymer confirm previous conclusions about oxidation of the metal centers of platinum complexes in the course of the polymerization, in contrast to the related nickel(II), palladium(II), and copper(II) compounds. In the process, the unstable Pt(III) disproportionates to give Pt(II) and Pt(IV) centers.

Samples of poly[Pt(qol)$_2$] were prepared for recording the electronic absorption spectra on optically transparent electrodes [quartz plates coated with a Sn(IV) oxide layer] by anodic polymerization. The thickness of the polymer layer was about 1.2 μm.

The electronic absorption spectra (EAS) of poly-[Pt(qol)$_2$] in the oxidized (curve *1*) and reduced (curve *2*) forms are shown in Fig. 7. The EAS of the initial monomeric complex (solution in DMF) and polymeric films are similar within the 300–400 nm range and show a strong absorption caused by π–π^* type electronic transitions.

The presence of an isobestic point at 440 nm suggest that two equilibrium forms of the polymer coexist: oxidized and reduced.

The EAS of both poly-[Pt(qol)$_2$] and the monomeric complex contain strong low-energy bands peaked at λ = 465 and λ = 485 nm for the oxidized and reduced forms, respectively. The blue shift of the band belonging to the oxidized form of the poly-

mer is probably caused by an increase in the energy gap between the adjacent polymeric chains because of polymer swelling due to incorporation of charge-compensating ClO_4^- ions into the polymer phase [26].

At the same time, the EAS of the oxidized form contain a new broad absorption band peaked at λ = 800 nm is observed. Based on published data on EAS of organic polymers [6, 27–30], this band in the red spectral range can be attributed to the existence of mobile charge carriers, radical-cations. At a high degree of oxidation and simultaneous incorporation of the supporting electrolyte into the polymeric membrane cavities, the number of free charge carriers (radical-cations) increases, which, in turn, makes higher the conductivity of the polymer and causes its transition from an insulator to a substance with semiconducting properties. The accumulation of radical-cations leads to adecrease in the energy level of the conduction band and causes an increase in the conductivity of the polymeric compound.

To confirm the existence of radical-cations in the oxidized form of the polymer, we studied the near-IR spectra of the initial monomeric complex and polymeric compounds.

The IR absorption spectrum of the complex (KBr pellet) and IR reflection spectra of polymer films deposited onto quartz plates with a platinum mirror coating were recorded on an IFS-88 IR Fourier spectrometer within the 4000–15000 cm^{-1} range.

The dependences of the transmission T (%) on the wave number ν (cm^{-1}) are shown in Fig. 8. As can be seen, the polymer in the oxidized form is characterized by virtually complete absorption ($T \sim 0$) within the above wave-number range, which confirms the presence of free charge carriers in the polymeric matrix of the oxidized form. At the same time, the transmission increases in the spectrum of the partially reduced form, which suggests a decrease in the radical-cation concentration and the loss of conductivity.

CONCLUSIONS

(1) The electrochemical polymerization of a Pt(II) complex with pyridine-type ligand, 8-quinolinol, in the potentiodynamic and potentiostatic modes was performed for the first time.

(2) The optimal conditions of poly-[Pt(qol)$_2$] synthesis were found, under which polymeric films with the maximum thickness of the electroactive layer are formed in unit time, are accumulation in the static mode at a potential E_a = 1.0 V for τ_a = 30–40 min.

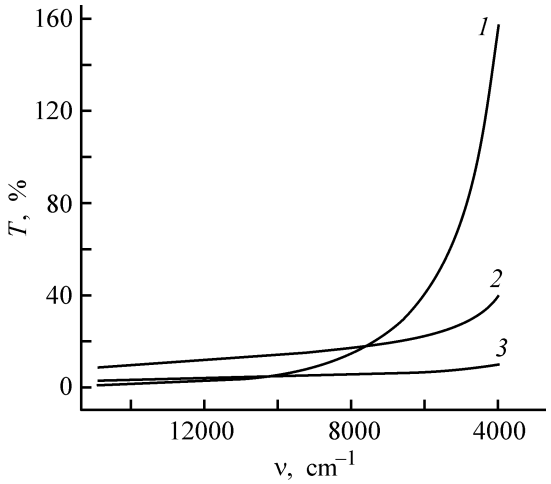

Fig. 8. Transmission T vs. the wavenumber ν. Sample: (*1*) [Pt(qol)$_2$], (*2*) poly[Pt(qol)$_2$] in the reduced form, and (*3*) poly[Pt(qol)$_2$] in the oxidized form.

(3) It was shown that an increase in the time of the polymer synthesis can lead to a decrease in the rate of charge transport in the polymer phase.

(4) The data of electronic and IR spectroscopy confirmed that only oxidized and partially oxidized forms of the polymer exhibit electroconducting properties.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Formation of 3*D* Chemical Networks in Siloxane Block Copolymers

Abstract—The formation of 3*D* chemical networks in siloxane block copolymers in the course of room-temperature vulcanization (RTV) was studied. The influence of the moisture content of the reaction medium on the RTV of the systems under consideration was analyzed for the case of preparation of films from solutions.

DOI: 10.1134/S1070427207060249

Siloxane copolymers whose macrochains consist of "rigid" and "flexible" blocks are characterized by a physical network formed by rigid block domains, which improves their physicomechanical properties as compared to linear silicone robbers. To attain the required level of elasticity and strength, it is necessary to form a 3*D* chemical network in the polymer. This network is formed in the course of vulcanization.

The well-known procedure for curing of two-component systems based on siloxane rubber involves the use of a cross-linking agent, e.g., $Si(OEt)_4$, and a curing catalyst [as a rule, dialkyltin dicarboxylates of the general formula $R_2Sn(OCOR')_2$, where R, R' = –Alk]. The process occurs via a series of successive reactions of heterofunctional condensation with the formation of Si–O–Si bonds [1].

Severnyi [2] suggested a model of the RTV process, which involves moisture sorbed by the polymer from the surrounding medium. The catalyst is activated by water and, in turn, activates the cross-linking agent. Molecules of the activated cross-linking agent react with hydroxy groups of the macrochains, thus forming a 3*D* chemical network.

For homopolyorganosiloxanes, self-vulcanizing (one-component) systems curable in the presence of atmospheric moisture have also been developed. In such systems, various cross-linking agents are used, e.g., trifunctional compounds of the general formula $RSiX_3$, where R = –Alk, X = –OAc, $–ONCR_2$, etc. [3, 4]. Severnyi [5] considers the formation of a 3*D* chemical network under the RTV conditions. It is assumed that, after the polymer and cross-linking agent are mixed, the reaction occurs until the OH groups of the polymer are completely exhausted; as a result, a system consisting of a siloxane polymer with functional X groups and excess cross-linking agent is obtained. Such systems can be stored in a hermetically sealed volume for a long time. On their contact with the environment, atmospheric moisture induces hydrolytic polycondensation to give Si–O–Si bonds, and a 3*D* chemical network is formed in a thin polymer layer.

The goal of this study was to examine the mechanism of formation and the parameters of the 3*D* chemical network in film-forming materials based on siloxane block copolymers.

The parameters of the 3*D* chemical network can be determined with a reasonable accuracy from the experimental data on the elastic strain of polymers under uniaxial extension. In this case, as a rule, the stress–strain relationship is described by the Mooney–Rivlin equation [6]

$$f^* = \sigma/(\lambda^2 - 1/\lambda) = C_1 + C_2\lambda^{-1}, \qquad (1)$$

where f^* is the reduced mechanical stress; C_1 and C_2, constant coefficients; $\lambda = 1 + \varepsilon$, relative elongation; and ε, relative strain.

From the initial portion of the dependence of f^* on λ^{-1}, in the range of initial strains, it is possible to determine the initial value of $f_0^* = C_1 + C_2$, char-

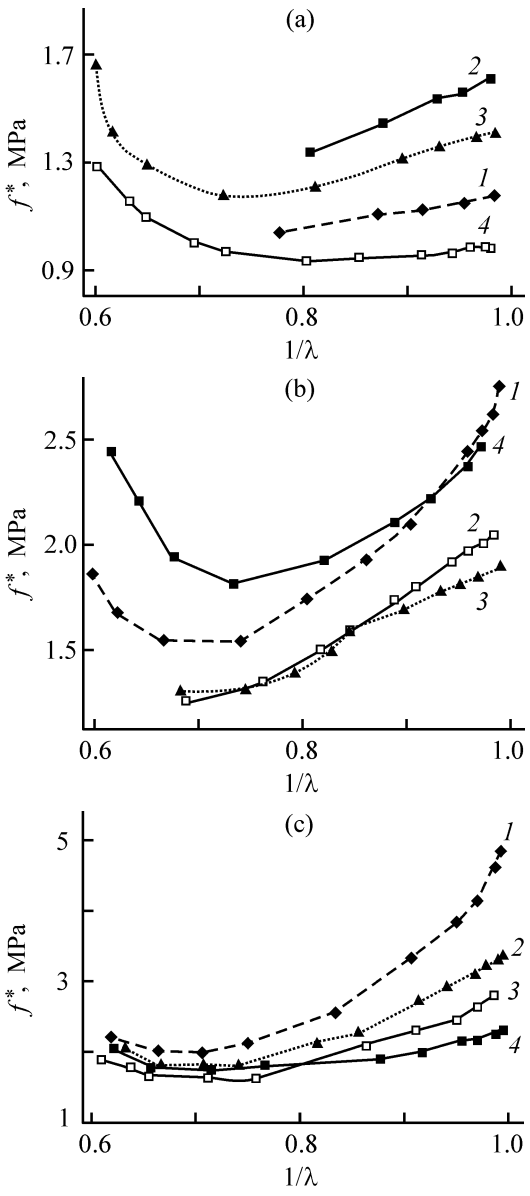

Fig. 1. Reduced mechanical stress f^* vs. reciprocal relative elongation $1/\lambda$ for films prepared by casting from various solvents. Cross-linking agent; (a) none, (b) **A**, and (c) **C**. Solvent: (*1*) toluene, (*2*) ethyl acetate, (*3*) chloroform, and (*4*) CCl_4.

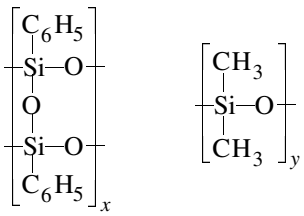
acterizing the network density, by the extrapolation $\lambda^{-1} \to 1$ ($\varepsilon \to 0$); the coefficient C_2 related to the deviation of the network from the ideal state can be estimated from the slope of the linear portion, for which the Mooney–Rivlin equation is valid.

EXPERIMENTAL

We used polysiloxane block copolymer of ladder polyphenylsilsesquioxane and polydimethylsiloxane (PPSSO–PDMS)[1] with >42 wt % fraction of flexible PDMS blocks:



We used the following cross-linking agents: vinyltris(isopropylidenaminooxy)silane CH_2=CH–Si–[O–N=C$(CH_3)_2]_3$ (vinyl oxime, **A**) and aminopropyltriethoxysilane NH_2–$(CH_2)_3$–Si–(O–CH_2–$CH_3)_3$ (**C**).

The use of other cross-linking agents does not involve the moisture in the formation of the 3*D* chemical network. Curing occurs by heterofunctional polycondensation throughout the bulk of the polymer.

Organosilanes used as cross-linking agents and the solvents (toluene, ethyl acetate, chloroform, CCl_4) were distilled before use and dried over zeolites. The block copolymer PPSSO–PDMS was dried in an oven at 120°C to constant weight.

To a solution of PPSSO–PDMS in one of the above-indicated solvents, we added 5 wt % cross-linking agent and stirred on a magnetic stirrer for 15 min. Films were formed from the solution on a cellophane support at a constant temperature of 30°C. The samples were baked for 2.5 h at 200°C.

The deformation behavior of films of the block copolymer were studied on an installation described in [7]. The installation design provided use of loads starting from 1 g. The extension was determined with a KM-6 cathetometer (accuracy 0.01 mm) from the positions of marks preliminarily made on the sample. With the aim to reduce the error of calculation of f_0^* and C_2, the data set for statistical treatment was constructed for strains $\varepsilon > 3\%$.

PPSSO–PDMS films were formed from solution. Naturally, it could be expected that the solvent would significantly affect both the mechanism of formation and the parameters of the network.

The elastic strain curves in the coordinates of the Mooney–Rivlin equation for films formed from the compounds without cross-linking agent are shown in Fig. 1a. It is seen that all the extension curves have a portion of a linear dependence $f^*(\lambda^{-1})$ described by

[1] Produced on the semicommercial scale by the Lebedev Research Institute of Synthetic Rubber.

Coefficients of the Mooney–Rivlin equation for films formed from various solvents with various cross-linking agents

Solvent	No cross-linking agent			Cross-linking agent **A**			Cross-linking agent **C**		
	f_0^*	C_2	$N \times 10^{21}$, cm^{-3}	f_0^*	C_2	$N \times 10^{21}$, cm^{-3}	f_0^*	C_2	$N \times 10^{21}$, cm^{-3}
	MPa			MPa			MPa		
CCl_4	1.00	0.33	0.5299	2.50	3.51	1.3244	2.30	3.34	1.1278
Toluene	1.19	0.67	0.6301	2.66	5.30	1.4107	4.68	13.80	2.4803
Chloroform	1.43	1.19	0.7606	1.89	2.36	1.0029	3.35	7.20	1.7750
Ethyl acetate	1.64	1.63	0.8675	2.07	3.28	1.0959	2.78	5.52	1.4726

Eq. (1). We determined the corresponding parameters C_1, C_2, and f_0^* (reduced mechanical stress at zero strains) in various solvents, and also the number of active chains in 1 cm^3 of the network N (see table). The table shows that, without a cross-linking agent, the solvent affects the density of the physical network. The coefficient C_2 is also solvent-dependent, which indicates that the network deviates from the ideal state owing to the solvent effect. Our results show that the density of the physical network for the films formed without a cross-linking agent increases in the order CCl_4 < toluene < chloroform < ethyl acetate. The calculated values of C_2 show that the deviations from the ideal state of the physical networks of polymer films formed from various solvents without a cross-linking agent are relatively small. Nevertheless, it can be noted that the extent of these deviations and the density of the physical network vary in the same direction.

Studies of the systems containing cross-linking agents show that the solvent affects also the 3*D* chemical network (Figs. 1b, 1c). With cross-linking agent **A**, the network density increases in the order chloform < ethyl acetate < CCl_4 < toluene, and with cross-linking agent **C**, in the order CCl_4 < ethyl acetate < chlroforom < toluene. It is seen from this table that the structure of films prepared with a cross-linking agent strongly differs from the ideal structure. The largest deviation of the network parameters is observed with films formed with cross-linking agent **C**. The solvent effect on the parameters of the 3*D* chemical network strongly depends on the cross-linking agent used, except ofr the films cast from CCl_4; in the latter case, an essentially similar supramolecular structure is obtained with cross-linking agents **A** and **C**.

As the RTV systems under consideration include solvents, it is necessary to analyze the effect of dissolved water on the formation of a chemical network. In particular, the solubility of water in toluene is very low, and films with high strength and good elastic and strain properties are formed from toluene solutions. As for the diffusion of water into a block copolymer after the solvent removal, it occurs via penetration of moisture into the free fluctuation volume of the polymer and is limited by the diffusion coefficient and water solubility in the block copolymer.

We performed a series of experiments on the formation of a chemical network in PPSSO–PDMS block copolymer containing moisture that remained in the polymer after the synthesis (~0.1 wt %), with gradual removal of moisture in the course of drying (samples of the block copolymer were taken at definite intervals). The films were cast from a solution in toluene. We found that the lower the initial content of water in the block copolymer, the higher the strength of the films prepared from it (Fig. 2a). With toluene replaced with ethyl acetate, the films prepared under

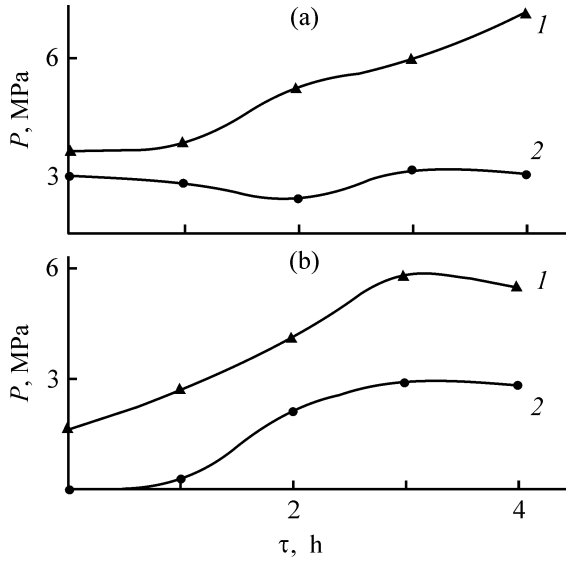


Fig. 2. Strength P of film materials vs. the time of drying of the block copolymer τ. Films cast from solutions in (a) toluene and (b) ethyl acetate. Cross-linking agent: (*1*) **A** and (*2*) **C**.

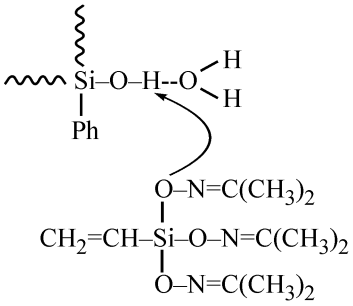
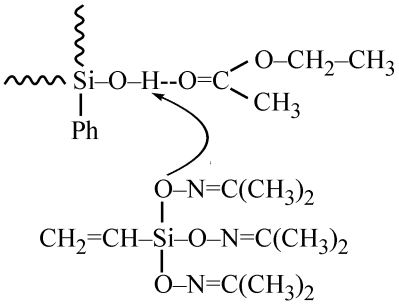
the same conditions showed worse elastic and strength parameters (Fig. 2b). Nevertheless, the trend toward improvement of the film properties in the course of drying was observed, too. These experiments show that even a small content of water in the systems negatively affects the formation of the 3*D* chemical network.

To refine the mechanism of the network formation, we analyzed the effects of the solvent and cross-linking agent on the strength characteristics of films at low (100%) strains. We found that, in the strain range examined, the parameters varied had no appreciable effect on the strength characteristics. This fact suggests that "rigid" blocks within the domains are not involved in the formation of the 3*D* chemical network. At the same time, if PDMS blocks were involved the network formation, the elastic strain would considerably increase, with the tensile strength remaining virtually the same. Thus, it can be assumed that in PPSSO–PDMS the 3*D* chemical network is mainly formed via OH groups arranged in defects of rigid blocks, not involved in the domain structure. The presence of such blocks is due to steric features of structures of polyblock copolymers. Since the system contains a solvent, the OH groups of the polymer are initially solvated either by water present in the system or by the solvent. Hence, to react with a functional group of the block copolymer, the cross-linking agent should enter into the competitive exchange, as shown in schemes I and II:



Scheme I.



Scheme II.

A more polar solvent forms more stable solvation complexes with a functional group of the block copolymer, hindering the access to it of cross-linking agent molecules. This fact accounts for differences in the formation of the 3*D* chemical network in films cast from different solvents.

CONCLUSIONS

(1) A study of the elastic strain at uniaxial extension showed that the solvent affects not only the supramolecular structure of the block copolymer itself, but also the structure of 3*D* chemical networks formed in the RTV process.

(2) In the synthesis of polyphenylsilsesquioxane–polydimethylsiloxane block copolymer, it is necessary to control the moisture content of the final product, because even a small content of moisture in the block copolymer negatively affects the set of elastic and strength parameters of films prepared from this copolymer.

(3) The 3*D* chemical network is formed in the ternary system polymer–solvent–cross-linking agent under the conditions of competitive solvation of the functional groups of rigid blocks in the interphase layer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Polyoxyethylene Block Copolymers and Their Aggregation in Water

V. V. Il'in, S. K. Filippov, and A. Yu. Bilibin

Received January 18, 2007

Abstract—The possibility of thermal degradation of polyoxyethylene in the course of high-temperature polycondensation was examined. Conditions were suggested for the low-temperature synthesis of ABA block copolymers whose molecules contain a polyoxyethylene central block and *p*-aromatic ester terminal blocks. The aggregation of the block copolymers in water was studied by dynamic light scattering and electron microscopy.

DOI: 10.1134/S1070427207060250

Micellization of block copolymers in water aroused increased researchers' interest in the mid-1980s. Studies of this phenomenon were stimulated by papers concerning the use of block-copolymeric micelles in pharmacology. Bader et al. [1] were the first to demonstrate that aqueous solutions of nontoxic block copolymers can be used as means for delivery of drugs in a living body. For this purpose, a hydrophobic drug can be introduced into the micell core in one of the following ways: (1) by covalent binding with functional groups of the core-forming block or (2) by noncovalent interactions within the core (van der Waals forces, hydrogen bonding). The pioneering studies concerned specifically the first alternative; polyoxyethylene-σ-poly(*L*-lysine) [1] and polyoxyethylene-σ-poly(aspartic acid) [2] were tested. Covalent binding makes the drug–micelle system stable to external effects; however, this mode of binding hinders the interaction with the target molecules in vivo, with partial loss of the biological activity of the drug. Recent studies mainly concerned the second mode of binding of a hydrophobic drug, involving noncovalent interaction with the core-forming block [3–5]. The structural stability of block-copolymeric micelles is primarily determined by the critical micelle concentration (CMC), and also by the stability to substances present in the surrounding medium (in a living body, e.g., to proteins and lipids). A novel approach to enhancement of the micelle stability has been suggested by Iijima et al. [6]: Cross-linking of a polylactide block after micellization of polyoxyethylene-σ-polylactide allows stabilization of the micelle core with covalent bonds. The constituent parts of micelles, core and shell, have definite functions. The core is used for loading and release (if required) of a drug. The shell is responsible for the surface interaction with the environment, which may be respondible for the delivery kinetics. The diameter of polymeric micelles (usually from 10 to 100 nm) is suited for long-term circulation in blood, because it appreciably exceeds the renal filtration threshold, but is lower than the sensitivity threshold for nonspecific capture with monocytes.

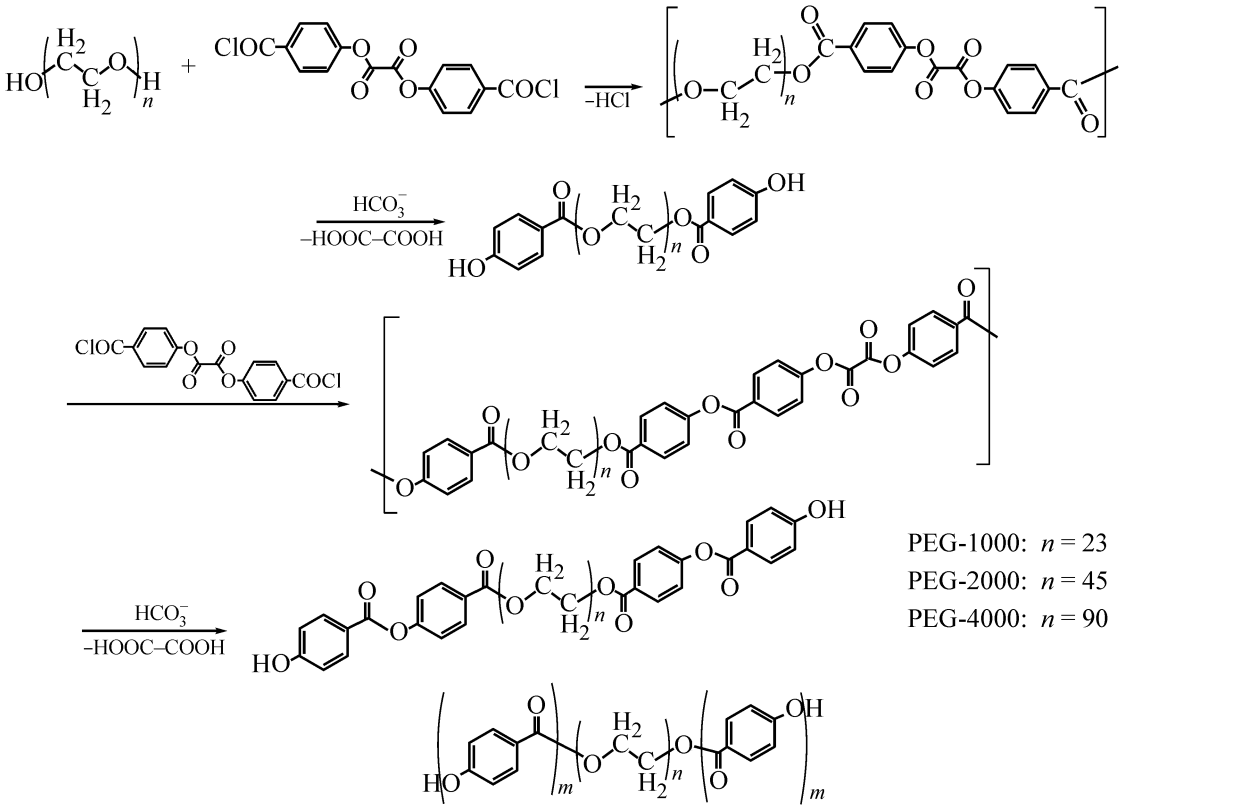
The goal of this study was to synthesize block copolymers capable of aggregation[1] in water and to examinae of this phenomenon by various methods. As objects of the study we chose ABA triblock copolymers whose macromolecules contain a polyoxyethylene central block and aromatic terminal blocks consisting of *p*-hydroxybenzoic acid residues. Strictly speaking, these substances are not block copolymers in the classical sense, because the terminal "blocks" are very short; in some cases, they consist of a single monomeric unit strongly differing in polarity from the remaining part of the macromolecule. To some extent, these substances can be regarded as compounds intermediate between true amphiphilic block copolymers capable of forming unimolecular micelles and common surfactants. There are examples in the literature when substances of similar molecular architecture are classed with ABA block copolymers. For example, in HEUR-type polymers, the terminal blocks

[1] The term "aggregation" expands the range of species under consideration. In contrast to micelles, which should have a definite structure, there are no structural requirements for aggregates.

are $-C_{16}H_{33}$ radicals [7]; in polyoxybutylene-σ-polyoxyethylene-σ-polyoxybutylene, the degree of polymerization of the terminal blocks is 4 [8]. Here we summarize raw data obtained by ^{1}H NMR spectroscopy for the polymers synthesized and also report the results furnished by the methods of dynamic light scattering and electron microscopy.

EXPERIMENTAL

The block copolymers were prepared by a multistep assembling–disassembling process tested in [9, 10] for the synthesis of liquid crystal multiblock copolymers. The assembling step involves esterification of diols with di(4-chlorocarbonylphenyl) oxalate, and the disassembling step, selective hydrolysis of oxalate ester groups with an aqueous solution of sodium hydrogen carbonate. Thus, after each assembling–disassembling step, a *p*-hydroxybenzoic acid residue is added to each terminus of the molecule of poly(ethylene glycol) or its derivative. The sequence involving two assmebling–disassembling steps and the conventional designations of the investigation objects are given in the scheme:



By successively performing several steps, the rigid-chain (*p*-aromatic) block is lengthened. An important advantage of this approach is that the terminal blocks show no polydispersity. Commercial poly(ethylene glycol) used in the study had molecular weights of 1000, 2000, and 4000 (PEG-1000, PEG-2000, and PEG-4000, respectively).

Initially, we performed the synthesis in the high-temperature mode for the PEG-2000 series. In this mode, the assembling is performed at 180°C for 2 h in an α-chloronaphthalene solution. In the ^{1}H NMR spectra recorded in $CDCl_3$, for all the polymers (triblock copolymers and their precursors, oxalyl-containing multiblock copolymers), three regions of signals can be distinguished (Fig. 1), corresponding to (1) nonterminal polyoxyethylene protons (with satellite signals), 3.5–4 ppm; (2) terminal protons of polyoxyethylene, adjacent to the ester bond, 4.4–4.5 ppm; and (3) aromatic protons, 6.8–8.5 ppm.

As a reference for the integration we chose the first region, because the signal of nonterminal protons of polyoxyethylene undergoes the least significant

changes in the course of the synthesis. It should be taken into account, however, that the multistep synthesis can be accompanied by changes in the molecular-weight distribution of polyoxyethylene. In this case, the pattern will be somewhat distorted. Figure 1 shows as an example the spectrum of B–(2000)–B. The ^{1}H NMR spectra of the PEG-2000 derivatives show that the polycondensation yields aromatic derivatives of poly(ethylene glycol). This is confirmed by the appearance of signals from polyoxyethylene protons adjacent to the ester group (terminal protons). As judged from the relative intensities of these signals, the esterification yield is as high as 70–100%. However, viscometric data cast doubt on the success of the syntheses. The intrinsic viscosity [η] of the initial PEG-2000 (chloroform, 25°C) is 0.10 dl g^{-1}; in going to the polymers of the first and second steps of assembling, [(2000)–BOxB–] and [(2000)–B–BOxB–B–], the intrinsic viscosity becomes 0.13 and 0.10 dl g^{-1}, respectively. The lack of increase in [η] suggests that the high-temperature polycondensation is accompanied by degradation of the polyoxyethylene chain. To confirm this assumption, we performed a model experiment with poly(ethylene glycol). PEG-4000 was heated under the conditions of high-temperature polycondensation (Ar, 180°C, 2 h). This treatment resulted in a decrease in the intrinsic viscosity from 0.18 to 0.13 dl g^{-1}. This fact indicates that polyoxyethylene undergoes degradation under the conditions of high-temperature polycondensation. Comparison of the ^{1}H NMR spectra of PEG-4000 before and after heating shows that the intensity of the signals corresponding to protons of the OH groups becomes several times higher after heating. The IR data are also consistent: The intensity of the O–H stretching band sharply increases after the heat treatment of poly(ethylene glycol). Thus, thermal degradation of poly(ethylene glycol) is accompanied by the appearance of hydroxy groups.

Because of the poor heat resistance of polyoxyethylene, we suggested and optimized a procedure for low-temperature acceptor polycondensation. In this procedure, the polycondensation of poly(ethylene glycol) with di(4-chlorocarbonylphenyl) oxalate was performed at room temperature in tetrahydrofuran (THF). As HCl acceptor we used 4-(dimethylamino)-pyridine (DMAP). The derivatives were prepared with all the three PEG samples: PEG-1000, PEG-2000, and PEG-4000. The ^{1}H NMR spectra in $CDCl_3$ solutions of poly(ethylene glycol) derivatives prepared under the conditions of low-temperature polycondensation fundamentally differ from the ^{1}H NMR spectra of the above-considered compounds. In the spectrum of the polymer [(2000)–BOxB–], the integral intensity of the signals of aromatic protons decreases by a factor of 10. At the same time, the ^{1}H NMR spectrum of this compound contains a triplet at 4.44 ppm from two methylene groups of polyoxyethylene, adjacent to the ester bond. The integral intensity of this triplet corresponds to 4H, suggesting the 100% functionalization of poly(ethylene glycol). Viscosity measurements give consistent results. In going from the starting PEG-2000 to the product of low-temperature polycondensation, the intrinsic viscosity in chloroform increases from 0.10 to 0.59 dl g^{-1}.

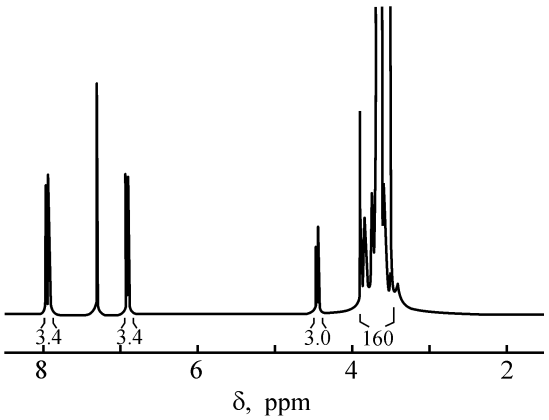


Fig. 1. ^{1}H NMR spectrum of B–(2000)–B in $CDCl_3$ (the signal at 7.28 ppm belongs to residual protons of the solvent). (δ) Chemical shift.

The abnormally low intensity of aromatic proton signals is caused by aggregation of the polymer in the solvent (chloroform). The possibility of solvation of the oxalylbis(oxybenzoic) fragment of macromolecular chains is strongly limited. Therefore, core–shell associates are formed. The cores consisting of aromatic fragments are surrounded by the polyoxyethylene shell. Because of the dense packing inside the cores, the protons of core fragments have relatively long relaxation times, which results in the disappearance of the aromatic proton signals from the ^{1}H NMR spectra. Similar examples can be found in the literature [11, 12].

In the ^{1}H NMR spectrum of the oligomer B–(2000)–B prepared by hydrolysis of the low-temperature polymer, the aromatic proton signals are also strongly suppressed. The total integral of multiplets in the range 6.8–8.4 ppm is as low as 1.0 (10% of the theoretical value). The occurrence of the hydrolysis is confirmed by the intrinsic viscosity [η] = 0.13 dl g^{-1} (before hydrolysis, [η] = 0.59 dl g^{-1}). In the ^{1}H NMR spectrum of the B–(2000)–B sample recorded in D_2O, the aromatic proton signals are suppressed to a still

Table 1. ^{1}H NMR data ($CDCl_3$) for samples prepared at low temperatures

Compound	Intensity		Intensity of signals with $\delta < 3$ ppm
	terminal protons of polyoxyethylene	aromatic protons	
B–(1000)–B	80	5	5.9
B_2–(1000)–B_2	87	6	6.7

B_3–(4000)–B_3	91	9	18.4

Table 2. Dynamic light scattering data for aqueous solutions of the samples

Compound	R, nm		
B–(1000)–B	–	21 ± 1	159 ± 8
B_2–(1000)–B_2	Does not dissolve		
B–(2000)–B	5 ± 1	29 ± 2	166 ± 8
B_2–(2000)–B_2	–	–	175 ± 12
B–(4000)–B	3.0 ± 0.5	39 ± 2	228 ± 11
B_2–(4000)–B_2	1.8 ± 0.3	39 ± 1	252 ± 4
B_3–(4000)–B_3	1.9 ± 0.1	37 ± 3	252 ± 8

greater extent, to less than 1% of their theoretical intensity. The ^{1}H NMR data ($CDCl_3$) for the block copolymers of all the three series are summarized in Table 1. As can be seen, the intensity of the aromatic proton signals is strongly underestimated in all the cases.

It should be noted that the ^{1}H NMR spectra of all the block copolymers prepared at low temperature contained anomalous high-field ($\delta < 3$ ppm) signals. The appearance of such signals is also attributed to aggregation. The polyethylene block forming the micelle shell should occur in the loop conformation. In this conformation, there are bending sites in the molecular chain. Furthermore, aggregation may be accompanied by interweaving of the molecules. The protons at the sites of bending and of chain contact may have particular properties and give rise to signals shifted relative to typical positions.

The method of dynamic light scattering (DLS) allows determination of the diffusion coefficient of the particles in solution. The hydrodynamic radius R_h can be calculated from the Stokes–Einstein equation:

$$D = \frac{kT}{6\pi\eta_0 R_h},$$

where D is the translational diffusion coefficient; k, Boltzmann constant; T, absolute temperature; and η_0, solvent viscosity.

We studied aqueous solutions of the concentration $c = 0.7$ g l^{-1}. All the modes revealed had the diffusion character. The hydrodynamic radii of particles observed in DLS measurements are listed in Table 2. It is seen that, in most cases, the size distribution is multimodal. Along with particles whose hydrodynamic radius is several nanometers, there are particles with R_h on the order of tens and hundreds of nanometers. This fact conclusively confirms the tendency of the polymers prepared toward association, because the distribution function of the initial poly(ethylene glycol) is unimodal, with particle sizes R_h on the order of nanometers. It is well seen that the sizes of intermediate and coarse particles detected in the polymer solutions correlate with the molecular weight of both polyoxyethylene block and aromatic blocks. An increase in the molecular weight leads to a rise in the aggregate size. It should be noted that particles of the smallest size (on the order of several nanometers) are also detected in solutions of the compounds studied. However, because of the small contribution of these particles to the overall scattering, quantitative determination of their diffusion coefficients requires long time for accumulation of the correlation function and is therefore difficult.

The hydrodynamic radii of particles consisting of molecules of structurally related ABA block copolymers (polyoxyethylene central block and hydrophobic terminal blocks) can be found in [7, 8, 11, 13–15]. The reported values correspond to particles of three types: (1) separate molecules, (2) flower-type micelles, and (3) aggregates (often termed intermicellar clusters). Comparison of the published data allows a conclusion that the hydrodynamic radius of separate molecules of the block copolymers studied here is within 1–2 nm (for PEG-1000 series, most probably, even smaller than 1 nm). The radius of flower-type micelles is 2 to 7 nm. Particles with the radius on the order of tens of nanometers and over are, apparently, intermicellar clusters. Thus, the large (hundreds of nanometers) and intermediate (tens of nanometers) hydrodynamic radii should be assigned to intermicellar clusters. The particles with R_h = 2–5 nm are, most probably, micelles.

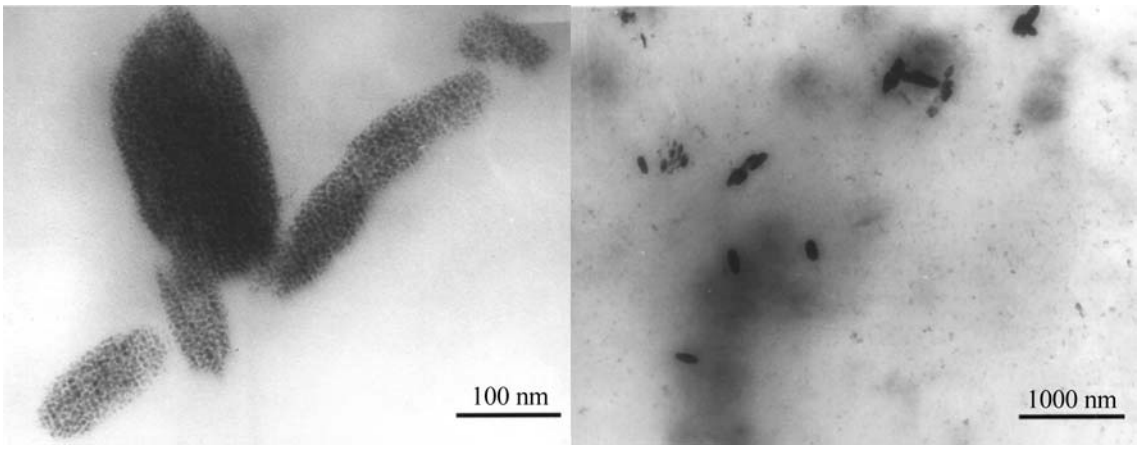

Fig. 2. Electron micrographs of aqueous solution of B–(4000)–B.

Electron microscopy. For the samples under consideration, we obtained TEM images. The specimens were prepared by solvent evaporation from 1 g dl^{-1} solutions. The general structural features of aggregates formed in aqueous solution are similar for all the compounds. Figure 2 shows as an example the electron micrographs of the B–(4000)–B sample. It is seen that the particles have an elliptic shape. Coarse aggregates are composed of a set of small particles (structural units). The structural units are spheres 5–10 nm in diameter, presumably the flower-type micelles. The size of structural units depends on a particular sample.

Coarse elliptic particles are intermicellar clusters. Turning back to the DLS results, we see that there are two or three values of the hydrodynamic radius on the order of hundreds (coarse particles) and tens (intermediate particles) of nanometers. Simple comparison with the particle size in the electron micrographs shows that specifically the intermediate value of R_h corresponds to intermicellar clusters. The correlation between the cluster size and the length of the polyoxyethylene chain, already mentioned when discussing the DLS data, is also seen from the electron micrographs. The micrographs taken with a smaller magnification show that intermicellar clusters tend to associate. The associates thus formed are apparently the coarse particles (R_h of hundreds of nanometers) that were detected in DLS experiments.

CONCLUSIONS

(1) A procedure was developed for low-temperature synthesis of ABA block copolymers whose molecules contain the polyoxyethylene central block.

(2) It was found that terminal blocks of triblock copolymer molecules, consisting of *p*-hydroxybenzoic acid residues, promote aggregation in water and chloroform.

(3) Particles of the size corresponding to micelles and intermicellar clusters were detected in aqueous solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Polyfunctional Sulfur-containing Oligomers and Their Effection SKI-3 Rubber and Its Vulcanizates

S. E. Mitrofanova and E. N. Cherezova

Abstract—Polysulfide oligomers with sterically hindered phenolic fragments were prepared. Their effect on the antioxidative stability and kinetics of vulcanization of rubber stocks based on SKI-3 rubber was examined.

DOI: 10.1134/S1070427207060262

Polysulfide oligomers (PSOs) are widely used as components of sealants. The use of PSOs as effective vulcanizing agents for unsaturated rubbers has been reported [1]. When used as vulcanizing agents, PSOs provide formation of more flexible cross-links compared to rigid sulfur bonds, thus imparting enhanced elasticity to the vulcanizates.

Along with acting as vulcanizing agents, polysulfide oligomers are potentially capable, owing to the presence of sulfide and terminal hydrosulfide groups, of inhibiting oxidation of polymers by decomposing hydroperoxides (HPs), i.e., can act as secondary antioxidants (AOs) [2]. It has been shown that terminal hydrosulfide groups of sulfur-containing oligomers can be used for introduction of functional groups [3], e.g., sterically hindered phenolic (SHP) fragments scavenging peroxy radicals. Apparently, combination in one molecule of centers inhibiting oxidation of organic substrates by different mechanisms will substantially enhance the stabilizing function of the oligomers.

The goal of this study was to develop a procedure for preparing polysulfide oligomers with terminal SHP fragments and evaluate their antioxidative and vulcanizing properties.

EXPERIMENTAL

The starting chemicals were 4-dimethylaminomethyl-2,6-di-*tert*-butylphenol (Mannich base, MB), mp 93–95°C, and commercial PSO NVB-5, TU (Technical Specification) 38.50309–93, content of total sulfur 37.20 and of SH groups 4.74 wt %.

The PSOs were prepared as follows. A flask equipped with a stirrer, reflux condenser, thermometer, and bubbler was charged with the synthesized polysulfides (PSs) and MB. The mannich base was taken in an amount theoretically required for the conversion of all the SH groups in the PS. The mixture was stirred at 110–120°C in a nitrogen flow for 3–3.5 h. The reaction course was monitored by the release of dimethylamine, which was absorbed by a 0.1 N H_2SO_4 solution, using Methyl Orange as indicator. When the release of dimethylamine ceased, the reaction was assumed to be complete.

The weight percentage of the SH groups was determined by a laboratory procedure according to GOST (State Standard) 12812–80.

The IR spectra were recorded in the range 4000–400 cm^{-1} with a Perkin–Elmer 16PC-FT-IR device.

Autooxidation of the polymer was performed in oxygen (P_{O_2} = 250 mm Hg) at 135°C (polymer sample weight 0.1 g). To introduce PSO into the rubber, 5% solutions of SKI-3 in toluene were prepared; the mixtures were stirred to complete homogenization, after which the solvent was vacuum-evaporated.

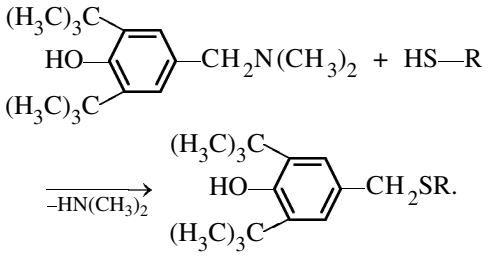
The rate and degree of vulcanization of rubber stocks were determined with a Monsanto 100 S rheometer at 151°C; the test time was 60 min.

In our study, we prepared PSs with different extents of branching at the molar ratio monomer : sodium tetrasulfide = 1 : 1, with the aim to examine the effect of the structure on the PS properties. As the starting monomer we used dichlorodiethyl formal, pure or with additions of other chlorinated monomers (molar ratios: dichlorodiethyl formal : 1,2,3-trichloropropane = 98 : 2; dichlorodiethyl formal : diethane : 1,2,3-trichloropropane = 84.5 : 15 : 0.5).

The high-molecular-weight PSs obtained were washed with water to remove excess sodium tetrasulfide and then cleaved to obtain oligomers. To do this, the washed dispersion was heated with continuous stirring at 65°C for 40–60°C in the presence of a cleaving agent (1 : 1 mixture of Thiuram D with zinc stearate, 5% of the total product weight). After that, the cleaved dispersion was coagulated with 20% H_2SO_4 to pH 4–5. The precipitated polymer was repeatedly washed with cold water and vacuum-dried at 80°C to constant weight.

The products obtained were yellowish oils. Their molecular weights and contents of total sulfur and SH groups are listed in Table 1.

Among our goals was synthesis of polyfunctional compounds exhibiting AO properties along with vulcanizing power. For this purpose, we performed the reactions of the PSOs with 4-dimethylaminomethyl-2,6-di-*tert*-butylphenol (MB), which allowed introduction of SHP fragments into the oligomer:



In accordance with this equation, the content of SH groups in the products was close to zero (Table 2).

The IR spectra of the PSOs contained absorption bands at 2600–2800, 1040–1200, and 600–800 cm^{-1}, characteristic of the stretching vibrations of the HS–, –OC–, and –SS– groups, respectively. The polysulfides SHP-PSO-4–SHP-PSO-6 also contained a well-defined peak at about 3600 cm^{-1}, corresponding to the OH group in the sterically hindered phenolic fragment, whereas the SH band at 2000–2800 cm^{-1} was absent.

The AO performance of the oligomers prepared was evaluated manometrically from the induction periods of oxidation of SKI-3 polymer at elevated temperatures. To compare the stabilizing performance of the PSOs prepared with that of the previously known polysulfides, we also determined the induction periods for the rubber containing commercial PSO NVB-2 widely used as a component of sealants, and also NVB-2 modified with SHP fragments.

We found that the PSOs under consideration increase the induction period (Table 3), well competing in the AO power with NVB-2. The most branched additive, PSO-3, surpassed NVB-2 by 15%.

Introduction of SHP fragments into PSOs led to a considerable increase in the induction period of the polymer oxidation. The most branched additive, SHP-PSO-6, showed the highest performance.

In the next stage of our study, the PSOs obtained were tested as vulcanizing agents in unfilled rubber

Table 1. Physicochemical characteristics of the compounds obtained

Polysulfide oligomer	Molecular weight	Content, wt %	
		SH groups	total sulfur
PSO-1	4400	1.48	27.80
PSO-2	3448	1.91	32.10
PSO-3	2857	2.61	51.40

Table 2. Content of SH groups in the synthesized SHP derivatives

PSO	Content, wt %			
	initial	final		total sulfur
		calculated	experimental	
SHP-PSO-4	1.48	0	0.030	25.44
SHP-PSO-5	1.91	0	0.066	27.86
SHP-PSO-6	2.61	0	0.060	43.68

Table 3. Induction period τ of thermal oxidation of SKI-3 rubber in relation to the type and concentration of the stabilizer added (P_{O_2} = 250 mm Hg, 135°C)

Stabilizer	τ, min, at indicated concentration of additive, wt %		
	1	2	3
NVB-2	15	20	50
PSO-1	20	30	60
PSO-2	20	30	60
PSO-3	25	40	70
SHP-NVB-2	60	80	100
SHP-PSO-4	50	70	90
SHP-PSO-5	60	80	100
SHP-PSO-6	80	100	120

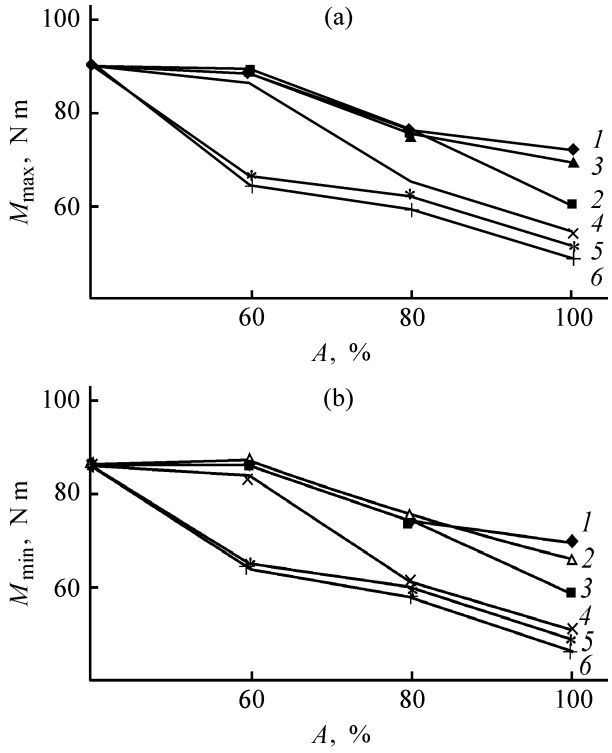

Fig. 2. (a) Maximal torque M_{max} and (b) minimal torque M_{min} vs. the amount of polysulfide added.

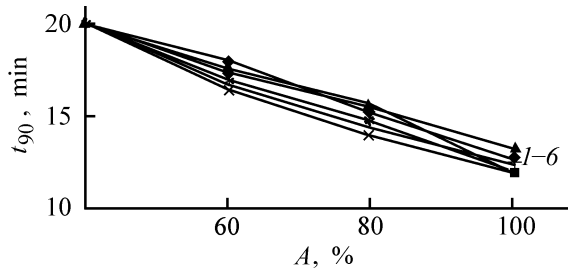

Fig. 3. Optimal vulcanization time t_{90} vs. the amount and type of polysulfide oligomer added.

stocks based on SKI-3 rubber, of the standard composition (wt parts): 100 SKI-3, 5 ZnO, 1 stearic acid, 0.6 altax, 3 diphenylguanidine, 1 Diafen FP, 1–0 sulfur, and 1–0 additive synthesized. In these stocks, 50–80–100% of sulfur was replaced with a PSO in such an amount that the total amount of sulfur was 1%.

Upon addition of the most branched PSOs (PSO-2, PSO-3) in a relative amount of 50%, the vulcanization onset time t_s sharply increased; however, further increase in the concentration of the additive affected t_s insignificantly (Fig. 1). Additions of linear oligomers, PSO-1 and SHP-PSO-4, did not appreciably alter t_s. The presence of the SHP fragment in branched PSOs led to an increase in the vulcanization onset time at the relative content of the additive exceeding 80% (SHP-PSO-5, SHP-PSO-6). Apparently, the additives inhibit the radical process.

The addition of the synthesized PSOs without SHP fragments in a relative amount exceeding 50% led to a decrease in both the maximal (Fig. 2a) and minimal (Fig. 2b) torques. The most pronounced decrease in these parameters was observed with the most branched oligomer, PSO-2.

Introduction of SHP fragments into the PSO molecules led to a more significant decrease in M_{max}. With SHP-PSO-5 and SHP-PSO-6, the torque sharply decreased even on replacement of 50% of sulfur in the stock.

Addition of the synthesized PSOs without SHP fragments made the optimal vulcanization time shorter (Fig. 3). This fact suggests that the polysulfides are good vulcanizing agents.

In the next stage of our study, we determined the main elastic and strength characterisitcs of the unfilled vulcanizates.

Experimental data show that introduction of the PSOs synthesized into the rubber stock cause an increase in the relative breaking elongation, compared to the control sample containing NVB-2. Upon addition of SHP-PSOs, the relative breaking elongation increased when more than 50% of sulfur was replaced with the additive. The strength of the PSO-containing vulcanizates appeared to be considerably higher than that of the control sample. In the vulcanizates with SHP-PSOs, these parameter also increased upon 50% replacement of sulfur and then varied linearly with a further increase in the content of the additive. The highest strength was attained with the branched additives: PSO-2, PSO-3, SHP-PSO-5, and SHP-PSO-6. It should be noted that the elongation set was observed only upon complete replacement of sulfur in

the vulcanizates with SHP-PSOs. In all the other cases, the elongation set was zero. Thus, the copolymers under consideration improved the plastoelastic properties of the vulcanizates relative to the composition with sulfur as vulcanizing agent.

The physicomechanical properties of vulcanizates prepared with the PSOs and SHP-PSOs synthesized were compared with those of vulcanizates prepared with sulfur and with commercial PSO NVB-2. It was found that the additives synthesized well compete with NVB-2 and even surpass it in some parameters. For example, with PSO-2, PSO-3, SHP-PSO-5, and SHP-PSO-6, the tear resistance and strength increased by 83–240% relative to the vulcanizate prepared with sulfur, whereas with NVB-2 and SHP-NVB-2 the increase was less pronounced (20–40%).

Since the synthesized PSOs contained SHP fragments enhancing the resistance to oxidation, we performed aging of vulcanizates (72 h, 100°C) and evaluated the stabilizing performance of the additives from the aging coefficients. The aging coefficients increased by 10–30% with the copolymers added to the stock, relative to the control sample. The most branched additives PSO-2, PSO-3, SHP-PSO-5, and SHP-PSO-6 ensured the best physicomechanical properties and aging coefficients of the vulcanizates.

CONCLUSIONS

(1) The synthesized polysulfide oligomeric additives containing sterically hindered phenolic fragments make longer the induction period of SKI-3 rubber oxidation.

(2) The synthesized polysulfide oligomers decrease the maximal and minimal torques and optimal vulcanization time and increase the vulcanization onset time.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Chemical Procedure for Reprocessing of Poly(Ethylene Terephthalate) Waste

R. Yu. Mitrofanov, P. N. Bochkarev, and V. P. Sevodin

Biisk Technological Institute, Branch of Polzunov Altai State Technical University, Biisk, Altai krai, Russia

Received October 10, 2006; in final form, March 2007

Abstract—A procedure was developed for degradation of poly(ethylene terephthalate) waste with water to the starting monomers. The possibility of preparing diethyl terephthalate without a catalyst in a rocking cylindrical pressure vessel with the rocking axis passing through the geometric center was examined.

DOI: 10.1134/S1070427207060274

Poly(ethylene terephthalate) (PET) patented in 1941 was initially intended for production of fibers; however, thanks to its unique properties, it is also widely used today as a structural material. As the volume of PET production grows, the amount of industrial and domestic PET waste increases also; only in Russia it amounts to 300–400 thousand tons annually.

The existing mechanical procedures for utilization of spent PET containers allow preparation of only a secondary raw material for production of finished items. However, the demand for items prepared in this way is low. Furthermore, the use of secondary raw materials in Russia and EU countries for packaging of foodstuffs is prohibited by the legislation.

An alternative solution is chemical reprocessing of spent PET containers and articles. The existing chemical methods for PET reprocessing can be subdivided into three types: (1) reprocessing to obtain the primary monomers, namely, ethylene glycol (EG) and terephthalic acid (TPA) or dimethyl terephthalate (DMT); (2) glycolysis of PET with ethylene glycol to obtain bis(hydroxyethyl) terephthalate and other oligomers, which are then either subjected to polycondensation to obtain PET or brought into reactions with dicarboxylic acids to obtain "polyester polyols" used in production of polyurethane foam or elastomers; (3) depolymerization of PET with propylene glycol, followed by the reaction of the decomposition product with maleic anhydride to obtain "unsaturated polyesters" used in production of reinforced fibers.

Methods of types 2 and 3 have been fairly well studied. These methods are mainly applicable to large-tonnage process waste. The final products obtained using methods of type 1 are TPA + EG or DMT + EG.

Degradation of PET waste into TPA can be performed in three modes: pressure hydrolysis, acid hydrolysis in the presence of strong mineral acids, and alkaline saponification. In all the cases, almost theoretical yields are attained. However, acid and base hydrolysis of PET waste exclude the possibility of EG regeneration and require use of aggressive chemicals, which causes drastic increase in the capital investments required for auxiliary reagents and effluent treatment.

In the 1960–1970s, a procedure for recycling of substandard PET [1] formed in the course of production was developed and commercially implemented. The process involves depolymerization of the waste in excess methanol in the presence of a catalyst at a pressure of 20–25 kgf cm^{-2} and 180°C for 3–5 h. The process is intended for large-scale use; it is sophisticated, involves a large number of operations, and requires regular supply of waste of the preset quality. Therefore, this process is inapplicable to small volumes of domestic wastes which are, as a rule, strongly contaminated with mineral and organic impurities.

Furthermore, there are fragmentary published data [2] that PET can be decomposed under appropriate

conditions with alcohols, esters, and amines, with the cleavage of the ester bond. These reactions are considerably accelerated at elevated temperatures and higher catalyst acidities. Aminolysis of PET yields polyamido esters. The extent of aminolysis depends on the amount and kind of the diamine.

A possible alternative solution to the problem of reprocessing of domestic PET waste into a valuable raw material for chemical, paint-and-varnish, or pharmaceutical industry is setting up small- or medium-scale shops.

For example, procedures have been suggested for preparing various paint-and-varnish materials, including powders (hydroxyl- and carboxyl-containing components for epoxy–polyester compounds), insullacs, alkyd oligomers, materials for road marking, etc. [3–5]. Film-forming agents are prepared by ester interchange of PET with various polyols [3]. The reaction occurs in two steps. The first step is destructive alcoholysis to give unsymmetrical oligomers; the second step, cross-linking, starts simultaneously, yielding a 3*D* polymer. Depending on the reaction time and PET : polyol ratio, it is possible to prepare oligomers with the prescribed softening and dropping points and with predictable solubility in organic lacquer solvents.

Along with the symmetrical polymer, it is possible to prepare polymers with various combinations of comonomers (terephthalic acid, ethylene glycol, *p*-hydroxybenzoic acid). Such polymers exhibit increased shrinkage and are well dyed with dispersible dyes without applying a pressure [6]. Polymers with prescribed properties can be prepared by varying the comonomer ratio.

Published data on the chemical processing methods show that the most widely used, economically feasible, and environment friendly method is hydrolysis of PET in a neutral medium to TPA and EG. The process is performed in excess water at 180–220°C for 5–6 h; it is fairly simple and requires no additional chemicals.

EXPERIMENTAL

To prepare crude TPA, we used spent TPE containers; their pretreatment involved removal of labels and adhesives, followed by shredding. No sorting by color was performed.

The process was carried out in a rocking pressure vessel [7] (a steel cylinder 1.1 m long, 0.065 m i.d.). The degree of filling was 0.6. The rocking rate was 20 min^{-1} [8].

The purity of the compounds obtained was monitored by TLC on Silufol UV-254 plates (Czechia), eluent benzene–acetone, 3 : 1. The melting points of the products were measured with a PTP(M) capillary device for melting point measurements and were not corrected.

Terephthalic acid. The pressure vessel was charged with 500 g of PET and 2000 ml of distilled water. The vessel was hermetically sealed. Agitation was switched on; the mixture was heated to 280–285°C, kept at this temperature for 10 min, and cooled to 30–35°C. The vessel was opened, and the TPA obtained was filtered off, washed with distilled water (4 × 250 ml), and dried at 100–120°C. Yield of TPA 431.42 g (99.8%); light brown crystals subliming in an open capillary without melting at approximately 300°C.

Diethyl terephthalate (DET). The pressure vessel was charged with 240 g of terephthalic acid and 2200 ml of 96% ethanol. The vessel was hermetically sealed, agitation was switched off, and the contents were heated to 230–240°C, kept at this temperature for 6 h, and cooled to 25–30°C. Then the vessel was opened, and the mixtrue was filtered and evaporated to 1/3 of the initial volume. The residue was refluxed for 30 min with addition of 2 g of activated carbon and then filtered. The filtrate was cooled in an ice bath with stirring; in so doing, the major fraction of the diethyl ester crystallized. An additional amount of the product was obtained by the filtrate evaporation.

The product was stirred with 1000 ml of 5% sodium hydrogen carbonate at 10–20°C for 30 min, filtered off on a Büchner funnel, and washed with distilled water (3 × 250 ml). The alkaline filtrate was acidified on cooling with sulfuric acid; as a result, a mixture of the monoester and TPA was obtained, which was delivered to the esterification step with addition of pure TPA.

The crystalline diethyl ester obtained was dried at 30–35°C for 48 h. Yield 279.36 g (87.3%), mp 43–44°C.

As a method of PET waste utilization, we examined hydrolysis without a catalyst. It is known [9] that, at temperatures exceeding 280°C, PET undergoes virtually instantaneous hydrolysis with cleavage of the ester bonds. As the reaction time is varied from 2 to 120 min, the TPA yield varies insignificantly (95.5–96.9%), which is consistent with published data.

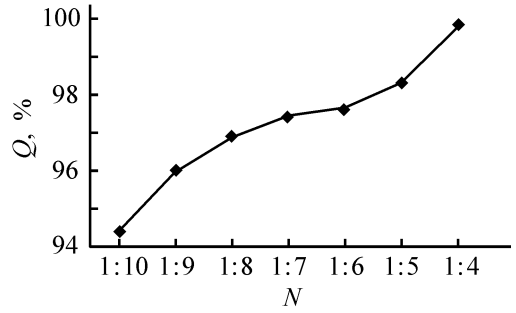

Fig. 1. TPA yield Q vs. the PET : water ratio N.

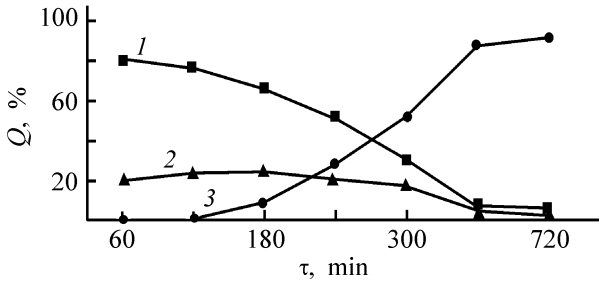

Fig. 2. Yield of esterification products, Q, vs. reaction time τ: (*1*) TPA, (*2*) ethyl hydrogen terephthalate, and (*3*) DET.

The influence of the PET : water ratio on the TPA yield is shown in Fig. 1.

The acid obtained is of low purity and cannot be returned to the polymer production. Purification by reprecipitation is labor-consuming and involves use of alkalis and strong mineral acids. According to published data [10, 11], TPA is a valuable raw material for preparation of compounds used in fine organic synthesis. One of such compounds is diethyl terephthalate (DET).

To prepare DET, we esterified crude TPA with ethanol in the pressure vessel at 230–240°C. The dependence of the yield of the esterification products on the reaction time is shown in Fig. 2.

The esterification results demonstrated that at a TPA : C_2H_5OH ratio of 1 : 9 the maximal DET yield was 87.3%. With an increase in the reaction time from 6 to 12 h, the yield increased by no more than 4%; therefore, it is not appropriate to perform the reaction for a time exceeding 6 h.

Advantages of the method are the high reaction yield and the absence of a catalyst. The mixture obtained after the reaction completion is a homogeneous transparent solution which can be readily purified by filtration to remove mechanical impurities and label paper; the costs for pretreatment of PET waste can thus be reduced.

CONCLUSIONS

(1) A convenient procedure was suggested for utilization of heavily contaminated domestic poly(ethylene terephthalate) waste, allowing its reprocessing on small and medium scales using nonstandard equipment.

(2) The process involves formation of an insignificant amount of waste.

Abstract—The kinetics of thermal oxidative degradation of a polyester resin and of its formulation with diethyldibenzylammonium bromide was studied. The rate constants of the thermal decomposition were determined.

DOI: 10.1134/S1070427207060286

This study further examinates the developed formulations of low-temperature noncorrosive solder creams based on a polyester resin modified with rosin and quaternary ammonium salts [1, 2].

The temperature and time limits of the working capacity are important characteristics of polymers. These limits are determined by the occurrence of physical or chemical transformations of polymers [3].

A thermal analysis can be performed in isothermal and dynamic modes. In the first case, the thermal degradation is monitored at a constant temperature, which allows comparison of the degradation rates of various materials at a given temperature. This mode is suitable when the working temperature range of a material is known.

To estimate the heat resistance of a material, it is necessary first to determine the temperature ranges of the occurrence of transformations that irreversibly alter the chemical nature of the polymer. This is done using dynamic thermal analysis.

EXPERIMENTAL

The parameters of thermal oxidative degradation of a polyester resin (sample no. 1) and its formulation with diethyldibenzylammonium bromide (DEDBAB) (sample no. 2) were determined by dynamic thermogravimetry [4]. For more accurate determination of the temperatures at which the samples start to decompose, we recorded along with the TG curves the DTG and DTA curves (Figs. 1a, 1b). Experiments were performed with an MOM Q-1000 derivatograph (Hungary) in the programmed-heating mode. Samples (0.05 g) were heated in a platinum crucible in air at rates of 5 and 10 deg min^{-1}. The sensitivities were as follows: balance, 100 mg; DTA galvanometer, 1/3; DTG galvanometer, 1/10.

When heated in air, sample no. 1 decomposes in three steps in the interval 80–600°C (Fig. 1a). The first step (80–250°C) involves removal of the residual solvent and free volatile components boiling in this range: water formed in the course of the resin synthesis, residual alcohol, and unsaponifiable substances. The second step (310–400°C) involves endothermic decomposition of the polyester resin and simultaneously occurring exothermic oxidation of a part of the products formed [1, 3, 5]. The third step is characterized by a complex exothermic effect with characteristic temperatures of 420 (onset of exothermic peak corresponding to the oxidation in the DTA curve) and 540°C. The strong peak at 540°C corresponds to oxidation of the gaseous products released in the course of the thermal decomposition of the polyester resin [1, 3, 5].

Sample no. 2, when heated in air, decomposed in three steps in the interval 100–560°C (Fig. 1b). The first step (100–220°C) is of the same origin as for sample no. 2. The second step (250–400°C) involves

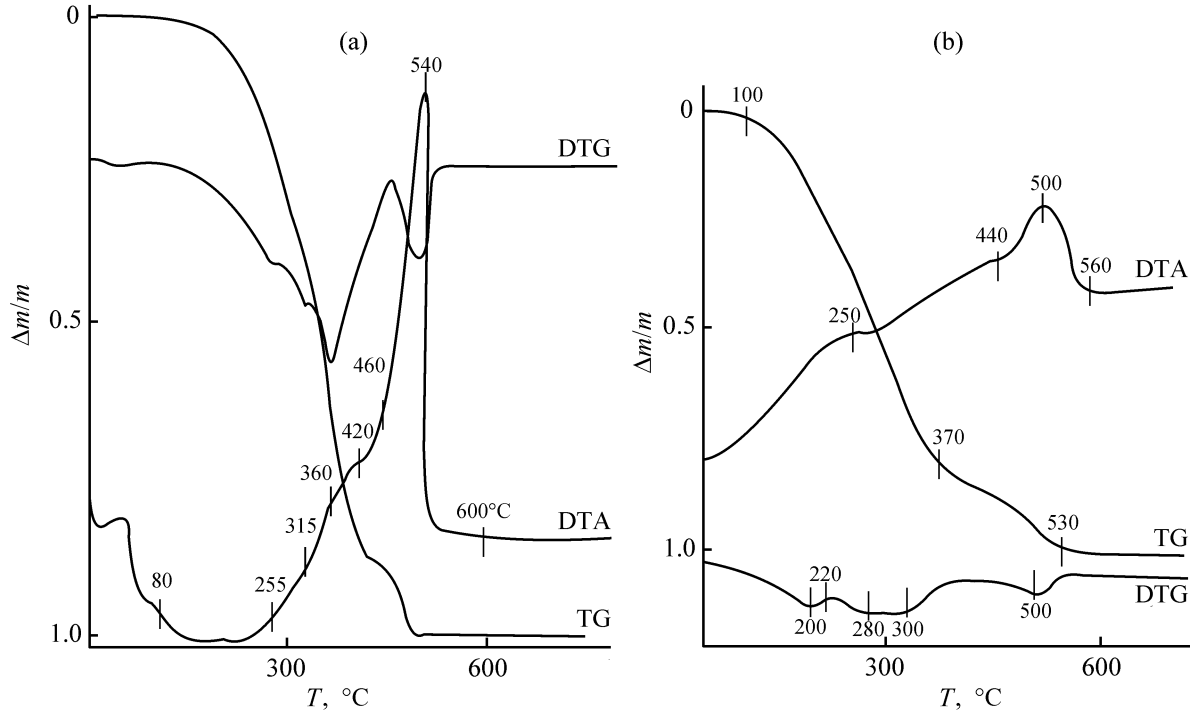

Fig. 1. Thermogram of (a) a polyester resin modified with rosin and (b) its formulation with diethyldibenzylammonium bromide. ($\Delta m/m$) Relative weight loss and (T) temperature.

endothermic decomposition of DEDBAB and simultaneously occurring exothermic oxidation of a part of the products formed [2, 5]. The third step is characterized by a complex exothermic effect with characteristic temperatures of 440 (onset of exothermic peak corresponding to the oxidation in the DTA curve) and 500°C. The strong peak at 500°C corresponds to oxidation of the gaseous products released in the course of the thermal decomposition of the polyester resin [2, 5].

The kinetics of thermal degradation was studied in the static mode by the manometric method, using a glass Bourdon zero gage at a residual pressure in the reaction volume of 10^{-1}–10^{-2} mm Hg in the temperature range 100–300°C. The temperature in the thermostat was maintained with an accuracy of ±(0.2–0.5)°C. The scheme of the installation and the experimental procedure were described in [6, 7].

To make the data comparable, the results of the manometric study were converted to the normal volume of gaseous products per gram of the starting compounds:

$$V_t = (T_0 V_r P_t)/(T P_0 m),$$

where V_r is the volume of the reaction space in the manometer (cm^3); P_t, pressure of decomposition products by the instant of time t (mm Hg); V_t, volume of gaseous decomposition products released by the instant of time t (cm^3); T_0, temperature corresponding to the normal conditions (273.15 K); T, experimental temperature (K); m, sample weight (g); and P_0, pressure corresponding to normal conditions (760 mm Hg).

The experimental data were plotted as the volume of the released gases per gram of the starting substance vs. time. The value of the maximal gas release V_∞ required for determining the reaction rate constant by a first-order equation, $k = (1/t)\ln[V_\infty/(V_\infty - V_t)]$, was taken from the experimental manometric curves. The quantity V_∞ is specific to each temperature, because, as the temperature is raised, the growing number of components become volatile. The character of the thermal degradation can be judged from the shape of the smoothed kinetic curve. For the decomposition by a first-order reaction, the dependence $V_i = f(t_i)$ is described by a flattening-out curve (which was actually observed in the experiment). In this case, the rate constant of the thermal decomposition (s^{-1}) was calculated by the formula

$$k = (1/t)\ln[V_\infty/(V_\infty - V_t)],$$

where V_∞ is the total volume of gaseous decomposition products under normal conditions, released from 1 g of the starting substance (cm^3).

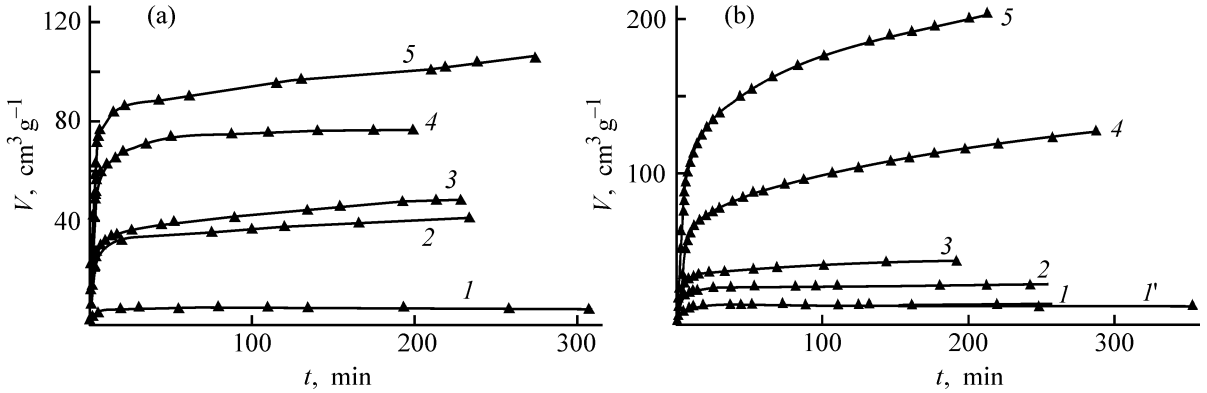

Fig. 2. Manometric curves of gas evolution from sample nos. (a) 1 and (b) 2 at temperatures of up to 300°C. (*V*) Volume of gaseous products per gram of the starting substance and (*t*) time; the same for Fig. 3. Temperature, °C: (*1*) 100, (*1*') 120, (*2*) 150, (*3*) 180, (*4*) 250, and (*5*) 300.

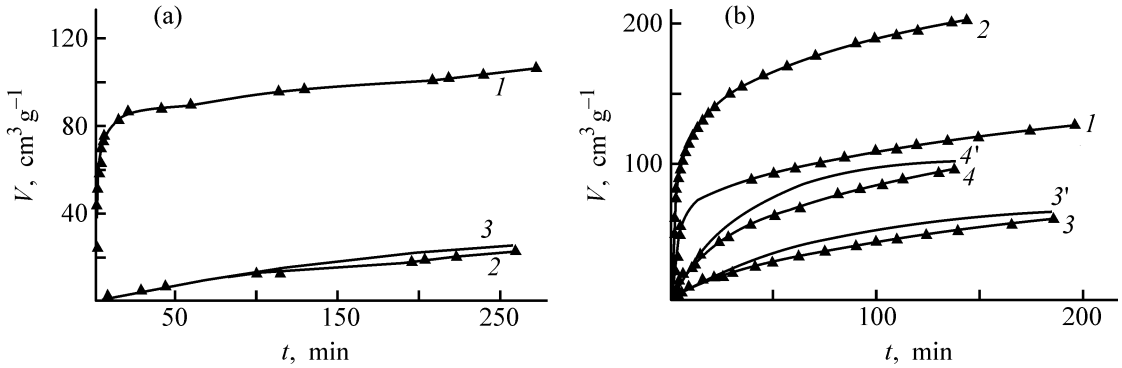

Fig. 3. Manometric curves of the gas release from (a) sample no. 1 at 300°C and (b) sample no. 2 at 250 and 300°C. (a) (*1*) Initial experimental curve, (*2*) curve with subtracted initial volume of gas release, and (*3*) approximating curve corresponding to a first-order reaction equation. (b) (*1*, *2*) Initial experimental curves, (*3*, *4*) curves with subtracted initial volume of gas release, and (*3*', *4*') approximating curves corresponding to first-order reaction equations; temperature, °C: (*1*, *3*, *3*') 250 and (*2*, *4*, *4*') 300.

The working reflow temperatures of low-temperature solder creams (°C) are as follows: POIn-52, 120; 45% Sn + 29% Pb + 17% Cd + 9% In, 140–150; POSK 50/18, 170–180; POS-61, 220–250. Therefore, manometric studies of sample nos. 1 and 2 were performed at 100, 120, 150, 180, 250, and 300°C [8].

Manometric studies of sample nos. 1 and 2 showed that the resins are thermally stable up to approximately 250°C (Figs. 2a, 2b). The gas release observed in the course of the experiment is caused by the removal of residual solvent and free volatile components: water formed in the course of the resin synthesis, residual alcohol, and unsaponifiable substances. The gas release was up to 60 ml per gram of the sample (depending on the experimental temperature).

Thermal degradation of sample nos. 1 and 2 starts at approximately 250°C. The initial portion of the manometric curve corresponds to the removal of the residual solvent, and this is followed by the thermal degradation proper (Figs. 3a, 3b). Thermal degradation of sample nos. 1 and 2 is described by a first-order reaction equation. The calculated rate constants of the thermal degradation are as follows: sample no. 1, 300°C, 6.9×10^{-5} s^{-1}; sample no. 2, 250°C, 2.2×10^{-4} s^{-1}; 300°C, 4.51×10^{-4} s^{-1}. That is, the samples are fairly heat-resistant. The higher resistance of sample no. 1 to thermal oxidation, compared to sample no. 2, may be due to acid catalysis of the resin decomposition, observed in the presence of DEDBAB (its hydrolysis leads to acidification of the reaction medium).

CONCLUSION

Isothermal and dynamic thermal analyses of a polyester resin and its formulation with diethyldibenzylammonium bromide showed that these substances are

resistant to thermal oxidative degradation at the reflow temperatures of low-temperature solder creams.

Abstract—Radical copolymerization of acrylic acid with acrylamide in the presence of sodium 1,3-diallyl isocyanurate cross-linking agent was studied.

DOI: 10.1134/S1070427207060298

Water-absorbing copolymers based on acrylic acid (AA) and its derivatives have been examined in numerous studies. Some papers consider in detail the relationship between the structural features and water-absorption capacity of copolymers [1–4].

At the same time, data on the effect of the counterions of the ionic groups in homo- and copolymers of AA and its derivatives and of the ionic strength of their aqueous solutions on the rate of water absorption of these polymers are virtually lacking. Therefore, we examined in this study the dependence of the amount of water absorbed by AA copolymer with acrylamide on the nature and concentration of counterions of the ionic groups in copolymers.

We studied NH_4^+, Li^+, Na^+, and K^+ cations as counterions of the acrylate groups in the copolymer. Copolymers with these counterions were prepared by treatment of AA copolymers with acrylamide (AM) with alkalis containing the above counterions. The macromolecular chains formed by copolymerization of AA and acrylamide were cross-linked with sodium 1,3-diallyl isocyanurate (Na-DAIC).

In all the copolymerization experiments, the total concentration of AA and its salts was 2 M (30% acrylates relative to AA in the monomer mixture). In preparing copolymers, the content of acrylamide was 30% relative to the total concentration of the other monomers.

Copolymerization of AA and acrylamide in the presence of Na-DIAC yielded cross-linked polymers, which acquire high water-absorption capacity upon treatment with appropriate alkalis.

The data on the amount of water absorbed by the copolymers in relation to the content of Na-DIAC and nature of counterions of the ionic groups in the copolymer are listed in Table 1.

Table 1. Water-absorption capacity of copolymers as influenced by the density of cross-linking and nature of counterions of the ionic groups

Monomer molar ratio [AK]+[M-AA]*+[AA]/ [Na-DIAC] in copolymer	Water-absorption capacity, mg H_2O/gram copolymer								
	NH_4^+	Li^+	Na^+	K^+	NH_4^+/Li^+	NH_4^+/Na^+	Li^+/Na^+	Li^+/K^+	Na^+/K^+
5	200	150	130	100	180	150	125	110	90
10	350	220	200	150	280	210	190	180	160
30	580	450	400	330	500	460	430	380	350
50	630	500	450	400	570	530	490	460	420
60	750	650	580	500	690	630	600	560	520

Note. Counterions M are NH_4^+, Li^+, Na^+, K^+, and their equimolar mixtures NH_4^+/Li^+, NH_4^+/Na^+, Li^+/Na^+, Li^+/K^+, and Na^+/K^+.

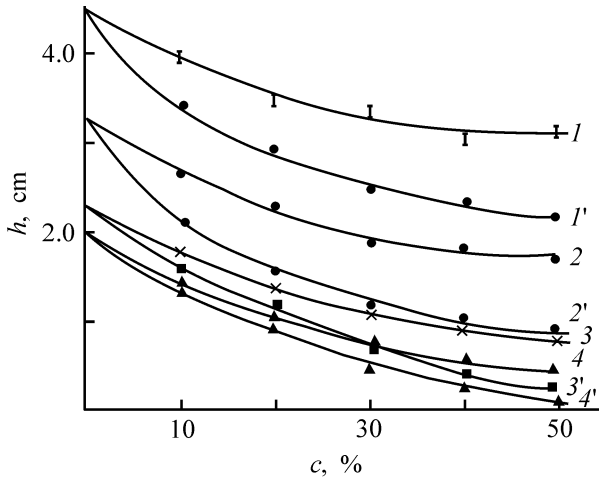
Table 2. Rate of water absorption in relation to the nature of counterions of the ionic groups in copolymers and to the concentration of aqueous salt solutions

Salt, wt %	Rate of water absorption, mg min^{-1}									
	NH_4^+	Li^+	Na^+	K^+	NH_4^+/Li^+	NH_4^+/Na^+	NH_4^+/K^+	Li^+/Na^+	Li^+/K^+	Na^+/K^+
0	0.5	0.35	0.2	0.18	0.3	0.25	0.23	0.21	0.2	0.18
NaCl:										
0.1	0.4	0.27	0.18	0.16	0.23	0.21	0.2	0.19	0.18	0.17
0.3	0.37	0.19	0.11	0.1	0.21	0.2	0.18	0.16	0.15	0.13
0.5	0.35	0.17	0.08	0.06	0.19	0.17	0.14	0.11	0.1	0.09
$CaCl_2$:										
0.1	0.33	0.21	0.16	0.06	0.28	0.19	0.17	0.14	0.095	0.05
0.3	0.25	0.125	0.075	0.02	0.16	0.12	0.095	0.08	0.07	0.03
0.5	0.2	0.085	0.025	0.008	0.09	0.06	0.04	0.03	0.02	0.01

As can be seen, copolymers whose ionic groups contain NH_4^+ counterions exhibit the highest water-absorption capacity. This is probably due to a higher hydrolytic activity of NH_4^+ ions as compared to the activity of the other counterions.

Moreover, copolymers containing ionic groups with different counterions exhibit lower water-absorption capacity than copolymers with the ionic groups containing the more active counterion only (NH_4^+ or Li^+).

It is known that the water-absorption capacity of cross-linked homo- and copolymers decreases with increasing concentration of dissolved salts [5]. In this context, we studied the water-absorption capacity of AA copolymers with acrylamide cross-linked with Na-DIAC in the presence of NaCl and $CaCl_2$ aqueous solutions of various concentrations.



Water absorption h of copolymers, as influenced by the salt concentration c and nature of counterions of the ionic groups. (*1*–*4*) NaCl and (*1'*–*4'*) $CaCl_2$. (*1*, *1'*) NH_4^+, (*2*, *2'*) Li^+, (*3*, *3'*) Na^+, and (*4*, *4'*) K^+.

The dependences of the amount of water absorbed by the copolymers on the nature and concentration of the aqueous solutions (NaCl and $CaCl_2$) and on the nature of counterions of the carboxy groups in copolymer are shown in the figure. The results were obtained using copolymers with the monomer molar ratio AA : M-AA : AM : Na-DIAC = 0.7 : 0.3 : 0.3 : 0.02. Ammonium acrylate was used as M-AA. It should be noted that the copolymer of the above composition can absorb up to 750 g of water per gram. Irrespective of the nature of the counterions of the ionic groups in the copolymer, absorption of water proceeds at a constant rate during 15 min after the being of the experiment.

Our experimental data showed that the counterions of the ionic groups in the copolymers affect not only the water-absorption capacity of copolymers but also the absorption rate.

The rates of water absorption, as influenced by nature of counterions of the ionic groups and by the concentrations of aqueous salt solutions, are listed in Table 2. As can be seen, copolymers containing NH_4^+ counterions exhibit not only high water-absorption capacity but also high rate of water absorption.

EXPERIMENTAL

Na-DIAC was prepared and purified by the procedure described elsewhere [6]. The fraction of AA with bp 141°C and n_D^{20} = 1.4224 was used. Acrylamide (mp 85°C) and ammonium persulfate were recrystallized from methanol and ethanol, respectively.

The ionic (carboxy) groups in copolymers were prepared using LiOH, NaOH, and KOH, of analytically pure grade and 18% NH_4OH. The copolymerization was carried out at 70 ± 0.5°C [3].

Copolymers with ionic groups and the corresponding counterions (NH_4^+, Li^+, Na^+, and K^+ and their mixtures) were prepared by addition of the required amount of an aqueous alkali solution of a definite concentration (wt %) to a preliminarily swollen copolymer gel. Then the mixture was thoroughly mixed and stored for 24 h. The swollen mass was first dried in air to completely remove water and then in a vacuum (1.5–2.0 mm Hg) at 65–70°C to constant weight. The degree of neutralization of the carboxy groups in the copolymer with the corresponding alkalis was determined by titration of the filtrate after neutralization of the repeatedly swollen copolymer gel with 0.1 N HCl solution.

The amount V (ml) of absorbed water in copolymers was calculated from the equation $V = \pi R^2 h$, where R is the capillary radius and h is the level of absorbed water in the capillary.

The rate of water absorption (ml min^{-1}) in copolymers was determined using the kinetic dependences of water absorption.

To determine the water-absorption capacity of copolymers, a weighed portion of a copolymer (0.125 g) was placed in a graduated cylinder (0.5 cm in diameter and 30 cm high); then water was added up to the upper mark, the mixture was thermostated at a required temperature, and the upward shift of the swollen gel boundary was monitored.

CONCLUSIONS

(1) The nature of counterions of the carboxy groups in copolymers affects both the water-absorption capacity and the rate of water absorption by copolymers of acrylic acid and acrylamide, cross-linked with sodium 1,3-diallyl isocyanurate and containing various ionic groups.

(2) The concentration and nature of the aqueous salt solutions (NaCl and $CaCl_2$) strongly affect both the water-absorption capacity and the rate of water absorption. With increasing concentrations of these salts in aqueous solutions, both the water-absorption capacity of the copolymers considerably decreases.

Abstract—Swelling of a sulfamide polymer of UPM brand in a series of alcohols was studied gravimetrically. Correlation analysis with multiparameter equations showed that solvation processes exert a decisive effect on the swelling.

DOI: 10.1134/S1070427207060304

The resistance of polymers to organic liquids is one of their important service characteristics. It is not surprising that, since the 1940–1950s, numerous papers concerning swelling of synthetic rubbers and other polymers have been published. Today, because of the increasing use of membrane technologies, studies of the resistance of polymers to the surrounding medium, of the membrane permeability, and of diffusion of liquids across membranes become more and more topical [1]. However, mostly carbon-chain polymers have been studied; heterochain polymers, showing much promise as membrane materials, are understood to a considerably lesser extent.

It should be noted that the published values of the degree of swelling (Q), diffusion coefficients (D), and permeability (P) have been obtained from data on the kinetics of the polymer weight gain in the solvents examined, monitored until an equilibrium was attained. At the same time, no reliable correlations between these quantities and physicochemical characteristics of organic liquids have been found. The most widely used Flory–Huggins approach based on the regular solution theory gives only fuzzy bell-shaped correlations of the maximal swelling $\log Q$ with the Hildebrand solubility parameter δ^2, with numerous outliers [2, 3]. This inadequacy is caused by the fact that specific solvation processes are disregarded. However, attempts to characterize the swelling solely by parameters of solvation processes, e.g., by the Reichardt electrophilicity parameter E_T or by the difference between the donor and acceptor numbers of the solvent DN – AN, have either failed or led to equations applicable to only homologous series of solvents [4]. A similar pattern has been observed with the diffusion coefficients: Chalykh [5, 6] has shown that the correlations between the diffusion coefficients of low-molecular-weight substances in polymers and their molecular weights or molar volumes are linear only within separate homologous series.

Aparently, penetration of a liquid into a polymer structure depends on many factors and cannot be described by a single characteristic of a liquid. The approach commonly used in the modern solution chemistry is based on the linear free energy relationship; within this approach, the solvent effect on the occurring processes is regarded as a sum of all the occurring effects [7]. In particular, this approach has been effectively applied to swelling of polyethylene and other hydrocarbon polymers [8], polyurethanes [9], and coals [10]. Therefore, it seemed appropriate to check its applicability to polymers containing bulky sulfamide groups capable of donor–acceptor interactions.

EXPERIMENTAL

In this study, we examined swelling in alcohols at 15°C of films of UPM sulfamide polymer, which is the product of polycondensation of 4,4'-diaminodiphenyl sulfone with terephthalic acid dichloride. To reveal the possible effect of hydroxy group on the swelling, we also studied the swelling in aprotic ethyl acetate. The degree of swelling as a function of time was determined gravimetrically with samples 105 μm

Limiting degrees of solvent absorption Q_∞, constants k of Eq. (2), and rate constants k' of swelling of UPM polymer (**I**) at 15°C and of polyurethane B600 (**II**) at 25°C [12]

thick, with a mean pore size of 50 nm. Polymer samples (1 g) were placed in weighing bottles filled with 30 ml of an appropriate solvent; at regular intervals, the samples were withdrawn, dried with a filter paper, and weighed. The swelling was monitored until complete saturation was attained. The temperature was measured with an accuracy of ±0.5°C. Weighing was performed with an accuracy of ±0.2 mg. However, it is hardly possible to ensure complete removal of high-boiling, relatively viscous alcohols from the sample surface; therefore, we estimated the actual accuracy at ±0.01 g. The limiting degrees of solvent absorption Q_∞ are listed in the table.

Figure 1 plots the amount of absorbed solvent Q vs. square root of time $\tau^{1/2}$ for a series of solvents. The curves have similar shapes: After the initial rapid absorption of a solvent, they flatten out, as in the case of other polymers [1, 11]. This shape of the curves is consistent with the well-known relationship found by Einstein, according to which the diffusion coefficient D is inversely proportional to the radius of the penetrating particle, r, and its viscosity η:

$$D = \text{const} r^{-1}\eta^{-1}. \quad (1)$$

The quantity Q_∞ and absorption rate decrease with an increase in the molecular weight and degree of branching (*tert*-butanol) of the alcohol; for ethyl acetate (four carbon and two oxygen atoms), Q_∞ is close to that of *n*-hexanol.

To compare the sorption power of the sulfamide polymer with that of polyurethane, also containing amide groups, we also included in the table data on the sorption of alcohols with a film of Vibrathane B600, a product of the condensation of poly(propylene oxide) with toluylene diisocyanate, cross-linked with 4,4'-methylenebis(*o*-chloroaniline) [12]. Similar experiments were performed with 0.25-mm-thick film samples. As can be seen, the data obtained are of the same order of magnitude as those obtained for the sulfamide polymer and show the same trend: Q_∞ regularly decreases with an increase in the molecular weight and in the degree of branching of the alcohol.

The shape of the curves of liquid absorption by the polymer up to 50% saturation can be generally described by the equation [11, 13]

$$Q_\tau/Q_\infty = k\tau^n, \quad (2)$$

where the constant k characterizes the structural features of the polymer and n depends on the mechanism of liquid penetration.

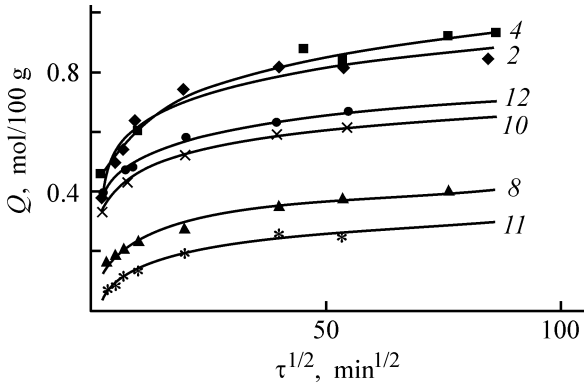

Fig. 1. Degree of swelling of sulfamide polymer in solvents, Q vs. time τ. *Figures at curves* are sample nos. in the table; the same for Figs. 2 and 3.

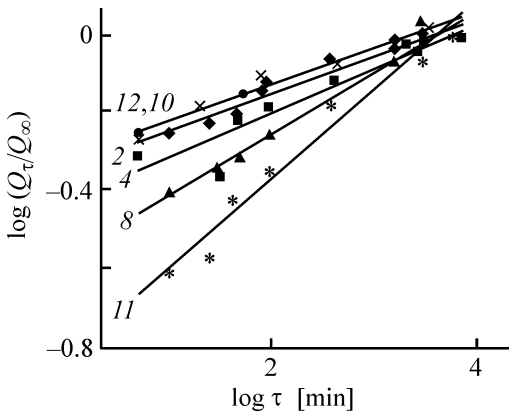

Fig. 2. Plot of $\log(Q_\tau/Q_\infty)$ vs. $\log(\tau)$ (τ is time).

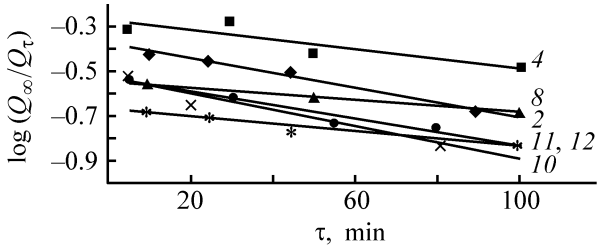

Fig. 3. Determination of the kinetic order of swelling from the plot of $\log(Q_\infty/Q_\tau)$ vs. time τ.

Without specific interactions of the system components, $n \sim 0.5$, i.e., the process is described by Fick's law. If the penetration kinetics is complicated by such interactions, n is in the range $0.5 < n < 1$. However, application of Eq. (2) to the experimental results obtained did not give positive results. Although there are linear correlations between $\log(Q_\tau/Q_\infty)$ and $\log\tau$, with the correlation coefficients R as high as 0.95–0.99 (Fig. 2), the values of $n < 0.5$ calculated from these correlations are of no real sense. This fact suggests a complex mechanism of sorption, apparently determined by the presence in the polymer of amide groups capable of donor–acceptor interactions with alcohol protons.

In accordance with [11], the constants k reflect the structural features of a polymer; hence, for a given polymer, they should be equal for all the solvents. These constants were determined for the sulfamide polymer from our sorption data, and taken from [12] for the polyurethane. However, k actually varies in the range $k = 0.27–0.49$, and for n-nonanol showing the maximal sorption k is even lower. Thus, apparently, depends not only on k particular polymer, but also on the sorbate.

The k values calculated for the sulfamide polymer are an order of magnitude higher than those for the sorption of esters (0.02–0.04) [11] and alcohols (0.007–0.02) [12] by polyurethane films, which also confirms the difference in the mechanism of absorption by these two polymers. In both cases, k decreases with an increase in the molecular weight of the alcohol (an exception is n-hexanol) and in the degree of its branching. The constants k for the sorption of alcohols with the polyurethane are also listed in the table.

Since the sorption rate of liquids is proportional to the difference between the osmotic pressures inside and outside the polymer film, i.e., is approximately determined by the corresponding vapor pressures, the sorption kinetics can be described by a first-order equation

$$dQ/dt = k'(Q_\infty - Q_\tau) \quad (3)$$

for which the rate constant is

$$k' = \{2.303\log[Q_\infty/(Q_\infty - Q_\tau)]\}/\tau. \quad (4)$$

Indeed, the correlation in the coordinates $\log(Q_\infty - Q_\tau)$–τ is linear (Fig. 3), but only in the initial period of the process, up to approximately 50% saturation. The corresponding values of k' (min^{-1}) for the sulfamide film, determined by Eq. (4), are listed in the table; they are of the same order of magnitude as those for the penetration of esters into a polyurethane membrane at 25°C [11].

As can be seen from the table, the quantities Q_∞, k, and k' are appreciably dependent on the organic solvent; however, these quantities do not clearly correlate with any separate property of the liquids. It has been shown recently that a good correlation for Q_∞ can be obtained with a multiparameter equation taking into account the capacity of solvents for both specific and nonspecific solvation, and also the structural characteristics of the solvents [7, 8]:

$$\log Q_\infty = a_0 + a_1(n^2 - 1)(n^2 + 2)^{-1} + a_2(\varepsilon - 1)(2\varepsilon + 1)^{-1} + a_3\delta^2 + a_4B + a_5E_T + a_6V_m, \quad (5)$$

where n is the refractive index; ε, dielectric permittivity of organic solvents (these parameters are related to the polarizability and polarity of solvents, responsible for nonspecific solvation of a substrate); B, Palm basicity [14]; E_T, Reichardt electrophilicity [15] (these parameters describe the capability of a solvent for acid–base interaction, i.e., for specific solvation); δ^2, Hildebrand solubility parameter squared, characterizing the cohesion energy of a solvent (its tendency to self-association), proportional to the energy required for accommodation of a foreign molecule in the solv-

ent structure, i.e., for cavity formation; and V_m, molar volume of the liquid.

Equation (5) allowed successful correlation of data on Q_∞ of polyethylene in 27 solvents [8], butyl rubber in 18 solvents [16], and polyurethane Vibrathane B601 in 36 solvents [9]. Therefore, it would be appropriate to apply the same approach to data from the table. In this case, however, the number of the examined solvents is small and equal to the number of parameters of the equation. Therefore, it becomes necessary to reveal insignificant factors by the leave-one-out procedure and construct equations with a smaller number of parameters. By so doing, we found that the factors δ^2 and V_m are insignificant for Q, despite relatively high pair correlation coefficient between Q and V_m (r = 0.851). The data on Q_∞ of the sulfamide polymer in alcohols are satisfactorily fitted by a four-parameter equation

$$\log Q_\infty = -8.047 + (13.94 \pm 1.80) f(n^2) + (24.13 \pm 1.76) f(\varepsilon) - (17.08 \pm 1.17) \times 10^{-3} B - (4.75 \pm 0.55) \times 10^{-2} E_T,$$
$$R = 0.996, \quad s = \pm 0.017. \qquad (6)$$

The factors of polarizability and electrophilic solvation also appeared to be of relatively low significance. Their exclusion led to an equation ensuring acceptable accuracy, although R was somewhat lower than the recommended value R = 0.95:

$$\log Q_\infty = -2.602 + (11.11 \pm 1.93) f(\varepsilon) - (8.66 \pm 1.55) \times 10^{-3} B - (1.15 \pm 1.07) \times 10^{-2} E_T,$$
$$R = 0.948, \quad s = \pm 0.062; \qquad (7)$$

$$\log Q_\infty = -2.498 + (9.83 \pm 1.68) f(\varepsilon) - (9.01 \pm 1.68) \times 10^{-3} B,$$
$$R = 0.936, \quad s = \pm 0.069. \qquad (8)$$

Thus, the factors determining the degree of swelling of the polymer are the polarity and basicity of solvents; their exclusion leads to a decrease in R to approximately 0.5, i.e., fully breaks the correlation. Here the positive effect of polarity is quite natural, taking into account the presence of sulfone and amide groups in the polymer. At the same time, amide groups containing tertiary nitrogen atom are incapable of solvation with electron-donor basic solvents, and the interaction is repulsive, as indicated by the negative sign of the coefficient at B.

The negative (though relatively insignificant) effect of the capacity of alcohols for specific electrophilic solvation of solutes is somewhat surprising; it may be associated with the acidic character of the proton of sulfamide groups. At the same time, with polyurethane, the effect of this factor is positive (promoting swelling), though also weak. The following equation was obtained for eight alcohols on the basis of data from [12]:

$$\log Q_\infty = -28.310 + (26.50 \pm 8.89) f(n^2) + (41.63 \pm 13.68) f(\varepsilon) + (4.05 \pm 1.76) \times 10^{-3} B + (0.93 \pm 2.31) \times 10^{-2} E_T + (1.60 \pm 1.13) \times 10^{-3} \delta^2 + (3.63 \pm 4.17) \times 10^{-3} V_m,$$
$$R = 0.985, \quad s = \pm 0.017. \qquad (9)$$

After exclusion of insignificant terms, we obtain

$$\log Q_\infty = -21.93 + (25.21 \pm 3.80) f(n^2) + (32.29 \pm 5.91) f(\varepsilon) + (1.47 \pm 0.31) \times 10^{-3} \delta^2,$$
$$R = 0.970, \quad s = \pm 0.024. \qquad (10)$$

Thus, absorption by polyurethane films involves nonspecific solvation of polar carbamate groups, mainly favoring the process. Note that, for swelling of the same polymers in 36 solvents of different nature, the decisive factors in the general correlation equation were the same [9].

By a similar procedure, we treated the constants k of Eq. (2), and for polysulfamide, also the swelling rate constants k'. For polysulfamide, we obtained the following equation:

$$\log k = -2.974 + (40.88 \pm 0.79) f(n^2) - (16.55 \pm 0.29) f(\varepsilon) + (5.23 \pm 0.13) \times 10^{-2} E_T - (2.30 \pm 0.03) \times 10^{-2} V_m,$$
$$R = 0.999, \quad s = \pm 0.003. \qquad (11)$$

In this case, further exclusion of any term makes R lower than 0.9, i.e., breaks the correlation.

For polyurethane, we obtain a simpler equation with different levels of significance of separate terms:

$$\log k = 0.486 + (0.178 \pm 0.330) \times 10^{-3} \delta^2 - (0.66 \pm 0.19) \times 10^{-3} V_m,$$
$$R = 0.972, \quad s = \pm 0.040. \qquad (12)$$

In this case, however, only the electrophilic solvation factor E_T is decisive; its pair correlation coefficient r is 0.970. The difference in the nature of factors governing R confirms the above assumption that the solvents interact with polysulfamide and polyure-

thane films essentially differently, primarily because of the different nature of the sulfamide and carbamate groups. For the swelling rate constants k' (min^{-1}) of the sulfamide film in alcohols, we obtained the correlation equation

$$\log k' = 0.429 + (56.12 \pm 5.61)f(n^2) - (29.11 \pm 2.07)f(\varepsilon) + (98.00 \pm 9.27) \times 10^{-3}E_T - (35.22 \pm 2.48) \times 10^{-3}V_m,$$
$$R = 0.995, \quad s = \pm 0.076. \qquad (13)$$

Thus, the swelling rate, i.e., rate of penetration of alcohol molecules into the structure of the sulfamide polymer, is favored by solvation interactions between the system components. At the same time, an increase in the size of solvent molecules leads to a decrease in the penetration rate, which is quite reasonable.

CONCLUSIONS

(1) The rate of swelling of UPM sulfamide polymer in alcohols is not described by Fick's law.

(2) The values of limiting swelling of UPM polymer can be correlated with solvent properties with multiparameter equations; the capacity of solvents for nonspecific solvation favors swelling, and their capacity for specific solvation exerts a negative effect.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Extractive Substances Formed from Buckwheat Grain Production Waste

Abstract—Properties of liquid and dry extracts produced in treatment of buckwheat fruit shells (husk) and straw with water or an acid solution were studied. The conditions of pigment concentration from aqueous extracts by ultrafiltration were determined.

DOI: 10.1134/S1070427207060316

A promising resource of raw materials for synthesis of various multifunctional products (chemical substances, pharmaceutical and cosmetic preparations, food additives, natural pigments, fillers, sorbents) is the presently poorly used waste from manufacture of buckwheat grain: fruit shells [husk (BH) or hull] and straw (BS). Analysis of published evidence shows that a large body of data has been accumulated for development of a versatile and economically feasible technology for deep processing of this waste: new methods have been devised for crushing of the starting plant material [1], extraction [2, 3], and production of dispergates (dry extracts) [4] and natural food pigments [5]. The conditions of synthesis of the following products from BH and BS have been studied: flavonoids [6], food additives [7, 8], cellulose [9, 10], polysaccharides [11], sorbents [12, 13], and inorganic components [14, 15]. It has also been found that aqueous extracts of buckwheat straw and husk inhibit corrosion of low-carbon steel [16]. However, not all of the products formed in processing of buckwheat waste, including extracts, have been studied in sufficient detail, which probably hinders organization of a modern industry on the basis of these products.

The present study continues the analysis of the possibility of integrated processing of buckwheat grain production waste [10–16] and is concerned with the composition of water-soluble extractive substances produced from buckwheat husk and straw and with the conditions of their concentration by ultrafiltration.

EXPERIMENTAL

The hull of the buckwheat of Pri-7 brand (BH-11) and straw (BS-4) of buckwheat of Izumrud brand, taken in Primorsky krai in 2002, served as objects of study (the numbering corresponds to that in the collection of the Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences). Samples of husk, with particle size of no less than 2 mm, and straw, shredded into fragments of up to 10 mm in size, were preliminarily washed with water and dried in air.

A weighed portion of the raw material, with volume ratio s : l = 1 : 25, was subjected to extraction with water or a hydrochloric acid solution of varied concentration (0.1 and 1.0 N) at 80–90°C in the course of 1 h. The extracts formed were filtered through a filter paper (blue ribbon) and analyzed for the content of inorganic components on a Nippon Jarrel Ash AA-780 flame atomic-absorption spectrometer (Japan). The data obtained are listed in Table 1. K^+, Na^+, Ca^{2+}, Mg^{2+}, Cu^{2+}, Zn^{2+}, Mn^{2+}, and Fe^{3+} ions were found in the solutions. The yield of extractive substances, which varies within the range 10–35% relative to the mass of dry raw materials, and the coloration of the extracts depend on treatment conditions and type of a waste (husk or straw). Aqueous and acid treatment of BH and BS results in that polysaccharides, whose content and composition have been studied previously [11], polyphenols determining the coloration of the extracts, and other water-soluble substances [7] are recovered into solution.

Table 1. Yield of water-soluble substances and content of metal ions in these substances

Raw material	Extractive agent	Yield of extractive substances, %	Solution color	Content of metal ions in solution, μg ml^{-1}							
				K^+	Na^+	Ca^{2+}	Mg^{2+}	Cu^{2+}	Zn^{2+}	Mn^{2+}	Fe^{3+}
BH	H_2O	10	Brown	240	10.0	11.0	37.0	1.40	0.4	0.4	0.4
	HCl, 0.1 N	22	Apricot	110	1.9	19.0	48.0	0.14	0.3	1.6	1.4
	HCl, 1 N	35	Red	114	2.1	23.0	59.0	0.15	0.9	1.5	3.0
BS	H_2O	21	Brown	525	7.5	10.0	30.5	0.02	0.9	1.4	2.2
	HCl, 0.1 N	30	Light	800	1.5	160	86.0	0.10	0.2	1.8	1.4
	HCl, 1 N	34	red	450	2.5	150	120	0.08	0.6	1.3	2.4

Samples of a dry extract (DE) were obtained by evaporation of liquid extracts on a water bath or by lyophilic drying. In the experiments carried out in this study, the DE yield, dependent on the concentration of extractive substances in solution, was no less than 2% relative to the mass of the starting raw material. Such a low DE yield, compared with the amount of extractive substances in solution, may be due to presence of volatile components in the extract. The DE samples produced by lyophilic drying were light brown, and those formed by drying on a water bath, dark brown, which indicates that substances extracted from buckwheat waste are thermally labile and more modern drying techniques are necessary [4]. The structure of the samples, studied by X-ray diffraction analysis (DRON-2 diffractometer, Cu_{K_α} radiation) was amorphous for DE produced from aqueous extracts of BH and BS, and crystalline in the case of acid extracts. Figure 1 shows typical X-ray diffraction patterns of DE samples. However, the crystalline phase could not be identified using the powder database (PDF-2).

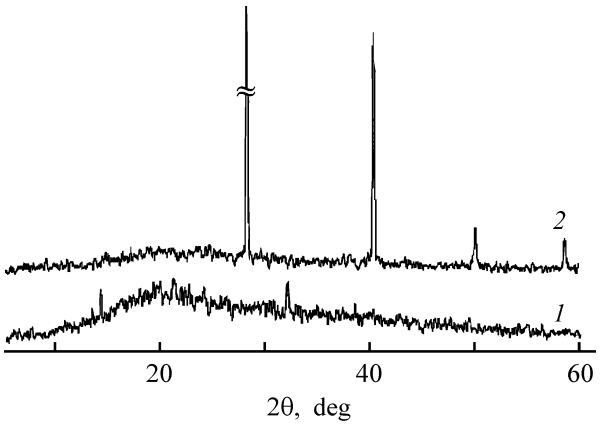

Fig. 1. X-ray diffraction pattern of DE samples produced from (*1*) buckwheat husk treated with water and (*2*) buckwheat straw treated with an acid (2θ) Bragg angle.

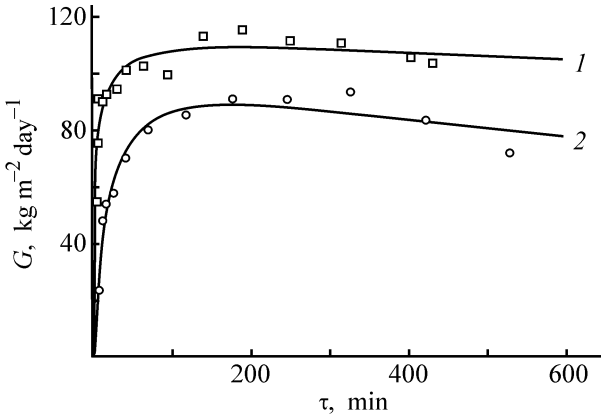

Fig. 2. Membrane throughput G in relation to pore diameter at ΔP = 0.2 MPa. (τ) Time; the same for Fig. 3. Membrane: (*1*) UAM-150P and (*2*) UAM-100P.

To intensify the process of DE synthesis, the ultrafiltration (UF) technique was employed. This method enables concentration and purification of substances with minimum energy expenditure and no need to use any reagents. The conditions of separation and concentration of pigments in solutions were optimized for the example of an aqueous extract of BH. The solutions were monitored for the content of polyphenols with an SF-256 UVI spectrophotometer by the optical density at 220–300 nm, with preliminary calibration by the standard procedure [17]. Baromembrane filtration of the aqueous extract of BH was carried out with cellulose acetate membranes with various pore diameters (UAM-100P and UAM-150P) at a pressure drop ΔP = 0.2–0.4 MPa and T = 20°C on an installation described in [18]. In the process, a filtrate (solution after ultrafiltration) and concentrate (or retentate, i.e., the residue of the starting solution over the membrane) were obtained.

The dynamics of ultrafiltration is shown in Fig. 2. It can be seen that the UAM-150P membrane reaches the steady-state mode in 10 min (curve *1*), whereas the UAM-100P membrane requires for this a longer time (curve *2*). It was found that the selectivity of separation of the starting solution (density d = 0.996 g cm^{-3}) into a colorless filtrate (d = 0.995 g cm^{-3}) and colored concentrate (d = 0.997 g cm^{-3}) at ΔP = 0.2 MPa is

Table 3. Elemental chemical analysis of DE samples produced from buckwheat husk and straw with (+) or without (–) ultrafiltration

Raw material	Extractive agent	UF	Content, %			Raw material	Extractive agent	UF	Content, %		
			C	H	N				C	H	N
BH	H_2O	–	37.9	4.8	5.1	BH	HCI, 0.1 N	–	33.2	4.2	5.0
		+	38.7	4.3	5.1	BS		–	32.8	4.2	5.0

higher for the UAM-100P membrane, compared with that of the UAM-150P type, but the former is inferior in the throughput G and the time in which the maximum degree of concentration is reached (6–10 h for UAM-100P and 3 h for UAM-150P). The throughput of the UAM-100P membrane increases by a factor of 4–5 on raising the pressure to ΔP = 0.4 MPa (Fig. 2, curve *2* and Fig. 3, curve *1*). However, the dynamics of ultrafiltration of an aqueous extract of BH changes in this case. The observe extremal behavior of the G–τ dependence (Fig. 3, curve *1*) may be due to a higher concentration rate, stronger membrane densification under pressure, and partial pore clogging by pigment particles.

It was also demonstrated that, under identical conditions of baromembrane filtration, the throughput for freshly prepared extracts is lower than that for extracts kept for $\tau \geq 10$ days (Fig. 3, curve *3*). A possible reason is that pigment molecules associate in the course of time into coarser particles, which diminishes the clogging of pores in the membrane and improves its throughput. The data obtained indicate that accumulation and storage of extracts before the ultrafiltration stage is admissible and can serve as a positive factor for the technological process.

The degree of pigment concentration was evaluated by a change in the dry residue mass in the over-membrane solution (retentate). The maximum (fivefold) increase in the mass of the substance was achieved on the UAM-100P membrane (ΔP = 0.4 MPa) at the best combination of throughput/selectivity parameters and minimum loss of the dispergate (about 2%).

A twofold increase in the concentration of the starting extract (to s : l = 1 : 12.5) leads to a decrease in the filtration rate (Fig. 3, curves *1*, *2*), but provides a faster attainment of the steady-state mode and makes shorter the total time of concentration.

The distribution of K^+, Ca^{2+}, and Mg^{2+} ions among fractions in ultrafiltration of an aqueous extract of BH is illustrated by Table 2. The data in the table indicate that these ions are accumulated in the extract.

The color of the dry extract produced by ultrafiltration (DE_{uf}) and by lyophilic drying of the concentrate was brown (similarly to the color of the starting extract) and its structure was amorphous. The results of a chemical analysis for the content of carbon, hydrogen, and nitrogen, made using the standard procedures [19], are listed in Table 3. The DE_{uf} sample differs from the others in a higher content of carbon. The thermal behavior of the sample, studied using

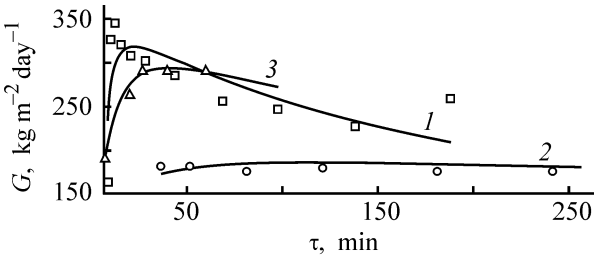

Fig. 3. Membrane throughput G in relation to pressure and concentration of the extract from buckwheat husk. ΔP (MPa): (*1*, *2*) 0.4 and (*3*) 0.2. s : l: (*1*, *3*) 1 : 25 and (*2*) 1 : 12.5.

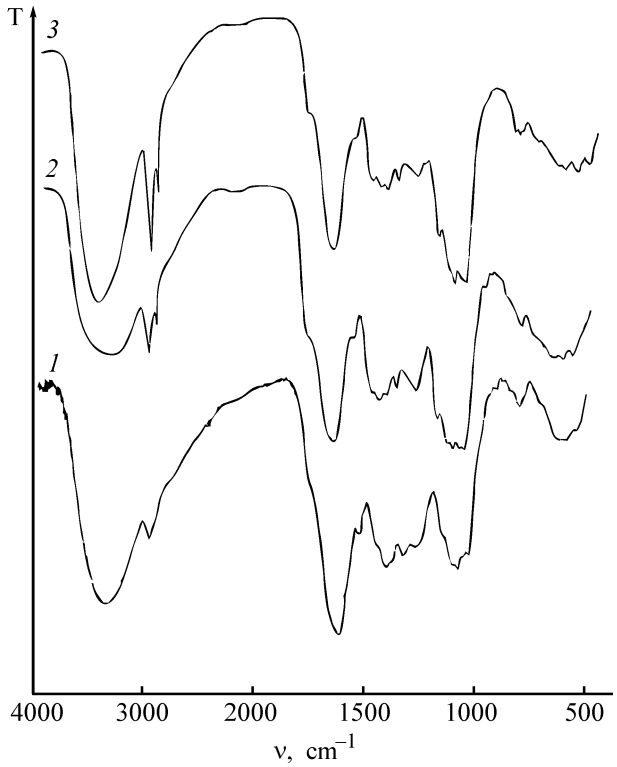

Fig. 4. IR spectra of DE samples obtained from an aqueous extract from buckwheat husk with (*1*) drying on a water bath, (*2*) ultrafiltration and lyophilic drying, and (*3*) lyophilic drying. (T) Transmission and (ν) wave number.

a Q-1000 derivatograph (Hungary) shows that the product starts to slowly decompose in the range 50–140°C. Further heating to 700°C leads to intensive continuous decomposition.

Figure 4 show IR absorption spectra measured in the range 400–4000 cm^{-1} on a Shimadzu IR Prestige 21 spectrophotometer (Japan) for three DE samples obtained from aqueous extracts of BH under different conditions. Analysis shows that the spectra contain groups of bands of different intensities in the following frequency ranges (cm^{-1}): 3600–2935, 1750–1516, 1450–1260, 1150–1020, and ~700–400, which is typical of polysaccharides of plant origin, including the buckwheat waste [11]. The use of baromembrane filtration and lyophilic drying in the extract processing yields a purer final product (DE), which is reflected by the IR spectra: absorption bands of dry substance, and especially those at 1242–1444 cm^{-1} (where frequencies of stretching and deformation vibrations of CH_2, CH, C–O and C–C groups appear), 2935–2850 cm^{-1} (region of stretching vibrations of CH bonds), and 3402–3248 cm^{-1} (stretching vibrations of OH groups), are more clearly pronounced and better resolved (Fig. 4, spectra *2*, *3*).

CONCLUSIONS

(1) It was shown that the yield of water-soluble substance from buckwheat husk and straw varies within the range 10–35% relative to the mass of a dry raw material, and the content of a dry extract at raw material to water ratio of 1 : 25 is not less than 2%.

(2) It was demonstrated that ultrafiltration (UAM-100P membrane at ΔP = 0.4 MPa) can be of use for concentration of pigments from aqueous extracts from buckwheat husk.

(3) Aqueous solutions with extractive substances and dry extracts were characterized by chemical, X-ray phase, and thermographic analyses and by IR spectroscopy.

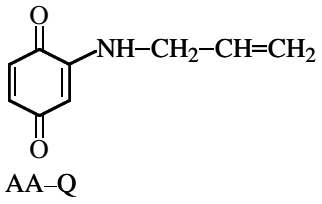
Abstract—Cationic polymerization of mono- and disubstituted derivatives of 1,4-benzoquinine and allylamine in the presence of hydrochloric acid was studied. The optimal conditions were found and the kinetic parameters of the process were evaluated.

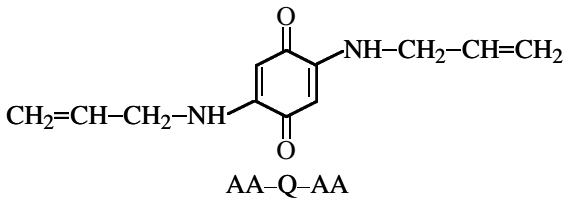
DOI: 10.1134/S1070427207060328

Allyl monomers, among them allylamine, polymerize difficultly [1]. It is well known [2–4] that their activity in radical polymerization increases upon introduction of electron-acceptor substituents directly bonded to the nitrogen atom. This is due to the fact that with increasing electron-acceptor power of substituents the rate constant of degradation chain transfer decreases.

From 1,4-benzoquinone, which is a strong electron acceptor [5], and allylamine, mono- and disubstituted derivatives of the following structures were obtained under mild conditions by the procedures developed previously [6]:



AA–Q



AA–Q–AA

Their activity in radical polymerization in the presence of benzoyl peroxide has been studied previously [7], and it was established that AA–Q monomer is more reactive than AA–Q–AA.

In this study, we examined the activity of mono- and disubstituted derivatives of 1,4-benzoquinone and allylamine in cationic polymerization.

EXPERIMENTAL

Redox monomers AA–Q and AA–Q–AA were prepared by the procedure described in [6]. Concentrated hydrochloric acid of ultrapure grade was used, d = 1.179 g cm^{-3}. Dimethylformaide (DMF) was purified by the procedure described in [8].

The polymerization of AA–Q and AA–Q–AA was performed by the ampule method in the presence of hydrochloric acid in DMF. Weighed portions of monomers AA–Q and AA–Q–AA were charged into glass ampules, DMF was added, and, after dissolution of the monomers, hydrochloric acid was added. The reaction conditions were varied in the following ranges: concentration of monomers 10–50 g l^{-1}, HCl concentration 0.04–0.29 M, temperature 7–28°C, and duration 0.5–5.0 h. The degree of polymerization was determined by the polarographic method from the amount of the residual nonpolymerized monomer.

The polarograms were recorded in a temperature-controlled cell at 25–0.5°C on a PU-1 polarograph, using a mercury drop electrode with a capillary char-

acteristic at open circuit $m^{2/3}t^{1/6}$ = 4.38 $mg^{2/3}\ s^{1/6}$; the supporting electrolyte was phosphate buffer solution with pH 7.4 in 25% DMF. Oxygen was removed from the solution by bubbling with argon for 5 min.

The catalysts of cationic polymerization are strong mineral acids [9]. It is well known [10] that, upon addition of protonic acids to allyl monomers that are Lewis bases, the rates of their radical polymerization and molecular weights of the resulting polymers significantly increase. In this case, the conservation of the radical nature of the process is confirmed by the fact that the process occurs only in the presence of a source of free radicals (γ-radiation) and is inhibited by radical inhibitors. We found that monomers AA–Q and AA–Q–AA are fairly easily involved in the polymerization in the presence of hydrochloric acid without radical initiators or additional action on the system. The yield of the polymer as a function of the catalyst amount is plotted in Fig. 1. It is seen that, to attain the maximum yield of the redox polymer based on AA–Q, a larger amount of hydrochloric acid (0.238 M) than that for AA–Q–AA (0.142 M) is required. It was found (Fig. 2) that the maximum permissible concentration of AA–Q and AA–Q–AA in their polymerization in DMF solution is 40 g l^{-1}. Use of more concentrated solutions of the monomers for polymerization is impossible because of their limited solubility in DMF.

The optimal reaction duration is 0.5 h (Fig. 3). In this case, the yield of polymers based on AA–Q and AA–Q–AA is 88 and 85%, respectively. For both monomers, the yield of the polymer decreases almost linearly as temperature increases in the temperature range studied (Fig 4). From the kinetic curves (Fig. 5) it was concluded that, in the initial period of the process, cationic polymerization is a first-order

Kinetic parameters of cationic polymerization of AA–Q and AA–Q–AA monomers in the presence of hydrochloric acid

Monomer	T, K	k, s^{-1}	log k	E_a, kJ mol^{-1}	Monomer	T, K	k, s^{-1}	log k	E_a, kJ mol^{-1}
AA–Q	280	0.000675	–3.17	–8.41	AA–Q–AA	280	0.000902	–3.05	–19.10
	287	0.000616	–3.21			287	0.000705	–3.15	
	294	0.000565	–3.25			294	0.000587	–3.22	
	301	0.000510	–3.29						

reaction with respect to the monomer concentration. Based on this fact, we evaluated the rate constants at various temperatures and found from the Arrhenius plot (Fig. 6) the activation energies of the process for AA–Q and AA–Q–AA (see table).

As can be seen from the table, the activation energies of cationic polymerization of AA–Q and AA–Q–AA are negative. It is well known [11] that, for cationic polymerization, the total activation energy E_{tot} determined from the reaction rate is

$$E_{tot} = E_i + E_p - E_t,$$

where E_i, E_p, and E_t are the activation energies of initiation, chain propagation, and chain termination, respectively.

The negative values of E_{tot} can be explained assuming that E_p is low and E_t is high. This is possible when the termination reaction is the reaction between solvated ionic pairs. In the common case, E_{tot} of cationic polymerization is in the range from –42 to 63 kJ mol^{-1}. The activation energies we found agree well with these values.

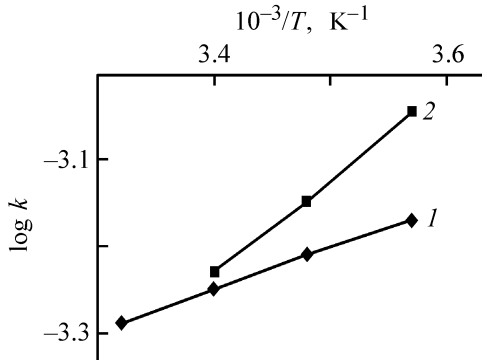

Fig. 6. Logarithm of the rate constant of cationic polymerization of (*1*) AA–Q and (*2*) AA–Q–AA monomers vs. T^{-1}.

CONCLUSIONS

(1) New allyl redox monomers AA–Q and AA–Q–AA can polymerize not only by free-radical mechanism but also by the cationic mechanism.

(2) A more promising procedure for synthesis of polymers from these monomers is cationic polymerization, since, in this case, the synthesis temperature and synthesis duration significantly decrease: from 87 to 7°C and from 21 to 0.5 h, respectively.

Abstract—The structure of complexes of nitronaphthols with aluminum bromide in nitromethane was studied by NMR.

DOI: 10.1134/S107042720706033X

It is assumed that mesomeric structures of the type of *N*-oxybenzoquinone oximes are involved in some reactions of nitrophenols. In particular, both phenol and oxime ethres are formed in methylation of nitrophenols with diazomethane [1]. Oxime ether is also formed by treatment of 9-nitro-10-hydroxyphenanthrene [2]. The intense color of nitrophenol salts is caused by mesomerism [3]. One would expect that mesomeric species can be fixed by complexation of nitronaphthols with strong Lewis acids.

It is well known that, in the reaction with aluminum halides, methylated phenols [4] and some alkyl- and phenylnaphthols [5–7] are quantitatively transformed into complexes of the keto form. The strong electron acceptor group ($-NO_2$) significantly decreases the basicity of the aromatic ring; therefore, formation of a complex of the keto form is difficult to expect, but formation of a complex of the aci form is not improbable.

To continue the studies of the complexation of phenols, we performed the reaction between 1-nitro-2-naphthol or 2-nitro-1-naphthol and aluminum bromide in nonaqueous solutions with the aim to elucidate the structure of the complexes.

Since nitronaphthols in contact with $AlBr_3$ in nonpolar solvents (benzene, petroleum ether, cyclohexane) are readily converted into salts, we selected nitromethane as a solvent in which fairly stable strongly colored complexes can be obtained at lowered temperatures.

To determine the structure of adducts, we recorded NMR spectra of nitronaphthols before and after the reaction with $AlBr_3$. The ^1H NMR chemical shifts are listed in Table 1. Since the ^1H NMR signals of H-4 and H-8 atoms of 1-nitro-2-naphthol in the nitromethane solution overlap, we additionally recorded the ^1H NMR spectrum of a solution in acetone-d_6, in which the signals of H-8 and H-4 are well resolved.

The existence of a mesomeric complex of the aci form can be confirmed by the ^{13}C NMR spectrum, because it is well known that the signal of the carbonyl

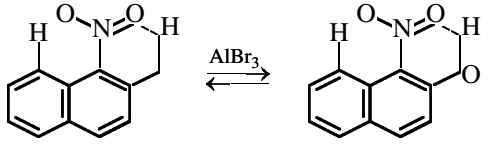
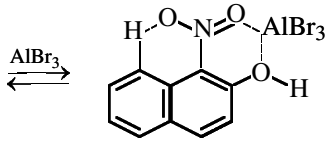
carbon atom should appear in the range 180–200 ppm in the spectra of the keto form [4]. However, we did not find this signal in the spectrum of the complex.

The coordination of $AlBr_3$ with 1-nitro-2-naphthol results in a downfield shift of the NMR signals of aromatic protons; the signals of H-8 are the most shifted. The significant downfield shift of H-8 is apparently caused by the formation of intramolecular hydrogen bond between H-8 and oxygen atom of the nitro group. This bond can be formed when nitro group is fixed in the plane of the naphthalene ring, i.e., in complexes **I** or **II**:



I

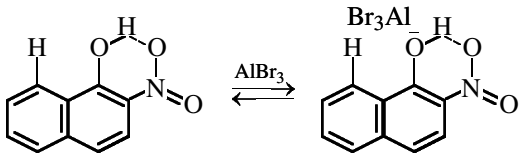


II

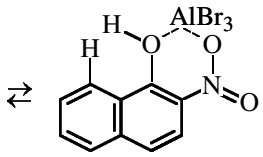
When complex **I** is formed, i.e., $AlBr_3$ is coordinated via hydroxy group, the intramolecular hydrogen bond between OH and NO_2 should be strengthened [8]. The ^1H signal of OH group should be downfield shifted, as it is observed in the complexes of the oxy form of methylated phenols [6]. Actually the ^1H NMR signal of the OH group is shifted upfield from 10.75 to 8.52 ppm.

A series of the effects observed can be explained by assuming that chelate complex **II** is formed in nitromethane solution. In this case, the oxygen atoms of the nitro and hydroxy groups lie in the plane of the naphthalene ring, and the intramolecular hydrogen bond with the nitro group is ruptured; therefore, the signal of hydroxyl proton is shifted upfield. It whould be expected that, in the complex of 2-nitro-1-naphthol with $AlBr_3$, the downfield shift of the H-8 signal should be absent because of the absence of a suitable partner for intramolecular hydrogen bond in the vicinity of peri-hydrogen.

In mixing of cooled solutions of $AlBr_3$ and 2-nitro-1-naphthol in nitromethane, a bright-colored complex is formed (C^{13} chemical shifts of the complex: C_1 137.248, C_2 135.621, C_3 116.099, C_4 124.602, C_5 126.611, C_6 126.846, C_7 126.850, C_8 127.076, C_9, C_{10} 124.668). Since in the ^{13}C NMR spectrum of the complex the signal in the range 180–200 ppm (signals of carbonyl carbon atoms) is absent, formation of a complex of the aci form can be excluded:



III



IV

Irrespective of whether the complex of 2-nitro-1-naphthol has structure **III** or **IV**, the hydrogen atom H-8 cannot form an intramolecular hydrogen bond; therefore, its chemical shift varies insignificantly, from 8.51 to 8.27 ppm, respectively.

As in the preceding case, the ^1H NMR signal of hydroxy group in the complex is shifted upfield (not downfield), from 12.24 ppm in 2-nitro-1-naphthol to 8.63 ppm in the complex.

The upfield shift of the ^1H NMR signal of the hydroxy group is apparently caused by the formation of chelate **IV**. Actually, the signal of the coordinated hydroxy group is shifted downfield to 12.7 ppm in the complex of 4-nitro-1-naphthol with $AlBr_3$ in $CDCl_3$ solution, in which formation of the chelate is impossible.

It should also be noted that the coordination of nitronaphthols with $AlBr_3$ does not noticeably affect the spin-spin coupling constants (Table 2).

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker Avance 200 spectrometer. We used TM as an internal reference, in recording spectra of free nitrophenols, and nitromethane (4.33 ppm) in recording spectra of complexes. The presence of $AlBr_3$ in a solution results in the shifts of the ^{1}H NMR signal of nitromethane by 0.1–0.2 ppm; mp (°C): 1-nitro-2-naphthol 103, 2-nitro-1-naphthol 128, 4-nitro-1-naphthol 164. The complexes were synthesized in a dry box at 0°C. The spectra were recorded at 20°C.

CONCLUSION

In the reaction with aluminum bromide in nitromethane solution, 2-nitro-1-naphthol and 1-nitro-2-naphthol form bright-colored chelate complexes, whereas 4-nitro-1-naphthol forms a typical complex of the oxy form.

Detoxication of Spent Bleaching-Fixative Solutions

N. A. Sklyarova, K. B. Grekov, and E. A. Andreeva

St. Petersburg State University of Cinematography and Television, St. Petersburg, Russia

Received February 16, 2007

Abstract—Various technological schemes for detoxication of spent bleaching-fixative solutions, with sodium peroxocarbonate as an oxidizing agent and multistage acid-alkaline treatment making possible recovery of separate valuable components, were studied. A method for minimization of the expenditure of the oxidizing agent was chosen.

DOI: 10.1134/S1070427207060341

A particular place among waste solutions formed in chemical-photographic processing of various photographic materials (primarily, modern color photographic paper) is occupied by bleaching-fixative solutions (BFS). These solutions present the most severe difficulties in utilization and recycling, as well as in detoxication in those cases when utilization is impossible or hindered. Modern color motion-picture and photographic materials are processed with BFS of various compositions, e.g.: Fe(III) EDTA · $2H_2O$ 35 g l^{-1}, $(NH_4)_2S_2O_3$ (70% solution) 150 ml l^{-1}, Na_2SO_3 10 g l^{-1}, and EDTA 30 g l^{-1}; with a pH value of up to 6.7 [1]. In addition, spent BFS commonly contain up to several grams of silver (in the form of dissolved complex compounds). Also, various agents activating the bleaching process, e.g., thiourea, thiosemicarbazide, or potassium (ammonium) bromide or iodide, are frequently introduced into the composition of various BFS based on an iron complexone in order to diminish the concentration of free silver ions in the reaction volume. Many of these compounds are reducing agents, and, therefore, they lead, when present in wastewater, to an increase in the chemical oxygen demand and biochemical oxygen demand.

A technological scheme for detoxication of solutions of this kind has been developed. This scheme is recommended for large regional centers engaged in regeneration of spent photographic solutions. After recovery of silver by an electrolytic or a reagent method, BFS are subjected to multistage acid-alkaline treatment, which enables successive extraction from these solutions of a number of valuable components (iron hydroxide, ammonia, sulfur, ethylenediaminetetraacetic acid). It has been suggested to use hydrogen peroxide for oxidation of organic and residual sulfur-containing compounds [2, 3].

However, the high cost, inflammability, and insufficient storage stability led us to an attempt to replace Perhydrol with an alternative oxidizing agent, sodium peroxocarbonate, which is largely devoid of the disadvantages mentioned above. Moreover, oxidation of a number of compounds, including those containing sulfur, requires alkalinization of the solution, and, therefore, presence of sodium carbonate in the composition of the oxidizing agent can diminish the expenditure of an alkali.

We performed preliminary studies of the oxidation efficiency with a model solution containing 16.5 g l^{-1} of sodium thiosulfate. It was shown that, at a sodium peroxocarbonate dose of 40 g l^{-1} (oxidizing agent is introduced in an excess amount), the duration of thiosulfate oxidation does not exceed 30–45 min.

As noted above, spent BFS are subjected for detoxication, after silver recovery by an electrolytic or a reagent method, to an acid-alkaline treatment. In this case, iron in the form of a hydroxide, ammonia, sulfur, and ethylenediaminetetraacetic acid are successively extracted, and organic and residual sulfur-containing compounds are oxidized by the oxidation method. To choose the simplest, convenient, economical, and safe detoxication technique, we compared various schemes of this process, in which sodium peroxocarbonate was used as an oxidizing agent:

(1) Treatment with an oxidizing agent after recovery of iron hydroxide by addition of sodium hydroxide to pH 13, followed by keeping and filtering.

(2) Treatment with an oxidizing agent after recovery of iron hydroxide (scheme 1), removal of ammonia by addition of sulfuric acid and calcium hydroxide to pH 10, followed by keeping of the resulting solution for several hours and decomposition of the thiosulfate by addition of concentrated sulfuric acid to pH 1, with the subsequent keeping and separation of precipitated sulfur by filtration.

(3) Treatment with an oxidizing agent after recover of iron hydroxide, decomposition of the thiosulfate with a strong acid (scheme 2) and isolation of EDTA in the crystalline form by addition of sodium hydroxide to pH 2, keeping for EDTA crystals to be formed, and separation of the solution by decantation or filtration.

(4) Solidification in the form of gypsum of the liquid waste produced by scheme 3, by addition of calcium hydroxide to pH 6–7.

A study of the technological schemes for BFS detoxication demonstrated that the degree of oxidation of BFS components by different detoxication schemes is the same: 98–99% and more. This enables us to recommend the first scheme for use in small photographic mini laboratories.

However, the most efficient and economically favorable is scheme 3, in which sodium peroxocarbonate used as oxidizing agent is introduced after a preliminary recovery of components. The chosen method provides the minimum expenditure of the oxidizing agent ($\leq$ 3–5 g l^{-1}) and recovery of valuable components. If the total dose of acid and alkali is raised in this scheme from 50 to 300–400 g l^{-1}, the most complete solution detoxication (up to 99.9%) is achieved in BFS processing.

Because BFS show, after detoxication, an acid reaction (pH 1–2) and contain a large amount of sulfate ions, calcium hydroxide can be used for neutralization of this solution. This reaction will yield gypsum and this, in turn, will totally preclude formation of any liquid waste.

BRIEF COMMUNICATIONS

A New Promising Method for Processing of Serpentinites

N. O. Zulumyan, A. R. Isaakyan, and Z. G. Oganesyan

Institute of General and Inorganic Chemistry, National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia

Received November 18, 2005; in final form, March 2007

Abstract—A new thermal-acid method for processing of serpentinized ultrabasic rocks was developed. The method makes it possible to recover, in a very short time and in good yield, magnesium and iron(III) in the form of salts (hydroxides or oxides) and two varieties of SiO_2 as an aqua silica gel and light silica.

DOI: 10.1134/S1070427207060353

Of particular importance for the development of national economies of numerous countries is elaboration of new methods for processing of such complex rocks as ultramafites. For example, such rocks as dunites, peridotites, pyroxenites, and their varieties form large mountain massifs in various continents of the Earth. It should be noted that serpentinized rocks widely occur in the Caucasian region. In Armenia, they, in particular, contain (%): 38–40 SiO_2, 37–41 MgO, 4 FeO_2 and about 15 Fe_2O_3, Al_2O_3, Cr_2O_3, NiO, CoO, etc. [1].

Recently, a new technique for thermal-acid processing of serpentinized ultrabasic rock has been developed [2]. Processing of rock by this method results in that salts of magnesium and iron(III) and a major part of SiO_2 in the form of orthosilicic acid pass into solution, and the acid is recovered using a sol–gel technique.

Production of an aqua silica gel by the method suggested can be regarded as a new, third method, because only two widely used techniques for synthesis of aqua silica gels by means of sol–gel processes have been known until recently: from soluble silicates and such silicon-containing compounds as SiH_4, $SiCl_4$, and $Si(OR)_4$ [3].

EXPERIMENTAL

The essence of the method developed consists in that serpentinite preliminarily calcined at 650–700°C is treated with dilute acid during several minutes. The resulting sludge is decanted and filtered [4, 5]. In the process, up to 95% of MgO and up to 80–90% of Fe_2O_3 pass into solution, as also does SiO_2 whose amount depends on the degree of rock serpentinization and on the variety of the primary mineral [6].

It has been believed until recently that, in thermal treatment of serpentinized rock at 600–800°C, there simultaneously occur two processes: removal of the constitution water and amorphization of serpentinite [7]. It has been found that the removal of the constitution water in this temperature range is accompanied by disintegration of the silicate network of serpentinite, and just the latter is the reason why orthosilicic acid passes into solution in acid treatment [4]. The degree of disintegration varies with the type of the primary rock (dunite, peridotite, pyroxenite) subjected to serpentinization. This is confirmed by the fact that different amounts of orthosilicic acid are obtained in solution. The table lists the percentage content of orthosilicic acid obtained from various

Degree of recovery of orthosilicic acid from various samples

Sample	SiO_2, %
Apodunite serpentinite:	
4135*	31.0
4246	37.6
4248	30.2
Apopyroxenite serpentinite 4147B	10.4
Partly serpentinized variety:	
4247	17.3
4254	9.80

* Number assigned by the authors.

samples of serpentinites. It can be seen that the yield of SiO_2 in thermal-acid processing of apodunite serpentinites exceeds that for apopyroxenite or other partly serpentinized varieties. It is noteworthy that, occasionally, the degree of SiO_2 recovery into solution is as high as 60%.

Numerous studies have shown that oxidation of Fe^{2+} ions, present in a mineral, to Fe^{3+} also favors disintegration of silicate networks of serpentinite. It is quite natural that, in this state, the interaction of silicate anions with ions of magnesium and iron(III) is unstable, and, therefore, the mineral readily enters into an ion-exchange reaction with both strong and weak acids.

One of the simplest variants of the disintegration of serpentines $Mg_6(Si_4O_{10})(OH)_8$ in the temperature range 600–800°C can be represented as

$$n\mathrm{Mg_6(Si_4O_{10})(OH)_8} \rightarrow 2n\mathrm{Mg_2SiO_4} + \mathrm{Mg_{2n}(Si_2O_6)_n} + 4n\mathrm{H_2O}. \quad (1)$$

Occasionally, forsterite Mg_2SiO_4 and enstatite $Mg_2(Si_2O_6)$ may be in the crystalline state [7], as indicated by X-ray diffraction patterns of calcined samples, but this does not affect the rate of ion-exchange reactions between forsterite, enstatite, and acids, which occur in accordance with the equations,

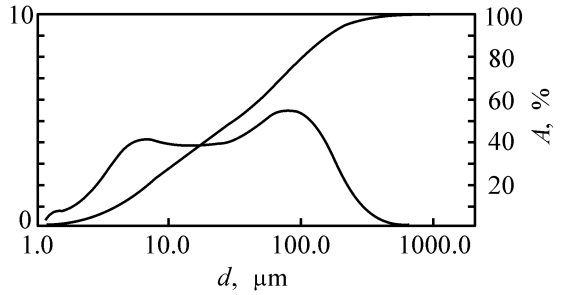
$$\mathrm{Mg_2SiO_4} + 4\mathrm{H^+} \rightarrow \mathrm{H_4SiO_4} + 2\mathrm{Mg^{2+}}, \quad (2)$$

$$\mathrm{Mg_{2n}(Si_2O_6)_n} + 4n\mathrm{H^+} \rightarrow \mathrm{H_{4n}(Si_2O_6)_n}\downarrow + 2n\mathrm{Mg^{2+}}. \quad (3)$$

It was demonstrated that, after a chemical reaction, metal salts, orthosilicic acid, and part of oligosilicic acid easily penetrate into solution through a filter. The resulting solution may contain about 8 g l^{-1} of SiO_2 and can remain in a stable state for a long time. It was also found that Fe^{3+} ions strongly affect the stability of this solution.

The aqua gel of orthosilicic acid can be easily recovered from solution, and, after filtration and washing at pH 6.5–7, a stable gel mass is formed with $\nu(SiO_2)/\nu(H_2O) \approx 1 : 65$. It was found that, depending on the method used to remove water from this mass, $SiO_2 \cdot nH_2O$ with different physical characteristics are formed.

The specific surface area of $SiO_2 \cdot nH_2O$ produced by one of these methods and treated at 300°C is 542 m^2 g^{-1}, and the particle size distribution is as follows (%): 10, up to 4.1 μm; 50, up to 30 μm; and 90, up to 146 μm. The measurements were made by the BET technique (see figure).



Differential particle size distribution of SiO_2 particles. (*d*) Particle size and (*A*) content of particles.

It can be seen from the data presented above that there exists a certain disagreement between the values of the specific surface area and the calculated particle sizes. A possible reason is that orthosilicic acid undergoes polycondensation in the acid medium and a high concentration of Mg^{2+} and Fe^{3+} ions is present, which probably leads to formation of specific aqua silica gel units. Heating of these units, with removal of bound water, leads to agglomeration of the forming highly dispersed $SiO_2 \cdot nH_2O$ particles. It should be noted that, owing to the polycondensation of orthosilicic anions, uniform acid centers are formed in the silica gel. This fact was taken into account when using this silica gel as a catalyst support.

The specificity and high purity of the silica gel obtained also enable its use in manufacture of optical glass and synthesis of nanocomposite materials [8].

After decantation and filtration of the solution obtained, silica containing 12% MgO and 8% Fe_2O_3 remains on the filter. Subsequent acid treatment of this silica gives an active light silica powder with a purity exceeding 99.5%.

According to preliminary calculations, the method suggested can produce up to 400–420 kg of MgO, 70–80 kg of Fe_2O_3, 120–150 kg of SiO_2 in the form of an aqua silica gel, and 280–300 kg of active silica powder from a ton of thermally treated serpentinite.

CONCLUSIONS

The suggested thermal-acid treatment method opens up new opportunities for processing of serpentinized ultramafites. It is not only a new technologically convenient and economically feasible method for production of magnesium and iron(III) compounds, but also new technique for production of a special silica gel and light silica powder.

If compounds of chromium, cobalt, and nickel and other compounds are originally present in the rock,

the unreacted residue obtained after decantation can serve as a concentrate of these compounds.

BRIEF COMMUNICATIONS

Relationship between Fluid and Vapor Densities and Enthalpy of Evaporation

A. I. Levinskii

Received April 12, 2006; in final form, January 2007

Abstract—A simple semiempirical formula relating the enthalpy of vaporization to the densities of a fluid and a vapor in equilibrium with this fluid is derived.

DOI: 10.1134/S1070427207060365

It is known [1] that the interaction energy of two molecules is well described by the Lennard–Jones potential, which can be represented as

$$\psi(r) = a/r^6 - b/r^{12}, \quad (1)$$

where r is the distance between molecules, and a and b are constants.

Let us consider a molecule in a fluid that is in equilibrium with its vapor. This molecule interacts with all other molecules of the fluid in accordance with formula (1), and the interaction energy is equal to the sum of energies of interaction with all molecules of the given volume of the fluid. Let us denote the molar volume of the fluid by V_f. Then the number of molecules in unit volume $n = N_A/V_f$, where N_A is the Avogadro number. The number of molecules in a spherical layer of radius r and thickness dr is d$n = (N_A/V_f)4\pi r^2 dr$. The energy of interaction of a molecule with molecules from this layer is given by

$$dE = \left(\frac{a}{r^6} - \frac{b}{r^{12}}\right)\frac{N_A}{V_f}4\pi r^2 dr,$$

and the full interaction energy, by

$$E = 4\pi\frac{N_A}{V_f}\int_R^\infty\left(\frac{a}{r^6} - \frac{b}{r^{12}}\right)r^2 dr = 4\pi\frac{N_A}{V_f}\left(\frac{a}{3R^3} - \frac{b}{9R^9}\right),$$

where R is the distance to the nearest-neighbor molecule.

The distance between the nearest molecules can be related to the volume v occupied by a single molecule by $v = kR^3$, where k is the structural factor close, in order of magnitude, to unity (for the cubic packing of molecules, $k = 1$; $k = \sqrt{3} \approx 1.732$ if the volume occupied by a molecule is tetrahedral, and $k = \pi/6 \approx 0.524$ if it is spherical). Then the molar volume of the fluid $V_f = kN_AR^3$, whence follows that $R^3 = V_f/kN_A$ and the interaction energy $E = 4\pi\frac{N_A}{V_f}\left(\frac{akN_A}{3V_f} - \frac{bk^3N_A^3}{9V_f^3}\right)$. If we introduce designations $A' = 4\pi N_A^2 ak/3$ and $B' = 4\pi N_A^4 bk/9$, the interaction energy can be represented as $E = A'/V_f^2 - B'/V_f^4$. Taking into account that the fluid density $\rho_f = M/V_f$, where M is the molecular weight and introducing designations $A = A'/M^2$ and $B = B'/M^4$, we finally obtain

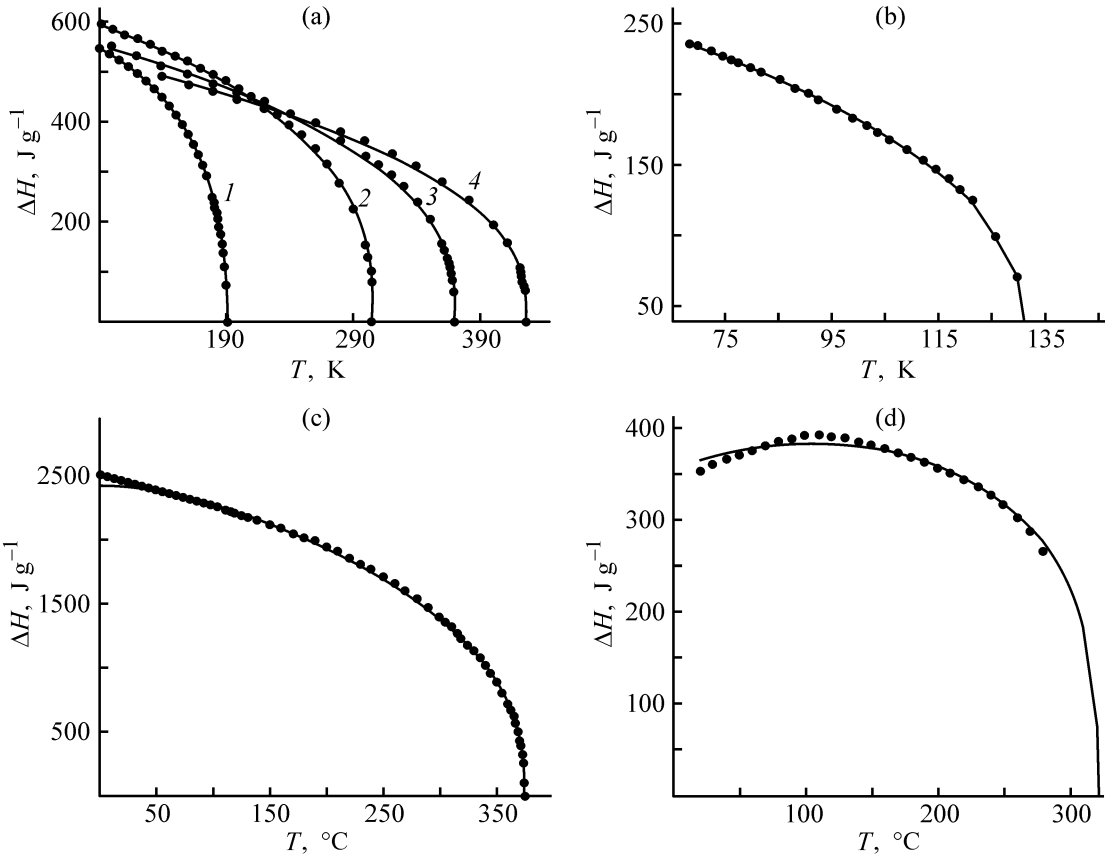
$$E = A\rho_f^2 - B\rho_f^4. \quad (2)$$

Formula (2) is valid for a real gas.

The vaporization of a molecule can be represented as occurring in two stages: (1) removal of the molecule from the fluid volume into a vacuum, with an energy $A\rho_f^2 - B\rho_f^4$; and (2) transfer of the molecule from a vacuum into the vapor volume, with an energy $A\rho_v^2 - B\rho_v^4$ released. Thus, the enthalpy of vaporization can be represented as the difference of these two energies:

$$\Delta H = A(\rho_f^2 - \rho_v^2) - B(\rho_f^4 - \rho_v^4). \quad (3)$$

To compare the values calculated by formula (3) with those obtained experimentally, we used published data [2]. We chose seven fluids: homologous series of methane (methane, nonpolar nearly spherical molecules; ethane, propane, and butane, virtually non-



Enthalpy of vaporization, ΔH, vs. temperature T for various fluids. (a) (*1*) methane (A = 4079.65, B = 6904.1), (*2*) ethane (A = 2213.33, B = 1925.62), (*3*) propane (A = 1634.26, B = 1124.35), (*4*) butane (A = 1350.45, B = 809.45); (b) carbon dioxide (A = 460.28, B = 184.37); (c) water (A = 3069.93, B = 647.72); and (d) acetic acid (A = 846.73, B = 469.50). *Lines*, calculation by formula (3); *points*, experimental data [2]. For rms deviations of the calculated curves from the experimental points, see text.

polar nonspherical molecules), carbon monoxide (polar molecules), water, and acetic acid (preence of a hydrogen bond). The results obtained are shown in the figure. Parameters A and B were found by the generalized least-squares method, i.e., so as to minimize the root-mean-square deviation of the calculated curve from experimental data (discrepancy). It can be seen that formula (3) is in good agreement with the experiment for fluids whose molecules have a nearly spherical shape and contain no hydrogen bonds: the rms deviation from the theoretical curve from the experimental points is 1.2 J g^{-1}, or 0.22% relative to the highest enthalpy of vaporization, for methane and 1.4 J g^{-1}, or 0.58%, for carbon monoxide). The agreement is somewhat poorer in the presence of a hydrogen bond (rms deviation of 26 J g^{-1}, or 1.0%, for water and 5.4 J g^{-1}, or 1.4%, for acetic acid) or in the case of strongly nonspherical molecules (4.9 J g^{-1}, or 0.83%, for ethane; 4.3 J g^{-1}, or 0.78%, for propane; and 5.4 J g^{-1}, or 1.1%, for butane). This is presumably accounted for by the fact that the dependence of the hydrogen bond energy on the intermolecular distance differs from the function specified by the Lennard–Jones potential, which is also the case in interaction of strongly nonspherical molecules.

Formula (3) can be used for practical purposes. To do so, it is necessary to know a single function (temperature dependence of the fluid density ρ_f) and two parameters, A and B. There is no need to know the temperature dependence of the vapor density, because it can be readily calculated using the known empirical rule: the sum of fluid and vapor densities linearly depends on temperature.

Also known are other formulas making it possible to calculate the enthalpy of vaporization, e.g., the Wattson formula [3]:

$$\frac{\Delta H_2}{\Delta H_1} = \left(\frac{1-\tau_2}{1-\tau_1}\right)^n.$$

This formula compares the calculated enthalpy of vaporization, ΔH_2, with the enthalpy of vaporization of a chemically related fluid, ΔH_1; τ_2 and τ_1 are "reduced" temperatures. This means that only a single function, $\Delta H_1(T_1)$, and three parameters (n, triple point temperature T_2^0, and critical temperature T_2^*) should be known for a practical calculation. In this case, the calculation error is 8–13% [3]. Thus, the accuracy of formula (3) suggested for calculating the enthalpy of vaporization is an order of magnitude better.

BOOK REVIEWS

Teplinskii, Yu.A. and Mamaev, N.I., *Korrozionnaya povrezhdaemost' podszemnykh truboprovodov* (Vulnerability of Underground Pipelines to Corrosion Damage),

St. Petersburg: Info-da, 2006, 406 pp.

DOI: 10.1134/S1070427207060377

The lack of an efficient corrosion protection of metallic members of apparatus and machines and of underground metallic constructions leads to a huge loss of metals. By 1990, the annual corrosion loss of metals in our country was estimated at 20 million tons [*Zashchita podzemnykh metallicheskikh sooruzhenii ot korrozii* (Corrosion Protection of Underground Metallic Constructions), Moscow: Stroiizdant, 1990]. A considerable fraction of this loss is associated with underground pipelines. The corrosion damage to important underground communications has a strongly detrimental effect on the country's economy and lead to irreversible ecological consequences. In view of the steadily expanding network of underground pipelines, their protection from various corrosion effects is of primary importance.

The industrial-technological book by Yu.A. Teplinskii and N.I. Mamaev is devoted to the problem of corrosion protection of underground natural-gas pipelines, primarily in the North-West region of the country. The book comprises an introduction, ten chapters, list of designations, and bibliographic list.

In the introduction (pp. 3–7), the authors mention extension of the service life of various kinds of metalwork and prevention of accidents as the most important task for specialists engaged in corrosion protection. In 2003, the total length of underground gas pipelines used by Gazprom Open Joint-Stock Company was 178.3 thousand kilometers. Of these pipelines, 44.7% have been in service for more than 20 years. The first chapter (pp. 8–36) considers in a rather popular form main kinds of corrosion damage, typical of underground pipelines. Stress corrosion, leakage-current corrosion, and methods and means of protection are discussed.

The second chapter (pp. 37–92) is devoted to analysis of the state of the corrosion protection of underground pipelines in the North-West region of Russia, working zone of Severgazprom Ltd. The existing methods for protection of main pipelines, principal reasons for damage to pipelines and the nature of this damage, and various corrosion-caused accidents are described. The third (pp. 93–134) and fourth (pp. 135–166) chapters are concentrated on cases of pitting of pipes of main gas pipelines. The fifth chapter (pp. 167–208) presents examples of stress-induced corrosion cracking of pipes made of various steels. The sixth chapter (pp. 209–231) analyzes corrosion processes associated with leakage currents.

The small seventh chapter (pp. 232–245) discusses accidents on neighboring objects, caused by corrosion of pipelines. The eighth chapter (pp. 246–297) contains evidence about laboratory tests of pipeline steels for corrosion resistance, corrosion-mechanical properties, and susceptibility to stress-induced corrosion cracking. The ninth chapter (pp. 298–342) considers the possibility of assessing the working capacity of pipes that suffered from various kinds of corrosion damage. The tenth chapter (pp. 343–389) is devoted to methods for maintenance of long-working gas pipelines. These are primarily aimed to reveal damage to insulating coatings and their repair.

The bibliographic list (pp. 393–404) contains references to 131 publications, including various regulation documents. In view of the steadily expanding network of gas pipelines, wear of pipes, and necessity for their corrosion protection, the usefulness of publication of the book is beyond any doubt. The book presents a large number of particular examples of corrosion damage to underground gas pipelines, analyzes accidents, and includes a widely diverse illustrative material and photographs.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Recovery of Metals from Raw Materials of Industrial Origin

V. Ya. Khentov, L. N. Velikanova, V. V. Semchenko, and A. B. Slabinskaya

Abstract—Interaction of *d* elements and their compounds (oxides, sulfides, carbonates, and other compounds poorly soluble in water) with organic ligands in aprotic solvents was studied. Methods for recovery of metals from nonaqueous solutions of the resulting complex compounds are suggested.

DOI: 10.1134/S1070427207070014

The capability of metal compounds for donor–acceptor interaction with organic ligands dissolved in organic solvents can be used as a basis for a technique for recovery of metals from mining tailings, spent catalysts from organic synthesis, and wastes from breakdown of finely disseminated ores.

Compounds of *d* elements (oxides, sulfides, carbonates, and other compounds poorly soluble in water) readily enter into donor–acceptor interaction with organic ligands dissolved in aprotic solvents [1, 2]. The resulting complex compound of a metal is in the dissolved state. The metal can be recovered from the solution by reduction [3]. Surface oxide compounds are involved in the interaction of *d* elements with ligands [4]. The logarithm of the reaction rate constant is directly proportional to the electrophilicity parameter E_T [5] characterizing the solvent. Values of E_T have been obtained for different solvents by studying the effect of a solvent on the electronic spectra of a standard solvatochromic dye, *N*-(4-oxy-3,5-diphenyl)phenyl-2,4,6-triphenylpyridinium betaine.

The aim of this study was to examine the effect of the nature of a metal, concentration and nature of a ligand, temperature, and introduction of proton-donor additives in order to develop a technique for processing of raw materials of industrial origin. We studied the following *d* metals: copper, nickel, iron, manganese, chromium, vanadium, titanium, molybdenum, tungsten, cadmium, and cobalt; as well as oxides, hydroxides, sulfides, phosphates, and carbonates of the *d* metals. Benzene, 1,4-dioxane, hexane, ethyl acetate, trichloroethylene, trichloroethane, dimethylformamide (DMF), dimethyl sulfoxide, acetone, acetonitrile, carbon tetrachloride, and methylpyrrolidone were used as aprotic solvents. The solvents were dried over molecular sieves. As ligands served salicylalaniline (SA) $C_6H_4OHCNC_6H_5$, α-benzoin oxime $C_6H_5CH(OH)C{=}NOH(C_6H_5)$, tetracyanoquinodimethane $(CN)_2C{=}C_6H_4{=}C(CN)_2$, and 1-nitroso-2-naphthol $NOC_{10}H_6OH$.

EXPERIMENTAL

We chose for study those *d* elements and their compounds which are contained in raw materials of industrial origin. These are wastes from abrasive processing of steel at machine-building plants and dust wastes, mining tailings, spent catalysts from organic synthesis, and finely disseminated ores. In chemical composition, these are *d* elements and their compounds poorly soluble in water (oxides, sulfides, carbonates, phosphates).

Metals in the form of 30 × 20 × 1 mm plates with a total surface area of 13 cm^2 (calculated as the sum of areas of all faces of a rectangular parallelepiped) or dispersed particles and compounds of these metals were treated in 60 ml portions of ligand solutions at a working propeller mixer (200 rpm). DMF was used as a solvent. To determine the effective surface area of dispersed particles, we measured their size with a measuring microscope, plotted a histogram, and found the most probable effective diameter of a particle. This enabled us to calculate the specific surface area of the powder and find the total surface area of the powder for each weighed portion. The rate of the chemical reaction (mol cm^{-2} h^{-1}) was calculated with account of the total surface area of a compact or powdered sample.

The concentration of the solution of the complex compound obtained was determined from the optical

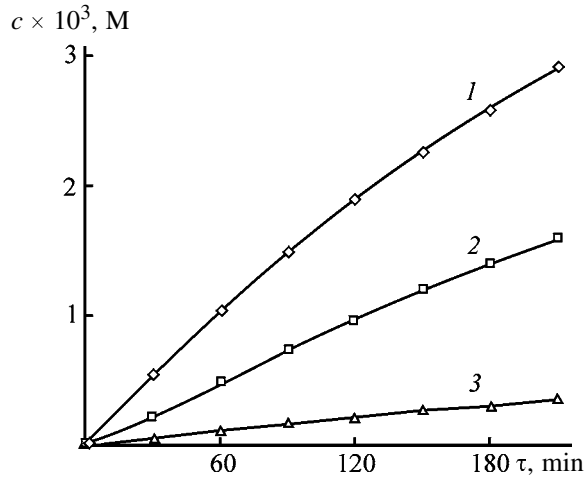

Fig. 1. Variation of the concentration of a complex compound with time τ. Powder: (*1*) copper with an oxide surface film, activated in a 30 g l^{-1} HCl solution for 30 s; (*2*) copper(I) oxide; and (*3*) copper(II) oxide.

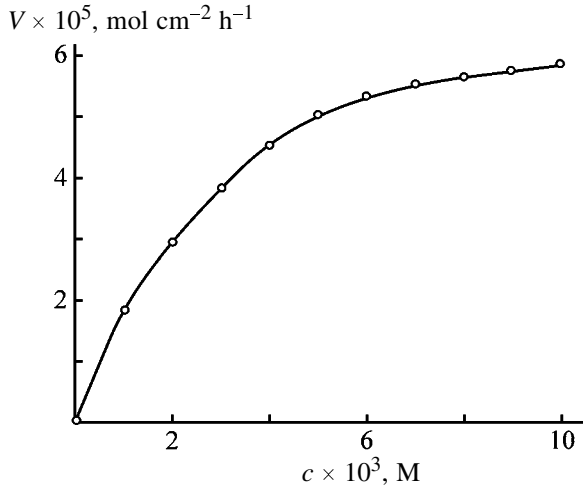

Fig. 2. Interaction rate *V* vs. the salicylalaniline concentration *c*.

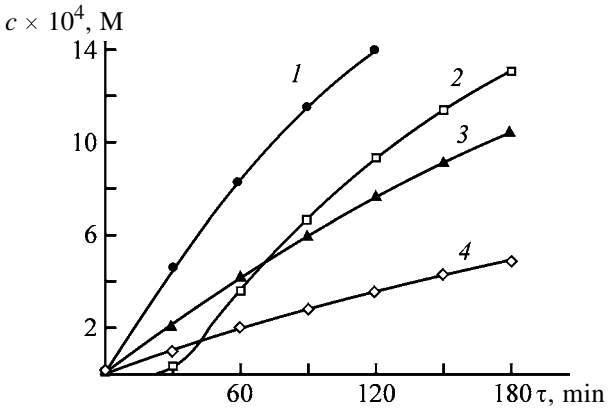

Fig. 3. Variation of the concentration of complex compounds *c* with time τ at varied ligand nature. Powdered copper, dimethylformamide as solvent. Ligand: (*1*) salicylalaniline, (*2*) α-benzoin oxime, (*3*) 1-nitroso-2-naphthol, and (*4*) tetracyanoquinodimethane.

density of the solution. Preliminarily, we plotted the corresponding calibration dependences. For this purpose, we synthesized complex compounds by the classical techniques. To identify the complex compounds synthesized by these techniques and those obtained in this study, we measured IR spectra in the range 3700–400 cm^{-1} on a Specord 75-IR instrument. Simultaneously, we determined the weight loss by the samples under study.

Metals react with solutions of a ligand in an aprotic solvent only in the presence of atmospheric oxygen, with no chemical reaction occurring in nitrogen. Hence follows that the surface oxide film enters into a reaction with the ligand. The oxide film is involved in the formation of a complex compound, this compound passes from the reaction zone into the solution, dissolved oxygen oxidizes the metal surface, and the process of formation of the complex compound is repeated [6].

It should be noted that the surface oxide reacts with the ligand at a higher rate, compared with the bulk oxide phase. Figure 1 shows how the concentration of the complex compound formed in the interaction of powdered copper and copper oxides with an SA solution in DMF varies with time. Similar results were obtained for copper sulfide.

A study of the temperature dependence of the process rate enabled us to calculate the activation energy of the reaction between copper or its oxides and SA. The activation energy was (kJ mol^{-1}) 36 ± 3 for the copper powder with an oxide film, 54 ± 4 for copper(I) oxide, and 71 ± 3 for copper(II) oxide.

Figure 2 shows how the rate of the donor–acceptor interaction of compact copper depends on the concentration of SA in DMF. The process rate is described by the equation of a first-order reaction. We determined the reaction order using the van't Hoff and Ostwald–Noyes method. The leveling-off run of the curve suggests that, as the ligand concentration increases and the complex compound is accumulated in solution, this hinders the removal of the complex compound from the reaction zone and the supply of oxygen to the metal surface through the solvent to form an oxide film. Thus, there exists a range of optimal ligand concentrations at which the rate of metal dissolution is high.

The effect of the ligand nature on the reactivity of metals is illustrated for the example of copper by Fig. 3. The rate of interaction between copper and a ligand decreases in the following order: SA > α-benzoin oxime > 1-nitroso-2-naphthol > tetracyanoquinodimethane.

Table 1. Relationship between the activation energy of interaction between metals and salicylalaniline, E_a (kJ mol^{-1}), and physical parameters of metals

Parameter	Functional dependence	R	Significance level
Binding energy E_b [7], kJ mol^{-1}	$E_a = -426.380 + 5.396E_b$	0.90	0.098
Melting point T_m, °C	$E_a = -333.323 + 0.315T_m$	0.96	0.172
Boiling point T_b, °C	$E_a = -1008.945 + 0.401T_b$	0.83	0.172
Surface energy of a crystallization nucleus, W [8], erg cm^{-1}	$E_a = -278.004 + 1.695W$	0.96	0.042
Atomic concentration of elements, $c_{at} \times 10^{-22}$ [7], cm^{-3}	$E_a = -1334.403 + 162.576c_{at}$	0.92	0.078

We revealed within a single period a relationship between the activation energy of the interaction of metals with SA and the physical parameters of the metals (Table 1). Presumably, all the physical parameters are related to oxidation of the metal surface. Indeed, there exist reliable linear relationships, with high correlation coefficients R, between the standard heat ΔH^0 of formation of oxides of metals in the lowest oxidation state (Cu_2O, FeO, CoO, NiO) and such physical parameters of metals as internuclear distance a, characteristic Debye temperature θ, and surface tension of a metal in the liquid state σ:

$$\Delta H^0 = -915.552 + 342.713a, \quad R = 0.98;$$

$$\Delta H^0 = 28.338 - 0.197\theta, \quad R = -0.98;$$

$$\Delta H^0 = 13.810 - 0.041\sigma, \quad R = -0.92.$$

Te rate of dissolution of the surface metal oxide film in an SA solution in an aprotic solvent is determined by the nature of a metal. Table 2 lists the dissolution rates of an oxide film on the metal surface and the activation energies of the process.

We obtained linear dependences of the logarithm of the reaction rate constant, $\log k$, on the electrophilicity parameter E_T characterizing a solvent. For oxygen-free solvents,

$$\log k = -14.43 + 0.31E_T, \quad R = 0.98.$$

For oxygen-containing solvents,

$$\log k = -10.49 + 0.19E_T, \quad R = 0.97.$$

In view of the aforesaid, prospects open up for removal of oxide films from the surface of a metal and metallic substrates, e.g., from the surface of optical materials. In addition, it seems possible to recover metals from wastes formed in abrasive processing at machine-building plants and from dust wastes. As the main reagent serve solutions of an organic ligand in an aprotic solvent.

To examine the possibility of metal recovery from ores, we analyzed dissolution of oxides, spinels, and preliminary ground finely disseminated minerals in solutions of SA in DMF. The iron–copper spinel was synthesized by sintering oxides at 1200°C. The composition of the spinel was confirmed by X-ray diffraction analysis. Table 3 lists the rates and activation energies of dissolution of preliminarily compacted pellets of area 1 cm^2.

It should be noted that the dissolution rate and the degree of recovery increase if the ligand solution is bubbled with air. This may be due to enhancement of mass-exchange processes at the solid–liquid phase boundary.

A topical problem is utilization of spent catalysts from industrial organic synthesis, composed of metal oxides and organometallic compounds of copper, bismuth, nickel, and chromium. For example, the re-

covery of copper in treatment of a copper–bismuth catalyst (150.1 g kg^{-1} copper and 26.3 g kg^{-1} bismuth) in a system composed of SA (0.01 M) and DMF occurs at a rate of 97.3 g h^{-1} m^{-2}, with a degree of recovery equal to 78%. For the copper–nickel–chromium catalyst (124.4 g kg^{-1} copper, 81.0 g kg^{-1} nickel, and 29.9 g kg^{-1} chromium), the rate and degree of recovery were, respectively, 78.7 g h^{-1} m^{-2} and 77% for copper, 20.6 g h^{-1} m^{-2} and 81% for nickel, and 29.9 g h^{-1} m^{-2} and 84% for chromium.

Of particular interest is recovery of metals from dust discharged from industrial plants. This can be done by bubbling washing of a dusty gas, with a simultaneously occurring chemical reaction. For this purpose, a dust–gas flow was directed into a solution of SA in DMF. Dust particles had an average size of 160 μm. The SA concentration was 0.1 M, and the solution volume, 60 ml. Air was supplied at a rate of 4 l min^{-1} (average bubble size 8 mm, depth of bubble floating-up 10 cm), and the solid phase, at a rate of 0.008 g min^{-1}. Table 4 lists the results obtained in a study of dissolution of dust particles delivered into the ligand solution directly with a dust–gas flow by bubbling or introduced directly into the solution.

It should be noted that the dissolution rate and, especially, the degree of metal recovery appreciably increase if the solution is bubbled with the dust–gas flow. The activation energy of the chemical reaction in activation of copper particles in the dust–gas flow was 18 ± 1 kJ mol^{-1} against 28 ± 2 kJ mol^{-1} in the direct interaction of the copper powder with the solution. The activated nature of the interaction of copper particles may be associated with tribocharging in the dust–gas flow. We determined the charge of dust particles. When passing the dust–gas flow between oppositely charged plates, we observed adhesion of the powder to one of these plates. Cu particles were positively charged, whereas CuS, V_2O_3, and VO_2 particles carried a negative charge. When passing powders taken from the reaction vessel between the capacitor plates, no powder adhesion was observed. The increase in the rate of the chemical reaction may be due to a rise in the chemical potential of dust particles upon their charging. In accordance with the Guggenheim equation, the chemical potential of a charged particle is given by

$$\mu = \mu_0 + ZF\Psi,$$

where μ is the chemical potential of a particle in the gas flow; μ_0, chemical potential of a particle; Z, number of electrons attached to the particle; F, Faraday constant; and Ψ, potential acquired by the particle in the flow.

Table 5 summarizes the results of our studies of metal recovery from raw materials of industrial origin. A metal can be recovered by decomposition of a complex compound, reduction with hydrazine, and electrochemical reduction from nonaqueous solutions of a complex compound [3]. Use of nonaqueous solvents may be of considerable interest, especially for recovery of those metals that cannot be, in principle, obtained in the free state from aqueous solutions. With hydrazine used as a reducing agent, it is thermodynamically possible to perform chemical reduction by the scheme

$$M^{z+}_{DMF-SA} + N_2H_4 \rightarrow M\downarrow + N_2\uparrow + 4H^+_{DMF-SA}$$

In reduction with hydrazine, metals are in an ultradispersed state and exhibit a high chemical activity. In this case, all operations should be performed in an inert atmosphere.

Of particular interest is the possibility of regeneration of spent catalysts from industrial organic synthesis. For this purpose, a catalyst is preliminarily treated with a solution of SA in DMF. In the process, the oxide and organometallic phases of the catalyst are

dissolved. The catalyst support (silica gel, graphite, kaolin) is impregnated with a solution of the complex compounds obtained and then thermally treated at 180°C. Metals are formed on the support surface in the ultradispersed state and are easily oxidized by atmospheric oxygen to oxides. In catalyst regeneration, there is no need to recover each metal. The percentage ratio of metals in the solution of the complex compound corresponds to their content on the catalyst surface. Table 6 lists the rates and degrees of recovery of the metals.

CONCLUSIONS

(1) Metals and their compounds poorly soluble in water can be transferred to the soluble state by interaction with salicylalaniline in nonaqueous solvents.

(2) There exists a linear relationship between the oxidation rate of metals, activation energy of the process, electrophilicity parameter E_T characterizing the solvent, and physical parameters of metals (boiling and melting points, binding energy, atomic concentration of an element).

(3) Metals can be recovered from ores, dust waste, and spent catalysts via complexation with organic ligands in nonaqueous solvents.

(4) The charging of solid particles in their interaction with the liquid reagent accelerates the process.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Interaction of a Carbonate-Containing Reagent with Heavy Metal Ions in Aqueous Solutions

E. M. Bayan, T. G. Lupeiko, and M. O. Gorbunova

Rostov State University, Rostov-on-Don, Russia

Received December 19, 2006; in final form, March 2007

Abstract—Results of interaction of a carbonate-containing water-treatment waste with ions of copper(II), zinc(II), nickel(II), iron(III), and chromium(III) in aqueous solutions are compared.

DOI: 10.1134/S1070427207070026

Modern domestic and foreign technologies for wastewater treatment can provide virtually any required degree of purification, with the economical feasibility of the corresponding methods acquiring primary importance. Of particular interest are low-cost techniques of wastewater treatment. A promising method of this kind is that using water-treatment waste.

Preliminary studies with waste formed in water treatment at a thermal power plant have shown that this material can efficiently remove quite a number of heavy metal ions [1–5]. An analysis of the waste has demonstrated that it is mainly composed of calcium and magnesium carbonates, is homogeneous and finely dispersed, has a comparatively constant composition, and is safe in chemical and radiation regards [6].

In this study, we made a comparative analysis of the results of interaction between this carbonate-containing reagent (CCR) and aqueous solutions of Fe(III), Cr(III), Cu(II), Zn(II), and Ni(II) heavy metal (HM) ions most frequently occurring in wastewater.

EXPERIMENTAL

We studied processes of recovery of HM ions with CCR as follows: a weighed portion of CCR with a particle size of 0.25–0.50 mm was added to 100 ml of a solution being purified, with a prescribed concentration c_{in} (mg l^{-1}) of a metal ion, and the mixture was vigorously agitated for a time τ (min). After that the solutions were filtered. The pH value and the concentration of metal ions in solution were measured before and after contact with the reagent. The degree of recovery of metal ions, DR (%), and the amount of a metal per gram of the reagent, A (mg g^{-1}), were calculated from the difference of the initial and residual concentrations.

The concentration of HM in solution was determined spectrophotometrically by the commonly accepted techniques [7]. The optical density was measured on a KFK-2MP photometer with an error not exceeding 5%. The pH value of the solutions was monitored potentiometrically with an I-120M ion meter with an accuracy as good as ± 0.05 pH units. The phase composition of the starting waste and solid phases obtained in purification was determined by X-ray diffraction analysis on a DRON-2 installation with CuK_α radiation.

We used as starting solutions those with HM concentrations of 50 and 100 mg l^{-1}, typical of wastewater.

The results of our experimental study of recovery of HM ions are listed in Table 1 and shown in Figs. 1 and 2 in relation to time.

The carbonate-containing reagent is based on calcium and magnesium carbonates and just these compounds apparently determine the nature of the interaction between CCR and solutions containing heavy metal ions. Because of the hydrolysis of the carbonate phases, the pH value of an aqueous solution of CCR (CCR : water = 1 : 5) is 8.7 [1]. Therefore, this solution acts as a "soft" neutralizer of acid HM solutions. In this case, the possible final product of HM precipitation is the hydroxide of the corresponding metal.

To achieve virtually complete recovery of metal ions from acidic aqueous solutions in the form of

* Residual metal concentration is lower than 10^{-6} M.

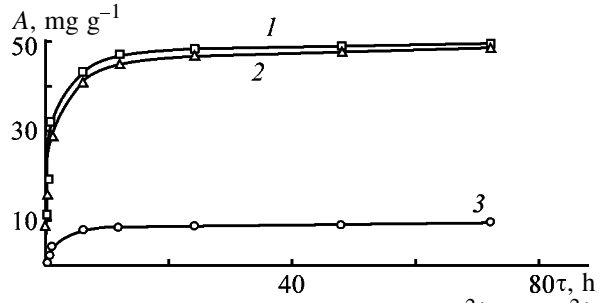

Fig. 1. CCR activity A vs. time τ for (*1*) Cu^{2+}, (*2*) Zn^{2+}, and (*3*) Ni^{2+} ions in purification of solutions containing 50 mg l^{-1} metal ions. CCR added in an amount of 1 g l^{-1}; the same for Fig. 2.

poorly soluble hydroxides, it is necessary to use a definite range of pH values (Table 2) [8]. Taking into account the pH values for a CCR solution, we expect that it can be used for efficient treatment of aqueous solutions to remove Fe^{3+}, Cr^{3+}, Cu^{2+}, Zn^{2+}, and Ni^{2+} ions. In this case, we can predict a number of specific features of the processes that occur with CCR as a precipitating agent. For example, it is apparent that the pH value at which precipitated hydroxides of these metals dissolve is not reached when CCR is used. This precludes "return" of metal ions into solution in the case of an overdose of the reagent.

However, the interaction of the carbonate-containing reagent with HM solutions may involve, in addition to "pure" hydrolysis, also other concurrent processes yielding, together with hydroxides, other poorly soluble compounds. Their solubility products (SP) are as follows: $SP_{MgCO_3} = 2.1 \times 10^{-5}$, $SP_{CaCO_3} = 3.8 \times 10^{-9}$, $SP_{ZnCO_3} = 1.45 \times 10^{-11}$, $SP_{CuCO_3} = 2.5 \times 10^{-10}$, and $SP_{NiCO_3} = 6.6 \times 10^{-9}$ [7], and, consequently, the interaction of CCR with aqueous solutions of these HM may involve an exchange interaction of calcium and magnesium carbonates to give zinc, copper, and nickel carbonates.

In the case of the Cu(II) ion, a basic carbonate of the type $Cu_2(OH)_2CO_3$ may precipitate together with the carbonate, by analogy with the malachite mineral widely occurring in nature, for which the solubility product is 1.7×10^{-34}. Probably, formation of basic carbonates is also possible for the Zn^{2+} and Ni^{2+} ions; however, no reliable data on the structure and solubility products of phases formed in this case can be found in reference books.

In addition to these compounds, mixed carbonates with anions from solution (e.g., Cl^-, SO_4^{2-}) and poorly soluble sulfates (in purification of sulfate solutions) can be formed and other reactions may occur between

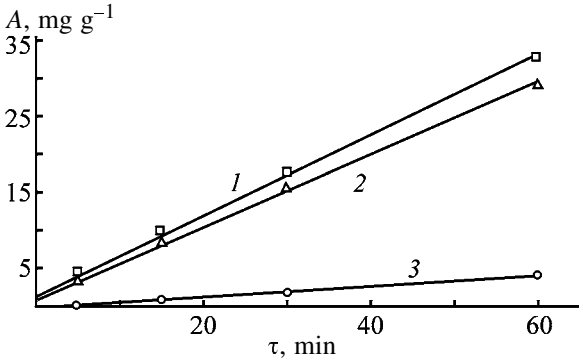

Fig. 2. CCR activity A vs. time τ for (*1*) Cu^{2+}, (*2*) Zn^{2+}, and (*3*) Ni^{2+} ions in the τ range 0–60 min in purification of solutions containing 50 mg l^{-1} metal ions.

CCR components and ions from a solution being purified [1].

The removal of heavy metal ions from solutions with the use of CCR can be represented as a set of the following possible schematic reactions.

Partial dissolution of the carbonate components of CCR to give hydroxy anions:

$$CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-. \quad (1)$$

Mutual enhancement of the hydrolysis of HM salts and carbonates from CCR, to the point of carbon dioxide evolution and precipitation of poorly soluble HM hydroxides:

$$HCO_3^- + H_2O \rightarrow OH^- + H_2CO_3,\ H_2CO_3 \rightarrow H_2O + CO_2 \quad (2)$$

$$M^{n+} + nHOH \rightarrow M(OH)_n\downarrow + nH^+,\ n = 2, 3. \quad (2)$$

Formation of poorly soluble copper, zinc, and nickel carbonates:

$$CaCO_3(s) + M^{2+} \rightarrow MCO_3(s) + Ca^{2+}. \quad (3)$$

Formation of poorly soluble basic carbonates (in the case of Cu^{2+}, Zn^{2+}, Ni^{2+}):

$$CaCO_3(s) + 2M^{2+} + 2HOH \rightarrow M_2(OH)_2CO_3(s) + Ca^{2+} + 2H^+. \quad (4)$$

Formation of mixed carbonates, with anions from solution possibly involved, e.g.:

$$CaCO_3(s) + 2M^{2+} + 2Cl^- \rightarrow M_2(CO_3)Cl_2(s) + Ca^{2+}. \quad (5)$$

Other side reactions of the CCR components with ions from a solution being purified, e.g., gypsum formation from the carbonate-containing component itself is possible in the case of high-concentration sulfate solutions:

$$CaCO_3(s) + SO_4^{2-} + 5H_2O \rightarrow CaSO_4 \cdot 5H_2O(s) + CO_3^{2-}. \quad (6)$$

Reactions (2)–(6) can occur in parallel in the initial period to give a nonequilibrium mixture of poorly soluble products. This process of initial precipitation from solutions occurs rather rapidly. The composition of the products obtained is primarily determined by the SP of the possible poorly soluble reaction products, with the product with a lower SP predominant in the precipitate composition.

Further conversion of the initial mixture into an equilibrium solid phase will consist in dissolution of mixture components having lower SP and in crystallization of those with higher SP. This process will occur at a considerably lower rate, compared with the processes of the first stage.

Thus, the time in which the precipitation of HM with CCR is complete and the final products of their interaction may widely vary from one HM to another.

It can be seen from the results of our study (Table 1) that the precipitation of Fe(III) and Cr(III) compounds from solutions is fast. Fe(III) compounds are virtually completely precipitated from starting solutions with concentrations of 50 and 100 mg l^{-1} in 5 and 15 min, respectively. For Cr(III), these times are 30 and 60 min, respectively.

In these processes, CCR acts as a neutralizing agent and precipitates iron(III) and chromium(III) ions in the form of hydroxide phases (aqua hydroxo complexes).

The hydroxide phases of iron(III) and chromium(III) are poorly soluble and have solubility products ($SP_{Fe(OH)_3} = 6.3 \times 10^{-38}$, $SP_{Cr(OH)_3} = 6.3 \times 10^{-31}$) many orders of magnitude lower than those of the other possible phases. Therefore, virtually no parallel formation of other phases occurs in the interaction of CCR with solutions of iron and chromium salts. Thereby, the subsequent slow processes of mutual transformation of the coprecipitated phases are automatically precluded. Presumably, the somewhat longer time required for the completion of chromium(III) precipitation, compared with precipitation of iron(III), can be attributed to the SP ratio of their hydroxides. As a result, diffusion of ions to and from the CCR surface is the rate-determining stage of the precipitation of hydroxide phases in these systems. Because the precipitation occurs under vigorous stirring, the diffusion rate is rather high and iron(III) and chromium(III) compounds are precipitated in several minutes.

As an indirect confirmation of the mechanism of this kind serve, in the case of iron(III) and chromium(III) ions, X-ray diffraction data. The following phases: $CaCO_3$ (calcite), $MgCO_3 \cdot 3H_2O$, and β-, γ-$Fe_2O_3 \cdot H_2O$, present in the starting reagent (CCR) [1], were found in samples of a precipitate obtained upon solution purification. It should also be noted that a strong background is present in X-ray diffraction patterns, which indicates that amorphous noncrystallized phases are present in the samples.

At the same time, the processes occurring in the case of copper, zinc, and, especially, nickel ions

require a substantially longer time for completion. The difference of copper, zinc, and nickel precipitation processes from those for triply charged metal ions presumably consists in that, in the latter, the precipitation of hydroxide phase is accompanied by concurrent precipitation and subsequent mutual conversion of hydroxide, hydroxo carbonate, carbonate, and other solid phases. The conversion of one solid phase into another is a prolonged process, and, in all probability, just this process is the rate-determining stage in the given case. This explanation is supported by the fact that the solubility products of the hydroxide phases of copper, zinc, and nickel ($SP_{Cu(OH)_2} = 5.6 \times 10^{-20}$, $SP_{Zn(OH)_2} = 4.6 \times 10^{-16}$, $SP_{Ni(OH)_2} = 1.6 \times 10^{-14}$) markedly exceed those of iron(III) and chromium(III) hydroxides. Therefore, formation of other solid phases, in addition to the hydroxide phases, is quite possible in these systems.

CONCLUSIONS

(1) The processes of interaction of a carbonate-containing reagent with copper(II), zinc(II), nickel(II), iron(III), and chromium(III) ions in aqueous solutions were compared and it was demonstrated that the metals can be ranked in the order of decreasing precipitation rate as follows: $Fe^{3+} > Cr^{3+} > Cu^{2+} > Zn^{2+} > Ni^{2+}$.

(2) The main, and the only in the case of iron(III) and chromium(III) ions, process occurring in the precipitation of the ion group under study is the formation of poorly soluble aqua hydroxo complexes because of the mutual enhancement of hydrolysis. Also possible for copper, zinc, and nickel ions is, in addition to hydrolytic precipitation, exchange of calcium(II) and magnesium(II) ions from the carbonate-containing reagent in an aqueous solution for the corresponding doubly charged metal ion to give a less soluble carbonate. In addition to those mentioned above, mixed hydroxo carbonate phases, solid solutions, etc. can also be formed. Also, metal ions can adsorb on the surface of an undissolved reagent and on freshly formed particles.

(3) The results obtained in purification of solutions to remove heavy metal ions with a carbonate-containing reagent demonstrate that this method can be recommended for implementation at industrial plants producing acid wastewater and wastewater containing iron(III), chromium(III), zinc(II), and copper(II) ions.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Optimization of the Process for Synthesis of a Ceramics Based on Lead Ferroniobate

L. E. Pustovaya

Don State Technical University, Rostov-on-Don, Russia

Received October 30, 2006; in final form, January 2007

Abstract—Microstructure, phase transitions, and electrical properties of a ceramics based on lead ferroniobate were considered. The possibility of optimizing the process for synthesis of this ceramics by using a glass-forming additive of lithium carbonate in synthesis via an intermediate phase with a columbite structure in order to provide steadily high pyroelectric properties was analyzed.

DOI: 10.1134/S1070427207070038

It is known that lead ferroniobate $PbFe_{0.5}Nb_{0.5}O_3$ (LFN) is an antiferromagnetic and a ferroelectric with a perovskite structure and exhibits a ferroelectric phase transition with a Curie temperature of 385 K and a transition into a state with magnetic ordering with a Néel temperature of 143 K. As a result, its activity is manifested in posistor, magnetoresistive, ferroelectric, and relaxor properties. The interest in materials based on LFN is due to its multifunctionality [5, 6]. However, the pyroelectric properties of this material have not been examined despite the large number of varied-purpose studies; the occurrence of the $R3m \rightarrow R3c$ phase transition in the ferroelectric range has not been confirmed, either. This circumstance can be attributed to shortcomings of the procedure for synthesis of lead ferroniobate, which result in its high conductivity and dielectric loss tangent and thereby preclude any detailed electrical studies.

EXPERIMENTAL

We chose as object of study the ceramics of the composition: $PbFe_{0.5}Nb_{0.5}O_3$ (LFN); $PbFe_{0.5}Nb_{0.5}O_3$–1 wt % Li_2CO_3, (LFN–Li); $(1 - x)PbFe_{0.5}Nb_{0.5}O_3$–$xPbTiO_3$, where $0.04 < x < 0.09$ mol % (LFN–Ti); $(1 - x)PbFe_{0.5}Nb_{0.5}O_3$–$xPbTiO_3$–1 wt % Li_2CO_3, where $0.02 < x < 0.1$ mol % (LFN–Ti–Li); $(1 - x)PbFe_{0.5}Nb_{0.5}O_3$–$xPbZrO_3$–1 wt % Li_2CO_3, where $0.1 < x < 0.35$ mol % (LFN–Zr–Li). The ceramics was synthesized in the following ways.

(1) Conventional solid-phase technique with varied degree of grinding (grinding time 2, 6, and 24 h).

(2) "Columbite" technique, which consists in that the synthesis is performed via an intermediate phase with a columbite structure:

$$Fe_2O_3 + Nb_2O_5 \rightarrow 2FeNbO_4,$$

$$2PbO + FeNbO_4 \rightarrow Pb_2FeNbO_6.$$

(3) "Semiceramic" method, in which various compounds are precipitated from solutions onto solid oxides, hydroxides, or carbonates of metals, preliminarily suspended in these solutions. In this study, niobium oxide and stoichiometric amounts of iron and lead hydroxides, precipitated with an ammonia solution from solutions of respective salts, served as starting substances.

(4) Hot compaction method. The synthesis was performed in two stages: (i) for 2 h at 700°C and (ii) for 2 h after regrinding (800°C); sintering was carried out at 1100°C for 2 h. The hot compaction was done at 800°C under a pressure of 150 kg cm^{-2} for 40 min.

The materials synthesized were subjected to X-ray diffraction analysis on a DRON-3M diffractometer (U = 35 kV, I = 36 mA) with filtered CuK_α radiation.

The microstructure was studied on polished surfaces with an MI-2E optical microscope. The fine structure of the material was determined with an EVM-100B transmission electron microscope by the method of single-step platinum–carbon replicas [7–9].

Temperature dependences of the pyroelectric constant were studied by the dynamic pyroelectric effect method [10–12].

A microstructural study of the pore distribution demonstrated that addition of lead zirconate or titanate to the LFN ceramics markedly impairs the course of sintering. The number of pores per unit area increases.

Microstructural studies of the LFN ceramics modified with 1 wt % Li_2CO_3 revealed trace amounts of a liquid phase formed at the sintering temperatures (Fig. 1). This phase forms rather thick (up to 0.5 μm) smooth films at grain boundaries and separate grains of the same type at joints between the grains of the main phase. All these facts indicate that the liquid phase is involved in sintering processes: it executes a transport function and facilitates diffusion processes.

The domain structure of the LFN–Li ceramics (Fig. 2) has the form conventional for the rhombohedral symmetry, i.e., it is represented by series of 70(110)-degree domains arranged in two of the eight crystallographic directions possible for rhombohedral modifications. The width of domains in a series is in the range from 0.03–0.05 to 0.1–0.2 μm. The domains have a lamellar shape, their wedging-out frequently occurs along their length. A typical phenomenon is splitting of the domains into thinner wedges. There occur structures of the 180-degree type in the form of arbitrary configurations crossing the 70(110)-degree boundaries.

The LFN ceramics synthesized by the same methods and under the same sintering conditions, but not modified with Li_2CO_3 has high porosity, which is occasionally of the through type because of the connected pores, which hinders studies of both the microstructure (different degrees of recrystallization give no way of selecting an efficient etching mode for all grains) and the electrical properties because of the impossibility of high-quality polarization.

We also examined the effect of stock dispersity on the microstructure and properties of the resulting ceramics. The ceramics obtained from a stock synthesized by methods 2–4 has a homogeneous finely grained structure with grain sizes of 0.1–1.5 μm and uniformly distributed low porosity. In the ceramics obtained from a stock synthesized by method 1 at different degrees of grinding (10–40, 6–10, and <1 μm for 2, 6, and 24 h of grinding, respectively), the grains are coarser (10, 1–5, and 0.5–1.5 μm). Simultaneously, the pores become coarser and their distribution density decreases. On the whole, the granular structure is comparatively homogeneous; however, the pore distribution type reveals a tendency toward development of secondary recrystallization areas, well seen from the distribution of pores and from their sparseness and rejection to the periphery of these areas.

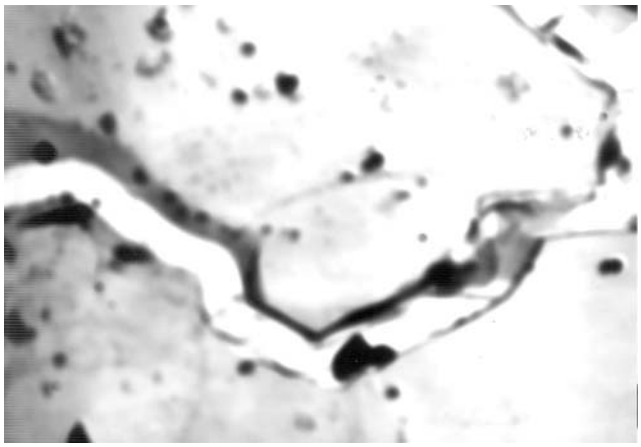

Fig. 1. Film of the glassy phase at grain boundaries in the LFN–Li ceramics. Magnification 16000.

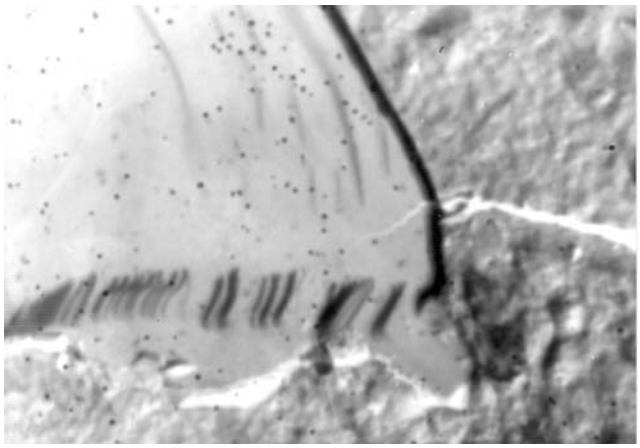

Fig. 2. Domain structure of the LFN–Li ceramics. Magnification 16500.

The ceramics sintered from a stock ground for 2 h (~10 μm) is markedly inhomogeneous and has a coarse-grained structure and a porosity of up to 15–20%. Analysis of the results obtained shows that diffusion processes are combined here, as a driving force of sintering, with interphase processes of dissolution and recrystallization. This is confirmed by the presence of growth steps on the surface of grains of the coarse-porous ceramic (Fig. 3).

Based on the results of X-ray diffraction analyses, we found the unit cell parameters for LFN with 1 wt % Li_2CO_3: a = 4.016 Å and α = 89°54′.

We studied hysteresis loops, from which we determined the residual polarization P_s and coercive field E_c (see table). The table also lists Curie temperatures T_C, dielectric constants ($\varepsilon^{sol}/\varepsilon_0$), dielectric loss tangent $\tan\delta$, and dynamic pyroelectric constant γ_d. The most pronounced pyroelectric properties are ob-

served for the ceramics synthesized by the columbite method with addition of Li_2CO_3. An analysis of the hysteresis loops demonstrated that the reason for the poorer pyroelectric properties of the other types of the LFN ceramics is their high electrical conductivity, especially for the ceramics produced by methods 3 and 4, rather than presence of phases having a cubic symmetry.

The table shows that the ways in which the dielectric constant varies in modification of the lead ferroniobate ceramics with lead titanate and zirconate are different. Upon introduction of titanium ions, the dielectric constant and the Curie temperature substantially increase, which is presumably due to approach to the morphotropic region of the phase transition to the tetragonal symmetry. Addition of zirconium ions leads to a gradual decrease in the dielectric constant and T_C, which indicates that no phase transformations occur in the $PbZrO_3$ concentration range studied. We can also note a significant decrease in the pyroelectric constant at T = 20°C upon LFN–Li modification with lead zirconate, with an increase in the content of the additive having only slight effect on this coefficient. We found that the LFN–Ti–Li and LFN–Zr–Li ceramics have very low coercive field energies, which makes them promising for use in a number of electronic devices.

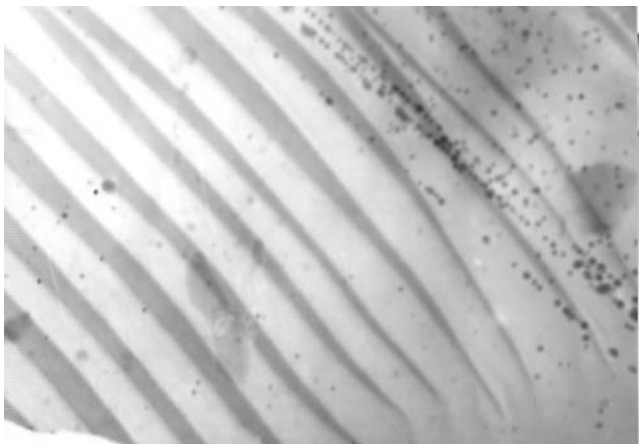

Fig. 3. Growth steps in the LFN–Li ceramics. Magnification 21 000.

We observed no visible anomalies in the temperature dependences of the conductance (*G*–*T*) and capacitance (*C*–*T*) for the materials under study. The temperature dependences of the dynamic pyroelectric constant (γ_d–*T*) and discharge current (*i*–*T*) of the LFN–Li ceramics (Fig. 4) show two distinct peaks: the first at around 97°C, which corresponds to a transition from the low- to high-temperature rhombohedral phase ($R3m \rightarrow R3c$), and the second at 118°C, associated with a transition to the cubic

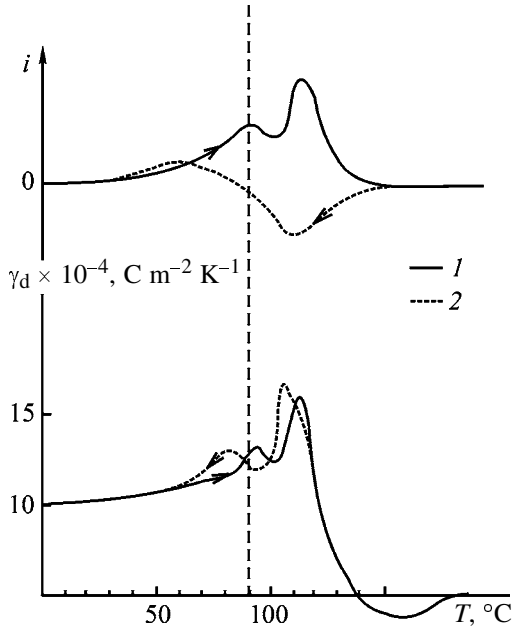

Fig. 4. γ_d and i vs. temperature T for the $PbFe_{0.5}Nb_{0.5}O_3$ + 1 wt % Li_2CO_3 ceramics. Curves: (*1*) heating and (*2*) cooling.

symmetry. The transition $R3m \rightarrow R3c$ is rather broad and shows a temperature hysteresis of approximately 10–15°C, which enables us to identify it as a second-order phase transition of the displacement type. The materials of the systems LFN–Ti, LFN–Ti–Li, and LFN–Zr–LI show in these temperature dependences only a single peak corresponding to a phase transition from the rhombohedral to the cubic crystal system.

We also observed for the LFN–Li ceramics a change in the sign of the γ_d–T dependence after passing the Curie point, which points to existence of fluctuation regions ("dipole glass"). The method of the dynamic pyroelectric effect enabled us to determine the existence range of complexes of this kind in the paraelectric phase.

CONCLUSIONS

(1) The optimal combination of pyro- and dielectric properties of a ceramics based on lead ferroniobate was provided by the columbite technology, with lithium carbonate used as a modifying additive.

(2) The method of the dynamic pyroelectric effect made it possible to determine the temperature ranges of existence of ferroelectric phases and of regions of a "dipole glass" in the paraelectric phase.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Application of Wilson's Method to the Calculation of Thermodynamic Properties of Liquid Ternary Metallic Systems from the Data on Boundary Binary Systems

Abstract—The possibility of applying Wilson's polynomial to the description of concentration dependences of thermodynamic functions in binary liquid metallic systems and to the calculation of thermodynamic properties of ternary systems from the data on boundary binary systems was considered.

DOI: 10.1134/S107042720707004X

At present, calculation methods based on the data on boundary binary systems are widely used to estimate integral thermodynamic functions of ternary and more complicated liquid metallic systems. Both integral values and activities of components in liquid alloys of the Ni–Fe–Co, Ni–Cu–Co, Ni–Cu–Fe, and Fe–Cu–Co systems were calculated in a series of studies aimed to simulate the thermodynamic functions of the Cu–Ni–Co–Fe system [1–6]. Numerous geometric models and a model based on Redlich–Kister's polynomial were used in these calculations. Irrespective of the model applied, the calculated integral thermodynamic functions, full and excess Gibbs energies ΔG and ΔG^{exc} and enthalpies of mixing ΔH, as a rule, agree fairly well with each other. All the models, both geometrical and polynomial, are based on the idea that the thermodynamic properties of ternary and more complicated liquid metallic systems are mainly determined by pair interactions of the components. Ternary interactions do not play an essential role. It is accepted that each binary system makes its independent contribution to the integral thermodynamic characteristic of the mixing process when a ternary or multicomponent system is formed. The difference between rather numerous geometric models consists only in the mode of considering contributions of each of the boundary binary systems. It should be noted that, when Redlich–Kister's polynomial for ternary systems is applied to liquid metal alloys, there is no need in considering coefficients calculated from the data related to the ternary system.

Experimental study of thermodynamic properties of the group of systems under consideration at high temperatures (1350–1600°C) is difficult, which restricts the possibility of direct comparison of the calculated and experimental data. Sufficiently reliable experimental data on thermodynamic properties of liquid alloys are available only for the Ni–Fe–Co [7] and Ni–Cu–Fe [8, 9] systems. In the study of both systems, mass-spectrometric analysis of the vapor phase with Knudsen's cell was applied. The calculations of the integral thermodynamic functions and activities of components in liquid alloys of the Ni–Fe–Co system at 1600°C [5, 10] are in very good agreement with the data of Tomiska [7]. The calculated activities of components in liquid alloys of the Cu–Ni–Fe system at 1350°C [2, 6] are close to the data of Pagador et al. [8, 9].

In studying two other metallic systems, Ni–Cu–Co [3] and Fe–Cu–Co [4], the only reliability criterion was the closeness of the thermodynamic properties calculated using six to eight different geometric models and the polynomial Redlich–Kister's method. Along with the calculation of integral values, the software tools provided an estimation of the corresponding partial quantities and the activity of each of liquid alloy components. This operation was based on the application of the Gibbs–Duhem equation to ternary and multicomponent systems by Darken's method [11].

$$\Delta G_1(x_1,x_2/x_3) = \Delta G(x_1,x_2/x_3) + (1 - x_1)(\partial\Delta G/\partial\Delta x_1)_{x_2/x_3},$$

$$\Delta G_1 = RT\ln a_1. \quad (1)$$

The activities of the two other components can be calculated similarly. The spline function method was used in the differentiation for the analytical representation of the dependence of an integral quantity on the composition along one or another cross section. The program provided also a possibility of estimating partial molar quantities and activities of each of ternary system components in the liquid state on the basis of the corresponding data for boundary binary systems without preliminary calculation of the integral quantities using expressions following from certain geometrical models (Toop's and Kohler's models). The same task can also be solved with the application of Redlich–Kister's polynomial.

As shown previously [12], Redlich–Kister's polynomial of form (2)

$$\Delta G_{12}^{\text{exc}}/RT = x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2 + ...] \quad (2)$$

is well applicable to the description of the concentration dependences of the thermodynamic functions and to the estimation of the limiting activity values for the components γ_1^∞ and γ_2^∞ in liquid metallic systems with various types of interactions between components. It was shown by the example of a wide group of liquid alloys that the increase in degree of polynomial (2) over two, as a rule, does not appreciably affect the difference between the experimental value of ΔG^{exc} and the approximated value [13, 14]. In the case of a ternary system, Redlich–Kister's equation takes form (3).

$$\begin{aligned}\Delta G_{123}^{\text{exc}}/RT = {} & x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2] \\ & + x_2x_3[b_{23} + c_{23}(x_2 - x_3) + d_{23}(x_2 - x_3)^2 \\ & + x_1x_3[b_{13} + c_{13}(x_2 - x_3) + d_{13}(x_1 - x_3)^2 \\ & + x_1x_2x_3[c_1 + d_1x_1 + d_2x_2]. \end{aligned} \quad (3)$$

As noted above, we may neglect the last term in the right part of Eq. (3) containing coefficients c_1, d_1, and d_2 determined from experimental data for a ternary system. Good agreement between the data calculated using Redlich–Kister's polynomial and the experimental data (3) was confirmed in the case of a series of ternary systems [5, 12, 15].

It seems reasonable to expand the number of polynomial models used for the description of concentration dependences of thermodynamic functions in liquid binary metallic systems and for the calculation of thermodynamic properties of ternary and more complicated systems. The polynomial expression offered by Wilson [16] and then modified by Orye and Prausnitz [17] is of interest in this respect. Wilson's equation is applicable to systems with organic components, has a small number of coefficients, and takes the following forms for components of a binary system and a system as a whole.

$$\ln\gamma_1 = -\ln(x_1 + \Lambda_{12}x_2) + x_2\left[\frac{\Lambda_{12}}{x_1 + \Lambda_{12}x_2} - \frac{\Lambda_{21}}{x_2 + \Lambda_{21}x_1}\right], \quad (4)$$

$$\ln\gamma_2 = -\ln(x_2 + \Lambda_{21}x_1) + x_1\left[\frac{\Lambda_{12}}{x_1 + \Lambda_{12}x_2} - \frac{\Lambda_{21}}{x_2 + \Lambda_{21}x_1}\right], \quad (5)$$

$$\Delta G^{\text{exc}} = RT[\ln(x_1 + \Lambda_{21}x_2) + \ln(x_2 + \Lambda_{21}x_1)]. \quad (6)$$

The coefficients Λ_{12} and Λ_{21} are estimated from the experimental values of γ_1 and γ_2 at several compositions, and for ideal systems $\Lambda_{12} = \Lambda_{21} = 1$. At x_1 (or x_2) tending to zero, the activity coefficients γ_1 (or γ_2) approach their limiting values (γ_1^∞ and γ_2^∞). The coefficients Λ_{12} and Λ_{21} are positive at any type of the deviation of a binary system from the ideal behavior and depend on temperature. It is noted in Turkdogan's monograph [18] that Wilson's polynomial well describes the concentration dependences of γ_1, γ_2, and ΔG^{exc} only when a system shows moderate deviations from the ideal behavior, and the best results are obtained at positive deviations.

Tarby and Stein [19] have applied Wilson's model to two liquid binary metallic systems (Cu–Fe, 1550°C; Fe–Ni, 1600°C). In the first system, positive deviations from the ideal behavior were observed, whereas the second system is close to ideal. The calculated activities of the components are close to the experimental data.

The application of certain polynomial expressions with small numbers of fitting coefficients to binary liquid metallic systems with various kinds of the interaction between components was discussed by Choi and Hucke [20]. They confirmed the fact that Wilson's equation better describes the concentration dependences of thermodynamic functions in systems with positive deviations from the ideal behavior.

In this study we consider the application of Wilson's polynomial to six liquid binary metallic systems at 1600°C: Cu–Fe, Cu–Co, Cu–Ni, Fe–Ni, Fe–Co, and Co–Ni. The accepted values of thermodynamic functions for these systems are based on the analysis

Table 1. Coefficients of Eqs. (4)–(6) and correlation coefficients r

System	Λ_{12}	Λ_{21}	r
Cu–Fe	0.2467	0.2195	0.9979

* x_2 is the content of the component indicated second.

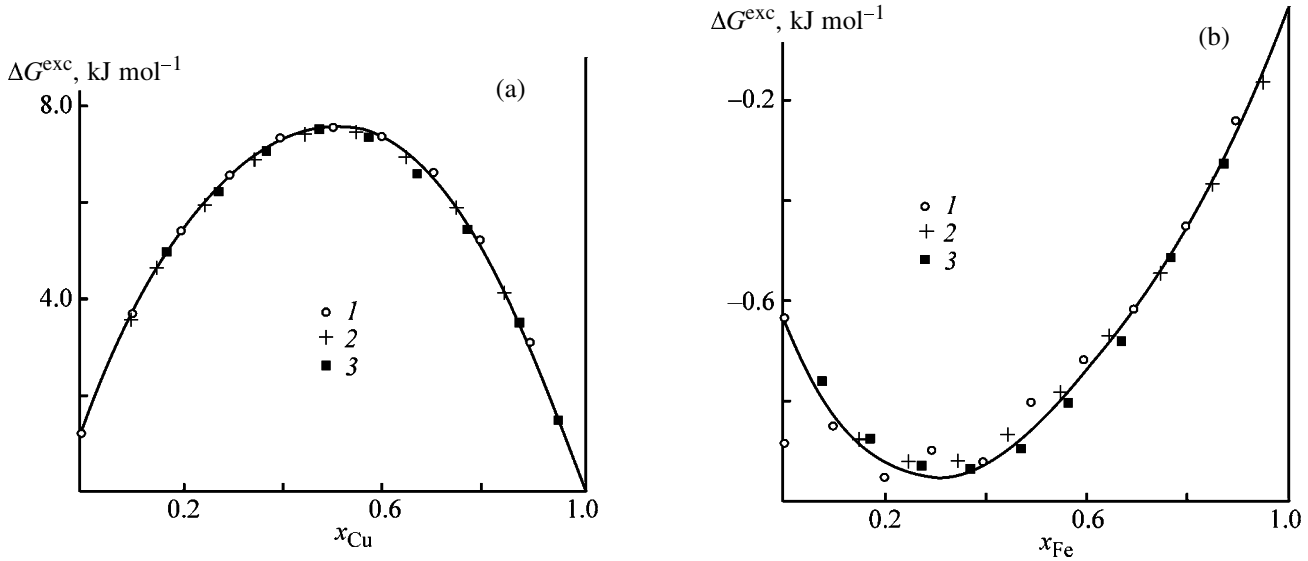

Fig. 1. Composition dependences of the integral molar excess Gibbs energy ΔG^{exc} for ternary systems (a) Fe–Cu–Co ($x_{Fe} : x_{Co}$ = 1 : 3) and (b) Ni–Fe–Co ($x_{Ni} : x_{Co}$ = 1 : 1) at 1600°C, calculated using (*1*) geometric models, (*2*) Redlich–Kister's method, and (*3*) Wilson's method; the same for Fig. 2.

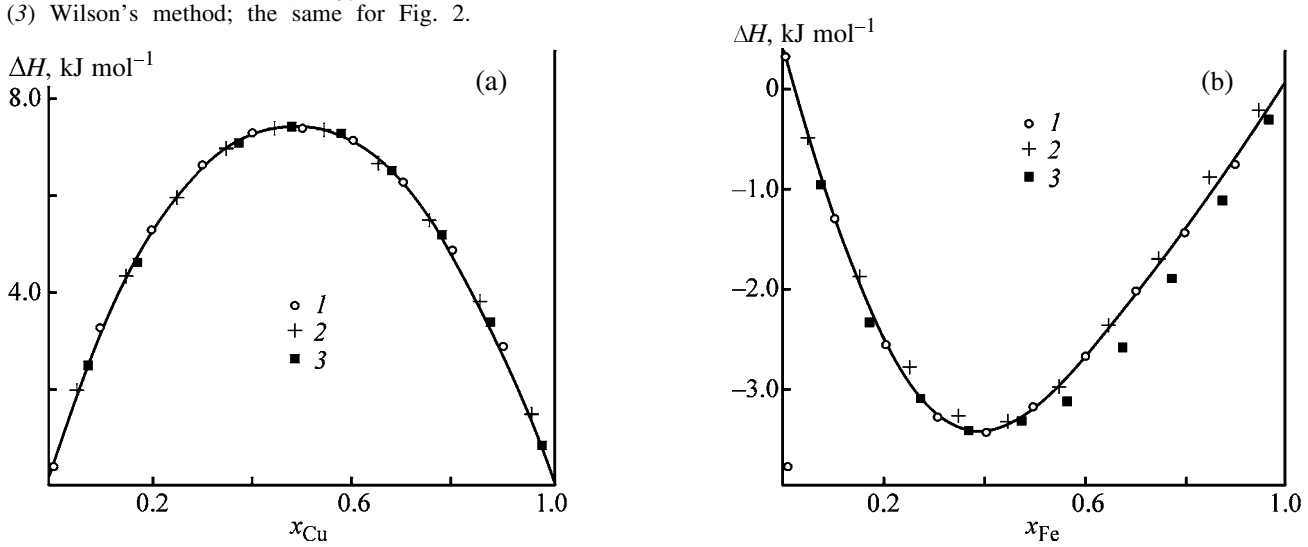

Fig. 2. Composition dependences of the integral molar enthalpy of mixing ΔH of ternary systems (a) Ni–Cu–Co ($x_{Ni} : x_{Co}$ = 1 : 3) and (b) Ni–Fe–Co ($x_{Ni} : x_{Co}$ = 3 : 1) at 1600°C.

consideration. According to [17], expression (7) based on Wilson's polynomial can be written for multicomponent systems:

$$\Delta G_{12}^{exc}/RT = -\sum_{i=1}^{n} x_i \ln\left[\sum_{j=1}^{n} x_j \Lambda_{ij}\right], \quad (7)$$

where ΔG^{exc} is the integral molar excess Gibbs energy of the system including n components, and Λ_{ij} are the positive fitting coefficients ($\Lambda_{ii} = \Lambda_{jj} = 1$).

A similar equation can be written also for the enthalpy of mixing of a multicomponent system.

The values of ΔG^{exc} and ΔH at 1600°C for four ternary systems under consideration, calculated on the basis of the data on boundary binary systems using Wilson's polynomials, are given in Table 3.

As noted above, the thermodynamic functions for this group of ternary systems were calculated previously from the data on boundary binary systems using a large number of geometric models (up to 6–8) and polynomial Redlich–Kister's method [2–6]. The results of the calculation of ΔG^{exc} and ΔH for certain cross sections of ternary systems based on geometric models (averaged values) and on Redlich–Kister's and Wilson's polynomials are compared with each other in Figs. 1 and 2. The agreement between these data can be considered as quite satisfactory.

CONCLUSIONS

(1) Wilson's polynomial method can be applied to the description of the concentration dependences of thermodynamic functions in liquid binary metallic systems with moderate deviations from the ideal behavior: Cu–Fe, Cu–Co, Cu–Ni, Fe–Ni, Fe–Co, and Co–Ni.

(2) The integral thermodynamic characteristics of mixing of liquid ternary systems Ni–Cu–Fe, Ni–Cu–Co, Fe–Cu–Co, and Ni–Fe–Co calculated using the data on boundary binary systems, certain geometric models, and Redlich–Kister's and Wilson's polynomial models agree with each other fairly well.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Properties of $KOH–H_2O_2–H_2O$ Solutions

Yu. A. Ferapontov, D. V. Zhdanov, and M. A. Ul'yanova

Abstract—Density, viscosity, and surface tension of $KOH–H_2O_2–H_2O$ solutions used to synthesize potassium superoxide in sprayer apparatus were studied with various relative amounts of the components in the temperature range 0–30°C. Analytical dependences of the above-mentioned quantities on temperature and solvent (water) content of the system were found.

DOI: 10.1134/S1070427207070051

Carrying out any process of chemical technology requires that the properties of the materials involved should be known. It has been found in the development of apparatus for a technological line for manufacture of potassium superoxide (KO_2) from hydrogen peroxide and potassium hydroxide in a sprayer apparatus [1–5] that most of physicochemical properties of the system $KOH–H_2O_2–H_2O$ (henceforth, an alkaline solution of hydrogen peroxide) for the ranges of interest of the concentrations of the starting components and temperatures cannot be found in the literature. As input data in calculations of spraying processes and apparatus serve those properties of a solution being dispersed, which determine the atomization spectrum of the nozzle employed. According to [6–10], these properties include the kinematic and dynamic viscosities, density, and surface tension. The reported [11] values of the dynamic viscosity and density of $KOH–H_2O_2–H_2O$ solutions lie outside the range of our interest, and, therefore, it was necessary to obtain the lacking experimental data.

EXPERIMENTAL

We prepared an alkaline solution of hydrogen peroxide by the previously described procedure [1–5, 12, 13] by mixing potassium hydroxide and hydrogen peroxide of various concentrations with the subsequent recalculation to the solvent (water) content of the solution. To preclude catalytic decomposition of peroxide products, we introduced magnesium sulfate as a stabilizing agent [14] into the alkaline hydrogen peroxide solutions under study. The molar ratios $H_2O_2/KOH = 1.7$ (at this ratio of the starting components, the final product obtained by the previously suggested technology contains the maximum amount of KO_2 [12]) and $MgSO_4 : H_2O_2 = 1/750$ remained the same for all of the solutions studied. The densities, viscosities, and surface tensions changed upon introduction of the stabilizing agent in the amount specified above within the experimental error. All the substances we used were of ultrapure grade.

The physicochemical properties of the solutions were studied in the temperature range 0–30°C at a solvent (water) content of 0.29 to 0.5 kg of water per 1 kg of a solution. We chose the water content as a criterial parameter in determining the density, viscosity, and surface tension in the system under study. This choice is due to the fact that it is the content of water to be removed from the reaction zone that is the dominant factor in further use of the data obtained in engineering calculations of apparatus for, and process parameters of potassium superoxide production in a sprayer apparatus. Recalculation of the density, viscosity, and surface tension of the solution under study as functions (as it is commonly accepted) of the contents of KOH and H_2O_2 in this solution, rigidly related by the molar ratio $H_2O_2/KOH = 1.7$, is not a complicated mathematical task.

The chosen range of variation of the temperature and the concentrations of the starting components is due to the economical feasibility of the process under study for synthesis of potassium superoxide, on the one hand, and to the possibility of mixing of the starting reagents without any significant loss of active oxygen by the system (temperature factor) at a high safety of the process, on the other hand [12, 13].

The density of the alkaline solution of hydrogen peroxide was determined pycnometrically with

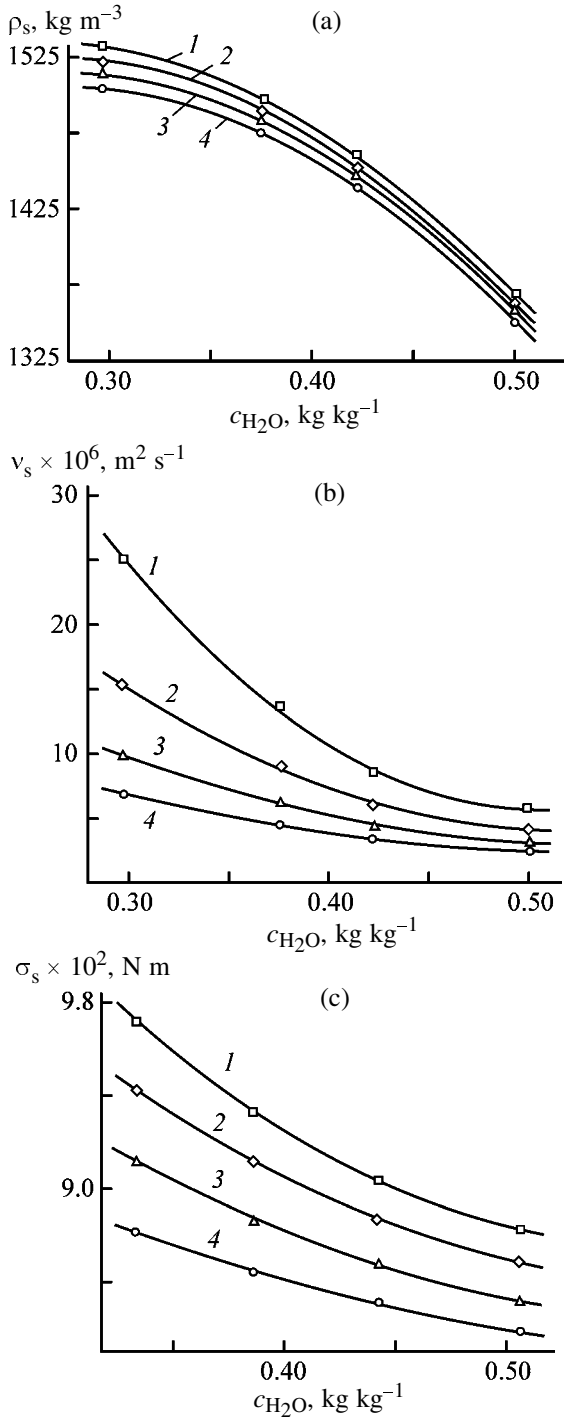

Fig. 1. (a) Density ρ_s, (b) kinematic viscosity ν_s, and (c) surface tension σ_s of an alkaline solution of hydrogen peroxide vs. the solvent concentration c_{H_2O}. Temperature, °C: (*1*) 0, (*2*) 10, (*3*) 20, and (*4*) 30.

an error not exceeding 0.3% [13]. The data obtained in determining the solution density, calculated as an arithmetic mean of the results of five parallel runs, are shown in Fig. 1a.

The experimental data are well described by a power series of the form

$$\rho_s = a_0 + a_1 c_{H_2O} + a_2 c_{H_2O}^2, \quad (1)$$

whose coefficients linearly depend on temperature:

$$a_0 = 1900.04 - 1.07878T_s, \quad (1a)$$

$$a_1 = 48.1161 + 5.44812T_s, \quad (1b)$$

$$a_2 = -1561.93 - 4.97642T_s. \quad (1c)$$

The maximum disagreement between the calculated and experimental densities did not exceed 1.2%.

We studied the kinematic viscosity of solution samples with a VPZh-2 glass capillary viscometer in conformity with GOST (State Standard) 33–66, using the results of the individual factory calibration of the viscometer. The required temperature was maintained by thermostating the viscometer within ±0.1°. The kinematic viscosity of the solution, ν_s, was found from the arithmetic-mean outflow time τ_{am} in five parallel runs by the formula

$$\nu_s = gk\tau_{am}/9.807, \quad (2)$$

where $g = 9.813$ m s^{-2} is the acceleration of gravity at the measurement site (Tambov), and $k = 3.136 \times 10^{-7}$ m^2 s^{-2} is the viscometer constant.

The results of an experimental study of the kinematic viscosity of the alkaline solution of hydrogen peroxide are shown in Fig. 1b as a family of isothermal curves.

For convenience of further use of the results of our study in engineering calculations, the dependence $\nu_s = f(c_{H_2O}, T_s)$ was represented in the analytical form as

$$\nu_s = 10^{-6}(a_0 + a_1 + a_1 c_{H_2O} + a_2 c_{H_2O}^2). \quad (3)$$

The coefficients a_0, a_1, and a_2 in expression (3) were calculated as functions of temperature by the formulas

$$a_0 = 9413.54 - 61.9307T_s + 0.10213T_s^2, \quad (3a)$$

$$a_1 = -38026.39 + 250.9153T_s - 0.4180T_s^2, \quad (3b)$$

$$a_2 = -39320.46 - 259.9735T_s + 0.43053T_s^2, \quad (3c)$$

where T_s is the solution temperature (K), and c_{H_2O} is the concentration of water in the solution (kg kg^{-1}).

The resulting approximating polynomial satisfactorily describes experimental data. The maximum

discrepancy between the calculated and experimental values does not exceed 2%.

The surface tension of the solution was determined by the method of the highest pressure in a bubble, developed by P.A. Rebinder [15]. The results obtained are shown in Fig. 1c and represented in the analytical form as

$$\sigma_s = a_0 + a_1 c_{H_2O} + a_2 c_{H_2O}^2, \quad (4)$$

$$a_0 = 49.6879 - 0.12943T_s, \quad (4a)$$

$$a_1 = -138.045 + 0.43386T_s, \quad (4b)$$

$$a_2 = 129.015 - 0.40980T_s. \quad (4c)$$

The maximum discrepancy between the calculated and experimental values of surface tension does not exceed 1.5%.

The coefficients in the functional dependences for density, kinematic viscosity, and surface tension were found using the least-squares method [16].

The results we obtained suggest that the density, viscosity, and surface tension increase as the solvent (water) content of the system under consideration becomes lower. This is in good agreement with the conclusions made by Loginov et al. [11], who studied these parameters of the KOH–H_2O_2–H_2O system in other temperature and concentration ranges.

CONCLUSIONS

(1) The density, viscosity, and surface tension of the KOH–H_2O_2–H_2O system were studied in the temperature range 0–30°C at a fixed molar ratio H_2O_2/KOH = 1.7 and various concentrations of the starting components (water content of 0.29 to 0.5 kg per 1 kg of solution). The results obtained were used to derive analytical dependences for these parameters. The dependences can be used to calculate apparatus and parameters of the process for synthesis of potassium superoxide from hydrogen peroxide and potassium hydroxide in a sprayer apparatus.

(2) Under the experimental conditions, the density, kinematic viscosity, and surface tension of an alkaline solution of hydrogen peroxide increase as the solvent (water) content of the system decreases.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility Diagrams of the Systems Nickel Sulfamate–Water and Cobalt Sulfamate–Water

V. I. Maksin and O. Z. Standritchuk

National Agrarian University of Ukraine, Kiev, Ukraine

Received July 14, 2006; in final form, February 2007

Abstract—Solubility diagrams of nickel and cobalt sulfamates in water in the temperature range from –40 to 145°C are presented.

DOI: 10.1134/S1070427207070063

The solubility of metal sulfamates is comparable with that of nitrates and acetates [1–8], which is essential for their applications [6–14]. The solubilities of sulfamic acid and ammonium sulfamate [1, 2, 15] are the most extensively studied, and those of sulfamates of lanthanides [4–7], silver, and lead [3] are less investigated. The solubilities of sodium, magnesium, calcium, barium, and nickel sulfamates was determined only at 20–25°C [1, 2, 8], and the experimental data for cobalt, iron, copper, and chromium sulfamates are lacking. Previously [16, 17], an attempt was made to substantiate theoretically the solubility values of sulfamates, the thermodynamic aspects were considered, and standard solubilities of the majority of sulfamates were calculated and compared to the known experimental data. However, no systematic experimental studies in this direction were carried out, and further studies of the solubility of sulfamates in water remain topical.

In this study we examined the temperature dependences of the solubility of nickel and cobalt sulfamates in water and constructed two-component phase diagrams in the systems $Ni(SO_3NH_2)_2$–H_2O and $Co(SO_3NH_2)_2$–H_2O.

EXPERIMENTAL

In the experiments we used nickel and cobalt sulfamates synthesized from sulfamic acid (chemically pure grade) and the corresponding metal carbonates (analytically pure grade) according to [16], and also preliminarily recrystallized commercial chemicals. We studied the solubility as follows. We used a Pyrex reactor with a temperature-control jacket, equipped with a propeller stirrer (50 rpm) and seats for a mercury thermometer and for sampling. The reactor was charged with 250 ml of double-distilled water and a metal sulfamate in an amount sufficient to obtain a saturated solution with a small excess of undissolved crystals. Then the vessel was closed with a lid equipped with a hydroseal, a thermometer was inserted, and the system was brought to a desired temperature using a thermostat. Thermal insulation supported a constant temperature within the limits of 0.1–0.2°C. After stirring for 2 h, 1 cm^3 of the resulting solution was sampled at 10-min intervals using a temperature-controlled pipet with a filtering tip. The metal content of the samples was determined chelatometrically [18]. The equilibrium in the systems under study was reached within 2–8 h, and then the bottom phase and the mother liquor were analyzed. To find the most reliable result, the data obtained from several parallel experiments at the same temperature were treated by the least-squares method.

It should be noted that constructing solubility diagrams of salts tending to form several crystal hydrates is a rather complicated task [19], especially in the case of studying phase diagrams of the systems $Ni(SO_3NH_2)_2$–H_2O and $Co(SO_3NH_2)_2$–H_2O where two isomeric and several tautomeric modifications characteristic for sulfamate ions can exist [20, 21], and at temperatures higher than 85°C sulfamate ions can, in addition, undergo hydrolysis [15]. Therefore, to simplify the experiment, we studied the temperature dependence of the solubility in the range from –15 to 85°C with the subsequent construction of the corresponding portions of the diagrams $S = f(T)$, where S is the solubility (wt %) at a temperature T (°C). Then the obtained portions of experimental curves $S = f(T)$ were superimposed, using a computer, on the

analogous solubility diagrams of other inorganic salts (chlorides, sulfates, nitrates, etc.) of nickel and cobalt [19] and of sulfamic acid [15] to reveal by comparative analysis correlations in the arrangement of singular points (eutectics and peritectics) and common features of the curve shapes. After that, Further missing portions of the diagrams above 85 and below –15°C were constructed on the basis of the revealed regular trends by extrapolating the experimental portions of $S = f(T)$ curves to probable peritectics and also to eutectics of stable and metastable forms of sulfamates under study in the calculated ebullioscopic and cryoscopic curves, respectively.

The results of studying solubility of nickel and cobalt sulfamates in water in the range from –15 to 85°C, given in Table 1, were used to build up the corresponding $S = f(T)$ diagrams. Analysis of bottom phases according to the lever rule (Schreinemakers' method of wet residues) shows that nickel and cobalt sulfamates form several crystal hydrates (containing 4, 3.5, 3, and 2 water molecules). The formation of these crystal hydrates in the systems under study was confirmed by thermographic studies.

The total solubility diagram of the $Ni(SO_3NH_2)_2$–H_2O system is shown in Fig. 1a. The shape of the experimental portion of the $S = f(T)$ curve shows that two more singular points *a* and *b* appear behind the eutectic in the range of the existence of the crystal hydrate with four water molecules. These peritectics in the curves near 8.7 and 26.8°C can be due to phase transitions from the zwitterionic $[^{+\delta}H_2NSO_3^{-(\delta+1)}]$ to the open ($H_2NSO_3^-$) structure, characteristic also for sulfamic acid in this temperature range [15, 16, 20, 21]. Correspondingly, this portion of the $S = f(T)$ curve from the eutectic to the peritectic in point *b* is divided into three regions of the existence of α-, β-, and γ-$Ni(SO_3NH_2)_2 \cdot 4H_2O$ modifications. The possibility of such transitions and also exact temperatures of their occurrence are proved by the conductometric studies. For example, the temperature dependences $\chi = f(T)$ of the conductivity χ of nickel sulfamate solutions contain bends in points *a, b, c, d*, and *g* (Fig. 2, curve *1*) in the regions of peritectic temperatures, which, in turn, well correlate with the corresponding transitions in the solubility diagrams (Fig. 1). A similar temperature dependence $\chi = f(T)$ is given in Fig. 2 (curve *1*) for the well-studied system sulfamic acid–water with pronounced manifestation of the regions of existence of several tautomeric and isomeric forms [15]:

$$\alpha\text{-}^+H_3NSO_3^- \rightleftarrows \beta\text{-}^+H_3NSO_3^- \rightleftarrows \gamma\text{-}^+H_3NSO_3^-.$$

Examination of the curves $\chi = f(T)$ (Fig. 2, curves *1* and *2*, regions *A–D*) shows that the revealed temperature ranges of existence of singular points practically coincide with the peritectics in the diagram $S = f(T)$ (Fig. 1a) and are associated with the following transitions:

$$\alpha\text{-}Ni(SO_3NH_2)_2 \cdot 4H_2O \rightleftarrows \beta\text{-}Ni(SO_3NH_2)_2 \cdot 4H_2O$$

$$\rightleftarrows \gamma\text{-}Ni(SO_3NH_2)_2 \cdot 4H_2O.$$

When comparing the two experimental methods, in addition to "true" eutectics and peritectics, we detected singular points (Figs. 1 and 2, points *e, d*, and *g*) in the regions of metastable existence of all the forms of sulfamates shown in Table 2.

In particular, the peritectic temperature $T_p = 84 \pm 2$°C (Fig. 1a, point *h*) associated with the transitions $Ni(SO_3NH_2)_2 \cdot 3H_2O \rightleftarrows Ni(SO_3NH_2)_2 \cdot 2H_2O$ is the boundary of the metastable existence of the γ-$Ni(SO_3NH_2)_2 \cdot 4H_2O$ modification and the onset of intense hydrolysis, whereas $T_p = 53 \pm 2$°C (Fig. 1a, point *c*) is the boundary of the region of the metastable existence of α- and β-$Ni(SO_3NH_2)_2 \cdot 4H_2O$. The temperature $T_p = 53 \pm 2$°C is the boundary corresponding to noticeable acceleration of the chemical reactions between sulfamic acid and metals, their oxides, and carbonates [1, 2, 9–14]. The latter conclusion also agrees well with the results of [15, 22]. In these studies it was suggested that the open structures of sulfamic acid, HSO_3NH_2, are more active than the zwitterionic structures, $^+H_2NSO_3^-$.

The occurrence of phase tautomeric transitions in metal sulfamates can also be confirmed by structural

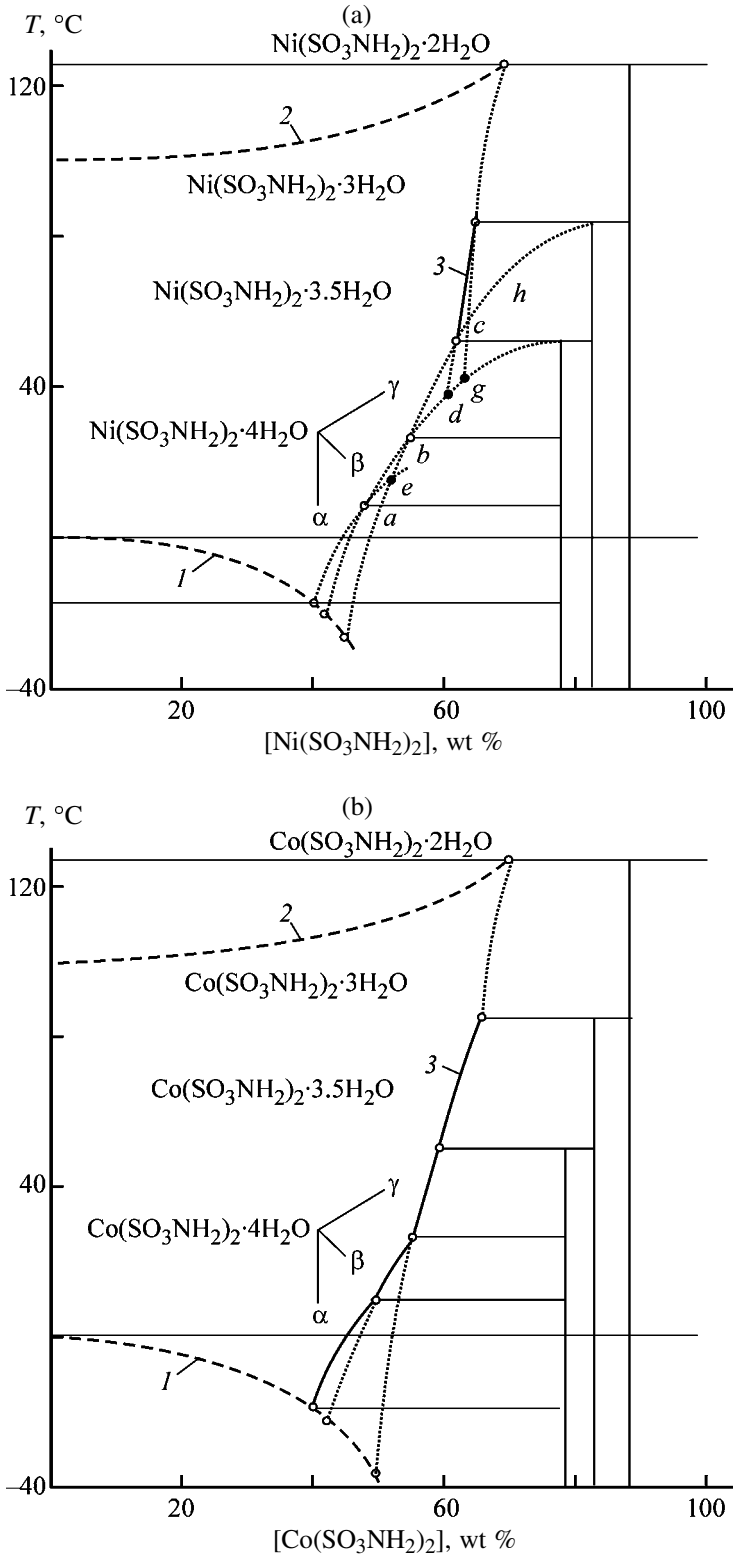

Fig. 1. Total solubility diagrams of the systems (a) $Ni(SO_3NH_2)_2$–H_2O and (b) $Co(SO_3NH_2)_2$–H_2O in the coordinates concentration of $Ni(SO_3NH_2)_2$ or $Co(SO_3NH_2)_2$–temperature *T*. * Positions of characteristic points determined with a probability of no more than 80% are given in braces.

** Probable positions of characteristic points found by extrapolation of experimental portions of curves for metastable forms are given in parentheses.

methods. In particular, when the temperature of an aqueous solution of lead sulfamate is increased from 4 to 40°C, the corresponding lines in its NMR spectra recorded at H_0 = 200.13 MHz (i.e., in the region of the $–NH_2$ absorption) were shifted downfield, and the line intensities increased. Similar splitting of the spectrum and the downfield shift are characteristic for the rearrangement $–NH_3 \rightleftarrows –NH_2 + H^+$ [23, 24]. Therefore, at T_p = 26.8°C (the temperature of the transition of zwitterion structures into open forms of sulfamate ions), the NMR spectrum was strongly split. If water molecules, which facilitate the transition from $^+H_3NSO_3^-$ to HSO_3NH_2 [15, 17], are involved in the exchange processes, separate stages of such transitions can be detected even as independent modifications. Thus, the coincidence of peritectic temperatures in points *a* (T_p = 8.7°C) and *b* (T_p = 26.8°C) in the curve $S = f(T)$ (Fig. 1a) with the conductometric analysis data [$\chi = f(T)$ (Fig. 2)] and the NMR data convincingly confirms the existence of α, β, and γ modifications of $Ni(SO_3NH_2)_2 \cdot 4H_2O$.

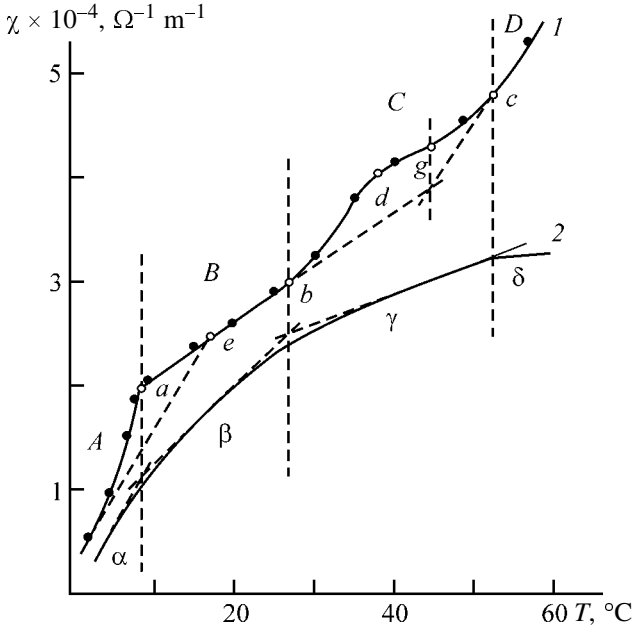

Fig. 2. Temperature dependences of the conductivities χ of (*1*) 25% $Ni(SO_3NH_2)_2$ solution and (*2*) HSO_3NH_2. Points, discrete measurements; solid line, automatic recording.

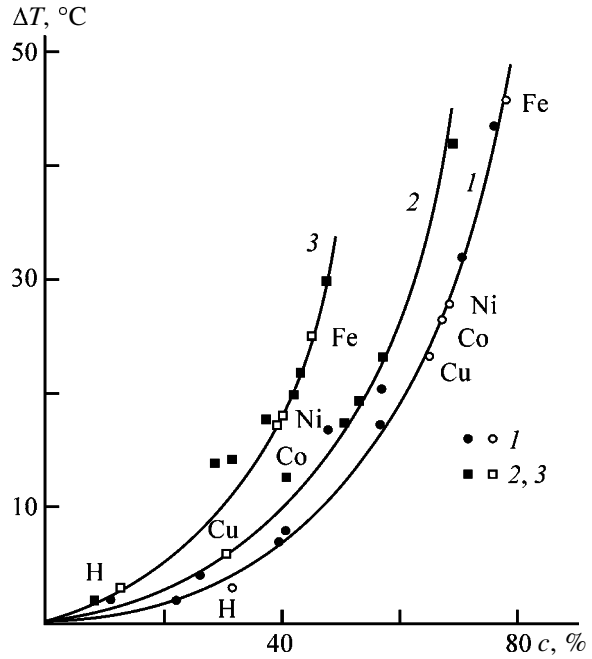

Fig. 3. Temperature shifts ΔT (°C) for (*1*) boiling (ebullioeutectics) and (*2, 3*) ice crystallization (cryoeutectics) points in saturated solutions of (filled squares and circles) chlorides, sulfates, and nitrates and (hollow squares and circles) sulfamates of double-charged metal ions, as functions of their limiting concentration c relative to the corresponding parameters of water.

The experimental study of the solubility above 85°C, especially construction of ebullioscopic curves by boiling points of saturated solutions, is strongly complicated by the onset of the hydrolysis of sulfamate ions according to the scheme

$$3M(SO_3NH_2)_2 + 4H_2O = [M(NH_3)_4](SO_3NH_2)_2 + 2M(HSO_4)_2,\ M = Ni,\ Co.$$

In this case, despite certain measures (performing saturation for shorter time, increasing the number of replicate experiments), the results were rather approximate. At the same time, the experimental determination of the eutectic was strongly complicated by the tendency of nickel sulfamate to supersaturation at low temperatures. Therefore, we calculated the courses of the ebullioscopic and cryoscopic curves and found the most probable variants by graphical comparison of the experimental portions of the $S = f(T)$ curves for the sulfamates under study (Fig. 1) with the known solubility diagrams of various inorganic salts (chlorides, sulfates, nitrates, etc.) of nickel, cobalt, and other double-charged metal ions [19]. As a result of the comparative analysis, we revealed correlations in the structures of such two-component diagrams. In particular, we found that the boiling and freezing curves of salt solutions and the arrangement of eutectics and peritectics clearly correlate with weight concentrations of the solutes. As an example we plotted in Fig. 3 the shifts of the boiling (curve *1*) and ice crystallization (curves *2, 3*) points vs. weight concentration of the salt dissolved in water for MA_2–N_2O systems ($M = Ni^{2+}$, Co^{2+}, and other double-charged metal cations; $A = Cl^-$, Br^-, ClO_4^-, NO_3^-, SO_4^{2-}, and $SO_3NH_2^-$ anions). Thus, the results obtained allowed us to correct the calculated portions of the total solubility diagram of the system $Ni(SO_3NH_2)_2$–H_2O (Fig. 1a) and also to refine positions of singular points which are presented in Table 2.

The solubility diagram of the cobalt sulfamate–water system (Fig. 1b) was constructed similarly using the data of Table 1; the parameters of singular points are given in Table 2. The comparison of both diagrams (Figs. 1a, 1b), and also of the results presented in Table 2, shows that cobalt sulfamate crystal hydrate with four water molecules, as well as the related nickel sulfamate, shows tautomerism with the formation of α, β, and γ modifications of $Co(SO_3NH_2)_2 \cdot 4H_2O$. Three more crystal hydrates of cobalt sulfamate $Co(SO_3NH_2)_2 \cdot 3.5H_2O$, $Co(SO_3NH_2)_2 \cdot 3H_2O$, and $Co(SO_3NH_2)_2 \cdot 2H_2O$ are also formed in this system.

Slow isohydric crystallization at room temperature makes it possible to obtain $Co(SO_3NH_2)_2 \cdot 4H_2O$ in the form of large (up to 5–10 mm in a diagonal) transparent dark pink prismatic single crystals with a refraction index of $N_{av} = 1.517$. Cobalt sulfamate crystal hydrate with four water molecules, which is very unstable in air, is gradually eroded to form light pink powders by gradual passing from $Co(SO_3NH_2)_2 \cdot 3.5H_2O$ to the most stable in air crystal hydrate $Co(SO_3NH_2)_2 \cdot 3H_2O$.

Unlike cobalt sulfamate, nickel sulfamate tends to form supersaturated solutions. When seed crystals are introduced into a dark green supersaturated solution of nickel sulfamate, a blue-green crystalline ($N_{av} = 1.583$) powder of $Ni(SO_3NH_2)_2 \cdot 4H_2O$, which is stable in air and to vacuum drying, precipitates from the solution.

The general view of the solubility diagrams of the nickel sulfamate—water and cobalt sulfamate–water systems correlates well with the solubility diagram of sulfamic acid HSO_3NH_2–H_2O [15]. Furthermore, all these diagrams are characterized by a phase transition from zwitterionic structures to open forms at 26.7–27.1°C and by the onset of hydrolysis of sulfamate ions at 84 ± 2°C.

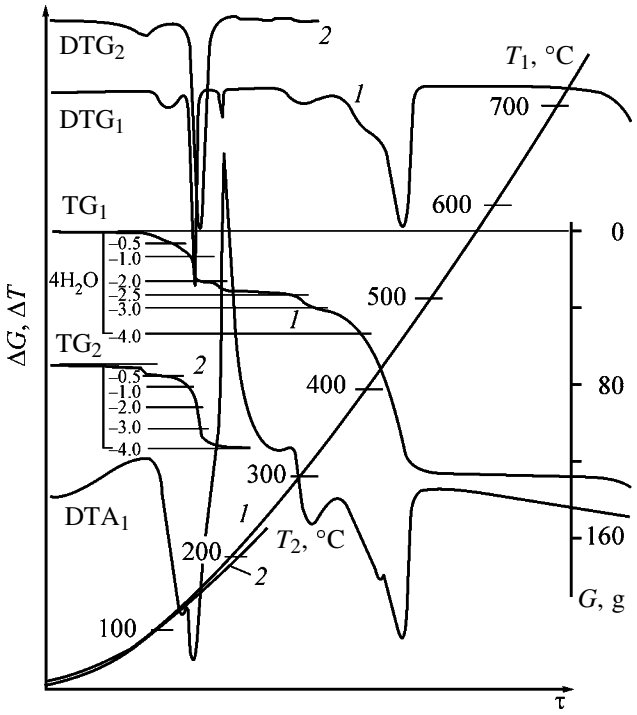

Fig. 4. Thermograms of crystalline samples of (*1*) nickel and (*2*) cobalt sulfamates. Automatic mode, heating rate 10 deg min^{-1}, DTA/DTG = 1/10, samples 250 mg of $Ni(SO_3NH_2)_2 \cdot 4H_2O$ (subscript *1*) and 185 mg of $Co(SO_3NH_2)_2 \cdot 4H_2O$ (subscript *2*). (ΔG) Weight loss rate, (ΔT) temperature difference, (T) temperature, (G) sample weight loss, and (τ) time.

The results of a thermographic study (Q-1500D derivatograph) of crystalline samples of $Ni(SO_3NH_2)_2 \cdot 4H_2O$ and $Co(SO_3NH_2)_2 \cdot 4H_2O$ at a heating rate of 10 deg min^{-1} are shown in Fig. 4. It is clearly seen (for obviousness, the region of loss of crystal hydrate water is specially denoted in Fig. 4) that nickel and cobalt sulfamates lose crystal water in several steps. First the processes go equally for both samples with successive of elimination of $0.5H_2O$ in two steps, and then, at temperatures close to ebullioscopic eutectics, the second molecule is lost with the formation of readily crystallizing crystal hydrates with two water molecules:

$$M(SO_3NH_2)_2 \cdot 4H_2O - 0.5H_2O = M(SO_3NH_2)_2 \cdot 3.5H_2O,$$

$$M(SO_3NH_2)_2 \cdot 3.5H_2O - 0.5H_2O = M(SO_3NH_2)_2 \cdot 3H_2O,$$

$$M(SO_3NH_2)_2 \cdot 3H_2O - 0.5H_2O = M(SO_3NH_2)_2 \cdot 2H_2O.$$

Then, long before the onset of sulfamate ion decomposition, cobalt sulfamate successively loses the third and the fourth H_2O molecules, forming anhydrous crystals, and nickel sulfamate continues to retain water up to the onset of sulfamate ion decomposition involving the fourth molecule of crystal hydrate water. These are the processes responsible for easier removal of supersaturation in the case of cobalt sulfamate, as compared to nickel sulfamate, in the course of vacuum-thermal crystallization.

It should be noted in conclusion that in the diagrams shown (Figs. 1a, 1b) the temperature dependences of the sulfamate solubility in water (curves *3*) denoted by solid lines were obtained experimentally, whereas the portions designated by dashed and dotted lines are tentative, as they were obtained on the basis of calculations and indirect theoretical studies. Nevertheless, our results were fruitfully used in the development of processes for producing electroplating electrolytes and crystalline nickel and cobalt sulfamates [14, 22].

CONCLUSIONS

(1) The solubilities of $Ni(SO_3NH_2)_2$ and $Co \cdot (SO_3NH_2)_2$ show strong temperature dependences, and the compounds exhibit tautomerism.

(2) The formation of tautomeric modifications of sulfamates is associated with multistage transformations from the zwitterionic form $^{+\delta}H_2NSO_3^{-(\delta+1)}$ to the open form $H_2NSO_3^-$.

(3) The diagrams obtained closely correlate with the solubility diagram of the HSO_3NH_2–H_2O system.

SORPTION AND ION-EXCHANGE PROCESSES

Gold(III) Sorption with Copolymers Derived from Divinyl Sulfide

Abstract—Sorption recovery of gold(III) from aqueous mineral acids with copolymers of 4-vinylpyridine and 2-methyl-5-vinylpyridine with divinyl sulfide was studied.

DOI: 10.1134/S1070427207070075

Preconcentration of trace amounts of precious metals in analysis of natural and industrial objects and recovery of these elements from hydrometallurgical waste with ion-exchange resins find growing use. The corresponding ion-exchange resins should have high sorption capacity and distribution coefficients [1, 2]. Previously [3, 4] we developed methods for preparing network copolymers of divinyl sulfide (DVS) with 4-vinylpyridine (VP) and 2-methyl-5-vinylpyridine (MVP) and examined the physicochemical properties of these macromolecular compounds.

In this study, we examined the sorption activity of copolymers of divinyl sulfide with vinylpyridines with respect to gold(III).

EXPERIMENTAL

Divinyl sulfide was separated from the stabilizer by distillation (bp 83–84°C/720 mm Hg). 4-Vinylpyridine and 2-methyl-5-vinylpyridine, which are commercial monomers, were purified by repeated distillation in a vacuum. Their purity was monitored chromatographically.

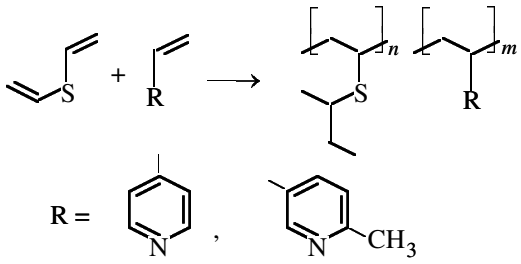
Radical copolymerization of DVS with VP or MVP was performed in dimethylformamide (DMF) by an ampule method in the presence of azobis(isobutyronitrile) (AIBN) at 60°C under argon. The copolymers were washed with solvents (benzene, acetone, water) and dried to constant weight in a vacuum. The copolymer composition was calculated from the data of elemental analysis, which was performed on a Thermo Finnigan gas analyzer. The IR spectra of compounds in KBr pellets and mineral oil were recorded on an IFS-25 spectrometer.

The reference Au(III) solution was prepared by dissolution of $H[AuCl_4]$ in water and standardized by the standard procedure [5]. The working solutions were prepared by dilution of the initial solutions just before experiments. The sorption ability of the copolymers with respect to gold(III) chloro complexes was studied in the static mode at room temperature as follows: 10 mg of a copolymer was introduced into a beaker, the required acidity of the solution was adjusted, and a definite amount of an Au(III) solution was added. The metal sorption was performed from 20 ml of solution in the static mode with vigorous stirring. After a definite time, the copolymer was filtered off. The Au(III) content was determined by atomic absorption spectroscopy.

The radical copolymerization of DVP with VP gives insoluble products in any case. In the DVS–MVP system, copolymerization in the presence of AIBN gives an insoluble copolymer only at a low content of the sulfur-containing monomer (<5 mol %). The maximal sulfur content of the sample is 1.2 wt % (Table 1). At a further increase in the DVS content of the initial mixture, soluble reaction products are formed. The yield of the copolymer decreases with increasing DVS content. The scheme of formation of network copolymers is shown below:

Table 1. Copolymers of DVS with VP and MVP

Copolymer	Composition of starting mixture, wt %		Content, wt %		Copolymer composition, mol %		Yield, %
	VP or MVP	DVS	N	S	VP or MVP	DVS	
DVS–VP	50.00	50.00	8.78	12.67	61.23	38.77	92
DVS–MVP	95.00	5.00	11.52	1.20	96.04	3.97	79



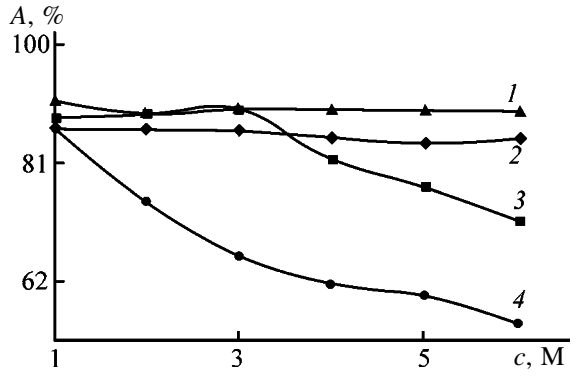


Fig. 1. Influence of the kind and concentration c of acid on the degree of gold recovery A from solution. m_{sorb} = 1.62 mg, sorption time 2 h. Copolymer: (*1, 3*) DVS–VP and (*2, 4*) DVS–MVP. Acid: (*1, 2*) H_2SO_4 and (*3, 4*) HCl; the same for Fig. 2.

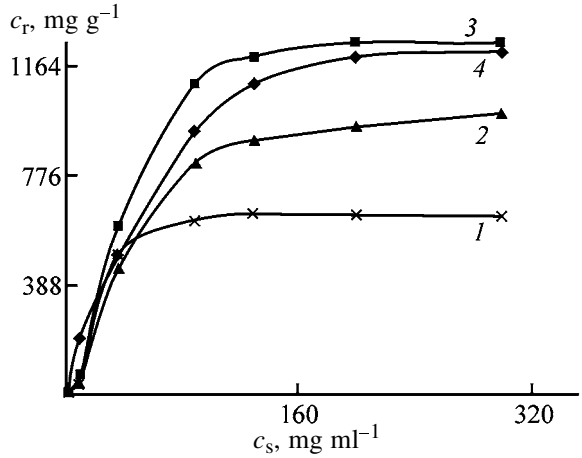

Fig. 2. Equilibrium distribution of gold(III) in its recovery from 1 M acids. m_{sorb} = 10 mg, sorption time 2 h. (c_s) Equilibrium gold(III) concentration in the solution and (c_r) equilibrium gold(III) content in the resin. Copolymer: (*1, 4*) DVS–VP and (*2, 3*) DVS–MVP.

The copolymers taken for studying the sorption activity are listed in Table 1. Among samples of DVS–VP copolymer, we chose that with a sulfur content of 12.67 wt %, prepared in the maximal yield at equimolar composition of the initial mixture.

The dependence of the efficiency of gold(III) recovery with DVS–VP or DVS–MVP copolymer on the nature and concentration of mineral acids is shown in Fig. 1. As seen, the degree of gold recovery decreases with increasing HCl concentration and is virtually independent of the sulfuric acid concentration. The first trend can be attributed to the competition of the Cl^- ion and anionic metal chloro complex for the resin. Such influence of the HCl concentration suggests an ion-exchange mechanism of gold(III) interaction with the resin in HCl, although the coordination mechanism cannot be ruled out either. The lack of any influence of sulfuric acid concentration on the gold sorption shows that in this case the sorption occurs mainly by the coordination mechanism. In the IR spectrum of the sorbent with sorbed gold (concentrate), a broad band in the 3000–2600 cm^{-1} range characteristic of the ammonium cation is observed. The shift of the absorption band maximum from 1600 to 1630 cm^{-1} is attributable to the coordination via nitrogen atom [2–6].

The curves of gold(III) distribution between the sorbent and solution in sorption from 1 M acids are shown in Fig. 2, and the calculated sorption capacities (SC) and distribution coefficients of gold D are listed in Table 2.

Table 2. Sorption capacities of copolymers based on DVS and gold(III) distribution coefficients in sorption from 1 M acids

Copolymer	SC, mg g^{-1}	D, cm^3 g^{-1}
	HCl	
DVS–VP	730	1.5×10^5
DVS–MVP	980	2.2×10^4
	H_2SO_4	
DVS–VP	1200	1.6×10^4
DVS–MVP	1190	1.5×10^4

The copolymers show high sorption capacities for the Au(III) chloro complex, which is probably caused by two types of interactions: ion-exchange and coordination. High distribution coefficients allow the use of these sorbents in analytical chemistry.

CONCLUSIONS

(1) Static sorption capacities and distribution coefficients of gold(III) in its recovery from aqueous solutions of sulfuric and hydrochloric acids with copolymers of divinyl sulfide with 4-vinylpyridine or 2-methyl-5-vinylpyridine were determined.

(2) These copolymers exhibit high sorption capacities for gold(III) chloro complexes and can recover small amounts of gold(III) from solutions.

SORPTION AND ION-EXCHANGE PROCESSES

Ion-Exchange Recovery of Palladium(II) from Multicomponent Chloride Solutions

Abstract—Ion-exchange sorption of palladium(II) from both concentrated aqueous hydrochloric acid solution containing Fe(III), Sn(II), Zn(II), and Cu(II) and weakly acidic concentrated aqueous ammonium chloride solution containing Zn(II) and Cu(II) was studied. The Purolite S920, Purolite S924, and Purolite S984 macroporous resins with the thiourea, thiol, and polyethylenepolyamine functional groups, respectively, were used as sorbents. Strongly basic Purolite A500 anion exchanger was also tested. The desorption of palladium(II) with aqueous ammonia, hydrochloric acid, and acidified aqueous thiourea was examined.

DOI: 10.1134/S1070427207070087

In refining platinum metals (PMs), large volumes of spent PM-containing solutions are formed. The palladium(II) content in them can be as large as 150 mg l^{-1}. The platinum metals are commonly recovered from spent refining solutions by precipitation in the form of poorly soluble compounds and also by cementation or electrolysis [1]. However, these methods do not ensure the required completeness of PM recovery. Furthermore, their use leads to the formation of poorly soluble products depleted of PMs, whose further processing to recover PMs is difficult.

Extensive published data on ion-exchange sorption of PMs show that resins with the thiourea, thiol, and polyethylenepolyamine functional groups selectively sorb these metals [1–3]. Therefore, we can expect that application of these resins will allow more complete recovery of PMs from spent refining solutions. However, currently ion-exchange sorption is rather seldom used for this purpose. The ion-exchange methods are mainly used for preconcentrating PMs before their chemical analysis [4–6]. Studies concerning industrial processing of PM-containing solutions mainly dealt with commercial resins nonselective to PMs [7–11].

The modern chemical industry produces a large number of resins with various selective functional groups, which allows selection of sorbents suitable for more complete recovery of PMs from spent multicomponent refining solutions.

In this study we examined the possibility of more complete selective ion-exchange recovery of palladium(II) from two kinds of spent refining solutions: after precipitation of ammonium hexachloroplatinate(IV) and *trans*-dichlorodiamminepalladium(II).

EXPERIMENTAL

We tested the following commercial macroporous complexing resins produced by Purolite Int. Ltd. company: Purolite S920, Purolite S924, and Purolite 984 with the thiourea, thiol, and polyethylenepolyamine functional groups, respectively. For comparison, Purolite A500 strongly basic anion exchanger was also tested.

In the static sorption experiments, weighed portions of a resin were brought in contact with solutions containing a constant amount of macrocomponents and impurity metals and variable amount of palladium(II) at 1 : 200 ratio of the dry resin (g) and liquid (ml). On attainment of the sorption equilibrium (5–7 days), the solution was separated from the resin and analyzed for palladium. The amount of palladium sorbed on the resin was determined by the difference between its concentrations in the initial and equilibrium solutions, taking into account the weighed portion of the resin, its specific volume, and the solution volume. In determining the degree of palladium desorption from the resin, its weighed sample preliminarily saturated with palladium(II) was washed with 0.3 M aqueous hydrochloric acid and then brought in contact with a desorbing solution.

The experiments on ion-exchange sorption of palladium(II) under dynamic conditions were carried out with a series of identical columns packed with an ion exchanger (8 ml) of commercial granulation. The ratio of the resin bed height to the column diameter was 9 : 1. After completion of the sorption of palladium(II), the column was washed with acidified water (11 g HCl l^{-1}), and then palladium was desorbed from the column. In sorption and desorption steps, the corresponding solutions were passed through the column at a rate of 1.0–1.5 and 0.7–1.0 column volumes per hour, respectively. The palladium(II) content in the desorbates was determined photocolorimetrically from the light absorption of a colored complex of palladium(II) with tin(II) chloride [12]. Before determination of iron(III) and copper(II) in the desorbate, the latter was treated with sulfuric and perchloric acids on heating to decompose thiourea. In the resulting solutions iron(III) was determined photocolorimetrically from the light absorption of its yellow complex with sulfosalicylic acid in aqueous ammonia (pH 8–10) [13]. Copper(II) was determined from the light absorption of its blue complexes with ammonia.

In this study we examined the ion-exchange recovery of palladium(II) from two solutions simulating the average chemical composition of the real mother liquors formed after precipitation of ammonium hexachloroplatinate(IV) (solution I) and *trans*-dichlorodiamminepalladium (solution II) from the refining shop at one of the domestic enterprises. Their salt and elemental composition was as follows (g l^{-1}): solution I: NH_4Cl 53.5, HCl 1.10, Cu(II) 3.2, Zn(II) 3.3, Fe(III), 2.8, and Sn(IV) 6.0; solution II: NH_4Cl 160, Cu(II) 3.2, Zn(II) 3.3, pH 3.3.

First we obtained the sorption isotherms of palladium(II) from solutions I and II (Figs. 1a, 1b).

Figure 1a shows that complexing resins with the thiourea (S920) and thiol (S924) functional groups sorb palladium(II) from strongly acidic solutions I containing large amounts of hydrochloric acid and ammonium chloride, and also fairly large amount of hydrolyzable metal cations Fe(III), Sn(IV), Zn(II), and Cu(II) tending to form negatively charged chloride complexes. It is seen that the sorption selectivity of S920 and S924 resins to palladium(II) is noticeably higher than that of both the A500 strongly basic anion exchanger poorly sorbing palladium(II) and S984 weakly basic anion exchanger. The sorption capacity of S920 resin for palladium(II) is higher than that of S924 over the entire concentration range studied.

As seen from Fig. 1b, in sorption of palladium from the weakly acidic solution (pH ~3) with a high

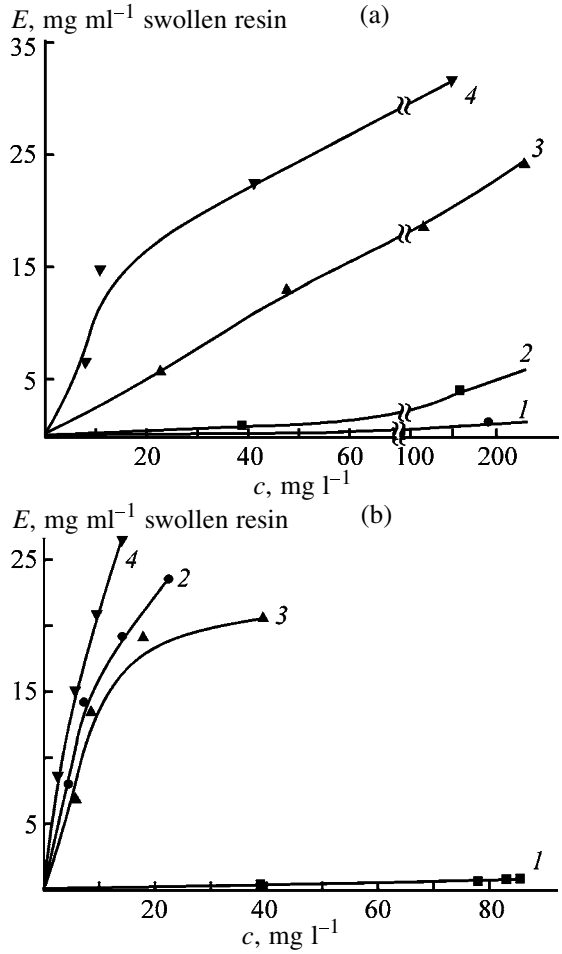

Fig. 1. Sorption isotherms of palladium(II) from solutions of various compositions on (*1*) A500, (*2*) S984, (*3*) S924, and (*4*) S920 resins. (*E*) Sorption capacity of resins for palladium(II) and (*c*) palladium concentration in the equilibrium solution. Solutions composition, g l^{-1}: (a) NH_4Cl 53.5, HCl 110, Cu(II) 3.2, Zn(II) 3.25, Fe(III) 2.8, and Sn(IV) 6.0; (b) NH_4Cl 160, Cu(II) 3.2, Zn(II), 3.3, pH ~3.3.

content of salts (solution II), high selectivity to palladium(II) is exhibited not only by S920 and S924 resins, but also by S984 weakly basic anion exchanger with the polyethylenepolyamine functional groups. Its sorption capacity for palladium(II) is only slightly lower than that of S920 resin.

On the contact of S984 anion exchanger with concentrated aqueous hydrochloric acid, its functional groups are protonated. Under these conditions, S984 loses its selectivity to palladium(II), because Pd(II) can be sorbed in this case only by the anion-exchange (onium) mechanism in the form of $[PdCl_4]^{2-}$, which is the major palladium species in solution. In going to weakly acidic solutions, the sorption selectivity of S984 sharply increases, apparently due to deprotonation of its functional groups and their strong inner-

Table 1. Desorption of palladium(II) from resins under static conditions

Resin	Desorbing solution composition, M	Degree of desorption, %
S920	HCl 12.0	24
	NH_4OH 6.0	~1
	$(NH_2)_2CS$ 0.66, HCl 0.3	98
S924	HCl 12.0	12
	NH_4OH 6.0	~1
	$(NH_2)_2CS$ 0.66, HCl 0.3	65
S984	HCl 12.0	35
	NH_4OH 6.0	10
	$(NH_2)_2CS$ 0.66, HCl 0.3	~100

sphere comlexation with palladium(II). As for S920 and S924, their thiourea and thiol groups are apparently capable of binding palladium(II) through inner-sphere complexation from strongly acidic solutions also.

The suitability of resins for practical application is governed not only by their sorption power and selectivity, but also by the feasibility of desorption of the sorbed component. It is known that desorption of PMs from ion-exchange resins often involves problems [8–14]. Analysis of data on the desorption of PMs from ion exchangers under static conditions [1, 7, 8, 12, 15] (Table 1) allows us to predict the possibility of palladium(II) desorption from S920, S924, and S984 resins with aqueous hydrochloric acid, ammonia, and thiourea.

Table 1 shows that neither concentrated aqueous hydrochloric acid nor concentrated aqueous ammonia are capable of desorbing palladium(II) from any of the resins under consideration. At the same time, treatment of resins with aqueous thiourea ensures virtually complete desorption of palladium(II) from S920 and S984 resins. At the same time, the degree of palladium desorption from S924 resin with aqueous thiourea does not exceed 65%.

The dynamic experiments on sorption of palladium(II) on resins were carried out taking into account our data on sorption of palladium(II) on the same resins under static conditions. The sorption of palladium(II) from solution I was studied on S920 and S924 resins, and the sorption from solution II {mother liquors after precipitation of *trans*-$[Pd(NH_3)_2Cl_2]$}, on S920 and S984 resins. Figures 2 and 3 show the breakthrough and desorption curves of palladium(II). The main characteristics of sorption and desorption of palladium(II) under dynamic conditions are listed in Table 2.

Our results show that, when solutions I and II are passed through the columns packed with the resins under consideration, palladium is sorbed virtually completely (taking into account the detection limit, 2 mg l^{-1}). In sorption of palladium from solution I on S920 resin, its DEC for palladium to breakthrough and the TDEC for palladium exceed the corresponding parameters of S924 resin by a factor of 3. Another advantage of S920 resin is that palladium(II) can be virtually completely desorbed with aqueous thiourea. The average palladium(II) concentration in the desorbate from S920 exceeds its concentraion in the initial solution by a factor of approximately 20. For several fractions of the desorbate, especially those highly enriched in palladium, this factor exceeds 70.

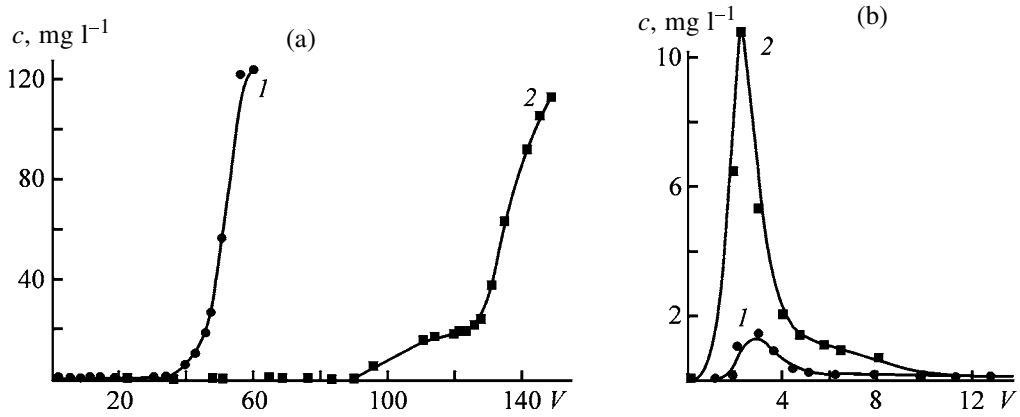

Fig. 2. (a) Breakthrough curves for palladium(II) sorption on resins (*1*) S924 and (*2*) S920, and (b) curves of palladium(II) desorption from the same resins with aqueous thiourea. (*c*) Palladium concentration in the (a) eluate and (b) desorbate and (*V*) eluate volume passed through the column (number of column volumes); the same for Fig. 3. Solution composition, g l^{-1}: Pd 0.150, HCl 109.5, NH_4Cl 53.5, Cu(II) 3.2, Zn(II) 3.25, Fe(III) 2.8, and Sn(IV) 6.

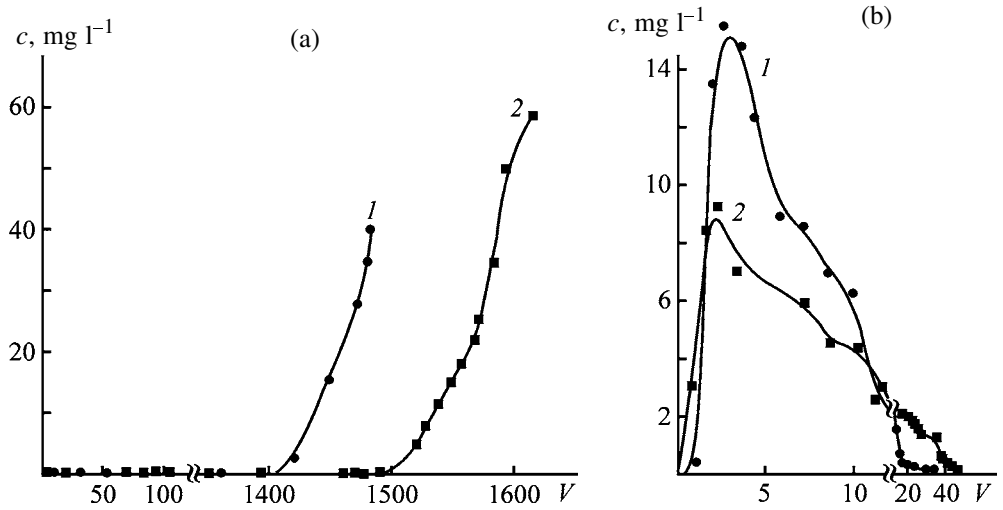

Fig. 3. (a) Breakthrough curbes for palladium(II) sorption on (*1*) S984 and (*2*) S920 resins from weakly acidic solution (pH 5.5) and (b) curves of palladium desorption from (*1*) S984 and (*2*) S920 resins with aqueous thiourea. (a) Solution composition, g l^{-1}: Pd 0.066, NH_4Cl 160, Cu(II) 3.2, and Zn(II) 3.25.

In these fractions, yellow crystalline complexes of palladium(II) with thiourea precipitate. As opposed to S920 resin, from S924 resin palladium is desorbed with aqueous thiourea incompletely (to less than 65%). Therefore, S924 resin was excluded from further experiments.

The S920 and S984 resins efficiently sorb palladium from solution II. In spite of the fact that the palladium(II) concentration in solution II is lower than in solution I, the sorption capacity of S920 for palladium(II) in sorption from solution II is higher than that in sorption from the solution I by a factor of 5. In agreement with the sorption isotherms, S984 anion exchanger exhibits almost the same sorption capacity. Although palladium is fairly completely desorbed with aqueous thiourea from both resins, its desorption from S984 anion exchanger is easier. In desorption of palladium from S920 resin, the mean palladium concentration in the desorbate exceeds its concentration in the initial solution by a factor of 50, and in the desorbate fractions most enriched in palladium this factor exceeds 140. For comparison, in desorption of palladium from S984 resin, these factors are 100 and 230, respectively. In desorption of palladium from both resins, a yellow crystalline complex of palladium(II) with thiourea precipitates.

Analysis of the desorbates for iron and copper shows that the content of these metals is below the detection limit (0.5 and 2.0 mg l^{-1}, respectively).

Table 2. Characteristics of sorption and desorption of palladium from resins under dynamic conditions

Solution composition, g l^{-1}	Resin	Sorption capacity for Pd(II),* mg ml^{-1}		Desorption of palladium(II), mg ml^{-1} resin	c_{Pd} in desorbate, g l^{-1}		Concentration factor	
		DEC	TDEC		average	maximal	average	maximal

* (DEC) Dynamic exchange capacity of resin for palladium to breakthrough; (TDEC) total dynamic exchange capacity of resin for palladium.

CONCLUSIONS

(1) Among resins tested for sorption of palladium from strongly acidic chloride solutions containing nonferrous metal ions and iron(III) (Purolite S920, Purolite S924, Purolite S984, and Purolite A500), Purolite S920 and Puriolte S924 resins with thiourea and thiol functional froups, respectively, show the best selectivity to palladium(II). In sorption of palladium from weakly acidic chloride solutions (pH ~3), the highest selectivity to palladium(II) is shown by Purolite S984 weakly basic anion exchanger with the polyethylenepolyamine functional groups.

(2) Aqueous thiourea virtually completely desorbs palladium(II) from the resins with the thiourea and polyethylenepolyamine functional groups, but from the resin with thiol functional groups the degree of desorption does not exceed 65%.

(3) The Purolite S920 resin efficiently sorbs palladium(II) from strongly acidic solutions simulating the chemical composition of mother liquors formed after precipitation of ammonium hexachloroplatinate(IV) from spent refining solutions. In the case of weakly acidic solutions simulating the chemical composition of the mother liquor after the precipitation of *trans*-dichlorodiamminepalladium from spent refining solutions, the sorption recovery of palladium can be performed with both Purolite S920 and Purolite S984 resins. The palladium can be readily desorbed from these resins with acidified aqueous thiourea.

SORPTION AND ION-EXCHANGE PROCESSES

Kinetics of Platinum(II) and Platinum(IV) Sorption from Hydrochloric Acid Solutions with a Complexing Ion Exchanger Containing Thiourea Functional Groups and with a Strongly Basic Anion Exchanger

N. D. Abovskii, A. A. Blokhin, and Yu. V. Murashkin

Received March 16, 2007

Abstract—The kinetics of platinum(II) and platinum(IV) sorption from 2 M HCl with Purolite S920 complexing ion exchanger containing thiourea functional groups and Purolite A500 strongly basic anion exchanger was studied in relation to the resin granule size, stirring intensity, and temperature.

DOI: 10.1134/S1070427207070099

Ion exchange is one of the most efficient methods for recovery of platinum metals (PM) from multicomponent chloride solutions [1, 2]. Among known ion exchangers, complexing ion exchangers containing thiourea functional groups exhibit particularly high selectivity to PM, including platinum [3–5]. However, choice of an ion exchanger is governed not only by its selectivity, but also by the sorption rate. The majority of papers on platinum sorption with ion exchangers containing thioamide functional groups [5–7] dealt with experimental samples of ion exchangers (in particular, fibrous sorbents, whose use involves certain problems). By now, many complexing ion exchangers with various functional groups (including thiourea groups) have become commercially available. In this study, we examined the kinetics of sorption of platinum(II) and platinum(IV) chloride complexes from hydrochloric acid solutions with Purolite S920 commercial ion exchanger containing thiourea functional groups and (for comparison) with Purolite A500 strongly basic anion exchanger.

EXPERIMENTAL

Experiments were performed with commercial macroporous ion exchangers on a polystyrene matrix, produced by the Purolite Int. Ltd. company: Purolite S920 with thiourea functional groups and strongly basic anion exchanger Putolite A500 (hereinafter S920 and A500, respectively). S920 was in the protonated form, and A500, in the chloride form. The ion exchangers were preliminarily separated into 0.16–0.25-, 0.25–0.5-, and 0.5–1.0-mm fractions (in the swollen state).

The kinetics of platinum(II) and platinum(IV) sorption was studied by the method of the restricted volume at s : l 1 : 1000 (gram of absolutely dry ion exchanger : milliliter of solution). The sorption was performed from a 2 M HCl solution with the initial platinum concentration of 0.5 mM. In the experiments, we varied the ion exchanger granulation, rate of stirrer rotation (from 100 to 500 rpm), and temperature (20, 30, 40, and 50°C). As it will be shown, the rate of platinum(II) and platinum(IV) sorption in all the systems studied is mainly controlled by inner diffusion. To calculate the apparent diffusion coefficient, we used the Boyd–Adamson–Myers equation [8]. In spite of the fact that this equation was intended for calculation of diffusion coefficients under conditions of renewable solution (method of thin layer), in our case its use is justified by the fact that the quantity $\omega' = \bar{c}\bar{V}/(cVK_u)$ parameter ($\bar{c}$ and c are the platinum concentrations in the ion exchanger phase and in solution; $\bar{V}$ and V are the volumes of the ion exchanger and contacting solution, respectively; and K_u, metal distribution coefficient) is 0.005–0.01 depending on the ion exchanger, i.e., is close to zero [9]. For each experimental value of F (degree of equilibrium attainment), using the table in [10], we found the corresponding value of dimensionless time $B\tau$ and constructed the dependence of $B\tau$ on τ. The effective diffusion coefficients were determined by the equation

$$D = B\tau^2/\tau\pi^2, \quad (1)$$

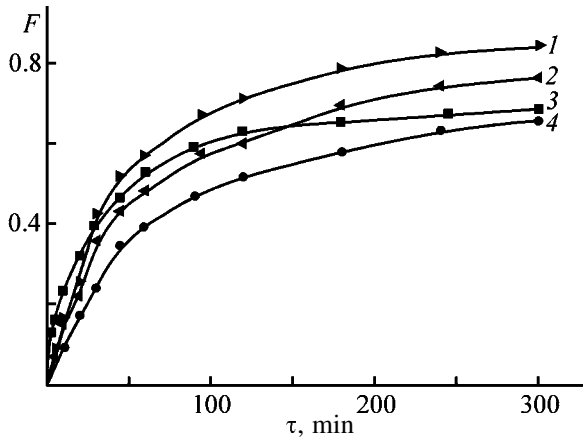

Fig. 1. Degree of the equilibrium attainment F as a function of time τ in Pt(II) sorption with (*1, 2*) A500 and (*3, 4*) S920 ion exchangers. Ion exchanger granulation: (*1, 3*) 0.16–0.25 and (*2, 4*) 0.5–1.0 mm. 20°C; Stirrer rotation rate 200 rpm; the same for Fig. 3.

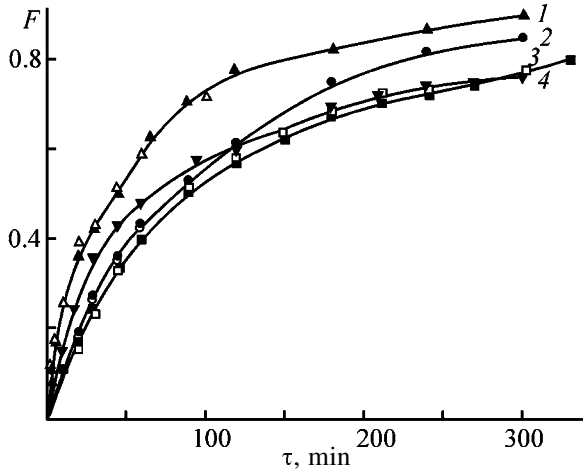

Fig. 2. Degree of the equilibrium attainment F as a function of time τ in sorption of (*1, 2*) Pt(IV) and (*3, 4*) Pt(II) with ion exchangers (*1, 3*) A500 and (*2, 4*) S920 at 20°C. Stirrer rotation rate, rpm: filled points, 60; hollow points, 400.

where r is the average radius of swollen ion exchanger grains.

The apparent activation energies E_a were calculated from the temperature dependences of the apparent diffusion coefficients by the Arrhenius equation

$$D = D_0 e^{-E_a/RT}. \quad (2)$$

The Biot criterion was estimated from the time dependences of $-\log(1 - F)$ [11], which at relatively large τ become straight lines cutting off $\log B_1$ segments on the ordinate axis. From the lengths of these segments, using the table in [12], we found the Biot criterion values.

The platinum concentration in the solution was determined photocolorimetrically from the intensity of the color of the Pt complex with tin(II) chloride [13]. The amount of sorbed platinum was found as the difference between the platinum concentrations in the initial solution and in the solution after contact with the sorbent, taking into account the amount of the ion exchanger and the volume of the contacting solution. The equilibrium capacity of the ion exchangers was determined through the change in the platinum concentration in the solution after stirring with the ion exchanger for 40–80 h depending on temperature. The preliminary experiments showed that this time is sufficient to attain the equilibrium.

The specific surface area of dried samples of the ion exchanger was estimated by the method of low-temperature argon adsorption [14]; total pore volume, by isooctane sorption [15]; and the mean pore radius, from the equation [16]

$$r = 2V/S, \quad (3)$$

where V is the total pore volume ($m^3\ g^{-1}$) and S, specific surface area ($m^2\ g^{-1}$).

First we studied how the resin granule size affects the rate of platinum(II) and platinum(IV) sorption. Figure 1 illustrates the influence of the resin granule size on the kinetics of attainment of the equilibrium for the platinum(II) sorption with A500 and S920 ion exchangers.

As can be seen, an increase in the granule size leads to a decrease in the rate of platinum(II) sorption on both ion exchangers. The same result is observed for platinum(IV) sorption.

Thus, the platinum(II) and platinum(IV) sorption with both A500 strongly basic anion exchanger and S920 complexing ion exchanger depends on the granule size. This fact shows that diffusion, rather than chemical reaction, is the slowest and hence the rate-determining step of the sorption.

Then we examined the influence of the stirring intensity on the platinum sorption kinetics (Fig. 2). As can be seen, the rate of equilibrium attainment in the sorption of both platinum(II) and platinum(IV) with both ion exchangers is virtually independent of the stirring intensity. This fact indicates that the sorption rate is controlled mainly by inner diffusion.

This conclusion is confirmed by the shape of the dependences F–$\tau^{0.5}$, $-\log(1 - F)$–τ, and $B\tau$–τ for the sorption of platinum(II) and platinum(IV) with S920 and A500 ion exchangers (Fig. 3).

Indeed, at degrees of equilibrium attainment F 0.3–

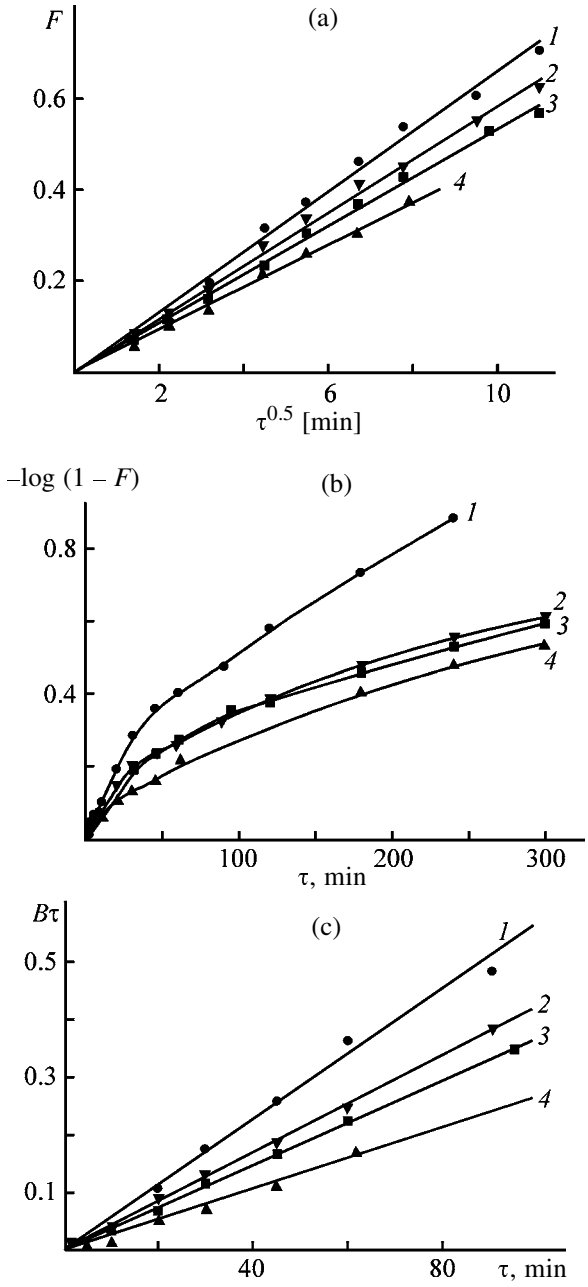

Fig. 3. Plots (a) F–$\tau^{0.5}$, (b) $-\log(1 - F)$–τ, and (c) B_t–τ for (*1, 2*) Pt(IV) and (*3, 4*) Pt(II) sorption with (*1, 3*) A500 and (*2, 4*) S920 ion exchangers. (F) Degree of equilibrium attainment, (τ) time, and ($B\tau$) dimensionless time parameter.

0.7, the F–$\tau^{0.5}$ dependences are straight lines issuing from the origin. The dependences $-\log(1 - F)$–τ deviate from linearity at low F (0.2–0.4) and become straight lines at high F, whereas the $B\tau$–τ dependences are straight lines at low F. Such a shape of the above dependences is characteristic for ion-exchange processes whose kinetics is controlled by inner diffusion [8].

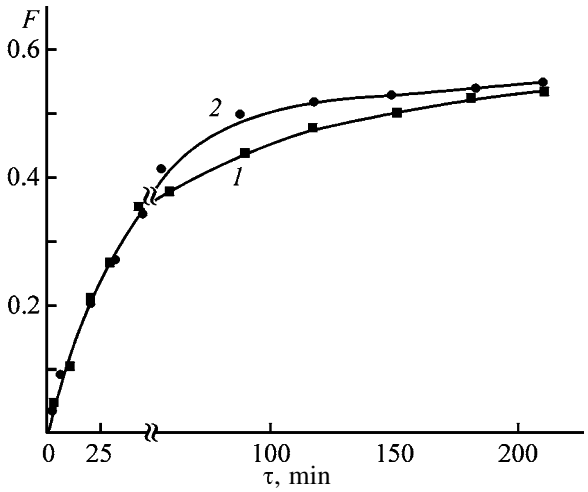

Fig. 4. Degree of the equilibrium attainment F as a function of time τ (*1*) without interruption and (*2*) with interruption of Pt(IV) sorption with S920 ion exchanger.

The interruption technique is considered as the most reliable method of revealing the rate-determining step of ion exchange (outer or inner diffusion) [8]. In such an experiment, when the kinetics of platinum(IV) sorption with S920 was studied, 45 min after starting the sorption the sorbent grains were separated from the contacting solution and then, after 90 min, these grains were again placed into the same solution. Immediately after the contact was resumed, the sorption rate increased (Fig. 4), which is characteristic of ion exchange processes whose kinetics is determined by inner diffusion. The absolute values of Biot criterion listed in the table lead to the same conclusion.

At a fixed rotation rate (200 rpm) and the same granulation (0.5–1.0 mm), we examined the influence of temperature on the rate of the equilibrium attainment in platinum(II) and platinum(IV) sorption with both ion exchangers. The temperature dependences of the apparent coefficients of platinum(II) and platinum(IV) inner diffusion are shown in Fig. 5.

The data on sorption kinetics for both S920 and A500 are summarized in the table.

As can be seen, the apparent diffusion coefficients of both platinum(II) and platinum(IV) vary within the $n \times 10^{-9}$–$n \times 10^{-8}$ $cm^2\ s^{-1}$ range depending on ion exchanger and temperature. The apparent activation energies we determined are typical of ion-exchange processes controlled by inner diffusion [8, 10].

In general, platinum(II) and platinum(IV) sorption on A500 strongly basic anion exchanger can occur only through exchange of negatively charged chloride complexes $[PtCl_4]^{2-}$ or $[PtCl_6]^{2-}$ with chloride ions neutralizing the charge of anion exchanger functional

Parameters of platinum(II) and platinum(IV) sorption kinetics with S920 and A500 ion exchangers

Ion exchanger	Pt oxidation state	T, °C	$\tau_{1/2}$, min	Bi	D, $cm^2\ s^{-1}$	E_a, $kJ\ mol^{-1}$

groups. On S920 ion exchanger with thiourea functional groups, the platinum(II) and platinum(IV) sorption should proceed through complex formation with thiourea functional groups of the ion exchanger, i.e., by exchange of chloride ions initially located in the inner coordination sphere of platinum for fixed ligands (ion exchanger functional groups) with the formation of complexes in the ion exchager phase [17]. In the process, platinum(IV) can be reduced with thiourea groups to platinum(II) [17]. However, the rates of these reactions are probably fairly high and, in any case, higher than the rate of diffusion inside ion exchanger granules. Therefore, in spite of the difference in the mechanism of platinum(II) and platinum(IV) sorption with A500 strongly basic anion exchanger (ion exchange) and S920 complexing resin (complex formation with ion exchanger functional groups and probably redox reaction), in all the systems studied, inner diffusion is the rate-determining step.

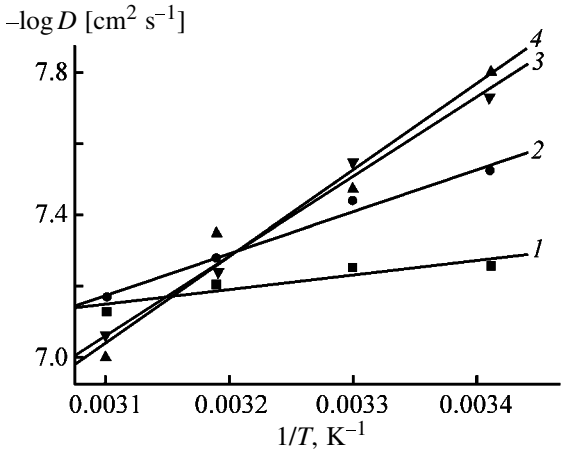

Fig. 5. Effective coefficients of inner diffusion D of (*1, 4*) Pt(IV) and (*2, 3*) Pt(II) as functions of temperature T in sorption with (*1, 2*) A500 and (*3, 4*) S920 ion exchangers.

At the same time, the rate of both platinum(II) and platinum(IV) sorption with A500 strongly basic anion exchanger and the effective diffusion coefficients of Pt(II) and Pt(IV) are noticeably higher than the rate of sorption with S920 complexing ion exchanger, whereas the effective activation energy is lower. This is probably caused by stronger hindrance of platinum(II) and platinum(IV) diffusion inside S920 grains because of their specific interaction with the sorbent functional groups. Differences in the pore structure of the sorbent matrixes can also cause differences in the kinetic characteristics of the ion exchange. The specific surface area of dry S920 and A500 ion exchangers is 6.8 and 23 $m^2\ g^{-1}$; total pore volume, 0.63 and 0.36 $cm^3\ g^{-1}$; and mean pore radius, 185 and 31 nm, respectively. Of course, it should be taken into account that, after swelling of macroporous ion exchangers in aqueous solution, their specific surface area and mean pore radius can change substantially. Furthermore, the characteristics of the pore structure of the dried ion exchangers were estimated by the simplified method. Nevertheless, we can suggest that certain differences in the pore structure of S920 and A500 matrices do exist, which can affect the permeability of these ion exchangers to chloride complexes of platinum(II) and platinum(IV).

In general, we believe that, although the rate of platinum(II) and platinum(IV) sorption with S920 and

A500 ion exchangers is moderate, the kinetic factor in their recovery in the dynamic mode will not lead to essential complications.

CONCLUSIONS

(1) The influence exerted by the ion exchanger grain size and stirring rate on the time dependence of the degree of the equilibrium attainment in platinum(II) and platinum(IV) sorption from 2 M hydrochloric acid with Purolite A500 strongly basic anion exchanger and Purolite S920 complexing ion exchanger with thiourea functional groups was examined. The sorption rate of both platinum(II) and platinum(IV) is mainly limited by inner diffusion.

(2) The apparent diffusion coefficients [$n \times (10^{-8}$–$10^{-9})$ $cm^2\ s^{-1}$], apparent activation energies (15–40 kJ mol^{-1}), and Biot criterion (>50) in platinum(II) and platinum(IV) sorption with Purolite A500 and Purolite S920 ion exchangers were estimated.

(3) Both platinum(II) and platinum(IV) are sorbed with Purolite A500 anion exchanger at a higher rate than with Purolite S920 complexing ion exchanger.

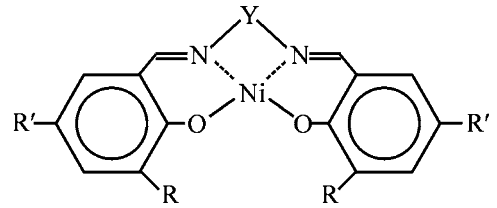
Abstract—Adsorption of a nickel(II) complex with a ligand *N,N'*-2,3-dimethylbutane-2,3-diylbis(salicylidenimine) on a powdered thermally expanded natural graphite and at the air–solution interface from an acetonitrile solution was studied at 283 and 293 K.

DOI: 10.1134/S1070427207070105

The chemistry of conducting polymeric compounds is a vigorously developing area of modern chemical science [1, 2]. Polymerization is always accompanied by adsorption of monomers on the electrode surface. In [3], the adsorption of a nickel(II) complex Ni(SalEn) on a powdered thermally expanded natural graphite from acetonitrile solutions was studied in the temperature range 273–313 K and thermodynamic parameters characterizing the adsorption of this compound were determined. This study is concerned with the adsorption on a nickel(II) complex with *N,N'*-2,3-dimethylbutane-2,3-diylbis(salicylidenimine) [Ni(SaltmEn)] at the air–solution interface and on powdered thermally expanded graphite at 283 and 293 K.

The structures of the compounds studied are presented below:



where R, R' = H, Y = $-CH_2-CH_2-$ [Ni(SalEn)] and R, R' = H, Y = $-C(CH_3)_2-C(CH_3)_2-$ [Ni(SaltmEn)].

The aim of our study was to determine parameters that characterize the binding of Ni(SaltmEn) molecules to the graphite surface.

If a surfactant is adsorbed at the air–solution interface and the adsorption is described by a Frumkin or Langmuir isotherm, then, as demonstrated in [4], the following equation is valid:

$$\Delta G_B^{\infty} = (\Delta G_{ads}^0)^s + RT\ln\gamma_{org}^s/\nu - RT\ln\gamma_{org}^{\infty}, \qquad (1)$$

where ΔG_B^o is the standard Gibbs energy of adsorption, which corresponds to an asymmetric choice of the standard state; ν, number of solvent moles displaced from the surface upon adsorption of 1 mol of the surfactant; γ_{org}^{∞} and γ_{org}^s, activity coefficients of the surfactant in an infinitely dilute solution and in the surface layer, which correspond to a symmetric choice of the standard state.

The activity coefficient γ_{org}^{∞} characterizes the properties of a very dilute solution and may vary, depending on the surfactant and solvent properties, within the range from unity (ideal solution) to 10^3–10^5 [5].

The standard Gibbs energy of adsorption $(\Delta G_{ads}^0)^s$, corresponding to the symmetric choice of the standard state in the solution bulk and in the near-surface layer, can be calculated using the equation [6]

$$(\Delta G_{ads}^0)^s = (\Gamma_{max})^{-1}(\sigma_{org} - \sigma_{solv}), \qquad (2)$$

where σ_{org} and σ_{solv} are the surface tensions of the surfactant and solvent, and Γ_{max}, maximum number of surfactant moles adsorbed on unit surface area.

If a surfactant is adsorbed on the surface of a metal M, graphite, or oxide, it is necessary to take into account the Gibbs energy of the interaction of the surfactant with the adsorbent surface. Because the Gibbs energy is an additive quantity, Eq. (2) should be written as

$$(\Delta G^0_{ads})^s_M = \Delta(\Delta G^0_{M-SA}) + (\Gamma'_{max})^{-1}(\sigma_{org} - \sigma_{solv}), \quad (3)$$

where $\Delta(\Delta G^0_{M-SA})$ is that component of the standard Gibbs energy $(\Delta G^0_{ads})^s_M$ which appears if an adsorbed surfactant molecule interacts with solvent molecules on the adsorbent surface,

$$\Delta(\Delta G^0_{M-SA}) = \Delta G^0_{M-SA} - \Delta G^0_{solv}, \quad (4)$$

where $\Delta(\Delta G^0_{M-SA})$ and $\Delta(\Delta G^0_{M-solv})$ are the standard Gibbs energies of adsorption, which characterize the adsorbent–surfactant and adsorbent–solvent binding.

It follows from Eqs. (1) and (3) that the following equation is valid for the adsorpiton of a surfactant on the adsorbent surface:

$$\Delta G^0_A = \Delta(\Delta G^0_{M-SA}) + (\Gamma'_{max})^{-1}(\sigma_{org} - \sigma_{solv}) + RT\ln(\gamma^\infty_{org})'/\nu' - RT\ln\gamma^\infty_{org}, \quad (5)$$

where ΔG^0_A is the experimental Gibbs energy of adsorption, calculated using the known equation [7]:

$$\ln(B\Sigma n) = -\Delta G^0_A/RT; \quad (6)$$

Σn, number of solvent moles in 1 l; B, adsorption constant in the Frumkin or Langmuir isotherm; (γ^s_{org}), ν', and Γ_{max}, parameters characterizing the adsorption of the surfactant on a metal, graphite, or oxide.

Subtraction of Eq. (1) from (5) gives

$$\Delta(\Delta G^0_A) = \Delta G^0_A - \Delta G^0_B = \Delta(\Delta G^0_{M-SA}) + [(\Gamma'_{max})^{-1} - (\Gamma_{max})^{-1}](\sigma_{org} - \sigma_{solv}) + RT\ln(\gamma_{org})'/\gamma_{org} - RT\ln\nu'/\nu. \quad (7)$$

If the surfactant orientation remains unchanged on passing from the air–solvent interface to that between a metal (oxide) and a solution, then

$$\Gamma'_{max} \approx \Gamma_{max} \text{ and } \nu' \approx \nu. \quad (8)$$

In this case, the following approximate equation is valid:

$$\Delta(\Delta G^0_A) = \Delta(\Delta G^0_{M-SA}) + RT\ln(\gamma^s_{org})'/\gamma^s_{org}. \quad (9)$$

EXPERIMENTAL

The procedure we used in studies with powdered thermally expanded graphite was the same as that described in [3]. The concentration of a saturated monomer solution was determined from a calibration plot of the optical density against concentration. We found that the saturation concentration of Ni(SaltmEn) in acetonitrile c^{sat}_{org} = 0.064 M at T = 293 K and 0.046 M at T = 283 K.

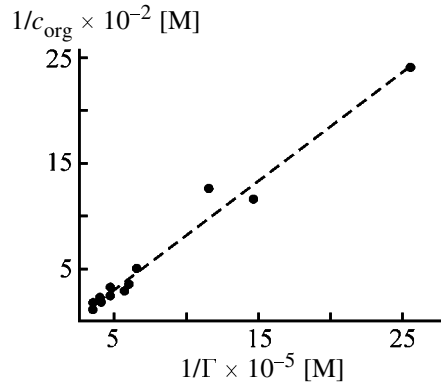


Fig. 1. Experimental dependence in the $1/c_{org}$–$1/\Gamma$ coordinates, described by the Langmuir isotherm (10), which characterizes the adsorption of the nickel complex Ni(SaltmEn) dissolved in acetonitrile on the graphite surface at T = 293 K. (c_{org}) Concentration of the complex in acetonitrile and (Γ) amount of monomer adsorbed on 1 m^2 of the graphite surface.

We studied the adsorption of Ni(SaltmEn) at the air–solution interface using several methods. In the first of these, the surface tension was determined by measuring the reflection of light (laser beam) from the meniscus [8], and in the second, the modified method of a Wilhelmy plate was used [9]. The absolute error in determining the surface tension by these methods was 0.5 mN m^{-1}.

The experimental data we obtained in a study of Ni(SaltmEn) adsorption on powdered graphite were described by the Langmuir isotherm

$$(c_{org})^{-1} = B\Gamma'_{max}/\Gamma_{max} - B \quad (10)$$

and by the Frumkin isotherm

$$\Gamma(\Gamma'_{max} - \Gamma_{max})^{-1}\exp(-2a\Gamma/\Gamma'_{max}) = Bc_{org}, \quad (11)$$

where Γ is the number of monomer moles adsorbed on 1 m^2 of the graphite surface, and a is the attraction constant in the Frumkin isotherm.

Figure 1 shows the experimental dependence of $1/c_{org}$ on $1/\Gamma$, obtained at T = 293 K. It can be seen that the experimental data are well described by the Langmuir isotherm. We used Origin software [3, 4] to find the parameters Γ'_{max}, a, and B in the Frumkin isotherm.

Table 1. Parameters characterizing the Ni(SaltmEn) adsorption at different temperatures

T, K	Frumkin isotherm			Langmuir isotherm	
	B, l mol^{-1}	$2a$	$\Gamma'_{max} \times 10^6$, mol m^{-2}	B, l mol^{-1}	$\Gamma'_{max} \times 10^6$, mol m^{-2}
283	600 ± 200	0.56	3.2 ± 0.2	700 ± 200	3.3 ± 0.2
293	220 ± 50	–0.3	4.0 ± 0.6	200 ± 40	4.5 ± 0.5

Table 2. Thermodynamic parameters characterizing the Ni(SaltmEn) adsorption

T, K	$-\Delta G^0_A$, kJ mol^{-1}	$\Delta(\Delta G^0_A)$, kJ mol^{-1}	$RT\ln\gamma^\infty_{org}$, kJ mol^{-1}	$-\Delta G^0_{ads}$, kJ mol^{-1}
283	22.5 ± 0.6	–19.0 ± 0.6	14.0	8.5 ± 0,6
293	20.5 ± 0.5	–17.5 ± 0.5	13.9	6.6 ± 0.5

The adsorption parameters characterizing the adsorption of Ni(SaltmEn) are listed in Table 1. It can be seen that the values of B and Γ'_{max}, found by processing the experimental data in terms of the Frumkin and Langmuir isotherms, are in agreement within the experimental error. This is due to the fact that the attraction constant $a \le 0.5$. At T = 283 K, the Γ'_{max} for Ni(SaltmEn) molecules virtually coincides with the value $\Gamma'_{max} = (3.5 \pm 0.5) \times 10^{-6}$ mol m^{-2}, obtained in [3] for adsorbed Ni(SalEn) molecules. The area occupied on the graphite surface by a Ni(SaltmEn) molecule at T = 283 K is $(55 \pm 0.5) \times 10^{-20}$ m^2 (molecule)$^{-1}$, which corresponds to the predominantly planar orientation of the adsorbed molecules. As temperature increases, Γ'_{max} slightly grows.

Equation (6) was used to calculate the values of ΔG^0_A, which characterize the monomer adsorption on the surface of the graphite powder. One liter contains 19.024 mol of acetonitrile at T = 298 K. Therefore, we took that $\Sigma n \approx 19$ in ΔG^0_A calculations. The values obtained are listed in Table 2. The parameters are in good agreement with the values of ΔG^0_A, found in [3] for Ni(SalEn), which means that replacement of the $-CH_2-CH_2-$ group with $-C(CH_3)_2-C(CH_3)_2-$ in the monomer molecule has virtually no effect on the Gibbs energy of adsorption.

A study of the Ni(SaltmEn) adsorption at the interface between air and an acetonitrile solution demonstrated that the monomer is very poorly adsorbed, because the change in the surface tension on passing from neat acetonitrile to a solution saturated with Ni(SaltmEn) is within 1 mN m^{-1}, which is comparable with the experimental error. Therefore, we cannot plot an experimental adsorption isotherm. If we assume that the Ni(SaltmEn) adsorption at the air–solution interface is described by the Henry isotherm, we can calculate ΔG^0_B by the equation [4]

$$\Delta G^0_B = -RT\ln[\Delta\sigma(x_{org})^{-1}(RT\Gamma_{max}\nu)^{-1}], \qquad (12)$$

where $\Delta\sigma$ is the change in the surface tension (assumed to be $\Delta\sigma$ = 0.5 mN m^{-1} on passing from neat acetonitrile to a saturated solution); x_{org}, mole fraction of the saturation solution; and ν, number of acetonitrile moles displaced from the surface layer upon adsorption of 1 mol of the surfactant. Taking into account the area occupied on the surface by a Ni(SaltmEn) molecule, we can take that ν = 3. Our calculations demonstrated that $\Delta G^0_B \approx 3$ kJ mol^{-1} at T = 293 K and –3.5 kJ mol^{-1} at T = 283 K. The values of $\Delta(\Delta G'_A)$, calculated by Eq. (7), are listed in Table 2.

It was shown in [10] that the hydrophilicity of a substance is related to its surface tension. The surface tension of graphite is low and close to that of mercury and bismuth [11]. Therefore, we can assume that the parameters characterizing the adsorption of a surfactant on the surface of mercury, bismuth, and graphite should be close to each other [10]. At the same time, it has been found in a study of the adsorption of acetonitrile from an aqueous solution that the value of $\Delta(\Delta G^0_A)$, calculated by Eq. (7), is close to zero [12]. In this case, it follows from Eq. (4) that

$$\Delta G^0_{Hg-CH_3C\equiv N} \approx \Delta G^0_{Hg-H_2O}. \qquad (13)$$

This gives reason to believe that the interaction of an acetonitrile molecule with the Hg surface is approximately the same as that of ν water molecules. In acetonitrile adsorption on the mercury surface, two water molecules are displaced [12]. Consequently, we can compare the value of $\Delta(\Delta G^0_A)$, found in a study of

the adsorption of the monomer from acetonitrile on the graphite surface, with those obtained in an analysis of the adsorption of other surfactants from aqueous solutions on the surface of mercury and bismuth.

The vast body of the available published data [12, 13] demonstrates that, in adsorption of organic molecules from aqueous solutions on an uncharged surface of mercury or bismuth, the values of $\Delta(\Delta G^0_A)$ fall within the range from +5 to –20 kJ mol^{-1}.

Thus, the large negative values of $\Delta(\Delta G^0_A)$ for Ni(SaltmEn) (Table 2) point to a rather strong interaction between an adsorbed monomer molecule and the graphite surface. If we take that $\gamma^\infty_{org}/\gamma_{org} \approx 1$, then, using the values of $\Delta(\Delta G^0_A)$ from Table 2 and the known thermodynamic equation [14]

$$\Delta(\Delta G^0_A) = \Delta(\Delta H^0_A) - T\Delta(\Delta S^0_A), \quad (14)$$

we can calculate the enthalpy of adsorption:

$$\Delta(\Delta H^0_A) = \Delta(\Delta H^0_{M-SA}) - \nu\Delta(\Delta H^0_{M-solv}). \quad (15)$$

Because the parameters $\Delta(\Delta H^0_A)$ and $\Delta(\Delta S^0_A)$ are temperature-independent in a narrow temperature range, calculations by Eq. (14) show that $\Delta(\Delta S^0_A) = -150$ J mol^{-1} and $\Delta(\Delta H^0_A) = -63$ kJ mol^{-1}.

It is commonly believed in studies of the surfactant adsorption on a solid surface from the gas phase that chemisorption is observed if the enthalpy of adsorption falls within the range –(50–400) kJ mol^{-1} [14].

If acetonitrile molecules interact with the graphite surface, then $\Delta(\Delta H^0_{M-solv}) < 0$ and, consequently, $\Delta(\Delta H^0_{M-SA}) > 63$ kJ mol^{-1}. These results point to a weak chemisorption binding of the monomer molecule to the graphite surface.

In [3], experimental data were analyzed in terms of the standard Gibbs energy of adsorption (Γ^0_{ads}), which corresponds to adsorption of the surfactant from a hypothetical ideal solution, calculated using the formula

$$\Delta G^0_{ads} = \Delta G^0_A + RT\ln\gamma^s_{org}. \quad (16)$$

If a surfactant poorly dissolves in the solvent, then the activity coefficient is given by

$$\gamma^0_{org} = (x^{sat}_{org})^{-1}, \quad (17)$$

where x^{sat}_{org} is the saturated surfactant concentration (mole fraction) [7].

Table 2 lists the values of $RT\ln\gamma^\infty_{org}$ and ΔG^0_{ads}. It can be seen that the difference $\Delta G^0_{ads} - \Delta(\Delta G^0_A)$ is

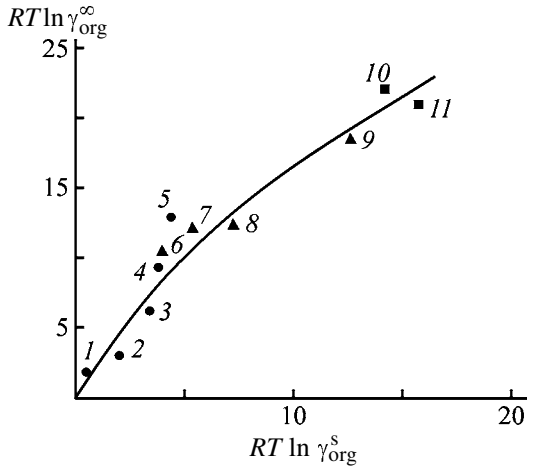

Fig. 2. $RT\ln\gamma^\infty_{org}$ vs. $RT\ln\gamma^s_{org}$ at T = 298 K for various classes of organic compounds. γ^∞_{org} and γ^s_{org} are the surfactant activity coefficients in the infinitely dilute solution and in the surface layer, respectively. (*1*) Methanol, (*2*) ethanol, (*3*) propanol, (*4*) butanol, (*5*) pentanol, (*6*) phenol, (*7*) aniline, (*8*) benzyl alcohol, (*9*) benzoic acid, (*10*) toluene, and (*11*) benzene.

10.5 kJ mol^{-1}. It follows from Eqs. (5), (7), and (8) that

$$\Delta G^0_{ads} - \Delta(\Delta G^0_A) \approx \Delta(\Delta G^0_{ads})^s + RT\ln\gamma^s_{org} - RT\ln\nu. \quad (18)$$

It was shown in [15] that an increase in the size of the hydrophobic part of a molecule results in that the activity coefficients γ^∞_{org} and γ^s_{org} become larger.

Figure 2 shows the dependence of $RT\ln\gamma^\infty_{org}$ on $RT\ln\gamma^s_{org}$. It can be seen that there is a certain correlation between the activity coefficients in the solution bulk and in the surface layer.

The Ni(SaltmEn) molecule contains two benzene rings and a –C(CH$_3$)$_2$–C(CH$_3$)$_2$–carbon chain, and its activity coefficient γ^∞_{org} = 305. All this suggests that $\gamma^s_{org} \gg 1$. Using the plot in Fig. 2, we can easily find that, for the monomer, $RT\ln\gamma^s_{org}$ = 7.5 kJ mol^{-1} and $\gamma^s_{org} \approx 20.5$. Then it follows from Eq. (18) that $(\Delta G^0_{ads})^s \approx 5.7$ kJ mol^{-1} at ν = 3, and we find from Eq. (2) that $\sigma_{org} \approx 50 \times 10^{-3}$ J m^{-2} for the monomer, because $\sigma_{solv} = 29 \times 10^{-3}$ J m^{-2} for acetonitrile [16].

The value of γ^s_{org} points to a strong positive deviation from the Raoult law [14]. This means that the energy of interaction between monomer and acetonitrile molecules substantially exceeds that for the monomer and solvent molecules. If the energy of interaction between the monomer and graphite atoms is not too high, stratification of the surface layer is

possible, with the result that islands of monomer molecules and solvent molecules can be formed.

CONCLUSIONS

(1) A study of the adsorption of the monomer on the graphite powder demonstrated that the experimental data can be described in terms of the Langmuir and Frumkin isotherms.

(2) It was found that the monomer is virtually not adsorbed at all at the air–solution interface.

(3) A calculation of the thermodynamic parameters characterizing the adsorption of the monomer on the graphite powder demonstrated that at least a weak chemisorption occurs.

(4) The activity coefficient of Ni(SaltmEn) in the surface layer $\gamma^{s}_{org} \gg 1$.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis of $H_3PW_{12}O_{40}$ Based Heteropoly Compounds Chemically Fixed on Silica Surface

Abstract—Possibility of activating the silica surface for chemical fixation of tungsten heteropoly compounds of the 12th series on its surface was analyzed.

DOI: 10.1134/S1070427207070117

Thanks to a combination of valuable properties, heteropoly compounds (HPCs) find wide use in numerous practically important processes. On the one hand, heteropoly acids (HPAs) are very strong Brønsted acids in both dissolved and solid states [1–3], which predetermines their successful use in homo- and heterogeneous acid–base catalyses [2–4] and also as solid electrolytes [5]. For this reason, both HPAs and their salts are promising in ion-exchange processes [6, 7]. On the other hand, HPCs include in their composition such elements as molybdenum, tungsten, and vanadium, which imparts redox properties to these compounds and enables their use in catalytic oxidation of organic compounds [2–4, 8, 9]. Thus, HPCs are clearly pronounced bifunctional catalysts. Also known are numerous examples of their use in adsorption [3, 6, 7, 10], membrane [11, 12], and other processes.

Together with possessing a wide variety of valuable properties, compounds of this class also have a number of shortcomings, mostly of technological nature. For example, HPCs have a small specific surface area, up to 5 $m^2 g^{-1}$ [2, 3], and a poorly developed porous structure, mainly represented by micropores [3], which restricts their applications in heterogeneous catalysis and adsorption. At the same time, HPA salts exhibit higher porosity and larger specific surface area, even though they most frequently belong to microporous materials [3, 13, 14] and this leads to slow attainment of equilibrium and impossibility of access of large reagent molecules to the inner surface of pores (diffusion hindrance). Another disadvantage is the comparatively low thermal stability: for HPCs of the 12th series, the Keggin structure disintegrates at 400–450°C [2], which restricts their applicability in some gas-phase catalytic processes.

The purely technological disadvantages of HPCs is their difficult granulation, poor filterability of finely crystalline HPC salts in processes performed in the liquid phase, and low mechanical strength [6]. In economical regard, HPC are rather expensive chemicals, which can also hinder their practical use. However, industrial processes in which HPCs are used as catalysts already exist [2–4].

One way to eliminate these disadvantages of HPCs is their deposition on porous solid supports, both inorganic and organic. Silicas of varied origin are the most frequently used supports for HPCs, as well as for the majority of catalysts.

This study is devoted to synthesis of HPCs on the surface of silica activated by groups that can bind phosphotungstic acid (PTA).

EXPERIMENTAL

A mesoporous aerosilogel with cylindrical grains was used as the starting silica [15]. This aerosilogel was preliminarily activated in two ways.

(1) Reaction of surface silanol groups with 3-aminopropylthriethoxysilane (APTES). It should be noted that this compound has already been used in HPC deposition onto the SiO_2 surface [16, 17]. The reaction itself between APTES and the silica surface is well understood [18]. In the present study, we obtained, by modifying the aerosilogel in an autoclave at 70 and 150°C (preliminarily the aerosilogel was vacuum-treated at 250°C), surface concentrations of amino groups of 0.34 and 0.68 mmol g^{-1}, or 2.2 and 5.9 μmol m^{-2} (supports 1 and 2, respectively).

(2) Reaction of silanol groups with polyhydric alcohols, butanediol and glycerol. The resulting con-

centrations of grafted groups were, respectively, 0.42 (support 3) and 0.31 mmol g^{-1} (support 4); in both cases, the reaction was carried out in an acetone solution in an autoclave at 200°C.

Then, PTA ($H_3PW_{12}O_{40}$) was deposited onto the activated supports from solutions at room temperature or in an autoclave at 150–250°C. After the deposition, the samples were thoroughly washed with acetone a room temperature and refluxed in methanol [19]. The course of silica activation and subsequent PTA deposition was qualitatively monitored by IR spectroscopy, on the basis of changes in the absorption intensity and appearance of new absorption bands (Specord M-80 spectrophotometer, double-beam mode, spectral range 4000–400 cm^{-1}, KBr pellets). In addition, the total pore volume of the supports V_σ and the specific surface area S were measured for the same purpose in all stages by impregnation with ethanol and by the method of thermal desorption of argon, respectively. As noted in [20], the total pore volume and the specific surface area steadily decrease in the case of grafting. The amount of grafted groups was found by an integrated derivatographic analysis in air [18] (Q-1500D instrument, temperature range 20–900°C, heating rate 10 deg min^{-1}). The concentration of the deposited PTA was calculated from the results of an X-ray fluorescence analysis (ElvaX spectrometer). The total acidity of the surface of samples with PTA was found from the chromatographically monitored pyridine adsorption at 130°C [21].

It should be primarily noted that the methods suggested for activation of the silica surface lead to different results in the subsequent attempts to immobilize PTA. For example, preliminary modification of the aerosilogel with polyhydric alcohols was followed by its treatment in an autoclave at 200–250°C with 20% PTA solutions in order to involve the OH groups of the grafted alcohol into the reaction that yields an ester bond with PTA, as it occurs in synthesis of phosphoric acid esters. However, formation of this kind of compounds could not be observed in the given case by the methods employed, and IR spectroscopy failed to reveal bound PTA on the surface even upon a treatment under rather severe conditions, at 250°C and a pressure of 55 atm. The same is suggested by the trends in variation of S and V_σ: they steadily decrease upon modification of the starting silica with alcohols (Table 1, sample nos. 13 and 15), but increase as a result of treatment of supports 3 and 4 with PTA solutions, to virtually reach the values for the starting aerosilogel (sample nos. 14 and 16). It has been found [18] that the acid catalyzes the rupture of the Si–O–C bond by which the diol or triol residue is attached to the surface. It is this behavior that is indicated by the run of the TG and DTA curves in the derivatogram. For example, an exothermic effect peaked at 390°C and mass loss in the same range, which corresponds to the content of grafted alcohol groups, are observed when heating glycerol-modified silica (support 4). At the same time, neither thermal effects associated with

removal of organic groups or PTA decomposition (which, according to the data obtained, ends for bulk samples in crystallization of tungsten trioxide at 615°C), nor any significant mass loss are observed for sample no. 15 (Table 1) at temperatures above 250°C.

If PTA is deposited onto SiO_2 with amino groups on the surface, it is chemically fixed in all cases. This is indicated by the IR spectra in Fig. 1 and by the band assignment in Table 2. As seen from Fig. 1, the spectra of samples with deposited PTA show, even after thorough washing of the samples, bands typical of the Keggin structure of PTA, which are also present in spectra of bulk PTA (Fig. 1, curve *1*): 1088, 975, 887, 800, 595, 525, 375, and 337 cm^{-1} [1, 22, 23]. The shift of the absorption bands from these positions for supported samples is due to the interaction of PTA with active centers of the support [24]. Apparently, the HPA forms surface compounds of the salt type with amino groups, which is also indicated by the strong shift to lower frequencies of the bands associated with stretching vibrations of the N–H bond. For example, the band at 3495 cm^{-1} shifts after the reaction of amino silica with PTA to 3360–3350 cm^{-1}, and the band at 3415 cm^{-1}, to 3260–3240 cm^{-1}. Similar results have been obtained in the case of interaction of NH_2 groups with surface silanol groups [18, 25].

For all the samples synthesized on supports 1 and 2, a sharp decrease in the specific surface area and total pore volume is observed in the stage of PTA deposition (Table 1), which confirms that PTA is chemically grafted. Interestingly, both the starting silica (aerosilogel) and supported PTA-containing samples obtained on its basis have a mesoporous structure, which is indicated by the values of d (nm).

It is known that the thermal decomposition of 3-aminopropyltriethoxysilyl groups occurs on the silica surface in a wide temperature range, with exo-

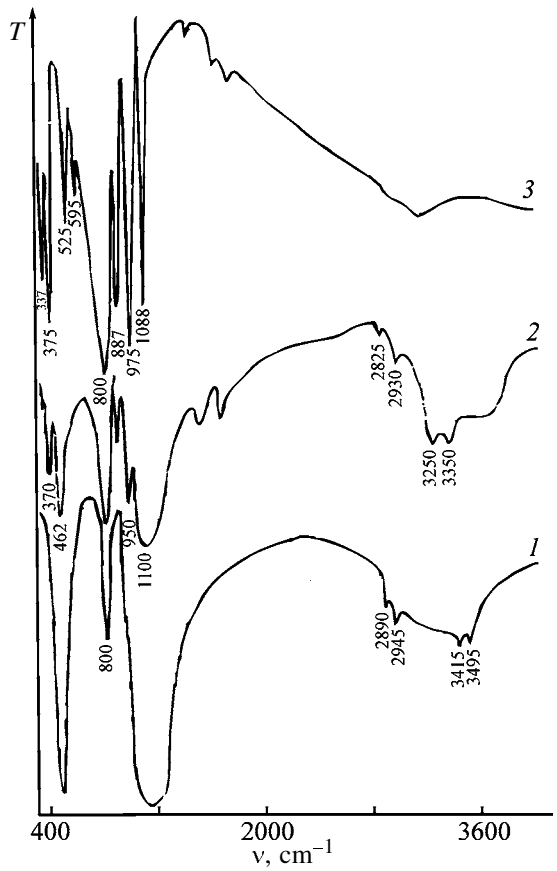

Fig. 1. IR spectra of the samples studied. Sample no.: (*1*) 8 (support 2), (*2*) 10, and (*3*) 1 (pure PTA).

thermic effects at 315°C (removal of pendant ether groups, with rupture of the Si–O–C bond) and 510°C (rupture of the Si–C bond) [26]. For the amino silicas obtained in this study, the modifying layer is removed from the surface at 250–600°C, with exothermic effects at 330 and 540°C. As found in a study of the supported samples, the surface compounds formed by grafted amino groups and PTA decompose in the same temperature range, with the effect at 330°C lacking in the TG and DTA curves (Fig. 2). As already mentioned, this may be due to decomposition of pendant ethoxy groups by the acid in the step of its deposition. In all probability, the exothermic effect at 545°C and the corresponding mass loss are associated with elimination of the whole modifying fragment, together with the supported PTA. A thermographic analysis of separately synthesized bulk samples in the PTA–3-aminopropyltriethoxysilane system confirmed that such salt decomposes in virtually the same temperature range as that for bulk PTA, at 615–645°C. Thus, it can be assumed that the thermal decomposition of the Keggin structure occurs in supported samples in parallel with the degradation of the organic layer above 400°C without crystallization of tungsten oxide, because the whole fragment is eliminated together with PTA at 540–550°C. This is the difference of the systems in question from those produced by impregnation, in which an increase in the thermal stability of supported HPA, compared to bulk acids, has been observed [2, 3, 27].

Table 1 also lists the total acidities c (μmol m^{-2}) of the synthesized supported samples. As is known [2], solid HPA show a purely Brønsted activity, which, apparently, is largely true for the case under consideration. Also consistent with published data is the sharp decrease in acidity upon PTA deposition onto a support [2, 28]. As seen from Table 1, the acidity c decreases by more than an order of magnitude upon impregnation of a pure (starting) silica with PTA. At the same time, c remains higher upon deposition of PTA onto a silica activated by amino groups. In all probability, the reason for such a behavior is in the extent of PTA interaction with the support surface. For example, on modified supports 1 and 2, the amino group to which PTA is bound lies rather far from the surface, at a distance of at least three $–CH_2–$ links. Therefore, even reacting via one or two protons with an NH_2 group, PTA still has unbound protons to exhibit acid properties. In this case, the acidity depends both on the concentration of amino groups on the support surface and on the conditions of PTA deposition. For example, the amount of PTA fixed on support 2, in which the density of NH_2 groups is 2.7 times that on support 1, is 2.5–3 times higher and the acidity increases by a factor of only 1.3–1.6. The latter may be due to a stronger interaction between the PTA molecule and binding centers (amino groups in the case in question) at their higher concentration (this interaction leads to a shift of the IR absorption bands of amino groups by 135–165 cm^{-1}). For example, it is known [5] that an HPA molecule can interact with five OH groups on the silica surface.

The conditions of PTA deposition (temperature, medium) also affect in a certain way the physicochemical parameters of the resulting samples. For example, an increase in temperature leads to a larger amount of deposited PTA and, accordingly, the acidity grows. In this case, both the specific surface area and the total pore volume decrease. Close values were obtained for all the parameters mentioned above in organic (acetone, ethanol) and aqueous media.

Mention should also be made of a test experiment on mechanochemical deposition of PTA onto support 2 in an aqueous medium (Fritch planetary mill, 700 rpm, agate balls; Table 1, sample no. 12). It can be seen that PTA is also fixed on the surface, but its acidity is somewhat lower, compared to samples produced in an autoclave.

Table 1 also lists the properties of supports 3 and 4 before and after an attempt to deposit PTA. It can be seen that their acidities are about the same and, naturally, close to the values for the starting aerosilogel.

Interestingly, 1- and 2-substituted "salts" synthesized for comparison purposes from PTA and 3-aminopropyltriethoxysilane at 20°C in acetone had a

rather high acidity (0.51 and 0.20 μmol m^{-2}, respectively), which was, however, naturally lower than that of bulk PTA.

CONCLUSIONS

(1) Samples with phosphotungstic heteropoly acid chemically fixed on their surface were produced by interaction of the heteropoly acid with silica modified with amino groups. The sample had the following properties: (i) Keggin structure of the heteropoly anion; (ii) presence of organic and inorganic groups on the surface; (iii) developed mesoporous structure; (iv) not too high, but widely controllable total acidity; (v) stability in aqueous and organic media; and (vi) rather high thermal stability, up to 550°C.

(2) The properties listed above suggest that such materials can serve as adsorbents and ion exchangers, and also can be used in liquid- and gas-phase (with certain limitations) catalysis.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Electrosurface Properties of Pectin Substances on Their Sorption Capacity for Water and Heavy Metals

Abstract—Three industrial pectins, viz., citrus, apple, and beet pectins were examined for the chemical composition, sorption, and electroosmotic transfer. The gelation concentrations, charge, and binding of the pectins to water and heavy metals were determined.

DOI: 10.1134/S1070427207070129

Pectins are natural components of plant tissues. They are commercially produced from various kinds of wastes from the food industry such as pomace, citrus peel, beet pulp, and sunflower heads [1–3].

The application of pectins as therapeutic, prophylactic, and detoxicant agents is based on their ability to form hydrogels and insoluble complexes with heavy metals [4–6]. These properties of pectin depend on such factors as the source, preparation route, and physicochemical characteristics of pectin itself. However, in the literature we found no systematic data on the relationship between the physicochemical and performance (hydrophilic, sorption, and electrosurface) characteristics of industrial pectins, which makes it difficult to optimize the dosage and therapeutic approach for these promising natural detoxicants in prophylactic and medical practice.

In this study we examined correlations between the chemical, sorption, and electrosurface properties of various industrial pectins.

We used tree kinds of pectins: PEKTOWIN citrus pectin (type NEC-A2), PEKTOWIN apple pectin (type NEJ-A2), and lab-made beet pectin. The characteristics of these pectins obtained by the standard analytical methods [7] are summarized in Table 1. Particularly, the uronic fraction, total carboxy group concentration, and free and methoxylated carboxy group concentrations were determined titrimetrically.

The electrosurface characteristics of pectins (maximal electroosmotic transfer, ζ potential, and charge of pectin molecules) were determined according to the procedures described in [8]. The gelling and sorption properties (sol/gel point, bound water, and sorption capacity for water and heavy metals) were characterized using the methods described in [9].

In all the experiments we observed the transport of the fluid across the pectin gel toward the cathode, suggesting a positive charge of the counterions, and, correspondingly, a negative charge on the pectin macromolecules. The experimental dependence of the electroosmotic transfer rate (ETR) on the pectin concentration in a gel membrane represents a curve with a maximum (Fig. 1, curves *1–3*), the initial section of which characterizes the increase in ETR with decreasing concentration of the dispersed phase. However, with further dilution, the disperse system passes into the free-disperse state. In this case, ETR abruptly decreases ((Fig. 1, curves *1–3*, the left branch of the curves). Therefore, the maximum point corresponds to the transition from the bound-disperse to the free-disperse state (sol/gel transition). This dependence can be described by Eq. (1):

$$P = \frac{k}{\alpha d c_T} - \frac{k(1+\beta)}{ad}, \quad (1)$$

where P is ETR ($cm^3\ C^{-1}$); c_T, pectin concentration (wt %); α, specific charge of the pectin particles ($C\ g^{-1}$); β, specific concentration of pectin-bound water ($g\ g^{-1}$); d, density of the dispersion medium ($g\ cm^{-3}$); and k, coefficient reflecting the ratio between the speeds of the fluid and counterions (it is close to unity in our case).

Table 1. Chemical characteristics of industrial pectins

Pectin source	Uronic fraction, wt %	Heavy metal content, μg kg^{-1}	Degree of esterification, wt %	Carboxy group content, wt %		
				total	free	methoxylated
Apple	57.9	>50	39.03	16.02	9.72	6.30
Citrus	50.5	>50	42.90	17.82	10.17	7.65
Beet	62.2	>20	52.30	18.90	9.00	9.90

The value of charge may characterize the ion-exchange and sorption capacities of pectin, and the fraction of bound water β (g g^{-1}), its hydrophilicity.

The maximal ETR can be used to determine the electrokinetic potential (mV) on the dispersed particles of pectin by Smoluchowski's equation (2):

$$\zeta = \eta KP/\varepsilon\varepsilon_0, \quad (2)$$

where K is the conductivity of the solution, and η and $\varepsilon\varepsilon_0$ are the viscosity and permittivity of the dispersion medium, respectively.

It follows from Eq. (2) that P is a linear function of $1/c_T$, allowing estimation of the charge on the pectin macromolecules and bound water concentration from experimental data. In so doing, from single series of ETR measurements in relation to c_T, we gained information on the charge and gelling point in the system pectin–water (Table 2).

As mentioned above, the gelling ability is among the most important characteristics of pectins. It increases with decreasing gelling concentration. Table 2 shows that, for the investigated pectins, the gelling concentration increases in the order apple < citrus < beet.

Table 1 shows that this order well correlates with the methoxy group content, total carboxy group content, and degree of esterification, suggesting that it is these chemical characteristics that control the gelling ability of pectins, which decreases on passing from apple pectin to beet pectin.

Binding of water on the surface of hydrophilic materials, particularly, pectins is caused by ionized carboxy groups and also by hydrogen bonding with a great amount of hydroxy groups. The number of bound water molecules per charged functional group can be estimated from the ratio of the above functional groups. The charged surface of pectin binds a considerable number of water molecules, making it a continuum. This imparts new properties to the surface, among them the ability to sorb metal cations.

The sorption characteristics of the industrial pectins were determined in the static mode. Sorption was studied from 0.1–10 mM aqueous solutions of $NiCl_2$, $CoCl_2$, $CuSO_4$, $ZnSO_4$, $CdCl_2$, and $Pb(NO_3)_2$, prepared using Ringer's solution as a supporting electrolyte at a sorbent to solution ratio of 1 : 250 and pH 6.2–6.5. The metal concentrations in the initial and equilibrium solutions were determined by atomic absorption spectroscopy on a Varian automatic analyzer (the United States). The sorption capacity of pectins for heavy metal ions A (mmol g^{-1}) was determined as

$$A = (c_0 - c_{eq})V/m, \quad (3)$$

where c_0 and c_{eq} are the initial and equilibrium concentrations of a heavy metal in the solution; V, solution volume; and m, sorbent weight.

The experimental data fit to the Freundlich isotherm (Table 3):

$$A = a_0 c_{eq}^n \quad \text{and} \quad \log A = \log a_0 + n \log c_{eq}, \quad (4)$$

where a_0 is the initial (standard) sorption capacity of pectins at $c_{eq} = 1$ M ($\log c_{eq} = 0$).

Analysis of the results obtained (Table 2) shows that apple pectin has the highest affinity (a_0) for cobalt(II); beet pectin, for copper(II) and cadmium(II); and citrus pectin, for nickel(II), zinc(II), and lead(II). However, judging from the fact that this characteristic does not correlate with the capacity factor n, one may expect that, at low metal concentrations, the sorption characteristics of pectins could be strongly different.

Comparison of the sorption, hydrophilic, and electrosurface properties of the industrial pectins shows that they are well correlated, and citrus pectin ranks first in all performance characteristics (Table 3).

As seen, free carboxy groups play a crucial role in both charging and sorption capacity of pectins. It should be pointed out that there is no common view of the binding mechanism of heavy metals to pectin. Most likely, it involves the formation of pectates through complexation of metal ions with the carboxy groups of the polysaccharide matrix. Also some inclusion compounds can be formed through uptake of a metal ions by the swollen macromolecule of the polysaccharide. Another possible mechanism is ion exchange involving functional groups of pectins.

CONCLUSIONS

(1) All the pectins studied are characterized by similar sol/gel points (3–4 wt %).

(2) A relationship is found between the chemical, electrosurface, and sorption characteristics of industrial pectins. The free carboxy group concentration is the key factor controlling both the charge on pectin and its sorption capacity for heavy metals.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Use of Diamond Stock in Chromium Plating

Abstract—Cathodic deposition of a chromium coating from the standard electrolyte in the presence of a diamond stock was analyzed. The microhardness and wear resistance of chromium–diamond coatings and the effect of the diamond stock on the electrical conductivity and throwing power of the electrolyte were studied.

DOI: 10.1134/S1070427207070130

Chromium plating is one of the most commonly employed electroplating processes. Chromium coatings are widely used to impart a decorative appearance to articles, to protect parts subject to wear (shafts and pistons) and molds that should have a high surface hardness, and to restore worn components. As a rule, articles of this kind are coated with a thick chromium layer (200–500 μm).

Because the deposition of thick chromium layers is a rather high-cost process, a topical task is to develop a procedure for deposition of composite chromium–diamond coatings (CDC) with the use of nanodiamonds (ND) in order to diminish the thickness and improve the physicochemical properties of chromium coatings. The possibility of codeposition of chromium and ND was first reported in [1], with the amount of ND in the chromium plating electrolyte varied from 5 to 40 g l^{-1}.

A method for CDC deposition on blade tools has found wide use. This method was industrially implemented at Elektrokhimpribor combine (Lesnoi), Cherepovets steel works, and others. Therefore, this process has been the subject of extensive research work with rather contradictory results, from enthusiastic to negative [1–3].

At present, composite electroplated coatings (CEC) with ND are not widely used because of the high cost of diamond synthesis. Therefore, it is suggested to consider, in order to lower the production cost of chromium–diamond coatings, use of the raw material from which ND are obtained, diamond stock (DS). Detonation conversion of high-power explosives with a negative balance in a nonoxidative medium (i.e., in that with an oxygen content lower than the stoichiometric value) yields a condensed ND-containing carbon phase. Such a condensed carbon, named the diamond stock, may contain up to 75% ND [4]. DS exhibits adsorption capacity and high chemical activity.

The aim of this study was to examine the effect of DS on the mechanism of the chromium plating process, electrical conductivity and throwing power of the electrolyte, physicomechanical properties of coatings (microhardness, wear resistance), and outward appearance of chromium coatings obtained in various modes.

EXPERIMENTAL

A versatile chromium plating electrolyte of the following composition (g l^{-1}): CrO_3 230–260 and H_2SO_4 2.3–2.6 (electrolyte no. 1), was chosen for the study.

This choice was due to the following: its composition is more stable than that of a diluted chromium plating electrolyte; can be used to produce both wear-resistant and hard chromium deposits; has a rather high throwing and covering power; causes no difficulties in determination of the ND and DS content of the electrolyte (in contrast to the self-regulating electrolyte).

The deposition was performed from the above-mentioned solution, with DS introduced in amounts of 1, 2.5, 5, and 10 g l^{-1} (electrolyte nos. 2, 3, 4, and 5, respectively). The optimal DS concentrations in the chromium plating electrolyte was determined by

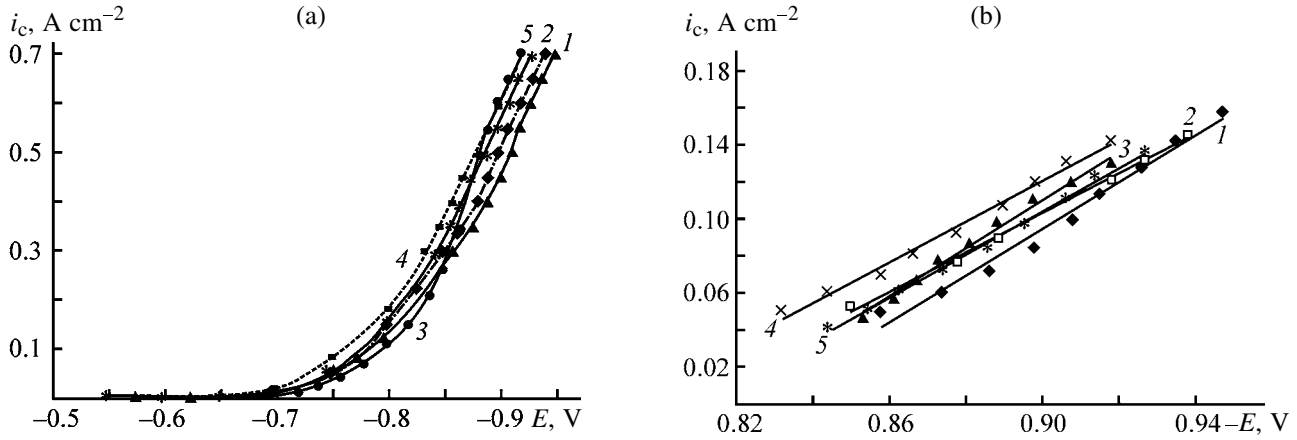

Fig. 1. (a) Overall and (b) partial polarization curves of chromium deposition from DS-containing electrolytes at 50 ± 1°C. (i_c) Current density and (E) potential; the same for Fig. 2. (*1*) Without additive; DS additive, g l^{-1}: (*2*) 1, (*3*) 2.5, (*4*) 5, and (*5*) 10.

analyzing the quality of the outward appearance of coatings and physicomechanical properties of chromium–diamond coatings obtained in various electrolysis modes. Experiments were carried out in the following modes: cathode current density (A dm^{-2}): 30, 40, 50, 60, 70; electrolyte temperature (°C): 45 ± 1, 50 ± 1, 55 ± 1.

The cathodic polarization curves were measured in a three-electrode cell with separated 50-ml electrode spaces with a P-5848 potentiostat by the potentiostatic method. A silver chloride reference electrode was used. The potentials were recalculated to the hydrogen scale. The current was measured with an M1104 milliammeter with an accuracy of 0.2%. The experiments were performed at 50 ± 1°C.

The throwing power (TP) of the electrolyte was evaluated using an indirect method by calculating the electrochemical similarity coefficient (Γ) defined as a product of the electrical conductivity of the solution (χ) and the electrode polarizability ($\Delta E/\Delta i_c$), which is a secondary distribution in determining the TP of an electrolyte [5, 6]. For this purpose, polarization curves were measured and the electrical conductivities of the solutions in the presence of DS and without it were determined. The electrical conductivity was found by measuring the voltage with a V7-40/4 voltmeter. Steel coated with chromium with a thickness of no less than 40 μm served as the working electrode (cathode), a lead plate was used as an auxiliary electrode (anode), and a silver chloride electrode served as reference.

The microhardness was measured with a PMT-3 microhardness meter. To obtain comparable data, the hardness was measured at a coating thickness of 45–50 μm and a constant load of 100 g. St. 20 steel plates were used as a support. The hardness was measured not earlier than 24 h after a coating was deposited.

Wear-resistance tests were performed on a machine with a reciprocal motion of samples under dry-friction conditions. The friction pair had the form of a brass disc with a 3.5–5-μm-thick coating to be tested, which rubs against a plane-parallel steel plate covered with hard chromium. All the tests were made under a constant load of 130 g in the course of 20 h, the wear resistance was evaluated by the mass loss by the samples upon abrasion [7].

The potentiostatic curves obtained in electrolytes in the presence of a diamond stock and without it, which reflect the overall electrode processes, are shown in Fig. 1a. Upon introduction of DS into the standard chromium plating electrolyte, the polarization curves somewhat shift in the positive direction (the polarization shift is up to 30 mV, which lies within the experimental error).

Figure 1b shows partial polarization curves of chromium deposition in solutions with and without DS additives. It can be seen that the slope of the polarization curves remains virtually unchanged. To plot partial polarization curves of chromium deposition from the standard chromium plating electrolyte with and without DS additive, the current efficiencies were measured at working current densities and a temperature of 50°C (Table 1). As seen from Table 1, addition of DS leads to a slight increase in the current efficiency (CE) by chromium. The maximum increase in CE relative to that for an electrolyte

Table 1. Effect of the cathode current density on the current efficiency by chromium at varied DS content of the electrolyte

c_{DS}, g l^{-1}	Current efficiency, %, at indicated cathode current density, A m^{-2}								
	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7
0	16.8	17.5	18.1	19.1	20.1	20.9	21.6	22.1	22.5
1	19.9	20.8	21.8	22.3	22.6	23.5	24.6	25.4	26.3
2.5	17.9	19.0	20.2	21.4	22.8	23.7	24.7	25.2	25.8
5	18.6	18.9	19.3	20.1	20.6	21.8	23.0	23.4	23.8
10	18.0	19.6	21.4	21.7	22.1	22.7	23.2	23.8	24.4

without additives (up to 3%) is observed in an electrolyte with a DS content of 2.5 g l^{-1}.

Upon addition of DS to the electrolyte, the hydrogen evolution curves shift in the negative direction (Fig. 2), because the discharge of hydrogen ions on the electrolyte surface with adsorbed DS particles is hindered, in agreement with an increase in the current efficiency by chromium.

The electrical conductivity of the chromium plating electrolyte somewhat increases in the presence of DS, which, in turn, should affect the throwing power of the solution. Table 2 shows that the electrochemical similarity factor for DS-containing electrolytes somewhat exceeds that for additive-free electrolytes, and, consequently, the throwing power of DS-containing solutions should be higher than that of an electrolyte without additives.

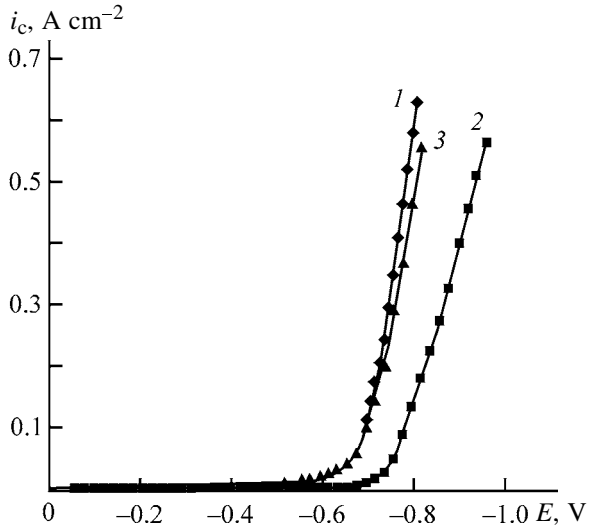

Fig. 2. Hydrogen curves measured in chromium anhydride with and without diamond stock on a chromium electrode at 50 ± 1°C. (*1*) Without additives; additive (g l^{-1}): (*2*) 2.5 and (*3*) 5.

The effect of DS on the microhardness of chromium coatings deposited at different temperatures is shown in Fig. 3. It can be seen that the microhardness of the chromium coatings increases with the cathode current density at the temperatures studied. The optimal concentration of DS in the electrolyte is 5 g l^{-1} (further increase in concentration has virtually no effect on the microhardness of the chromium coatings).

5	2.4	2.8	2.2	1.9	2.4	2.6
10	2.5	3.2	2.9	2.0	2.8	2.7

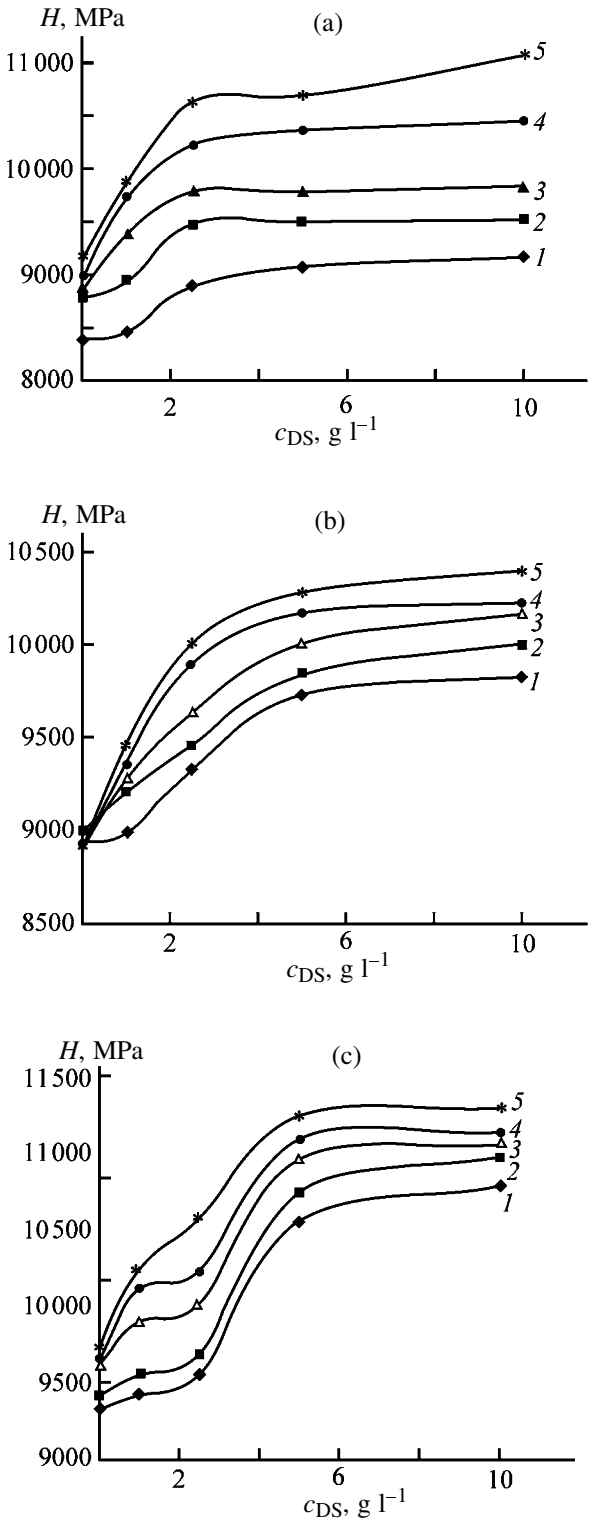

Fig. 3. Effect of DS concentration c_{DS} on the microhardness H of chromium coatings obtained at different temperatures and current densities. Temperature, °C: (a) 45 ± 1, (b) 50 ± 1, and (c) 55 ± 1. Current density, A dm^{-2}: (*1*) 30, (*2*) 40, (*3*) 50, (*4*) 60, and (*5*) 70.

The microhardness of chromium–diamond coatings is 15–20% higher. The increase in the microhardness of the chromium coatings in the presence of DS can be attributed to introduction of DS particles into the coatings via adsorption and to deposition of more finely crystalline coatings.

The microhardness of thermally treated coatings was also measured. The thermal treatment was carried out at 200 ± 20°C for 2 h. It was found that the microhardness of the chromium coatings regularly decreases upon thermal treatment. For example, the decrease in microhardness upon thermal treatment is 10–15% for a purely chromium coating and that deposited in the presence of 1 g l^{-1} of DS and 6–10% for the coating obtained from an electrolyte with 10 g l^{-1} of the stock.

It should be noted that lustrous chromium coatings can be deposited from an electrolyte containing 2.5 g l^{-1} of DS in a wide range of current densities without any preliminary polishing of a support. The coatings obtained upon a further increase in the DS concentration to 10 g l^{-1} are not lustrous and identical in outward appearance to those deposited from an additive-free electrolyte.

Table 3 lists data on the effect of the additives on the wear resistance of the resulting chromium coatings. It can be seen that, on the average, the wear resistance of chromium–diamond coatings is 2–3 times that of pure chromium. The best wear resistance is observed for coatings deposited from electrolytes containing 2.5–5 g l^{-1} of DS.

CONCLUSIONS

(1) Introduction of the DS additive into the standard chromium plating electrolyte has virtually no effect on the hydrogen evolution overvoltage and the polarizability of the process.

(2) The electrical conductivity and throwing power of DS-containing solutions somewhat exceed those of the standard chromium plating electrolyte. At DS concentrations of 1–2.5 g l^{-1}, the deposition range of lustrous coatings becomes wider.

(3) Introduction of DS into the electrolyte can improve the microhardness and wear resistance of chromium coatings. The microhardness increases by 15–20%. The optimal DS concentration is 5 g l^{-1}. The best wear resistance is observed for coatings deposited in the presence of 2.5–5 l^{-1} of DS.

Abstract—An electrolytic method was suggested for the synthesis of nipecotic acid ethyl ester in a diaphragm electrolytic cell on a copper cathode in aqueous–alcoholic alkali solution.

DOI: 10.1134/S1070427207070142

Nipecotic (3-piperidinecarboxylic) acid and its various esters are widely used in medicine as agents preventing thrombus formation, and also in clinical practice as an antiepileptic (Tiagabin).

No data on electrocatalytic synthesis of nipecotic acid and its esters have been reported. Osadchenko and Tomilov [1] prepared isonipecotic acid with a current efficiency of 60% by electrolytic reduction of the pyridine ring of isonicotinic acid on a copper cathode.

Reduction of the pyridine ring has been studied to a greater extent on electrodes with a low hydrogen overvoltage, e.g., on silver, and on those with a high overvoltage (lead, mercury). The course of pyridine reduction depends on the process conditions and structural features of pyridine derivatives; bis(piperidines) are frequently formed [2]. It is advisable to perform pyridine reduction in an electrocatalytic system on cathodes activated with Raney nickel or cobalt. At a current density of 2–8 kA m^{-2} and a pyridine concentration of 0.2–0.3 kmol m^{-3}, the piperidine yield based on the hydrogen uptake is 90% [3].

With the aim to develop an electrocatalytic procedure for preparing isonipecotic acid ethyl ester, we examined in this study exhaustive hydrogenation of nicotinic acid ethyl ester in aqueous and aqueous–alcoholic solutions.

EXPERIMENTAL

Electrolytic hydrogenation of nicotinic acid ethyl ester **I** was performed in a diaphragm electrolytic cell with the anode and cathode compartments separated by an MK-40 membrane. The cell volume was 60 ml (Fig. 1). As anode we used platinum grid, and as cathode, a cooper plate (support) with a visible surface area of 0.05 dm^2, closely adjoining the electrolyzer bottom. For cathode activation we used Raney nickel which was held on the electrode surface with a permanent magnet arranged outside the electrolyzer [1].

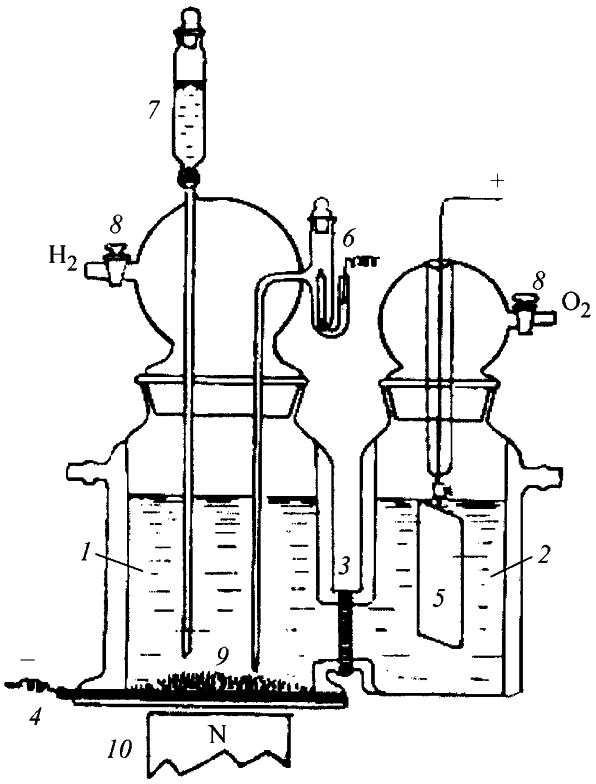

Fig. 1. Cell for electrocatalytic processes: (*1*) catholyte, (*2*) anolyte, (*3*) diaphragm, (*4*) cathode support, (*5*) anode, (*6*) calomel electrode, (*7*) funnel, (*8*) hydrogen and oxygen outlet, (*9*) catalyst, and (*10*) magnet.

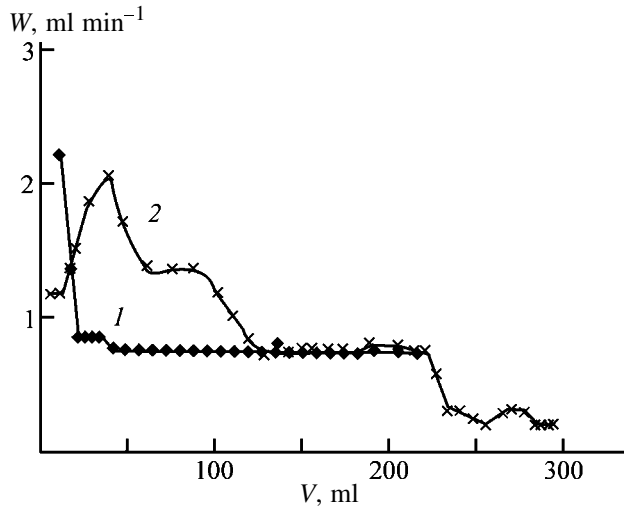

Fig. 2. Hydrogen uptake rate W as a function of volume V of hydrogen taken up in (*1*) aqueous and (*2*) aqueous–alcoholic NaOH solutions.

As organic solvent we used ethanol. The catholyte was a 1 : 1.5 mixture of alcohol with 20% aqueous NaOH, and the anolyte was 20% NaOH. The electrolysis was performed with gentle stirring (50–60 rpm) at a current of 1.0 A and solution temperature of 20–40°C, until the hydrogen uptake ceased; the amount of Raney nickel on the cathode surface was 1.0 g dm^{-2}. After the electrolysis completion, the target product was extracted from the catholyte with ether and purified by common procedures. According to Faraday's law, 300 ml of hydrogen should be absorbed by 0.78 g of the ester. The system was sealed, and gases evolving from the cathode and anode compartments could be collected in 500-ml graduated gas burets.

From the volume of the released oxygen and hydrogen, we calculated the reduction rate W, hydrogen uptake percentage, hydrogen utilization coefficient η, and current efficiency.

The reduction rate, (ml H_2) min^{-1}, was calculated by the equation

$$W = k(2V_O - V_H)/\Delta\tau,$$

where V_O and V_H are the volumes (ml) of the released oxygen and hydrogen, respectively; Δt, process time (min); and k, barometric coefficient for converting the gas volumes to normal conditions.

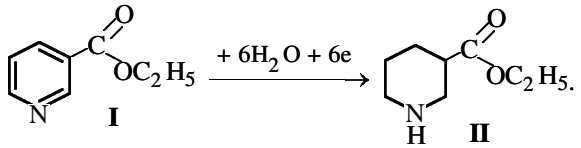
The hydrogen utilization coefficient, i.e., the ratio of hydrogen added to the organic substrate (pyridine ring) to the total volume of hydrogen released at the cathode, was calculated by the formula

$$\eta = (2V_O - V_H)/2V_O.$$

The best results were obtained when the electrolytic reduction of nicotinic acid ethyl ester was performed in aqueous–alcoholic solution (Fig. 2), which may be due to higher solubility of the starting ester in an aqueous–organic solution.

The pyridine molecule is not a regular hexagon: it has a dipole moment due to nonuniform charge distribution [4]. The nitrogen atom in pyridine is an electron acceptor withdrawing the electron density from the ring. Furthermore, formation of two σ bonds and one π bond between the *o*-C atoms and N atom of the ring results in orientation of the nitrogen lone electron pair outside the ring, which favors complexation with Lewis acids and solubility in proton-donor solvents.

In aqueous alkali, the hydrogen uptake does not go to completion (it does not exceed 74–78%), and the mean hydrogenation rate is 0.8 (ml H_2) min^{-1}. On adding ethanol to the catholyte, the hydrogen uptake accelerates [2 (ml H_2) min^{-1}] and reaches 100%. An analysis shows that electrocatalytic hydrogenation of **I** on the cathode occurs with a substance yield of 98% and current efficiency of 63%, following the scheme



The structure of nipecotic acid ester **II** was proved by IR and ^{1}H NMR data, and the composition was confirmed by elemental analysis. The IR spectra were recorded on an Avatar-320 spectrometer from mulls in mineral oil, and the ^{1}H NMR spectra, on a Tesla BS-587 spectrometer (80 MHz) in DMSO-d_6 relative to HMDS. The IR spectrum of **II** contains a strong band at about 1740 cm^{-1} caused by stretching vibrations of the C=O group and a broad absorption band at about 3440 cm^{-1} belonging to NH stretching vibrations. In the ^{1}H NMR spectrum, the methylene protons of the piperidine core give a multiplet at 1.5–2.0 ppm, and the methyl protons of the ethoxy group give a triplet at 1.25 ppm (J 7.0 Hz).

CONCLUSION

A procedure was developed for electrolytic synthesis of nipecotic acid ethyl ester in aqueous–alcoholic alkali solution on a copper cathode with Raney nickel. The target product is prepared with almost

quantitative substance yield and 63% current efficiency.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Dechlorination of Persistent Organic Pollutants Polychlorobiphenyls by Catalytic Carbonylation

Abstract—A new approach to dechlorination of "dioxin-like" ecotoxicants, polychlorinated biphenyls, based on carbonylation, was suggested. The weakly reactive aryl halides are activated by effective catalytic systems based on epoxide-modified cobalt carbonyl in alcoholic alkali solutions.

DOI: 10.1134/S1070427207070154

Polychlorinated biphenyls (PCBs) have a set of unique physicochemical properties and are widely used as dielectrics in transformers and capacitors, as hydraulic fluids, and as heat carriers. At the same time, PCBs are highly toxic; they damage the immune, endocrine, and nervous systems and exhibit carcinogenic properties [1, 2]. Because of the high vapor pressure and noticeable volatility, they are capable of transboundary transport to long distances. Being lipophilic, these compounds accumulate in adipose tissues of animals and humans and get involved in food chains. Polychlorobiphenyls are extremely resistant to biological and chemical degradation and can exist in the environment for centuries. Therefore, along with superecotoxicants, dioxins (polychlorodibenzodioxins) and polychlorodibenzofurans, they are included in the main list of persistent organic pollutants (POPs). According to Stockholm convention on POPs, which came into force in 2004, these compounds are to be destroyed or utilized [1].

Today the production of PCBs has been stopped. However, by the beginning of the 1990s, more than 1.5 mln tons of technical PCB mixtures (including approximately 180 thousand tons in the former Soviet Union) have been produced in the world. In Russia, up to 35 000 t of PCBs are still in use, including more than 1000 t in St. Petersburg and Leningrad oblast (according to incomplete data) [1].

Much attention is given today to the development of procedures for rendering polychlorobiphenyls harmless. It is known that spent technical oils that are not subjected to regeneration are commonly incinerated, but this procedure is unacceptable for PCB-containing oils, because of formation of dioxins in the process. The most promising way to decrease the amount of PCBs in the environment is their chemical reprocessing into environmentally safe products. Much attention is given to the development of methods for PCB reduction with alkali metals and alkali metal hydrides [2, 3], and also of safer and more feasible methods of catalytic reductive dehalogenation [2, 4]. It is also suggested to treat PCBs with alkali metal polyglycolates with the formation of ethers [5].

In this study we examined the principal possibility of reprocessing technical PCB mixtures by carbonylation, with the aim to subsequently develop a process for PCB utilization and conversion into useful products (acids and their derivatives: salts, esters, amides). These products can find wide use in production of dyes and pigments, polymers and resins, lubricants, surfactants, corrosion inhibitors, and additives to oils and bitumens.

The suggested procedure is based on the previously developed [6–8] principally new catalytic systems based on modified cobalt carbonyl, capable of activating aromatic halides and involving them in carbonylation with the formation of carboxylic acids and their derivatives. For the carbonylation of PCBs, which are inert aryl chlorides, we chose the most active catalytic systems promoted with propylene oxide (PO). The advantages of this procedure are the use of cheap and available raw materials and low power consumption

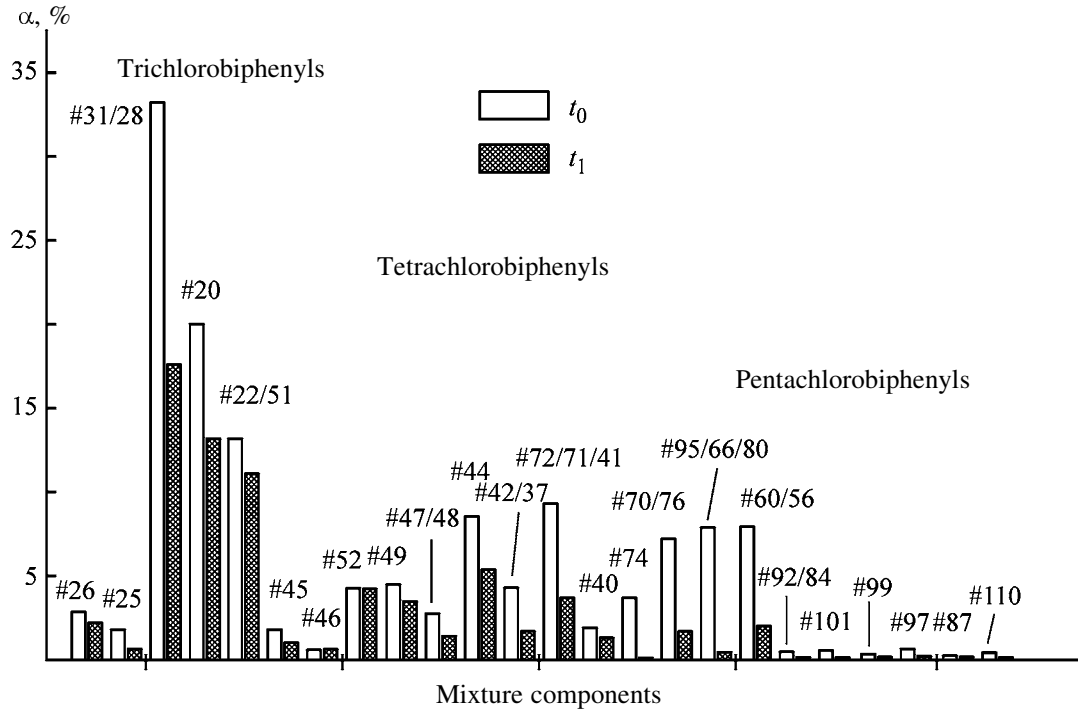

Fig. 1. Conversion α of tri-, tetra-, and pentachlorobiphenyls in carbonylation of technical-grade trichlorobiphenyl mixture: (t_0) before the start of the reaction and (t_1) in 5 h. (#) Congener no. according to IUPAC nomenclature.

due to the mild reaction conditions (CO pressure 1 atm, temperature 60–65°C).

To check the principal possibility of using this procedure, we performed carbonylation of technical-grade trichlorobiphenyl (TCB) mixture containing 43 wt % Cl and consisting, according to [9], of 14% di-, 49% tri-, 32% tetra-, 4% penta-, and 1% hexachlorobiphenyls. The chlorine content corresponds to the mean composition $C_{12}H_{6.8}Cl_{3.2}$, i.e., slightly more than three H atoms per biphenyl molecules are replaced by Cl. The reaction was performed at 60°C and atmospheric pressure of CO in methanol in the presence of K_2CO_3. As activator we used PO at the molar ratio [TCB] : [$Co_2(CO)_8$] : [PO] = 20 : 1 : 20 and $Co_2(CO)_8$ concentration of 0.015 M. The degree of dechlorination was determined from the Cl^- concentration in the solution after the reaction completion; it was about 30% in 5 h.

After the reaction, we analyzed the organic residue of the unchanged PCB mixture by gas chromatography. The compositions of the recycled PCB mixture and the starting mixture are compared in Fig. 1.

It can be seen that the conversion of various trichlorobiphenyl isomers ranges from 5 to 80%; that of tetrachlorobiphenyls, from 20 to 100%; and that of the minor components, penta- and hexachlorobiphenyls, is close to 100%. The reaction products, mixtures of methyl esters of polychlorobiphenylcarboxylic acids, were converted to the corresponding acids by hydrolysis in aqueous–alcoholic KOH, followed by acidification with HNO_3. According to elemental analysis, the Cl content in the final reaction product is 29 wt %. This means that approximately one chlorine atom per molecule is replaced by the carboxy group under the reaction conditions.

Our next series of experiments was performed with Sovtol-10 technical dielectric. Sovtol-10 consists of 90% Sovol technical mixture and 10% trichlorobenzene. The chlorine content of Sovtol-10 is about 55 wt %.

The major components of technical mixtures of Sovol type are pentachlorobiphenyls (53%). They also contain tri- (1%), tetra- (23%), hexa- (22%), and heptachlorobiphenyls (1%) [9], i.e., on the average, approximately five hydrogen atoms per biphenyl molecule are replaced by chlorine. The reaction was performed under the same conditions as with TCB (Table 1).

The degree of dechlorination was determined from the concentration of the Cl^- ion in the solution after the reaction completion. Also, the conversion was determined by GLC analysis of the reaction mixture

from the sum of the intensities of peaks belonging to all the residual congeners relative to the peak of the least reactive congener (Fig. 2).

Figure 2 illustrates not only the extent of the reaction, but also complete disappearance from the reaction mixture of the most toxic PCB congeners, dioxin-like coplanar tetra- and pentachlorobiphenyls, which was also confirmed by gas chromatography–mass spectrometry. The degree of dechlorination, estimated from the concentration of mineral chlorine in the solution after performing the reaction to 99% conversion of Sovtol-10, is about 60%.

To isolate the carbonylation product and separate it from the unchanged PCB residue, the mixture was hydrolyzed in an aqueous–alcoholic KOH solution and then was treated with HNO_3. The resulting mixture of polychlorobiphenylcarboxylic acids was separated and dried.

The mixture of acids from run no. 3 (almost complete PCB conversion) was treated with diazomethane. The resulting mixture of methyl esters of polychlorobiphenylcarboxylic acids (Fig. 3) was studied by gas chromatography–mass spectrometry.

The substances giving peak nos. 1–5 in the chromatogram (Fig. 3) have peaks with m/z = 314 (M^+) in the mass spectra, corresponding to Cl_3Ph_2COOMe

(considering ^{35}Cl), with the consistent isotopic pattern (m/z = 316, 318, 320).

Substances giving peak nos. 6–8 and 12 in the chromatogram have peaks with m/z = 338 (M^+) in the mass spectrum, corresponding to $Cl_2Ph_2(COOMe)_2$. Substances giving peak nos. 9–11 and 13–15 in the chromatogram have peaks with m/z = 372 (M^+) in the mass spectrum, corresponding to $Cl_3Ph_2(COOMe)_2$. Substances giving peak nos. 16–21 in the chromatogram have peaks with m/z = 372 (M^+) in the mass spectrum, corresponding to $Cl_2Ph_2(COOMe)_3$.

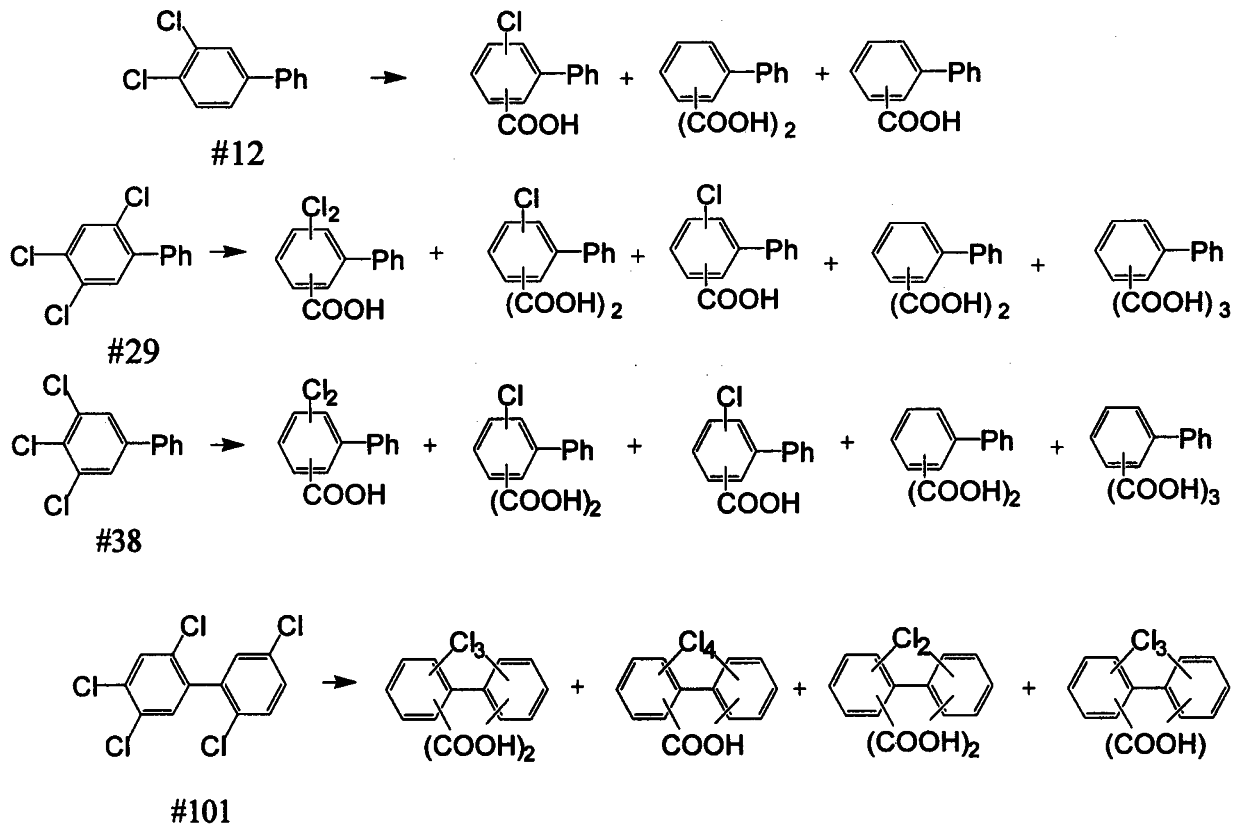
An NMR analysis of the mixture of methyl esters of polychlorobiphenylcarboxylic acids also revealed the presence of two, on the average, ester groups per substituted biphenyl molecule, which coresponds to 40% conversion with respect to chloride ion, whereas analysis for mineral chlorine gives 60%. This discrepancy may be due to hydrodechlorination of highly chlorinated congeners. This process was observed previously in studies of the carbonylation of individual congeners [8, 10, 11]. Analysis of the reaction mixtures by gas chromatography–mass spectrometry (GC–MS) revealed formation of reductive dechlorination products (Scheme 1) along with products of mono- and polycarbonylation.

The absence of monochlorobiphenyls among the reaction products and their inertness in carbonylation suggest that the carbonylation of PCBs precedes the hydrodechlorination.

In all cases when the hydrodechlorination occurs, the starting substrate contains two Cl atoms in the *o*-position relative to each other. As the PCB mixture contains a large amount of highly chlorinated congeners with such structural fragments, the occurrence of hydrodechlorination in the system should be confidently expected. This is also confirmed by the results of elemental and GC–MS analyses [11]. Comparison of the conversions estimated from the NMR data (40%) and analysis for Cl^- (60%) shows that the contribution of hydrodechlorination to the total conversion with respect to Cl^- ions in carbonylation of Sovtol-10 under the examined conditions is about 30%.

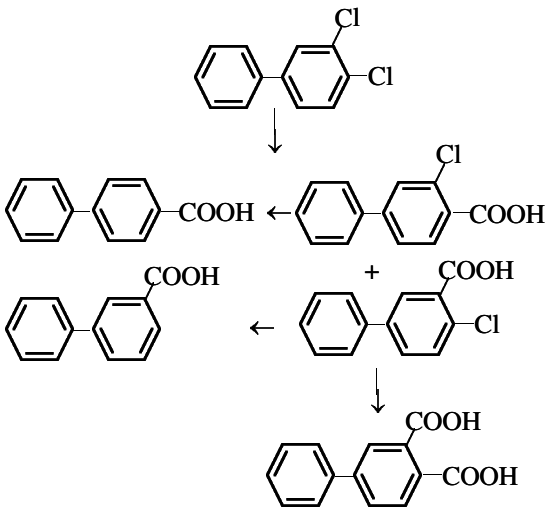
With the aim to develop principles of a technology for reprocessing of commercial PCB mixtures, we worked through a process for carbonylation of Sovtol-10 mixture using a 1-l pressure vessel (Table 2).

The results obtained show that the use of Na_2CO_3 as a base instead of K_2CO_3 leads to a decrease in the degrees of dechlorination and carbonylation (run no. 3). An increase in the process temperatrue and working pressure (run no. 5) does not lead to an increase in the PCB conversion. In this case, increased CO uptake is due to the occurrence of a side reaction, carbonylation of propylene oxide, as shown by analysis of the reaction mixture after isolation of the reaction products.



Scheme 1. Products of carbonylation of some individual congeners present in Sovtol-10 technical PCB mixture (data of mass spectrometry)

Sequence of transformations suggested for 3,4-dichlorobiphenyl (#12)



Reductive hydrodechlorination under similar conditions was observed previously in laboratory experiments performed in glassware (Table 1). The results obtained in experiments at elevated pressure (Table 2) show that the hydrodechlorination is pronounced only in those experiments when decomposition of the catalyst was followed by base hydrolysis. This fact indicates that, firstly, carbonylation and hydrodechlorination under the examined conditions occur by different catalytic mechanisms; secondly, subjected to hydrodechlorination are carbonylation products rather than the initial polychlorobiphenyls, and in the form of salts rather than esters.

In contrast to other procedures for reprocessing polychlorobiphenyls, the suggested procedure does not involve formation in the reaction mixture of other hazardous ecotoxicants: polychlorodibenzodioxins and polychlorodibenzofurans.

At the same time, technical PCB mixtures virtually always contain as microimpurities polychlorodibenzodioxins and polychlorodibenzofurans. Some of them strongly exceed PCBs in the toxicity. They can be formed in the course of both PCB production and their operation at elevated temperatures, and also upon photolysis of PCBs with sunlight [1, 2]. Therefore, in developing a procedure for detoxication of technical PCB mixtures by carbonylation, it is necessary to check whether this catalytic system is applicable to

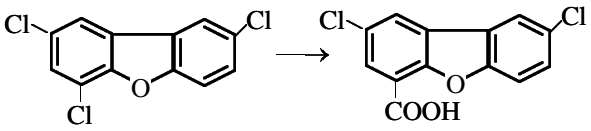
dechlorination of polychlorodibenzodioxins and polychlorodibenzofurans.

With 2,4,8-trichlorodibenzofuran as example, we showed that polychlorodibenzodioxins and polychlorodibenzofurans can also be readily dechlorinated with this catalytic system. Carbonylation of 2,4,8-trichlorodibenzofuran is highly selective. The reaction product is 2,8-dichlorodibenzofuran-4-carboxylic acid:



The structure of the product obtained confirms the relationship found previously for carbonylation of polychlorobiphenyls [10, 11]: The halogen atom located in the most substituted ring of a polycyclic aromatic system is replaced first.

The new economical carbonylation procedure that we developed for dechlorination, detoxication, and utilization of PCBs was protected by a patent [12].

EXPERIMENTAL

Carbonylation of Sovtol-10 technical mixture and technical-grade TCB was performed under atmospheric pressure of CO at 60°C in temperature-controlled glass installations with vigorous stirring. The reaction completion was judged from the results of GLC analysis of samples taken in a CO flow, treated with KOH, and extracted with ether. After the reaction completion, the aqueous-alkaline layer was acidified with HCl, and the precipitate of the mixture of reaction products, polychlorobiphenylcarboxylic acids, was filtered off, washed with water, and dried. The acids obtained were treated with diazomethane, and the resulting methyl esters were analyzed by GC–MS and ^1H NMR.

Chromatographic identification was made on a QO-500 Shimadzu device equipped with a capillary column (60 m × 0.25 mm, stationary phase SE-54) in the programmed heating mode: 40°C, 1 min; 40–180°C, 20 deg min^{-1}; 180–300°C, 5 deg min^{-1}. Vaporizer temperature 260°C; detector (ECD) temperature 250°C.

The ^1H NMR spectra of reaction mixtures and methyl esters of polychlorobiphenylcarboxylic acids were measured on a Bruker spectrometer (300 MHz) in $CDCl_3$ and 1 : 2 DMSO-d_6–CCl_4 mixture.

GLC analysis of technical-grade TCB and Sovtol-10, and of PCB mixtures after the carbonylation was performed with a Varian chromatograph equipped with an electron capture detector and a quartz capillary column (40 m × 0.25 mm); carrier gas N_2. The column temperature schedule was as follows: 160°C, 5 min; heating to 280°C, 20 deg min^{-1}. The analysis time was 40 min.

The carbonylation of technical PCB mixtures in a pressure vessel was described previously [13].

Structural analysis of 2,8-dichlorodibenzofuran-4-carboxylic acid was made by two-dimensional NMR correlation techniques (PFG, DQF) ^1H, ^1H COSY; PFG ^1H, ^{13}C (HMQC); and PFG ^1H, ^{13}C (HMBC). The spectra were taken in acetone-d_6 at 30°C on a Bruker Avance DRX 500 device (500 MHz). The molecular formula of 2,8-dichlorodibenzofuran-4-carboxylic acid was determined by mass spectrometry with electrospray ionization (ESI-TOF MS) with a TOF Micromass LCT mass spectrometer.

The content of mineral chlorine in aqueous solution of PCB carbonylation products was determined by argentometric titration.

CONCLUSIONS

(1) A novel procedure, based on carbonylation, was suggested and developed for detoxication and utilization of ecotoxicants, polychlorobiphenyls.

(2) Chemically stable polychlorobiphenyls can be activated with available catalytic systems based on epoxide-modified cobalt carbonyl and can be involved in carbonylation under mild conditions (atmospheric pressure of CO, 60–65°C).

(3) All the toxic components of the technical mixture of polychlorobiphenyls enter into the carbonylation to form a mixture of derivatives of aromatic carboxylic acids (esters, salts) containing two or three carboxy groups per molecule. The conversion of polychlorobiphenyls reaches 99%. The organic residue of polychlorobiphenyls (up to 1–2%) contains no initial toxic ("dioxin-like") polychlorobiphenyl congeners.

(4) It was demonstrated by the example of 2,4,8-trichlorodibenzofuran that polychlorodibenzodioxins and polychlorodibenzofurans can be readily dechlorinated with the suggested catalytic system.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Extraction from Raw Materials with a Two-Phase System of Extractants in an Apparatus for Oscillating Vacuum Boiling

E. V. Ivanov, M. A. Artemova, and A. A. Maslov

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received January 23, 2007

Abstract—Extraction of hydrophilic and lipophilic compounds from vegetable raw materials with a two-phase system of extractants in an apparatus for oscillating vacuum boiling was studied. Dependences of the yield of target components on the time and hydrodynamic mode of the process were obtained.

DOI: 10.1134/S1070427207070166

If a raw material contains several groups of compounds with widely different solubilities, extraction is, as a rule, performed in several stages, with different solvents used in each stage. Recently, a new method has found use for extraction of hydrophilic and lipophilic compounds from vegetable raw materials with a two-phase system of extractants [1–4]. Hydrophilic compounds well dissolve in one of these, e.g., in an aqueous solution of ethanol, and lipophilic compounds, in the other, e.g., in vegetable oil. It has been shown that both hydrophilic and lipophilic compounds are extracted from raw materials mostly by the alcoholic-aqueous phase, from which lipophilic compounds subsequently pass into the oil phase [2, 4]. Thus, two main consecutive-paallel processes occur simultaneously: extraction of target components from vegetable raw materials with the alcoholic–aqueous phase and extraction of lipophilic compounds from the alcoholic–aqueous phase into the oil phase. The third process, extraction of lipophilic compounds from raw materials with oil, is insignificant.

Despite the strong interest in the given extraction technique, the effect of hydrodynamic mode in apparatus on the process intensity has been insufficiently studied, and, therefore, studies in this area are topical.

The aim of this study was to examine the extraction of hydrophilic and lipophilic compounds from vegetable raw materials with a two-phase system of extractants in an apparatus for oscillating vacuum boiling of the extractant.

The boiling-up of an extractant in an apparatus for oscillating vacuum boiling occurs as a result of periodic changes in the volume of a thermostated system constituted by a suspension being processed and a vapor [5]. As the volume of the system increases, the pressure in it decreases, the alcoholic–aqueous phase becomes superheated and boils up, with vapor bubbles forming and growing. As the volume of the system decreases, the pressure in it grows, vapor bubbles collapse, boiling terminates, and the heat of evaporation (condensation) is returned into the system. Vapor bubbles are formed throughout the volume of the alcoholic–aqueous phase. Their number and size depend on the frequency of boiling-up of the extractive agent and on the amplitude of oscillations in the suspension, which characterizes the variation amplitude of the volume of the system. As the frequency of boiling-ups of the extractant grows, the number of vapor bubbles increases and their size decreases. As the amplitude of suspension oscillations grows, the growth rate of vapor bubbles and, consequently, the intensity of their hydrodynamic impact on the suspension become higher.

The process was carried out at 50 to 90°C. The boiling-up frequency of the extractant was varied in the range 1–7.5 s^{-1}, and the amplitude of suspension oscillations, from 0.005 to 0.035 m.

A finely divided (2–3 mm) grass of common John's wort satisfying the requirements of State Pharmacopoeia [6] was used as a raw material. The two-phase system of extracting agents was composed of vegetable oil (low-polarity solvent) and a 70% aqueous solution of ethanol (polar solvent). The use of the alcoholic–aqueous mixture of the given concentration provides the most complete recovery of lipophilic substances from vegetable raw materials [2]. As tracers characterizing the rate and extent of the process were chosen chlorophyll derivatives (in terms of

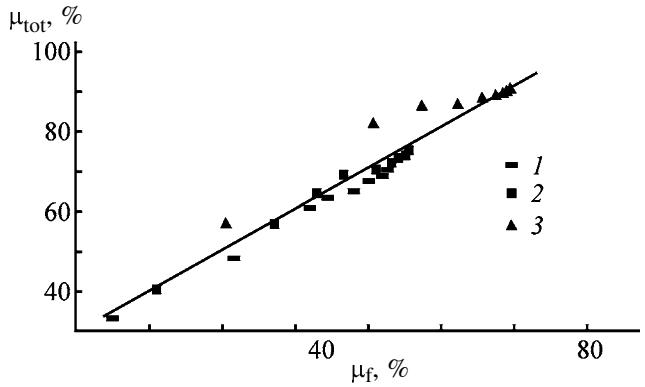

Fig. 1. Comparison of the total yield (into the alcoholic–aqueous and oil phases) of chlorophyll derivatives (μ_{tot}) and of the yield of flavonoid compounds (μ_f) at the same instants of time. Amplitude of suspension oscillations 0.035 m, boiling-up frequency of the alcoholic–aqueous phase 2.5 s^{-1}. *T*, °C: (*1*) 50, (*2*) 60, and (*3*) 90.

pheophytin A) and flavonoid compounds (in terms of rutin). The sum of flavonoids was quantitatively determined by spectrophotometry [6]. The content of chlorophyll derivatives in oil extracts was found spectrophotometricaly at a wavelength λ = 668 nm [7, 8]. Alcoholic–aqueous extracts were analyzed for the content of chlorophyll derivatives as follows: to 2 ml of an extract was added 5 ml of 70% ethanol, the mixture was agitated, and the optical density of the solution was measured at a wavelength of 668 nm. As a reference solution served a 70% aqueous solution of ethanol. The ratio between the raw material, oil, and ethanol was 1 : 10 : 10.

The extraction was performed in the course of 3 h. Samples of the two-phase system of extractants were separated into the alcoholic–aqueous and oil phases and then the content of chlorophyll derivatives in both phases and that of flavonoids in the alcoholic–aqueous phase were determined spectrophotometrically.

It was found that each 10°C increase in the process temperature is accompanied by a rise in the "apparent" equilibrium yield of flavonoid compounds by 5–10% and in that of chlorophyll derivatives by 8–12%. This is presumably due to a decrease in the viscosity of the vegetable oil and to an increase in the coefficients of transfer of target components in particles of the vegetable raw material. The highest process rate was observed at 90°C. In this case, the yield of the target components approached 90% and the "apparent" equilibrium was attained in 120–140 min.

An increase in the amplitude of suspension oscillations from 0.005 to 0.035 m was accompanied by a 20% rise in the yield of the target components, and the extraction time decreased to 60–80 min. Raising the frequency of boiling-ups of the alcoholic–aqueous phase from 1 to 7.5 s^{-1} led to a 15% increase in the apparent equilibrium yield, and the process duration decreased to 60–80 min. It should be noted for comparison that, all other conditions being the same, the equilibrium yield of 85% was reached in extraction from the grass of St. John's wort in an apparatus with an agitator in 120–180 min.

Thus, the best results were obtained when the extraction was performed, with the process parameters varied in the range under study, at 90°C, amplitude of suspension oscillations equal to 0.035 m, and boiling-up frequency of the alcoholic–aqueous phase of 7.5 s^{-1}.

A comparison of the total yield (into the alcoholic–aqueous and oil phases) of chlorophyll derivatives (μ_{tot}) and of the yields of flavonoid compounds (μ_f) at the same instants of time (Fig. 1) demonstrated that they are virtually equal. Therefore, to determine the total yield of some target components (hydrophilic or lipophilic), it suffices to know the total yield of other components, e.g., compounds whose analytical determination is less labor-consuming. In addition, Fig. 1 demonstrates that both flavonoid compounds and chlorophyll derivatives are extracted simultaneously and at equal rates.

Experimental data on the kinetics of two-phase extraction were processed using the relations suggested in [9, 10]. In the initial stage of the process ($0 \le \theta \le 0.25$), when the content of the target components in the main volume of the extractive agent has no effect on the extraction rate and the process rate is determined by the convective mass transfer in coarse pores, the following relation was used:

$$\mu = u_1\theta^{1/2}, \quad (1)$$

where μ is the yield of the target components (%); θ, dimensionless extraction time equal to the ratio of the running time to the time of attainment of the apparent equilibrium (80 min in this study); and u_1, parameter dependent on the hydrodynamic situation in the apparatus (%).

Experimental data on the extraction kinetics in the final stage of the process ($0.25 \le \theta \le 1$), in which the content of the target components in the main volume of the extractive agent affects the process rate, were approximated with the relation

$$\mu = w - u_2\theta^{-1/2}, \quad (2)$$

where w is an empirical coefficient (%), and u_2 is

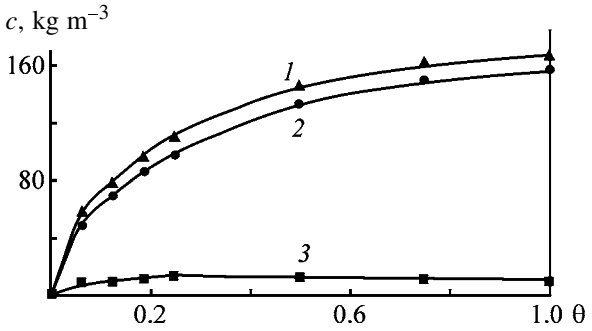

Fig. 2. Variation of the content c of chlorophyll derivatives in the extractants with time θ. Amplitude of suspension oscillations 0.035 m, boiling-up frequency of the alcoholic–aqueous phase 2.5 s^{-1}. (*1*) Sum in alcohol and oil, (*2*) in oil, and (*3*) in alcohol. Solid lines, calculation; points, experimental data.

a parameter dependent on the hydrodynamic situation in the apparatus.

The dependences of the total yield of chlorophyll derivatives into the alcoholic–aqueous and oil phases (with account of the aforesaid and the yield of flavonoid compounds into the alcoholic–aqueous phase) on the dimensionless time have the form

$$\mu_{tot} = [74 + 173.7(A\nu)]\theta^{1/2}, \quad 0 \le \theta \le 0.25; \quad (3)$$

$$\mu_{tot} = 118.8 - [40.9 - 43.4(A\nu)]\theta^{-1/2}, \quad 0.25 \le \theta \le 1, \quad (4)$$

where A is the amplitude of suspension oscillations (m), and ν is the boiling-up frequency of the alcoholic–aqueous phase (s^{-1}).

Experimental data on the extraction kinetics of chlorophyll derivatives from the alcoholic–aqueous phase into the oil phase were processed using the equations

$$dM/dt = k_{vo}V_o(c_o^* - c_o), \quad (5)$$

$$dM/dt = k_{va}V_a(c_a^* - c_a), \quad (6)$$

where M is the mass of chlorophyll derivatives that passed from the alcoholic–aqueous into the oil phase (kg); τ, time (s); k_{vo} and k_{va}, volumetric (related to the volume of the respective phase) coefficients of mass transfer of chlorophyll derivatives from the alcoholic–aqueous phase into the oil phase (s^{-1}); V_o and V_a, volumes of the oil and alcoholic–aqueous phases (m^3); c_o and c_a, concentrations of chlorophyll derivatives in the oil and alcoholic–aqueous phases (kg m^{-3}); and c_o^* and c_a^*, equilibrium concentrations of chlorophyll derivatives in the oil and alcoholic–aqueous phases (kg m^{-3}).

It was found that, in Eq. (5), $c_o^* = 159$ kg m^{-3} and $k_{vo} = 3.08 + 14.1A\nu$ (s^{-1}). Chlorophyll derivatives are poorly soluble in the alcoholic–aqueous phase and are present in this phase "in the form of an emulsion," and, therefore, their equilibrium concentration c_a^* depends on the hydrodynamic situation in the apparatus. The dependence of the mass-transfer coefficient on the complex $A\nu$ in Eq. (6) is described with the same accuracy by the formulas $k_{va} = 0.59 - 0.354\ln(A\nu)$ and $k_{va} = 0.78(A\nu)^{-1/4}$.

The yield of chlorophyll derivatives into the oil phase can be found with high precision without solving differential equations (5) and (6). Processing of the experimental data in terms of (1) and (2) gave the following dependences:

$$\mu_o = [65 + 153(A\nu)]\theta^{1/2}, \quad 0 \le \theta \le 0.25; \quad (7)$$

$$\mu_o = 115.1 - [41.3 - 38.3(A\nu)]\theta^{-1/2}, \quad 0.25 \le \theta \le 1. \quad (8)$$

For the adopted ratio between the raw material and extractants, the concentration of chlorophyll derivatives in the alcoholic–aqueous phase is related to their total yield into the alcoholic–aqueous and oil phases, μ_{tot}, and to the yield into the oil phase, μ_o, by $c_a = 1.87(\mu_{tot} - \mu_o)$. Therefore, expressions (3), (4), (7), and (8) can be used to obtain

$$c_a = [16.8 + 39.7(A\nu)]\theta^{1/2}, \quad 0 \le \theta \le 0.25; \quad (9)$$

$$c_a = 6.9 + [0.75 + 9.54(A\nu)]\theta^{-1/2}, \quad 0.25 \le \theta \cong 1. \quad (10)$$

The precision of these relations is illustrated by Fig. 2, in which calculated and experimental data are represented by solid lines and points, respectively.

CONCLUSIONS

(1) The total yield (into the alcoholic–aqueous and oil phases) of chlorophyll derivatives is virtually equal to that of flavonoid compounds at the same instants of time. The extraction of both flavonoid compounds and chlorophyll derivatives occurs simultaneously and at equal rates.

(2) Each 10°C increase in the temperature of two-phase extraction in an apparatus for oscillating vacuum boiling of the extractive agent is accompanied by a rise in the apparent equilibrium yield of flavonoid compounds by 5–10% and in that of chlorophyll derivatives by 8–12%. The highest process rate is observed at 90°C. In this case, the yield of target components approaches 90% and an apparent equilibrium is attained in 120–140 min.

(3) An increase in the amplitude of suspension oscillations from 0.005 to 0.035 m leads to a rise in the yield of recovered target components by 20% and to a decrease in the process duration to 60–80 min. An increase in the boiling-up frequency of the alcoholic–aqueous phase from 1 to 7.5 s^{-1} leads to a rise in the apparent equilibrium yield by 15% and to a decrease in the process duration to 60–80 min.

(4) The dependences describing the kinetics of extraction of chlorophyll derivatives from the raw material and the alcoholic–aqueous phase are in good agreement with experimental data. The model parameters depend on the hydrodynamic situation in the apparatus through the complex $A\nu$.

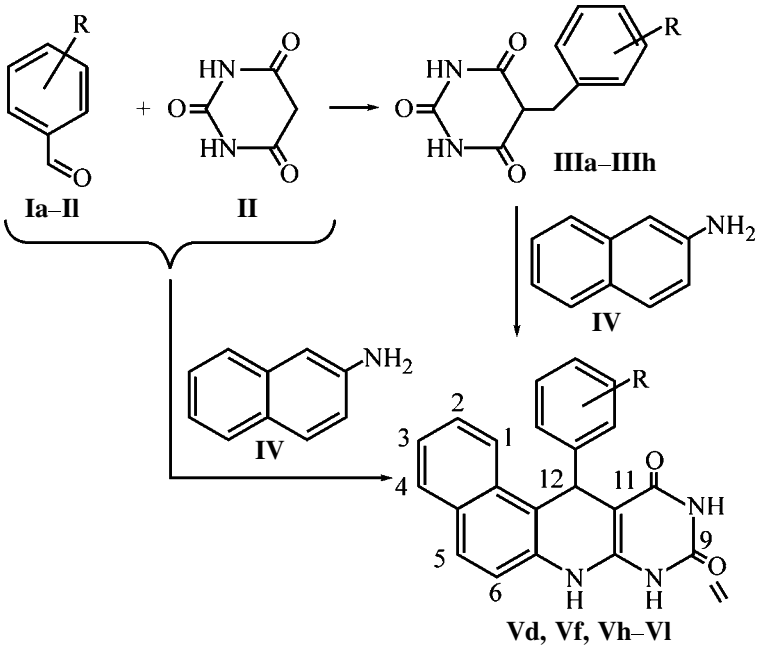
Abstract—5-Arylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones and 12-aryl-8,12-dihydrobenzo[*f*]pyrimido-[4,5-*b*]quinoline-9,11-(7*H*,10*H*)diones were synthesized, and their spectral-luminescence and nonlinear-optical properties were examined.

DOI: 10.1134/S1070427207070178

Organic luminophores containing a carbonyl group, either in the open chain or incorporated into the cyclic system, are of great practical significance. These compounds include, in particular, arylmethylpyrimidinetriones, both known and new, and pyrimidoquinolinediones prepared by the scheme



where R = $N(CH_3)_2$ (**a**), $N(C_2H_5)_2$ (**b**), 3,4-di-(OH) (**c**), 2,4-di-OMe (**d**), 3,4-di-OMe (**e**), 3-OEt-4-OH (**f**), 3-OMe-4-OCOEt (**g**), 3-OMe-4-$OCO(CH_2)_2Me$ (**h**), 2,4-di-Cl (**i**), 3-OMe-4-OH (**j**), 3-OMe-4-$OCOC_6H_5$ (**k**), and 2-F-6-Cl (**l**).

Refluxing equimolar amounts of appropriate benzaldehyde **Ia**–**Ih** and 2,4,6-(1*H*,3*H*,5*H*)pyrimidinetrione (barbituric acid) **II** in an alcohol solution resulted in selective formation of 5-arylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones **IIIa**–**IIIh.**

Table 1. Properties of 5-arylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones **IIIf–IIIh** and 12-aryl-8,12-dihydrobenzo[*f*]-pyrimido[4,5-*b*]quinoline-9,11-(7*H*,10*H*)diones **Vd, Vf,** and **Vh–Vl**

Pyrimidoquinolinediones **Vd, Vf, Vh** and **Vi–Vl** can be prepared both by the reaction of arylmethylpyrimidinetriones with 2-naphthylamine and three-component condensation of benzaldehydes **Ii–Il**, barbituric acid, and 2-naphthylamine via formation of arylidenetriones which further react with 2-naphthylamine. The latter, having the highest electron density on the carbon atom in the α position with respect to the amino group, enters into the addition reaction at the double bond of arylmethylpyrimidinetriones **III**. Previously [1] we reported that this pathway is possible for multicomponent condensation of benzaldehydes, 1,3-diketones, and 2-naphthylamine. In this study, we prepared pyrimidoquinolinediones by two pathways: **Vd, Vf, Vh** by the first pathway, and **Vi–Vl**, by the second pathway. Physicochemical constants of arylmethylpyrimidinetriones **IIIa–IIIe** are identical to those published in [2–4]; for constants of **IIIf–IIIh** and **Vd, Vf, Vh** and **Vi–Vl**, see Table 1.

The position and multiplicity of the aromatic proton signals in the ^{1}H NMR spectra of arylmethylpyrimidinetriones **IIIa–IIIh** and pyrimidinequinolinediones **Vd, Vf,** and **Vh–Vl** correspond to the structures of compounds of this kind [5].

The IR spectra of arylmethylpyrimidinetriones **IIIa–IIIh** and pyrimidinequinolinediones **Vd, Vf,** and **Vh–Vl** contain bands associated with the stretching vibrations of secondary amines (a band at 3520–3185 cm^{-1}) and carbonyl groups (a band at 1729–1701 cm^{-1}). Pyrimidoquinolinediones **Vi** and **Vl** exhibit an intense absorption band at 860 and 830 cm^{-1}, respectively, associated with the stretching vibrations of the C–Cl bond.

The mass spectra of arylmethylpyrimidinetriones **IIIa–IIIh** synthesized contain a molecular peak $[M]^+$, which is the strongest (I_{rel} 100%), and several fragment peaks. The mass spectra of pyrimidoquinolinediones **Vd, Vf,** and **Vh–Vl** contain a peak with the maximal intensity (I_{rel} 100%) at *m*/*z* 264, corresponding to the $[M - C_6H_4]^+$ ion, a peak with *m*/*z* 265 corresponding to the $[M - C_6H_4 + 1]$ + ion (I_{rel} 65–70%), and peaks of the molecular ion M^+ (28–35%) and positive ions with *m*/*z* 111 (29–33%), 134 (56–60%), 139 (90–96%), 148 (72–78%), 153 (47–55%), 166 (32–39%), and 222 (18–23%) formed from the $[M - C_6H_4]^+$ fragment ion and constant for all these compounds.

The electronic absorption spectra of arylmethylpyrimidinetriones **IIIa–IIIh** and pyrimidinequinolinediones **Vd, Vf,** and **Vh–Vl** in ethanol are characterized by a number of vibronic bands (their λ_{max} and relative intensities are listed in Table 2); the spectra of **IIIa** and **Vl** are shown in the figure.

Pyrimidoquinolinediones **Vd, Vf,** and **Vh–Vl** in an ethanol solution exhibit a weak fluorescence with a maximum near 380 nm. Arylmethylpyrimidinetriones **IIIa–IIIh** in an ethanol solution also exhibit weak fluorescence, with the spectra shifted to long waves relative to those of **Vd, Vf,** and **Vh–Vl**.

All the compounds examined in the crystalline state at room temperature exhibit fluorescence of different intensities. The fluorescence spectra were recorded at λ_{exc} = 340 nm. Arylmethylpyrimidinetriones **IIIa, IIIb, IIIe** and pyrimidinequinolinediones **Vd, Vf, Vh, Vl** are characterized by intense fluorescence, and the remaining compounds examined, by weak fluorescence. The maxima in the fluorescence spectra vary over a wide spectral range. Fluorescence of polycrystals of **Vd, Vf,** and **Vh–Vl** is charac-

Table 2. Spectral-luminescence properties of arylmethylpyrimidinetriones **IIIf–IIIh** and pyrimidoquinolinediones **Vd, Vf,** and **Vh–Vl** in ethanol solution and as polycrystals at room temperature

terized primarily by maxima near 400 nm, while that of **IIIa–IIIh**, by maxima varying within 400–650 nm (see figure and Table 2).

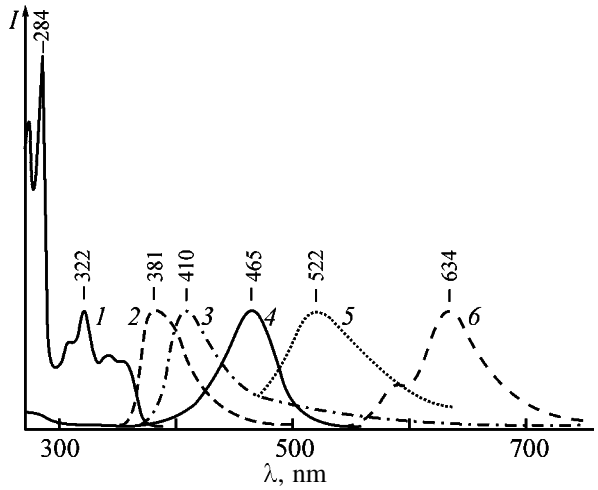
Polycrystals of some compounds display nonlinear-optical properties, i.e., are able of converting the laser radiation frequency. For example, when excited by the first harmonics of radiation of a YAG : Nd^{3+} laser (λ_{exc} = 1.06 μm, E_{exc} = 80 mJ, pulse length 20 ns) polycrystalline arylmethylpyrimidinetriones **IIIa** and **IIIb** exhibited bright red two-photon-excited fluorescence (TEF) with λ_{max} ~640 nm, and arylmethylpyrimidinetrione **IIIa**, less intense yellow TEF at 600 nm.

Arylmethylpyrimidinetriones **IIIf** and **IIIg** exhibited a different nonlinear-optical effect, generation of the second harmonics of laser radiation (GSG). It consists in converting the wavelength of the first harmonics of a neodymium laser (1.06 μm) into the second harmonics wavelength (532 nm) by the polycrystals. Thus, both these substances emit bright red luminescence at 532 nm when irradiated with intense invisible IR radiation (1.06 μm). For arylmethylpyrimidinetrione **IIIh** we recorded a weak GSG effect.

The nonlinear-optical effects revealed for arylmethylpyrimidinetriones **IIIa, IIIb, IIIe** (TEF) and **IIIf–IIIh** (GSG) make these compounds candidate materials for preparing elements for visual imaging of invisible IR laser radiation, optical recording of information, and development of nonlinear-optical elements for GSG.

EXPERIMENTAL

The IR spectra of the arylmethylpyrimidinetriones and pyrimidoquinolinedions examined were recorded on a Nicolet Protege-460 Fourier spectrophotometer from a thin layer or KBr pellets, and mass spectra, on a Hewlett–Packard 5890/5979 Chrommas GC/MS chromatograph–mass spectrometer, HP-5MS column (70 eV). The absorption spectra of the solutions were measured at room temperature on a Cary-500 (Varian, the United States) spectrophotometer, and the fluores-



(*1, 4*) Absorption and (*2, 3, 5, 6*) fluorescence spectra of (*4–6*) **IIIa** and (*1–3*) **Vl** in (*1, 2, 4, 5*) ethanol and (*3, 6*) polycrystals at 293 K. (*I*) Intensity and (λ) wavelength.

cence spectra, on a wide-aperture setup [6]. Two-photon excitation was achieved with the first harmonics of a YAG : Nd^{3+} pulse laser with the wavelength of 1.06 μm.

5-Arylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones IIIf–IIIh. Barbituric acid **II** [1.3 g (0.01 mol)] and 0.01 mol of appropriate aldehyde **Ia**–**Ih** in an alcohol solution were refluxed for 20–30 min. The precipitate formed after cooling the reaction mixture was filtered off and recrystallized from alcohol.

12-Aryl-8,12-dihydrobenzo[*f*]pyrimido[4,5-*b*]-quinoline-9,11-(7*H*,10*H*)diones Vd, Vf, Vh. A solution of 0.01 mol of appropriate 5-(4-arylmethyl)-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetrione **IIId, IIIf, IIIh** and 0.01 mol of 2-naphthylamine **IV** in 20 ml of butanol was refluxed until crystals formed. The precipitate was filtered off and recrystallized from a 1 : 1 alcohol–benzene mixture.

12-Aryl-8,12-dihydrobenzo[*f*]pyrimido[4,5-*b*]-quinoline-9,11-(7*H*,10*H*)diones Vi–Vl. A solution of 1.43 g (0.01 mol) of 2-naphthylamine **IV**, 0.01 mol of appropriate aromatic aldehyde **Ii**–**Il**, and 1.3 g (0.01 mol) of barbituric acid **II** in 20 ml of butanol was refluxed until crystals formed (30–60 min). The precipitate formed after cooling the reaction mixture was filtered off, washed with hot water and ether, and recrystallized from a 1 : 1 alcohol–benzene mixture.

CONCLUSIONS

(1) 5-Arylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones **IIIa**, **IIIb**, **IIIe** and 12-aryl-8,12-dihydrobenzo[*f*]pyrimido[4,5-*b*]quinoline-9,11-(7*H*,10*H*)diones **Vd, Vf, Vh, Vl** exhibit intense fluorescence.

(2) These compounds exhibit nonlinear-optical effects. Specifically, two-photon-excited fluorescence was revealed for already known 5-dimethylamino- (**IIIa**), 5-diethylamino- (**IIIb**), and 5-(3,4-dimethoxy)-phenylmethyl-2,4,6-(1*H*,3*H*,5*H*)-pyrimidinetriones (**IIIe**)], and generation of the second harmonics of the laser radiation, for previously unknown 5-(4-hydroxy-3-ethoxy- (**IIIf**), (4-carboxy-3-methyoxy)-(**IIIg**), 5-(4-carbpropoxy-3-methoxy)phenylmethyl-2,4,6-(1*H*,3*H*,5*H*)pyrimidinetriones (**IIIh**). The effects revealed make these compounds candidate materials for preparing elements for visual imaging of invisible IR laser radiation, optical recording of information, and development of nonlinear-optical elements for generation of the second harmonics of laser radiation.

Abstract—Products of the reaction of 1,2,4-trimethylbenzene with chlorine dioxide in aqueous solution were studied. A scheme of 1,2,4-trimethylbenzene transformations was suggested. The influence exerted on the number of the reaction products by the ClO_2 dosage and time of its contact with the substrate was examined.

DOI: 10.1134/S107042720707018X

Disinfection of water with chemical reagents improves its microbiological parameters. Water disinfection is usually performed with molecular chlorine, sodium hypochlorite, chloramine, ozone, or chlorine dioxide, or by UV irradiation [1–3]. Today it is important to find a method that would combine the advantages of various disinfection methods and reduce the formation of secondary toxicants [4].

Chlorine dioxide, which is an available and effective oxidant, finds growing use both in industry and in water preparation [5]. It improves the microbiological and organoleptic parameters of water and considerably reduces the amount of toxic disinfection products such as trihalomethanes, which are the main by-products in chlorination of water with molecular chlorine. This is particularly important in disinfection of water containing not only natural humic compounds but also manmade organic pollutants. According to published data, chlorine dioxide is a mild oxidant. Benzene and its simplest alkyl derivatives (toluene, ethylbenzene, xylenes, diphenylmethane) do not react with chlorine dioxide under the conditions of potable water treatment in the absence of traces of molecular chlorine [6].

In this study we examined transformations of organic compounds of industrial origin in aqueous solution under the action of chlorine dioxide. As organic substrate we chose 1,2,4-trimethylbenzene (1,2,4-TMB), which is a possible water pollutant in regions adjacent to petrochemical enterprises.

Our main analytical procedure for determining organic compounds was gas chromatography with mass-selective detector (GS–MSD), which is one of the most reliable methods for identification of components of complex organic mixtures [7].

EXPERIMENTAL

Chlorine dioxide was prepared by the reaction of sodium chlorite with hydrochloric acid [8]. Sodium chlorite (main substance content 80%) was purchased from Aldrich. The sodium chlorite concentration was determined by titration [9, 10]. The chlorine dioxide concentration was determined spectrophotometrically with a Specord M40 device (Carl Zeiss, Jena) in quartz cells (l = 0.1 cm) in the range of the ClO_2 absorption maximum (354–362 nm) just before each experiment.

In the experiments we used 1,2,4-TMB [GSO (State Reference Sample) 3309–85] and deionized water (Milli-Q Gradient). To attain 25 : 1 molar ratio of ClO_2 to the organic substrate, to Milli-Q water (V = 1 dm^3) containing 1,2,4-TMB (10 mg dm^{-3}, 8.32×10^{-5} M) we added ClO_2 to a concentration of 2.08×10^{-3} M. To attain 40 : 1 ratio, to Milli-Q water (V = 1 dm^3) containing the substrate (1 mg dm^{-3}, 8.32×10^{-6} M) we added ClO_2 to a concentration of 3.33×10^{-4} M. The exposure time was 6 and 24 h, respectively. The water treatment with ClO_2 was performed at room temperature. The reaction was stopped by

Table 1. Main parameters of devices for analysis of products of the reaction of 1,2,4-TMB with ClO_2 aqueous solution

Gas chromatograph	Agilent 5890N	G6000 Vega Series 2	HRGC Mega Series
Detector	MSD	FID	ECD
Column type	HP-5MS 30 m × 0.25 mm × 0.25 μm	DBWAX 30 m × 0.25 mm × 0.25 μm	DB-5 30 m × 0.32 mm × 1 μm
Carrier gas	Helium	Helium	Nitrogen
Carrier gas flow rate, $cm^3\ min^{-1}$	2	2	2
Temperature schedule, °C	35 to 60, 30 deg min^{-1}; 60 to 280, 6 deg min^{-1}; 280, 10 min	60, 9 min; 60 to 120, 10 deg min^{-1}; 120, 4 min	70
Temperature, °C:			
vaporizer	250	120	120
detector	–	300	330
ion source	230	–	–
quadrupole	150	–	–
transition channel	280	235	–
Ionization mode	Electron impact	–	–
Electron energy, eV	70	–	–

adding sodium thiosulfate which deactivates excess ClO_2 [11]:

$$5Na_2S_2O_3 + 8ClO_2 + 9H_2O \rightarrow 10NaHSO_4 + 8\ HCl.$$

To study the dynamics of formation of volatile organic compounds, at 15-min intervals we took from the reaction volume (V = 1 dm^3) 10 cm^3 samples of water into specially prepared vials with sodium thiosulfate and analyzed the samples by GC–MSD. Volatile aromatic hydrocarbons (VAHs) were determined by head space analysis with a flame ionization detector (GC–FID; Vega chromatograph, Carlo Erba Instruments). Volatile halogenated hydrocarbons (VHHs) were determined similarly using an electron capture detector (GC–ECD; Mega device, Carlo Erba Instruments, Head Space 850 unit).

The 1,2,4-TMB transformation products were extracted from aqueous solution with methylene chloride (Merck, 2 × 10 cm^3). The extract was dried over anhydrous sodium sulfate and analyzed on a 6890N gas chromatograph with a mass-selective detector (5973, Agilent). The characteristics of the quartz capillary columns used and the analysis and detection conditions for all the three methods are given in Table 1. The components were identified by comparing the experimental mass spectra with those from the Wiley 138 and NBS 75 libraries (coincidence quality 70–90% on the average) and by interpreting the fragmentation patterns under electron impact, taking into account well-known relationships [7].

For the chloro derivatives of 1,2,4-TMB, the response factors, reflecting the extraction coefficient, ionization cross section, contributiopn of the characteristic ion to the total ion current, and mass discrimination of the mass spectrometer used, were taken equal to unity. The concentrations of chloro derivatives of 1,2,4-TMB, c_{comp}, were quantitatively estimated with an external reference by the formula $c_{comp} = S_{comp}c_{ref}/S_{ref}$, where S_{comp} and S_{ref} are the areas of the chromatographic peaks of the product and external reference, respectively (mV s), and c_{ref} is the 1,2,4-TMB concentration (M). As external reference we used a 1,2,4-TMB solution. The analysis results are given in Table 2.
