* BPL—Bone (Total) Phosphate of Lime.

Table 2. Distribution of cadmium salts at the phosphoric acid manufacturing by dihydrate method

Technological object	Consumption norm (yield) per 1 ton of P_2O_5 in acid	Cadmium content, ppm	Fraction of cadmium trace contaminant in the object (phase), %
I. Grinded Maroc phosphorite used for extraction			
Sulfuric acid (93% H_2SO_4)	3.32	0.98	5.6
Maroc phosphorite (31.6% P_2O_5, 69 BPL)	3.38	16.2	94.4
Phosphogypsum (41% H_2O total)	7.2	2.2	28.2
Extractive sulfuric acid (26% P_2O_5)	3.85	10.5	71.8
II. Apatite floated concentrate of Kolskii burthplase (Russia) is used for extraction			
Sulfuric acid (92.5 % H_2SO_4)	2.69	1.00	40.5
Floated apatite concentrate (39.4% P_2O_5, 86 BPL)	2.64	1.50	59.5
Phosphogypsum (40.0% H_2O total)	5.50	0.33	26.7
Extractive phosphoric acid (22% P_2O_5)	4.55	1.12	73.4

fertilizer, feed and technical phosphates. The acid concentration defines the methods of its further processing.

In this work we studied phase distribution of cadmium in respect of dihydrate methodology of manufacturing extractive phosphoric acid in the plant of phosphoric fertilizers in Bolgaria (town Devna) and in Polikhim company (Ukraine, town Vinnitsa). The first plant uses Maroc phosphorites (Cd content 16.2 ppm), the second producer uses flotation concentrate of Kolskii birthplace containing 1.5 ppm of cadmium compounds recalculated on Cd. The results obtained are listed in Table 2.

We established that 60 to 95% of cadmium trace contaminant incomes to the extraction process from phosphate raw material and remaining amount (2.7–3.25 ppm in 1 ton of P_2O_5 of extraction phosphoric acid) comes with "oil of vitriol". In the process of stripping natural phosphate, crystallization of gypsum and washing, 72–74% of cadmium compounds is passed into liquid phase, remaining cadmium co-crystallized with gypsum. At higher phosphoric acid concentration less cadmium is precipitated. For example, in Devna plant at manufacturing phosphoric acid containing 26% of P_2O_5 (36% H_3PO_4) which further processed into superphosphate, 71.8% of incoming cadmium is transferred into liquid phase. At the manufacturing of less strong acid (22% P_2O_5) in "Polikhim" plant (Ukraine) which is used further for producing sodium tripolyphosphate, 73.7% of cadimium incoming with raw material is passed to liquid phase. Relative error of determination of phase distribution is 3–4% that is quit acceptable. These measurements are consistent with published data [1]. According to the data

Table 3. Distribution of cadmium compounds at manufacturing superphosphate from Maroc phosphorite (31.6% P_2O_5)

Technological object	Consumption norm per 1 ton of P_2O_5 in fertilizer	Cadmium content, ppm	Cadmium fraction in the object trace contaminant, %
Extractive phosphoric acid (39% P_2O_5)	1.52 1	5.0	48.1
Maroc phosphorite (31.6% P_2O_5)	1.52 1	6.2	51.9
Double superphosphate (41.0% assimilat. P_2O_5)	2.44 1	8.0	95.8

presented by van Kauwenburgh, at processing phosphate raw material the liquid phase (extractive phosphoric acid) obtains 55 to 90% (average 68%) of the toxic metal incoming with raw material. The data obtained shows that processing of apatite flotation concentrate gives extractive phosphoric acid less contaminated with the toxic admixture.

At manufacturing double superphosphate in Devna plant alongside the return scheme of Dorr–Oliver firm [6, 7] partially evaporated phosphoric acid (39% of P_2O_5) and Maroc phosphorite are used, and the product contains 15–18 ppm of the contaminant. The process is carried out with deficiency of extracting phosphoric acid. The product contains 41–42% of phosphorus pentoxide (assimilating P_2O_5) dissolvable in 2% formic acid [2]. The balance on cadmium is achieved with error 4.2 rel%; it is shown in Table 3.

As follows from the data of Table 3, the cadmium content in the intermediates of superphosphate technology (extractive phosphoric acid and Maroc phosphorite at the second phase of separation) and in final products are closely related (15–18 ppm).

Table 4 shows distribution of toxic trace contaminants (mercury, chromium, lead, cadmium, arsenic, cobalt, nickel and copper) at manufacturing sodium tripolyphosphate ($Na_5P_3O_{10}$, STPP) from extractive phosphoric acid ob the basis of flotation concentrate of Kolskii birthplace and calcinated and caustic soda by stepwise technology [4, 8–10]. Join stock company "Metakhim" uses sodium carbonate produced from nepheline, and Open join stock "SUMS" uses sodium carbonate produced by classical Solve technology.

These data show that applied in domestuic plants two-step scheme of manufacturing sodium tripolyphosphate from apatite flotation concentrate allows removing heavy metal salts contaminants in the step of purification to obtain technical salts satisfying requirements on trace contaminants. The degree of purification from cadmium

Table 4. Content of toxic components trace contaminants in sodium tripolyphosphate (55.5–57% P_2O_5)

No.	Component	Maximal allowed level according to MDU 87 for feed phosphates, ppm	Content of component in the products, ppm, produced in plants:	
			Metakhim [8, 9]	SUMZ [10]
1	Mercury	0.1	0.01	-
2	Cadmium	0.4	0.03	0.03
3	Cromium	5.0	1.0	0.75
4	Nickel 2	0	2.0	2.1
5	Lead 5	0	1.0	1.4
6	Arsenic	50 2	.0 4	.0
7	Cobalt 5	00 0	.5 0	.4
8	Copper 5	00 3	.0 3	.5

over the technological chain that includes production of extractive phosphoric acid by extraction method with crystallization of gypsum, two-step neutralization with sodium carbonate and isolation of contaminant precipitate, drying and roasting of the salt achieves 99%.

1. INTRODUCTION

Having entered the XXI century, the humankind encountered a number of problems on which depends further normal development of the modern civilization. One of these issues is how the present level and rate of social and economic development can be provided with energy [1–3].

Most of key decisions concerning the energetic safety problems, aimed to minimize climatic changes upon an increase in the energy consumption, diminish toxic discharges into the living environment, and save energy resources were formulated in the cooperation agreement between the European Community and the United States, signed on June 25, 2003, in Washington by the EC President R. Prodi, Greek Prime Minister K. Simitis, and United States President J. Bush [4]. The energy policy of the countries that signed the agreement was based on hydrogen energetics and use of fuel cells as the most optimal variants of implementation of stable energy supply systems.

In Russia, research in hydrogen energetics and fuel cells was commenced by studies carried out in the middle of the last century. In 1947, Davtyan published a monograph [5] in which theoretical foundations and principles of direct generation of electric power with the use of chemical processes were presented. This publication served as a basis for studies in the field of hydrogen energetics and fuel cells (FC).

A fuel cell is a galvanic cell in which the energy of a chemical reaction of fuel combustion is converted into electric power. The fuel (H_2) and oxidizing agent (O_2), separately delivered to the cell electrodes, interact at electrodes to give an electric current.

The operation principles of fuel cells and fields of their efficient use are widely represented in the scientific literature [5–8]. The general operation scheme of an FC is shown in Fig. 1.

The term "fuel cell" is considered to mean a single-cell fuel cell comprising electrodes with a deposited catalytic layer and an electrolyte separating the anode and cathode spaces of FC. The fuel and the oxidizing agent are delivered into the anode and cathode spaces, respectively. The occurring physicochemical processes yield ions transported across the electrolyte. The flow of ions is compensated for by a flow electrons in the external circuit, which generates an electric current. Depending on the type of electrolyte and kind of fuel and oxidizing agent, various electrode processes may

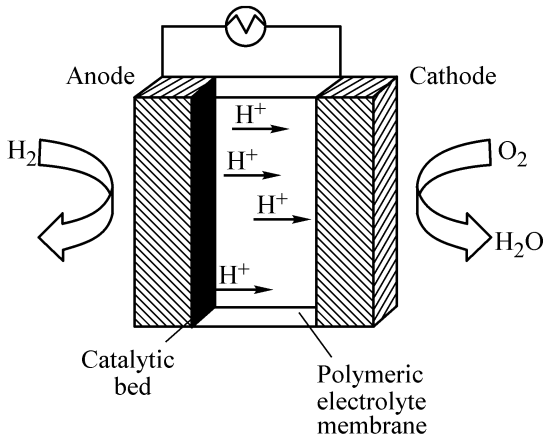

Fig. 1. Schematic of FC operation. Chemical reactions: at the anode: $H_2 \rightarrow 2H^+ + 2e$; at the cathode: $0.5O_2 + 2H^+ + 2e \rightarrow 2H_2O$; overall reaction $H_2 + 0.5O_2 \rightarrow H_2O + Q_1 + Q_2$.

Table 1. Types and selected characteristics of FC

FC type	Electrolyte	Fuel	Mobile ion	Working temperature, °C
Alkaline	Aqueous KOH	H_2	OH^-	100–250
Phosphoric acid	H_3PO_4	H_2	H^+	150–250
Carbonate-melt	$(Na, K)_2CO_3$	H_2, hydrocarbons, CO	CO_3^{2-}	500–700
Solid-oxide	$(Zr, Y)O_2$	H_2, CH_3OH	O^{2-}	700–1000
Membrane	Polymeric	H_2, CH_3OH	$H^+(H_2O)_n$	70–110

occur in FC. Table 1 lists the basic parameters of the most widely used FC [8].

Ii all these cases, atmospheric oxygen serves as the oxidizing agent. The only exception are alkaline FC, which require that pure oxygen should be used. The common advantage of all the FC is their high efficiency, resulting from the direct conversion of the chemical interaction energy into electric power, and ecological safety (with only H_2O and CO_2 as by-products). Specific difficulties are encountered in the development of each of these types of FC.

A most important condition for alkaline FC is that CO_2 should be absent in the gases supplied, in order to preclude the possible carbonization. An important problem for phosphoric acid FC is the degradation of the catalytically active layers on the electrodes and of the porous matrix used to immobilize H_3PO_4. In the case of carbonate-melt fuel cells, there appear problems associated with difficulties in retaining the carbonate melt within the porous matrix and with the stability of construction materials capable of working at temperatures of 700–1000°C. A more topical problem for membrane FC is raising their working temperature to diminish the sorption of CO contained in technical-grade hydrogen on the platinum catalyst, in order to prevent its poisoning. The fact that membrane FC cannot operate at high temperatures is presumably due to the ability of the polymeric electrolyte to retain water under this conditions, which is necessary to provide proton-conducting properties of a membrane, rather than to its thermal stability.

Despite each type of FC has its own specific features of functioning, general problems are encountered in their development, which are associated with the FC design and its improvement, enhancement of the catalyst efficiency, and functioning of the electrolyte in FC.

The electrolyte is one of the most important components of FC. On the one hand, the electrolyte provides transport of ions from one electrode to the other, and on the other hand, it precludes penetration of the fuel from the anode space into the cathode space or diffusion of the oxidizing agent in the opposite direction, both of which can result in their direct interaction. Solid electrolytes (solid oxide or polymeric) have advantages over their liquid analogues because of the wide opportunities in design and exploitation of FC.

By now, considerable advances have been made in the field of FC operating with polymeric electrolytes in the form of thin membranes. The development in this area is governed by the wide variety of application fields of membrane FC. As for solid-oxide FC, their use is presumably limited to development of high-power installations in which the loss of heat into the environment can be minimized.

Taking into account the aforesaid, we analyze in what follows the problems solely associated with polymeric electrolytes for membrane FC.

A strong stimulus to activation of research in the field of membrane FC was given by the agreement on hydrogen energetics, concluded by the Russian Academy of Sciences and Noril'skii Nikel' combine [9]. In accordance with this agreement, the research program envisaged a wide variety of studies in hydrogen energetics and fuel cells, including development of polymeric proton-conducting membranes for FC, improvement of catalytic systems on FC electrodes, improvement of the FC design, and fabrication of FC batteries. Taking into account the wide diversity of the problems associated with these tasks, we consider in more detail the development of polymeric membrane FC and analyze the synthesis and fabrication of proton-conducting polymeric (primarily fluoropolymeric) membranes for FC.

2. POLYMERIC ELECTROLYTES

Nafion. When choosing the structure of materials for polymeric electrolytes (PE), it is necessary to con-

sider the operation conditions of FC and the resulting requirements to the properties of PE.

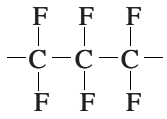
(1) The material should have high ionic (proton) conductivity.

(2) The polymeric electrolyte should be stable in redox media, including cases of elevated temperatures.

(3) The polymeric electrolyte should be indifferent to the catalyst used, carried by the electrolyte.

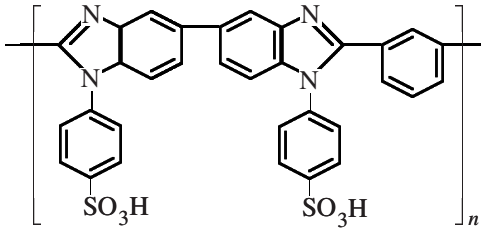
(4) The polymeric electrolyte should have low permeability to the fuel used or its components (hydrogen, methanol, oxygen, etc.)

(5) The material used should possess mechanical strength, because the polymeric electrolyte is used in FC in the form of a thin membrane, and this strength should be preserved at a sufficient level in exploitation of the membrane in the hydrated state during a long time (up to 30000 h).



(6) With account of the fact that the proton transport occurs in the hydrated form of PE, the material should be able to retain water under the working conditions.

(7) The material should preserve its characteristics in prolonged exploitation (tens of thousands of hours).



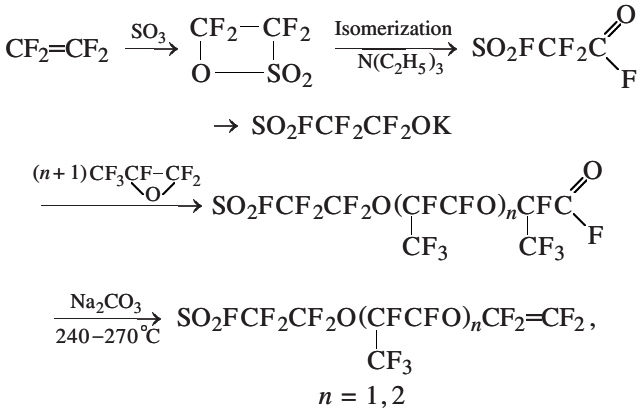
(8) The polymeric electrolyte should be comparatively inexpensive in order to provide the economic efficiency of FC.

Presumably, there is no PE fully satisfying the whole set of the above requirements now. Therefore, the development of membranes for FC is largely associated with a search for optimal variants for a particular FC.

In principle, the properties of a PE can be to a first approximation predicted on the basis of the chemical composition of the elementary unit of the polymer. For example, the proton conductivity of PE is predetermined by presence in the structure of functional groups capable of dissociation, most frequently acid groups. In practice, these may be sulfate, phosphate, or carboxy groups. If account is taken of the capacity of these groups for dissociation, sulfo groups are preferable to phosphate and, even to a greater extent, to carboxy groups. The organic radical also affects the proton conductivity of the functional groups bound to this radical. In this sense, the sulfo group bound to an aromatic ring will be more effective than that bound to an aliphatic moiety. Acid groups bound to fluorinated radicals are close in their properties to strong inorganic acids and they are more preferable, compared with structures based on aromatic compounds. The proton-conducting properties are also affected by the heat of hydration [10] and by the ability of the proton-conducting group to disintegrate (to be decarboxylated). From the standpoint of polymer chemistry, the choice of optimal solutions in this area is based on specific features of the chemical structure of the elementary unit of the polymer with account of its thermal stability and resistance to oxidative transformations. These criteria are satisfied by perfluorinated systems of the type

and by aromatic polymeric systems of the type of polybenzimidazoles (PBI)

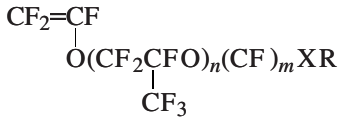
or polymers composed of aromatic fragments of another type [poly(ester–ester)ketones etc.]



The first solution aimed to obtain a PE and fabricate FC on its basis was implemented in 1962 in the development of a power supply system for the Gemini satellite, with a PE membrane based on sulfated polystyrene [11]. The FC developed had a working life of 800 h.

The next important step in the design of a PE and fabrication of FC on its basis was made by Du Pont company in 1963 [12], which developed and patented an FC based on a copolymer of tetrafluoroethylene and perfluorinated sulfo-containing monomer of general structure

where Y = F or CF_3; R = F or C_mF_{2m-1} (m = 1–10); n = 1–3; M = F, OH, OCH_3, NH_2.



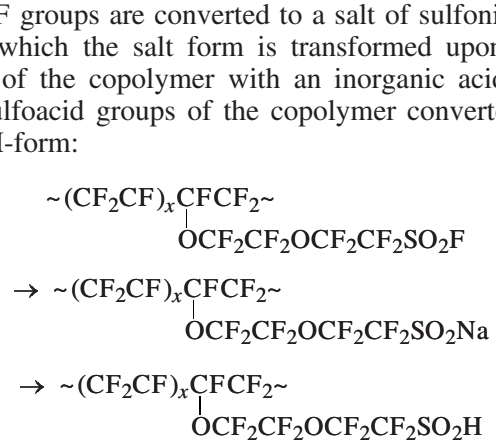
The examples in the patent [12] were mainly for structures containing Y = CF_3, R = F, n = 1, and M = F. A method used to obtain such a functionalized polymer was described in [13, 14] and consisted in a five-stage synthesis by the scheme

at n = 1—perfluoro(3,6-dioxo-4-methyl-7-octene)sulfonyl fluoride.

The know-how of each synthesis stage has not been disclosed. In Russia, the monomer received a technical name FS-141.

A sulfo-containing monomer with a close chemical structure, which was somewhat later patented by Asahi Chemical (Japan) for producing PE, had the structure [15, 16]:

where n = 0–1; m = 3–5; X = –S–, SO_2; and R = C_1–C_{10}, alkyl, perfluoroalkyl.



Dow Chemical developed and patented a monomer system with a sulfo group situated close to the sulfo group [17, 18]:

However further studies aimed to introduce this monomer into practice were suspended because of the lower efficiency of its use to produce a polymeric electrolyte.

The possibility of using perfluoroallyl compounds in synthesis of fluoropolymers with sulfoacid groups has been noted in the literature [19]. However, allyl derivatives of perfluorinated monomer systems failed to find real application later.

The structure of the monomer systems being synthesized shows that, both in synthesis of monomers and in their copolymerization, sulfated monomers are used as precursors containing, most frequently, sulfonyl fluoride groups, rather than sulfoacid groups. The choice of such a monomer structure makes it possible to preclude side reactions in the course of copolymerization. In this case, however, a membrane ion-exchange polymer can be obtained if the copolymerization is followed by alkaline hydrolysis and $-SO_2F$ groups are converted to a salt of sulfonic acid, after which the salt form is transformed upon treatment of the copolymer with an inorganic acid, with the sulfoacid groups of the copolymer converted into the H-form:

Copolymerization of perfluorinated sulfo-containing monomers-precursors [e.g., perfluoro(3,6-dioxa-4-methyl-7-octene)sulfonyl fluoride (FS-141)] with tetrafluoroethylene is performed, irrespective of their structural difference, mostly in a fluorocarbon solvent (Khladon 318, 350, or 113) with various initiators, peroxides of varied structure (carbon, perfluorinated, diazo compounds of N_2F_2, azo isobutyronitrile, etc.) [12, 15–21].

There is evidence, mostly in patents, that copolymerization can be performed in an aqueous medium [22–24]. These variants envisage use of water-soluble initiators (e.g., persulfates) or redox initiating systems based on persulfates or perfluorinated emulsifiers (e.g. salts of perfluoropelargic acid). The copolymer is obtained in the form of a dispersion. The process is distinguished by the possibility of performing polymerization to conversion degrees of about 50% in terms of the sulfo monomer. However, the method of emulsion polymerization have not found practical use for production of Nafion-type polyelectrolytes so far.

The copolymerization in a solution of khladons is commonly performed at temperatures of 30–80°C, depending on the initiator type. The pressure of the tetrafluoroethylene (TFE) used in the process is not a critical parameter [12] and can be chosen so as to create in the liquid phase a TFE concentration providing the necessary relative amounts of the monomers for obtaining a copolymer of the required composition. The pressure is most frequently chosen within the range 3–8 kg cm^{-2}.

The main difficulty encountered when performing copolymerization of TFE with FS-141 is in the strong difference in activity between the monomers being co-

polymerized. There are no data on the activity of TFE and the sulfo monomer in the nonclassified literature. Using information about the activity of the structurally similar analogues containing carboxy and ester groups [25], we can assume that this difference in activity is as strong as two orders of magnitude. Therefore, the whole amount of the less active sulfo-containing fluoromonomer is charged into the reactor for copolymerization, and TFE is batched in the course of the process, with its constant pressure maintained. As a rule, the process is carried out to low conversions of the monomer (~20%) in order to maintain a constant ratio between the reacting monomers and an invariable initiator concentration in the reaction medium. These conditions provide synthesis of a polymer with a comparatively narrow molecular mass distribution and functional groups uniformly arranged along the chain. The copolymerization process can be illustrated by the scheme

$$CF_2{=}CF_2 + mCF_2{=}\underset{\displaystyle OCF_2CF_2OCF_2CF_2SO_2F}{\underset{|}{CF_2}}$$

$$\xrightarrow{R^{\bullet}} R[(-CF_2CF_2)_xCF_2\underset{\displaystyle OCF_2CF_2OCF_2CF_2SO_2F}{\underset{|}{CF}}\sim]_n$$

It has been shown recently that the structure of the peroxide initiator used strongly affects the thermal stability and service characteristics of the PE obtained [26, 27]. It was experimentally confirmed that use of perfluorinated peroxide initiators in copolymerization makes it possible to obtain membranes with an improved thermal stability. A detailed study of how the service life of perfluorinated PE of the Nafion type decreases depending on the nature of terminal groups in the polymer was reported in [27].

When determining the properties of PE, the composition of copolymers is evaluated using the notion "equivalent mass" (EM), the molecular mass of a polymer chain fragment per a sulfo group. Experiments demonstrated that the EM of the polymer formed in copolymerization should fall within the interval between the limiting values, the upper of which is related to the percolation threshold, i.e., the minimum content of ionogenic groups at which an ionic (proton) conductivity appears in the membrane because of the formation of ionic clusters. The lower limit is due to deterioration of the physicomechanical properties of the polymer because of the pronounced water absorption (swelling) and even dissolution of PE in water. According to the data of [20], the EM should be in the range 800–1500. According to [29], the PE of the Nafion type have the optimal properties at EM of 1000–1100.

Table 2. Properties of membranes based on Nafion-117

Property	Value achieved
Exchange capacity, mg-equiv	~0.91 (up to 1.0)
Surface resistance Ω cm^{-2}	~0.09–0.12
Working life, h	Thousands (tens of thousands)
Proton conductivity, S cm^{-1}	~10^{-1}–10^{-2} (~0.1 at 80°C)
Current density, mA cm^{-2}, at a voltage of 0.45 V	~250–640
Methanol diffusion coefficient,	2×10^{-6}
Water absorption capacity, %	~15
Specific power mW cm^{-2}	600–800
Cost, USD/m^{-2}	~700

No information about the type of distribution of monomer links in the chain of the macromolecule is available in the literature.

After a certain extent of transformation of the monomers is reached (the corresponding amount of TFE is introduced), the polymerization process is terminated, the reactor is cooled to 15°C, the unreacted TFE is blown away, and a suspension of the copolymer in khladon is discharged. Khladon is evaporated under atmospheric pressure, and the polymer is separated, washed with khladon to remove the unreacted comonomer, and dried first in air at room temperature under agitation in the course of 24 h and then in a vacuum box at 60°C for 16 h. The polymer obtained is analyzed and processed into a film by hydrolysis and conversion of $-SO_3Na$ groups into the H-form, to give a perfluorinated ion-exchange membrane of the Nafion type.

The principles described above formed a basis of techniques used to manufacture industrially used perfluorinated membranes of the Nafion type (Flemion, Aciplex, etc.). Membranes of this type have found wide use in the development of FC. The potentialities of such materials were described in a number of reviews [7, 8, 30, 31]. To advantages of this class of membranes should be attributed their high chemical resistance, mechanical strength, and high proton conductivity in the temperature range 40–90°C.

Table 2 lists some basic parameters of membranes of the type under consideration for the example of the Nafion-117 material. Comparison of the proton conductivities of Nafion membranes and nonfluorinated

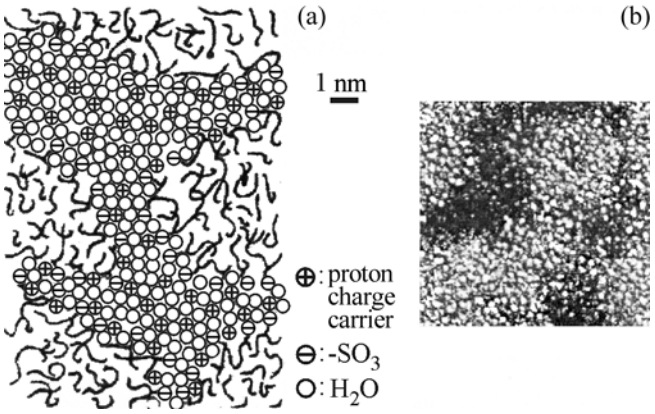


Fig. 2. Structure of perfluorinated sulfonated copolymers of the Nafion type. (a) Nanosize phase distribution according to the small-angle X-ray scattering and (b) microstructure according to the results of modeling by the molecular dynamics method.

polycondensation systems [31] clearly shows the advantage of the former.

Haile [8] analyzed the structure of the nanosize phase distribution according to the results of small-angle X-ray scattering in a membrane of the Nafion type (Fig. 2). It can be seen that the PE of the Nafion type is a submicroheterogeneous system with sulfo groups in nanosize clusters connected by channels through which the proton transport occurs.

The method of small-angle neutron scattering was first used to determine the internal structure of a polymeric electrolyte of the Nafion type and compare this structure with that of polyester ketones [32, 33]. It was shown that the maximum radius of the structural unit (cluster) is 31 Å for moistened Nafion and about 27 Å for a dry membrane. For the sulfonated polyester ketone, no structuring in the range 13–300 Å was found. An anisotropy of neutron scattering was also noted for Nafion.

Recently, the structure of perfluorinated sulfonated polymers of the Nafion type, manufactured by Du Pont, and of its domestic analogue (Plastpolimer Research and Production Association) with a technical name MF-4SK has been studied by the method of small-angle neutron scattering [34]. The new method enabled evaluation of the size characteristics of nanosize clusters and channels in the submicroheterogeneous system of the polymeric proton-conducting membranes under study.

To reveal differences in internal structure between Nafion manufactured by Du Pont and an MF-4Sk membrane, membrane samples were studied in three states: initial, that after drying at 100°C, and that after saturation of dried samples with D_2O. An analysis of the scattering intensity as a function of the momentum transferred demonstrated that, in the momentum range $q > 0.2$ nm^{-1}, the scattering intensities for Nafion and MF-4SK are close. At small momenta ($q < 0.2$ nm^{-1}), a noticeable increase in the scattering was observed for MF-4SK, whereas for Nafion, this change is small. These results indicate that small scatterers (pores) are predominant in Nafion, and the contribution of coarser pores is noticeable in MF-4SK. A processing of the experimental data demonstrated that the number of fine pores in Nafion is approximately 7 times that in MF-4SK.

The difference in the number of coarse pores is also significant. At a comparable size of about 20 nm, their number in MF-4SK is substantially larger. However, the polymeric matrix of MF-4SK is saturated with D_2O at a considerably lower rate than Nafion (in 2.5 h, 17.2% D_2O is introduced into Nafion, and only 12.3% into MF-4SK). This means that not all coarse pores in MF-4SK are connected by channels, with the result that part of the pores is not filled and, consequently, excluded from the conduction process. Thus, the MF-4SK membrane has a lower "conductivity" because of the specific features of fabrication (or storage) of this material.

A comprehensive study of the nanosize submicroheterogeneous distribution of sulfoacid groups and channels connecting these groups was found to be very important not only for a clear explanation of the mechanism of proton conduction in Nafion membranes, but also for substantiation of new approaches to modification of this kind of membranes, aimed to improve their working capacity at temperatures higher than 90°C.

It is known that the optimal working temperatures of FC based on PE of the Nafion type do not exceed 80–90°C. These conditions can only be satisfied if hydrogen used as the fuel contains no admixtures of CO, which can poison the Pt catalyst supported by the electrode at a content exceeding 10 ppm.

At temperatures higher than 130°C, the adsorption equilibrium of CO and H_2 sorption on the platinum catalyst is shifted toward H_2, which precludes catalyst poisoning. However, the proton conductivity of the membranes substantially decreases at elevated temperatures (~120–140°C) via dehydration of Nafion, because the proton conduction (or, more precisely, transport of H^+) occurs in the hydrated form (with simultaneous transfer of more than 10 molecules of water).

A recently published study by carrier out at Princeton University, was concerned with the sorption–desorption of water and the water-permeability of membranes with different thicknesses, based on Nafion-112, 115, 1110, and 1123, as a function of temperature in the range 30–90°C [35]. Emphasizing the important role of the sorption and transfer of water in PE in the control over the operation of fuel cells, the authors point to the necessity for analyzing the distribution of water in the fuel cell, which, in turn, affects the local proton conductivity. It was shown that the permeabilities of a membrane to water from the liquid aqueous phase and humidified gas are different. The membrane has a smaller swellability in the presence of a water vapor. This results in that a thin layer of the hydrophobic polytetrafluoroethylene is formed on the dry side of the membrane, and this layer makes lower its water permeability. The water permeability weakly depends on the membrane thickness. The data obtained demonstrate that the rate of water desorption from a water-saturated membrane is an order of magnitude higher than the rate of water sorption. Analysis of the data on water permeability and sorption makes it possible to determine those modes of water transfer and sorption in Nafion, which correspond to diffusion across the membrane–gas interface and swelling of the polymer in saturation with water.

Thus, despite the important advantages of proton-conducting Nafion type membranes, such as chemical resistance, mechanical strength, and high proton conductivity, it is necessary to modify the structure and properties of Nafion in order to choose the optimal mode of their exploitation with account of temperature, preservation of water content, and effect of impurities in the hydrogen-containing fuel.

In the last decade, the work on Nafion modification has acquired a decisive importance for further development of the technology of polymer-electrolyte membranes (PEM).

3. MODIFICATIONOF COMMERCIAL MEMBRANES OF THE NAFION TYPE WITH POLYMERIC SYSTEMS

Figure 2 shows specific structural features of Nafion type membranes, which are a consequence of the incompatibility of the main fluorocarbon polymeric matrix with sulfo groups grafted to the polymetric matrix. The hydrophobic nature of the fluorocarbon fragment of macromolecules and the hydrophilicity of sulfonic groups give rise to nanostructural heterogeneities composed of cluster up to 3 nm in radius, connected by 1–2-nm-wide channels. A change (e.g., decrease) in the EM of the membrane may be accompanied not only by an increase in the proton conductivity of FC, but also by deterioration of the mechanical strength of the membrane because of the increased water absorption and the resulting change in the volume of the swollen material.

In this context, intensive studies of structural transformations that alleviate these disadvantages have been performed in the last decade. In particular, methods for surface modification of Nafion membranes by radiation grafting of polystyrene [36] or by grafting of styrene in supercritical CO_2 [37], followed by sulfonation in concentrated sulfuric acid have been suggested. A study of the resulting grafted modified systems revealed an increase in the glass-transition temperature of the material of the membrane and a slight decrease in its crystallinity (because of the incorporation of amorphous fragments of polystyrene). Simultaneously, the ionic conductivity of the new modified system increases, compared with the starting material of the Nafion type [37].

In the patent [38], a variant was suggested for modification of Nafion membranes with polystyrene in a mixture with divinylbenzene or water-impermeable copolymers: polyethylene, polyhexafluoropropylene, copolymers of hexafluoropropylene with propylene or ethylene, copolymers of vinylidene fluoride with tetrafluoroethylene, etc. The grafting is initiated by irradiation with accelerated electrons. Owing to their water-impermeable properties, the resulting membranes are rather promising for use in FC employing methanol as a fuel.

A method of Nafion impregnation with polypyrrole has been suggested for surface modification of Nafion type membranes [39]. This method improves the efficiency of electron removal from the platinum layer of the electrode.

It has also been suggested to introduce polypyrrole electrochemically in situ into membrane pores [40] in order to preclude the through penetration of methanol across the membrane in the case of its use in methanol systems.

Variants of structural modification via introduction into a polymeric system of monomers containing an amino group that cross-links the monomers with two or more epoxy or isocyanate functional groups in order to raise the strength properties of Nafion membranes have been suggested [41]. The joint dissolution of these groups in Nafion and subsequent formation of a partly cross-linked or bridged polymer improves the properties of the membranes.

In the patent [42], a method was described for modification of a proton-containing membrane based on Nafion by in situ polymerization of cation monomers deposited onto the membrane surface:

$$R^1R^1C{=}CR^2\underset{\underset{O}{\|}}{C}O(CR^1R^1)_n{-}CR^1N(R^3)_3^+A^-$$

or

$$R^1C{\equiv}CR^2\underset{\underset{O}{\|}}{C}O(CR^1R^1)_n{-}CR^1N(R^3)_3^+A^-$$

where R^1 = F or H; R^2 = H, CH_3, or halogen; R^3 = CH_3, C_2H_5; A^- = SO_3^-, Cl^- anion.

Chemical or radiation initiation of the polymerization of polymers of this kind results in the formation of a protective layer that precludes partial dissolution of silicone contacts in the interaction with perfluorosulfonic acid contained in the membrane and to a substantial increase in the membrane resistance.

Methods have been patented for production of membranes with enhanced mechanical strength and increased proton conductivity at a small thickness (0.025 mm) by combining an inert highly porous polytetrafluoroethylene with impregnation with a proton-conducting Nafion [43] or by creating a three-layer proton-conducting membrane with an inner layer with EM increased by 20% and outer layers with lowered EM [44]. As shown by studies, such a three-layer design is equivalent in conductivity to a membrane with composition identical to that of the outer layer.

The patent [45] described various methods for fabrication of composite two-component membranes, based on impregnation with polymeric electrolytes of the Nafion type (or with other polymeric electrolytes) of inert polymers (perfluorinated polymers and copolymers, polyvinyl chloride, polyvinylfluorostyrene, polyester ketone, polyestersulfone, etc.) or porous inorganic materials (glass fibers, oxides, silicates). An important issue in this case is combination of an inert polymer and a polymeric electrolyte (or its precursor). If a precursor is used, it is converted into the ion-conducting form. Variants of production of polymeric membranes by this method can provide control over the physicochemical properties by varying the ratio between the components or the degree of precursor conversion into the active form.

The possibility of modifying Nafion-115 with a polymerized phenol-formaldehyde resin to improve the properties of Nafion-115 to be used in FC operating on methanol was described in [46]. After being introduced into Nafion, the resin is subjected to sulfonation. A good dispersive ability of phenol-formaldehyde resin in Nafion was demonstrated. Composite membranes of this kind are close to Nafion in proton conductivity and are more suitable for use as regards their permeability to methanol. The composite membrane substantially surpasses Nafion-115 in the maximum power density (114 and 78 mW cm^{-2}, respectively).

A research group from Uppsala University (Sweden) [47] obtained a composite membrane based on Nafion modified by diffusion of a polybenzimidazole solution at various concentrations and drying temperatures. The possibility of raising the conductivity by 50% as compared with pure Nafion, combined with a decrease in the permeability to methanol, was demonstrated.

Attention should also be given to the resumed attempts to create new types of PEM by replacing the so usual sulfo-containing polymeric systems with other industrially manufactured polymers with aryl skeleton: polystyrenes, polycarbonates, polysulfones, and other compounds subject to sulfonation by appropriate reagents [48]. The membranes synthesized were studied by various physicochemical methods in order to identify proton transport centers, determine the thermal stability of the resulting membrane systems, and their water sorption and desorption parameters. The experimentally measured ion-exchange capacities were found to be comparable with the values for industrial Nafion-type membranes. The best parameters were observed for sulfonated polycarbonates: exchange capacity as high as 0.57 meq g^{-1}, tensile strength 157 N mm^{-2}, and glass-transition temperature 120°C, at a low affinity for methanol (sorption 2.97%). The results obtained give reason to hope that new inexpensive proton-conducting membranes can be developed.

To this kind of studies can also be referred those in which ion-exchange membranes are produced by the method of graft polymerization, initiated by a preliminary irradiation, of styrene or a mixture of styrene with divinylbenzene on structured films of polytetrafluoroethylene (RX–PTFE), followed by sulfonation of the grafted polymers [49]. The achieved values of ion-exchange capacity of the membranes are within the range 1.5–2.8 meq g^{-1} and can exceed the ionic conductivity of Nafion-112.

In [50], the possibility of obtaining polystyrenes or similar polymeric systems grafted to polytetrafluoro-

ethylene with the use of ultraviolet irradiation, followed by sulfonation.

Particularly noteworthy is the recently published study [51] devoted to grafting of functionalized vinyl monomers to tetrafluoroethylene or copolymer films. The authors described a method for producing a PE membrane combining high proton conductivity and high thermal stability by grafting a vinyl monomer containing a trimethoxysilyl group (*p*-styryltrimethoxysilane) to films of a copolymer of ethylene with tetrafluoroethylene, subjected to a preliminary gamma irradiation. Films with a grafted *p*-styryltrimethoxysilane were sulfonated for groups of sulfonic acid to be added to aromatic rings of grafted chains and then were subjected to hydrolysis and condensation to give silanol cross-links between the grafted chains. In this way, a cross-linked proton-conducting polymer-electrolyte hybrid membrane was produced. The preparation conditions (grafting and sulfonation) and the properties of the polymer-electrolyte membrane obtained (ion-exchange capacity, proton conductivity, water-absorption capacity, and thermal stability) were analyzed to determine the possibility of its use in fuel cells. It was shown that the new hybrid polymer-electrolyte membrane with grafted *p*-styryltrimethoxysilane is comparable in its properties to Nafion and surpasses membranes with grafted styrene.

Recently, considerable attention has been given to modification of Nafion with various polymers in order to reduce its permeability to methanol and enable use of the polymer-electrolyte composite in fuel cells operating directly on methanol. For example, modification of Nafion-117 with organic silanes containing thiol groups was considered in [52], with the result that the permeability to methanol was reduced by 50%, but the proton conductivity also somewhat decreased.

A proton-conducting membrane operating on methanol was produced on the basis of a composite constituted by Nafion and poly(*p*-phenylenevinylene) [53]. The structure of the composite was characterized by IR spectroscopy and scanning electron microscopy. Also, the conductivity, wettability, and water-retaining capacity of the membranes obtained were determined.

In [54], production from Nafion-117 of a composite system of sulfated polystyrene and Nafion, formed on the principle of a semi-mutually penetrating network, was described. An increased proton-conductivity of the resulting membranes at temperatures higher than 110°C was noted.

A multilayer proton-conducting membrane composite has been obtained on the basis of Nafion and sulfonated polybenzimidazole by impregnation of films of sulfated polybenzimidazole with a Nafion solution [55].

In [56], synthesis of a proton-conducting membrane for methanol FC from Nafion coextruded with carbon nanotubes was reported. It was stated that the permeability of the material obtained to methanol becomes lower without any decrease in the proton conductivity.

In [57], a review of developments in the field of membranes of varied structure for fuel cells was made, with the conditions of their optimal operation and relationships between the structure and properties of the membranes, on the one hand, and their applicability in fuel cell systems, on the other, considered.

The analysis made revealed a high intensity of studies devoted to modification of properties and possibility of use of proton-conducting Nafion type membranes. Also impressive is the wide variety of polymeric systems used for modification and the diversity of methodological modification procedures. The progress made is primarily associated with the improvement of the barrier properties of membranes and strengthening of the polymer matrix. The analysis on purpose disregarded the possibility of using polymers with a clearly pronounced hydrophilicity for modification of Nafion-type systems. These systems will be considered upon analysis of membrane modification with inorganic compounds. Nevertheless, it is well seen just now that the modification of Nafion, which can improve the efficiency of its use at elevated temperatures (120–130°C), is not simple and requires further in-depth studies with the use of integrated methodological approaches.

4. MODIFICATION OF MEMBRANES OF THE NAFION TYPE WITH INORGANIC COMPONENTS

Modification with inorganic components as an approach to improvement of service characteristics of Nafion-type membranes is due to the necessity for improving the water-retaining capacity of the membranes and for precluding their dehydration because of the hydrophilicity of the inorganic component and its capacity for chemical or coordination binding of water. This variant of Nafion modification can compensate for the loss of water by membranes working at elevated temperatures and reduce or completely eliminate the deactivation of the catalytic Pt layer,

Table 3. Proton conductivity of membranes of the Nafion type, modified by repeated casting and treated with ultrasound [66]

Membrane type	Thickness, μm	Surface resistance, Ω cm^{-2}	Proton conductivity, S cm^{-1}, at a relative humidity of 70%
Nafion-115	100	1.23	8.13×10^{-3}
Nafion-115–SiO_2	100	0.92	1.07×10^{-2}
Nafion-115–SiO_2–PTA	120	0.45	2.67×10^{-2}

thereby making possible the functioning of the membrane at temperatures higher than 130°C.

In a number of studies [58–60], the possibility of improving the properties of Nafion-type membranes by introduction of silicon dioxide into their composition was considered. The modification was performed by placing a membrane in the H^+-form in a solution of tetraalkoxysilane (TEAS), with the subsequent hydrolysis of TEAS absorbed by the membrane. It was shown that modified membranes can efficiently operate at temperatures higher than 100°C (up to 140°C). The proton conductivity of the membrane increases with the SiO_2 content to reach a maximum at 10–12% and then decreases as the content of silicon dioxide introduced grows further.

Nearly simultaneously with the analysis of the influence exerted by the SiO_2 additive on the properties of Nafion-type membranes, the intrinsic proton conductivity of the class of heteropolyacids: phosphotungstic acid (PTA), silicotungstic acid, etc., was studied [61–64]. It was shown that heteropolyacids have a high room-temperature proton permeability [61] and can be immobilized in Nafion [62] to give composites with a high proton conductivity (>10 S cm^{-1}) at room temperature. However, heteropolyacids are commonly immobilized in silica gel because of their high solubility in water [61]. PTA immobilized in a silica gel, combined with polyethylene oxide, gives a hybrid proton-conducting system with a conductivity of 10^{-3}–10^{-2} S cm^{-1} in the range from room temperature to 140°C [64]. These opportunities were used in [65], whose authors replaced polyethylene oxide with Nafion and obtained a Nafion–SiO_2–PTA composite, which was successfully tested in a fuel cell operating on methanol at 145°C.

Later, the possibility of improving composite membranes of a similar composition by repeated casting with the use of a Nafion solution preliminarily subjected to ultrasonic mixing with SiO_2 and PTA was described [66]. The parameters of the material synthesized were compared with the properties of the Nafion–SiO_2 composite obtained using a similar mixing procedure. The material was studied by the following techniques: scanning electron microscopy; X-ray diffraction, thermographic, and differential-thermal analyses; and IR Fourier spectroscopy. The study revealed important advantages of the above-described method for forming a composite membrane: it provided an increase in the degree of crystallinity and in the water-absorption capacity of the membranes obtained. The crystallinity increased by 18% for a repeatedly cast starting membrane, 25% for the Nafion–SiO_2 composite, and 20% for the Nafion–SiO_2–PTA system. The increase in the water-absorption capacity for these systems after their repeated casting was 26 to 32% for the starting membrane, up to 34% for the Nafion–SiO_2 composite, and up to 38% for the Nafion–SiO_2–PTA system.

The results obtained in a study of membranes modified by the method described in [66] (Table 3) indicate that their proton conductivity substantially increased.

Thus, the suggested ultrasonic treatment of the membrane composites modified with the SiO_2–PTA system leads to a threefold increase in their proton conductivity.

The effects observed can be attributed to the hydrophilic nature of SiO_2 and PTA, changes in the degree of crystallinity of the membrane, and stronger interaction of absorbed water with the modified matrix. Previously, Zawodzinski and co-workers noted [67] that the proton conductivity of a Nafion-type membrane virtually linearly increases with its water-absorption capacity. A repeated casting of the membrane improves its properties and raises its water-absorption capacity as compared with the starting material. With composite Nafion–SiO_2 and Nafion–SiO_2–PTA membranes, higher current densities were obtained, equal to 320 and 540 mA cm^{-2}, compared with 95 mA cm^{-2} for the starting Nafion-115 membrane.

Also, the effect of various inorganic modifiers (SiO_2, SiO_2–PTA, Al_2O_3, and ZrO_2) on the proton-conductivity of Nafion-type membranes has been compared in relation to the water-retaining capacity of the modifiers and the acid-base properties of their surface [68]. The highest efficiency of the SiO_2–PTA system, resulting from its own acidity and a large amount of crystal-bound water in PTA ($H_3PW_{12}O_{40} \cdot$

$36H_2O$), was confirmed. An extremal run of the temperature dependence of the membrane resistance, with a minimum at 140–150°C, was revealed for most of the above-mentioned fillers, which is due to desorption of water contained in pores and physically sorbed on the surface. In [69], the effect of addition of highly dispersed TiO_2 powders on the properties of Nafion-type composite membranes was analyzed. In the same study, the possibility of modification of the membrane material by introduction of fluorinated montmorillonite into the Nafion structure was described. The systems obtained show improved barrier properties without any decrease in the proton conductivity.

Of particular interest is introduction into Nafion of highly dispersed SiO_2 surface-modified with $–SO_3H$ groups [70, 71]. Mixing with Nafion of modified SiO_2 produced by functionalization of the starting aerosil with 1,2,2-trifluoro-2-hydroxy-1-trifluoromethylethanesulfonic acid yields a membrane with an increased proton conductivity dependent on the concentration of the modifier introduced (the maximum value of 0.12 S cm^{-1} was achieved at a modifier content of 3%). The modified membrane also shows improved barrier properties.

The possibility of obtaining sulfonated SiO_2–SO_3H nanoparticles has been noted previously, without description of the preparation technique. For example, modification of polyesterketone-based membranes with SiO_2–SO_3H nanoparticles to give membranes with increased strength and conductivity, which can be used in methanol FC, was considered in [72].

To conclude, we note that the proton-conductivity of Nafion can be raised by the effect of physical treatments in the course of membrane casting and, in particular, that with electric field, on the formation of directionally oriented ionic channels [73].

The effect of formation of oriented nanodomain structures has also been noted for production of polyelectrolytes by plasma-initiated graft polymerization [74]. The morphology of the nanodomain structure was determined by scanning electron microscopy and IR Fourier spectroscopy. A sixfold increase in the proton conductivity, compared with the starting Nafion, was recorded.

Analysis and generalization of the data obtained and their theoretical substantiation show that a considerable progress has been made in the last decade in improvement of service characteristics of Nafion-type proton-conducting membranes by modifying their structure by introduction of polymeric and inorganic components. The possibility of extending the working temperature range of membranes to higher temperatures, raising the proton-conductivity, and improving the water-retaining capacity and barrier properties has been demonstrated. It has been shown that the structure of membranes can be modified to enable their use in fuel cells operating on methanol.

When summarizing the material being analyzed, it is necessary to take into account the data presented in some of project reports of 2003–2005 in the framework of the US Program of hydrogen energetics, which involved leading universities, national laboratories, and companies [75]. Advances in the following areas can be noted.

(1) The mechanism of the peroxide attack in the course of membrane operation has been determined.

(2) Fluorinated initiating systems providing formation of fluorinated terminal groups have been chosen.

(3) The physicomehanical properties of membranes have been improved by, in particular, the following kinds of modification: synthesis and introduction of dispersed modified silica with added sulfone groups and modification with the use of dendrite structures.

(4) Water-insoluble organic–inorganic hybrid systems mixed with Nafion, which are thermally stable up to 300°C and have a proton conductivity of 0.35 S cm^{-1} at 80°C and relative humidity of 5%, have been developed.

(5) Polyblock polymeric systems with high proton-conductivity have been created and ionic liquids have been used as proton-conducting media.

The results mentioned above presumably form an incomplete list of the achievements of the program, but demonstrate that Nafion-type polymeric membranes remain highly competitive among the so far developed proton-conducting materials and keep the leading position both in the level of their development and in the proton conductivity and service life.

5. ACHIEVEMENTS IN DEVELOPMENT OF POLYCONDENSATION PROTON-CONDUCTING MEMBRANES AND HYBRID MEMBRANE SYSTEMS [29–31]

In [30], the level (state) of the technological development and potentialities of membrane polymers of varied structure for FC operating on hydrogen and methanol and for high-temperature FC is shown graph-

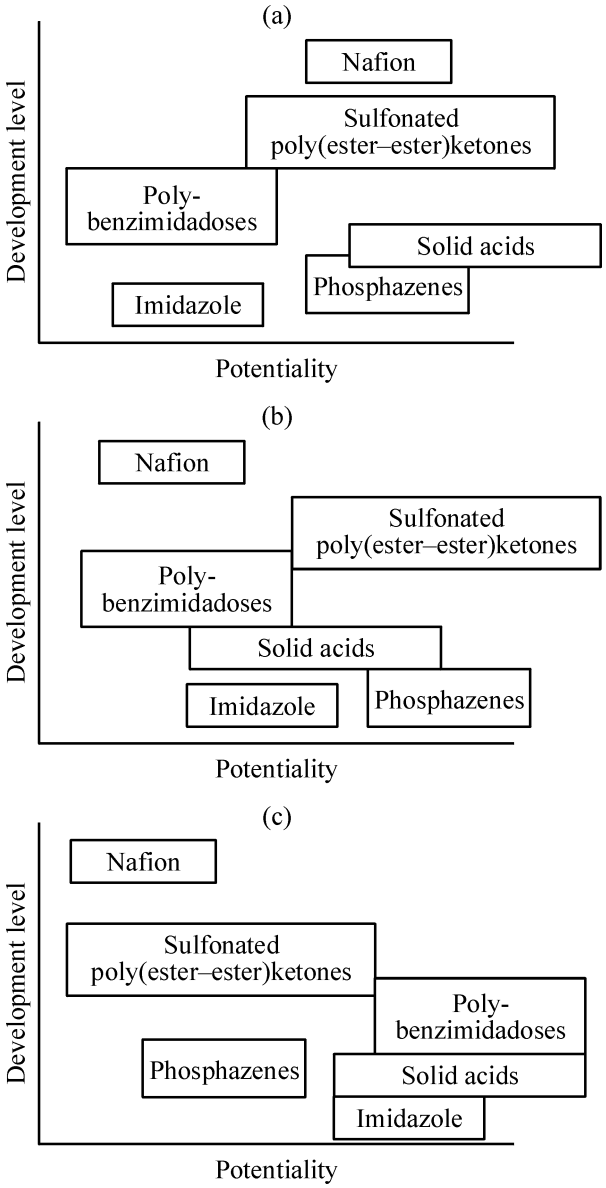

Fig. 3. Relationships between the development level and potentialities of various materials for use in (a) hydrogen, (b) methanol, and (c) high temperature FC [30].

ically (Fig. 3). It can be seen that, for methanol FC, Nafion is inferior in its potentialities to some polycondensation membranes despite the high level of development of Nafion-type membranes. For high-temperature FC, polycondensation membranes, especially those based on polybenzimidazoles, surpass Nafion-type membranes in their potentialities.

At the same time, experimental data obtained for a number of polycondensation membranes show that most of systems of this kind are inferior to Nafion in proton conductivity [31]. First industrial success in manufacture of polybenzimidazole membranes and FC operating on ethanol has been achieved and patented by Pemeas Fuel Cell Technologies with the use of a pilot installation put into operation in 2004. The Celtex-MEA membrane based on poly-2,2'-*m*-phenylene-5,5'-dibenzimidazole, developed by this company, is intended for a system composed of 35% H_2, 64.8% N_2, 2000 ppm Co, and admixtures of CO_2 and H_2O, has a service life of more than 8000, can operate in the temperature range 120–200°C, and tolerates CO in concentrations exceeding 50000 ppm. Another variety of the membrane, manufactured under the name Celtex-V, is intended for use in methanol FC.

Studies aimed to develop new improved membranes are continued. For example, sulfated poly(phthalazanone-esterketones) filled with sulfonated SiO_2–SO_3H nanoparticles have been suggested [72]. Polyblock-copolymers containing benzophenone units and methyl fragments that can be cross-linked under UV irradiation [77], cross-linkable sulfonated polyarylene esters that are soluble in organic solvents and can form flexible and transparent membranes by casting from solutions [78] have been obtained.

Another new and intensively developing area of research is associated with synthesis of hybrid polymeric membranes. Honma and co-workers [79] suggested a new class of amphiphilic organic-inorganic hybrid membranes produced by the sol–gel method from bridged polysiloxanes with acid fragments of phosphotungstic acid by the scheme

$$HO(CH_2)_nOH + 2\,(EtO)_3Si(CH_2)_3NCO \rightarrow (Et)_3Si(H_2C)_3NHCOO(CH_2)_nOCONH(CH_2)_3Si(OEt)_3$$

Dobrovol'skii and co-workers suggested [80] to use as high-efficiency proton-conducting membranes polymeric systems based on polyvinyl alcohol (PVA) esterificated with phenolsulfonc acids (PSA) of structure

The conductivity of PE of this kind depends on the PVA : PSA ratio (increases with the PSA content), only slightly depends on humidity, and is preserved at a high level up to 80°C.

Hybrid polymeric membranes produced by the sol–gel method at various ratios of 3-glycidyloxypropylmethoxysilane and phosphonoacetic acid are distinguished by thermal stability preserved up to 200°C, mechanical strength, high transparence, and conductivity of up to 8.7×10^{-2} S cm^{-1} [81]. A method for synthesis of organic–inorganic hybrid PE from trimethoxysilylmethylstyrene and phenylvinylphosphonic acid by radical polymerization and a study of their properties have been reported [82]. These membranes remain stable up to 180°C and their proton conductivity is as high as 3.7×10^{-2} S cm^{-1}.

A rather interesting idea of how hybrid membrane PE and electrode ensembles on their base can be produced has been implemented in a set of patents [83–87]. In this approach, a proton-conducting polymeric system is formed by copolymerization of the readily available and inexpensive hydrophilic and hydrophobic monomers containing an ionogenic group (e.g., SO_3H). The copolymers obtained on their basis can contain water and transport ions across their structure, with proton conductivity exhibited by them at moderate temperatures. The accessibility and low cost of such PE make it possible to cast an ensemble of cells and recover the expensive platinum catalysts from worked-out cells by simple burning.

We made an attempt to reproduce PE in accordance with the patents [83, 84]. The results of experiments aimed to synthesize membranes failed to give satisfactory results: the polymeric systems produced in accordance with the patents had poor strength characteristics, especially at elevated temperatures (70–90°C). Possibly, this is due to the know-how undisclosed in the patents. Therefore, another approach was used to obtain polymeric systems with improved characteristics by forming a polymeric matrix by the method of mutually penetrating networks. This technique has been employed previously in synthesis of biphase polymeric hydrogels for ophthalmologic lenses for prolonged wearing [88, 89]. The formation of mutually penetrating polymeric networks from systems constituted by polyethylene oxide and polybutadiene and by polyethylene oxide and polycarbonate was recently described in [90, 91]. Selected characteristics of the resulting hydrogel proton-conducting membranes are listed in Table 4.

As can be seen in Table 4, membrane proton-conducting systems with satisfactory strength characteristics, moisture content, and proton conductivity could be produced from the available monomers.

We attempted to analyze the basic areas of research aimed to create proton-conducting PE, with the chronology of their appearance and developments observed. In doing so, we systematized and studied the most important of the published data, which characterize the development of new approach to development of proton-conducting PE and modification of their properties.

Three structural variants of approaches to fabrication of PE for fuel cells have been revealed: (i) methods for fabrication of perfluorinated Nafion-type PE and their analogues, which have become classical in the last half-century; (ii) approaches to synthesis of nonfluorinated polycondensation aromatic systems of the type of poly(ester–ester)ketones, polybenzimidazoles, and PE on their basis; and (iii) methods for obtaining PE from the comparatively new class of hybrid polymeric systems.

Sulfoacid Nafion-type PE have been considered most fully. For these PE, methods and technology of synthesis, internal microheterogeneous phase structure with nanoclusters connected by nanosize channels, proton conduction mechanism, and various techniques for modification of their performance characteristics have been described in detail. There is no way of not mentioning here the success in wide application of Nafion-type PE in limited-power FC.

Nonfluorinated systems based on polybenzimidazoles, poly(ester–ester)ketones, polysulfones, and other polymeric systems are understood in less detail, despite being extensively studied now. Materials of this kind are believed to be promising for application in FC working at temperatures of up to 200°C; they are less sensitive to admixtures of CO in the fuel and can be used in FC operating on methanol. There have been first successful attempts of industrial manufacture of membranes of this type (Pemeas company), with a service life of about 8000 h.

Hybrid polymeric systems are being extensively studied by many research teams; however, the results accumulated by now are so far insufficient for their use in technology.

We are forced to admit the lagging behind of our studies for all the three classes of PE with respect both to the operation mechanism of membranes on their basis and to the possibility of controlling the service properties of membranes in FC.

Rather important in this context is development of a strategy of planning of actions aimed to catch up in studies and in the development of the fabrication technology of small-size fuel cells with the use of polymeric proton-conducting membranes. The principle "to overtake without catching up," previously put forward when concluding an agreement between the Presidium of the Russian Academy of Sciences and Noril'skii Nikel' Joint-Stock Company seems to be somewhat disputable.

With account of the all-inclusive nature of the problems of development of FC with the use of polymeric membrane systems, which are associated with (a) synthesis of PE and their operation in fuel cells, (b) development of catalysts and improvement of their efficiency, and (c) improvement of the FC design, it seems that coordination of R & D works is necessary, with joint discussion of their results and correction of the corresponding plans and programs.

6. CONCLUSIONS

(1) In the last decade, three groups of polymeric systems that can be used as polymeric proton-conducting membranes in fuel cells have been clearly distinguished. The first group is constituted by perfluorinated sulfo-containing polymeric systems of the Nafion type and their analogues; the second, by aromatic polycondensation systems of the type of polybenzimidazoles, polyesterketones, and polyphosphazenes; and the third, new permanently growing group, by hybrid polymeric electrolytes.

(2) The best understood and most advanced toward practical use are Nafion-type systems. Nevertheless, the potentialities of these systems are far from being exhausted and further improvement of their properties and appearance of new fields of their application would be expected. This illusory contradiction is due to the fact that the practical use of Nafion-type materials outpaced the accumulation of a critical volume of the fundamental knowledge necessary for development of substantiated technologies. At present, this knowledge continues to be accumulated, which will possibly give new effective solutions concerning the application of materials of the classes under consideration.

(3) The scientific basis for design and fabrication of optimal structures of polycondensation polymeric electrolytes is only being formed now. The potentialities of this type of polymeric proton-conducting systems are far from being exhausted. We believe that basic research should be enhanced for this group of materials, without forcing direct technological developments.

(4) Studies of hybrid polymeric systems, including hydrogels, seem to be the least developed and exceedingly promising and require a fundamental approach to their development.

(5) An analysis of the special literature demonstrated that achievements in development of polymeric membrane systems with optimal characteristics are in most cases associated with use of a specially modified Nafion.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Technology of Fabrication and Study of Porous Oxide Films on Aluminum Alloys

Yu. I. Shtern

Moscow State Institute of Electronics, Moscow, Russia

Received April 16, 2007

Abstract—Technology for fabrication of porous anodic oxide films on aluminum alloys is suggested. All the films have good electrical parameters in a wide temperature range. The results obtained were used to fabricate metal-insulator substrates for manufacture of electronic devices.

DOI: 10.1134/S1070427208040022

In this communication, a technology for fabrication of porous anodic oxide films (AOF) on aluminum alloys is suggested. The results obtained in studies of these films have been used to fabricate metal-insulator (MI) substrates for electronic devices, including thermoelectric units operating on the Peltier effect [1, 2]. At present, MI substrates are successfully used to fabricate microassemblies and hybrid integrated circuits [3]. It should be noted that oxide films are a promising material for nanotechnologies [4]. This circumstance also makes the study performed more topical. The optimal starting material for fabrication of MI substrates are aluminum alloys having high thermal conductivity, low density, and necessary mechanical strength. Aluminum alloys are easy to process and, when subjected to electrochemical oxidation, can form a uniform and homogeneous oxide with good dielectric properties [3, 5]. An important advantage of aluminum substrates, compared with other metallic substrates, is that the adhesion strength of a AOF–substrate system exceeds 12 kg mm^{-2}, and the strength of AOF is as high as 14 kg mm^{-2}.

The technology under consideration was tested on various aluminum alloys that, in principle, satisfy the requirements to MI substrates: AD, AV, AMTs, and AMg alloys. It should, however, be noted that, when MI substrates are used in electronics, thin metallic films are formed on their surface. This factor predetermines the necessity for subjecting the substrates to a mechanical treatment to a roughness not exceeding 0.1 μm. The most technologically convenient in this regard are AMg alloys. The physicochemical properties of AOF are largely determined by the electrolyte composition [3, 5]. The technology uses an oxalic acid electrolyte of the following composition (g l^{-1}): oxalic acid 100 and boric acid 20. This electrolyte makes it possible to form oxide films with improved dielectric properties. The presence of boric acid lowers the chemical activity of the electrolyte toward the anodic film and diminishes the surface roughness of AOF [6].

EXPERIMENTAL

In the technological process under consideration, MI substrates are fabricated in the galvanostatic mode of electrochemical oxidation at current densities of 1.5–2.0 A dm^{-2}. The study demonstrated that the current–voltage (I–V) characteristics of AOF formed at these current densities have high initial breakdown voltage and resistance. The current density in anodization was maintained constant with a current generator, with the formation voltage of the oxide layer varying from 80 to 120 V at an AOF thickness of about 60 μm. The anodization was performed at electrolyte temperatures of 291–298 K. Raising this temperature to above 300 K enhances the etching effect and makes lower the growth rate of the oxide layer, with the porosity of AOF increasing. As temperature is raised, the surface roughness of an MI substrate becomes more pronounced, the process voltage increases, and, accordingly, the thickness of the barrier layer grows.

The electrolyte temperature was stabilized in the course of anodization with water circulated within a closed circuit mounted on the outer perimeter of the electrolytic bath. The water temperature was controlled by a Lauda RC6 CP liquid thermostat. The electrolyte was agitated by bubbling of filtered

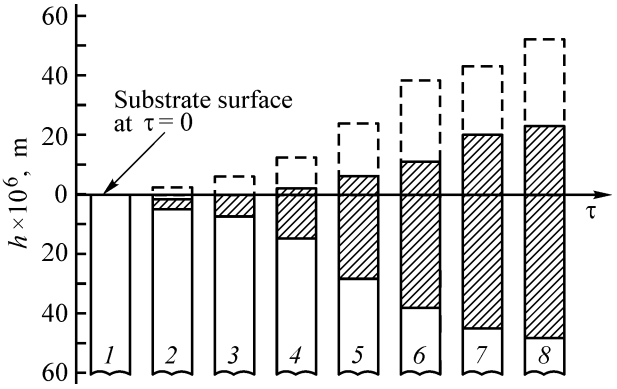

Fig. 3. Growth diagram for an AOF formed at a current density of 2 A dm^{-2} and different electrolysis durations τ. (*h*) Thickness. τ, min: (*1*) 0, (*2*) 5, (*3*) 15, (*4*) 30, (*5*) 60, (*6*) 90, (*7*) 120, and (*8*) 150.

compressed air. The AOF thickness was determined using a microscope and a Kristall-2 machine for making spherical metallographic sections. In addition, the thickness of AOF and metallic support was measured on a stand equipped with a micrometer head (scale division 1 μm). *I–V* characteristics of AOF were measured with a PNKhT-2 instrument. For this purpose, a structure constituted by a metallic contact (nickel), AOF, and metallic substrate was fabricated (see Fig. 1b). A measuring probe was attached to the metallic contact fabricated on the AOF surface by magnetron sputtering of nickel. Another probe was attached, through an opening produced in the AOF by a grinding ball, to the metallic substrate.

Figure 1 shows *I–V* characteristics of anodic oxide films of various thicknesses, produced at a current density of 2.0 A dm^{-2}. It was found that substrates with a dielectric film of thickness of about 8 μm sustain a voltage exceeding 400 V. It should be noted that the growth rate of AOF decreases in the course of anodization (Fig. 2) (as the growth rate is taken the change of the film thickness in unit time). The growth rate decreases because the supply of oxygen into the zone in which the primary oxide is formed becomes hindered as the AOF thickness increases. To control the anodization process in order to obtain MI substrate with the optimal properties, it is necessary to have data on the growth kinetics of AOF. Of particular interest is analysis of how the metal–oxide interface moves and the thickness of the MI substrate varies in the course of electrochemical oxidation.

Figure 3 shows the AOF growth diagram plotted using the results obtained by measuring the AOF and substrate thicknesses in the course of anodization. According to these data, the interface between aluminum and aluminum oxide moves into the aluminum substrate in the course of oxidation. However, the increase in volume, observed in this case, results in that the outer surface of AOF does not coincide with the original surface of the aluminum substrate. The chemical reaction in which aluminum oxide is formed is as follows:

$$4Al + 3O_2 = 2Al_2O_3.$$

Taking into account the atomic weight and the density (d = 2.7 g cm^{-3}) of aluminum and the molecular weight and the density (d = 2.55 g cm^{-3}) of the oxide film, it is possible to find the relative volumes of the AOF formed and of the metal consumed for its formation. The volume of 1 g-at Al is 10 cm^3, and that of 1 g-at Al_2O_3, 40 cm^3. Thus, it is apparent that an AOF of thickness *h* should grow at the expense of an aluminum layer of thickness 0.5 *h*. However, the results obtained by measuring how the AOF and

substrate thicknesses vary in the course of anodization show that the substrate boundary does not coincide with the calculated position represented in the diagram by a dashed line (Fig. 3). The decrease in the AOF thickness with respect to the calculated value is accounted for by the etching effect of the electrolyte on the surface of the oxide film. The calculated AOF thickness, found, taking into account the oxidation reaction, from the ratio of the specific volumes of Al and Al_2O_3, is true only at the strictly stoichiometric form of AOF and disregards the possible hydrated forms of Al_2O_3 and incorporation of electrolyte anions into AOF, which results in that the density of the oxide layer may be even lower. However, the transfer of aluminum ions into the electrolyte is disregarded too. If it is assumed that these two processes neutralize each other in anodization, then the position of the AOF boundary should correspond to the dashed line in Fig. 3.

It should be noted that, in the initial stage of anodization, the surface layer of the metal, disrupted in mechanical processing, and the oxide formed are intensely dissolved, which positively affects the properties of the AOF obtained. In the process, the substrate thickness decreases. The porosity of the oxide films strongly affects the properties of the MI substrates. According to [3], the density of pores in AOF formed in electrolytes dissolving the oxide film may reach values of 10^9–10^{10} pores/cm^2, and their volume, 36% relative to the AOF volume. The pore diameter commonly varies within the range 100–1000 Å. The presence of pores in the oxide layer is rather important for the mechanical stability of the system constituted by the oxide film and the metallic substrate. This is so because aluminum oxide has a thermal linear expansion coefficient (TLEC) $\alpha = 7 \times 10^{-6}$ K^{-1} that is strongly different from the TLEC of the metal ($\alpha = 26 \times 10^{-6}$ K^{-1}). Under a thermal treatment, the difference in TLEC gives rise to internal tensile stresses in the oxide film and compression stresses in the surface layer of the metal. The large difference in TLEC between the AOF and the metallic support should have resulted in crack formation in the oxide layer under insignificant thermal treatments. However, the presence of pores in the AOF, which serve as a kind of dampers, can neutralize the appearing mechanical stresses.

When fabricating MI substrates, particular attention was given to the state of the substrate surface, because connector elements are formed on this surface by deposition of metallic films in a vacuum [6]. Prior to anodization, AMg alloy substrate blanks are subjected to mechanical processing, including grinding with abrasive powders with particle size of 5 to 1 μm. Then, the substrates are polished with a 0.5-μm abrasive powder and diamond pastes. As a result, a 12th to 13th class of surface smoothness is obtained. After cleaning with organic solvents to remove the polishing pastes, the substrates are thermally flattened at a temperature of 650–700 K. The anodization of MI substrates ends with a thorough washing in deionized water and drying in a flow of nitrogen, after which the substrates are annealed at 730 K.

Climatic tests demonstrated that the MI fabricated by the given technology sustain temperature variations in the range 170–700 K, with the basic properties preserved, which is of key importance in fabrication of MI substrates for electronic devices, including thermoelectric units.

CONCLUSIONS

(1) The optimal aluminum alloys for fabrication of metal-insulator substrates for electronic devices were found to be AMg alloys.

(2) A study of the effect of electrochemical oxidation modes on the dielectric properties of anodic oxide films demonstrated that the optimal parameters of the galvanostatic mode are as follows: current density 1.5–2.0 A dm^{-2} and electrolyte temperature 291–298 K.

(3) It was shown the metal-insulator substrates fabricated using the technology suggested sustain temperature variations in the range 170–700 K, with their basic properties preserved.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Method of Gas Hydrate Formation for Evaluation of Water Desalination

A. M. Aliev, R. Yu. Yusifov, A. R. Kuliev, and Yu. G. Yusifov

Institute of Chemical Problems, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received May 14, 2007

Abstract—Experimental technique for analysis of hydrate formation processes with an AAS-300 atomic-absorption spectrometer was developed and used to study hydrate formation in a system constituted by water and Freon R-142V.

DOI: 10.1134/S1070427208040034

The development of methods for precluding hydrate formation in natural gas pipelines [1], implementation of techniques developed for utilization of gas-hydrates formed in industry in gas storage [2, 3], separation of gas mixtures [2, 4, 5], and recovery of normal paraffin hydrocarbons from oil fractions, the drying of gases, and the intensive studies of gas-hydrate methods for desalination of salt water [5–7] presently require a detailed experimental analysis of the mechanism and kinetics of formation of gas hydrates by precision physicochemical analytical procedures.

At present, the kinetic aspects of gas hydrate formation processes are experimentally studied in batch and continuous crystallizers with gas-liquid chromatographs, automated titration apparatus, and crystallizer weighing systems. The errors of these analytical instruments fall within the range 1–2%, which is insufficient for experimental studies of the mechanisms of gas hydrate formation and development of theoretically substantiated kinetic models of the above processes. From this viewpoint, it is important, both practically and theoretically, to develop an experimental procedure for analysis of gas hydrate formation processes with a precision atomic absorption spectrometer.

In this communication, an experimental setup with a batch crystallizer and a procedure for analysis of hydrate formation processes with an AAS-300 atomic-absorption spectrometer are described and the results obtained in a study of the hydrate formation in a system constituted by water and Freon R-142V by this procedure are presented.

The experimental setup is schematically shown in Fig. 1. The setup comprises four main units. The first serves for gas preparation and delivery. The second, main unit, is a crystallizer. The third unit serves for evacuation, measurement of the vacuum and pressure, and cooling the crystallizer.

The gas preparation and delivery system comprises cylinders with nitrogen (*1*) and Freon (*2*), reducers *3* and *4*, a fine-control valve *6*, and a rotameter *7*. A three-way cock *8* serves to feed Freon into water or into the free volume over the water surface in the crystallizer.

The crystallizer *21* is made of organic glass to enable visual observation of how gas hydrates are formed. The crystallizer has two lids, *18* and *22*, having the form of flange joints with gaskets. The upper lid is made of stainless steel, and the lower lid, of organic glass. On the upper lid are mounted pipes *9* and *16* of the cooling coil *23* through which a cooling mixture circulates, feed lines for Freon delivery through water (*10*) or into the free volume over water (*12*), well *11* for a thermometer or thermocouple, stuffing box *19*, sealing rod connecting multiblade stirrer *24* to an electric motor *20*, gas outlet line *13* with a control valve *35* at its end, nipple *14* for evacuation and measurement of the vacuum and pressure in the crystallizer, and sampler *15*.

The system for evacuation and measurement of the vacuum and pressure comprises a vacuum pump *34*, vacuum gauge *27*, standard pressure gauge *28*, and four stopping valves *29–32*. Penetration of a vacuum oil into the crystallizer is prevented by a trap *33*.

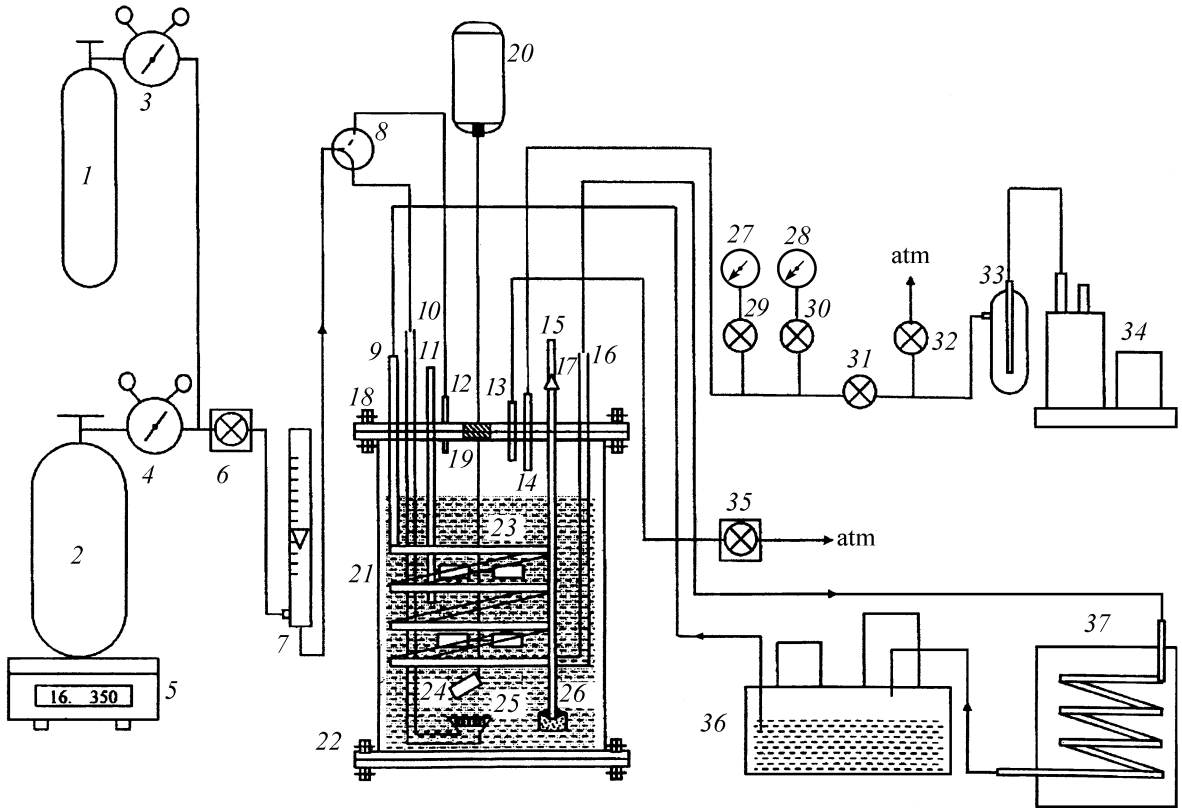

Fig. 1. Schematic of the experimental setup for studying the hydrate formation: (*1*) nitrogen cylinder, (*2*) Freon cylinder, (*3*, *4*) reducers; (*5*) electronic balance, (*6*, *35*) control valves, (*7*) rotameter, (*8*) three-way cock, (*9*, *16*) inlet and outlet a cooling mixture, (*10*, *12*) inlet for Freon through water and over water, (*11*) thermometer well, (*13*) outlet for Freon, (*14*) nipple for evacuating air and measuring pressure in the crystallizer, (*15*) sampler, (*17*) pneumatic batcher, (*18*, *22*) crystallizer lids, (*19*) stuffing box, (*20*) electric motor, (*21*) crystallizer, (*23*) cooling coil, (*24*) stirrer, (*25*) Freon distributer, (*26*) filter, (*27*) vacuum gauge, (*28*) standard pressure gauge, (*29–32*) stopping valves, (*33*) trap, (*34*) vacuum pump, (*36*) pump for cooling mixture circulation, and (*37*) refrigerator.

The system for crystallizer cooling comprises a refrigerator *37*, pump *36* for circulating the cooling mixture, and cooling coil *23* within the crystallizer.

Experiments were carried out on this installation as follows. Solutions were prepared from FIXANAL and twicedistilled water and contained a minor concentration of sodium chloride (10^{-2}–10 mg l^{-1}) to minimize the effect of ions on the hydrate formation. Into crystallizer *21*, a sodium chloride solution of certain concentration was poured. The volume of the crystallizer was 1.6 l, and that of the solution, 1.5 l. The crystallizer was closed with a lid. A multiblade (4–7 blades) stirrer *24* was connected to an electric motor *20* and all pipelines were attached to the connectors on the lid. Nitrogen from cylinder *1* was passed under a pressure of 2.0–2.5 atm through inlet pipe *12*, and the vacuum tightness of the crystallizer was checked with manometer *28*. The tightness could be also verified by evacuating the system. Valves *29* and *31* were shut when letting nitrogen into the system, and valve *30*, when evacuating the system. After that, the electric motor having eight controlled rotation rates was switched on and the stirrer was rotated. Then, air was evacuated from the crystallizer through nipple *14* in the course of approximately 30 min. The evacuation of the system was monitored with gauge *27*. After closing valve *31* and prior to beginning the experiment, the system was kept under a residual pressure of 1–2 mm Hg. Freon in cylinder *2* was weighed on electronic balance *5*. After the Freon cylinder was opened (reducer *4* and fine-control valve *6*), the gas was passed through rotameter *7* and inlet *12* and rapidly filled the volume over the water layer to a certain pressure. The pressure in the crystallizer was controlled and fixed using a standard pressure gauge *28*. A flow of Freon, controlled by valve *8*, passed through a fine-mesh distributor *25* into water at a fixed rate. This time was recorded as the beginning of an experiment. In 0.5–1.0 min, solution samples were taken from the crystallizer with a sampler

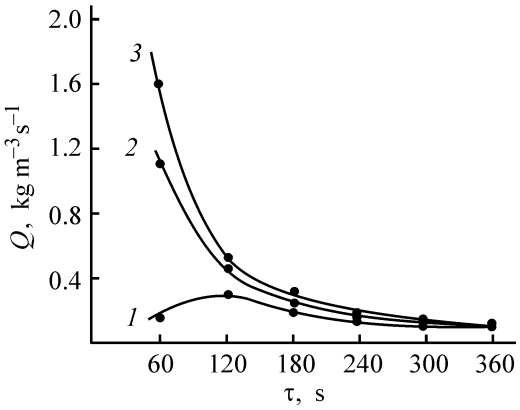

Fig. 2. Throughput Q of the reactor vs. the reaction time τ at varied stirring rate. V = 1000 ml, d_b = 0.5–1.0 mm, T = 5°C, P = 0.9 atm., c_{NaCl} = 0.01 mg l^{-1}. Stirring rate (rpm): (*1*) 200, (*2*) 950, and (*3*) 1350.

15 and a pneumatic batcher *17*, using the excess pressure over the solution layer. The samples were passed through filter *26* to inhibit penetration of gas hydrates. Up to ten samples were taken during the experiment and then analyzed on an AAS-300 atomic-absorption spectrometer. The required low temperature in the crystallizer was maintained with a cooling mixture passed through cooling coil *23* preliminary cooled in refrigerator *37* and purged with pump *36*.

After the completion of an experiment, Freon cylinder *2*, reducer *4*, and valve *6* were closed, and three-way cock *8* was brought in the neutral position. The residual Freon was weighed again and its expenditure during the experiment was determined. The excess pressure of Freon over the solution layer and the pressure of Freon produced in decomposition of gas hydrates were relieved through control valve *35*.

The amount of water involved in the clathrate formation was determined from the change in the concentration of sodium ions in the system by the formula

$$G = G^0\left(1 - \frac{\alpha^0}{\alpha}\right), \quad (1)$$

where G^0 is the amount of the initial solution (kg); α^0, salt content of the initial solution; and α, salt content of a solution after the reaction, as determined by atomic-absorption spectrometry.

The throughput of the reactor was found by the formula

$$Q = \frac{G}{\tau V}, \quad (2)$$

where τ is the reaction time (s), and V, the volume of the reaction zone [5].

The conversion X (%) was found as

$$X = \frac{\alpha - \alpha^0}{\alpha} \times 100. \quad (3)$$

The gas hydrate method for desalination of salt water is the most promising, compared with the existing methods. Hydrate-forming properties are characteristic of substances rather different in chemical nature, such as paraffin hydrocarbons and their numerous halide derivatives (Freons etc.). The properties of a hydrate-forming agent directly affect the desalination efficiency. A hydrate-forming agent should have a high temperature and low (close to atmospheric) pressure of hydrate formation, low solubility in water, high rates of hydrate formation and decomposition, low heat of formation, high chemical stability in water and be nontoxic, nonexplosive, and inexpensive. From this viewpoint, Freon R-142V is the most favorable agent for desalination of salt water. It has high temperature and low pressure at the upper invariant point, low rate of hydrolysis, and high rate of hydrate formation. In addition, Freon R-142V is noncorrosive and insoluble in water. So far, the fundamental aspects of hydrate formation in the system constituted by twice-distilled water and Freon 142-V have not been studied.

The process of hydrate formation should proceed with a high yield of crystals per unit volume and time, low energy expenditure for agitation, and small driving forces. It is reasonable to perform desalination to obtain large crystals with uniform size distribution, which depends on the hydrodynamic conditions of the process.

The influence exerted by the hydrodynamic conditions on the course of hydrate formation in the system constituted by twice-distilled water and Freon 142-V was studied on the experimental laboratory setup (Fig. 1) by the procedure suggested.

Figure 2 shows the results obtained in a study of the influence exerted by the stirring rate on the course of hydrate formation. The stirring rate was varied in the range 200–1350 rpm. As follows from Fig. 2, raising the stirring rate from 200 to 1350 rpm leads to a considerable intensification of the process of hydrate formation. This can be attributed to a decrease in the outer-diffusion resistance.

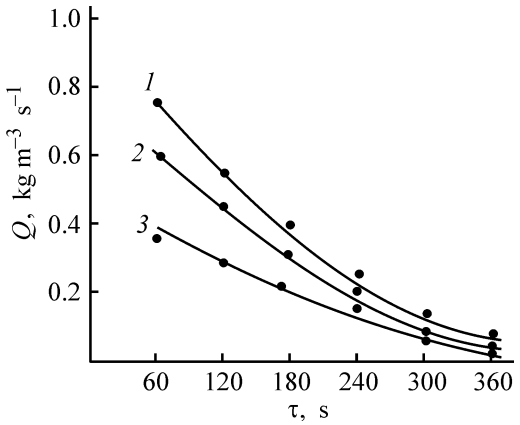

Fig. 3. Throughput Q of the reactor vs. the reaction time τ at varied diameter of gas bubbles. T = 4°C, P = 0.9 atm, c_{NaCl} = 0.01 mg l^{-1}, stirring rate 1350 rpm. Bubble diameter (mm): (*1*) 0.5–1.0, (*2*) 2.0–2.5, and (*3*) 3.0–3.5.

Figure 3 demonstrates the results obtained when studying the effect of the diameter of gas bubbles on the course of hydrate formation. The diameter of gas bubbles was varied in the range d_n = 0.5–3.5 by changing the size of apertures in the gas distributor. As follows from Fig. 3, decreasing the bubble diameter from 3.0–3.5 to 0.5–1.0 mm intensifies the hydrate formation, which can be accounted for by a decrease in the inner-diffusion resistance.

CONCLUSIONS

(1) An experimental procedure employing an AAS-300 atomic-absorption spectrometer for studying the hydrate formation was developed. The efficiency of the procedure was confirmed for the example of a system constituted by twice-distilled water and Freon 142-V.

(2) The conditions for efficient hydrate formation in the system constituted by twice-distilled water and Freon 142-V were found. Raising the stirring rate from 200 to 1350 rpm and diminishing the bubble diameter from 3.0–3.5 to 0.5–1.0 mm results in intensification of the hydrate formation.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Comparison of the Reactivities of Main Boron-containing Additives Used in Electrodeposition of Nickel–Boron Coatings

V. V. Rogozhin

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received June 29, 2007

Abstract—Reactivities of the main boron-containing additives used in electrodeposition of nickel–boron coatings were compared by measuring the rate of boron incorporation into a nickel coating and the effective activation energy.

DOI: 10.1134/S1070427208040046

Nickel–boron coatings produced by chemical deposition or electroplating possess high hardness and wear resistance, are solderable, can be ultrasonically welded, and have low electrical resistance stable in the course of time [1]. The combination of these properties of the coatings allows their use in manufacture of radio electronic articles for various purposes [2].

Electroplating with nickel–boron alloys is the most available because it can be carried out from standard electrolytes. This process implements all the conventional advantages of electrodeposition over chemical methods. Nickel–boron coatings are electrodeposited from sulfuric acid, sulfamine, ammonia citrate, and chloride electrolytes, with addition of various boron-containing compounds [3]. The composition, structure, and properties of these coatings are readily controlled by varying the electrolysis mode (current density, temperature, pH value) and the amount of a boron-containing additive in the electrolyte.

The choice of the optimal boron-containing additives for deposition of nickel–boron coatings is governed by the availability of additives, rather than by the degree of technological development of the corresponding process. Therefore, it is advisable to compare the reactivities of the boron-containing additives used and the conditions of their application in a search for new interchangeable boron-containing additives.

The results of this study make it possible to systematize the data obtained with respect to the alloy composition, electrodeposition conditions, and mechanism of boron incorporation and to relate these data to the structure and properties of the additives themselves.

EXPERIMENTAL

The experimental conditions were the same for all the additives: coatings were deposited from a sulfate electrolyte with pH 4.5 at a current density of 2 A dm^{-2} and temperature of 40°C. The content of boron was found by potentiometric titration [4]. The activation energy of nickel deposition was determined by the temperature-kinetic method, and that of boron deposition, from the dependence of the boron incorporation rate on inverse temperature. The chemical contribution in the coating deposition was evaluated by the increase in the sample mass and, theoretically, from polarization diagrams [5]. The boron incorporation rate was calculated from the resulting alloy composition. The boron-containing substances used in the study are listed in Table 1.

Table 1. Boron-containing substances under study

Additive	Formula	Initial tent, %	Working concentration, g l^{-1}	TU (Technical Specification)
Dimethylamineborane (DMAB)	$(CH_3)_2HNBH_3$	98	50	TU 2439-035-10645057–96
Sodium dicarbaundecaborate (SDCDB)	$NaC_2B_9H_{12}$	40–45	25	TU 6-02-1-453–84
Sodium decahydrodecaborate (SDHDB)	$Na_2B_{10}H_{10}$	25–27	18	TU 6-02-1-513–86
Potassium dodecaclosododecaborate (PEB)	$K_2B_{12}H_{12} \cdot 4H_2O$	99.9	12	Pilot batch

Boron is incorporated into a nickel coating in electrodeposition by the chemical-catalytic mechanism associated with decomposition of boron-containing additives on the surface of a freshly deposited nickel acting as a catalyst [6, 7]. To standardize plots for different boron-containing additives, their working concentrations were recalculated to active boron. For SDHDB and SDCDB, the initial working concentrations were taken as those of anions, and for DMAB and PEB, as those of the substances themselves.

A comparison of the effects of the chosen additives demonstrated that the DMAB additive shows the highest reactivity with respect to the boron incorporation rate and leads to the highest content of boron in a coating deposited, at the smallest amount of the additive in terms of active boron (Fig. 1). The SDHDB and SDCDB additives are similar and yield approximately the same, amounts of boron in a coating, which are smaller than that with DMAB. The boron incorporation rates are also approximately the same for these additives. Compared with the other boron-containing compounds, the PEB additive yields the smallest amount of boron in a coating, with the concentrations of PEB in the electrolyte being the highest, and the boron incorporation rate, the lowest.

The slopes of the initial portions of the curves in Fig. 1 ($\tan\alpha$) make it possible to indirectly estimate the stability of the boron-containing substances against catalytic decomposition on a growing nickel coating and, accordingly, their reactivity with respect to boron incorporation. Below are listed values of $\tan\alpha$ for various additives:

Additive	DMAB	SDHDB	SDCDB	PEB	PEB, 60°C
$\tan\alpha$	0.49	0.24	0.25	0.02	0.03

The different reactivities of the additives correlate with the activation energies of boron incorporation, obtained from characteristic dependences of the logarithm of the boron incorporation rate for each additive on the inverse temperature (Table 2). Among the additives studied, PEB has the minimum reactivity with respect to boron incorporation, but, as temperature increases, the content of boron in a coating increases, with a sharp decrease in the activation energy, which may be due to acceleration of the chemical stage of decomposition of the boron-containing anion [7]. Other comparative data on the reactivity of the additives are presented in Table 3. The differences in reactivity are apparently due to different structures of the boron-containing additives.

The SDHDB and PEB additives belong to the class of polyhedral boranes and contain $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ anions, respectively. The additive with $B_9C_2H_{12}^-$ belongs to the class of substances with nidocarborane anions, derivatives of $B_nH_n^{2-}$, produced from these anions by substitution of the BH^- moiety with a CH analogue [8]. The DMAB additive belongs to the class of aminoboranes with a linear molecular structure [9]. The structure of SDHDB and PEB was studied in [10], using the LCAO–MO method and that of resonant structures.

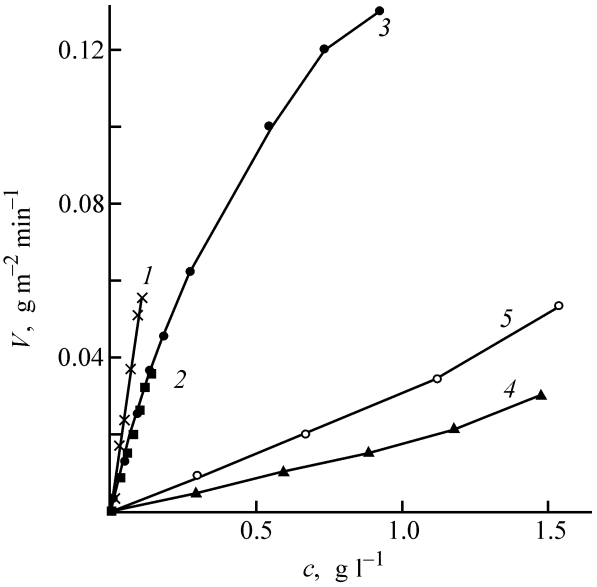

Fig. 1. Rate V of boron incorporation into a coating vs. the concentration c (in terms of boron) of various boron-containing additives (i = 2 A dm^{-2}). Additive: (*1*) DMAB, (*2*) SDHDB, (*3*) SDCDB, and (*4*, *5*) PEB. Temperature (°C): (*1*–*4*) 40 and (*5*) 60.

An equilateral rectangle on which rest equilateral triangles was taken as a basis when calculating the parameters of the $B_{10}H_{10}^{2-}$ anion. As the base of the $B_{12}H_{12}^{2-}$ anion serves an equilateral pentagon, on

which equilateral triangles also rest (Fig. 2a). The basic parameters characterizing the structure of the polyhedral anions $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ and some of their properties are listed in Table 4 [10].

It was found in [10] that the adsorption capacity of boron-containing additives increases in the order B_2H_6–B_5H_9–$B_{12}H_{12}^{2-}$–$B_{10}H_{10}^{2-}$–$B_{10}H_{14}$, which can be attributed to the structure and different charge distribu-

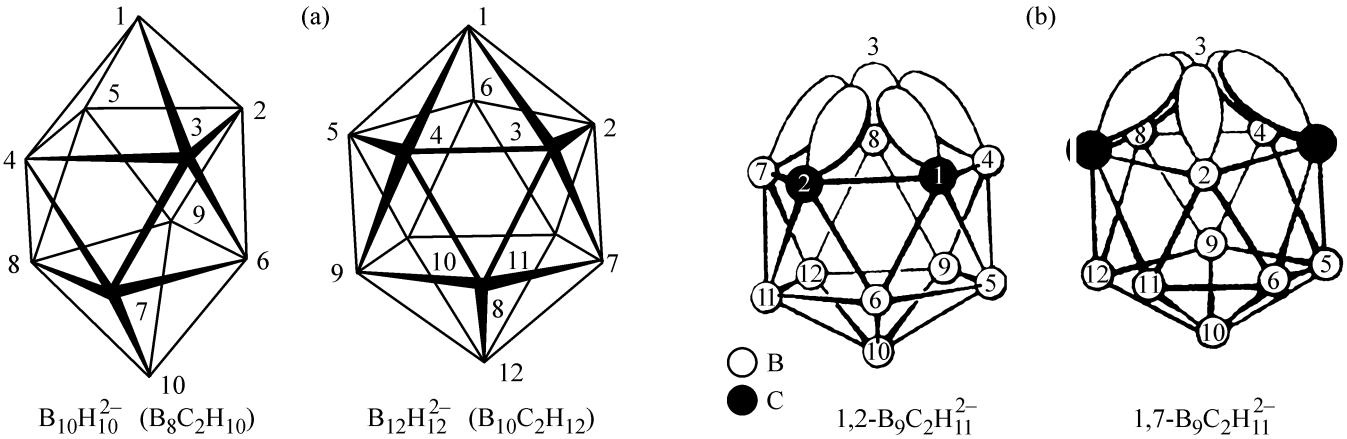

Fig. 2. Structure of (a) polyhedral anions and (b) isomeric nido-anions used in the study.

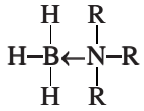
tions on boron atoms. On the negatively charged surface of the nickel cathode, the adsorption will in all probability occur at boron atoms bearing the smallest negative charge (Fig. 2, positions 2–9). The bond length for these positions is the largest, and the energy is lower than that of boron atoms in other positions. The original detachment of boron from these positions will occur with lower energy expenditure, which accounts for the rather high boron incorporation rate and for the possibility of bulk decomposition of the nickel plating solution in the absence of current at high temperatures and concentrations of the additive. Simultaneously, the high adsorption capacity of $B_{10}H_{10}^{2-}$ markedly raises the activation energy of the concurrent process of nickel electrodeposition.

A somewhat different situation is observed for nido-carborane anions (1,2-$B_9C_2H_{12}^-$ and 1,7-$B_9C_2H_{12}^-$) produced from $C_2B_{10}H_{12}$ via detachment of boron atoms in a reaction with alcoholate ions. The structure of nido anions of this kind is shown in Fig. 2b.

Calculations by the method of molecular orbitals (MO) in [8] demonstrated that carbon atoms in carboranes have high electron-acceptor properties. The most electron-deficient are borons situated near these carbons. These are positions 3 and 6 in the 1,2-$B_9C_2H_{12}^-$ anion and positions 2 and 3 in 1,7-$B_9C_2H_{12}^-$ (Fig. 2). Boron atoms of this kind will have a more positive charge and, in all probability, boron is originally incorporated into a coating from these positions.

In the $B_{12}H_{12}^{2-}$ anion, all the bonds are equivalent in length and energy. Its structure is more perfect, compared with other additives, and is believed to be hypersymmetric, with the result that the stability of the additive in the electrolyte is high, it does not undergo bulk decomposition at high temperatures, and no metal is deposited via chemical reduction.



For the $B_{12}H_{12}^{2-}$ anion, boron can be detached from the borane skeleton from any position, but with high energy expenditure.

Because of its lower adsorption capacity, the anion only slightly affects the activation energy of the concurrent process of nickel electrodeposition.

The reactivity of the $B_{12}H_{12}^{2-}$ anion can be affected by the impurities it contains and by the polarizing effect of cations.

According to [11], $B_{12}H_{12}^{2-}$ readily reacts with Lewis bases. For example, an admixture of triethylamine in the $B_{12}H_{12}^{2-}$ additive may lead to formation of a substituted anion, $(Et_3NH)_2B_{12}H_{11}^-$, with the anion charge changed, and to a pronounced change in its properties, compared with the unsubstituted anion. In this case, the structure of the $B_{12}H_{12}^{2-}$ anion is also affected by the polarizing action of the cation [11]: the larger the cation charge, the more significant the distortion of the $B_{12}H_{12}^{2-}$ skeleton. According to [11], the polarizing effect of the cation in the $(Et_3NH)_2B_{12}H_{12}$ compound is at a minimum because of its large size, and the B–B bond lengths are approximately the same and equal to 1.781 Å. In the compound $CaB_{12}H_{12}$ [12], the boron skeleton is strongly distorted and the bond lengths vary from 1.72 to 1.84 Å. It is also not improbable that, under the electrodeposition conditions, the nickel cation can exert a polarizing influence on the structure of the $B_{12}H_{12}^{2-}$ anion when a surface complex is formed, as it has been reported for the $B_{10}H_{10}^{2-}$ additive [13].

In aminoboranes (borozanes), boron with three covalent bonds is connected to nitrogen by the lone electron pair of nitrogen, and their structural formula is frequently shown as

The nature of the boron–nitrogen bond formed by a shift of the electron pair of the trivalent nitrogen toward boron has not been elucidated unambiguously. The bond strength is affected by the nature of groups connected to both boron and nitrogen atoms, and, consequently, the stability of aminoboranes (borozanes) may vary very widely [9].

Aminoboranes of the R_3BH_3 type show high thermal stability only when they contain no hydrogen bonded to nitrogen. If a compound has a hydrogen bonded to nitrogen, which is the case for DMAB [$(CH_3)_2HNBH_3$], then the additive is characterized by reactions in which the boron–nitrogen bond is cleaved. This leads to the maximum reactivity of the additive in electrodeposition of nickel–boron alloys and to incorporation of boron by the known mechanism of dissociative adsorption [5, 14].

CONCLUSIONS

(1) A comparison of the reactivities of various boron-containing additives used in electrodeposition of nickel–boron coatings demonstrated that the highest activity is observed for dimethylamineborane, and the lowest, for potassium dodecaclosododecaborate, which is due to the dissimilar mechanisms of boron incorporation, different bond lengths, and

metastability of boron atoms in certain positions of the anion.

(2) Judging from the structure of the boron-containing additives used, the activation energy of boron incorporation into the nickel matrix will increase in the order $(CH_3)_2HNBH_3$–$Na_2B_{10}H_{10}$–$NaC_2B_9H_{12}$–$K_2B_{12}\cdot 4H_2O$. The reactivity of the additives decreases in the same order.

(3) Ways to raise the reactivity of the $B_{12}H_{12}^{2-}$ anion will be determined by the following parameters: working temperature of the electrolyte; charge, nature, and size of the cation; and possibility of interaction between the anion and a Lewis base. The effect of technological factors on the reactivity of the additives makes it possible to equalize their reactivities at optimal values, which makes the additives more interchangeable in practical use.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Solvent Nature on the Reaction of Metallic Iron with Benzoic Acid in a Bead Mill

A. M. Ivanov and E. A. Grechushnikov

Kursk State Technical University, Kursk, Russia

Received February 22, 2007

Abstract—Results of an experimental study of the influence exerted by the solvent nature on the reaction rate, achieved degree of acid expenditure, selectivity with respect to salts of iron(II) and (III), and phase state of the reaction mixture in a single-stage reaction of iron with benzoic acid and atmospheric oxygen in the presence of a stimulating iodine additive are presented.

DOI: 10.1134/S1070427208040058

Iron(III) and (II) benzoates are rather widely used in various industries [1–11].

Commonly, these salts are obtained by one of the following three methods: (i) exchange interaction of iron salts and mineral acids with sodium benzoate or by a direct reaction of an iron oxide with benzoic acid in the temperature range 125–260°C in the presence of an organic dispersing agent [12]; (ii) reaction of benzoic acid with the metal nitrate in the presence of an inert organic solvent, followed by addition to the reaction mixture of ammonia and(or) amine, and(or) tetraalkylammonium hydroxide at a temperature of 20–40°C and pressure of $(1–50) \times 10^5$ N m^{-2} [13]; and (iii) direct electrosynthesis [14]. These methods require certain auxiliary substances and rather severe conditions and yield by-products that need utilization. Moreover, some of these methods cannot be performed in a single stage.

It was of interest to obtain iron benzoates in a single-stage process in accordance with the stoichiometric overall equations (HA stands for carboxylic acid)

$$2Fe + 4HA + O_2 \rightarrow 2FeA_2 + 2H_2O, \quad (1)$$

or

$$4Fe + 12HA + 3O_2 \rightarrow 4FeA_3 + 6H_2O, \quad (2)$$

i.e., with atmospheric oxygen as an oxidizing agent, crushed iron or its alloys (including those of waste origin) as a reducing agent, and also an organic solvent and iodine (the latter as a stimulating additive). By now, iron(II) and (III) formates and acetates have been synthesized by this method [15–18]. The process occurs in a single technological stage to give the target product mainly in the form of a suspension easily separated by filtration. The filtrate containing dissolved products of conversion of the stimulating additive and iron salts is recycled and thereby requires neither separation, nor repeated utilization.

The overall processes (1) and (2) are heterogeneous, complex, and multistage. Their principal stages are the following [19–22]:

$$Fe + I_2 \rightarrow FeI_2, \quad (3)$$

$$2FeI_2 + 4HA + O_2 \rightarrow 2FeA_2 + 2I_2 + 2H_2O, \quad (4)$$

and(or)

$$4FeI_2 + 12HA + 3O_2 \rightarrow 4FeA_3 + 4I_2 + 6H_2O, \quad (5)$$

and also [17, 18]

$$4FeA_2 + O_2 + 4HA \rightarrow 4FeA_3 + 2H_2O, \quad (6)$$

$$Fe + 2FeA_3 \rightarrow 3FeA_2. \quad (7)$$

Together, stages (3) + (4), (3) + (5) or (3) + (4) + (5) constitute cyclic processes of consumption and formation of iodine, and just this circumstance is the reason why it is used as a catalyst.

The main purpose of the liquid phase is the transport function. The place where the basic stages occur is the iron surface onto which the reactants are de-

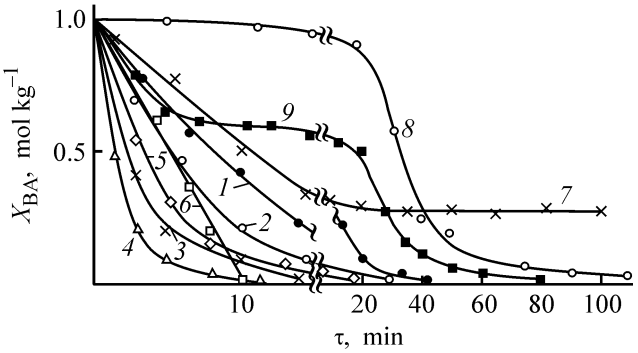

Fig. 1. Kinetic curves of benzoic acid consumption for formation of iron salts at varied nature of a solvent in the liquid phase of the charge. Reactor: vertical bead mill with a four-blade stirrer rotating at 1560 rpm; mass of beads 200 g; 1 : 1 mass ratio of beads to the liquid phase of the charge; charge: crushed cast iron 60 g, iodine 0.03 mol kg^{-1} liquid phase; temperature 60 ± 2°C. Solvent: (*1*) dimethylformamide, (*2*) 2 : 3 (*v*/*v*) mixture of dimethylformamide and butanol, (*3*) *n*-butanol, (*4*) chlorobenzene, (*5*) bromobenzene, (*6*) ethyl cellosolve, (*7*) toluene, (*8*) petroleum spirit, and (*9*) ethylbenzene.

livered by means of adsorption. The solid products formed on the surface should be removed into the solution bulk to preclude full passivation of the surface by their deposits. Their desorption cannot play any significant part in systems of this kind. Considerably more important is their dissolution or mechanical removal (scraping, scuffing, stripping). The role of the solvent is also important. On the whole, the solvent nature should largely determine the competitive ability of reactions (3)–(7) and, consequently, that of (1) and (2), as well as the selectivity with respect to the iron(II) and (III) salts and the heterophase state of the final reaction mixture, which may either facilitate or hinder its separation and product recovery. In this study, an attempt was made to evaluate the effect of the solvent nature on the reaction of iron with benzoic acid in a bead mill.

EXPERIMENTAL

The experiment was performed in a vertical bead mill with a high-speed (1440 and 1560 rpm) blade stirrer whose shaft was connected to that of a 0.5-kW motor. The stirrer case was made of stainless steel and had a wall thickness of about 10 mm. The blades and the shaft of the stirrer were made of st.45 or stainless steel. In both cases, their working life was rather short (1–2 months), which was predetermined by their involvement in the redox process under consideration as a source of reacting iron. To preclude rapid wear, the case and bottom of the bead mill were protected with an inserted steel shell and a well-fit false bottom with a foot bearing for the blade stirrer. As a grinding agent served glass beads 0.8–3.1 mm in diameter, both individually and together with powdered reduced iron, sieved fractions of crushed cast iron, and fragmented steel shavings with the maximum linear particle size of 5 mm. The mass ratio between the glass beads and ground iron and(or) its alloys was widely varied.

The bead mill was equipped with a reflux condenser and heat supply via a liquid bath that could be moved along the longitudinal axis of the reactor. The course of the process was monitored by sampling, with the content of carboxylic acid and its iron(II) and (III) salts determined. The monitoring results were used to plot the corresponding kinetic curves.

The reagents were charged in various orders. Most frequently, glass beads, solvent, and carboxylic acid were charged first and then agitation was switched on and thereby a solution of carboxylic acid was prepared. Occasionally, this solution was prepared preliminarily and then batched into the reactor. After that, ground iron or iron alloys and the catalyst were charged and air was fed into the reactor for bubbling. The bubbler was fabricated in an elastic version to preclude its disintegration upon contact with moving beads or heavy particles of iron or its alloys.

It was found that, without iodine, the process begins, but rapidly terminates at acid conversions not exceeding 2–3%. Therefore, if the chosen temperature mode was to be strictly maintained (in the range 15–90°C), the stimulating additive was introduced at the instant when the system reached the working temperature.

Figure 1 shows kinetic curves of benzoic acid consumption for the process performed in various solvents. The role of the solvent is manifested not only in different rates of acid consumption, but also in the existence of the period of self-accelerated development (e.g., in petroleum spirit), intermediate self-deceleration (in ethylbenzene), self-termination (in toluene), and self-resumption of the process (in ethylbenzene), in its selectivity with respect to iron(II) and (III) salts, and in the manner in which the selectivity varies in the course of the process.

In all of the solvents chosen, the amounts of iodine used for stimulation were completely soluble. Therefore, the maximum concentrations of iodine were determined only by its close. At the same time, its running concentrations were 10–20 times lower than the maximum values. This indicated that, in the course of the process, the main part of iodine

being introduced was in the form of FeI_2, which was confirmed by direct analysis.

The acid must also be to some extent soluble in the solvent used (see table), but this extent remains unknown. The process could also be performed in dimethylformamide, in which the solubility of benzoic acid exceeds 4 mol kg^{-1}, and in petroleum spirit, in which the solubility is more than 100 times lower and the main part of the acid charged into the reactor remained in the solid phase in the course of the process. The conclusion that the solubility of the acid is not a key factor is also confirmed by the fact that the rate and time characteristics of the process depend on the initial content of the acid in the charge not only in a rather complicated way, but also not too strongly (Figs. 2, 3). In addition, clear requirements to the role played by the solubility of salt products in the liquid phase could not be formulated. At a high solubility of the metal iodide, there appears an important mass-exchange pathway to disintegration and removal of its surface deposits from iron. In this case, reactions (4) and (5) partly pass into solution, i.e., into homogeneous conditions. The FeA_2 and FeA_3 salts being accumulated are first present in solution and then, beginning at a certain instant of time, form independent solid phases. The solid phase of green FeA_2 appears first, which correlates with its poorer solubility, compared with FeA_3. As a direct experiment demonstrated, transformations of dissolved and suspended salt products into components of surface deposits on the metal are unlikely.

At the same time, at a poor solubility of iron(II) iodide in the liquid phase used (e.g., in petroleum spirit), reactions (4) and (5) will be predominantly

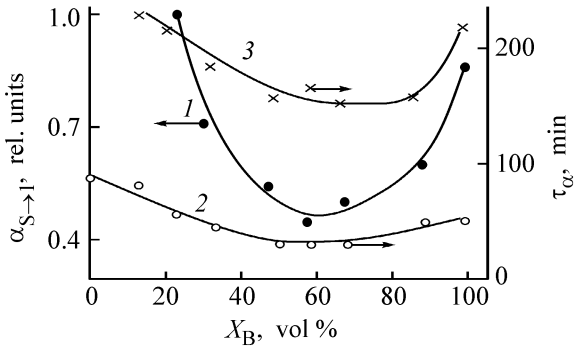

Fig. 2. Conversion α of benzoic acid in a single-stage reaction with fragmented iron in the presence of iodine vs. the content X_B of *n*-butanol mixed with dimethylformamide as a solvent of the liquid phase. Dosage: benzoic acid in accordance with its solubility at 21°C and iodine 0.125 mol kg^{-1}; 4 : 1 mass ratio of the liquid phase and reduced iron; mass of the liquid phase 200 g; temperature 60 ± 1°C; rotation rate of the blade stirrer of the vertical bead mill 1560 rpm. Time $\tau_{\alpha\to1}$ in which a virtually quantitative conversion of benzoic acid mainly into the iron(III) salt is reached vs. the initial concentration X^0_{BA} of the acid in a 2 : 3 (*v*/*v*) mixture of dimethylformamide and butanol, taken as the liquid phase for the reaction of 30 wt % (relative to the liquid phase) crushed cast iron with benzoic acid at 60°C in the presence of 0.075 mol kg^{-1} of a stimulating iodine additive and bubbling with air. Reactor: vertical bead mill with a four-blade stirrer rotating at 1550 rpm; 1 : 1 mass ratio of beads and the liquid phase charge; air expenditure for bubbling 2.2 l min^{-1} kg^{-1} liquid phase.

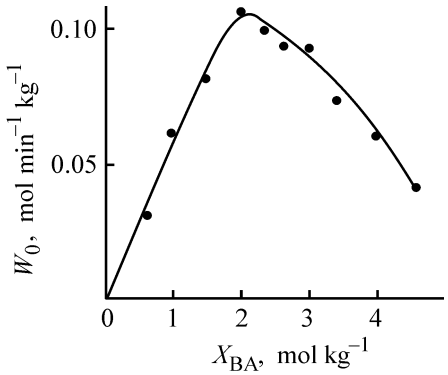

Fig. 5. Initial rate W_0 of the conversion of benzoic acid into iron salts vs. the initial content X_{BA} of benzoic acid in the liquid phase of the system. Process conditions the same as those for Fig. 4.

heterogeneous, and FeA_2 and FeA_3 remaining on the surface can well be transformed into important components of the surface deposits on iron. Mechanical methods for disintegration and removal of surface deposits become the most important in this case. Because both these variants have been implemented in practice, with the process rates and durations being comparable, there is no good reason to prefer one of them.

The following circumstance appeared to be the most important in this regard: the viscosity of the system grows as the product is accumulated both in solution and as a suspension, with the increase being self-accelerated in deep stages. This leads to a synchronous decrease in the operation efficiency of the bead mill, to the point of complete loss of its working capacity. The results obtained demonstrate that this occurs when iron salts are accumulated in a total amount of 1.2–1.5 mol kg^{-1}. Consequently, the maximum content of the acid in the charge, determined with account of the fact that its whole amount can be converted into salts, must not exceed 3.6–4.5 mol kg^{-1}. However, this does not mean that just these initial concentrations of the acid will be optimal (Figs. 2, 4, 5), because the corresponding dependences are complicated. For example, the solubilities of benzoic acid and iron(III) benzoate substantially fall as the content of *n*-butanol in the mixed solvent increases (Fig. 3), whereas the time in which a 50% or >98% conversion of benzoic acid into iron salts is reached passes through a minimum at a 60–65% content of *n*-butanol in the mixed solvent. Consequently, it is better that the solubility of the final product in the liquid phase used should not be too high, so that the product would accumulate in the form of a suspension. In this case, the viscosity grows more slowly and the product itself can be easily isolated by simple filtration.

Comparison of the data in Figs. 4 and 5 shows that the manner in which the process duration increases with the initial content of benzoic acid is associated not only with the pronounced differences in the viscosities of the reaction mixtures in deep-conversion stages, but with the fact that the initial rates pass through a maximum as functions of the content of the acid. At the beginning of the process, the viscosity of the liquid phase will also grow with the content of benzoic acid. However, this increase is incomparable with the rise in the viscosity of the reaction mixture, observed as the acid expenditure for salt formation becomes quantitative.

Experiments with different solvents revealed variants in which the reaction mixture becomes, in the course of the process, a glue-like viscous mass that entraps glass beads and solid particles of the metal. In these cases, the process is always doomed to self-termination because of the complete loss of working capacity by the bead mill. This is a rather rare phenomenon for benzoic acid (e.g., in toluene; Fig. 1, curve *7*). By contrast, this situation is one of the most frequently occurring for butyric acid.

However, not any self-termination of the process is due to a strong thickening of the reaction mixture or to its transformation into a glue-like mass. As an example can serve curve *9* in Fig. 1. Whose intermediate portion is associated with blocking of the metal surface by surface deposits of salt products, which becomes weaker in the course of time and self-resumption of the process occurs.

In some cases, self-termination of the process was observed in systems in which products were mostly accumulated as suspended solid phases, and no noticeable decrease in the operation efficiency of the bead mill was observed in the course of their accumulation. For example, self-termination occurred in water (not shown in Fig. 1, the corresponding kinetic curve is similar to curve *7*) by the 85th–90th minute, with no self-resumption observed in the following 150 min. This self-deceleration also occurred because of the blocking of the iron surface by a mixture of benzoates of iron(II) (green) and iron(III) (brown). An inspection of unreacted particles of cast iron revealed a greenish-gray deposit on their surface. The filtered-off precipitate of the salt products had the same coloration.

The nature of the solvent used strongly affects the accumulation kinetics of iron(II) and (III) salts and, consequently, the achievable selectivity with respect to the target product. This can be illustrated by the example of the mixed solvent used in this study, with varied ratio of dimethylformamide and *n*-butanol in the solvent (Fig. 2, curve *1*). The conversion on reaching and exceeding which the selectivity with respect to iron(III) salt tends to unity passes through a minimum. This minimum is observed at a content of *n*-butanol within the range 50–70% and acid conversions into the product of about 50%. It is this range of alcohol contents in the mixed solvent that should be regarded as the most interesting, although the solubility of benzoic acid in this region is substantially lower than 4 mol kg^{-1} (at 21°C).

The solubility of both the acid and iron(III) salt in dimethylformamide is considerably higher (Fig. 3). It additionally increases as temperature is raised. In dimethylformamide, the process can be brought virtually to complete expenditure of the acid for salt formation, provided that its initial concentration does not exceed 5.5 mol kg^{-1}. However, the 100% selectivity with respect to the iron(III) salt cannot be reached neither in the end, nor in the course of the process. It was found that it is impossible to obtain products in the solid phase in this medium: at so large initial contents of benzoic acid, the final reaction mixture is something intermediate between a poorly flowable paste and a glue-like mass that does not release the solid phase neither under rapid cooling, nor in the case of natural or artificially decelerated cooling. A similar pattern is observed in all the other cases when the content of *n*-butanol in the mixed solvent is smaller than 20 vol %.

The iron(III) salt can be selectively obtained at the instant of virtually quantitative consumption of the acid with such solvents as *n*-butanol, petroleum spirit, butyl acetate (not shown in Fig. 1) and the above-mentioned mixtures of dimethylformamide and *n*-butanol. The kinetic curve of iron(II) salt accumulation in these solvents passes through a weak maximum lying close to the ordinate axis and further approaches the abscissa axis and virtually runs into it. In such solvents as dimethylformamide, formamide (not shown in Fig. 1; the process is slower than that in dimethylformamide, but goes to completion and shows no self-termination), and water, iron(II) and (III) salts are always accumulated in comparable amounts.

The nature of the solvent used strongly affects, through the dynamics of variation of the phase state of the reaction mixture, the operation efficiency of the bead mill. This, in turn, is transformed to a certain extent to the apparent efficiency of the stimulating additive used and, consequently, affects its optimal amount, which is far from being the same in different solvents.

CONCLUSIONS

(1) The liquid phase predetermines the type of the kinetic curve of consumption of benzoic acid in its reaction with metallic iron in a mechanically activated process: quantitative characteristics of its separate portions, duration of the process as a whole, occurrence of autoacceleration and autodeceleration, self-termination and self-resumption, and selectivity with respect to iron(II) and (III) salts, and also the dynamics of their variation in the course of the process.

(2) At the instant of virtually quantitative consumption of benzoic acid, a selectivity for iron(III) benzoate that tends to 100% is provided by use of such solvents as white spirit, *n*-butanol, butyl acetate, and some mixtures of *n*-butanol and dimethylformamide, in which case a significant amount of the target salt is accumulated in the solid phase in the form of a suspension.

(3) The complete dissolution of the acid in the solvent for the liquid phase, used in the study, is not

a necessary condition for rapid and, a fortiori, quantitative and selective course of the redox process of the given type.

(4) The least favorable variant, as far as the rate and extent of the process, its selectivity for salts, and their isolation from the reaction mixture are concerned, was obtained with a solvent composed of dimethylformamide and its mixtures with up to 20% *n*-butanol (by volume). In this case, non of the salts is accumulated and the reaction mixture turns into a viscous glue-like system.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Physicochemical Modification of Nanodiamonds

I. I. Obraztsova and N. K. Eremenko

Received June 18, 2007

Abstract—Thermal modification of nanodiamonds in the atmosphere of argon and hydrogen and their chemical modification with oleum and chlorine at different temperatures were studied. The effect of the modification conditions on the catalytic activity of palladium catalysts supported by nanodiamonds in the reaction of nitrobenzene hydrogenation and on the adsorption properties of nanodiamonds with respect to benzene, chloroform, and water was analysed.

DOI: 10.1134/S107042720804006X

The increased scientific and practical interest in synthesis and study of substances in the nanostate is due to the fact that they possess new functional properties because the size of nanoparticles is in the range 10^{-9}–10^{-7} m, which is comparable with that of molecules. An object of this kind are nanodiamonds (ND) produced by detonation synthesis with explosives having a negative oxygen balance in a nonoxidative medium, which yields a carbon stock containing the diamond fraction.

The recovery and purification of ND or, as they are also named, utradispersed diamonds (UDD) can be divided into the gas- and liquid-phase methods. Oxygen and air are used in the first case, and oxidizing mixtures (H_2SO_4–HNO_3, HNO_3–$HClO_4$, HNO_3–H_2SO_4–$H_2S_2O_7$, etc.), in the second [1–4]. In the process, new functional groups are added to those already present on the UDD surface, depending on the recovery technique.

The presence of functional groups with various chemical compositions on the surface of ND predetermines their widely diverse and unique properties. Therefore, methods used to modify ND may be of key importance for various applications.

At present, nanodiamonds are used in electrodeposited metal–diamond coatings, antifriction additives, various lubricants, lubricating-cooling fluids for physical modification of ferrolacquer coatings of magnetic tapes and disks, as composite materials in polymeric films and membranes, in various rubbers, and as carriers of biological and medicinal preparations [5, 6].

Development of methods for controlling the chemical composition of the nanodiamond surface by varying the amount and nature of functional groups opens the way to their modification for creating new types of ND, including those with a multifunctional surface composition.

In this study, thermal and chemical modification of nanodiamonds was carried out in order to expand the application fields of UDD.

EXPERIMENTAL

ND recovered from a detonation diamond stock by the previously developed technique [4, 7] and additionally dried in air at 150°C was used in the study.

ND were thermally treated for 4 h in a quartz reactor similar to that used for determining carbon and hydrogen in organic compounds [8]. Argon or hydrogen served as a carrier gas. Prior to an experiment, the system was purged with carrier gas for 10 min. The released water was absorbed with anhydrone and its amount was found from the increase in the mass of this drying agent. Carbon dioxide was absorbed with a $Ba(OH)_2$ solution of a known concentration (with subsequent titration with 0.2 N HCl). The amount of the released carbon monoxide was found by its absorption with an acetone solution of palladium(II), with metallic palladium recovered and the unreacted Pd^{2+} gravimetrically determined with dimethylglyoxime [9].

Table 1. Amounts of released products in relation to the thermal treatment conditions of nanodiamonds

T, °C	Concentration, mmol g^{-1} ND				
	CO_2		H_2O		CO
	Ar	H_2	Ar	H_2	Ar
200	0.19 ± 0.01	0.30 ± 0.01	1.73 ± 0.10	2.20 ± 0.12	–
400	1.85 ± 0.07	1.00 ± 0.03	2.03 ± 0.04	3.83 ± 0.25	0.38 ± 0.02
600	7.00 ± 0.16	1.23 ± 0.03	5.60 ± 0.03	5.31 ± 0.06	4.44 ± 0.12
800	4.81 ± 0.08	0.98 ± 0.04	0.86 ± 0.03	7.53 ± 0.07	6.01 ± 0.09

To study the adsorption properties of ND, a weighed portion of ND was calcined at a prescribed temperature for 4 h, cooled in a desiccator over $CaCl_2$, weighed, and placed in a desiccator with various solvents (water, benzene, and chloroform) at 21°C. The amount of an adsorbed reagent was found from the increase in the weighed portion of ND and then the procedure was repeated many times to constant weight of the sample.

The time in which equilibrium was attained was, for all the samples, 14 days in chloroform, 28 days in water, and 21 and 2 days in benzene for samples modified in argon and hydrogen, respectively.

Samples were sulfated by boiling in oleum at 180°C for 20 h. ND were chlorinated with molecular chlorine in a flow-through quartz reactor at 400 and 600°C. Chlorine and sulfur in the samples was determined by the procedure described in [8].

Nitrobenzene was hydrogenated under an atmospheric pressure of hydrogen. The method used to synthesize palladium catalysts and nitrobenzene (NB) hydrogenation conditions were the same as those in [10], but, in some cases, the catalyst was prepared without triphenylphosphine.

IR spectra were measured on a Bruker Tensor-27 IR Fourier spectrometer with a diffuse-reflection attachment.

In thermal treatment of nanodiamonds in inert (Ar) and reducing (H_2) atmospheres, the products are formed in different relative amounts (see Table 1).

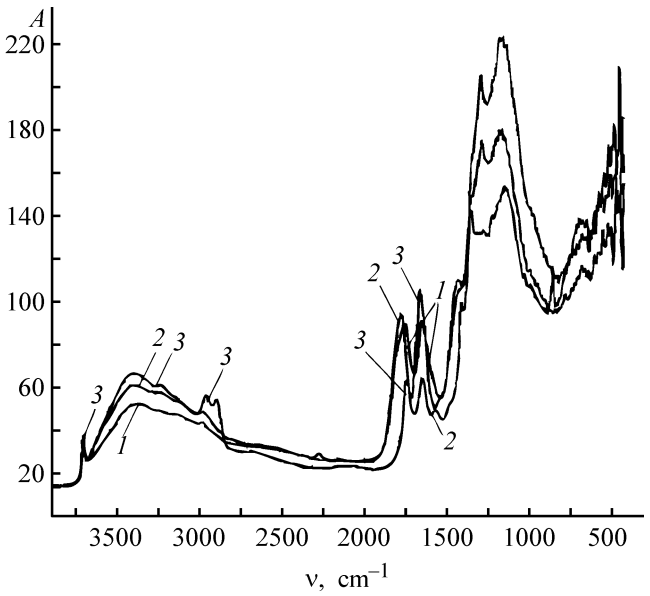
The amount of carbon dioxide formed in the inert atmosphere of argon exceeds that produced in the reducing atmosphere of hydrogen. This occurs because mainly decarbonization of various carbonyl-containing groups (=C=O, –COOH, =COH) and removal of –OH groups and adsorbed water from, the ND surface occur in Ar at temperatures below 600°C. At temperatures of 600–800°C, processes in which carbon monoxide is released start to predominate, which is accompanied by a decrease in the released amounts of CO_2 and H_2O (0.89 mmol g^{-1} ND at 800°C). The formation of CO can be attributed to interaction of carbon dioxide and water with the surface carbon of nanodiamonds. The release of CO commences in the temperature range 300–400°C and its amount increases with temperature.

In the reducing atmosphere, the modifying gas interacts with the ND surface in a different way. It can be seen that the amount of released water grows and reaches the maximum value at 800°C, whereas in the argon atmosphere, it sharply decreases.

All these phenomena are accounted for by the occurrence of reducing reactions with hydrogen on the nanodiamond surface. As it is believed by the authors of [11], hydrogen is adsorbed on the ND surface at treatment temperatures below 300°C. However, this temperature is sufficient, as also in the case of thermal desorption in a flow of Ar, for the decarbonization and dehydration processes to commence. As the modification temperature is raised further (in the range 300–600°C), hydrogen reacts with oxygen-containing groups, which results in that the amount of water released in thermal treatment below 600°C exceeds that of carbon dioxide. At temperatures of 600–800°C, hydrogen continues to react with the ND surface, which results in the maximum release of water at 800°C. The decrease in the amount of CO_2 formed in H_2 at this temperature is possibly also due to the reaction of carbon dioxide with the surface, but it is impossible to determine the amount of CO released, because, in the method used, palladium acetate is reduced by the modifying hydrogen gas to metallic palladium.

The assumptions that chemical reactions occur on the ND surface in the course of modification at various temperatures are in agreement with IR spectroscopic data obtained in this study and previously [11, 12]. The modification leads to pronounced changes in the position and intensity of absorption bands associated with carbonyl groups (see figure). Treatment at 400°C in argon shifts the peak of the band at 1730 cm^{-1} to the range 1780–1790 cm^{-1}, which indicates that –C(O)–O–C(O)– structures are formed. Modification with hydrogen gives rise to an absorption band associated with isolated –OH groups (~3680 cm^{-1}) and to absorption bands at 2938 and 2867 cm^{-1}, which point to the presence of C–H bonds at the carbon atom. The changes in the IR spectra confirm that the modification of nanodiamonds change the chemical state of their surface.

After treatment with oleum, the content of sulfur in the samples modified in hydrogen and argon was 0.26 and 0.30%, respectively. A more prolonged sulfation (up to 100 h) did not lead to any increase in the content of sulfur in the samples. Probably, these conditions are insufficient for complete sulfation of nanodiamonds; however, the IR spectra obtained after treatment with oleum clearly show a new band at 620 cm^{-1}, characteristic of sulfo groups.



Various ND samples were chlorinated at 400 and 600°C. The results obtained are listed in Table 2.

It can be seen that chlorination of the starting sample and that modified in argon at 600°C results in that the content of chlorine increases with the chlorination temperature, whereas for samples modified in hydrogen, the content of chlorine remains constant and is independent of the ND treatment conditions and chlorination temperature.

The effect of the ND surface modification conditions on the catalytic activity of palladium catalysts supported by nanodiamonds was studied in the reaction of NB hydrogenation, chosen as the model reaction. The results obtained are listed in Table 3.

Modification of the ND surface affects the catalytic activity of nanodiamond-supported palladium catalysts in the reaction of NB hydrogenation. The relative amounts of surface groups vary with the modification conditions [13], and this circumstance is responsible for the difference in the average reaction rates. In thermal treatment, CO_2 and H_2O are removed from the surface the most easily, and phenol, ketone, and lactone groups, more difficultly [13].

As can be seen in Table 3, the highest activity is observed for the catalyst treated in a flow of argon at

IR diffuse reflection spectra of nanodiamonds. (*A*) Reflectance and (ν) wave number. (*1*) Starting sample and (*2*, *3*) that treated at 400°C with (*2*) argon and (*3*) hydrogen.

400°C (sample no. 2). As the treatment temperature is raised to 800°C, the activity of the samples modified in the atmosphere of argon somewhat falls, but remains twice that for the starting sample (sample no. 1).

Modification of nanodiamonds in the atmosphere of hydrogen (sample nos. 5–7) does not change the catalytic properties, compared with the starting ND (sample no. 1). In the case of treatment with argon, functional groups are removed and the nanodiamond surface is freed for NB adsorption, whereas in hydrogen, presumably only the chemical composition of the surface is changed (see figure).

Table 2. Effect of nanodiamond chlorination conditions on the chlorine content

ND treatment conditions	Chlorination temperature, °C	Chlorine content, %
Starting	400	11.0 ± 0.3
	600	16.0 ± 0.5
Ar, 600°C	400	8.8 ± 0.3
	600	12.0 ± 0.5
H_2, 600°C	400	10.6 ± 0.4
	600	10.6 ± 0.3
H_2, 800°C	400	10.6 ± 0.4

Table 4. Effect of ND modification conditions on the amount of adsorption

Solvent	Adsorption, mmol g^{-1} at indicated modification temperature, °C								
	Starting ND	200	400	600	800	200	400	600	800
		Ar				H_2			
Benzene	12.3	12.6	12.7	13.2	13.6	11.4	12.1	18.7	24.9
Chloroform	13.5	14.0	14.2	14.5	14.9	14.3	14.5	14.7	15.8
Water	41.6	–	57.1	60.2	64.6	–	55.4	53.4	50.8

It can also be seen in Table 3 that modification of ND with sulfo and chloro groups makes the catalyst activity higher.

Thus, it can be concluded that the most efficient way to modify nanodiamonds is their thermal treatment in argon, which makes it possible to raise the rate of NB hydrogenation by more than a factor of 2, with ND used as a support for palladium catalysts. The nature of the support surface affects the formation of active centers in palladium catalysts and, accordingly, their catalytic activity.

A property important for various applications of nanodiamonds is their adsorption capacity. It was pointed out in [5] that UDD has a high adsorption capacity, 9 to 14 mmol g^{-1} for benzene vapor and 10.5 to 17 mmol g^{-1} for chloroform vapor, depending on a UDD brand. The adsorption properties of modified nanodiamond forms were studied. The adsorption capacity of ND for benzene, chloroform, and water vapors was determined (with an average determination error not exceeding 3 wt %). The results obtained are listed in Table 4.

It can be seen that the adsorption of chloroform is independent of the nanodiamond modification conditions and is virtually constant. Its average value is 14.55 mmol g^{-1}. The adsorption of benzene vapor on the surface of the starting nanodiamond and that modified in an inert atmosphere at various temperatures is also virtually constant, with its average value equal to 12.88 mmol g^{-1}.

Thus, the chemical composition of the ND surface (presence of functional groups of different types) weakly affects its adsorption properties. Presumably, the factor responsible for the adsorption of benzene and chloroform is the presence in a sample of sufficiently narrow pores, because nanodiamonds form stable aggregates from particles 4–5 nm in size. It should, however, be noted that the adsorption capacity for benzene vapor increases for samples modified in a flow of hydrogen, and, at the maximum thermal treatment temperature (800°C), the amount of adsorption is 24.9 mmol g^{-1}, which is more than two times the adsorption capacity of the starting ND and that modified in an inert atmosphere. Presumably, this is so because reduction reactions occur in the atmo-

sphere of hydrogen at high thermal treatment temperatures and, as a result, oxygen-containing groups are virtually absent on the nanodiamond surface and alkyl functional groups appear.

It should be noted that the maximum adsorption capacity for benzene vapor is reached in only 48 h for samples treated in a flow of hydrogen, and in 21 days for all other samples.

As can be seen in Table 4, the adsorption of water on the ND surface is two to three times that of benzene and chloroform. The adsorption capacity of samples treated in a flow of argon increases with the modification temperature and, at 800°C, exceeds that of the starting ND by a factor of 1.5. A somewhat different situation is observed for samples treated in a flow of hydrogen: the adsorption capacity slightly decreases as the sample modification temperature increases, but the amount of adsorption also exceeds that of the starting nanodiamonds. Probably, this is due to occurrence of reducing reactions in the course of thermal treatment in the atmosphere of hydrogen, with a large number of oxygen-containing groups reduced to hydrocarbon radicals at the maximum temperature (800°C). However, the adsorption capacity of samples treated in hydrogen is higher than that of the starting ND because, probably, adsorption occurs in this case at the remaining functional groups with which water forms hydrogen bonds and at active centers that appeared on the surface because of the desorption of other functional groups (amino groups, sulfo groups, etc.).

The high adsorption capacity of nanodiamonds for water can be attributed to the formation of hydrogen bonds with carboxy and hydroxy groups contained on the ND surface. Formation of strong chemical bonds between water and the ND surface is unlikely [14], which is confirmed by experiments on desorption of water from the surface with calcium chloride. Samples that absorbed water were placed in a desiccator with calcium chloride, and, after 4 days, the mass of the weighed portion of nanodiamonds took its original value. This experiment shows that a chemical interaction with the ND surface is unlikely, because chemisorption is a virtually irreversible process [15].

Thus, the higher (by a factor of 3–4.5) adsorption capacity of nanodiamonds for water, compared with chloroform and benzene, can be noted. Comparison of the amounts of adsorbed water (>100 wt %) rather unambiguously points to the physical mechanism of water adsorption in nanodiamond pores.

CONCLUSIONS

(1) Quantitative characteristics of thermal transformations of functional groups on the surface of nanodiamonds in their modification in various atmospheres were determined. It was found that a larger amount of carbon dioxide and water is released in thermal treatment of nanodiamonds in an inert atmosphere, and the maximum amount of carbon monoxide, at 800°C. In thermal treatment in a reducing atmosphere, the amount of released water exceeds that of carbon dioxide.

(2) The conditions of modification of the nanodiamond surface affect the catalytic activity of supported palladium catalysts in the reaction of nitrobenzene hydrogenation. Nanodiamonds thermally treated in the atmosphere of argon were found to be the best support for these catalysts (with the rate of nitrobenzene hydrogenation increasing by more than a factor of 2).

(3) A study of the effect of the modification conditions on the adsorption properties of nanodiamonds with respect to benzene, chloroform, and water demonstrated that the adsorption of chloroform vapor is independent of the conditions in which the nanodiamond surface is modified. The adsorption capacity for benzene vapor is independent of the modification temperature for samples treated in argon and increases with this temperature for samples treated in hydrogen. The adsorption capacity of nanodiamonds for water vapor is two to three times that for benzene and chloroform vapors.

Abstract—Desorption and adsorption of water on the surface of ZrO_2 particles obtained under hydrothermal conditions were considered. The heat effect of desorption was determined.

DOI: 10.1134/S1070427208040071

The large specific surface area of nanopowders and the active state of functional groups on the surface of nanoparticles [1–5] make promising their use in development of highly efficient sorbents, catalysts, and catalyst supports and in syntheses of substances with a developed and active surface. ZrO_2-containing materials are known as sorbents [6–8] and are widely used as catalysts [9–13]. Because ZrO_2 particles have a hydrophilic surface and actively adsorb water [14–17], data on the adsorption and desorption of water on the surface on ZrO_2-based nanocrystalline powders are necessary for development and use of these materials. It should be noted that data on these processes for ZrO_2 nanoparticles are also exceedingly important for development of a technology for production of ceramic materials from nanopowders, because adsorption and desorption of water on the surface of nanoparticles exert a decisive influence on the densification of materials in their compaction and, particularly, sintering [18–24].

This study is devoted to a thermochemical examination of the adsorption and desorption of water on the surface of nanocrystalline ZrO_2 particles by the method of comprehensive thermal analysis.

EXPERIMENTAL

Nanocrystalline zirconium dioxide was produced by hydrothermal treatment of zirconium hydroxide precipitated from a solution of $ZrOCl_2 \cdot 8H_2O$ (chemically pure grade) with a concentrated solution of NH_4OH. The hydrothermal treatment was carried out at a temperature of 250°C and pressure of 70 MPa in the course of 4 h. The parameters of synthesis of ZrO_2 nanocrystals were chosen in accordance with [25–27] and corresponded to complete dehydration of zirconium oxyhydroxide.

The structural state of ZrO_2 nanoparticles was determined by X-ray phase analysis (XPA). X-ray diffraction patterns of samples were measured on a DRON-3 diffractometer (Cu_{K_α} radiation).

The size of crystallites (coherent-scattering regions, CSR) was found from the line broadening in X-ray diffraction patterns by the Scherrer formula. In addition, the particle size was determined by transmission electron microscopy (TEM) on an EM-125 electron microscope with U_{acc} = 75 kV and from small-angle scattering data obtained on the installation described in [28].

The specific surface area of the nanopowder was found by analyzing isotherms of butanol adsorption.

The desorption and adsorption of water on the surface of nanoparticles was studied in a flow of air containing H_2O in an amount corresponding to a 70–80% relative humidity of air and to a saturated vapor pressure at atmospheric pressure and temperature of 25°C ($P_{H_2O\,(sat)}$ = 0.0312 atm [29]) by the method of comprehensive thermal analysis on a Netzsch STA-429 installation. The heat effects accompanying these processes were found from data furnished by differential scanning calorimetry. The composition of the gas phase over a sample was monitored by mass spectrometry [QMS 403C Aecolos (Netzsch)].

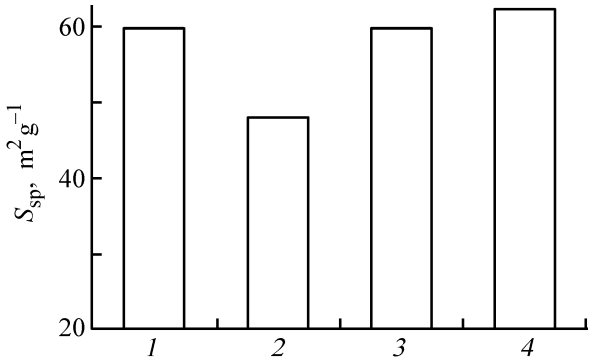

Fig. 2. Specific surface area of nanocrystalline ZrO_2, found by analyzing (*1*) small-angle X-ray scattering data, (*2*) widths of X-ray diffraction lines, (*3*) TEM data, and (*4*) data on butanol adsorption. (S_{sp}) Specific surface area of nanoparticles.

Comparison of the values obtained for the specific surface area of nanoparticles by the adsorption–desorption method and from the nanoparticle sizes found from X-ray diffraction line broadening (Fig. 1a) and by TEM (Fig. 1b) shows that these values coincide within the experimental error (Fig. 2). This coincidence is only possible if the following conditions are satisfied: nanoparticles have an isometric shape, are single crystals, the amorphous phase is virtually absent, and the nanoparticle size distribution is narrow. These characteristics of the zirconium dioxide nanoparticles under study, produced in hydrothermal conditions, is confirmed both by published data [25–27, 30] and by the results of separate experimental methods used in the study. For example, TEM data (Fig. 1b) show that the nanocrystals have an isometric shape and only slightly vary in size. It should be noted that the most pronounced, even though only falling within the experimental error, discrepancy between the specific surface areas is observed for the method in which S_{sp} is calculated from the SCR size. This, presumably, occurs because the procedure used to calculate the SCR size by the Scherrer formula for the most part takes into account coarser crystals, which results in that S_{sp} values are underestimated.

The results of a comprehensive thermal analysis of ZrO_2 nanocrystals (Fig. 3) indicate that two endothermic effects associated with the desorption of water from the surface of zirconium dioxide nanoparticles and with the transition of the monoclinic modification of ZrO_2 to *t*-ZrO_2, the equilibrium modification at the given temperature. Four exothermic effects, accompanied by a noticeable loss of mass, are presumably due to a structural rearrangement of ZrO_2 nanoparticles. A mass-spectrometric analysis of the gas phase over a sample demonstrated that mainly water is desorbed (Fig. 3b). The loss of mass by the sample, attributed to the desorption process, is virtually independent of the rate at which temperature is raised, but depends on the partial pressure of water of the sample in its isothermal keeping at 25°C. The data obtained demonstrate that the loss of mass by a nanopowder kept under saturated-vapor conditions at 25°C is about 3.7 wt %, and that by samples kept at room temperature in an atmosphere with a humidity of 70–80% is 2.2–2.7 wt %. It is noteworthy that the latter data are also confirmed by the results of other studies of ZrO_2 nanopowders obtained under similar conditions [13, 14, 30].

The area of the landing site for a water molecule is $\delta = 0.102$ nm^2 [31]. With account of the values obtained for the specific surface area of ZrO_2 nanocrystals [$S_{sp} = 61 \pm 1$ m^2 g^{-1} (Fig. 2)] and for the amount of water adsorbed on their surface [$\Delta m = (2.2–2.7) \times 10^{-2}$ or 3.7×10^{-2} g H_2O per gram of a sample], it can be concluded that, to within the error in the available data, a water layer that approaches a bimolecular layer as the air humidity increases to saturation is present in both cases on the surface of zirconium dioxide nanoparticles. This conclusion is based on the fact that the surface area that would be oc-

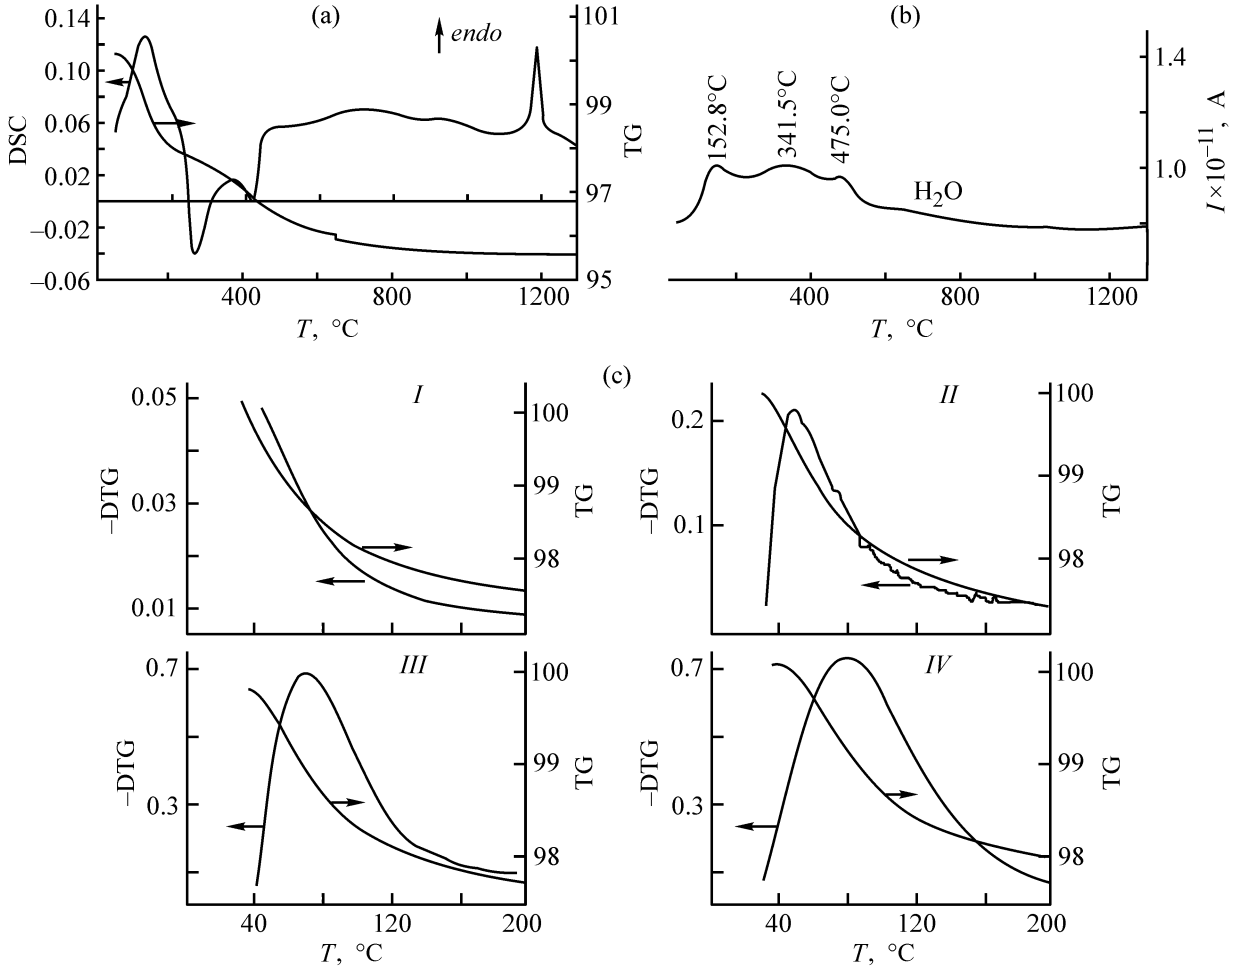

Fig. 3. Results of (a) differential-thermal, (b) mass-spectrometric, and (c) thermogravimetric analyses of nanocrystalline ZrO_2. (T) Temperature and (I) ionic current. Heating rate (deg min^{-1}): (*I*) 1, (*II*) 5, (*III*) 10, and (*IV*) 20.

cupied by a monomolecular layer of water released in desorption is $S_{sp.\ mono}$ = 75–92 or 126 m^2 (saturated vapor), which exceeds by a factor of 1.2–1.5 or nearly 2 (for the saturated vapor) the real specific surface area of ZrO_2 nanoparticles.

Analysis of the thermogravimetric data shows that, at a heating rate of 1 deg min^{-1}, the curves that describe the loss of mass (TG and –DTG) and characterize the evaporation intensity monotonically decrease as temperature becomes higher (Fig. 3c). At the same time, at heating rates of 5, 10, and 20 deg min^{-1}, the TG curves remain monotonically decreasing, whereas the –DTG curves show a maximum that is shifted, depending on the heating rate, from 60 to 80°C (Fig. 3c). The peak in the –DTG curves is presumably due, on the one hand, to a kinetic hindrance to the desorption process at low temperatures, which becomes less pronounced as temperature is raised, in accordance with the known kinetic equations [32]. On the other hand, the fall of the desorption rate, observed as temperature is raised above a certain value may be due, in accordance with the desorption equation [32], both to a decrease in the amount of the adsorbed substance in the course of desorption and to a stronger binding of water molecules, desorbed at higher temperatures, to the surface of ZrO_2 nanoparticles.

It should be noted, when analyzing the case in which a virtually bimolecular layer of adsorbed waster is present on the surface of ZrO_2 nanoparticles (Fig. 4), that the desorption rate decreases if a predominantly monomolecular layer of H_2O, known to be more strongly bound to the hydrophilic surface [33], remains on the nanoparticle surface. According to [34], a virtually monomolecular layer remains on hydrophilic surfaces when temperature is raised 65–70°C, in good agreement with the results obtained in the present study (Fig. 3). The absence of a maximum

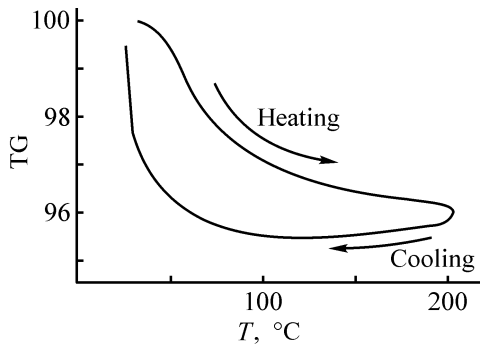

Fig. 4. Results of a thermogravimetric analysis (heating–cooling) of zirconium dioxide nanocrystals at P_{H_2O} = 0.0312 atm. (T) Temperature.

in the desorption rate at a heating rate of 1 deg min^{-1} presumably indicates that the kinetic factor is unimportant, i.e., this mode is close to the equilibrium desorption of water from the surface of ZrO_2 nanoparticles.

As follows from the results of the thermal analysis, the process of water adsorption on the surface of ZrO_2 nanoparticles is substantially slower than the desorption process and starts to occur with high intensity only at comparatively low temperatures (Fig. 4).

The DSC and DTG data were used to determine how the heat effect of desorption of 1 mol of H_2O from the surface of ZrO_2 nanoparticles depends on temperature. The results obtained indicate that, within the experimental error mostly associated with plotting of the differential curve describing the loss of mass, the heat effect can be considered constant in the whole range of desorption temperatures studied and equal to $\Delta H_{des} = 35 \pm 7$ kJ mol^{-1}. It is noteworthy that ΔH_{des} coincides within the experimental error with the enthalpy of water evaporation $\Delta H_{ev} = 40$ kJ mol^{-1} [35].

CONCLUSIONS

(1) It was shown that, upon an increase in the air humidity from 70% to a saturated vapor at room temperature, 1.2 to 2 molecular layers of water are adsorbed on the surface of nanoparticles.

(2) The heat effect of water desorption from the surface of zirconium hydroxide nanoparticles was determined ($\Delta H_{des} = 35 \pm 7$ kJ mol^{-1}) and it was demonstrated that ΔH_{des} coincides within the experimental error with the heat effect of water evaporation.

(3) It was found that, in the range of air humidities under consideration, the desorption of the monomolecular layer from the surface of zirconium dioxide nanoparticles begins at a temperature of about 74°C.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Electrodeposition of Semiconducting $CuInSe_2$ Films On Glassy Carbon Electrode from Sulfuric Acid Electrolytes

M. B. Dergacheva and V. V. Chaikin

Abstract—Electrochemical behavior of selenium(IV), copper(II), and indium(III) ions in joint deposition onto a glassy carbon electrode from sulfuric acid electrolytes was studied. The optimal conditions for formation of a stoichiometric compound $CuInSe_2$ were determined. The structure and composition of the compound synthesized were studied by X-ray phase, electron microscopic, and electron microprobe analyses.

DOI: 10.1134/S1070427208040083

Indium-copper diselenide $CuInSe_2$ is the most promising material for solar cells. Owing to its unique properties, such as the high absorption coefficient and band gap width (1.1 eV) that enables conversion of sunlight into photocurrent, the $CuInSe_2$ compound can find wide use in manufacture of thin-film solar cells.

Thin $CuInSe_2$ films can be formed by various methods. To these belong chemical pyrolysis sputtering, pulsed deposition, fast thermal recrystallization, and radio-frequency sputtering with oxygen batching. The electrodeposition technique is the most inexpensive and technologically convenient. It can be performed in a single stage at low temperatures not exceeding 90°C and is inexpensive.

Simultaneous electroreduction of three components to form a compound with a prescribed stoichiometric composition is a complicated task because of the considerable difference between the standard electroreduction potentials of the ions. To accomplish this task, it is necessary to study the influence exerted by the electrolysis conditions on the composition of a deposit being formed. Making studies of the electrodeposition of multicomponent semiconductor materials more extensive will enable synthesis of new materials and fabrication of new structures.

A necessary stage after a film is formed by electrodeposition is its subsequent annealing for crystallization or changing the conduction type. The effect of this stage on the characteristics of a semiconductor is not fully understood.

The aim of this study was to find the optimal conditions of electrodeposition of the $CuInSe_2$ compound of stoichiometric composition from sulfuric acid electrolytes. The structure and composition of the compound synthesized were subjected to X-ray phase (XPA), electron microscopic, and electron microprobe analyses. Characteristics of thin $CuInSe_2$ films were examined after their annealing in argon.

EXPERIMENTAL

As the working electrode we used a pyrographite disc with an apparent surface area of 0.07 cm^2. The three-electrode cell contained an electrode under study, auxiliary platinum electrode with an area of 1.5 cm^2, and a silver chloride reference electrode, relative to which all the potentials are given. Prior to each experiment, the working electrodes were trimmed with a Al_2O_3 powder and washed with ethanol and water. The following salts were used: $CuSO_4 \cdot 7H_2O$, Na_2SeO_3, and $In_2(SO_4)_3$ (all of analytically pure grade). As the supporting electrolyte served a 0.05 M H_2SO_4 + 0.45 M Na_2SO_4 solution. The voltammetric curves were recorded without agitation. The deposit was accumulated on the electrode with agitation of the electrolyte with a magnetic stirrer. The study was performed at room temperature. The films used for analysis of the structure and composition were deposited onto a glassy carbon substrate with an area of 1.5 cm^2. The working temperature in the electrodeposition was 75°C, and the deposition time, 30 to 40 min. The electrodeposited samples were washed

with distilled water and calcined at 410°C for 10 min. The X-ray phase analysis of the copper selenide deposits was made on a DRON-4 diffractometer (Co_{K_α} radiation). Simultaneously, the deposits were analyzed on an EM-125-K electron microscope by the single-stage replica technique.

The joint deposition of three components [Cu(II), In(III), Se(IV)] from sulfuric acid solutions was studied in two sets of experiments. In the first set, the concentrations of copper and selenium ions were constant [$c_{Cu(II)} = 5 \times 10^{-4}$ M and $c_{Se(IV)} = 1 \times 10^{-3}$ M], whereas the concentration of indium ions steadily increased. In the second set, the concentrations of indium and selenium ions were constant $c_{In(III)} = 1 \times 10^{-3}$ M and $c_{Se(IV)} = 5 \times 10^{-4}$ M], and the concentration of copper(II) ions was gradually raised.

Voltammetric measurements in the first set of experiments demonstrated that the cathodic branch of the voltammetric curve for reduction of Cu(II) and Se(IV) ions is in agreement with the data of [1]. It was found that, at potentials of +0.15 to –0.2 V, there occurs the main process of joint reduction of copper and selenium to give a $CuSe_x$ compound:

$$Cu^{2+} + xH_2SeO_3 + 4xH^+ + (2 + 4x)e \rightarrow CuSe_x + 3xH_2O. \quad (1)$$

The current peak associated with the formation of the Cu_2Se compound and evolution of hydrogen selenide is present in the cathodic branch at more negative potentials:

$$2CuSe_x + 2xH^+ + 2xe \rightarrow Cu_2Se + xH_2Se. \quad (2)$$

The current peak in the anodic branch of the voltammetric curve at $E_{1,A} = +0.25$ V is due to oxidation of copper ions from the two-component compound Cu_2Se

$$Cu_2Se - 2e \rightarrow 2Cu^+ + Se^0. \quad (3)$$

The current peak at $E_{2,A} = +1.1$ V corresponds to oxidation of the elementary selenium formed on the electrode to Se(IV)

$$Se(0) + 3H_2O \rightarrow H_2SeO_3 + 4e + 4H^+. \quad (4)$$

Upon addition of indium(III) ions and the subsequent increase in their concentration in the electrolyte, the cathodic branch of the voltammetric curve remains virtually unchanged. The reduction wave of indium(III) itself is not observed.

However, additional oxidation peaks, characteristic of only the ternary system and absent on the voltammogram of a copper–selenium binary system, appear on the anodic branch of the voltammetric curves. An additional oxidation peak at the potential +0.70 V, associated with the dissolution of a three-component compound, appears even at low concentrations (1×10^{-4} M) of indium(III) ions in the solution. The peak current increases with the indium(III) concentration. In a solution with an indium(III) concentration of 1×0^{-3} M and more, another two additional oxidation current peaks appear (Fig. 1). The current of the oxidation peak at –0.37 V is not characteristic of copper–selenium and indium–selenium binary systems and appears solely in joint deposition of selenium(IV), copper(II), and indium(III) at a large excess of indium(III) ions (Fig. 1). This peak can be attributed to oxidation of indium from a three-component compound

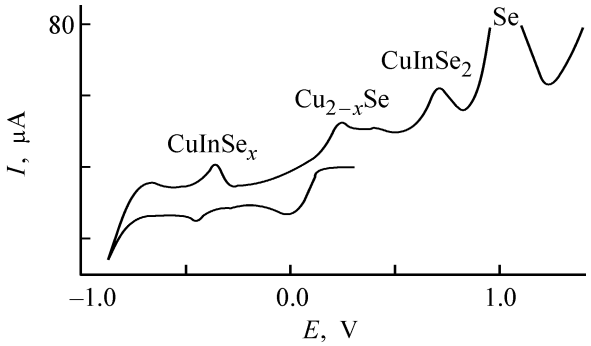

Fig. 1. Voltammetric curves obtained in a supporting electrolyte containing 0.05 M H_2SO_4 + 0.45 M Na_2SO_4. $c_{Cu(II)} = 5 \times 10^{-4}$ M, $c_{Se(IV)} = 1 \times 10^{-3}$ M, $c_{In(III)} = 2 \times 10^{-3}$ M; $v = 20$ mV s^{-1}. (I) Current and (E) potential.

$$CuInSe_2 - 3e \rightarrow In^{3+} + CuSe_x. \quad (5)$$

Comparison of the voltammograms with the data of [1, 2] for binary systems suggests that the current peak at $E_{1,A} = +0.25$ V is due to oxidation of copper from the binary compound Cu–Se.

The second set of experiments demonstrated that the joint reduction of a two-component indium(III)–selenium(IV) system is characterized by two cathodic waves ($E_{1,K} = +0.10$ V and $E_{2,K} = -0.75$ V) and two anodic waves ($E_{1,A} = +0.20$ V and $E_{2,A} = +1.10$ V). The cathodic wave appearing at a potential of +0.10 V is associated with selenium(IV) reduction, the first oxidation wave at $E_{1,A} = +0.20$ V belongs to oxidation of indium from the two-component indium–selenium system, and the oxidation wave at $E_{2,A} = +1.10$ V corresponds to reaction (4).

Addition of minor concentrations of copper(II) ions strongly changes the voltammetric curve: the limiting current of the cathodic wave beginning at the potential of +0.10 V grows. This is accounted for by the fact

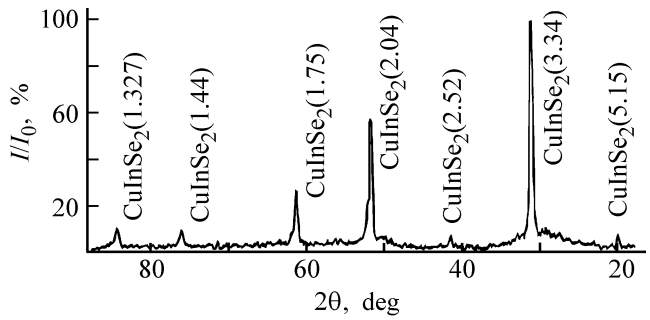

Fig. 2. X-ray diffraction pattern of the electrodeposited film. $c_{Se(IV)} = 1.3 \times 10^{-2}$ M, $c_{Cu(II)} = 5 \times 10^{-3}$ M, $c_{In(III)} = 2 \times 10^{-2}$ M; Deposition conditions: $E = -0.75$ V, $T = 75$°C, $\tau = 35$ min. (I/I_0) Relative intensity and (2θ) Bragg angle.

that the joint reduction of copper and selenium occurs at close potentials. The current peak of oxidation of the three-component compound appears in the anodic branch of the voltammetric curve at a potential of +0.70 V. The peak becomes weaker as the copper concentration in the solution increases and, at $c_{Cu(II)} > 1 \times 10^{-3}$, disappears at all by merging with the current peak of Se^0 oxidation to Se^{4+}. At the same time, the current peak of oxidation of the ternary compound, observed in the first set of experiments at a potential of –0.37 V, appears only at a concentration $c_{Cu} = 3 \times 10^{-4}$ M, and the current of the peak increases with the concentration of copper(II) ions. The increase in the current of the anodic peak of copper oxidation at the potential of 0.25 V was found to be well predictable. At a copper(II) concentration exceeding 1×10^{-3} M, an additional current peak of copper oxidation appears at a potential of 0.045 V in the anodic branch.

The effect of the concentration of indium ions in the electrolyte on the currents of the cathodic and anodic peaks was studied, with the concentration of indium ions varied in the range $(0–2.5) \times 10^{-3}$ M at a constant concentrations of copper and selenium ions in the electrolyte [($c_{Cu(II)} = 5 \times 10^{-4}$ M and $c_{Se(IV)} = 1 \times 10^{-3}$ M]. An increase in the concentration of In(III) ions results in that the current of Se(0) oxidation grows, which points to additional accumulation of selenium on the electrode via decomposition of the compounds formed on the electrode. The anodic current peak of oxidation of the ternary compound also grows. The oxidation current of the binary compound Cu_2Se decreases and then remains constant as the indium concentration is varied from 5×10^{-4} to 2×10^{-3} M. In the same concentration range, the oxidation current of the ternary compound increases. The current peak associated with In_2Se_3 oxidation remains small and depends only slightly on the concentration of indium(III) ions. Changing the concentration of indium ions has virtually no effect on the potentials of the peaks associated with the cathodic process. The cathodic current due to reduction to Se^{2-} ions sharply falls at a concentration of indium ions of 5×10^{-4} M and then gradually decreases.

In joint deposition of the three components to obtain deposits of the $CuInSe_2$ compound, the choice of the electrolyte composition was based on the results of the two sets of experiments described above. The primary goal was to choose the relative concentrations and the deposition potential at which the deposition of the ternary compound $CuInSe_2$ would prevail and that of the copper–selenium and indium–selenium binary phases would be insignificant.

It was found from the voltammetric curves obtained (Fig. 1) that two peaks of oxidation of the ternary compound at potentials of –0.37 and +0.72 V are the most pronounced at the following concentration ratio in the electrolyte: Cu : In : Se = 1 : 4 : 2.5. At other ratios, an increase in the oxidation peaks corresponding to copper-selenium or indium-selenium binary compounds is observed. In the case of a strong deviation from this ratio toward an excess of copper(II) or selenium(IV) ions in solution, excess copper(0) or selenium(0) is deposited.

The boundary regions of the deposition potentials of the $CuInSe_2$ ternary compound were chosen taking into account the previously determined deposition potentials of binary compounds [1, 2] and the chosen electrolyte composition. To accumulate a deposit on the electrode, the three components were codeposited in the potentiostatic mode at potentials of –0.4…–0.8 V (s.ch.e.). The maximum oxidation current of the corresponding peaks was used to choose the optimal deposition potential (–0.75…–0.80 V).

At the chosen potential and ratios of the component concentrations in the electrolyte, a film of the $CuInSe_2$ ternary compound was potentiostatically deposited onto glassy carbon electrodes with an area of 1.5 cm^2 at 75°C in the course of 30–40 min.

The electrodeposited samples were washed with distilled water and annealed at 410°C for 10 min in air. The phase composition of the films obtained was determined by XPA. According to the XPA data, the thus obtained films contain, in addition to the $CuInSe_2$ compound, a certain amount of the binary copper–selenium phase. The indium oxide phase also appeared. This suggested that a part of indium on the film surface is oxidized by atmospheric oxygen in the course of the annealing.

The following samples were annealed in argon under the same conditions. The X-ray diffraction pattern of the film annealed in argon is shown in Fig. 2.

The diffraction pattern contains only reflections of the ternary compound $CuInSe_2$ and, according to the ICPDS database (Table 23-209) for this phase, corresponds to the tetragonal structure.

The stoichiometric composition of this film was confirmed by electron microprobe analysis (see table). Micrographs of the surface show a rather uniform and dense coating by the film being deposited.

Thus, the compound $CuInSe_2$ with a prescribed stoichiometry can be electrodeposited from electrolytes containing copper(II), selenium(IV), and indium(III) ions, with 0.05 M sulfuric acid as the supporting electrolyte, at the chosen conditions of electrolysis and annealing.

The photoelectric properties of the obtained $CuInSe_2$ film were studied by measuring *I–E* curves under exposure to a scattered daylight. A photosensitivity was found, with the maximum short-circuit current of 6 mA and open-circuit potential of 0.4 V.

Results of an electron microprobe analysis of the surface of a $CuInSe_2$ film

Spectrum no.	Content of indicated elements, at. %			
	Si	Cu	Se	In
1	0.97	23.11	51.72	24.20
2	–	27.96	51.87	20.17
3	–	24.90	52.16	22.94
Maximum	0.97	27.96	52.16	24.20
Minimum	0.00	23.11	51.72	20.17

CONCLUSIONS

(1) The conditions of potentiostatic deposition of a stoichiometric compound $CuInSe_2$ were determined by analysis of current–voltage curves recorded in joint electrodeposition of copper(II), selenium(IV), and indium(III) ions onto a glassy carbon electrode.

(2) The composition of the compound formed was confirmed by X-ray phase and electron microprobe analyses.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Structuring of Aromatic Solvents in the Presence of Small Amounts of Fullerene C_{60}

B. M. Ginzburg and Sh. Tuichiev

Received August 10, 2007

Abstract—Changes in the structure and some properties in a series of aromatic solvents, such as *p*-xylene, toluene, and benzene, under the action small amounts of dissolved fullerene C_{60} were studied by small- and wide-angle X-ray diffractometry.

DOI: 10.1134/S1070427208040095

Because fullerenes are well soluble in aromatic solvents [1], they are widely used for recovering fullerenes from fullerene soot and for preparing and studying various fullerene-containing (e.g., fullerene-polymer) systems. However, studies of the thermal stability of systems based on fullerene C_{60} and some polymers [2] revealed some experimental facts that cannot be adequately explained without assumption that the solvent noticeably changes its properties and structure in the stage of preparation of fullerene-polymer solutions.

The high solubility itself indicates that fullerene interacts with the aromatic solvent relatively strongly. This suggests that the structure of aromatic solvent can change under the action of the dissolved fullerene C_{60}.

Previously, we have reported data on solutions of fullerene C_{60} in toluene and *p*-xylene found by small-angle X-ray scattering [3, 4]. In this paper, we analyze changes in the structure and some properties of *p*-xylene, toluene, and benzene under the effect of small amounts ($\geq 10^{-4}$%) of dissolved fullerene C_{60}, determined by small- and wide-angle X-ray diffractomertry and densitometry.

EXPERIMENTAL

The X-ray diffraction measurements were carried out using Cu_{K_α} radiation and Ni filter. The intensity of small-angle X-ray scattering was measured on a KRM-1 installation with a slit collimation of the primary radiation beam; the half-width of the beam was 2.5 min. The intensity of wide-angle X-ray scattering was measured on a DRON-2 installation with a slit collimation; the half-width of the primary beam was 36 min. Rectangular cells were made of a thin polymer film (7.5–10 μm); the thickness of the cell with a sample studied was 1.0–1.5 mm.

The solutions were studied approximately 16 h after their preparation. Before measurements, each solution was agitated and placed in a cell with a calibrated syringe; then the cell was sealed and shaken directly before the measurement to decrease the possible fullerene clustering. The scattering measurements were performed in the transmission mode as follows. First, a cell containing a sample was placed at the center of a goniometer perpendicularly to the primary beam, and the diffraction pattern (curve *1*) was recorded. Then, the sample was placed in front of the first slit and the contour of the primary beam was recorded taking into account its absorption by the sample (curve *2*). Then, by subtracting curve *2* from curve *1*, we obtained the differential curve, which represents the scattering from the cell with the sample studied, with account of the absorbed X-ray radiation and minus various kinds of parasitic scattering from slit edges, air, etc. To obtain the scattering curve of the solution, the curve of scattering from the cell should be subtracted from the differential curve. However, the scattering ability of the empty cell is very small in the angle range studied and can be neglected. As a result, the differential X-ray diffraction patterns can be represented as the $I = f(s)$ curves, where I is the intensity; $s = 4\pi \sin\theta/\lambda$; 2θ, scattering angle; and λ, wavelength of the X-ray radiation. In small-angle measurements, we took $s = 4\pi\theta/\lambda$. It should be noted

that no normalization to the intensity of the primary beam was performed, because the intensity of curves *2* at minimal angles from which we started the recording was the same (within the measurement error) for the solvent and all the fullerene solutions in the entire concentration range studied. Some small-angle X-ray diffraction patterns were processed in terms of the Guinier theory [5] by evaluating the radius of gyration of the scattering particles.

The density of the solvents and fullerene C_{60} solutions was determined pycnometrically; the measurement accuracy was ± 0.0001 g cm^{-3}, and the measurement error for a single sample was 0.01%. The main measurement errors arose upon repeated preparation of solutions and reached 4–5%. The widest data scatter was found for solutions in toluene, in which the aggregation of C_{60} is the most pronounced.

The experimental solutions were prepared using fullerene C_{60} (99.7% purity) and solvents of chemically pure grade after their double distillation.

Homogeneous liquids and glasses are characterized by a constant intensity I of small-angle X-ray scattering in the range of the scattering angles accessible to measurements [6]. In all the cases, the intensity increases with temperature. The scattering itself is due to thermal density fluctuations. The comparatively small geometric size of density fluctuations in pure glasses and their small contrast with respect to the average density of the medium are due to the solid state of the glasses.

A different situation is observed for fluctuations in liquids. The small-angle X-ray patterns of the solvents and fullerene solutions studied are shown in Fig. 1. As can be seen, in all the curves, I first monotonically decreases with increasing scattering angle (range 1) and then reaches a certain constant value I_C (range 2).

For pure benzene, *p*-xylene, and toluene (boiling point at normal pressure 80.1, 110.6, and 138.35°C, respectively [7]), the noticeable increase in I in range 1 under the ambient conditions can be only due to the relatively large number of density fluctuations acting as nuclei of a new phase. In toluene and *p*-xylene, these nuclei are characterized by approximately the same radius of gyration (1.25–1.30 nm) under the ambient conditions, whereas in benzene, the radius of gyration is an order of magnitude larger (see table).

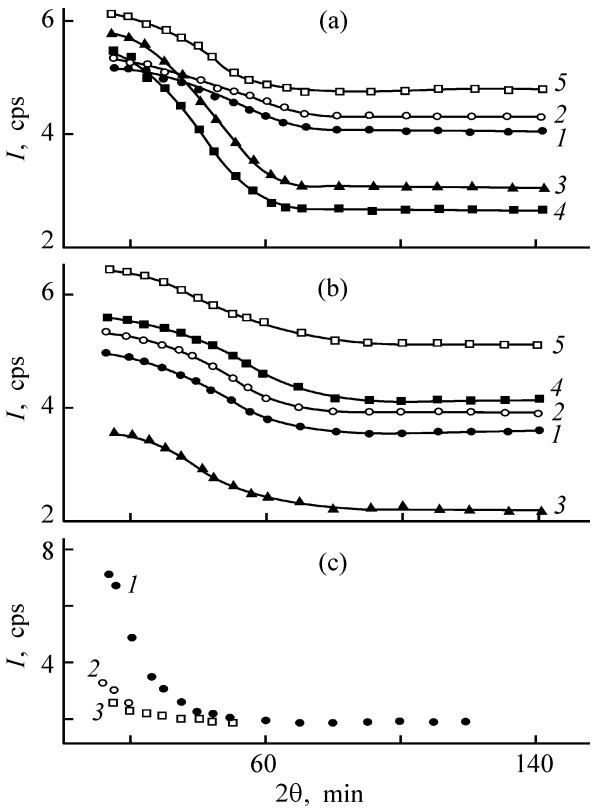

Fig. 1. Small-angle X-ray diffraction scattering curves (Cu_{K_α} radiation) of fullerene C_{60} solutions in (a) toluene, (b) *p*-xylene, and (c) benzene (T 25°C). (I) Intensity and (2θ) scattering angle; the same for Fig. 2. Fullerene concentration, %: (a) (*1*) 0 (pure toluene), (*2*) 0.001, (*3*) 0.01, (*4*) 0.1, and (*5*) 0.2; (b) (*1*) 0 (pure *p*-xylene), (*2*) 0.001, (*3*) 0.01, (*4*) 0.1, and (*5*) 0.5; and (c) (*1*) 0 (pure benzene), (*2*) 0.001, and (*3*) 0.075.

Size of heterogeneities in the samples studied*

Sample	R_g	R_e	Sample	R_g	R_e
	nm			nm	
Toluene	1.2	1.5	*p*-Xylene + 0.1% C_{60}	1.25	1.6
Toluene + 0.001% C_{60}	1.0	1.3	*p*-Xylene + 0.5% C_{60}	1.0	1.3
p-Xylene	1.25	1.6	Benzene	14	18
p-Xylene + 0.001% C_{60}	1.25	1.6	Benzene + 0.001% C_{60}	5.5	7
p-Xylene + 0.01% C_{60}	1.55	2.0			

* R_g is the radius of gyration and $R_e = R_g/(3/5)^{1/2}$ is the radius of an equivalent uniform sphere.

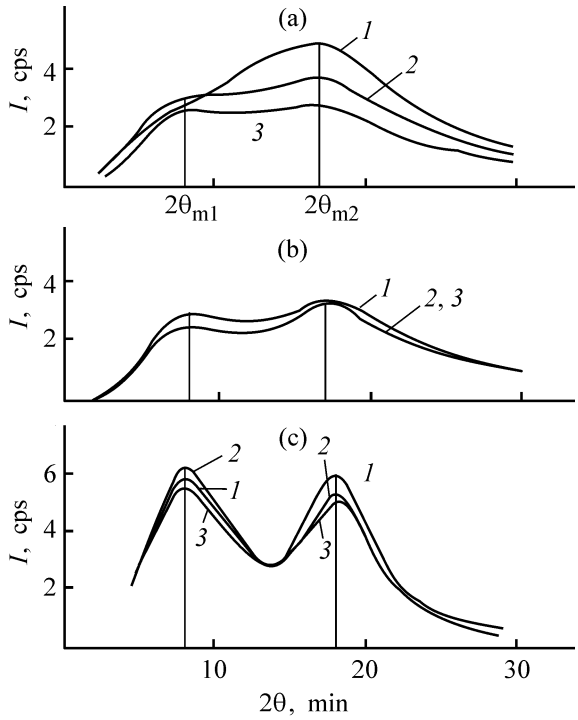

Fig. 2. Wide-angle X-ray diffraction scattering curves (Cu_{K_α} radiation) of fullerene C_{60} solutions in (a) *p*-xylene, (b) toluene, and (c) benzene. Fullerene concentration, %: (a) (*1*) 0 (pure *p*-xylene), (*2*) 0.005, and (*3*) 0.05; (b) (*1*) 0 (pure toluene), (*2*) 0.005, and (*3*) 0.05; and (c) (*1*) 0 (pure benzene), (*2*) 0.001, and (*3*) 0.075.

The most intriguing is the fact that, in the case of fullerene C_{60} solutions in toluene and *p*-xylene, the dependence of the intensity on the fullerene concentration is nonmonotonic. At a fullerene concentration of 0.001%, the scattering curves for both solvents are nearly idential (Figs. 1a and 1b, curves *2*), and their shape reproduces that of the pure solvents, but at slightly higher intensities. Sharp changes are observed as the fullerene concentration increases to 0.01% (Figs. 1a and 1b, curves *3*). Almost the whole scattering curve for toluene and the whole scattering curve for *p*-xylene lie below the scattering curves for the pure solvents. Such changes in *I* of the scattering curves can be accounted for by structuring of the solvent in the presence of fullerene (by structuring in this case is understood the suppression of the thermal density fluctuations). The structuring of a solvent is probably accompanied by an increase in its average density. In the case of toluene solutions, the observed decrease in the intensity of the small-angle X-ray scattering is accompanied by a sharp increase in the inclination of the small-angle section of the scattering curves to the abscissa (Fig. 1a, curves *3*, *4*), which can be only due to the formation of fullerene C_{60} aggregates.

At the same time, in the case of *p*-xylene (Fig. 1b), the shape of the small-angle scattering curves changes insignificantly. The X-ray diffraction patterns only shift along the intensity scale, which is due to the changes in the electron density of the scattering elements with respect to the density of the medium.

No aggregation of C_{60} molecules was observed. After the minimal intensity is reached (at some concentration c_{str} ~0.01% for *p*-xylene), the scattering intensity increases as the fullerene concentration is raised further.

In benzene (Fig. 1c), the scattering intensity in range 1 strongly decreases even at the smallest examined concentrations of fullerene. Apparently, the concentration range of fullerene in which the growth of the scattering intensity gives way to its decrease is significantly smaller than 0.001%, and concentration c_{str} is inaccessible in principle because of the relatively low solubility of fullerene in benzene. However, the structuring of benzene is confirmed by the sharp decrease in the size of density fluctuations (see table).

Among the solvents studied, the highest ordering on the molecular level is observed for *p*-xylene (Fig. 2, curve *1*): its wide-angle X-ray diffraction patterns exhibit a single amorphous halo with a small shoulder on the small-angle side. For toluene (Fig. 2, curve *1*), two poorly resolved amorphous halos are observed. As for benzene, its X-ray diffraction pattern is characterized by two pronounced amorphous halos whose half-width is comparable with that of the crystal lattice reflections (Fig. 2c, curve *1*).

The stronger the disordering of the initial system, the greater the changes in the solvent structure, observed on adding a small amount of fullerene. As a result, two amorphous halos are observed in the case of *p*-xylene (Fig. 2a, curves *2*, *3*), similarly to toluene. Addition of fullerene C_{60} to toluene decreases the width of the amorphous halos (Fig. 2b, curves *2*, *3*), but these changes are insignificant because of the fullerene aggregation. In benzene, fullerene addition does not noticeably affect the resulting scattering curves (Fig. 2c, curves *2*, *3*).

It should be noted that the angular positions of both the first ($2\theta_{m1}$) and second halos ($2\theta_{m2}$) remain essentially constant. We calculated the intermolecular distances X_m using the equation $2X_m/\sin\theta_m = K\lambda$ (where K = 1.2–1.3) [5] and found that, for all the three solvents and fullerene C_{60} solutions studied, X_{m1} = 1.3–1.4 nm and X_{m2} = 0.6–0.7 nm for the first and second halos, respectively.

Since the longitudinal sizes of the solvent molecules strongly differ (~7.8, 6.8, and 5.8 Å for *p*-xylene, toluene, and benzene, respectively), the above amorphous halos characterize the short-range order in a direction perpendicular to this size and most probably in the direction perpendicular to the plane of the benzene ring.

Methyl groups in toluene and *p*-xylene obviously break the intermolecular order as compared to benzene. In accordance with the theory of paracrystalline disturbances [8], the equation for the transition from diffraction peaks to diffuse scattering can be represented as follows: $n\Delta/X_m = 0.25$, where m is the order of the maximum and Δ is the disordering parameter (rms deviation of the distance X_m from the average value). For benzene and toluene ($n = 2$), $\Delta = 1.6–2.0$ Å, whereas for *p*-xylene, this parameter is greater by a factor of 2.

For almost all the fullerene solutions in toluene, the aggregation of fullerene molecules cannot be neglected. Thus, taking into account the cluster structure of the aggregates [1], analysis of the small-angle diffraction patterns in terms of the radii of gyration of the scattering elements becomes ambiguous. Therefore, we presented R_g in the table only for pure solvents and solutions without a pronounced fullerene aggregation.

Apparently, six-membered rings of fullerene molecules are the ordering factor. It can be assumed that benzene molecules interacting with these rings form stacks similar liquid-crystal discotics. However, the steric hindrance prevents ordering around the fullerene molecules throughout the solvent bulk and causes formation of areas with decreased density at a certain distance from C_{60} molecules.

In accordance with the data presented in [9], the fullerene molecule can be represented as a truncated icosahedron with an inner cavity with zero electron density; the radius of the inner cavity R_f is 0.2 nm and the otlet radius is 0.357 nm [10]. To a first approximation, taking into account the above sizes, we can represent the fullerene C_{60} molecule as a spherical envelope with a uniform density distribution. For such an envelope, the radius of gyration is 0.30 nm, which is significantly smaller than the radii of gyration listed in the table. This fact indicates that the fluctuations of the solvent density are the main scattering elements.

Let us compare the results of X-ray diffraction studies with published data on the densities of fullerene C_{60} solutions [11]. The density of C_{60} solutions in toluene changes nonmonotonically with increasing fullerene concentration: first it sharply decreases,

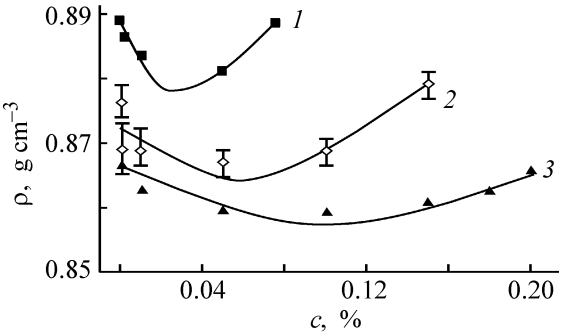

Fig. 3. Density ρ of fullerene solutions in (*1*) benzene, (*2*) toluene, and (*3*) *p*-xylene vs. fullerene C_{60} concentration c (T = 10°C).

after which it passes through a minimum and then increases. Such a dependence for solutions in *p*-xylene, toluene, and benzene is confirmed by our measurements (Fig. 3). THe nonmonotonic concentration dependences of the density of fullerene C_{60} solutions in the solvents studied are qualitatively consistent with the concentration dependence of the intensity of small-angle X-ray scattering. Probably, just this decrease in the solution density, observed at various temperatures and for various solvents, gave grounds to present in an incomplete study [11] a loose lyophobic shell around the fullerene C_{60} molecule without any additional comments.

After passing through a minimum, the solution density increases up to the density of the pure solvent and sometimes even becomes higher. Because the amounts of the denser fullerene added are very small and cannot account for the observed density increase, some compaction (structuring) of the solvent should be suggested. Thus, to account for a decrease in the intensity of small-angle scattering, we should take into account, along with the lyophobic shell around fullerene molecules, the next, lyophilic shell of the structured (compacted) solvent.

Structuring is obviously typical not of all the solvents, but only of those ("good" solvents) in which the solubility of fullerene is the highest. It should be noted that, although the density passes through a minimum in benzene solutions, the density of the pure solvent is not attained with a further increase in the fullerene concentration (Fig. 3). In the case of fullerene solutions in a "bad" solvent (e.g., CCl_4), the attainable concentrations are lower those that for aromatic solvents by an order of magnitude, and only a decrease in the solution density is observed within the possible fullerene concentrations [11].

To evaluate the number of molecules of the structured solvent per fullerene molecule, we assumed that the whole solvent is structured at c_{str} for which the in-

tensity of the small-angle X-ray scattering is minimal. Simple calculations show that there are N_S ~70000 molecules of *p*-xylene per fullerene C_{60} molecule. Let us estimate the long-range action of fullerene molecule in *p*-xylene. At such low concentrations of C_{60} studied the volume of fullerene in solution can be neglected. The density of *p*-xylene under the ambient conditions is 0.8611 g cm^{-3} [7]. Using the Avogadro number for 1 mol of C_{60}, we can determine that the volume per fullerene molecule at its critical concentration in *p*-xylene of 0.01% is about 14×10^{-18} cm^3, which corresponds to a cube with an edge of 2.5×10^{-6} cm (25 nm); and this is the distance between C_{60} molecules at their uniform distribution. Thus, the long-range action of fullerene C_{60} in *p*-xylene covers approximately 25 nm.

In conclusion, we suggest the following mechanism of changes in the intensity of small-angle X-ray scattering with increasing fullerene concentration in the case of zero aggregation. On adding fullerene to a solvent, two competing trends are observed: (1) increase in the scattering intensity with the concentration of the electron density fluctuations,which occurs because fullerene generates additional stable fluctuations with a decreased electron density, and (2) decrease in the scattering intensity owing to suppression of the thermal density fluctuations in the solution bulk.

At small concentrations (~0.001%), the first process prevails. As a result, the scattering intensities slightly increase owing to the appearance of new scattering centers, namely, fullerene macromolecules surrounded by a lyophobic shell.

With increasing fullerene concentrations, the second mechanism becomes predominant. In this case, lyophilic shells of elevated density are formed around the lyophobic centers (2.5–3.0 mm in diameter), and the size of these shells increases with the fullerene density and reaches ~25 nm at the critical concentration c_{str}. Then, the lyophilic shells merge and the intensity of X-ray scattering decreases to a minimum. The concentration c_{str} is far from the saturation concentration, and the subsequent increase in the fullerene concentration does not affect the solvent, but the heterogeneity of the system again grows, causing the intensity of the X-ray scattering to increase. It should be noted that this increase is slower than that in the case of a simultaneous structuring of the solvent.

CONCLUSIONS

(1) Changes in the structure of *p*-xylene, toluene, and benzene in the presence of small amounts ($\leq 10^{-4}$%) of fullerene C_{60} were studied by small- and wide-angle X-ray diffraction analyses under ambient conditions. These changes are attributed to the suppression of the thermal fluctuations of the solvent density and to the ordering of the solvent on the molecular level.

(2) The X-ray diffraction data agree with the nonmonotonic variation of the solution density with the fullerene concentration.

(3) Based on experimental data, the mechanism of changes in the solvent structure under the action of fullerene on the supramolecular level was suggested.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Prediction of Separating Characteristics of Pervaporation Membranes by Inverse Gas Chromatography

Abstract—The potentiality of inverse gas chromatography to predict separating properties of pervaporation membranes is studied for the example of a membrane composed of a mixture of polyvinyl alcohol and polyacrylic acid. Correlation relationships between the retention time of substances and relative rate of their mass transfer across the membrane were derived. A comparative method for assessment of the membrane selectivity was suggested proposed, and its consistency was checked for pervaporation separation of methanol–methyl acetate–water–acetic acid, methanol–toluene, and ethanol–ethyl acetate mixtures, including those with an azeotropic composition.

DOI: 10.1134/S1070427208040101

Currently there is a steadily growing interest in energy-saving processes for separation and purification of organic mixtures. In this relation, membrane pervaporation is among the most promising processes. With highly permeable and selective membranes used, membrane processes could be well competitive with distillation, rectification, and evaporation [1–3]. Fabrication of a high-performance pervaporation membrane for a specific separation task is a very difficult problem. Even in the case of single-polymer or composite polymer membranes, prediction of the performance characteristics of the polymer material on the basis of sorption and permeation data may be inadequate and requires experimental confirmations in each particular case. Further problems arise in film formation, in determining their transport characteristics with respect to each penetrant, and in separation because of the insufficient efficiency on relatively thicker films. Making smaller the thickness of the selective layer on passing to composite or multilayer membranes even more complicates the system. In this case, decision on the membrane material and prediction of performance characteristics of the resulting membranes become very difficult, requiring development of some new approaches. Therefore, there is a need in easy and reliable methods for determination of the selectivity of membrane-forming polymers.

Inverse gas chromatography (IGC) is an old-established physicochemical method for characterization of polymers [4]. In this method, the polymer to be examined is applied to a sorbent to form a stationary phase. The method is widely used for determination of thermodynamic parameters characterizing polymer–solvent interactions [4, 5]. It has also been used to determine the glass transition temperature [6], crystallinity [7], phase transition temperatures in liquid-crystalline polymers [8], and supramolecular structure in microheterogeneous systems built by polyblock copolymers [9].

Roberts et al. [10] have employed IGC to predict thw separating characteristics of pervaporation membranes. They analyzed published data on the Kovats retention indices and McReynolds constants for several hundreds of stationary phases, chose those selective to components to be separated, examined their composition, and, finally, suggested to synthesize highly selective membrane-forming polymers with functionalities responsible for the desired specific interactions. This approach was used to solve the problem of separation of cyclohexane from cyclohexanol and cyclohexanone.

Moulay et al. [11] have employed IGC to determine the activity coefficients, Flory–Huggins parameters, and enthalpies and entropies of interaction of alcohols and their aldehydes with the membrane material (polydimethylsiloxane). Then they attempted to predict separating properties of pervaporation membranes on the basis of these data.

Park Hyun-chae et al. [12] have performed a similar study for polymer blends with various contents of polyvinyl alcohol (PVA) and polyacrylic acid (PAA), including determination of such thermodynamic characteristics as the activity coefficients and Flory–Huggins parameters.

A wide spectrum of polymers has been examined to select those promising as materials for fabrication of pervaporation membranes. The separation properties of polymers were determined by various methods, including IGC [13].

Previously, we have demonstrated the applicability of IGC to study of transport characteristics of cellulose ester membranes [14]. It was shown that the direction of selective mass transfer across the cellulose myristate (CM) membrane can be predicted from the IGC retention times corrected for the boiling points of components to be separated.

In this study, we applied the approach suggested in [14] to prediction of separation characteristics of PVA–PAA membrane. Further development of the approach was aimed at quantitative estimation of the membrane selectivity.

EXPERIMENTAL

In the experiments, we used PVA–PAA or CM to form a stationary phase of the packing in a chromatographic column and also to form a diffusion layer of the pervaporation membrane. Two kinds of the packing were prepared.

(1) An aqueous solution containing 80 wt % PVA and 20 wt % PAA was applied to Chromosorb W sorbent. The solvent was removed, and the packing was dried to constant weight at 110°C. The total polymer content of the packing was 10 wt %. With this packing, an 1-m-long chromatographic column (internal diameter 3 mm) was prepared for the subsequent use for determining the retention times of the components belonging to three homologous series (aliphatic alcohols, acetic acid esters, and aromatic hydrocarbons). The experiments were carried out at room temperature on a Tsvet chromatograph with a flame-ionization detector. The gas flow rates were as follows (ml min^{-1}): He 30, H_2 30, and air 300.

(2) Cellulose myristate was deposited from a dilute acetone solution onto Celite 22 support. The CM content of the packing was 10 wt %. With this packing, a 3-m-long chromatographic column (inner diameter 3 mm) was prepared. The experiments were carried out on an LKhM chromatograph with a thermal conductivity detector. The carrier gas (He) flow rate was 30 ml min^{-1}.

With both columns and for each component i, we obtained the concentration dependences of the retention time t_r on the peak height in the chromatogram, to determine the t_r^{15} values corresponding to the peak height of 15 cm (h_{15}) (15 cm is the half of the chart recorder scale).

Also, we prepared three kinds of pervaporation membranes with diffusion layers containing the test polymers.

(1) A composite membrane was formed by spraying 6 wt % aqueous solution of PVA–PAA (80 : 20) onto the working surface of a commercial UFM-20 ultrafiltration membrane (Vladipor), followed by drying to constant weight and heating at 110°C [this temperature corresponded to that of heat treatment of the stationary phase (column conditioning)].

(2) A homogeneous CM film (nonporous membrane) was formed by spraying a polymer solution onto the glass surface, followed by drying to constant weight.

(3) A composite membrane was prepared by applying a thin CM layer to the surface of commercial UPM-20 ultrafilter (Vladipor) according to the procedure described in [14].

The pervaporation characteristics of the membranes were determined in separation of methanol–toluene (70 wt % MeOH) and ethanol–ethyl acetate (74 wt % EtOH) mixtures at 40°C on a pervaporation unit with an effective membrane area of 12.4 cm^2. The pressure under the dry membrane (before pervaporation) was about 0.1 mbar. The pressure over the membrane was ambient. The feed solution and permeate were analyzed gas-chromatographically and refractometrically. The membrane selectivity was characterized by the partition factor $F_{i/j}$ defined as

$$F_{i/j} = (c_i/c_j)_p/(c_i/c_j)_f,$$

where $(c_i/c_j)_p$ and $(c_i/c_j)_f$ are the component concentration ratios in the permeate and feed solution, respectively.

The permeate flow across the membrane, Π (kg m^{-2} h^{-1}), was estimated from the effective surface area of the membrane and the amount of the permeate that passed across the membrane in a fixed time.

The permeates containing methanol–toluene and ethanol–ethyl acetate mixtures were analyzed on a column with 2% TCEP [1,2,3-tris(2-cyanoethoxy)-

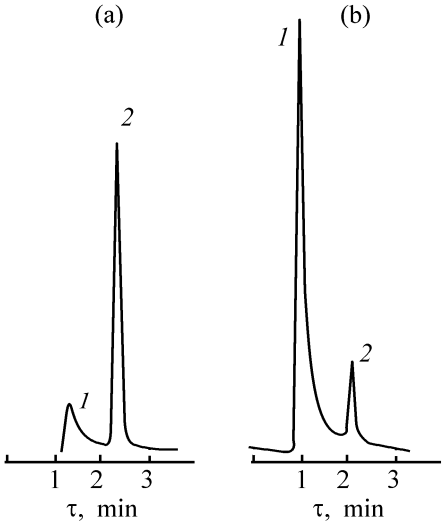

Fig. 1. Chromatograms obtained in separating methanol–toluene mixtures (column with TCEP stationary phase on Chromosorb P). (τ) Time (min); the same for Fig. 2. (a) Feed solution and (b) permeate; the same for Fig. 2. (*1*) Methanol and (*2*) toluene.

propane] on Chromosorb P. The methanol–toluene mixtures were separated at 80°C and carrier gas (He) flow rate of 60 ml min^{-1}; and the ethanol–ethyl acetate mixtures, at 60°C and 30 ml min^{-1}.

Quantitative analysis was carried out by the internal reference method, using the relative calibration coefficients K_c, which were estimated from data obtained for reference mixtures. The K_c values were obtained for methanol–toluene mixtures, for methanol (K_m) with respect to toluene ($K_t = 1$), and for ethanol–ethyl acetate mixtures, for ethyl acetate (K_{ea}) with respect to ethanol ($K_e = 1$). Therefore, the calibration coefficients were estimated as

$$K_m = \frac{q_m}{q_t}\frac{S_t}{S_m},$$

where q_t and q_m are the toluene and MeOH concentrations in the standard mixture (%), and S_t and S_m, toluene and MeOH peak areas, calculated from the chromatogram by multiplying the peak height h by the width at half-height $\omega_{1/2}$.

The chromatograms of the mixtures are shown in Figs. 1 and 2. The estimated K_m and K_{ea} values are listed in Tables 1 and 2, respectively.

To verify the estimated K_m values, we analyzed a standard methanol–toluene mixture (70/30 w/w). The compositions of the feed solution and permeate were calculated by the following relationships:

$$q_m = \frac{S_m K_m}{S_m K_m + S_t},\ q_t = \frac{S_t}{S_m K_m + S_t}.$$

The results obtained in several replicate experiments and averaged are listed in Tables 3 and 4.

The permeate composition in the system ethanol–ethyl acetate was determined similarly with allowance for K_{ea} (Table 5).

In quantitative chromatographic analysis of the permeates obtained in the system methanol–methyl acetate–water–acetic acid, the separation was carried out using two columns: water, methyl acetate, and methanol were determined on a Porapak-Q column; and acetic acid, on a column with 10 wt % Reoplex-400 on Celite 545. The concentrations were estimated using the absolute calibration method.

The background of this study is based on the assumption that two processes, pervaporation and gas chromatography of fluids, can be described using interrelated parameters, if polymers of the separating diffusion layers are physicochemically identical. There is good reason to believe that this basic assumption is valid, since both processes can be described in terms of the diffusion–sorption model. Among the abovementioned parameters are primarily those characteriz-

ing the separation selectivity. Therefore, we find correlations between the partition factor of the pervaporation membrane and retention time ratio of the components to be separated with allowance for their boiling points. If found, such a correlation would open the door for optimization of the membrane structure, to solve specific separation tasks.

In so doing, we measured the t_r^{15} values for each substance, using a column with PVA/PAA supported by Chromosorb W. Then we plotted a log–log dependence of t_r^{15} on the boiling point of the component T_b (Fig. 3). Such dependences were obtained for three homologous series. Figure 3 shows that the points obtained for homologous compounds fall on a straight line, with the line for the alcohols running above that for the esters, and the line for the esters, above that for the aromatic hydrocarbons. In a GC column, the retention time is controlled by both dispersion interactions and specific interactions of the eluent with the stationary phase. For a pair of compounds with the same boiling points, the longer the retention time of a compound, the higher the contribution of specific interactions and the higher the selectivity of the column with respect to this compound. Therefore, one may suggest that the higher the line runs in the plot, the more selective is the column with respect to the corresponding homologous series.

Figure 3 shows that the selectivity of the stationary phase increases in the order aromatic hydrocarbons < acetic acid esters < aliphatic alcohols. Since the separating properties of the membrane increase with its affinity for one of components to be separated, it may be suggested that, for the test polymers, the mass transfer rate will decrease on passing from the alcohols to aromatic hydrocarbons.

Predictions made on the basis of the IGC results (Fig. 3) are consistent with data on the selectivity of the composite membrane with PVA/PAA diffusion layer (PVA : PAA = 80 : 20), obtained in the pervaporation experiments on separation of such practically significant solvent mixtures as methanol–toluene and ethanol–ethyl acetate, among them those of the azeotropic composition [15, 16]. Results of a GC analysis of the initial methanol–toluene mixtures and corresponding permeates are summarized in Tables 3 and 4. Table 3 shows that the concentrations determined by the GC analysis are well consistent with those obtained with the standard mixture. Using the estimated $K_m = 7.74$, we performed a quantitative analysis of the initial methanol–toluene mixtures and permeates sampled in the course of pervaporation. The concentrations determined by GC and the estimated partition

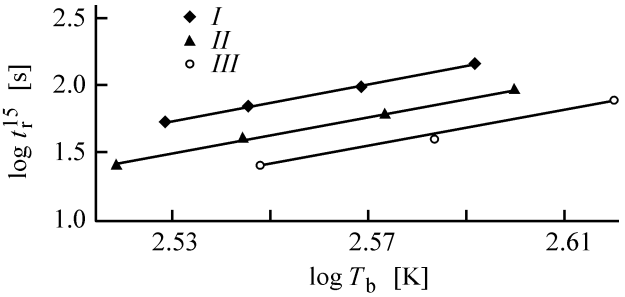

Fig. 3. t_r^{15} vs. the boiling point T_b, plotted in log–log coordinates for three homologous series: (*I*) aliphatic alcohols, (*II*) acetic acid esters, and (*III*) aromatic hydrocarbons.

factor are listed in Table 4. Similarly were determined the concentrations of the initial mixtures and permeates and the partition factor for the ethanol–ethyl acetate system (Table 5).

Tables 4 and 5 show that, indeed, the permeates are enriched in the alcohols, the effect being strongly pronounced for the mixture with the aromatic hydrocarbon, and only slightly for that with the ester. Therefore, the dependences plotted in Fig. 3 demonstrate a high prognostic power, allowing prediction of what component pairs can be separated on a given polymer membrane.

Furthermore, these plots allow comparative assessment of the selectivity of the polymeric material. With this purpose, one has to connect points corresponding to the retention times of the test components with the origin and to estimate the slope of the resulting curves (tan α). The larger the slope, the higher the selectivity of the polymeric material with respect to this compound, and the more readily it will pass across the membrane.

Table 6 shows the slopes obtained for the components of two mixtures to be separated. The slope for methanol is larger than that for toluene, and the slope for ethanol is larger than that for ethyl acetate. There-

fore, methanol and ethanol will pass across the membrane more readily than toluene and ethyl acetate, respectively. In other words, our results show that the selectivity of the membrane can be judged from a comparison of the slopes of the lines connecting the origin with the points corresponding to the components to be separated.

We applied the above approach to predict the separating characteristics of CM membrane with respect to the mixture methanol–methyl acetate–water–acetic acid, which is formed in methanol esterification. The t_r^{15} values for each component of the mixture are plotted in Fig. 4 in the coordinates log t_r vs. log T_b, and the slopes tan α are listed in Table 7.

Table 7. Slopes tan α for components of the system methanol–methyl acetate–water–acetic acid

Component	T_b, K	t_r, s	tan α
Methanol	337.96	24.80	48.5
Methyl acetate	329.3	27	81.32
Water	373	27.50	20.07
Acetic acid	390.7	28	15.76

Table 8. Chromatographic analysis of the mixture methanol–methyl acetate–water–acetic acid

Sample	Membrane	Composition, wt %			
		methyl acetate	methanol	water	acetic acid
Initial mixture	–	54.1	16.7	11.6	17.6
Permeate I	Nonporous film	92.4	4.8	1.3	1.5
Permeate II	Composite	85.2	7.6	5.1	2

Based on tan α, it may be suggested that it is acetic acid that is the component most readily penetrating across the CM membrane. Results of a GC analysis of the permeates obtained in separating the indicated quaternary system on two CM membranes (homogeneous and composite) are listed in Table 8. In both cases, the permeates are enriched in methyl acetate, but strongly depleted of acetic acid. The water and methanol contents of the permeates also decrease as compared to the initial mixture, the effect being more clearly pronounced for water, which correlates with the slopes.

Therefore, to predict the separating properties of a polymeric pervaporation membrane using IGC, there is no need to obtain chromatographic data for all the members of a homologous series. It is sufficient to measure the retention time for two or more components of interest and to estimate the slopes of the straight lines connecting the origin with the points corresponding to these components in the coordinates log t_e–log T_b. The results will show whether the mixture can be separated on a given polymeric material.

To check the above procedure for consistency, we analyzed the results of [11]. The specific retention volumes of alcohols and aldehydes were obtained in [11] by IGC using PDMS (polydimethylsiloxane) as a stationary phase. We plotted these results as log V_r vs. log T_b (V_r is directly proportional to t_r) (Fig. 5) and calculated the slopes (Table 9). Table 9 also shows the activity coefficients at infinite dilu-

Table 9. Slopes tan α obtained to predict the selectivity of PDMS membrane with respect to alcohols and aldehydes

Component	T_b, K	V_r, ml	tan α	ln γ^∞	χ_i
n-Propanol	370.2	118.91	30.40	3.97	2.57
Propionaldehyde	321.8	70.60	243.60	2.05	1.05
n-Butanol	390.5	231.67	25.82	4.14	3.14
Butyraldehyde	347.7	126.18	51	2.37	1.37

tion, γ^∞, and Flory–Huggins parameters χ_i, obtained at 40°C.

It follows from Table 9 that the calculated tan α increases in the order *n*-butanol < *n*-propanol < butyraldehyde < propionaldehyde, suggesting that the column is more selective with respect to propionaldehyde, and that the permeability should decrease in the order propionaldehyde > butyraldehyde > *n*-propanol > *n*-butanol. The authors of [11] judged the membrane permeability from the thermodynamic characteristics obtained by IGC and characterizing the interaction of the alcohols and aldehydes with PDMS. The permeability decreases in the order propionaldehyde > butyraldehyde > *n*-propanol > *n*-butanol, which is consistent with the order we predicted using two different approaches.

CONCLUSIONS

(1) Method developed for predicting the separating characteristics of pervaporation membranes on the basis of inverse gas chromatographic data can be recommended for characterization of any soluble membrane-forming polymers.

(2) The method suggested for quantitative assessment of the selectivity of polymers in separation of various mixtures of liquid penetrants allows prediction of the direction of their mass transfer across the membrane.

Abstract—Decomposition of ozone on commercial and pilot filtering microfibrous materials based on polymers, glass fibers, and carbonized polymeric fibers was studied.

DOI: 10.1134/S1070427208040113

In view of the wide use of ozone in chemical and pulp-and-paper industries, microelectronics, water treatment, and medicine, a topical issue is development of methods for decomposition of excess ozone, including those to be used in individual and collective means for protection of the human respiratory system in those case when the maximum permissible concentration (MPC) of ozone in air is exceeded. Ozone is commonly decomposed with heterogeneous catalysts containing metals, such as Cu, Mn, Co, Fe, Ni, Ti, and Ag, and their oxides in various ratios [1]. Combined filters have also received recognition. These filters contain, in addition to catalysts, various sorbents and fibrous materials: glass fibers, carbon fibers [2, 3], and polymeric materials used both as porous supports and as active ozone-binding reagents [4–7]. Ozone is bound with various cyclic polymers: polyarene esters and sulfur-containing polymers [4], thioesters [5, 6], unsaturated polycycloolefins, and nonbornene and its higher homologues: nonbornodiene and dicyclopentadiene [5, 6]. An ozone-binding polymer can be used in a combined filter as a powder, grains, films, coatings, and finely fibrous materials. An advantage of fibrous materials is their low hydrodynamic resistance, developed surface equally accessible to ozone molecules, and room working temperatures. At present, fibrous filtering materials are efficiently used to catch aerosol particles. Industrially manufactured polymeric microfibrous materials, Petryanov filters (PF), are in common use [8, 9]. These materials are readily available and inexpensive.

A topical task is to create fibrous filtering materials for air purification to simultaneously remove aerosols and gaseous impurities. So far, several brands of materials for catching of radioactive iodine and oxidation of carbon monoxide have been developed and studies are being performed to develop new sorption-filtration materials [10–12]. It is of interest to find out whether PF and other fibrous filtering materials can be used to bind ozone. A separate issue is a search for ozone-resistant filtering materials for air purification to remove aerosol impurities in the presence of high concentrations of ozone.

The aim of this study was to examine decomposition of ozone on microfibrous filtering materials of various types in the context of the problems mentioned above. As objects of study served commercial filtering materials and pilot materials synthesized at the laboratory of aerosols at Karpov Research Physicochemical Institute.

EXPERIMENTAL

Industrial Petryanov filters [FPA-15-2.0,[1] FPP-70-0.5 (EKhMZ, Elektrostal', Moscow oblast); FPSAN-70-0.5 (Esfil, Simolaye, Estonia)], pilot materials (FPAN-10-3.0, FPF42-10-3.0, FPS-15), ultrathin glass fibers, and carbonized microfibers were studied.

All the FP samples, except glass fibers, were fabricated by electroforming [8, 9, 13]. Carbonized fibrous materials were produced by carbonization of

[1] The first figure in the designation of a filter is the average fiber diameter in tenths of a micrometer, and the second figure is the resistance to an air flow in millimeters of water at a flow velocity of 1 cm s^{-1}.

Table 1. Parameters of the microfibrous filtering materials under study

Material	Composition	Average fiber diameter, μm	Packing density, %	Specific surface area, $m^2 g^{-1}$
FPP-70-0.5	Chlorinated polyvinyl chloride	5–7	2.5	0.7
FPA-15-2.0	Cellulose diacetate	1.4	2.5–3	1.3
FPAN-10-3.0	Polyacrylonitrile	1.0	3–4	Not measured
FPF42-10-3.0	Copolymer of tetrafluoroethylene with vinylidene fluoride	1.0	3–4	″
Glass fibers	Silicon, boron, aluminum, and calcium oxides	0.2	5	″
FPSAN-70-0.5	Copolymer of styrene wit acrylonitrile	5–7	2–4	0.67
FPS-15 (pilot sample)	Polystyrene	1.5	3	1.83
Carbonized fibers	Carbon	2.0	4–5	1.56

microfibers composed of a phenol-formaldehyde resin [12]. The specific surface area of the samples was determined by the BET method on the basis of adsorption of krypton, using the standard procedure [14]. Some parameters of the materials are listed in Table 1.

The decomposition of ozone on microfibrous materials was studied using the flow-through method [15]. A gas with a known content of ozone was passed through a tube with a material under study. The change in the content of ozone after passing the gas through the tube was used to find the amount of bound ozone. The initial mass of the samples under study was 0.2 g. A tube with an inner diameter of 0.4 cm was densely packed with the material, with a 5–7-cm-long layer obtained. Ozone was produced by the electrolysis method [16]. The concentration of ozone was found by iodometric titration, with optical UV spectroscopy used in separate experiments.

The experimental setup used in the study is schematically shown in Fig. 1. Electrolyzer *1* is made of molybdenum glass. As electrolyte *2* serves a $NaClO_4$ solution. Pt-electrode *3* serves as the anode, and Ni-electrode *4*, as the cathode. Ozone-containing oxygen is liberated at the Pt-electrode, and hydrogen, at the Ni-electrode. The anode and cathode spaces are separated by ion-exchange membrane *5*. To prevent warming-up of the electrolyte, the electrolyzer is cooled with tap water (jacket *6*). Ozone-containing oxygen is delivered from the electrolyzer into fluoroplastic tube *9* packed with the material under study, passes optical cuvette *10*, and comes to a flask with a KI solution *11*. The parts of the setup are connected by fluoroplastic tubes. The loss of ozone on this ma-

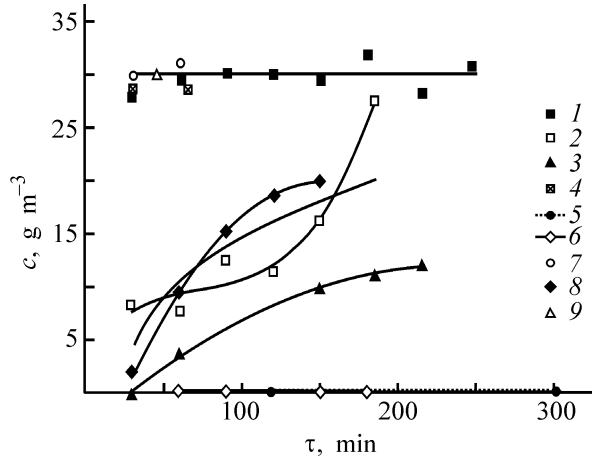

Fig. 3. Ozone concentration *c* after passing ozone-containing oxygen trough the layer of a material vs. time τ. (*1*) Empty tube, (*2*) FPP-70-0.5, (*3*) FPA-15-2.0, (*4*) FPAN-10-3.0, (*5*) FPS-15, (*6*) FPSAN-70-0.5, (*7*) glass fibers, (*8*) carbonized fibers, and (*9*) FPF42-10-3.0.

terial is insignificant because it has a small coefficient of heterogeneous decomposition of ozone [1, 17]. The tubes used in the experiments were treated with ozone for 1 h for passivation.

A UV spectrum of the ozone being formed, measured with a Perkin Elmer UV spectrometer in the range 2000–4000Å, is shown in Fig. 2. In this spectral range, only the characteristic absorption band of ozone, peaked at 2540 Å (Hartley band [18]), is present. It also follows from Fig. 2 that no chlorine dioxide (absorption band peaked at 3600 Å [18]) is formed in electrolysis of the $NaClO_4$ solution.

The content of ozone in oxygen increases with the current through the electrolyzer. The electrolyzer can produce and ozone–oxygen mixture containing 20.6 to 33.2 g m^{-3} of ozone as the current strength is varied from 296 to 550 mA. The corresponding flow rate of the ozone–oxygen mixture varies within the range 1.22–2.27 ml min^{-1}. The experiments were performed at a current strength of 510 mA. In this case, the flow rate of the ozone–oxygen mixture was 2.0 ± 0.1 ml min^{-1}. The electrolyzer was calibrated by measuring the amount of ozone absorbed by the KI solution at the outlet of an empty fluoroplastic tube of the same size as that with the material under study. The amount of ozone absorbed at this current in the course of 30 min in each of the several runs corresponded to an ozone concentration of 30 ± 2 g m^{-3} or to a content of about 1.5 vol %. The error in determining the ozone concentration is due to a minor instability in the current through the electrolyzer at a stabilized voltage across the electrodes. On absorbing ozone, the KI solution became first yellow, and then brown. In the course of the experiments, the solution was titrated, with monitoring by changes in coloration.

Figure 3 shows how the average concentration of ozone (during sampling) at the tube outlet varies with time. Straight line *1* shows the ozone concentration at the outlet of an empty tube. It can be seen in Fig. 3 that, with FPSAN-70-0.5 (points *6*) and FPS-15 (points *5*) filters, there is no ozone at the tube outlet for 6–7 h. For glass fibers (points *7*) and FPF42-10-3.0 (points *9*) and FPAN-10-3.0 (points *4*) filters, the ozone concentration at the tube outlet is the same as that in the case of an empty tube. For FPP-70-0.5 (points *2*) and FPA-15-2.0 (points *3*) filters and carbonized fibers (points *8*), a noticeable concentration of ozone is observed at the tube outlet, but this concentration is considerably lower than that observed with an empty tube.

On the basis of the data presented, all the materials studied can be divided into three groups: (i) materials inert toward ozone, on which the conversion of ozone is lower than 10% during a whole day of operation; (ii) active materials providing an ozone conversion exceeding 90%; and materials with an intermediate activity. On the materials of the third group the ozone conversion decreases during the first hours of operation.

The most active in ozone decomposition are polystyrene-containing materials: FPSAN-70-0.5 and FPS-15. These materials were used in experiments in which their activity was studied as a function of the duration of treatment with ozone. The results of seven successive runs with FPS-15 are shown in

Fig. 4. The experiments were carried out during a working day, with intervals between the runs equal to 12 to 48 h. It can be seen that, during the first three runs, the filter bound the whole amount of ozone delivered to the filter. At the end of run no. 4, a measurable ozone concentration appeared at the tube outlet (curve *4*). At the beginning of run no. 5, the ozone conversion was about 100% during 4 h and decreased to 80% by the end of the day (curve *5*). A similar behavior was also observed in the subsequent runs. By the end of run no. *7*, the conversion decreased to 50%. Similar results were obtained with FPSAN-70-0.5 filter, but its activity decreased considerably faster than that of FPS-15 filter, which may be due both to the lower specific surface area of FPSAN-70-0.5 (Table 1) and to the presence of acrylonitrile inert toward ozone in this filter. The results obtained demonstrate that the activity of the polymer with respect to ozone decomposition decreases (poisoning) both irreversibly and reversibly. The irreversible poisoning occurs via chemical reactions between a polymer and ozone, with chemical bonds in the polymer ruptured [15, 19]. The reversible poisoning may be due to formation of intermediate oxygen-containing compounds on the surface, which prevent adsorption of ozone. In a break in operation, these compounds partly decompose.

On the materials with an intermediate activity, the ozone decomposition was studied in detail on carbonized microfibers of phenol-formaldehyde resin. Four successive runs were made. Their results are shown in Fig. 5. In run nos. 1 and 2, the conversion decreased from 100 to 30% in 2 h of operation (curves *1*, *2*), but in run no. 2, the conversion gradually increased to 50% in the following 4 h. After a break of 4 days in run no. 3, a strong increase in activity was observed, so that the conversion was close to 100% during 7 h and then decreased to 80% (curve *3*). The next day, such a decrease in conversion occurred earlier (curve *4*). Thus, a complicated variation of activity was observed on carbonized fibers: under the action of ozone, the material of the filter is first deactivated and then activated. Possibly, the activation is partly due to loosening of the carbonized filter under the action of ozone and to an increase in its specific surface area.

Table 2 summarizes the results obtained in a study of the ozone treatment of microfibrous filtering materials with high and medium activity: data on the amount of ozone bound by a filter until its conversion decreases to below 90% and the corresponding duration of filter operation. A 0.2-g sample of FPS-15 filter worked for 40 h until the conversion reached

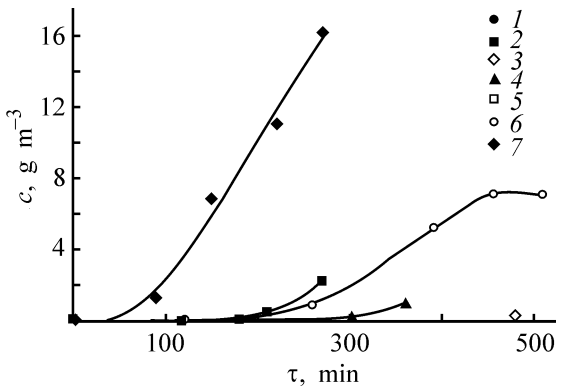

Fig. 4. Ozone concentration c after FPS-15 filter vs. time τ. *Digits at points* are run numbers.

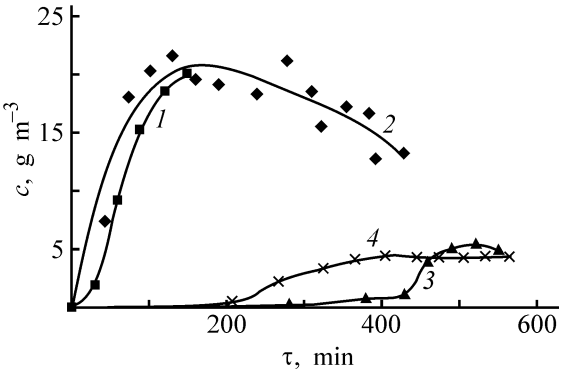

Fig. 5. Ozone concentration c after a layer of carbonized fibers vs. time τ. *Digits at points* are run numbers.

90% (inlet concentration 1.5%), with 0.15 g of ozone decomposed. The concentration of ozone in air at an MPC exceeded by an order of magnitude [19] is 4×10^{-5}%, i.e., a value four orders of magnitude lower than that in the experiments performed in this study. Under these conditions, the filter will provide a high conversion during a virtually unlimited time. This also refers to FPSAN-70-0.5 and FPA-15-2.0 filters.

Table 2. Experimentally observed efficiency of ozone catching by the materials under study

Material	Mass of ozone bound by a sample,* g	Duration of filter operation,* h
FPS-15	0.144	40
FPSAN-70-0.5	0.088	25
FPA-15-2.0	0.0066	2
Carbonized fibers	0.0018	18

* At an ozone conversion exceeding 90%.

CONCLUSIONS

(1) Analysis of the ozone decomposition on commercial and pilot filtering materials shows that filters based on polystyrene (FPS-15, FPSAN-70-0.5) exhibit a high activity in ozone binding; FPF42-10-3.0 and FPAN-10-3.0 filters and glass fibers are inert toward ozone; FPP-70-0.5 and FPA-15-2.0 filters and carbonized microfibers possess an intermediate activity.

(2) The activity of the polymeric filters decreases under the action of ozone and is partly restored in its absence. The activity of carbonized filters increases upon treatment with ozone.

(3) Carbonized fibers show a complicated variation of activity in ozone binding.

ACKNOWLEDGMENTS

The authors are grateful to E.M. Kasatkin and N.F. Potapova for the provided technique for production and titration of ozone and for detailed consultations in the course of the study and to N.V. Kozlova for measuring the UV absorption spectrum of ozone.

The study was financially supported by the International Scientific-Technological Center (grant no. 3288).

Abstract—Anodic dissolution of niobium in anhydrous methanol in the presence of sodium methylate was studied. A method for recovery of niobium methylate from sodium hexamethoxyniobate by the reaction with ammonium chloride was developed.

DOI: 10.1134/S1070427208040125

The permanent need of the electronic industry in high-purity materials and, in particular, special-purity niobium used in manufacture of niobium slug capacitors enforces a search for new methods for its production and purification. Of particular interest are purification of niobium to remove admixtures of other metals and recovery of pure niobium from the raw metal and alloys. The most promising for this purpose is the electrochemical way to obtain metal alkoxides, followed by their separation. The electrochemical synthesis of niobium alkoxides has been considered previously [1, 2]. A similar method can be used to produce not only simple alkoxides, but also complex compounds, e.g., sodium hexamethoxyniobate $NaNb(OMe)_6$, whose specific properties can serve as a basis for development of a new method for recovery of pure niobium from niobium-containing alloys.

The available published data for this compound are rather scarce. This compound was first obtained by a chemical reaction of sodium and niobium methylates [3]. The principal properties of the substance were described and the electrical properties of its solutions were reported. The existence of $[Nb(OMe)_6]^-$ ions was also demonstrated in [4] by conductometric titration. No evidence about the electrochemical method for synthesis of complexes of this kind could be found in the literature.

In this study, the possibility of obtaining the sodium-niobium methoxy complex by the electrochemical method was considered and its properties and formation mechanism were analyzed.

EXPERIMENTAL

Because, according to [5], the synthesis of alkoxides is sensitive to presence of moisture, methanol of chemically pure grade used in the study was subjected to additional drying by boiling with magnesium shavings [6]. The final content of water was less than 0.01%. LiCl used in the study was also of chemically pure grade. Lithium chloride was dried by calcination at 350°C for 5 h. Sodium methylate was obtained by a direct reaction of metallic sodium (chemically pure) with methanol. The anodes were made of niobium of Nb-1 brand [GOST (State Standard) 16099–80].

Experiments were performed in a diaphragmless electrolyzer having the form of a 90-cm^3 glass cylinder equipped with a thermostating jacket and a cock at the bottom for discharging the electrolyzate. The electrolyzer was hermetically closed with a cover into which a thermometer, gas-discharge pipe with a calcium chloride packing, and current leads to the electrodes were inserted. The niobium anode was mounted below the cathode at a distance of 0.5 cm.

The working area of the anode was 8 cm^2. The cathodes were made of a platinum wire 1 mm in diameter and had a working area of 24 cm^2. Prior to each electrolysis, the electrodes were trimmed and degreased

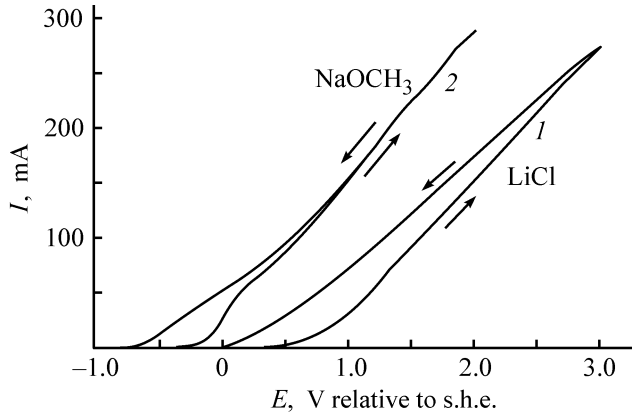

Fig. 1. Voltammetric curves obtained on Nb in 1 M solutions of (*1*) LiCl and (*2*) $NaOCH_3$ in methanol. Temperature 25°C, potential sweep rate 0.2 V s^{-1}; the same for Figs. 2, 3. (*I*) Current and (*E*) potential; the same for Figs. 2, 3.

with Vienna lime, washed with water, and weighed. After an experiment was complete, the electrolyzate was discharged into a leak-proof flask for further processing. The amount of the dissolved metal was found from the loss of mass by the anode.

To isolate niobium pentamethoxide (methylate), the alcohol was evaporated from the electrolyzate and then the product was extracted from the still bottoms with hexane. After the extractive agent was evaporated, a light yellow liquid that crystallized upon cooling remained in the flask. The resulting yellowish crystals had mp 61°C.

Sodium hexamethoxyniobate was isolated by evaporation of the alcohol from the electrolyzate and washing of the remaining white needle-like crystals with hexane.

The content of sodium methylate in the still bottoms was found by their dissolution in water and titration of the resulting solution with an alkali. The content of niobium in the still bottoms was found by their dissolution in water, addition of an acid, and gravimetric determination of the precipitated niobium pentaoxide.

Voltammetric measurements were made with an IPC computer-controlled electronic potentiostat in a 45-cm^3 cylindrical diaphragmless glass cell equipped with a thermostating jacket. Electrodes and a gas-discharge pipe were inserted into the cell cover. The electrode system comprised a niobium stationary working electrode with an area of 0.5 cm^2, platinum auxiliary electrode, and silver chloride reference electrode.

For measuring the anodic polarization curve, an electrolyte solution of a required concentration was poured into the cell and bubbled with dried argon via the gas-discharge pipe for 0.5 h. Then the required temperature was set and a trimmed electrode was placed in the cell and polarized in accordance with the preset program.

$NaNb(OMe)_6$ was synthesized as follows. Prior to electrolysis, the niobium anode was thoroughly degreased and weighed. The electrolyzer was charged with an electrolyte solution [1.1 g of $NaOCH_3$ in 90 ml of methanol (0.54 M solution)]. The content of moisture in the solution was less than 0.05 wt %. The electrolysis was performed at a constant current strength of 1 A and temperature of 18–20°C. In the course of electrolysis, the solution remained transparent, with the electrolyzer voltage equal to 10 V at the beginning of a run and increasing to 11 V by its end. In 7 h 16 min, the current was switched off and the niobium anode was weighed. The loss of mass by the anode was 4.14 g, which corresponds to a 89% current efficiency by pentavalent niobium. Methanol was evaporated from the electrolyzate under a reduced pressure (15 mm Hg). A white crystalline substance identified as $NaNb(OMe)_6$ remained in the still bottoms.

A known method for obtaining alkoxides of the aliphatic series consists in anodic dissolution of a metal in an appropriate alcohol containing a supporting electrolyte that makes the system electrically conducting [1]. Previously, a method for synthesizing niobium pentamethoxide by dissolution of a niobium anode in methanol in the presence of lithium chloride has been developed. With certain conditions satisfied, niobium pentamethoxide can be obtained with a current efficiency exceeding 95% [2].

A study of the influence exerted by the nature of a supporting electrolyte on the niobium dissolution potential in methanol solutions by cyclic voltammetry (CVA) revealed an anomalously high dissolution rate of niobium in the presence of sodium methylate. Figure 1 shows CVA curves for niobium dissolution in the presence of lithium chloride and sodium methylate. It can be seen from the CVA curve that, in the presence of $NaOCH_3$, the onset of niobium dissolution is shifted to the region of negative potentials by approximately 750 mV. Because of this circumstance, the current of anodic dissolution of niobium at a potential of 1 V in the presence of $NaOCH_3$ exceeds that in the presence of LiCl by more than a factor of 2. The so pronounced shift of the niobium dissolution potential may indicate that niobium ions formed at the anode are bound into a stable complex.

Results of a preparative synthesis of sodium hexamethoxyniobate ($NaOCH_3$ concentration 0.5 M, voltage 6–11 V, current density 0.125 A cm^{-2}, temperature 25–30°C)

Run no.	Na : Nb molar ratio	Current efficiency by Nb(V)	Yield of $NaNb(OMe)_6$	Fraction of niobium bound into sodium hexamethoxyniobate	Yield* of $Nb(OMe)_5$
		%			
1	1 : 1	99.9	99	99	0
2	1 : 2.5	98.8	97	41.6	55.3
3	1 : 5	97.2	98	18.9	79.09

* Isolated by extraction with hexane after the evaporation of methanol.

The occurrence of two anodic processes is the most clearly reflected by the voltammetric curve obtained in the presence of lithium chloride with a minor addition of lithium methylate (Fig. 2). It can be seen that, in this case, the dissolution of niobium begins at a more negative potential, a region of limiting currents appears, and the onset of the second reaction is observed when the niobium dissolution potential in the presence of lithium chloride is reached. It follows from the voltammetric curve obtained in the presence of the methoxy complex (Fig. 3) that the niobium dissolution potential lies in the intermediate region between the dissolution potentials in the presence of $NaOCH_3$ and LiCl. However, the process rate is lower.

The data obtained suggest that, in anodic polarization of the niobium electrode, the dissolution of the metal is substantially facilitated in complexation with methylate ions, whereas the reaction with chloride ions is more hindered, which leads to an increase in the potential. In the absence of ions reacting with niobium, the dissolution rate is lower.

In contrast to the process of electrosynthesis of niobium pentamethoxide in the presence of lithium chloride, in which both anodic and cathodic reaction products are involved and niobium methylate is formed in the solution bulk upon their mixing [2], the hexamethoxy complex is probably formed directly at the anode in the course of the anodic reaction

$$Nb + 6OMe^- \xrightarrow[-5e]{} [Nb(OMe)_6]^-.$$

The preparative electrolyses performed in the study with 0.1 M NaOMe as a supporting electrolyte demonstrated that niobium is converted to the pentavalent state in a nearly quantitative yield, but no free niobium pentamethoxide is formed until the concentration of Nb(V) in solution reaches a value of 0.1 M. Niobium pentamethoxide starts to appear only after the Nb : Na molar ratio in solution exceeds 1 : 1 (see table).

Sodium hexamethoxyniobate is stable in a methanol solution; however, a similar compound with the ammonium cation does not exist. On the basis of this property, the compound obtained in this study was used to isolate niobium methoxide by the exchange reaction

$$NaNb(OCH_3)_6 + NH_4Cl \rightarrow Nb(OCH_3)_5 + NaCl\downarrow + CH_3OH + NH_3\uparrow.$$

The reaction was performed in a methanol solution of the complex to give niobium pentamethoxide in 87% yield.

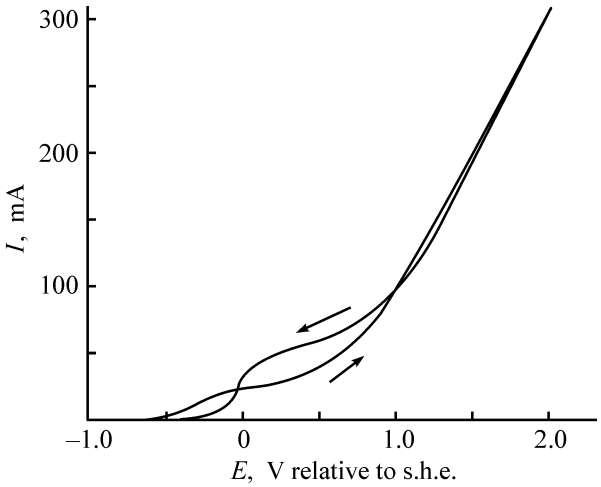

Fig. 2. Voltammetric curve obtained on Nb in a 1 M solution of LiCl in methanol containing 0.1 M $LiOCH_3$.

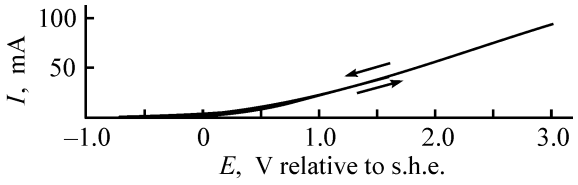

Fig. 3. Voltammetric curve obtained on Nb in a 1 M solution of $NaNb(OCH_3)_6$ in methanol.

Sodium hexamethoxyniobate is formed as white thin needle-like crystals. The substance is well soluble in methanol and insoluble in benzene and hexane. The methanol solution is electrically conducting, which indicates that this compound dissociates by the equation

$$NaNb(OMe)_6 \rightarrow Na^+ + [Nb(OMe)_6]^-.$$

An elemental analysis and calculation gave the following:

Found, %: Na 7.4, Nb 30.6.

$NaNb(OMe)_6$.

Calculated, %: Na 7.6, Nb 30.79.

Crystalline sodium hexamethoxyniobate is comparatively well soluble in water to give a weakly opalescent solution that is stable at room temperature. Evaporation of water yields coarse cubic crystals containing no carbon. Presumably, such a behavior is accounted for by instantaneous hydrolysis to give a hydroxo complex $NaNb(OH)_6$, which is well soluble in water and insoluble in a water–methanol solution.

The possibility of obtaining a compound stable in aqueous solution may be of interest for separation of niobium from admixtures of other metals.

CONCLUSIONS

(1) Sodium hexamethoxyniobate $NaNb(OMe)_6$ was electrochemically synthesized for the first time.

(2) It was demonstrated that the anodic dissolution of niobium is substantially facilitated in the presence of sodium methylate as a supporting electrolyte, compared with solutions containing lithium chloride, because of the formation of complexes with methylate ions directly in the anodic process.

(3) It was shown that pure niobium methoxide $Nb(OMe)_5$ can be obtained in the reaction of the $NaNb(OMe)_6$ formed with ammonium chloride.

(4) It was demonstrated that a water-soluble hydroxo complex $NaNb(OH)_6$ is formed in hydrolysis of $NaNb(OMe)_6$.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Effect of Amalgamation on the Passivation of Transition Metals in Their Anodic Dissolution in Tetrahydroadipic Acid Solutions

Abstract—Effect of anode amalgamation on the degree of passivation of the electrodes and on the current efficiency in electrosynthesis of coordination compounds of copper(II), nickel(II), zinc(II), and cadmium(II) with galactaric acid was studied. An improvement of anodic synthesis characteristics was observed when amalgamated zinc, copper, and cadmium were used. Complex compounds of 1 : 1 composition were obtained and the structure of the coordination environment of the metal ion was determined by IR spectroscopy.

DOI: 10.1134/S1070427208040137

In some cases, the anodic dissolution of transition metals in solutions of various organic substances is accompanied by the formation of coordination compounds. The method of anodic synthesis [1, 2] is a rather widely used preparative technique for synthesis of coordination compounds, which can yield substances that are occasionally different in composition from those chemically synthesized. However, this method frequently encounters difficulties associated with the anode passivation by poorly soluble reaction products with low electronic conductivity. This leads to a decrease in the current density in the course of synthesis and strongly decelerates the process. Researchers' efforts in this area have been focused on solving the problem of premature passivation of electrodes. In [3], a method based on application of an asymmetric ac current with pulses with various duty factors was described. The group headed by Kharisov successfully used an ultrasonic treatment of the reaction cell for this purpose [4]. In the present study, it is suggested to use as anodes amalgamated electrodes having a semiliquid surface with a high slip coefficient, on which poorly soluble compounds are more difficultly fixed, compared with ordinary metallic anodes. Moreover, many metals used as anodes in electrosynthesis are readily amalgamated and well soluble in mercury [3–7].

The effect of amalgamation of anodes on their passivation was studied in solutions of tetrahydroxyadipic and galactaric acid (H_2Gala), which is a dibasic tetraoxyacid, a product of galactose oxidation at aldehyde and terminal alcoholic groups, used in medicinal and pharmaceutical industries. The main difficulty in obtaining salts of galactaric acid is its low solubility both in water and in organic solvents, which is due to the existence of strong intermolecular hydrogen bonds.

The aim of this study was to synthesize copper(II), nickel(II), zinc(II), and cadmium(II) galactarates and examine the effect of amalgamation of anodes made of these metals on the degree of their passivation in galactaric acid solutions.

EXPERIMENTAL

A solution of galactaric acid (Merck) was prepared by dissolving its precisely weighed portion. A solution of lithium perchlorate of chemically pure grade was used as a supporting electrolyte. The electrodes were amalgamated by keeping them in a saturated solution of $Hg_2(NO_3)_2$ under agitation.

Galactarates of *d*-metals were synthesized in an aqueous solution of galactaric acid in a two-electrode cell under permanent agitation, with metallic and amalgamated electrodes serving as soluble anodes. Prior to synthesis, the solution was bubbled with argon to remove electrically active oxygen. The electrolyzer voltage in synthesis was 10 V, and the initial concentrations of galactaric acid and the supporting electrolyte were 0.01 M. A VS-24m dc power source served as a voltage source. The areas of the metallic and corresponding amalgamated anodes submerged in the solution were the same, as also the distance between the cathode and the anode. The current density in electrosynthesis was 0.5–1.0 mA cm^{-2}.

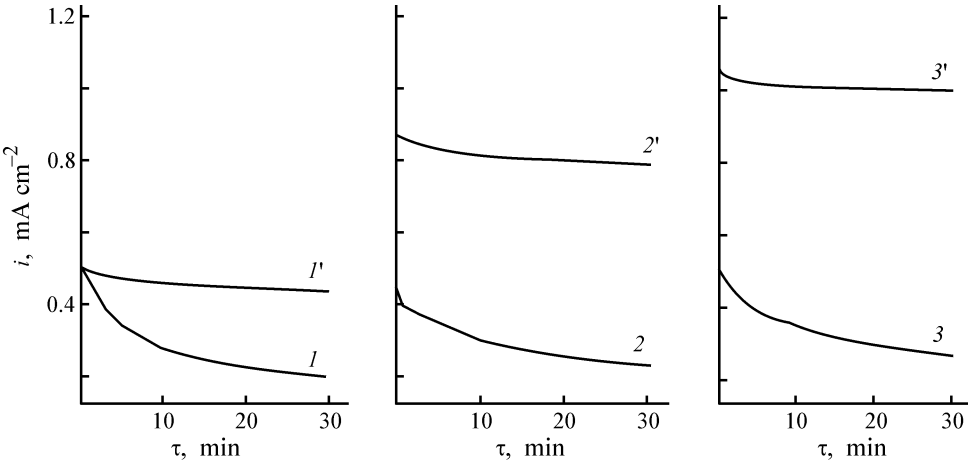

Fig. 1. Current density i vs. the electrolysis time τ with (*1'–3'*) amalgamated and (*1–3*) unamalgamated anodes. (*1*, *1'*) Cu, Cu (Hg); (*2*, *2'*) Zn, Zn (Hg); and (*3*, *3'*) Cd, Cd (Hg).

The following processes occur at the electrodes in the course of synthesis:

$$\text{A: } M - 2e \rightarrow M^{2+} \text{ or } M(Hg) - 2e \rightarrow Hg + M^{2+},$$

$$\text{K: } H_2Gala + 2e \rightarrow H_2\uparrow + Gala^{2-}.$$

The pH value was not monitored in the course of synthesis because introduction of a buffer solution into the cell would deteriorate the purity of the experiment via influence of foreign ions on the course of the process and on the composition of the compound being formed. In the course of a synthesis, the current strength was recorded and the time dependence of the current density, which reflects the degree of anode passivation, was plotted.

An anodic synthesis yielded poorly soluble solid copper(II), nickel(II), zinc(II), and cadmium(II) galactarates, which were then filtered-off under a vacuum and dried in a desiccator over phosphoric anhydride to constant weight. Near- and mid-IR spectra of the compounds synthesized were recorded on an INFRALYuM-FT-02 Fourier spectrometer at wave numbers of 4000–400 cm^{-1}. The samples for spectral measurements were prepared by compaction under a vacuum (residual pressure 5 mm Hg, pellets with 1 mg of a sample and 100 mg of KBr). The mass fraction of a metal was determined by complexonometric titration [8]. The composition was confirmed by gasvolumetric elemental analysis for C and H.

The thermal stability of the substances obtained was determined by thermogravimetric analysis on an MOM derivatograph at a heating rate of 10 deg min^{-1}, with calcined aluminum oxide as a reference and filler. The heating time was 100 min, and the final temperature, 1000°C.

The effect of amalgamation of the anodes on the degree of their passivation, which characterizes the variation of the electrosynthesis rate, was monitored by the decrease in the current density in the course of synthesis. The smaller the degree of passivation of the anode, the lesser the extent to which the current density decreases in the course of the process. It can be seen from the plots of the current density against the electrolysis duration (see figure) that, with amalgamated zinc, cadmium, and copper electrodes, the current density does not decrease significantly, compared with the corresponding metallic electrodes. This means that the degree of anode passivation decreases, and, consequently, the synthesis rate grows. This fact can be understood as follows: for the systems used in the study. amalgamated anodes have a smooth, semiliquid surface with a higher slip coefficient than that of the metallic anodes, with the result that poorly soluble reaction products are more difficultly fixed on an electrode. This was also noticeable under visual inspection: the layer of the substance formed on the amalgamated anode was thinner than that on an ordinary anode.

Use of amalgamated nickel for anodic synthesis was found to be inefficient. Nickel belongs to a group of metals for which the energy of the M–M bond exceeds that of the M–Hg bond. However, the surface nickel atoms are unsaturated and, therefore, mercury atoms enter into an electron–electron interaction with these atoms and amalgamate the surface, but further dissolution of nickel in mercury is hindered [3, 6]. Presumably, this is the reason why nickel atoms cannot be transferred, when electric current is passed, through the volume phase of the mercury coating on the amalgamated anode. After a potential difference ΔE = 10 V was reached, mercury oxidized to give

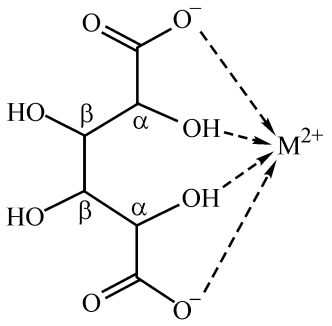
a mercury compound and the mercury layer was completely removed from the surface of the nickel electrode. The rest of the metals used in the study are easily amalgamated and well soluble in mercury [3–7], and, therefore, no undesirable effects were observed in anodic dissolution of these amalgam electrodes.

A strong increase (by a factor of 2–3) in the initial current density was observed in the case of amalgamated Zn and Cd (see figure). This indicates that the amalgamation of the electrodes markedly raises the process rate. This fact can be accounted for by the high diffusion coefficients of these metals in amalgams and by the good solubility of Zn and Cd in mercury, which makes higher the electrical conductivity of the amalgams of the metals [7]. Owing to these factors, a metal more easily passes into the amalgam and is more rapidly ionized.

The results of titrimetric and gas-volumetric elemental analyses, element composition, and presumed formulas of the substances obtained and the current efficiencies of the processes are listed in Table 1. It can be seen that a noticeable increase in the current efficiency is observed in synthesis with amalgamated copper. The possible reason is that a brick-red substance is formed in the course of electrolysis with a copper anode, and this substance partly remains on the electrode surface and is partly oxidized further to give Cu(II) galactarate. An analysis of this substance for the metal demonstrated that univalent copper oxide Cu_2O is formed. With amalgamated copper, no Cu_2O is formed and the increase in the current efficiency can be attributed to this fact. The aforesaid suggests that the anodic dissolution of copper with and without amalgamation in galactaric acid solutions occurs by different mechanisms.



The data in Table 1 demonstrate that the synthesis yielded galactarates of *d*-metals of a 1 : 1 composition. The results of a thermographic analysis of the substances obtained show that the DTA curves of all the compounds have a peak in the temperature range 185–210°C, which points to the presence of crystallization water.

Analysis of the IR spectra of the substances obtained (Table 2) shows a complete substitution of

hydrogen in both the carboxy groups of galactaric acid in the compounds with Cu(II), Ni(II), Zn(II), and Cd(II), which is confirmed by the absence of the band associated with stretching vibrations of a free carboxy group in the IR spectra of the corresponding compounds in the range 1700–1760 cm^{-1}. At the same time, the spectra of the galactarates contain bands of asymmetric stretching vibrations of a deprotonated carboxy group at 1650–1550 cm^{-1} and symmetric stretching vibrations of the same group at 1420–1300 cm^{-1}. It is known that finding the parameter $\Delta\nu(COO^-)$, which is the difference of the wave numbers corresponding to the bands of asymmetric and symmetric stretching vibrations of the deprotonated carboxy groups, makes it possible to determine the dentate state of these groups [9]. Because $\Delta\nu(COO^-)$ exceeds 210 cm^{-1} in all cases, it can be suggested that carboxy groups are monodentate in all of the compounds synthesized [9–11].

Stretching vibrations of hydroxo groups of galactaric acid appear at around 3290 cm^{-1}. For salts of this acid, this band is shifted by approximately 100 cm^{-1} to shorter wavelengths, which may be due to a decrease in the number of hydrogen bonds in the substances obtained, caused by deprotonation of carboxy groups and coordination of oxygen atoms to the metal ion.

The bands of stretching vibrations of C–O, α- and β-OH groups are shifted in the compounds synthesized to longer wavelengths, which indicates that these groups are involved in binding to the metal ion via formation of hydrogen bonds. Comparison with data on compounds of galactaric acid with other metals (K^+, Ca^{2+}, Ba^{2+}, La^{3+}) [9] shows that only a single pair of hydroxo groups is involved in the coordination. It can be assumed that α-OH groups of galactaric acid are coordinated to the metal, which is stereochemically favorable and does not create a steric hindrance that would appear in the case of coordination of β-OH groups to the metal. The suggested structure of the coordination unit of the compounds synthesized is as follows:

CONCLUSIONS

(1) It was shown that the amalgamation method can be used in practice to improve the efficiency of the anodic electrosynthesis.

(2) A significant increase in the initial current density was observed in electrosynthesis of metal galactarates in the case of amalgamated Zn and Cd.

(3) It was demonstrated that use of amalgamated nickel in anodic synthesis is inefficient and undesirable because of the oxidation of the surface layer of mercury.

(4) It was found that the metal ion is bound to the galactarate ion at carboxy and α-hydroxo groups.

Abstract—Procedures were developed for preparing veratraldehyde, oximes of veratraldehyde and citral, and esters of these oximes, which are readily accessible fragrance compounds that can be synthesized from commercially available raw materials.

DOI: 10.1134/S1070427208040149

Veratraldehyde (3,4-dimethoxybenzaldehyde) is present in small amounts in *Cymbopogon javanensis* essential oil. It is used in relatively few perfume compounds, odorants, and food aromatizers, and also as intermediate in synthesis of certain drugs [1]. Citral (3,7-dimethyl-2,6-octadienal) is present in lemongrass, cubeb, citrus, and some other essential oils. It is a 7 : 3 mixture of *E* and *Z* isomers. Citral is widely used in many perfume compounds, odorants, and food aromatizers [1–3].

The goal of this study was to develop of procedures for preparative synthesis of veratraldehyde and citral oxime esters from commercially available raw materials: vanillin and citral. Veratraldehyde **II** was prepared by Schotten–Baumann methylation of vanillin **I** with Me_2SO_4 in the presence of KOH. We developed a synthesis procedure that is simpler and more convenient than the procedure described previously [4] and allows preparation of veratraldehyde **II** of high purity in 90% yield. Veratraldehyde oxime **III** was prepared in 92% yield by the reaction of **II** with hydroxylamine; the procedure was similar to that described in [5].

Veratraldehyde and citral oxime esters were prepared by reactions of oximes of veratraldehyde (**III**) and citral (**IV**) with alkanecarboxylic acid anhydrides in absolute benzene in the presence of catalytic amounts of $HClO_4$ or with alkane- and arenecarboxylic acid chlorides in the presence of pyridine by the procedure developed for synthesis of related compounds [6–8]. The reactants were mixed, and the mixture was allowed to stand at 20–23°C for 24–36 h. Intense cooling and stirring were not required. Oxime esters derived from veratraldehyde (**Va**–**Vs**) and citral (**VIa**–**VIt**) were prepared in 82–92% yields:

where R = Me (**Va**), Et (**Vb**), Pr (**Vc**), Me_2CH (**Vd**), Bu (**Ve**), Me_2CHCH_2 (**Vf**), $Me(CH_2)_4$ (**Vg**), $Me(CH_2)_5$ (**Vh**), **$Me(CH_2)_6$** (**Vi**), $Me(CH_2)_7$ (**Vj**), $Me(CH_2)_8$ (**Vk**), $Me(CH_2)_{11}$ (**Vl**), *cyclo*-C_6H_{11} (**Vm**), C_6H_5 (**Vn**), $C_6H_5(CH_2)_2$ (**Vo**), **$C_6H_5MeCHCH_2$** (**Vp**), *trans*-$C_6H_5CH{=}CH$ (**Vq**), MeO (**Vr**), EtO (**Vs**).

where R = Me (**VIa**), Et (**VIb**), Pr (**VIc**), Me_2CH (**VId**), Me_2CHCH_2 (**VIe**), $Me(CH_2)_4$ (**VIf**), $Me(CH_2)_5$ (**VIg**), **$Me(CH_2)_6$** (**VIh**), $Me(CH_2)_7$ (**VIi**), $Me(CH_2)_{11}$ (**VIj**), $Me(CH_2)_{16}$ (**VIk**), *cyclo*-C_6H_{11} (**VIl**), C_6H_5 (**VIm**), $C_6H_5(CH_2)_2$ (**VIn**), *cis*-$C_6H_5CH{=}CH$ (**VIo**), $C_6H_5CH{=}C(C{\equiv}N)$ (**VIp**), 3-$O_2NC_6H_4$ (**VIq**), MeO (**VIr**), EtO (**VIs**), $MeOC(O)(CH_2)_2C$ (**VIt**).

Oxime esters **Va–Vs** and **VIa–VIt** are colorless viscous liquids or crystalline compounds crystallizing from benzene–hexane (see table). The esters do not require additional purification, contain no admixtures of the starting compounds, benzene, and pyridine, and can be directly used in fragrance and food industry [3]. According to the ^{1}H NMR spectra, the compounds were 97–98% pure. Oxime esters **Va–Vs** and **VIa–VIt** can be well stored at a temperature below +5°C in the dark under anaerobic conditions. Unsaturated compounds **VI–VIt** were stabilized by adding 0.5% hydroquinone to prevent polymerization.

The compositions and structures of oxime esters **Va–Vs** and **VIa–VIt** were confirmed by elemental analysis, cryoscopic determination of the molecular weight (see table), and ^{1}H NMR and IR spectroscopy.

The IR spectra of veratraldehyde oxime esters **Va–Vs** contain the following absorption bands, cm^{-1}: CH_{Ar} in the range 3100–3000, CH_{Alk} at 3000–2800, C=O at 1770–1730, C=N at 1675–1665, Ar at 1600–1360, C–O at 1300–1000, CH_{Ar} at 880–620. In the ^{1}H NMR spectra of veratraldehyde oxime esters **Va–Vs**, the MeO protons give two singlets at 3.90–4.10 ppm. The aromatic protons appear as a multiplet at 6.70–7.50 ppm. The HC=N proton signal is a singlet at 8.20–8.30 ppm.

The IR spectra of citral oxime esters **VIa–VIt** contain the following absorption bands, cm^{-1}: CH_{Alk} in the range 3000–2800, =CH at 3050–3020, C=O at 1770–1740, C=C at 1670–1665, C=N at 1645–1635, CH_2 at 1667–1663, C–O at 1250–1180. The IR spectra of aromatic carboxylic acid esters **VIm–VIq** also contain the CH_{Ar} absorption bands at 3100–3000 and 707–690, and the Ar absorption bands at 1600–1595, 1455–1450, and 1380–1370 cm^{-1}. The C≡N group in the IR spectrum of **VIp** gives a band at 2219 cm^{-1}, and the NO_2 group in the spectrum of **VIq** gives two characteristic bands at 1535 and 1350 cm^{-1}. In the ^{1}H NMR spectra of **VIa–VIt**, the Me_2C=C protons are manifested as two broadened singlets at 1.60±0.05 and 1.66±0.04 ppm, and the MeC=C protons, as a broadened singlet at 2.05±0.05 ppm. The HC=C protons appear as signals at 4.90–6.40 ppm. The signals of aromatic protons in **VIm–VIq** are observed as a multiplet at 7.10–9.00 ppm.

The ^{1}H NMR spectra of **Va–Vs** and **VIa–VIt** also contain the characteristic signals of the ester fragments.

EXPERIMENTAL

The IR spectra were recorded on a Protege-460 IR Fourier spectrometer (Nicolet) from thin films or KBr pellets. The ^{1}H NMR spectra were measured on a BS-587A spectrometer (100 MHz, Tesla) from 5% solutions in $CDCl_3$; the chemical shifts were determined relative to internal tetramethylsilane. The molecular weight *M* was determined cryoscopically in benzene. The physicochemcial characteristics of veratraldehyde **II** and of oximes of veratraldehyde (**III**) and citral (**IV**) were in agreement with reference data [1, 9, 10].

Veratraldehyde II. A 14-g portion of 90% KOH was dissolved in 210 ml of water. The solution was cooled to 20–23°C, and 0.2 mol of vanillin was added with vigorous stirring. After vanillin fully dissolved, 22 ml of Me_2SO_4 was added in a single portion. The mixture was stirred for 6 h at 20–23°C, after which the stirring was stopped, and the mixture was cooled to 5°C and left for 10–12 h. The crystalline precipitate of veratraldehyde **II** formed in the process was filtered off on a glass frit, washed with a small amount of water, and dried in air. Yield 90%.

Veratraldehyde oxime III. A mixture of veratraldehyde **II** (0.21 mol), hydroxylamine hydrochloride (0.27 mol), sodium hydrogen carbonate (0.28 mol), and 96% ethanol (75 ml) was refluxed for 1 h. Then the mixture was poured into a beaker with 300 ml of water, cooled to 5°C, and left for 10–12 h. The crystalline precipitate of veratraldehyde oxime **III** formed in the process was filtered off on a glass frit, washed with a small amount of water, and dried in air. Yield 92%.

Veratraldehyde and citral oxime esters Va–Vd and VIa–VId (general procedure). Veratraldehyde oxime **III** or citral oxime **IV** (0.01 mol) and appropriate acid anhydride (0.011 mol) were dissolved in 20 ml of absolute benzene, and a drop of 47% $HClO_4$ was added. The mixture was shaken and allowed to stand at 20–23°C for 24–36 h. Then the mixture was

diluted with water, and the product was extracted with benzene. The organic layer was separated, washed with water and 5% aqueous $NaHCO_3$, and dried over $CaCl_2$. The solvent was removed at reduced pressure (13–20 kPa), avoiding heating above 25–30°C.

Veratraldehyde and citral oxime esters Ve–Vs and VIe–VIt (general procedure). Veratraldehyde oxime **III** or citral oxime **IV** (0.01 mol) was dissolved in 50 ml of absolute benzene, and 0.01 mol of absolute pyridine was added. Appropriate acid chloride (0.01 mol) was added to the resulting solution with cooling to 15°C and careful shaking. The mixture was allowed to stand at 20–23°C for 24–36 h, after which it was diluted with water, and the product was extracted with benzene. The organic layer was separated, washed with water and 5% $NaHCO_3$ solution, and dried over $CaCl_2$. The solvent was removed at reduced pressure (13–20 kPa), avoiding heating above 25–30°C.

CONCLUSIONS

(1) A procedure was developed for preparing veratraldehyde and citral oxime esters in high yields by reactions of the corresponding oximes with carboxylic acid anhydrides and chlorides.

(2) A series of previously unknown veratraldehyde and citral oxime esters were synthesized and characterized. The compounds are highly pure and can be directly used in fragrance and food industry.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Alginic Acid Hydrazide and Its Reactions with Aromatic Aldehydes

S. I. Anson, E. V. Novikova, and A. A. Iozep

St. Petersburg State Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received September 21, 2007

Abstract—Alginic acid hydrazide was prepared, and its reactions with aromatic aldehydes were studied. The effect of a substituent in the benzene ring of the aldehyde on the number of arylidene groups introduced into the polymer was examined.

DOI: 10.1134/S1070427208040150

Modified polysaccharides acquire growing importance in medical practice. Chemical fixation of biologically active substances on a polysaccharide allows improvement of the existing and development of new medicinal of prolonged action and low toxicity. In this context, much promise is shown by alginic acid, which is used not only in food and cosmetic industry, but also in medicine. Alginic acid salts bind and remove from a living body decay products of carbohydrates, fats, and proteins, and also heavy metal salts and radionuclides [1]. Medicinal based on alginic acid are used for treatment and prevention of diseases of gastrointestinal tract, liver, and gall bladder [2]. Unfortunately, the chemical properties of alginic acid are poorly studied, which prevents its extensive use in synthesis of physiologically active polymers.

Therefore, our goal was to prepare alginic acid hydrazide and study its reactions with aromatic aldehydes.

Chemical modification of alginic acid was performed as follows:

$$[C_6H_5O_2(OH)_2(COOH)]_n$$
I

$$\xrightarrow[2.\ NaOH]{1.\ NH_2NH_2} [C_6H_5O_2(OH)_2(COONa)_{1-k}(CONHNH_2)_k]_n$$
II

$$\xrightarrow{ArCH=O} [C_6H_5O_2(OH)_2(COONa)_{1-k}(CONHNH_2)_k]_n$$
III

where Ar = 4-$C_6H_4NO_2$, 4-C_6H_4Cl, –C_6H_5, 4-C_6H_4–CH_3, 4-$C_6H_4OC_2H_5$.

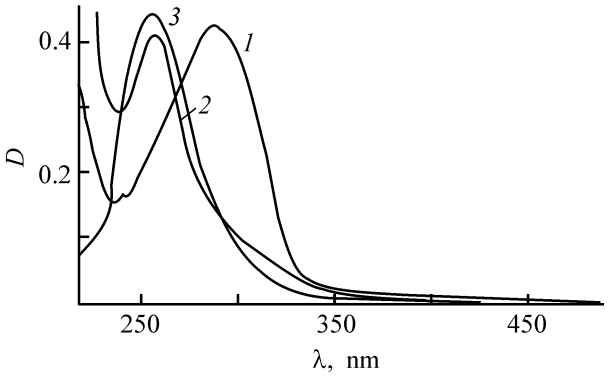
Alginic acid hydrazide **II** was synthesized by three procedures previously suggested for preparing hydrazides of carboxyalkyl polysaccharides. According to the first protocol [3], alginic acid **I** was heated in a hydrazine hydrate medium at 100°C for 2–14 h, after which a solution of an alkali was added and the polysaccharide was precipitated with alcohol. To remove ionically bound hydrazine, the product was precipitated from aqueous solutions with an acid and then from an alkaline solution with alcohol. The resulting product was washed with alcohol and ether and dried in a vacuum at 60°C. The second procedure involved treatment of alginic acid with a hydrazine hydrate–butanol–toluene mixture, preliminary dehydrated by azeotropic distillation of water, at 70–75°C for 12 h in the presence of acidic alumina. After the reaction completion, the catalyst was removed, the aqueous layer was separated, and the product was isolated as described above. Also, the hydrazide was prepared by mixing alginic acid lactone with hydrazine hydrate and keeping for 24 h at 18–20°C.

The obtained samples of alginic acid hydrazide are yellowish amorphous powders readily soluble in water but insoluble in alcohol, ether, and other organic solvents.

The IR spectra of alginic acid hydrazide samples in the H^+ form contain absorption bands at 1737 [ν(C=O), carboxy group], 1625 [ν(C=O), amide I], and 1537 cm^{-1} [δ(N–H), amide II]. The last two bands are absent in the spectrum of alginic acid [4].

The alginic acid hydrazide samples were characterized by the degree of substitution, DS (number of hydrazide groups per monomeric unit of the polysac-

Table 1. UV spectra of aqueous solutions of aldehydes and their alginoylhydrazones



Aldehyde	λ_{max} of aqueous solutions, nm	
	aldehyde	alginoylhydrazone
4-NO_2–C_6H_4CHO	268	315
4-Cl–C_6H_4CHO	259	287
C_6H_5CHO	258	280
4-CH_3–C_6H_4CHO	260	278
4-C_2H_5O–C_6H_4CHO	283	297

charide), which was calculated from the results of iodometric titration [5].

We found that the most convenient route to alginic acid hydrazide is heating of the polysaccharide in hydrazine hydrate at 100°C, which allows preparation of samples with DS of up to 0.6. In the hydrazide samples prepared from the lactone and in the presence of alumina, DS did not exceed 0.17 and 0.13, respectively. Therefore, all the subsequent samples were prepared by the first procedure. We found that DS increased with the reaction time (at 100°C):

τ, h	DS
2	0.200 ± 0.006
4	0.347 ± 0.004
6	0.460 ± 0.004
8	0.510 ± 0.003
10	0.541 ± 0.003
12	0.572 ± 0.003
14	0.610 ± 0.002

It is known that hydrazides of carboxymethyl and carboxyethyl polysaccharides are poorly soluble in water even at low DS. This fact is accounted for by cross-linking of the polymer molecules with the formation of diacylhydrazine fragments, which was confirmed by iodometric and spectrophotometric determinations of DS [6]. All the alginic acid hydrazide samples are readily soluble in water. Therefore, it can be suggested that, with alginic acid, diacylhydrazine fragments are not formed in noticeable amounts. To confirmed this conclusion, we studied the reactions of alginic acid hydrazide with aromatic aldehydes.

UV spectrum of aqueous solutions of (*3*) 4-chlorobenzaldehyde, (*1*) its alginoylhydrazone, and (*2*) solution after completion of the hydrolysis. (*D*) Optical density and (λ) wavelength.

Aldehyde alginoylhydrazones **III** were prepared by refluxing alginic acid hydrazide **II** with benzaldehyde or its 4-nitro, 4-chloro, 4-methyl, or 4-ethoxy derivative in ethanol for 3 h in the presence of catalytic amounts of glacial acetic acid. The reaction product was filtered off and washed with hot alcohol to remove excess aldehyde.

The absence of impurities of the initial aldehydes was checked by TLC and UV spectroscopy (Table 1).

The aldehyde alginoylhydrazones are brownish amorphous powders insoluble in alcohol, ether, and other organic solvents. The solubility in water depends on the substituent in the benzene ring and decreases in going from nitro to ethoxy group.

The IR spectra of the acylhydrazones contain absorption bands at 1625 (stretching vibrations of the C=N group in the $R^1R^2C{=}NNHR^3$ fragment), 1530 (N–H bending vibrations in the amide group), 770–730 (vibrations of disubstituted benzene ring), and 1737 cm^{-1} (C=O stretching vibrations of the carboxy group).

The content of benzylidene groups in the polymer was evaluated by spectrophotometric determination of the initial aldehydes after hydrolysis of alginoylhydrazone samples in aqueous solutions of an acid in the presence of formaldehyde [7]. Replacement of sulfuric acid with acetic acid and proper choice of the reactant ratio allowed analysis under homogeneous conditions, with good reproducibility of the results.

The hydrolysis completion was checked spectrophotometrically. The UV spectra of the solution after the hydrolysis completion contain the absorption bands of the starting aldehydes only (see figure).

In addition, we performed a quantitative UV-spectrometric analysis of alginoylhydrazones without their

hydrolysis. As model compounds for constructing calibration plots were used specially prepared acetylhydrazones of the corresponding aromatic aldehydes. Their absorption peaks in aqueous solutions coincide with those of the corresponding alginoylhydrazones. This procedure allows quick and easy analysis of alginoylhydrazones. However, the calibration plots can be constructed only if the corresponding model compounds can be synthesized, which is not always the case.

The spectrophotometric methods suggested for analysis of alginoylhydrazones give comparable results (Table 2).

A study of the reactions of alginic acid hydrazide with aromatic aldehyde showed that, as with carboxyethyl dextran hydrazide [8], electron-withdrawing substituents in the benzene ring of the aldehyde accelerate the formation of alginoylhydrazones, whereas electron-donating substituents hinder it. The DS correlates with σ constants of the substituents: DS = $0.1047\sigma + 0.0839$, $R^2 = 0.999$). By contrast, 4-ethoxybenzaldehyde alginoylhydrazone is hydrolyzed considerably more readily than 4-nitrobenzaldehyde alginoylhydrazone.

By taking 4-nitrobenzaldehyde in a higher concentration and larger excess relative to alginic acid hydrazide, we achieved a quantitative conversion of the hydrazide groups of the polymer. This fact confirms the absence of diacylhydrazide fragments in the polysaccharide. In addition, the reaction can be used for a quantitative analysis of alginic acid hydrazides, because 4-nitrobenzaldehyde acylhydrazones are chromophores and become yellow in alkaline solutions [9]. The suggested conditions of spectrophotometric analysis allow quantitative analysis of alginic acid hydrazides with a relative error not exceeding 5% (Table 3).

CONCLUSIONS

(1) The degree of conversion of carboxy groups of alginic acid into hydrazide groups in hydrazine hydrate depends on the reaction time (varied from 2 to 14 h).

(2) In the reactions of alginic acid hydrazide with aromatic aldehydes, the conversion depends on the nature of the substituent in the benzene ring: electron-donating substituents reduce, and electron-with-drawing substituents raise the content of benzylidene groups in the polymer.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Correlation between the Structure and Chromatographic Retention of Some Azole Derivatives

S. V. Kurbatova, O. V. Parshikova, and Z. P. Belousova

Samara State University, Samara, Russia

Received February 22, 2007

Abstract—The chromatographic retention of nitrogen-containing heterocycles was studied in relation to their structure. The role of the type and position of the substituents and functional groups in the chromatographic behavior of these compounds was demonstrated. THe separation in a selected chromatographic system was studied in relation to the dipole moment of the sorbates.

DOI: 10.1134/S1070427208040162

Nitrogen-containing heterocycles exhibit a wide range of biological activity [1–4]. Many of these compounds are widely used for preparing vasodilating and antispasmodic (Dibasol), antimicrobial (metronidazole), analeptic (Etimizol), adrenomimetic (naphthizin), and other pharmaceuticals. In addition, many important natural compounds such as histamine, histidine, allantoin, etc., contain an imidazole fragment. Promising in this respect are sulfonic acid imidazolides, some of which exhibit antiviral, antituberculous, antifungal, and other activities [4, 5].

An important step in preparation of biologically active compounds is identification and quality control of the pharmaceuticals prepared since they can be contaminated with intermediate products or isomers. High-performance liquid chromatography (HPLC) is one of powerful tools for analysis of heterocyclic compounds. This method is also used in physicochemical considered [6]. A study of the chromatographic behavior of nitrogen-containing heterocyclic derivatives can give insight into the retention mechanism of other heterocyclic compounds. Based on the results of such studies, the selectivity of chromatographic systems can be predicted and the conditions of chromatographic separation can be optimized.

Derivatives of five-membered heterocycles are polyfunctional compounds containing several sorption sites which can interact with the components of the chromatographic system (sorbent and eluent). The retention factors of the simplest imidazole derivates under the HPLC conditions, some physicochemical and topological properties of these compounds, and correlations between these parameters were studied in [4, 5, 7]. It should be noted that, because the range of the compounds listed was not representative, no general conclusions on how the structure of azoles and their derivatives affects their HPLC behavior were made. In this study we extended the range of azoles examined by including triazole and tetrazole derivatives and the derivatives with hydroxy, hydrazide, and nitro groups.

The aim of this study was to determine the correlation between the structure of some azole derivatives and their retention under conditions of reversed-phase HPLC (RP HPLC).

EXPERIMENTAL

The experiments were performed on a Biotronik Chromatographic system with a BT 8100 HPLC Pump. A 4×150 mm column packed with Separon SGX-C_{18} (grain size 6 μm) was used. The elution was performed in the isocratic mode using an acetonitrile–water mixture (1 : 1, 5 : 3, and 3 : 1, v/v) as the eluent.

Prior to analysis, the eluent was degassed with a UZDN-2T degasser and filtered. Substrate solutions were prepared by dissolution of dry pure heterocyclic compounds in appropriate solvents. The volume of an injected sample was 20 μl. Sodium nitrite was used as nonsorbed compound. The structural formulas and names of the compounds are listed in Table 1.[1]

[1] The compounds were prepared at the Chair of Organic Chemistry of Samara State University.

The UV detection was done at 220, 254, and 280 nm. The analysis was performed at 20°C.

The retention was characterized by the retention factor k and the relative retention r:

$$k = t'_R/t_m = (t_R - t_m)/t_m, \quad r = k_i/k_{st},$$

where t_R is the retention time of a compound examined and t_m is the retention time of unsorbed compound; k_i and k_{st} are the retention factors of the compound examined and the reference, respectively.

To evaluate the difference in retention between the nitrogen-containing heterocycles, we determined the differences between the molar Gibbs free energies of sorption of a compound examined and the reference $\delta(\Delta G)_{i,st}$:

$$\delta(\Delta G)_{i,st} = -RT\ln(k_i/k_{st}) = -RT\ln(r_{i/st}) \quad (T = 293\ \text{K}),$$

where $\delta(\Delta G)_{i,st}$ is the difference between the differential molar free energies; R, universal gas constant; and T, temperature (K).

We used benzene as the reference. Five parallel runs were performed for each point. The results are listed in Table 1.

Table 1. Relative retention r of azole derivatives under conditions of reversed-phase HPLC

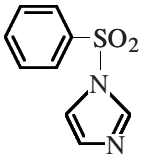
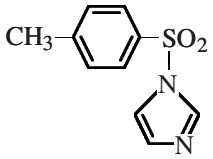
The structure of the compounds examined was confirmed by IR and NMR spectroscopy and the results of elemental analysis.

The quantum-chemical calculations were performed using the QSAR HyperChem software (version 7.0) with full optimization of the geometry of the molecules by the AM1 semiempirical method [8]. The calculated van der Waals volume V_{VdW}, molecular refraction MR, distribution log P ratio in the *n*-octanol–water system, polarizability α, and dipole moment μ of the compounds are summarized in Table 2.



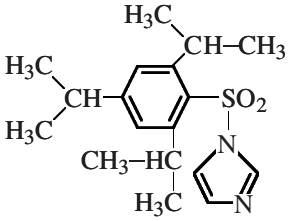
Effective methods for chromatographic analysis of complex organic compounds are, as a rule, based on the correlation between the structure of these compounds and their chromatographic retention. However, it is very difficult to take into account all the possible intermolecular interactions in a chromatographic system under conditions of liquid chromatography [6]. To study the structural influence on the chromatographic retention, different models based on the known sorption mechanism in similar chromatographic systems are used [9].

Simulation of the chromatographic retention of sorbates with a complex structure can be based on simple additive models allowing estimation of retention parameters from the set of increments. These models are frequently constructed by the method of structural similarity, based on the molecular structure–property relationship [10]. According to this method, groups of compounds with a similar substructural fragment and different substituents in a chosen position are formed. The properties of the main substructural fragments of these compounds are believed to be the same and the changes in the compound properties to be determined by the substituents [11].



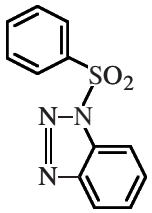
Compounds examined in this study were subdivided into structurally similar groups formed by successive introduction of one or several heteroatoms and substituents, going from azoles to sulfonic acid azolides, etc.

The main structural fragments of the compounds are imidazole, triazole, or tetrazole, which are aromatic π-deficient heterocyclic compounds. The acidity of these compounds changes owing to the redistribution of the electron density, caused by an increase in the number of nitrogen atoms in the heterocycle in going from imidazole to triazole and tetrazole. Imidazole exhibits both basic (pK_b 1.1×10^{-7}) and acidic (N–H bond) properties. The basicity of 1,2,4-triazole is significantly lower (pK_b 2×10^{-12}). Tetrazole is a weak acid in which the pyrrole hydrogen atom can migrate from one nitrogen atom to another [1].

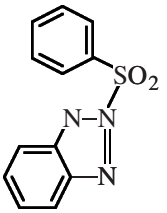


Because the interaction of sorbate molecules with the nonpolar hydrophobic surface of the stationary phase in the course of reversed-phase HPLC is mainly caused by dispersion forces, the physicochemical properties of the sorbates (such as polarizability, volume, and lipophilicity determined as the distribution ratio in the *n*-octanol–water system) significantly affect the retention [6]. As a rule, the retention of azoles increases, with the above parameters (unless other factors are important):

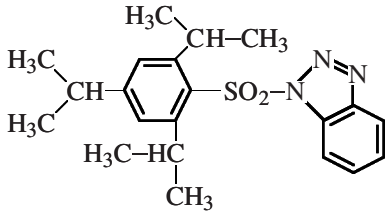
k = 0.373
V = 592 Å^3
log P = –0.11
α = 18.40 Å^3



k = 0.680
V = 634 Å^3
log P = 1.55
α = 20.23 Å^3

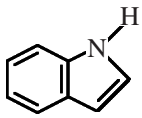


k = 2.219
V = 968 Å^3
log P = 4.92
α = 35.04 Å^3

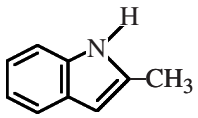


The relative retention and δ(ΔG) show similar trends. The similar dependence is observed for both sulfonic acid imidazolides and triazolides.

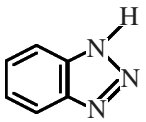
k = 8.086
V = 670 Å^3
log P = 1.59
α = 23.87 Å^3



k = 11.219
V = 739 Å^3
log P = 2.68
α = 26.92 Å^3

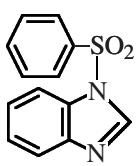


k = 15.577
V = 1036 Å^3
log P = 5.79
α = 41.60 Å^3

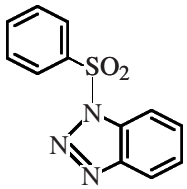


Previously we have shown [5] that introduction of the second and third nitrogen atoms into azole molecules weakens the interaction between the sorbate and the stationary phase, thus decreasing the retention. Similar dependences were observed for different compositions of the mobile phase and compounds with different substituents (Table 1). As the number of nitrogen atoms in the heterocyclic core increases, the retention factors of azole derivatives decrease, irrespective of the type of the substituent or radical bound to the heterocycle:

k = 2.746

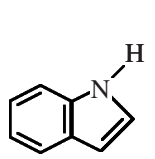


k = 0.601

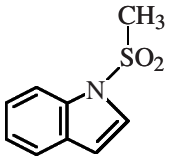


k = 0.373

Introduction of highly lipophilic phenyl substituent does not noticeably increase the retention of tetrazole derivatives, despite a significant increase in the molecular volume and liphophilicity as compared to heterocycles with a smaller number of the nitrogen atoms. At the same time, an increase in the number of heteroatoms in sulfonic acid imidazolides enhances their retention:

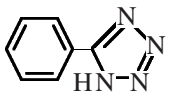


k = 0.527

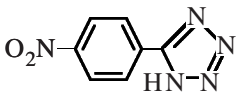


k = 8.086

A similar phenomenon is observed in going from 2,4,6-triisopropylbenzenesulfonic acid imidazolide to 2,4,6-triisopropylbenzenesulfonic acid 1,2,4-triazolide and from benzenesulfonic acid imidazolide to benzenesulfonic acid 1,2,4-triazolide. However, it should be noted that the change in the retention factors is inversely proportional to the dipole moment of these molecules. As can be seen from Table 2, the significant dipole moments of almost all of the compounds examined should noticeably affect their interaction with the components of the chromatographic system. Since the mobile phase was modified with acetonitrile whose dipole moment is 3.51 D, the orientation component should significantly contribute to the total interaction energy of the sorbates with the eluent. This fact confirms that an increase in the dipole moment decreases the retention factor of the indole derivatives, despite an increase in volume and polarizability of their molecules:

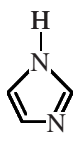


k = 2.746
μ = 1.884 D
V = 414 Å^3
α = 14.49 Å^3

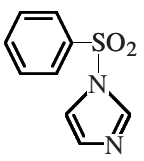


k = 1.269
μ = 3.729 D
V = 567 Å^3
α = 17.46 Å^3

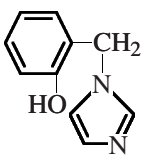
The dipole moment effect can be also illustrated by the change in the retention in going from pehenyltetrazole to nitrophenyltetrazole. Introduction of the nitro group into the phenyl substituents changes the dipole moment of the sorbate molecule. As a result, the retention factors of these compounds differ, although their other properties are similar:



k=0.547

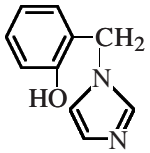


k=1.278

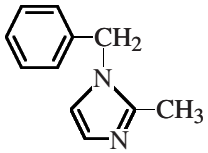


The retention of nitrogen-containing heterocycles is determined by both the type and position of a substituent in a heterocycle [8]. In particular, introduction of a substituent at the nitrogen atom of imidazole enhances the retention owing to weakening of the interaction with the eluent. This occurs irrespective of the type of the group substituting the hydrogen atom of the pyrrole nitrogen:

k=0.296



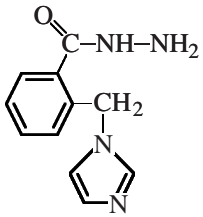
k=0.550



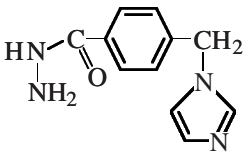
k=14.089

A significant increase in the retention of 2-[(1*H*-imidazol-1-yl)methyl]phenol is probably due to its higher lipophilicity as compared to that of imidazole and benzenesulfonic acid imidazolide (1.96, –0.04, and –0.11, respectively).

The position of the substituents at the benzene ring bound to the heterocycle significantly affects the azole retention. The data presented below show that the retention of imidazole with tolyl substituents with the *ortho*-OH group is higher than that of the compound with the *para*-OH group:



k = 14.089
μ = 2.674 D



k = 1.243
μ = 4.600 D

In going from the *ortho* to *para* derivative, the dipole moment substantiality increases, with the interaction with the eluent thereby enhanced. However, in the case of para isomers the crucial factor is formation of hydrogen bonds with the eluent. For example, the retention of the corresponding hydrazine derivatives noticeably differs, although the dipole moments, lipophilicity, and molecular volume of the compounds are similar:

k = 1.213
μ = 3.857 D
V = 666 Å^3

k = 0.355
μ = 3.861 D
V = 674 Å^3

The eluent composition also affects the retention. A decrease in the content of the organic component improves separation of the compounds, but significantly raises the elution time. For example, the retention factor of 2-[(1*H*-imidazol-1-yl)methyl]phenol at the acetonitrile content in the eluent of 75 and 50% is 1.645 and 14.089, respectively. In the case of the *para* isomer, the retention factor increases to a lesser extent (from 0.402 to 1.243), which additionally confirms the significant role of hydrogen bonds in the interaction of these compounds with the mobile phase. The relative retention of these sorbates changes in a similar manner.

Thus, the retention of azole derivatives under conditions of RP HPLC is determined by a number of

factors, which are mainly associated with the sorbate structure. The presence of functional groups and substituents and their type and position in the heteroring affects the molecular properties, and mainly their volume, liphophilicity, polarizability, and dipole moment, which, in turn, enhances the interaction of the sorbate either with the stationary phase or with the eluent. Clearly, the chromatographic behavior of azoles also depends on the eluent.

CONCLUSIONS

(1) The retention factors of azole derivates under conditions of reversed-phase HPLC were determined. Analysis of the dependence of the retention factors on the molecular structure of the sorbates demonstrates significant role of the type and location of the substituents and functional groups in chromatographic behavior of the azole derivatives.

(2) Although retention of azoles is caused mainly by the dispersion forces, the dipole moment of the sorbates significantly affects their chromatographic separation by enhancement of the interaction of the polar sorbates with the components of the mobile phase.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparation of Dichloride of Dimerized Fatty Acid and of Oligoamides Thereof by Low-Temperature Polycondensation

Abstract—Dichloride of dimerized fatty acid was prepared and characterized. Conditions were developed for synthesis of oligoamides by low-temperature polycondensation of the dichloride with di- and triamines, and properties of these oligoamides were studied.

DOI: 10.1134/S1070427208040174

This study continues our research in the field of synthesis of oligo- and polyamide derivatives of dimerized fatty acid (DFA). Previously, we have reported on the preparation of these compounds by high-temperature polycondensation in a melt [1, 2].

Intramolecular plasticiziation characteristic of oligo- and polyamides of DFA, caused by the presence of bulky alkyl groups, allows wide use of these compounds as high-performance hot-melt adhesives, plasticizers and curing agents for epoxy resins, and components of paint-and-varnish materials for preparing chemically stable corrosion-resistant coatings [3–6].

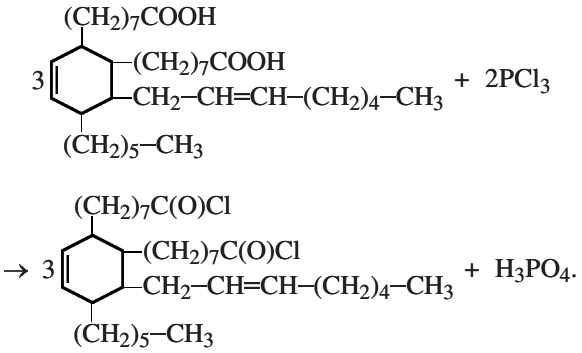
Synthesis of oligo- and polyamides by equilibrium polycondensation of DFA with di(tri)amines occurs under harsh conditions (160–240°C, 5–6 h) in an inert gas and involves final evacuation of the reaction system. At the same time, similar oligoamides can be prepared from DFA dichloride and appropriate amines by irreversible polycondensation at 20°C within a few minutes [7]. In this context, it seemed topical to prepare a series of new oligomeric structures taking advantage of the milder synthesis conditions excluding amide interchange and thermal and oxidative degradation.

There are no systematic data in the literature on the formation conditions and physicochemical properties of DFA dichloride.

The goal of this study was to develop a procedure for preparing DFA dichloride, to examine its reactions with di- and triamines under the conditions of low-temperature synthesis in a stirred vessel, and to analyze how the properties of the products depend on the nature and ratio of the starting reactants.

EXPERIMENTAL

As starting compounds we used DFA of PRIPOL 1013 DIMER ACID brand (linoleic acid dimer) containing no less than 97% main substance (CAS registry no. 61788-89-4); phosphorus trichloride [GOST (State Standard) 91–73]; hexamethylenediamine, HMDA (CAS registry no. 124-09-4); diethylenetriamine, DETA (EC no. 203-865-4), fraction distilled at 65–68°C/133.33 Pa; 4,4'-diaminodiphenylmethane, 4,4'-DADPM [TU (Technical Specification) 6-09-1374–71]; preliminarily distilled triethylamine, TEA (GOST 9966–88) and toluene (GOST 5789–78); chemically pure grade acetone (GOST 2603–79); sodium hydroxide (GOST 4328–77, with revision 1); distilled water (GOST 6709).



The structures of the compounds were determined by IR and NMR spectroscopy. The IR spectra were measured on a Specord M80 spectrophotometer in the range 4000–400 cm^{-1}. Liquid samples were taken as films between KBr plates, and solid samples, as KBr pellets. The NMR spectra were recorded on a Bruker

DPX-200 spectrometer operating at 200 MHz for ^1H and 50 MHz for ^{13}C. Samples were dissolved in $CDCl_3$. TMS was used as internal reference.

The amine numbers (AmNs), acid numbers (AcNs), and molecular weights evaluated chemically from the content of terminal functional groups were calculated according to the procedure described in [8]. The softening points T_s of the oligomers were determined by the ring-and-ball method (GOST 11506–73).

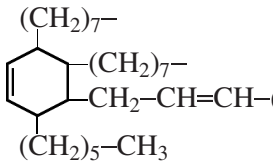
Attempts to prepare DFA dichloride by treatment with thionyl chloride led to the formation of a black product containing no more than 70% main substance. With PCl_3, dichloride of high quality was obtained, and the synthesis was well reproducible. Halogenation was performed according to [9–11]. The maximal conversion of carboxy groups was observed at 1.8-fold excess of PCl_3 relative to the reaction stoichiometry.

The formation of DFA dichloride is described by the scheme

I

Synthesis of the dichloride was performed in a flask equipped with a reflux condenser and a dropping funnel with $CaCl_2$ tubes. Phosphorus trichloride (82.5 g, 0.6 mol) was added dropwise over a period of 40–60 min to 280 g (0.5 mol) of DFA. The contents were heated on a water bath at 50°C for 3 h and left overnight at room temperature. Then the reaction mixture was diluted with 150 ml of toluene, stirred, and heated at 50°C for an additional 2 h. The toluene solution of dichloride **I** was separated from the precipitate of phosphorous acid by decantation, and the solvent with unchanged PCl_3 were distilled off at 50–60°C under reduced pressure (5.33–1.33 kPa). The resulting dichloride **I** was vacuum treated at 133 Pa for 1 h and was brought into subsequent transformations without additional purification. Yield 95.6%.

Dichloride of dimerized fatty acid is a mobile goldish virtually odorless liquid, n_D^{20} = 1.4895, d_4^{20} = 0.9902.



Found, %: C 77.00, H 10.81, Cl 11.72
$C_{36}H_{62}O_2Cl_2$.
Calculated, %: C 77.14, H 11.07, Cl 11.89.

In the IR spectrum of dichloride **I**, there is a pronounced absorption band of C=O stretching vibrations at ~1805 cm^{-1}. The other functional groups have no characteristic bands. In the ^1H NMR spectrum, signals at 0.85–0.88 ppm belong to CH_3 groups; a strong signal at 1.26 ppm, to CH_2 groups; and signals at 4.5–5.36 and 6.79–7.0 ppm, to the CH=CH group. It can be seen from the ^{13}C NMR spectrum that the peak at 14.2 ppm and peaks in the range 22.8–47.2 ppm belong to CH_3 and CH_2 groups, respectively. The characteristic carbon signal of the C(O)Cl group is observed at 173.6 ppm.

Dichloride **I** was used as active monomer for preparing oligoamides by low-temperature polycondensation with various amines:

$$n\mathbf{I} + n\underset{\mathbf{II–IV}}{H_2N–R–NH_2} \xrightarrow[-HCl]{\text{Acid acceptor}} \underset{\mathbf{V–VII}}{[–C(O)–R^1–C(O)–NH–R–NH–]_n},$$

where R = $(CH_2)_6$ (**II**, **V**); $C_2H_4NHC_2H_4$ (**III**, **VI**); $C_6H_4–CH_2–C_6H_4$ (**IV**, **VII**);

R^1 =  (**V–VII**);

n = 2–6.

It is known [12] that the reaction temperature, solvent, and acid acceptor strongly affect the yield and molecular weight of oligomers prepared by phase-transfer polycondensation.

Taking into account the available data, we performed the reaction at 20°C in a two-phase aqueous–organic system using toluene or toluene–acetone as organic phase. Sodium hydroxide or triethylamine was used as acid acceptor.

To obtain an oligomer of high quality by phase-transfer polycondensation in high yield, it is necessary to prevent hydrolysis of the acid dichloride. It is known [13] that the susceptibility of acid chlorides to hydrolysis is determined by their solubility in the aqueous phase. Therefore, long-chain fragments present in the dichloride make the molecule hydrophobic and hinder the hydrolysis.

To prepare the oligoamide from DFA dichloride and hexamethylenediamine, a beaker equipped with a stirrer was charged with a calculated amount of an aqueous solution of NaOH, HMDA was dissolved and a solution of the dichloride in toluene was added from a dropping funnel over a period of 5 min (Table 1).

In the process, a white clotted mass was formed, which partially adhered to the beaker walls. The contents were stirred for 10 min, after which 250 ml of water was added, the mixture was vigorously stirred for 30 min, and the oligoamide was separated on a glass frit. The precipitate was repeatedly washed with toluene and water to negative reaction for chloride ions. The isolated product was dried in air at 40–50°C and then in a vacuum oven at 60°C to constant weight. The dried oligoamides were pale yellow odorless powders. Their properties are listed in Table 2.

A striking fact follows from Tables 1 and 2: An increase in the HMDA concentration relative to dichloride **I** by a factor of 1.4 does not lead to significant changes in the molecular weight and softening point of the oligomers (run nos. 1a–1c), whereas in equilibrium polycondensation of DFA with HMDA, an increase in the diamine concentration by a factor of 1.4 leads to a decrease in the molecular weight by a factor of 4 [1].

The reaction of DFA dichloride with diethylenetriamine in the ratios indicated in Table 3 gave interest-

Table 4. Conditions of low-temperature polycondensation of DFA dichloride with 4,4'-DADPM

3b	0.05	0.06	0.145	600.0	300.0	81.0
3c	0.05	0.07	0.15	600.0	300.0	80.0

ing results. The synthesis was performed similarly to **V**, except that, after adding the dichloride to an aqueous-alkaline solution of DETA, stirring was performed for 50 min. In the process, the white milk-like reaction mixture gradually transformed into a clotty porous product. The oligoamide was squeezed through a Capron fabric and repeatedly washed with toluene and distilled water until the wash water became neutral and gave negative reaction for Cl^-. The resulting oligomer was dried in air at 60°C and then in a vacuum to constant weight.

The products obtained are soft yellow odorless lumps insoluble in isopropyl alcohol, acetone, and toluene, which did not allow determination of their amine and acid numbers and calculation of molecular weights. The compounds were infusible, and their softening points could not be determined. In the IR spectra of the oligoamides, there are well-defined bands at 1650–1680 (C=O stretching vibrations, amide I) and 1510–1570 cm^{-1} (NH bending vibrations, amide II). A distinctive feature of the spectra of these oligoamides is a weak band of C=O stretching vibrations at 1640 cm^{-1}, belonging to the tertiary amide group. The samples dissolved in $CDCl_3$ looked like a swollen gel. The ^1H NMR spectrum contained, along with signals of DFA fragments, also peaks at 2.17, 2.5, and 3.46 ppm belonging to the methylene protons of the CH_2NHCH_2 and $C(O)NHCH_2$ groups. Peaks of the broad signals of the C(O)NH groups were observed at 5.8, 6.3, and 6.8 ppm. The ^{13}C NMR spectra of compounds **VI** were of poor quality because of the low solubility of the compounds.

The observed cross-linking of oligoamides derived from FDA and DETA is apparently due to the higher reactivity of C(O)Cl groups, compared to carboxy groups (in equilibrium polycondensation), and, as a consequence, to the lower selectivity, namely, to the attack of both primary and secondary amino groups of diethylenetriamine.

Along with preparing oligoamides by low-temperature condensation of FDA dichloride with aliphatic di- and triamines, it seemed important to prepare oligoamides derived from an aromatic diamine, 4,4'-diaminodiphenylmethane.

THe particular interest in this matter is due to the fact that polycondensation in a melt is virtually inapplicable to the synthesis of oligo- and polyamides derived from aromatic diamines. The point is that, in a high-temperature process, both the starting amines themselves and the reaction products can undergo thermal degradation, because the melting points of these compounds often coincide with their decomposition points [13]. Therefore, low-temperature polycondensation can be promising for preparing a series of new oligo- and polymeric structures whose synthesis by other methods is difficult and often impossible at all.

Because 4,4'-DADPM is insoluble in water, its reaction with DFA dichloride was performed as follows: A beaker equipped with a stirrer was charged with 4,4'-DADPM, toluene, and acetone and was heated on a water bath at 50°C until the amine dissolved completely. After cooling to 20°C, we added with stirring TEA and then, dropwise, a solution of the dichloride in toluene. The reactant ratio is given in Table 4. The mixture was stirred for 3 h, after which the dark yellow precipitate was filtered off on a Büchner funnel through a Capron fabric, thoroughly washed with acetone to remove low-molecular-weight impurities and with water to negative reaction for the chloride ion, and dried to constant weight. A yellow-brown powder with a weak amine odor was obtained.

When the polycondensation is performed in solution, the hydrolysis of dichloride **I** is excluded, but some other problems arise. For example, to prevent a side reaction between 4,4'-DADPM and the released HCl, we took a certain excess of an acid acceptor, TEA. In turn, to prevent a side reaction between TEA and DFA dichloride, the latter was added to the solution of 4,4'-DADPM and TEA prepared beforehand. The possible contact of the reactants was thus excluded.

VIIc	26.0	49.2	1490	110		

Table 5 shows that the product prepared at the equimolar ratio of the reactants has the highest molecular weight; even a slight deviation from the equimolar ratio leads to a certain decrease in the molecular weight of the oligomer. The dependence we obtained confirms the higher sensitivity of the polycondensation in solution to the reactant ratio, compared to the phase-transfer polycondensation.

It should be noted that the oligoamides derived from 4,4'-DADPM show higher softening points, which is due to structural features of the oligomeric chain incorporating aromatic rings [14].

Our data allow comparison of the results of oligoamide synthesis by high-temperature [1] and low-temperature processes.

For example, the yield of compounds prepared by room-temperature acylation of the amines is relatively low. This may be due to the loss of a certain amount of low-molecular-weight fractions of the oligoamides, which are removed with the filtrate in the course of separation and washing of the solid product.

It should also be noted that the products prepared by phase-transfer polycondensation and by polycondensation in solution have, on the whole, a lower molecular weight and a higher softening point, compared to the oligomers prepared by reactions of the diamines with DFA in a melt. The observed decrease in the molecular weight may be attributed to broadening of the molecular-weight distribution, typical of these products, with an increase in the content of the low-molecular-weight fraction [13].

In turn, the revealed increase in the softening point may be due to the more ordered structure of oligoamide macromolecules formed by low-temperature polycondensation, because, as already noted, the probability of degradation processes is reduced to a minimum in this case.

CONCLUSIONS

(1) Dichloride of dimerized fatty acid was prepared and characterized (yield 95.6%).

(2) A procedure was developed for preparing oligoamides by low-temperature reaction of the dichloride of dimerized fatty acid with di- and triamines. Small deviations of the reactant ratio from the stoichiometry do not noticeably affect the molecular weight and softening point of the oligoamides obtained.

(3) The use of trifunctional diethylenetriamine leads to cross-linking of the oligomer.

Abstract—The effect of fullerene C_{60} on copolymerization of methyl methacrylate with compounds, one of which is a typical allyl monomer and the other is a vinyl monomer with a side allyl bond, was examined. The kinetic parameters of the reactions and the copolymerization constants of monomers in the absence and in the presence of fullerenes were determined. Based on the UV spectrometric data, the material balance was calculated and a variation of the molar extinction coefficient of fullerene was revealed.

DOI: 10.1134/S1070427208040186

The synthesis of practically important fullerene-containing polymers requires solving many problems. In view of the fact that these macromolecular compounds well combine the characteristics of both polymers and fullerenes, procedures for introduction of fullerenes into the composition of polymer chains are being actively developed [1–3].

Fullerene can be introduced into both the main chain and side chain by radical copolymerization of vinyl and allyl monomers of various structures. As a consequence, the resulting substances have the characteristics that strongly differ from those of the initial substances. The presence of a covalently bonded fullerene affects the size and shape of a polymer globule as a whole and fundamentally changes the optical and dielectric characteristics of macromolecules [4].

Highly symmetric fullerene molecules are also widely used as structural units of polymer chains in synthesis of macromolecular products [5, 6].

Here, we discuss the common and specific features of the influence of fullerene C_{60} on the radical copolymerization of methyl methacrylate (MMA) with allyl methacrylate (AMA) and allyl chloride (AC) on the basis of the kinetic dependences, composition of copolymers, and data of UV spectroscopy and gel chromatography.

EXPERIMENTAL

Methyl and allyl methacrylates were purified to remove the stabilizing agent with an 8% KOH solution, washed with water to neutral reaction, dried with $CaCl_2$, and twice distilled in a vacuum. For polymerization, we took a fraction of MMA with bp 48°C/70 mm Hg and AMA with bp 73°C/53 mm Hg. Allyl chloride was purified by distillation at atmospheric pressure in an inert medium, bp 44°C. Benzoyl peroxide was three times recrystallized from methanol and dried in a vacuum at room temperature to constant weight, mp 108°C (with decomposition). In all the experiments, the initiator concentration was the same: 2.0×10^{-2} M.

The copolymerization was performed in the bulk at 60 ± 0.05°C. The process kinetics was studied by the dilatometric method [7]. Fullerene C_{60} was used in the form of a saturated solution in *o*-dichlorobenzene ($[C_{60}] = 9.3 \times 10^{-3}$ M).

The content of C_{60} in the samples was measured by UV spectroscopy on a Shimadzu UV VIS NIR 3100 device, using chloroform as a solvent. The molar extinction coefficients of fullerenes at the absorption peaks, ε, were determined from the calibration dependences of the optical density on the concentration of the solutions with $[C_{60}] = 2.0 \times 10^{-4}$–$2.0 \times 10^{-5}$ M, which had the optical density of 3.6 and lower in the transparency range of chloroform, 250–750 nm. We also found the ε values of monomers at the wavelengths of the absorption peaks of C_{60}. The 7.0×10^{-4}–5.0×10^{-5} M solutions of the monomers in the range of the main absorption peak of C_{60} in chloroform λ_{350nm} had the optical density of 0.095 and lower.

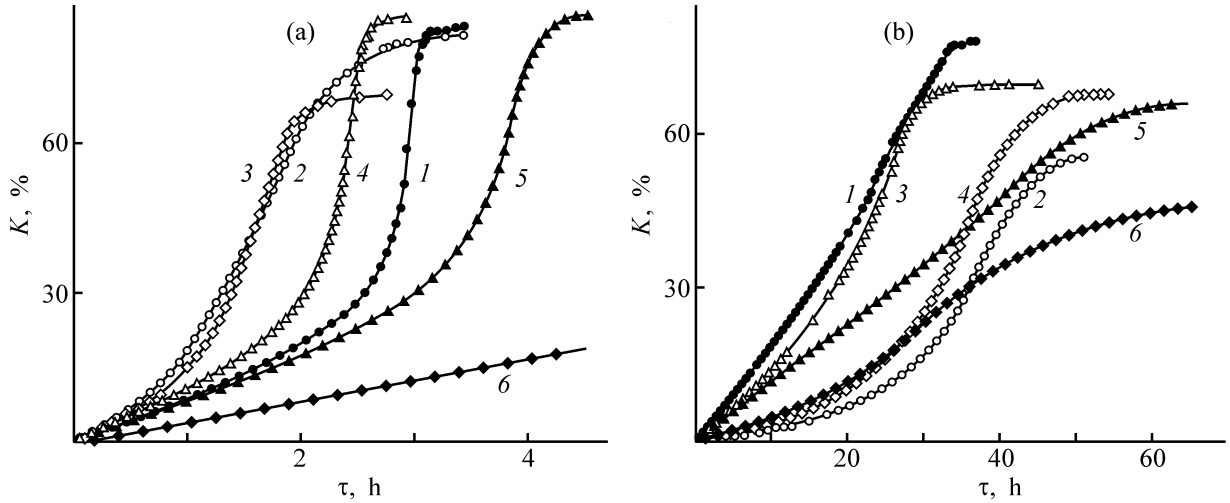

Fig. 1. Degree of conversion, K, of the monomer mixture vs. time τ in copolymerization of MMA with AC and AMA (a) in the absence and (b) in the presence of 2.25×10^{-3} M fullerene C_{60}. (*1*, *4*) AMA and (*5*, *6*) AC. Content in the initial mixture, mol %: (*1*) 0, (*2*, *5*) 10, (*3*, *6*) 50, and (*4*) 100.

The molecular-weight characteristics were determined by gel permeation chromatography. The analysis were performed on a Waters Alliance^{TM} GRC 2000 Systems liquid chromatograph at 30°C at a solvent flow rate of 1 ml min^{-1}. Tetrahydrofuran was used as an eluent. For calibration of the columns, we used close-cut polystyrene references.

In copolymerization of methyl and allyl methacrylates in the absence of fullerene, the process rate increases with the mole fraction of AMA in the initial mixture (Fig. 1a, curves *3*, *4*), which results in the onset of gel effect in earlier stages of conversion. It should be noted that the homo- and copolymerization of allyl methacrylate is accompanied by cross-linking via side allyl groups [8], contributing to an increase in the coefficient of contraction. As a result, an apparent increase in the copolymerization rate with the content of AMA in the reaction mixture is observed.

In the reaction of MMA with AC in the absence of fullerene, an increase in the amount of the allyl component in the reaction mixture leads to a decrease in the process rate (Fig. 1a, curve *6*), typical of copolymerization of allyl compounds, due to the increasing contribution of "allyl additions" [9]. The gel effect is less pronounced in this case, and at equimolar and higher content of AC it is absent at all.

At a fixed concentration of fullerene C_{60}, an increase in the mole fraction of both AMA (Fig. 1b, curves *3*, *4*) and AC (Fig. 1b, curves *5*, *6*) leads to a decrease in the copolymerization rate. However, the course of the process has its own features in each case.

In copolymerization of MMA with AMA, the degree of cross-linking of macrochains decreases owing to the reaction of allyl radicals of the side chain with fullerene and, correspondingly, the yield of the soluble polymer increases. However, steric hindrance is possible in the formation of macromolecules, which apparently results in that the process rate decreases as the content of the allyl ester increases. Just this factor is apparently responsible for the significant difference in the kinetic features of homopolymerization of allyl and methyl methacrylates in the presence of fullerene. The structure of fullerene-containing copolymers of the above compounds can be characterized as "a bracelet with pendants."

In copolymerization with the allyl monomer (Fig. 1b, curves *5*, *6*), the decrease in the rate with increasing content of AC in the reaction system is less significant than that with AMA. This is apparently caused by the high electron-acceptor power of the product formed in the reaction of the allyl monomer with fullerene and involved in the polymerization process. In copolymerization of MMA with AC, fullerene enters into the main chain of the copolymer, but formation of branched structures as a result of addition of propagating chains to C_{60} is not excluded.

The kinetic parameters of copolymerization are listed in Table 1. The results obtained suggest that the reaction orders with respect to initiator and the sum of monomers do not noticeably vary and correspond to the characteristics of the radical processes. Nevertheless, the apparent rate constant decreases and the activation energy of copolymerization increases in the presence of fullerene C_{60}. For AMA, E_a

increases particularly strongly, which is typical of polyfunctional compounds [10].

The results of kinetic studies are in good agreement with the data obtained when studying the composition of copolymers and with experimental values of copolymerization constants (Table 1).

The behavior of AMA and AC in copolymerization is governed by their activity. According to these data, in copolymerization without fullerene, allyl and methyl methacrylates are involved to the same extent in formation of the polymer chain, and in the case of AC, the copolymers are enriched in methyl methacrylate, which is confirmed by the composition curves (Fig. 2, curves *1a*, *2a*). It is seen that, in copolymerization of two vinyl compounds with the relative activities close to 1 (Table 1), the composition of the copolymers virtually coincides with the composition of the monomer mixture.

In the presence of fullerene, the fraction of allyl (Fig. 2, curve *2a*) and vinyl (with allyl group) monomers (Fig. 2, curve *1a*) in the copolymerization products increases, which is apparently caused by the reaction of the allyl radicals with C_{60}. As a result, the relative activities of the compounds with the allyl bond grow (Table 1). In this case, the copolymerization constant of AC varies most strongly.

The presence of covalently bonded fullerene in the macromolecule composition is confirmed by the UV data.

Each event of C_{60} involvement in the radical process results in rupture of a π bond and addition of a radical to the fullerene core [11]. The total number of ruptured π bonds can be judged quantitatively from the optical densities at the π–π^* absorption peaks of fullerene ($\lambda_{max} = 330$ nm) in the electronic absorption spectra of the products isolated in the course of synthesis. In copolymerization of MMA with AMA and AC in the presence of fullerene, the optical density of the π–π^* absorption of C_{60} ($\lambda = 330$ nm) decreases with increasing degree of conversion of the initial monomer mixture.

The complete entering of fullerene into the polymer chain was confirmed on the basis of the material balance of the reaction. An increase in the mole fraction of AMA and AC in the initial mixture results in a decrease in the fullerene content in the precipitant solu-

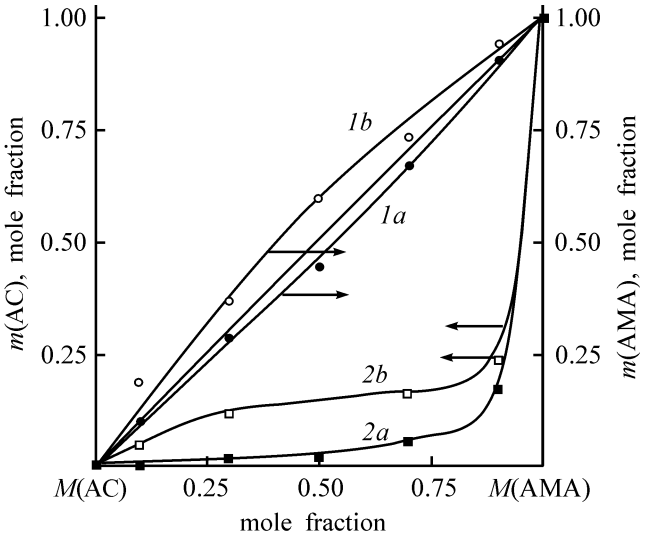

Fig. 2. Composition curves for copolymers of MMA with (*1*) AMA and (*2*) AC (*a*) in the absence and (*b*) in the presence of 2.25×10^{-3} M fullerene C_{60}.

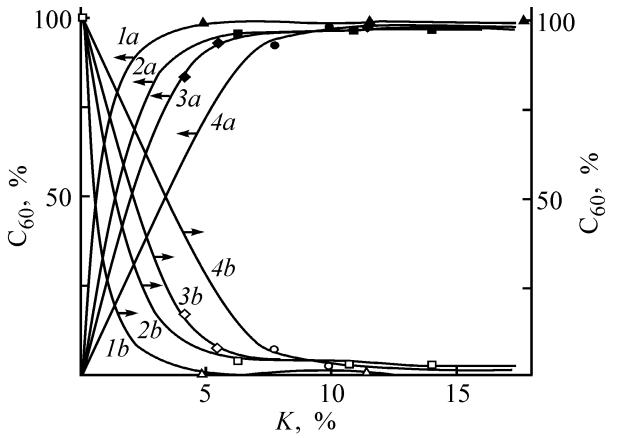

Fig. 3. Content of fullerene C_{60} (*a*) in copolymers of MMA with AMA and AC and (*b*) in the mother liquor for the samples with various degrees of conversion of the monomer mixture *K*. (*1*, *2*) AMA and (*3*, *4*) AC. Content in the initial mixture, mol %: (*1*, *4*) 10 and (*2*, *3*) 50.

tion (mother liquor) (Fig. 3, curve *2*) and a faster increase in the amount of fullerene in the reaction products (Fig. 3, curve *1*). It is important that involvement of the compounds with allyl bonds into copolymerization with MMA allows introduction of fullerene into the polymer chain in concentrations of up to 4.5×10^{-2} mol per mole of copolymer even in earlier stages of conversion of the monomer mixture (up to 10%). At the same time, the content of C_{60} in PMMA is only 3.0×10^{-3} mol per mole.

An algorithm that involves a system of equations with three unknowns and allows parallel determination of both the true extinction coefficient of fullerene and the amount of C_{60} in the resulting polymer in the mother residue was developed. An important result is that variation of the molar extinction coefficient was revealed, which decreases with increasing number of fragments joined to the C_{60} core and mole fraction of AMA and AC in the reaction mixture.

A study of the molecular-weight characteristics demonstrated that, in the absence of fullerene in the examined range of conversion, the molecular weight (MW) of copolymers of MMA with AMA does not noticeably depend on the content of their monomers in the initial mixture. The molecular weight of copolymers with AC decreases as its content in the polymerization system increases (Table 2). The dynamics of formation of macromolecules in the presence of fullerene has some features. Contrary to the stationary dependences typical of the reactions of radical homo- and copolymerization, the MW increases in the presence of C_{60} virtually during the entire process. This

is apparently caused by addition of propagating chains to fullerene, which results in a decreasing concentration of radicals in the system. Therefore, the polydispersity of fullerene-containing samples is lower.

CONCLUSIONS

(1) The copolymerization reactions in the presence of fullerene C_{60} have some common and specific features. The common trend is the inhibiting influence of fullerene, which is manifested differently, depending on comonomers.

(2) For the systems studied, the reaction orders with respect to the initiator and to the sum of the monomers correspond to the parameters of radical processes. In the presence of fullerene C_{60}, the activation energy increases for both systems, but to different extents: in the case of copolymerization of vinyl monomers, E_a increases by a factor of 2, and in the reaction with allyl chloride, by only 10 kJ mol^{-1}. Hence, incorporation of fullerene bound to an allyl compound into the polymer backbone is preferable in comparison with its addition to side allyl groups of the vinyl monomer. As a consequence, the mole fraction of allyl methacrylate in the reaction products increases by only a factor of 1.5, and the fraction of allyl chloride, by an order of magnitude.

(3) The molecular weight and polydispersity of fullerene-containing copolymers of allyl methacrylate and allyl chloride decrease in both cases. The most significant change in the molecular weight was found for the system with allyl methacrylate (by a factor of 10), and in the system with allyl chloride it decreased by a factor of 3.

(4) In the case of allyl methacrylate, fullerene C_{60} enters into the polymer chain at lower degrees of conversion.

Abstract—Copolymers with a mole fraction of acrylate units of 0.20 to 0.69 were prepared by radical copolymerization of methyl methacrylate with acrylic acid. The heat resistance and thermomechanical properties of copolymer films formed from dimethylformamide solution were evaluated, and the possibilities of improving these characteristics were demonstrated.

DOI: 10.1134/S1070427208040198

Thanks to high light transmittance, polymeric compounds based on poly(methyl methacrylate) (PMMA) are widely used in optical systems for information recording, but their applicability is restricted by the relatively low glass transition and flow points of methyl methacrylate (MMA) polymers and the insufficient adhesion of the material to silicate glasses. In this context, an urgent problem is modification of PMMA properties with the aim to improve its thermomechanical properties and enhance the heat resistance and adhesion, with preservation of the optical transparency. It has been found previously [1, 2] that materials with the required characteristics can be obtained by radical copolymerization of MMA with acrylic acid (AA). However, the dependence of the properties of the copolymers (CPs) on their composition has not been studied.

In this study we examined how the composition of MMA–AA copolymers affects their thermal properties.

EXPERIMENTAL

Radical copolymerization in the bulk was performed in a nitrogen flow at 60°C for 4 h in a glass test tube equipped with a reflux condenser [3]. The AA : MMA molar ratio was varied from 1 : 4 to 4 : 1. As initiator we used 2,2'-azobis(isobutyronitrile). After the synthesis completion, the polymer sample was ground and washed at room temperature with water and ethanol to remove the unchanged monomers and a part of AA homopolymer. Then the sample was dried and dissolved in dimethylformamide (DMF). The solution was passed through a glass frit, after which the copolymerization product was precipitated from the solution into water. A small amount of PMMA, which is insoluble in DMF, remained on the filter. The AA homopolymer remained in the CP precipitant. The CP composition was determined by acid–base titration of carboxy groups in organic solvents.

Poly(methyl methacrylate) and polyacrylic acid (PAA) were prepared under the same conditions as the MMA–AA copolymer. The molecular weights (MW) of PMMA and PAA were determined viscometrically in trichloromethane at 25°C ($K = 0.48 \times 10^{-4}$, $a = 0.80$; MW $= 3.85 \times 10^5$) and in water at 30°C ($K = 7.6 \times 10^{-4}$, $a = 0.5$; MW $= 1.62 \times 10^6$), respectively. To estimate the lengths of molecular chains in CPs of various compositions at 25°C, we measured the specific viscosities of their 0.5% solutions in a common solvent, acetic acid.

The thermal properties of the CPs were studied using film samples prepared from DMF solutions. Because of the high adhesion to glass, the films could not be detached from glass supports. Therefore, when preparing film samples for studying the thermal properties of the CPs, we used as supports polypropylene

plates. After solvent evaporation, transparent polymer films were obtained. They could be readily separated from the surface of the polypropylene plates. To remove residual DMF, the films were repeatedly washed with distilled water.

The thermal properties of MMA–AA were studied by the methods of combined thermal and thermomechanical analysis. A combined thermal analysis was performed on an OD-103 derivatograph (MOM, Hungary). The TG, DTG, and DTA curves were recorded in air at a heating rate of 5 deg min^{-1}. The sample weight was 100 mg. From the TG curves, we determined the temperatures T_5 and T_{10} corresponding to 5 and 10% weight loss, respectively. From the position of the minimum in the DTG curves, we determined the temperature of the maximal degradation rate, T_m.

The thermomechanical analysis was performed with a UIP-70 device (Central Design Office with Pilot Plant, USSR Academy of Sciences) in air at the same heating rate. A pressure of 0.59 MPa was applied to the sample. The film thickness was 50–90 μm. The thermomechanical properties were evaluated from the curves of the relative punching strain ε (%) vs. temperature T (°C).

Analysis of the chemical composition of the CPs (Table 1) showed that it coincided with the composition of the monomer mixture up to AA mole fraction in the mixture equal to 0.2. With a further increase in the AA content of the monomer mixture, the CP became depleted of AA units.

Solubility tests of the CPs in various organic solvents (acetone, ethanol, 1,4-dioxane, aromatic and chlorinated hydrocarbons, acetic acid, DMF) showed that the CPs dissolve to give concentrated solutions only in DMF and glacial acetic acid. Poly(methyl methacrylate) forms in these solvents only dilute solutions.

Table 1. Resistance of MMA–AA copolymers to thermal oxidative degradation

Mole fraction		T_5	T_{10}	T_m
AA in monomer mixture	AA units in CP	°C		
0	0	161	182	283
0.2	0.20	239	267	390
0.3	0.24	240	272	380
0.4	0.28	259	280	387
0.5	0.34	240	270	380
0.6	0.40	233	261	375
0.7	0.60	161	185	380
0.8	0.69	135	168	380
1.0	1.0	131	159	255

Figure 1 shows that, as the mole fraction of AA units in the CP is raised to approximately 0.3 (monomer molar ratio AA : MMA = 1 : 1.5), the specific viscosity of the CP increases relative to PMMA. As the mole fraction of AA units is raised further, the viscosity decreases, and, at the mole fraction of AA units equal to 0.69, becomes equal to the specific viscosity of PAA. Apparently, variation of the monomer ratio in the course of the CP synthesis was accompanied by variation of not only the chemical composition but also the polymer chain length, with the maximal chain length attained at approximately equimolar ratio of the monomers.

The thermogravimetric curves of MMA and AA homopolymers and of MMA–AA copolymers of various compositions (Fig. 2) show that the weight

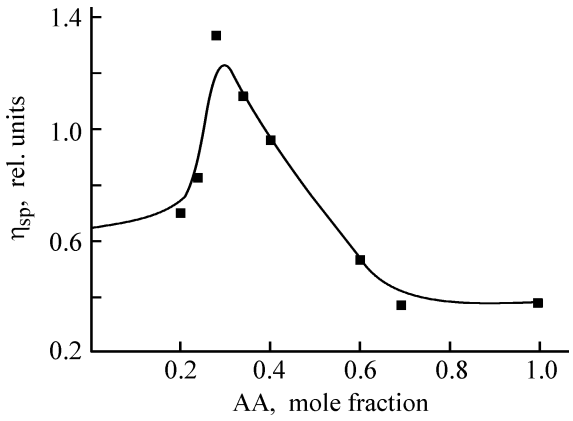

Fig. 1. Specific viscosity η_{sp} of 0.5% solutions of homo- and copolymers of MMA and AA in acetic acid vs. the mole fraction of AA units in CP.

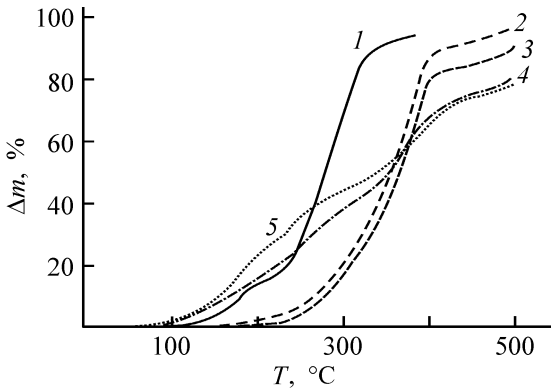

Fig. 2. Weight loss Δm vs. temperature T in thermal gravimetric analysis of (*1*) PMMA, (*2–4*) MMA–AA copolymers, and (*5*) PAA. Mole fraction of AA units in CP: (*2*) 0.20, (*3*) 0.28, and (*4*) 0.69.

Table 2. Glass transition and flow points of MMA–AA copolymers

Mole fraction of AA units in CP	T_g	T_f
	°C	
0	76	168
0.28	72	212
0.34	93	230
0.40	64	130
1.0	85	160

loss by the CPs may be either smaller or larger than the weight loss by the homopolymers, depending on the composition and temperature. For example, the weight loss by the CPs with the mole fraction of AA units equal to 0.20 and 0.28 (curves *2* and *3*, respectively) in the range from room temperature to 365–370°C is lower than the weight loss by PMMA (curve *1*) and PAA (curve *5*), and only at temperatures exceeding 370°C, the weight loss by the CPs becomes larger, compared to PAA, but remains smaller, compared to PMMA. At the mole fraction of AA units in the CP equal to 0.69, the weight loss in the range from 100 to 240–250°C (curve *4*) is smaller, compared to PAA (curve *5*), but larger, compared to PMMA (curve *1*). In the temperature range 250–500°C, the weight loss by the CP with a high content of AA units is smaller than that by PMMA and similar to that by PAA.

Thus, the CP with a relatively low content of AA units is the most resistant to thermal oxidative degradation. The observed effect is apparently associated with the decreased efficiency of cleavage of chemical bonds in the CP backbone, due to changes in the chemical nature of pendant functional groups in going from the homopolymers to CP. The low resistance to thermal oxidative degradation of the CP with a high content of AA units, compared to PMMA, in the range of up to 250°C is apparently caused by the possible decarboxylation of relatively long blocks of AA units. At temperatures exceeding 250–260°C, when the decarboxylation is complete and the observed weight loss is caused by the cleavage of chemical bonds in the CP backbone, the enhanced resistance of the copolymers to thermal oxidative degradation, compared to PMMA, is clearly manifested.

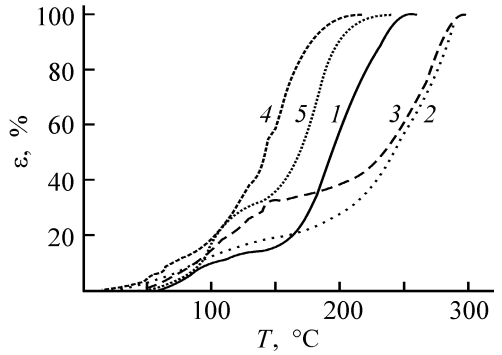

Fig. 3. Thermomechanical curves of (*1*) PMMA, (*2–4*) MAA–AA copolymers, and (*5*) PAA. (ε) Strain and (*T*) temperature. Mole fraction of AA units in CP: (*2*) 0.28, (*3*) 0.34, and (*4*) 0.40.

Data on the resistance of MMA–AA copolymers to thermal oxidative degradation (T_5, T_{10}, T_m) in relation to their composition are listed in Table 1. It can be seen that MMA and AA homopolymers show similar resistances to thermal oxidative degradation: For PMMA, T_5, T_{10}, and T_m are 161, 182, and 283°C, and for PAA, 131, 159, and 255°C, respectively. The MMA–AA copolymers with the mole fraction of AA units of 0.20 to 0.40 are more resistant to thermal oxidative degradation than PMMA and PAA. The largest values of T_5 and T_{10}, exceeding those of PMMA and PAA by almost 100°C, are attained at the mole fraction of AA units in the CP equal to 0.28, i.e., at the same copolymer composition at which the specific viscosity of 0.5% solutions of the CP in acetic acid becomes maximal. With a further increase in the mole fraction of AA units in CP to 0.60 and 0.69, T_5 and T_{10} dramatically decrease, approaching the values characteristic of PAA. It is important that the specific viscosity of 0.5% solutions of such CPs in acetic acid also becomes lower than that of the 0.5% PMMA solution. Therefore, apparently, the lower resistance to thermal oxidative degradation of the CP with a high content of AA units, observed in the initial steps of weight loss, may be due not only to possible decarboxylation of long blocks of AA units, but also to increased tendency of shorter CP chains to degrade. A certain contribution to the weight loss may also be made by removal of sorbed moisture whose amount increases with the content of AA units in the CP.

At high temperatures corresponding to active cleavage of chemical bonds in the backbone, the resistance of the CPs to thermal oxidative degradation is virtually independent of their composition. The temperature of the maximal degradation rate, T_m, of CPs fluctuates in the range 375–390°C as the mole fraction of AA units in the CP is varied from 0.20 to 0.69, whereas for PMMA, T_m is 283, and for PAA, 255°C.

The thermomechanical curves of PMMA, PAA, and MMA–AA copolymers are shown in Fig. 3, and the temperatures of transitions from one relaxation state to another are listed in Table 2. As can be seen from

Fig. 3, the thermomechanical curve of PMMA is typical of amorphous polymers. The temperature ranges corresponding to glassy, hyperelastic, and viscous-flow states can be distinguished. The temperatures of transitions from glassy to hyperelastic (glass transition point, T_g) and from hyperelastic to viscous-flow states (flow point, T_f) for PMMA are 76 and 168°C, respectively (Table 2). The thermomechanical curve of PAA is also typical of an amorphous polymer and is characterized by the temperatures T_g and T_f close to those of PMMA: 85 and 160°C, respectively.

The thermomechanical curves of MMA–AA copolymers do not differ essentially from those of PMMA and PAA. However, their position on the temperature scale relative to the curves of the homopolymers depends on the CP composition. The thermomechanical curves of CP samples with a AA mole fraction equal to 0.28 and 0.34 are shifted toward higher temperatures relative to the homopolymers. The glass transition points T_g of the CPs of these compositions are close to those of MMA and AA, whereas the flow points T_f exceed those of the homopolymers by more than 40°C. At the same time, the thermomechanical curve of the CP sample with a AA mole fraction equal to 0.40 is shifted toward lower temperatures, and T_g and T_f become lower than those of the homopolymers. Apparently, the sharp decrease in the flow point of the CP with a AA mole fraction equal to 0.40 is due to the short chain length (Fig. 1).

CONCLUSIONS

(1) Resistance to thermal oxidative degradation of methyl methacrylate–acrylic acid copolymers with the mole fraction of acrylic acid units of 0.20 to 0.40 exceeds that of the corresponding homopolymers. The heat resistance enhancement takes place for the step of cleavage of chemical bonds in the macromolecular backbone.

(2) The dependences of the glass transition and flow points of the methyl methacrylate–acrylic acid copolymers on the copolymer composition pass through a maximum at the mole fraction of acrylic acid units equal to 0.34.

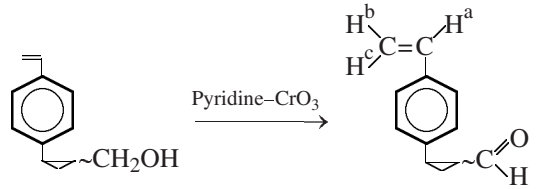
MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of 2-Formyl-1-(*p*-vinylphenyl)cyclopropane and Its Polymerization and Copolymerization with Styrene

K. G. Guliev

Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgaiyt, Azerbaijan

Received July 5, 2007



Abstract—2-Formyl-1-(*p*-vinylphenyl)cyclopropane was prepared, and its homopolymerization and copolymerization with styrene were performed. The effect of the substituent on the monomer reactivity and the photosensitivity of the copolymer obtained were examined.

DOI: 10.1134/S1070427208040204

Functional polymers find growing use in microelectronics owing to their high heat resistance, good electrical properties, and high deformation-and-strength characteristics. Such a set of properties makes some functional polymers useful for preparing protective and insulating layers in the production of microelectronic devices and circuits. A topological pattern is usually created in a polymer film by optical photolithography using a multilayer system of resists, or by appropriate modification of the polymer to make it photosensitive [1–5]. The latter alternative has a number of significant advantages, as it considerably simplifies and reduces the process of pattern formation and increases the resolving power of lithography.

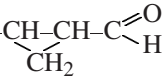
The aim of this study was to prepare a new formyl-substituted cyclopropylstyrene monomer, 2-formyl-1-(*p*-vinylphenyl)cyclopropane (FVPC), and to examine its radical polymerization and copolymerization with styrene. We also intended to study systematically the influence exerted on the photosensitivity of cyclopropane-containing polymers by the substituent at the cyclopropane ring in the pendant chain of the macromolecule [6, 7].

2-Formyl-1-(*p*-vinylphenyl)cyclopropane is a new promising monomer for preparing polymers with valuable properties for microelectronics. FVPC was synthesized as follows. First, we prepared 2-ethoxycarbonyl-1-(*p*-vinylphenyl)cyclopropane. Then, this ester was reduced to 2-hydroxymethyl-1-(*p*-vinylphenyl)cyclopropane [8], which was subsequently oxidized to FVPC according to [9]:

The structure of the aldehyde prepared was determined from the IR and ^{1}H NMR spectra. The results of spectroscopic studies and GLC analysis show that FVPC is a mixture of two geometric isomers, *cis* and *trans*, in a 30 : 70 ratio.

The IR spectrum of FVPC shows absorption bands at 1635–1640, 1035–1045, 1500, and 1605 cm^{-1}, characteristic of the vinyl group in cyclopropane and benzene rings. It also contains a band at 3010 cm^{-1} characteristic of the aldehyde C–H bond and a band at 1709 cm^{-1} corresponding to the C=O group.

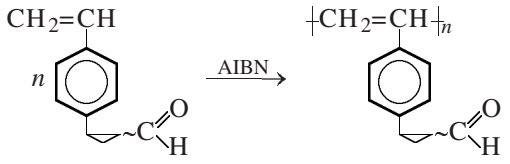
In the ^{1}H NMR spectrum, the vinyl proton signals are observed at 6.76 (H^a), 5.38 (H^b), and 5.80 ppm (H^c). The aromatic ring protons are manifested at 6.60–7.30 ppm. The aldehyde proton appears as a singlet at 9.1 ppm.



The vinyl proton signals are shifted downfield relative to unsubstituted styrene (H^a, 6.4; H^b, 5.11; H^c, 5.58 ppm). This shift is mainly caused by the mesomeric effect of substituents; specific distribution of the electron density in the cyclopropane ring also has a certain effect. The spectra suggest that all the synthesis steps leave the vinyl group and cyclopropane ring intact.

Copolymerization of FVPC (M_1) with styrene (M_2) in benzene at 333 K ($\Sigma[M] = 0.2$ M; 0.1% AIBN)

FVPC fraction in starting mixture, mol %	Yield, %	Aldehyde group, %	$[\eta]$, dl g^{-1}	Copolymer composition, mol %	
				m_1	m_2
90	12	15.5	1.19	92.19	7.81
75	8.5	13.67		81.10	18.9
50	10	10.6	1.08	63.97	37.03
25	80	7.06		41.86	58.14
10	7.5	3.79	1.05	22.48	77.52



From the monomer synthesized, we prepared new homo- and copolymers. The FVPC polymerization was performed in the bulk and in benzene at 70°C in the presence of azobis(isobutyronitrile) (AIBN). Polymerization in the bulk yields 1–2 wt % of an insoluble fraction. In polymerization in solution, no insoluble fraction is formed. The polymerization occurs without induction period at a constant rate up to 85% conversion. The polymers after precipitation and drying to constant weight are white powders readily soluble in benzene, chloroform, and dimethylformamide.

The structure of the polymer was examined by IR and ^{1}H NMR spectroscopy, and the polymer composition was determined by elemental analysis.

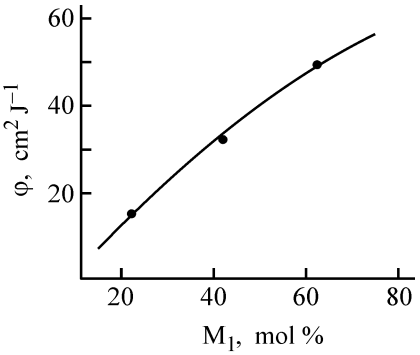
We found that the radical polymerization occurs via vinyl groups with the formation of macromolecules containing  pendant fragments. This is confirmed by the fact that the cyclopropane ring and aldehyde group remain intact in the course of polymerization. Comparison of the IR spectra of the starting FVPC and polymer thereof shows that the positions and intensities of the absorption bands of the cyclopropane ring and aldehyde group do not change noticeably, whereas the bands of the vinyl group disappear. The same conclusion follows from the ^{1}H NMR spectra.

The ^{1}H NMR spectrum contains signals from protons of the benzene (δ 6.85–7.25 ppm) and cyclopropane (δ 0.75–1.75 ppm) rings. The aldehyde proton gives a signal at 9.1 ppm. The signals of the vinyl protons fully disappear.

The IR and ^{1}H NMR data suggest the following structure of the polymer:

To reveal specific features in the behavior of FVPC under the conditions of radical polymerization, we also studied its copolymerization with styrene.

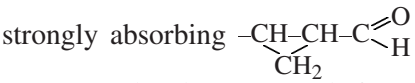
The structures of copolymer macromolecules obtained at various conversions and containing units of both monomers in the macrochain were examined by IR spectroscopy. The IR spectra of copolymer samples prepared at various ratios of the starting monomers contain absorption bands of the aldehyde carbonyl group at 1709 cm^{-1} and bands of the cyclopropane ring at 1035–1040 cm^{-1}. Analytical data confirm the occurrence of the copolymerization. We found that the radical copolymerization of the starting monomers follows regular trends characteristic of vinyl monomers. The polymers prepared contain reactive formyl-substituted cyclopropane fragments in the pendant chains.



The ratio of styrene and FVPC monomer units in the copolymer macromolecule was determined by elemental analysis and titration of aldehyde groups. The results are listed in the table.

These data show that FVPC is a more active monomer than styrene.

The higher activity of FVPC, compared to styrene, also following from the calculated Fineman–Ross copolymerization constants [10] of FVPC, may be due to conjugation of the cyclopropane ring with an electron-withdrawing formyl substituent, which is consistent with the data of [11, 12]. The copolymerization constants, $r_1 = 1.25 \pm 0.025$ and $r_2 = 0.32 \pm 0.01$, demonstrate the effect of the carbonyl group in the monomer on the electronic structure of the whole molecule. This conclusion is consistent with the UV spectra in which the absorption peaks of FVPC and styrene are observed at essentially different wavelengths: 300 and 240 nm, respectively.



In the monomer, the vinyl group is activated and the protonating radical is stabilized by not only *–J*, but also *–M* effect of the aldehyde group.

Our results and published data suggest that this behavior of FVPC is primarily due to the effect of

Photosensitivity φ of copolymer of FVPC (M_1) with styrene vs. copolymer composition.

the cyclopropane ring directly bonded to the carbonyl group and apparently conjugated with the vinylphenyl group. Therefore, the FVPC molecule can be considered a common conjugated system.

The presence of strongly absorbing  groups in polymer macromolecules prepared from FVPC monomer makes these polymers suitable as a photosensitive base for photoresists. The two reactive groups in the pendant chains, cyclopropane and aldehyde, readily cleavable under irradiation, make the polymers highly sensitive to UV irradiation. Under UV irradiation, the polymers fairly readily transform into the insoluble form.

The decrease in the sensitivity of the absorption bands belonging to the cyclopropane and aldehyde groups in the initial steps of UV irradiation is insignificant. Upon longer UV irradiation (30 min), these absorption bands fully disappear. This fact indicates that the cyclopropane and aldehyde groups are involved in photochemical reactions apparently resulting in the photochemical cross-linking of the polymer.

Experiments showed that the presence of a three-membered ring and an aldehyde group, capable of opening and cross-linking under UV irradiation [13, 14], in the pendant chains of the polymers allows preparation of negative photoresists. The photosensitivity of the homopolymer prepared from FVPC is 56 $cm^2 J^{-1}$. As for the photosensitivity of the copolymers obtained, it depends on the copolymer composition and increases with the mole fraction of FVPC (see figure).

Also, it is possible to prepare from the polymers synthesized thin uniform coatings with low defectiveness and good adhesion to the support.

The polymers synthesized also open up wide prospects for chemical transformations of the aldehyde groups by reactions with, e.g., phenylhydrazine, hydrazine hydrochloride, or aniline with the aim to obtain polymers with required properties.

EXPERIMENTAL

2-Formyl-1-(*p*-vinylphenyl)cyclopropane was prepared by the reaction of 2-hydroxymethyl-1-(*p*-vinylphenyl)cyclopropane with a pyridine–CrO_3 complex solution (Sarett reagent) [9]; bp 88–90°C/1 mm Hg, n_D^{20} 1.5810, d_4^{20} 1.082, MR_D: calculated 52.15, found 52.98.

Found, %: C 83.52, H 6.35.

Calculated, %: C 83.72, H 6.98.

Homopolymerization of FVPC and its copolymerization with styrene were performed in the bulk and in a benzene solution at 333 K in the presence of AIBN. The molar ratios of the monomers are listed in the table. The reaction was performed in ampules under nitrogen for 3 h, after which the ampules were opened, and the product was precipitated with methanol, washed with methanol, and vacuum-dried at 40°C.

The content of aldehyde groups in the copolymer was determined by titration. A 0.2–0.3-g portion of the copolymer was dissolved in 10–15 ml of dimethylformamide. After the dissolution was complete, a 15-fold excess (by weight) of hydroxylamine hydrochloride in dimethylformamide was added. The mixture was allowed to stand for 2 h at room temperature. Then, 50 ml of distilled water was added. The precipitate was filtered off and washed once more on the filter with 50 ml of distilled water. Then, 0.8 ml of a 1% solution of Bromophenol Blue was added, and the solution was titrated with 0.1 N NaOH until the color became blue-green.

Photochemical cross-linking of the polymers was studied as described in [7].

The molecular weight of the homo- and copolymers was estimated from their intrinsic viscosity determined in benzene in an Ubbelohde viscometer at 20°C; for the homopolymer, $[\eta] = 1.03$ dl g^{-1}, and the values for the copolymer are listed in the table.

The IR spectra of the synthesized monomer and its homo- and copolymers were measured on a UR-20 spectrometer, and the ^1H NMR spectra, on a Tesla BS-487B spectrometer (80 MHz) in CCl_4. The purity of the compounds was determined by GLC on an LKhM-8MD chromatograph, model 3.

CONCLUSION

A new monomer, 2-formyl-1-(*p*-vinylphenyl)cyclopropane, its homopolymer, and copolymer with sty-

rene were prepared. The compounds show high photosensitivity due to the presence of cyclopropane and aldehyde groups in the macromolecule.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Parameters of Integrated Mechanothermochemical Reclaiming on the Physicochemical Properties of Vulcanized Rubbers

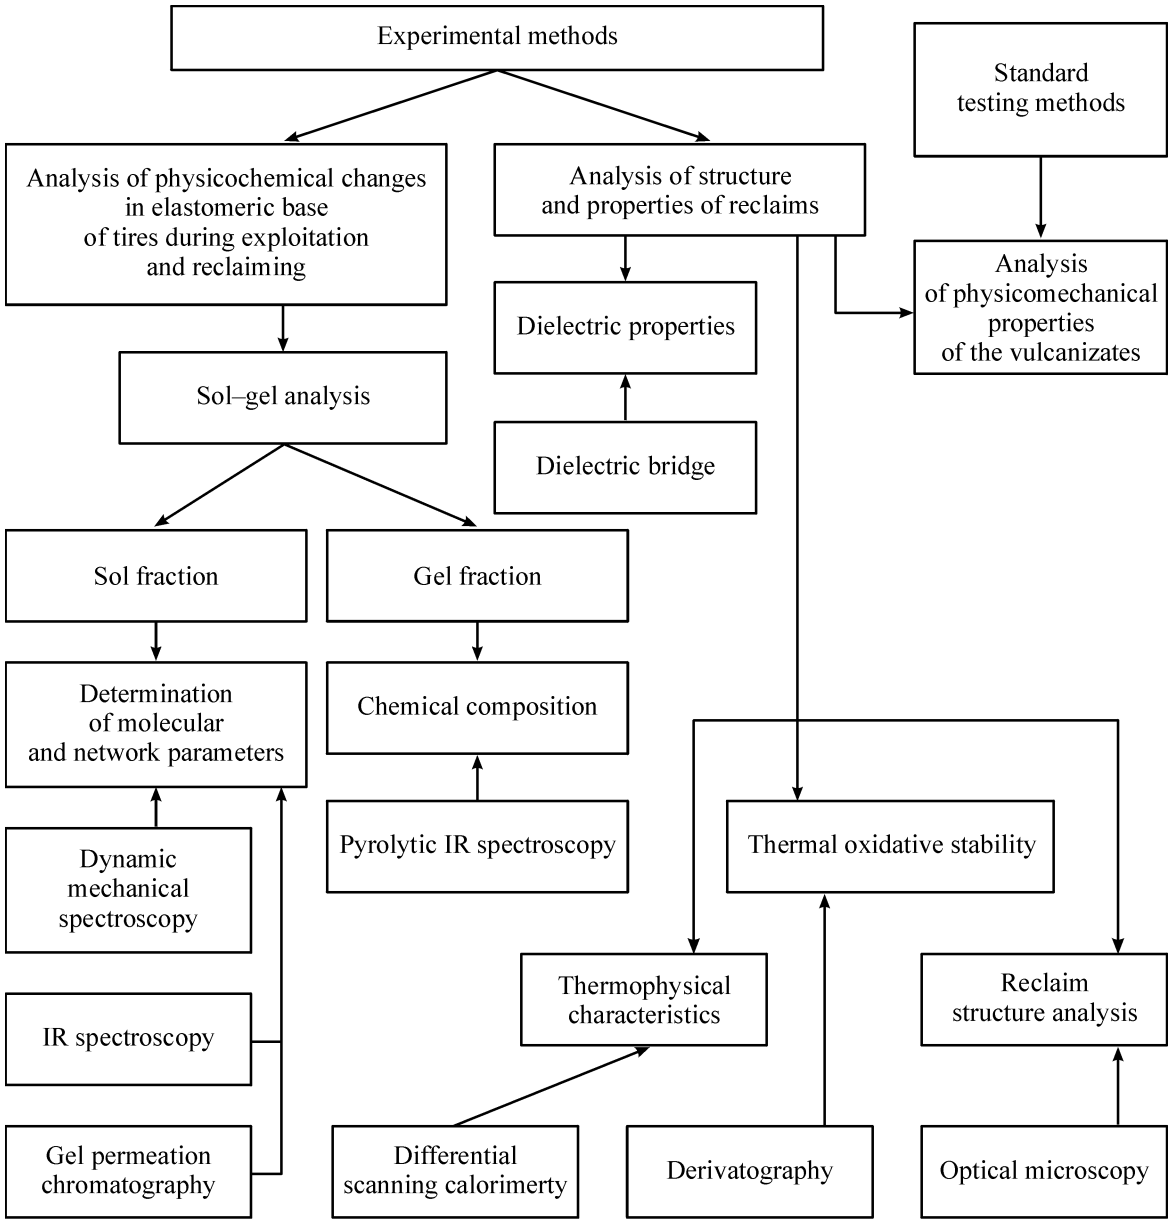
Abstract—The influence of integrated reclaiming of vulcanized rubbers, combining the high-temperature mechanothermochemical and steam degradation methods, on the properties of reclaims was elucidated.

DOI: 10.1134/S1070427208040216

The existing methods for reclaiming of vulcanized rubber are underlain by breaking the cross-links. The available experience suggests that it is expedient to combine high-temperature mechanothermochemical and steam degradation methods in reclaiming [1, 2]. This not only provides a more extensive impact on the material being reclaimed but also excludes "harsh" modes of the process, resulting in an undesirably deep degradation.

From the economical viewpoint, the reclaiming technology is acceptable only if implemented in the continuous mode. This requirement can be satisfied with worm-gear machines. This inevitably generates a problem of intensive cooling of the equipment. At the same time, the closed design of worm-gear machines allows introduction into the processing zone of water which can, in parallel, act as a coolant and, via vaporization, as a degrading agent (the role of the latter can also be played by other substances, including those occurring in the liquid phase). Special worm-gear machines were designed for implementation of such processes [3]. They exhibit high performance characteristics with tire crumb as the raw material. The reason is twofold: This avoids emergency operation modes for the equipment in cases when foreign inclusions from vulcanized rubber pieces get into working heads, and the interface surface area between the material and the operating elements of the equipment is substantially increased, thereby providing uniform warming and uniform external impact on the material.



We estimated here the efficiency of the suggested procedure by analyzing how the integrated mechanothermochemical reclaiming affects the physicochemical properties of vulcanized rubbers.

EXPERIMENTAL

General information about the investigation methods we used is presented in the scheme. Below, some testing techniques and the facilities are specified.

The tire material undergoes numerous physicochemical changes during exploitation and subsequent processing. We examined here the changes in the molecular composition; micro- and macrostructures of the rubbers in the tire rubber formulation and their chemical structure; microaggregation states governed by the nature of interaction of rubbers with the filling agent; vulcanization network density; and the extent of degradation in different stages of the tire processing.

Our study was concerned with the material of the treads of automobile tires manufactured in Russia and other countries, both fresh and spent (climatic zones of the Russian Federation and the Western Europe); different size fractions of the tire rubber crumb, as well as the reclaim obtained in the com-

Scheme.

bined mechanothermochemical–steam degradation mode from a tire crumb on the worm-degradation unit we developed.

For all the objects examined, the material was separated into the gel and sol fractions in solvents convenient for subsequent analysis.

For the fresh tire samples, as well as for those spent or processed, we carried out structural analysis based on the dynamic mechanical spectroscopic data. The tests were carried out over a wide temperature range (from –100 to +150°C) at a frequency of 20 Hz on a Kuvshinskii–Sidorovich pendulum resilience tester. The measurements were carried out in the temperature scanning mode at the scanning rate of 5 deg min^{-1}.

The viscoelastic properties were estimated from two parameters, mechanical loss tangent $\tan\delta$ and dynamic modulus of elasticity E:

$$\tan\delta = \ln(A^2/B^2)/\pi, \quad E = (\pi HM)/(t^2S),$$

where A and B are the pendulum deviations before and after the impact, respectively; t, impact duration; H, height of the sample; and S, cross-sectional area of the sample.

We compared the initial and processed tire tread samples with the use of the IR data as well. The samples were extracted with tetrahydrofuran (THF); after filtration, the drops of the extract were applied to a KBr plate. The samples were dried under an IR lamp and then placed in a spectrograph.

For the soluble (sol) fraction we determined the molecular composition, chemical structure, and heterogeneity (by optical microscopy and light scattering).

The MWD parameters were determined by high-performance gel permeation chromatography on a Waters chromatograph. The samples were extracted with THF at room temperature for 24 h and then filtered. Next, we determined the amount of the polymer dissolved in THF, the number-average and weight-average molecular weights, and MWD parameters. Also, we calculated the viscosity.

The amount of the gel fraction was determined in two solvents, THF and toluene. The samples were extracted for 24 h at room temperature. The amount of the gel, %, was calculated by the formula

$$X = (m_1 \times 100)/m,$$

where m and m_1 are the weights of crushed vulcanized rubber and dried residue, g, respectively.

For the insoluble (gel) fraction we determined the chemical composition by pyrolytic IR spectroscopy and examined the heterogeneity.

The efficiencies of different reclaiming methods were compared using the optical microscopic data for the sizes of the vulcanized rubber inclusions that were preserved and remained unchanged during the treatment. To this end, we prepared dilute 1 : 10 blends of the reclaim in polyisobutylene and 1 : 10 solutions of the reclaim in toluene. The samples were applied to the object-plate of a microscope to determine the size and nature of the inclusions.

From the crumb and reclaim we prepared identically compounded vulcanizates and tested their physicomechanical properties by standard procedures.

Reclaiming substantially modifies the physicochemical properties of the material. Above all, the gel content of the material (solvent THF) sharply decreases. For example, the reclaim from imported rough material (vulcanized rubber granulate prepared using a rotary milling cutter) contains 74.8% gel; the rubber content of the sol fraction increases to 78.2% (M_w = 38000; M_n = 11000; K = 3.4; intrinsic viscosity η = 0.36 dl g^{-1}); the reclaim from the imported tire crumb contains 67.9% gel; the rubber content of the sol fraction increases to 93.3% (M_w = 46900; M_n = 13370; K = 3.5; η = 0.41). The corresponding characteristics of the reclaim from Russian crumb are as follows: gel content 67.4%; M_w = 36100; M_n = 10240; K = 3.5; η = 0.41 dl g^{-1}.

For comparison, the 0.04-mm vulcanized rubber crumb prepared by mechanical degradation combined with ultrasonication contains 77% gel (solvent toluene). In this case, the crumb preparation is accompanied by more exhaustive degradation of rubber into a wide spectrum of low-molecular-weight products. This demonstrates the high efficiency of the method we suggested.

Our data provide a fairly comprehensive information about the structural changes occurring in the spent vulcanized rubber during reclaiming. The following structural changes accompany the vulcanized rubber processing. According to data of pyrolytic IR spectroscopy, the content of the oxygen-containing groups in the reclaim obtained from the spent treads made of imported rough material decreases from 0.30 to 0.19. This can be attributed dilution of the reclaim by additives such as softeners, fillers, etc. The content of unsaturated groups remains virtually unchanged, although that of the conditionally hydroxy groups tends to increase. Hence, during preparation of the reclaim in the presence of steam, hydroxy groups are formed at the degradation sites of the macromolecules, rather than at the double bonds.

The content of oxygen-containing groups in the sol fraction from the same reclaim, estimated from the solution IR data, slightly increased, compared to the pyrolysis data (the plasticizers and stabilizer precipitated with an alcohol were removed from the sol fraction), the content of unsaturated groups decreased, and the amount of hydroxy groups slightly increased relative to the initial tread. As to the gel fraction, all the determined parameters increased. The reason is that the formation of polar groups favors interaction with the carbon black surface, and virtually all the groups having a functionality (oxygen-containing, hydroxy, and unsaturated groups) are adsorbed by the filler.

For the reclaims prepared from a crumb, the general trends in variation of the properties of the materials are preserved. At the same time, the total content (according to the data of pyrolytic IR spectroscopy) of hydroxy groups, rings, and styrene groups is increased. This is due to the change in the chemical composition of the pyrolysis products, because they are obtained from the "whole tire" crumb in which the content of the divinyl–styrene rubber is higher

than that in the tread component. However, MWD broadening in going from the rough material to the crumb can intensify the oxidation in preparation of the reclaim, especially under exposure to steam.

The characteristics of the reclaims obtained from the imported and Russian crumbs are close, which suggests that the processes occurring in different materials are identical. In particular, like in the case of the reclaim from imported tires, the gel fraction is enriched in fragments of the rubbers containing functional groups, because they are more actively sorbed by the carbon black surface.

An indirect evidence concerning the role played by the oxidation processes in preparation of the reclaim was obtained from mechanical spectroscopic data. The reclaims prepared from fresh and spent tires exhibit the tan δ maxima at identical temperatures (Fig. 1). At the same time, the position of the tan δ maximum for the imported granulate prepared by tire milling is shifted to higher temperatures (Fig. 2). For example, $T_{t\delta_{max}}$ for the reclaims from imported rough material was estimated at –30°C, and that for the Russian and imported crumb, at –35 to –40°C. It is seen that the reclaims obtained from a crumb (both Russian and imported) are characterized by virtually identical tan δ_{max} parameters; at the same time, the reclaim from imported crumb is more severely degraded, and at T ~100°C a flow area is observed for the reclaim. This reclaim exhibits a fairly extended area of a stable state of the soot-rubber gel (from 0 to 30°C).

For the reclaim obtained from the Russian tire crumb, the area of a stable state of the soot-rubber gel is narrower (from –20 to –10°C) and shifted to lower temperatures. This suggests a lower temperature stability of the reclaim. The widest area of existence of the soot-rubber gel is exhibited by the reclaim prepared from imported rough material (from –20 to +25°C), but it comprises a number of temperature steps characterizing the degradation of the soot-rubber gel in different structural formations of the reclaim. Transitions from –30 to 0…+10°C are observed for both the initial and worn tread samples. The lack of flow areas for the reclaims from the Russian crumb and imported rough material suggests that the extent of degradation of the vulcanized network is too low.

To validate this conclusion, we prepared identically compounded vulcanizates from the reclaims examined. Indeed, all the vulcanizates obtained from reclaims based on the Russian and imported crumb and rough material give close temperature dependences of

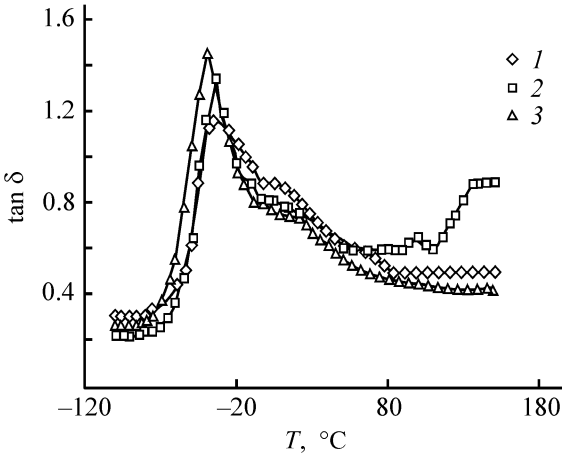


Fig. 1. Temperature dependence of the mechanical loss tangent tan δ for the samples of tread rubbers. Tread: (*1*) spent and (*2*) fresh.

tan δ; $\tan\delta_{max}$ is close to 0.82 (Fig. 3). The Russian crumb exhibits the tan δ maximum at –35°C, and imported crumb, at –25°C. A shoulder in the curve, a manufestation of the mobility of molecules in the soot-rubber gel, is observed at tan δ of ~0.7, and for the Russian material it is shifted to lower temperatures, –25 to –30°C, relative to the imported material (–20 to –10°C). This fact also evidences a high temperature stability of the soot-rubber gel in the imported reclaim.

To summarize, by contrast to exploitation, the processing of the material causes both the content and the average molecular weight of the soluble (sol) fraction of the material to sharply increase; a large contribution comes from the oxidation processes responsible not only for the formation of oxygen-containing groups (the α-transition temperature increases by over 10°C) but also for the increase in the aggregation stability of the soot-rubber gel; the chemical bonds of the vulcanization network for the reclaim obtained from imported crumb undergo a more exhaustive degradation, which is manifested in its flowability at 110°C.

Although the physicochemical changes in the Russian and imported materials proceed differently, the formal parameters of all the reclaims examined are close. Moreover, the recycled vulcanizates from the reclaims meet the requirements imposed by the appropriate branch standard (Table 1).

A high efficiency of the integrated mechanothermochemical reclaiming is also suggested by comparison of the properties exhibited by the tire reclaim obtained by the thermomechanical procedure (RShT, RShTN, Tchekhov Reclaim Plant) and the procedure we suggested (RShTA, Elast-Tekhnologiya) (Table 2).

Thus, the reclaiming procedure suggested affords products of the desired quality.

CONCLUSIONS

(1) The procedure suggested for integrated mechanothermochemical reclaiming of rubbers affords products of the desired quality. It compares favorably with the existing procedures in the working mode (continuous), as well as in the performance characteristics and economic efficiency, due to the use of coarser crumb as the raw material.

(2) The procedure suggested is distinguished by the possibility of fine control over the mechanothermochemical degradation.

Abstract—Effect of dispersity, content, and nature of silica on the deformation-strength parameters of latex films obtained under various conditions was studied.

DOI: 10.1134/S1070427208040228

An effective way to modify properties of polymeric materials is to introduce various fillers (solid, liquid, or gaseous). Caoutchouc can be reinforced with solid fillers with particle sizes of 5 to 1000 nm, with fillers having particles 10 to 50 nm in size exhibiting the strongest reinforcing properties [1]. The most frequently used solid fillers are technical-grade carbon (carbon black) or silica in the form of a precipitated silicon dioxide (white carbon black, perkasil, etc.). A polymer is filled by its direct mixing with a filler or by introduction of the filler in the latex stage. Introduction of a filler into the latex yields a more uniform distribution of components, compared with introduction of fillers into a dry caoutchouc in a rolling mill of a rubber mixer, and diminishes the energy expenditure for mixing.

A promising reinforcing filler is colloid silica. Modern industry manufactures colloid silica in the form of a hydrosol that is, as a rule, stabilized with NH_4^+ or Na^+. Silica particles have a spherical shape and their size (diameter) is approximately 6 to 30 nm, depending on a brand. Both mono- and polydispersed sols are manufactured. A filler of this kind can find use in production of various rubber articles, and especially thin-walled articles fabricated by dipping (gloves, bladders, etc.)

In this communication, results obtained in a study of the influence exerted by the dispersity of silica on the deformation-strength characteristics of latex films produced by drying under various conditions are reported.

EXPERIMENTAL

The latex films were produced from an SKD-1S polybutadiene carboxylate latex manufactured by Voronezhsintezkauchuk Open Joint-Stock Company. The latex was a product of joint emulsion polymerization of butadiene with methacrylic acid (about 1 %) in the presence of sodium alkylbenzene sulfonate. As active fillers were used silica hydrosol of Sialit-30 brand (Silikat Private Company) and white carbon black of BS-100 brand. The particle size d of silica in the hydrosol was 6.3 nm (according to the results of adsorption titration by the Sears method [2]). Prior to introduction of white carbon black into the latex, an aqueous dispersion was preliminary prepared. For this purpose, a weighed portion of white carbon black (~30 g) and water (~170 ml) were introduced into a ball mill, and grinding was performed for approximately 10 h. The size of silica particles in the resulting suspension and that of polymer particles in the latex were determined by the optical method with a FEK-56 photoelectrocolorimeter to be 303 and 110 nm, respectively.

The latex films were produced by casting-and-drying on cellophane. The films were dried in two modes: at 60°C for 120 min ("mild" drying) or at 140°C for 50–60 min ("severe" drying).

To obtained filled films, a mixture of a latex and a silica hydrosol or a suspension of white carbon black was preliminarily prepared with required rela-

tive amounts of silica and the polymer. The deformation-strength characteristics of the films obtained was measured on a tensile machine by the standard procedure.

In the first stage, the influence exerted by the conditions in which films of unfilled and filled polymers with varied content of SiO_2 are dried on the deformation-strength parameters (DSP) of the films was studied. It was found (Table 1) that, for the unfilled polymer, the drying mode has no effect on the relative tensile strength (conditional strength limit) f_t (0.40–0.43 MPa), but drying under severe conditions leads to a decrease in the relative tensile elongation at break (ε_b), residual relative tensile elongation after break, ε_{res}, and tear resistance B. This indicates that molecules are cross-linked at tertiary atoms of molecular chains of the polymer, with its separate DSP decreasing in the course of thermal treatment. Making the drying mode even more "severe" (thermo-oxidative aging at 100°C for 72 h) presumably leads to the maximum possible degree of cross-linking of the polymer, with the deformation parameters steeply decreasing (ε_b to 30% and ε_{res} to 0%) and strength parameters increasing (f_t by more than a factor of 20, and B by a factor of 10) (Table 2).

Table 3. Deformation-strength parameters of latex films produced by severe drying at varied content of BS-100

In mild drying of polymer samples filled with the sol in an amount of up to 5 wt %, the content of silica has virtually no effect on the DSP of the films (Table 1). This is apparently due to the considerable residual humidity of the sol-filled polymer. The moisture bound to the surface of particles of the hydrophilic filler hinders its interaction with the polymer macromolecules. The hydrophilicity of the SiO_2 sol is confirmed by the equilibrium degree of swelling of the filled polymer in water, W = 8.9–14.8 wt % against 5.5 wt % for the unfilled polymer (Table 1).

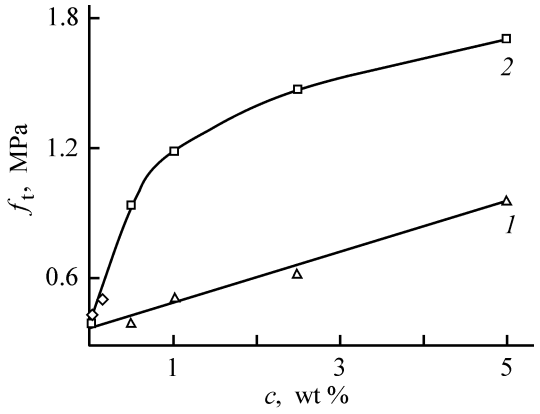

Fig. 1. Tensile strength f_t of latex films subjected to severe drying vs. content c at different sizes of filler particles. (*1*) SiO_2 sol and (*2*) white carbon black; the same for Fig. 2.

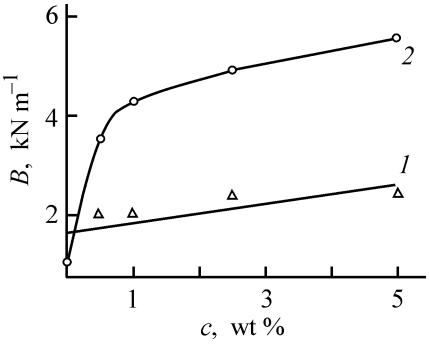

Fig. 2. Tear resistance B of latex films (severe drying) vs. content c at different sizes of filler particles.

Passing to a severe drying mode makes lower the content of the residual moisture, raises the probability of chemical cross-linking of polymer macromolecules (with ε_{res} decreasing from 18.4–49.0 to 7.0–8.75%, and W, to 1.8–9.7 wt %), and reveals the effect of SiO_2 on the DSP of filled films. As the content of silica sol increases (to 5 wt %), the tensile strength f_t and tear resistance B grow (from 0.40 to 0.98 MPa and from 2.05 to 2.44 kN m^{-1}, respectively), compared with the unfilled polymer, and the relative tensile elongation at break, ε_b, grows (by a factor of 1.7–2.7) at a residual strain ε_{res} preserved at a level of 7–9% (Table 1). Thus, the severe drying of the polymer filled with the SiO_2 sol reveals the strengthening effect of the filler (the strength of the polymer increases at unchanged deformation properties without acceleration of the chemical cross-linking of its molecules). Further studies were performed with the use of this drying mode.

In the presence of the sol, films subjected to accelerated thermo-oxidative aging exhibited an even more pronounced strength enhancement as the content of SiO_2 was raised: f_t increased to 15.6–20.4 MPa, and B, to 20.7–30.4 kN m^{-1} (at a silica content of up to 1.3–5 wt %), with ε_b and ε_{res} becoming zero (Table 2).

The results obtained upon introduction of a coarser dispersed silica in the form of a dispersion of BS-100 white carbon black are listed in Table 3. It can be seen that, compared with the case of a nanodispersed SiO_2 sol, a considerable increase in the strength parameters f_t and B of the films is observed (by a factor of 1.5 and more), but, at the same time, ε_b and ε_{res} substantially decrease. For example, f_t increased from 0.4–0.98 to 0.94–1.71 MPa, and B, from 2.05–2.44 to 3.54–5.58 kN m^{-1} (Figs. 1, 2); whereas ε_t and ε_{res}

decreased from 239–368 to 32–86% and from 7–8.8 to 0–2.2%, respectively.

Thus, on passing from the sol to white carbon black, with the filler dispersity decreasing (average particle size increasing from 6 to 303 nm), the strength of the polymer is enhanced to a greater extent but its elastic properties are strongly deteriorated.

Figure 3 shows how the stress f in polymeric latex films depends on the strain ε at a varied content and size of silica particles introduced as a hydrosol or white carbon black. The size of filler particles at the same filler content affects the slope of the f–ε straight line. Coarse particles provide a higher f at a small ε of the films. This can be attributed to acceleration of the chemical cross-linking of SKD-1S polymer in the presence of white carbon black, which leads to a decrease in ε_b and ε_{res}, i.e., to loss of elastic properties.

It should be noted that, in the presence of small amounts of BS-100, a larger degree W of equilibrium swelling of films in water is observed despite the increase in the degree of cross-linking of the polymer (Table 3).

According to the existing concepts [1], the 3D macromolecular network of an elastomer is irregular, and, therefore, deformation gives rise to considerable overstresses in its certain parts, with macromolecules ruptured there, but the most part of the network being only slightly strained. In addition, the microheterogeneity of the latex film produced by casting and drying is superimposed on the irregular 3D network of the elastomer. The residues of the emulsifier undissolved in the polymer are concentrated at places of contact between adhering globules of the elastomer and introduce additional defects into its supramolecular structure [3, 4]. The reinforcement of the elastomer with active fillers consists in that, being concentrated in the interglobular space, nanosize filler particles favor equalization of stresses in the elastomer.

The results obtained are in agreement with data on how the particle size of such a filler as chalk affects the deformation-strength properties of polyurethane elastomers [5]. Presumably, the observed effects are due to the influence exerted by the particle size on the structure and state of the network of transverse bonds of the macromolecular matrix. As the size of filler particles increases, the role of internal stresses appearing upon incorporation of particles into the 3D intermolecular network becomes more important and the fraction of the polymer volume subject to their action grows. The coarser the particles, the larger the defects in the network of transverse bonds of

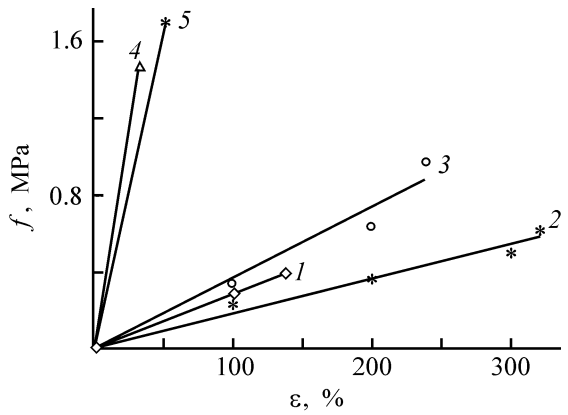

Fig. 3. Stress f vs. strain ε in latex films (severe drying). Content (wt %) of SiO_2 introduced as a sol: (*1*) 0, (*2*) 2.5, and (*3*) 5.0; and as white carbon black: (*4*) 2.5 and (*5*) 5.0.

macromolecules [6, 7]. As is known, large defects more strongly affect the DSP of the polymer, e.g., the relative tensile elongation at break, than smaller ones [7–9].

The imperfection of the network of transverse bonds in the presence of coarse particles of white carbon black also accounts for the increase in the degree of swelling in water of a polymer filled with these particles at a smaller ε_{res}, i.e., at a higher level of cross-linking of the elastomer.

CONCLUSIONS

(1) No reinforcing properties of the filler are observed in films of a sol-filled polymer, obtained in the mild drying mode (60°C for 120 min). On making the drying mode more severe (140°C for 50–60 min), f_t, B, and ε_b increase, depending on the sol content, with ε_{res} remaining unchanged.

(2) Introduction of white carbon black particles in an amount of up to 5 wt % into the polymer of latex films subjected to a similar drying improves the tensile strength, but markedly reduces the elongation and the residual strain. This is accounted for by acceleration of the cross-linking of polymer macromolecules in the presence of BS-100 particles with an average size of 303 nm.

(3) Presence of a SiO_2 sol in an amount of up to 5 wt % in polymeric latex films subjected to severe drying leads to an increase in both the strength and relative tensile elongation at break, with the residual strain preserved. The invariable level of the residual strain in polymeric latex films filled with the SiO_2 sol indicates that the cross-linking rate of polymer macromolecules in the films remains unchanged, and

the lower degree of swelling in water shows that a more ordered cross-linking structure of macromolecules is formed, compared with the unfilled polymer and that with BS-100.

(4) A linear dependence of the stress on strain is observed for films of the sol-filled polymer. The content of sol determines the strain in a wide range of strains.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Styrene-(Meth)Acrylate Copolymers in the Presence of 1-Nitroso-2-naphtholatocobalt(III)

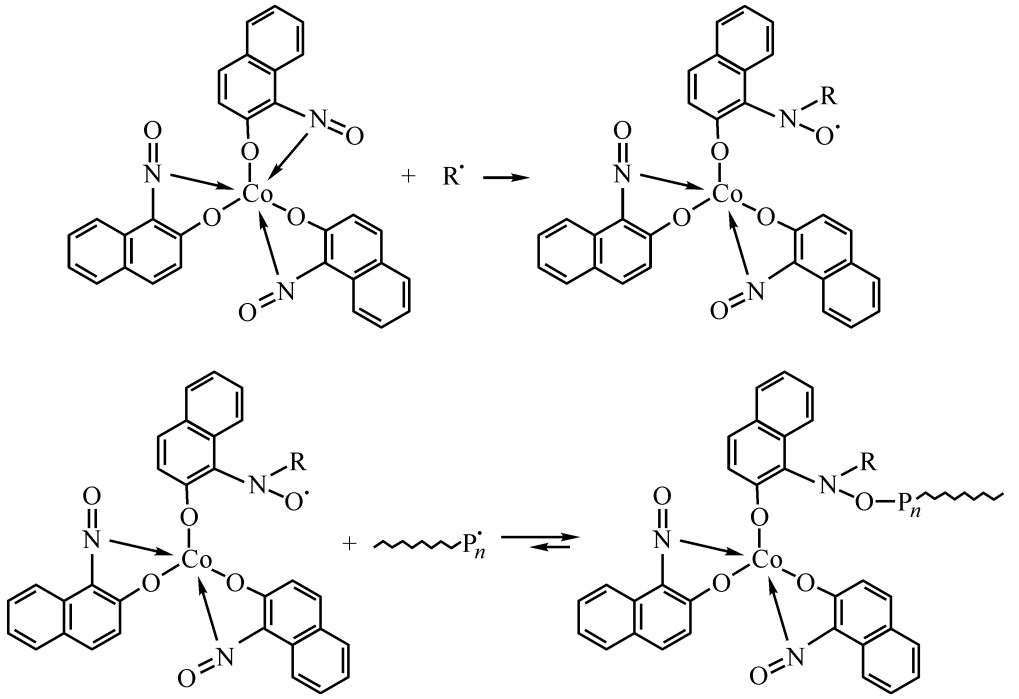
Abstract—Preparation of styrene–methyl methacrylate, styrene–butyl methacrylate, and styrene–butyl methacrylate copolymers by pseudolive radical polymerization was studied.

DOI: 10.1134/S107042720804023X



Pseudoliving radical polymerization finds growing use in preparation of new polymers. For this purpose, a wide range of sterically hindered stable nitroxyl radicals (derivatives of 2,2,6,6-tetramethylpiperidine-1-oxyl, TEMPO, di-*tert*-butylnitroxyl, etc.) can be used [1]. A significant disadvantage of TEMPO is that it provides pseudoliving polymerization of only a narrow range of monomers (mainly styrene and its derivatives). Irreversible reaction of the propagating radical with the nitroxyl radical to form hydroxylamine and a "dead" polymer prevents controlled polymerization of (meth)acrylates in the presence of alkoxyamines [2]. The range of vinyl monomers polymerizing by the pseudoliving mechanism can be extended by in situ generation of nitroxyl radicals during polymer synthesis. In this case, block copolymers of the required block length and narrow molecular-weight distribution can be prepared. These copolymers consist of blocks of varied chemical nature. Among these compounds are nitrones and nitroso compounds which are effective free-radical acceptors (spin traps) and react with free radicals to form stable spin adducts [3, 4]. We have shown [5] for the first time that 1-nitroso-2-naphtholatocobalt(III) (NNC) could be used for this purpose.

The aim of this study was to prepare block copolymers of styrene (ST) with methyl methacrylate (MMA), butyl acrylate (BA), and butyl methacrylate (BMA) in the presence of NNC generating in situ stable radicals.

EXPERIMENTAL

The block copolymers were prepared in two steps. In the first step, polystyrene (PST) blocks, in which NNC fragment is reactive at a particular temperature, were prepared at 120°C. In the second step, MMA, BA, or BMA was added to PST as a macroinitiator. The concentration of "activated" PST was 4.12 wt %. The activated PST prepared at [NNC] = 7×10^{-3} M and [AIBN] = 5×10^{-3} M and isolated at the conversion of 72 and 79 wt %, with the molecular weights of 5.4×10^4 and 4.3×10^4, was used for preparing the PST–polymethyl methacrylate (PMMA) and PST–polybutyl methacrylate (PBMA) block copolymers. PST prepared at [NNC] = 3×10^{-3} M and [AIBN] = 2×10^{-3} M and isolated at a conversion of 71 wt %, with molecular weights of 9.3×10^4, was used for preparing the PST–polybutyl methacrylate (PBMA) block copolymer. The polymerization was performed in sealed ampules after degassing by threefold freezing-pumping-thawing. The block copolymers were purified by triple reprecipitation from chloroform solutions with methanol (PST–PBA, PST–PBMA) and petroleum ether (PST–PMMA) and dried in a vacuum to constant weight at room temperature. The molecular-weight characteristics of the copolymers were studied by gel permeation chromatography at 40°C on a Prominence LC-20VP chromatograph (Shimadzu) with columns packed with polystyrene–divinylbenzene copolymer with a pore size of 1×10^6 and 1×10^5 Å. A differential refractometer was used as the detector. The eluent was tetrahydrofuran.

Previously [5] we have found that polymerization of ST and BA in the presence of NCC in the "living" chain mode was characterized by the following features: absence of the gel effect, linear dependence of the molecular weight on conversion, and linear dependence of the logarithm of conversion $\ln [M]_0/[M]$ ($[M]_0$ and [M] are the initial and current monomer concentrations) on the reaction time. Based on the kinetic features of the polymerization and analysis of the molecular-weight properties, we suggested the following polymerization mechanisms in the presence on NNC:

In the case of polymerization in the "living" chain mode, a polymer isolated at any conversion can initiate polymerization of a fresh monomer portion, i.e., can act as a macroinitiator. To test whether PST prepared in the presence of NNC is suitable as a macroinitiator, we performed the postpolymerization. To PST prepared at 120°C ([NNC] = 7×10^{-3} M and [AIBN] = 5×10^{-3} M) and isolated at a conversion of 22.3 wt % with a molecular weight of 34.8×10^5, a fresh portion of the monomer was added and polymerized at the same temperature. The dependence of the viscosity-average molecular weight of PST on the conversion for the primary polymerization of ST and ST polymerization in the presence of the macroinitiator is shown in Fig. 1. It is seen that the number of the macromolecules involved in both processes remains constant.

Synthesis of block copolymers with the use of another monomer in the second step is of practical interest. Figure 2 shows the semilog plot of $\ln [M]_0/[M]$ vs. reaction time for MMA conversion with the use of activated PST prepared in the presence of NNC.

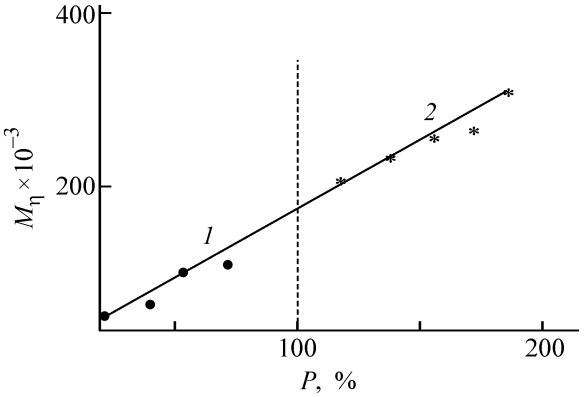


Fig. 1. Viscosity-average molecular weight of PST M_η vs. the conversion P for (*1*) primary and (*2*) secondary polymerization. T = 120°C, [AIBN] = 5×10^{-3} M, [NNC] = 7×10^{-3} M, ω_{PST} = 4.12 wt %.

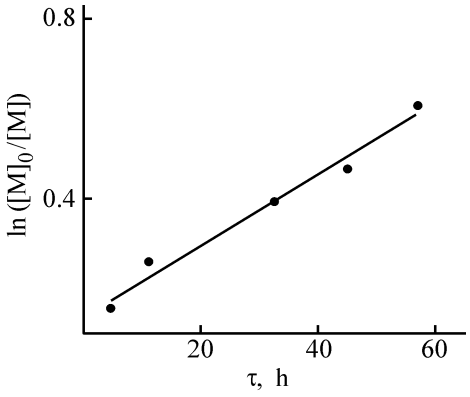

Fig. 2. $\ln [M]_0/[M]$ vs. of the time τ of MMA polymerization initiated by active PST. [AIBN] = 5×10^{-3} M, [NNC] = 7×10^{-3} M, conversion 40 wt %, $M_n = 3.1 \times 10^4$. T = 120°C, ω_{PST} = 4.12 wt %.

Molecular-weight characteristics and conversion P of activated PST and its block copolymers

Property	PST–PMMA block copolymer*			PST–PBA block copolymer**		
	Activated PST	Polymerization product		Activated PST	Polymerization product	
		mode 1 (block copolymer)	mode 2 (PMMA)		mode 1 (block copolymer)	mode 2 (PBA)
P, %	72	6.5	6.5	79	10	10
$M_n \times 10^{-4}$	5.4	7.03	99	4.3	4.8	174
M_w/M_n	1.95	1.77	1.31	1.63	1.61	1.25

* Corresponds to Fig. 3.

** Corresponds to Fig. 4.

As can be seen from Fig. 2, no gel effect typical of the conventional radical polymerization of MMA is observed. The gel permeation patterns of the initial activated PST and PST–PMMA block copolymer isolated at a conversion of 6.5 wt % are shown in Fig. 3. The presence of the high-molecular-weight peak (M_n = 8.4×10^5) in the molecular-weight distribution curve and the absence of absorption in the range of phenyl rings suggest a thermally initiated polymerization of MMA. The shift of the low-molecular-weight peak of activated PST to higher molecular weights suggests the formation of the PST–PMMA block copolymer whose molecular-weight parameters are listed in the table. The results of synthesis of PST–PBA block copolymer are presented in Fig. 4 and the table. It can be seen that, as in the preceding case, the block copolymer formation is accompanied by spontaneous polymerization of BA.

We studied block copolymerization of ST with BMA in more detail. The copolymer prepared from activated PST (molecular weight 9.4×10^4; isolated at a conversion of 7.2 wt %) was fractionated on a Soxhlet apparatus by selective extraction with isopropanol. As can be seen from the gel permeation chromatograms (Fig. 5), a significant part of PST is not converted to PST–PBMA block copolymer (curve *2*). The content of unchanged PST in the polymerization product was 75%. The unimodal curve *3* shown in

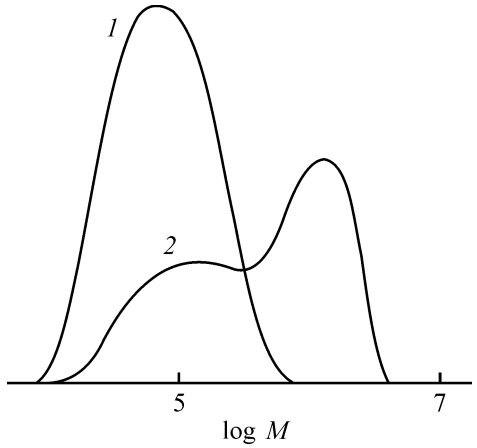

Fig. 3. Gel permeation chromatogram of (*1*) initial PST macroinitiator ([AIBN] = 5×10^{-3} M, [NNC] = 7×10^{-3} M, conversion 72 wt %, M_n = 5.4×10^4) and (*2*) PST–PMMA copolymer. T = 120°C, ε_{PST} = 4.12 wt %, conversion 6.5 wt %, refractometric detector. (M) Molecular weight of activated PST used for preparing the corresponding block copolymers; the same for Figs. 4, 5.

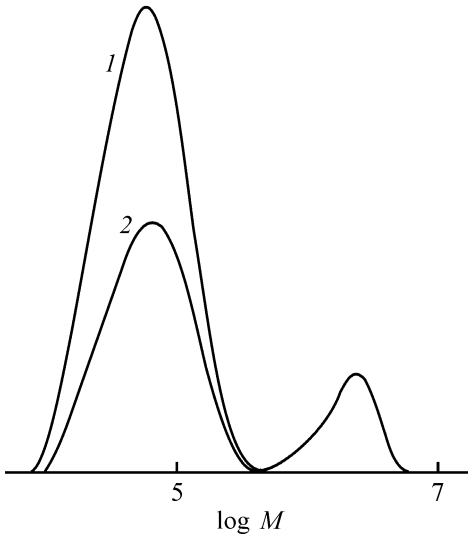

Fig. 4. Gel permeation pattern of (*1*) initial PST macroinitiator ([AIBN] = 5×10^{-3} M, [NNC] = 7×10^{-3} M, conversion 79 wt %, M_n = 4.3×10^4) and (*2*) PST–PBA copolymer. T = 120°C, ε_{PST} = 4.12 wt %, conversion 10 wt %, refractometric detector.

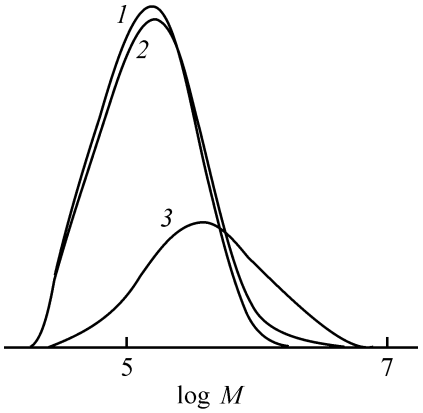

Fig. 5. Gel permeation chromatogram of (*1*) initial PST macroinitiator ([AIBN] = 2×10^{-3} M, [NNC] = 3×10^{-3} M, conversion 71 wt %, $M_n = 9.4 \times 10^4$), (*2*) unchange PST recovered from copolimerization, and (*3*) PST–PBMA copolymer. T = 120°C, ε_{PST} = 4.12 wt %, conversion 7.2 wt %, refractometric detector.

Fig. 5 is assigned to PST–PBMA copolymer ($M_n = 2.2 \times 10^4$, $M_w/M_n = 2.2$). Thus, the block (co)polymer is formed by the uncontrolled pseudoliving polymerization.

CONCLUSIONS

(1) Polystyrene prepared in the presence of 1-nitroso-2-naphtholatocobalt(III) initiates polymerization of a fresh monomer portion.

(2) Polymerization of methyl methacrylate, butyl methacrylate, and butyl acrylate in the presence of polystyrene containing the reactive fragment of 1-nitroso-2-naphtholatocobalt(III) yields the corresponding block copolymers.

Abstract—The rheological properties of dilute and moderately concentrated aqueous solutions of methyl cellulose with carboxymethyl cellulose having different degrees of ionization, were examined. The solvent vapor sorption method was applied to examine the compatibility of the polymers in the solid state and elucidate how the amount of nonionized carboxy groups in carboxymethyl cellulose affects its compatibility with methyl cellulose.

DOI: 10.1134/S1070427208040241

As is known, a number of cellulose compounds in aqueous solutions form physical thermoreversible gels. These compounds include methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and methyl ethyl cellulose (MEC). These cellulose ethers are widely used as gelation agents, thickeners, stabilizers, and emulsifiers in food industry. The most widely used cellulose compound is MC.

The properties of aqueous solutions of MC, as well as of films and fibers thereof, can be changed by chemical or physicochemical modification of the polymer. We have shown earlier [1, 2] that introduction into the MC macromolecules of polar (cyanoethyl) and nonpolar (propyl) groups changes the thermodynamic affinity of the polymer for water and the rheological properties of the solutions of mixed cellulose ethers; the gelation onset temperature T_{gel} in solution decreases, as also does the phase segregation temperature in solutions, or the cloud point T_{cloud}. Also, the rheological properties of polymer solutions can be modified by combining in the same solvent two polymers with different chemical structures to obtain polymer blends with controlled properties. Depending on the chemical composition, rigidity of the macromolecules, degree of polymerization, and type of solvent, the blended polymers can form in solution differently organized structures with different stabilities [3–7].

Among the cellulose ethers containing ionic groups, the most widely used compound is carboxymethyl cellulose (CMC) available as the sodium salt NaCMC.

In aqueous solutions of NaCMC, solvated macromolecules undergo association. The size, shape, and mutual ordering of the associates in solutions vary, depending on the conditions. Unusual properties are displayed by films prepared from aqueous solutions of CMC in the acid form (HCMC). In concentrated aqueous solutions of HCMC, the opalescence and gelation are gradually enhanced [8, 9]. Films obtained from such solutions become water-insoluble because of the formation in them of a system of strong intra- and intermolecular H bonds [10]. The gelation in HCMC solutions reflects the change in the thermodynamic characteristics of interaction of the polymer with the solvent. The reason is the enhancement of the intermolecular interaction of solvated CMC macromolecules via hydrogen bonding because of the appearance of nonionized carboxy groups.

Modification of the rheological properties of aqueous MC solutions by adding solutions of CMC with different degrees of ionization is of scientific and practical interest. Aqueous solutions of blends of NaCMC with other cellulose ethers and synthetic polymers exhibit deviations of the viscosity from additivity [11, 12]. It is presumed that changing the number of dissociated and nondissociated carboxy groups in

the CMC macromolecules will enable varying the system of hydrogen bonds in concentrated solutions of polymer blends and the compatibility of polymers in the solid state.

We examined here the viscous properties of dilute and moderately concentrated aqueous solutions of blends of MC with CMC, having different degrees of ionization, as well the thermodynamic compatibility of the polymers in the solid state.

EXPERIMENTAL

As initial materials we used MTs-100 commercial samples of MC with the degree of substitution (DS) of 1.62 and the degree of polymerization (DP_η) of 830, as well as NaCMC with DS = 0.46 and DP_η = 460. Distilled water served as the solvent. The molecular weight and DP_η of MC were determined viscometrically, using the Mark–Kuhn–Houwink equation for MC in water [13]:

$$[\eta] = 2.8 \times 10^{-3} M^{0.63}.$$

The molecular weight of CMC was estimated viscometrically from the viscosity of the polymer in 6% aqueous NaOH solution. For calculation we used the expression $[\eta] = 7.3 \times 10^{-3} M^{0.93}$ [10]. The degree of substitution for NaCMC was estimated from its Na content by the formula

$$DS_{Na} = 162n/(2300 - 80n), \quad (1)$$

where n is the Na content of the polymer, wt %.

The Na content of CMC was determined by conductometric titration with 0.1 M HCl solution. To calculate the degree of substitution of HCMC with respect to carboxy groups DS_{COOH}, we used the expression

$$DS_{COOH} = 162m/(4500 - 58m), \quad (2)$$

where m is the content of carboxy groups, wt %.

The content of carboxy groups was determined by conductometric titration of the sample with 0.1 M NaOH solution. The degree of ionization of CMC was calculated by the expression

$$\alpha = DS_{Na}/(DS_{Na} - DS_{COOH}). \quad (3)$$

Commercial samples of NaCMC may contain low-molecular-weight impurities, chlorides of reactants used in the carboxymethylation of cellulose [10]. Therefore, the NaCMC sample was preliminarily washed to remove impurities with a hot 70% aqueous isopropanol solution in a Soxhlet apparatus. The washing was carried out for 4 h to negative reaction to Cl^- ions with an $AgNO_3$ solution. The washed sample was vacuum-dried at 50°C for 12 h. The DS_{Na}, DS_{COOH}, and DP_η parameters were determined for the samples washed to remove impurities. NaCMC was converted to the H form in an aqueous solution of the polymer (2 wt %) [8]. The 2% aqueous MC solution and dilute solutions (0.2 wt %) were prepared according to [7].

The 0.2 wt % solutions obtained by dilution of the prepared 2 wt % solutions were examined viscometrically. Films were prepared from aqueous solutions of polymer blends by casting the solution through a laboratory draw plate with a controlled slit onto Teflon plates at 20°C, which was followed by drying at 30°C. The film was detached from the support after 1 day.

The viscous characteristics of dilute 0.2 wt % solutions were determined on an Ubbelohde capillary viscometer at 20°C. The rheological properties of the concentrated solutions were examined on a Rheotest 2.1 rotary viscometer with a cylinder-cylinder working unit in the shear stress range 3–600 Pa at 20–40°C.

To evaluate the compatibility of the blended polymers, we used the solvent vapor sorption method [14]. The films prepared from aqueous solutions of polymers by the above-described procedure were vacuum-dried to constant weight. The residual content of the solvent did not exceed 0.02%. The water vapor sorption by the films was measured at 20°C in a vacuum setup with a McBain quartz-spring balance (spring sensitivity 0.5–0.7 mg mm^{-1}, accuracy within 0.01%) at the saturated solvent vapor pressure.

The polymer–solvent interaction parameters χ_1 for MC, NaCMC, CMC (α = 0.6), HCMC, and their blends were calculated from the sorption data by the Flory–Huggins equation [15]

$$\ln a_1 = \ln(P_1/P_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \chi_1\varphi_2^2, \quad (4)$$

where a_1 is the solvent vapor activity, and P_1/P_1^0, relative pressure of the solvent vapor. The experiments were carried out at the saturated solvent vapor pressure, i.e., at $a_1 = P_1/P_1^0 = 1$ and, accordingly, $\ln a_1 = 0$.

The polymer–polymer interaction parameter was calculated from the sorption data by the Patterson relation [16]

$$\chi_{23} = (\chi_{12}\varphi_a + \chi_{13}\varphi_b - \chi_{1(23)})/(\varphi_a\varphi_b), \quad (5)$$

where χ_{12}, χ_{13}, and $\chi_{1(23)}$ are the respective Flory–Huggins interaction parameters for the MC, NaCMC, CMC ($\alpha = 0.6$), and HCMC polymers taken separately and for their mixtures with water, and φ_a and φ_b, respective volume fractions of the polymers in the blend.

For blends of compatible polymers, $\chi_{23} < 0$ [17].

Figures 1–3 show the flow curves of aqueous solutions of MC and CMC with different degrees of ionization and of their blends. The flow curves of the solutions are partial flow curves of non-Newtonian liquids. The structural viscosity branch for the MC solution becomes prominent at shear stresses over $\log \tau = 2.8$ ($\tau = 630$ Pa $\times 10^{-1}$). Upon conversion of NaCMC to the H form, structure formation occurs in the solution, resulting in an increase in viscosity and appreciable change in the shape of the flow curve [8]. The solution becomes more sensitive to changes in the shear stress.

The pattern of variation of the viscosity of dilute solutions of the polymer blends suggests possible interaction of different kinds of macromolecules in solution [4–7]. To test this assumption, we examined the pattern of variation of the reduced viscosity η_{red} of 0.2 wt % solutions of the blend of MC with NaCMC, CMC with the degree of ionization $\alpha = 0.6$, and HCMC ($\alpha = 0$). Figures 4a–4c demonstrate how the reduced viscosity of dilute solutions and the logarithm of viscosity of moderately concentrated solutions vary with the composition of the mixed systems.

For the dilute solutions of all the three polymer blends, η_{red} exceeds the additive value. In going from NaCMC to HCMC, the η_{red} parameters of the CMC solutions significantly decrease, which is consistent with our previous data [8].

The fact that the viscosity of the blends of the dilute solutions exceeds the additive value suggests that intermolecular interactions between the different kinds of macromolecules dominate in solution. This is responsible for the formation of structures whose hydrodynamic volume exceeds the weight-average hydrodynamic volume of the two components taken separately. The fact that the reduced viscosity of the solutions of the blends is lower than the additive value can be associated both with the compaction of the polymer macromolecules if they are incompatible and with the formation of mixed complexes whose hydrodynamic volume is smaller than those of the macromolecules of either polymer.

In going to the concentrated solutions, the shape of the curves representing log η in relation to the blend composition considerably changes, depending on the state (degree of ionization) of CMC in the blends.

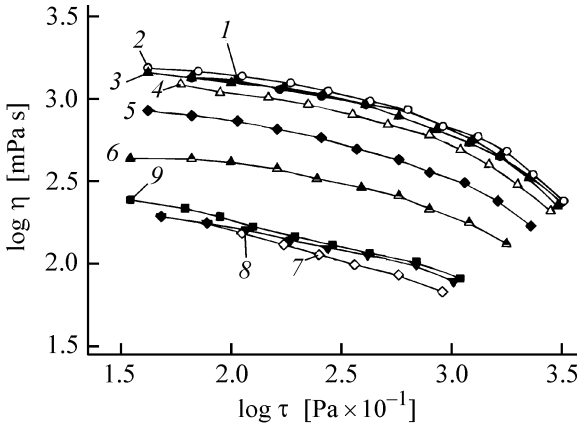

Fig. 1. Flow curves of 2 wt % solutions of (*1*) MC, (*2–8*) MC–NaCMC blends, and (*3*) NaCMC at 20°C. (η) Viscosity and (τ) shear stress; the same for Figs. 2 and 3. NaCMC content, wt %: (*2*) 5, (*3*) 10, (*4*) 23, (*5*) 50, (*6*) 70, (*7*) 90, and (*8*) 95.

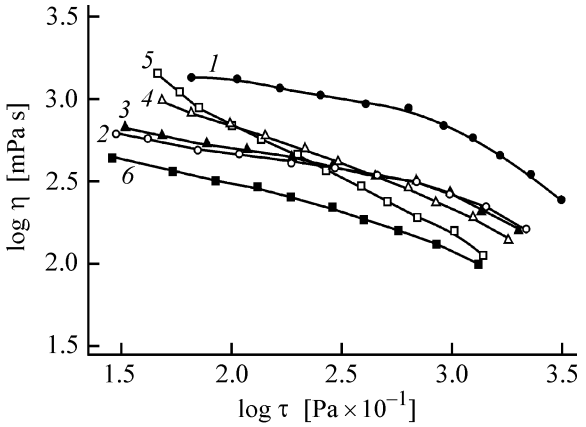

Fig. 2. Flow curves of 2 wt % solutions of (*1*) MC, (*2–5*) MC–NaCMC ($\alpha = 0.6$) blends, and (*6*) CMC at 20°C. NaCMC content, wt %: (*2*) 10, (*3*) 20, (*4*) 50, and (*5*) 70.

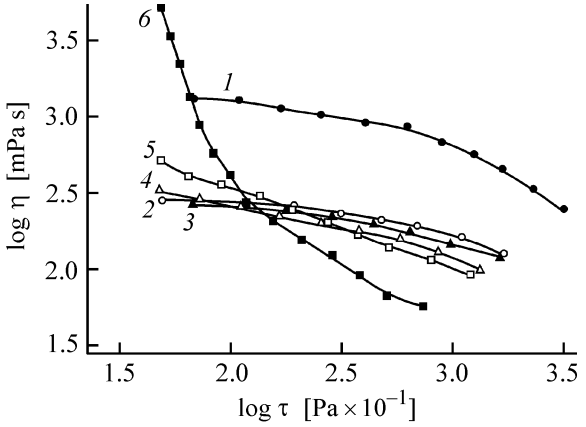

Fig. 3. Flow curves of 2 wt % solutions of (*1*) MC, (*2–5*) MC–HCMC ($\alpha = 0$) blends, and (*6*) HCMC at 20°C. HCMC content, wt %: (*2*) 10, (*3*) 20, (*4*) 50, and (*5*) 70.

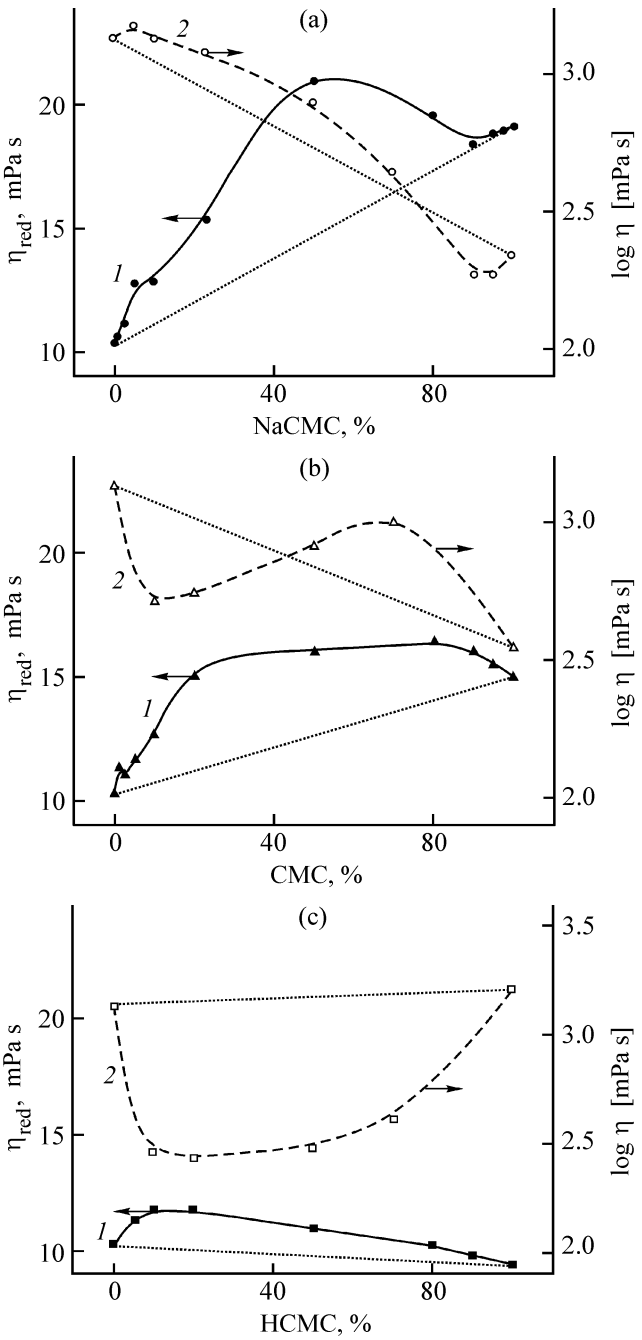

Fig. 4. (*1*) η_{red} and (*2*) log η in relation to the composition of dilute (0.2 wt %) and concentrated (2 wt %) solutions of MC–NaCMC blends at 20°C. Dotted lines denote the additive values. Blend: (a) MC–NaCMC, (b) MC–CMC, and (c) MC–HCMC.

The viscosity of the concentrated solutions of the polymer blends is affected by many factors. In blends of polymer solutions, new systems of hydrogen bonds can be formed, stronger than those in solutions of MC, NaCMC, and HCMC taken separately. It should be noted that addition to the MC solution of a different polymer can cause changes in the thermodynamic quality of the solvent (water) with respect to MC. The influence exerted on the solvent quality by a different macromolecular compound introduced into polymer solution was clearly demonstrated in [18–20]. The viscosity of concentrated solutions of polymer blends can be both higher and lower than the additive values.

At a NaCMC content of up to 80 wt %, the viscosity exceeds the additive values. For the compositions with over 80 wt % NaCMC, the viscosity is lower than the additive value (Fig. 4a). In concentrated solutions of the MC blends with a partly neutralized polyelectrolyte (CMC with $\alpha = 0.6$), the range of the compositions in which the viscosity of the solutions is lower than the additive value is wider (Fig. 4b). Finally, upon conversion of NaCMC to the H form, log η is lower than the additive value throughout the composition range examined. Major changes in the shape of the curve representing log η in relation to the composition, caused by variation of the degree of CMC ionization, can be associated with a change in the range of compositions at which the polymers are thermodynamically compatible, as well as in the hydrogen bond system in concentrated solutions of the polymers.

The table lists the results of examination of the thermodynamic compatibility of the two blended polymers in the solid state (according to solvent vapor sorption data). It is seen that MC and NaCMC are thermodynamically incompatible throughout the composition range examined. In the case of the blends of MC with partly neutralized CMC, the compatibility of polymers is observed in films containing up to 50 wt % MC. In the MC–HCMC blends, the thermodynamic compatibility of the polymers is observed at a MC content of up to 30 wt %. It can be presumed that, on passing from NaCMC to a partly neutralized polyelectrolyte, the number of carboxy groups COOH involved in the formation of a mixed system of hydrogen bonds among the functional groups of different kinds of polymers increases. With a further increase in the number of carboxy groups (passing to HCMC), the interaction of the carboxy groups is intensified so strongly that HCMC becomes virtually insoluble in water. This is responsible for the increase in the share of interactions between the macrochains of the polyelectrolyte in the blends and for the narrowing of the range of the compositions at which MC and HCMC are compatible.

Thus, by varying the amount of a different polymer introduced into an aqueous solution of MC (in particular, CMC with different degrees of ionization), it is possible to change the rheological properties of solu-

tions and the gelation conditions in them and also to obtain films of blends in which the polymers can be thermodynamically compatible and incompatible. Solutions of MC–CMC blends are suitable as stabilizers and emulsifiers in food industry, and film materials thereof are attractive as packaging materials for foodstuff.

CONCLUSIONS

(1) The observed deviations of the viscosity from additivity in dilute and concentrated solutions of blends of methyl cellulose with carboxymethyl cellulose, having different degrees of ionization, are associated with the change in the conformation of the polymer macromolecules in the blends and structural rearrangements in solutions.

(2) Methyl cellulose is incompatible with the sodium salt of carboxymethyl cellulose. In blends of methyl cellulose with partly ionized carboxymethyl cellulose and that in the acid form, the two polymers are partially compatible. The range of the compositions in which the polymers are compatible varies with the degree of ionization of carboxymethyl cellulose.

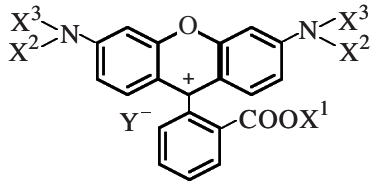
Abstract—Spectral and protolytic properties of two hydrophobic rhodamine dyes and fluorescein *n*-decyl ester were studied in Langmuir–Blodgett films based on a polyamido acid. The possibility of weakening the concentration quenching of rhodamine dye fluorescence with a polymeric matrix was demonstrated.

DOI: 10.1134/S1070427208040253

The Langmuir–Blodgett (LB) procedure allows preparation of nanosize highly ordered layers of biphilic molecules with exactly controllable thickness and directed orientation in space [1, 2]. Preparation of LB films (LBFs) containing dyes is of special interest because their optical and protolytic properties allow development various sensors in this way [3–8].



Xanthene dyes having high extinction coefficient and quantum yield of fluorescence are suitable for this purpose. Monolayers of rhodamines in stable matrices were studied in [3, 9–16]. Xanthenes are important group of dyes used in lasers [12], as photosensitizers [16], and in many other fields of photophysics and photochemistry. Both general questions of formation of mono- and *N*,*N*'-dioctadecylrhodamine B multilayers in various matrices (arachic acid and methyl arachate [9], dipalmitoylphosphatidic and dioleylphosphatidic acids [10]), and the ability of phosphors to form aggregates in films [10] have been considered. Preparation of *N*,*N*'dioctadecylrhodamine B monolayers on a subphase containing sodium lauryl sulfate was described in [11].

LBFs containing dyes in polymeric matrices have been studied to a considerably lesser extent. At the same time, films based on polymers are widely used owing to their high mechanical and chemical stability [1]. To obtain multilayer LBFs, polyamido acids (PAAs) are often used [1, 3, 4]. The structural formula of one of PAAs, poly(4,4'-diphenyl oxide)-2-carboxyisophthalamide (R = H) is shown below:

To make PAA macromolecules more hydrophobic, alkyl chains [R = $(CH_2)_{17}$–CH_3] are introduced into the PAA structure, or amines are added to form salts [17, 18]. To retain polymeric monolayers with carboxylic groups on the water surface, subphases containing metal ions are also used [1, 19, 20].

In this study, we prepared LBFs based on PAA containing immobilized xanthene dyes and examined properties of such well-ordered systems. Hydrophobic (lipoid) dyes: Rhodamine B *n*-heptadecyl ester perchlorate **1**: X^1 = *n*-$C_{17}H_{35}$, X^2 = X^3 = C_2H_5, Y^- = ClO_4^-, and *N*,*N*'-dioctadecylrhodamine chloride **2**: X^1 = X^2 = H, X^3 = *n*-$C_{18}H_{37}$, Y = Cl^-

1, **2**

and fluorescein *n*-decyl ester **3**, whose structural formulas (for the molecular and ionic form) will be presented below, were chosen as investigation objects. To prepare monolayer films, the above dyes were added to matrices that can form stable layers on the water surface. It should be taken into account that xantenes can form dimers in various matrices [21], which leads to concentration quenching of the fluorescence and to worsening of the luminophore performance. These luminophores are also used as probes; in a number of cases, they allow estimation of local electrostatic potentials [22]. Therefore, the goal of this study was not only to develop methods for preparing polymeric xantene-containing LBFs, but also to determine the optimal conditions of their probable functioning as elements of sensor devices.

EXPERIMENTAL

Dyes were synthesized by methods described in [23, 24] and identified by elemental analysis, ^{1}H NMR, and TLC. Stearic acid, *n*-octadecyl alcohol (ODA), and *n*-octadecylpyridinium bromide (ODPB), and also surfactants used in experiments with aqueous micellar solutions [cetylpyridinium chloride (CPC), cetyltrimethylammonium bromide, cetyldimethylammoniopropanesulfonate, and sodium lauryl sulfate] were purchased from Fluka (as a rule, they contained 99% main substance). Buffer mixtures were prepared from chemicals of chemically pure grade. Oligomeric PAA with a molecular weight of the chain unit of 374 g mol^{-1} was used.[1]

The initial 1×10^{-3} M PAA solutions were prepared in a 1 : 1 mixture of chemically pure dimethylformamide and chloroform, and the initial solutions of stearic acid, ODA, and ODPB of the same concentration, in chloroform. $Pb(NO_3)_2$ was of chemically pure grade. Before an experiment, a bath was successively treated with 96% aqueous ethanol and chloroform and then filled with double-distilled water or a lead nitrate solution. Double-distilled water or a 1×10^{-5} M lead salt solution was used as a subphase; a decrease in the salt concentration makes weaker the influence of lead ions on the polymer.

Measurements were performed in a Langmuir bath with two 6.5×60 cm sections. The surface pressure π was recorded with a Wilhelmy balance (measurement error ± 0.3 mN m^{-1}) at 20 ± 5°C. An organic solvent containing PAA was applied onto the water surface, and the system was allowed to stand for 5 min (time required for a monolayer to spread over the surface of the aqueous subphase, evaporation of the solvent, and accommodation of polymeric molecules). Then, the monolayer formed was compressed by an unwettable mobile barrier at a 3 cm min^{-1} velocity to a required pressure, which was then automatically kept constant.

The state of monolayers on the surface of the aqueous subphase was studied by plotting the π–A compression isotherms, where A is the surface area per recurring chain unit (Å^2). The limiting surface area S_m occupied by one chain unit was found by extrapolation of the linear portion of the isotherm to the abscissa; the determination error was $\pm$(1–3) Å^2. From the compression isotherms, we determined the optimal surface pressure of applied monolayers corresponding to the most condensed state (in the middle of the linear portion). To prepare a mixed monolayer, the dye dissolved in chloroform was added to a mixture of PAA and *n*-octadecyl alcohol (or *n*-octadecylpyridinium bromide), or stearic acid, and then the resulting mixture was applied dropwise onto the surface of the aqueous subphase.

Monolayers were deposited onto glass or quartz plates by the Scheffer method; in so doing, π was 35 mN m^{-1} in the case of **1** and 30 (25) mN m^{-1} for **2** (in stearic acid or ODPB matrix, respectively). The pressure of transfer for the PAA + ODPB + **3** mixture was 25 mN m^{-1}. Prior to monolayer deposition, supports were pretreated with a peroxide–ammonia mixture and then washed with double-distilled water, acetone, and chloroform [3].

The glass supports with deposited multilayers of ODPB + **2** and PAA + ODPB + **3** were kept for 5 and 1 min, respectively, in aqueous solutions with known pH and dried for several minutes in air. It has been shown previously that introduction of a lead salt into the subphase is the optimal method for stabilization of PAA monolayers on the water surface [20]. Pb^{2+} ions can pass into the aqueous phase because of the interaction with Br^- ions introduced with ODPB. However, special experiments showed that only a small part of lead ions pass into the aqueous phase. The Pb^{2+} content of the monolayers was monitored by analysis of LBFs by X-ray photoelectron spectroscopy (Kratos XPS-800 spectrometer; photoelectrons were excited by $Al(Mg)_{K_\alpha}$ radiation; power of X-ray tube 15 kV × 20 mA).

The pH value [$\pm$(0.01–0.04)] was monitored with a glass electrode in an electric circuit with transfer.

[1] Oligomeric polyamido acid was synthesized in the Chernigov Pedagogical University by the known procedure [25] and identified in the Kiev National University, Chair of Macromolecular Compounds.

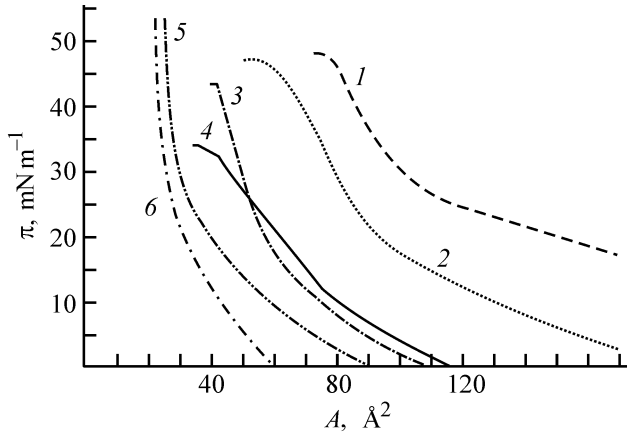


Fig. 1. Surface pressure π vs. the surface area *A* per repeating unit of polymer for different systems: (*1*) PAA : ODPB = 1 : 1 + 28 mol % **1**, (*2*) PAA : ODA = 1 : 1 + 22 mol % **1**; (*3*) PAA : ODA = 1 : 1, (*4*) PAA : ODPB = 1 : 1, (*5*) stearic acid + 3 mol % **1**, and (*6*) stearic acid + 1.5 mol % **1**. Dependences (*1–4*) were obtained with films prepared on a Pb^{2+}-containing subphase. The dye concentration is expressed in molar percent relative to the total number of moles of the components in the mixture.

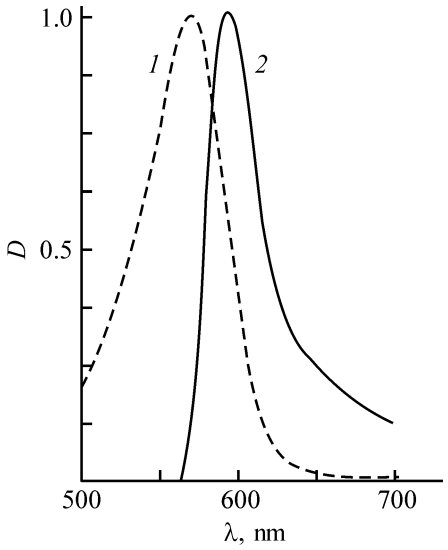

Fig. 2. (*1*) Absorption and (*2*) fluorescence spectra of dye **1** in PAA : ODPB = 1 : 1 + 6 mol % **1** film. Film was applied by the scheme ABBBABBB (n = 60, N = 240). (*D*) Optical density and (λ) wavelength; the same for Figs. 3–5.

The absorption spectra of films containing dyes were recorded on a Specord M 40 spectrophotometer, and the fluorescence spectra, on a Hitachi F-4010 spectrophotometer; the films without dyes were used as reference samples.

The fluorescence of LBFs containing dyes **1**–**3** was extremely weak. This may be due both to probable aggregation (dimerization) of dye molecules and to concentration quenching. Therefore, we recorded fluorescence using the method described in [10]. A multilayer structure was prepared by alternation of layers ABBBABBB (A is a layer of a dye-containing mixture, prepared on a Pb^{2+}-containing subphase; B is ODPB layer prepared on a pure subphase). Such a separation of layers containing a dye (their number n in all cases was 60) leads to a sharp enhancement of the fluorescence, despite that the pyridinium ring also exerts a quenching effect. The total number of layers we denoted as N.

Preliminarily, we studied the behavior of monolayers of PAA + ODA and PAA + ODPB mixtures on the surface of both pure and lead-containing water subphases. The surface areas per repeating unit of the polymer for the mixtures PAA : ODA = 1 : 1 (counting on repeating unit, S_m = 62 Å^2) and PAA : ODPB = 1 : 1 (S_m = 92 Å^2), evaluated from the compression isotherms, agree with the values published earlier for similar systems [18].

Typical compression curves for mixed layers containing dye **1** are shown in Fig. 1. Introduction of a dye into the matrix of stearic acid increases the surface area per molecule from 27.5 [content of dye **1** 1.5 mol %] to 33.4 Å^2 (3 mol %). At a dye content of 22 mol % in the PAA : ODA = 1 : 1 mixture, the maximal surface area increases to 112.7 Å^2 (in the mixture without dye, it is about 56 Å^2). The S_m value in the PAA : ODPB = 1 : 1 mixture increases from 92 to 131 Å^2 upon introduction of 28 mol % hydrophobic rhodamine **1** into the film. Figure 1 shows that mixtures without dye form a denser monolayer whose loosening becomes possible when large dye molecules are introduced.

The absorption and fluorescence spectra (wavelength of fluorescence excitation λ = 520 nm) of polymeric films containing dye **1** are shown in Fig. 2. The absorption and fluorescence peaks (±2 nm) are observed at 564 and 593 nm, respectively. For aqueous micellar solutions of both cetyltrimethylammonium bromide and sodium lauryl sulfate at a surfactant concentration of 0.01 M, these values are 555 and 579 nm, respectively, and binding of dye molecules insoluble in water with surfactant micelles is beyond any doubt. The red shift of both bands in the LBF spectra, compared to the spectra of aqueous micellar solutions, suggests a more dehydrated surrounding of the dye molecules in the multilayers.

With increasing content of dye **1** in LBF of both stearic acid and PAA + ODPB, the absorption maximum is shifted bathochromically from 564 to

Table 1. Effect of matrix on the D_2/D_1 ratio in multilayer films ($n = N = 60$) containing (**1**) Rhodamine B *n*-heptadecyl ester and (**2**) *N*,*N*'-dioctadecylrhodamine

[*] Films were prepared with the introduction of sandwiching layers of ODA ($n = 60$, $N = 240$). The other films were prepared without additional ODA layers ($n = 60$).

[**] The data are related to the zwitterionic form of dye **2**, prevailing in neutral and alkaline media.

[***] For cationic form of dye **2** (measurements at HCl concentration of 0.06 M), 0.29–038.

572 nm. In going from the polymeric matrix to stearic acid and neat dye film prepared by casting, the intensity of absorption in the region of 530 nm increases and the absorption band becomes strongly broadened (Table 1, Fig. 3), which may be caused by formation of dimers and other aggregates of the dye upon an increase in its content in the film.

The main spectral maximum of monomer **1** in the LBF spectrum lies at $\lambda_1 \sim 570$ nm. The shortwave shoulder caused by the vibrational structure of the spectrum lies at $\lambda_2 \sim 530$ nm, as in the spectra of sandwich-type dimers [10]. The presence of dimers in the film studied (Fig. 3) is usually judged from the ratio of the absorption intensities at λ_2 and λ_1 (D_2/D_1). For systems with monomers, this ratio falls within 0.3–0.5 [10, 15]. Ishibashi et al. [14] reported a decrease in D_2/D_1 when the matrix with the maximal surface area at the phase boundary (dipalmitoylphosphatidylcholine as compared to dipalmitoylphosphatidic acid) was used. The decrease in D_2/D_1 was also noted [10] when dioleylphosphatidic acid characterized by a larger surface area of the molecule as compared to dipalmitoylphosphatidic acid was used.

The D_2/D_1 ratio for dye **1** is greater in stearic acid in comparison with the polymeric matrix and is considerably greater in the neat dye film prepared by casting (Table 1, Fig. 3). It is interesting that the use of both ODPB and ODA for PAA stabilization at the water–air interface shows the same effect of a decrease in the number of dimers in monolayers containing dye **1**. This can be accounted for by the fact that the polymer chain stabilized by a long-chain alcohol or amine molecule occupies larger surface area on the surface of the water subphase as compared to stearic acid molecule. As a result, in the polymeric multi-

layers, the volume concentration of dye molecules becomes smaller, and they become more isolated from each other at virtually the same molar concentration in the monolayer (Fig. 3).

Introduction of intermediate ODA layers into the PAA + ODPB + **2** (2 mol % dye) film does not substantially change the D_2/D_1 ratio (0.79). At the same time, in 50 and 88 wt % aqueous ethanol, in 0.005 M solutions of cetyltrimethylammonium bromide and sodium lauryl sulfate, and in 0.001 M solution of sodium cetyldimethylammoniopropanesulfonate, the D_2/D_1 ratio for the acid and alkaline dye forms vary within 0.288–0.380 and 0.275–0.332, respectively. Since the dye concentration was 2×10^{-6} M, the monomer is the dominant form here.

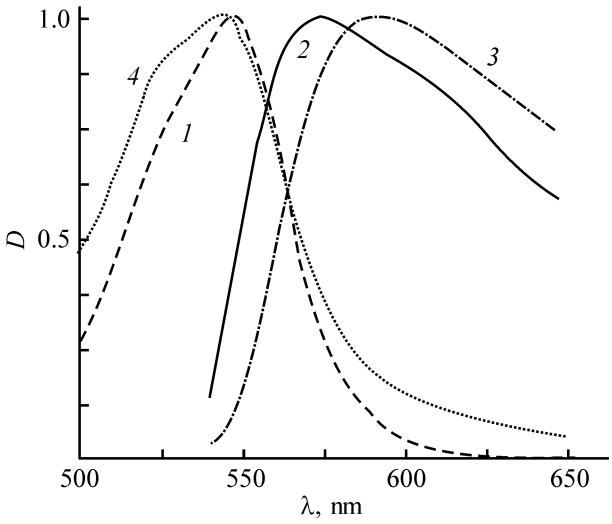

Fig. 4. (*1*) Absorption and (*2*) fluorescence spectra of PAA : ODPB = 1 : 1 + 2 mol % dye **2** films. Film was applied by the scheme ABBBABBB (n = 60, N = 240) at π = 30 mN m^{-1}; (*3*) fluorescence spectrum of the same film after treatment with a solution with pH 1.3 for 3 min; (*4*) absorption spectrum of ODPB + 2 mol % **2** ($n = N = 60$) film.

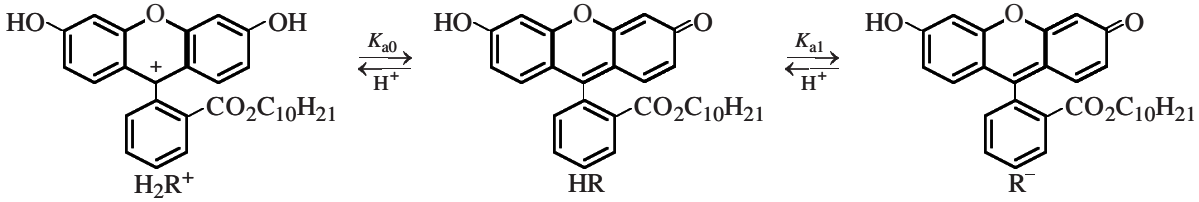
To obtain monolayers containing dye **2**, we used matrixes able to form monolayers at the water–air interface, because by applying neat dye **2** onto the surface of the water subphase (~10^{-5}–10^{-7} M) we failed to obtain a film with a sufficient surface pressure. This observation is in accordance with data for the other dyes [9].

Applying layers of ABBBABBB type causes a shift to shorter wavelengths (574 nm) as compared to alternate application of the monolayers (583 and 590 nm at a transfer pressure of 15 and 30 mN m^{-1}, respectively). Such effects are described in [10] and are associated with the dye concentration in the monolayer with increasing 2*D* compression.



Dye **2** containing a free carboxy group can change its spectral properties with the acidity of the medium (Table 2, Fig. 4). The absorption and fluorescence peaks in the spectra of the initially prepared film lie at 543 ± 1 and 583 ± 1 nm, respectively, but after its immersion into an acid medium (aqueous HCl solution with pH 1.3) both bands are red-shifted. Similar features are observed upon introduction of dye **2** into an ODPB film. The band shift is associated with the transition of the dye molecule into the protonated form. At the same time, in micellar solutions of various surfactants, the above values of λ_{max} are lower by 20–30 nm than those for LBF, which, as in the case of dye **1**, suggests the more dehydrated surrounding of rhodamine **2** as compared to aqueous micellar solutions.

Fluorescein *n*-decyl ester **3** is one of dyes with a pH response, used for study of lyophilic dispersions [22, 26]. The possibility of preparing a Langmuir monolayer of neat dye 3 and its mixture with stearic acid was examined in [16]. In this study, we prepared

Table 3. Parameters of equilibrium for fluorescein *n*-decyl ester **3** in various systems

Parameter	LBF PAA : ODPB = 1 : 1	Aqueous solution of CPC with addition of 0.4 M NaCl	Aqueous solution of fluorescein ethyl ester as homolog of **3** [22]
λ_{max}, H_2R^+, nm	456	449	438
λ_{max}, HR, nm	470, 505	465, 490	450, 465
λ_{max}, R^-, nm	525	516	491
pK^a_{a0}	1.63 ± 0.10	1.32 ± 0.01	2.94
pK^a_{a1}	6.48 ± 0.16	5.52 ± 0.02	6.31

colored and fluorescent multilayer polymeric films based on this dye. Depending on pH of the solution, three forms of **3** exist: cationic (H_2R^+), molecular (HR), and anionic (R^-) [22, 26]:

After treatment of the support with acid solutions, dye **3** in multilayers transforms into the H_2R^+ form, which is undoubtedly confirmed by the existence of a strong absorption band at 456 nm (Fig. 5). At high pH, dye **3** in LBF transforms into anion R^- (Fig. 5, band at 525 nm). After treatment with solution with pH 2.6 (Fig. 5), a three-band spectrum characteristic of the molecular form HR is observed [22, 26]. Thus, in LBF, two steps of protolytic transformations of dye **3**, $H_2R^+ \rightleftarrows HR + H^+$ and $HR \rightleftarrows R + H^+$, are also observed. In the course of experiments, LBF was immersed into aqueous solutions whose pH was adjusted with acetate, phosphate, and borate buffer solutions and with HCl; as a rule, the ionic strength of the solution was kept constant (0.05 M) by NaCl additions.

The spectra of micellar solutions are, on the whole, similar, but all values of λ_{max} are noticeably lower (Table 3). This fact confirms the conclusion made above for rhodamines **1** and **2** about dehydration of LBF dried in air. The apparent ionization constants pK^a_{a0} and pK^a_{a1} for dye **3** in LBF and micellar CPC solution and the same parameters for a short-chain analog, fluorescein ethyl ester, found by the standard spectrophotometric method [26] are listed in Table 3.

Both values of pK^a_a for CPC in micellar solutions are lower than those in aqueous solutions, which is associated with the positive charge of the micellar surface, at which ionized groups are probably localized [22, 26]; at lower concentration of the supporting electrolyte (0.05 M instead of 0.4 M NaCl), the pK^a_a values are still lower: pK^a_{a0} 0.79 ± 0.10 and pK^a_{a1} 4.92 ± 0.07 [22]. In the case of LBF of composition PAA + ODPB at low pH values, the dye surrounding

is close to that in CPC micelles, whereas with increasing pH the carboxy groups in the polymer undergo ionization, the charges of the carboxylate and pyridinium ions are mutually neutralized, and the pK_{a1}^{a} value corresponds to a weakly charged or even neutral layer.

From the viewpoint of the practical use of such LBFs, it is important how the optical density and fluorescence intensity respond to changes in the pH of the aqueous phase in which the films are immersed. In the case of dye **3**, the transition interval covers the physiological range of pH values (Fig. 6). Unusual for acid-base indicators extension of the transition interval is of interest. Such "nonclassical" phenomena are typical of complex sensor devices [27, 28]. They may be associated with the multiplicity of localization sites of the dye in the film and with the existence of islets of the neat dye. In CPC micellar solutions (Table 3) and in other colloidal systems [22, 26], the transition intervals are quite traditional.

In general, unambiguous interpretation of the indicator behavior in sensors is a complex problem [29]. A series of fluorescent pH sensors based on derivatives of fluorescein *n*-octadecyl ester (without using LBF) was examined by Wolfbeis et al. [30, 31].

The measurements performed showed that the pH dependences of the absorption and fluorescence (Fig. 6) are well reproducible and can be used as calibrating curves in optical sensors. The films studied do not decompose and do not change their properties for two years, if kept in the dark at room temperature. The growth of the fluorescence intensity in the physiological region of pH allows use of multilayer polymeric films based on compound **3** as elements of sensor devices in biochemical studies.

CONCLUSIONS

(1) Langmuir–Blodgett multilayer films containing xanthene dyes Rhodamine B *n*-heptadecyl ester, *N*,*N*'-dioctadecylrhodamine, and fluorescein *n*-decyl ester were prepared on the basis of a polyamido acid. Their spectral-luminescence and acid–base properties were studied.

(2) The use of a polymeric matrix makes lower the possibility of formation of dimers from Rhodamine B *n*-heptadecyl ester and *N*,*N*'-dioctadecylrhodamine in Langmuir–Blodgett films.

(3) Changes in the light absorption and fluorescence of the indicator, fluorescein *n*-decyl ester, immobilized in a polymer matrix, observed in the physiological range of acidities, are well reproducible and can be used to prepare stable ultrathin nanodimensional pH-sensitive sensor films for multiple use.

ACKNOWLEDGMENTS

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Performance of Intumescent Fire Retardant for Wood

N. K. Luneva and L. I. Petrovskaya

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received December 6, 2007

Abstract—Performance characteristics of new fire-retardant formulations are studied, including their water resistance and the effect of additives.

DOI: 10.1134/S1070427208040265

Wood has always been high among man's preferred building materials for many reasons. It is highly workable and has minimal environmental pollution. However, the use of wood can be restricted by safety requirements and regulations concerned with its ignitability and fire spreading characteristics. The most significant loss by fire falls at untreated wood constructions and buildings. Of course, one can raise the fire resistance only to a certain limited extent, and no building is completely fireproof. Until now, the problem of wood protection against fire remains very topical. At present, intumescent fire retardants (FRs) are mostly used for treatment of timbers. However, the mechanisms of chemical transformations in intumescent FRs under heating still remains to be understood. The reasons are their complex composition and the fact that the main reactions occur at high temperatures.

The goals of this study were to develop new green intumescent fire retardants for wood and to examine the effect of their composition and kind of binder (of various viscosities) on the protective action and water resistance. The formulations studied consisted of polyposphorous compounds, a water-organic dispersion, and fire inhibitors (organic amides and polyols providing expansion of the intumescent fire-retardant coating). Finally, thermal degradation of FR-treated wood was studied at 20–700°C.

Therefore, we report here the properties of phosphorus–nitrogen-containing fire retardants: effect of their composition on the protective action, water resistance of the formulations, and thermal decomposition and stability of phosphorus- and nitrogen-containing compounds in FR-treated wood samples.

EXPERIMENTAL

Among diverse organic amides and polyols, we selected those whose thermal decomposition occurs within the same temperature range as the thermal degradation of wood. We used as a binder water–organic dispersions of various kinds. The components were intimately ground and then mixed with a binder for 30 min to obtain a homogeneous paste. As samples served $30 \times 60 \times 150$ mm wood blocks. The FR consumption was 270–300 g m^{-2}. The fire and water-resistance tests were performed according to GOST (State Standard) 16 363–98 [1] and GOST 16 712–71 [2], respectively.

A DTA analysis of FR-treated wood samples (200 mg) was carried out on a Paulik–Paulik–Erdey derivatograph at a heating rate of 20 deg min^{-1}. For analysis, we used sawdust (3–5 mm) treated with phosphorus–nitrogen-containing formulations (wet weight increment of the fire retardant was 170% relative to dry sawdust) and then dried to constant weight at 45°C. The initial and heat-treated samples were analyzed for phosphorus and nitrogen. Phosphorus was determined photocolorimetrically [3], and nitrogen, by the method described in [4]. X-ray diffraction patterns were obtained using a DRON-3 instrument with Cu_{K_α} radiation (Ni filter) over the 2θ range 2°–60°.

Currently, phosphorus–nitrogen-containing intumescent fire retardants are most widely used for wood. We have developed high-performance green phosphorus–nitrogen-containing intumescent fire retardants consisting of Craymul 2322 vinyl acetate aqueous-organic dispersion [CRAY VALLEY (Italia)], ammonium phosphate, a polyol, an organic amide, and organometallic compounds [5]. It was demonstrated that

the fire retardancy is a function of the FR composition. Fire tests showed that the formulations developed are classed with the First Group in their fire-retardant efficiency, and FR-treated wood, with poorly flammable materials (Table 1) [6].

Fire tests showed (Table 1) that the phosphorus–nitrogen-containing formulation consisting of ammonium phosphate, vinyl acetate dispersion, and aluminum hydroxide (PMA formulation) is characterized by a weight loss of 22.9 wt %. Samples treated with this formulation meet the requirements for poorly flammable materials. Introduction of an organic amide (10 wt %) reduces the weight loss from 22.9 to 17.2%, whereas introduction of the same concentration of a polyol, from 22.9 to 7.2%. When both additives were introduced (10 wt % each), the weight loss decreased to the minimal value of 5.0%. The decrease in the polyol content from 10 to 7 wt % and in the amide content from 10 to 5 wt % had only a slight effect on the fire retardancy (weight loss ranged from 6.4 to 4.5%).

It is known that introduction of polyvalent organometallic compounds into some fire retardants improves the fire retardancy [7, 8]. Our previous results show that introduction of the inorganic additives into the phosphorus–nitrogen-containing formulations in amount of 2–4 wt % has practically no effect of the weight loss [6]. We also studied the effects of the nature of aqueous dispersions on the water resistance of FR-treated wood. With this purpose, we replaced Craymul 2322 vinyl acetate dispersion in the formulation providing the best fire retardancy with other aqueous-organic dispersions. Results of water-resistance tests are summarized in Table 2.

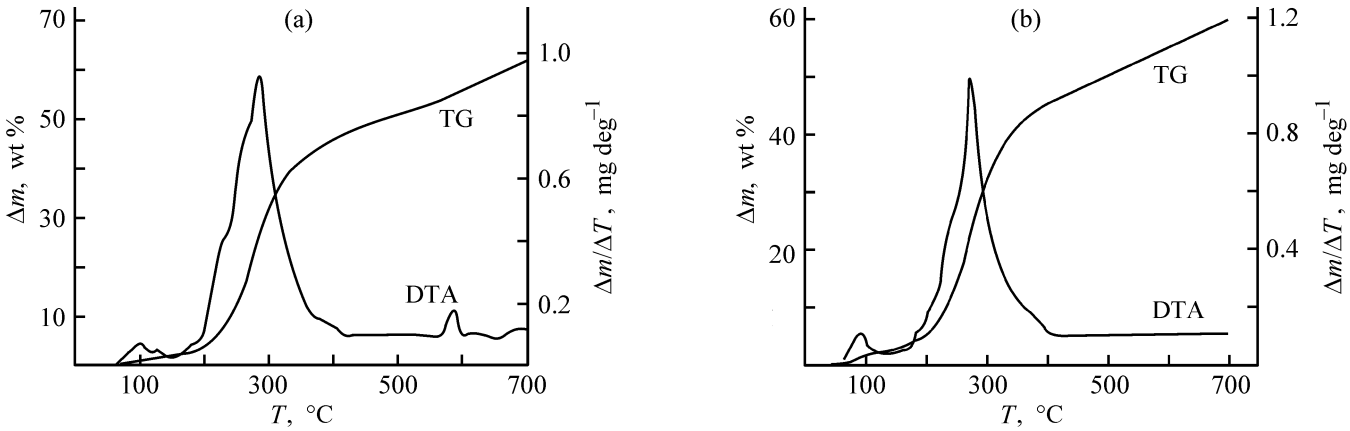

Fig. 1. TG and DTA curves. (Δm) Weight loss, ($\Delta m/\Delta T$) weight loss rate, and (T) temperature. Samples: wood treated with (a) initial fire retardant formulation and (b) that containing natural oxide additive.

Our results show that the smallest phosphorus loss is observed for HW-1 aqueous-organic dispersion (FINNDISP). With this dispersion, the phosphorus loss is lower by a factor of 1.9 as compared to Craymul 2322 (the phosphorus content increases from 18.2 to 34.4 wt %). Note that all the dispersions tested allowed keeping the phosphorus content after soaking in water or water treatment in amounts considerably exceeding (by a factor of 1.9 to 3.6) the critical value (~2%) required for providing the fire retardancy.

Table 3. Chemical analysis of pyrolysis products of wood treated with phosphorus–nitrogen-containing FR formulations

T, °C	Weight loss Δm, %	Content, wt %		Conservation of element,* wt %	
		nitrogen	phosphorus	nitrogen	phosphorus

* Conservation of element is defined as the ratio between the current element content at a fixed temperature (recalculated to the current weight) and its initial content (before heating).

** Additives 1, 2, and 3 differ in the natural oxide content varied within the following ranges (%): SiO_2 75–33, Al_2O_3 0.5–18, MgO 1–31, and Fe_2O_3 1–17.

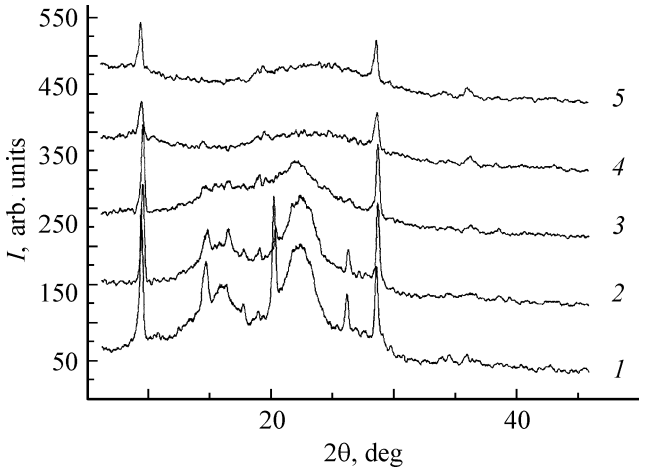

Fig. 2. X-ray diffraction patterns of pyrolysis products of wood treated with the formulation containing natural oxide additive. (*I*) Intensity and (2θ) Bragg angle. Pyrolysis temperature (°C): (*1*) 20, (*2*) 200, (*3*) 300, (*4*) 400, and (*5*) 500.

Pyrolysis products (20–700°C) of wood treated with the fire retardant formulation containing HW-1 suspension and some special inorganic additives (5 wt %) were examined by DTA, XRD, and chemical analyses. Figure 1 shows DTA curves for the initial fire retardant and that containing some natural oxides. Pyrolysis proceeds essentially within the temperature range 200–350°C, and the maximal decomposition rate is observed at 275–285°C, 0.93 to 1.02 Δm, depending on the formulation. A chemical analysis of the pyrolysis products of the FR-treated wood revealed that, on heating from 20 to 500°C, the phosphorus content in the carbonaceous residue increases, and its loss, as recalculated to the reduced mass, decreases for the formulations containing inorganic additives (Table 3). No weight loss was observed after pyrolysis (500°C) of wood treated with FR formulations containing additives, whereas without additives, the weight loss was 11.1%. It should be pointed out that the stability of the FR-treaded wood with respect to nitrogen loss is considerably lower, 41.8 to 46.4, depending on the FR formulation. Introduction of additives into the fire retardant formulation proved to have no significant effect on the TG curves (ash content is 38–41% at 700°C). An X-ray diffraction analysis revealed that, as FR-treated wood is heated, the diffraction peaks of the components constituting the FR formulation disappear, and at 500°C, only the peaks of inorganic additives are observed (Fig. 2). The residue after pyrolysis (500°C) of wood treated with the formulation containing no additives has no crystalline phases.

CONCLUSIONS

(1) Phosphorus–nitrogen-containing fire retardant developed for wood, containing ammonium phosphate, a polyol, an organic amide, organometallic compounds, and HW-1 dispersion, provides high fire retardancy and high water resistance of FR-treated wood.

(2) Introduction of natural oxide materials into the protective layer using HW-1 aqueous–organic dispersion has no significant effect on the thermal degradation of fire-retardant treated wood. Thermal degradation (weight loss) is observed essentially within the temperature range 250–350°C. The ash content is 38–41% at 700°C.

Abstract—Fundamental aspects of the complexation of cobalt(II) and nickel(II) ions with chitosan hydrochloride in water and chitosan in an aqueous solution of acetic acid were studied. The relation between the numbers of chitosan moles and metal ions involved in the interaction was found.. The optimal conditions for synthesis of complexes were determined and their chemical composition and spectral properties were analyzed. The possible reaction mechanisms were discussed.

DOI: 10.1134/S1070427208040277

Chitosan is an active sorbent of heavy metal ions [1]. It has been shown [2, 3] that a reason why this biopolymer exhibits sorption properties is that chelate complexes are formed between metal ions and functional groups of chitosan. However, formation of metal-containing composites in the system formed by chitosan and a solution of a metal salt is also possible via other physicochemical interactions without complexation [4].

No systematic studies of the interaction between this polymer and metal salts have been carried out under homogeneous conditions not complicated by phenomena at the phase boundary.

In aqueous solutions of acids, chitosan can be quantitatively determined by conductometric analysis [5]. It was found in [6] that, when solutions of chitosan and cobalt(II) nitrate in 0.1 M acetic acid are mixed, the content of chitosan decreases to equilibrium values. Subsequent, more detailed analysis of the titration curves of reaction mixtures revealed a portion corresponding to the formation of poorly soluble cobalt hydroxide ($L_{Co(OH)_2,\ 25°C} = (2.0–4.7) \times 10^{-16}$ in water [7, 8]) from metal cations that were unreacted with chitosan. The possibility of determining equilibrium amounts of metal ions enabled a study of this reaction and reaction with nickel nitrate ($L_{Ni(OH)_2,\ 25°C} = (1.2–2.0) \times 10^{-16}$ in water [7, 8]). In addition, the interaction of nickel(II) and cobalt(II) chlorides and nitrates with chitosan hydrochloride in aqueous solutions was examined. The aim of these studies was to analyze fundamental aspects and reveal the nature of interaction between the cations of these salts and dissolved forms of chitosan, obtained under different conditions.

EXPERIMENTAL

We used chitosan hydrochloride (CTSH) with a molecular weight of 38.2 kDa and chitosan (CTS) with a molecular weight of 120 kDa (Bioprogress Private Company, Shchelkovo, Moscow oblast). The degree of deacetylation of chitosan hydrochloride, found from the content of protonated amino groups by potentiometric and conductometric analyses of its aqueous solutions, is 81%. It should be noted that the titration curves contain no portion responsible for the HCl titration, commonly clearly manifested in analysis of chitosan dissolved in aqueous solutions of hydrochloric acid [5, 6, 9]. The data obtained suggest that the starting product contains no free HCl. Upon storage of the salt, the analytical results were reproduced.

The degree of chitosan deacetylation, determined by its conductometric and potentiometric analyses in aqueous solutions of 0.2 M acetic acid and 0.1 M hydrochloric acid, is 80%. The molecular weight of chitosan was calculated by the formula $[\eta] = KM^{\alpha}$, where $K = 3.41 \times 10^{-3}$ and $\alpha = 1.02$, from the data obtained by measuring the viscosity of chitosan solutions in a mixture of 0.33 M acetic acid and 0.3 M NaCl [10] with an Ubbelohde viscometer.

We used cobalt(II) and nickel(II) salts of analytically pure grade. Analyses for the metal cations were

made by conductometric titration with NaOH at concentrations of cobalt(II) and nickel(II) ions in the range 0.02–0.08 M in water or 2 M acetic acid. Preliminarily, we found the concentration of the cations in these solutions by titration with ethylenediaminetetraacetic acid (EDTA). The deviation from the results of analyses by titration with NaOH did not exceed 7.5% for cobalt(II) salts and 3.5% for nickel salts.

To perform the reactions, we first prepared starting solutions of the salts (0.5 M) and chitosans (0.1 M in terms of the elementary unit) and then used these solutions to obtain reaction mixtures with prescribed reagent concentrations. The experiments were carried out at initial concentration of the reagents in the range from 0.02 to 0.08 M and relative amounts of each of the reagents ranging from 1 : 1 to 1 : 4. The reaction mixtures were allowed to stand at room temperature. Their equilibration was monitored by the time variation of the content of chitosan and a metal ion, determined by conductometric titration of aliquots of the reaction mixtures.

The reaction products were isolated as follows. A 20-ml portion of acetone was poured from a pipette into 20 ml of a reaction mixture obtained at initial concentrations of the reagents equal to 0.1 M in a separating funnel without agitation. A gel-like clot was formed in the acetone layer at the phase boundary appearing because the fluid densities are different. The lower aqueous layer was separated. To remove metal ions unreacted with chitosan from the clot, and additional 20-ml portion of acetone was added, the clot was washed, and the acetone layer was separated. The treatment of the clot with acetone portions was repeated many times until the acetone layer became colorless. The completeness of removal of the ions was monitored by conductometric analysis of an aliquot part of the clot, dissolved in water. The necessary result was achieved faster if, after two or three washings with acetone, the clot was additionally washed with ethanol. Then the clot was placed in a Petri dish and dried first at 30–40°C and then to constant weight, with account of the conditions of water removal from chitosan. Chitosan is commonly dried at 105°C [5, 11]. However, according to the results of DSC studies [12], water is removed from chitosan at lower temperatures with an endothermic effect centered at 83.2°C. Therefore, samples of films composed of the reaction product were dried in two modes: at 85 and 105°C. The results of analyses of samples of dry films of the product, obtained in different conditions, coincided within the experimental error. The yield of a dry product from a single portion of the reaction mixture was 20–25% in terms of the initial amounts of the reactants. To accumulate the product, the isolation procedure was repeated.

Table 1. Results of analyses of the chemical composition of films with products formed in reactions of cobalt and nickel salts with chitosan hydrochloride in water and chitosan in a 0.2 M aqueous solution of acetic acid

Film	Content, wt %	
	metal	CTS
CTSH:		
with $Ni(NO_3)_2$	6.9	26.3
with $NiCl_2$	5.6	28.6
with $Co(NO_3)_2$	3.7	48.9
with $CoCl_2$	2.5	56.9
CTS:		
with $Ni(NO_3)_2$	2.4	21.2
with $Co(NO_3)_2$	2.5	19.9

IR spectra of film samples were measured on a Perkin-Elmer mod. 180 IR spectrophotometer. Electronic absorption spectra were obtained for aqueous solutions of the films on an SF-26 spectrophotometer. An approximately 0.5-g portion of a sample was dissolved in a 25-ml volumetric flask and analyzed by conductometry.

According to conductometric data, the isolated films contain, in addition to the reaction product, $-^{+}NH_3$ groups unreacted with the metal ion. Probably, the films are composed of polymers containing glucosamine rings with and without metal ions. The content of metal ions in the films was determined by titration with EDTA. The possibility of quantitative determination of the content of metal ions in the product by a reaction with a complexon was verified by analysis of the reaction mixtures in the simultaneous presence of the reaction product and equilibrium amounts of metal ions. In all the cases, the analysis demonstrated the initial content of the metal. This indicates that metal ions are bound to chitosan in the reaction products considerably more weakly than in the complex with EDTA. Table 1 lists data obtained chemical analyses of the films formed.

Let us consider the results of interaction of metal salts with chitosan hydrochloride in water. First, it should be noted that hydrolysis of $^{\pm}NH_3$ groups of chitosan hydrochloride is unimportant:

$$R^{+}NH_3 + H_2O \rightleftarrows RNH_2 + H_3O^{+}. \quad (1)$$

Indeed, pK_b for amino groups of chitosan is 7.7 [6, 9, 13, 14], and the dissociation of $^{\pm}NH_3$ groups,

* $c_{0\,CTS}/c_{0\,Ni(NO_3)_2}$ are the initial concentrations of chitosan and nickel (M); n, number of moles of chitosan involved in the reaction with a mole of metal ions; and x, conversion of metal ions, $(c_0 - c_{eq})/c_0$.

e.g., that at a salt concentration of 0.1 M, does not exceed 0.3%. This also agrees with the IR spectra of solid films of chitosan hydrochloride, which contain two well resolved absorption bands peaked at 1645 and 1535 cm^{-1}, associated with deformation vibrations of the N–H bonds in $^{\pm}NH_3$ groups [15, 16]. Absorption bands of deformation vibrations of these bonds in $–NH_2$ groups are not observed in the spectra under study.

Table 2 lists as an example data obtained in conductometric titration of reactions with nickel nitrate. The results of conductometric analyses of the equilibrium concentrations of the reactants were used to calculate the ratio between the moles of the amino groups of chitosan and metal ions, involved in the reaction ($n = R^{\pm}NH_3/M^{2+}$).

It can be seen in Table 2 that CTSH reacts with nickel nitrate in a stoichiometric ratio of 2 : 1. A similar pattern was obtained for the reaction with nickel chloride. A somewhat different ratio is observed with cobalt salts. The stoichiometric ratio between the reactants is 1 : 1 in the reaction of chitosan hydrochloride with $CoCl_2$ and about 1.5 : 1 in the reaction with $Co(NO_3)_2$.

It can be seen in Table 2 that, for the reaction with $Ni(NO_3)_2$ the conversion of metal ions increases with the ratio $c_{0CTS}/c_{0Ni(NO_3)_2}$. Similar data were obtained for the reactions of chitosans with $Co(NO_3)_2$. In the reaction with metal chlorides, the conversion is somewhat lower and does not exceed 0.5 for the reactant concentrations used.

Under the experimental conditions, the content of protonated amino groups decreased by more than 0.01 M, but the pH value remained unchanged during a run. Despite that chitosan hydrochloride is a salt of a weak base, its aqueous solution has, at the con-

centrations used, a low buffer capacity: upon addition of hydrochloric acid to the solution to a concentration of 0.01 M, the pH value of the mixture decreased from 5.4 to 2.8.

The fact that the pH values of the reaction mixture remain invariable in the course of a run indicates that $^{+}_{-}NH_3$ groups are involved in the interaction with metal ions without loss of a proton. This means that, having no free pair of electrons, the nitrogen atom in the alkyl ammonium ion cannot enter into complexation with a metal ion by the donor-acceptor mechanism, and, consequently, there must be another mechanism of interaction between the metal and the protonated amino group of chitosan. This conclusion is in agreement with the electronic absorption spectra of the reaction mixtures and solutions of films of products formed in the reaction under study. In these spectra, the absorption bands of cobalt(II) and nickel(II) ions, peaked at 515 and 395 nm, are not shifted to any noticeable extent. It is known that cobalt(II) and nickel(II) ions exist in aqueous solutions in the form of octahedral aqua complexes $[Co(H_2O)_6]^{2+}$ and $[Ni(H_2O)_6]^{2+}$ [17]. The replacement of the ligands in the formation of amino complexes strongly affects the energy of the *d–d* electron transitions [18]. The absence of pronounced changes in the spectra of samples of the system under study suggests that the ligand in the aqua complexes of metal ions is not replaced by the amino group of chitosan.

The results observed can be accounted for by the interaction in solution of $^{+}_{-}NH_3$ groups with water molecules in metal aqua complexes by the mechanism of hydrogen bond formation. These interactions are also observed in solid films of the products. The IR spectra of the films obtained from reaction mixtures with cobalt(II) salts show a shift of the absorption band associated with deformation vibrations of the $^{+}_{-}NH_3$ group at 1645 cm^{-1} to 1635 cm^{-1} for the product formed in the reaction with cobalt chloride and to 1615 cm^{-1} for that formed with cobalt nitrate. The second absorption band associated with deformation vibrations of $^{+}_{-}NH_3$ groups is observed at 1530 cm^{-1} in films formed in both the reactions. In the spectra of the films obtained in the reaction with nickel chloride, these absorption bands are shifted to 1615 and 1510 cm^{-1}, respectively.

The IR spectra of the products isolated substantially differ from the spectra of chitosan hydrochloride in the region of stretching vibrations of –C–O groups and deformation vibrations of –O–H groups. The spectra of chitosan hydrochloride show, in the frequency range 1000–1200 cm^{-1}, strong absorption with a virtually unresolved band structure, whereas in the IR spectra of films formed of the products formed in the reaction with cobalt salts, this region is represented by three strong absorption bands peaked at 1050, 1100, and 1170 cm^{-1}. A similar spectrum was obtained for a film produced in the reaction with $NiCl_2$. Presumably, this is due to interaction of the metal ion with an oxygen atom from a hydroxy group of chitosan.

Thus, the whole set of the data presented suggests that, in solution, the metal ion is coordinated with an oxygen atom from the glucosamine ring and $^{+}_{-}NH_3$ groups form hydrogen bonds with oxygens from water molecules in the aqua complex of the metal ion.

When the product is obtained in the solid state and dried to constant mass, molecules of coordination water can be replaced with counter ions. For example, thermochemical studies with cobalt(II) complexes $[Co(NH_3)_5 \cdot H_2O]X_2$ demonstrated that the process of water replacement by a counter ion X^- is exothermic and, e.g., in the case when X = Cl, its ΔH = –19.2 kJ mol^{-1} [17]. This is due to the difference in the coordination energies of the bonds Co^{2+}–H_2O and Co^{2+}–X.

When studying reactions with cobalt salts, we obtained films that, being dried to constant mass, take on a blue color characteristic of fully or partly dehydrated salts of this metal [19]. The film produced by the reaction of CTSH with nickel(II) ions is light yellow. In this case, a salt with a complex metal cation M, $[MRN^+H_3(H_2O)_2X^-]^{2+}X^{2-}$, or a neutral complex $[MRN^+H_3(H_2O)_2X_3^-]$ can be suggested as probable structures for reaction products obtained in the solid state. Metal complexes with positively charged ligands have been more than once described in the literature [20–22].

Let us now consider the results obtained for the reaction of chitosan in an aqueous solution of acetic acid. It is noteworthy that the following equilibrium in this solvent can be suggested for the state of chitosan:

$$RNH_2 + CH_3COOH \rightleftarrows RN^+H_3 + CH_3COO^-. \quad (2)$$

To evaluate the constant of equilibrium (2), we represent this equation as an algebraic sum of the following equations:

$$(+)\ RNH_2 + H_2O \rightleftarrows RN^+H_3 + OH^-,$$

$$(+)\ CH_3COOH + H_2O \rightleftarrows CH_3COO^- + H_3O^+,$$

$$(-)\ 2H_2O \rightleftarrows H_3O^+ + OH^-.$$

Thus, the constant of equilibrium (2) can be expressed in terms of K_b of the amino group of chitosan, dissociation constant K_a of acetic acid, and ionic product for water, K_w:

$$K = K_b K_a / K_w.$$

In view of this circumstance, the content of unprotonated RNH_2 groups for a chitosan solution may be, e.g., at 0.1 M of chitosan in 0.2 M acetic acid, up to 10%. In agreement with this conclusion is the IR spectrum of a solid film produced by evaporating the solvent from a thin layer of the chitosan solution mentioned above. In addition to the absorption bands associated with deformation vibrations of $-N^+H_3$ groups (1640 and 1530 cm^{-1}), this spectrum contains absorption bands at 1670 and 1570 cm^{-1}, attributed, by analogy with [15], to deformation vibrations of $-NH_2$ groups.

This spectrum also additionally contains, compared with the spectrum of chitosan hydrochloride, absorption bands of the ionized acetate group at 1610 and 1315 cm^{-1} [15]. The presence of acetic acid residues in the film is indicated by the absorption band at 1710 cm^{-1}.

It would also be expected that, in an aqueous solution of acetic acid, metal ions interact with the unprotonated amino group of chitosan. Conductometric studies demonstrated that titration curves of reaction mixtures in this reaction have a more complex form. Particularly distinctly pronounced is a new portion in the reaction with nickel nitrate, which is presumably associated with the interaction of NaOH with the new product. It can be seen in Table 2 that, for the reaction of CTS with nickel nitrate, the number of chitosan moles reacting with a mole of metal ions varies with the ratio of the initial reactant concentrations. A similar behavior was also observed for the reaction with cobalt nitrate.

In the electronic absorption spectrum of an aqueous solution of a film produced in the reaction of cobalt nitrate with CTS, the absorption peak at 515 nm is shifted to shorter wavelengths by 10 nm. In contrast to the product formed in the reaction of this salt with CTSH, the dry film has in this case a pink color. Probably, these facts are a consequence of the interaction with the aqua complex of the cobalt(II) ion with the ligand in this complex replaced by the $-NH_2$ group. The data obtained give no way of determining the stoichiometry of the reaction of this type.

In the IR spectra of films obtained in the system CTS + $Co(NO_3)_2$, the above-mentioned absorption bands associated with deformation vibrations of $-NH_2$ groups are shifted to 1650 and 1550 cm^{-1}, respectively. The absorption band at 1640 cm^{-1}, associated with deformation vibrations of the $^{\pm}NH_3$ group, is shifted to 1630 cm^{-1}, and the second band at 1530 cm^{-1} is observed as a broad shoulder with absorption in the frequency range 1500–1550 cm^{-1}. The absorption band at 1610 cm^{-1} presumably corresponds not only to the ionized acetate group, but also to the nitrate anion [15]. In the spectrum of a film produced in the system CTS + $Ni(NO_3)_2$, one of the absorption bands associated with deformation vibrations of $-NH_2$ groups is shifted to 1660 cm^{-1}, and the region 1510–1550 cm^{-1} shows a strong absorption that can be attributed to deformation vibrations of $^{\pm}NH_3$ and $-NH_2$ groups. The film has a yellow-green color.

Thus, the data presented here indicate that metal ions are complexed with amino groups of chitosan when the reaction is performed in an aqueous solution of acetic acid. On the whole, the results of our study demonstrate that both coordination interactions and interactions by the mechanism of hydrogen bond formation occur between the metal ions and the functional groups of chitosan in the reactions under study.

CONCLUSIONS

(1) The stoichiometry of the reaction of cobalt(II) and nickel(II) salts with chitosan hydrochloride in water and chitosan in an aqueous solution of acetic acid was determined by conductometric analysis. In the number of amino groups, chitosan hydrochloride reacts with metal ions in ratios of 2 : 1 in the reactions with $NiCl_2$ and $Ni(NO_3)_2$, 1 : 1 in the reaction with $CoCl_2$, and 1.5 : 1 in that with $Co(NO_3)_2$. In the reactions with chitosan in an aqueous solution of acetic acid, the number of reacting amino groups per mole of metal ions increases with the ratio between the initial concentrations of chitosan and metal ions.

(2) Different types of interaction of soluble forms of chitosan with metal salts were revealed by pH-metry and electronic absorption and IR spectroscopies. When complexes of metal ions with chitosan hydrochloride are formed, the amino groups in the ligand remain protonated, with its oxygen atoms acting as donor centers. In the reaction of chitosan in an aqueous solution of acetic acid, complexation with $-NH_2$ groups occurs in parallel with this interaction.

Received December 14, 2007

Abstract—The kinetics of degradation of polymethyl methacrylate, polybutyl methacrylate, and poly-2,2,3,3-tetrafluoropropyl methacrylate synthesized by pseudoliving radical polymerization at 270°C in air in the presence of bis(triphenylphosphine)(3,6-di-*tert*-butyl-1,2-semiquinolato)copper(I) was studied. The possibility of improving the thermal treatment of the resulting polymers was revealed.

DOI: 10.1134/S1070427208040289

Pseudoliving radical polymerization allows synthesis of polymers and copolymers with controlled molecular weight and narrow molecular-weight distribution, which largely affects their physicomechanical characteristics. There are several methods for implementation of this process: radical polymerization with reversible inhibition by stable free radicals (SFRP), radical polymerization with halogen atom transfer (ATRP), and polymerization by degenerate chain transfer by reversible addition-fragmentation (RAFT) [1–3]. In all these cases, the chain termination is controlled by the reversible reaction of the chain-terminating agent with the propagating radical. Macromolecules of polymers contain terminal groups bound to the chain by a labile bond that can be activated under thermal or photochemical action.

In this study, we used a copper semiquinolate complex, bis(triphenylphosphine)(3,6-di-*tert*-butyl-1,2-semiquinolato)copper(I) (CSQ) for synthesis of polymethacrylates by the SFRP method. The structure of this complex is presented below:

The process was performed at 25°C under UV irradiation. Methyl methacrylate (MMA), butyl methacrylate (BMA), and 2,2,3,3-tetrafluoropropyl methacrylate (FMA) were used as monomers. Under the above conditions, the polymerization exhibited all features of a pseudoliving radical process: linear dependences of the average molecular weight on the degree of conversion, lower values of the polydispersity parameter M_w/M_n, and initiation of secondary polymerization of monomers with polymers synthesized in the presence of CSQ [4, 5].

The kinetic curves of degradation of reprecipitated samples of polymers are shown in Figs. 1 and 2.

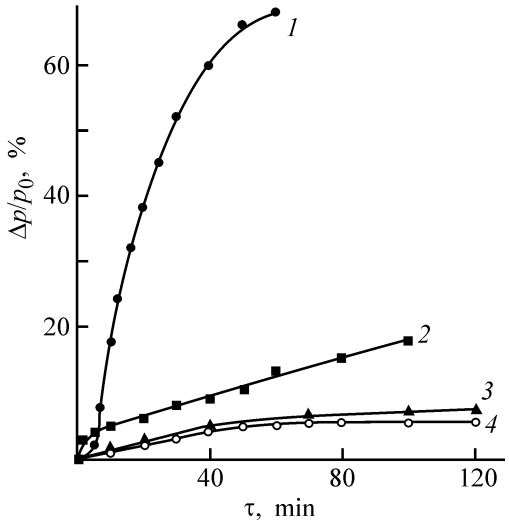

Fig. 1. Kinetic curves of degradation of polyMMA in air at 270°C. ($\Delta p/p_0$) Decomposition of volatile products, and (τ) time; the same for Fig. 2. (*1*) [CSQ] = 0, (*2*) CSQ is introduced into the prepared polymer via the solution, (*3*) polymer is synthesized by secondary polymerization of MMA initiated with polyMMA (5 wt %) from run no. 4, and (*4*) [CSQ] = 4×10^{-3} M.

The process was performed in air at 270°C. The synthesis conditions are listed in Table 1 and in the Experimental. It follows from Figs. 1 and 2 that, in the course of decomposition for 60 min, the amount of volatiles decreases by a factor of 6–12 in comparison with polymethacrylates synthesized in the absence of CSQ. Introduction of CSQ into the finished polymer (Fig. 1, curve *2*) is less efficient than its introduction in the course of the synthesis. This is apparently caused by the presence of double bonds at the ends of polymethyl methacrylate macromolecules formed in the course of the polymer synthesis in the absence of CSQ by disproportionation of macroradicals. To elucidate the role of CSQ in the enhancement of the heat resistance of the polymers, we synthesized two polystyrene samples by pseudoliving radical polymerization. One sample was prepared in the presence of CSQ by UV-induced polymerization, and the other, by thermal polymerization at 120°C in the presence of a stable radical, 2,2,6,6-tetramethylpyperidine-1-oxyl (TEMPO). The reprecipitated samples were heated at 300°C in air. It was found that, in 60 min, the first sample degraded by 10%; the second, by 29%; and polystyrene prepared by common radical polymerization, by 22%. Thus, nitroxyl radicals do not exert a stabilizing influence on the polymer degradation. The stabilization of thermal degradation of methacrylates by CSQ is apparently caused by the inhibiting effect of decomposition products of the semiquinolate complex: di-*tert*-butyl-*o*-benzoquinone, triphenylphosphine, and copper. It is well known [6, 7] that all these compounds can react with radicals and thereby can terminate the chain reaction of degradation of macromolecules.

Thus, polymethacrylates whose macromolecules contain fragments of CSQ inhibitor at the chain ends have an increased thermal stability.

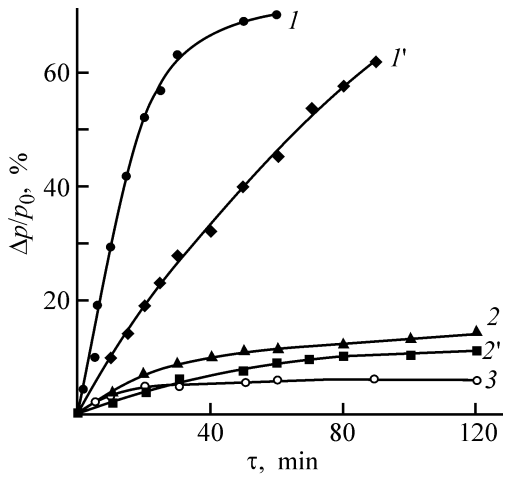

Fig. 2. Kinetic curves of degradation of (*1*, *2*) polyFMA and (*1'*, *2'*) polyBMA in air at 270°C. (*1*, *1'*) [CSQ] = 0, (*2*, *2'*) [CSQ] = 1.5×10^{-3} M, and (*3*) polyFMA synthesized by secondary polymerization of FMA initiated with polyFMA (5 wt %) from run no. 2.

EXPERIMENTAL

The procedures of purification of monomers and synthesis of polymers are described in detail in [8]. The CSQ complex was synthesized by the procedure described in [9]. The substance was a dark violet powder stable in air and readily soluble in monomers. Polymethacrylates were synthesized via formation of CSQ adduct with radicals of the initiator, azobis(isobutyronitrile) (AIBN), in the monomer medium at 70°C and then at 25°C under UV irradiation with a PRK-400 lamp. After the required conversion was reached, the ampules were opened, and the isolated polymers were purified by threefold reprecipitation, dried in a vacuum to constant weight, and then used in experiments on thermal degradation in air. The weight

Synthesis conditions of polymethacrylates (UV irradiation, 25°C, [AIBN] = 1×10^{-2} M)

Polymer	Run no.	[CSQ] × 10^2, M	Conversion, %	$M_n \times 10^{-4}$	M_w/M_n
PolyMMA	1	0	10	9.4	4.3
	2	4**	10	9.4	4.3
	3*	–	15	11.1	2.1
	4	4	10	8.2	2.0
PolyFMA	1	0	15	–	–
	2	1.5	35	12.2	1.8
	3*	–	16	330	1.4
PolyBMA	1'	0	35	8.8	2.1
	2'	1.5	15	10.1	1.6

* PolyMMA (polyFMA) synthesized under conditions of run no. 4 (no. 2) was used as an initiator.

** PolyMMA was synthesized similarly to run no. 1, but CSQ was added to the polymer solution.

loss was determined with a torsion balance. A support (metal foil) with the polymer in the form of fine chips (approximately 0.2 g) was suspeded by a metallic thread to the arms of the balance, the zero point was fixed, and then the thread was placed in a furnace heated to the required temperature for thermal decomposition. The furnace was kept in the isothermal mode.

CONCLUSION

The pseudoliving radical polymerization of methacrylates in the presence of copper semiquinolate complex allows control over the molecular weight and molecular-weight distribution of the resulting polymers and also enhancement of the heat resistance of the polymers by direct addition of the chain-terminating agent, copper semiquinolate complex, into the polymerizing system.

Abstract—Preparation of fireproof polymer compounds and properties of the resulting materials were studied. The synergistic effect of mixtures of fire-retardant additives based on thermally expanding graphite was examined.

DOI: 10.1134/S1070427208040290

Most procedures for diminishing the combustibility of polymer materials are based on decreasing the burning limits and affecting the heat and mass transfer of the flame with the surface of the burning polymer. This problem is solved by changing the thermal and thermochemical characteristics of the condensed phase and by lowering the rate of release of combustible gases (products of polymer degradation), the combustion efficiency, and the rates of oxidation in the gas phase and coke formation. This can be done by chemical modification of the polymer backbone and by addition of fire-retardant additives or other fillers that are characterized by high endothermic effect and release inert reaction products or affect the degradation pathway in the condensed phase [1, 2].

Swelling fireproof coatings are of particular interest for construction industry, machine building, transport, etc. [3]. A formulation for swelling coatings containing ammonium polyphosphate as an agent for initiation of the foamed coke formation was suggested in [4].

In this study, we examined the effect of fillers, such as thermally expanding graphite (TEG), ammonium polyphosphate (APP), and pentaerythritol (PE), on the fireproof properties of polymer materials.

EXPERIMENTAL

Thermally expanding graphite [5] bloating at elevated temperatures was used as the main component of the system. In combustion, the volume of TEG considerably increases, which is accompanied by heat absorption and formation of a heat-shielding carbon foam preventing fire propagation. However, the strength of the resulting carbon foam layer is low, and it is easily broken under the conditions of real fire.

The mechanical strength of the protective carbon foam can be enhanced by modification with various fire-retardant additives.

The refractoriness of the polymer materials was studied by the UL-94 international procedure [GOST (State Standard) 28 157–89], according to which a material of group V-0 is characterized by the highest refractoriness.

The oxygen index (i.e., the minimal content of oxygen in the oxygen–nitrogen mixture at which the candle-like combustion is possible under the conditions of special tests) was determined in accordance with GOST 12.1.044–89 [6]. The physical and mechanical properties of the polymer materials were studied on an RMI-5 tensile-testing machine, and the elasticity, on an METEFEM-khr01 unit.

When exposed to high temperatures in the course of combustion, a polymer composite containing TEG is bloated, and a crust is formed on its surface.

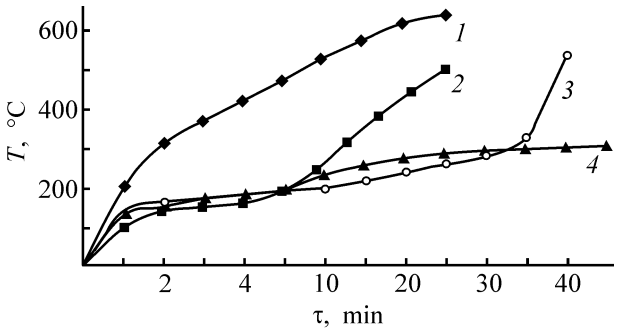
It was found that the resulting coke layer (foam) prevents further fire propagation toward the protected surface. The intumescence coefficient K_{sw} of the polymer material was determined as follows:

$$K_{sw} = (h_b - h_n)/(h_0 - h_n),$$

Physicomechanical properties of PVC polymer compounds at various contents of the fillers

PVC : APP–PE–TEG mixture	Relative elongation at break %	Breaking tensile stress, kg cm^{-2}
No filler	350	28.1
1 : 0.5	300	29.3
1 : 1	280	33.85
1 : 1.5	150	24.45
1 : 2	120	16.8

where h_0 is the initial thickness of the sample (mm), h_b is the thickness of the sample after treatment in the furnace ($T = 650 \pm 20$°C) for 10 min (mm), and h_a is the support thickness (mm).



The result was averaged from the data of five and more tests.

The formulations were prepared by mechanical mixing of the components. To attain the uniformity, the mixture was ground on a three-roll mill. The 2-mm film of polyvinyl chloride (PVC) material was prepared by the plastisol procedure using dioctyl phthalate plasticizer. The coking ability was evaluated by formation of the solid layer (resistant to mechanical stresses) on the sample surface.

The refractoriness of the samples was tested by the "fire tube" procedure [6].

The formulated fireproof paint-and-varnish coatings were cast on metal supports (1 mm thick). The coating thickness was 1 mm. Wood samples were coated by partial immersion; the coating thickness was 0.6 mm.

First, we performed the blank test to determine the temperature made of the fire tests. In this case, we used the metal support (1 mm thick) without a faire-proof coating. This support was placed on top of a quartz tube, and a thermocouple was fixed at its back at the center. Then, the air-propane mixture in a gas jet was ignited and the flame temperature of 650°C was controlled with a thermocouple.

Temperature of the support T vs. time τ of fire treatment of the protective acryl coating. (*1*) Metal support without coating, (*2*) coating containing APP and PE, (*3*) coating containing TEG, and (*4*) coating containing APP, PE, and TEG.

In the second step, the metal supports with the fireproof coatings were tested using the balanced jet flame.

We attempted to enhance the strength of the foam formed after the TEG degradation, using pentaerythritol whose degradation at high temperatures yields a 3*D* network [7].

We also used a mixture of PE and APP. Under the flame treatment, this mixture degrades, yielding ammonia and forming a so-called blanket on the sample surface, protecting it from the fire.

Our tests allowed evaluation of the optimal mixture of fire-retardant additives in the blend (weight fraction): APP 2, PE 1, and TEG 1. This component ratio provides high mechanical strength of the foamed coke on the surface of the protected material. These components were added in the PVC polymer matrix, polychlorovinyl resin, and acryl dispersion.

The dependences of physicomechanical properties of the modified PVC compositions on the PVC : filler ratio are listed in the table. As can be seen, filler being added decreases the relative elongation and breaking tensile stress. It should be noted here that the physicomechanical properties of the filled composites remain relatively high.

As a result, we prepared a fireproof PVC compound exhibiting the following characteristics [8]: refractoriness corresponds to group V-0 (UL-94 procedure), bloating ratio at 650°C 20–25, oxygen index 31%, breaking tensile stress 33.85 kg cm^{-2}, and relative elongation at break 280%.

The above ratio of fire-retardant additives was also used for preparing a fireproof paint-and-varnish coating based on perchlorovinyl resin and acryl dispersion [9]. The test results are illustrated in the figure.

The sample without coating attains the critical temperature in 12 min. The samples coated with the composition containing APP and PE protect the metal for 10 min, after which the coating breaks down. Coating of the sample with the composite containing TEG strongly decreases the temperature at the back side of the support, but at prolonged high-temperature treatment the coating degrades. The best results were ob-

tained when the support was coated with the compound containing a mixture of TEG, PE, and APP. This fireproof compound provides the first protection group for timbering (film thickness 0.6 mm) and the fourth protection group for metal structures (film thickness 1 mm).

CONCLUSIONS

(1) A fireproof compound based on thermally expanding graphite, ammonium polyphosphate, and pentaerythritol was prepared.

(2) The synergistic effect increases the effectiveness of the mixture of fire-retardant additives.

(3) Fireproof polymer coatings based on polyvinyl chloride, perchlorovinyl resin, and acryl dispersion were developed.

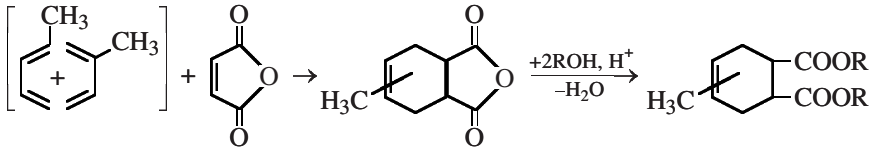
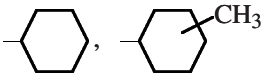
Abstract—New plasticizers for polyvinyl chloride polymeric compounds, based on 2(3)-methylcyclohexenedicarboxylic acid diesters, were suggested. The optimal formulation was found, and its physicochemical properties were characterized.



DOI: 10.1134/S1070427208040307



Ester plasticizers used for processing of polyvinyl chloride (PVC) compounds are large-tonnage commercial products, and the demand for them steadily increases [1–5]. Because of the wide and diverse applications of PVC compounds and large demand for ester plasticizers, a search for new promising high-quality plasticizers remains a topical issue, the more so as one of the most widely used plasticizers, dibutyl phthalate, being an aromatic compound, is very toxic.

The goal of this study was to develop PVC compounds with improved consumers properties, using high-quality environmentally clean plasticizers.

In this study, we used diesters of 2(3)-methylcyclohexenedicarboxylic acid, prepared from aliphatic 1,3-pentadienes present in the C_5 pyrolysis fraction by the scheme shown below.

The physicochemical parameters of the diesters are listed in Table 1.

EXPERIMENTAL

In the experiments, we used PVC of suspension (S-7058 M, S-7059 M) or emulsion (E-7050 M) brand, a thermostabilizer (calcium stearate), and fillers (chalk and pigments). As plasticizers we used dialkyl or dicycloalkyl esters of 2(3)-methylcyclohexenedicarboxylic acid.

To prepare the polymeric compounds, the ingredients (proportion by weight), PVC resin 100, plasticizer 30–70, calcium stearate 2–5, filler 8–10, and pigment ≤0.5, were loaded into a mixer for swelling and were compounded for 10 min at 90–110°C. The swollen mixture was fed to rollers where it was homogenized at 120–130°C for 15–20 min.

From the polymeric compound obtained, we prepared samples and determined their physicochemical parameters by standard methods. The composition and properties of PVC compounds are listed in Table 2.

It can be seen that the diesters we prepared exhibit good plasticizing properties. With a decrease in the amount of the plasticizer in the compound, the plasticization and, correspondingly, the physicomechanical properties of the compound become worse.

The physicochemical characteristics of the newly synthesized dibutyl 2(3)-methylcyclohexenedicarboxylate and commercial plasticizers, dibutyl phthalate and dioctyl phthalate, are compared in Table 3.

It can be seen that dibutyl 2(3)-methylcyclohexenedicarboxylate has better properties and shows much promise as a plasticizer for PVC compounds.

The general procedure for preparing 2(3)-methylcyclohexenedicarboxylic acid diesters was as follows. A reactor was charged, using a dosing pump, with the required amounts of the starting reactants, a catalyst was added (mineral acid, 0.1–0.4% relative to the total weight), and the mixture was stirred for 1.5–2.0 h at 80–110°C. Then the reaction was continued for 4.0–4.5 h more, with slow evaporation of water released in the reaction and of excess alcohol. Water was evaporated first, as it formed a relatively low-boiling azeotrope with excess alcohol. After the reaction completion (when the water release ceased), the contents were loaded into barrels or pumped into a tank for finished products.

CONCLUSION

Dialkyl and dicycloalkyl esters of 2(3)-methylcyclohexenedicarboxylic acid were prepared and characterized. They can be used as plasticizers for PVC compounds.

Abstract—Effect of high concentrations of electrolytes (Na_2SO_4, NaCl, and $NaNO_3$) on the rate of ozone decomposition in water was studied. The conversion kinetics of O_3 dissolved in these solutions was analyzed. The rate constants of ozone decomposition were determined.

DOI: 10.1134/S1070427208040319

Aqueous ozone solutions are instable in storage. The mechanism of their decomposition has already been studied for 70 years [1]. During this period, the main intermediate radical (HO_2, O_3^-, OH) and molecular (H_2O_2, O_2) products formed in the reactions of ozone and water have been identified, the rate constants of the corresponding reactions have been determined, and the chain reactions responsible for the decomposition have been elucidated [1–8].

Ozone is an exceedingly strong oxidant in water (its redox potentials are 2.07 and 1.27 V in acid and alkaline media, respectively) [9]. Ozone is widely applied for disinfection of drinking water and for oxidative decomposition of hazardous (organic and inorganic) impurities present in technological and household wastewater. In particular, ozone is used at radiochemical and nuclear power plants to decompose organic compounds in processing of a liquid radioactive waste containing high concentrations of dissolved salts (nitrates, chlorides, sulfates, etc.) [10]. Therefore, it is very important to take into account the effect of high electrolyte concentrations on the rate of ozone decomposition.

This study was aimed to determine the influence exerted by considerable concentrations of salts (Na_2SO_4, NaCl, and $NaNO_3$) on the rate of ozone decomposition in water.

EXPERIMENTAL

As objects of study served aqueous solutions (pH ~6) of Na_2SO_4, NaCl, and $NaNO_3$ (all of chemically pure grade) with concentrations of 0.35 to 3.5 M. The ozonization was performed in a temperature-controlled cell at 20°C. Ozone was obtained in a TRINITY ozonizer equipped with a capillary discharge chamber in which an ozone-oxygen mixture (OOM) with an ozone concentration of up to 180 mg l^{-1} was formed. The ozone-oxygen mixture was passed through a solution under study at a given temperature until a necessary concentration of O_3 was attained. The measurements were performed in a special quartz cell filled with a solution and in the absence of a gas phase. The concentration of ozone in the solution was continuously monitored by its absorption spectrum (λ_{max} = 258 nm, ε = 2900 l mol^{-1} cm^{-1} [11]), which made it possible to determine the time in which the limiting solubility is reached.

It has been found previously [12] that the solubility of ozone in water decreases as the salt concentration becomes higher. Ozone decomposes in water and in aqueous solutions of salts, which is manifested as a decrease in the intensity of its optical absorption in the course of time (Fig. 1). The kinetic dependences

of ozone decomposition are shown as an example for aqueous solutions of Na_2SO_4 in Fig. 2. It can be seen that the decomposition rate increases with the concentration of the dissolved salt. Similar dependences are also observed for aqueous solutions of NaCl and $NaNO_3$.

It was found that the kinetics of ozone decomposition in water and in aqueous solutions of Na_2SO_4, NaCl, and $NaNO_3$ is well described by the first-order equation. In Fig. 3, the kinetic dependences of ozone decomposition in water and in aqueous Na_2SO_4 solutions are plotted in the coordinates $\ln(c_0/c_t)$–t, where c_0 and c_t are the initial and current concentrations of ozone, respectively, and t is time. Figure 4 shows how the obtained effective rate constants k_{ef} depend on the concentration of the dissolved salt. The variation of k_{ef} with the salt concentration can be described by the equation

$$k_{ef} = k_w + k_r c_r,$$

where k_r is the true rate constant, and k_w is the rate constant of ozone decomposition in water.

It can be seen that, for all the salts, k_{ef} is virtually proportional to their molal concentration. This means that the reaction of ozone decomposition in aqueous solutions of salts is bimolecular. The slope of the dependence was used to determine the following true rate constants k_r of ozone decomposition (l mol^{-1} s^{-1}): 1.2×10^{-3} for Na_2SO_4, 5.8×10^{-3} for NaCl, and 3.5×10^{-4} for $NaNO_3$. This indicates that, at the same molar concentrations of the salts, the ozone decomposition in $NaNO_3$ solutions is a factor of 3–4 slower than that in Na_2SO_4 solutions and a factor of 17 slower than that in NaCl solutions. The intercept on the ordinate axis by the linear dependences of k_{ef} at zero salt concentration corresponds to the rate constant of ozone decomposition in pure water, k_w (2.9×10^{-4} s^{-1}). The thus calculated rate constant coincides with the experimentally measured value.

The mechanism of ozone decomposition in the presence of salts is rather complicated. The dependence of the decomposition rate on the nature of an electrolyte shows that the ionic strength of the solutions is not a predominant factor responsible for this effect. The specific effect of a salt is possibly due to decomposition of ozone in two processes involving free water and water specifically bound to the electrolyte (e.g. water from the hydrate sphere of the ion). The concentration of the hydration water, which reacts with ozone more vigorously, is proportional to the salt concentration in the solution.

CONCLUSIONS

The kinetics of ozone decomposition in aqueous solutions of salts (Na_2SO_4, NaCl, and $NaNO_3$) is described by a pseudo-first-order equation in the salt concentration. The rate increases with the concentration of the dissolved salt. Depending on the nature of a salt, the rate constants of the reactions vary in the following order: $k(NaNO_3) < k(Na_2SO_4) < k(NaCl)$.

Abstract—Extraction of an anthocyan dye with poly-*N*-vinylpyrrolidone (PVP) and poly-*N*-vinylcaprolactam (PVC) under the conditions of separation of aqueous solutions of this polymer into two phases in the presence of salting-out agents (sodium chloride and sodium or ammonium sulfate) was studied.

DOI: 10.1134/S1070427208040320

Heterogeneous systems containing water-soluble polymers poly-*N*-vinylpyrrolidone (PVP) and poly-*N*-vinylcaprolactam (PVC) are used in biotechnology for separation of proteins, cells, and biologically active substances, including amino acids and vitamins [1, 2]. The main advantages of application of PVP and PVC as extractants are their nontoxicity, high hydrophilicity, and ability to form complexes with many low- and high-molecular-weight organic compounds [3].

The majority of natural red pigments are derived from anthocyans, phenolic compounds, whose structure is similar to that of plant glycosides. These compounds are readily soluble in water and form anthocyanides upon hydrolysis [4]. These dyes are used in food industry [5].

The common methods for recovery and preconcentration of anthocyan dyes from plant raw materials and aqueous solutions are based on their repeated extraction with organic solvents [5]. We believe that liquid extraction of anthocyan dyes can be improved by using two-phase aqueous systems based on water-soluble polymers containing no toxic organic solvents. Such extraction systems based on PVP and PVC have not been studied previously.

In this study, we examined the extractive preconcentration of an anthocyan dye from aqueous solutions with PVP and PVC.

EXPERIMENTAL

Anthocyan dye was extracted from black-currant berry with ethanol at 50–55°C by the procedure reported in [6]. The PVP polymer of medical grade with a molecular weight $M_\eta = 1 \times 10^4$ was used. Poly-*N*-vinylcaprolactam was prepared by radical polymerization of its monomer in isopropanol at 70°C in the presence of azobis(isobutyronitrile) initiator at various monomer concentrations. The polymer was precipitated by adding hexane to the reaction mixture and then vacuum-dried at 55–60°C. The molecular weights of the polymers were calculated from the intrinsic viscosity [η] of their solutions by the formula $[\eta] = 1.5 \times 10^{-4} M_\eta^{0.68}$ [3]. PVC samples with the molecular weights of 1×10^4, 6×10^4, and 16×10^4 were prepared.

NaCl, $(NH_4)_2SO_4$, and Na_2SO_4 (chemically pure grade) were used as salting-out agents providing separation of aqueous solutions of the polymer into two phases within a wide range of polymer and salt concentrations.

A solution of anthocyan dye (10 ml), containing a salting-out agent, was placed in a vial with a ground-glass stopper, and then 1 ml of an aqueous solution of the polymer (concentration 0.001–2 wt %) was added to obtain a two-phase extraction system. The extraction was carried out on a vibra-

tion mixer until the phase equilibrium was attained (3–5 min).

The efficiency of the extraction recovery of the dye was characterized by the degree of its recovery R (%):

$$R = [(A_0 - A)/A_0] \times 100,$$

where A_0 and A are the optical densities of aqueous anthocyan dye solutions before and after extraction (KFK-2MP spectrophotometer, λ = 490 nm, 1-cm optical cell).

The content of the red pigment in the anthocyan dye was determined with a reference solution of $CoSO_4 \cdot 7H_2O$ by the standard procedure [5].

As a rule, two-phase aqueous systems based on water-soluble polymers are prepared by their salting-out from homogeneous aqueous solutions [7]. The conditions of formation of heterogeneous systems by salting-out of PVP and PVC from their homogeneous aqueous solutions were elucidated from their phase diagrams (Fig. 1) obtained by titration of these polymers with standard salt solutions to the cloud point [8]. We found that, in all the systems under consideration, except PVP–sodium chloride–water, stable two-phase systems are formed. In phase diagrams, the fields of two-phase systems lie above binodal curves of approximately exponential shape. Irrespective of a particular poly-*N*-vinylamide, the strongest salting-out effect is reached in the presence of ammonium sulfate. It should be noted that the molecular volume and electronic structure of ammonium cations are close to those of water molecules, and ammonium cations form hydrogen bonds with surrounding water molecules. These factors favor stronger hydration of ammonium cations. To obtain the maximal amount of the aqueous phase enriched in the polymer, the salting-out is carried out at the salt concentration close to saturation.

Figure 2 shows that the extraction of anthocyan dyes is dependent on both the polymer concentration and particular dye. In salting-out with ammonium sulfate, the dye recovery is more complete. In single-step extraction, the degrees of recovery of dyes in the presence of ammonium sulfate and sodium sulfate are 95 and 79%, respectively.

In extraction of anthocyan dye with PVC, the more efficient recovery of the dye is reached with sodium chloride compared with ammonium and sodium sulfates. We believe that this difference is primarily caused by the difference in the effect of salts on the phase separation temperature T_{ps} of aqueous PVC.

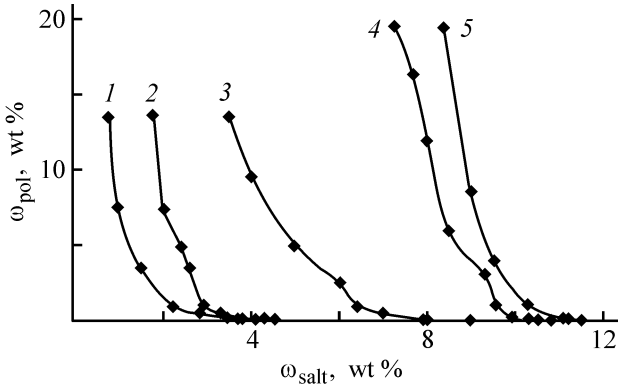

Fig. 1. Phase diagrams of the systems (*1*) PVC–ammonium sulfate, (*2*) PVC–sodium sulfate, (*3*) PVC–sodium chloride, (*4*) PVP–ammonium sulfate, and (*5*) PVP–sodium sulfate. (ω_{pol}) Weight fraction of polymer and (ω_{salt}) weight fraction of salt.

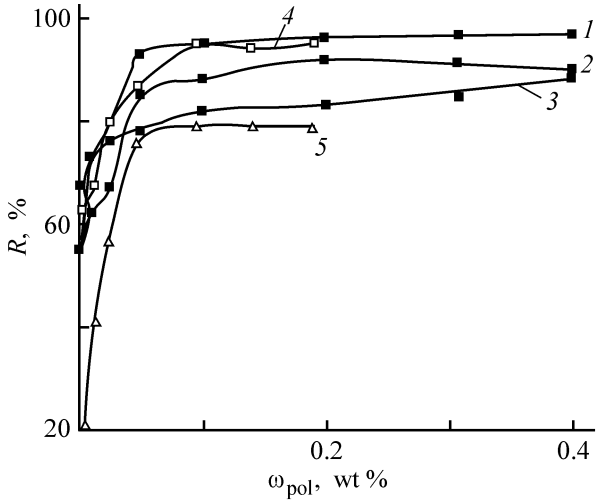

Fig. 2. Degree of extraction of anthocyan dye R from aqueous-salt solutions vs. polymer concentration ω_{pol} Polymer: (*1–3*) PVC and (*4*, *5*) PVP Salting-out agent: (*1*) sodium chloride, (*2*, *5*) sodium sulfate, and (*3*, *4*) ammonium sulfate.

It is known [9] that, in the absence of salt, the T_{ps} of this polymer is close to the temperature of warm-blooded living bodies. At the same time, on adding NaCl, the phase-separation temperature decreases to room temperature. Therefore, we suggest that the increase in efficiency of extraction of the anthocyan dye in the system poly-*N*-vinylcaprolactam–NaCl–H_2O is caused not only by salting-out of the dye and polymer but also by changes in the structure of the polymer–H_2O complex.

Figure 3 shows how the PVC molecular weight and pH affect the degree of recovery of anthocyan dye from saturated aqueous NaCl. It is seen that, irrespective of PVC concentration and its molecular weight,

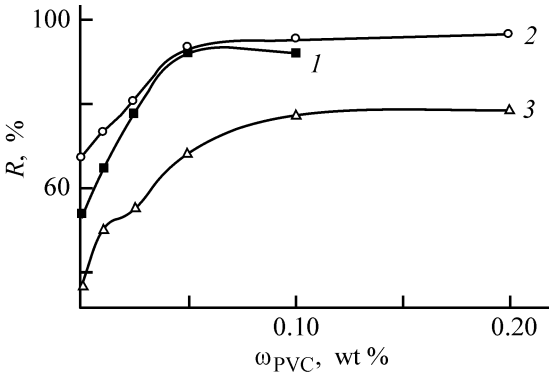

Fig. 3. Degree R of extraction of anthocyan dye from saturated aqueous NaCl vs. PVC concentration ω_{pol}. M_η: (*1*) 1×10^4 (pH 3.5), (*2*) 6×10^4 (pH 3.5), and (*3*) 6×10^4 (pH 1).

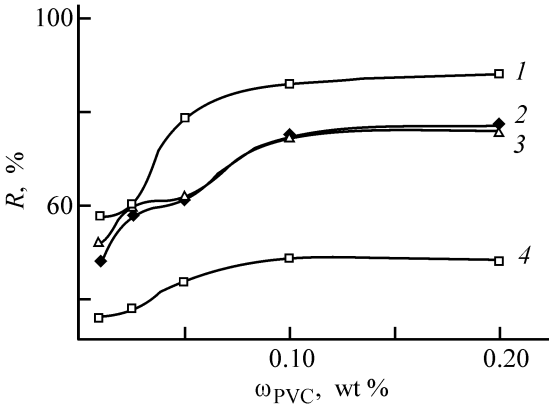

Fig. 4. Degree R of extractive recovery of anthocyan dye with aqueous PVC at phase separation induced by heating vs. the polymer concentration ω_{PVC}. M_η: (*1*) 16×10^4 (pH 3.5), (*2*) 6×10^4 (pH 3.5), (*3*) 1×10^4 (pH 3.5), and (*4*) 1×10^4 (pH 1).

the degree of recovery of the dye considerably decreases with decreasing pH. At a PVC concentration of 6×10^4 M, raising pH from 1 to 3.5 increases the degree of recovery of the anthocyan dye from 77 to 92–95%. The extraction of dyes at pH > 7 in the systems under consideration was not studied because of the chemical degradation of anthocyan dye in alkaline media [10].

Variation of the molecular weight of the polymer from 1×10^4 to 6×10^4 at pH 3.5 in the extraction systems based on PVC does not noticeably affect the degree of recovery of the anthocyan dye (Fig. 3, curves *1* and *2*). A similar behavior is exhibited by PVC in its complexation with fluorescent dyes [3].

We found that, in the extraction systems based on PVP, all factors being the same (M_η, pH, salting-out agent), the degree of recovery of the anthocyan dye was higher than in the systems based on PVC (Fig. 2, curves *3* and *4*). This difference is apparently caused by the stronger complexation of PVP with the dye. This polymer is more sterically accessible and less hydrophobic because of the smaller length of hydrocarbon chains in *N*-vinylpyrrolidone, compared to *N*-vinylcaprolactam.

The high efficiency of the extraction systems based on PVP and PVC is caused by complexation of PVP and PVC with dye molecules. This complexation is manifested in the UV absorption spectra as the absorption band at 274 nm, absent in the spectra of the aqueous solutions of particular polymers. The complexation between the polymers and anthocyan dye occurs by the mechanism of hydrogen bonding between the carbonyl groups of polymer and the hydroxy groups of the dye. Upon acidification, the complexation between the polymer and dye weakens because of the protonation of the C=O groups [11] and, as a result, the degree of recovery of the dye decreases.

In contrast to aqueous PVP, aqueous poly-*N*-vinylcaprolactams have a lower critical solution point at 32–37°C [3]. Therefore, PVC allows extraction of anthocyan dye (up to 86%) from aqueous solutions without salting-out agents at temperature exceeding the lower critical solution point (33.5°C). As can be seen from Fig. 4 (curve *4*), the extraction of the dye considerably decreases upon acidification of the extraction system based PVC to pH 1 before phase separation by heating.

CONCLUSIONS

(1) Two-phase systems based on water-soluble poly-*N*-vinylpyrrolidone and poly-*N*-vinylcaprolactam are suitable for efficient extractive recovery and preconcentration of anthocyan dyes from aqueous solutions. The highest extraction efficiency is exhibited by the two-phase extraction systems ammonium sulfate–poly-*N*-vinylpyrrolidone–water and sodium chloride–poly-*N*-vinylcaprolactam–water at pH 3.5.

(2) The anthocyan dye concentrates prepared by extraction with poly-*N*-vinylpyrrolidone and poly-*N*-vinylcaprolactam can be used for coloration of food products.

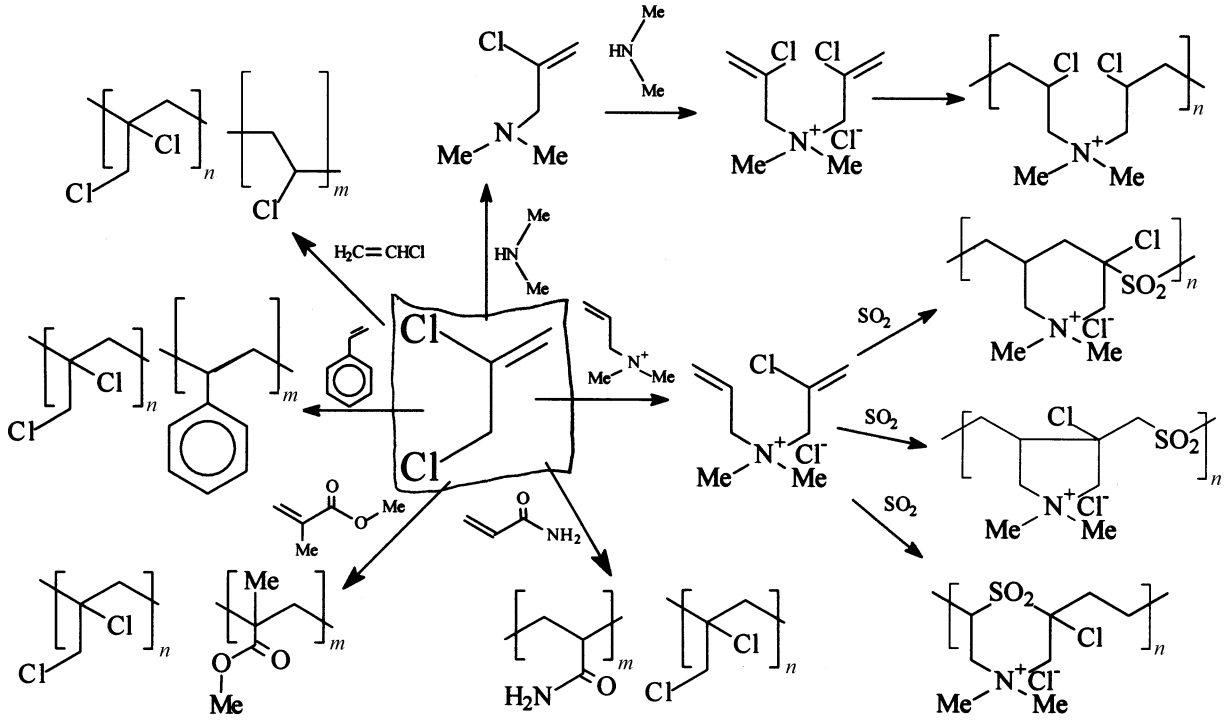
Abstract—Possibilities of utilization of by-products formed in manufacture of epichlorohydrin are considered. A promising way to utilize wastes from production of epichlorohydrin by synthesis of 2,3-dichloropropene from 1,2,3-trichloropropane is suggested.

DOI: 10.1134/S1070427208040332

Epichlorohydrin (EPI) is the main component in synthesis of glycerol, epoxy resins, and a number of other products, including chlorohydrin caoutchoucs. At present, more than 1 million tons of epichlorohydrin is manufactured by the chlorine method all over the world.

Synthesis of EPI is accompanied by a number of side reactions, which leads to formation of large amounts of organochlorine wastes: allyl chloride, 2,2-dichloropropane, 1,2-dichloropropane, 1,3-dichloropropene, 1,2,3-trichloropropane, dichloropropanols, and chloroesters. In the opinion of the authors of [1], about 400 and 100 kg of the dichloropropane and 1,2,3-trichlopropane fractions, respectively, is produced per ton of EPI.

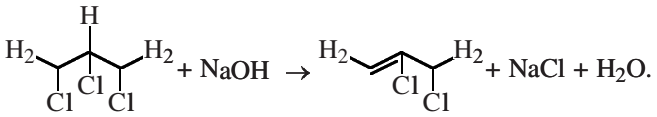
By now, virtually no economically efficient and ecologically safe methods have been developed for utilization of organochlorine wastes. Industrial utilization of these wastes encounters severe difficulties. At the same time, all the above-mentioned kinds of by-products are promising raw materials for manufacture of valuable materials that are in steadily increasing demand.



Commonly, organochlorine wastes are neutralized by the following methods: regeneration, oxidation, burning, chemical and plasmochemical processing, electrocracking, and burial [1–3]. In the present study, a method for isolation of 1,2,3-trichloropropane (TCP) from a mixture of organochlorine wastes was developed and the conditions in which 2,3-trichloropropene (DCP) is produced by dehydrochlorination of the trichloropropane fraction were analyzed.

2,3-Dichloropropene is an important and promising half-product for synthesis of a large number of polyfunctional highly reactive polymeric compounds. It has been used to find simple and convenient pathways [4] to synthesis of tertiary and quaternary polymeric salts that can be used in oil and textile industries (see scheme).

EXPERIMENTAL



TCP was isolated from a mixture of organochlorine wastes as follows. First, all the water-soluble impurities (epichlorohydrin, dichloropropanols, chloroesters) were extracted with distilled water containing 2–3 g l^{-1} of soda ash (or an alkali for maintaining the pH of the medium at 7–8). After the water-soluble impurities were removed (with monitoring by GLC), the mixture was subjected to azeotropic dehydration, and then TCP was isolated by rectification (≥99%).

1,2,3-Trichloropropane (1 mol) was treated with a 10% alcoholic solution of NaOH at room temperature for 4 h. In the process, a white water-soluble precipitate (NaCl) is formed. After the precipitate was filtered off, the liquid phase was distilled and the fraction with bp 94°C was taken.

Scheme.

The DCP synthesized is a colorless liquid that is rather stable, does not become dark in storage under normal conditions, and is not dehydrochlorinated in prolonged storage, d_4^{20} = 1.209, n_D^{20} = 1.4609. The yield of DCP is 80%. The reaction scheme can be represented as

An elemental analysis was made on a Thermo Finniqan gas analyzer. IR spectra of the copolymers were measured in KBr pellets on a Specord IR-75 spectrophotometer, and ^{13}NMR spectra, on a Varian VXR-500S spectrometer, with HMDS as internal standard.

The physicochemical constants of the compound isolated coincide with similar values for the reference DCP.

The ^{1}H NMR spectrum of DCP contains signals of protons of the vinyl and chloromethyl groups at 5.48 and 4.19 ppm, respectively. The ^{13} NMR spectrum shows absorption signals of the chloromethyl, $=CH_2$, and =CCl groups at 47.49, 116.44, and 138.44 ppm, respectively.

The IR spectrum contains an absorption band at 1605 cm^{-1}, associated with the vinyl group. The absorption band at 680 cm^{-1} can be attributed to the C–Cl bond.

CONCLUSION

A method for isolation of 1,2,3-trichloropropane from chlorine-containing wastes formed in manufacture of epichlorohydrin and for its conversion to 2,3-dichloropropene by the dehydrochlorination reaction was developed.

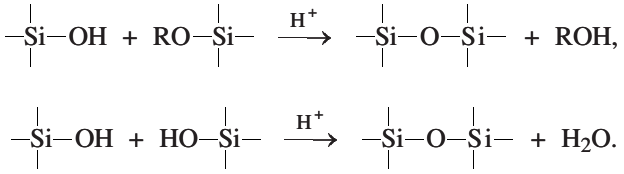
Abstract—The effect of the reactant ratio in the $Si(OEt)_4$–H_2O–EtOH–HCl system on the hydrolytic polycondensation of tetraethoxysilane and gelation rate was examined. A mass-spectrometric study showed that the primary products of the sol–gel process are linear and cyclic oligosiloxanes containing hydroxy and ethoxy groups at the silicon atoms.

DOI: 10.1134/S1070427208040344



Hydrolytic polycondensation of tetraethoxysilane was historically the first studied reaction of organosilicon compounds [1, 2]. In the second half of the XX century it found wide use in many branches of industry as a sol–gel process [3]. Grebenshchikov and Suikovskaya suggested to use the sol–gel process or, more precisely, hydrolysis products of tetraethoxysilane for the so-called blooming of optics, i.e., formation on the glass surface of thin films reducing the light reflection from the surface [4]. Grebenshchikov et al. also developed a method for increasing the surface hardness of organic glasses by applying a coating based on tetraethoxysilane hydrolysis products [5].

In the subsequent period, the sol–gel method based on hydrolytic polycondensation of tetraethoxysilanes was widely used by Voronkov and numerous collaborators for hydrophobization and improvement of other service properties of building [6–9] and textile [10, 11] materials, glass [12, 13], fiber glass [14, 15], and metals [16]. They examined the influence exerted on the sol–gel synthesis by the catalyst, solvent, reactant ratio, pH of the medium, and presence of metal salts and oxides [17–22]. They also studied the formation conditions and properties of the resulting xero- and aerogels [12, 16, 17, 23].

Until recently, the mechanism of acid hydrolysis of tetraalkoxysilanes has been described by the following general schemes [20–22]:

Further hetero- and homofunctional condensation processes are described by the general equations

Owing to cyclization, cross-linking, and branching of siloxane chains, the primary products of the hydrolytic polycondensation are oligomers and polymers containing the ≡Si–O–Si≡, ≡Si–OH, and ≡Si–OR groups in various combinations and ratios in one molecule or macromolecule. Thermally stable linear peralkoxysiloxanes $(RO)_3SiO[Si(OR)_2]_nOR$ (n = 0, 1, 2, 4, 6; R = CH_3) and peralkoxycyclosiloxanes ($[(RO)_2SiO]_n$) (n = 4, 6; R = CH_3) have been isolated and identified [24].

With the aim to further study the acid hydrolysis of tetraethoxysilane in the $Si(OEt)_4$–H_2O–EtOH–HCl system, we examined the influence exerted on the process by the reactant ratio, HCl concentration, and gelation time. Our goals were, first, to elucidate the nature

Table 1. Gelation rate in the $Si(OEt)_4$–H_2O–EtOH–HCl system at various amounts of HCl solution

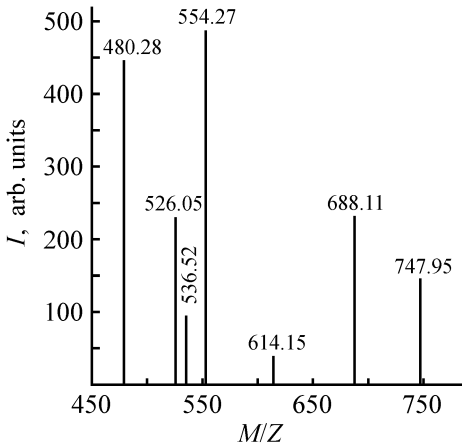
of primary labile oligomeric products by mass spectrometry and, second, to optimize the conditions of hydrolytic polycondensation of tetraethoxysilane with the aim to obtain relatively stable structures with the maximal SiO_2 content. Such highly concentrated systems are of interest from the viewpoint of their use as inorganic component in synthesis of organic–inorganic hybrids.

EXPERIMENTAL

The mass spectra were measured on an MKh-5303 device equipped with an electrospray ionization source and a time-of-flight mass analyzer [25].

The silicon content of the reaction mixture before the gelation was determined gravimetrically by decomposing the sample with a mixture of 20% oleum and concentrated nitric acid and then calcining the residue at 800°C to constant weight [26].



Mixtures of linear and cyclic oligoethoxysiloxanes and oligoethoxysiloxanols (which could not be separated into individual components) have been prepared by controlled hydrolytic polycondensation of tetraethoxysilane under the conditions of acid catalysis [27]. Numerous experiments have shown that the best catalyst for preparing liquid oligomer mixtures with a high SiO_2 content is 0.01 N HCl. At lower acid concentrations, the gelation time becomes several times longer, and at higher acid concentrations the reaction becomes so fast that isolation of liquid oligomers with a high SiO_2 content becomes impossible.

The $Si(OEt)_4$: EtOH molar ratio was kept constant (1 : 2.2), and the amount of a 0.01 N HCl solution was varied. To perform the process, we added 9.8 g (0.044 mol) of $Si(OEt)_4$ to a mixture of 4.8 g (0.104 mol) of EtOH and measured amount of an HCl solution. The mixture was placed in polypropylene jars with threaded caps (three vessels for each system) and kept in them for 1–4 days in a thermostat at 90°C until a gel was obtained. The hydrolytic polycondensation of alkoxysilanes accelerates as the amount of acid in the system increases. Thus, it becomes possible to control the reaction progress (gelation time) (Table 1).

The difference between t_1 and t_2 is caused by the fact that water was taken for the sol–gel process in deficiency, to ensure the relatively low rate of cross-linking in the system. In this case, after the time t_1 is elapsed, the system is no longer a classical sol and gradually loses mobility, but a continuous 3*D* structure has not yet been formed.

According to mass-spectrometric data, a mixture of oligoethoxysiloxanols of various molecular weights is formed in system nos. 1–3. The mass spectrum of oligomer mixture no. 1 is shown as an example in the figure.

It should be noted that oligomers having a higher molecular weight are formed when the acid solution is taken in a minimal amount. The major relatively stable oligomeric products of hydrolytic polycondensation of $Si(OEt)_4$ are linear octaethoxytetrasiloxanediol **I**, decaethoxypentasiloxanediol **II**, hepta-

Mass spectrum of oligoethoxysiloxanol mixture no. 1: (*I*) intensity and (*M*/*Z*) weight-to-charge ratio.

Table 2. Composition of oligosiloxanol mixture nos. 1–3

Oligomer mixture no.	Molar ratio $Si(OEt)_4 : H_2O : HCl : EtOH$	Minor components of oligomer mixtures (molecular weight)
1	$1 : 1.39 : 2.5 \times 10^{-4} : 2.36$	$(HO)_2[Si(OC_2H_5)O]_5(OEt)_3$ (614) (**V**), $[Si(OEt)O]_4$ (536) (**VI**), $(EtO)_{10}(HO)_2Si_6O_6$ (748) (**VII**)
2	$1 : 1.52 : 2.7 \times 10^{-4} : 2.36$	$HO[Si(OC_2H_5)O]_5$ (614) (**V**), $[Si(OEt)O]_4(OEt)_4$ (536) (**VI**), $HO[Si(OEt)_2O]_2Si(OEt)_3$ (448) (**VIII**)
3	$1 : 1.64 : 2.95 \times 10^{-4} : 2.36$	$[Si(OEt)O]_4(OEt)_4$ (536) (**VI**), $HO[Si(OEt)_2O]_2Si(Oet)_3$ (448) (**VIII**)

ethoxy tetrasiloxanetriol **III**, and cyclic compounds hexaethoxycyclotetrasiloxanediol **IV** and decaethoxycyclohexasiloxanediol **V**. A number of minor components were also detected and characterized (Table 2).

CONCLUSIONS

(1) A procedure was developed for hydrolytic polycondensation of tetraethoxysilane to obtain a mixture of polyalkoxysiloxanols with a high silica content.

(2) A number of organosilicon derivatives of linear (octaethoxytetrasiloxanediol **I**, decaethoxypentasiloxanediol **II**, heptaethoxytetrasiloxanetriol **III**) and cyclic (hexaethoxycyclotetrasiloxanediol **IV**) structures were identified.

Abstract—Formation of α-Al_2O_3 in thermal treatment of ultradispersed aluminum oxide powders produced by shock-wave synthesis with addition of Cr_2O_3–$(NH_4)_2Cr_2O_7$ as a precursor was studied. The acceleration of the conversion of δ-and θ-Al_2O_3 to α-Al_2O_3 upon introduction of additives in the stage of synthesis of aluminum oxide was examined.

DOI: 10.1134/S1070427208040356

Dynamic methods for synthesis of ultradispersed powders of various chemical compositions have high output capacity [1]. The synthesis parameters used in shock-wave loading of metals and free separation of explosion products in an oxygen-containing atmosphere make it possible to obtain metal oxide powders with unusual properties. The thus synthesized ultradispersed aluminum oxide has an average particle size of 75 nm and contains, according to the results of an X-ray phase analysis, only metastable δ- and θ-modifications in a ratio of approximately 7 : 1. This oxide exhibits a high phase stability under static annealing and shock-wave impact [2].

The topicality of development of methods for production of a submicrometer corundum powder used in composite construction and polishing materials makes urgent a study of the effect of various factors on the formation temperature of α-Al_2O_3 [3]. To these factors belongs introduction of additives, including chromium(III) oxide, in the course of thermal treatment of the powders, with both Cr_2O_3 itself and its precursors used [4–7]. The manner in which temperature varies and the rate of phase transformations that occur on heating the mixtures depend on the method employed to obtain aluminum oxide and on its characteristics. It has been shown [4] that introduction of Cr_2O_3 in production of aluminum oxide fibers stabilizes the transition δ- and θ-forms of Al_2O_3 and hinders formation of α-Al_2O_3. In [5], an increase in the rate of corundum formation was observed in calcination of ammonia alum with addition of minor amounts of ammonium bichromate (0.2 wt % in terms of Cr_2O_3). At a higher content of $(NH_4)_2Cr_2O_7$ in the starting mixture, the onset of α-Al_2O_3 crystallization was shifted to lower temperatures. In thermal treatment of a mixture of hydrargillite γ-$Al(OH)_3$ and $(NH_4)_2Cr_2O_7$ with steam, raising the chromium content to more than 0.3 wt % results in a slower formation of corundum [6]. In [7], a conclusion that Cr_2O_3 exerts a stabilizing influence on the δ- and θ-forms of Al_2O_3 was based on an analysis of the results of thermal treatment of a mixture of aluminum and chromium(III) oxides.

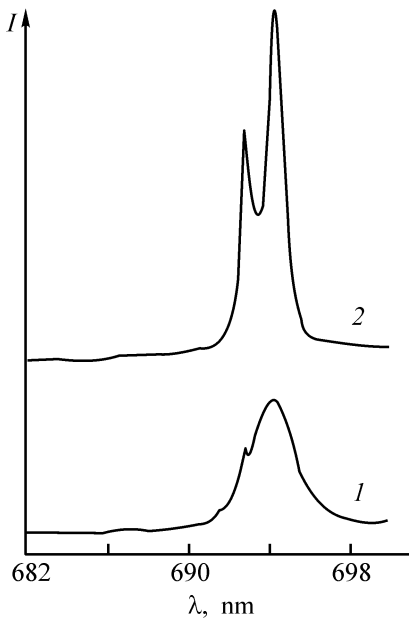
The aim of this study was to analyze the influence exerted by addition of the precursor Cr_2O_3–$(NH_4)_2Cr_2O_7$ on the formation of α-Al_2O_3 in thermal treatment of aluminum oxide produced in shock-wave synthesis.

EXPERIMENTAL

A uniform distribution of the ammonium bichromate additive in a mixture with aluminum oxide was provided by ultrasonic dispersion of an Al_2O_3 powder in an ethanol solution of $(NH_4)_2Cr_2O_7$. A differential-thermal analysis (DTA) was made on a Q-100 M derivatograph, with heating in air at a rate of 15 deg min^{-1} from 290 to 1770 K.

The average size of powder particles was found by processing of electron micrographs obtained with a JEM-100C electron microscope. The X-ray phase analysis (XPA) was made by the Debye–Scherrer

method on a DRON-4 diffractometer (copper radiation, Ni filter). The relative content of α-, δ-, and θ-Al_2O_3 in the powder was evaluated by the normalized amplitudes of the peaks at 2θ angles of 43.4 ($I_\alpha^{100\%}$), 44.8 ($I_0^{80\%}$), and 45.7 deg ($I_\delta^{50\%}$). The chemical phase analysis (CPA) of Al_2O_3 was made using the procedure developed for aluminum oxide powders produced by shock-wave synthesis [8].



Luminescence spectra of the powders were obtained at 290 K, with excitation by quasi-CW second-harmonic emission of a Nd^{3+}:YAG laser with a wavelength λ = 530 nm.

According to DTA data, introduction of ammonium bichromate into a mixture with aluminum oxide produced by shock-wave synthesis in amounts corresponding to formation of 1.5–6 wt % Cr_2O_3 results in that the peak temperature of the exothermic effect associated with the phase transformation decreases from 1570 to 1500 K. The additive strongly affects the results of thermal treatment of Al_2O_3 under isothermal conditions: according to XPA data, upon annealing at 1470 K for 1 h, the content of corundum does not exceed 2 wt % in the absence of the additive and increases to 90% with 4 wt % $(NH_4)_2Cr_2O_7$. The average particle size in powders of this kind is 130 nm.

The luminescence spectra of powders with ammonium bichromate additive, annealed at temperatures exceeding 900°C for 1 h show luminescence of Cr^{3+} ions isomorphically incorporated into the corundum structure. The intensity of the lines at 692.8 and 694.3 nm, characteristic of ruby, increases with the powder annealing temperature (see figure). As can be seen in the figure, the luminescence spectra of the powders annealed in the temperature range studied, 870–1470 K, show no doublet lines associated with chromium(III) ions incorporated into the θ-Al_2O_3 lattice: 682 and 686 nm according to [9] or 684.5 and 688.2 nm [10]. These data are in agreement with the direct transition δ→α observed in [2], which is characteristic of Al_2O_3 produced by shock-wave synthesis and possible for the well-crystallized δ-form of aluminum oxide [11].

The phase composition of aluminum oxide and its further transformations under thermal treatment can also be affected by introduction of $(NH_4)_2Cr_2O_7$ into the aluminum powder subjected to a shock-wave treatment [12]. The table lists the XPA data on the phase composition of powders with varied content of chromium.

The experimental data indicate that introduction of ammonium bichromate in shock-wave synthesis of aluminum oxide also accelerates the corundum formation in thermal treatment of the powders.

Luminescence spectrum of chromium-containing aluminum oxide powders. (*I*) Relative intensity and (λ) wavelength. Treatment temperature (K): (*1*) 870 and (*2*) 1470.

According to the data furnished by the luminescence method (recommended for determining the phase composition of Al_2O_3 [9]), the effect of θ-Al_2O_3 stabilization is also absent at lowered annealing temperatures. The data obtained differ from those reported in [4, 7], where a clearly pronounced stabilization of δ- and θ-Al_2O_3 was observed at treatment temperatures of up to 1070 [7] and 1270 K [4], with the amount of corundum formed decreasing as the concentration of chromium in the starting mixture was raised [4]. The authors attributed this effect to a change in the oxidation number of chromium: partial oxidation of Cr^{3+} to Cr^{6+} in joint heating of Al_2O_3 and Cr_2O_3 in air [13–15] at temperatures below 1270 K [4]. The experimental fact of the partial oxidation $Cr^{3+}\rightarrow Cr^{6+}$ in the presence of Al_2O_3 [13–15], which contradicts data on thermal stability of CrO_3, is attributed

in [15] to partial hydration of Al_2O_3 and Cr_2O_3 crystals and formation of structures close to $Al(OH)_3$ and $Cr(OH)_3$ in the surface layers. It is the oxidation of $Cr(OH)_3$ that leads to the appearance of Cr(VI) compounds in the system Al_2O_3–Cr_2O_3. Accordingly, their amount increases with the dispersity of the oxide and with the degree of hydration of their surface, which is equivalent to a rise in the number of chemically active hydroxy groups [15]. The presence of Cr(VI), which is prone to tetrahedral coordination, stimulates formation of δ- and θ-Al_2O_3. In the lattices of these modifications, aluminum cations are distributed over tetra- and octahedral positions (in θ-Al_2O_3, the role of tetrahedral positions is the most important) and hinders appearance of α-Al_2O_3 with octahedral coordination of cations [4].

Aluminum oxide Al_2O_3 produced by shock-wave synthesis is highly dispersed. However, an analysis of the surface-electrical properties of its particles demonstrated a low degree of surface hydroxylation [16]. Similarly to the enhanced phase composition stability, this is due to the decreased structural defectiveness of aluminum oxide formed by rapid cooling of liquid Al_2O_3 drops. Consequently, the main influence on the phase transformations is exerted in this case by the fact that corundum is isostructural to chromium(III) oxide with octahedral coordination of atoms, formed in decomposition of ammonium bichromate. A similar decrease in the corundum formation temperature was also observed when α-Fe_2O_3 was used as a precursor additive [3].

Incorporation of chromium(III) ions into the lattice of aluminum oxide produced by shock-wave synthesis positively affects the mechanical properties of a corundum ceramic fabricated from the flotation waste of an alumina shop and ultradispersed additives. Sintering of compacts from a mixture of Al_2O_3 micropowders and ultradispersed aluminum oxide produced by shock-wave synthesis makes it possible to preserve the finely grained structure of the material characterized by increased density, hardness, and wear resistance [17]. Use of chromium-containing ultradispersed Al_2O_3 powders provides an additional increase in the density and microhardness of sintered samples by 10–15%.

CONCLUSIONS

(1) Introduction of an ammonium bichromate additive in thermal treatment of ultradispersed aluminum oxide powders produced by shock-wave synthesis leads to a shift of the temperature range of α-Al_2O_3 formation to lower temperatures.

(2) The chromium-containing powders obtained are promising for use as an ultradispersed additive in production of a corundum ceramic with improved properties.

Abstract—Conversion of natural langbeinite into schoenite in a suspension in a multicomponent solution, as influenced by the process time, liquid phase composition, and temperature (10–40°C), was studied.

DOI: 10.1134/S1070427208050017

Halurgical processing of polymineral potassium ores of the Ciscarpathian region is complicated by simultaneous presence in them of readily soluble potassium and potassium–magnesium minerals (sylvite KCl, kainite $K_2SO_4 \cdot MgSO_4 \cdot 3H_2O$, etc.) and difficultly soluble components (langbeinite $K_2SO_4 \cdot 2MgSO_4$, kieserite $MgSO_4 \cdot H_2O$, polyhalite $K_2SO_4 \cdot MgSO_4 \cdot 2CaSO_4 \cdot 2H_2O$). In the course of their dissolution, only 22–23% of langbeinite passes into the liquid phase, and its remaining amount and virtually the whole amount of polyhalite are dumped.

Procedures have been developed for the halurgical processing of ores with the preliminary conversion of langbeinite into readily soluble schoenite [1] or kainite [2], or with dissolution of the starting ore in water [3] to obtain a saturated solution and a langbeinite–polyhalite residue of the following composition (at 1 : 1 weight ratio of water and ore, counting on dry substance, %): K_2O 19.5–20.0, MgO 16.1–16.7, SO_4^{2-} 62.6–62.9, Cl^- less than 5.0. The sum of nutritive materials, K_2O + MgO + S, in this product is 56.5–57.7, which corresponds to a concentrated chloride-free potassium-magnesium fertilizer of prolonged action, similar in quality to a potassium–magnesium fertilizer produced from langbeinite ores in the United States [4]. The saturated solution is heated and mixed with potassium–magnesium salts from the second stage of evaporation of the schoenite solution to obtain a finely dispersed langbeinite suspension from which schoenite is crystallized after separation of coarsely crystalline NaCl. In this process, schoenite is obtained from a langbeinite suspension on cooling. Since the conversion of langbeinite into schoenite occurs in a suspension rather than in a solution, large volumes of process streams are to be heated prior to dissolution of the ore and cooled to crystallize the product. The conversion of langbeinite into schoenite is accompanied by heat release and follows the equation

$$K_2SO_4 \cdot 2MgSO_4 + 13H_2O = K_2SO_4 \cdot MgSO_4 \cdot 6H_2O + MgSO_4 \cdot 7H_2O.$$

The thermal effect of the process, calculated from the heats of solution of schoenite, epsomite, and langbeinite, is –145.2 kJ mol^{-1}. Hence, it can be expected that the conversion will increase with decreasing temperature. The conversion is accompanied by the dissolution of langbeinite from the surface, diffusion of the dissolution products into the bulk of the solution, and crystallization of the new mineral. The slowest step is the langbeinite dissolution. Its rate increases with temperature. Therefore, in this study we examined how the conversion of langbeinite into schoenite in a saturated solution in equilibrium with schoenite depends on the temperature and liquid phase composition. The formation of schoenite from langbeinite involves binding of water from the liquid phase into crystal hydrates. The process is accompanied by crystallization of NaCl contaminating the product.

EXPERIMENTAL

We examined under the laboratory conditions the effect of various factors on the conversion of langbeinite into schoenite in a schoenite solution in equilibrium with the solid phase. Langbeinite samples

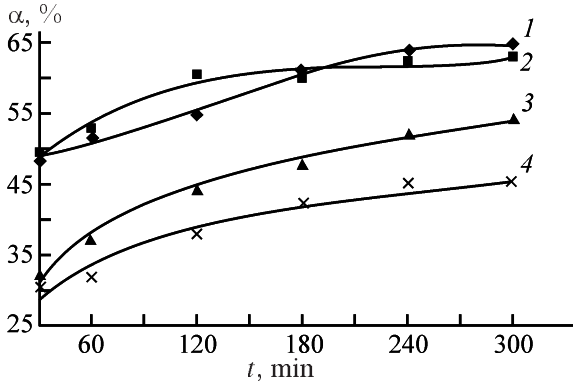

Fig. 1. Degree of langbeinite conversion α as a function of time t at various temperatures. T, °C: (*1*) 10, (*2*) 20, (*3*) 30, and (*4*) 40; the same for Fig. 2.

taken from a potassium mine were crushed to a particle size less than 0.2 mm and washed to remove impurities of soluble salts with a large amount of tap water with stirring, after which the suspension was filtered. The residual moisture was removed by washing with acetone. The washed material was dried at 50°C and sieved with wire sieves to obtain a fraction of size 0.1–0.2 mm. The langbeinite sample thus prepared had the following composition (wt %): K^+ 18.17, Mg^{2+} 11.67, Na^+ 0.11, Cl^- 0.44, SO_4^{2-} 68.07, and H_2O 1.54 (or 96.1% langbeinite, 0.5% halite, and 3.4% arcanite K_2SO_4). To perform the conversion, we used a solution with a density of 1.284 g cm^{-3}, of the following composition (wt %): K^+ 3.90, Mg^{2+} 3.40, Na^+ 4.11, Cl^- 15.99, SO_4^{2-} 5.15, and H_2O 67.45, which is formed in the course of schoenite crystallization and occurs in an equilibrium with the crystallized schoenite.

The prepared samples of langbeinite (100 g) and solution (500 ml) were kept for 24 h in an air thermostat to attain the required temperature, after which they were transferred into a temperature-controlled reactor and stirred under isothermal conditions for 300 min. Experiments were performed in the temperature range 10–40°C. After definite intervals of time, samples of the liquid and solid phases were taken for the analysis. The solid phase was additionally centrifuged on a laboratory centrifuge at 5000 rpm for better separation from the liquid phase. The samples were analyzed for K^+ and Na^+ by flame photometry, for Mg^{2+} by complexometric titration, and for SO_4^{2-} by gravimetric procedure [5]. From the results of the analysis, the material balances were constructed with a computer, and the mineral compositions of the solid phases of the suspension were calculated using a special program.

The degree of conversion α of langbeinite into schoenite was calculated by the formula

$$\alpha = m_1c_1c_2/(m_2c_3), \quad (1)$$

where m_1 is the weight of the solid phase of the suspension from the material balance; m_2, weight of the initial langbeinite; c_1, content of schoenite in the solid phase of the suspension; c_2 and c_3, content of SO_4^{2-} in schoenite (leonite) and langbeinite, respectively.

We examined the influence of temperature on the conversion. It is known [6] that the mineral composition of the solid phase depends on temperature: Schoenite is the stable phase up to 30°C, and leonite, at higher temperatures. Therefore, we substituted in formula (1) the corresponding data.

Our experiments showed (Fig. 1) that the conversion is the slowest at 40°C, and in 300 min the conversion reaches 45.7%. With decreasing temperature, the conversion increases, and at 20°C the 60.6% conversion is reached in 120 min. As the temperature is decreased to 10°C, the conversion does not change noticeably. On the other hand, performing the process at 10°C requires additional expenditures for cooling the suspension, which is unpractical. Therefore, further experiments were performed at 20°C.

As the conversion of langbeinite into schoenite involves dissolution of langbeinite, we applied to the process the Shchukarev rate equation

$$dc/dt = kS(c_s - c), \quad (2)$$

where c is the running concentration of the solute in solution (%); c_s, saturation concentration (%); t, time (min); S, surface area of langbeinite particles (dm^2); and k, dissolution rate constant.

After integration, Eq. (2) takes the form

$$\ln[c_s/(c_s - c)] = kSt. \quad (3)$$

To perform calculations by Eq. (3), it is necessary to take into account changes in the surface area of the solid phase in the course of dissolution. Therefore, we assumed that the surface area of the solid phase S in the course of conversion decreases in proportion with α:

$$S = S_{in}(1 - \alpha), \quad (4)$$

where S_{in} is the initial surface area of langbeinite.

We assumed that the solid phase is monodisperse and all the crystals have the form of a regular triangular pyramid. The mean particle size of the 0.1–0.2-mm fraction is 0.15 mm. The total surface area S_{in} of the initial langbeinite sample was calculated by determining its volume and the number of particles, with the subsequent summation of the surface areas of all the particles.

Variation of $\ln[c_s/(c_s - c)]/S$ with time is shown in Fig. 2. The kinetic curves in these coordinates are straight lines, suggesting the diffusion control of the process. At 20°C, the rate constant is maximal. To calculate the activation energy, we used the Arrhenius equation

$$\ln k = \ln A - E/(RT). \quad (5)$$

From the plots in Fig. 2, we determined the rate constants at each temperature as slopes of the straight lines, using Eq. (3). To determine the activation energy E, we plotted $\ln k$ vs. $1/T$ (Fig. 3) and found E from the slope of the straight line, $\tan\alpha = E/R$. The quantity E is as low as 14.1 kJ mol^{-1}, suggesting diffusion control of the langbeinite conversion in saturated solution.

It is known [8] that dissolution of langbeinite in water under the conditions of forced convection is not a diffusion-controlled process. Hence, the mechanism of conversion in saturated solution differs from that of dissolution in water.

We also examined how the $MgCl_2$ concentration in the liquid phase of the suspension affects the conversion at 20°C. The $MgCl_2$ concentration was 4, 6, 8, and 10 wt %. The composition of the initial solution was varied using analytically pure grade $MgCl_2$ and Na_2SO_4. The $MgCl_2$ concentration in the initial multicomponent solution was 8 wt %; it was increased by adding $MgCl_2$ and decreased by adding Na_2SO_4. Experiments were performed similarly to the previous ones. The data were treated with the Shchukarev equation. The results we obtained are plotted in Fig. 4. From these data we determined the rate constant of the process. We found that, at a $MgCl_2$ concentration in the starting solution of 4, 6, 8, and 10 wt %, the rate constant of the process is 0.0792, 0.1217, 0.11, and 0.1029 min^{-1}, respectively, i.e., it passes through a maximum at 6% $MgCl_2$.

The data we obtained will be used for developing a procedure for processing of polymineral potassium ores by conversion of langbeinite suspension into schoenite.

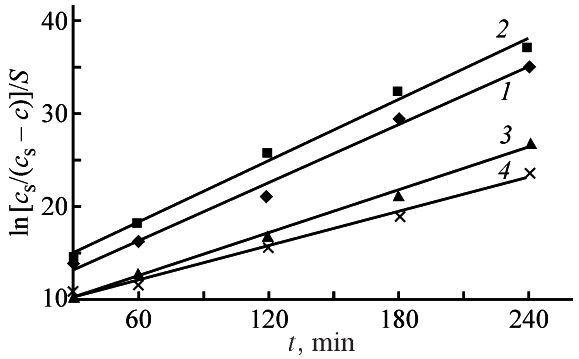

Fig. 2. Plot of $\ln[c_s/(c_s - c)]/S$ vs. time t at various temperatures. (c) Running langbeinite concentration, (c_s) saturation concentration, and (S) surface area of langbeinite particles; the same for Fig. 4.

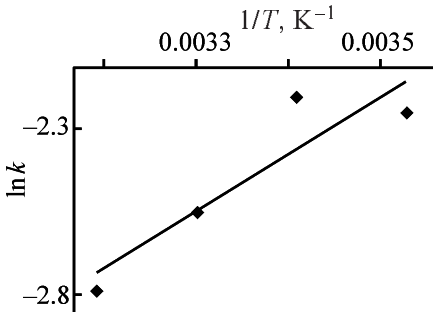

Fig. 3. Temperature dependence of the rate constant k.

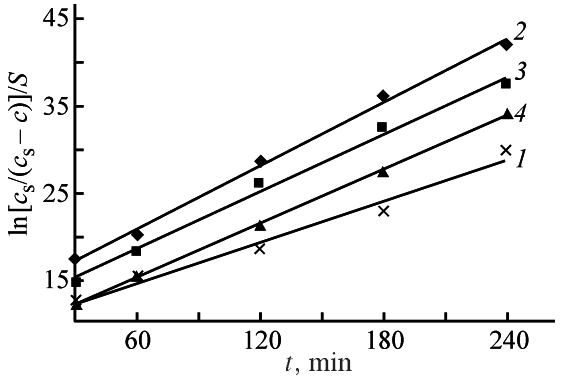

Fig. 4. Plot of $\ln[c_s/(c_s - c)]/S$ vs. time t at various concentrations of $MgCl_2$ in the initial solution. c_{MgCl_2}, wt %: (*1*) 4, (*2*) 6, (*3*) 8, and (*4*) 10.

CONCLUSIONS

(1) The highest rate of conversion of langbeinite into schoenite in a multicomponent solution is attained at 20°C.

(2) The activation energy of the conversion is 14.1 kJ mol^{-1}, suggesting the diffusion control of the process.

(3) The rate constant of the conversion is max-

imal at 6 wt % concentration of $MgCl_2$ in the liquid phase.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Enhancing the Strength of Granules and Thermal Stability of Ammonium Nitrate

I. M. Ryshchenko, N. S. Kulatskii, A. S. Savenkov, I. N. Protiven', and L. N. Ratushnaya

Kharkov Polytechnic Institute, National Technical University, Kharkov, Ukraine

Received April 4, 2007

Abstract—The effect of sulfate ions on the physicochemical properties of ammonium nitrate with a dolomite additive was examined. Changes in the rate of the IV → III phase transition, granule strength, number of thermal cycles, and content of ammonium nitrate aerosol in air after the granulation tower were evaluated.

DOI: 10.1134/S1070427208050029

Analysis of the quality of ammonium nitrate produced by a number of enterprises showed that even a small number of thermal cycles lead to degradation of granules, increased caking, and formation of strong monoliths. Furthermore, insufficient strength of granules favors an increase in the content of ammonium nitrate dust in exhaust air from the granulation tower.

One of the most efficient ways to improve physicochemical and mechanical properties of ammonium nitrate is stabilization of the II → IV polymorphous transition when the fusion cake is cooled with minimal changes in the volume and structure. The quality of granulated ammonium nitrate is largely determined by the IV → III polymorphous transition which occurs at 32.5°C under equilibrium conditions and is accompanied by a 3.7% change in the specific volume [1]. Repeated IV → III transitions lead to a decrease in the strength, loosening of the surface, and caking of ammonium nitrate granules. Polymorphous transitions of ammonium nitrate are stabilized by conditioning additions of salts and minerals in various steps of its production. Modification transitions of ammonium nitrate were studied by DTA. The derivatograms were recorded on an OD-103 derivatograph. The phase composition of ammonium nitrate was studied by X-ray phase analysis on a DRON-1 diffractometer (Cu radiation). The moisture content of the samples was determined by Fischer titration.

The temperatures of polymorphous transitions in relation to the number of thermal cycles are given in Table 1. Sample no. 1 is ammonium nitrate with addition of nitric acid dolomite extract, without introduction of sulfuric acid; sample nos. 2–4 differ in the $CaSO_4$ content (0.65–0.75 wt %).

It follows from Table 1 that the temperatures of the IV → III and III → II polymorphous transitions are essentially independent of the number of thermal cycles. An increase in the temperature of the IV → III transition is indicative of a decrease in the the moisture content of ammonium nitrate. At a low moisture content, the dissolution and recrystallization are slow; as a result, the caking of ammonium nitrate decreases and the strength of its granules increases. A decrease in the moisture content of ammonium nitrate with an addition of sulfuric acid is due to moisture uptake by calcium sulfate with the formation of crystal hydrates [2–4]. X-ray phase analysis of ammonium nitrate samples with addition of sulfate ions revealed the presence of the $CaSO_4 \cdot 2H_2O$ and $CaSO_4 \cdot 0.5H_2O$ phases in 1.5 : 0.5 ratio. With an increase in the number of thermal cycles, the hemihydrate content increases. The formation of calcium sulfate decelerates the melting and crystallization of ammonium nitrate owing to formation of solid solutions restricting the mobility of structural elements of its lattice.

We examined the kinetics of modification transformation of ammonium nitrate with a calcium-containing additive upon addition of sulfuric acid after performing different numbers of thermal cycles, and also with different amounts of $CaSO_4$ added. To calculate the kinetic parameters of the IV → III

Table 1. Temperatures of polymorphous transitions T_{pt}

Sample no.	T_{pt}, °C, at indicated number of thermal cycles									
	1		2		3		4		5	
	IV→III	III→II	IV→III	III→II	IV→III	III→II	IV→III	III→II	IV→III	III→II

2	48	91	46	92	47	93	48	93	47	92
3	47	93	48	93	48	92	46	91	47	91
4	48	92	46	92	48	91	47	93	48	90

modification transition, we used the dependence of the conversion α on time τ:

$$d\alpha/d\tau = k(1 - \alpha)^n = k_0\exp[-E/(RT)](1 - \alpha)^n, \quad (1)$$

where k is the rate constant; n, kinetic parameter; k_0, preexponential factor of the Arrhenius equation; and E, activation energy of the process (kJ mol^{-1}).

The conversion α is related to the magnitudes of thermal effects in the DTA curve by

$$(1 - \alpha) = (\Delta H_i)/(\Delta H_{tot}), \quad (2)$$

where ΔH_{tot} and ΔH_i are the total and partial enthalpies of transition, respectively (J).

The quantities E, k_0, and n were calculated by the formula obtained by taking the logarithm of Eq. (1), taking into account (2):

$$\ln[(dH_i/d\tau)(1/\Delta H_{tot})] = \ln k_0 - E/(RT) + n\ln(\Delta H_i/\Delta H_{tot}), \quad (3)$$

where $dH_i/d\tau$ is the instantaneous rate of heat release in time τ (J s^{-1}).

The kinetic parameters of the IV → III transition were found by solving the system of equations of form (3). The calculation results and the rate constants k of the IV → III modification transition at 315 and 320 K, respectively, are given in Table 2.

Table 2. Kinetic parameters of the IV → III transition in ammonium nitrate with various additives

Additive	n	$k_0 \times 10^3$, s^{-1}	E, kJ mol^{-1}	Rate constant $k \times 10^9$, s^{-1}
Extract from dolomite	1	8	22	1800
Extract from dolomite, H_2SO_4	1	12	38	10

Table 2 shows that the formation of $CaSO_4$ from calcium nitrate in the dolomite extract and sulfuric acid, followed by formation of calcium sulfate crystal hydrates, considerably increases the activation energy of the IV → III modification transition and decreases the rate constant of the process by two orders of magnitude. Deceleration of the IV → III transition leads to stabilization of the physicochemical properties of ammonium nitrate: decrease in the caking and enhancement of the mechanical strength.

Data on the thermodynamic characteristics of ions in an ammonium nitrate melt are lacking. As the ammonium nitrate melt is an electrolyte, like water, the thermodynamic analysis of the reactions of precipitation with sulfate ion can be based on data on the composition and thermodynamic properties of products of similar reactions in aqueous solutions.

According to [5], at temperatures above 333 K in the $CaSO_4$–H_2O system, anhydrous $CaSO_4$ is the most thermodynamically stable solid phase, whereas in the $MgSO_4$–H_2O system at temperatures exceedintg 340.5 K kieserite $MgSO_4 \cdot H_2O$ is thermodynamically stable. The temperature dependences of the solubility products (SPs) of these compounds in the range including the reaction temperature in the industrial process, and also the related dependences for calcium sulfate hemihydrate $CaSO_4 \cdot 0.5H_2O$ and gypsum $CaSO_4 \cdot 2H_2O$ are given in a handbook [6]. These data allow us to perform a thermodynamic analysis of the reactions

$$Ca^{2+} + SO_4^{2-} \rightleftarrows CaSO_4\downarrow, \quad (4)$$

$$Ca^{2+} + SO_4^{2-} + 0.5H_2O \rightleftarrows CaSO_4 \cdot 0.5H_2O\downarrow, \quad (5)$$

$$Ca^{2+} + SO_4^{2-} + 2H_2O \rightleftarrows CaSO_4 \cdot 2H_2O\downarrow, \quad (6)$$

$$Mg^{2+} + SO_4^{2-} + H_2O \rightleftarrows MgSO_4 \cdot H_2O\downarrow. \quad (7)$$

Table 3. Thermodynamic characteristics of precipitation of calcium and magnesium sulfates

Precipitation product	log SP	Gibbs free energy, kJ (mol M^{2+})$^{-1}$	
		standard, $\Delta_r G_T^0$	of reaction, $\Delta_r G_T$
$CaSO_4$	–6.52	–56.5	–71.1
$CaSO_4 \cdot 0.5H_2O$	–6.10	–52.8	–45.8
$CaSO_4 \cdot 2H_2O$	–5.04	–43.6	28.4
$MgSO_4 \cdot H_2O$	–2.93	–25.4	–6.2
$CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$	–4.81	–41.6	–74.0
$5CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$	–22.95	–39.7	–57.9
$MgSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$	–4.92	–42.6	144.0

It should be taken into account that the formation of the sulfate precipitate can involve ions of the main component, NH_4NO_3 [7, 8]. Double calcium ammonium sulfates syngenite $CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$ and pentasulfate $5CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$ [9, 10] are known; in the system magnesium sulfate–ammonium sulfate–water, schoenite $MgSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ is formed [9, 10]. The solubility products of these salts were estimated in [11] from data of [8, 9]. These data allow us to perform a thermodynamic analysis of the reactions

$$Ca^{2+} + 2SO_4^{2-} + 2NH_4^+ + H_2O \rightleftarrows CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O\downarrow, \quad (8)$$

$$5Ca^{2+} + 6SO_4^{2-} + 2NH_4^+ + H_2O \rightleftarrows 5CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O\downarrow, \quad (9)$$

$$Mg^{2+} + 2SO_4^{2-} + 2NH_4^+ + 6H_2O \rightleftarrows MgSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O\downarrow. \quad (10)$$

The standard Gibbs energies of reactions (4)–(10) were calculated by the equation

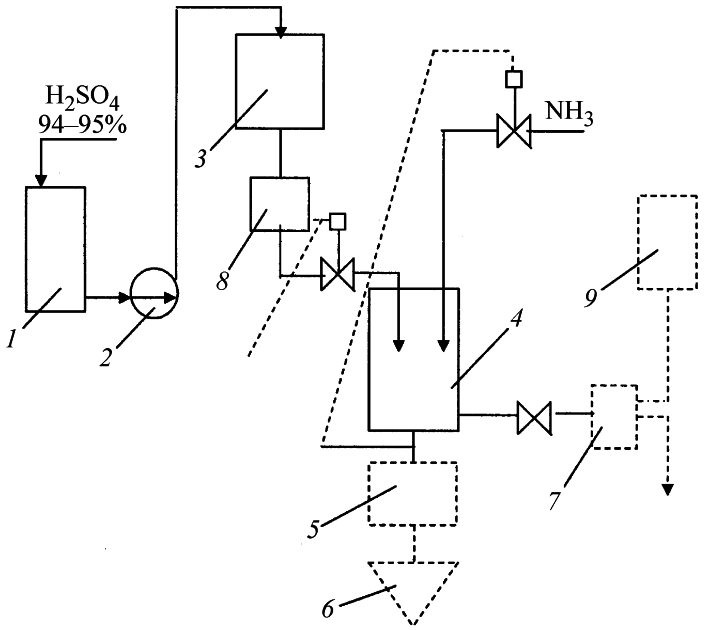
$$\Delta_r G_T^0 = 2.3RT\log SP. \quad (11)$$

The results obtained were used for calculating the Gibbs energhies of reactions (4)–(7) and (8)–(10) under industrial conditions by Eqs. (12) and (13), respectively, for the case when the mixtures contained additions of calcium and magnium nitrates in an amount of 0.5% counting on CaO:

$$\Delta_r G_T = \Delta_r G_T^0 - 2.3RT\log a_{M^{2+}} a_{SO_4^{2-}} a_w^n = \Delta_r G_T^0 - 2.3RT\log m_{M^{2+}} m_{SO_4^{2-}} a_w^n, \quad (12)$$

$$\Delta_r G_T = \Delta_r G_T^0 - 2.3RT\log a_{M^{2+}}^k a_{SO_4^{2-}}^{k+1} a_{NH_4^+}^2 a_w^n = \Delta_r G_T^0 - 2.3RT\log m_{M^{2+}}^k m_{SO_4^{2-}}^{k+1} m_{NH_4^+}^2 m_w^n, \quad (13)$$

where M^{2+} is Ca^{2+} or Mg^{2+}; k and n are the stoichiometric coefficients at M^{2+} and H_2O, respectively; a_i is the activity of ions; and a_W is the activity of water.



In the calculations, the activities of ions a_i were replaced by the molal concentrations of the components m_i, because the high ionic strength of the concentrated solution does not allow calculation of the activity coefficients. The calculation results are given in Table 3.

It follows from Table 3 that, among calcium sulfates, the most probable products of precipitation with sulfate ion are anhydrite $CaSO_4$ and double calcium ammonium sulfates. Precipitation of magnesium sulfates is thermodynamically impossible. Hence, sulfate ion is an efficient additive favoring the phase partitioning of calcium and magnesium ions [2].

EXPERIMENTAL

Pilot tests on introduction of sulfuric acid into a melt of ammonium nitrate containing a dolomite additive (0.4–0.55% counting on CaO) were performed on an installation shown in the figure. The installation includes a unit for the transfer of sulfuric acid from a mobile tank to a supply vessel, a unit for feeding sulfuric acid from a supply vessel to a head tank, and a unit for feeding sulfuric acid directly to an ammonium nitrate melt, with the subsequent neutralization of the reaction acid with gaseous ammonia prior to granulation. Because calcium sulfate can precipitate on internal surfaces of evaporation and afterevaporation vessels, thus impairing the heat exchange, sulfuric acid was introduced into the afterneutralizer after taking the melt from the afterevaporator.

The reaction of sulfuric acid with calcium nitrate

Scheme of introduction of sulfuric acid into ammonium nitrate melt: (*1*) receiving tank, (*2*) high-pressure pump, (*3*) supply vessel, (*4*) afterneutralizer, (*5*) filter, (*6*) granulator, (*7*) receiving tank for melt, (*8*) batcher, and (*9*) afterevaporator.

results in the evolution of free nitric acid, which should be neutralized with ammonia to pH 5.7–6.2. In the course of studies, we took samples of ammonium nitrate before and after introduction of sulfuric acid, analyzed them for the content of moisture, $CaSO_4$, and main substance, and determined the granule strength, pH of 10% aqueous solution, and content of ammonium nitrate aerosols in air after the granulation tower (Table 4). The sulfuric acid dosage was varied within 1.0–2.5 l min^{-1}. All the process parameters of the granulation tower were left unchanged.

Table 4. Influence of pH and degree of conversion of $Ca(NO_3)_2$ into $CaSO_4$ (α) on the strength of ammonium nitrate granules

pH	$CaSO_4$, wt %	Moisture, wt %	Strength, kg granule^{-1}	α, %
6.4	–	0.14	1.35	–
5.75	0.29	0.13	1.9	25.1
3.7	0.42	0.15	1.6	37.7
5.75	0.46	0.12	1.7	37.7
5.9	0.37	0.13	1.9	36.2
5.95	0.34	0.14	1.7	33.2

Table 5. Influence of pH on the strength of granules and number of thermal cycles of ammonium nitrate

pH	Strength, kg granule^{-1}		Number of thermal cycles	
	initial	with H_2SO_4	initial	with H_2SO_4
4.8	1.3	1.3	1	1
5.8	1.3	1.8	1	4
5.9	1.3	1.9	1	6
6.8	1.3	1.3	1	2

Examination of the influence exerted by pH and degree of conversion of $Ca(NO_3)_2$ into $CaSO_4$ on the strength of ammonium nitrate granules on introduction of sulfuric acid showed that pH should be kept in the range 5.6–5.8, i.e., the content of free ammonia in the melt should be 0.001–0.005%.

The results of examining the influence of pH of ammonium nitrate solution on the granule strength and number of thermal cycles are given in Table 5. It can be seen that pH of the solution should be brought to 5.9. In our experiments we managed to obtain ammonium nitrate with the strength exceeding 2.3 kg granule^{-1}, withstanding five to six thermal cycles (Table 6).

The sulfuric acid dosage was 2.0–2.4 l min^{-1} (samples with pH 5.9, 6.2). The concentration of sulfate ions was higher than 0.6 wt %, and the moisture content decreased to 0.14%. The granule strength was enhanced, suggesting the formation of $CaSO_4$ which exerts a strengthening effect. At pH > 6, the number of thermal cycles was 2–5, and at pH < 6, 5–6.

Table 6. Properties of ammonium nitrate granules

pH	$CaSO_4$, wt %	Moisture, wt %	Initial strength, kg granule^{-1}	Strength, kg granule^{-1}, after indicated number of thermal cycles					
				1	2	3	4	5	6
6.8	–	0.26	1.4	1.3	0.8	0.8	0.6	–	–
6.48	0.34	0.22	1.6	1.3	1.2	0.8	0.6	–	–
6.15	0.57	0.21	2.2	1.7	1.1	1.4	1.0	0.7	–
5.6	0.70	0.20	2.2	1.6	1.6	1.8	1.0	1.1	0.8
5.2	0.80	0.20	2.3	1.8	1.6	1.9	1.0	1.1	0.7
5.35	0.83	0.21	2.1	1.1	0.9	0.8	0.7	–	–
5.9	0.75	0.14	>2.3	2.2	1.9	1.8	1.5	1.3	1.0
6.2	0.7	0.14	>2.3	2.0	1.7	1.7	1.5	0.9	0.7

Published data on the behavior of the NH_4NO_3–$Ca(NO_3)_2$ system in the presence of sulfate ions suggest that, when the granules contain free ammonia (pH > 6), the compounds $(NH_4)_2SO_4$, $CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$, and $2CaSO_4 \cdot (NH_4)_2SO_4 \cdot H_2O$ can be formed along with $CaSO_4$. As a result, the number of thermal cycles decreases [12]. At pH 5.5–5.9, the amount of free ammonia is at a minimum; therefore, the number of thermal cycles is as large as 5–6. The discharge of ammonium nitrate with exhaust gases is decreased by 15%.

CONCLUSIONS

(1) Variation of the phase composition of the system based on ammonium nitrate upon introduction of sulfate ions leads to a decrease in the moisture content of the product, which, in turn, leads to deceleration of the dissolution and recrystallization processes. As a result, the caking of ammonium nitrate decreases and the strength of its granules is enhanced.

(2) The optimal degree of neutralization of the forming nitric acid with ammonia corresponds to pH 5.5–5.9 of a 10% aqueous solution of ammonium nitrate.

(3) The optimal dosage of sulfuric acid is 1.6–1.7 l min^{-1}, or 5–6 kg per ton of ammonium nitrate. In this case, the degree of conversion of calcium nitrate into calcium sulfate is 65–75%.

(4) The strength of the granules after six thermal cycles remains within the limits of the GOST (State Standard) requirements: 0.9–1.2 kg granule^{-1} (required 0.8), whereas the initial ammonium nitrate loses strength after one or two thermal cycles.

(5) The content of ammonium nitrate in the exhaust gases decreased by 15%.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Phase Stabilization of Ammonium Nitrate with Binary Additives Consisting of Potassium Nitrate and Complexone Salts

G. F. Klyakin and V. A. Taranushich

South-Russian State Technical University, Novocherkassk, Rostov oblast, Russia

Received August 2, 2007

Abstract—The paper deals with the search for and optimization of a method for preparing phase-stabilized ammonium nitrate as oxidant for solid propellants with environmentally friendly combustion products. The effect exerted on the energy of the V → IV and IV → III polymorphous transitions of ammonium nitrate by the total content of the binary additive potassium nitrate–disodium tetrahydrogen nitrilotris-(methylenephosphonate), component ratio, and temperature and time of the cocrystallizate treatment was examined.

DOI: 10.1134/S1070427208050030

The principal possibility of prepaing phase-stabilized ammonium nitrate (PSAN) undergoing no polymorphous transitions in the temperature range from –50 to +100°C by cocrystallization of ammonium nitrate (AN) with binary additives consisting of potassium nitrate and sodium or potassium salts of complexones was demonstrated in [1]. However, the total content of the binary additive in AN (7 wt %) appreciably decreases the rated specific impulse of a solid propellant based on the suggested PSAN. Therefore, decreasing the concentration of additives introduced is a topical problem. Preliminary experiments showed that the strongest effect on the phase stability of AN is exerted by the total content of a binary additive consisting of potassium nitrate and a complexone salt and by the ratio of its components. It was also noted that, despite the measures taken to ensure maximal dehydration of the cocrystallizing components and the use of dry atmosphere for the subsequent operations, heat treatment of the finished cocrystallizates considerably decreases the height of the peaks of the V → IV and IV → III down to their full suppression. Therefore, we also examined the effect exerted by the temperature and time of the heat treatment of the cocrystallizates.

For a detailed study, as a complexone salt we chose disodium tetrahydrogen nitrilotris(methylenephosphonate), $NTPNa_2$, as a substance that shows the highest inhibiting activity toward polymorphous transitions of AN and is commercially available.

EXPERIMENTAL

A wide test tube made of heat-resistant glass was charged with analytically pure grade ammonium nitrate dried to a moisture content not exceeding 0.05% (according to Fischer titration). The test tube was placed in an oven and heated to melting. Dehydrated $NTPNa_2$ was added to the AN melt at 175–180°C and dissolved with stirring, after which the melt was cooled and the fusion cake was finely divided. All manipulations with samples after cooling the melt were performed in a box with the relative humidity of air not exceeding 50%. All the experiments were duplicated.

Differential thermal analysis of the powder (fraction <400 μm) was performed in the temperature range from –50°C to melting. The sample weight was about 0.1 g, and the heating rate, 3 deg min^{-1}. The DTA curves were recorded in the coordinates sample temperature–difference between the temperatures of the sample and reference. The energies of the polymorphous transitions J (J g^{-1}) were estimated from the areas of the corresponding peaks in the DTA curve, using a calibration chart.

With the aim to gain a general pattern of variation of the PSAN characteristics, the experimental material was presented in the form of polynomial mathematical models constructed by standard procedures [2]. When constructing the model, we excluded insignificant (with respect to the Student test) terms with the subsequent recalculation, which

allowed us to obtain adequate models with smaller numbers of terms.

We examined the effect of the above-mentioned factors on the energy of the key polymorphous transitions of ammonium nitrate, V → IV and IV → III. In the first step, two factors, the total content of the binary additive in AN and the relative content of $NTPNa_2$ in the binary additive, were set constant (3 and 44%, respectively), and the effect exerted on the energy of the V → IV and IV → III transitions by the heat treatment temperature (from 84 to 99°C, four levels of variation) and time (from 0.5 to 6 h, five levels of variation) was examined.

The dependence of the energy of the PSAN V → IV polymorphous transition on the temperature and time of the heat treatment is adequately described by the equation

$$J_{V-IV} = 174.1 - 3.974t + 0.0226t^2, \quad (1)$$

where t is the heat treatment temperature (°C).

The statistical insignificance of the coefficients at terms taking into account the time factor [Eq. (1)] indicates that the transition energy is independent of the heat treatment time varied within the examined range. The graphical interpretation of Eq. (1) is shown in Fig. 1. The curves in Fig. 1 and the subsequent figures are lines of equal energy of the corresponding polymorphous transition ($J\ g^{-1}$).

As follows from Fig. 1, degradation of the PSAN structure with the V → IV polymorphous transition starts at the heat treatment temperature exceeding 90°C practically within 30 min after the sample reaches the preset temperature, and the energy of the transition increases in proportion with the temperature squared.

The dependence of the energy of the IV → III polymorphous transition on the temperature and time of the heat treatment is more complex and is adequately described by the equation

$$J_{IV-III} = 342.5 - 7.9t - 12.07\tau + 0.137t\tau + 0.0463t^2. \quad (2)$$

Analysis of the graphical interpretation of Eq. (2) (Fig. 2, nonshaded area) shows that the energy of the IV → III transition also nonlinearly increases with an increase in the heat treatment temperature.

The dependence of J_{IV-III} on the heat treatment time is complex. The temperature of 90°C is a threshold of a sort, above which the energy of the IV → III transition nonlinearly increases, and below

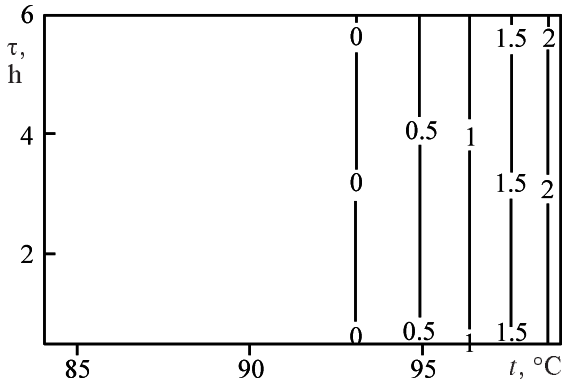

Fig. 1. Two-dimensional section of the response surface of model J_{V-IV} [Eq. (1)]. (τ) Heat treatment time and (t) temperature; the same for Fig. 2.

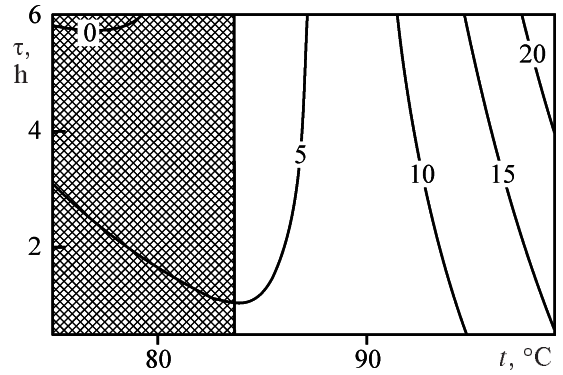

Fig. 2. Two-dimensional section of the response surface of model J_{IV-III} [Eq. (2)].

which, decreases in the entire range of heat treatment times examined. The lowest energy of the transition is attained at the lowest temperature and the longest heat treatment time. Extrapolation of the two-dimensional section toward lower heat treatment temperature (75°C; Fig. 2, shaded area) allowed us to find the area of zero energies of the transition.

At the boundary of this area (heat treatment temperature 80°C, time 6 h), we performed a series of experiments to reveal the dependence of the energy of the IV → III polymorphous transition on the total content c of the binary additive (from 2 to 4 wt %, three levels of variation) and relative content of $NTPNa_2$, c_{NTP}, in the binary additive (from 0 to 75 wt %, four levels of variation). Adequate models of the energies of the V → IV and IV → III polymorphous transitions have the form

$$J_{V-IV} = 0.83 - 0.0149c\,c_{NTP} + 0.000075c_{NTP}^2. \quad (3)$$

$$J_{IV-III} = 17.03 - 2.93c - 0.411c_{NTP} + 0.0075c_{NTP}^2. \quad (4)$$

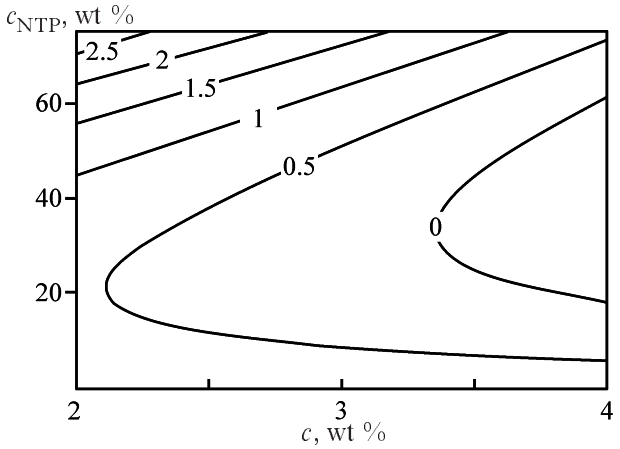

Fig. 3. Two-dimensional section of the response surface of model J_{V-IV} [Eq. (3)]. (c_{NTP}, c) Content; the same for Fig. 4.

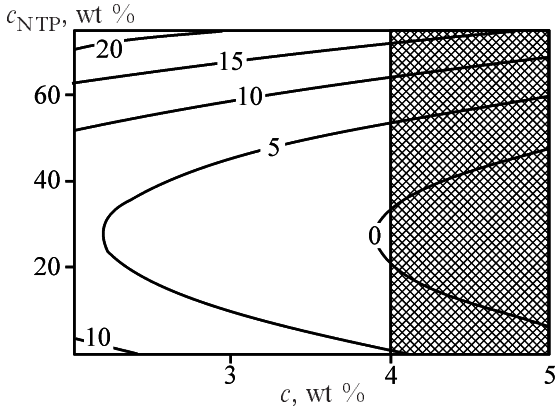

Fig. 4. Two-dimensional section of the response surface of model J_{IV-III} [Eq. (4)].

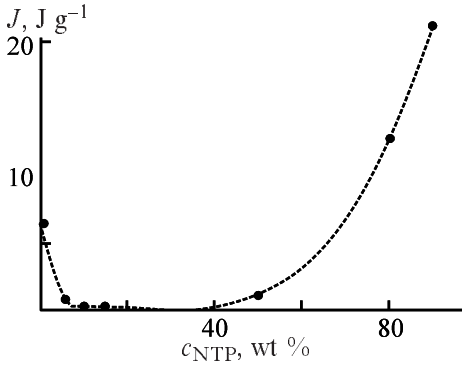

Fig. 5. Energy of the IV → III polymorphous transition as a function of the relative content of $NTPNa_2$, c_{NTP}, in the binary additive (total content 5 wt %).

Analysis of the graphical interpretation of Eqs. (3) and (4) (Figs. 3, 4) shows that, at a total content of the binary additive exceeding 3 wt %, there are areas of the zero energy of the transition, bounded by certain values of c_{NTP}.

The area of zero values of the V → IV transition energy (Fig. 3) starts at a lower total content of the bonary additive and exists in a wider range of relative amounts of $NTPNa_2$ in the additive, compared to the IV → III transition (Fig. 4, nonshaded area).

Extrapolation of the two-dimensional section (Fig. 4) toward an increase in the total content of the binary additive from 4 to 5 wt % (Fig. 4, shaded area) demonstrates the possibility of considerably expanding the area of the zero energy of the transition. The synergistic effect of the binary additive is confirmed experimentally (Fig. 5).

Figure 5 shows that, within the range of relative content of $NTPNa_2$ in the binary additive from 10 to 40 wt %, the IV → III polymorphous transition is suppressed. The V → IV transition in this series of experiments is observed only at $NTPNa_2$ concentrations of 0 and 90%. The PSAN sample with a total content of the binary additive of 5% and relative $NTPNa_2$ content of 20% stood ten cycles of heating and cooling from –50 to +50°C and thermostating at –50°C for 24 h without deterioration of the phase stability.

We performed experiments on the cocrystallization of AN with the binary additive from highly concentrated aqueous solutions of AN containing from 1 to 5 wt % water. We found that the presence of water in an amount exceeding 1 wt % fully suppresses the synergistic effect on introducing the binary additive. The pattern of polymorphous transitions of the samples obtained does not noticeably differ from that for AN without additives.

Recent studies [3] showed that the mechanism of IV $\rightleftarrows$ III polymorphous transitions of AN, including An containing a KNO_3 additive, can be considered as a chain of several successive events. Prior to the onset of the phase transition, crystallites and separate blocks are broken down. This is followed by transition of the initial phase into a certain intermediate X-ray amorphous state which subsequently transforms into the new phase. The limiting step is the transition of the initial phase into the intermediate X-ray amorphous state, rather than the nucleation and growth of centers of the new phase.

Based on this pattern, the mechanism of the synergistic effect in the system under consideration can be presented as follows. Like any topochemical reaction, the transformation of the initial phase starts on active centers located on defects of the external or internal surface of a crystal. In the salt $NTPNa_2$, the anion size is too large to form a substitution

solid solution with ammonium nitrate. Therefore, in the course of cocrystallization with ammonium nitrate, $NTPNa_2$ and products of exchange reactions with system components are adsorbed on defects of the crystal structure of AN or solid solution of KNO_3 in AN. Interaction of phosphonic acid groups of the complexone with potassium ions results in formation of a fairly strong structure suppressing the active centers and thus impeding the transition of the initial phase into the X-ray amorphous state. The same reasoning can also be applied to the V → IV polymorphous transition.

CONCLUSIONS

(1) Heat treatment of cocrystallizates of ammonium nitrate with modifying additives is the necessary step for ensuring phase stabilization of ammonium nitrate.

(2) Exceeding the threshold temperature of 90°C in the heat treatment of phase-stabilized ammonium nitrate containing the binary additive potassium nitrate–disodium tetrahydrogen nitrilotris(methylenephosphonate) is exceeded, the structure of phase-stabilized ammonium nitrate ensuring its phase stability is broken down.

(3) Phase-stabilized ammonium nitrate containing 5 wt % binary additive KNO_3–$NTPNa_2$ and undergoing no polymorphous transitions V → IV and IV → III can be obtained at a relative content of $NTPNa_2$ in the binary additive of 6–48 wt %.

(4) Analysis of the mathematical models describing the dependences of the energy of the polymorphous transition in ammonium nitrate on the concentration characteristics of the binary additive and on the temperature and time of the heat treatment allowed determination of the conditions for preparation of phase-stabilized ammonium nitrate exhibiting phase stability in the range from –50 to +100°C.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Processes Occurring in Boron- and Molybdenum-Containing Glass-Forming Phosphate Solutions

Ya. I. Vakhula, M. Ya. Matsigin, K. S. Besaga, and L. V. Zhuk

Abstract—Phosphorus-containing formulations of low-melting glass coatings prepared from solution were developed. The chemical processes occurring in the glass-forming solution and their effect on the melting temperature of the glass coatings were examined. The optimal composition of a coating with the preset properties was determined.

DOI: 10.1134/S1070427208050042

Industrial progress places heavy demands on the service characteristics and external appearance of surfaces. The required characteristics can be attained, in particular, by applying various coatings. A special role is played by glassy coatings which can be readily formed, show good adhesion to the support, and impart required surface properties to the material [1].

In many cases glassy coatings are prepared using phosphate systems [2–4]. Thanks to the lower connectivity of the anionic framework compared to silicate glass, phosphate glass has lower hardness and lower elastic modulus. The strength of bonding between P–O groups depends on the modifier cation. A specific feature of phosphate coatings is that they have increased temperature coefficient of linear expansion, high adhesion to the support, and low formation temperature [5]. In cases when high chemical resistance is not required, these coatings can be used as connecting and priming layers, and also for decoration of articles [4, 5]. Sol–gel process is used with colloidal solutions, and solution process, with true solutions.

The aim of this study was to develop formulations of low-melting glassy coatings of phosphate system, prepared by a solution process, and also to examine processes that occur in the course of preparation and storage of boron- and molybdenum-containing phosphate glass-forming solutions.

EXPERIMENTAL

Published data [5, 6] show that, to prepare glassy coatings with the above-indicated properties, it is appropriate to use systems $Na_2O–B_2O_3–P_2O_5$ **(I)** and $Na_2O–MoO_3–P_2O_5$ **(II)**.

The procedure for forming glassy coatings involved preparation of homogeneous aqueous solutions of the required composition and their spraying onto a heated steel plate with the subsequent heat treatment. To prepare the solutions, we used H_3PO_4, $Na_2HPO_4 \cdot 12H_2O$, $Na_2B_4O_7$, $NaNO_3$, and $Na_2MoO_4 \cdot 2H_2O$ of pure grade, and H_3BO_3 of analytically pure grade. The glass formulations (see table) were chosen taking into account the data of [6] and the specific features of the solution process related to the solubility of separate components.

Compositions of glassy coatings of the systems $Na_2O–B_2O_3–P_2O_5$ and $Na_2O–MoO_3–P_2O_5$

Formulation no.	Content, wt %			
	Na_2O	P_2O_5	B_2O_3	MoO_3
System **I**				
1	31	54	15	–
2	33	54	13	–
3	35	54	11	–
4	37	54	9	–
5	39	54	7	–
System **II**				
1	33	37	–	30
2	28	37	–	35
3	23	37	–	40
4	23	32	–	45
5	23	27	–	50

When preparing coatings, it is important to understand the properties of solutions used and the processes that occur in the course of their formation. To prepare a glass-forming molybdenum-containing solution, we used H_3PO_4, $Na_2MoO_4 \cdot 2H_2O$, and $Na_2HPO_4 \cdot 12H_2O$. The salts were dissolved in water with the formation of true colorless solutions. This fact suggests that the dissolution of the molybdenum salt is not accompanied by hydrolysis, as molybdic acid formed by hydrolysis would impart to the solution a yellow color [7]. At the same time, the transparent solution obtained from system **II** is yellow, irrespective of the order of mixing the components, which suggests the occurrence of the reaction [8]

$$Na_2MoO_4 \cdot 2H_2O + H_3PO_4 = MoO_3 \cdot 2H_2O + Na_2HPO_4 + H_2O. \quad (1)$$

To confirm these assumptions, we examined the products obtained from the solution, after drying at 60°C, by X-ray phase analysis.

The results of X-ray phase analysis show that the powder contained $MoO_3 \cdot 2H_2O$ (interplanar spacings *d/n* 0.343, 0.336, 0.331, 0.325, 0.304, 0.288, 0.265, 0.245, 0.231 nm), $NaPO_3$ (*d/n* 0.507, 0.465, 0.421, 0.343, 0.298, 0.280, 0.254, 0.245, 0.226 nm), and $Na_2HPO_4 \cdot 12H_2O$ (*d/n* 0.730, 0.444, 0.384, 0.363, 0.343, 0.331, 0.325, 0.321, 0.298, 0.280 nm). The presence of molybdic acid confirms the occurrence of reaction (1). $NaPO_3$ may be formed by the reaction

$$Na_2HPO_4 \cdot 12H_2O + H_3PO_4 = 2NaPO_3 + 14H_2O. \quad (2)$$

The presence of $Na_2HPO_4 \cdot 12H_2O$ in the powder suggests that reaction (2) does not go to completion.

When preparing solutions of borate system **I**, we found no qualitative evidence for the occurrence of chemical reactions. Furthermore, we failed to dry these solutions, because in the course of storage, even at room temperature, they transformed into viscous transparent masses. This may be due to low melting points of the solution components, e.g., 42.35°C for H_3PO_4 and 34°C for $Na_2HPO_4 \cdot 12H_2O$ [7]. Therefore, X-ray phase analysis of the system was impossible.

Glassy coatings of the system Na_2O–B_2O_3–P_2O_5. To obtain coatings of this system, we prepared two series of solutions: first, from sodium phosphate, phosphoric acid, and boric acid, and second, from sodium nitrate, sodium tetraborate, and phosphoric acid. All the solutions were colorless, without visible precipitate. Aerosol spraying of the solutions onto a steel plate heated to 350°C results in deposition of a raw mixture of the preset composition as a white powder. The products were then heat-treated in a gradient furnace at the maximal temperature of 770°C.

The quality of a glassy coating (in particular, its homogeneity, continuity, adhesion strength) was evaluated visually and with a microscope. The results obtained with the first series of solutions show that, as the content of sodium oxide is increased from 31 to 39 wt %, the lower boundary of the film formation (first signs of appearance of a glassy coating) is shifted from 650 to 575°C. Comprehensive evaluation shows that, among coatings of system **I**, formulation no. 5 is the best. This coating has a low temperature of the lower boundary of the film formation (575°C). It should be particularly noted that all the coatings obtained become dull after storage for 3 weeks, i.e., their chemical resistance is poor.

Coatings prepared from the second series of solutions are not continuous and show pronounced foaming. The bubble diameter increased from 1 to 3 mm with an increase in the temperature from 575 to 750°C. This phemonenon is associated with low viscosity and high spreadability of the molten raw mixture at elevated temperatures. As in the first series, the lower boundary of the film formation decreases from 725 to 575°C with an increase in the sodium oxide content. The coatings are pale green.

Glassy coatings of the system Na_2O–MoO_3–P_2O_5. Experiments showed that in this case the lower boundary of the film formation is 250°C, and it increases to 520°C with an increase in the molybdenum oxide content from 30 to 50 wt %. The coating color varies from transparent greenish to black, which is characteristic of molybdenum-containing glasses.

In system **II**, formulation no. 1 is the best. It covers uniformly the surface of a metal plate and provides the minimal lower boundary of the film formation (250°C).

It should be noted that, with an increase in the MoO_3 content and a decrease in the Na_2O content, the surface tension of the glass coatings increases, which allows preparation of thicker coatings. This trend is due to the fact that, with a decrease in the Na_2O content, the viscosity and the amount of the liquid phase at fusion decrease. At a high tempera-

ture, the melt viscosity becomes so low that the coating transforms into separate drops because of poor wettability.

CONCLUSIONS

(1) Low-melting molybdenum-containing phosphate coatings were developed. The components of the glass-forming solution used for their preparation have relatively low melting points. Fusion results in formation of eutectics which provide melting and formation of a coating at low temperatures. In particular, formulation no. 1 of system **II**, containing the maximal amount of $Na_2HPO_4 \cdot 12H_2O$, is characterized by the minimal lower boundary of the film formation: 250°C.

(2) Because of high formation temperature and low chemical resistance of borate coatings, molybdenum-containing phosphate coatings are more efficient.

Abstract—Aluminum oxyhydroxides were prepared by oxidation with water (55°C) of nanodispersed aluminum powders obtained by electric explosion of conductors in argon, nitrogen, carbon dioxide, and their mixtures. The structure and texture of aluminum oxyhydroxides were studied using methods of thermal desorption of nitrogen, derivatography, electron microscopy, and X-ray phase analysis.

DOI: 10.1134/S1070427208050054

Nanotechnology is today one of priority fields in developed countries. Nanomaterials are used in composites for preparing ceramics, catalysts, and sorbents, as molecular sieves, aerogels, and materials for solar batteries and fuel cells, and also in magnetic tomography, optoelectronics, photonics, microbiology, and medicine. The use of nanomaterials as sorbents is based on their high sorption ability toward various kinds of substances [1–5].

One of procedures for preparing nanomaterials is electric explosion of conductors (EEC) [6]. The first studies and semicommercial production of submicrometer aluminum powders by this method were performed in an inert gas (argon) atmosphere, with the subsequent passivation of the particles by admitting air into the explosion chamber. Aluminum nanopowders exhibit unique properties compared to submicrometer powders and, the more so, to bulk materials. For example, aluminum nanopowders react with water even at room temperature, and even slight (to 40–50°C) heating of the reaction mixture results in vigorous hydrogen evolution and self-heating of the system [7–12]. Oxidation of aluminum with water yields a mixture of finely dispersed products (aluminum oxyhydroxides) whose composition and properties strongly depend on the synthesis conditions: oxidation temperature, pH, time and temperature of aging, and time and temperature of the heat treatment of the sample [13, 14].

Today nanodispersed aluminum is produced by electric explosion process in nitrogen, carbon dioxide, and their mixtures, with nitrogen, argon, air, and carbon dioxide as passivating media [15]. In this study we examined how the media used for explosion and passivation affect the activity of nanodispersed aluminum in reactions with water and the composition of the oxidation products.

EXPERIMENTAL

In the study we used samples of nanodispersed aluminum powder (NDP) prepared by electric explosion of aluminum wire in argon, nitrogen, carbon dioxide, and their mixtures and passivated with nitrogen, air, and carbon dioxide (Table 1). We used the following notation: medium in which the wire was exploded–slash–gas used for powder passivation.

The kinetics of the oxidation of nanodispersed aluminum with water were studied with a gasometric unit provided with software for measuring the gas volume [16]. The cell with distilled water was ther-

$N_2 + CO_2/N_2$	32.4	61	34
CO_2/CO_2	30.8	16	38
Ar/air	54.6	80	17

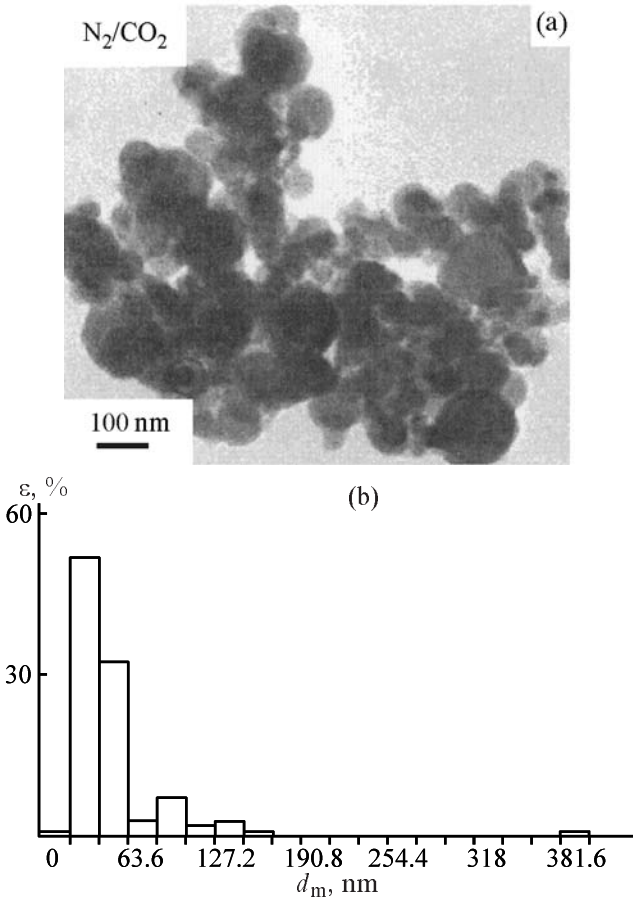

Fig. 1. (a) Electron micrograph and (b) size distribution of nanodispersed aluminum particles prepared in N_2/CO_2. (ε) Content of fraction and (d_m) mean particle diameter in fraction.

mostated at 60°C to completely remove gases dissolved in water, after which nanodispersed aluminum was added, and the volume of the released hydrogen was measured. From the kinetic curves we determined the maximal and mean rate of hydrogen evolution. We also calculated the conversion α as the ratio of the hydrogen volume actually released during the reaction to the theoretically expected volume.

The active metal content of aluminum samples was evaluated volumetrically from the hydrogen evolution in oxidation of nanodispersed aluminum with a NaOH solution [17].

Aluminum oxyhydroxides (AOHs) were prepared by the procedure described in [13]. Aluminum powders were thermostated in water (salt content 50 g l^{-1}, 55°C) with vigorous stirring of the suspension. Then the AOH powders were filtered off, washed with distilled water to neutral reaction, and dried.

The specific surface area S_{sp}, pore volume, pore size, and distribution of mesopore volume with respect to size were determined by thermal desorption of nitrogen on a Sorbtometr-M surface area analyzer (Katakon Private Company, Novosibirsk). The landing area of the adsorbate gas was taken equal to 0.162 nm^2 [18].

The content of structural water in AOHs was calculated from the results of derivatographic studies performed with a Q-1500 D deriovatograph in the dynamic mode (heating rate 10 deg min^{-1}) in the range 20–1000°C in air. The phase composition of AOHs was determined from the diffraction patterns taken with a DRON-3 diffractometer in the range of medium and large angles (2θ = 3°–60°, CuK_α radiation) with continuous scanning at a rate of 1 deg min^{-1}.

The morphology of nanodispersed aluminum particles and aluminum oxyhydroxides was studied with by transmission electron microscopy (TEM, 125 kV). A suspension of a powder in ethanol was applied onto an object-plate and dried. A carbon layer was sputtered in a vacuum onto the object-plate with the sample. The extract carbon replica was separated with an aqueous solution of gelatin. After dissolving gelatin, the carbon replica with the powder was placed on a copper grid. To determine the mean size of powder particles and their size distribution, 300–500 particles were measured.

The maximum of the size distribution of aluminum nanoparticles is at 30–55 nm, with the smallest particles formed in CO_2 (Table 1). The electron micrograph and histogram of particle distribution of one of the samples prepared in N_2/CO_2 are shown in Fig. 1. Aluminum nanoparticles prepared in Ar and passivated with air (Ar/air) contain 80%, and the N_2/N_2 and N_2/air samples, about 75% active aluminum. Introduction of CO_2 into the explosion chamber leads to aluminum oxidation. The active aluminum content decreases to 16% on complete replacement of N_2 by CO_2. Simultaneously, the specific surface area of the samples increases with increasing concentration of CO_2. A considerable increase in the specific surface area of aluminum nanopowders prepared by electric explosion may be due both to formation of smaller particles and to formation on their surface of oxides having a larger surface area than aluminum metal (Table 1).

All the aluminum NDPs studied are oxidized with water in one step (Fig. 2). The initial oxidation rate

is maximal for the N_2/CO_2 nanopowder. Oxidation of the powder prepared and passivated in CO_2 starts after the induction period and occurs slowly. The maximal rate of hydrogen evolution is 4.41, 2.22, and 0.16, and the mean rate, 1.47, 1.59, and 0.12 $cm^3\ g^{-1}\ s^{-1}$ for samples N_2/CO_2, N_2/N_2, and CO_2/CO_2, respectively (Table 2). The first sequence is apparently determined by the particle size and thickness of the protective shell. The former factor is decisive for the first two samples, and the latter factor, for the CO_2/CO_2 sample. The mean rate of hydrogen evolution is controlled exclusively by the content of active aluminum in the nanoparticles. The conversion α at 60°C in 2000 s of powders obtained in N_2/N_2, N_2/CO_2, and CO_2/CO_2 is 1.0, 0.96, and 0.38, respectively.

Oxidation of nanodispersed aluminum with water yields an ultradispersed product which is a mixture of oxyhydroxides. As shown previously for Ar/air aluminum [13, 14], the AOH phase composition is determined by oxidation conditions. Oxidized nanopowders prepared in N_2/air, N_2/N_2, and N_2/CO_2 give AOHs whose structural and texture characteristics are comparable with those of Ar/air AOHs. In the course of oxidation of these samples, pH of the reaction medium steadily increases and reaches 9.7 in 2 h. The reaction products contain virtually equal amount of structural water (Table 2). Oxidation of the CO_2/CO_2 sample ends in a less alkaline medium (pH 8.2), and the corresponding oxyhydroxide contains only 0.42 mol of structural water, i.e., three times smaller amount compared to the other samples.

The AOH samples prepared from aluminum samples of various kinds can be classed with mesoporous materials (isotherms of type IV) [19]. The capillary-condensation hysteresis loops observed with these samples correspond to type N3 characterized by slitlike pores. The maximum of the mesopore size distribution is at 4 nm for all the samples (Fig. 3). The Ar/air AOH sample has the largest mesopore volume and the smallest mean size of mesopores (Table 2). The curves of the mesopore volume distri-

bution with respect to the pore size for the CO_2/CO_2 AOH sample have a weakly pronounced maximum at approximately 4 nm, and the mean pore size is 8.0 nm, i.e., it is larger than in the other samples.

Electron-microscopic images of particles of the N_2/N_2 and CO_2/CO_2 AOH samples are shown in Fig. 4. The N_2/N_2 AOH sample (Fig. 4a) consists mainly of amorphous flaky formations of different shapes and sizes, characteristic of pseudoboehmite. The AOH samples prepared by oxidation of the N_2/air, N_2/CO_2, $N_2 + CO_2/N_2$, and Ar/air aluminum powders have a similar morphology. The CO_2/CO_2 AOH sample (Fig. 4c) mainly consists of round-shaped particles of size 50–250 nm, of 100–200-nm chips forming flat agglomerations, and of separate relatively coarse (1000–1500 nm) particles.

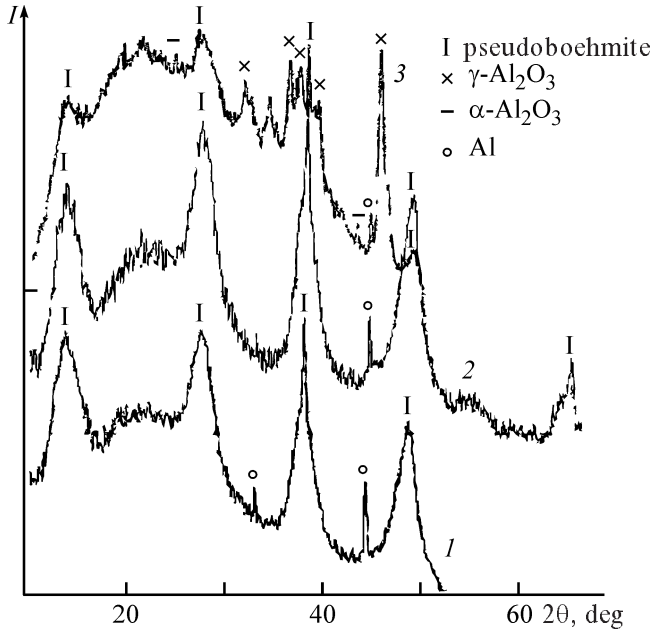

Fig. 5. Diffraction patterns of aluminum oxyhydroxides prepared from Al powders that were formed in (*1*) N_2/N_2, (*2*) N_2/CO_2, and (*3*) CO_2/CO_2. (*I*) Radiation intensity and (2θ) Bragg angle.

Oxidation of nanodispersed aluminum with water initially yields amorphous trihydroxide from which a series of oxyhydroxides are formed in the course of aging, depending on the conditions [14]. After 2 h, the dispersed phase of the reaction mixture consists of amorphous trihydroxide (halo at ~20°), pseudoboehmite (broadened reflections corresponding to interplanar spacings of 0.611, 0.316, 0.234, and 0.186 nm), and residual aluminum (d = 1.97 nm etc.) for the N_2/N_2, N_2/CO_2, N_2/air, $N_2 + CO_2/N_2$, and Ar/air samples (Fig. 5, curvese *1, 2*) [20]. Oxidation of the CO_2/CO_2 sample, complicated by aging, ends in a less alkaline medium (Table 2), which affects the product composition: The concentration of pseudoboehmite decreases and the content of α- and γ-Al_2O_3 increases (Fig. 5, curve *3*).

Thus, by varying the media of the explosion and passivation of nanodispersed aluminum powders, it is possible to vary the structural and texture characteristics of the products of aluminum oxidation with water. Complete replacement of Ar or N_2 by CO_2 leads to a decrease in the concentration of pseudoboehmite, characterized by developed surface of particles and high sorption activity, in the mixture of oxyhydroxides.

CONCLUSIONS

(1) Aluminum nanopowders prepared in Ar/air, N_2/air, and N_2/N_2 contain 75–80% active aluminum.

With an increase in the CO_2 concentration in the explosion chamber, the content of active aluminum in the samples decreases and the specific surface area increases.

(2) The rate of oxidation of nanodispersed aluminum powders depends on the particle size and active aluminum content. The N_2/CO_2 sample is characterized by the highest rate of oxidation with water.

(3) The oxyhydroxide prepared by oxidation with water of aluminum powders prepared in CO_2/CO_2 are characterized by low pseudoboehmite concentration, small specific surface area, and small mesopore volume.

Abstract—Effect of the degree of hydration and the phosphorus to titanium ratio in sorbents based on hydrated oxotitanium hydrophosphate on their sorption properties: constant of heterogeneous substitution of hydrogen ions by cations of sodium, cesium, and strontium and static exchange capacity, was studied.

DOI: 10.1134/S1070427208050066

Titanium(IV) phosphates are of special interest as sorption materials. It has been shown that sorbents of this kind can absorb cations of radionuclides [1–6] and nonferrous metals and iron [7–10] from strongly diluted aqueous solutions.

Operating nuclear power plants yield liquid radioactive waste (LRW) in the form of radionuclide-contaminated seawater (possibly diluted with fresh water), in which γ- and β-emitters are mostly constituted by ^{137}Cs and ^{90}Sr [11]. Together with radionuclides, such LRW contains up to 32 g l^{-1} of salts: mostly chlorides and, to a lesser extent, sulfates and hydrocarbonates of alkali and alkaline-earth metals. Being present in substantially higher concentrations (e.g., that of sodium cations may be 10.5 g l^{-1}) and having close chemical properties, these cations can compete with radionuclides in sorption. It has been shown that a sorbent based on amorphous hydrated oxotitanium hydrophosphate can be efficient in LRW deactivation [12–14].

Depending on synthesis conditions, products of the following compositions can be obtained: $[TiO(OH)_2]_x \cdot [TiOHPO_4]_{1-x} \cdot nH_2O$, where $0 \le x < 1$ and $n \ge 1$. Despite numerous studies of sorbents belonging to this class, the sorption mechanism remains unclear, because the cations being sorbed can, in principle, replace both the proton of a hydroxy group bonded to the central titanium atom and the proton of a hydroxy group bonded to the phosphorus atom (proton of the HPO_4^{2-} anion).

The aim of this study was to analyze how the sorption properties [constant of heterogeneous substitution of hydrogen ions by cations of sodium, cesium, and strontium and static exchange capacity (SEC)] depend on the phosphorus to titanium ratio in the sorbent and on the degree of its hydration.

EXPERIMENTAL

The starting oxotitanium hydrophosphate of the composition $[TiO(OH)_2]_x \cdot [TiOHPO_4]_{1-x} \cdot nH_2O$ was synthesized directly in an aqueous medium. To a concentrated solution of ammonia taken in a 30% excess relative to the stoichiometry, we gradually added a warmed-up acid fluoride solution of titanium(IV) ($c_{Ti(IV)}$ = 1.22 M, c_{F^-} = 7.33 M or $c_{Ti(IV)}$ = 1.73 M, c_{F^-} = 10.38 M) to pH 10–11 with continuous stirring. The reaction in which the solid phase of hydrated ammonium metatitanate is formed can be represented by the equation

$$H_2TiF_6 + (6 + x)NH_4OH_{conc} \rightarrow 7(NH_4)_xH_{4-x}TiO_4 + 6NH_4F + (2 + x)H_2O. \quad (1)$$

After filtration, the precipitate formed was washed to remove fluoride ions by triple repulpation in a 5% solution of ammonia. According to the results of an analysis, the content of F^- ions did not exceed 10^{-2} wt %. The second stage consisted in substitution of ammonium cations with hydrogen ions in formation of titanium(IV) oxohydroxide and substitution of hydroxy groups in this oxohydroxide with phosphate groups. For this purpose, the synthesized hydrated ammonium titanate $(NH_4)_xH_{4-x}TiO_4$ was repulped in water and a solution of hydrochloric

acid was introduced into the resulting suspension to pH 4–5:

$$(NH_4)_xH_{4-x}TiO_4 + xHCl \rightarrow TiO(OH)_2 + xNH_4Cl + H_2O. \quad (2)$$

The content of ammonium cations was monitored using Nessler's reagent. After double treatment of the solid phase being synthesized with a hydrochloric acid solution, no ammonium cations were found in the suspension. Then, the filtered-off solid phase of the freshly precipitated titanium(IV) hydroxide was treated with an orthophosphoric acid solution under vigorous agitation. The precipitate was dried and excess orthophosphoric acid captured by the solid phase from the solution was removed by washing with water. The composition of titanium(IV) phosphate synthesized was photocolorimetrically analyzed for the content of titanium(IV) and phosphorus(V), using hydrogen peroxide and ammonium molybdate, respectively. The error in the results of the analysis did not exceed 0.5%.

Previously, the anionic substitution in the hydrated oxohydroxide matrix of titanium(IV) in synthesis of oxotitanium hydrophosphate (P : Ti = 1 : 1) was performed in suspensions with a large excess of orthophosphoric acid [12–14]. In this case, the high degree of hydration of the solid phase provided the occurrence of the process in the bulk.

In this study, the interaction of phosphoric acid with titanium(IV) hydroxide was examined at 20, 65, and 95°C in order to optimize the synthesis conditions of hydrated titanium hydroxophosphate with a prescribed P : Ti ratio. A weighed portion of titanium hydroxide was placed in a phosphoric acid solution at a preset initial molar ratio of the contents of H_3PO_4 and titanium(IV) and was kept there for 30 min under agitation. The unchanged H_3PO_4 was filtered off, with the concentration $c_{H_3PO_4}$ in the filtrate and the phosphorus to titanium(IV) molar ratio in the solid phase determined. The results obtained are listed in Table 1.

Table 1 shows that raising the temperature of the titanium(IV) oxohydroxide suspension in a phosphoric acid solution results in an increase in the phosphorus to titanium molar ratio in the solid phase. The heterogeneous anionic substitution in the oxohydroxide matrix of titanium(IV) can be represented by the equation

$$TiO(OH)_2 \cdot nH_2O + (1 - x)H_3PO_4 \rightleftarrows [TiO(OH)_2]_x[TiOHPO_4]_{1-x} \cdot nH_2O + 2(1 - x)H_2O. \quad (3)$$

Table 1. Phosphorus to titanium ratio in the suspension ($N_{P(in)}$) and in the solid phase (N_P) at different temperatures of thermal treatment of the suspension, s : l = 1 : 70

55.8	21.8	22.4	$[TiO(OH)_2]_{0.56} \cdot [TiOHPO_4]_{0.44} \cdot H_2O$

The influence exerted by the composition of a sorbent on its ion-exchange properties was studied with samples whose composition is presented in Table 2. The heterogeneous cationic substitution was studied potentiometrically, by analyzing the variation of pH of aqueous suspensions containing the synthesized sorbents and chloride solutions of sodium, cesium, or strontium. The studies were carried out at 20°C and constant ionic strength μ of 0.5, 1.0, and 2.0. As equilibrium values we took steady-state pH values obtained using an I130.2M.1 ion meter with an accuracy of ±0.02. In the course of a drift of pH with time τ, its steady-state value was found by extrapolation of the pH–1/τ dependence to the ordinate axis at 1/τ = 0. An ESL-43-07 electrode selective toward hydrogen ions, with the isopotential point pH_i at 7±0.3, served as indicator electrode, and an EVL-1M3 saturated silver chloride electrode whose potential at 20°C is 202±2 mV relative to the standard hydrogen electrode, as auxiliary electrode. The equilibrium concentration and activity coefficient of hydrogen ions were found from the calibration dependence pH–c_{H^+} (c_{H^+} is the total

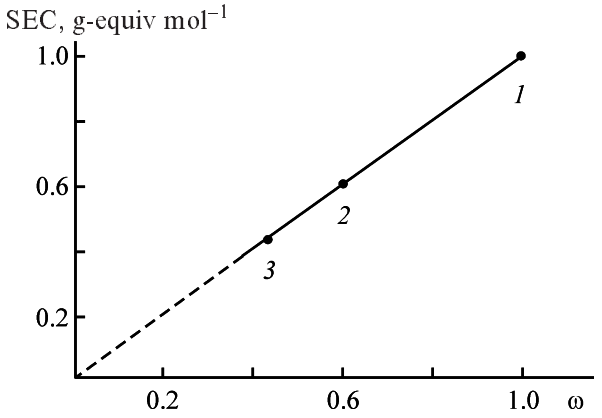

Fig. 1. SEC for cesium cations vs. the ratio ω of the specific molar content of oxotitanium hydrophosphate to the total content of titanium in various sorbents. (*1*) $TiOHPO_4 \cdot 6H_2O$, (*2*) $[TiO(OH)_2]_{0.39} \cdot [TiOHPO_4]_{0.61} \cdot 2.38H_2O$, and (*3*) $[TiO(OH)_2]_{0.56} \cdot [TiOHPO_4]_{0.44} \cdot H_2O$.

concentration of hydrogen ions in solution) at appropriate constant values of the ionic strength of the solution and from reference data. The static exchange capacity was determined with an accuracy of ±0.04 mg-equiv g^{-1}. The error in determining the logarithm of the constant of heterogeneous substitution of hydrogen ions by cations of sodium, cesium, or strontium was ±0.02. The reproducibility of the sorption parameters for sorbent samples taken from the same batch of the product synthesized confirmed that homogeneous distribution of phosphorus throughout the volume of the titanium matrix is achieved in synthesis of sorbents with a prescribed P : Ti ratio.

Figure 1 shows how the SEC of the initial samples, reduced to a mole of titanium(IV) in the sorbent, depends on the specific molar content ω of oxotitanium hydrophosphate in these samples, i.e., on the HPO_4^{2-} : Ti molar ratio. The linear dependence obtained indicates that active sorption centers are formed in the samples under study by just the hydrophosphate group, whereas protons of the hydroxy groups bonded directly to the central titanium atoms have no effect on the cation exchange. The dependences of SEC variation with the water content n of the samples was studied. For this purpose, a starting synthesized sample of the sorption matrix was gradually dehydrated by heating with an infrared lamp, with the loss of water mass determined and then SEC_{ex} found in 1 M solutions of CsCl, NaCl, and $SrCl_2$ at pH 6. The results obtained were compared with the theoretical value SEC_{theor}, calculated on the assumption that the molar concentration of the cation-exchange proton is equal to the concentration of HPO_4^{2-} groups in the sorbent.

Figure 2 shows $SEC_{ex} : SEC_{theor}$ ratios in dehydration of samples of initial compositions $TiOHPO_4 \cdot 6H_2O$ and $[TiO(OH)_2]_{0.39} \cdot [TiOHPO_4]_{0.61} \cdot 2.38H_2O$. The final compositions of the products can be described by the formulas $TiOHPO_4 \cdot 1.54H_2O$ and $[TiO(OH)_2]_{0.39} \cdot [TiOHPO_4]_{0.61} \cdot 0.30H_2O$. Figure 2 shows that the experimentally found values of SEC in dehydration of air-dry products first coincide with the theoretical values. However, as the content of crystallization water in the samples decreases further, the $SEC_{ex} : SEC_{theor}$ ratio starts to decrease and does so to dissimilar extents for different cations under study: the smallest deviation is observed for the cesium cation, and the largest, for the strontium cation. The extent to which the $SEC_{ex} : SEC_{theor}$ ratio decreases for the cations under study varies oppositely to the effective ionic potential of the cations, determined by the ratio of the cation charge to the radius of the hydrated cation.

The constants of heterogeneous substitution of the proton by cations of sodium, cesium, and strontium were found for the sorbents obtained under the conditions providing a $SEC_{ex} : SEC_{theor}$ ratio equal to unity. The constant is given by the equation

$$K_{ex} = (a_{H^+}/N_H)(N_M/a_{M^{z+}})^{1/z}, \quad (4)$$

where a_{H^+} and $a_{M^{z+}}$ are the activities of the H^+ and

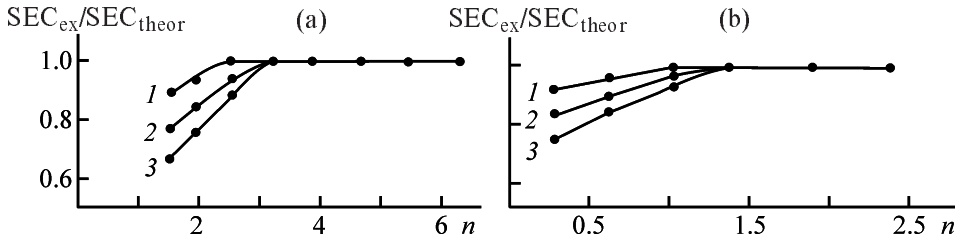

Fig. 2. $SEC_{ex} : SEC_{theor}$ ratio for (*1*) Cs^+, (*2*) Na^+, and (*3*) Sr^{2+} cations vs. the specific molar content n of water in (a) $TiOHPO_4 \cdot nH_2O$ and (b) $[TiO(OH)_2]_{0.39} \cdot [TiOHPO_4]_{0.61} \cdot nH_2O$.

Table 3. Effect of the specific molar content n of water in a sorbent of the composition $TiOHPO_4 \cdot nH_2O$ on the exchange constant $\log K_{ex}$

Composition	n	$\log K_{ex}$		
		Na^+	Cs^+	Sr^{2+}
$TiOHPO_4 \cdot 3.17H_2O$	3.17	–3.14	–1.60	–2.60
$TiOHPO_4 \cdot 4.65H_2O$	4.65	–2.99	–1.71	–2.48
$TiOHPO_4 \cdot 6.30H_2O$	6.30	–2.94	–1.80	–2.39

Table 4. Effect of the ratio between the content ω of oxotitanium hydroxophosphate and the total content of titanium in the sorption matrix on the exchange constant $\log K_{ex}$

Composition	ω	$\log K_{ex}$		
		Na^+	Cs^+	Sr^{2+}
$TiOHPO_4 \cdot 3.17H_2O$	1	–3.14	–1.60	–2.60
$[TiO(OH)_2]_{0.39} \cdot [TiOHPO_4]_{0.61} \cdot 2.38H_2O$	0.61	–2.69	–1.92	–2.42
$[TiO(OH)_2]_{0.56} \cdot [TiOHPO_4]_{0.44} \cdot H_2O$	0.44	–2.61	–1.98	–2.28

M^{z+} ions in solution; N_H and N_M, mole fractions of oxotitanium hydroxophosphate unsubstituted and substituted with metal cations; and z, charge of metal ions M^{z+}.

In the general case, this constant characterizes the substitution of hydrogen ions in a sorbent containing oxotitanium hydroxophosphate with metal cations M^{z+} present in solution, which occurs by the reaction

$$TiOHPO_4 + 1/zM^{z+} \rightarrow H^+ + 1/zM(TiOPO_4)_z. \quad (5)$$

Table 3 lists the thermodynamic constants of the cation exchange in relation to the content of water in hydrated oxotitanium hydroxophosphate. It was found that, as the degree of sorbent hydration becomes smaller, K_{ex} decreases for sodium and strontium cations and increases for cesium cations. Thus, dehydration of the sorbent leads to an increase in the selectivity of sorption of metal cations with a larger ratio of the cation charge to the radius of the hydrated cation.

The effect of the molar ratio ω between the contents of phosphorus and titanium on the exchange constant was studied (Table 4). A decrease in ω results in that the exchange constant becomes larger for sodium and strontium cations and smaller for cesium cations, i.e., it makes lower the sorption selectivity. Thus, presence of the oxohydroxide component leads to a decrease in the sorption selectivity.

The whole body of the data obtained suggests that the cation substitution processes under study are strongly affected by the number of HPO_4^{2-} cation-exchange groups and by the degree of hydration of a sorbent.

CONCLUSIONS

(1) Synthesis conditions of oxotitanium hydroxophosphate of the stoichiometric composition by reacting titanium(IV) oxohydroxide and orthophosphoric acid were substantiated.

(2) The sorption activity of the hydroxide–phosphate sorbents synthesized, $[TiO(OH)_2]_x \cdot [TiOHPO_4]_{1-x} \cdot nH_2O$, is determined by the hydrophosphate, rather than by the hydroxy group.

(3) Dehydration of the sorption matrix leads to a decrease in SEC and increase in the selectivity of recovery of cations with a higher effective ionic potential. The extent to which the SEC decreases varies oppositely to the effective ionic potential of the cations.

(4) A decrease in the phosphorus-to-titanium ratio in the hydroxide–phosphate sorbent makes lower the sorption selectivity.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Anion Chromatography and Redox Photometry in Potable Water Analysis

E. V. Shlyapunova and G. M. Sergeev

Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received December 26, 2006

Abstract—Anion chromatography with ANIEKS-N selective ion exchanger and redox photometry with an antimony(V) ionic associate as selective oxidizing agent were suggested for determination of low concentrations of toxic (F^-, Br^-, NO_2^-, NO_3^-) and biogenic (SeO_3^{2-}, I^-) ions in some potable waters available from central water supply systems and mineral water springs.

DOI: 10.1134/S1070427208050078

Anion chromatography is a versatile method for determination of the anionic composition of various potable waters [1, 2]. It should be noted that the material analysis of every water type has its specific features. Potable waters available from different water supply systems contain the analyzed components in low concentrations. In this situation, the best ion-chromatographic procedure is that with which the detection limit of, above all, toxic ions, F^-, Br^-, NO_2^-, NO_3 can be decreased [SanPiN (Sanitary Rules and Regulations) 2.1.4.1074-01]. At the same time, for mineral waters with their complex matrix composition, of primary importance is the selectivity of analysis [GOST (State Standard) 13273–88]. This makes problematic determination of the above-mentioned microcomponents in the presence of large amounts of sulfate, chloride, and hydrocarbonate ions.

These problems can be overcome using the universal conductometric detection method utilized in the available liquid chromatographs. However, this signal-recording procedure does not allow determination of nanogram amounts of biologically active selenite and iodide ions [3]. In this situation, it is expedient to apply two independent methods, ion chromatography (IC) and redox photometry. The latter enables determination of 10^{-4} mg l^{-1} of selenite and iodide ions in the presence of a large number of concomitant substances without additional preconcentration, separation, and masking procedures [4]. At the same time, under the correctly chosen chromatographic analysis conditions, the detection limits for the target analytes in the "standard" mixture comprised of F^-, Cl^-, Br^-, NO_2^-, NO_3^-, HPO_4^{2-}, and SO_4^{2-} ions can be decreased by an order of magnitude (relative to the commonly practiced methods [5, 6]), with the selectivity of analysis preserved at a sufficiently high level. The ion chromatography and redox photometry complement each other in the type of information they provide; they are characterized by good accuracy and resolution. These are reliable, easy to implement methods that do not require expensive instrumentation and reagents.

In this study we applied a combination of two methods, anion chromatography and redox photometry, to determination of some toxic and biogenic ions in potable waters available from central water supply systems and mineral water springs.

EXPERIMENTAL

We used a Tsvet-306 liquid ion chromatograph equipped with a conductometric cell. The chromatographic experiments were run in the two-column version: The separating column (100 × 6 mm) was packed with surface-grafted ANIEKS-N anion exchanger in the OH form (20-μm mesh), and the suppressing column (200 × 6 mm), with a strongly acidic KU-2 × 8 sulfonic cation exchanger in the H form (50-μm mesh). The ion-exchange resins were preliminarily freed from impurities by the known techniques. The columns and the conductometric cell were thermostated at 20.0 ± 0.2°C. At the detector outlet, a throttling column was placed to prevent carbon dioxide from entering the flow system. A

solution containing 2.8 mM $NaHCO_3$ and 2.0 mM Na_2CO_3 served as eluent; it was supplied at a rate of 3 ml min^{-1}. The solutions of the analytes were prepared in deionized water with the specific electric conductivity $\xi \leq 50$ μS m^{-1}. The content of the anions, mg l^{-1}, in the working standard solutions was varied within 0.1–50 for fluoride, 0.2–100 for chloride, 0.5–100 for hydrophosphate, bromide, and sulfate, and 1.5–100 mg dm^{-3} for nitrate and nitrite ions. The ultrapure and chemically pure grade salts utilized were freed from organic impurities and adsorbed moisture. The volume of the sample introduced was 50 μl (a loop sampler).

Sample preparation for analysis consisted in addition of an eluent "concentrate" (with $NaHCO_3$ and Na_2CO_3 concentrations by two orders of magnitude exceeding those mentioned above) in amount of 250 μl per 25 ml of the solution analyzed. If necessary, the sample was diluted with deionized water. With this sample preparation procedure, the results of processing of the chromatograms were unaffected by the "carbonate" peak. The calibration plots were constructed with the use of 5–7 solutions (five measurement runs). The content, mg l^{-1}, of the anions in the sample was calculated from the area of the chromatographic peaks (SAA-06 automatic data processing block). The correctness of the recommended ion-chromatographic technique was verified by the method of standard additions. The regular error was insignificant, since the difference between the results of analyses of the samples with and without addition falls within the confidence interval for this difference. The total relative error was estimated at 15–20% for the anion concentrations within 0.1–2 mg dm^{-3} and at 5–10% for those within 10–100 mg dm^{-3}.

In redox-photometric extraction determination of selenium(IV) and iodide ions, we used a toluene solution of the antimony(V) ionic associate. The latter is comprised of the anion of pentavalent antimony hexachloride complex and the cation of a basic dye, Crystal Violet. For preparing the ionic associate we used ultrapure grade metallic antimony, chemically pure grade sodium nitrite, ultrapure grade urea, analytically pure grade Crystal Violet purified by recrystallization, and concentrated H_2SO_4 and 6 M HCl solutions (ultrapure grade chemicals). A standard antimony(III) solution (10 ml; 1 μg l^{-1}) was poured into a separating funnel, into which 1 ml of 10% $NaNO_2$ solution was further added. The resulting mixture was stirred for 2 min to ensure Sb(III) oxidation to Sb(V). Excess oxidant was decomposed by adding 0.5 ml of saturated urea solution, after which 20 ml of double-distilled water and 3 ml of 0.2% solution of Crystal Violet were added. The colored ionic associate $[CVSbCl_6]$ was extracted with 30 ml of chemically pure grade toluene (in 10-ml portions). Along with the above-mentioned reagents, we used elemental selenium and ultrapure grade KI, whose standard solutions were prepared by known techniques. Also, we used chemically and ultrapure grade HCl, HNO_3, CH_3COOH, and NH_4OH.

The experiments in which $[CVSbCl_6]$ reacted with the analyzed reducing agents were run in test tubes (170 × 17 mm) with ground-glass stoppers. To determine Se(IV), identical volumes (3 or 4 ml) of the toluene solution of the ionic associate, the standard solution, or analyzed water, as well as of the acetate–ammonia buffer solution with pH 6 were added into the test tubes. To get reproducible results, the contents of the test tubes was mixed in a vibromixer at 20 ± 2°C and a rate of 180–200 shakings per minute for a fixed period (20 min). The optical density of the organic layer was measured on an SF-46 spectrophotometer in a 1-cm-thick cell at λ = 615 nm. The molar absorption coefficient of the toluene solution of the ionic associate ε was (8.4 ± 0.4) × 10^4 mol^{-1} cm^{-1} l. A similar system in which the solution of the analyte was replaced by a "blank sample" served as the control. To decrease the contribution of the regular error into the accuracy of the results, the experiments with the analyzed solutions were paralleled by those with the blank sample.

In analysis of iodide ions we changed to the acetate–ammonia buffer solution with pH 3 and the mixing rate of 25–30 shakings per minute to prevent alterations of the analyte species and escape of elemental iodine from the reaction system. The techniques for determining the content of selenium(IV) and iodide ions in potable waters from water supply systems and in low-mineralized waters are similar to those described above. In the case of the waters containing over 2–3 g l^{-1} mineral salts, the sample preparation for Se(IV) analysis consisted in a 5–10-fold dilution of an aliquot (20–30 ml) of the sample with double-distilled water, followed by removal of the iodide ions. If the concentration of the iodide ions exceeded 10^{-2} mg l^{-1}, the diluted sample was heated on a water bath (60–80°C) for 30–40 min with stirring to prevent the loss of the condensate.

The correctness of determination of Se(IV) and iodide ions in potable waters was verified by the

"additions" and "weighted portion variation" methods. We found that the results of analysis of the solutions containing selenium(IV) are unaffected by Se(VI), S(IV), As(III, V), Te(IV, VI), and iodide ions, whose weight proportions to Se(IV) are no greater than 50, 50, 10^6, 10^6, and 100, respectively. The iodide ions in the amount of 1×10^{-4} mg l^{-1} can be determined in the presence of a 10^6-fold excess of the carbonate, chloride, and sulfate ions, as well as of sodium, potassium, calcium, magnesium, and some other concomitant anions and cations. The relative error is within 20%. Table 1 lists the retention times, resolution of the chromatographic peaks, and metrological characteristics of the experimental results.

The nitrate ion exhibits enhanced affinity for the ANIEKS-N anion exchanger. The change in the retention time of NO_2^- in the anion mixture is due to the competing action of bromide. The NO_3^- and NO_2^- ions are separated with the resolution factor R_s of two, which is of special importance for determination of these toxic anions in a mixture; for chloride–monohydrophosphate and monohydrophosphate–bromide pairs, $R_s = 1.0$. The fluoride and chloride give sufficiently resolved signals unaffected by the "carbonate" peak. The detection limits achieved for the majority of the analyzed ions are 5–10 times lower than those in the similar IC method. It should be noted that the above-mentioned characteristics were achieved without the use of a preconcentration column whose application is not universally justified and typically leads to overlap of the chromatographic peaks for ion-exchange resins with particle size over 5–7 μm.

Thus, the correctly chosen selective sorbent and chromatographic analysis conditions can essentially expand the potentialities of the classical "basic" version of IC with conductometric detection. We found that the ratios of the maximum permissible concentrations of the analytes of interest in potable waters to the detection limits of the anions are as follows: Br^- 2, NO_2^- 6, F^- 50, NO_3^- 90, Cl^- 5000, and SO_4^{2-} 5000.

We studied the two-phase redox reactions of selenium(IV) with iodide ions, using antimony(V) hexachloride complex as the selective oxidizing agent.

Our experimental results and published data [7, 8] suggest that the ionic associate is involved in the following process occurring at the organic phase

Table 1. Retention times τ_R, chromatographic peak resolutions R_s, calibration plot slopes a,* detection limits, and range of detectable concentrations of the analyzed anions ($n = 5$; $P = 0.95$)

Anion	τ_R, min	R_s	$a \pm \Delta a$	c_{min}, mg l^{-1}	c, mg dm^{-3}
F^-	0.6		11.5 ± 0.2	0.03	0.1–50
		1.3			
Cl^-	2.4		6.71 ± 0.05	0.07	0.2–100
		1.0			
HPO_4^{2-}	3.4		5.13 ± 0.02	0.09	0.5–100
		1.0			
Br^-	8.6		4.81 ± 0.06	0.1	0.5–100
		1.5			
SO_4^{2-}	9.4		4.64 ± 0.07	0.1	0.5–100
		1.1			
NO_3^-	11.8		1.02 ± 0.06	0.5	1.5–100
		2.0			
NO_2^-	21.7		0.97 ± 0.05	0.5	1.5–100

* S, μV s = $(a \pm \Delta a)c$.

(o)|water (w) interface:

$$[CVSbCl_6]_{(o)} + 4H_2O + 2e \rightleftarrows CV^+_{(w)} + [Sb(OH)_4]^-_{(w)} + 6Cl^-_{(w)} + 4H^+_{(w)}. \quad (1)$$

The conventional redox potentials for reaction (1) vary from 0.78 (pH 2) to 1.0 V (pH 10). The optical density of the photometric organic layer decreases in proportion to the increase in the selenium(IV) concentration in the aqueous solutions analyzed. Selenium(IV) in the two-phase redox system exhibits the following specific features. The concentration of the Cl^- ions yielded by reaction (1) is sufficient for binding microamounts of Se(IV) into a chloride complex

$$HSeO_3^- + 6Cl^- + 5H^+ \rightleftarrows [SeCl_6]^{2-} + 3H_2O. \quad (2)$$

The Crystal Violet cation CV^+ acts as a phase-transfer catalyst transferring the substrate into the organic phase:

$$2CV^+_{(w)} + [SeCl_6]^{2-}_{(w)} \rightleftarrows [(CV)_2SeCl_6]_{(o)}. \quad (3)$$

Oxidation of the ion pair of the analyte proceeds as follows:

$$[(CV)_2SeCl_6]_{(o)} + 4H_2O - 2e \rightleftarrows SeO^{2-}_{4(w)} + 6Cl^-_{(w)} + 8H^+_{(w)} + 2CV^+_{(o)}. \quad (4)$$

Table 2. Parameters of the calibration dependence equations α(or β) = $(a \pm \Delta a)c + (b \pm \Delta b)$, detection limits, and ranges of detectable concentrations for the redox-photometric monitoring of the selenite and iodide ions ($n = 5$; $P = 0.95$).

Anion	Function	Parameter of equation		c_{min}, mg l^{-1}	c, mg l^{-1}
		$a \pm \Delta a$	$b \pm \Delta b$		
$HSeO_3^-$	α	48.6 ± 1.8	2.26 ± 0.13	5×10^{-5}	1×10^{-4}–1×10^{-3}
I^-	β	130 ± 6	0.012 ± 0.001	3×10^{-5}	1×10^{-4}–2×10^{-3}

The overall process can be described by the equation

$$[(CV)_2SeCl_6]_{(o)} + [CVSbCl_6]_{(o)} + 8H_2O \rightleftarrows 3CV^+_{(w)} + SeO^{2-}_{4(w)} + 12Cl^-_{(w)} + [Sb(OH)_4]^-_{(w)} + 12H^+_{(w)}. \quad (5)$$

The total concentration of Crystal Violet in the two-phase system remains unchanged. The calculations and experimental data suggest that reaction (5) goes at pH ≥ 6. This is the best pH value for selective determination of selenium(IV) in the presence of the variable-valence concomitant elements.

The measured parameter was the difference of the optical densities of the blank test A_0 and the analyzed solutions of the ionic associate A_{an}. We calculated the proportion of the ionic associate α_{as} that entered into the redox reaction, which is proportional to the selenium(IV) concentration: $\alpha_{as} = \Delta A/A_0$, where $\Delta A = A_0 - A_{an}$. The data obtained for the reaction of iodide ions with antimony(V) ionic associate suggest proceeding in the aqueous phase of the reactions yielding elemental iodine, a triiodide complex, and an ion pair of the analyte:

$$2I^- - 2e \xrightarrow[\leftarrow]{[CVSbCl_6]} I_2, \quad (6)$$

$$I_2 + I^- \rightleftarrows [I_3]^-, \quad (7)$$

$$CV^+ + [I_3]^- \rightleftarrows [CVI_3]. \quad (8)$$

In final stage (8), the Crystal Violet cation forms with the triiodide ion a product extracted with toluene.

The overall process occurring in the redox system can, apparently, be represented by the reaction

$$2[CVI_3]_{(o)} = [CVSbCl_6]_{(o)} + 4H_2O \rightleftarrows 3CV^+_{(w)} + 3I_{2(o,w)} + 6Cl^-_{(w)} + [Sb(OH)_4]^-_{(w)} + 4H^+_{(w)}. \quad (9)$$

Reactions (6)–(9) are confirmed by an increase in the optical density of the organic layer with increasing iodide concentration in the aqueous solution. Also, the calculated data proved to be identical to the experimental results for the standard solutions containing various amounts of the equimolar mixture of iodide ions and elemental iodine. To calculate the coefficients in the calibration dependence equation, we estimated the proportion β of the product of reaction (8): $\beta_{as} = \Delta A/A_0$, where $\Delta A = A_{an} - A_0$. The parameters A_0 and A_{an} designate the optical densities of the blank sample and the toluene solutions of the ionic associate subjected to photometric analysis, respectively. Table 2 lists the parameters of the calibration equations and detection limits of selenium(IV) and iodide ions. The c_{min} parameters were calculated using the tripled standard deviation of the background signal, taking into account the corresponding sensitivity coefficients.

The main advantage offered by the suggested redox-photometric techniques consists in selective determination of low concentrations of Se(IV) and iodide ions with the available instruments and reagents. The method we proposed successfully competes with state-of-the-art instrumental control methods [9–11]. Table 3 presents the results of the ion-chromatographic and redox-photometric analyses of the water available from some mineral water springs and central water supply systems, containing F^-, Cl^-, NO_3^-, SO_4^{2-}, I^-, and SeO_3^{2-} ions.

For analysis we used 5–7 samples of each mineral water brand. The Fisher's F and Student's t tests revealed no difference in the content of the analytes in different batches of the products with the same trademark or for containers made of different materials. The Vetluzhskaya mineral water contains, along with a large amount of chlorides and sulfates, increased concentrations of fluorides and nitrates compared to other mineral waters. The amount of the fluoride ions is identical to that calculated from the solubility product of the CaF_2 mineral. The Sarovo, Diveevskaya, Ya, and Borzhomi Rodniki mineral waters are characterized by low concentra-

* Waters characterized by the nitrite, bromide, and hydrophosphate content under c_{min}: [1–3] mineral waters: [1] Russia, Nizhni Novgorod oblast; [2] Russia, Vladimir oblast; [3] Georgia, Borzhomi (spring no. 1, Daba deposit) and [4] waters from the centralized water supply system (artesian wells).
** Determined by the redox-photometric method.

tions of the above-mentioned analytes in comparison with Gor'kovskaya-2 and Vetluzhskaya mineral waters.

The potentialities of the technique of interest were tested in analysis of some waters available from the central water supply systems. Among the tap waters from Nizhni Novgorod, Bor, Krasnye Baki, and Nizhni Novgorod oblast, the maximal content of sulfate ions and increased concentration of chlorides and nitrates are characteristic of Nizhni Novgorod water. The lowest concentration of the analyzed anions is observed for the tap water from Krasnye Baki settlement, extracted from a 75-m-deep artesian well. Interestingly, the Vetluzhskaya mineral curative table potable water with the anionic composition essentially different from that of the above-mentioned waters is extracted from a deeper aquifer well in the same raion of the Nizhni Novgorod oblast. For all the tap waters analyzed (Table 3) the content of each of the analytes is below the maximum permissible concentration established by the valid sanitary regulations.

As to the content of the selenite and iodide ions in the water from mineral water springs and the central water supply systems, we obtained the following results. In most cases, the concentration of these biogenic anions is equal to the background level, which validates the iodine and selenium deficiencies characteristic of waters in Nizhni Novgorod and Vladimir oblasts. Increased content of selenium(IV) was revealed for the Vetluzhskaya and Borzhomi Rodniki mineral waters. The water from the Borzhomi deposit is characterized by increased content of iodide ions, which is a distinctive feature of the Caucasian region waters. Despite the difference in the salt compositions of these mineral waters, the content of the fluoride and selenite ions (along with a high mineralization) for the Vetluzhskaya water and the iodide and selenite concentrations for the Borzhomi Rodniki water are suitable as authenticity labels for traded products.

Thus, by contrast to waters available from central water supply systems, mineral waters are characterized by diversified anionic compositions. In each case, the nature and concentration of the anions are predetermined by the geochemical processes of formation of natural waters in a specific region. The impurities contained in the waters can have both anthropogenic and technogenic origins. Hence, the authenticity of mineral waters can be established only on the basis of a complete set of data on the content of the macro- and microcomponents (including toxic and biogenic species).

CONCLUSIONS

(1) An ANIEKS-N selective anion exchanger and a carbonate eluent were suggested for decreasing the detection limits and improving the resolution

of the ion-chromatographic determination of the F^-, Br^-, NO_2^-, and NO_3^- toxic ions in potable waters.

(2) The redox-photometric method utilizing the antimony(V) ionic associate as the selective oxidizing agent provides information about the content of nanogram amounts of biogenic Se(IV) and I(I) species in waters from mineral water springs and central water supply systems.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Sorption of Cs^+ and Sr^{2+} by Ion Exchanger Based on Titanium Phosphate

M. V. Maslova, L. G. Gerasimova, and N. V. Motina

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received November 2, 2007

Abstract—Sorption capacity of a composite ion exchanger based on titanium phosphate for Cs^+ and Sr^{2+} cations was studied. The effect of pH and concentration of salts and, in particular, sodium chloride in solution on the sorption efficiency and distribution coefficient was analyzed. The diffusion coefficients were calculated for the Cs^+ and Sr^{2+} cations and the time of half-exchange of the Na^+ cation for the Cs^+ and Sr^{2+} cations was found.

DOI: 10.1134/S107042720805008X

An inevitable consequence of exploitation of any object at which radioactive substances are mined, processed, or used is that a liquid radioactive waste (LRW) is formed. The considerable decrease in the volume of the final radioactive product in selective sorption predetermines the advantage of this technique over other methods for LRW processing because of its ability to concentrate radionuclides in a small volume of a sorbent. The sorption material should exhibit selectivity and high capacity for the radionuclides being recovered, possess a certain chemical stability and mechanical strength, and be readily available and stable in prolonged storage. Ion-exchange materials based on titanium phosphates have selective properties with respect to Cs^+ and Sr^{2+} radionuclides [1–3]. Granulated titanium phosphate can be used for a long time in contact with weakly alkaline or weakly acidic aqueous media without being changed to any significant extent. The observed disintegration of the material is slow and not catastrophic [4, 5]. It is known that spent inorganic ion exchangers are well compatible with cement matrices. A heat treatment of a mixture of this kind before disposal can markedly diminish the volume of radioactive waste [6]. All these prerequisites make titanium phosphates a promising collector of radionuclides.

This study is concerned with ion-exchange properties of a new composite sorbent that contains, in addition to titanium(IV) phosphate, hydrated silica, up to 3 wt % in terms of SiO_2. The conditions in which a material of this kind can be obtained were described in detail in [7–9].

EXPERIMENTAL

The composite sorbent was studied in the Na^+ form. Cs^+ and Sr^{2+} cations were sorbed under static conditions from chloride solutions of concentration 0.01 M in terms of Cs^+ and Sr^{2+} cations. A 0.5-g portion of the sorbent was brought in contact with a solution with a prescribed pH value adjusted by addition of 1 N solutions of NaOH or HCl. The liquid to solid phase mass ratio was 1 : 200. After the equilibrium was attained, the solution was separated from the sorbent, the filtrate was analyzed, and the analytical data were used to calculate the amount of the adsorbed substance in weight percent relative to the initial value. Figure 1 shows

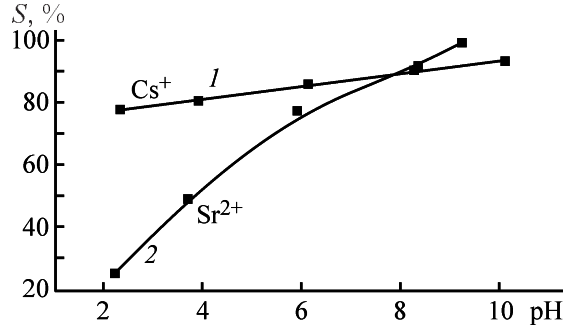

Fig. 1. Sorption of Cs^+ and Sr^{2+} cations from chloride solutions vs. pH. (*S*) Degree of sorption.

data on the sorbability of Cs^+ and Sr^{2+} in the pH range 2–10.

The behavior of heavy metal cations in sorption by titanium phosphate is determined by the number and quality of functional groups and by the structure of the sorbent. As regards the composite sorbent, it can be stated that the degree of sorption increases with pH for the elements studied. The presence of strongly acidic groups in the ion exchanger enables efficient purification of solutions to remove Cs^+ ions even at low pH values. The maximum degree of sorption for this ion is 92%, or 245 mg g^{-1}. The strong affinity of phosphate sorbents for Cs^+ is accounted for by the specific interaction of phosphate groups of the ion exchanger with the low-hydrated cesium ion.

The sorption activity of titanium phosphate toward the strontium cation strongly depends on pH of the starting solution. As the basicity of the solution increases, the degree of dissociation of the functional groups of the sorbent grows and, as a result, its ion-exchange capacity becomes higher. The composite ion exchanger under study, which contains titanium(IV) phosphate, is a microporous material and, therefore, the ion exchange is sterically hindered. The capacity of such an ion exchanger for strontium ions is 80 mg g^{-1} in acid media and becomes more than two times higher at pH 9–10.

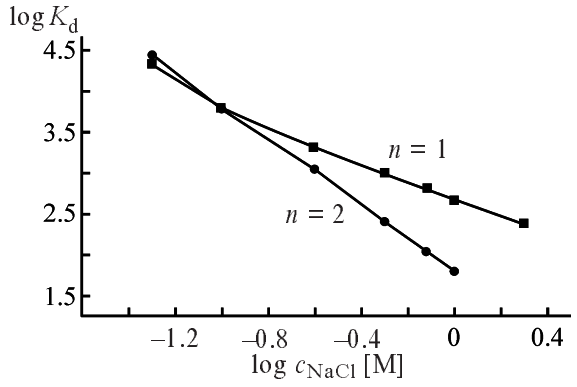

Fig. 2. Distribution coefficient K_d of cesium (n = 1) and strontium (n = 2) cations vs. the initial concentration c_{NaCl} in solution.

In a study of the sorption capacity of the ion exchanger in salt systems and, in particular, in a sodium chloride solution of concentration 0.05–2 M, the content of the microelement was 0.01 M and the l : s ratio was 1 : 200 (Table 1).

As the concentration of the electrolyte increases, the distribution coefficient K_d becomes smaller, which indicates that the sorption occurs by the ion-exchange mechanism. At up to 0.5 M of NaCl contained in the system, the distribution coefficient for Cs^+ is 10^4–10^3, and raising the NaCl concentration to 1–2 M leads to a decrease in K_d; for Sr^{2+}, K_d becomes less than 10^2. The selectivity can be regarded as a competition of cations of the solution, functional groups of the ion exchanger, and water molecules of both phases for the solvation of the ion being exchanged. Because of their dehydrating activity, the selectivity in concentrated salt solutions is higher for a larger ion (cesium), whose solvation demands are weaker than those of strontium ion.

According to the mass action law, the ion exchange in concentrated electrolyte solutions is expressed by the equation [10]

$$\log K_d = B - n\log c,$$

where c is the equilibrium electrolyte concentration; B, constant including the maximum exchange capacity of the ion exchanger and the exchange constant; and n, slope of the straight line, numerically equal to the ratio between the charges of the ion being exchanged and the ion of the macrocomponent.

This expression is valid at an insignificant intrusion of the electrolyte into the solid phase and a constant ratio between the activity coefficients. In the case of an ideal exchange, the distribution coefficient as a function of the electrolyte concentration should be expressed by a straight line with a slope n = 1 in Na^+–Cs^+ exchange and n = 2 for Na^+–Sr^{2+}. Data processing in terms of this equation suggests that the exchange of Cs^+ and Sr^{2+} ions at electrolyte concentrations in the range 0.05–2 M is nearly ideal (Fig. 2).

To analyze the statics of the interphase distribu-

tion, a set of samples with different concentrations of Cs^+ and Sr^{2+} ions in a 0.05 N solution of NaCl were prepared. The sample volume was 200 ml; weighed portion of the sorbent, 0.5 g; and time of contact between the phases, two weeks. During this time, an empirical equilibrium was attained in the system and dependences of the cesium and strontium concentrations in the sorbent on their equilibrium concentrations in solution were obtained using analytical data.

As seen from the results obtained (Fig. 3), the ion exchanger has a good sorption capacity for the metal ions under study. All the isotherms show a steep rise in the range of low equilibrium concentrations of these ions and a saturation limit from which the static capacity of the sorbent under the chosen conditions can be estimated. The amount of the cation absorbed by the ion exchanger steadily grows as its content in the starting solution increases to 400 mg l^{-1} and then remains constant, which is due to appearance of a diffusion hindrance to transport of cations across a layer of new formation on the sorbent surface. According to the degree of sorption (Fig. 4), the ion exchanger under study provides virtually complete purification to remove metal ions in solutions with initial concentrations of up to 200 mg l^{-1}.

For a more detailed analysis of the exchange of these ions, the Na^+–M^{n+} exchange constants (M^{n+} = Cs^+, Sr^{2+}) were determined by the static method at pH 7 (Table 2). The value of the ion exchange constant enables evaluation of the preferential sorption of one of the two ions being exchanged. The concentration exchange constant was calculated in accordance with the exchange reactions

$$Cs^+ + R\text{–}Na \rightleftarrows RCs + Na^+,$$

$$Sr^{2+} + 2R\text{–}Na \rightleftarrows R_2Sr + 2Na^+,$$

where R is the matrix of the ion exchanger with a bonded exchanging ion,

$$K = \bar{c}_{Cs^+} c_{Na^+}/(\bar{c}_{Na^+} c_{Cs^+}),$$

$$K = (\bar{c})^{1/2}_{Sr^{2+}} c_{Na^+}/(\bar{c}_{Na^+} c^{1/2}_{Sr^{2+}}),$$

where $\bar{c}_M$ is the concentration of the ions in the ion exchanger (mg-equiv g^{-1}), and c_M is that in solution (mg-equiv ml^{-1}).

The data obtained indicate that, in exchange of Na^+ for Cs^+, the exchange constant remains constant in the whole concentration range and independent of the ionic composition of the ion exchanger. The low-hydrated cesium ion is easily transferred into the inner zones of the ion-exchanger matrix and the ion exchange occurs without any noticeable hindrance. The average value of the exchange constant is 55.2, which is close to the data obtained previously [11] in a study of the sorbability of cesium on zirconium(IV) phosphates. In exchange of Na^+ for Sr^{2+} at solid phase compositions with an equivalent fraction $N_M < 0.3$, the exchange constant K_{ex} is virtually independent of the ionic composition of the ion exchanger and has an average value of 3.63, whereas at $N_M > 0.3$, K_{ex} sharply decreases. This fact can be accounted for by steric hindrance to incorporation of cations into the sorbent matrix and by the action of repulsion forces of likely charged counterions. The values obtained for the Na^+–Sr^{2+} exchange constant are an order of magnitude smaller than those for Na^+–Cs^+.

under study in solution was 100 mg g^{-1}; volume of the contact solution, 200 ml; and weighed portion of the sorbent, 1 g. The sorption was performed at pH 7.5; the starting solutions were thermostated at a prescribed temperature for 1 h and then the sorbent was introduced. The sorption was carried out with vigorous stirring at 300 rpm. By taking samples at certain intervals of time, the manner in which the concentration of the solution in contact with the ion exchanger varies until equilibration was determined.

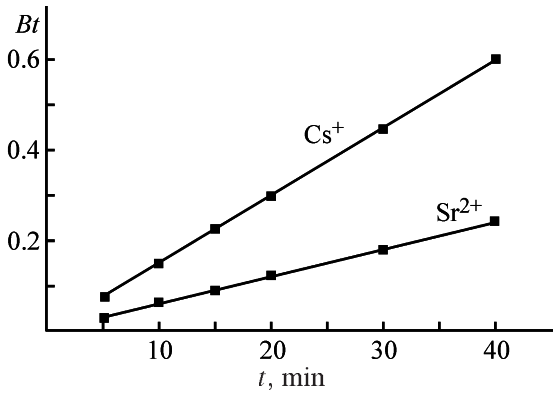

Fig. 5. Bt vs. time t.

The limiting stage of the process was determined by the interruption method. It was found that, after the process is interrupted, the absorption rate of the ions increases. Such a behavior is characteristic of the gel kinetics, in which the sorption rate depends on the diffusion of ions within the matrix of the ion exchanger.

The kinetic characteristics of the ion-exchange process whose limiting stage is the gel diffusion was approximately calculated using the rate equation of

the isotope exchange at a constant ion concentration in solution (Boyd's equation):

$$F = 1 - (6/\pi^2)\sum_{n=1}^{\infty}(1/n^2)\exp(-Dt\pi^2 n^2/R^2),$$

where $D\pi^2/R^2 = Bt$ is the kinetic coefficient; F, degree of equilibration; t, time (s); R, radius of ion exchanger particles (m); D, diffusion coefficient ($m^2\ s^{-1}$); and natural numbers n range from unity to infinity.

The degree of equilibration F was calculated by the formula $F = SEC_t/SEC_\infty$, where SEC_t and SEC_∞ ($mg\ g^{-1}$) are the amounts of ions sorbed by instant of time t and on reaching the maximum sorption. After an experimental determination of the degree of equilibration F by a prescribed time t, the dependences $Bt = f(t)$ were plotted using the reference value of Bt [13]. The plots (Fig. 5) are straight lines with a slope equal to B, which confirms the gel-diffusion control of the ion exchange on the ion exchanger under study. The diffusion coefficients were calculated by the formula $D = Btr^2/t\pi^2$ (Table 3).

The average values of the diffusion coefficient are 2.56×10^{-7} $cm^2\ s^{-1}$ for cesium ions and 1.01×10^{-7} $cm^2\ s^{-1}$ for strontium ions. The half-exchange time calculated by the formula $t_{1/2} = 0.03r^2/D$ is 1.5 min for Cs^+ and 50 min for Sr^{2+}.

CONCLUSIONS

(1) In a study of the sorption capacity of a composite ion exchanger based on titanium(IV) phosphate for Cs^+ and Sr^{2+} cations, the optimal range of pH values of solutions, in which the maximum degree of their purification is achieved, was found and substantiated.

(2) Raising the concentration of salts and, in particular, sodium chloride in solutions is accompanied by a decrease in the sorption efficiency, with a lower distribution coefficient characteristic of the more hydrated Sr^{2+} cation.

(3) The diffusion coefficients were calculated for the Cs^+ and Sr^{2+} cations and the time of half exchange of the Na^+ cation for the Cs^+ and Sr^{2+} cations was determined.

(4) The data obtained can be used for optimizing the purification of radionuclide-contaminated process wastewater.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Critical Parameters of Tetraethyltin and Its Chlorine Derivatives

I. B. Sladkov and M. A. Shmakova

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received March 4, 2008

Abstract—Critical parameters of tetraethyltin and its chlorine derivatives were estimated by calculation methods. Reliability of the results obtained was confirmed by three independent methods.

DOI: 10.1134/S1070427208050091

Applications of organometallic compounds are steadily expanding and include such important chemical technologies as organic synthesis and fabrication of metallic coatings, plastics, semiconducting materials, etc. [1, 2]. Many organometallic compounds can be considered as derivatives of tetraethyltin $Sn(C_2H_5)_4$. The properties of tetraethyltin and its derivatives are studied poorly. For example, data on the critical parameters of these substances are lacking. At the same time, knowledge of these parameters allows many physicochemical properties to be predicted by calculation procedures based on the thermodynamic similarity theory [3, 4].

The goal of this study was to obtain data on the critical parameters of tetraethyltin and its chlorine derivatives. The choice of compounds was governed by the fact that available data on the properties of these compounds, from which the critical parameters may be predicted, are scarce.

The critical parameters (temperature T_{cr}, volume V_{cr}, and pressure P_{cr}) were calculated by formulas [5] that were already used for predicting the critical parameters of organometallic compounds.

$$T_{cr} = T_b/\theta, \quad (1)$$

$$V_{cr} = 80\Pi - 11, \quad (2)$$

where θ is the reduced temperature at the boiling point (T_b/T_{cr}), which was calculated by the relationship

$$\theta = 0.092\ln\Pi + 0.515, \quad (3)$$

where Π is parachor. Its numerical values were taken from [6, 7].

$$P_{cr} = 1.039T_{cr}/b, \quad (4)$$

where b is the van der Waals constant, which was calculated through the molar volume of a liquid at the boiling point by the equation [6]

$$b = 1.27V_b - 6. \quad (5)$$

The input data and the calculation results are listed in Table 1.

The reliability of the results obtained was assessed by three independent procedures. In the first procedure, the accuracy of the calculation formulas was checked with compounds that are thermodynamically similar to tetraethyltin, with the experimental critical parameters available from the literature. To such compounds belong tetraethylsilane and its chlorine derivatives. The input data are taken from [5], and the calculation results are listed in Table 2.

Table 1. Physicochemical properties of tetraethyltin and its chlorine derivatives [8–10]

Compound	Π, $J^{1/4}\ cm^{5/2}\ mol^{-1}$	T_b, K	V_b, $cm^3\ mol^{-1}$	T_b, K	V_{br}, $cm^3\ mol^{-1}$	P_{cr}, MPa
$Sn(C_2H_5)_4$	7.92	451.4	228.7	640	622	2.34
$Sn(C_2H_5)_3Cl$	7.13	483.0	202.6	694	559	2.87
$Sn(C_2H_5)_2Cl_2$	6.34	493.2	174.1	720	496	3.48
$Sn(C_2H_5)Cl_3$	5.55	468.0	155.8	696	433	3.77

Table 2. Error in calculating the critical parameters by Eqs. (1)–(5)

Compound	Calculation error, %		
	T_{cr}	V_{cr}	P_{cr}
$Si(C_2H_5)_4$	1.0	0.1	–8.8
$Si(C_2H_5)_3Cl$	0.7	0.5	–5.3
$Si(C_2H_5)_2Cl_2$	–0.1	1.1	0.6
$Si(C_2H_5)Cl_3$	–0.3	–1.6	–0.4
Mean absolute error	0.5	0.8	3.8

As seen from Table 2, the calculation equations used can ensure reasonably adequate prediction of the critical parameters for substances that are similar to those under consideration.

The second procedure for assessing the reliability of the results obtained consisted in the following. At present, methods based on the thermodynamic similarity theory with critical parameters of a substance as input data are used to predict with high reliability the density of molecular liquids. Experimental data on the density of liquid tetraethyltin at various temperatures are available from the literature [10]. The density was calculated from the equation based on the thermodynamic similarity theory using the T_{cr} and V_{cr} values obtained in this study. The comparison of the calculated densities with the experimental data can serve as criterion of the reliability of the critical parameters obtained. For this purpose, we calculated the density of liquid $Sn(C_2H_5)_4$ by the Matias equation [6]:

$$\rho = (M/V_{cr})[2(2 - T/T_{cr})]. \quad (6)$$

The calculation results are given in Table 3. As can be seen, they are similar to the experimental data.

Finally, the reliability of calculation of the critical parameters can be checked by a procedure of comparative calculation [6]. The procedure is based on the fact that, for similar substances, there is a linear correlation in variation of one property in two different series of the compounds (alternative 1) or of two different properties in the same series of the compounds (alternative 2).

The variation of each critical parameter in two series of similar substances was studied using alternative 1. Each series begins with tetraethyl derivative and ends with tetrachloride: EEt_4–EEt_3Cl–EEt_2Cl_2–$EEtCl_3$–ECl_4, where the E denotes element (Si or Sn) and Et, C_2H_5. The plot for the critical volume is shown in Fig. 1 as example. The scale of the critical volumes of the silicon compounds is given along the abscissa, and the scale of the critical volumes of the corresponding tin compounds, along the ordinate.

Table 3. Error in calculating the density of liquid $Sn(C_2H_5)_4$ from the critical parameters found in this study

T, K	ρ(calc.)	ρ(exp.) [10]	Deviation, %
	g cm^{-3}		
273	1.232	1.222	0.81
289	1.212	1.203	0.76
305	1.193	1.184	0.71
329	1.163	1.156	0.64
337	1.154	1.147	0.61
353	1.134	1.128	0.56
Mean error, %			0.7

The variations of the critical parameters with respect to any other property in the series of tin compounds, $SnEt_4$–$SnEt_3Cl$–$SnEt_2Cl_2$–$SnEtCl_3$–$SnCl_4$, were studied by alternative 2. The critical

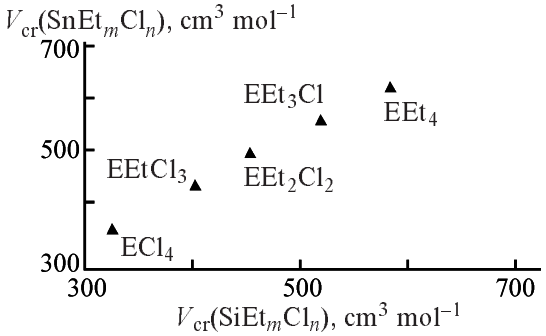

Fig. 1. Variation of the critical volume V_{cr} in the series of chlorine derivatives of tetraethyltin and tetraethylsilane.

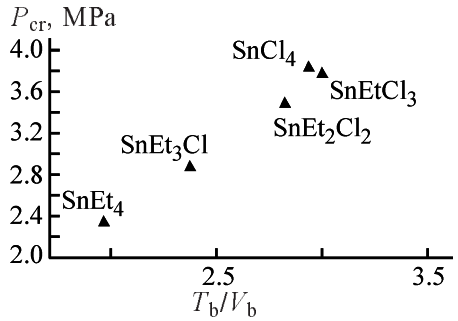

Fig. 2. Critical pressure P_{cr} vs. the T_b/V_b ratio in the series of similar tin compounds.

Table 4. Correlation coefficient r and root-mean-square error s for the dependences obtained by the comparative calculation procedure

Property	Alternative	Correlation	r	s
T_{cr}	1	Si compounds–Sn compounds	0.846	3.9
V_{cr}	1	Si compounds–Sn compounds	0.999	0.8
P_{cr}	1	Si compounds–Sn compounds	0.921	7.8
T_{cr}	2	T_{cr}–T_b	0.986	1.2
V_{cr}	2	V_{cr}–$\prod$	0.998	1.4
P_{cr}	2	P_{cr}–T_b/V_b	0.993	2.3

pressure vs. the ratio of the temperature to the molar volume at the boiling point is plotted in Fig. 2 as example.

The parameters of all the correlations considered, obtained by the comparative calculation procedure, are listed in Table 4. As can be seen, the degree of linearity is always high and the root-mean-square error is always comparatively small.

The data presented confirm reliability of the critical parameters of tetraethyltin and its chlorine derivatives obtained in this study.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Correlation of Charge Transfer and *d–d* Transition Spectra of Cobalt(II) Bromide Solutions in Trimethyl Phosphate

T. S. Markova and O. V. Yanush

St. Petersburg State Technological University of Vegetable Polymers, St. Petersburg, Russia

Received June 2, 2006

Abstract—Solutions of cobalt(II) bromide in trimethyl phosphate were studied by electronic spectroscopy at 20 and 60°C.

DOI: 10.1134/S1070427208050108

The data on the charge transfer (CT) and *d–d* transition spectra of transition metal complexes in relation to the composition of an interglass polymeric matrix are necessary for developing modern light-variable and energy-saving glasses. Trimethyl phosphate (TMP) is known as a plasticizer of polymeric compounds used for this purpose. It has a high donor number and a low solvating power with respect to halide ions, which makes it possible to study properties of the entire diversity of cobalt(II) complexes and to find general relationships of their mutual transformations depending on temperature, which is necessary for optimizating the properties of chromogenic materials.

Charge transfer spectra of transition metal halide complexes originate from the excitation of electrons on σ- and π-bonding or nonbonding orbitals localized predominantly on the ligand, with the transfer of these electrons onto vacant σ- and π-antibonding orbitals mainly localized on the central metal atom [1]. The CT spectra of cobalt tetrahalide complexes $[CoHal_4]^{2-}$ (Hal is a halide ion) have been studied in detail in crystals [2–4] and solutions [3, 4]. However, the dependence of the spectral position and intensity of CT bands on the metal coordination number and on the covalence of M–L bonds [2–5] were not studied. Furthermore, actually it was not determined whether the CT and *d–d* transition spectra could be assigned to the same complexes. At the same time, these problems are of basic importance for developing light-variable materials [6–8], as CT spectra can be used for shielding undesirable short-wave solar radiation.

To study spectroscopic features and correlations of CT and *d–d* absorption bands for each type of complexes (with different symmetry and different numbers of halide ions), we have chosen solutions of cobalt(II) bromide complexes in TMP as a model system. Furthermore, this solvent is one of plasticizers of polymeric compounds suitable for fabricating light-variable devices.

The results of this study can be used for developing real thermochromic systems (solutions and films) with variable optical transmission, which should contain water as an essential component [7, 8, 11] and should be highly concentrated with respect to the content of pigments (0.1–1.0 M). Therefore, we studied in addition the relationships of the complex formation as influenced by the water content of the system.

EXPERIMENTAL

To prepare solutions of cobalt nitrate $[Co(NO_3)_2 \cdot 6H_2O]$ or bromide $(CoBr_2 \cdot 6H_2O)$ in TMP with LiBr additions, we used 0.5 M solutions of these salts (pure grade). Correspondingly, such solutions contained no less than 3 M H_2O. The content of anhydrous LiBr was varied within the limits of its solubility (0–7.5 M). In what follows, we will designate such systems as $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP.

To reveal the role of water in the complex formation, it was added to the anhydrous system $CoBr_2$–LiBr–TMP in amounts of 0–13 M. Anhydrous cobalt bromide was prepared by calcining $CoBr_2 \cdot 6H_2O$ at 130–140°C for 8 h.

Preliminarily it was shown by IR spectroscopy of TMP–H_2O solutions (analytical frequency 3350 cm^{-1}) that 1 mol of TMP is capable of binding

up to 0.25 mol of water; at a higher water content, its state changes, as seen from a break of the plot of the optical density at $\nu = 3350$ cm^{-1} vs. water concentration. Trimethyl phosphate dried for 400 h over dehydrated (for 7 h at 200°C) $MgSO_4$ was purified by vacuum distillation. According to the IR spectral data, the solution thus obtained contained less than 0.25 M H_2O. The study of the effect of water additions was also of practical interest, as an increase in its content can enhance the performance of thermochromic materials [7, 8].

Cobalt(II) bromide solutions in TMP were prepared at 60°C, and "freshly prepared" samples were studied (*d–d* transitions and CT spectra were measured within 1–2 h after the synthesis), as the solutions are unstable. With time, especially at elevated temperatures, a solid phase is formed in the solutions. According to the IR spectra, it is a product of the reaction of lithium bromide with TMP (when lithium bromide is added to TMP, a band in the region of 3350 cm^{-1} appears in the IR spectrum of TMP, which disappears upon precipitation of the solid phase). These reactions, which proceed slowly at room temperature (in the course of days and weeks) and faster on heating, were monitored by electronic absorption spectra taken at certain intervals, in particular, every 15–20 min during heating at 100°C until a stable chemical equilibrium was attained in solutions. It was found that in the anhydrous system $CoBr_2$–LiBr–TMP the decomposition of high-halide anionic complexes and the formation of low-halide onium complexes are faster than in the system $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP containing water.

The IR and electronic absorption spectra of solutions were recorded on computerized Specord M-80 and Specord M-40 spectrophotometers at a spectral slit width from 20 to 40 cm^{-1} at 20 and 60°C in quartz or fluorite cells temperature-controlled to within 1°C.

The spectra of individual complex species were resolved from the total electronic spectra by the Wallace–Katz method [12] consisting in the determination of the number of linearly independent rows of the optical density matrix at fixed frequencies in each experimental spectrum, which allowed the number of the complexes coexisting in solutions to be objectively estimated. To determine the structure of CT and *d–d* absorption bands more precisely, we examined even derivatives of the initial spectra.

The extinction coefficients of the strongest absorption bands of the resolved spectra belonging to individual complexes were calculated by the balance equation

$$\Sigma (D_i/\varepsilon_i) = c_{MCo^{2+}}, \quad (1)$$

where D_i is the optical density in the absorption band maximum; ε_i, peak extinction coefficient (l cm^{-1} mol^{-1}); and $c_{MCo^{2+}}$, total cobalt concentration in solution, M.

To obtain additional information on the properties of complexes,[1] we studied positions of centers of gravity λ_{cg} [Eq. (2)], integral extinction coefficient [Eq. (3)], and effective half-width of *d–d* absorption bands [Eq. (4)] as functions of the content of bromide ions in solutions.

$$\lambda_{cg} = \int_{400}^{800} D(\lambda)\lambda d\lambda / \int_{400}^{800} D(\lambda) d\lambda, \quad (2)$$

$$\varepsilon^{int} = \int \varepsilon(\lambda) d\lambda, \quad (3)$$

$$\Delta\lambda_{eff} = \left[\int D(\lambda) d\lambda / D^{max} \right] \quad (4)$$

(the integrals were taken within the limits of the band contour).

The dependence of the absorption spectra of freshly prepared $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP solutions on the concentration of bromide ions is shown in Fig. 1. Absorption bands assignable to cobalt(II) "internal" *d–d* transitions in octahedral [$^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$] or tetrahedral [$^4A_2(F) \rightarrow T_1(P)$] complexes are observed in the visible region, in the range 460–520 nm or 550–750 nm, respectively. The CT spectra caused by "intraligand transitions" (200–250 nm) [13, 14] and by transitions in cobalt(II) complexes between molecular orbitals localized on the ligand and metal ions (250–320 nm) [2–4] are located in the UV region.

The study of even derivatives of the spectra, especially in the region of $\nu_{max} = 700$ nm (Fig. 2), and the analysis by the Wallace–Katz method [12] allowed us to reveal four types of complexes in the whole examined range of bromide ion concentrations. We found only two species, $[CoBr_4]^{2-}$ and $[Co(TMP)Br_3]^-$, in the range of ratios Br/Co = 4.5–

[1] Mathematical treatment of the spectra and their resolution into components were carried out using Matlab 6.0 and MicroCal Origin 7.1 program packages.

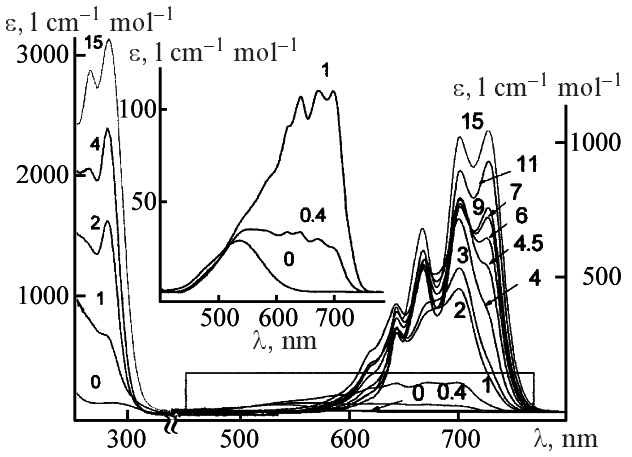

Fig. 1. Absorption spectra of "freshly prepared" $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP solutions; insert shows the spectra at Br/Co = 0–1. T = 20°C, c_{Co} = 0.5 M. (ε) Molar extinction coefficient and (λ) wavelength; the same for Figs. 3 and 7. Figures at curves are the initial Br/Co molar ratios; the same for Fig. 2. The range 200–350 nm corresponds to the CT spectra, and the range 400–900 nm, to *d*–*d* transition spectra.

15. Examples of the resolution of spectra of the $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP system into components are shown in Fig. 3.

As a result, in the visible region we have resolved the spectra corresponding to $[Co(TMP)_2Br_2]$, $[Co(TMP)Br_3]^-$, and $[CoBr_4]^{2-}$. Less reliably we resolved the spectra tentatively assignable to $[Co \cdot (TMP)_x(H_2O)_{6-x}]^{2+}$ and $[Co(TMP)_x(H_2O)_{5-x}Br]^+$, for which we failed to determine the TMP/H_2O ratio. We found that the resolution by the same procedure in the whole examined wavelength range (200–900 nm) automatically leads to constant (independent of solution composition) spectra for the revealed complex species in both the visible and UV ranges. The spectral forms of absorption bands found in the UV and visible ranges are shown in Fig. 3c, and the diagram of the content of complexes built using Eq. (1), in Fig. 4.

The validity of this diagram (Fig. 4) is supported by the dependences of the effective half-width $\Delta\lambda_{eff}$ and intensities of the spectra in maxima on the system composition. We found that the enrichment of a solution with one type of complexes, i.e., without overlap of absorption bands of different complexes, results in a decrease in $\Delta\lambda_{eff}$ and in the appearance of relatively narrow strong bands in accordance with the speciation diagram, for both CT and *d*–*d* bands. Spectroscopic characteristics of *d*–*d* absorption bands and CT bands (these latter are determined

less accurately because of overlap with intraligand bands) of the complexes revealed in the $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP system are given in the table.

Coincidence of the data on the content of complexes (Fig. 4), found by the analysis of CT and *d–d* transitions, confirms the assignment of the spectra in the UV and visible regions to the same complexes. When the composition of complexes varies owing to variations in the ligand field strength and in the symmetry of environment, spectral properties of the *d–d* and CT bands (see table, Fig. 5) correlate with each other. Sequential replacement of trimethyl phosphate ligands by bromide ions in the inner coordination sphere of tetrahedral cobalt complexes gives rise to a gradual increase in the extinction coefficients of *d–d* and CT absorption bands (ap-

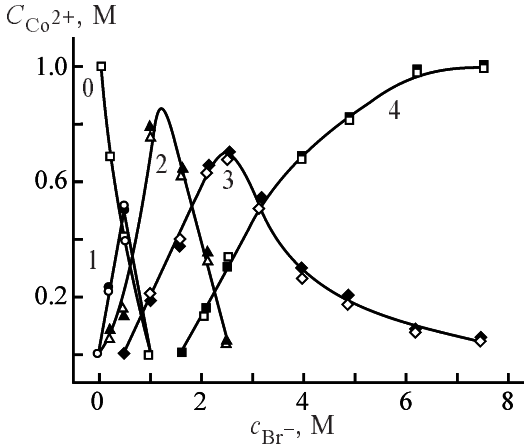

Fig. 4. Relative content of complexes in $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP solutions at 20°C, calculated on the basis of resolution of the visible spectra (*d–d* transitions, "filled" symbols) and UV spectra (CT, empty symbols) into components. ($c_{Co^{2+}}$) Concentration of cobalt(II) ions and (c_{Br^-}) concentration of bromide ions.

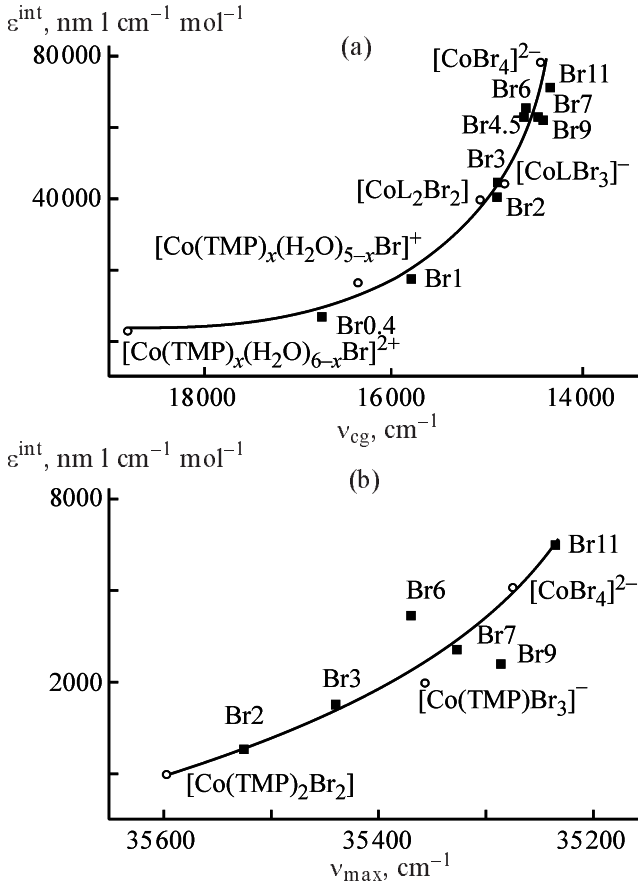

Fig. 5. Correlation of the dependences of extinction coefficients and positions of the maxima for (a) *d–d* and (b) CT bands in the resolved spectra of the indicated complexes (empty symbols) and in the total spectra of $Co(NO_3)_2 \cdot 6H_2O$–LiBr–TMP solutions (filled symbols; Br*N*, ratio of the initial molar concentrations Br/Co in solutions). (ε^{int}) Integral molar extinction coefficient, (ν_{cg}) position of the center of gravity of the absorption band, (ε_{max}) molar extinction coefficient in the maximum, and (ν_{max}) frequency of the maximum.

proximately twofold for both peak extinction coefficients of low-frequency maxima in CT spectra and integral extinction coefficients of *d–d* absorption bands), accompanied by their long-wave shift.

This correlation can be accounted for by the fact that, in the charge transfer, an electron is transferred from a ligand molecular orbital [2] to the same excited level of Co^{2+} *d* shell as in the *d–d* transition. The low-frequency shift of *d–d* absorption bands can be interpreted as a consequence of the fact that the ligand field becomes weaker as the fraction of bromide ions in the complex increases. For the examined absorption bands of *d–d* transitions, the shift ν_{cg} of the center of gravity is 1300 cm^{-1} in going from $[Co(TMP)_2Br_2]$ to $[CoBr_4]^{2-}$, and for low-frequency components of the CT spectrum, ~300 cm^{-1} (Fig. 5). This difference is attributable to the fact that *d–d* transitions occur from the $^4A_2(F)$ term and that the position of its center of gravity does not remain constant on varying composition of complexes.

As to the intensity of the spectra, according to the common reasoning [1], it can be expected that the oscillator strength of *d–d* transitions should increase as the symmetry of complexes decreases in the series $[CoBr_4]^{2-} > [Co(TMP)_2Br_2] > [Co(TMP)Br_3]^-$. This fact, together with the shift of bands toward the region of maximum sensitivity of human eye, would be attractive for developing materials with variable optical transmission. However, actually the trend is opposite (see table, Fig. 5). Similar trend was also found in the Co^{2+} (0.05 M)–LiBr (14 M)–LiCl (0–10 M)–H_2O system containing Br^- and Cl^- ligands strongly differing in the field strength. Here the extinction coefficients of the absorption bands decreased monotonously in the order $[CoBr_4]^{2-} > [CoBr_2Cl_2]^{2-} > [CoBrCl_3]^{2-} > [CoCl_4]^{2-}$ (Fig. 6).

The preservation of the high symmetry and "fine" structure of mixed tetrahalide complexes is attributable to certain delocalization of bonds and collectivization of the electron density in coordination compounds [1]. The preservation of strictly tetrahedral symmetry in the complexes $[CoBr_4]^{2-}$, $[Co(TMP)\cdot Br_3]^-$, and $[Co(TMP)_2Br_2]$ and the closeness of TMP and bromide ions in the ability for covalent bonding are manifested in the fact that, to a first approximation, even derivatives of the spectra of *d–d* transitions reveal the same maxima for different complexes (Fig. 2).

It was found that in all the examined solutions the extinction coefficients increase as ν_{max} of *d–d* and CT bands is shifted to lower frequencies (Fig. 5). The trend is described by the relationship $\ln\varepsilon^{int} \sim (-\nu_{cg})$. This common dependence can be attributed to the fact that the overlap of the wave functions increases as the energy eigenvalues approach each other, which results in an increase of the transition matrix element determining the intensity of the absorption band.

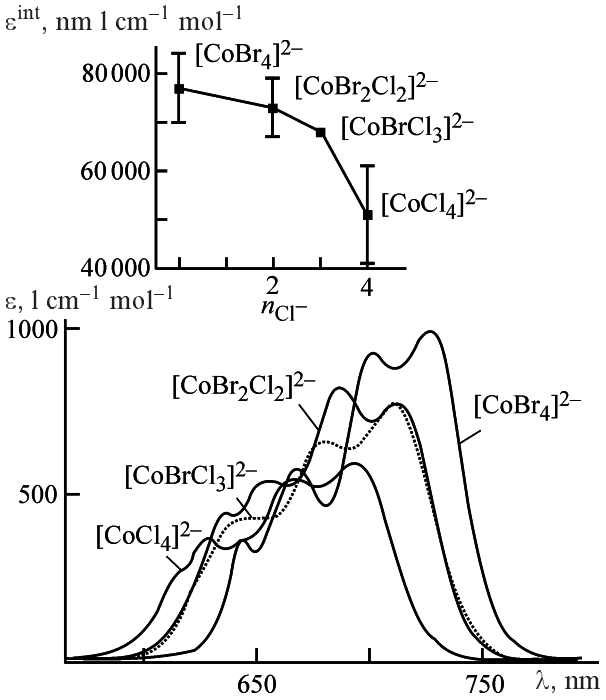

Fig. 6. Resolved components in the spectra of Co^{2+} (0.05 M)–LiBr (14 M)–LiCl (0–10 M)–H_2O solutions and a decrease in the integral extinction coefficients of *d–d* bands of these complexes in passing from $[CoBr_4]^{2-}$ to $[CoCl_4]^{2-}$ (insert). (ε^{int}) Integral molar extinction coefficient, (n_{Cl^-}) number of chloride ions in complexes, (ε) molar extinction coefficient, and (λ) wavelength.

It should be noted that the extinction coefficients of $[CoBr_4]^{2-}$ complexes for *d–d* bands (ε_{727} = 1000 ± 50 l cm^{-1} mol^{-1}) and CT bands (ε_{283} = 2500 ± 100 l cm^{-1} mol^{-1}) are characteristic and are the same in different media, e.g., in ethanol, water, and TMP. The outer-sphere effect of the solvent on the complex $[CoBr_4]^{2-}$ is manifested only in negligible (compared to the band width) shifts of the maxima, close to those observed for transition metals in nitrate melts [15]. The maximal shifts of the CT bands (about 300 cm^{-1} in the examined series of solvents) are larger by an order of magnitude than those for the *d–d* transitions (approximately 50 cm^{-1} in the same series), which is attributable to the weak effect of outer-sphere solvent molecules on the well-

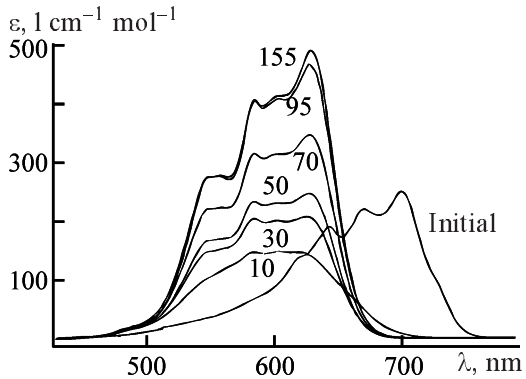

Fig. 7. Variation of the spectra of *d–d* transitions of TMP–$Co(NO_3)_2 \cdot 6H_2O$ (0.5 M)–LiBr (1 M) solution (Br/Co = 2) in the course of its heating at 100°C with the formation of an intermediate complex (10 min) and $[Co(TMP)_4]^{2+}$ (30, 50, 70, 95, and 155 min). The curve denoted as initial corresponds to the spectrum of the freshly prepared solution. Figures at curves denote heating time.

shielded levels of the *d* shell. The shifts of the CT bands are determined not only by the solvent effect on the excited state energy in the *d* shell, but also by the much stronger effect on the ligand electrons.

Unlike other high-donor solvents (e.g., H_2O), TMP has a low solvating ability toward bromide ions. Therefore, both TMP and bromide ions are equally capable to participate in the formation of the inner coordination sphere. It was found that the same spectral contour (Fig. 7, curves corresponding to 30, 50, 70, 95, and 155 min) appears in the spectra of all bromide systems under study (anhydrous and hydrated) and also of $Co(NO_3)_2 \cdot 6H_2O$–TMP and $CoI_2 \cdot 2H_2O$–TMP as a result of the ionization reactions

$$[CoBr_2(TMP)_2] + x\text{TMP} \rightarrow [CoBr_{2-x}(TMP)_{2+x}]^{x+} + x\text{Br}^-$$

occurring on heating, and also on long-term (for more than 1 month) storage of cobalt bromide solutions in TMP at room temperature. However, the complex giving this spectrum is not formed under the same conditions in cobalt chloride solutions in TMP. A high extinction coefficient (ε_{580} = 400 l cm^{-1} mol^{-1}), its weak temperature dependence, and also the structured character of the spectrum count in favor of the tetrahedral structure of this complex. Most likely, the composition of the cobalt complex with TMP containing no water, NO_3^-, Br^-, and I^- in the inner sphere can be presented as $[Co(TMP)_4]^{2+}$.

The results obtained show that the complex $[Co(TMP)_4]^{2+}$ is formed most rapidly in the system with iodide ions. In the case of bromide solutions, the formation of $[Co(TMP)_4]^{2+}$ is preceded by the formation of an additional "intermediate" complex (Fig. 7, curve for 10 min) apart from $[Co(TMP)_4]^{2+}$ and complexes in freshly prepared solutions (Fig. 3c). In the system with chloride ions, a certain low-halide complex is also formed, which is stable and is not converted to $[Co(TMP)_4]^{2+}$. These relationships are attributable to a greater strength of cobalt bonds with chlorine than with bromine and, the more so, with iodine.

The results of studying the absorption spectra show that small water additions comparable with those introduced with hydrates neither reduce the intensity, nor change the spectrum shapes within the first hours, which is accounted for by the hydration of lithium bromide in solutions. The analysis of changes in the intensities of the spectra of the systems under study in relation to the weight ratio of water and lithium bromide, analogous to that suggested in [16], allowed us to determine the average hydration number of lithium bromide equal to 4.06 ± 0.08, which agrees well with the data of other methods [17].

CONCLUSIONS

(1) The charge transfer spectra and the spectra of *d–d* transitions belong to the same complexes $[Co(TMP)_x(H_2O)_{6-x}]^{2+}$, $[Co(TMP)_2Br_2]$, $[Co(TMP)Br_3]^-$, and $[CoBr_4]^{2-}$.

(2) A correlation was found between the increase in the extinction coefficients and the long-wave shifts of charge transfer and *d–d* bands with the increase in the extent of bond covalence in the order $[Co(TMP)_2Br_2] < [Co(TMP)Br_3]^- < [CoBr_4]^{2-}$.

(3) The dependence $\ln \varepsilon^{int} \sim (-\nu_{cg})$, valid both for *d–d* bands of octahedral and tetrahedral cobalt(II) complexes and for charge transfer bands of tetrahedral cobalt(II) complexes, was obtained.

(4) The revealed relationships will be useful for developing high-performance thermochromic glasses.

Abstract—Effect of the nature of carbon–graphite materials on the kinetics of intercalation of lithium ions into the matrix of electrodes of lithium power cells, on the physicochemical characteristics of lithium intercalation–deintercalation, and discharge characteristics of compacted graphite-containing electrodes was subjected to a comparative study.

DOI: 10.1134/S107042720805011X

The improvement of lithium–ion batteries is inseparably associated with the development of effective electrode materials [1]. Lithium-intercalated carbon–graphite materials (CGM) are promising materials for negative electrodes. The kinetic features (and the mechanism) of intercalation–deintercalation in materials of this kind are governed by the nature of the carbon–graphite materials, dispersity of active paste components, methods used for pretreatment of the active paste, presence of modifying additives, and other factors [2–6].

In this study, the possibility of using artificial graphite produced by thermal modification of hydrolysis lignin (AGL) as a component of electrodes of chemical power cells was examined and this kind of graphite was compared with other graphite materials.

EXPERIMENTAL

The following materials were used to prepare the active paste of working composite electrodes: AGL; commercial powdered graphite materials GT and GT_{up} (crucible graphite and ultrapure crucible graphite); special low-ash graphite GSM-1; artificial graphite produced from oil coke and pitch (AG); and thermally expanded graphites produced from GT_{sp} (TEG) and AGL (TEGL). The thermally expanded graphites were produced from bisulfates of AGL and GT_{up} by thermal shock at 750–900°C in the course of 5–15 s. The graphite bisulfates were obtained using the method described in [7–10].

The active pastes of the composite electrodes had the following composition (wt %): composite graphite electrodes: graphite 90, PM-90V carbon black (to enhance the conductivity of the active paste) 5, and binder (F-42L fluoroplastic dissolved in acetone) 5; composite graphite electrodes in a sulfur matrix: crystalline sulfur of pure grade 10–80, graphite 80–10, and F4 fluoroplastic (Teflon) in the form of a suspension (F4D) 10.

The components were ground and then the mixture was thoroughly mixed in a magnetic mixer until a homogeneous paste was obtained. The current leads were fabricated from a 0.5×10 cm^2 nickel-plated steel or nickel grid, weighed, and degreased in acetone for 2 h. The active paste was applied onto the current leads, dried in air for 15 min, and compacted under a pressure of 1 MPa. The electrodes obtained were dried at 60–70°C. The working surface area of the electrodes was 1 cm^2, and their thickness, 100 μm.

The kinetics of intercalation–deintercalation and the effect of the nature of graphites on the electrochemical discharge characteristics of the electrodes were studied in a nonaqueous 1 M solution of $LiClO_4$ in a mixture of propylene carbonate (PC) and dimethoxyethane (DME) (1 : 1 by volume). The content of water in the electrolyte solution did not exceed 0.003–0.005%.

The intercalation of lithium into the graphite electrodes was performed in the potentiostatic mode at a potential of –3.1 V in the course of 2 h. Analysis

of the dependences $I = f(t)$ in Fig. 1 shows that, in the initial stage, lithium is intercalated into the electrodes under study at current densities in the range from 49–52 to 35–42 mA cm^{-2}; in 10 min, the current density decreases to 5±2 mA cm^{-2} and stabilizes.

To quantitatively analyze the decelerated stage in the initial phase of polarization and reveal the fundamental kinetic aspects of the process of lithium intercalation into CGM, the initial portions of the i–t curves were plotted in the coordinates i–$1/t^{1/2}$ (Fig. 2). The linear dependences obtained exhibit breaks indicating that the process occurs in two stages: in stage I, a passivating film with conduction by Li ions is formed on the graphite surface; in stage II, Li is intercalated into deep layers of graphite to give Li_xC_6 compounds.

According to the Cottrell equation [11]

$$K_i = \Delta i/\Delta(1/t^{1/2}) = zFc^0_{Li}(D_{Li})^{1/2}/\pi^{1/2},$$

where c^0_{Li} is the initial lithium concentration, and D_{Li} is the diffusion coefficient of lithium.

The intercalation constants K_i and the product $c^0_{Li}(D_{Li})^{1/2}$ were calculated for each stage of the process (Table 1).

It follows from the data in Table 1 that lithium is intercalated most easily into electrodes based on crucible graphite and AGL. It should be noted, however, that the formation rate of the surface film (portion I) is the highest for GT. This indicates that a denser film is formed, which further adversely affects the charging–discharge characteristics of the electrodes. The rates of lithium intercalation into the structure of graphite (portion II) are approximately the same for different CGMs.

Anodic chronopotentiograms were obtained in discharge of Li_xC_6 electrodes at a discharge current density of 2 mA g^{-1} (0.03 mA cm^{-2}) (Fig. 3). The chronopotentiograms were used to evaluate the output capacity of the electrodes.

The most lithium-saturated electrodes with the highest energy content are formed in a matrix of AGL graphite (Fig. 3, Table 1). This is accounted for by their homogeneous finely dispersed structure (particles smaller than 20 μm in size) and by the AGL particle structure more suitable for lithium intercalation, which has a somewhat larger interlayer spacing as compared to natural graphite (0.0336 nm) [11].

It is known that the lithium–sulfur system has one of the highest values of specific energy, 1675 A h kg^{-1} [12], and, therefore, use of sulfur as a cathode material in lithium power cells is of particular interest. The electrochemical reduction of sulfur is a complex multistage process. According to

the results of studies of the electrochemical behavior of sulfur in aprotic solvents (dimethylformamide, dimethyl sulfoxide) by the method of potentiodynamic curves, two electrochemical reactions, (1) and (3), can occur at the electrode and be accompanied by chemical reactions (2) and (4) [13]:

$$S_8 + 2e \rightarrow S_8^{2-}, \quad (1)$$

$$4S_8^{2-} \rightleftarrows 4S_6^{2-} + S_8, \quad (2)$$

$$S_6^{2-} + 2e \rightarrow 2S_3^{2-}, \quad (3)$$

$$2S_3^{2-} + S_6^{2-} \rightarrow 3S_4^{2-}. \quad (4)$$

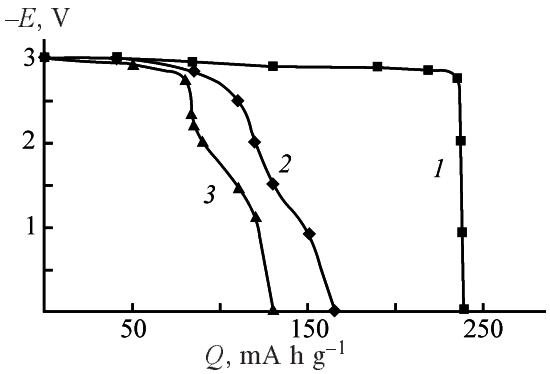

Fig. 3. Discharge curves of Li_xC_6 electrodes with matrices of different types of graphite. i_d = 0.03 mA cm^{-2}, T = 25°C. (*E*) Potential and (*Q*) discharge capacity.

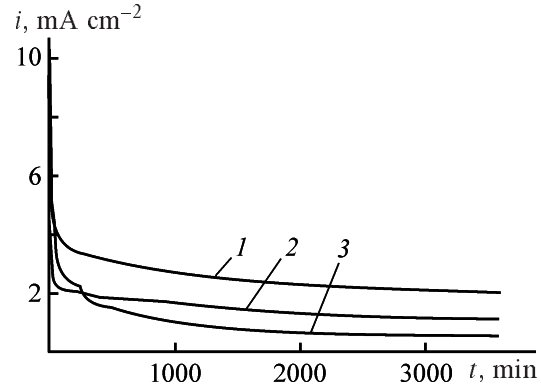

Fig. 4. Chronoamperograms of sulfur electrodes with matrices of different types of graphite at E = –2.8 V in a 1 M solution of $LiClO_4$ in PC + DME. Volume ratio 1 : 1; the same for Figs. 5 and 6. (*1*) AGL, (*2*) TEG, and (*3*) AG.

In the study, the possibility of fabricating a cycled lithium–sulfur electrode in a matrix of various carbon–graphite materials (AGL, TEG, and AG) was examined. The content of sulfur in the composite electrodes was 30%, and that of graphite, 60%. The cathodic intercalation of lithium was performed in the potentiostatic mode at potentials from –2.8 to –2.0 V in the course of 1 h. The process is the most stable for the electrodes with AGL and occurs with an insignificant decrease in the current density (Fig. 4).

An analysis of the *i*–*t* curves demonstrated that straight lines with a break are obtained in the i–$1/t^{1/2}$ coordinates, i.e., the process of intercalation of lithium ions occurs in two stages [similarly to the process of intercalation into graphite electrodes (Fig. 2)]. It can be suggested that, first, a layer of lithium polysulfides is formed on the surface via reactions (1)–(4), which is followed by the lithium intercalation proper into the structure of the electrode.

The values of the intercalation constants K_i and of the product $c_{Li}^0(D_{Li})^{1/2}$, calculated for each of the electrodes in accordance with the Cottrell equation (Table 2), indicate that films are formed on the matrix surface and lithium intercalation occurs in AG and AGL faster than in TEG.

2.2	88.3	51.7	155.1	70.0	56.9	50.2

The electrodes were discharged in the galvanostatic mode at anode current densities of 0.1, 0.3, 0.5, 0.7, and 1.0 mA cm^{-2}. The E–t dependence was used to determine the transition time τ_{tr} [14]. The results of galvanostatic measurements made it possible to find the value of $c^0_{Li}(D_{Li})^{1/2}$ by plotting the q–I dependence, where $q = i\tau$ (Fig. 5), and extrapolating the q–I straight line to the ordinate axis [15]. The intercept on the ordinate axis, q at $i = 0$, is related to the lithium ion concentration c^0_{Li} by the relationship

$$c^0_{Li} = \Delta q_\tau/(zF).$$

The diffusion coefficient of lithium was found from the slope $\Delta i/\Delta q_\tau$:

$$D_{Li} = l\Delta i/(3\Delta q_\tau),$$

where l is the electrode area.

The values of c^0_{Li} and D_{Li} are listed in Table 3. It follows from these data that the nature of graphite strongly affects characteristics of the lithium–sulfur electrode: AGL is distinguished by a higher value of c^0_{Li}, which indirectly confirms the high degree of AGL graphitization; the diffusion coefficient of lithium in AGL exceeds that in TEG; the discharge voltage of cells with AGL is lower than that of cells with TEG, which can be attributed to the more developed surface of thermally expanded graphite. At the same time, the discharge voltage of cells with AGL exceeds that for cells with AG, which is possibly due to the more "regular" graphite structure and to the higher electrical conductivity of AGL.

The good discharge characteristics of TEG-containing electrodes demonstrated that it is advisable to perform similar studies with thermally expanded graphite produced from AGL (TEGL). The kinetics of electrochemical reactions on a sulfur electrode modified with TEGL was studied at a varied content of sulfur.

It was found that varying the content of sulfur (10, 30, 50, and 80 wt %) and, accordingly, that of the TEGL carbon additive (80, 60, 40, and 10 wt %) ambiguously affects the rate of cathodic intercalation of lithium (Table 4).

The run of the potentiostatic curves plotted in the coordinates i–$1/t^{1/2}$ indicates that the lithium intercalation occurs in two stages. According to Table 4, the intercalation constants increase as the S content (%) is varied:

K_{i1}: 30 S < 80 S ≤ 10 S < 50 S,

K_{i2}: 50 S < 80 S ≤ 30 S < 10 S.

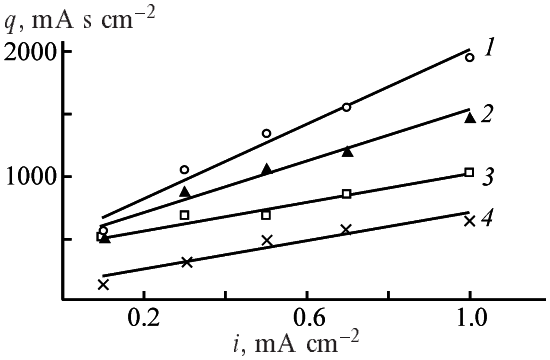

Fig. 6. q–i curves for Li–S electrodes with a TEGL matrix, measured on keeping the electrodes in a 1 M solution of $LiClO_4$ in PC + DME at E = –2.6 V for 1 h. Sulfur content, %: (*1*) 10, (*2*) 30, (*3*) 50, and (*4*) 80. (*1*) $y = 1491.7x + 509.37$, (*2*) $y = 1042.5x + 481.83$, (*3*) $y = 555.84x + 443.46$, and (*4*) $y = 557.59x + 131.04$.

Table 6. Effect of the sulfur concentration on the characteristics of the sulfur electrode with a TEGL matrix. E = –2.6 V, t = 1 h

S content, %	$q^0_\tau \times 10^3$, C cm^{-2}	$c^0_{Li} \times 10^5$, mol cm^{-2}	$D \times 10^8$, cm^2 s^{-1}
10	509	525	20.2
30	482	499	50.4
50	443	466	26.5
80	131	135	60.2

In the initial stage, the highest rate of lithium intercalation, K_{i1}, is observed on the sulfur electrode containing 50 wt % sulfur. In the case of a longer polarization, when the process rate is limited by diffusion in the solid phase, the maximum value of K_{i2} is observed for the electrode containing 10 wt % sulfur.

The longest galvanostatic discharge and the highest delay potential in the E–t curves (–2.0 to +0.15 V) correspond to a sulfur content of 10 wt %; the transition time τ_{tr} and c^0_{Li} increase as the intercalation potential is shifted in the negative direction. According to Table 5, τ_{tr} increases, as the S content (%) is varied, in the order: 80 S < 50 S < 30 S < 10 S.

The dependences q–i are shown in Fig. 6. The values of q^0_τ and of the lithium content c^0_{Li} of the electrode, found by extrapolation to the ordinate axis, and the diffusion coefficients calculated from the slope ratio $\Delta i/\Delta q_\tau$ are listed in Table 6.

Thus, the results obtained indicate that the diffusion-kinetic parameters of the lithium–sulfur electrode depend on the content of sulfur and, accordingly, of graphite in the electrode. A sulfur content of 10% (TEGL 80%) corresponds to the largest values of the specific capacity of the electrode, determined by the length of the time delay of the potential and by the lithium concentration in the electrodes (Table 6).

CONCLUSIONS

(1) The possibility and comparatively high efficiency of use of artificial graphite produced from lignin as a matrix for synthesis of graphite intercala-

tion compounds and the efficiency of thermally expanded graphite produced from lignin as a component of the active paste for electrodes of lithium power cells was confirmed.

(2) Artificial graphite produced from lignin surpasses all other graphite materials studied as a matrix for lithium intercalation and can be used to fabricate a graphite electrode for a lithium–ion battery with a high specific energy content (720 W h kg^{-1}).

(3) Sulfur electrodes with TEG and TEGL matrices have the best charging–discharge characteristics. For example, the concentration c^0_{Li} of lithium ions for sulfur electrodes containing 30% sulfur and 60% TEGL is 499×10^{-5}, which substantially exceeds the concentrations in similar electrodes with an AGL matrix ($c^0_{Li} = 363 \times 10^{-5}$ mol cm^{-2}). In turn, the electrodes with TEGL surpass those with TEG in discharge characteristics (q^0_τ = 482 and 270 mC cm^{-2}, respectively).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Specific Features of Cathodic Deposition of Nickel–Boron Coatings from a Sulfuric Acid Electrolyte with Addition of Polyhedral Borates

Received June 8, 2007

Abstract—Specific features of the cathodic deposition of nickel–boron coatings from a sulfuric acid electrolyte with addition of polyhedral borates were considered.

DOI: 10.1134/S1070427208050121

Nickel–boron coatings with a low content of boron attract a considerable attention in manufacture of radioelectronic articles because of the possibility of imparting to these articles multifunctional characteristics by varying the formulation-and-technological modes of their deposition. Depending on the profile of articles being metal-plated, coatings of this kind can be deposited locally (chemically) or cathodically onto larger metallization surfaces [1–4]. Of interest for electrodeposition of such coatings is addition of polyhedral borate anions ($C_2B_9H_{12}^-$, $B_{10}H_{10}^{2-}$, $B_{12}H_{12}^{2-}$) [5], which can be introduced into standard nickel-plating electrolytes [6, 7]. Additives of this kind exhibit low electrochemical activity, and their parallel transformations in the course of reduction of nickel ions can be eliminated.

EXPERIMENTAL

The coatings were electrodeposited from the standard Watts electrolyte with anions of polyhedral borates at 40–45°C onto copper and nickel supports. Electrochemical studies were performed with PI-50 and P-5848 potentiostats and a standard YaSE-2 cell. The effective activation energy of the nickel deposition and boron incorporation was determined by Gorbachev's temperature-kinetic method from the effect of temperature on the rate of the electrode process at fixed potentials. X-ray diffraction analysis was made on a DRON-2 diffractometer with MoK_α radiation. The interplanar spacings were calculated by the Bragg formula. An Auger spectral analysis was carried out on a PHI-545 instrument (USA) and also on a laser mass-reflectron. As samples served Polycor plates with a vacuum-deposited copper layer, onto which coatings were deposited.

It was found that polyhedral additives do not exhibit any noticeable electrochemical activity at the cathode under polarization conditions in an electrolyte containing no nickel salt, with only hydrogen evolution observed at the cathode. Auger spectroscopy of surfaces of various metallic electrodes in the absence of polarization demonstrated that spontaneous decomposition of the additives occurs only at those electrodes which show catalytic activity with respect to this decomposition. Certain saturation of the surface with elemental boron was observed on nickel electrodes, whereas no boron was found on the surface of copper even after prolonged keeping of the electrode in a boron-containing solution without polarization (Fig. 1).

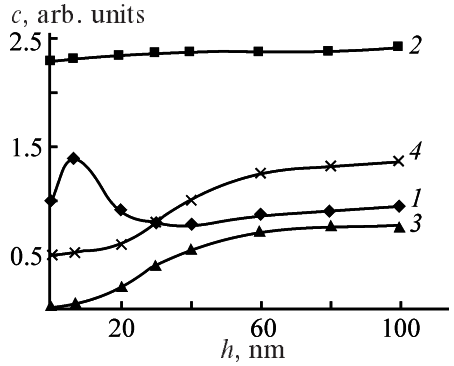

Fig. 1. Auger profiles of (*2, 4*) nickel and (*1, 3*) boron distribution on (*1, 2*) nickel and (*3, 4*) copper supports. Time of keeping the supports in a solution containing $C_2B_9H_{12}^-$ in the absence of polarization 1 h. The content of nickel is given on a 1 : 5 scale. (*c*) Content of element and (*h*) distance from the support.

The catalytic properties of the nickel surface are enhanced as its renewal in the course of cathodic deposition of the metal from the nickel-plating electrolyte is accelerated. At higher current densities, the rate of boron incorporation increases (Fig. 2) and its absolute amount in a coating becomes larger. In this case, such factors as the slow delivery of the additive to, and its adsorption on the reaction surface may be important, which is indicated by the activation energy of boron incorporation into the coating: 80–120 kJ mol^{-1} at low temperatures (kinetic control) and 25–35 kJ mol^{-1} at the working temperatures (diffusion control).

By the method of "hydrogen delay" [8] we found that a 0.8-monolayer coverage of the reaction surface is reached even at low $B_{10}H_{10}^{2-}$ concentrations of about 0.1 M, i.e., the nickel deposition and boron incorporation into the coating occur under conditions of formation of a near-cathode boron-containing film, especially at high concentrations of the additive raising the activation energy of nickel deposition at the working potentials from 40–50 to 80–90 kJ mol^{-1}.

Despite the considerable difference between the standard potentials of nickel and boron, equal to approximately 0.6 V, the cathodic curves of deposition of nickel–boron coatings are close to curves of nickel deposition and differ only by tenths and hundredths of a volt, which can only be attributed to the effects of energy release in alloying and adsorption (Fig. 3). The adsorption was confirmed by changes in the capacitance of the electrical double layer of an unpolarized nickel–boron electrode in the presence of boron-containing additives in the electrolyte.

The absence of the electrochemical mechanism of boron incorporation into a coating is clearly demonstrated by cathode balances for deposition of nickel–boron coatings, according to which the whole amount of the cathode electricity is completely expended for nickel deposition and hydrogen evolution, although the content of boron in the coating may be as high as 20–30 at %.

The results obtained make it possible to state that, in cathodic deposition of nickel–boron coatings, the coating components are deposited by different mechanisms: nickel base, by the conventional electrochemical, and boron, by chemical-catalytic under diffusion-kinetic control.

X-ray diffraction studies of the nickel–boron coatings failed to reveal any particular crystal structure characteristic of metallurgical alloys. At a comparatively low boron content of a coating, its structure is an interstitial solid solution of boron in nickel and the crystallite size decreases from 25 to 3 nm as modifying additives (sulfur, manganese) are introduced and the amount of boron in the alloy is raised (see table). The latter is achieved by making higher the concentration of boron-containing additives in

the electrolyte, which results in a considerable increase in the cathodic polarization and activation energy of discharge of nickel ions. As the amount of the boron-containing additive in the electrolyte increases, the preferential crystallographic orientation of nickel–boron coatings changes from [111] to [100]. Such a change in the orientation of crystallites in the coating is probably due to predominant adsorption of ions of the boron-containing additives on faces forming the frontal growth surface of the coating.

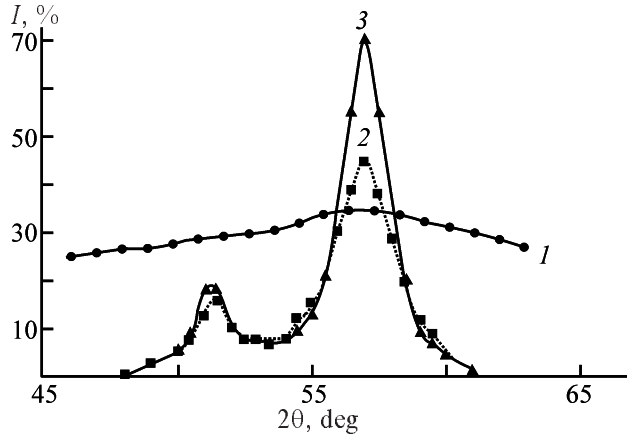

Fig. 4. X-ray diffraction pattern of nickel–boron coatings with different contents of boron. (*I*) Relative intensity and (2θ) Bragg angle.

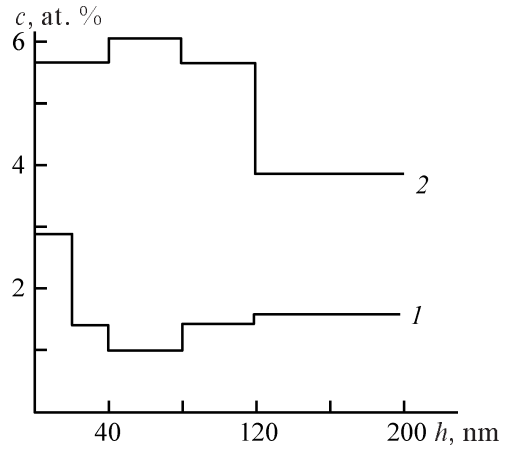

Fig. 5. Distribution of the content *c* of (*1*) boron and (*2*) oxygen in the upper layers of a nickel–boron coating after a thermal treatment at 450°C (2 min) and 380°C (8 min) in air according to the results of Auger spectroscopy. (*h*) Deposit thickness.

As the content of boron in a thermally untreated Ni–B coating is raised to 2.6%, the profile of Ni reflections (111), (200), (220), and (311) in the X-ray diffraction patterns markedly changes. The lines become broader and their intensity decreases. The coating was amorphized at a boron content of 4.3% ($B_{12}H_{12}^{2-}$ additive was used); there are no peaks characteristic of the crystalline state in the X-ray diffraction pattern of this coating (Fig. 4).

The small size of boron atoms and the absence of strong intercrystallite bonds in the alloy provide a high rate of thermal diffusion of boron atoms to the coating surface, where they are for the most part oxidized. The Gibbs energies of formation of boron and nickel oxides are –1186 and –217 kJ mol^{-1}, respectively, and, therefore, the resulting film is mainly composed of boron oxides. In the process, boron favors self-fluxing of the nickel surface by the reaction

$$3NiO + 2B = B_2O_3 + 3Ni.$$

A thermal treatment, e.g., that simulating attachment of a semiconducting crystal by means of an Au–Si eutectic and thermal-compression bonding of chip leads, results in that oxide films of thickness exceeding 200 nm are formed on the surface of nickel–boron coatings and boron diffuses toward the surface of the deposit (Fig. 5).

At high temperatures of the surface of nickel–boron coatings, boron is oxidized by the reaction

$$4B + 3O_2 = 2B_2O_3.$$

Forming a solid surface film, boron oxides mechanically hinder oxidation of nickel and simultaneously exert a self-fluxing influence. The protective film composed of boron oxides makes coatings thermally stable, and, when necessary, e.g., in high-temperature assembly of electronic devices, can be easily removed by ultrasonic treatment, with fluxes or aqueous solutions, etc.

CONCLUSIONS

(1) When nickel–boron coatings are formed from nickel-plating electrolytes with addition of polyhedral borates, the coating components are deposited by different mechanisms: nickel base by the conventional electrochemical mechanism, and boron, by the chemical-catalytic mechanism under diffusion-kinetic control.

(2) These processes mutually affect each other: acceleration of the cathodic stage of nickel deposition makes higher the rate of boron incorporation; simultaneously, as the concentration of boron-containing additives increases, the crystal structure becomes finer and the orientation of crystallites changes, with a transition from a polycrystalline solid solution of boron in the lattice of nickel to an X-ray amorphous coating.

(3) Thermal treatment of the coating causes boron diffusion to the surface, with protective oxide films formed.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Ytterbium on the Corrosion-Electrochemical Behavior of Aluminum in a Neutral Medium

T. M. Umarova and I. N. Ganiev

Nikitin Institute of Chemistry, Academy of Sciences of Republic of Tajikistan, Dushanbe, Tajikistan

Received June 18, 2007

Abstract—Effect of ytterbium on the corrosion-electrochemical behavior of aluminum and an aluminum–manganese alloy in a neutral 3% solution of NaCl was studied.

DOI: 10.1134/S1070427208050133

Ytterbium, one of the least widespread and worst studied rare-earth elements of the yttrium group, is a paramagnetic material that is easily mechanically processed and has high electrical conductivity, which exceeds that of other lanthanides by a factor of 3. Ytterbium is weakly oxidized in air and is one of the few rare-earth metals (REM) that have distinctive properties, compared with other metals in this series. For example, the structure of the electron shell of elements in their metallic state largely predetermines the physicochemical properties of a metal. With exception of ytterbium and europium, REMs (R) are trivalent. Ytterbium exists also in the bivalent state and, therefore, its properties in alloying can differ from those of trivalent metals.

All the REMs (except ytterbium) have at room temperature a close-packed hexagonal structure of the magnesium type (A3), whereas ytterbium crystallizes in a cubic face-centered lattice of the copper type (A1) [1]. In contrast to many REMs, ytterbium has a comparatively low melting point (816°C), which facilitates alloying [2].

The aim of this study was to examine the effect of ytterbium on the corrosion-electrochemical behavior of aluminum and an aluminum–manganese alloy containing 1.9 wt % Mn in a 3% solution of NaCl. This study continues previous investigations [3–6] of the effect of alloying elements on the corrosion behavior of aluminum and alloys based on this metal.

By now, there are no data on the corrosion behavior of aluminum alloyed with ytterbium. Therefore, the electrochemical behavior of alloys containing up to 0.5% ytterbium was examined in the study.

EXPERIMENTAL

The alloys studied were prepared from aluminum of A85 brand [GOST (State Standard) 4784–74], ytterbium of Itb M1 brand [TU (Technical Specification) 48-4-204–72), and electrolytic manganese of Mr00 brand (GOST 6008–82). To study the corrosion behavior of aluminum–manganese alloys alloyed with ytterbium, alloys of the Al–Mn–Yb system were synthesized from the corresponding addition alloys Al–Mn (10%) and Al–Yb (10%), which made it possible to obtain alloys of homogeneous chemical composition in the systems under study.

A molten aluminum alloy was poured into a steel mold in order to obtain cylindrical rods 8 mm in diameter and 100 mm long. The thus fabricated electrodes were lapped, polished to mirror shine, and washed and degreased with ethanol.

The study was performed using the experimental procedure described in [3]. A silver chloride electrode served as reference in the electrochemical cell, and a platinum electrode, as auxiliary electrode. The solution temperature of 20°C was maintained by a thermostat. The potential sweep rate was 2 mV s^{-1}, a 3% solution of sodium chloride served as a corrosion medium. The electrodes were polarized in the potentiostatic mode, with the potential shifted in the anodic direction from the free-corrosion potential (steady-state potential) to a constant current of 2 mA and then backwards to a value of –1.6 V, after which an anodic curve was measured. A full polarization curve is shown in Fig. 1.

The results of a potentiodynamic study of ytterbium-alloyed aluminum in a 3% solution of sodium chloride are listed in Table 1. All the potentials are

* E_{fc}, E_{cor}, E_{rp}, E_{pox}, and E'_{pox} are the potentials of free corrosion, corrosion, repassivation, and pitting in the presence and absence of a natural oxide film on the surface, respectively; ΔE_{pas}, passivation interval; i_{repass} and i_{cor}, current densities of dissolution in the repassivation region and corrosion.

given relative to the standard hydrogen electrode. The corrosion current was calculated from the cathodic curve (b_c = 0.12 V) [7].

The corrosion rate as a function of the corrosion current density was found using the formula

$$K = i_{cor}k,$$

where k is the electrochemical equivalent whose numerical value is 0.335 g A^{-1} h^{-1} for aluminum [8].

As the concentration of the alloying component (Yb) increases, the passivation interval becomes wider, which indicates that the tendency of the alloys toward passivation is enhanced because of the formation of a stable protective film on the alloy surface. This behavior is also confirmed by the dissolution current densities in the repassivation region, i_{repass}, which are lower than those for pure aluminum. Comparison of the corrosion current densities of ytterbium-alloyed aluminum with those of alloys of the systems Al–R (R = Y, La, Ce, Pr, Nd, etc.) considered in [6, 9–11] shows that alloys of aluminum with ytterbium are the most corrosion-resistant.

Ternary alloys of the system Al–Mn–Yb have good castability and mold-fillability, show no shrinkage, and are outwardly characterized by strong shine and whiteness, compared with the previously studied similar alloys of the systems Al–Mn–Sc (Y, Ce, La, etc.). Table 2 lists the results of a study of the corrosion-electrochemical behavior of an aluminum–manganese alloy of a eutectic composition (1.9% Mn), alloyed with ytterbium to 0.5%, in a neutral aqueous medium. It can be seen that, as the ytterbium content increases, the free-corrosion and pitting potentials, found from the forward-run anodic polarization curve, are shifted into the region of positive values. Analysis of the full polarization curve shows that all the free-corrosion potentials of alloys of the system Al–1.9% Mn–Yb are in the passivation region.

The free-corrosion and pitting potentials are the most strongly affected by minor additions of ytterbium (0.01%). Presumably, this occurs because just these two parameters are affected to a greater extent by the initial state of the alloy surface not subjected to any treatment (cathodic polarization, etching, etc.). The alloy of composition Al–1.9% Mn–0.01% Yb is characterized by the minimum densities of the current of dissolution in the repassivation region and corrosion current. As the ytterbium content increases further, the manner in which this additive affects the characteristics under study is preserved,

but, even at the maximum content of ytterbium (0.5%), the corrosion resistance of the alloy exceeds that of the starting unalloyed alloy, which is only characteristic of this REM.

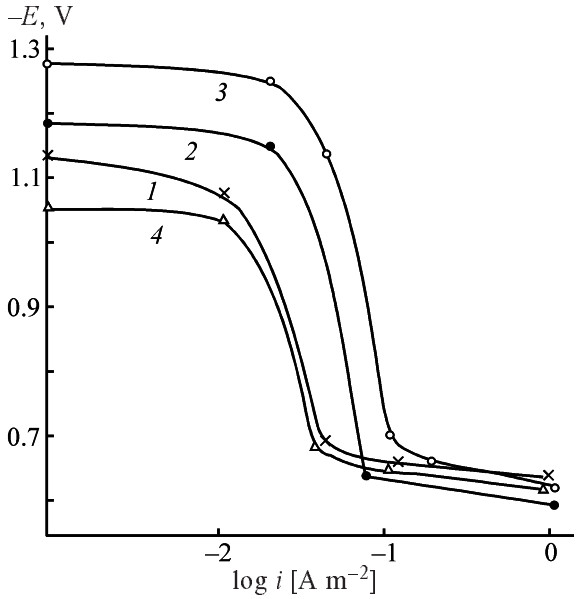

Fig. 2. Anodic polarization curves of Al–Mn–Yb alloys with a varied content of ytterbium in a 3% NaCl solution. Yb content, wt %: (*1*) 0.01, (*2*) 0.05, (*3*) 0.10, and (*4*) 0.50.

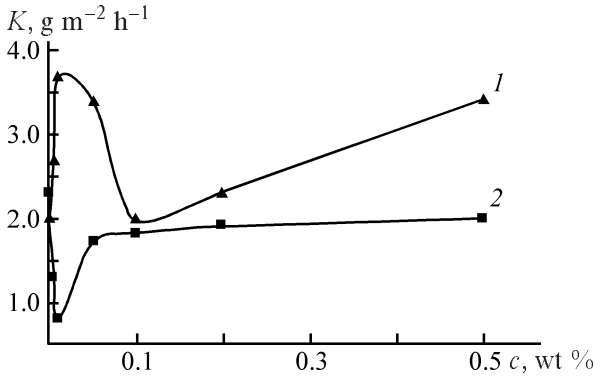

Fig. 3. Corrosion rate K of alloys of the systems (*1*) Al–Yb and (*2*) Al–Mn–Yb vs. the ytterbium content c.

Comparison of the corrosion-electrochemical parameters of alloys of the systems Al–Yb and Al–Mn–Yb (Tables 1 and 2, respectively) shows that, in the presence of manganese, the corrosion rate of the aluminum alloy is substantially lower and, consequently, alloys of the system Al–Mn–Yb are 2–3 times more corrosion-resistant than binary alloys (at ytterbium content of 0.005–0.05%). At an ytterbium content of 0.01%, the difference between the corrosion currents of the aluminum–ytterbium (0.012 A m^{-2}) and aluminum–manganese–ytterbium alloys (0.0025 A m^{-2}) is the most pronounced, which is accounted for by the stronger influence of manganese. With ytterbium added in an amount of 0.05% to aluminum and the aluminum–manganese alloy, the corrosion currents differ by a factor of 2. At an ytterbium content of 0.10%, the corrosion current densities of the binary and ternary alloys virtually coincide (0.0060 and 0.0055 A m^{-2}, respectively); the free-corrosion potentials are also equal. Thus, manganese has no effect on the corrosion behavior of aluminum at an ytterbium content of 0.10%, but at the maximum content of ytterbium (0.5 wt %), the effect of manganese again becomes noticeable.

Figure 2 shows anodic polarization curves for alloys of the system Al–Mn–Yb in a 3% NaCl solution. It can be seen that the passivation interval becomes wider at ytterbium content of 0.05–0.10% (curves *2*, *3*). To these alloy compositions correspond the highest currents of dissolution in the repassivation region. Upon addition of the maximum amount of REM (0.5% Yb), the passivation interval becomes narrower, and the dissolution currents in the repassivation region, lower.

Figure 3 shows dependences of the corrosion rate K (g m^{-2} h^{-1}) of aluminum (curve *1*) and of an aluminum–manganese alloy containing 1.9% Mn

(curve *2*) on the content of ytterbium (wt %). It can be seen that the corrosion rates of the binary and ternary alloys change to the greatest extent at ytterbium contents of 0.005 to 0.1%. In this concentration range, the ytterbium content has opposite effects (curves *1* and *2*).

Thus, addition of ytterbium in an amount of 0.01% to aluminum and the aluminum–manganese alloy (1.9% Mn) leads to an increase in the corrosion rate in the former case, and to a decrease, in the latter. Consequently, the key role in alloying of aluminum and the Al–1.9% Mn alloy with ytterbium will be played by manganese, whose presence in an alloy improves its corrosion resistance. As the ytterbium content reaches 0.10%, the corrosion rates of the binary and ternary alloys become virtually equal, and further increase in the ytterbium content leads to a steady increase in the corrosion rates of alloys of the systems Al–Yb and Al–Mn–Yb.

The optimal, with respect to corrosion, composition of the ternary alloys is that with ytterbium added in an amount of 0.005–0.10 wt %. The alloy of composition Al–1.9% Mn–0.01% Yb is the most corrosion-resistant and has a high stability against pitting corrosion in a neutral medium containing chloride ions. This is accounted for by the strong modifying effect of ytterbium.

A comparison of the effect of REM additives on the corrosion rate of aluminum and an Al–Mn alloy made it possible to arrange the metals studied in order of increasing modification efficiency as follows: La < Ce < Y < Yb.

CONCLUSIONS

(1) The free-corrosion potentials of ytterbium-containing binary alloys are in the passivation region.

(2) The optimal content of ytterbium in aluminum and the Al–1.9% Mn alloy for improving the corrosion resistance is 0.01 wt %.

Abstract—Oxidation of tetracycline® in an electrochemical cell with separated cathodic and anodic compartments on smooth platinum was studied. The extent of electrochemical degradation of tetracycline and the energy consumption for eliminating the biological activity of its aqueous solutions were estimated.

DOI: 10.1134/S1070427208050145

Tetracycline® (TC) is a widely used antibiotic. However, in a human body it undergoes only partial metabolism. When getting into sewage, it suppresses the vital activity and growth of microorganism colonies used on water treatment plants. This results in environmental pollution with untreated wastewater [1–3] and in penetration of harmful substances into living bodies [2].

To prevent ingress of TC into water treatment plants, it is suggested to use electrochemical anodic oxidation on anodes-catalysts [4]. This method is widely used for neutralization of toxic organic substances polluting waste and natural waters. In the process, relatively small molecules such as phenol and its derivatives can be completely mineralized by electrochemical oxidation to CO_2 and H_2O with addition of 10–16 electrons [5–7]. Canizares et al. [6] suggested a method for electrochemical oxidation of phenol in a concentration of 200–400 mg l^{-1} in sewage with acceptable outlay.

According to the previous data [8], reducing the biological activity of a TC solution by an order of magnitude does not require its complete mineralization. It is sufficient to break down the initial TC molecules. However, the level of electric power consumption for electrochemical oxidation of TC, required to completely eliminate its biological activity, was not determined previously.

In this study we examined oxidation of TC on a platinum anode at various TC concentrations, determined the product yields as functions of current, and calculated from these data the amount of electricity spent for the oxidation of TC on platinum.

EXPERIMENTAL

Electrochemical oxidation of TC was performed in a glass cell with the anodic and cathodic compartments separated by an ion-exchange membrane. The anode and cathode were arranged parallel to each other at a distance of 2 cm. A platinum plate of the surface area 10 cm^2 served as a cathode. The same platinum plates served as anodes. The current density was 5 mA cm^{-2}. The anode potential vs. silver chloride electrode was 1.82–1.89 V. The TC concentration was 50–500 mg l^{-1}. As supporting electrolyte we used 0.1 N aqueous H_2SO_4. The solutions were analyzed by HPLC and polarimetry. The gas phase was analyzed by GLC.

Chromatographic analysis of the reaction mixtures from TC oxidation revealed formation of several products. The content of one of them monotonically increases in the course of the reaction, whereas the content of the other products, irrespective of the TC conversion, does not exceed 5% of the content of the major product. The TC content of the solution decreases with time (Fig. 1), and for all the concentrations studied it can be described by a first-order equation

$$c_t = ce^{-kt}, \quad (1)$$

where c and c_t are the initial and running TC concentrations in the solution (M); t, time from the reaction start (s); and k, oxidation rate constant equal to $(0.9–1.1) \times 10^{-3}$ min^{-1}.

Chromatographic analysis showed that the CO_2 release from the cell was negligible and did not exceed 0.5%. This allowed us to determine the current

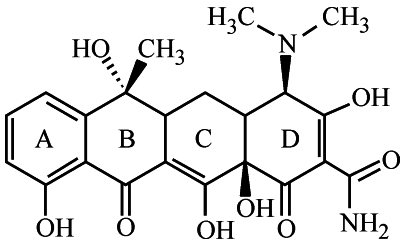
efficiency of the reaction P (%) by the formula

$$P = \frac{V_0 - V_y}{V_0} \times 100, \quad (2)$$

where V_y is the oxygen volume released from the anodic compartment in the course of TC oxidation to the given conversion (ml); V_0 is the rate of oxygen evolution in the experiment with TC (ml).

Variation of the current efficiency with the TC conversion determined by HPLC is given in the table. It is seen that P does not exceed 11% and decreases in the course of the reaction. From the found values of P, we calculated the amount of electricity Q_y spent for the oxidation of TC to the preset conversion y:

$$Q_y = ItP, \quad (3)$$



where t is the experiment time (min); I, total current passing through the cell (A); and Q_y, amount of electricity (C).

From the preset TC conversion y, we calculated the amount of electricity required for reaching this value of y, assuming that the TC oxidation is a one-electron process:

$$F_y = m/(Fmy), \quad (4)$$

where m is the TC weight (G); M, molecular weight of TC; F, Faraday number; and y, TC conversion.

The number of electrons n_e actually participating in the TC oxidation was calculated as the ratio of Q_y to F_y. Variation of all the calculated quantities in the course of the reaction is given in the table. It can be seen that decomposition of one TC molecule with the formation of the major product requires no less than 12 electrons. The quantity n_e does not appreciably vary in the course of the reaction. On the whole, this corresponds to the results of the chromatographic analysis, namely, to the fact that, irrespective of TC conversion, in the reaction mixture there is a single major product whose content exceeds the content of the other products by an order of magnitude. High value of n_e suggests that the initial molecule (see formula below) undergoes deep oxidation.

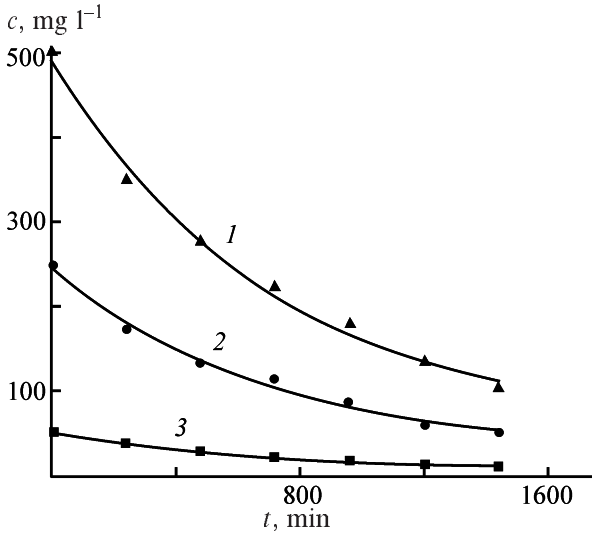


Fig. 1. Kinetic curves of electrocatalytic oxidation of tetracycline on platinum. (*c*) Tetracycline concentration and (*t*) oxidation time. Concentration of the initial tetracycline solution, mg l^{-1}: (*1*) 500, (*2*) 250, and (*3*) 50.

Oxidation of TC may occur at any ring. In each alternative, deep oxidation of TC with cleavage of C–C bonds in six-membered rings can be expected, as it is observed, e.g., in oxidation of phenol or salicylic acid [8]. In any case, cleavage of a C–C bond requires no less than 10–12 electrons. It can be seen that the charge required for the TC neutralization appears to be approximately an order of magnitude lower than the charge required for complete mineralization of TC according to the equation

$$C_{22}H_{24}O_8N_2 + 34H_2O - 92e = 22CO_2 + N_2 + 92H^+.$$

To determine what ring undergoes oxidative degradation, we used polarimetry. Figure 2 shows the dependence of the specific optical activity of the products of electrocatalytic oxidation of TC $[\alpha]_D$ on the concentration of the initial TC solution. It can be seen that this quantity linearly decreases with increasing conversion of TC. Extrapolation of the

Characteristics of electrocatalytic oxidation of tetracycline on platinum

Q_y, C	P, %	y, %	F_y, C mol^{-1}	n_e
80	11	30	6.5	12.1
115	8	45	9.8	11.7
150	6.8	56	12.1	12.1
165	5.8	65	14	11.9
180	5.1	74	16	11.5
195	4.5	79	17.2	11.3

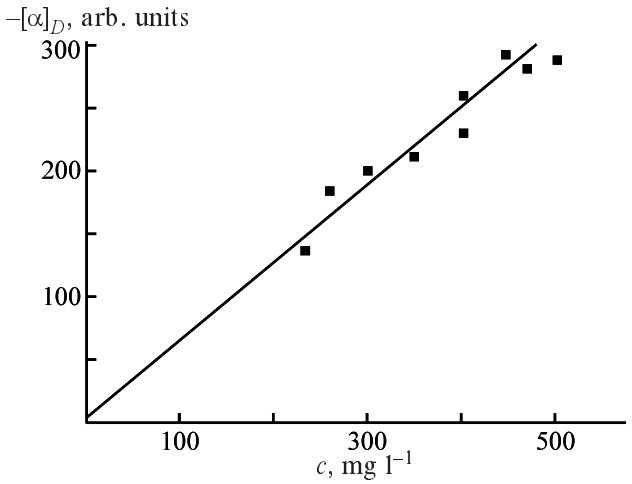

Fig. 2. Variation of the specific optical activity $[\alpha]_D$ in the course of electrocatalytic oxidation of tetracycline. (c) Tetracycline concentration.

straight line shows that, at complete conversion of the substrate, $[\alpha]_D$ is zero. The optical activity of the initial TC is caused by the presence in its molecule of four asymmetric carbon atoms in rings B and C. If only rings A and D were broken down in the course of TC oxidation, $[\alpha]_D$ would not decrease to zero. Therefore, it can be concluded that the oxidative degradation involves rings B and C and leads to disappearance of the chiral centers. Preservation of rings A and D may be responsible for the fact that the degradation of TC molecules to an extent required for the loss of the biological activity of TC aqueous solution [8] requires not 92 but only 12 electrons. The results of our study, even without identification of the major product of TC oxidation, allow a conclusion that the electricitiy consumption for neutralization of TC solutions should not appreciably exceed the electricity consumption for electrochemical degradation of phenol or salicylic acid solutions.

CONCLUSIONS

(1) Electrochemical oxidation of tetracycline on platinum involves its internal rings (two out of four).

(2) The amount of electricity required for neutralization of aqueous solutions of tetracycline was calculated from the yields of products as functions of current. This amount should not essentially exceed the electricity consumption for electrochemical degradation of phenol and salicylic acid solutions.

Abstract—IR spectroscopy, X-ray phase, chemical, kinetic, and thermodynamic analyses were used to determine the nature of chemical reactions occurring in electric pulse dispersion of a metal (Fe) in aqueous solutions of inorganic substances ($MnSO_4$, NaH_2AsO_4, H_3AsO_3, $K_2Cr_2O_7$).

DOI: 10.1134/S1070427208050157

Electric discharges (ED) in solutions find practical application in water treatment to remove impurities and in synthesis of highly dispersed materials. Therefore, problems associated with determining the composition of the products formed, raising the yield, and controlling the process parameters are topical. A rather interesting area in this field is application of pulsed electric discharges (PED) in a layer of metallic grains placed in an aqueous solution [1–6]. The energy introduced acts upon the electrodes, whose part is played by metallic grains, and leads to their erosion and formation of highly dispersed particles. In a system of this kind, not only the output capacity becomes higher, but also the temperature and dispersity of the material are easily controlled. However, the composition of the products formed and chemical mechanisms of these processes remain insufficiently understood.

It has been shown [7] that, at least in the case of ED between electrodes with insulating sheaths (barrier ED) or those spaced far apart, the prevalent effect is the oxidizing action on solutes. This effect is mostly attributed [7, 8] to formation of $OH^{\cdot}$ radicals under the action of the ED plasma. The reducing effect of barrier ED in aqueous solutions is, as a rule, insignificant and is less understood [7, 9]. It may be associated with such primary products of water decomposition as hydrated electrons e_{aq} and H atoms. The oxidation by $OH^{\cdot}$ radicals is also assumed to occur under the action of ED on metallic grains (zero-barrier ED) [10]. For example, it has been shown [5] that the oxidizing action of zero-barrier ED is observed in water treatment to remove As(III), with at least part of arsenic converted to As(V). However, the metal is dispersed in this case and, if it is active, this must lead to a reducing effect of PED on a solution. This has been confirmed experimentally for the example of water treatment to remove the Cr(VI) impurity [4]. However, the role of redox reactions and the extent to which products formed in water decomposition and metal particles are involved in these processes cannot be considered well understood because the composition of the products removed from solution has been insufficiently studied.

This study was aimed to determine the composition of the products and the type of reactions occurring in PED treatment of a layer of iron grains in solutions containing oxidizing ($Cr_2O_7^{2-}$, $H_2AsO_4^-$) and reducing agents (Mn^{2+} and As^{3+}). The kinetics of water treatment to remove impurities with oxidizing and reducing properties were compared.

EXPERIMENTAL

The experimental setup comprised a 1.5-l reactor and a pulsed power source. Iron shavings ($10 \times 5 \times 2$ mm) were placed in an amount of 200 g on the bottom of the reactor fabricated from a dielectric material. A pulsed voltage (pulse amplitude 500 V, repetition frequency 300 s^{-1}, width 15 μs) was applied to two external feeding electrodes submerged into the shavings to a depth of 3 cm. The maximum discharge current was 250 A. The pulse energy was 0.5 J per pulse. St.3 served as the material of iron

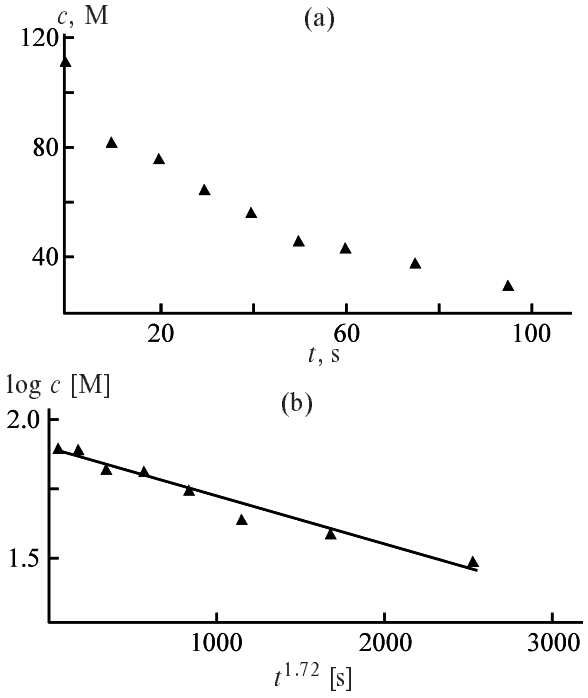

Fig. 1. (a) Concentration c of Mn^{2+} cations vs. the PED treatment time t and (b) $\log c$–$t^{1.72}$ dependence for PED treatment of iron grains in a salt solution containing Mn^{2+} cations. $c_0(Mn^{2+})$ = 110 mg l^{-1}, solution volume 100 ml.

shavings and feeding electrodes. Working solutions containing $H_2AsO_4^-$, Mn^{2+}, and $Cr_2O_7^{2-}$ ions of various concentrations were prepared from distilled water and $MnSO_4 \cdot 5H_2O$, NaH_2AsO_4, and $K_2Cr_2O_7$. Solutions containing As(III) were prepared from GSO (State Reference Sample) 7264–96 standards by dissolving As_2O_3 in HCl at pH 2.

A PED treatment of metallic grains submerged in a working solution leads to formation of a suspension composed of eroded metal particles and a solution. To obtain dry electroerosion powders, the suspension was passed through a "blue ribbon" filter and the resulting solid product was dried at room temperature. The content of Fe^{2+}, Fe^{3+}, As^{5+}, and Mn^{2+} in the filtrate was found by photocolorimetry [11]. The concentration of As^{3+} was determined by voltammetry [12].

The dry electroerosion powders were subjected to an X-ray phase analysis on a DRON-3.0 diffractometer (powder method). The X-ray diffraction patterns were interpreted using the Powder Diffraction File (PDF) compiled by Joint Committee on Powder Diffraction Standards (JCPDS). The dispersity and morphology of the particles were determined by analysis of carbon replicas with extraction on an EM-125 transmission electron microscope. The chemical composition and the structure of the compounds formed in electroerosion of metallic grains in water and aqueous solutions were found by IR spectroscopy on a Nicolet IR Fourier spectrometer in the range 4000–400 cm^{-1} with an attachment for diffuse reflection in KBr (spectral resolution 4 cm^{-1}).

It has been shown previously [6] that the electroerosion of iron grains in water and solutions under the action of PED occurs to give nano- and microparticles by the law

$$[Fe_s] = k_e t^{0.72}, \quad \text{(I)}$$

where $[Fe_s]$ is the concentration of the eroded metal in the suspension (mg l^{-1}); t, time of PED action (s); and k_e, empirical constant dependent on the PED parameters and properties of the electrodes and the medium [mg $(l\,s^{0.72})^{-1}$], with the exponent 0.72 accounting for the variation of the PED conditions in the course of electroerosion.

For dilute [$(0–5) \times 10^{-3}$ M] solutions of $H_2AsO_4^-$ and $Cr_2O_7^{2-}$ anions, the impurity is removed from the solution in accordance with the equation [4, 5]

$$\log c_i = k_i^{1+0.72} + \log c_0, \quad \text{(II)}$$

where c_0 and c_i are the initial and running concentrations of an ion in solution (mg l^{-1}), and k_i' is the effective rate constant including k_e.

Equation (II) was derived by integration of Eq. (III) with account of Eq. (I) under the condition that the concentration of the dispersed metal in the suspension changes only via erosion, i.e., increases.

$$dc_i/dt = k_i [Fe_s] c_i, \quad \text{(III)}$$

Consequently, the reaction of dispersed iron with the impurity is of partial first order with respect to both the reactants. This means that all Fe_s particles are activated and react in the discharge zone. The adequacy of the description was verified by experiments in which the PED was terminated and the initial concentration of the impurity was varied and by calculations in terms of other equations, which demonstrated a considerably poorer agreement with the experiment.

Similar experiments were carried out with a $MnSO_4$ salt solution. Figures 1a and 1b show raw data on removal of Mn^{2+} ions from water and the

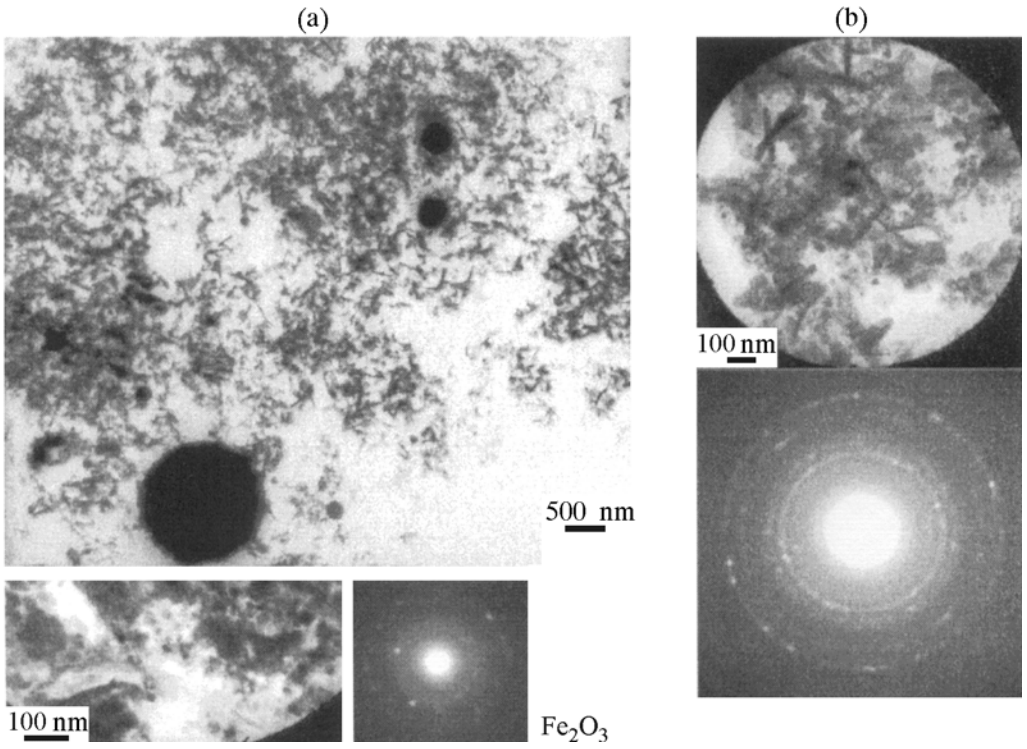

Fig. 2. Electron micrograph of (a) Fe_2O_3 and (b) Fe_3O_4 particles in a sample produced by a PED treatment of iron grains in water. PED treatment time 10 min.

same data plotted in the coordinates of Eq. (II). It can be seen that the experimental data are described by the same relations as those for $H_2AsO_4^-$ and $Cr_2O_7^{2-}$ anions [4, 5], i.e., Mn^{2+} ions are removed in accordance with the same laws, despite the possibly different chemical mechanisms.

In the next stage of the study, we determined by XPA and IR spectroscopy the composition of the products formed under the action of PED on a bed of iron grains in water and salt solutions containing $H_2AsO_4^-$, $Cr_2O_7^{2-}$, and Mn^{2+} ions and examined the occurring reactions with account of the necessary condition $\Delta G_{298} < 0$.

Fe–distilled water. A study of electroerosion powders and the suspension by transmission electron microscopy demonstrated that they contain particles with sizes ranging from several nanometers to several micrometers (largest size 5–10 μm). Two maxima are observed in the particle size distribution: at 1–30 nm and 0.2–10 μm. Particles of regular (spheres) and irregular (faceted particles, plates, rods, fibers) shapes can be found (Figs. 2a, 2b).

It can be seen from the electron micrographs that crystalline particles are observed together with those of amorphous structure, as follows from the appearance of rings constituted by point reflections. A calculation of interplanar spacings and their comparison with reference data demonstrated that, in sample produced by a PED treatment of iron grains, all fine particles (<100 nm) are composed of oxides: Fe_2O_3, Fe_3O_4, FeO. Coarse particles cannot be identified by electron diffraction analysis and are probably composed of Fe, which follows from XPA data and results of a chemical analysis, according to which the suspension produced by PED contains, immediately after the treatment, 85–90% Fe^0. This content decreases in the course of time, to become 20–40% in dry powders, which is due to oxidation of iron by atmospheric oxygen in storage, filtration, and powder drying. XPA data demonstrated that the products formed in electroerosion of iron grains mainly contain α-Fe^0, FeO, and Fe_2O_3 phases (see table). A comparison of the IR spectra obtained in this study (Figs. 3–5) with those reported in the literature [13, 14] demonstrated that the following compounds are formed in PED of a bed of iron grains in distilled water (stretching vibration frequencies are given in parentheses): Fe_2O_3 (560 and 1480 cm^{-1}), $FeFe_2O_4$ (415 cm^{-1}), FeOOH (485 cm^{-1}), and $FeOOH \cdot nH_2O$ (700, 1030, 1650 cm^{-1}). The whole body of data furnished by chemical analysis, XPA,

11	99.892	6886	1.169	27	1.170	30	α-Fe

and IR spectroscopy shows that the main solid products formed in iron dispersion by PED in distilled water are α-Fe, α-FeO, Fe_2O_3, Fe_3O_4, FeOOH, and $FeOOH \cdot nH_2O$.

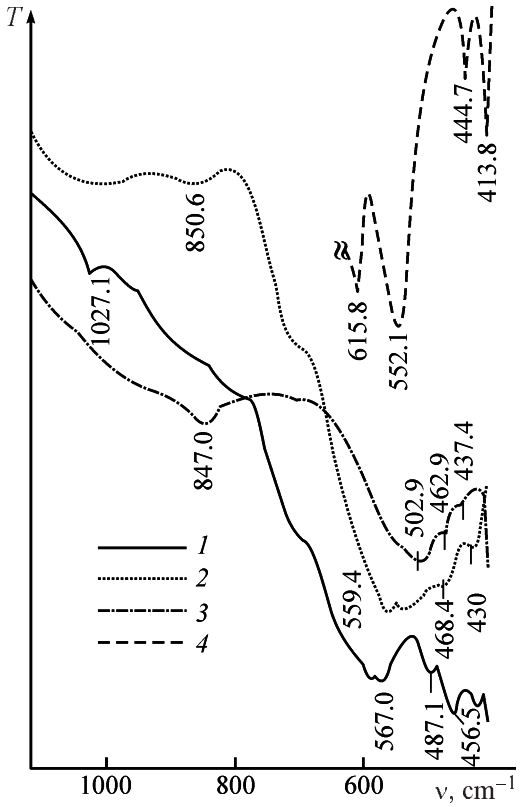

Fig. 3. IR spectra of samples produced by PED in a reactor with iron grains in (*1*) distilled water and (*2*) salt solution containing $Cr_2O_7^{2-}$ ions. (*3, 4*) Spectra of $Cr(OH)_3$ and Cr_2O_3 produced by a chemical method. (*T*) Transmission and (ν) wavenumber; the same for Figs. 4 and 5.

Thus, the results of the study suggest that, in a PED treatment of a bed of Fe grains in water, exclusively its oxidizing action is manifested. The PED energy is mostly expended for heating and dispersion of the metal, rather than for chemical reactions [1, 3, 6, 15]. Further, the dispersed iron is oxidized by water and atmospheric oxygen by the reactions

$$Fe^0 + H_2O = FeO + H_2, \quad (1)$$

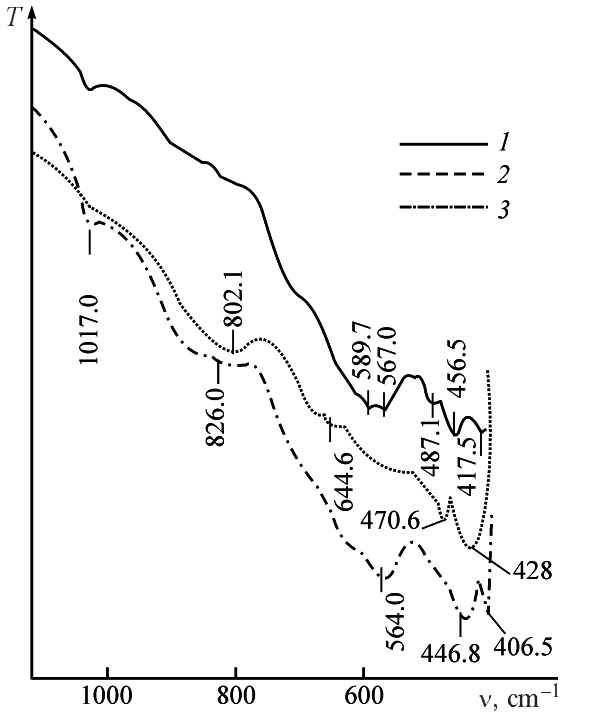

Fig. 4. IR spectra of samples produced by PED in a reactor with iron grains in (*1*) distilled water and (*2*) salt solution containing $H_2AsO_4^-$ ions. (*3*) Spectrum measured after sorption of $H_2AsO_4^-$ ions from solution on the product of electroerosion of Fe grains.

$$4FeO + O_2 + 2H_2O = 4FeOOH, \quad (2)$$

$$FeO + Fe_2O_3 = Fe_3O_4. \quad (3)$$

FeO is probably formed via $Fe(OH)_2$ decomposing because of the high local temperature in the discharge channel [15]. Also possible is oxidation of the metal by products of water decomposition. These are mainly OH radicals [8]:

$$H_2O \xrightarrow{PED} OH^{\cdot} + H^{\cdot}. \quad (4)$$

However, the steep decrease in the yield of the oxidized metal, observed as the solution temperature is lowered [1], indicates that radicals make only a small contribution to formation of the electroerosion products.

Fe–$K_2Cr_2O_7$ solution. The following vibration bands appear in the IR spectrum of a sample obtained by PED in a salt solution containing $Cr_2O_7^{2-}$ ions: band at 559 cm^{-1}, which belongs to Cr_2O_3 (552.1 cm^{-1}); bands at 430 and 850.6 cm^{-1}, which correspond to those associated with $Cr(OH)_3$ (437 and 847.0 cm^{-1}); and also a band at 846 cm^{-1}, which can be attributed to $[CrO_4]^{2-}$. Thus, it can be suggested that, as a result of PED treatment of a salt solution containing $Cr_2O_7^{2-}$ ions, the compounds Cr_2O_3, $Cr(OH)_3$, $Fe[CrO_4]$, and $Fe_2[CrO_4]_3$ are formed. Apparently, heated drops of dispersed iron reduce bichromate ions by the reactions

$$Cr_2O_7^{2-} + 3Fe + 7H_2O = 2Cr(OH)_3 + 3Fe(OH)_2 + 2OH^-, \quad (5)$$

$$Cr_2O_7^{2-} + 2Fe + 7H_2O = 2Cr(OH)_3 + 2Fe(OH)_3 + 2OH^-. \quad (6)$$

Further, Cr(III) hydroxide decomposes to give the oxide. It is also possible that insoluble chromates are formed because "superequilibrium" iron ions and an exchange interaction of $Cr_2O_7^{2-}$ with iron hydroxide occur at high temperatures:

$$2Fe^{2+} + Cr_2O_7^{2-} + H_2O = 2FeCrO_4 + 2H^+, \quad (7)$$

$$2Fe(OH)_2 + Cr_2O_7^{2-} = 2FeCrO_4 + 2OH^- + H_2O. \quad (8)$$

Fe–NaH_2AsO_4 and H_3AsO_3 solutions. The IR spectrum of a sample obtained by PED in a salt solution containing $H_2AsO_4^-$ ions shows bands associated with this ion adsorbed on erosion products (bands at 470.6 and 802 cm^{-1}) and with compounds $FeAsO_4$ or $FeAsO_3$ (band at 644.6 cm^{-1}). According to the data of [16], the presence of bands at 784–805 cm^{-1} clearly points to partial reduction of As(V) to As(III) (Fig. 4). Special-purpose experiments with an $H_3AsO_3^-$ containing solution demonstrated that, under the action of PED, the recovery of As(III) ions is incomplete and As(III) is oxidized to As(V), with the fraction of As(V) in solution constituting 7.5% relative to the initial concentration of As(III). The presence of bands associated with adsorbed anions is in agreement with published data on water treatment to remove arsenic impurities via adsorption on Fe and Al hydroxides [16]. In the case under consideration, inner-sphere complexes XH_2AsO_4 and XH_2AsO_3 (X is the goethite matrix) [16] are formed:

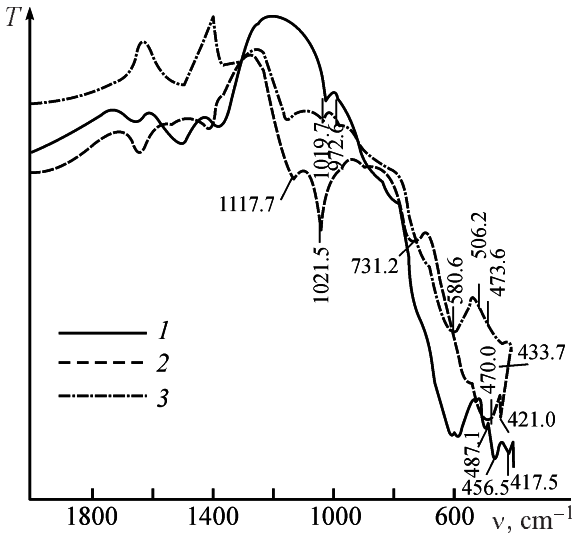

Fig. 5. IR spectra of samples produced by PED in a reactor with iron grains in (*1*) distilled water and (*2*) salt solution containing Mn^{2+} ions. (*3*) Spectrum measured after sorption of Mn^{2+} ions from solution on the product of electroerosion of Fe grains.

$$XOH + H_3AsO_4 \rightleftarrows XH_2AsO_4 + H_2O, \quad (9)$$

$$XOH + H_3AsO_3 \rightleftarrows XH_2AsO_3 + H_2O. \quad (10)$$

The transformation $As^{3+} \rightarrow As^{5+}$ in solution has been confirmed by chemical analysis [5]. This transformation virtually does not occur under the action of dissolved oxygen under ordinary conditions, even though it is thermodynamically possible. This process can occur in particular conditions because of heating or formation of $OH^{\cdot}$ radicals:

$$2H_3AsO_3 + O_2 \xrightarrow{T} 2H^+ + 2H_2AsO_4^-, \quad (11)$$

$$H_3AsO_3 + OH^{\cdot} = H^+ + H_2AsO_4^-. \quad (12)$$

As can be seen from the composition of the products, back transformation $As^{5+} \rightarrow As^{3+}$ is also possible and can occur in accordance with the equations

$$2H_2AsO_4^- + 2Fe = 2FeAsO_3 + 2OH^- + H_2O, \quad (13)$$

$$H_2AsO_4^- + 2H = H_3AsO_3 + OH^-, \quad (14)$$

$$H_2AsO_4^- + 2e_{aq} = H_3AsO_3 + 3OH^-. \quad (15)$$

However, a kinetic analysis demonstrated that both the redox reactions (11), (12) and the adsorption (9), (10) are described under PED conditions by Eq. (II), according to which the rate is proportional to the suspension concentration [Fe_s]. Hence follows that the main channel involves reactions initiated by repeated activation by the discharge of the steadily increasing number of suspension particles, i.e., reactions (11) and (13). Thus, in the case of As compounds, there may occur adsorption on erosion products [reactions (9), (10)], oxidation of As(III) by dissolved oxygen [reaction (11)], and reduction of As(V) by the discharge-dispersed metal [reaction (13)].

Fe–$MnSO_4$ solution. The IR spectrum of a sample obtained by PED in a salt solution containing Mn^{2+} ions shows absorption bands at 972.6, 731.2, 470.0, and 420.1 cm^{-1} (Fig. 5), associated with MnO_2 (characteristic bands at 970, 720, and 420 cm^{-1}) and MnOOH compounds (740, 550, and 485 cm^{-1}). The increase in the intensity of the absorption band at 1021 cm^{-1}, compared with the absorption band in the IR spectrum of a sample obtained by PED in H_2O, shows that the content of hydroxy groups in the sample increases. Thus, the following products are found experimentally: MnO_2, $Mn(OH)_4$, and MnOOH. The reduction of Mn^{2+} by iron is impossible because Mn is a more active metal than Fe. The removal of Mn^{2+} from solution may be due either to its oxidation to insoluble oxides and hydroxides of Mn^{3+} and Mn^{4+} or to precipitation of $Mn(OH)_2$. Also possible is reduction of the sulfate ion to SO_2 or to sulfide ion. Because no sulfides were found in the precipitate, the following reaction is more probable:

$$SO_4^{2-} + 2H_2O + Fe = SO_2 + Fe(OH)_2 + 2OH^-. \quad (16)$$

At the same time, oxidation of Mn^{2+} by the sulfate ion is thermodynamically impossible.

Because the removal of this ion from water is described by Eq. (II), it cannot be governed by the oxidation with the $OH^{\cdot}$ radical, which is a primary product of ED in water. The proportionality of the reaction rate to the concentration of dispersed iron may be associated with precipitation of $Mn(OH)_2$ by the hydroxide after reaction (16) and with the hydrolysis of Mn^{2+}, initiated by heated particles of the suspension and followed by oxidation of the hydroxide being formed:

$$Mn^{2+} + 2H_2O \xrightarrow{T} Mn(OH)_2 + 2H^+, \quad (17)$$

$$Mn(OH)_2 + 1/2O_2 + H_2O \xrightarrow{T} Mn(OH)_4. \quad (18)$$

Thus, the analysis of the reactions occurring under the action of PED on a bed of Fe grains in solution demonstrated that, in solutions of typical oxidizing agents (SO_4^{2-}, $Cr_2O_7^{2-}$, $H_2AsO_4^-$), these oxidants are reduced, whereas in solutions that contain reducing agents (H_3AsO_3, Mn^{2+}), these latter are oxidized. Also, to explain the results obtained, it is necessary to assume that there occur hydrolysis reactions and secondary reactions involving primary highly dispersed solid products. Such a multichannel behavior is accounted for both by the composition of the reagents and by the occurrence of the reactions under conditions of rapid temperature rises and falls.

CONCLUSIONS

(1) The products formed in chemical reactions that occur under the action of a pulsed electric discharge on a bed of iron grains in solutions of inorganic substances ($MnSO_4$, NaH_2AsO_4, H_3AsO_3, $K_2Cr_2O_7$) were identified. The composition of the products indicates that the reactions proceed in several thermodynamically possible, including opposite (oxidation and reduction), directions.

(2) The rate of recovery of a dissolved substance from water under the action of pulsed electric discharge is proportional both to the concentration of the substance and to that of dispersed iron, which points to a secondary activation of particles in subsequent discharges.

(3) The products of water decomposition in a discharge ($H^{\cdot}$ and $OH^{\cdot}$) do not contribute noticeably to the reactions with dissolved substances.

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received May 16, 2007

Abstract—Effect of a hydroacoustic treatment in a rotary-pulsed apparatus on the properties of sodium alginate solutions: dynamic viscosity, intrinsic viscosity, surface tension, and optical density, was studied. The contribution of the mechanical degradation of macromolecules to the observed decrease in the viscosity of alginate solutions was determined. The effect of the ionic strength of the solutions on their stability against hydroacoustic degradation was analyzed.

DOI: 10.1134/S1070427208050169

Sodium alginate is a polysaccharide of vegetable origin, produced from brown algae. This natural polymer is well-soluble in water and forms viscous thixotropic solutions. Owing to its unique physicochemical properties, good binding capacity, and film-forming ability, sodium alginate finds wide use in rather diverse fields: textile, paper, and food industries, as well as in cosmetology and medicine. The alginate is frequently used in mixtures with other polymers, which makes it possible to impart improved technological or consumers' properties to formulations of this kind. Highly homogeneous polymeric blends can be produced in rotary hydroacoustic apparatus. In these devices, a liquid polymeric material is subjected to an integrated action of ultrasonic vibrations and, accordingly, cavitation and also to high shear stresses created in the liquid in narrow (0.1–0.5 mm) gaps between elements of the rotor and stator [1]. Target processes of homogenization or fine dispersion under a hydroacoustic treatment (HA treatment) are, as a rule, accompanied by mechanically initiated structural and chemical transformations in polymers. Previously, data have been reported on the effect of an HA treatment on properties of solutions of certain polysaccharides: carboxymethyl cellulose [2], chitosans [3], and starch hydrogels [4]. In these studies, the primary attention was given to structural effects of the HA treatment and to its influence on the rheological properties of polysaccharide solutions. The fundamental aspects of initiation of mechanical degradation with rupture of polysaccharide molecules have been only considered for the example of starch [4]. No data on how the HA treatment affects the properties of sodium alginate solutions can be found in the literature.

The aim of this study was to examine the effect of HA treatments in a flow-through rotary-pulsed apparatus on properties of aqueous solutions of sodium alginate. A considerable attention was given to the problem of stability of sodium alginate against degradation in an HA treatment of its aqueous solutions.

EXPERIMENTAL

Aqueous solutions of sodium alginate (M = 340 000), used in the study, had concentrations in the range 0.25–8.0 wt %. The solutions were subjected to a mechanical treatment in a laboratory rotary-pulsed apparatus (RPA). The average gap between the rotating and immobile elements of the working chamber was 0.5 mm. The treatment conditions were as follows: rotor rotation rate 5000 rpm, to which corresponds a shear rate gradient of 17.7×10^4 s^{-1}; duration 4–60 s; and temperature 50°C. The choice of temperature was governed by the fact that, under an intense mechanical treatment, the solutions warm-up and heat is released into the environment. It was found experimentally that, at the chosen temperature, it can be maintained constant in the course of treatment, irrespective of the solution concentration. The only exception are solu-

tions with concentrations higher than 5 wt %, for which the treatment time did not exceed 30–40 s, which prevented an excessive warming-up.

The optical density of the solutions was measured on a Spekol-221 spectrophotometer at a wavelength $\lambda = 400$ nm. The molecular weight of sodium alginate was found using the Mark–Kuhn–Houwink equation

$$[\eta] = KM^{\alpha},$$

where K and α are empirical constants for a given polymer–solvent system; for aqueous solutions of sodium alginate, $K = 0.002$, $\alpha = 1$ [5].

The kinematic viscosity of the solutions was measured with Ubbelohde capillary viscometers (VPZh-2) with inner diameters of 0.99, 1.31, and 2.37 mm. The intrinsic viscosity was found by the viscometer with an inner diameter of 0.56 mm. The dynamic viscosity of sodium alginate solutions was measured with a Rheotest-2 rotary viscometer with a cylinder–cylinder working unit in the shear rate range 1.5–1312 s^{-1}. The surface tension of sodium alginate solutions at the interface with air was measured with a Rebinder instrument [6]. The method is based on measuring the rarefaction at which an air bubble breaks through a thermostated liquid being measured. The ratio between the diameters of the capillary and glass tube was 0.12.

The joint action of high tangential stresses and the ultrasonic field in RPA causes structural transformations in the polysaccharide solutions being treated and, accordingly, changes the structure-sensitive properties [3]. Figure 1 shows how the kinematic viscosity (a), optical density (b), and surface tension (c) of sodium alginate solutions depend on the duration of their treatment in RPA.

The viscosities of alginate solutions with different concentrations strongly differ and viscometers with different capillary diameters are to be used to measure these viscosities. Therefore, Fig. 1a presents data in the form of a ratio between the viscosity of mechanically treated solutions (η_A) and their initial viscosity (η_{in}). This approach enables comparison of the rates at which the viscosity decreases for solutions with different concentrations. Figure 1a shows that the rate of viscosity decrease increases with the solution concentration. The extent to which the viscosity decreases under mechanical treatment is determined by the degree of structuring of the solutions, which can be judged from the manner in which their dynamic viscosity depends on the shear

Sodium alginate solutions have small structural elements [7], which do not form any strong fluctuation network at moderate concentrations. Therefore, moderately concentrated solutions of this polysaccharide show high plasticity and a weakly pronounced anomaly of viscosity. As the alginate concentration increases, the solution becomes more structured. For example, the run of the dependence under consideration for a 5% solution indicates that there exists a pronounced anomaly of viscosity (Fig. 2, curve *1*). As a result of a mechanical treatment in RPA, the fluidity and plasticity of the solutions increases, which is evidenced by a considerable decrease in the slope of the curve (Fig. 2, curve *2*). Solutions of sodium alginate used in the study, with concentrations of 6, 7, and 8 wt %, have the form of a very thick mass (at a concentration of 8% the solution has virtually zero fluidity). As a result, these solutions cannot be introduced into the apparatus in the conventional way, through a feeding pipe. In these cases, an aqueous suspension of an as yet undissolved alginate was poured into the apparatus and kept there for a time necessary for dissolution, after which the resulting solution was treated in the RPA. Already after 30 s of an HA treatment, the concentrated solutions acquired fluidity.

The decrease in the structural component of the viscosity of sodium alginate solutions under an HA treatment is due to rupture of intermolecular hydrogen bonds and disintegration of aggregates of alginate macromolecules. The latter is also confirmed by the that the optical density of the solutions steadily decreases as the time of their mechanical treatment in RPA increases (Fig. 1b).

Figure 1c shows how the surface tension of sodium alginate solutions varies under mechanical treatment. The increase in the surface tension is due to the action of strong shear stresses on the solution in narrow gaps between the rotor and stator of the apparatus. Application of shear stresses results in that the conformation of macromolecules changes via their elongation in the direction of shear forces. After the shear load is removed, the system tends to return to the equilibrium state; however, a certain structural strain is preserved because of the fixation of forced deformations at the instant of treatment. In the course of the treatment, the deformed state of macromolecules can be fixed via formation of a network of molecular entanglements, associative contacts, and cavitation-induced cross-links. The extremal nature of the dependences presented suggests that processes of formation of a strained 3D network and its mechanical disintegration simultaneously occur in the course of treatment. In storage of RPA-treated solutions, the surface tension decreases via relaxation, which is promoted by agitation and temperature rise.

To elucidate the role of the mechanical degradation of alginate macromolecules in the decrease in the viscosity of the solutions, the intrinsic viscosities of polymer samples obtained from mechanically treated solutions by drying were determined by extrapolation. The alginate films obtained were comminuted and used to prepare solutions with a concentration of 0.005 g ml^{-1}, from which solutions of lower concentrations were produced by dilution. The experimental values of the intrinsic viscosity were used to calculate the molecular weight of the samples by the Mark–Kuhn–Houwink equation presented above.

The response of polymer–solvent systems to a hydroacoustic treatment is largely determined by the polymer concentration. The table lists parameters of the hydroacoustic degradation of the alginate in relation to its concentration in the solution at the instant of treatment. After 60 s of treatment at a rotor rotation rate of 5000 rpm, the maximum decrease in the molecular weight (from 340000 to 2200000) was observed for the least concentrated solution (0.25 wt %). For other concentrations, the molecular weight that could be reached was 270000–300000. As for the degradation rate, the effect of viscosity is more pronounced in this case. The degradation rate V (ruptures/s) was calculated as the number of elementary events of rupture of macromolecules in unit time by the formula

$$V = [10c(1/P - 1/P_0)V_c N_A]/(159t),$$

where P_0 and P are the degrees of polymerization

of sodium alginate in the initial and RPA-treated solutions; c, solution concentration (wt %); V_c, volume of the working chamber (l); 159, molecular weight of the elementary unit of the alginate; and t, treatment time (s).

It can be seen from the table that, as the alginate concentration is raised, the degradation rate first somewhat decreases, reaches the minimum value at c = 1.0 wt %, and then again starts to increase as the polymer concentration in solution grows further. With account of the fact that the rate is expressed in terms of the total number of macromolecule ruptures that occurred in the working chamber of RPA, i.e., actually by the amount of the work done, the result obtained can be understood as follows. It was confirmed in [8] that, at low concentrations and, accordingly, low viscosities, the main factor affecting the polymer is the ultrasonic cavitation. As the concentration of the polymer increases, the specific, i.e., that per unit mass of the polymer, acoustic energy decreases. Accordingly decreases the number of ruptures initiated in unit time. At concentrations exceeding 2 wt % alginate, the viscosity starts to steeply increase and the contribution of the shear component of the HA treatment to initiation of the mechanical degradation of macromolecules becomes more pronounced. In this concentration range, the effect produced by the rise in the total mechanical energy because of the larger shear component exceeds the decrease in the specific energy, caused by the increase in the polymer concentration.

In an RPA treatment of solutions with the highest concentrations of sodium alginate (7 and 8 wt %), its molecular weight increased in accordance with the values obtained for the intrinsic viscosity. Such an increase in the length of macromolecular chains may be due to recombination of macroradicals formed under the hydroacoustic treatment.

Sodium alginate is a polyion whose solutions are characterized by polyelectrolyte swelling of polymer molecules. It is natural to assume that the variation of the hydrodynamic radius of particles in solution with its ionic strength causes a change in the stability of the polymer against hydroacoustic degradation. To verify this assumption, 2% sodium alginate solutions whose ionic strength was varied by introducing different amounts of NaCl were subjected to a mechanical treatment in RPA. After the treatment, the ionic strength of the solutions was brought to the same maximum value (0.05 M) in order to measure the intrinsic viscosity under identical conditions. At the given ionic strength, the viscosity of the starting sodium alginate was 558 ml g^{-1} (675 mg l^{-1} without the salt). For the alginate treated in RPA in the form of a 2% solution containing no salt, the intrinsic viscosity measured at the same ionic strength (0.05 M) was 451 ml g^{-1}. The intrinsic viscosities of the alginate after a mechanical treatment for the same time (30 s) of 2% solutions with ionic strengths of 0.01, 0.02, 0.03, and 0.05 M were 475, 492, 504, and 505 ml g^{-1}, respectively. It can be seen that the rate at which the intrinsic viscosity decreases becomes lower as the ionic strength of the solution grows. The values reached by the intrinsic viscosities of solutions treated at ionic strengths of 0.03 and 0.05 M virtually coincide. This experimental result is in agreement with the data of [8], where it was found that, as the ionic strength increases, the swelling coefficient of macromolecules in a sodium alginate solution steeply decreases until the ionic strength of the solution reaches a value of 0.02 M and then remains virtually constant as the ionic strength grows further.

CONCLUSIONS

(1) The viscosity of sodium alginate solutions decreases under hydroacoustic treatment both because of the rupture of hydrogen bonds and decrease in the size of supramolecular formations and via mechanical degradation whose rate is determined, all other conditions being the same, by the concentration of the polymer in solution.

(2) The hydroacoustic treatment gives rise to a structural strain in sodium alginate solutions, which is manifested in a reversible increase in the surface tension.

(3) The stability of sodium alginate macromolecules against hydroacoustic degradation grows as the hydrodynamic radius of the macromolecules decreases and the ionic strength of polymer solutions increases.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Hydroacoustic Treatment on the Rate of Hydrolytic Degradation of Chitosan in Acetic Acid Solutions

I. M. Lipatova and N. A. Kornilova

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received November 15, 2007

Abstract—Effect of a hydroacoustic treatment in a rotary-pulsatory apparatus on the rate of hydrolytic degradation of chitosan in acetic acid solutions was studied. The influence exerted on the rate of activated hydrolysis of chitosan by its molecular weight and the process temperature was considered.

DOI: 10.1134/S1070427208050170

The permanent expansion of the possible application fields of chitosan makes topical a search for new methods for production of its chemical derivatives and finely dispersed formulations based on this polymer. One of new methods of this kind consists in that the polymer is subjected to intensive mechanical treatments in the presence of chemical reagents or other modifying ingredients. The capabilities of the solid-phase mechanochemical modification of chitosan in devices creating high shear stresses in strongly compressed solid substances are being rather intensively studied [1, 2]. The liquid-phase mechanochemical modification of dissolved chitosans has not been studied. The liquid-phase mechanochemical modification of polysaccharides can be performed via hydroacoustic treatment in rotary-pulsatory apparatus (RPA) [3, 4]. In apparatus of this kind, the most important factors of the activating effect on a substance dissolved or dispersed in a liquid are ultrasonic vibrations and the resulting cavitation, as well as strong uniaxial stresses to which the liquid is subjected in the narrow (0.1–0.5 mm) gaps between elements of the rotor and stator [5, 6].

In this study, the effect of the hydroacoustic treatment on the rate of chemical transformations in dissolved chitosan was analyzed for the example of the hydrolytic degradation. It is known that chitosan, a polyglucosamine of linear structure, dissolves only in acid media, and, therefore, the acid-catalyzed hydrolysis of glycoside bonds is the most characteristic process occurring even in storage of solutions at room temperature [7].

In this study we examined the effect of hydroacoustic treatment in a rotary-pulsatory apparatus on the rate of the hydrolytic degradation of chitosan in acetic acid solutions.

EXPERIMENTAL

The study was performed with chitosan samples of domestic manufacture (Bioprogress, Shchelkovo, Moscow oblast) with molecular weights $M = 5 \times 10^5$ (Kh-500), 3.6×10^5 (Kh-360), 1.2×10^5 (Kh-120, and 0.87×10^5 (Kh-87) whose degrees of deacetylation (DD) were 0.68, 0.73, 0.78, and 0.82, respectively. Weighed portions of chitosans were dissolved in aqueous solutions of 2% acetic acid under agitation in the course of 4–5 h.

Chitosan solutions were treated in a laboratory rotary-pulsatory apparatus in the recycle mode. The thermostated working chamber of the apparatus is formed by a rotor and a stator whose cylindrical rings have rectangular channels. In rotor rotation, there occurs fast alternation of the coincidence and noncoincidence of the rotor and stator channels, which gives rise to mechanical vibrations in the liquid in a wide frequency range, including ultrasonic vibrations. The average gap between the rotating and immobile elements of the working chamber is 0.5 mm. The rotor rotation rate was 5000 rpm, to which corresponds a shear rate gradient of 17.4×10^4 s^{-1}. The treatment duration was varied in the range 4–60 s.

The relative level of the cavitation appearing in mechanically treated chitosan solutions of various concentrations was evaluated by the degree of dis-

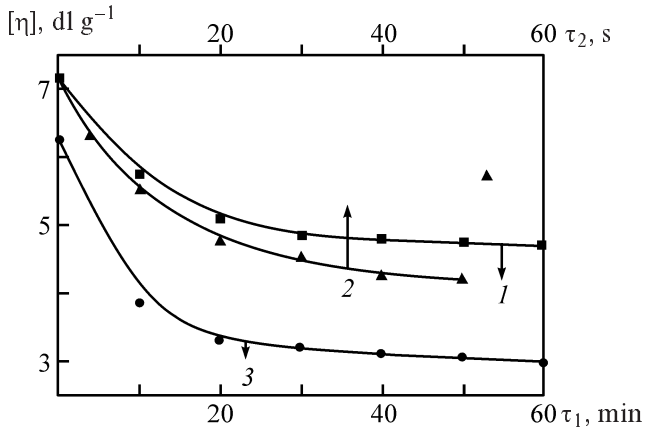

Fig. 1. Intrinsic viscosity [η] of Kh-360 chitosan vs. the duration τ_1, τ_2 of hydrolysis in a 2% acetic acid (60°C), with the process carried out in (*1*) thermostat without activation, (*3*) thermostat with activation, and (*2*) RPA.

persion of a powdered reference substance, *p*-iodonitrobenzene (initial particle size D = 50 μm). In a special-purpose experiment, this substance was introduced into chitosan solutions of various concentrations prior to mechanical treatment. The average particle size after treatment of the dispersions in RPA, d_p, was measured with an ANALYSETTE 22 COMPACT laser diffraction analyzer. The extent to which the cavitation level decreases as the viscosity of the medium becomes higher was evaluated by the ratio $(D - d_p)/(D - d_w)$ (d_w is the particle size reached in water).

The intrinsic viscosity [η] of dissolved chitosan samples was determined at 25°C in an Ubbelohde viscometer (capillary diameter 0.56 mm) by successive dissolution with 2% acetic acid. A 0.2 M solution of sodium acetate was introduced as a supporting electrolyte. The pH of the resulting buffer solution was 5.4.

The shear viscosity of the chitosan solutions was measured with a Brookfield rotation viscometer with the cylindrical rotor in the shear rate range 0.1–132 s^{-1} at 25±0.5°C.

The degree of deacetylation of the chitosans was found by potentiometric titration by the method described in [8].

The concentration of terminal reducing groups in chitosan was determined using the reaction with 3,5-dinitrosalycilic acid (DNSA) from the coloration intensity of the reaction product. According to the data of [9], the concentration of the reducing groups, found using this reagent, well correlates with the viscosity-average molecular weight of chitosan at its sufficiently low values, i.e., in those cases when chitosan can pass into solution at those rather high pH values of 10–12 at which DNSA dissolves. In this study, weakly colored precipitates were formed upon introduction of an alkaline solution of DNSA into solutions of the chitosans being analyzed. Upon densification in a centrifuge and separation, the precipitates were placed in planar transparent cells and, after scanning, the color differences between these precipitates and reference precipitates obtained at the same pH without DNSA were measured. The measurements were made on a colorimetric complex intended for determining the ratio of color coordinates of two similarly colored samples by the Kolorist program. The complex was calibrated against precipitates obtained from chitosan solutions into which different amounts of glucosamine sulfate were preliminarily introduced.

To study the effect of mechanical activation on the rate of hydrolytic degradation of chitosan in acetic acid solutions, the process was carried out at the same temperature (60°C) by three methods: (i) in a temperature-controlled flask with a stirrer, (ii) in a temperature-controlled vessel with a stirrer after a short (4 s) preliminary treatment in RPA, and (iii) in the working chamber of RPA. The values of [η] were found for samples taken in the course of the process. For the third method, the starting chitosan solution was subjected to several treatments, with the treatment duration increasing each time. The kinetic curves obtained for all the methods are shown in Fig. 1. It can be seen that the same decrease in the intrinsic viscosity (by 27%) is reached in 15 min without activation and in 20 s if the process is carried out in the RPA. In the case when the process is performed with a preliminary activation, the initial point of the kinetic curve lies lower, because even a short treatment of the solution in the RPA leads to a decrease in [η] of the polymer.

Treatment of chitosan solutions in RPA causes a substantial decrease in their viscosity, which is, as follows from Table 1, an overall result of the simul-

taneous occurrence of mechanically initiated structural and chemical processes. The decrease in the degree of structuring of mechanically treated solutions is evidenced by the increase in the dynamic stability of their structure (DSS), calculated from the results of rheological measurements by the formula

$$DSS = (90 - \alpha)/(\alpha - 45),$$

where α is the slope of the linear portions of the log–log dependences of the shear rate on the shear stress.

The decrease in the degree of structuring of the solutions is presumably due to mechanically initiated dispersing processes, i.e., to disintegration of stable aggregates of associated chitosan macromolecules under combined action of cavitation and shear stresses.

As follows from Table 1, the content of reducing groups in the system increases with the duration of hydroacoustic treatment. It should be noted that the molecular weights of mechanically treated chitosans, calculated from the intrinsic viscosities, were found to exceed those calculated from the concentrations of the reducing groups, whose values seem to be overestimated. The overestimation may be due to errors of calibration in the measurement procedure used. Nevertheless, the very fact of increasing content of reducing sugars confirms that the decrease in the intrinsic viscosity of chitosan after several seconds of mechanical treatment results from its mechanically activated hydrolysis by the conventional mechanism of nucleophilic substitution SN_1. As the treatment duration of the solutions in RPA increases, the concentration of the reducing groups again starts to decrease, which may be due to their activated oxidation. It is not impossible, either, that the terminal aldehyde groups can interact with the amino groups of chitosan to give a Schiff base [10]. The data in Table 1 also indicate that the depolymerization is accompanied by an increase in the degree of deacetylation of chitosan.

It is known that, the higher the content of acetylated monomer units in the polymer chain of chitosan, the faster the acid depolymerization [11]. With account of the fact that deacetylation occurs simultaneously with depolymerization in acid hydrolysis, the reaction conditions cannot be considered invariable in the course of time. Moreover, the reaction conditions additionally change with time because of the mechanically initiated structural transformations. Therefore, the reaction rates were not calculated in this study and it was considered possible to use the initial rate of the decrease in the intrinsic viscosity for comparative analysis of the kinetic curves. This rate is numerically equal to the slope of the tangent to the kinetic curve at the point corresponding to zero time. The rates V_{ah} of activated hydrolysis, calculated in this way for a reaction performed directly in the working chamber of RPA at chitosan concentrations of 0.1–1.0 wt %, were found to be, on average, two orders of magnitude higher than those for the process in a flask with a stirrer.

Table 2. Effect of the concentration of Kh-360 chitosan in 2% acetic acid on the efficiency of mechanical activation

The key factor of chemical activation in the hydroacoustic treatment is the ultrasonic cavitation. For polymer solutions, the acceleration of processes involving rupture of macromolecular chains results from the action of both the chemical effect of cavitation and its hydrodynamic factor (formation and collapse of cavities, appearance of shock waves). As seen from Table 2, the rate of activated hydrolysis in solution decreases as the chitosan concentration becomes higher. In this case, the effect of the concentration is manifested in two ways. As the polymer concentration increases, the energy dissipation becomes stronger and its amount per unit mass of the polymer decreases. In addition, as the polymer concentration increases, the viscosity of the solutions grows and, after it reaches a certain critical value, the cavitation starts to be suppressed. Table 2 lists relative values of the cavitation level with respect to water, CL_{rel}, for various concentrations of Kh-360 chitosan in the solutions being treated. For chitosan concentrations exceeding 2 wt %, a value at which no cavitation is observed, treatment in RPA leads to an increase in the intrinsic viscosity.

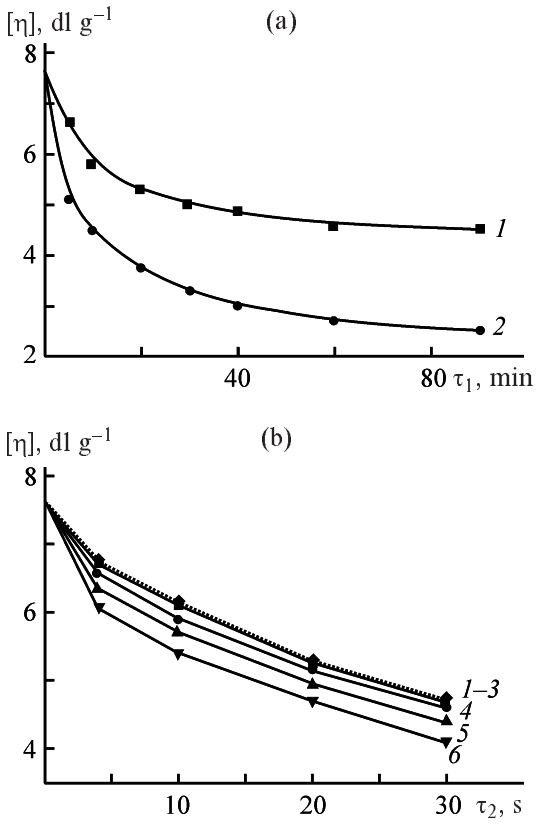

Fig. 2. Intrinsic viscosity [η] of Kh-360 chitosan vs. duration τ_1 and τ_2 of hydrolysis in 2% acetic acid at different temperatures for the process performed in (a) thermostat and (b) RPA. Temperature, °C: (a) (*1*) 60 and (*2*) 70; (b) (*1–3*) 30, 40, 50; (*4*) 60; (*5*) 70; and (*6*) 80.

The effect of the preliminary activation of solutions on the rate of the reaction performed under ordinary conditions was evaluated by the ratio of the reaction rate in an activated solution to that without activation, V_A/V. It follows from Table 2 that, as the chitosan concentration in solution increases from 0.25 to 2 wt %, the effect of preliminary activation becomes more pronounced, with V_A/V varying from 1.13 to 3.22. The increase in the process rate can be attributed to mechanical splitting of stable supramolecular formations in the solutions being treated. The degree of structuring of the solutions grows with the polymer concentration and, accordingly, the effect of activation due to the structural factor becomes more pronounced. It should be taken into account that the degradation and deacetylation processes have enough time to occur during preliminary mechanical treatment in less concentrated solutions to a greater extent, compared with more concentrated solutions. The final values of the intrinsic viscosity of chitosan, reached in the same hydrolysis time in preliminarily activated solutions of various concentrations, differ only slightly. A negative effect of preliminary activation was obtained for a 3% chitosan solution. The possible reason is that, in the absence of cavitation and high shear stresses, conditions for appearance of new stable supramolecular formations are created in sufficiently concentrated solutions. The increase in the degree of structuring of mechanically activated 3% solutions is evidenced by the decrease in the dynamic stability of their structure from 6.5 to 5.2.

When macromolecules are deformed in a mechanical field, their bond angles change and interatomic spaces increase, which leads to a decrease in the activation energy of rupture of strained bonds. It was of interest to study the effect of temperature on the rate of the mechanically activated hydrolysis of chitosan. Figure 2 shows kinetic curves for the hydrolytic degradation process performed at different temperatures in the ordinary conditions (a) and under hydroacoustic treatment (b). It can be seen that, in the latter case, the effect of temperature is considerably less pronounced, but not absent at all, which indicates that the activation of macromolecules has thermal and mechanical components. As can be seen in Fig. 2b, the initial rate of activated hydrolysis remains invariable as the temperature is changed from 30 to 50°C.

The effect of temperature on the rate of chemical reactions under a hydroacoustic treatment is due to changes in the efficiency of cavitation. As temperature increases, the water evaporation rate grows and the partial pressure of its vapor within a cavitation bubble becomes higher, which may cause a transition from gas cavitation to vapor cavitation. Thus, the appearance of cavitation is facilitated as temperature increases; however, the efficiency of bubble collapse becomes lower in this case [12]. On passing to higher temperatures (60–80°C), the temperature coefficient of the reaction increases, which may be due to a decrease in the contribution of the mechanical component to the activation of macromolecules.

The effect of the molecular weight of chitosan on the rate of mechanically activated hydrolysis depends on its concentration in solution. As follows from Table 3, the efficiency of mechanical activation at low concentrations increases with the initial molecular weight. The situation changes at higher concentrations, when the effect of viscosity on the cavitation level may be manifested. For example, the rate of hydrolysis at a polymer concentration of

Table 3. Effect of the molecular weight of chitosan on the initial rate of activated hydrolysis

c_{ch}, wt %	V_{ah}, dl g^{-1} s^{-1}			
	Kh-87	Kh-120	Kh-360	Kh-500
0.25	0.220	0.280	0.350	0.440
0.5	0.190	0.240	0.290	0.340
1.0	0.150	0.190	0.175	0.110
2.0	0.120	0.105	–	–

1.0 wt % is lower for the Kh-360 sample, compared to the Kh-120 sample. For the Kh-360 and Kh-500 samples, and increase in the intrinsic viscosity was observed at a polymer concentration of 2.0 wt % after a treatment of the solution in RPA. Naturally, the lower the molecular weight of the chitosan used, the higher will be the critical concentration of cavitation damping.

The experimental data on the influence exerted on the rate of activated hydrolysis by the concentration of a polymer, its molecular weight, and temperature confirm the decisive role of the ultrasonic cavitation in the increase in the reaction rate.

CONCLUSIONS

(1) The hydrolytic degradation under hydroacoustic treatment occurs at rate exceeding, on the average, by two orders of magnitude that under the ordinary conditions. The rate of activated hydrolysis decreases as the chitosan concentration in solution increases.

(2) Preliminary mechanical activation of solutions causes an increase in the rate of the process performed after that under ordinary conditions by a factor of 1.5–3. The efficiency of the preliminary activation grows with the chitosan concentration in solutions.

(3) The initial rate of activated hydrolysis is independent of temperature at its moderate values (30–50°C). In the range 60–80°C, the temperature coefficient of the reaction increases with temperature.

Abstract—The influence of zirconium dioxide nanopowders on the thermal oxidative degradation of an amine-cured epoxy polymer was studied.

DOI: 10.1134/S1070427208050182

Introduction into polymers of nanodispersed fillers is a simple and efficient method of controlling the mechanical and thermal properties of composite materials. Zirconium dioxide nanopowders are promising fillers for composite materials based on epoxy oligomers [1]. In epoxy polymers (EPs) containing such a filler, the mechanical properties vary with the ZrO_2 content in an unusual fashion depending on both the degree of dispersion of the ZrO_2 powder and its ability to form aggregates and agglomerates with different modes of particle binding [2].

At the same time, it is known that finely dispersed transition metal oxides are catalysts of various processes that can occur at elevated temperatures in polymeric and composite materials and can affect their heat resistance [3, 4]. In particular, transition metal oxides are catalysts of decomposition of hydroperoxides [5–7], which are initial stable products of high-temperature oxidation with oxygen of organic compounds, including polymers. Catalytic decomposition of hydroperoxides with a high yield of active radicals accelerates the thermal oxidative degradation of polymers. At a low yield of active radicals, the contribution of degenerate branching of oxidation kinetic chains in thermal oxidative degradation, the steady-state concentration of hydroperoxy groups, the oxidation autoacceleration factor, and the maximal oxidation rate decrease [8–10]. All the above factors substantially enhance the heat resistance of epoxy and other polymeric materials.

The mechanism of catalytic decomposition of hydroperoxides in the presence of transition metal compounds is not fully understood. In this study, we examined how the phase composition of zirconium dioxide powder, degree of its dispersion, and ability to form aggregates and agglomerates affect the thermal oxidative degradation of amine-cured EPs.

EXPERIMENTAL

Epoxy polymers and composites filled with ZrO_2 nanopowder were prepared from a mixture of diglycidyl ether of diphenylolpropane (DGDPP) and diglycidyl camphorate (DGC) and were cured with a stoichiometric amount of cyanoethylated diethylenetriamine UP-0633M. The curing of the compounds was performed at room temperature for 20 h with the subsequent heat treatment at 60°C for 2 h. Film samples 200 ± 5 μm thick were prepared on glass plates with a polysiloxane release coating. DGDPP samples were prepared by molecular distillation of ED-22 epoxy oligomer at a residual pressure of no more than 10 Pa. The melting point of crystalline DGDPP was 36.3°C; epoxy number 25.1. DGC [TU (Technical Specification) 88 Ukr. SSR 21 533-83; epoxy number 26.0, $n_D^{20} = 1.4832$; $\eta_{25} = 0.30 \pm 0.05$ Pa s) and UP-0633M (TU 6-05-1863–78; $d_4^{20} = 1.100 \times 10^6$ g m^{-3}; $n_D^{20} = 1.4822$; $\eta_{25} = 0.18$ Pa s) were used without additional purification.

Nanopowders of zirconium dioxide were prepared by physical impacts (UHF, pulsed magnetic field, ultrasound) after precipitation of zirconium oxynitrate (to obtain the monoclinic phase) and a mix-

ture of zirconium oxynitrate and yttrium nitrate in a 0.97 : 0.03 molar ratio counting on ZrO_2 and Y_2O_3 (to obtain the tetragonal phase) with the subsequent filtration and drying.[1] Calcination of the powders provided conversion (with crystallization) of the hydroxide into oxide and growth of particles to required size controlled by the heat treatment temperature.

The calcination temperature T_c and particle size D_{CSR} found from the X-ray diffraction patterns (mean size of coherent scattering regions, CSR), considering nanoparticles as single crystals, are listed in Table 1, together with the BET specific surface area S_{BET} found from the nitrogen adsorption and the specific surface area S_{CSR} calculated assuming the powder to be a set of spherical particles of the size equal to CSR size. The fractional composition and morphology of ZrO_2 powder were studied by transmission electron microscopy. Preliminarily the powders were treated by a special procedure [11] with ultrasonic sputtering over a carbon support. The D_{CSR} value was calculated by the Selyakov–Scherrer formula from the halfwidth $B_{0.5}$ of (111) diffraction peaks.

The kinetics of oxygen uptake was studied at a pressure of 0.1 MPa and a temperature of 200°C on a laboratory gas-volumetric device with an optoelectronic sensor whose sensitivity with respect to the rate of oxygen uptake by the polymers was 10^{-6} mol kg^{-1} s^{-1}. The rate of oxygen uptake was reduced to 1 kg of the organic component of the composite. The thermal gravimetric analysis (TGA) was performed on a Q-1500 derivatograph at a heating rate of 10 deg min^{-1} and free access of atmospheric oxygen. A 200-mg sample of a polymer film cut into 2 × 2-mm pieces was introduced into ceramic crucibles. Calcined aluminum oxide was the reference.

The study of the influence of the ZrO_2 concentration on the high-temperature autooxidation of EP showed that the oxidation of unfilled EP started after a relatively short (16–18 min) induction period (Fig. 1). Usually autooxidation of EP obtained by cationic polymerization proceeds without induction period [8–10]. Its appearance for amine-cured EP may be due to the inhibiting effect of unchanged amino groups of the curing agent. As known [12], at the stoichiometric ratio of the components of epoxy–amine systems, the polyaddition does not go to completion, and unchanged epoxy and amino groups inevitably remain in the polymer phase. In turn, amines are acceptors of peroxy radicals and exhibit antioxidative effect in motor fuel and polymers [13]. The thermal oxidative stability of hydrocarbons is substantially enhanced in the presence of not only aromatic but also aliphatic amines. Among the latter, secondary amines, including those obtained by polyaddition of epoxy compounds [14], are the most effective antioxidants.

Table 1. Characteristics of ZrO_2 powders

Powder no.	T_p, °C	Lattice type	D_{CSR}, nm	S_{CSR}	S_{BET}

1	500	Monoclinic	16	65	65
2	700	Monoclinic	21	52	37
3	1000	Monoclinic	48	22	8.6
4	800	Tetragonal	22	44	30

After the induction period, the dependence of the oxygen uptake on time is typical of noninitiated oxidation of polymers, with a short period of autoacceleration and a fairly long period when the oxidation proceeds at a practically constant rate (maximal oxidation rate, or rate of developed oxidation). This is followed by a relative decrease in the oxidation rate associated with decreasing "concentration" of polymeric chain fragments that are

the most susceptible to oxidation. The rate of the developed oxidation for unfilled EP reaches 4.9×10^{-4} mol kg^{-1} s^{-1}.

Introduction into the polymeric matrix of ZrO_2 powder nos. 1–4 (2 wt %) does not noticeably affect the duration of the induction period (Fig. 1) and slightly decreases the rate of developed oxidation (Fig. 2). This rate decreases in the order 1 > 2 > 3 > 4 for the composites filled with powder nos. 1–4, respectively. The decrease in the maximal rate of polymer oxidation without a change in the induction period is observed, as a rule, in the case of suppression of degenerate branching of oxidation kinetic chains because of decomposition of hydroperoxides (primary stable oxidation products) by metal compounds including oxides [8–10].

In the presence of 2 wt % ZrO_2 in the polymeric matrix, the decrease in the oxidation rate is insignificant. However, at the filler content increased to 10 wt %, the rate of the polymer oxidation decreases by a factor of 1.3–3.6. The highest antioxidative activity is observed with filler nos. 3 and 4 (Fig. 2). Powder nos. 3 and 4 also decrease the maximal rate of EP oxidation, but their antioxidative power is substantially weaker. With an increase in the ZrO_2 content to 20 wt %, the stabilizing effect of the filler against thermal oxidative degradation tends to decrease, but the ratio of the rates of polymer oxidation with additives of various nanopowders remains similar: The rate of the developed oxidation for the composites filled with powder nos. 3 and 4 is lower than that for the composites filled with powder nos. 1 and 2.

The thermal gravimetric (TG) study of thermal and thermal oxidative degradation of the composite showed that introduction into the amine-cured polymer of 10 wt % ZrO_2 weakly affects the variation of its weight on heating. Typical TG and differential thermogravimetric (DTG) curves of the filled and unfilled EPs are shown in Fig. 3. The TG and DTG curves for the unfilled sample are typical of amine-cured EPs. Within the range 170–200°C, the weight loss is small and is associated with evaporation of low-molecular-weight impurities. Further heating leads to the main stage of the thermal and thermal oxidative degradation with a maximum of the weight loss rate at 300°C.

Zirconium dioxide does not noticeably affect the evaporation of low-molecular-weight impurities, and at the same time the position of maximum *I* in the DTG curves remains unchanged (Table 2). The maximum corresponding to the main stage of the degradation splits in two components: *II* and *III* (Fig. 3). The similar effect was observed in [15] for a system consisting of epoxy–novolac block copolymer and amorphous boron. This splitting is due to the effect of the filler surface on the structure of the boundary layers of the polymeric matrix. On introduction of ZrO_2 into the polymer, in most cases, the temperatures of 5% and 10% weight loss (T_5, T_{10}), temperatures of the onset of the main degradation stage T_O, and temperatures of DTG maxima T_M vary within the limits of the measurement accuracy (Table 2). Only for the composite containing ZrO_2 powder no. 4 (it exhibits the most pronounced

antioxidant properties), the temperatures characterizing thermal and thermal oxidative degradation slightly increase.

The difference in the effects exerted by ZrO_2 on the rate of oxidation of the amine-cured polymer and on its weight loss during a thermal gravimetric experiment can be attributed to the fact that the oxidation processes in thickly cross-linked EPs are accompanied by formation of additional cross-links hindering evaporation of the decomposition products [16]. Therefore, the data of derivatography and gas volumetry do not always quantitatively correlate with each other. In addition, gas-volumetric data characterize the stability of polymers with respect to thermal oxidative degradation in the initial stages of the process at relatively low temperatures, whereas derivatography gives the corresponding information for high temperatures, when pyrolytic degradation of the polymer makes a substantial contribution to the total degradation process.

It follows from the above data that the antioxidative performance of zirconium dioxide, on the whole, increases with the temperature of the ZrO_2 thermal treatment. The temperature of calcination of ZrO_2 powders substantially affects the degree of their dispersion and the ability to form aggregates. We found that, with increasing T_c from 500 to 1000°C, the mean size of the powder particles of the monoclinic modification increases from 16.5 to 48.2 nm, and their specific surface area decreases by a factor of 7 (Table 1). In the process, the particles of powder no. 1 form planar aggregates of the size exveeding 2000 nm (Fig. 4a). The fact that interparticle gaps are observed suggests that these nanoparticles are weakly bound with each other. Powder no. 2 prepared at 700°C is also characterized by relatively low degree of binding and aggregation of particles (Fig. 4b). At 1000°C, powder no. 3 is formed, which is characterized by high degree of aggregation and forms agglomerates including strongly bound particles (Fig. 4c). Such bonding is provided by diffusion processes of agglomeration type and gives polycrystalline aggregates. Powder no. 4 doped with 3 mol % Y_2O_3 has a tetragonal lattice and is characterized by small degree of particle aggregation (Fig. 4d).

The observed trends in variation of antioxidative properties of the composites, caused by the influence of ZrO_2 nanopowders, are hardly associated with differences in the specific surface area of the filler and, the more so, with the degree of their aggregation. Variation of the surface properties of the filler is apparently a more significant factor.

It is known that metal oxide nanopowders are characterized by the high degree of defectiveness of the surface, mainly associated with the oxygen nonstoichiometry. The defects give rise to excess charge and enhance the interaction with the polymeric matrix, which leads to hydroperoxide decomposition due to acceleration of the catalytic reactions. The differences in the degree of defectiveness of nanopowders are determined by conditions of their preparation, in particular, by T_p. This factor may be responsible for quantitatively different effects of powder nos. 1–3, although they all have a monoclinic lattice.

In the case of nanopowder no. 4 doped with Y_2O_3 (it has a tetragonal lattice), there is one more factor. When ZrO_2 powder is doped with Y_2O_3, replacement of one Zr(IV) atom by one Y(III) atom is accompanied by formation of two oxygen vacancies. As a result, the surface, which is neutral in monoclinic particles, becomes positively

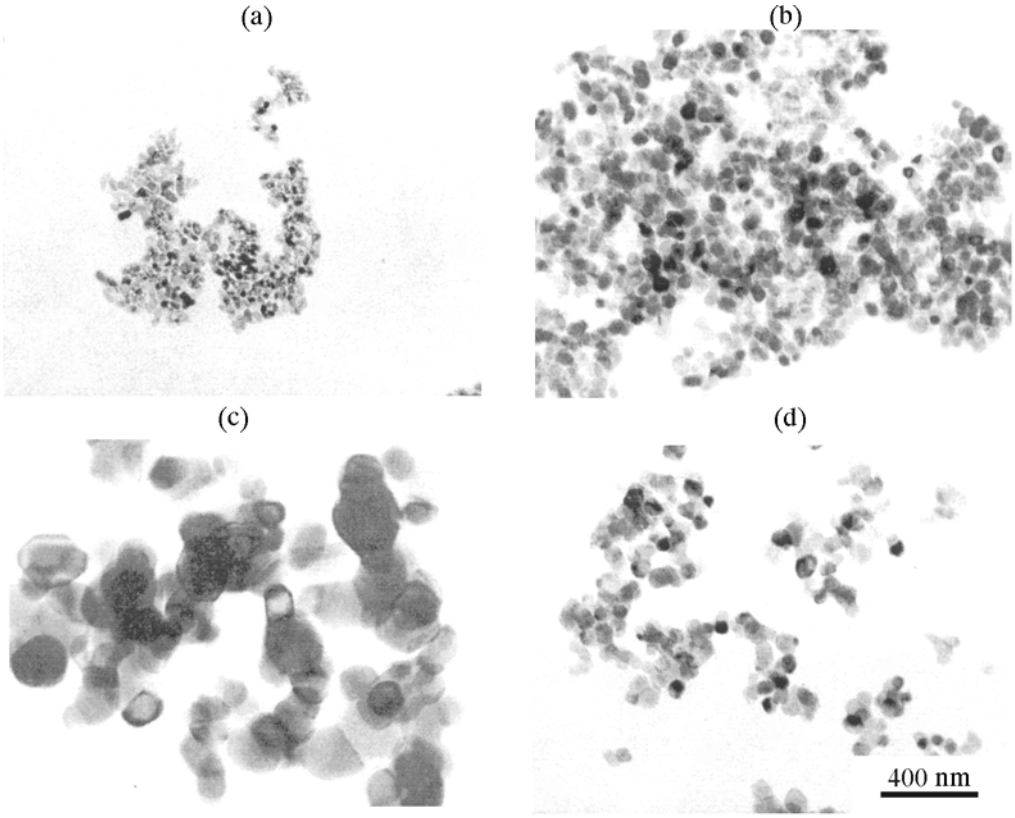

Fig. 4. Electron micrographs of ZrO_2 nanopowder nos. (a) 1, (b) 2, (c) 3, and (d) 4.

charged. This factor can favor catalysis of the hydroperoxide decomposition with a low yield of active radicals, suppression of the degenerate branching of oxidation kinetic chains, and decrease in the rate of thermal oxidative degradation.

Gas-volumetric study confirms this assumption. As seen from Fig. 2, composites containing 2 and 10 wt % powder no. 4 are characterized by the lowest oxidation rate. For such nanocomposites, the temperatures of the maxima in the DTG curves and the temperature of completion of thermal oxidative degradation are the highest.

CONCLUSIONS

(1) ZrO_2 nanopowders exhibit high antioxidative activity in amine-cured epoxy polymers, which is caused by the high defectiveness of the nanoparticle surface.

(2) The value of the antioxidant effect depends on conditions of nanopowder preparation (T_p, doping) and filler concentration.

Abstract—The effect of the heat treatment of aluminum hydroxide on the heat resistance and mechanical strength of composite materials based on ED-20 epoxy oligomer cured with isomethyltetrahydrophthalic anhydride was studied.

DOI: 10.1134/S1070427208050194

Polymeric compounds based on the system ED-20 epoxy–4,4'-isopropylidenediphenol oligomer–isomethyltetrahydrophthalic anhydride (iso-MTHPA) are widely used as structural and functional materials owing to the developed production basis and long-term operation experience. ED-20–iso-MTHPA formulations have low viscosity which changes insignificantly during a period of several hours. The properties of finished materials can be controlled by using various modifiers of epoxy systems. The most widely used method is introduction into polymers of small amounts of active fillers [1]. Fillers with active surface can affect certain properties of polymeric materials, in particular, enhance the heat resistance and improve the physicomechanical characteristics [2]. Metal oxides are widely used as fillers of thermoplastics and thermosetting plastics.

In this study we chose as modifying filler aluminum oxide whose surface chemistry has been extensively and comprehensively studied [3–7]. The improvement of properties of polymeric materials on adding active fillers is due to various kinds of interaction of the filler surface with the matrix and to a change in the mobility of macromolecules on the phase boundary. The chemical composition and specific surface area of aluminum oxide are also important [8, 9].

The goal of this study was the development of anydride-curable epoxy compounds with a high level of process and service characteristics using active fillers-modifiers.

EXPERIMENTAL

As starting materials we used the following substances. Components of the polymeric compound: ED-20 epoxy–4,4'-isopropylidenediphenol oligomer [GOST (State Standard) 1587–84], iso-MTHPA [TU (Technical Specification) 6-08-3321–73]; 2,4,6-tris-(dimethylaminoethyl)phenol (Alkofen, TU 22-362–95); modifiers of the epoxy–anhydride polymer: γ-AlO(OH) (S_{sp} = 20–30 $m^2 g^{-1}$), Al_2O_3 (S_{sp} = 20–30 $m^2 g^{-1}$), and α-Al_2O_3 (S_{sp} = 15–25 $m^2 g^{-1}$).

As starting compound for preparing aluminum oxide we used aluminum hydroxide precipitated from a concentrated solution of aluminum nitrate with ammonium hydroxide. The physicochemical properties occurring in aluminum hydroxide under thermal action were studied by derivatography (Fig. 1; MOM Q-1500D derivatograph, heating rate

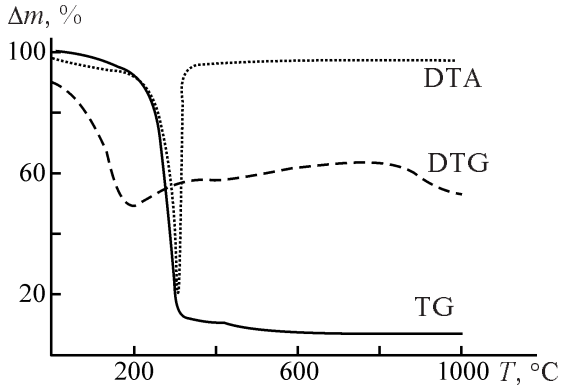

Fig. 1. Derivatograms of aluminum hydroxide powder: (Δm) weight loss and (T) temperature.

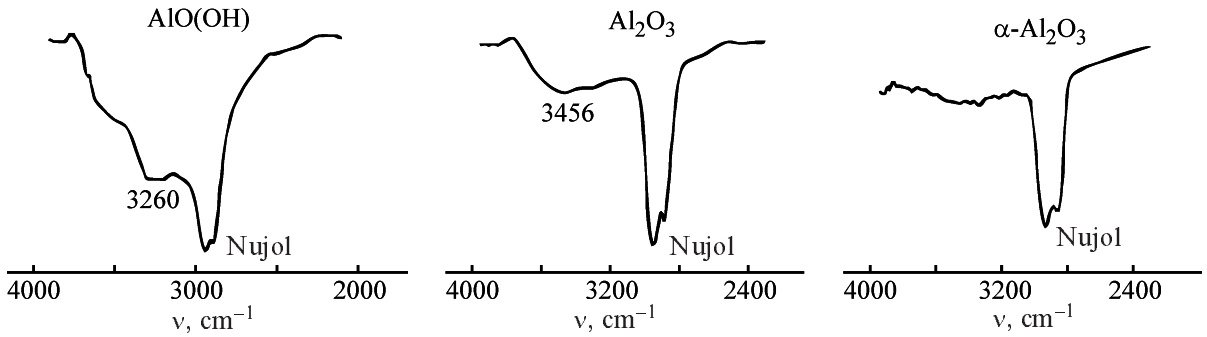

Fig. 2. Fragments of the IR spectra of products formed by thermal decomposition of aluminum hydroxide. (ν) Wavenumber.

10 deg min^{-1}). As seen from Fig. 1, the weight loss associated with the removal of adsorbed water and hydroxy groups is observed in the temperature range 150–600°C. Above 600°C, the weight does not change noticeably. Taking these data into account, to prepare modifiers with different content of surface hydroxy groups, we heated aluminum hydroxide to constant weight at 200, 600, and 1200°C. The sample of aluminum oxide prepared by isothermal heating at 200°C was identified by IR spectroscopy (IR Prestige 21) and chemical analysis as γ-AlO(OH) [10]. The sample of aluminum oxide (Al_2O_3) prepared at 600°C is X-ray amorphous. Calcination of aluminum hydroxide at 1200°C, according to X-ray phase analysis (Shimadzu XRD-6000), yields α-Al_2O_3 (corundum).

The obtained polymorphous modifications of aluminum oxide contain various amounts of hydroxy groups. An IR study showed (Fig. 2) that the intensity of the peak at 3400–3200 cm^{-1} originating from stretching vibrations of the hydroxy groups noticeably changes depending on the polymorphous modification of aluminum oxide, which indicates that different modifications contain different amounts of hydroxy groups: γ-AlO(OH) contains more OH groups and adsorbed moisture than does X-ray amorphous Al_2O_3, and α-Al_2O_3 contains no OH groups.

By differential scanning calorimetry (Shimadzu DSC-60 calorimeter) we studied the thermal effects of the polycondensation of the epoxy oligomer with the anhydride in the presence of active additives, aluminum oxides of various polymorphous modifications (Fig. 3). It can be seen that additions of γ-AlO(OH) and α-Al_2O_3 shift the exothermic peak toward higher temperatures by 15–20°C, whereas Al_2O_3 prepared at 600°C decreases the reaction onset temperature by 20°C. In the γ-AlO(OH)–oligomer–anhydride system, there is the second exothermic peak of curing at 170°C, suggesting that the oligomer/curing agent stoichiometry is disturbed by the large amount of OH groups present on the filler surface. Thus, Al_2O_3 prepared at 600°C exhibits the properties of active filler-modifier of the epoxy system: It reacts with the system components and decreases the onset temperature of the polycondensation of the epoxy oligomer with the anhydride.

The chemical reaction of the surface hydroxy groups with the epoxy groups was proved experimentally (GOST 12497–78) by the example of the model system phenyl glycidyl ether (PGE) : aluminum oxide (600°C) = 50 : 50. The results of determining the amount of epoxy groups in relation to the treatment temperature and time are given in Table 1.

It can be seen that the chemical reaction of the

hydroxy and epoxy groups with opening of the epoxy ring occus even at 20°C and becomes considerably faster at elevated temperatures; at 160°C, the epoxy groups disappeare virtually completely in 2 h.

The heat resistance after Martens for samples with various filler contents was determined according to GOST 21341. As seen from Table 2, addition of Al_2O_3 (600°C) increased the heat resistance relative to the unfilled polymer by approximately 15°C. In the polycondensation of the epoxy oligomer with the anhydride, aluminum oxide particles form additional network points and react with the epoxy matrix, which increases the adhesion of the polymer to the filler.

0.25	110 ± 2	27 ± 3	67 ± 5
0.5	114 ± 3	25 ± 1	70 ± 4
1.0	110 ± 2	25 ± 5	65 ± 4
1.5	114 ± 2	24 ± 4	60 ± 2
5.0	115 ± 3	33 ± 1	72 ± 4

Physicomechanical characteristics of the filled epoxy composites were determined with an IR 5057-50 testing machine (Table 2). The polymers modified with X-ray amorphous Al_2O_3 showed satisfactory mechanical strength. The tensile strength varied insignificantly, and the bending strength increased by approximately 15% with an increase in the modifier content by 1–1.5 wt %.

Thus, our results show that aluminum oxide prepared at 600°C exhibits properties of an active filler of epoxy–anhydride polymers. In the course of polycondensation of epoxy oligomer with the anhydride, aluminum oxide particles are incorporated in a polymeric matrix with the formation of chemical bonds between the polymer and filler, enhancing the heat resistance and mechanical strength of the material.

CONCLUSIONS

(1) The occurrence of a chemical reaction of active centers on the aluminum oxide surface with epoxy groups was proved by the example of a model system phenyl glycidyl ether–aluminum oxide.

(2) Al_2O_3 prepared at 600°C decreases the onset temperature of the polycondensation by 20°C.

(3) The highest heat resistance, increased by 15°C, is attained with X-ray amorphous Al_2O_3 used as modifier.

(4) On introducing 1–1.5 wt % X-ray amorphous Al_2O_3, the bending strength increases by approximately 15%.

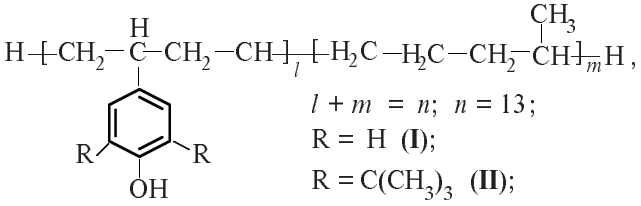
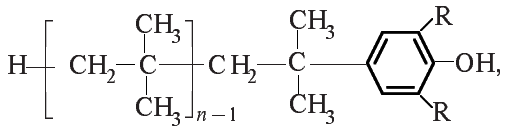
Abstract—The mutual influence of olefin and diene oligomers and bisoligoisobutenylsuccinimide, functionalized with sulfur and phenols, in model oil formulations in evaluation of their solubilizing effect and antioxidant activity was examined. The solubilizing power of the synthesized water-and-oil-soluble surfactant, sodium salt of oligomeric sulfur-containing phenol, in the presence of small concentrations of water was evaluated.

DOI: 10.1134/S1070427208050200



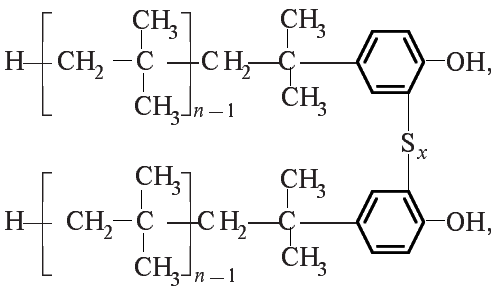
The modern level of the production of polymers and lubricants calls for the development of new additives capable to protect these materials in the course of processing, service, and storage. The problem is complicated by the fact that different kinds of actions require the presence of several additives, rather than a single additive, acting by different mechanisms. In this case, both synergistic and antagonistic effects of the components are possible. In the latter case, the consumption of ingredients reqiured to attain the desired result becomes unduly high.

It is well known that a dispersing detergent is a necessary component of additive kits. The demand for them grows annually by more than 1000 t [1]. Along with detergent, antioxidant and antiwear components are used [2]. Since separate compounds have different service properties, the required total result is attained only when the components are combined properly, taking into account the mechanism of their action [3]. The mutual influence of additives in a multicomponent system such as an oil formulation is poorly understood. At the same time, this problem is important for practice, because in going from model systems (a solution of an additive in isooctane) to real composites the mutual influence of components alters the required dosage of the ingredients.

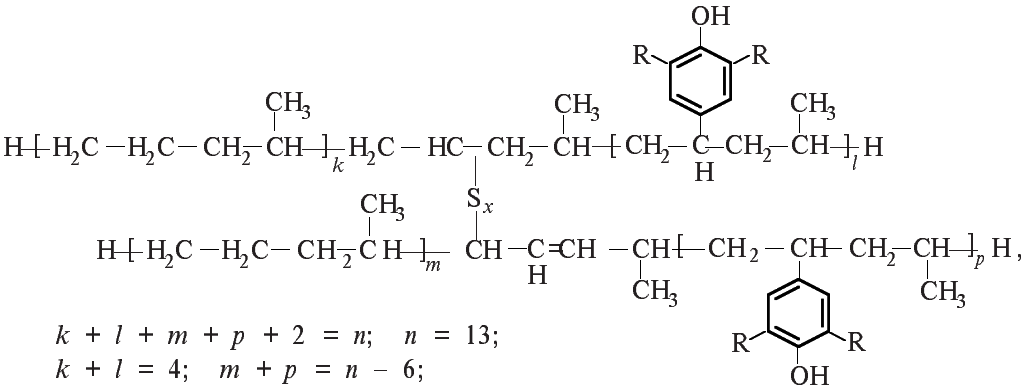


For controlling the properties of polymers and lubricating materials, additives based on oligomers with reactive groups have virtually unlimited potential. Among such oligomers, we should primarily mention oligoolefins and oligodienes. Olefin and diene oligomers functionalized with sulfur acquire antiscuff and antiwear properties, and introduction of phenolic fragments also imparts to the additives the antioxidative activity. Successive modification with introduction of sulfur and oxygen heteroatoms into oligomeric molecules expands the spectrum of their useful properties. In this study we examined the mutual influence of olefins, dienes, and bisoligoisobutenylsuccinimide, modified with sulfur and phenols, in model systems simulating oil formulations.

EXPERIMENTAL



To study the mutual influence of ingredients of a model oil formulation, we prepared oligoolefinyl- and oligodienylphenols by successive modification of oligoisobutylene ($\overline{M}_n$ = 390, 880) and oligopiperylene ($\overline{M}_n$ 910) with phenols and sulfur. The synthesis of the compounds was described previously in [4]. The notations are given in Table 1, and the structural formulas are shown below.



$l + m = n$; $n = 13$;
R = H (**I**);
R = C(CH$_3$)$_3$ (**II**);

R = H, n = 7 (**III**);
R = $C(CH_3)_3$, n = 7 (**IV**);
R = H, n = 16 (**V**);
R = $C(CH_3)_3$, n = 16 (**VI**);

n = 7 (**IX**); 16 (**X**);
x = 1–2.

$k + l + m + p + 2 = n$; n = 13;
$k + l$ = 4; $m + p = n - 6$;
R = H (**VII**); $C(CH_3)_3$ (**VIII**);
x = 1–2.

To optimize the concentrations of components of an oil formulation, we considered the effect of the above additives and succinimide (SI) as dispersing agent in studying their solubilizing effect and antioxidant activity (AOA). The effect of functionalized oligomers on the solubilizing effect of succinimide was evaluated on the quantitative level by calculating the critical micelle concentrations (CMCs) of products **I**–**X**. The CMC was determined spectrophotometrically at room temperature, by monitoring the variation of the optical density on varying the substance concentration in isooctane. For this purpose, we used bisoligoisobutenylsuccinimide **XI** prepared from oligoisobutylene of molecular weight 880.

Analysis of the spectrophotometric data (Fig. 1, Table 2) shows that the CMC ranges for sulfur-containing compounds are relatively narrow. A colloidal system of oligomeric alkylphenols is formed in a wider concentration interval.

The CMC values of the additives were found using the method for determining the solubilizing power of surfactants in isooctane, described in [5]. All the types of the examined compounds exhibited

the capability to solubilize Rhodamine C (Figs. 2a–2c). In the experiments with Rhodamine C, two types of curves were mainly obtained, with a steep (compounds **IX**, **IX** + **XI**, **VIII**, and **VIII** + **XI**) and gradual (compounds **VI**, **IV**, **II**) increase in the optical density with increasing concentration of the additive. This is caused by the fact that the transition from the nonaggregated system to a micellar solution in the first case occurs in the narrower concentration range than in the second case. For some formulations of the synthesized compounds with SI in isooctane, the concentration dependence of the solubilizing effect (SE, difference between the optical densities of the system before and after adding the dye) has an extremum (compounds **X** + **XI**, **VI** + **XI**, **IV** + **XI**, **II** + **XI**). Apparently, in this case the ingredients interact with each other (e.g., the hydroxy group of phenol alkylated with the oligomer can form a hydrogen bond with the amino group of **XI**), and the micelle structure changes.

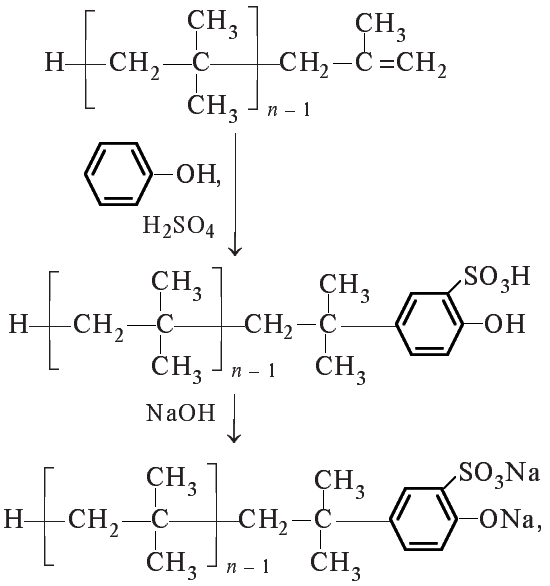
* In the presence of **XI**.



A combination of **XI** with sulfur- and oxygen-containing oligomeric additives enhances the solubilizing power with respect to the dye, which is manfested in a shift of CMC of the additives toward lower concentrations and in an increase in dD/dC (optical density increment, i.e., the slope of the dependence of the optical density on the concentration of the additive without the dye; Tables 2, 3).

Oligopiperylene functionalized with sulfur and with 2,6-di-*tert*-butylphenol and its mixture with **XI** are more effective solubilizing agents compared to the similar products of modification of oligoisobutylene. The synthesized compounds with a similar length of the hydrocarbon radical clearly demonstrate the effect of the sulfur content: CMC decreases, and its range becomes narrower. It should be noted that the CMC values of the oligomers modified with sulfur and phenols, determined by two different methods, are in good agreement (Table 2).

A study of the mutual influence of **XI** and oligomers modified with phenols and sulfur revealed that, when taken in combination, these compounds become effective solubilizing agents substantially shifting the CMC intervals toward lower values.

Effective functioning of lubricating materials implies that they should not contain even small concentration of water. Taking into account the fact that the water content of oils is subject to stringent limitations, it was interesting to examine the effect of water on the solubilizing action of oligomeric sulfur- and oxygen-containing surfactants, the more so as it was not studied previously. To examine the influence of the water concentration, we synthesized disodium salt of 4-oligoisobutenylphenolsulfonic acid by alkylation of phenol with oligoisobutylene in the

presence of sulfuric acid, followed by neutralization of the intermediate with sodium hydroxide:

where $n = 16$.

As seen from Fig. 3, introduction of a fixed amount of water (up to 0.03 wt %) leads to an increase in SE and in a shift of the CMC interval toward lower values (from 2.86×10^{-3} to 1.90×10^{-3} M). Water molecules penetrate into surfactant micelles and are bound by the functional groups, thus making the core more polar. In the process, the size and structure of micelles change and the tendency to micelle formation increases. As a result, the solubilizing power of disodium salt of 4-oligoisobutenylphenolsulfonic acid is enhanced. In so doing, the negative effect of water is eliminated. Furthermore, small concentrations of water enhance the solubilizing effect of surfactants.

Introduction of sulfur atoms into molecules of oligomeric phenolic oxidation inhibitors allows preparation of phenol (poly)sulfides that differ essentially from their low-molecular-weight analogs. In a molecule containing different inhibiting groups, e.g., a phenolic fragment and sulfide groups, intramolecular synergism is possible [6, 7]. A combination of sulfur- and oxygen-containing inhibitors in a formulation with other additives (antiwear, detergent-dispersing), can also enhance their action and give rise to a synergistic effect [8].

To examine the effect of a surfactant (we used compound **XI**) on the antioxidant activity of an inhibitor in a model oil formulation (with isopropylbenzene as substrate), we examined a combined effect of mixtures of **XI** with piperylene and isobutylene oligomers modified with phenol and sulfur, **I**–**X**. The quantitative characteristics of the antioxidative effect of individual oligomers functionalized with sulfur and phenol and of succinimide **XI** itself were determined previously [9]. The reactivity of the samples in combination with SI as antioxidants was

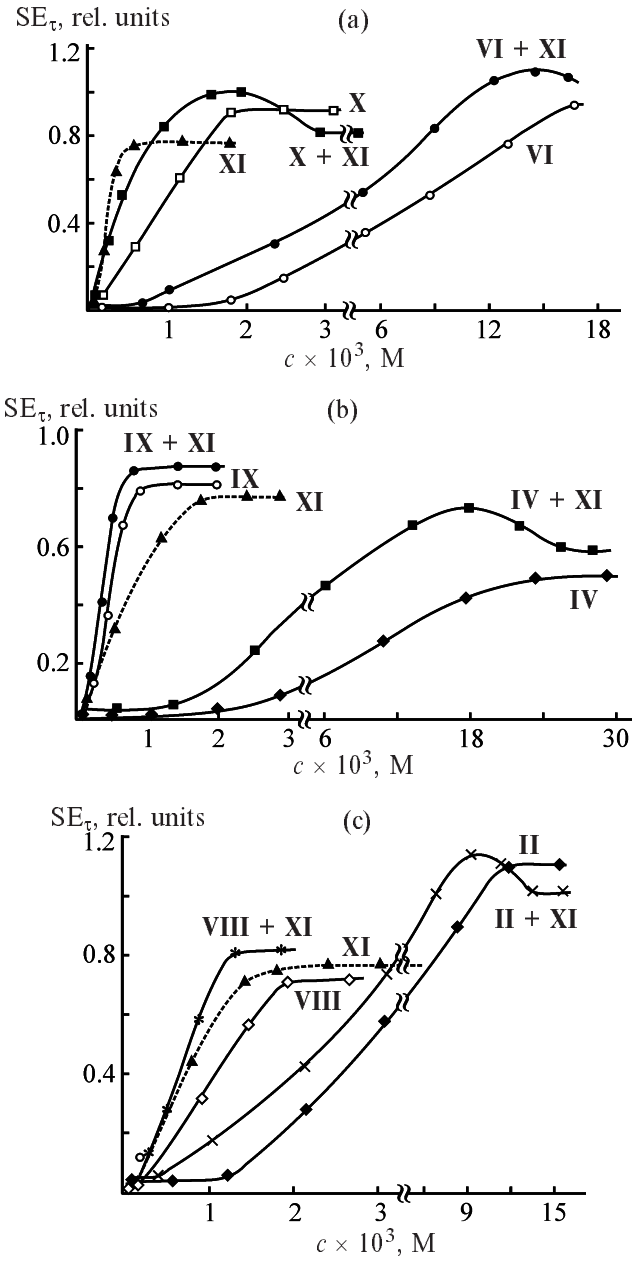


Fig. 2. Solubilizing effect SE_τ of modified oligomers as a function of their concentration c in isooctane: (a) modified oligoisobutylene (starting oligomer: $\overline{M}_n$ = 390; τ = 15 min), (b) modified oligoisobutylene (starting oligomer: $\overline{M}_n$ = 390; τ = 15 min), and (c) modified oligopiperylene (τ = 24 h). Concentration of bisoligobutenylsuccinimide in formulations with oligomeric additives 0.3 wt %.

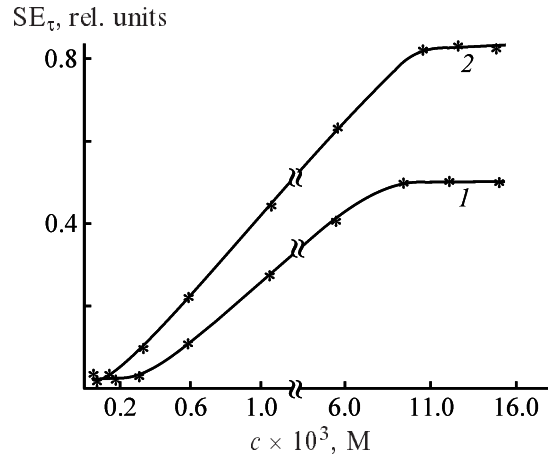

Fig. 3. Effect of water on the solubilizing effect SE_τ of disodium salt of 4-oligoisobutenylphenolsulfonic acid. (*c*) Concentration. (*1*) Without water and (*2*) in the presence of 0.03 wt % water.

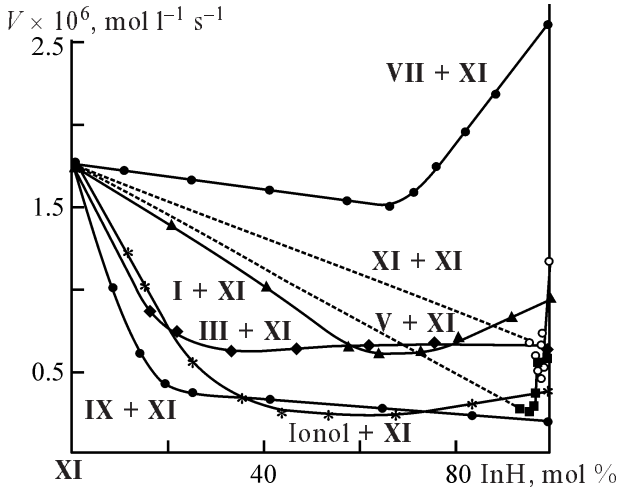

Fig. 4. Rate of cumene oxidation V as a function of the fraction of inhibitor InH in a binary mixture with bis-oligoisobutenylsuccinimide. Total concentrations, M: **III** + **XI** 1.5×10^{-4}, **IX** + **XI** 1.2×10^{-4}, **V** + **XI** 3.0×10^{-3}, **X** + **XI** = 4.5×10^{-3}, **I** + **XI** 3.0×10^{-4}, **VII** + **XI** 3.5×10^{-4}, and Ionol + **XI** 1.2×10^{-4}.

evaluated under standard conditions (T = 333 K, $V_i = 7.21 \times 10^{-8}$ mol l^{-1} s^{-1}) from the rate of the oxygen uptake (by the example of a model reaction of liquid-phase oxidation of isopropylbenzene under kinetic control, using a universal manometric unit; the relative error of the measurements does not exceed 10%). As oxidation initiator we used azobis(isobutyronitrile). The kinetic purity of cumene was estimated by comparing the specially measured oxidizability parameter $k/(2k_6)^{1/2}$ with the published data (k_2 and k_6 are the rate constants of chain propagation and termination for oxidation involving cumylperoxy radicals). The experimental value we obtained, $k_2/(2k_6)^{1/2} = (3.2 \pm 0.1) \times 10^{-3}$ (l mol^{-1} s^{-1})$^{1/2}$ (333 K, correlation coefficient r 0.9953) is in good agreement with published data [10]. The antioxidative performance of the samples was evaluated by the extent to which the initial rate of oxygen uptake in oxidation of the model substrate decreases in their presence. As reference we chose 2,6-di-*tert*-butyl-4-methylphenol (Ionol) for which we found $fk_{In} = (2.0 \pm 0.2) \times 10^4$ l mol^{-1} s^{-1}, which is also consistent with the published data [10].

The dependences of the rate of cumene oxidation on the fraction of the inhibitor in a mixture with **XI** (Fig. 4) show that, up to a certain component ratio, the inhibiting effect is stronger than the additive value. This fact is indicative of a synergistic effect. Further increase in the content of **XI** in the system leads to a decrease in the antioxidative effect. The inflection point corresponds to the concentration of the additive at which the behavior of the inhibiting system changes. A decrease in the antioxidative activity with an increase in the content of **XI** is apparently due to interaction of the system components and deactivation of the inhibiting compounds.

CONCLUSIONS

(1) The effect of oligomers modified with sulfur and phenols on the solubilizing action of bisoligoisobutenylsuccinimide was demonstrated. Introduction of the latter compound into an oil formulation makes narrower the interval of critical micelle concentrations of these compounds and shifts it toward lower values by 40% on the average.

(2) In the presence of small concentrations of water in the model colloidal system isooctane–surfactant, the solubilizing power of the synthesized surfactant, disodium salt of 4-oligoisobutenylphenolsulfonic acid, toward a dye increases.

(3) The effect of bisoligoisobutenylsuccinimide on the antioxidative activity of oligomers functionalized with sulfur and phenol was revealed. A synergistic effect in the antioxidative action is observed when products of chemical modification of oligopiperylene and oligoisobutylene are introduced into a model substrate in combination with bisoligoisobutenylsuccinimide.

(4) By taking into account the mutual influence of the synthesized oligomeric sulfur- and oxygen-containing additives and of a detergent, bisoligo-

isobutenylsuccinimide, in an oil formulation, it is possible to reduce the dosage of the additives to a minimum necessary for ensuring high service characteristics of the lubricating materials.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Imidazole and Benzotriazole Derivatives as Catalysts of Curing of Epoxy–Anhydride Binders

M. S. Fedoseev and I. V. Zvereva

Institute of Technical Chemistry, Ural Branch, Russian Academy of Sciences, Perm, Russia

Received July 14, 2007

Abstract—Derivatives of imidazole and 1,2,3-benzotriazole were prepared and studied as catalysts of curing of epoxy–anhydride binders. The physicomechanical properties and thermal endurance of the cured polymers were determined.

DOI: 10.1134/S1070427208050212

Epoxy binders for anhydride curing based on 4,4'-isopropylidenediphenol resins are widely used in production of polymer composites, in particular, organoplastics and of carbon- and glass-reinforced plastics. Curing of epoxy–anhydride binder is catalyzed by tertiary amines (triethylamine, benzyldimethylamine), Mannich bases, Lewis acids, 2,4,6-tris(dimethylaminomethyl)phenol, BF_3 complexes with aniline, α-naphthylamine, and monoethanolamine.

Imidazoles and their derivatives are also effective curing agents and catalysts of curing of epoxy compounds. The curing mechanism of epoxy oligomers in the presence of imidazole is described in detail by Jisova [1]. She showed that imidazoles containing substituents at position 2 exhibited the highest catalytic activity and could be used in practice.

Wang and Wong [2] studied properties of epoxy compounds containing 3,4-epoxycyclohexylmethyl 3,4-epoxycyclohexanecarboxylate, hexahydro-4-methylphthalic anhydride, and curing catalysts (1-cyanoethyl-2-ethyl-4-methylimidazole, imidazole, 2-ethyl-4-methylimidazole, and triphenylphosphine).

Polymers prepared by curing a mixture of epoxy oligomers containing two or three functional groups with methylendic anhydride in the presence of 2-ethyl-4-methylimidazole have relatively high glass transition point (185°C), which characterizes their thermal endurance.

Imidazole derivatives are used as latent catalysts for preparing a stable one-pot epoxy compound cured by thiols at low temperatures [4]. Imidazoles masked by reactions with toluylene, phenylene, and naphthylene diisocyanates are also used as promoters for curing epoxidized condensation products of phenol and bisphenol with formaldehyde, which, in turn, are used in production of printed-circuit boards [5].

Complexes of zinc chloride with some *N*-vinylimidazoles cure ED-6 epoxy resin in the presence of 2,4,6-tris(dimethylaminomethyl)phenol as a promoter at elevated temperatures. The Vicat softening points of the polymers cured under these conditions are higher than those of the polymers cured by anhydrides [6].

Brown et al. [7] studied the reaction products of phenyl glycidyl ether, 2-ethyl-4-methylimidazole, and Mn, Co, Ni, Cu, and Ag acetates and halides as ponetial latent curing systems for commercial epoxy resins. No data on thermal endurance of the cured polymers are reported.

The physicochemical and catalytic properties of imidazole and its substituted derivatives in curing of epoxide-containing polymer systems and in synthesis of various polymer binders used in production of composites are reviewed in [8, 9].

The aim of this study was to examine curing of epoxy resins by isomethyltetrahydrophthalic anhydride (IMTHPA) in the presence of imidazole derivatives and 1,2,3-benzotriazole (benzotriazole) and to determine elastic-deformation properties and thermal endurance of the cured polymers. As imidazole and benzotriazole derivatives we studied products of reactions of imidazole and benzotriazole with glycidol, phenyl glycidyl ether, and low-molecular-weight aliphatic epoxy resins (DEG-1 and Lap-

roksid-703), and also imidazole complex with zinc chloride.

EXPERIMENTAL

Imidazole derivatives were prepared from imidazole (99%, Johnson Mutthey Co.); 1,2,3-benzotriazole [pure grade, TU (Technical Specification) 6-09-1291–87] recrystallized from chloroform (mp 98°C), Laproksid-703 (TU 6-05-221-496–79) with 14.3% content of epoxy groups; DEG-1 (TU 6-05-1223–69) with 19.3% content of epoxy groups; phenyl glycidyl ether (PGE, TU 2225-510-00 203 521–94) with 27.0% content of epoxy groups; glycidol (TU 38.402-62-162–96) with 53.0% content of epoxy groups; and imported zinc chloride (98%).

The content of epoxy groups in all epoxy compounds was determined by back-titration [GOST (State Standard) 12497, paragraph 3]. The oligomer derivatives were prepared as follows. Imidazole or benzotriazole was dissolved in ethanol or toluene. An equivalent amount of an appropriate epoxy compound was added to the solution with stirring. The reaction mixture was stirred at 50–70°C for 1–5 h. The solvent was evaporated. The reaction of highly reactive glycidol with imidazole was performed at room temperature. In this case, glycidol was added dropwise to an ethanol solution of imidazole, and the resulting mixture was stirred for 3 h. The reaction products are viscous liquids. Their properties are given in Table 1.

The complex of imidazole with zinc chloride was prepared by mixing 1 mol of zinc chloride in diethyl ether with 2 mol of imidazole in the solvent at room temperature. The crystals precipitated in 24 h were filtered off on a Buchner funnel. The resulting crystals (mp 153–156°C) are insoluble in water, chloroform, and hexane but soluble in acetone and ethanol.

The zinc content of the complex was determined by complexometric back-titration with copper sulfate in the presence of 2-pyridylazo-2-naphthol (PAN) as an indicator [10]. The calculated and found zinc contents are 23.4 and 24.0%, respectively, which corresponds to the composition $ZnCl_2(imidazole)_2$.

Curing of ED-20 : IMTHPA = 100 : 70 compound in the presence of 1% imidazole, benzotriazole, and their reaction products was studied by differential scanning calorimetry (DSC) on a DSC-111 calorimeter (SETARAM, France) under the dynamic conditions at a heating rate of 5 deg min^{-1} in the range 20–250°C. The activation energy and enthalpy of the reaction were determined from the initial portion of the DSC curve (Piloyan's method [11]). The results are presented in Table 2.

Table 1. Properties of reaction products

Reaction product	Content of epoxy groups, %	Viscosity at 50°C, Pa s
DEG-1/imidazole	3.49	27.5
Laproksid-703/imidazole	2.78	2.5
PGE/imidazole	2.10	1.8
Glycidol/imidazole	4.47	1.8
DEG-1/benzotriazole	1.33	7.3
Laproksid-703/benzotriazole	0.30	2.5

Table 2. Kinetic parameters of curing of ED-20/IMTHPA compound in the presence of imidazole, benzotriazole, and their reaction products as catalysts

Catalyst	E_{eff}, kJ mol^{-1}	Q, J g^{-1}
DEG-1/imidazole	78.6	300
Laproksid-703/imidazole	83.1	262
PGE/imidazole	70.6	293
Glycidol/imidazole	70.6	305
DEG-1/benzotriazole	103.0	175
Laproksid-703/benzotriazole	130.0	190
1-Methylimidazole	70.6	326
Imidazole	74.6	330
Alkophen	75.6	283
$ZnCl_2$/imidazole	101.5	341.5

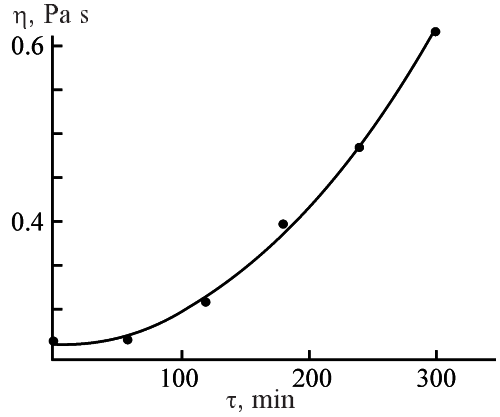
The viscosity of ED-20 : IMTHPA compound containing 1% $ZnCl_2(imidazole)_2$ complex was measured on a Rheotest-1 viscometer at 60°C in the course of 5 h (see figure).

The mechanical properties of epoxy polymers cured at 150°C for 2 h in the presence of the reaction products were determined according to GOST 270–75. The results are presented in Table 3.

As seen from Table 2, the reaction products of imidazole with glycidol and phenyl glycidyl ether exhibit the highest catalytic activity in curing of IMTHPA epoxy resin. The activation energy of curing in the presence of these catalysts is 70.6 kJ mol^{-1}. It should be noted that the activation energy of curing in the presence of widely used 2,4,6-tris(di-

Table 3. Physicomechanical properties and softening points of cured epoxy polymers

Epoxy resin	Catalyst	Tensile strength at 25°C, MPa	Relative elongation, ε, %	Vicat softening point, °C
ED-20	Alkophen	45	9.0	71
	DEG-imidazole	46	9.5	138
UP-610	Alkophen	65	12.0	153
	DEG-imidazole	68	10.0	190
EkhD	Alkophen	54	12.0	250
	DEG-imidazole	52	10.0	280



methylaminomethyl)phenol (Alkophen) and unsubstituted imidazole is 75.6 and 74.6 kJ mol^{-1}, respectively.

The reactivity of the system (activation energy 101.5 kJ mol^{-1}) in the presence of zinc chloride complex with imidazole is significantly lower, which suggests its latent catalytic activity. This is also confirmed by a small change in the viscosity of the system at 60°C in the course of 5 h.

The catalytic activity of the reaction products of benzotriazole with DEG-1 and Laproksid-703 is lower. The activation energy of the process in their presence is 103 and 130 kJ mol^{-1}, respectively. The heat release in curing is weaker.

The results of a DSC study of the curing kinetics of ED-20 epoxy resin show that the catalytic activity of the imidazole derivatives in question is comparable to that of conventional catalysts such as Alkophen.

The physicomechanical properties and softening points of epoxy resins with different functional groups cured in the presence of a conventional catalyst of anhydride curing (Alkophen) and the reaction product of imidazole with DEG-1 aliphatic resin are presented in Table 3. The softening point of the polymer cured in the presence of the imidazole derivative is higher, which is probably due to incorporation of imidazole molecules in the polymer chain, thus increasing the rigidity and density of packing of the polymer chains.

Kinetic curve of an increase in the dynamic viscosity of ED-20 : IMTHPA compound in the presence of $ZnCl_2$/imidazole at 60°C. (η) Viscosity and (τ) time.

As we expected, the tensile strength and softening point of the polymers increase in going to tri- and tetrafunctionalized UP-610 and EDX epoxy resins. Polymers with more heat-resistant and more rigid matrix formed from these resins can be used in the development of new heat-resistant polymer compounds.

CONCLUSIONS

(1) The catalytic activity of the reaction products of imidazole and 1,2,3-benzotriazole with epoxy compounds is higher than that of the reaction products of imidazole with phenyl glycidyl ether, glycidol, and DEG-1. 1,2,3- Benzotriazole derivatives exhibit a weak catalytic activity.

(2) The reaction product of imidazole and DEG-1 is an active curing catalyst. Some epoxy resins cured in the presence of this catalyst exhibit increased softening point.

(3) The complex of imidazole with zinc chloride exhibits latent catalytic activity, which allows an increase in the shelf life of the epoxy compounds at room temperature (increase in the vitality) and their rapid curing at a high temperature.

Abstract—The activity of tris(diethylamino)diallylaminophosphonium tetrafluoroborate and chloride in radical polymerization reactions was studied. The kinetic relationships of the copolymerization with sulfur dioxide were examined.

DOI: 10.1134/S1070427208050224

Synthesis of complexing ion exchangers for selective uptake of definite ions from multicomponent solutions is an important practical problem. One of research lines in the synthesis of selective ion exchangers is preparation of phosphorus-containing complexing ion exchangers exhibiting specific features in sorption [1]. The interest in polymeric phosphorus derivatives considerably increased owing to success in the synthesis and use of organophosphorus extractants exhibiting high potential as complexing agents. An important advantage of these compounds is the possibility of widely varying substituents at the phosphorus atom and hence the electron-donor power and steric conditions of the complexing center.

Phosphorus-containing sorbents exhibit a wider range of properties compared to other known sorbents [1]. It is known that the heteroatoms N, O, and S, tending to coordinate with metals, when present in molecules of organophosphorus complexones, impart to them the specificity toward certain cations [2]. Nitrogen atoms of phosphorylated polyamine derivatives also participate in coordination with metal ions. Phosphorylated polyamines exhibiting selective action can be successfully used for fractional determination and isolation of cations occurring in difficult-to-separate combinations. The separation of transition and rare-earth metals is considerably simplified by a large difference in the strength of complexes of phosphorylated polyamines with these elements. High stability constants of complexes of some phosphorylated polyamines with Cu^{2+} and Fe^{3+} make these complexones promising in agriculture for curing of copper and iron chlorosis of plants [2]. The capability of aminopolyphosphonic compounds to form complexes with various elements (Cu, Be, U, Pb, etc.) opened prospects for their use for removing these metals from a living body [2, 3]. Thus, synthesis of novel phosphorylated polyamines is a topical problem.

In this study we examined the reactivity of diallylaminophosphonium salts in radical (co)polymerization reactions and the properties of the resulting copolymers.

EXPERIMENTAL

Tris(diethylamino)diallylaminophosphonium chloride (EAAP-Cl) was prepared as follows. To 392 g (1.5 mol) of tris(diethylamino)diallylaminophosphazohydride, we added with vigorous stirring 600 g (7.5 mol) of freshly distilled allyl chloride, and the stirring was continued until self-heating of the reaction mixture ceased. Then, with the stirring continued, 225 g (6.4 mol) of NaOH in the form of a 50% aqueous solution was added. In the process, the temperature was maintained within 38°C. After adding the whole amount of NaOH, the mixture was stirred for an additional 30–45 min and then was gently refluxed for 10–12 h with stirring. After cool-

ing, the middle layer was separated, and EAAP-Cl was extracted with dichloromethane. The extract was evaporated on a rotary evaporator at 100°C in steps: first in a water-jet-pump vacuum and then in a rough vacuum (5–7 mm Hg). Yield of EAAP-Cl 490 g (86.5%). The purity was checked by elemental analysis and ^{13}C NMR (Table 1). Elemental composition:

Found, %: C 56.82, H 11.06, N 14.55.
Calculated, %: C 57.07, H 10.57, N 14.79.

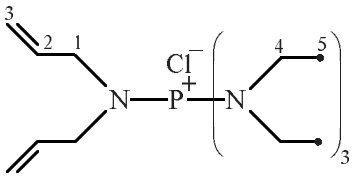
Tris(diethylamino)diallylaminophosphonium tetraphenylborate (EAAP-BF_4) was prepared as follows: 490 g (1.3 mol) of EAAP-Cl was dissolved in 2.0 l of distilled water, and 960 g of 20% aqueous solution of sodium tetrafluoroborate (1.7 mol of dry matter) was added dropwise with vigorous stirring. The mixture was stirred for 15–20 min and allowed to stand for 24 h at room temperature. Then the precipitate was filtered off, washed with distilled water, and dried in a vacuum at 80°C to constant weight. Yield of EAAP-BF_4 390 g (70.1%). The purity was checked by elemental analysis and by ^{13}C and ^{1}H NMR spectroscopy (Table 1). Elemental composition:

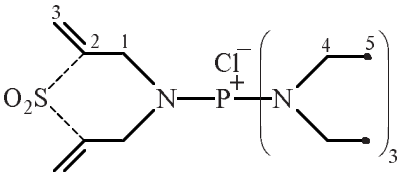
Found, %: C 49.72, H 10.03, N 12.83.
Calculated, %: C 50.23, H 9.30, N 13.02.

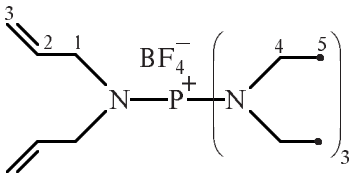
The monomers (acrylonitrile AN, methyl methacrylarte, acrylamide, *N*-vinylpyrrolidone), initiators [azobis(isobutyronitrile) AIBN, potassium persulfate, benzoyl peroxide], and solvents (dimethyl sulfoxide DMSO, methanol, tetrahydrofuran THF, dichloromethane) after purification by standard procedures had characteristics agreeing with the reference data. Sulfur dioxide was dried by passing through concentrated H_2SO_4 and freshly calcined $CaCl_2$.

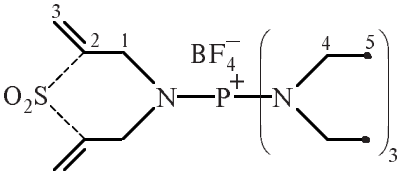
Homo- and copolymerization of diallylaminophosphonium salts with vinyl monomers was performed in solution in the presence of the above initiators in evacuated ampules, and the copolymerization with SO_2, in a glass reactor as described in [4]. The polymers were purified by twofold reprecipitation from a solution in appropriate solvent into a precipitant (THF), washed with THF, and vacuum-dried to constant weight at 50°C. The composition of the copolymers was calculated from the results of elemental analysis.

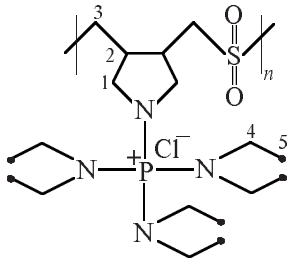
The NMR spectra were recorded on a Bruker AM-300 spectrometer operating at 300 MHz for ^{1}H and 75.5 MHz for ^{13}C. The ^{13}C NMR spectra were recorded with broad-band proton decoupling and in the JMOD mode. As solvents we used DMSO-d_6 for the copolymer of EAAP-BF_4 with SO_2 and D_2O for the copolymer of EAAP-Cl with SO_2. The internal reference was tetramethylsilane and 2,2-dimethyl-2-silapentane-5-sulfonic acid, respectively.

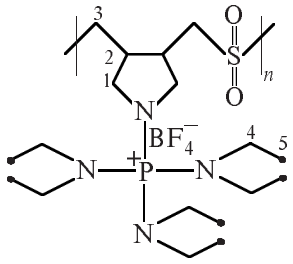












The acute toxicity parameters of copolymers of diallylaminophosphonium salts with sulfur dioxide were determined by the method described in [5]. The antimicrobial activity was studied on two strains of conditionally pathogenic cultures (*E. coli*, strain 25922; *St. aureus*, strain 906) by double serial dilutions [6]. As solvents in screening experiments we used DMSO for EAAP-BF_4–SO_2 copolymer and water for EAAP-Cl–SO_2 copolymer.

A study of the activity of the diallylaminophosphonium salts EAAP-BF_4 and EAAP-Cl showed that these compounds do not undergo substance-initiated radical homopolymerization. The diallylaminophosphonium salts exhibit also low activity in the copolymerization with vinyl monomers (AN, methyl methacrylate, acrylamide, *N*-vinylpyrrolidone, etc.): The reaction rates are low, and incorporation of the diallylaminophosphonium units into the polymer chain is insignificant. In particular, in copolymerization of EAAP-BF_4 (30 mol %) with AN (70 mol %) in DMSO solution in the presence of AIBN (3 wt %) at 80°C, a copolymer of the composition EAAP-BF_4 : AN = 2.6 : 97.4 (mol %) is formed in 27% yield in 10 h. Similar product compositions and copolymerization rates were observed in copolymerization of diallylaminophosphonium salts with the other vinyl monomers described above.

Diallylaminophosphonium salts showed considerably higher activity in copolymerization with sulfur dioxide exhibiting high electron-acceptor activity. The copolymerization occurs at high rates with the formation of alternating copolymers of equimolar composition, irrespective of the monomer ratio in the starting mixture and reaction conditions (temperature, solvent, initiator, degree of conversion).

The ^{13}C NMR spectra of mixtures of EAAP-BF_4 and EAAP-Cl with SO_2 showed that the signals of the carbon atoms of the allyl groups become noticeably shifted relative to the free monomers (Table 1). This fact suggests formation of donor–acceptor complexes of both monomers with SO_2. However, the shifts are considerably larger than those in the previously studied complexes of SO_2 with *N*-allyl

monomers, in particular, with diallylhydrazines [7]. Apparently, in diallylaminophosphonium salts, the P and N atoms of the electron-donor $-PN(C_2H_5)_2$ groups also participate in the complexation.

A kinetic study of the copolymerization of diallylamimophosphonium salts with SO_2 at low conversions showed that the reaction rate as a function of the monomer ratio passes through a maximum at

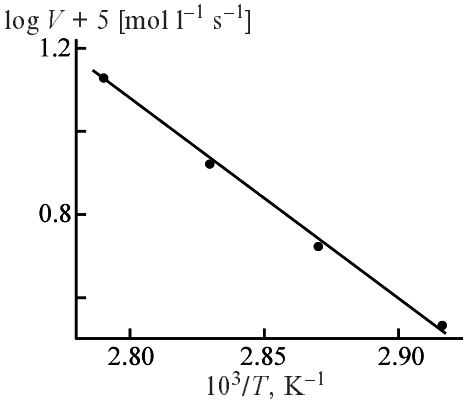

Fig. 1. Initial copolymerization rate V of EAAP-BF_4 (M_1) with SO_2 (M_2) as a function of temperature T. $[M_1 + M_2] = 1$ M; $M_1 : M_2 = 1 : 1$; 3.0×10^{-2} M AIBN.

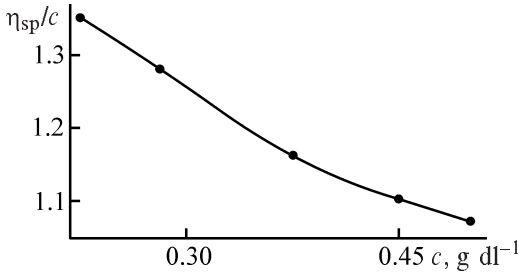

Fig. 2. Reduced viscosity η_{sp}/c of copolymer of EAAP-BF_4 (M_1) with SO_2 as a function of concentration c (DMSO, 25°C).

the equimolar ratio. Deviations from the equimolar ratio toward both sides lead to a decrease in the reaction rate due to a decrease in the concentration of the reactive complex in the system.

Kinetic studies of the copolymerization of EAAP-BF_4 with SO_2 in methanol in the initial steps of conversion showed that the reaction order is 0.75 with respect to the initiator and 1.35 with respect to the monomer (to the sum of the monomers at their equimolar ratio). Increased reaction orders with respect to the initiator and monomer (compared to those common for radical polymerization) are apparently associated with the fact that the copolymerization occurs via complexation, and also with the high viscosity of the system even at low conversions. The overall activation energy of the copolymerization of EAAP-BF_4 with SO_2 in a methanol solution at 70–90°C, calculated from the Arrhenius dependence, is 91.0 ± 2.0 kJ mol^{-1} (Fig. 1). The reaction rate and the copolymer yield depend on the medium (Table 2), with the best results obtained in methanol.

Table 2. Influence of the reaction conditions on the yield of the copolymer of tris(diethylamino)diallylaminophosphonium tetrafluoroborate with SO_2. $M_1 : M_2 = 50 : 50$, $[M_1 + M_2]$: solvent = 50 : 50 (wt %), 3 wt % AIBN, 7.0 h

Copolymerization conditions		Yield, %
T, °C	medium	
70	In bulk	39.1
80	In bulk	58.7
80	Methanol	62.9
90	In bulk	61.8
90	Methanol	70.7
90	Methanol*	76.7
90	Chloroform*	71.4

* Reaction time 10.5 h.

The ^{13}C NMR spectra (Table 1) of the copolymers contain low-field triplets from the *cis/trans*-isomeric C^1 and $C^{1'}$ atoms of the heteroring and from the C^3 and $C^{3'}$ atoms, and also doublets from the C^2 and $C^{2'}$ atoms. The content of *cis*-stereoisomeric units in the copolymers of EAAP-BF_4 and EAAP-Cl with SO_2 is four times higher than that of the *trans* units. The spectra show that the copolymerization of EAAP-Cl and EAAP-BF_4 with SO_2 involves both double bonds and occurs as intramolecular cyclization with the formation of pyrrolidine structures.

Owing to the cyclolinear structure, the copolymers obtained are soluble. The EAAP-BF_4–SO_2 copolymers are soluble in DMSO, DMF, methanol, acetone, and chloroform but insoluble in other common solvents (THF, ethyl acetate, diethyl ether, benzene, etc.). The EAAP-Cl–SO_2 copolymers are also soluble in water. Because of the polyelectrolytic effect, the reduced viscosity of the copolymer solutions increases with dilution (Fig. 2).

Experiments showed that the EAAP-Cl–SO_2 copolymer forms colored precipitates with CrO_4^{2-}, $AuCl_4^-$, and $PtCl_6^{2-}$. From a solution of $HAuCl_4$ in 0.3 M HCl (initial Au concentration 20.9 mg l^{-1}), the copolymer taken in six- and eightfold excess precipitates 92 and 98% of $AuCl_4^-$, respectively.

The copolymer of EAAP-BF_4 with SO_2 sorbs noble metal salts from solutions. We estimated the static capacity of the EAAP-BF_4–SO_2 copolymer (278 mg l^{-1}) for gold ($HAuCl_4$, 20.9 mg l^{-1} Au, 0.3 M HCl). The residual concentration of gold after keeping for 8 h, determined spectrophotometrically, was 4.4 mg l^{-1}. The static capacity of the copolymer was 59.3 mg Au/g.

Toxicological tests showed that the copolymers of

EAAP-BF_4 and EAAP-Cl with SO_2 belong to compounds of hazard class 4 and are suitable for medical applications.

Antimicrobial activity tests show that both copolymers exhibit an inhibiting effect toward *E. coli* in a concentration of 62.5 μg ml^{-1} and a bactericidal effect in a concentration of 125.0 μg ml^{-1}. The EAAP-BF_4–SO_2 and EAAP-Cl–SO_2 copolymers inhibit the growth of *St. aureus* in the concentration range 15.6–31.2 and 7.8 μg ml^{-1}, respectively. The bactericidal activity of the EAAP-BF_4–SO_2 copolymer toward gram-positive bacteria was noted at its concentration of 31.2 μg ml^{-1}, and that of the EAAP-Cl–SO_2 copolymer, at 15.6 μg ml^{-1}. Furthermore, the EAAP-BF_4–SO_2 copolymer exhibits antiulcer effect on the chosen model (indometacin), decreasing the number of ulcers by a factor of 20 relative to the control. Thus, the copolymers obtained can be used in drug production and in biotechnology.

CONCLUSIONS

(1) Diallylaminophosphonium salts in the presence of radical initiators do not undergo homopolymerization and show low activity in copolymerization with vinyl monomers.

(2) Tris(diethylamino)diallylaminophosphonium tetrafluoroborate and chloride exhibit high activity in radical copolymerization with sulfur dioxide. The copolymerization yields alternating copolymers of equimolar composition, irrespective of the monomer ratio in the starting mixture and reaction conditions. The copolymerization involves both double bonds of the monomer, which undergo intramolecular cyclization with the formation of pyrrolidine rings.

(3) Copolymers of tris(diethylamino)diallylaminophosphonium chloride with SO_2 precipitate the CrO_4^{2-}, $AuCl_4^-$, and $PtCl_6^{2-}$ ions, and copolymers of tris(diethylamino)diallylaminophosphonium tetrafluoroborate, which are insoluble in water, sorb these ions from solutions.

(4) The copolymers obtained are nontoxic (hazard class 4) and exhibit antiulcer and pronounced antimicrobial activity toward gram-positive and gram-negative bacteria.

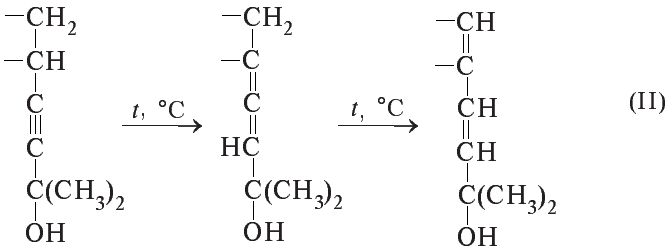
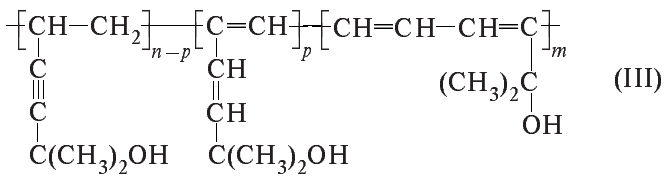
Abstract—Radical polymerization of dimethyl(vinylethynyl)carbinol on ceramic monolithic supports was studied with the aim to synthesize composite monolithic sorbents with applied hydrophilic–hydrophobic polymer.



DOI: 10.1134/S1070427208050236

Dimethyl(vinylethynyl)carbinol (DMVEC) polymers, which contain a hydrophilic alcoholic group along with a hydrophobic hydrocarbon chain, are of certain interest for synthesis of organoceramic composite sorbents. Variation of hydrophilic–hydrophobic characteristics of the surface layer of the sorbents provides the possibility of controlling their selectivity in fairly wide limits. It should be noted that the initial monomer, dimethyl(vinylethynyl)carbinol (2-methylhex-5-en-3-yn-2-ol) $H_2C{=}CH{-}C{\equiv}C{-}C(CH_3)_2OH$ is a commercially available raw material used in organic synthesis and in production of adhesives.



The mechanism of radical polymerization of vinylacetylene monomers, in particular, DMVEC, was studied previously [1–5]. At present, the commonly accepted mechanism of polymerization is the mechanism according to which radical polymerization of vinylacetylene monomers proceeds through the 1,2 and 1,4 positions of the vinylacetylene group ($C^1{=}C^2{-}C^3{\equiv}C^4$) [5]. This radical polymerization is a random process, and the subsequent allene–diene isomerization results in the formation of the conjugation blocks in polymers [scheme (I)]. The increase in the number of conjugation blocks upon heat treatment is caused by acetylene–allene–diene isomerization [schemes (II) and (III)]:

(I)

(II)

(III)

EXPERIMENTAL

All the chemicals used were of analytically pure or chemically pure grade. DMVEC of technical grade (Nairit Research and Production Association, Yerevan) was used after twofold distillation in a vacuum (bp 52°C/10 mm Hg, n_D^{20} 1.4750).

Permeable ceramic monoliths conventionally denoted as A and B were used as supports. Monolith A had the total porosity of 85–90% and contained macropores at practically zero specific sorption pore volume (V_s < 0.1 $cm^3\ g^{-1}$). Monolith B with a sorption pore volume of 0.38 $cm^{-3}\ g^{-1}$ and specific surface area of 101.5 $m^2\ g^{-1}$ was prepared by treating monolith A with colloidal silica [6]. The average diameter of colloidal silica particles was 22 nm. Polymerization of DMVEC on ceramic supports was performed by two procedures: (1) preim-

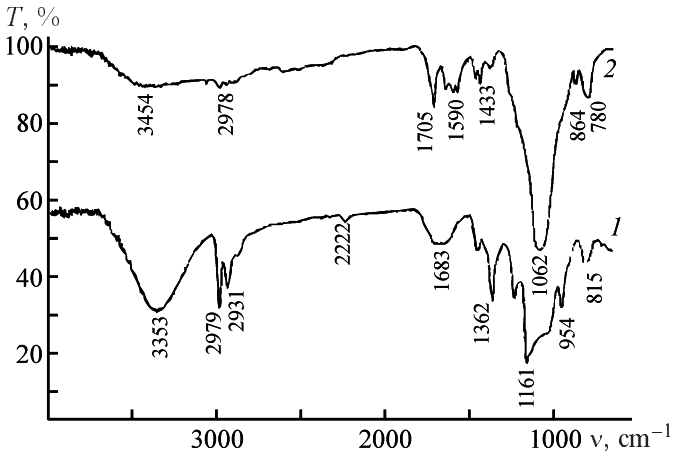


Fig. 1. IR spectra of (*1*) ceramic monolith modified with DMVEC polymer and (*2*) adduct with maleic anhydride. (*T*) Transmission and (ν) wavenumber.

pregnation of monoliths with a neat monomer or a solution of the carbinol in isopropanol in the presence of 1 wt % benzoyl peroxide, followed by polymerization in an oven at 120°C for 3 h, and (2) polymerization in a 15–50 wt % solution of isopropanol or dimethylformamide (DMF) in the presence of 1 wt % benzoyl peroxide at 80°C for 4 h in a flask equipped with a reflux condenser, followed by drying to remove the solvent and unchanged monomer in an oven at 120°C (in some experiments, at 180°C) for 2 h. After the polymerization completion, the composite monoliths modified with polymers were washed by boiling in distilled water for 2–3 h, and the samples heat-treated at 180°C were washed with isopropanol. The amount of immobilized polymer was estimated from the increase in the weight of the modified monolith, which depended on the monomer concentration in the initial solution; the higher was monomer concentration, the higher was the yield of the immobilized polymer.

The polymeric adduct of DMVEC with maleic anhydride, immobilized on a ceramic support, was synthesized by heating the ceramic monolith modified with DMVEC polymer thermally pretreated at 180°C with a twofold molar excess of maleic anhydride relative to the immobilized polymer in a methyl ethyl ketone solution for 20 h at 80°C. Then, the resulting samples were washed with distilled water and dried to constant weight at 100°C.

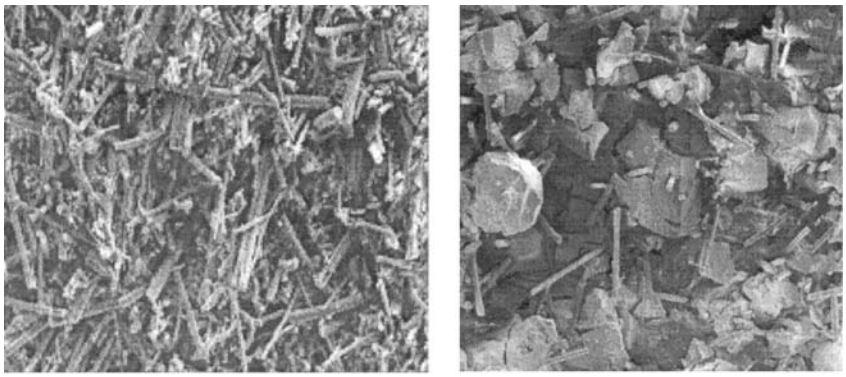
To determine the retention of copper ions, 0.20 ml of a 1 M solution of Cu(II) prepared from $CuSO_4 \cdot 5H_2O$ was added with a micropipet into an Eppendorf column loaded with the sorbent to be tested in the form of a cylinder 17 mm long and 5.1 mm in diameter. After 3 min, the phases were separated by centrifugation at 400*g*, and the residual content of Cu(II) ions in the liquid phase was determined spectrophotometrically at a wavelength of 650 nm using a Shimadzu 1202 spectrophotometer.

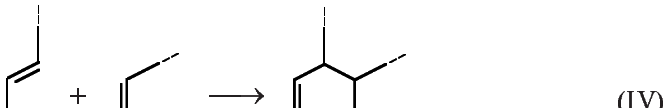
The ATR IR spectra were recorded on an Avatar Nicolet FTIR spectrometer, and the ESR spectra, on an E-3 Varian spectrometer; diphenylpicrylhydrazyl was used as a reference. The SEM images were obtained on a TESCAN 3115 scanning electron microscope. The specific surface areas of the samples and the pore volume were determined by the BET method with an Accusorb 2100E adsorption analyzer (Micrometrics Co.).

The results obtained show that the polymer is accumulated on ceramic support A considerably faster than on support B. All the resulting composite organoceramic monoliths are intensely colored from yellow to dark brown depending on treatment temperature, which is caused by the presence of segments of conjugated double bonds in the polymer structure. The materials prepared by impregnation of the ceramic support with a monomer solution with subsequent polymerization were readily washed out and contained (as judged from the optical density of the washing solution) a noticeable amount of the organic material, apparently, low-molecular-weight products of DMVEC oligomerization. This is confirmed by low values of viscosity-average molecular weight of DMVEC polymer, which was determined by the formula $[\eta] = 0.89 \times 10^{-4} M^{0.7} = 20\,000$ [7]. The polymer was isolated by extraction with methanol in a Soxhlet apparatus. The best results were obtained in polymerization of DMVEC on the surface of a ceramic support from isopropanol or DMF solution at 80°C. The wash water contained significantly smaller amount of the organic substance, which agrees well with fairly high values of the viscosity-average molecular weight of DMVEC polymer, $(120–150) \times 10^3$.

As already noted, thermal treatment of DMVEC polymers is accompanied by acetylene–diene rearrangement leading to the growth of polyconjugation blocks. This process also takes place in the case of polymers immobilized at the support surface, which is confirmed by the presence of a narrow singlet in the ESR spectrum (with *g*-factor close to that of free electron, equal to 2.0023) and an increase in the concentration of unpaired electrons from 10^{16} to 10^{18} spins per gram upon heat treatment of the polymers at 180°C for 2 h.

The IR spectra of ceramic supports modified with DMVEC polymers are shown in Fig. 1. In the IR





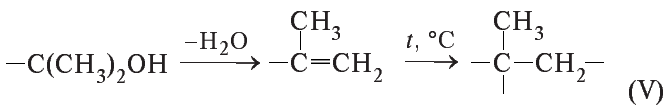


Fig. 2. SEM images of (a) unmodified ceramic monolith and (b) ceramic monolith modified with DMVEC polymer.

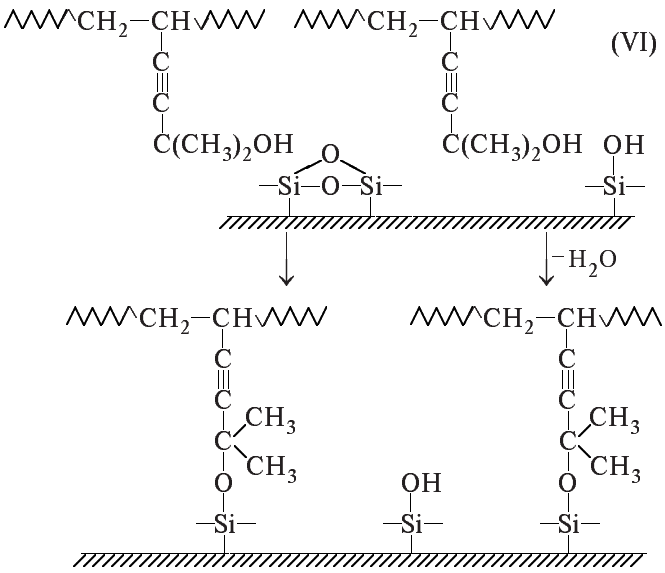
spectrum of the ceramic monolith modified with DMVEC polymer (Fig. 1, spectrum *1*), there are a broad absorption band of OH groups with a maximum in the region of 3350 cm^{-1}, a broad absorption band of polyconjugated C=C bonds in the range 1610–1680 cm^{-1}, and an absorption band of internal C≡C bond in the region of 2230 cm^{-1}, particularly pronounced in the case of the untreated polymer, which also suggests the growth of the blocks of polyconjugated C=C bonds by scheme (II).



A comparison of the SEM images (Fig. 2) of (a) nonmodified ceramic monolith and (b) ceramic monolith modified with DMVEC polymer showed clearly pronounced macroporous structure of the unmodified monolith, presented by interconnected pores, and also uniform distribution of the polymer in the bulk of the modified monolith.

We revealed an interesting fact of thermal curing of DMVEC polymers applied to a ceramic support at 180°C with the transformation of the polymer into an insoluble and infusible state, which is not observed in the case of ordinary DMVEC homopolymers. In the course of heat treatment, the modified ceramic monoliths become less hydrophilic. This fact may be accounted for by the following schemes:

(IV)

(V)

Scheme (IV) suggests that thermal curing occurs as the diene synthesis involving the conjugation segments, when one fragment of conjugated double bonds of the chain acts as diene and the other, as dienophile. Apparently, only segments of conjugated double bonds with the cisoid structure can act as diene fragments in the diene synthesis. This pathway of intermolecular cross-linking of the polymer is the least probable, as it should take place in the case of (unapplied) DMVEC homopolymer also. Scheme (V) suggests that thermal curing involves dehydration of the *tert*-butanol group on the surface of dehydrated silica with formation of the isopropenyl group and subsequent cross-linking of the polymer due to cleavage of the double bond of the isopropenyl group at elevated temperatures. According to scheme (VI), transition of the polymer into the insoluble state is due to grafting of the polymer with the participation of siloxane or/and silanol groups of the silica surface [8]:

(VI)

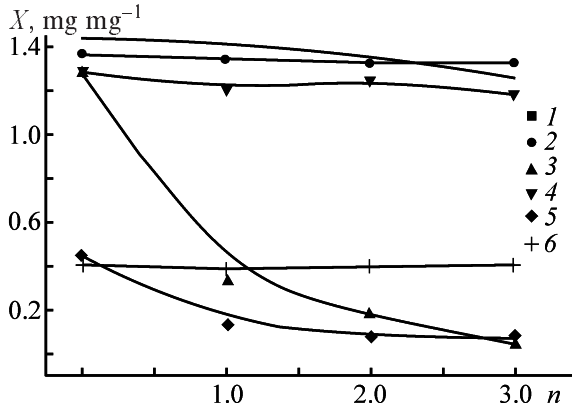


Fig. 3. Wash-out X of DMVEC polymers immobilized on ceramic supports (*1–4*) A and (*5, 6*) B. (n) Number of washing runs. Drying temperature, °C: (*1, 3*) 120 and (*2, 4*) 180. (*1, 3*) After polymerization, boiling in distilled water and drying to constant weight at 120°C; (*3, 4*) after polymerization, washing with isopropanol and drying to constant weight at 120°C; (*5*) polymerization at 80°C in solution, drying at 80°C, washing with isopropanol, and drying to constant weight at 80°C; and (*6*) polymerization at 80°C in solution, drying at 180°C, washing with isopropanol, and drying to constant weight at 180°C.

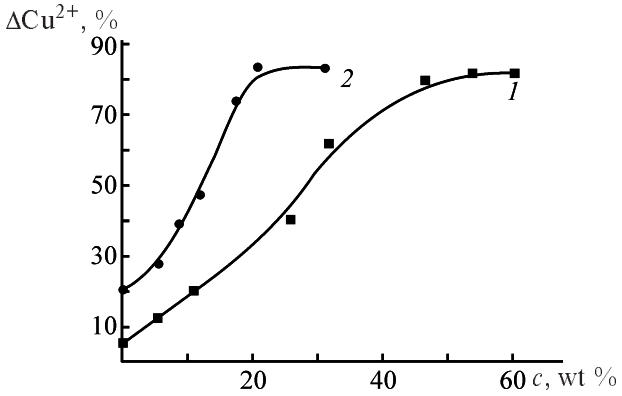

Fig. 4. Retention of copper ions ΔCu^{2+} by sorbents based on monoliths of types (*1*) A and (*2*) B as a function of the content of adduct of PDMVEC with maleic anhydride c.

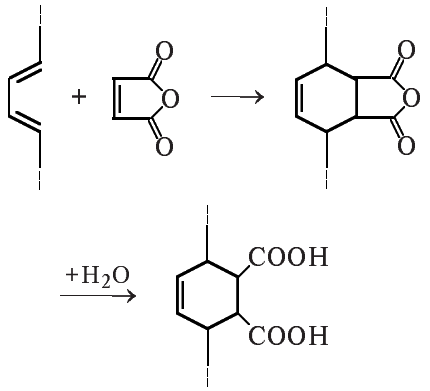

Thus, only schemes (V) and (VI) can account for the influence of the support surface on cross-linking of the polymer applied to the ceramic support. The increase in the intensity of the bands corresponding to OH vibrations in the range 3350–3365 cm^{-1} after heat treatment of immobilized DMVEC polymer at 180°C counts in favor of these schemes.

The wash-out of the applied DMVEC polymer (the amount of the residual polymer expressed in milligrams per milligram of the ceramic support) as a function of the number of washing runs for the samples washed and dried under various conditions is plotted in Fig. 3. In all cases, polymerization of DMVEC was performed from solutions at 80°C.

Curves *4* and *6* (Fig. 3) confirm the cross-linking of DMVEC polymers in thermal treatment at 180°C: the polymer is not washed out with isopropanol, DMF, and other organic solvents.

To increase the degree of hydrophilicity (control of hydrophilic–hydrophobic balance of the polymer layer) and functionalization of the polymer with the aim to synthesize cation-exchange organoceramic sorbent, we performed the diene synthesis reaction of DMVEC polymer pretreated with maleic anhydride at 180°C. The occurrence of the diene synthesis follows from the changes in the IR spectrum of the adduct (Fig. 1, spectrum *2*): appearance of absorption bands of carboxy group at 1700 cm^{-1} and of an extremely broad diffuse band in the range 2700–2500 cm^{-1}, changes in the absorption band of polyconjugated double bonds in the range 1600–1670 cm^{-1}, appearance of several narrow absorption bands instead of this band, and also from an increase in the weight and hydrophilicity of the composite ceramic monolith.

The occurrence of the diene synthesis confirms the presence of the blocks of conjugated double bonds in the polymer. However, as already mentioned, only segments of conjugated double bonds with the cisoid configuration can participate in the diene synthesis reaction as diene fragments:

The resulting sorbents based on ceramic monoliths A and B and PDMVEC adduct were tested for retention of copper ions from a 1 M copper sulfate solution. The dependence of the retention of copper ions on the amount of the applied polymer is shown in Fig. 4. It is seen that, in the case of monolith A, the retention of copper ions is 81% at 54% content of the polymer in the composite sorbent, while in the case of ceramic B 83% retention of copper ions is

reached even at significantly lower content of the polymer in the sorbent.

From the results obtained it follows that, in the case of monoliths of the type A (without additional porous silica coatings), the polymer content of these monoliths should be significant (more than 40%) for reaching sufficient sorption capacity. In the case of monoliths of type B (with applied silica coating), significantly smaller amount of the polymer (10–20%) is required.

CONCLUSIONS

(1) Polymerization of dimethyl(vinylethynyl)carbinol on ceramic monolith supports takes place at the 1,2 and 1,4 positions of the vinylacetylene groups with the formation of a polymer containing segments of conjugated double bonds. The subsequent acetylene–allene–diene rearrangement results in the growth of the polyconjugation blocks. Heat treatment of immobilized dimethyl(vinylethynyl)carbinol polymers at 180°C results in cross-linking of these polymers, making them more stable with respect to wash-out.

(2) The occurrence of the diene synthesis reaction follows from the IR spectrum of the adduct and from an increase in the hydrophilicity of the composite ceramic monolith.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Ion-Exchange Selectivity of a Sulfonic Cation Exchanger Based on Immobilized *cis*-Tetraphenylcalix[4]resorcinolarene

O. G. Al'tshuler, L. A. Sapozhnikova, and G. N. Al'tshuler

Kemerovo Branch, Institute of Solid State Chemistry and Mechanochemistry, Siberian Branch, Russian Academy of Sciences, Kemerovo, Russia

Received May 14, 2007

Abstract—The ion-exchange equilibrium of protons in SO_3H groups of a sulfonic cation exchanger based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene with cations of Li^+, Na^+, Ag^+, Cu^{2+}, In^{3+}, and protonated 1,3,5,7-tetraazaadamantane in aqueous solutions of electrolytes at 293 K was studied. The corrected coefficients of the cation exchange selectivity were calculated.

DOI: 10.1134/S1070427208050248

Thanks to unique structure, *cis*-calix[4]resorcinolarenes attract much researchers' attention. The presence in *cis*-calix[4]resorcinolarenes of a large internal cavity and an upper hydrophilic rim containing eight hydroxy groups makes them a convenient matrix for the design of molecular ensembles realizing the complementary host–guest stereoelectronic interactions [1].

The prospects for the development of the calixarene chemistry are associated with introduction into their composition of functional groups, with the aim to obtain new types of highly organized steric structures with preset properties. Functionalized calixarenes are of interest as new complexing agents, polymer stabilizers, and extractants [2]. Immobilization of calixarenes in the polymer phase allows realization of their capability for complementary interactions with neutral molecules and multicharged ions. Previously [3–9] we prepared network polymers containing immobilized *cis*-calix[4]resorcinolarenes [3–9]. We demonstrated that these polymers are weakly acidic cation exchanges [3, 4, 7] and nanoreactors for catalytic hydrogenation processes [8, 9].

Functionalization of immobilized calixarenes by introducing carboxy [10], furylhydroxymethyl [4], and phosphoric acid [11] groups enhances the selectivity of interaction of polymers with cations. It was shown previously [12, 13] that the new sulfonated polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene, owing to the presence of SO_3H groups, is a strongly acidic cation exchanger surpassing in the service characteristics the known cation exchangers derived from calixarenes. In particular, this sulfonic cation exchanger exhibits cation-exchange properties in a wide range of pH, high ion-exchange capacity [12, 13], and good kinetic characteristics [14].

The elementary unit of the sulfonic cation exchanger based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene, in contrast to that of the commercially available sulfonic cation exchanghers, has an ordered steric structure [13]. Figure 1 shows the simulated structure of the elementary unit of the

polymer, optimized with respect to the enthalpy of formation: The sulfur atoms occur in the vertices of a parallelogram with the side lengths of 5 and 5.5 Å. Hence, anions of the sulfo groups are distributed in the polymer matrix within structural fragments that bear four negative charges arranged near the parallelogram vertices. This steric structure may affect the cation exchange selectivity; in particular, the affinity of the polymer for multicharged cations may increase. Therefore, it is interesting to study the ion-exchange equilibria in systems consisting of a sulfonic cation exchanger based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene and of binary and multicomponent electrolyte solutions.

The goal of this study was to examine the selectivity of proton exchange in ionic SO_3H groups of the polymer:

$$z\bar{H}^+ + Cat^{z+} \rightleftarrows \overline{Cat}^{z+} + zH^+, \quad (1)$$

where the overscore denotes the polymer phase; $Cat^{z+} = Li^+$, Na^+, Ag^+, Cu^{2+}, In^{3+}, or protonated 1,3,5,7-tetraazaadamantane ($C_6H_{12}N_4$) cation; and z is the cation charge.

EXPERIMENTAL

The sulfonic cation exchanger was prepared in the form of spherical granules 0.01–0.05 cm in diameter by sulfonation of a network polymer prepared by resol polycondensation of *cis*-tetraphenylcalix[4]resorcinolarene with formaldehyde [4, 5]. The sulfur content of the polymer, determined according to [15], was 7.8 wt %. The dynamic ion-exchange capacity of the polymer with respect to sulfo groups was determined in columns by passing a 0.01 M NaCl solution through a bed of the polymer in the H^+ form until the cation concentrations at the inlet and outlet of the column became equal. The exchange capacity was reduced to 1 g of the polymer in the H^+ form, dried to constant weight at 105°C. The capacity was 2.25 mg-equiv g^{-1}.

The ion exchange selectivity was studied by the dynamic method [5]. Aqueous solutions containing two electrolytes (HCl and LiCl, HNO_3 and $AgNO_3$, HCl and $C_6H_{12}N_4$, HCl and NaCl, HCl and $CuCl_2$, HCl and $InCl_3$) were passed at 293 K through a column packed with the sulfonic cation exchanger in the H^+ or Cat form until the concentrations of the electrolytes in the initial solution and several successively taken filtrate samples became equal, which was considered as the attained equilibrium. The equilibrium composition of the polymer phase was independent of the initial ionic form of the sulfonic cation exchanger. The ionic strength of the equilibrium solutions of strong electrolytes was 0.1, and for a $C_6H_{12}N_4$ solution, 0.01 M. The mean ionic molal activity coefficients of the electrolytes in solution were calculated by the Debye–Hückel equation, with the distances of the closest mutual approach of the ions assumed to be 4.5 and 6 Å [16] for $CuCl_2$ and $InCl_3$, respectiveloy. The quantum-chemical calculations were performed by the PM3 semiempirical method using the MOPAC 2000 program. The corrected coefficients of the cation exchange selectivity $k^a_{Cat/H}$ [17] were calculated by the equation

$$k^a_{Cat/H} = \frac{x_{Cat} m^z_H \gamma^{2z}_{\pm HAn}}{x^z_H m_{Cat} \gamma^{z+1}_{\pm HAn}}, \quad (2)$$

where x_i is the equivalent fraction of the cation in the polymer; m_i, molality of the cation in solution; and $\gamma_\pm$, mean ionic molal activity coefficient of the electrolyte (HAn or $CatAn_z$) in aqueous solution.

The experimental data on the equilibrium compositions of the solution and polymer phases and the

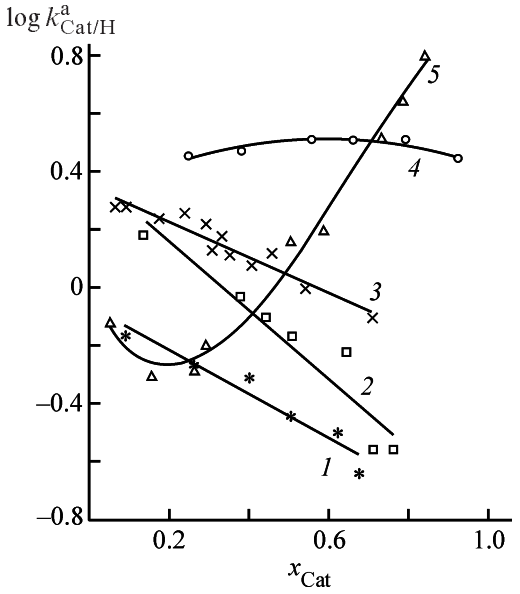

Fig. 2. Logarithm of the corrected coefficient of the ion exchange selectivity $\log k^a_{Cat/H}$ as a function of the equivalent fraction of cations x_{Cat} in the sulfonic cation exchanger derived from *cis*-tetraphenylcalix[4]resorcinolarene at 293 K. Exchange: (*1*) $H^+ \rightarrow Li^+$, (*2*) $H^+ \rightarrow Na^+$, (*3*) $H^+ \rightarrow Ag^+$, (*4*) $H^+ \rightarrow Cu^{2+}$, and (*5*) $H^+ \rightarrow In^{3+}$.

corrected coefficients of the cation exchange selectivity [reaction (1)] at the equivalent fraction of cations in the polymer close to 0.5 are given in the table.

In the systems under consideration, the counterion composition of the polymer phase strongly affects the corrected coefficient of the ion exchange selectivity. Figure 2 shows the plots of $\log k^a_{Cat/H}$ vs. equivalent fraction of cations in the sulfonic cation exchanger derived from immobilized *cis*-tetraphenylcalix[4]resorcinolarene. For single-charged cations, interactions in the polymer phase are determined by the Coulomb attraction of the sulfo group anions and exchanging cations. The exchanging sites of the cation exchanger, as a rule, are nonequivalent in energy [18]. It was shown [19] that the population of each energy level in the ion exchanger is determined by the Gibbs canonical distribution. The probability density of the exchange sites of the polymer with the energy ε is described by the equation

$$\rho = e^{(\psi - \varepsilon)/\theta}, \quad (3)$$

where ρ(ε) is the probability density of the phase with energy ε; ψ, a constant; and θ, distribution modulus.

If $\theta \gg \psi - \varepsilon$, ρ is a linear function of ε:

$$\rho = 1 + (\psi - \varepsilon)/\theta. \quad (4)$$

For an ion exchanger containing two exchanging ions, $\ln k^a_{i/j}$ is a continuous function of energy varying throughout the ion exchange isotherm from $\ln k^a_{i/j}$ at $x_i = 0$ to $\ln k^a_{i/j}$ at $x_i = 1$. In this case, the composition of the ion exchanger, determined by the mole fraction of component *i*, corresponds to the probability density of separate phases occurring in a random equilibrium. In other words, for a binary exchange the canonical energy distribution leads to a linear dependence of the logarithm of the corrected selectivity coefficient on the mole fraction of counterions in the ion exchanger phase [19]:

$$\ln k^a_{i/j} = A_{i/j} + B_{i/j}\bar{x}_i, \quad (5)$$

where $A_{i/j}$ and $B_{i/j}$ are constants.

It follows from the table that the experimental dependences of $\log k^a_{Cat/H}$ on x_{Cat} for the single-charged Li^+, Na^+, and Ag^+ cations are linear, whereas for the double-charged Cu^{2+} cations they pass through a maximum at $x_{Cu} = 0.6$. Probably, one copper cation interacts with two anions of the sulfo groups of the polymer unit. For the triple-charged In^{3+} cations, the shape of the function $\log k^a_{Cat/H}(x_{Cat})$ can be accounted for by the fact that an increase in the fraction of the triple-charged In^{3+} cations in the polymer phase leads to an increase in the probability of supramolecular interactions of the cation with the adjacent polymer chains. It is well known [20] that such interactions increase the ion exchange selectivity.

The protonated 1,3,5,7-tetraazaadamantane cation occupies a paticular place. Despite the presence of several protonation sites, this compound has a single association constant K_a [20] corresponding to the reaction $C_6H_{12}N_4 + H^+ \rightleftarrows [C_6H_{13}N_4]^+$. The coefficient of the selectivity of the $H^+/[C_6H_{13}N_4]^+$ ion exchange is given in the table. It is comparable with the corresponding quantity for Li^+. The related quantity for the ion exchange with a weakly acidic cation exchanger derived from *cis*-tetramethylcalix[4]resorcinolarene is lower by several orders of magnitude (0.2×10^{-4} [5]).

The polymer under consideration is characterized by a wider range of the selectivity coefficients of the ion exchange of inorganic cations compared to the known sulfonic cation exchangers. For the sulfonic cation exchanger based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene, the corrected coefficients of the ion exchange selectivity $k^a_{Cat/H}$ at the degree of filling $x_{Cat} = 0.8$ (Fig. 2) varies from 0.25 (Na^+–H^+ exchange) to 3.2 (Cu^{2+}–H^+ exchange) and 6.3 (In^{3+}–H^+ exchange). For commercial sulfonic

cation exchangers, $k^{a}_{Cat/H}$ at x_{Cat} = 0.8 varies in a narrow range from 1.6 (Na^+–H^+ exchange on KU-2×8 [21] and Dowex-50×8 [22]) to 2.3 (Cu^{2+}–H^+ exchange on Dowex-50×8 [23]).

The wide interval of the coefficients of the ion exchange selectivity creates prerequisites for using the sulfonic cation exchanger that we prepared for separation of binary and multicomponent electrolyte mixtures. The study of the kinetics and mechanism of the interaction of metal ions with the functional groups in the elementary unit of the sulfonic cation exchanger derived from immobilized *cis*-tetraphenylcalix[4]resorcinolarene is of theoretical and applied interest.

CONCLUSIONS

(1) The ion-exchange selectivity of a strongly acidic sulfonic cation exchanger, a sulfonated network polymer based on immobilized *cis*-tetraphenylcalix[4]resorcinolarene, strongly depends on the kind of the sorbate cation and on the counterionic composition of the polymer. For the single-charged metal cations Li^+, Na^+, and Ag^+, the logarithm of the corrected coefficient of the ion exchange selectivity linearly depends on the equivalent fraction of metal cations in the ion exchanger phase. For the Cu^{2+} and In^{3+} cations, the dependence of $\log k^{a}_{Cat/H}$ on x_{Cat} suggests the occurrence of supramolecular interactions in the polymer phase.

(2) The sulfonic cation exchanger derived from immobilized *cis*-tetraphenylcalix[4]resorcinolarene is characterized by the wider range of coefficients of the ion exchange selectivity compared to the known sulfonic cation exchangers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Gas-Discharge Plasma Treatment in the Electrolyte Bulk on the Cellulose Properties

Abstract—The effect exerted on cellulose properties by plasma–solution treatment using the atmospheric-pressure diaphragm and end discharges was examined.

DOI: 10.1134/S10704272080502 5X

Modification of properties of polymer materials is a multi-aspect problem, topical for various industries. This typically implies modification of the surface properties of a material in the desired direction without affecting its bulk properties. However, certain applications require more profound changes of not only the surface but also the bulk properties of materials. In the former case, modification implies functionalization (creation in the surface layer of a material of new functional groups) and formation of a new surface microstructure. In the latter case, there is a need for a more profound selective chemical impact on the macromolecular compound, e.g., selective oxidation of lignin accompanied by its conversion to a water-soluble form.

The surface properties of polymers are successfully modified using low-pressure nonequilibrium plasma [1]. However, treatment of materials with a capillary porous structure within the framework of selective processes (e.g., delignification) entails major difficulties in application of low-pressure plasma. First, there are technical problems associated with relatively complex and expensive vacuum facilities and the need in combining vacuum and solution processes. The second problem consists in low selectivity and low efficiency of treatment of the inner surface of the capillaries because of a short lifetime of active species [2]. The use of plasma–solution systems which allow, in principle, a plasma-induced redox reaction to be combined with a selective process in solutions seems fairly attractive. In this context, practically convenient options are discharges with an electrolyte cathode, in which both direct-current and variable-frequency sources with a fairly low voltage of about one or several kilovolts are used. Among such discharges are glow and sliding discharges excited above the solution surface [3–6] and the so-called "underwater" discharges, in particular, the diaphragm discharge and closely related end discharge [3, 7].

In plasma–solution modification of polymer materials using a glow discharge with an electrolyte cathode, the primary active species, including H and OH radicals and solvated electrons, very rapidly (within approximately a microsecond) react in the cathode spot area, and the subsequent interaction can involve more stable secondary reactive species only [3, 4, 8]. The rate of removal of the reaction products is determined by the flows initiated by the transfer of the solution components from the cathode spot area to the plasma zone [9]. The active plasma particles exert the minimal impact on the polymer material samples placed into solution.

A slightly stronger impact of active plasma particles on polymer materials can be expected in the case of a diaphragm discharge initiated by passing current through a small hole in a dielectric diaphragm dividing the reactor with an electrolyte solution into two segments (Fig. 1). Intense warming-up of the solution in the diaphragm area leads to formation in the hole of a gas–vapor bubble disconnecting the electric circuit. At a sufficiently high emf of the source, an electric breakdown occurs in the bubble, followed by collapse of the plasma bubble and spread in the solution of a sound wave. Repetition of this process leads to a quasiperiodic discharge [3, 4, 7].

Efficient plasma treatment of polymeric materials implies that a plasma area should be formed inside

the solution and exist there for a prolonged period during which both the plasma and the thin solution layer it activates can contact the material being treated. The latter should be washed by this layer. This plasma–solution system, in which the action of solution activated by plasma is combined with direct plasma action of the discharge on the material, was developed comparatively recently; this is a so-called end discharge system [7]. The end discharge is most similar to the diaphragm discharge; it is excited in the end segments of the tubes vertically immersed in a solution together with the electrodes inside them. When current is passed through this system, a plasma zone is formed in the space separating the electrode from the tube cross section, where a gas bubble is formed by ordinary electrolysis before the breakdown (Fig. 2).

This study was concerned with cellulose extracted from a flax fiber by cooking with various oxidizing agents. In this process, the oxidation and degradation rate of the noncellulose components should be higher than that of cellulose proper. Unfortunately, chemical oxidizing agents exhibit low selectivity, and both the oxidation and removal of lignin are accompanied by intensive cellulose degradation. In this situation, plasma–solution treatment instead of oxidizing cooking, alone or combined with conventional methods, seems highly attractive.

We examined the cellulose properties as influenced by plasma–solution treatment. Specifically, we elucidated the influence of the diaphragm and end discharges on the following characteristics of flax cellulose: the content of aldehyde (HCO) and carboxy (COOH) groups, degree of polymerization, and α-cellulose content. The capillary-porous structure of various cellulose samples was characterized by the water-retaining power (WRP).

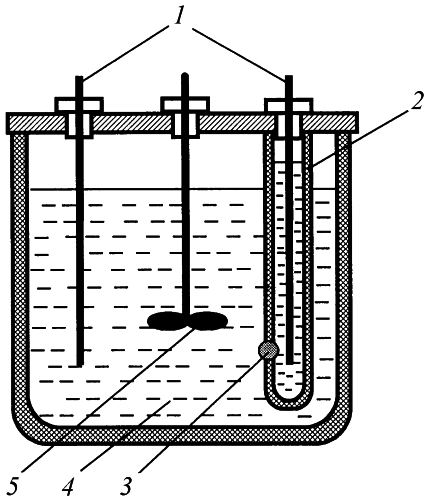

Fig. 1. Schematic of the experimental cell for diaphragm discharge: (*1*) electrodes, (*2*) quartz ampule, (*3*) plasma zone, (*4*) electrolyte solution, and (*5*) stirrer.

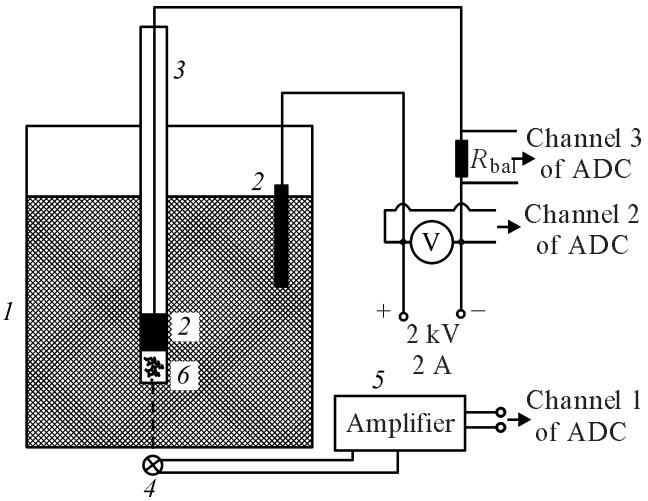

Fig. 2. Flow sheet of the end discharge setup: (*1*) electrolyte solution, (*2*) electrodes, (*3*) glass tube, (*4, 5*) radiation recording scheme, and (*6*) plasma zone.

EXPERIMENTAL

The cellulose extracted from flax fiber contained 0.8–0.95% lignin, 90.5–91.4% α-cellulose, and 7.6–8.5% hemicelluloses; the degree of polymerization (DP) was 1000–1400.

Cellulose was mechanically ground to the fiber size of 3–5 mm.

Samples of mechanically ground cellulose (fiber length 0.5–2 mm) extracted from flax fiber (3 g) were placed into a 1-l glass vessel. To elucidate the influence of the chemical composition of the electrolyte solution, we used 0.01 M NaOH, 0.01 M Na_2SO_4, and 0.05 M HNO_3 as the working solutions. At these concentrations of the solutions, the electrical conductivities of the electrolytes were virtually identical in all the cases, irrespective of pH of the medium, specifically, about 2 mS cm^{-1}. The solution volume was 600 ml.

We used an ac source for the discharges. In the cases of diaphragm discharge, the discharge current was 0.2 A. The end discharge current at the initiation time was 1 A, but after several minutes of burning it also decreased to 0.2 A, and at this current most of the treatment was carried out. In both cases we used graphite electrodes.

Changes in the cellulose properties, caused by plasma–solution treatment with discharge at a current of 200 mA

Figure 3 presents the schematic of the reactor with electrodes for end discharge excitation. The plasma zone was formed alternately on either electrode, and the discharge was burning virtually uninterruptedly. In the case of diaphragm discharge, one of the electrodes was replaced by a ceramic ampule with a 3-mm-long slot-like diaphragm (Fig. 1). During the discharge treatment, the solution and the cellulose added were mixed with a magnetic stirrer. The treatment time was 10–30 min. After treatment in the plasma–solution system was complete, cellulose was taken out of the reactor, washed, and analyzed. The content of the aldehyde and carboxy groups was determined by standard iodometric and acid–base titration techniques, respectively [10]. The degree of polymerization of cellulose was estimated from the viscosity of the solution of cellulose in Cadoxen [11], and the content of hemicelluloses and α-cellulose, by a standard technique [12]. The water-retaining power was determined according to [13].

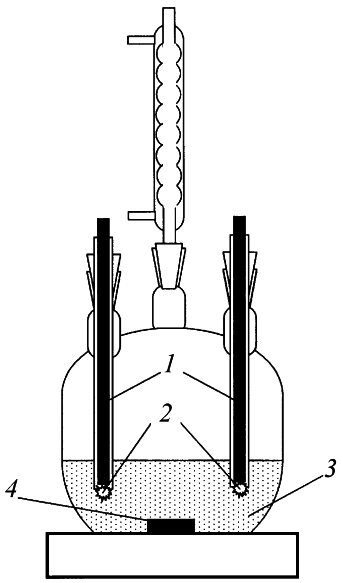

Fig. 3. Schematic of the reactor for end-discharge treatment of the polymer material: (*1*) electrodes, (*2*) plasma zone, (*3*) solution with the material being treated, and (*4*) magnetic stirrer.

The changes of the cellulose properties, caused by plasma–solution treatment (see table), correlate with the extents of degradation (change in DP) and oxidation (change in the content of aldehyde and carboxy groups). Plasma treatment causes the degree of polymerization of cellulose to decrease, depending on the type of discharge, treatment time, and electrolyte composition. In the case of diaphragm discharge, the DP decreases more profoundly, most likely because of the action of the sound wave spreading in the system when this type of discharge is burning. In the Na_2SO_4 and HNO_3 media, a decrease in the DP is accompanied by a decrease in the α-cellulose content and, despite the increase in the proportion of hemicelluloses, by weakening of the

water retention power of cellulose (WRP). The end discharge leaves the supramolecular structure of cellulose virtually unaffected. Such characteristics as WRP and the α-cellulose content are virtually unaffected by the plasma–solution treatment.

The cellulose oxidation features also depend on the discharge type. The lignin content of the resulting cellulose is under 1% (0.8–0.95%). This residual lignin content is unaffected by the plasma–solution treatment, which allows its contribution to the content of aldehyde and carboxy groups to be neglected. The resulting samples comprise basically two components, α-cellulose and hemicelluloses (noncellulose part). The change in the content of carboxy and aldehyde groups during plasma–solution treatment is associated with oxidation of both cellulose and hemicelluloses. In the case of the end discharge, their ratio remains virtually unchanged; the content of carboxy groups increases relative to the initial cellulose, and that of aldehyde groups remains virtually unchanged. Presumably, end discharge causes more profound oxidation, and the resulting aldehyde groups are oxidized to carboxy groups. In the case of diaphragm discharge, the content of the aldehyde groups increases, and that of carboxy groups remains virtually unchanged, with the composition of the medium being of minor importance.

CONCLUSIONS

(1) The α-cellulose content and water retention power of the flax cellulose samples examined are virtually unaffected by plasma-discharge treatment. The content of the aldehyde and carboxy groups increases, and the degree of polymerization of cellulose decreases, depending on the type of discharge.

(2) The plasma–solution treatment initiating the oxidizing processes in the material being treated is more efficient in the case of the frontal discharge which affords direct contact of the material with plasma zone and the activated solution layers.

(3) Application of plasma–solution systems to treating cellulose-containing materials requires careful selection of the discharge conditions and modes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Biopolymer Compositions Based on Products of Collagen Hydrolysis and Polysaccharides

V. I. Chursin

Central Research Institute of Leather-Shoe Industry, Moscow, Russia

Received September 29, 2006

Abstract—Physicochemical properties of biopolymer compositions based on products of collagen hydrolysis and polysaccharides were studied. The effect of the component ratio on their compatibility was examined.

DOI: 10.1134/S1070427208050261

Advances in studying the structure and properties of collagen allow principally new approaches to reprocessing and efficient utilization of cheap collagen-containing raw materials [1]. Development of studies on preparing new collagen-based materials is determined, on the one hand, by availability and unique properties of this protein and, on the other hand, by appearance of new areas of its use in engineering, medicine, and light industry. Active studies are performed with the aim to prepare composite film materials based on blends of products of collagen hydrolysis (PCH) and other film-forming compounds (e.g., polyacrylates, polyvinyl alcohol, cellulose derivatives) [2]. This interest is determined by the possibility of improving some properties of the collagen films: enhancing their thermal and biological stability and strength, decreasing the extension, and increasing the sorption capacity. Application of environmentally friendly water-soluble polymers is also of particular importance.

As initial components we used polysaccharides, namely, chitosan and hydroxyethyl cellulose (HEC). The chitosan structure is close to that of cellulose, and its derivatives exhibit fiber- and film-forming properties. The use of chitosan soluble in aqueous solutions strongly simplifies preparation and decreases the environmental hazard in fabrication of finished items from these polymers [3, 4]. Hydroxyethyl cellulose, which is widely used in various branches of industry, is a cellulose ether containing nonionic hydroxyethyl groups.

In this work we prepared and studied new compositions based on PCH and polysaccharides exhibiting film-forming properties, which are of particular interest as biologically active cosmetic and pharmaceutical materials.

EXPERIMENTAL

In this study we used the 3% solutions of PCH prepared by thermal denaturation [5] of the cattle skin derma. A 3% solution of chitosan in 3% acetic acid (solution pH 4.1) was prepared from the reagent purchased from the Sonat Private Company (degree of deacetylation 0.86). Hydroxyethyl cellulose purchased from the Politsell Private Company [TU (Technical Specification) 2231-013-32957739–01] was used as a 3% aqueous solution. The molecular weights of PCH, chitosan, and HEC determined by viscometry were 34000, 120000, and 32000 Da, respectively. The formation of biopolymer compositions based on the products of collagen hydrolysis and polysaccharides was judged by the rheological characteristics (viscosity) using a Brookfield viscometer, electrical conductivity measured on a conductometer (Hanna Instruments), refractive index, and appearance of the resulting films. The size of supramolecular particles was determined by the turbidity spectrum procedure [6] at $\lambda = 300-600$ nm on a KFK-3 photocolorimeter at 20°C. The compositions were prepared from solutions of the starting reagents take in required ratios, with stirring for 1 h at 20–22°C. The films were prepared by casting of the resulting solutions onto glass or polyethylene supports, followed by drying in air for 2 days. The film quality was evaluated visually by changes in the color, transparency, and flexural strength.

Taking into account ambiguous data on the behavior of the systems containing carboxy groups

and HEC in aqueous solutions [2, 7], we studied the compatibility of PCH and HEC at various component ratios. The compatibility of the components was evaluated from the experimental data on the above characteristics and their deviation from the calculated additive values. Our studies showed that the viscous but flowable solutions are formed in the entire range of the component ratios studied.

As seen from Fig. 1, the dynamic viscosity of the compositions in question decreases with increasing PCH content and this effect is the most pronounced in the PCH–HEC system. This decrease in the system viscosity suggests formation of more compact polymer macromolecules owing to formation of mixed complexes with a smaller molecular volume. As shown in [4], the intra- and intermolecular interactions in HEC solutions are due to hydrogen bonds. Thus, we can assume that, upon addition of PCH, the hydrogen bonds formed by the functional ether groups of the polysaccharide are substituted by hydrogen bonds of these groups with the protein molecules, which weakens the intermolecular interaction and thus decreases the dynamic viscosity of the polymer composition. With increasing PCH content, deviations of the viscosity and refractive index from the additive values increase, which is probably due to the steric hindrance in interaction of relatively large macromolecules of the polymers studied. Similar changes in the viscosity upon addition of PCH were observed for chitosan (structural analog of HEC).

The experimental data on the refractive index of the PCH–HEC system (Fig. 2) show that the compatibility is the lowest at 70 : 30 component ratio. When the content of HEC in the mixture is higher than 50%, the system of hydrogen bonds in the collagen becomes weaker owing to penetration of the polysaccharide structural elements incompatible with protein, which block the active collagen centers and increase the intermolecular distances. On the contrary, free amino group in each unit of the chitosan molecule can interact with a carboxy group in collagen, which results in formation of mixed complexes at chitosan : PCH ratio of 75 : 25.

It is known that in acetic acid solutions chitosan occurs in the salt form and bears a positive charge, which leads to higher electrical conductivity. This fact suggests that, upon mixing acetic acid solution of chitosan with PCH, the polymers can interact with each other owing to the presence of carboxy groups in collagen. Indeed, as seen from the dependence shown in Fig. 3, the minimal conductivity

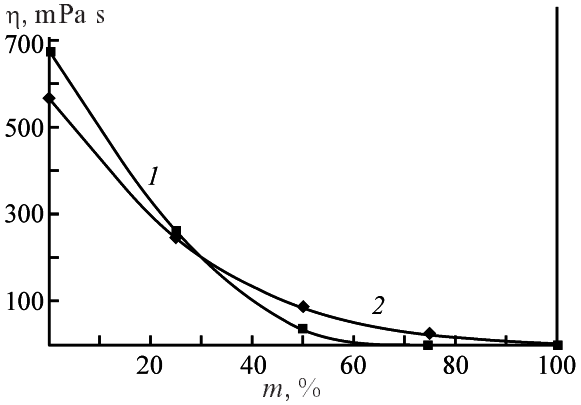

Fig. 1. Viscosity η as a function of the composition of (*1*) PCH–HEC and (*2*) PCH–chitosan systems (3% solutions). (*m*) Relative PCH content; the same for Figs. 2–4.

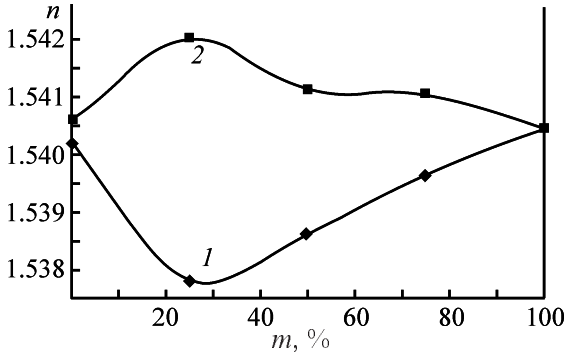

Fig. 2. Refractive index n as a function of the composition of (*1*) PCH–HEC and (*2*) PCH–chitosan systems.

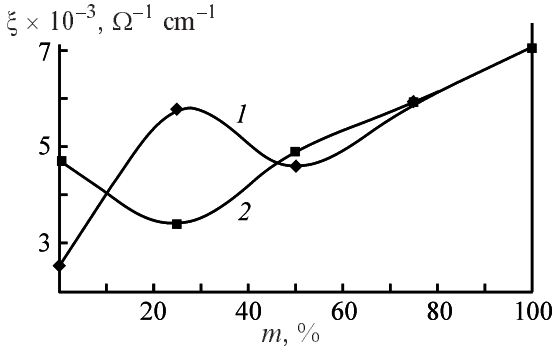

Fig. 3. Electrical conductivity ξ as a function of the composition of (*1*) PCH–HEC and (*2*) PCH–chitosan systems.

of the mixture is observed at a PCH content of 25 wt %. Such a nonmonotonic trend is apparently due to the electrostatic interaction of the protonated amino group of chitosan with the carboxy groups of protein, providing association of the macromolecules in the solution.

The electrical conductivity of the HEC solution increases with increasing content of PCH acting as weakly ionized amphoteric polyelectrolyte. In this case, a certain fraction of the functional groups

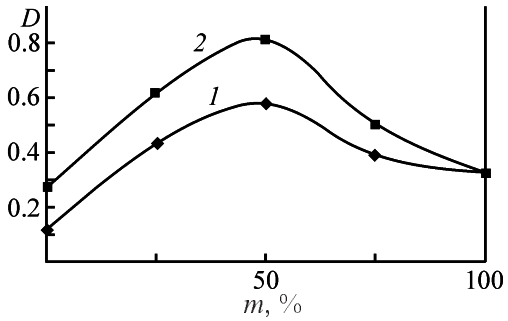

Fig. 4. Optical density D as a function of the composition of (*1*) PCH–HEC and (*2*) PCH–chitosan systems.

forms hydrogen bonds with the HEC hydroxy groups, which, in turn, promotes dissociation of oppositely charged collagen molecules.

The results of photometric studies (Fig. 4) show that, on addition of PCH into the polysaccharide solutions, the optical density of the solutions increases, reaching a maximum at the polysaccharide : PCH ratio of 50 : 50. The observed increase in the optical density upon mixing of the initial components can be probably due to the complexation (in the case of chitosan) or aggregation of macromolecules to form colloidal particles stable to sedimentation (in the case of PCH). Examination of the PCH–polysaccharide blends by the turbidity spectrum procedure allowed estimation of the average size of supramolecular particles in the solutions [6].

As seen from the table, the size of particles in the HEC–PCH blend is greater than that in the initial components and is independent of the component ratio, which confirms the absence of interaction between the components. This is probably due to the

Particle size and properties of the biopolymer films

PCH content (wt %) in composition based on polysaccharide	Particle size, nm	Film properties
HEC:		
0	100	Opaque dry elastic
25	160	Semitransparent elastic
50	165	Semitransparent brittle
75	155	Transparent brittle
100	128	No film formed
Chitosan:		
0	110	Yellow transparent semirigid
25	200	Semitransparent brittle
50	180	Opaque brittle
75	135	Opaque brittle

breakdown of intermolecular hydrogen bonds in the collagen structure as a result of penetration of polysaccharide elements incompatible with the protein, which increases the particle size. It should be noted that the size of supramolecular associates in the compositions based on two and more polymer solutions is often greater than that of the initial components [8]. However, in some cases the microheterogeneity parameters of solutions of polymer blends do not agree with visual characteristics of the films. For example, a film prepared from the HEC solutions is opaque, whereas from the HEC–PCH solutions a semitransparent film is obtained. In the chitosan–PCH system, more significant differences in the particle size depending on the PCH content are observed, as compared to the initial chitosan solution. The coarser particles are formed at a chitosan : PCH ratio of 75 : 25, their calculated size is 200 nm, whereas the particle size of the initial chitosan is 110 nm. With increasing PCH content in the solutions to 75 wt %, the particle size decreases. The observed dependences agree with experimental data on the compatibility of the polymers in the solution.

Thus, our study of the compatibility of collagen and polysaccharides in solutions, based on the analysis of deviations of the experimental data in the property–composition diagrams, show that the compatibility of the systems studied depends on the chemical structure and ratio of the initial components. In the case of chitosan, we conclude that intermolecular complexes are formed in the system, with their maximal yield at the chitosan : PCH ratio of 75 : 25. In the case of HEC, no thermodynamic compatibility is observed. Modification of polysaccharides with PCH exhibiting biological activity but incapable of film formation in the given concentration range allows utilization of these compositions in various branches of industry. Purposeful variation of the structure of biopolymer materials in combination with the unique properties of the initial components suggests that the films prepared from these materials can be used as supports for the systems with controlled release of biologically active compounds.

CONCLUSION

Data on the viscosity, electrical conductivity, refractive index, and optical density of biopolymer compositions based on polysaccharides and products of collagen hydrolysis and also on the visual characteristics of the resulting films indicate that the

compositions based on chitosan are thermodynamically compatible at the content of the protein component of 25–40 wt %, whereas the compositions based on hydroxyethyl cellulose are thermodynamically incompatible but form kinetically stable systems in the solutions studied.

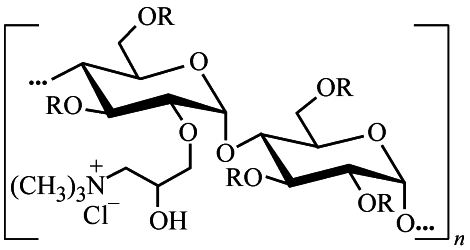
Abstract—The flocculation properties of a series of cationic starches with the substitution degree of 0.25–1.54 in kaolin dispersions were studied, and the dependence of the kaolin retention with fiber on the surface content of starch, degree of its substitution, and amylose : amylopectin ratio was evaluated.

DOI: 10.1134/S1070427208050273

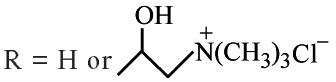
Starch (typical homopolysaccharide) is a mixture of linear polysaccharide amylose and branched amylopectin. The ratio of these components, which is determined by the source of starch, strongly affects its solubility and the gelling properties, gelation temperature, and viscosity of starch solutions. In contrast to the majority of polysaccharides, starch exhibits unique physicochemical properties in combination with a high nutritive value, which determines its extensive industrial use. Paper industry is one of the most important consumers of starch. Native starch and its derivatives (sometimes in combination with synthetic polymers) are used in paper industry to prepare chemical systems for loading, retention, and reinforcement of paper [1].

The best properties in this field are exhibited by cationic starches, whose degree of substitution (DS) can be varied in a wide range, but it is usually within 0.01–0.1 mol mol^{-1} and does not exceed 0.2–0.4 mol mol^{-1}. As compared to the native polysaccharide, cationic starches exhibit such advantages as solubility in cold water, effective adsorption on the cellulose fiber surface, and enhanced fiber–fiber interaction, which improves the strength properties of paper and increases the extent of binding of fillers (talc, kaolin, pigments) with the paper stock.

The necessity of increasing DS of cationic starches and of studying in detail their properties is determined by the following factors. First, the modern paper industry tends to increase the content of fillers in the paper. In some brands of enamel-paper the degree of filling is more than 35%. Cationic starches with low and medium DS cannot provide the required retention of fillers without additional reagents. At insufficiently high DS of starch, the retention of starch itself and of the filler on the fiber surface can be incomplete. In combination with economical expenses caused by the reagent loss, the presence of starch and fillers in recycled water strongly deteriorates its properties and requires additional treatment with flocculants.



The properties of low-substituted starches were studied in detail [1–5], whereas the data on starches with medium DS (0.15–0.4) are scarce.



In this study we examined the flocculation properties of a series of highly substituted cationic starches (DS 0.25–1.54) in kaolin dispersions, the features of their adsorption on the cellulose fiber surface, and the effect of DS and amylose : amylopectin ratio on the performance of highly substituted cationic starches as flocculants and binders for paper industry.

EXPERIMENTAL

The kaolin dispersion in TRIS buffer system (pH 8) was prepared by ultrasonic treatment for 15 min. The cationic starches with DS from 0.25 to 1.54 mol mol^{-1} were prepared by the procedure presented elsewhere [6] using potato starch containing 28% amylose (Emsland Stärke GmbH, Germany) and corn starch containing 70% amylose (National

Starch and Chemical Ltd., the United Kingdom). The starch solutions were prepared by dissolution of weighed portions of starch with continuous stirring at 60°C and subsequent storage at room temperature for 24 h.

Bleached softwood pulp (Schopper–Riegler freeness value 22 deg) was supplied by the Institute of Paper (Heidenau, Germany).

The apparent charge density of cationic starches and the particle charge in kaolin dispersions were determined by colloidal titration. The experimental setup consisted of a precision dosing device (702 SM Titrino, Metrohm, Switzerland), a particle charge detector (PCD-03, Mütek, Germany), and a computer. The particle charge detector consists of a cylindrical Teflon cell in which a Teflon plunger moves at a constant rate and a colloidal solution being studied is placed between the cell walls and the plunger. The operation principle is as follows. The moving plunger shifts the ionic atmosphere of the colloidal particles adsorbed on the porous wall of the Teflon cell, giving rise to the electrokinetic flow potential which is detected by the electrode pair located in the top and bottom sections of the cell [7]. Although the flow potential depends on many factors and, in contrast to ζ potential, is not an absolute parameter, this procedure can be used to determine the charge sign of the polymers and colloidal particles and to evaluate the charge density in the course of colloidal titration with oppositely charged polyelectrolytes. As titration solutions we used standard (1 mg-equiv l^{-1}) solutions of sodium polyenthylenesulfonate (polyanion) and polydiallyldimethylammonium chloride (polycation).

To study the flocculation properties of starch, a 50-ml portion of an aqueous kaolin dispersion was mixed with an aliquot of the starch solution, stirred for 15 min on a magnetic stirrer, and allowed to stand for 20 min for sedimentation. The difference between the optical densities of the initial dispersion and supernatant at a wavelength of 500 nm gave the residual turbidity of the solution, which was used as a parameter of the flocculation efficiency. The minimal portion of the flocculant providing the residual turbidity of no more than 1% was taken as the effective flocculant dose.

Adsorption of cationic starches on cellulose fibers was performed using TRIS buffer system (pH 8) at 22°C for 48 h; the solid : liquid (s : l) ratio was 1 : 200 counting on cellulose dried for 4 h at 110°C. Before addition of the starch solution, the wet cellulose fibers were swollen for 4 h in the buffer solution with continuous stirring. The adsorption capacity was evaluated from the difference of the initial and equilibrium concentrations of the starch. The latter was determined by colloidal titration of the supernatant filtered through porous glass.

To a suspension of cellulose fiber with preliminarily adsorbed cationic starch, we added an aliquot of a kaolin dispersion. After stirring for 5 min, the system was allowed to stand for 5 min for sedimentation, and the optical density of the supernatant at λ = 500 nm was measured. The residual kaolin concentration was found from the calibration turbidity curve and was used for calculating the adsorption of kaolin on the modified fiber from the difference of the initial and equilibrium concentrations.

Beginning from the 1980s, there has been a tendency in the paper industry to pass from a common acidic procedure with aluminum sulfate to the more efficient alkaline technology. New operation conditions require reactants active at pH 8, which determines advantages of cationic starches with quaternary ammonium groups as compared to primary, secondary, and tertiary amines, whose positive charge decreases with increasing pH. The dependences of the apparent charge density on pH for the given series of cationic starches confirmed that, in the pH range 3–8, the charge density of starches remains constant and depends only on the degree of substitution (see table). As seen from Fig. 1, with addition of cationic starch up to a certain concentration into a kaolin dispersion (whose particle surface is charged negatively at pH 8), this dispersion becomes unstable owing to adsorption of starch on the kaolin particles. In this case, the amount of starch required for destabilization of the dispersion decreases with increasing DS.

Comparison of the system turbidity and charge density of the particles at various contents of the cationic starch (Fig. 2) shows that the efficient flocculation starts long before complete neutralization

Characteristics of cationic starches

of the surface charge with the adsorbed polymer. Recharging of the particle surface in the area of the plateau of the adsorption isotherms [8], typical for adsorption of highly charged polyelectrolytes, is also observed with cationic starches, providing stabilization of the kaolin dispersions upon addition of excess flocculant.

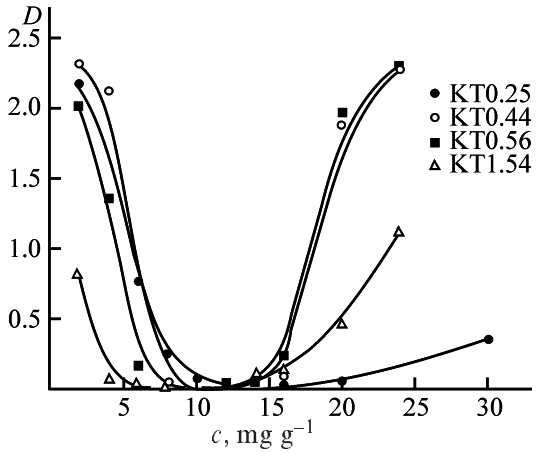

Fig. 1. Efficiency of the dispersion flocculation as a function of DS of the cationic starches. (*D*) Optical density at λ = 500 nm and (*c*) flocculant content.

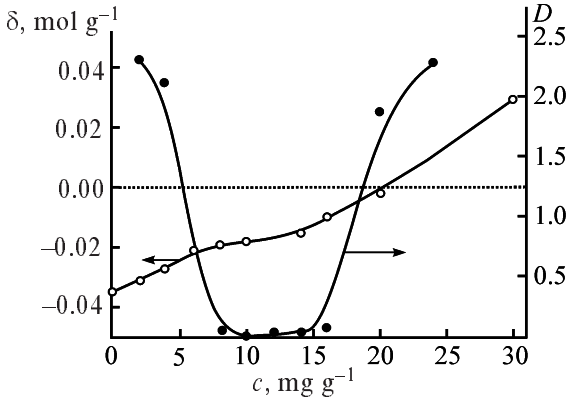

Fig. 2. Optical density and charge density on the kaolin particle surface as functions of the content of KT0.44 starch. (δ) Charge density, (*D*) optical density at λ = 500 nm, and (*c*) flocculant content.

Since the increase in the degree of cationic substitution of starch not only increases the starch cost but also affects its toxicity and biodegradability, it was of particular importance to determine the highest degree of substitution of the starch at which the increase in the starch performance as flocculant and binder in the paper production compensates the cost of its production.

Analysis of the experimental data shows that the apparent charge density of the cationic starches linearly depends on DS only in a certain concentration range. The experimental apparent charge density determined by colloidal titration at DS 1.54 is significantly smaller than the expected value (Fig. 3), which is probably due to the structural features of amylopectin. At small DS, modification proceeds predominantly through easily accessible sections of starch macromolecules, but with increasing DS certain fraction of cationic centers inevitably appears to be localized in the inner areas of the amylopectin branched fragments. Presumably, the cationic centers localized on the surface and in the bulk of amylopectin spheroids exhibit strongly different accessibility and activity.

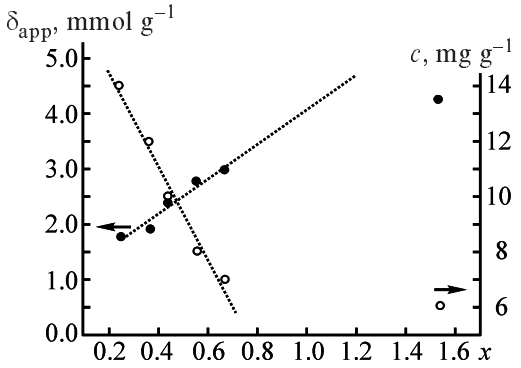

Fig. 3. Apparent charge density δ_{app} of the cationic starch in solution and their minimal effective flocculation dose *c* in dispersions as a function of the degree of cationic substitution *x*.

As seen from Fig. 3, the minimal content of the polymer required for the phase separation in the dispersion linearly decreases with increasing DS for the starch derivatives with DS < 0.7 and then slightly decreases. This fact distinguishes starch derivatives differ from linear synthetic flexible-chain polymers whose flocculation ability, as a rule, linearly depends on DS. Apparently, the steric factor acting in this case restricts the area of efficient cationic substitution of amylopectin by the upper DS level of 0.6–0.7; further increase in the starch DS is unprofitable.

To examine how DS of the cationic starches affects their performance as binding agents in adsorption of fillers on the surface of the cellulose fibers, we studied the starch adsorption on the cellulose fiber and the relationships of the kaolin retention on the fibers preliminarily modified with the starch.

We found (the data are not given in this paper) that the adsorption isotherms strongly depend on the ratio of amylopectin and amylose in the cationic starch. Irrespective of DS, for starches with the predominant content of amylopectin high-affinity adsorption isotherms were obtained. In contrast to weakly substituted starches, which are characterized by a sharp decrease of the limiting adsorption with increasing DS [1], for the starches studied (SD 0.25–1.54) the limiting adsorption only slightly depends on DS, though a certain decrease in the adsorption with increasing DS is still observed.

One of the most important functions of cationic starches in paper industry is to improve the retention of the filler and pigments by the cellulose fibber. The surface of the initial cellulose fiber is negatively charged at pH of the paper chalking. Therefore, similarly charged filler particles cannot be retained on the cellulose fiber surface without binding agents. As seen from Fig. 4, the kaolin adsorption by unmodified cellulose does not exceed 25–30 mg g^{-1}, which is smaller by an order of magnitude than the parameters required for the modern paper industry. Weakly substituted starches (DS 0.05) enhance the kaolin adsorption on the cellulose surface, but the parameters of the maximal retention of the filler are still significantly lower than the modern requirements.

With increasing DS of the cationic starch to 0.25, the degree of filling of the cellulose fibers with inorganic components increases to 50%, but this is possible only at a high surface content of the starch, close to the limiting adsorption capacity. Apparently, attainment of so high parameters involves additional problems related to possible incomplete retention of excess starch on the cellulose surface even at small fluctuations of the system composition. Thus, the performance of cationic starches with DS 0.25 only slightly exceeds that of the widely used weakly substituted derivatives.

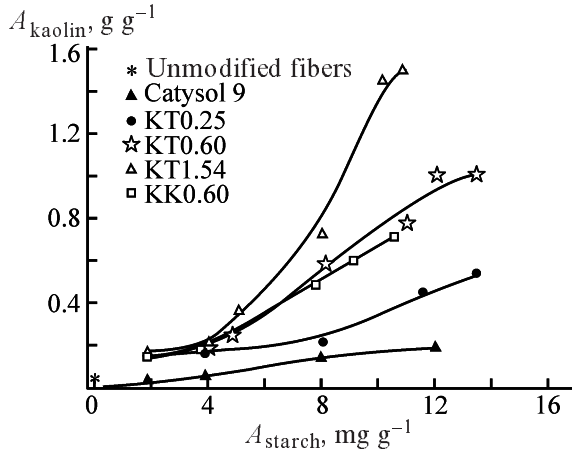

Fig. 4. Limiting adsorption of kaolin filler on the surface of cellulose fibers with various surface contents of cationic starches. (A_{kaolin}) Kaolin adsorption and (A_{starch}) starch adsorption.

As seen from Fig. 4, the behavior of cationic starches with medium (0.6) and high (1.54) DS is advantageous as compared to the weakly substituted analogs. The required degree of filling of the fiber with kaolin (up to 50%) is attained at the surface starch content of 6–8 mg g^{-1}, which is considerably lower than the limiting adsorption values. Under these experimental conditions, cationic starches are adsorbed on the surface of cellulose fiber in 30–60 s with 100% retention, which virtually completely eliminates the losses of the reagent and thus its negative effect on the quality of recycled water. It should be noted that the binding performance of the medium-substituted starch (DS 0.6) is only slightly dependent on the amylose–amylopectin ratio.

An increase in SD allows a considerable increase in the content of inorganic fillers in the paper, up to an excess of kaolin over cellulose in the system with highly substituted starch (DS 1.54), but the paper with so high content of the filler is of no practical interest because of its brittleness and too high density. However, at the kaolin content in the range 35–50%, which is of the most practical interest, more than twofold increase in DS (from 0.6 to 1.54) leads to a decrease in the content of starch required for the fiber modification by no more than 20%.

Taking into account that the production of starches with DS ≥ 1.0 is difficult [6] and their per-

formance as flocculation agents and binders increases only slightly in the DS range from 0.6 to 1.54, we concluded that the optimal DS of cationic starches is 0.6–0.7.

CONCLUSION

The optimal degree of substitution of cationic starches is 0.6–0.7, and its further increase only slightly improves their performance as flocculation agents and binders for paper production.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

The Use of Monolithic Polymeric Sorbents to Simulate Virus–Cell Interactions

I. V. Kalashnikova, N. D. Ivanova, and T. B. Tennikova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April 2, 2008

Abstract—A simple virus–cell complementary model system can be obtained using polymer-analogous reactions of the epoxy groups of glycidyl methacrylate–ethylene glycol dimethacrylate monolithic macroporous polymeric support and of the carboxy groups of styrene–methyl methacrylate polymeric nanospheres. The effect of thus designed microenvironment on the affinity binding parameters of virus-mimicking nanoparticles with the functionalized sorbent surface is studied by high-performance monolithic disk affinity chromatography.

DOI: 10.1134/S1070427208050285

Diversity of surface properties of cells and viruses causes the occurrence of different mechanisms of their adsorption interaction via highly specific (affine) or weaker nonspecific (ionic, hydrophobic, coordination, etc.) bonding. These mechanisms can be simulated by introduction of different specific ligands into model systems.

Original macroporous monolithic sorbents [1], fabricated as thin disks (BIA Separations, Ljubljana, Slovenia) [2], as well as chromatographic processes realized with these stationary phases [high-performance monolithic disk affinity chromatography (HPMDAC) and chromatography on ultrashort monolithic columns] offer unique opportunities for studying specific complexation [3–6]. In other words, HPMDAC is an ideal method allowing adequate simulation of interactions of biocomplements and assessment of the effect of the microenvironment on these interactions. Furthermore, it was demonstrated recently that monolithic sorbent based on glycidyl methacrylate (GMA)–ethylene glycol dimethacrylate (EDMA) copolymer is well suitable to realize interfacial processes proceeding via affine binding of large particles [7] such as viruses [8, 9].

Functionality of biological macroparticles (cells, viruses) is controlled by their complex multilevel structure, which could be modeled through successive combination of different (macro)molecules. In our previous experiments, the components (phospholipids, carbohydrates, and proteins) composing cell walls were introduced into surface structure of the monolithic GMA–EDMA sorbent, while the nanoparticles with finely tuned surface structure, close in its composition to that of the membrane of the virus attacking the cell, were in the mobile phase. The virus-mimicking nanoparticles were prepared on the basis of polymeric nanospheres with a size close to that of human viruses.

Construction of such model systems adequately simulating natural ones and allowing examination of the adsorption behavior of viruses is a topical problem in studying mechanisms of their interaction with a cell. Results obtained in these studies can be used as a basis in developing procedure of affine separation of virus particles from native biological fluids. Additionally, data obtained for such model systems can be useful in selecting promising targets in developing new antiviral drugs.

EXPERIMENTAL

In the experiments we used trypsin (TR) and soybean trypsin inhibitor (SBTI) from PanEco (Russia); glucosamine hydrochloride (GA), Schiff's reagent, and ninhydrin from Sigma–Aldrich Chemie GmbH (Germany); and phosphatidylethanolamine (PTEA) from Tekhnologiya–Standart (Russia).

To activate carboxy groups of the polystyrene latex particles, we used water-soluble 1-ethyl-(3-di-

methylaminopropyl)carbodiimide (EDC), 2-(*N*-morpholino)ethanesulfonic acid (Sigma–Aldrich), and 1-hydroxybenzotriazole (HBT) [Fluka AG (Switzerland)].

All buffer solutions were prepared from analytically pure grade chemicals and distilled water and were then filtered through an 0.45-μm Millipore filter [Millipore Inc. (Austria)].

As a stationary phase, we used commercial sorbents, namely, monolithic macroporous GMA–EDMA disks (CIM Epoxy Disks, BIA Separations, Ljubljana, Slovenia). The mean pore size of the sorbent was 1.5 μm; specific pore surface area, 10–15 m^2 g^{-1}; and total porosity, 0.6 ml ml^{-1}. The sorbent volume was 0.34 ml. The disks were arranged in an original cartridge from the same manufacturer.

The HPMDAC process was carried out using Gilson chromatographic system (France) consisting of two plunger pumps (models 303 and 305), a 2138 Unicord S UV detector [LKB Bromma (Sweden)], and a 2210 Recorder from the same manufacturer.

The optical density of solutions was determined with an SF-26 spectrophotometer [LOMO (Russia)].

In fabricating the virus-mimicking particles, we used polymeric nanospheres (for their characteristics, see Table 1).[1] Carboxylated PS- and PMMA-based polymeric particles were modified with ligands using the well-known two-step procedure of activation of carboxy groups with 1-hydroxybenzotriazole and a water-soluble carbodiimide [10–12].

A polystyrene latex (7.2 mg), passed through a column with G-25 using 0.1 M morpholinoethanesulfonic buffer solution (pH 5.5) as a mobile phase, was successively activated with HBT and EDC taken in equimolar amounts with respect to the amount of the surface carboxy groups. The reaction was carried out at 0°C for 15–20 min. Then the suspension was purified to remove excess reagents by gel filtration on a G-25 column buffered with 0.01 M sodium borate (pH 8.5–8.7). To obtain polymeric particles experienced to the most complex surface functionalization, 30 min after introduction of 1.6 mg of TP, we added GA and PTEA (1 mg each) to the purified suspension of the polymeric nanospheres. In all cases, surface modification of the nanospheres was carried out for 4–6 h at 20°C. After the reaction completion, excess components were removed from the suspension by dialysis or gel filtration on a column with Sephadex G-200 and 0.01 M sodium phosphate buffer (pH 7.0) containing 0.15 M sodium chloride (FSB) as a mobile phase. The other functionalized particles were prepared similarly (Table 2).

The amount of a protein required to cover the nanosphere surface was 1–3 mg per 1 m^2 of the surface area. The number of polymeric particles involved in the reaction was controlled by the volume of the latex suspension taken for the experiment. In the case of polydisperse polymeric nanospheres based on poly(methyl methacrylate) stabilized with dextran (PMMAD), fine particles were removed by gel filtration prior to modification. The PMMAD particle concentration in the eluate was determined using the calibration curve obtained for the solution optical density vs. nanosphere concentration at the UV absorption maximum (340 nm).

The amount of protein immobilized on the surface was determined by the Lowry method [13]. The amounts of GA and PTEA bound to the carboxy groups of the polymeric nanoparticles were estimated from the difference in their concentrations in the initial solution and in the solutions after dialysis.

To quantitatively determine PTEA, the mixture containing 0.5 ml of the PTEA-containing solution and 2.5 ml of 0.1% aqueous solution of Schiff's reagent was thoroughly stirred and incubated for 1 h at room temperature. It was demonstrated in the preliminary experiments that a colored complex of

[1] Polymeric nanospheres based on poly(methyl methacrylate) and polystyrene were provided by T.G. Evseeva and A.Yu. Men'shikova (Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg).

Table 2. Characteristics of virus-mimicking particles

Particle	Maximal number of ligand molecules bound to the surface of nanosphere, N_{max}		Coverage of nanosphere surface with ligand, %
	theory	experiment	
PS–TP	1600	775	48.4
PS–TP/PTEA	1600/9400	690/3530	43.1/37.5
PS–TP/GA	1600/9400	390/3380	45.0/36.0
PS–TP/PTEA/GA	1600/9400/9400	670/1100/4200	41.9/11.7/44.6
PMMAD–TP	1010	675	66.8

PTEA with Schiff's reagent has an absorption maximum at 550 nm and that the detection limit is 5 μg ml^{-1}. The calibration curve of the optical density vs. PTEA concentration allowed precise determination of PTEA.

Glucosamine was determined using the reaction with ninhydrin. To 2.5 ml of the sample, 0.5 ml of 1% aqueous ninhydrin was added. The system was thoroughly mixed and heated for 30 min at 120°C in a thermostat. The calibration curve of the solution optical density vs. GA concentration was obtained at 540 nm. The detection limit was determined to be 1 μg ml^{-1}.

Immobilization of the protein or simultaneously of three NH_2-containing ligands, SBTI, PTEA, and GA, was carried out according to the previously reported procedure [14, 15]. Just prior to modification of the surface of the monolithic sorbents, the disks were successively rinsed (in a flow of the liquid phase at a rate of 5 ml min^{-1}) with ethanol, ethanol : water = 1 : 1, water, and, finally, with the corresponding reagent, to remove organic impurities from the pores of the support. After pretreatment, a monolithic disk with native epoxy groups was immersed into 2 ml of a buffer solution [0.0125 M sodium borate solution (pH 9.3) containing the protein (SBTI) or simultaneously three ligands (SBTI, PTEA, and GA)]. The ligand concentration was 5 mg ml^{-1}. The disk was allowed to stand in the solution for 16 h at 22–30°C. The amount of the ligand covalently bound to the support was estimated as the difference between the ligand concentrations before and after immobilization taking into account the ligand concentration in the washings. The Lowry test [13] was used to determine the protein concentration, and the GA and PTEA contents were determined by the above-described methods.

The chromatographic experiments were carried out in the frontal elution mode. As a result, adsorption isotherms were obtained, which were used then to estimate parameters of the affine interaction such as the maximal adsorption capacity Q_{max} and the dissociation constant of the affine complex K_d [14–17]. A solution of nanospheres modified with trypsin or with two (TP–PTEA) or three (TP–PTEA–GA) ligands simultaneously was passed through a disk with the immobilized ligand(s) until full saturation of all adsorption sites of the stationary phase. The TP concentration in solutions varied from 0.002 to 0.7 mg ml^{-1}, and the elution rate was 2.0 ml min^{-1}. In the adsorption stage, 0.01 sodium phosphate buffer solution (pH 7.0) containing 0.15 M NaCl was used as a mobile phase, and complete desorption was attained by elution with 0.01 M HCl (pH 2.0). Intermediate washing with 2 M NaCl and 2% ethanol in FSB was used to remove particles nonspecifically bound to the surface of the monolithic sorbent. Fractions thus obtained were collected in volumetric vials, and the protein concentration was determined using the Lowry test [13].

Previously [7, 18], to build simple models for viruses, we used model proteins (trypsin, ovalbumin, and soybean trypsin inhibitor), whose behavior on monoliths was well known. It was demonstrated using two variants of chromatography on monoliths that the adsorption of the resulting coarse protein-bearing particles on the outer surface is controlled by the nature and amount of the graft protein [7]. It is evident that functionalization of the surface of polymeric nanospheres with other ligands will affect the final mechanism of adsorption interactions of virus-like particles with the sorbent surface. It is well known that, in addition to proteins-antigens participating in the virus–cell interaction, the viral envelope contains also such components as lipids and carbohydrates that a virus takes over when coming away from a cell [19]. Therefore, to build more elaborated model for viruses, we made the

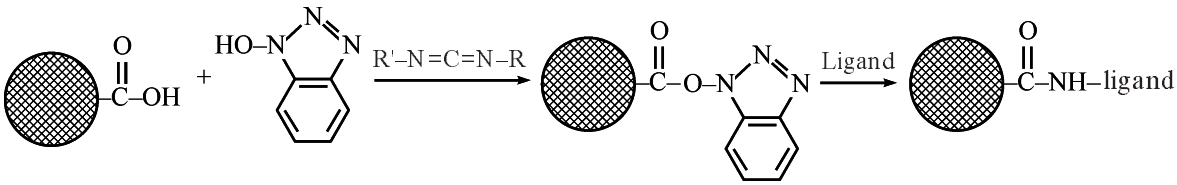

Fig. 1. Surface modification of polymeric nanospheres with amino ligands.

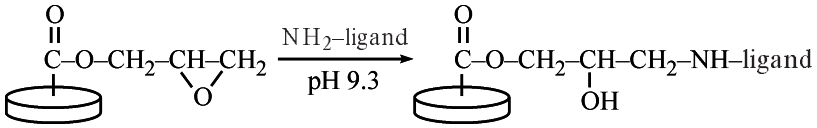

Fig. 2. Surface modification of monolithic sorbents with amino ligands.

microenvironment of a protein on the surface of polymeric nanoparticles more and more complex, thus approaching the composition of the viral envelope using low-specificity ligands of nonprotein nature.

As a basis for preparation of virus-like particles we took polymeric nanospheres of two types, namely, PS- and PMMA-based nanospheres. In the latter case, dextran arranged in the surface layer imitated the oligosaccharide component of the microenvironment to be modeled. Trypsin played the role of virus antigen on the surface of polymeric nanoparticles. Phosphatidylethanolamine and glucosamine, the most abundant components of cell membranes [20–22], were selected as ligands mimicking the lipid and carbohydrate components of the microenvironment of the protein. Covalent immobilization of amine ligands on the surface of the carboxylated nanospheres was performed by the above-described method (see scheme in Fig. 1). As a result, we obtained particles containing one or several ligands of different nature and specificity (Table 2). The coverage of the surface of nanospheres with trypsin was estimated as the ratio between the theoretical number of the protein globules that can be arranged on the smooth surface of a nanosphere to that obtained experimentally using the Lowry test [13]. The theoretical amount of molecules of the other ligands (GA and PTEA) that can be bound to a nanosphere corresponded to the amount of the carboxy groups on the surface of the particles. The experimental amount of the ligands was determined as the difference between the ligand concentrations in the solution before and after the reaction.

Table 3. Concentration of affine ligands immobilized on the surface of CIM Epoxy disks

Ligand	Ligand concentration	
	mg/ml of sorbent	$c \times 10^{16}$ SBTI globules/ml of sorbent
SBTI	3.2 ± 0.2	8.0 ± 0.5
SBTI/PTEA/GA	3.9 ± 0.3/1.2 ± 0.05/ 6.5 ± 0.4	9.8 ± 0.6

The affine partner of trypsin (soybean trypsin inhibitor), covalently bonded to the surface of the polymeric GMA–EDMA sorbent, played a role of a model cell receptor. To more adequately simulate virus–cell interaction using adsorption of virus-mimicking particles on the sorbent surface, the same phospholipid and carbohydrate were taken to build a simplified structure of a cell membrane on the surface of the monolithic sorbent. The selected amino ligands were immobilized by single-step covalent binding to the epoxy groups of the macroporous copolymer (Fig. 2, Table 3).

Thus, by modification of the surfaces of latex nanoparticles and monolithic sorbent, we obtained a simplified complementary system in which the surface of the polymeric support imitated the external shell of a cell and the combination of different ligands constructed on the nanoparticle surface imitated the shell of a virus particle attacking the cell. Schematic representation of the model system design is shown in Fig. 3. The use of the affine pair SBTI–TR as a model for the receptor–antigen interacting pair allowed control of the affinity recognition in constructing virus–cell interaction model.

Quantitative assessment of biospecific binding of virus-like particles, realized in the high-flow affinity chromatographic mode, allowed adequate estimation of the interaction of biological complements (SBTI–TR) and of the effect of the microenviron-

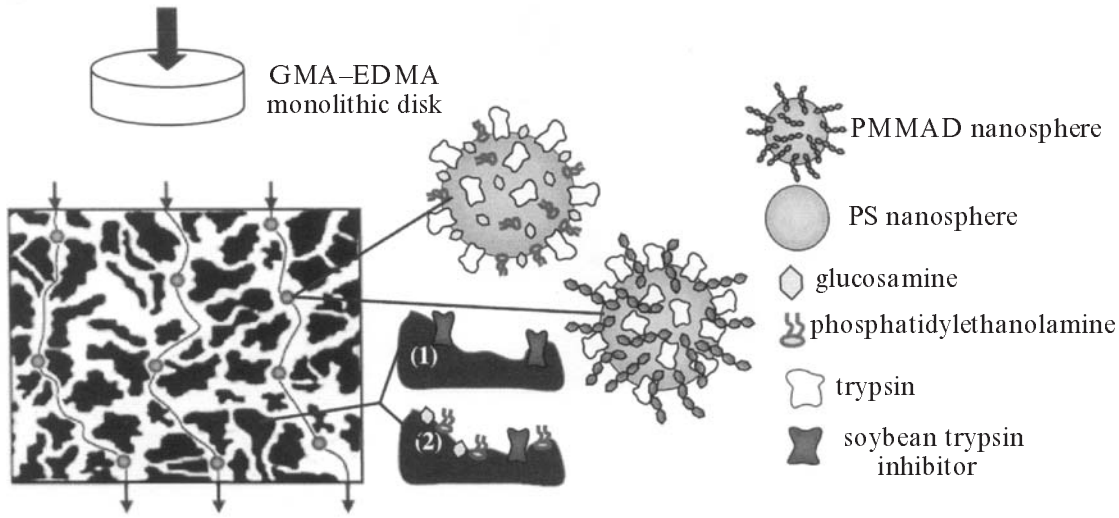

Fig. 3. Schematic representation of the model system design and biospecific binding assessment modes.

ment on the process (Table 4):

$$Q'_{max} = (Q_{max}/Q)/\rho, \quad Q = q/N; \qquad (1)$$

$$K'_d = (K/Q) \times 1/N_A, \qquad (2)$$

where Q_{max} is the maximal adsorption capacity, i.e., the amount of protein (mg) calculated from the results of frontal analysis; Q'_{max}, maximal adsorption capacity estimated by Eq. (1); N_A, Avogadro number; Q, amount of the protein (mg) bound to a nanosphere; q, total amount of the protein (mg) bound to all nanospheres in the solution; N, number of the nanospheres in the solution; ρ, concentration of the ligands immobilized in unit volume of the sorbent; K'_d, dissociation constant of the affine complex, estimated by Eq. (2); and K, constant derived from the adsorption isotherms $1/Q$ vs. $1/C$ (r 0.9895–0.9987).

Two cases were compared (Fig. 3): (1) immobilization of a single protein (SBTI) on the sorbent surface and (2) combination of two selected components (PTEA and GA) forming the microenvironment of this protein on the surface of the monolith, thus simulating the cell surface under virus attack.

Preliminarily we performed chromatographic experiments with a monolithic sorbent, SBTI covalently bount to it, PMMAD in the mobile phase, and PS particles modified with PTEA (coverage 68.2%) or GA (coverage 57.1%). The goal of these experiments was to prove or disprove the occurrence of nonspecific interactions of the lipid and saccharide ligands in hand with the surface of GMA–EDMA–SBTI sorbent.

These experiments revealed that PS–GA particles preliminarily adsorbed under physiological conditions can be totally removed from the sorbent surface only by elution with 2% ethanol in sodium phosphate salt buffer solution, suggesting the hydrophobic adsorption mechanism. As in the case of double-affinity complexation, complete desorption

Table 4. Quantitative characteristics of affine interaction, obtained by frontal analysis

Complement	SBTI		SBTI–GA–PTEA	
	$Q'_{max} \times 10^{-5}$, particles/ligand globules	$K'_d \times 10^6$, mol	$Q'_{max} \times 10^{-5}$, particles/ligand globules	$K'_d \times 10^6$, mol
PS–TR	7.2	1.0	3.3	1.9
PS–TR–GA	2.5	0.6	4.2	0.6
PS–TR–PTEA	2.1	0.6	3.1	0.2
PS–TR–GA–PTEA	1.4	1.4	1.5	0.3
PMMAD–TR	1.2	3.8	1.6	9.2

of PMMAD and PTEA-modified PS particles took place with 0.01 M HCl as an eluent (pH 2.0), suggesting stronger binding of the functionalized nanoparticles to the sorbent. This result can be attributed to the occurrence of a strong specific interaction between PTEA and graft protein in addition to the weak hydrophobic interaction.

Table 4 shows that step-by-step complication of the surface structure of the nanospheres weakened their adsorption on the sorbent surface modified with a single protein, suggesting that somewhat smaller amount of particles with a more complicated surface (compared to nanospheres modified with trypsin only) are involved in the formation of the biospecific complex SBTI–TR. Our results can be attributed to both steric factors and formation of different bonds that may compete with the specific interaction ligand–complement.

The opposite pattern was observed in adsorption of particles of different surface composition on a multicomponent surface of the sorbent (Table 4). Except for the nanospheres modified with trypsin only, for which the number of the adsorbed nanoparticles decreased by more than half as compared to adsorption on the monolith modified with a single ligand (SBTI), fine tuning of the surface microenvironment of the protein on the sorbent increased the maximal adsorption capacity (Table 4). For PS–TR particles, the increased dissociation constant of the complex (Table 4) suggests that the microenvironment of the ligand on the sorbent surface contributed to some extent to the destabilization of the affine complex.

The occurrence of an amino saccharide on the surface of PS–TR–GA particles had practically no effect on the dissociation constant of the affine complex formed from two different components in the SBTI microenvironment. Evidently, it is the lipid component of PS–TR–PTEA and PS–TR–GA–PTEA particles that imparted some extra strength to the affine complex as compared to simpler interaction mode, when only SBTI was immobilized on the sorbent surface.

In the case of PMMAD–TR particles, it may be suggested that the polysaccharide chains inhibited binding of the virus-like particles to the complicated surface of the sorbent, since the dissociation constant increased by a factor of about 2.5 (Table 4), even though this had no significant effect on the adsorption capacity, i.e., here one may say, most likely, about pseudoaffinity adsorption with lower interaction energy of the complements.

CONCLUSIONS

(1) Microenvironment of specifically interacting proteins, simulated on both the nanoparticle and sorbent surfaces, contributes significantly to the affinity binding parameters, but only slightly to the adsorption capacity of the support.

(2) The results obtained give a view of complexation of proteins surrounded by variously specific ligands. However, from the practical viewpoint, i.e., in developing high-performance biorecognition systems, designing of microenvironment can be eliminated from the procedure for preparation of stationary phases for separating viruses.

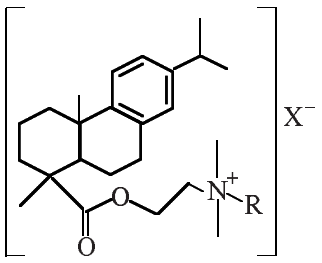
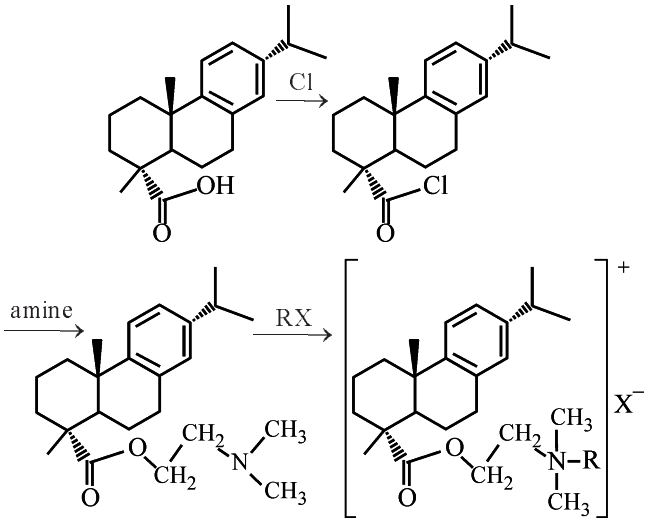
Received November 1, 2007



Abstract—Quaternary ammonium compounds based on resin (diterpene) acids and rosin were prepared. Their colloidal-chemical and biocidal properties were studied, and possible applications were outlined.

DOI: 10.1134/S1070427208050297

It is well known that introduction of nitrogen-containing functional groups into molecules of resin acids, the main components of rosin, is a route to very interesting environmentally friendly products finding diverse applications [1]. Of particular interest is the fact that many nitrogen derivatives of resin acids exhibit biological activity and pharmacological properties. In particular, it was shown that dehydroabietylamine is a fairly effective bactericidal and fungicidal agent [2]. Azomethines (Schiff bases) prepared from dehydroabietylamine and benzaldehyde derivatives also exhibit bactericidal properties [3].



Some azomethines surpass in the bactericidal activity the starting dehydroabietic acid (DAA). Some resin acid amides are also physiologically active. In particular, they exhibit hypocholesteremic action, i.e., are capable of controlling the cholesterol level in blood of warm-blooded animals [4, 5], and also gastroprotective and cytostatic action [6].

Quaternary ammonium salts (QASs) derived from resin (diterpene) acids and rosin of the general formula

where R = ethyl or benzyl, X = Cl or Br, were developed previously [7].

The commercial name of the product is Biotsik. Here we report on the synthesis of these QASs and on their colloidal-chemical and biocidal properties. The QAS synthesis is based on the known reactions and follows the scheme

1, DAA, R = Et, X = Br; **2**, DAA, R = Bz, X = Cl; **3**, mixture of resin acids, R = Et, X = Br; **4**, disproportionated rosin, R = Et, X = Br.

As the carboxy group in resin acids is sterically hindered, many reactions characteristic of aliphatic acids occur difficultly. Therefore, the first step in-

Table 1. Compositions and properties of QASs

Compound	Empirical formula	T_m, °C	Found, %/Calculated, %					Ammonium nitrogen, %	
			C	H	N	Br	Cl	found	calculated

volves synthesis of DAA chloride [8] or chlorides of a mixture of resin acids and of disproportionated rosin. In the second step, the chlorides are treated with dimethylethanolamine (DMEA) to obtain the corresponding amino esters, which are subsequently quaternized by the standard procedure with excess ethyl bromide or benzyl chloride in a solvent. The physicochemical properties of the compounds prepared and their compositions are given in Table 1. The empirical formulas of the QASs were confirmed mass-spectrometrically by the fragment peak with *m*/*z* 385.299. The IR and ^{1}H NMR spectra of all the compounds prepared are similar. In the UV spectra, there are three absorption bands at about 259, 267, and 276 nm, characteristic of the aromatic ring of DAA. In the UV spectrum of **2**, the band at 250–285 nm is somewhat broadened, which is typical of compounds with the benzyl C–H bond.

The IR spectra of all the QASs contain three characteristic absorption bands (cm^{-1}): 3400 (N–H bond), triplet at 3000–2800 (C–H), and 1727 (C=O). The bands at 1460 and 1380 cm^{-1} in the spectra of **1**, **3**, and **4** are assigned to CH_2 and CH_3 vibrations in the ethyl group.

The NMR spectrum contains characteristic signals (δ, ppm) at 6.7–7.3 (H of aromatic ring); 1.14, 1.17, and 1.22 (H of isopropyl and two CH_3 groups); a broadened signal at 4.5 (H of CH_2 group in the ester fragment C–O–CH_2–); 3.7 (4H, CH_2 groups bonded to nitrogen); and approximately 2.7 (4H, m, CH_2).

The spectral and analytical data obtained confirm the suggested structures of the quaternary ammonium salts synthesized. The compounds are soluble in water, ethanol, toluene, dioxane, acetone, acetonitrile, and carbon tetrachloride; they are stable in air at ambient temperature; they exhibit pronounced surface activity and biocidal properties. It is practically important that the colloidal-chemical and biocidal properties of the individual QASs (**1**, **2**) and of QASs derioved from rosin and a mixture of resin acids (**3**, **4**) are similar.

Figure 1 shows the surface tension isotherm characteristic of all the QASs studied, plotted in the normal and semilog coordinates. The minimal surface tension σ_{min} (mN m^{-1}) for the QASs is as follows: **1**, 35–36; **2**, 38–39; and **3** and **4**, 40–42. The critical micelle concentration (CMC) for all the QASs is 5×10^{-3} M (0.24%). From the second portion of curve *2* (Fig. 1), using the Gibbs equation, we calculated the maximal adsorption of QAS on the water–air phase boundary, $\Gamma_{max} = 4.3 \times 10^{-10}$ mol cm^{-2}. The same quantity calculated by the Shishkovskii equation for high concentrations is 3.8×10^{-10} mol cm^{-2}.

The specific electrical conductivity of the aqueous QAS solutions linearly increases with the concentration (Fig. 2). This fact demonstrates the capability

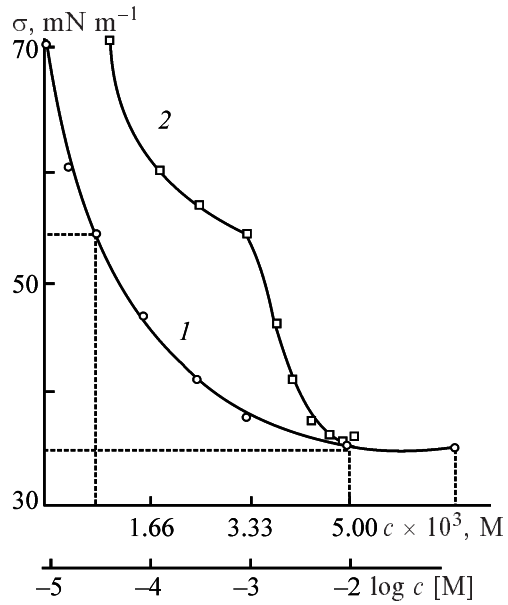

Fig. 1. Surface tension (σ) isotherm of aqueous QAS solution, plotted in (*1*) normal and (*2*) semilog coordinates. (*c*) Concentration.

of QASs for dissociation in aqueous solutions and their tendency to adsorption on negatively charged surfaces, in particular, on particles in polar media.

The dependence of the wetting angle of waxed glass on the QAS concentration in aqueous solution (Table 2) shows that the QASs studied are effective film-forming agents favoring hydrophilization of hydrophobic materials. It is well known that such surfactants are capable of chemisorption on hydrophobic surfaces and of selective wetting, which is important for using them as flotation agents and components of shampoos and conditioners.

Table 2. Wetting of the surface of waxed glass with aqueous QAS solutions

QAS concentration in water		Wetting angle	
$c \times 10^3$, M	c, g l^{-1}	θ, deg	cos θ

6.66	3.2	54	0.59

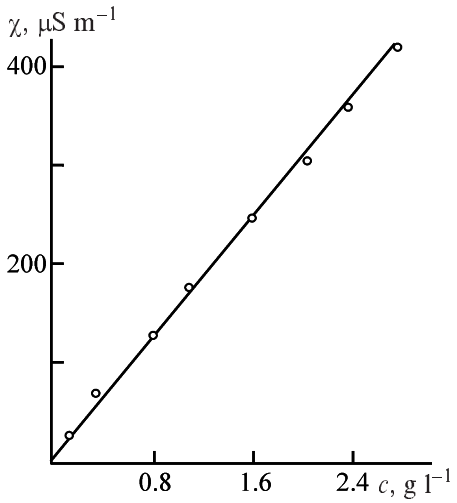

Fig. 2. Specific electrical conductivity χ of aqueous QAS solution as a function of QAS concentration *c*.

Calculation by the approximate Davies equation showed that the hydrophilic–lipophilic balance (HLB) of the QASs studied is 8.4. Calculation by the spreading coefficient (Griffiths method) gave a close HLB value, 9.

The bactericidal and fungicidal activity of QASs based on resin (diterpene) acids and rosin was studied by standard procedures, namely, by measuring the zone of microorganism growth suppression (Table 3). The characteristics of the bactericidal and fungicidal activity of some widely used biocides, determined under similar conditions, are also given for comparison. It can be seen that the QASs derived from individual resin (diterpene) acids (compounds **1** and **2**) and from a mixture of resin acids and rosin (compounds **3** and **4**) exhibit essentially similar bactericidal and fungicidal activity, although rosin, an environmentally clean, virtually inexhaustible raw material of plant origin, contains up to 10% neutral diterpenoids. Table 3 also shows that the QASs well compete in the biological activity with the known and widely used biocides, Aseptodin and Biopag-2 (the latter exhibits virtually no fungicidal properties), as well as with well-advertised biocide Triclosan (Ciba-Geigy, Switzerland), 2,4,4'-trichloro-2'-hydroxydiphenyl ether, which is environmentally hazardous as potential source of dioxins.

It is known that many QASs of various structures exhibit biocidal activity. The presence of a terpenoid fragment in the molecules of the QASs prepared undoubtedly enhances their activity.

The whole set of bactericidal-fungicidal and colloid-chemical properties of the QASs studied

Table 3. Bactericidal and fungicidal activity of QASs

suggests the following fields of their possible applications: in pulp-and-paper industry, for protection of the equipment from biological contamination, recycled wastewater treatment to remove bioformations, stabilization of the starch products used, and suppression of the development of microorganisms in them; in building, for preventing biocorrosion of building materials and structures, especially of those containing cellulose, and of buildings; for inhibiting corrosion; for enhancing the flotability of minerals; for static elimination; and in production of shampoos, conditioners, and specialty soaps (the commercial name of QAS **1** is Biotsik K, for cosmetics).

Some of these possibilities have been confirmed by practical tests.

Based on the results of our study, we developed an agent, QAS **4**, derived from a readily available and relatively cheap raw material, disproportionated rosin. This agent was termed Biotsik T [biocidal rosin for technical purpose, TU (Technical Specification) 2453-012-25588394–2005]. It exhibits fungicidal and bactericidal action (registry no. 15.245.P.002302.12.04 of December 19, 2004).

EXPERIMENTAL

For preparing **1** and **2**, we used DAA with mp 172.5°C and main substance content of 97.5 wt % (GLC). For preparing **3**, we used a crystalline mixture of resin acids isolated by the standard procedure from disproportionated oleoresin rosin, mp 169°C, acid number 184 mg KOH/g, of the following composition (GLC): DAA 70.5, dihydroabietic acid 18.1, sum of pimaric acids 10.3, and sum of acids with conjugated double bonds (of abietic type) 0.8. For preparing **4** (Biotsik T), we used disproportionated tall rosin (TU 13-00281074-265–95) with the following physicochemical characteristics: glassy, partially crystallized substance; acid number 164 mg KOH/g; weight fraction of acids with conjugated double bonds 0.8%.

The other chemicals used in the syntheses were of

chemically pure or analytically pure grade and were used without additional purification.

The UV spectra were recorded on Specord M-40 (in ethanol) and Hewlett–Packard 8453 spectrophotometers. The IR spectra were measured on a Perkin–Elmer spectrophotometer (NaCl cells, layer thickness 1.05 mm, solvent CCl_4). The ^1H and ^{13}C NMR spectra were taken on a Bruker DPX-200 spectrometer (200 and 50 MHz, respectively; $CDCl_3$). The mass spectrum was taken on a Finnigan MAT-8200 device (ion source temperature 173°C, scanning rate 1.2 scan s^{-1}, m/z range 30–350). The elemental composition of QASs was determined with a Carlo Erba automatic CHN analyzer. Ammonium nitrogen was determined as described in [9].

The melting point was determined according to GOST (State Standard) 14618.12–78 with a PTP device. The surface tension of aqueous solutions of QASs was determined by the method of maximum pressure of bubble formation and by the Wilhelmy plate method. In the first case, double-distilled water (σ = 73.05 mN m^{-1} at 18°C) was used as reference liquid. The Wilhelmy plate measurements were performed with a Waga Torsyna-WT torsion balance. The platinum plate size was 1×2 cm^2. The calibration curve of the dependence of the balance readings in the medium of the liquid surface tension was constructed on the basis of σ values of reference liquids that fully wet the platinum plate (methylene iodide, benzene, methylene chloride, toluene). All the reference liquids were of chemically pure grade.

The electrical conductivity of aqueous solutions of the QASs was measured with a DIST-3 conductometer. The device was immersed in a solution (volume 40 ml). Three replicate measurements were performed.

The wetting angles were measured on the surface of waxed glass. For this purpose, the support was kept for 1 min in a 1% solution of paraffin in hexane and then was dried in air for 30 min. A sample (1 μl) was applied with a microsyringe onto a sample stage placed in a hermetically sealed cell. The atmosphere in the cell was saturated with the vapor of the test liquid by placing this liquid on the cell bottom. The sample was applied through a hole in the cell lid. The dimensions of the drop (chord of the profile l and height h) were determined with an MPB-2 horizontal microscope, and the wetting angle θ was calculated by the formula $\theta = 2\arctan(2h/l)$.

Chlorides of resin (diterpene) acids and rosin were prepared as described in [8]. To prepare the amino esters, a reactor equipped with a stirrer, a heating jacket, and a reflux condenser was charged in succession with 85 g of dimethylethanolamine (DMEA) and 85 ml of toluene, after which 200 g of a 50% solution of appropriate acid chloride in toluene was added in portions. The mixture was heated to 95–97°C and kept at this temperature for 4 h. Then the mixture was filtered, and the filtrate was washed with water to neutral reaction of the wash waters and dried. After distilling the toluene off under reduced pressure, the corresponding dimethylaminoethyl ester was obtained in 86–88% yield.

To prepare QAS **1**, **3**, and **4**, a similar reactor was charged with 100 g of appropriate amino ester, after which 350 g of ethyl bromide was added in portions with stirring. Quaternization was performed at 30°C for 5 h. After distilling excess ethyl bromide off under reduced pressure, the corresponding QASs were obtained in virtually quantitative yields.

To prepare QAS **2**, a reactor was charged with 103 g of DAA aminoethyl ester and 15 ml of acetonitrile. The mixture was stirred at 45°C until a transparent homogeneous solution was obtained. After cooling to ambient temperature, a solution of 38.5 g of benzyl chloride in 100 ml of acetonitrile was added in portions with continuous stirring. The mixture was allowed to stand for 1 h, after which it was heated to 80°C, and the quaternization was performed for 5 h. After the reaction completion, the acetonitrile was distilled off at 50°C under reduced pressure, and 135 g of QAS **2** was obtained.

CONCLUSIONS

(1) Quaternary ammonium compounds derived from resin (diterpene) acids and rosin exhibit pronounced bactericidal and fungicidal properties and surface activity.

(2) It is appropriate to use Biotsik T agent in building industry for protection of building materials and buildings from biocorosion, and also in pulp-and-paper industry for protection of the equipment from biological contamination, recycled wastewater treatment, and stabilization of starch products used.

Abstract—The simplest polynomial expressions were applied to the description of the concentration dependences of integral molar excess Gibbs energy and enthalpy of mixing of the Fe–Ni, Co–Fe, and Co–Ni liquid alloys.

DOI: 10.1134/S1070427208050303

The dependences of thermodynamic properties of liquid metallic systems on the composition can be presented in the form of graphs, tables, or analytical expressions. Each form has some advantages and drawbacks in relation to accurate and clear description of the functional dependence, compactness, and convenient use of the data [1, 2].

In calculations using computer programs it is desirable to have analytical expressions for thermodynamic properties of the phases of variable composition. To create the corresponding data bank, it is appropriate to include different methods for describing the concentration dependences of thermodynamic functions, to use them depending on user's preference. In this case, one should clearly understand what characteristics are specific for each method of modeling of thermodynamic properties, depending on the character of component interaction.

In application of any mathematical model, it is rather important to assess the reliability of the input experimental data. At present, a number of criteria characterizing data reliability have been developed in practice. To them belong the author's evaluation of the measurement accuracy and the reproducibility (convergence) and self-consistency of data. Impartial assessment of data reliability in high-temperature studies is always difficult. In any specific case, the whole complex of probable errors must be taken into account and a certain experience is required. One should remember that applying the mathematical methods of averaging the set of available data for a particular system does not always give desirable result, because, in so doing, characteristic local features of the concentration dependence of the partial molar functions of components can be smoothed out.

When assessing the suitability of mathematical models used for analytical representation of the concentration dependences of the thermodynamic functions of liquid alloys, it should be taken into account whether the correct information about the thermodynamic function under consideration in the composition range studied at a given temperature can be obtained, whether the data bank is available, and whether the thermodynamic functions can be extrapolated to the composition region for which experimental data are lacking. By physical meaning, the functions of mixing in the homogeneity region must be reasonably smooth and their derivatives, continuous.

In the given study, we applied the simplest methods to the description of the dependence of the integral molar Gibbs energy ΔG^{exc} and enthalpy ΔH, which characterize the mixing in the Fe–Ni, Co–Fe, and Co–Ni liquid alloys. We choose for description the most reliable experimental data. The ΔG^{exc} values were obtained by Knudsen cell mass spectrometry [3–6], and the ΔH values, by high-temperature calorimetry [7–9]. Results of the experimental studies for binary systems under consideration are analyzed

in detail in [9]. All the three systems differ in the magnitudes and signs of deviation from the ideal behavior.

The concentration dependence of the integral functions of mixing was described by the following expressions [10]: for a regular solution we used the expression

$$\Delta\Phi = A x_1 x_2; \quad (1)$$

for a subregular solution, the expression

$$\Delta\Phi = x_1 x_2 (B x_1 + A x_2), \quad (2)$$

the Khair polynomial

$$\Delta\Phi = A x_1 x_2 \exp(B x_1), \quad (3)$$

the Redlich–Kister polynomial

$$\Phi = x_1 x_2 [b + c(2x_1 - 1) + d(2x_1 - 1)^2], \quad (4)$$

and the Wilson polynomial

$$\Phi = -RT[x_1 \ln(x_1 + A x_2) + x_2 \ln(x_2 + B x_1)], \quad (5)$$

where the symbol $\Delta\Phi$ denotes ΔG^{exc} or ΔH; x_1 and x_2 are mole fractions of components; A, B, b, c, and d are the coefficients in the equations.

The coefficients of Eqs. (1)–(5) describing the dependences of ΔG^{exc} and ΔH on composition are listed in Tables 1 and 2 along with the correlation coefficients R. The latter quantities show how adequately a given equation describes the corresponding dependence. As seen from Table 1, the regular-solution equation (1) describes well the ΔG^{exc} vs. composition dependence only for the Co–Ni system, and Eqs. (2)–(5), for all the three systems considered. The accuracy of the experimental determination of ΔH is considerably lower than that of ΔG^{exc}, which affects the correlation coefficients (Table 2). First of all, this concerns the Co–Ni liquid alloys, where ΔH is small in the absolute value (less than 0.5 kJ·mol^{-1}) and scatter of the available experimental data is considerable. It should be noted that the correlation coefficient itself cannot be considered as absolute criterion of applicability of a given equation to describing the concentration dependence of a thermodynamic function. The quality of the experimental data also plays an important role.

CONCLUSION

The possibility of describing the mixing in the Fe–Ni, Co–Fe, and Co–Ni liquid alloys by using

the simplest polynomial expressions with minimal number of parameters for the concentration dependence of integral thermodynamic functions was demonstrated.

Abstract—The neutralization of magnesium chloride solutions and their treatment to remove iron compounds was studied. The possibility of neutralization of free hydrochloric acid with brucite was determined. The effect exerted by the method of stirring of the solution in the course of neutralization was analyzed, and variations of neutralization rate with the solution temperature and with the amount and size of particles of the neutralizing agent were studied.

DOI: 10.1134/S1070427208050315

Prior to be used in production of synthetic carnallite, magnesium chloride solutions must be approximately neutral (pH ≥ 5) and the content of impurities in them must be no larger than (g dm^{-3}): 0.26 Fe, 0.08 Si, 0.003 Ni, 0.004 Cu, 0.03 Mn, 0.013 Al, 0.009 Ti, 0.004 Cr, at a $MgCl_2$ concentration of 400–450 g dm^{-3} [1, 2].

Magnesium chloride solutions obtained by leaching of oxide magnesium-containing raw material contain free hydrochloric acid and increased concentration of iron. The most suitable treatment method to remove impurities is fractional precipitation of hydroxides. The method is based on the property of metals to form hydroxides in a certain narrow range of pH [3]. Data on fractional precipitation of iron hydroxide are available from the literature [4]. From the process standpoint, the best neutralizing agent for magnesium chloride solutions is magnesium hydroxide (brucite). It is known [5] that the thermal decomposition and prolonged grinding of brucite increase the activity of magnesium hydroxide with respect to mineral acids.

In this study we determined the most active form of brucite as neutralizing agent and the conditions providing its minimal consumption and high quality of the resulting solutions.

The experiment was performed in a glass reactor which was charged with 1 l of a solution to be neutralized. The solution was obtained by leaching brucite with hydrochloric acid and contained (g l^{-1}): $MgCl_2$ 405, Fe^{n+}_{tot} 0.68, and HCl 5.5. For neutralization we used calcined and uncalcined brucite of different degrees of grinding. The solution being neutralized was stirred with a magnetic stirrer or by bubbling with compressed air. The temperature and pH of the solution were controlled in the course of the experiment. After the solution was neutralized, the contents of magnesium chloride, Fe_{tot}, and suspended substances in it were determined. The results and conditions of the experiments are presented in Figs. 1–4.

We used uncalcined brucite (d_{av} = 100 μm) to study how the amount of brucite and the method of mixing affect the neutralization rate. The data presented show that the neutralization rate is largely determined by the amount of brucite fed for neutralization (Fig. 1). For example, as the coefficient of brucite excess over stoichiometry is increased from 2 to 4, the neutralization rate increases by a factor of 5. Decreasing the solution temperature from 80 to 20°C results in a twofold decrease in the neutralization rate.

The effect exerted by the method of mixing is demonstrated in Fig. 2. The neutralization rate is shown to be independent of the method of mixing at low temperatures (20°C). At 80°C, the neutralization rate somewhat increases in the case of bubbling with compressed air. The effect of temperature on the neutralization rate is the most pronounced in the case when the brucite obtained by wet grind-

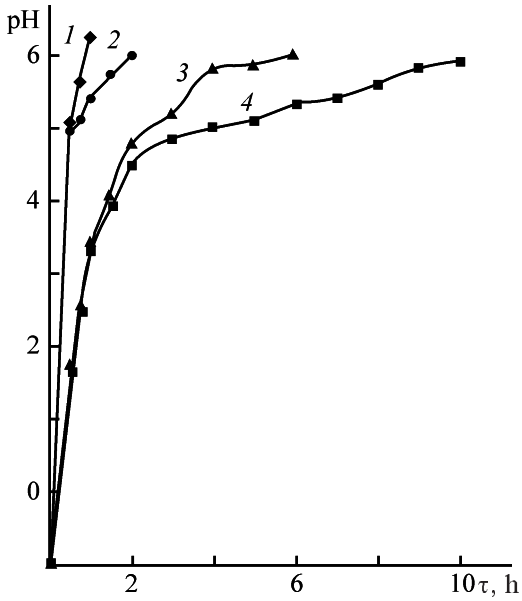

Fig. 1. Dependence of the neutralization rate on the excess of brucite. (τ) Mixing time; the same for Figs. 2–4. Coefficient of brucite excess K and T, °C: (*1*) 4.0, 80; (*2*) 3.0, 80; (*3*) 2.0, 80; and (*4*) 2.7, 20.

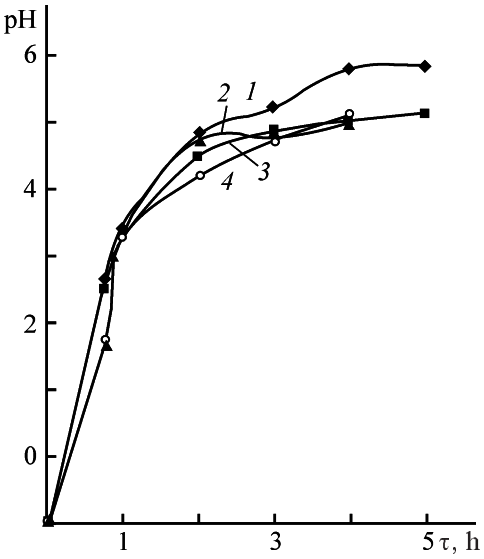

Fig. 2. Effect of mixing method on the neutralization rate: (*1*) bubbling with compressed air, T = 80°C, K = 2.0; (*2*) mechanical stirring , T = 80°C, K = 2.0; (*3*) bubbling with compressed air, T = 20°C, K = 2.7; and (*4*) mechanical stirring, T = 20°C, K = 2.7.

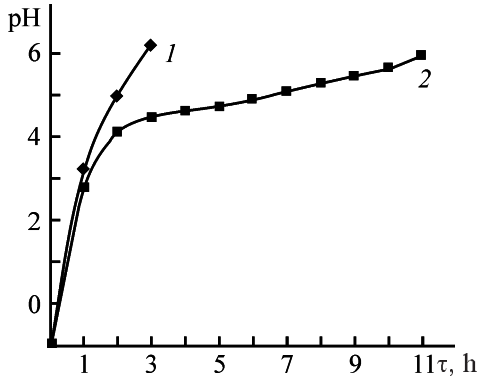

Fig. 3. Effect of temperature on the neutralization rate. Uncalcined brucite, d_{av} = 20 μm. Coefficient of brucite excess K and T, °C: (*1*) 1.5, 80 and (*2*) 2.0, 20.

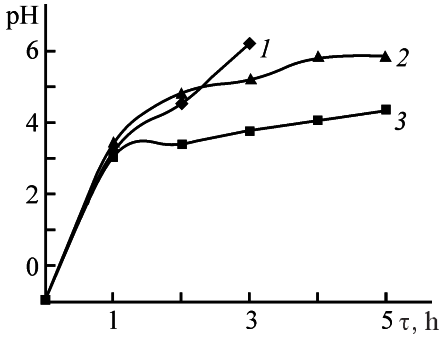

Fig. 4. Effect of particle size on the neutralization rate (T = 80°C). Brucite: (*1*) uncalcined (d_{av} = 20 μm), K = 1.5; (*2*) uncalcined (d_{av} = 100 μm), K = 2.0; and (*3*) calcined (d_{av} = 100 μm), K = 1.7.

ing on a bead mill for 30 h is used as neutralizing agent (Fig. 4).

The effect exerted by the size of particles of a neutralizing agent on the neutralization rate is demonstrated in Fig. 4. With brucite suspension obtained by wet grinding on a bead mill, the rate is maximal, which is due to the larger area of contant of brucite particle surfaces with hydrochloric acid. The lowest rate of neutralization of a brucite suspension obtained from calcined brucite can be accounted for as follows. As known, after 24 h of reaction of MgO with water, the degree of hydration is no more than 70%. This is because the hydration process is a topochemical reaction, with the reaction front at the MgO–$Mg(OH)_2$ interface. A hydroxide film on the MgO surface impedes diffusion of H_3O^+ ion toward the magnesium oxide surface. The character of the curve (Fig. 4) shows that, initially (during 1 h at pH < 3), the neutralization rate is virtually the same for all the neutralizing reagents. Evidently, till this moment, $Mg(OH)_2$ particles are formed on the surface of MgO particles. At pH 3, a film of iron(III) hydroxide is formed on brucite particles, which decreases the neutralization rate.

To evaluate the efficiency of treatment of the $MgCl_2$ solutions to remove Fe_{tot}^{n+}, we carried out a number of the experiments on the precipitation of

Solution purification with brucite

Component concentration, g l^{-1}				Degree of purification, %
before purification		after purification		
$MgCl_2$	Fe^{n+}	$MgCl_2$	Fe^{n+}	
361	0.09	389.9	0.002	97.7
108.1	0.05	115.2	0.002	96.0

246.9	0.16	250.8	0.005	96.9

iron hydroxides with milled brucite. To do this, a glass flask was charged with 200 ml of a solution containing various concentrations of iron salts and magnesium chloride. The solution having a temperature of 20°C was stirred with a magnetic stirrer, and a <100-μm fraction of natural brucite was charged to pH 0.5–7. Then the contents of the flask were heated to 100°C, kept at this temperature for 30 min, and filtered. The results of experiments on the solution purification are listed in the table. The data obtained show that the treatment of magnesium chloride solutions with natural brucite to remove iron compounds ensures high degree of its purification.

The results obtained were checked in the experiment with a solution volume of 230 l. To oxidize Fe^{2+} to Fe^{3+}, the solution was chlorinated for 1 h with a chlorine consumption of 5 kg h^{-1}. The solution obtained was poured into a tank equipped with a stirrer, and 9 kg of magnesium oxide (<1.5-mm fraction) was loaded. The mixture was stirred for 1.5 h. After that, 6 kg of MgO, preliminarily pulped with water to a volume of 15 l, was added. Stirring was performed for 20 min. Then the solution was heated to 100°C and boiled for 15 min. After cooling to 60°C, the solution was filtered. The resulting solution had a volume of 170 l. The solution contained (g l^{-1}) Fe^{3+} 21.1 and $MgCl_2$ 220 before purification, and Fe^{3+} 0.003 and $MgCl_2$ 369 after purification. The degree of purification was 99%. The precipitate contained (wt %) Fe 16.8, Mg 16.2, Si 3.3, and H_2O 19.9.

The data obtained show that the precipitation method is highly efficient for treatment of magnesium chloride solutions to remove iron compounds.

In the next stage of the study, the purified solutions were used for the production of synthetic carnallite. The carnallite obtained contained no less than 0.02 wt % Fe, which does not exceed the Fe concentration in artifical carnallite.

CONCLUSIONS

(1) The possibility of neutralizing hydrochloric acid in solutions obtained by leaching of magnesium-containing raw material with brucite was demonstrated.

(2) The neutralization rate increases as the temperature of the solution and the excess of brucite increase and as the size of particles of the neutralizing agent decreases.

(3) It is appropriate to use compressed air for stirring the solution in the course of neutralization.

(4) The most efficient method for treatment of magnesium chloride solutions to remove iron compounds is precipitation with finely ground natural brucite. The method ensures high degree of purification and, owing to neutralization of free hydrochloric acid whose concentration is 5–10 g l^{-1}, allows a 5–7% increase in the magnesium chloride concentration in the solution.

Abstract—Granulated sorbents that can recover zinc salts from aqueous solutions were produced by polycondensation of organochlorine wastes from manufacture of epichlorohydrin with sodium polysulfide on the surface of ash-and-slag particles formed at thermal power plants in the system constituted by aqueous hydrazine and an alkali.

DOI: 10.1134/S1070427208050327

Sulfur atoms in organic molecules (sulfides, di- and polysulfides, xanthates, and other compounds) can form complexes with transition metal salts [1]. This enables use of sulfur-containing products of this kind in medicine, homogeneous catalysis, analytical chemistry, ore dressing, and extraction of metals in hydrometallurgy [2–4]. Together with the use of low-molecular-weight sulfur compounds, studies aimed to synthesize sulfur-containing polymers with sulfur atoms incorporated into the polymer matrix and to analyze their sorption properties are being performed [4, 5]. The industrially produced polysulfide polymers, thiokols, are, as a rule, highly viscous rubber-like substances [6] which cannot be used as sorbents. Polyethylene monosulfide $(–CH_2CH_2S–)_n$, which has high sorption capacity for silver(I) and mercury(II) ions, has been synthesized in the form of a powder by the reaction of dichloroethane with sodium sulfide [7]. However, the use of a finely dispersed powder as sorbent gives rise to certain technological difficulties (caking, high hydraulic resistance, easy carryover by a flow of water).

A solid sorbent was obtained by polycondensation of 1,2,3-trichloropropane (TCP) with Na_2S_n (n = 2–4), with simultaneous addition of thiourea and lignin to the reaction mixture [8]. The sorbent effectively recovers Au, Pt, Pd, and Hg ions from aqueous solutions containing these elements in low concentrations in, apparently, the most widely occurring valence states.

A solid sorbent with a fairly uniform granulometric composition was obtained from wastes formed in large-tonnage manufacture of epichlorohydrin, which is the main monomer in production of epoxy resins. Industrial synthesis of epichlorohydrin is accompanied by formation of more than 0.5 t of organochlorine wastes per ton of the commercial product [9]. At present, utilization of organochlorine wastes is a complicated environmental problem [10, 11].

Depending on the sampling place, the forming wastes are enriched in 1,2-dichloropropane, 1,2,3-trichloropropane, dichloropropanols, and epichlorohydrin. The waste composition is determined by the process mode and operation stability of the installation [9].

EXPERIMENTAL

Sulfur-containing sorbents were obtained from a fraction of organochlorine wastes that was enriched in TCP and had the following component composition (wt %): TCP 76.6, dichloropropanols 17.4, 1,2-dichloropropane 2.0, dichloropropenes 2.1, and other products 1.9.

Sodium polysulfide was prepared from elemental sulfur and sodium hydroxide in an aqueous solution in the presence of hydrazine hydrate as reducing agent [12]:

$$2nS + 4NaOH + N_2H_4 \cdot H_2O \rightarrow 2Na_2S_n + N_2 + 5H_2O.$$

Synthesis conditions and parameters of the adsorbents obtained. NaOH 10 g (0.25 mol), H_2O 50 ml, hydrazine hydrate 5 ml, organochlorine waste 11.8 g (0.08 mol counting on TCP), temperature 40–60°C

Run no.	S/NaOH molar ratio	Ash mass, g	Product yield, g	Grain color	Grain size, mm	Found, wt %	
						S	Cl
1	2	10	22	Light brown	2	60.4	3.7
2	2	5	22	Green	3	55.0	8.0
3	2	3	19	Yellow-green	3.5	62.0	8.8
4	2	1	13	Yellow	1.5–5	64.5	7.3
5	1.5	5	16	Yellow	2.5	48.9	9.6
6	1.5	3	14	Yellow-green	3.5	53.4	9.0

The value of n in the sodium polysulfide obtained is determined by the molar ratio S : NaOH: $n = 3$ at 3 : 2 and 4 at 2 : 1.

To produce polycondensation centers, an ash-and-slag material formed as a waste at thermal power plants was added into the resulting sodium polysulfide solution as a fine powder (average particle size 0.05 mm) [13]. When the resulting mixture is agitated, polysulfide anions are adsorbed on the surface of ash particles. Addition of organochlorine components (waste from manufacture of epichlorohydrin) results in the formation of polymer molecules that envelop ash particles to form grains. The synthesis of a sulfur-containing polymer can be represented by the scheme

$$3mS_n^{2-} + m\,CH_2(Cl)-CH(Cl)-CH_2(Cl) \longrightarrow \left[S_nCH_2-CH(S_n)-CH_2S_n\right]_m$$

The size of the grains formed depends on the number of polycondensation centers, which is, in turn, determined by the mass of the ash-and-slag material. As the amount of the ash material added increases, finer grains are obtained. The table lists the synthesis conditions of the adsorbents and their most important parameters.

If the amount of ash is substantially raised (10 g of ash per 10 g of NaOH used to obtain the polysulfide), a part of the ash is present in the unchanged form as an admixture to adsorbent grains. On lowering the amount of ash to 1 g per 10 g of NaOH, the grains obtained are nonuniform in size. Presumably, polymer formation without inclusion of ash occurs in this case in addition to polycondensation on the surface of ash particles.

The grains obtained have an ellipsoidal shape; the bulk density is 0.7–0.8 g cm^{-3}. If the adsorbents are heated to above 150°C, the polymer decomposes, with the grains becoming dark and cracking. For the adsorbent synthesized in run no. 2, its sorption capacity for zinc(II) ions (pH 5–6) was studied and found to be 57 mg g^{-1}. The sorption capacity for Methylene Blue was 45.8 mg g^{-1}, and that for iodine, 36.8%. The mass fraction of water was determined to be 0.89%. An excess amount of the sorbent virtually quantitatively recovers mercury(II) from an aqueous solution of $Hg(NO_3)_2$, copper(II) from a $CuSO_4$ solution, silver(I) from an $AgNO_3$ solution, and zinc(II) from a $ZnCl_2$ solution.

The sorption capacity of the material for heavy metal ions was estimated using sorption isotherms [14]. It can be seen from Fig. 1 that the sorption isotherm of Zn(II) ions corresponds to type I of isotherms in the Brunauer classification [15], characterized by a monotonic approach of the adsorption to a certain limiting value corresponding to a filled monolayer. This shape of the curves is a consequence of surface nonuniformity or corresponds to

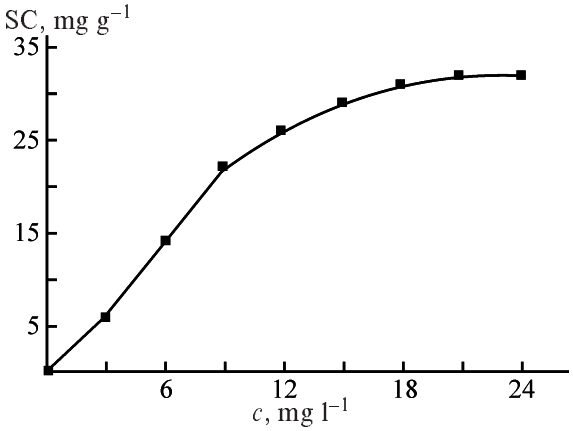

Fig. 1. Sorption isotherm of Zn(II) ions. (SC) Sorption capacity and (c) Zn(II) concentration in solution.

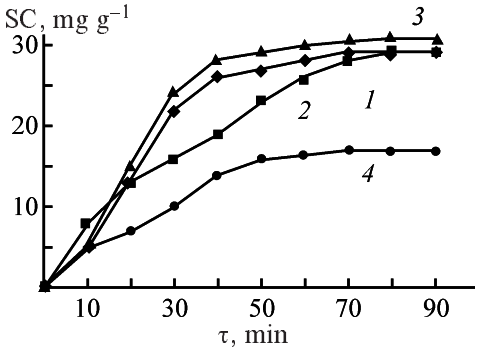

Fig. 2. Kinetic curves of sorption of Zn(II) ions. (SC) Sorption capacity and (τ) process duration. Temperature, °C: (*1*) 20, (*2*) 40, (*3*) 60, and (*4*) 80.

the case in which adsorbates may undergo phase transitions [16].

We also examined the effect of temperature on the sorbent capacity and on the sorption rate of Zn(II) ions at temperatures of 20, 40, 60, and 80°C. The kinetic curves of sorption of Zn(II) ions at different temperatures are shown in Fig. 2. It was found that the sorption interaction in the system constituted by a metal-containing solution and a sulfur-containing sorbent occurs rather intensively: the sorbent is 80–90% saturated in 30–40 min at an initial metal concentration of 23–25 mg l^{-1}.

Figure 2 shows that, as temperature is raised from 20 to 60°C, the sorption capacity of the sorbents increases, which can be attributed to an increase in the rate of diffusion processes in the sorbent matrix. The maximum capacity is observed at 60°C. At higher temperatures, the desorption rate markedly increases.

Also, the fundamental aspects of desorption of Zn(II) ions from a saturated sorbent were studied. Solutions of hydrochloric acid diluted in 1 : 1, 1 : 2, 1 : 5, and 1 : 10 ratios were used as eluents. It was found that, all other conditions being the same, the maximum desorption (>95%) occurs at a $HCl_{conc} : H_2O$ mass ratio of 1 : 1, i.e., in a strongly acidic medium.

CONCLUSIONS

(1) Solid granulated products containing 50–65% sulfur were obtained in the system constituted by sulfur, hydrazine hydrate, and alkali with the use of wastes from manufacture of epichlorohydrin and ash-and-slag wastes from thermal power plants.

(2) The granulated materials obtained can be used as sorbents in recovery of metal ions from aqueous solutions.

Received June 20, 2007

Abstract—Possibility of obtaining magnesium oxide from sulfate, nitrate, and chloride solutions from acid processing of serpentinite and producing magnesium oxide suitable for manufacture of transformer steel was studied.

DOI: 10.1134/S1070427208050339

Recently, recovery of magnesium from silicate materials, e.g., serpentinite containing up to 38–43 wt % magnesium oxide, has been extensively studied. Magnesium is recovered from serpentinite by leaching with mineral acids (H_2SO_4, HNO_3, HCl) [1–4] to obtain the corresponding salts. The salt solutions formed by leaching are contaminated with impurities present in serpentinite: Fe(II), Mn(II), Cu(II), Ni(II), Co(II), Al(III), Cr(III), etc. After a reagent purification, the resulting solutions can be used to obtain pure salts of magnesium and magnesium hydroxide or oxide.

The aim of this study was to produce from serpentinite magnesium oxide satisfying the requirements to transformer steel production. Solutions prepared by leaching of serpentinite with mineral acids at 80–90°C for 3–4 h with a stoichiometric expenditure of an acid were used in the study. The compositions of the solutions obtained upon neutralization with brucite to pH 6–7 are listed in Table 1.

The technology used to obtain magnesium oxide from solutions includes the following stages: precipitation of magnesium hydroxide, filtration, washing of the $Mg(OH)_2$ paste, drying, and calcination of $Mg(OH)_2$ to MgO. Magnesium hydroxide was precipitated with aqueous ammonia. The results obtained in precipitation of magnesium hydroxide from $MgSO_4$ solutions are listed in Table 2.

The data obtained show that the filtration throughput becomes 2.5 times lower and the degree of magnesium precipitation decreases as the concentration of the magnesium sulfate solution increases. The precipitate was washed to remove ammonium sulfate with water at s : l = 1 : 20. The filtration throughput in washing was 0.28–0.06 $m^3 m^{-2} h^{-1}$. Magnesium hydroxide was dried at 100°C and calcined at 650°C for 2 h. The resulting magnesium oxide contained 83–87% MgO and failed to satisfy the technical requirements to magnesium oxide to be used in manufacture of transformer steel. Repeated washing of magnesium oxide at s : l = 1 : 20, followed by calcination at 650°C, yielded a product of the following composition (wt %): MgO 96.5, SO_4^{2-} 0.42, Ca not found. The sample did not satisfy the requirements imposed by the technical specification, either. Use of sodium hydroxide to obtain magnesium oxide from $MgSO_4$ solutions failed to produce positive results.

From a magnesium nitrate solution, magnesium hydroxide was precipitated with aqueous ammonia to pH ~9.2. In this case, the degree of magnesium precipitation was 87.5% After separating the precipitate (paste) of magnesium hydroxide, the solution contained (g dm^{-3}): Mg 10, Ca 4.4, and NH_4NO_3 168.9. The magnesium hydroxide paste was washed with water on a filter at s : l = 1 : 25, dried, and calcined at 500°C for 2 h. The resulting magnesium oxide contained (wt %): MgO 98.1, Fe 0.016, Cl 0.12, and CaO 0.12; calcination loss 0.72 wt %; citric number 40 s. Its properties failed to satisfy the requirements of the technical specification.

From chloride solutions (350 g dm^{-3} $MgCl_2$), magnesium was precipitated with aqueous ammonia whose expenditure was 100–200% relative to the

Table 1. Composition of solutions used to obtain magnesium oxide

180	10.1	35.2	3.9	89
200	10.3	33.7	3.3	89

stoichiometry. The results of these experiments are listed in Table 3.

The experimental data show that the degree of magnesium precipitation is 76% at the stoichiometric ratio between the reagents, 89% at a 60% excess of ammonia, and further remains invariable because the precipitation of magnesium hydroxide is reversible and occurs under standard conditions to an equilibrium $MgCl_2$ concentration of about 35 g dm^{-3}.

Magnesium hydroxide was washed with hot (90°C) water at various s : l ratios, with the subsequent settling, decanting, and filtration of thickened slurry. The washed precipitate was dried at 150–200°C and calcined at 800°C. It was found that washing at s : l = 1 : 40 can reduce the content

Table 4. Effect of temperature T and duration τ of calcination on the quality of magnesium oxide

T, °C	τ, h	L, s	L_{av}, s
500	1	28	30
500	2	32

750	1	78	80
750	2	82	
800	1	92	94
800	2	96	
900	1	106	108
900	2	110	

Table 5. Physicochemical parameters of a pilot batch of magnesium oxide

Parameter	Value
Content, wt %:	
MgO	98.8
CaO	<0.01
chlorides	0.03
iron (FeO)	0.05
carbon	0.6
Calcination loss, %	1.0
Bulk density, g cm^{-3}	0.27
Citric number, s	80

of chloride ions to 0.12%. Washing of magnesium oxide after calcination can reduce the content of Cl^- to 0.03%. The calcination temperature strongly affects the citric number L, which is an important parameter of magnesium oxide used in manufacture of transformer steel (Table 4).

It follows from Table 4 that the optimal calcination temperature is 750°C, with the corresponding citric number (80 s) satisfying the requirements of the technical specification. The granulometric composition of magnesium oxide obtained under the optimal conditions was determined by sedimentation analysis:

Fraction, μm	Content, %	Fraction, μm	Content, %
+40	3.4	–20 ± 10	9.5
–40 ± 30	5.4	–10 ± 5	18.1
–30 ± 20	11.7	–5	51.9

This method cannot precisely determine the <1-μm fraction. The technology we suggested was used to obtain a pilot batch of magnesium oxide (Table 5). Tests performed at Verkhnyaya Iset metallurgical plant demonstrated that this magnesium oxide can be used to manufacture transformer steel. The yield of class I metal was 75.2%, which compares well with the best commercial batches.

CONCLUSIONS

The studies and tests performed demonstrated that magnesium oxide suitable for manufacture of transformer steel can be produced from chloride solutions.

BRIEF COMMUNICATIONS

Kinetics of Formation of Lead and Zinc Sulfides in Sulfiding Roasting in a Superheated Steam Atmosphere

I. G. Antropova and D. L. Khaludorov

Baikal Institute of Nature Management, Siberian Branch, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia

Received July 21, 2007

Abstract—The kinetics of the formation of sulfides in reactions of oxidized lead and zinc compounds with pyrite in a superheated steam atmosphere was studied. The dependences of the rate on the roasting duration at various temperatures were found, the kinetic parameters and modes of sulfide formation were determined, and the mechanism of the process was suggested.

DOI: 10.1134/S1070427208050340

One of effective approaches to the activation of oxygen-containing minerals for the further flotation is the sulfiding of difficult-to-concentrate minerals in the course of roasting in a superheated steam atmosphere. The purpose of sulfiding roasting is the conversion of the oxidized forms entering into the composition of the initial ore to readily floatable sulfide forms for the subsequent treatment according to the traditional manufacturing scheme. Furthermore, roasting in a steam atmosphere is accompanied by selective cracking of minerals, which considerably improves the further separation of valuable ore components.

Kinetic studies are necessary for intensifying industrial processes, i.e. they are of practical interest along with theoretical importance. Therefore, it is of interest to study topochemical reactions in the system oxidized lead compounds–sulfiding agent–steam. To calculate the degree of lead and zinc conversion from the oxidized forms to sulfide forms (degree of sulfiding), we used a procedure for separate determination of different forms of lead and zinc compounds in solid products [1]. The experimental data were treated by using classical differential and integral methods of determination of kinetic parameters of sulfiding processes.

EXPERIMENTAL

Lead and zinc in oxidized lead–zinc ores are presented mainly by cerussite and smithsonite (carbonates). Therefore, we used analytically pure grade lead and zinc carbonates as starting materials and pyrite (FeS_2) as a sulfiding agent. The reaction of carbonates with pyrite in a steam atmosphere was studied on a flow-type installation. The degree and rate of sulfiding were determined in an isothermal mode in the temperature range 400–700°C. The experimental technique was as follows. A furnace was heated to a preset temperature, after which steam was passed through the working area of the furnace and a boat with a mixture of carbonate and pyrite was arranged in it. Pyrite was taken in a small excess over the stoichiometry. The charge weight was 1 g, and the water flow rate, 50 ml h^{-1}. The phase compositions of the resulting solid products were determined on DRON-3 and D8 ADVANCE (Bruker AXS) X-ray diffractometers.

The dependences of the degree of sulfiding on the duration of roasting at various temperatures and the temperature dependences of the rate constants of the reactions of lead and zinc carbonates with pyrite in a steam atmosphere are qualitatively similar, but slightly differ quantitatively. Here we report the results of the kinetic study using lead carbonate sulfiding as an example. The X-ray analysis of reaction products (Table 1) shows that the primary stage of roasting in a steam atmosphere is the lead carbonate decomposition to the oxide. Pyrite dissociation occurs in parallel to form products which react with water to liberate hydrogen sulfide and a small amount of sulfur dioxide. In the temperature range 600–700°C, reaction products present a mixture of PbS, $Fe_{1-x}S$, Fe_3O_4, and γ-Fe_2O_3, with the content of lead compounds in the nonsulfide form being no higher than 2%.

The integral kinetic curves (Fig. 1a) show that the temperature strongly affects the degree of sulfiding. For example, the degree of the conversion of products of lead carbonate decomposition to the sulfide increases from 30% at 400°C to 90% at 500°C. No induction period is observed in the kinetic curves obtained in the range 500–700°C. The curves are not sigmoidal as would be typical of topochemical reactions in which products do not appear evenly on the whole surface of grains. High reactivity of lead carbonate caused by its high specific surface area is apparently responsible for atypical kinetic curves obtained in these experiments.

Using primary experimental data, we calculated the time dependences of the reaction rates at specified temperatures. The character of time variation of the process rate at various temperatures is the same, but the curves differ quantitatively (Fig. 1b). The rate maximum is reached within 5 min of roasting. The reaction rate first sharply increases, but then it abruptly decreases, which means that the formation, rise, and fusion of nuclei occur rather rapidly and, above all, at high degrees of conversion of the initial solid substances (except for 400°C). In the initial stage, the reaction occurs under the kinetic control (up to the maximal rate), and then it becomes controlled by the hydrogen sulfide diffusion through a lead sulfide layer to the PbO–PbS boundary. The parameters of the reaction rate maximum at various temperatures are given in Table 2.

We carried out the formal-kinetic analysis using commonly applied topochemical Erofeev–Kolmogorovs equation [2]:

$$\alpha = 1 - \exp(-kr^n), \quad (1)$$

where n is a constant depending on particular substance, the presence of initial reactions centers (at $r = 0$), the shapes of nuclei, and the number of intermediate stages of the formation of the initial centers.

The constants k and n in Eq. (1) are determined by plotting the experimental data in the coordinates $Y = \log[-\log(1 - \alpha)]$, $X = \log\tau$. The values of $\log[-\log(1 - \alpha)]$ as a function of $\log\tau$ at various temperatures are presented in Table 3. On the basis of these dependences we constructed the plots in which the experimental points were fairly well fitted by straight lines. This fact suggests that the process is described by topotaxic relationships and that the choice of the equation for the kinetics description was correct.

Table 1. Results of X-ray phase analysis of reaction products

T, °C	Compounds found
Initial sample	$PbCO_3$, FeS_2
400	PbO, PbS, FeS_2, γ-Fe_2O_3

T, °C	n	$\log k$	K
400	0.62	–2.59	0.000042
500	0.56	–1.14	0.0052
600	0.59	–1.06	0.0094
700	0.52	–0.74	0.0198

ditions; the value of the kinetic parameter $n < 1$ shows that the process under study (within the experiment boundaries) is diffusion-controlled.

Linearization of the known Eq. (3) of the activated complex theory [4] in the coordinates $y = \ln K/T$ and $x = 1/T$ gives the activation energy E of 199.89 kJ mol^{-1} in the temperature range 400–500°C and 25.45 kJ mol^{-1} at 500–700°C.

$$K = l(k_B T/h)e^{\Delta S/R}e^{-E/(RT)}. \quad (3)$$

All these facts confirm the above conclusions on the character of the sulfiding process. At the roasting temperature of 500°C and higher, the reaction is controlled by internal diffusion. The tendency to equalizing temperature in grains results in constant cracking of the initial mineral, which favors the formation of sulfides within the entire bulk of the grains. We carried out a qualitative analysis of the sulfur-containing off-gas by the standard procedures [5]. The off-gas was sequentially passed through two absorption vessels, one of which contained a $CuSO_4$ solution, and the other, an H_2O_2 solution. As a result of roasting carbonates with pyrite in a superheated steam atmosphere, the solution containing copper sulfate became black and turbid because of precipitation of copper sulfide by the reaction

$$H_2S + CuSO_4 = CuS\downarrow + H_2SO_4.$$

As a result of this reaction, owing to the formation of sulfuric acid, pH of the $CuSO_4$ solution decreased from 5 to 3. The presence of sulfur dioxide in the off-gas was determined by measuring the acidity of the solution containing H_2O_2 before and after the experiments. The pH of the medium changed from 6 to 5 owing to the occurrence of the reaction $SO_2 + H_2O_2 = H_2SO_4$. Thus, hydrogen sulfide and a small amount of sulfur dioxide are present in the gas.

Based on the above facts, we can present the following mechanism of the sulfiding of oxidized forms of lead and zinc. The thermal dissociation of iron disulfide is known to be accompanied by S^0 release according to the reaction

$$FeS_2 \rightarrow FeS + 1/2S_2.$$

Then, at temperatures higher than 400°C, the products of the iron disulfide dissociation, free sulfur and iron sulfide, react with superheated steam to form hydrogen sulfide:

$$3S + 2H_2O = 2H_2S + SO_2,$$

$$FeS + H_2O = FeO + H_2S.$$

The resulting FeO is metastable and is subsequently oxidized to Fe_3O_4. Therefore, when iron sulfide reacts with water, hydrogen sulfide in the gas phase prevails. The Gibbs energy calculations show that the sulfiding of oxidized lead and zinc compounds with hydrogen sulfide is thermodynamically the most probable in a heterogeneous process. On the whole, our experimental data on the sulfiding of oxidized lead and zinc compounds are in agreement with the thermodynamic calculations. The reactions of lead and zinc carbonates with iron sulfide in a superheated steam atmosphere with the formation of lead and zinc sulfides occur on the solid–gas, namely, MO–H_2S boundary.

CONCLUSIONS

(1) The kinetic features of the lead and zinc sulfiding in the reactions of oxidized lead and zinc compounds with iron sulfide in a steam atmosphere were determined. It was shown that lead and zinc sulfides are formed in the whole volume of particles.

(2) The reactions of oxidized lead and zinc compounds with iron sulfide in a superheated steam atmosphere to form sulfides occur on the solid–gas, namely, MO–H_2S boundary.

(3) Examination of the kinetic curves and parameters obtained shows that, at roasting temperatures lower than 500°C, the reaction is kinetically controlled, and after reaching the roasting temperature of 500°C it becomes controlled by internal diffusion.

Received October 2, 2007

Abstract—The possibility of replacing zinc chloride by a zinc-containing complex as a catalyst of chloromethylation of styrene–divinylbenzene copolymer was examined, and the effect of the catalyst on the service characteristics of the highly basic anion exchanger obtained was evaluated.

DOI: 10.1134/S1070427208050352

The main industrial procedure used today for producing anion-exchange resins is based on polymer-analogous transformations of styrene–divinylbenzene (DVB) copolymers of various modifications (gel, macroporous, isoporous), with introduction of ionogenic amino groups into the inert polymer [1].

Synthesis of an anion exchanger by this procedure involves two main steps of polymer-analogous transformations: chloromethylation and amination. The first step is decisive, because the extent of chloromethylation ultimately determines the properties of anion exchangers and, primarily, their most important characteristic, exchange capacity. Chloromethylation consists in direct replacement of a hydrogen atom by a chloromethyl group $-CH_2Cl$. In the synthesis of anion exchangers, the chloromethylation occurs at a carbon atoms of an aromatic ring of styrene–DVB copolymer [1]. In the second step, amination of chloromethylated styrene–DVB copolymer with approptiate amine, the chlorine atoms are replaced by amino groups. In the synthesis of strongly basic multifunctional anion exchanger AV-17, the amination is performed with trimethylamine, with the replacement of chlorine atoms by quaternary ammonium groups $-N^+(CH_3)_3\ Cl^-$ [1, 2].

Numerous procedures for chloromethylation of styrene–DVB copolymer under various conditions, using various catalysts and chloromethylating agents, have been reported [2–6]. The most widely used agent is monochlorodimethyl ether (MCDME) in which the styrene–DVB copolymer swells well, the catalyst dissolves, and the reaction rate is fairly high. The catalysts are aprotic Lewis acids used for performing Friedel–Crafts reactions: anhydrous $ZnCl_2$, $FeCl_3$, $AlCl_3$, $SnCl_4$, and $TiCl_4$ [3–6], with $ZnCl_2$ used most frequently.

In the production of a highly basic anion exchanger of the AV-17 type, the existing chloromethylation procedure with $ZnCl_2$ is imperfect because of high hygroscopicity of the catalyst. The use of $ZnCl_2$ containing 2–7 wt % water negatively affects quality of the desired product with respect to osmotic stability, because too vigorous reaction in some cases may lead to formation of cracks on the surface of anion exchanger granules.

We found that replacement of straight $ZnCl_2$ by a zinc-containing complex prepared from $ZnCl_2$ and MCDME provides more uniform course of the chloromethylation in time, which decreases the risk of cracking of ready anion exchanger granules:

$$CH_3OCH_2Cl + ZnCl_2 \rightarrow [CH_3OCH_2]^+ZnCl_3^-.$$

EXPERIMENTAL

With the aim to evaluate the advantages of the zinc-containing complex compared with the classical $ZnCl_2$ catalyst, we performed experiments on the synthesis of AV-17 resin with both catalysts and examined their effect on the service characteristics of AV-17 resin: osmotic stability, number of intact granules, amount of water required for washing, and mechanical strength.

To choose the optimal chloromethylation condi-

tions such as charge formulation, temperature, and process duration, the sample of the styrene–DVB copolymer was analyzed with respect to the main quality parameters: specific volume of limiting swelling in toluene (2.8 $cm^3 g^{-1}$ in 1 h 45 min) and MCDME (2.62 $cm^3 g^{-1}$ in 30 min) and content of the main fraction with the granule size of 0.25–0.8 mm (95.5%). A kinetic study of the chloromethylation of this copolymer with MCDME in the presence of $ZnCl_2$ and the zinc-containing complex showed that, in the latter case, the reaction occurred more uniformly from the first hour and up to attainment of the same final chlorine content of the chloromethylated copolymer (CMC) in both runs, 16%. This is particularly important for obtaining a strongly basic anion exchanger with high service characteristics (see figure).

On the basis of these data, we chose the optimal chloromethylation conditions and performed two series of experiments on the preparation of laboratory CMC samples: first, with $ZnCl_2$, and second, with the zinc-containing complex. Both samples were subjected to amination with the formation of AV-17 strongly basic anion exchanger. The mean quality parameters for each series of anion exchangers are given in Table 1.

We found that the technical anion exchanger prepared with the zinc-containing complex, owing to the more uniform chloromethylation course, exhibited higher levels of the mechanical strength, osmotic stability, total static exchange capacity, and dynamic exchange capacity.

To determine how the catalyst affects the specific consumption of water for washing the anion exchanger, we washed averaged samples of both series with H^+-cationized water, after their regeneration with sodium hydroxide, until the specific electrical conductivity of the filtrate reached 1.5 μS cm^{-1} (Table 2).

In washing of the anion exchanger sample of series 2, prepared with the zinc-containing complex,

Chlorine content of the chloromethylated copolymer as a function of time τ. Copolymer : MCDME weight ratio 1 : 2.4, catalyst : copolymer molar ratio 0.45 : 1.0, 45–50°C. Catalyst: (*1*) $ZnCl_2$ and (*2*) zinc-containing complex.

Table 2. Washing of AV-17 anion exchanger with H^+-cationized water after regeneration with NaOH (specific consumption of 100% NaOH 120 kg m^{-3})

Series	Specific electrical conductivity of filtrates, μS cm^{-1}, at indicated volume of H^+-cationized water, m^3 m^{-3}													
	before washing	6	7	8	9	10	11	12	13	14	15	20	30	40
1	3.40	4.18	2.62	2.46	1.95	1.91	1.75	1.61	1.60	1.35	1.41	1.40	1.4	1.4
2	3.41	2.9	2.5	2.0	1.6	1.5	1.4	1.4	1.4	1.4	1.4	1.4	1.2	1.1

the specific consumption of water for washing to the required pH value was lower than for series 1, 10 m^3 m^{-3} against 14, which is indicative of its better kinetic properties.

We prepared in the laboratory a batch of samples of AV-17 strongly basic anion exchanger from various samples of styrene–DVB copolymer, using the zinc-containing complex. All the samples met the requirements of GOST (State Standard) 20301–74 with revisions 1–5 with respect to all the quality parameters.[1]

CONCLUSIONS

(1) AV-17 anion exchanger prepared with the zinc-containing complex exhibits increased levels of the osmotic stability, mechanical strength, matrix permeability, and dynamic exchange capacity. It is better washed at the same consumption of the regenerating agent.

(2) An improved process was developed for the production of AV-17-8 highly basic anion exchanger, allowing production of the resin with improved kinetic and mechanical properties, in accordance with the more stringent requirements to the quality.

[1] With the aim to make the technical requirements to the quality of the Russian anion exchanger more stringent and to expand the assortment demanded by the market, the Azot Kemerovo Joint-Stock Company with the particilation of VTI Joint-Stock Company developed technical specification TU 2227-062-05761637–2006: Ion-Exchange Resins. AV-17-8 anion exchanger (with improved kinetic properties).

Paraffin Fractions as Additives to Diesel Fuels Increasing Their Cetane Number

A. S. Lytkin and G. K. Ivakhnyuk

St. Petersburg State University of Communications, St. Petersburg, Russia
St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received April 4, 2008

Abstract—Paraffins were purified by recrystallization. The extent to which the paraffin fractions C_{10}–C_{13}, C_{14}–C_{17}, and C_{18}–C_{23} increase the cetane numbers of summer and winter grades of Russian diesel fuel was examined. The cetane numbers of the initial diesel fuels and those with additions of paraffin fractions were determined on an IDT-69 installation by the method of flash coincidence.

DOI: 10.1134/S1070427208050364

In this study we examined the effect exerted by the C_{10}–C_{13}, C_{14}–C_{17}, and C_{18}–C_{23} paraffin fractions on the main characteristics of diesel fuel (DF). The required samples of Russian commercial diesel fuels (winter, DTZ-0.2minus35[1]; summer, DTL-0.2-62) and fractions of liquid petroleum paraffins were obtained from the Kirishi Oil Refinery. Preliminary experimental studies were performed on samples of commercial DFs purchased from St. Petersburg filling stations. Fractions of liquid petroleum paraffins were additionally purified by recrystallization to remove aromatic compounds.

To remove arenes from the C_{18}–C_{23} fraction, we used urea dewaxing, recrystallization from acetone, and acid–alkali treatment followed by urea dewaxing. The degree of arene removal from the paraffin fraction was monitored by measuring n_D^{20} [1] and by comparing its value after the purification with the tabulated value [2]. Recrystallization proved to be the most efficient purification method. The cloud and congelation points of DFs were determined by standard procedures [3]. As a cooling agent we used a mixture of acetone and solid CO_2.

The cetane numbers (CNs) of the initial DF samples and those with additions of paraffin fractions were determined in accordance with GOST (State Standard) 3122, by the method of flash coincidence on an IDT-69 installation. The CNs of the initial DF samples (both winter and summer) were 48. Samples were tested at the KINEF Limited Liability Company and in laboratories of the St. Petersburg State Institute of Technology.

[1] Congelation point below –35°C.

Cetane numbers of DF samples with paraffin additives*

Diesel fuel	Additive, wt %	CN
DTL-0.2-62	C_{10}–C_{13}, 3	50
	C_{14}–C_{17}, 3	53
DTZ-0.2minus35	C_{10}–C_{13}, 3	49
	C_{14}–C_{17}, 3	51
	C_{10}–C_{13}, 5	52
	C_{14}–C_{17}, 5	53

* CN was determined by the motor method (GOST 3122–67).

We found that the paraffin fractions studied are fairly effective CN-increasing additives to diesel fuels even in concentrations of 3.0–5.0 wt %, at which the CN number increases by 1 to 5 points (see table), in conformity with the modern requirements [4, 5].

With respect to the cloud and congelation points, the examined samples of the summer and winter DFs with paraffin-containing high-cetane additives also meet the requirements prescribed by GOST 305–82.

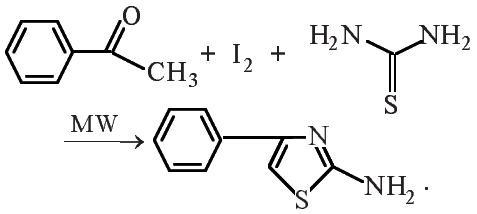
Synthesis of 2-Amino-4-phenylthiazole under Conditions of Microwave Irradiation

D. P. Khrustalev, A. A. Suleimenova, and S. D. Fazylov

Institute of Organic Synthesis and Coal Fuel Chemistry of the Kazakhstan Republic, Limited Liability Company, Karaganda, Kazakhstan



Received July 11, 2007

Abstract—The possibility of preparing 2-amino-4-phenylthiazole from acetophenone, iodine, and thiourea under the conditions of microwave irradiation was studied.

DOI: 10.1134/S1070427208050376

2-Amino-4-phenylthiazole derivatives exhibit high biological activity [1–3]. Published methods for preparing 2-amino-4-phenylthiazole are time-consuming and involve the use of highly toxic solvents [4, 5]. Therefore, the development of new synthetic routes to thiazole derivatives is of practical interest.

Here we suggest a new procedure for preparing 2-amino-4-phenylthiazole in a high yield:

We found that microwave irradiation allows the reaction time to be considerably shortened (by a factor of 280) compared to the traditional process and ensures the product yield as high as 92%.

We performed an independent synthesis of 2-amino-4-phenylthiazole (yield 94%) by the procedure described in [4]. Comparison of the melting points and IR spectra of the samples proved full identity of the substances obtained by the traditional procedure and under the conditions of microwave activation.

EXPERIMENTAL

A beaker flask made of heat-resistant glass was charged with a mixture of 7.2 g (0.06 mol) of acetophenone, 9.13 g (0.12 mol) of thiourea, and 15.23 g (0.06 mol) of iodine. The mixture was thoroughly stirred, loosely closed with a glass lid, and placed in a microwave oven at a radiator power of 70 W. The vessel was radiated for five 1-min periods with 30-s pauses. After that, 100 ml of water was added, and the mixture was heated at a power of 150 W for 5–7 min until the precipitate dissolved. Then the resulting yellow solution was decanted from a tarry liquid formed on the flask bottom and was filtered to separate a small amount of sulfur. After cooling, the filtrate was alkalized with aqueous ammonia to a weakly alkaline reaction. The precipitate formed in the process was filtered off on a glass frit, recrystallized from ethanol, and washed with diethyl ether. Yield of the crude product 92%, mp 148–149°C. IR spectrum, ν, cm^{-1}: 3420, 3240 (NH_2, two bands); 3170 (CH of C_3HNS); 3100 (CH of C_6H_5); 420, 1500, 1575 (C=C of C_6H_5); 1460 (C=N).

Found, %: C 61.45, H 4.47, N 15.55.
$C_9H_8N_2S$. Calculated, %: C 61.34, H 4.58, N 15.90.

The IR spectra were recorded on a UR-20 spectrophotometer (pellets).

CONCLUSIONS

(1) 2-Amino-4-phenylthiazole was prepared in a >90% yield by condensation of acetophenone with thiourea in the presence of iodine under the conditions of microwave irradiation.

(2) The reaction time is 280 times shorter compared to the traditional procedure.

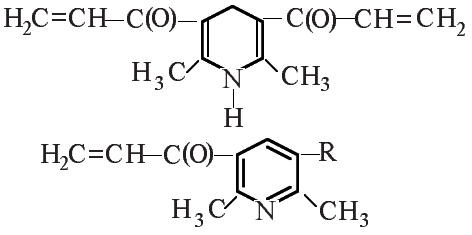
Received August 23, 2007

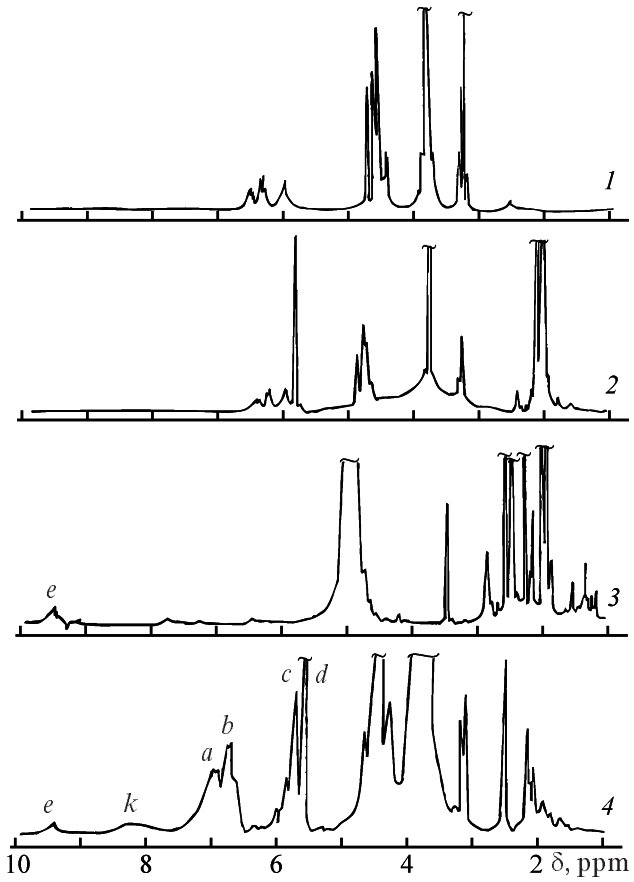
Abstract—The effect of acetylacetone and ammonia in urea–formaldehyde resins on the reactions occurring in their presence was examined. The formation of 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine in urea–formaldehyde resins was confirmed by ^{1}H NMR spectroscopy.

DOI: 10.1134/S1070427208050388

Structural studies of urea–formaldehyde (UF) resins and reduction of their free formaldehyde content are urgent problems [1–3]. Various additives and procedures decreasing the concentration of free formaldehyde have been reported. One of efficient methods is addition of β-diketones. Previously [4] we reported on a possible way to decrease the concentration of free formaldehyde in UF resin by adding acetylacetone and ammonia which enter into the Hantzsch reaction with formaldehyde:



In this study we examined the mechanism of the Hantzsch reaction in UF resins by ^{1}H NMR spectroscopy.



EXPERIMENTAL

Additives were introduced in amounts corresponding to the free formaldehyde content of UF resin [4]. The ^{1}H NMR spectra were recorded on a Gemini-200 spectrometer operating at 200 MHz in DMSO-d_6, reference TMS, 298 K. UF resin of the KF-MTS-15 brand [TU (Technical Specification) U-3,50-14 308 351-055–95 with revision 1] was used.

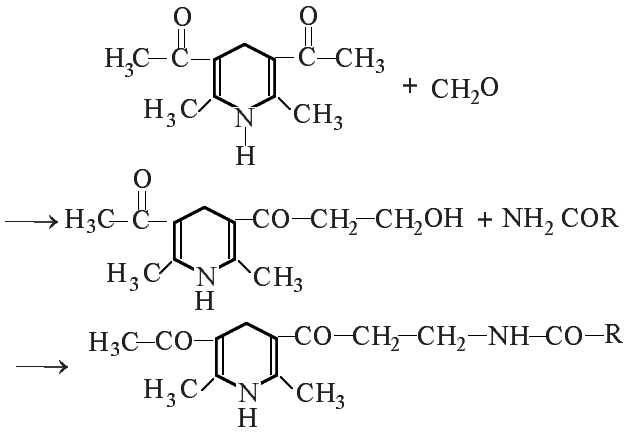
The reaction of acetylacetone and ammonia with formaldehyde, performed according to [5], yields 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine **I**. According to published data [6, 7], in such compounds the chemical shift of the NH proton varies within 8.2–9.6 ppm depending on solvent, pH, and substituents. In the ^{1}H NMR spectrum of the reaction mixture, recorded 10 min after starting the reaction, there is a broadened NH signal at δ 9.4 ppm. Proton signals of the starting compounds (ketone, enol, formaldehyde) disappear (see figure, spectrum *2*). After 24 h, the NH proton signal disappears, and a signal appears at 7.4 ppm, which corresponds to the CH proton in the pyridine ring (compound **II**). These data show that, at pH > 7, the reaction occurs via 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine.

As the reaction occurs in an alkaline solution, addition of formaldehyde to the OH group of the enol form of acetylacetone can be ruled out. Signals that could correspond to the CH protons at the double bond are absent. Compound **I** can subsequently react with formaldehyde to form substituted vinyl ketones [8]:

^{1}H NMR spectra. (δ) Chemical shift. (*1*) Aqueous formaldehyde solution (δ_{CH_3} 3.1–3.4, δ_{CH_2} 4.5–4.8, δ_{OH} 5.8–6.6 ppm); (*2*) mixture of acetylacetone and Formalin (acetylacetone occurs in DMSO-d_6 solution in keto and enol forms, δ_{CH_2} 3.8, δ_{CH} 5.8 ppm); (*3*) model composition (acetylacetone + Formalin + ammonia), 10 min after mixing (signal *e*, δ 9.4 ppm, corresponds to 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine); and (*4*) UF resin with addition of acetylacetone and ammonia, 10 min after mixing (δ_{NH} 7.3–8.5 ppm, signal *k* corresponds to UF resin that has reacted with compound **I** or **II**).

In the ^{1}H NMR spectrum of the reaction mixture, we did not observe a multiplet that could correspond to CH_2=CH protons at a nonconjugated double bond (4.5–6.5 ppm) (see figure, spectrum *3*). Unfortunately, in the ^{1}H NMR spectra of the modified resin this region is obscured by the CH_2 and NH protons of the resin (see figure, spectrum *4*).

The ^{1}H NMR spectrum of the UF resin without modifying additives is fully consistent with the spectra given in [9]. In the range 4–7 ppm, it contains partially resolved signals of the NH groups in monomethylolurea, dimethylolurea, and oligomeric chains (range 6.2–7.3 ppm), and also of the NH_2 groups in oligomers and free urea (5.4–6.0 ppm).



Relative content of NH_2 and NH fragments, according to ^{1}H NMR data

Range of δ, ppm	Structural fragment*	Relative content at indicated τ, min	
		10	40
5.4–6.0	NH_2 (*d*/*c*)	0.75	0.50
6.2–7.3	NH (*b*/*a*)	1.0	1.75
7.3–8.8	NH (*k*/*a* + *b*)	0.16	0.32

* (*d*) NH_2 group in free urea, (*c*) NH_2 group in oligomers, (*b*) NH group in oligomers, (*a*) NH group in monomethylolurea and dimethylolurea, and (*k*) NH group in components of the composition obtained by reaction with compound **I** or **II**. The designations are similar to those made in [9].

On introducing modifying additives (acetylacetone, ammonia) into the resin (see figure, spectrum *4*), a proton signal at δ 9.4 ppm, characteristic of the NH group of the dihydropyridine proton, and signals of methylene protons with the chemical shifts coinciding with those of the corresponding protons in the model compound (see figure, spectrum *3*) appear in the ^{1}H NMR spectrum. This fact confirms that the processes occurring in the modified resin are identical to the above-described reaction.

The table shows that the intensity of the signals from NH_2 and NH protons in oligomeric chains in the modified resin increases with time. Furthermore, chain lengthening in reactions of **I** or **II** with components of the composition is possible:

A downfield shift of the NH signal (δ_{NH} 7.3–8.8 ppm) is possible owing to a decrease in the electron density on the NH group under the influence of the electron-withdrawing C(O) group.

The signals of CH_3 groups observed in the region of methylol proton signals, as judged from the dis-

appearance of the CH_2 and CH signals of the starting formaldehyde and acetylacetone, should be assigned to products of the above reactions (see figure, spectra *3*, *4*).

CONCLUSIONS

(1) The Hantzsch reaction performed in urea–formaldehyde resin initially yields 2,6-dimethyl-3,5-diacetyl-1,4-dihydropyridine.

(2) Compounds containing vinyl fragments were not detected in the model reaction.

(3) 2,6-Dimethyl-3,5-diacetyl-1,4-dihydropyridine and pyridine derivatives, formed in urea–formaldehyde resin in the presence of additives (acetylacetone and ammonia), can undergo chain lengthening.

Abstract—Catalytic activity of oligonuclear cobalt(III) and cobalt(II, III) oxoacetate complexes in homogeneous oxidation of glutathione with hydrogen peroxide was studied.

DOI: 10.1134/S107042720805039X

Commercial preparations based on oxidized glutathione (γ-glutamylcysteinylglycine, GSH), GSSG, are produced by GSH oxidation catalyzed by *cis*-$[Pt(NH_3)_2Cl_2]$ [1, 2]. High cost and potential renal toxicity of platinum compounds make urgent replacement of *cis*-$[Pt(NH_3)_2Cl_2]$ by another catalyst.

In addition, peptides with thiol groups can be oxidized not only to disulfides but also to sulfenic (R–SOH), sulfinic (R–SO_2H), and sulfonic (R–SO_3H) acids [3]. Therefore, a search for selective catalysts of mild oxidation of thiols to disulfides is of interest.

In this study we examined catalytic oxidation of GSH with hydrogen peroxide by high-performance liquid chromatography (HPLC). Oligonuclear cobalt(III) and cobalt(II, III) oxoacetate complexes $[Co_3^{III}(\mu_3\text{-}O)(\mu\text{-}O_2CCH_3)_6(H_2O)_3]NO_3 \cdot CH_3COOH$ **(I)** and $[Co_4^{II}Co_3^{III}(\mu_4\text{-}O)(\mu_3\text{-}OCH_3)_4(\mu\text{-}O_2CCH_3)_6 \cdot (H_2O)_8]F_2 \cdot 12H_2O$ **(II)** in trace amounts (10^{-9} M) were examined as catalysts of mild selective oxidation to compounds containing the –S–S group (GSSG).

The choice of these catalysts is governed by the fact that polynuclear cobalt oxoacetate complexes can effectively transfer electron and hydroperoxy radicals in oxidation of organic compounds [4].

Complexes **I** and **II** were prepared by treatment of "cobalt(III) acetate" with glacial acetic acid in the presence of nitrate ion (complex **I**) [5] or with acetone–methanol mixture in the presence of fluoride ions (complex **II**) [6].

The reaction course was monitored by high-performance liquid chromatography (HPLC) on a Gilson chromatograph (France). We used a 4.6 × 250-mm Lichrospher 100-rp-18 column (Taiwan, China), a UV-220 detector, and 0.1% trifluoroacetic acid + 2% acetonitrile as the mobile phase. The flow rate was 1.50–2.50 ml min^{-1}; the injected sample volume was 10 μl.

A model system containing 2 mg ml^{-1} GSH (1.3×10^{-4} M), equimolar amount of sodium hydroxide, and half amount of hydrogen peroxide was used to study the oxidation kinetics. The total volume of the system was brought to 20 ml with double-distilled water. The resulting solutions contained 1.7×10^{-7} M catalyst (DSH/catalyst molar ratio 1000).

The time reading started after adding an aliquot of the oxidizing agent (H_2O_2 solution) to the system. Then, the samples of the solution were taken and analyzed by HPLC. The content of oxidized GSH was determined from the chromatogram of a standard GSSG solution. The reaction systems were thermostatically controlled at 22±1°C with stirring. GSH was oxidized at pH 5.0–5.1.

According to HPLC data, the only product of catalytic oxidation of GSH is the hexapeptide with the –S–S– bridge (GSSG), with the catalytic activity of complexes **I** and **II** being similar.

Since complexes **I** and **II** are highly active catalysts of selective oxidation of GSH, these com-

pounds can be used instead of expensive catalyst, *cis*-$[Pt(NH_3)_2Cl_2]$.

Abstract—The melting point and crystallinity of molecular complexes are studied in aprotic solvents in relation to the solvent donor number.

DOI: 10.1134/S1070427208050406

It is well known that, in chemical reactions in solutions, a solvent is not only a medium, but also a reagent. The contribution of a solvent is complex. Basic parameters characterizing properties of solvents are the dielectric constant, dipole moment, donor–acceptor power, etc. However, Fialkov et al. [1] have pointed out that, in complexation, the key factor is the specific character of solvation of ions rather than the dielectric constant of a solvent.

Donor–acceptor properties of solvents characterize their chemical activity responsible for the solvent effect on reactions in solutions. In this respect, it was interesting to study the solvent effect on structure and phase formation of complexes of polyethers with low-molecular-weight salts and their properties.

Previously we examined the solvent effect on these systems for several aprotic solvents using optical microscopy and X-ray diffraction analysis.

In this work, we studied the structure and composition of complexes polyethylene glycol–sodium tetraphenylborate in one more aprotic solvent, dimethyl sulfoxide (DMSO), and discussed the results obtained for a series of aprotic solvents.

EXPERIMENTAL

Sodium tetraphenylborate $NaB(C_6H_5)_4$ (analytically pure grade) was dried prior to use. Polyethylene glycol (PEG) (MW 15000) (Schuchardt, Germany) was dried in a low vacuum. DMSO was purified using the standard procedure [2].

The complexes were synthesized by mixing solutions of individual components under ambient conditions. The solvent was removed in a vacuum at room temperature. Then, samples were vacuum-dried to constant weight at 303–308 K for several days.

The melting points of the starting components and their molecular complexes were determined on a Boetius optical microscope (Rapido, Germany) at a magnification of 16.

Large-angle X-ray diffraction patterns were obtained on a DRON-3 instrument with CuK_α radiation (35 kV, 20 mA).

Based on the X-ray diffraction data, a structural diagram for the system PEG–$NaBPh_4$ was obtained, which consists of five sections (Fig. 1). Curves *1* and *2* show the correspond to $NaBPh_4$ and PEG.

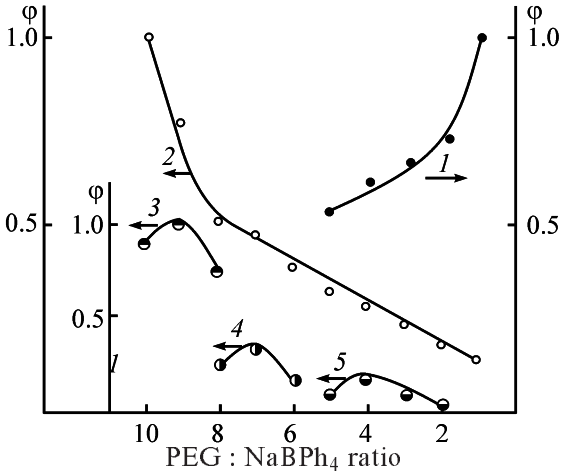

Fig. 1. Structural diagram of the system PEG–$NaBPh_4$ in DMSO: (*1*) $NaBPh_4$, (*2*) PEG, and (*3–5*) molecular complex.

The intensity of the peaks of crystalline PEG strongly decreases with increasing content of the second component, and at a component ratio of 1 : 1 these peaks disappear. The reflecitons of the crystalline salt alst decrease and at a PEG : $NaBPh_4$ ratio of 6 : 1 are not observed. Curves *3*–*5* correspond to molecular complexes. The interplanar spacings *d* (Å) of the complexes are as follows: 11.32, 7.36, 6.41, 5.60, 4.79, 4.69, 3.94, 3.70, and 3.08 (curve *3*); 6.80, 4.79, 4.69, and 3.53 (curve *4*); and 7.36, 6.41, 4.69, and 3.53 (curve *5*). As seen from Fig. 1, these curves pass through a maximum, being broken at certain component ratios. The maxima in the curves φ–(PEG : $NaBPh_4$) suggest the formation of stoichiometric molecular complexes.

The phase diagram built on the basis of the melting point data for the system PEG (MW 15000)–$NaBPh_4$ is presented in Fig. 2. The melting points of the complexes strongly differ from those of the individual components, suggesting complexation. The phase diagram contains a distectic point at a component ratio of 4 : 1 (mp 490 K) and two peritectic points at component ratios of 9 : 1 (mp 406 K) and 7 : 1 (mp 460 K). An eutectic point is observed at a component ratio of 15 : 1 (mp 328 K). For PEG, the melting point is 338 K.

The liquidus curve and the solidus lines divide the phase diagram into eight regions. Region *1* above the liquidus curve $T_{PEG}EP_1P_2M$ corresponds to a liquid phase. The other regions contain two phases (liquid and solid) each. In the region of melts from T_{PEG} to point *E*, the liquid phase coexists with PEG crystals (region *2*). The liquid phase coexists with crystals of compound MC_1 (region *3*). If a straight horizontal line is drawn from point *E* to the vertical straight line drawn through point P_1, the region of existence of PEG and MC_1 crystals is found below it (region *4*). If a horizontal line is drawn from point P_1 to the vertical line drawn through point P_2, in the region below this line (region *6*), two solid phases (MC_1 and MC_2) coexist. Along curve P_1P_2, molecular complex MC_2 crystallizes, and the crystals of MC_1 dissolve (region *5*). In this region, a liquid coexists with MC_2 crystals. If a straight horizontal line is drawn from point P_2 to a vertical line drawn through point *M*, in the region below this line, MC_2 and MC_3 crystals coexist (region *8*). In the region below curve P_2M (region *7*), a liquid coexists with a mixture of MC_2 and PEG crystals. In point *M*, a carbonized product starts to form. Then, starting from the 3 : 1 ratio to the 1 : 1 ratio, the melting point decreases. Below this curve, a liquid coexists with MC_3 crystals.

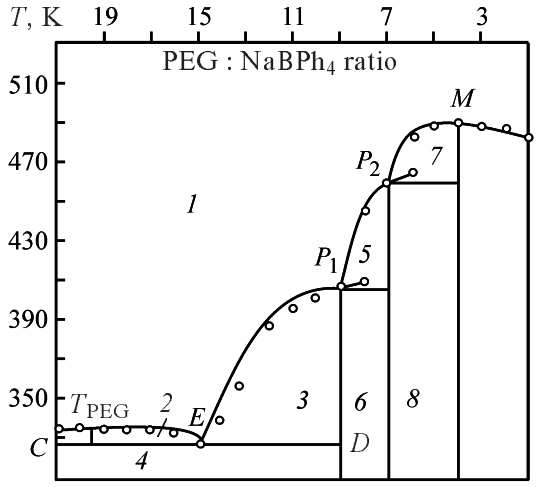

Fig. 2. Phase diagram of the system PEG (MW 15000)–$NaBPh_4$ in DMSO. (*T*) Temperature, (*M*) distectic point, (P_1, P_2) peritectic points, and (*E*) eutectic point; the same for Fig. 3.

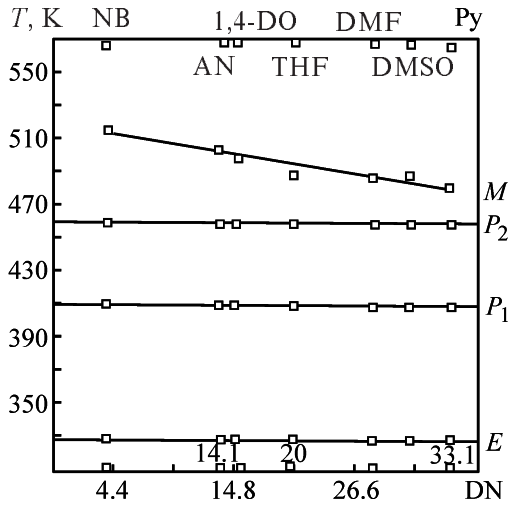

Fig. 3. Melting point *T* of molecular complexes in the system PEG (MW 15000)–$NaBPh_4$ as a function of the donor number DN of aprotic solvents.

The compositions obtained for the complexes from the structural data [9 : 1 (MC_1), 7 : 1 (MC_2), and 4 : 1 (MC_3)] are well consistent with those obtained from the phase diagram.

Complexes MC_1 (mp 406 K) and MC_2 (mp 460 K) melt incongruently. They are characterized by peritectic points P_1 and P_2. Complex MC_3 melts congruently, i.e., a distectic maximum *M* is observed.

Finally, combination of the X-ray diffraction and optical microscopic data reveals that three different molecular complexes are formed in DMSO.

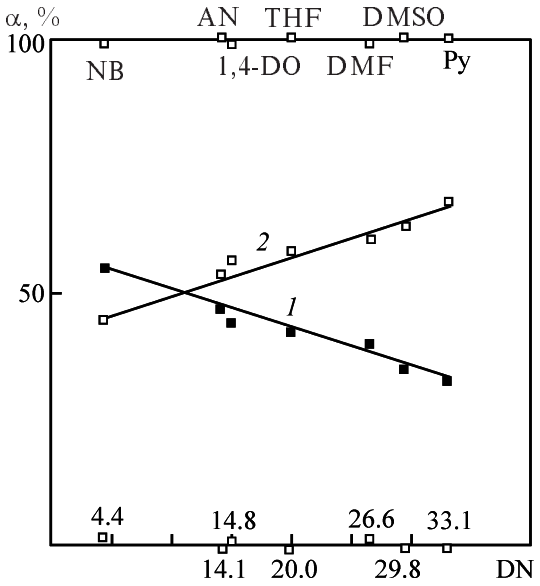

Fig. 4. Crystallinity α and degree of amorphicity (distectic point) of molecular complexes formed in the system PEG (MW 15000)–$NaBPh_4$ as functions of the donor numbers of aprotic solvents: (*1*) crystallinity and (*2*) amorphicity.

As mentioned above, the Gutmann donor number DN is among parameters characterizing the electron-donor power of solvents. We plotted the dependence of the melting points of the molecular complexes on the donor number of aprotic solvents (Fig. 3) using data from [3–5]. The peritectic and eutectic melting points are found to be independent of the donor number of the solvents. For the molecular complexes obtained in various aprotic solvents, the melting point (distectic point) is a linear function of the donor number (melting points decreases with increasing DN).

For the system $LiBF_4$–PEO (MW 5×10^6), Rayne and Wright [6] have separated a high-melting product (mp 433 K) from a chloroform–acetone mixture, and a low-melting product (mp 340 K) from methanol (solvating solvent for cations). The authors attributed the higher melting points to continuous highly ordered double-helical domains, and lower melting points, to an imperfect low-ordered structures. This interpretation is consistent with our X-ray diffraction results. Figure 4 shows linear dependences of the crystallininty and amorphicity of the complexes on the donor number of the solvents. As seen, the crystallinity is maximal and the amorphicity is minimal for complexes obtained in solvents with low DN.

CONCLUSION

More ordered high-melting complexes of polyethylene glycol (MW 15000) with $NaBPh_4$ are formed in solvents with low donor numbers, and defective disordered low-melting structures, in solvents with high donor numbers.

Received August 23, 2007

Abstract—The rate of gelation of the maghesium–silicate aqueous systems was studied in relation to pH and concentration of particular magnesium salts. The magnesium and silicate ions were found to interact in solutions at low temperature.

DOI: 10.1134/S1070427208050418

Forsterite ceramics are formed at low sintering temperature (normally as low as 1400 °C) and are widely used in various branches of modern engineering, primarily in electronic devices. To prepare highly homogeneous ceramics, mechanical mixing of the components is insufficient.

The sol–gel process is one of the most effective modern techniques for preparing highly dispersed powders. This technique allows preparation of ultradispersed uniform multicomponent powders suitable for preparing ceramics at reduced sintering temperature, with controlled morphology and phase composition of the product. These advantages are reached owing to uniform distribution of ceramic precursor throughout the system.

The significant contribution to study of sol–gel processes involving the effect of particular components of sol on the temperature of forsterite formation was made by researchers of the Mendeleev Russian University of Chemical Engineering [1, 2]. It was found that, in the case of precursors based on magnesium chloride, sulfate, citrate, and, particularly, nitrate, the synthesis of forsterite is decelerated and proceeds at lower temperature than for magnesium acetate. The kind of the initial magnesium salt and silicon-containing gelling agent considerably affects the course of solid-phase reactions, size distribution of crystals, their shape, and degree of dispersion of the forsterite powder.

In this study, the gelation rate in the system Mg^{2+}–SiO_3^{2-}–H_2O was examined in relation to particular magnesium salt and the initial ratio of components. The physicochemical processes accompanying the gelation were also analyzed.

EXPERIMENTAL

The initial uniform sols were prepared by adding tetraethoxysilane (TEOS) hydrolyzate (HCl) as gelling agent to aqueous magnesium salt (chloride $MgCl_2 \cdot 6H_2O$, acetate $Mg(CH_3COO)_2 \cdot 4H_2O$, and sulfate $MgSO_4 \cdot 7H_2O$) or anhydrous $MgSO_4$. The TEOS hydrolyzate is widely used for gelation of metal-containing aqueous solutions [3]. Apart from TEOS, other gelling agents, e.g., white black or silica sol, are used [1, 2]. However, we used TEOS to compare our results with other published data on this subject.

The initial magnesium salt was dissolved in distilled water at room temperature. In all the experiments the concentration of magnesium salt was 1 M.

Fifteen minutes after completion of the dissolution of the magnesium salt, pH of the mixture was measured. Table 1 shows that, except for magnesium acetate, the initial solutions were weakly acidic or neutral (pH 5.8–7.6). The aqueous magnesium acetate solution was weakly alkaline (pH 8.6).

The initial sols were prepared by adding TEOS hydrolyzate to aqueous magnesium salt in a prescribed ratio. This mixture was stirred and its pH was measured. As seen from Table 1, in all the systems pronounced acidification was observed. This effect was expected, since pH of TEOS hydrolyzate was approximately 2 by itself.

After addition of TEOS hydrolyzate, all the mix-

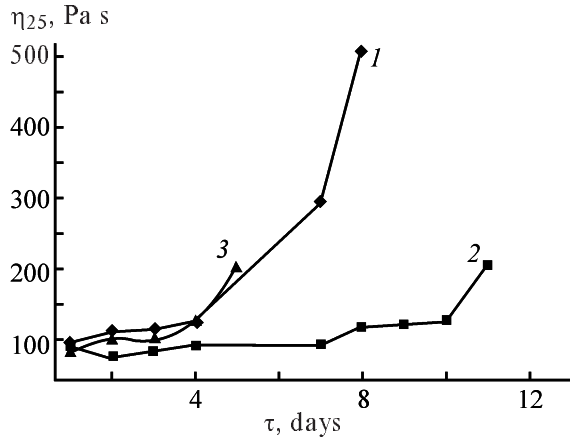

Table 1. pH of aqueous sols in systems magnesium salt–SiO_3^{2-}–H_2O–TEOS hydrolyzate

Magnesium salt	pH of aqueous system	
	initial	after adding TEOS hydrolyzate
$Mg(CH_3COO)_2 \cdot 4H_2O$	8.60	6.78
$MgSO_4 \cdot 7H_2O$	6.35	3.92
$MgCl_2 \cdot 6H_2O$	7.65	2.67
$MgSO_4$	5.87	3.90

Table 2. Gelation time τ_{gel} of systems magnesium salt–SiO_3^{2-}–H_2O–TEOS hydrolyzate

Magnesium salt	c, M	τ_{gel}, days
$Mg(CH_3COO)_2 \cdot 4H_2O$	1	10 min
	0.9	45 min
$MgSO_4 \cdot 7H_2O$	1	1
	0.7	6
$MgCl_2 \cdot 6H_2O$	1	6
	0.7	11
$MgSO_4$	1	3
	0.7	8

tures were kept at room temperature. We found that, within 10 min, the uniform stable aqueous sol based on magnesium acetate is irreversibly converted to a uniform gel for which we failed to measure the viscosity. The initial viscosity of the sol based on $MgSO_4 \cdot 7H_2O$ was 5.75 Pa s, and the gelation time was 24 h. The gelation of the system based on anhydrous $MgSO_4$ is slower. Immediately after adding TEOS, the viscosity of this system was 4.65, and in 24 h it increased to 6.4 Pa s. Within 3 days after mixing the reagents, the sol transformed into a gel.

Viscosity of sols η vs. the keeping time τ. (*1*) $MgSO_4$ (c_M = 0.7 M), (*2*) $MgCl_2 \cdot 6H_2O$ (c_M = 0.7 M) and (*3*) $MgCl_2 \cdot 6H_2O$ (c_M = 1 M).

The most long-lived sols are formed in the system based on aqueous $MgCl_2 \cdot 6H_2O$. As seen from the figure, during the first day the viscosity of this system changes insignificantly, but during the subsequent two days, and especially on the fourth day after starting the experiment, it sharply increases. The gelation was complete within 6 days after mixing the components.

The gelation of silicate-containing colloidal solutions is a complicated physicochemical process affected by numerous factors such as SiO_2 and metal concentrations, temperature, and pH.

According to Iler [4], the most stable metal silicate sols are formed at pH 2–3 and 10–12, and the plot of the gelation time vs. pH has a minimum at pH 5–6. This relationship agrees with our results, in particular, with the lifetime of sols based on magnesium acetate.

As seen from Table 2 and the figure, the gelation time τ_{gel} increases with decreasing concentration of magnesium salt. For example, with decreasing $MgCl_2 \cdot 6H_2O$ concentration from 1.0 to 0.7 M, the gelation time increases by a factor of approximately 2. The figure shows that the plots of η vs. τ consist of three portions reflecting the processes that are described in detail in the literature [4, 5].

To complete the gelation, the gel obtained by the above procedure was kept for 2–3 days at room temperature and then was dried at 115°C for 30 h. The final xerogels presented small granules, powders, or separate flakes. This material was crushed in an agate mortar to the 60–100 μm fineness suitable for X-ray phase analysis.

The powder X-ray patterns were obtained for gel samples based on $Mg(SO_4)_4 \cdot 7H_2O$ and $Mg(CH_3COO)_3 \cdot 4H_2O$ prepared at various pH values.

The X-ray phase analysis showed that the gel based on $Mg(SO_4)_4 \cdot 7H_2O$ contained the following components: $MgSiO_3$ (*d*/*n* 0.252, 0.256, 0.272, 0.290, 0.293, and 0.318 nm), $Mg(SO_4)_4 \cdot 6H_2O$ (*d*/*n* 0.268, 0.292, 0.404, 0.438, and 0.510 nm), and $Mg(OH)_2 \cdot MgSO_4 \cdot 5H_2O$ (*d*/*n* 0.229, 0.268, 0.485, and 0.545 nm).

As suggested in [6], the magnesium cations in the gel structure interact with the negatively charged

surface by the electrostatic forces. This assumption agrees with the fact that the gel prepared in our experiments contains $MgSiO_3$, which also suggests that magnesium cations interact with the SiO_3^{2-} anions already in the aqueous systems at low temperature. The thermodynamic possibility of such interaction is confirmed by the large negative value of the calculated Gibbs free energy of this reaction, $\Delta G^0_{298} = -63960$ kJ mol^{-1}.

The X-ray pattern of the gel based on $Mg(CH_3 \cdot COO)_3 \cdot 4H_2O$ shows that it is X-ray amorphous (absence of sharp reflections belonging to crystalline phases, presence of two halo at $2\theta = 10°$ and 24°).

CONCLUSIONS

(1) The chemical composition of the magnesium salt strongly affects the course of gelation in the system Mg^{2+}–SiO_3^{2-}–H_2O.

(2) The Mg^{2+} cations interact with SiO_3^{2-} anions at low temperature, and this interaction most likely occurs in the solution. The alkalization of aqueous magnesium acetate due to hydrolysis (pH > 7) hampers the gelation.

(3) With decreasing concentration of magnesium salt in the aqueous sol, the gelation time increases. For the systems based on $MgCl_2 \cdot 6H_2O$, in going from 1.0 to 0.7 M solution, the gelation time increases by a factor of 2.

ANNIVERSARIES

Professor Yu. I. Archakov (to His 80th Birthday)

DOI: 10.1134/S10704272080504 2X

On June 17, 2008, Yurii Ivanovich Archakov, doctor of technical science, professor, and honored scientist and technologist of the Russian Federation, is 80.

Yu.I. Archakov is a known scientist and researcher, prominent physical chemist, and specialist in analysis of hydrogen–metal systems and corrosion protection of metals.

Archakov was born in 1928. He graduated from the Leningrad Technological Institute in 1951, finished his postgraduate education at the same institute and received the degree of a candidate of science in 1957, and defended his doctoral dissertation in 1971 to become a professor.

Since 1957, Archakov has been working at the All-Union Research Institute of Petrochemical Processes, since 1969 he has been heading the laboratory of physicochemical studies and corrosion protection of metals at this institute. Archakov has also been conducting pedagogical work; in 1969–1975, he pluralistically organized and headed the chair of theoretical foundations of materials science at the Leningrad Technological Institute. More than 20 candidate and 5 doctoral dissertations have been defended under his supervision.

His research work combines theoretical studies with solution of practical problems.

Archakov has developed the theory of hydrogen-resistant alloying of metals and alloys and theoretical foundations of metal protection from saturation with gases.

In a series of studies concerned with the solubility and diffusion of hydrogen in metals, he for the first time established the validity of the law of gas dissolution in metals (Henry law) at high pressures, relationship between the solubility and diffusion of hydrogen in metals, on the one hand, and their electronic structure, on the other, and suggested equations for calculating the solution and diffusion constants at high pressures.

His basic research into the effect of alloying elements on the hydrogen resistance of steel has revealed that the key factors are the nature of the carbide phase and its chemical composition. He suggested a phenomenological theory of alloying of hydrogen-resistant steels, based on estimating the corrosion resistance of a steel in hydrogen by its phase composition. This theory enables development of new steels with prescribed hydrogen-resistance parameters and determination of safe application conditions of the already existing metals and alloys on the basis of their phase composition.

He has developed theoretical foundations of metal protection from gas saturation. For a steady and nonsteady gas flow through the metal, mathematical dependences have been derived, which make it possible to assess in advance the promise of new coatings.

Archakov has performed extensive studies aimed to determine fundamental kinetic and thermodynamic aspects of the hydrogen corrosion of steels, develop new original procedures to be used in analysis of corrosion processes in gas media at high pressures and temperatures. Recommendations on ap-

plication of construction steels in hydrogen-containing media have been developed.

Archakov is the author of more than 200 scientific publications and inventions, including the monographs *Vodorodnaya korroziya stali* (Hydrogen Corrosion of Steel, 1985, translated and published in Japan in 1988), *Vodorodoustoichivost' stali* (Hydrogen Resistance of Steel, 1978), *Vliyanie vodoroda na khimicheskoe i neftyanoe oborudovanie* (Effect of Hydrogen on Chemical and Petroleum Equipment, 1976, with co-authors), reference book *Korroziya i zashchita khimicheskoi apparatury* (Corrosion and Protection of Chemical Apparatus, 1974, 1990, with co-authors), and a number of reviews and sections in reference books.

Archakov is actively involved in organizing and holding Russian and international conferences and symposia on corrosion and metal protection. Archakov's scientific works are internationally acknowledged.

Dear Yurii Ivanovich! We congratulate you on your jubilee and wish you health and happiness for many years to come!

Inna Aleksandrovna Tsvetkova: 50 Years of Working Activity

DOI: 10.1134/S1070427208050431

Inna Aleksandrovna Tsvetova has been working now for 50 years at Nauka St. Petersburg Publishing House, Russian Academy of Sciences. After having graduated from the Leningrad Technological Institute, she started to work at the Publishing House of the Academy of Sciences of the USSR as an expert in the literature of the department of periodicals, and, since March 1976, she has been heading the Editorial Office of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry). She is a specialist of very high qualification, with a broad experience of journal work, always well-wishing and attentive. Inna Aleksandrovna is invariably respected by staff members of the publishing house, numerous authors, and members of the Editorial Board of the Journal.

The staff of the Nauka Publishing House, Editorial Board and Editorial Office of *Zhurnal Prikladnoi Khimiii* heartily congratulate respected Inna Aleksandrovna on the remarkable working jubilee and wish her health and a further success in work.

BOOK REVIEWS

Kiiko, V.S., Makurin, Yu.N., and Ivanovskii, A.L., *Keramika na osnove oksida berilliya: poluchenie, fiziko-khimicheskie svoistva i primenenie* (Ceramics Based on Beryllium Oxide: Synthesis, Physicochemical Properties, and Use)

Yekaterinburg; Ural'skoe Otd. Ross. Akad. Nauk, 2006, 440 pp.

DOI: 10.1134/S1070427208010443

Thanks to the whole set of their unique properties, beryllium and its oxide find wide use in various fields of technology. The main consumers of beryllium in the former USSR were the nuclear and aerospace industries. At present, beryllium and beryllium-based oxide ceramics are not manufactured in Russia because of the geopolitical changes that have occurred. The previously existing two plants in Ust-Kamenogorsk now belong to the Republic of Kazakhstan. The lack of its own beryllium-manufacturing plants makes Russia dependent on the import of this important strategic commodity. Rather topical is the problem of expanding the resources of mineral raw materials and creating Russia's own beryllium industry.

The monograph by V.S. Kiiko and co-authors reflects the present-day state of studies of the physicochemical characteristics of beryllium oxide ceramics and considers its use in certain new industries and special technology. The book comprises an introduction and six chapters. References are given to each chapter separately, with the total number of references to all the chapters being very large (598 items).

The introduction (pp. 7–11) briefly characterizes the world's production of beryllium materials and lists their application fields. Chapter 1 (pp. 12–100) discusses a wide variety of issues: state of the resources of beryllium raw materials in Russia, specific features of the decomposition of beryllium-containing ores, and production of a pure beryllium oxide powder and ceramic articles thereof. Russia is one of the first in the world in the beryllium ore resources. As industrial sources of beryllium can serve both its own deposits and complex deposits in which beryllium is an associated component. Considerable attention is given in Chapter 1 to results of comprehensive studies of the structural transformations in beryllium-containing powders, which occur in technological procedures. The results presented can promote an improvement of the quality of BeO ceramics.

Chapter 2 (pp. 101–158) analyzes the electronic structure of beryllium oxide from the standpoint of modern quantum-chemical concepts. The authors make an attempt to model the most important physicochemical characteristics of beryllium oxide on the basis of quantum-chemical calculations.

Chapter 3 (pp. 159–201) considers the defective structure of the BeO powder and ceramics on its base, which largely determines the technological and service characteristics of the BeO ceramics. Particular attention is given to surface defects and to the electrical conductivity of the beryllium oxide ceramics. The electrical characteristics of the ceramics, which are its most important service characteristics, are fully governed by the defective structure of beryllium oxide.

The physicochemical properties of the BeO ceramics are strongly affected by impurities that find way into the ceramics in the course of the process or are purposefully introduced in order to modify its properties. These issues are discussed in Chapter 4 (pp. 202–281). It is noted that impurities are localized in the ceramics mostly at grain boundaries. Data on the dynamics of variation of the impurity content in the course of the process are discussed in detail. A particular attention is given to admixtures of carbon and iron, which markedly affect the service characteristics of the BeO ceramics.

Chapters 5 (pp. 282–351) and 6 (pp. 352–440) discuss the application of the beryllium oxide

ceramics in widely diverse fields of technology. Particular emphasis is placed by the authors on the use of the BeO ceramics in laser technology and the dosimetry of ionizing radiation. On the whole, the authors succeeded in generalizing, systematizing, and analyzing a large body of evidence on the synthesis technology, physicochemical properties, service characteristics, and use of the beryllium oxide ceramics in various fields of technology. The book is well written and accessible, as regards the presentation manner, to a broad audience of specialists in various fields of science and technology. It contains the results of the most recent studies.

BOOK REVIEWS

Meretukov, M.A., *Zoloto i prirodnoe uglerodistoe veshchestvo* (Gold and Natural Carbonaceous Substance)

Moscow: Ruda i Metally, 2007, 110 pp.

DOI: 10.1134/S1070427208010455

The book written by Prof. M.A. Meretukov, a known specialist in metallurgy of noble metals, is devoted to a rather narrow issue, nature of the scattered carbonaceous matter (SCM) contained in gold ores and deposits and its influence on the cyanidation process.

The monograph comprises an introduction and nine chapters, each with its own bibliographic list. In the brief introduction (pp. 5–8), the author gives notion of the essence of the phenomenon he describes. Small Chapter 1 (pp. 9–13) familiarizes the reader with the basic terms and concepts. Chapter 2 (pp. 14–20) characterizes various gold ore deposits. Chapter 3 (pp. 21–29) discusses the basic concepts of the origin of the carbonaceous matter in gold deposits. Chapters 4 (pp. 30–34) and 5 (pp. 35–48) are devoted to the types and structure of kerogen, the conditionally insoluble component of the organic matter scattered in sedimentary rock. Chapter 6 (pp. 49–64) discusses the genetic relationship between gold and the carbonaceous matter. Chapter 7 (pp. 65–83) contains evidence about the structure and properties of the carbonaceous matter contained in gold ores. Chapter 8 (pp. 84–95) discusses various methods for neutralizing the activity of SCM before cyanidation of gold ores. The final Chapter 9 (96–109) makes an attempt to explain specific features of the interaction between gold-containing solutions and scattered carbonaceous matter.

The monograph by Meretukov is of interest for specialists working directly with the technology of processing of gold-containing ores and methods for their cyanidation. Probably, it would be instructive to more widely use as examples the domestic deposits and technologies. The author mostly relies on the experience of the United States, Canada, and South African Republic.

Polyacrylonitrile: Carbonization Problems

A. V. Gribanov and Yu. N. Sazanov

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April 16, 2008

DOI: 10.1134/S1070427208060013

INTRODUCTION

Polyacrylonitrile (PAN) is one of widely used and industrially mastered substituted polyolefins. Its properties and applications have been described in detail in numerous monographs and reviews and form an independent field of research in chemistry, physics, and technology of synthetic macromolecular compounds, closely related to the materials science [1–10]. Much attention in these books and articles is given to PAN carbonization as a process yielding carbon materials that are indispensable for many branches of modern industry. Detailed studies of PAN carbonization give much useful information for choosing conditions required to obtain carbon articles with the best characteristics from PAN. However, specific features of thermochemical reactions leading to the formation of the carbon structure from PAN are still poorly understood. Heat treatment is the major factor determining the features of PAN carbonization. Despite enormous number of papers on PAN carbonization, there is still no generally accepted mechanism of PAN thermal transformations in a wide temperature range.

STATE OF THE ART

As in other related cases, the problem is to separate the effects of PAN heat treatment conditions on the course of two competing thermochemical reactions, degradation and cross-linking, typical of carbonization of any polymers. Already in an early book concerning thermal transformations of carbo- and heterochain polymers [11] it was noted that thermal transformations of PAN start with the reactions of nitrile groups. As a result, various cyclic (mostly six-membered) and partially cross-linked structures can be randomly formed.

Already in this step of interpretation of the cyclization process, different hypotheses related to the experimental conditions and to the structure and purity of the starting PAN samples were put forward. Comparison of the published data shows that the interpretation of the mechanism of transformation of a linear soluble PAN into an insoluble polycyclic product involves many contradictions concerning the structure of the intermediate and final compounds. The following features of the thermochemical transformation of PAN into a carbonized structure are now recognized and confirmed by the majority of researchers.

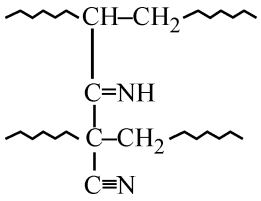
(1) When heated, linear PAN cyclizes via opening of the nitrile groups, but the number of rings in a block and their mutual arrangement in intra- and intermolecular packing are still the matter of discussion.

(2) With increasing temperature of heat treatment, the degree of polyconjugation and aromatization of PAN grows.

(3) The ambient atmosphere and the temperature conditions of the heat treatment have a decisive effect on all reactions of PAN carbonization and on the structure of the intermediate and final products.

(4) Only some of the papers consider the steric organization of the initial PAN as a factor governing the structure of the carbonizate.

The above features of the extremely complex process of polymer-analogous PAN transformations are only general criteria in the development of carbon materials with a set of unique valuable properties. The contributions of different researchers to understanding and interpretation of the results of basic and applied studies have certain specific features concerning the terminology, goals of



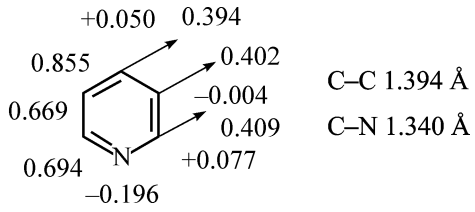
experiments, and technical, technological, economic, environmental, and other aspects. Each of these criteria is important for gaining complete information.

First, it is appropriate to discuss certain terminological issues.

The polymer name, polyacrylonitrile, means nothing other than a compound synthesized by acrylonitrile polymerization. However, without information on the chemical and physical structure formed in the course of the synthesis, numerous questions arise. Without answers to them, the results of the experiment as a whole remain obscure and open to question. There are many reasons for the scarcity of the initial information, and some of them are objective. They are associated with the lack of synthesis standardization and of the necessary minimal set of characteristics of the initial polymer. The other factor is the use of technical slang in which the term PAN is applied not only to the acrylonitrile homopolymer, but also to its copolymers. This factor is mentioned by Varshavskii [7], but even the author himself does not always follow this rule. Obviously, for PAN copolymer samples in which participation of an oxygen-containing copolymer is put on the same footing as thermal oxidative treatment of PAN, the mechanism of thermochemical transformations is strongly different from the thermochemistry of the homopolymer. Therefore, in the majority of original papers considering the mechanism of lowtemperature carbonization, which is identified with the oxidation or stabilization, the use of PAN copolymer is, as a rule, implied, but not indicated directly.

From the applied standpoint, the use of oxygen-containing compounds accelerates and simplifies preparation of carbon materials (as a rule, fibers). However, from the standpoint of elucidating the fine mechanism of cyclization involving only the initial structure of the acrylonitrile homopolymer, i.e., a macromolecule consisting of only C, H, and N atoms, introduction of oxygen further complicates the unclear pattern of thermal cyclization of PAN.

It was believed that PAN cyclization is impossible in the absence of oxygen in the reaction medium [12], but this assumption was rejected by model experiments with succinic acid dinitrile and nitriloacetic acid esters, which formed cyclic oligomers by opening of nitrile bonds via formation of dimeric complexes [13–15]. A thorough analysis of the IR spectra of the examined compounds confirmed the mechanism involving formation of cyclic structures of the naphtharidine type, suggested by Grassie and Hay [16] on the basis of experiments on isothermal heating of isolated model samples. These results disprove the scheme of intermolecular cross-linking of PAN via formation of azomethine links [17]



Thus, it can be considered that the first step of thermochemical transformations of PAN is the formation of six-membered naphtharidine rings. This pathway fits in the general scheme of low-temperature (100–200°C) transformations of PAN. Furthermore, the occurrence of reactions in defective areas of the molecular structure and in the comonomer unit is assumed. The last two pathways were given particular attention in view of the applied significance of PAN, and the cyclization was considered to be governed by the occurrence of thermal oxidative reactions. In addition, a question arises: Is the primary cyclization event, not complicated by oxidative reactions, the first step of PAN carbonization From the viewpoint of an increase in the carbon concentration in a sample, the PAN cyclization is not carbonization, but just a process favoring cross-linking of the substance and enhancing its heat resistance.

Only in very few studies, the PAN cyclization was not accompanied by release of volatile thermal degradation products. This pathway is possible theoretically, but actually ideal cyclization yielding long cyclic sequences does not occur. As a rule, only macrochains consisting of three to ten conjugated nitrogen-containing rings can be obtained. Some authors attribute this fact to different tacticities of PAN samples [4, 5, 18–20]. The regularity in arrangement of nitrile substituents along the PAN chain is the decisive factor in the formation of ladder naphtharidine structures, and in this respect, as indicated in [18], the isotactic PAN structure is preferable. This seeming simplicity, apparently, led to certain mistakes in schematic presentations of the cyclization mechanism in early papers on thermal degradation of PAN [21–24]. In [25], we drew attention to the importance of the steric orientation of PAN macromolecules and of geometric and energetic characteristics of all bonds participating in the formation of intermediate and final carbonization products. In this aspect, the repeatedly pres-

ented scheme of the parquet packing of carbo- and heterorings is inconsistent with the actual size of separate fragments of the cyclic structure of PAN.

When tackling with the problem of steric organization of PAN and of intermediate and final products of its carbnization by simulating structural fragments of linear and cyclic PAN [26], the model compounds 2,4-dicyano-*n*-pentane, 2,4,6-tricyano-*n*-heptane, and their higher homologs simulating linear uncyclized PAN exhibit no steric hindrance with increasing chain length. A different pattern is observed for macromolecules of cyclized PAN, in which the growth of cyclic sequences along the PAN chain is strongly restricted by a number of factors. First, the degree of tacticity of the initial PAN determines the possibilities of its cyclization. In the ideal case, the maximal length of fused cyclic units in the PAN backbone could be attained at the 100% isotactic arrangement of the nitrile groups. However, as shown in [13, 19], preparation of such PAN stereoisomers is impossible. Second, the high dipole moment of the CN group, 3.9 D, opens up wide possibilities for competing reactions, especially for an intermolecular interaction with an adjacent PAN molecule. In addition, the orbital of the lone electron pair is oriented oppositely (180°) to the C=N bond axis, which favors hydrogen bonding, donor–acceptor interaction with PAN surrounding, and, in particular, formation of molecular associates on the level of PAN monomers and oligomers.

Particular attention should be given to the poorly understood geometry of cyclic PAN structures. According to the calculations [27, 28], this is the major factor restricting the growth of cyclic sequences in PAN. Let us discuss it in more detail. The pyridine and naphtharidine structures formed by PAN cyclization and found in many papers cannot be regarded as strictly planar and, the more so, coplanar. In contrast to benzene and its fused homologs, the bond lengths and bond angles in the six-membered rings of pyridine and naphtharidine are nonequivalent. Despite the high electron delocalization energy in pyridine (33.8 kcal mol^{-1}) and pronounced aromatic properties, its geometric structure is not a regular hexagon like that of benzene:

Electronic indices of pyridine.

This gives rise to strain of the pyridine ring via its bending, and, as a result, to a decrease in the stability, compared to benzene. Furthermore, the nonuniform electron density distribution over the pyridine ring leads to its polarization and thus enhances its reactivity.

Thus, already in the step of initiation of PAN cyclization, a pyridine ring is formed, whose nitrogen atom is a certain source of strain for the whole cyclic system of PAN. The strain increases as further rings are formed along the chain. Hence it can be concluded that nitrogen (an apparently other heteroatoms, especially oxygen) plays a decisive role in the formation of rings in the early step of cyclization, i.e., it is an initiator of a polymer-analogous transformation of linear PAN. With an increase in the number of conjugated rings, the effect of steric and thermodynamic factors of pyridine and its fused derivative enhances the strain of the whole system, and the nitrogen atom starts to prevent, rather than promote, the cyclization. In this case, apparently, the number of nitrogen-containing rings in the conjugated block reaches a certain critical value dependent on many factors (both on those noted above and on purely process factors), after which the function of the nitrogen atom changes, and it ceases to participate in the further growth of the homologous series of polyheterocycles.

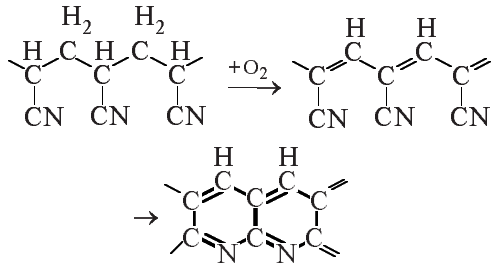
Without going into details of the organic chemistry of cyclization, we should note that nitriles form associates (stable dimers) via interaction of nitrile groups, with the association energy of 4–8 kcal mol^{-1}. In the PAN macromolecule, in which the mobility of nitrile groups is restricted by the hydrocarbon chain, their strong polarization at low temperatures creates conditions for the occurrence of competing intra- and intermolecular reactions. In an isolated PAN macromolecule, the adjacent CN groups repel each other, which leads to the formation of a twisted helical structure with the mean cross section not exceeding 0.6 nm [13]. In this packing, some nitrile groups protrude beyond the perimeter of the cross section of the individual PAN macromolecule, providing an intermolecular dipole–dipole interaction. Depending on the inclination angle of the CN bond relative to the axis of the PAN helix and on the angle between the CN bonds in the projection onto the plane of the cross section of the PAN molecule, the energy of intermolecular interaction of the adjacent molecules, calculated from data of [29], is close to the energy of the interaction between free macromolecules.

As for the interaction of PAN macro-molecules in a specific article (film or fiber), their steric arrangement is determined by the article forming conditions. In this case, the role of the nitrogen atom in the formation of a cyclic carbonizate structure becomes less significant, because an ordered supramolecular organization is formed under the action of external loads. It was shown in numerous papers [5–7] that, under the conditions of forced orientation, helical structures of PAN are arranged in a planar zigzag, the intermolecular interaction forces become weaker, and zones with ordered packing appear. Such zones can be formed only at a syndiotactic arrangement of the CN groups in the plane of the PAN hydrocarbon chain. This structure is the least favorable for the formation of cyclic PAN structures, but the orientation of PAN chains in the course of extension makes higher the probability of intermolecular cross-linking. In this case, the nitrogen atoms of the nitrile groups will act, owing to antiparallel orientation of the dipoles, as cross-linking agents, thus inhibiting the cyclization, the more so as the cyclization is accompanied by an additional chain strain because of the nonequivalence of the bond lengths in pyridine and naphtharidine.

Apparently, the superposition of these processes does not allow formation of conjugated cyclic sequences of lengths exceeding five to seven conjugated pyridine rings in real PAN samples [30, 31]. The results obtained show that, in an inert atmosphere, the probability of intramolecular cyclization in a nonoriented PAN macromolecule is close to zero. In an oriented isolated macromolecule, the possibility of intramolecular cyclization is determined by the steric arrangement of nitrile groups and by the molecular-weight characteristics, which depend on the PAN synthesis conditions and on conditions in which PAN-based articles are formed.

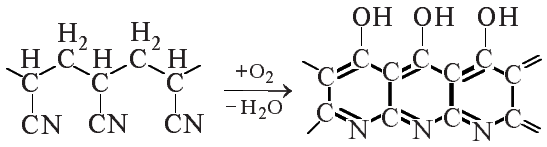
Hence, the orientation along the chain axes is the necessary condition for the intramolecular cyclization of PAN. As a rule, it is attained by using various procedures for fiber and film forming. The formation of primary PAN structures is of crucial importance for the transformation of PAN into a carbonized product in the course of its high-temperature treatment. However, because of the above-noted limitations in the geometry of nitrogen-containing heterocycles, the subsequent carbonization of PAN with the formation of a planar parquet packing of symmetrical hexagons, which was postulated by Grassie [21–24] and reproduced in numerous subsequent papers to become a certain axiom, disagrees with the calculation results.

A more rational model has been suggested by Rumynskaya et al. [32]. They convincingly confirmed the interplanar interaction of conjugated cyclic units of PAN, occurring as a donor–acceptor interaction of cyclic formations strongly polarized at the N atom with the hydrocarbon chain of an adjacent PAN macromolecule. This interaction fixes the layered macromolecule packing facilitating their subsequent carbonization and graphitization with increasing temperature.



Returning to the primary step of low-temperature reactions of PAN, which initiate cyclization via nitrile groups, we should note once again that strictly speaking, this process is not carbonization, as it is not accompanied by an increase in the carbon concentration in the system. In this context, introduction of oxygen atoms into PAN is an impulse initiating carbonization. Oxygen can be introduced into the reaction system in different ways. The first way involves performing thermal transformations of PAN in an oxidizing atmosphere. The second way is introduction of oxygen-containing comonomers, mainly carboxylic acids and their esters. The third way is associated with the presence of residual catalysts and solvents used in acrylonitrile polymerization and fiber forming.

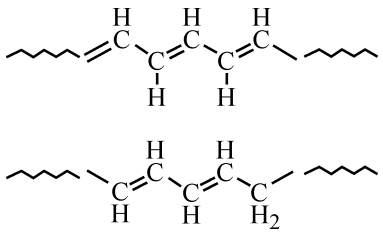
The presence of oxygen in any form substantially expands the set of thermochemical reactions in early steps of PAN heat treatment. Among these reactions are dehydrogenation, generation of free radicals, formation of hydroxy, carbonyl, carboxy, and keto imine groups. Further heating leads to activation of thermal oxidative degradation processes accompanied by the release of water, carbon oxides, hydrogen cyanide, ammonia, acrylonitrile, and other readily volatile thermal degradation products whose ratio and release sequence depend on many factors that are difficult to analyze on the quantitative level to construct the general scheme of low-temperature carbonization.



According to [33], carbonization of a PAN fiber (no characteristics of the initial sample are given) in an oxidizing atmosphere starts above 100°C with the oxidative dehydrogenation to give water, with elimination of HCN and NH_3 by disproportionation. Above 190°C, cyclization and aromatization of PAN are observed, which is followed by depolymerization at 200°C. The process ends at 250°C to give heteroaromatic units consisting of four to five naphtharidine rings. In an inert atmosphere, oxidative dehydrogenation does not occur, no carbon oxides are detcted, and the content

of nitrogen-containing volatile degradation and depolymerization products is somewhat higher. An oxidizing medium accelerates the cyclization and aromatization, but at 270–310°C causes degradation of naphtharidine rings.

This example is specific to a given PAN sample and to the experimental procedure used. There are also numerous other studies performed under other conditions and with other PAN samples (also insufficiently characterized), and the trends observed are quantitatively and qualitatively different, depending on a specific experiment. In some papers, thermochemical transformations of PAN in early steps of heat treatment were interpreted in terms of the formation of a polyene conjugation chain, competing with the cyclization via nitrile groups. It was believed that oxygen accelerates the formation of aromatic structures via generation of free radicals initiating formation of polyconjugated systems in the hydrocarbon chain [5]:



In another paper [2], it is suggested that the polyconjugated system is formed via oxidative dehydrogenation of PAN:

However, none of these schemes is provided with well-defined temperature limits from which it would be possible to determine the priority of formation of the polyconjugated system in the hydrocarbon chain. Furthermore, data on the oxygen concentration in the reaction mixture are also lacking. Therefore, the question of formation of a polyconjugated chain remains open, especially taking into account that oxygen can both initiate and inhibit the PAN cyclization [34]. Apparently, the presence of oxygen in any form in the PAN reaction system makes it impossible to distinguish the step of formation of the polyene structure against the background of cyclization via nitrile groups, also leading to the formation of a polyconjugated system. As the polyconjugation effect is a driving force of carbonization of many organic compounds [5, 6, 11], this approach is quite applicable to PAN carbonization.

The effect of separation of conjugation blocks, allowing preservation of the coplanarity of separate cyclized fragments participating in further rearrangements of the PAN structure at elevated temperature, is discussed in [35] on the basis of a hypothesis that cyclic fragments, which are conjugation blocks, catalyze further carbonization of PAN. The concept conjugation blocks catalyzing PAN carbonization have a critical size independent of the sample microtacticity and history was put forward. These conclusions were indirectly confirmed by Geidrikh et al. [36]. Based on an analysis of PAN samples heat-treated in different atmospheres in a wide temperature range (100–2800°C), they suggested preservation of the supramolecular organization and orientation of chains of the initial PAN whose carbonization yields nongraphitizing carbon forms.

The possibility of formation of carbon-chain polyconjugated systems of the type

was discussed by Artemov et al. [37]. With the reference to X-ray spectra, they demonstrated prevalence in the carbon bulk of sp^2 -hybridized carbon atoms incorporated into carbo- and heterocyclic aromatic structures. That is, the polyconjugation in the carbonizate is due to fusion of aromatic fragments into polycyclic systems.

However, the thermodynamic factor testifies against such structures. Formation of a –CH=CH– unit in a polyconjugated system $(–CH=CH–)_n$ requires an energy of +98.74 kJ mol^{-1}, i.e., the formation of such systems is strongly exothermic. The formation of cyclic structures, such as benzene and naphthalene, from short polyconjugation chains $(–CH=CH–)_3$ and $(–CH=CH–)_5$ involves the consumption of –108 and –343 kJ mol^{-1}, respectively. Therefore, the formation of long conjugation chains at low temperatures with the subsequent formation of six-membered rings and hydrogen release is improbable. To conclude the discussion of the attempts to elucidate the mechanism of low-tempera-

ture carbonization of PAN, it can be noted that all the hypotheses are associated with a process scheme for preparing materials with prescribed properties. This approach is justified in the applied aspect, because the use of oxygen in the course of production of carbon articles (fibers in most cases) by PAN carbonization is appropriate from the technological and economic viewpoints.

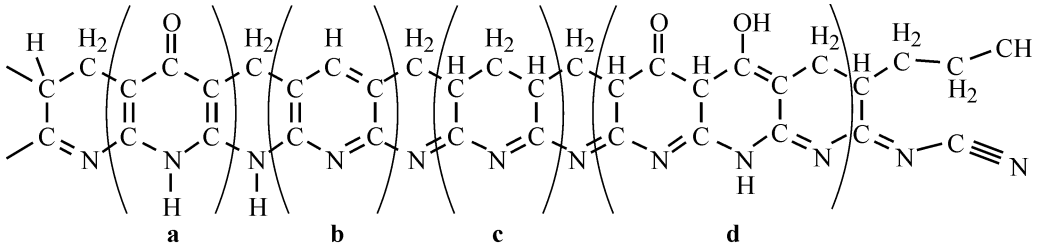
Attempts to elucidate the details of "oxygen-free" carbonization face the above-mentioned problems associated with the requirements of a high purity of the monomer, thorough identification of the initial polymer, and exclusion of thermal oxidation in the first step of carbonization (up to ~300°C). In so doing, it should be borne in mind that, as already noted, the terms carbonization and low-temperature cyclization are not identical as applied to PAN.

The first condition is the most difficult to meet, as it requires complex procedures of laboratory synthesis with special catalysts and reaction vessels reliably isolated from the ambient atmosphere. Furthermore, such polymers are hardly promising from the economic viewpoint. The chemical specificity of such polymers as carbon fiber precursors will be discussed below. The possibility of a more detailed examination of the mechanism of low-temperature carbonization of PAN under "sterile" conditions is of basic scientific interest, and certain attempts in this area have already been made. Unfortunately, experiments on PAN carbonization in an inert atmosphere with acrylonitrile homopolymers of insufficiently characterized structure and composition and, the more so, with acrylonitrile copolymers are of little use for this purpose.

To approach the solution of this problem, we can analyze data on PAN synthesis using anionic systems [19, 38–41] or channel complexes [18]. Such PAN samples have high high molecular weight (up to 8×10^5), narrow MWD with a polydispersity close to unity, absence of low-molecular-weight fractions and branchings, and increased stereoblock structure parameter [20]. A low-temperature treatment of these samples was not accompanied by formation and release of volatile products in the initial step of heat treatment. Structural changes occurred only as a result of intramolecular polymerization of nitrile groups. Furthermore, these polymers did not form a polymeric complex with the solvent (DMF) [42].

One could say that the onset of formation of a polyconjugated chain through naphtharidine units initiates further transformation of linear PAN into cyclic product, but the subsequent carbonization with gradual dehydrogenation and increase in the carbon concentration requires the action of oxygen in any form accepted in technology. Thus, the modeling of "sterile" conditions of the initial step of thermochemical transformations of PAN gave insight into the elementary events of carbonization on the level of a heat-driven microreactor consisting of carbon, hydrogen, and nitrogen atoms bound in a PAN macromolecule.

The interaction between carbon and nitrogen atoms participating in PAN carbonization has always attracted researchers' attention. With the development of solid-state analytical spectroscopy, there have been published papers on examination of carbonized residues of polymers containing heteroatoms.



In one of early basic reviews on pyrolysis and carbonization of polymers [11], it was suggested that heteroatoms play a significant role in the formation of aromatic carbon monolayers. It was found [35, 36] that the carbon–nitrogen bond in the conjugation chain arising from PAN cyclization is very strong and determines the structural thermochemical reactions in the course of carbonization. The enhanced heat resistance of PAN heat treatment products with a conjugation system consisting of nitrogen-containing rings was substantiated from this viewpoint. This interpretation was supported [43] by the results of heating of dilute PAN solutions in an inert medium, when formation of cross-linked intermolecular structures is ruled out and formation of longer chains of conjugated C=N bonds is favored because of increased conformational mobility in solution.

Further discussion of the experimental evidences for the effect of the conjugation system on the PAN carbonization considered the effect of oxygen introduced by various methods into the PAN carbonization process. This position is based on the authors' interest related to materials science and on the principal goal of preparation of carbon fibers from PAN fibers with a set of valuable service characteristics. From this viewpoint, Varshavskii's book [7] is the most comprehensive and interesting. It summarizes the experience of a whole generation of specialists of the Khimvolokno Research and Production Association on the development of unique multiprophile carbon fibers and articles based on them. One of the main advantages of this book is the encyclopedic completeness of generalized data on carbonization of the main polymeric raw materials

used for production of carbon fibers (celluloses, pitches, PAN).

A prominent place is occupied by an ingenious hypothesis about the mechanism of high-temperature carbonization of PAN. Without going into details of this book, whose fragments have been published in periodicals [2, 6, 44], it should be noted that the majority of observations, characterizitics, and appraisals concern fibers whose specific features pose certain restrictions on the conclusions about the mechanism of PAN carbonization. As a rule, copolymer fibers are concerned, and, in almost all the cases, thermal oxidative effect on the polymer throughout the temperature range of carbonization is considered.

From the viewpoint of the mechanism of PAN carbonization, the primacy of polyconjugated systems is kept, but there are no convincing examples of the predominant formation of a polyconjugation chain by oxidative dehydrogenation or by polymerization of pendant nitrile groups. Alternative pathways of formation and lengths of systems of conjugated –C=C– and –C=N– bonds are discussed in relation to the molecular weight and steric charac-teristics of the reacting macromolecules. The results of some papers concerning the effect of PAN tacticity on the polymerization of nitrile groups are discussed very cautiously. This indirectly disproves the postulate of the infinite length of polyconjugated ladder chains of PAN. Much attention is given to specific features of the formation of the supramolecular structure on the level of PAN fibers. In one of the conclusions, the following formula is given for the macromolecule of oxidized PAN fiber:

with the ratio of units **a** : **b** : **c** : **d** = 4 : 3 : 2 : 1.

However, this is followed by a reservation that the formula is valid for the surface layer of a fiber, 4–5 nm thick. Deep layers of a fiber can have a different composition because of the effect of diffusion factors governing the degree of oxygen penetration into the fiber. This parameter depends on the heating rate in different steps of carbonization. These and many other factors related to the preparation and thermal oxidation conditions exert a significant influence on processes occurring in the course of fiber heating. It is noted that heating can lead to relaxation of internal stresses, with a decrease in the strain of bonds and angles. From the viewpoint of the maximal length of cyclic sequences, discussed above, and the role of stereoisomerism in their formation, it is unclear whether the relaxation promotes or hinders cyclization.

An interesting interpretation of the mechanism of chemical reactions occurring in the course of carbonization of oxidized PAN fibers has been suggested. The conclusions on the carbonization kinetics, based exclusively on calculations of the apparent activation energy by the laws of formal kinetics, do not give grounds to conclude that the mechanisms of chemical transformations under a catalytic effect are the same. The activation energy is of neither physical nor chemical sense for thermochemical processes in polymers. Therefore, the conclusion about the catalytic effect on the PAN carbonization process as a whole is doubtful.

An attempt to elucidate the role of polyconjugated systems in the formation of carbon structures is more interesting and ingenious. A hypothesis of the autocatalytic character of formation of aromatic conglomerates, with the forming polyconjugated systems acting as catalysts, has been put forward. The main pathways in the suggested mechanism are virtual schemes of formation of polyconjugated systems of two types: via oxidative dehydrogenation and via polymerization of nitrile groups, which is consistent with the results of experimental studies [5, 11, 33].

Further schematic construction of ladder and parquet aromatic structures somewhat resembles Grassie's schemes [21–24], without taking into ac-

count the geometry of the polyheterocycles [25]. In addition, the previously suggested empirical formula of the polystructure of oxidized PAN fiber is not reflected in the mechanism of thermal transformations at elevated temperatures. Despite the use of topochemical relationships and appeal to the complexity of solid-phase reactions on the polymeric level, regular construction of a cyclic set propagating in space like a zipper is hardly compatible with the random set of elementary structures indicated in the above formula.

The energy-related interpretation of the intermolecular interaction of propagating chains from the standpoint of adsorption–desorption and vacation of the active surface for continuing the subsequent regular cross-linking is a very fruitful, though debatable, prerequisite to the development of a theory correlating the macromolecular interactions in the polymer matrix with fine electronic rearrangements of atomic bond parameters. The application of the main postulates of catalysis on semiconductors in the suggested semiempirical virtual scheme is debatable, but, nevertheless, this is a serious step in elucidation of the extremely complex mechanism of PAN thermolysis.

Further experimental confirmation of the suggestions made, such as introduction of a boron atom as an electron-acceptor agent and counterbalance for nitrogen atoms [45], offers not only a practical proof of the autocatalytic effect of polyconjugated nitrogen-containing systems, but also a reliable tool for controlling the PAN thermolysis rate.

Unfortunately, apart from [6], there are no new studies concerning the development and confirmation of the above hypothesis. With certain admissions, there are some analogies with the concept of self-associated multiplet in the coal structure [46], but, in this case, a consistent terminological system should be developed for combining the concepts of coal chemistry and physical chemistry of macromolecular compounds.

Some papers were published later on modification of fibrous PAN precursors for improving the quality of carbon fibers. As a rule, these studies concern certain modifications of the process of low-temperature treatment of commercial copolymeric PAN fibers. For example, Ko [47] tested a four-zone scheme of heat treatment of Courtelle fiber (copolymer of PAN with 6% methyl acrylate and 1% itaconic acid) at 190, 230, 230 (275), and 230 (200, 300°C) (in parentheses are temperatures of different experiments) for 145 min. Further carbonization was performed in dry nitrogen at temperatures of 400 to 1300°C (100°C steps) on an apparatus used in the previous study [48]. As a result, carbonized fibers with the maximal modulus of almost 200 GPa, tensile strength of 3.36 GPa, and density of 1.766 $g\,cm^{-3}$ were obtained.

In another paper [49], with the aim to improve the mechanical properties of PAN fibrous precursor of carbon fibers (Courtelle copolymer), Chen and Harrison applied postplasticization extension in dimethylformamide–water (80 : 20). As a result, the elongation of the precursor increased by 18% and the tensile strength, by 12%, and for the fibers carbonized at 1000°C these parameters increased by 68 and 14%, respectively. The treatment was accompanied by an increase in the long-range order (according to X-ray diffraction analysis) and removal of surface defects. As in the paper discussed above, transformations of the chemical structure of PAN were not discussed.

One more study of the modification of PAN precursors based on carbon fabric with KOH solutions was aimed to obtain porous carbon materials [50]. The suggested process allowed preparation of inert sorbents with a specific pore area of 2500–3000 $m^2\,g^{-1}$.

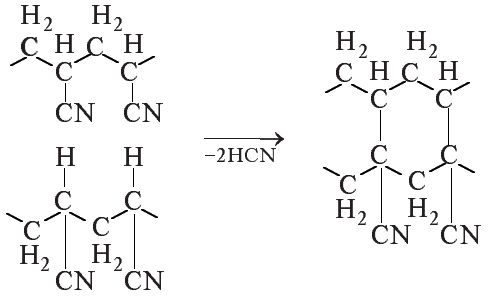
Interest in the mechanism of low-temperature carbonization is expressed in [47–52]. In a recent paper [53], a copolymer of acrylonitrile with 1% itaconic acid (MW 158000) was subjected to stabilizing heat treatment using a ten-zone heating scheme at temperatures from 195 to 253°C for 1 h. After the stabilization, the low-temperature carbonization in a flow of pure nitrogen and of nitrogen with an oxygen impurity was performed using a four-zone heating scheme at fixed temperatures from 100 to 600°C. Using a set of different samples and various analytical methods (DSC, Fourier IR spectroscopy, X-ray diffraction, ESR, elemental analysis) for examining the intermediate and final products of the heat treatment, the authors postulated a three-step mechanism of the stabilization and precarbonization of the fiber. The first step (300–450°C) involves cross-linking and aromatization under the action of free radicals generated by decomposition of oxygen-containing groups. In the second step (450–550°C), generation of free radicals is continued as a result of an avalanche-like degradation of linear fragments of the fiber. The process is characterized by superposition of numerous thermal oxidative reactions and results in the aromatization of

the whole structure. However, separate aromatic fragments do not exceed in size the fragments that existed before the pyrolysis. In the third step (550–600°C), cross-linking of ladder polymers into basic planar structures starts, and the polyaromatic formations grow in size.

However, the conclusions of [53] do not differ significantly from those made in numerous previous papers by other authors. Apparently, statistical accumulation of results of polyvariant experiments will ultimately lead to fixation of the main statements and conclusions concerning the specific features of PAN carbonization. K.E. Perepelkin, a prominent specialist in the field of synthetic fibers and their materials-science characteristics, arrived at such a conclusion. In [8] he distinguishes three steps of thermal oxidative transformations of PAN fibers: (1) fast diffusion of oxygen to external zones of the fiber and oxidation in this zone; (2) relatively slow cyclization of partially oxidized polymer in the external zone of the fiber; and (3) further oxidation and cyclization in the boundary zone, gradually moving to the fiber center at a rate controlled by diffusion processes.

During this time, the oxidation in the external zone with the formation of cyclic and polyene structures imparting black color to the fibers continues and comes to the end.

As for the chemical structure of oxidized PAN, a multiplet formula reflecting fragments of nitrogen-containing heterocycles with a certain amount of oxygen functional groups is reproduced with reference to [3, 6]. The supramolecular structure of these fibers preserves, on the whole, the main features of the initial PAN. In copolymeric PAN fibers, there is no 3*D* ordering because of the nonuniform chemical and steric structure of the macromolecule. An important role is played by orientation procedures in the course of fiber formation, namely, by the degree of stretching and tension in the course of oxidation. These factors enhance the strength, increase the strain modulus, and decrease the deformability of fibers.



Depending on the structure of the raw material and a process used for preparing oxidized PAN fibers (Oksipan, the name suggested by Perepelkin [9]), the main physicomechanical parameters of these fibers vary within 10–30%: density, from 1.36 to 1.4 g cm^{-3}; breaking elongation, from 15 to 27%; strain modulus, from 7 to 10 GPa; strength, from 200 to 240 MPa; sorption of moisture from air (at 65% humidity and 20°C), from 8 to 9%; and oxygen index, from 45 to 50%. The bulk resistivity of the material exceeds 10^8 Ω m. Oksipan fibers are heat-resistant up to 300°C and higher temperatures. They are also resistant to acids of moderate concentrations, dilute alkalis, moderate oxidants, and all kinds of solvents.

These valuable properties of Oksipan fibers are used for high-temperature insulation in protective heat-insulating layers of clothes for hot shop workers, firemen, rescuers, and other dangerous professions, and also in interior of airplanes, trains, cars, ships, etc. The facile processing by common methods of textile industry, relatively low cost of Oksipan, low cost and availability of the precursor (PAN fibers), and relatively simple technology make the production of Oksipan fibers in Russia profitable and promising.

In these characteristics, Oksipan fibers are preferable to other heat-resistant fibers based on aromatic monomers and polymers, for which the starting monomers, multistep production process, and regeneration of production waste are incommensurably more expensive compared to the cost of production of PAN fibers. The above characteristics of PAN and the scheme of thermal oxidative transformations of PAN fibers under heat treatment at temperatures of up to 600°C refer to commercial copolymeric samples.

The apparent success in attainment of high thermomechanical characteristics of carbonized and graphitized PAN fibers at 1000–3000°C overshadowed the problem of the mechanism of the intermediate step of PAN carbonization, providing formation of regular carbon materials. In some papers concerning this problem [47, 48, 51, 52], the conclusions are based on the conclusions and schemes of early Watt's papers [54–57] on the mechanism of thermal oxidation of PAN copolymers.

In these schemes, possible combinations of carbo- and cyclochain structures are discussed in relation to the heat treatment conditions and steric arrangement of PAN macromolecules. The model of intermolecular cross-links yielding bridging pyridine rings and a ladder carbocyclochain structure deserves particular attention. In the latter process, cyano groups are partially eliminated in the form of HCN. The rest of cyano groups remain as substituents in the carbocyclic chain and do not participate in the formation of heterorings:

Because various pathways of thermochemical transformations of PAN are discussed for commercial copolymeric fibers, frequently without taking into account the effect of comonomers, studies of the thermochemistry of the homopolymers [20, 25, 58] are of particular interest. In the last study, we chose as objects three types of PAN. PAN of the first type was prepared by the anionic polymerization mechanism (A-PAN) in the presence of butyllithium. This polymer has a high molecular weight and a narrow molecular-weight distribution. It contains no low-molecular-weight fractions and branchings and is characterized by an increased parameter of the stereoblock structure. That is, it is the closest in molecular structure to the ideal polymer. PAN of the second type was prepared by the radical polymerization mechanism (R-PAN) in the presence of a widely used catalytic redox system. In contrast to A-PAN, R-PAN samples are characterized by high polydispersity, presence of branched polymer chains, noticeable content of low-molecular-weight fractions, and presence of oxygen-containing terminal groups. PAN of the third type is A-PAN partially cyclized in the course of the synthesis (C-PAN).

The samples were subjected to complex thermal analysis (TGA, DTA) in the temperature range 20–600°C. Calorimetric measurements revealed thermal effects in the range 400–600°C. Both exo- and endothermic effects were observed in thermograms of all the three PAN samples. The peak shapes suggest that these peaks reflect melting and crystallization processes.

Comparison of the peak temperatures, peak areas, and sequences of the thermal effects shows that the thermal effects are the most pronounced in A-PAN, less pronounced in C-PAN, and the least so in R-PAN. Such differences are apparently associated with the molecular-weight characteristics of the objects. It is known that thermal cyclization of R-PAN is accompanied by release of low-molecular-weight thermal degradation products [59]. This is due to the broad MWD and to the presence of branchings in R-PAN chains. Therefore, the density of packing of R-PAN macromolecules upon precipitation from solution is low, and samples are oxidized more actively, which is reflected in the temperature and area of the exothermic peak. Structural features of A-PAN samples are responsible for their higher density and for the corresponding changes in thermal effects compared to R-PAN. The 3*D* ordering of A-PAN macromolecules is an additional factor responsible for the high packing density.

In solution, A-PAN macromolecules can be represented as double helices linked by a series of weak bonds betwen the cyano groups and α-H atoms, between the cyano groups of the adjacent chains, and sometimes between the naphtharidine rings [3, 13, 32]. These structural features of A-PAN lead to the predominant occurrence of the cyclization, compared to thermal degradation, which is reflected in the TG and DTA curves. Furthermore, the stereoblock structure of A-PAN is apparently responsible for the presence of two endothermic effects in the range 400–600°C, each of which reflects the melting of the iso- or syndiotactic block. R-PAN may also contain ordered blocks, but their size and relative content are considerably smaller than in A-PAN. As for the DTA curve of the C-PAN sample, the shift of the temperature maxima of its two endothermic peaks reflects the enhanced heat resistance of the cyclic stereoblocks formed in the course of the synthesis.

The pattern of low-temperature carbonization of PAN shows that the "diffusion factor" should be taken into account for structural rearrangements to occur in the direction of formation of new condensed structure. This factor, well known in the coal chemistry, is associated with the hindered escape of low-molecular-weight thermal degradation products from the area of thermochemical reactions. As a result, the degradation $\rightleftarrows$ cross-linking balance is shifted to the right.

The simplest way to obtain effect is to raise the weighed portion and density of the substance, and also the time of heat treatment in the isothermal mode. By so doing, it becomes possible to monitor more clearly the thermal phase changes in the PAN samples. The most pronounced pattern is observed with the A-PAN sample on keeping it for 10 h at 350°C. At this temperature, the exothermic process of A-PAN cyclization with the formation of the most oriented stereoblocks of the syndiotactic structure is complete. Because this process is charac-

ter-ized by the lowest activation energy, compared to isotactic A-PAN and R-PAN, prolonged heating at 350°C leads to gradual formation of segments of a turbostratic structure, which melt at 407, 443, and 489°C and are related to different steric orientations of the cyclic blocks formed in the polymer. At lower annealing temperatures, the block structure is formed incompletely, and heating to higher temperatures leads to degradation of strained cyclic blocks and to the progress of carbonization.

The role of the diffusion factor was revealed in measurements of the packing density. Irrespective of the PAN synthesis procedure, the packing density of a sample and its isolation from the oxidizing environment strongly affect the pattern of thermal effects in the samples tested. Some of the samples exhibit not only the growth of the energy of endothermic effects associated with quantitative characteristics of ordered areas, but also exothermic effects assignable to crystallization of the labile structure of the precarbonizate. It should be noted that the sample compaction leads to an increase in the coke number, compared to small powdered samples.

An additional indirect evidence for the structural rearrangement of PAN in the temperature range 400–600°C, with the formation of ordered turbostratic fragments, is provided by data on the structural polymorphism of coals in the same temperature range. According to X-ray diffraction data [11, 37], the maximum of the internetwork ordering is observed at 450–525°C, i.e., in the range of the plastic state of coals and formation of semicoke. As the temperature is raised to 700°C, the mutual ordering of networks forming the carbon structures is disturbed, and they undergo disorientation, which is followed at temperatures exceeding 1000°C by the repeated orientation on the level of graphitizing structures. The decrease in the internetwork ordering above 700°C is attributed to the "wedging" effect of the growing carbon networks, with the preservation of strong valence bonds between them through the irregular part of the structure, which prevents mutual ordering of the networks.

Thus, even in such a complex system as coking coals, there is a temperature zone of increased molecular ordering, in which ordered carbon structures with well-defined orientation parameters are formed. The coincidence of the temperature boundaries of this zone with the region of occurrence of the endo- and exothermic effects in PAN suggests a certain analogy between these processes.

The above-noted similarity between the low-temperature carbonization of PAN and structurization of coals supports the concept of polymer cocarbonization [60] via thermochemical reactions of two polymers to give carbon structures whose thermal characteristics differ from those of the starting compounds.

An additional evidence of the low-temperature structural rearrangement on the level of formation of transition states from the polymer macromolecule to nuclei of the oriented carbon structure is obtained by comparing the results of X-ray monitoring of the carbonization of poly-*p*-phenylenebenzoxazole and PAN [61]. It was noted in that study that a combination of the high heat resistance of a polymer with a sufficient homogeneity of the supramolecular structure provides smooth transition into polyaromatic oriented compounds, precursors of graphite-like formations.

Because pyrolysis of poly-*p*-phenylenebenzoxazole occurs at approximately 500°C and aromatic structures are accumulated at the same temperature, conditions are created for combination of sixmembered rings in a plane with 2*D* ordering. This structure has a high density and is characterized by regular alternation of denser carbon areas and less dense polycondensation areas of the initial polymer structure. Hence, the turbostratic structure of carbon arises before complete breakdown of crystallites in amorphous intercrystallite areas of polyoxadiazole. Similar conclusions were made for carbonization of hydrated cellulose and PAN. All these observations and conclusions confirm the existence of ordered polymer–carbon oriented formations whose thermal effects were recorded calorimetrically [58].

An additional valuable property of PAN is that it is possible to obtain different kinds of precursors by blending with other polymers, in the form of both fibers and composites with thermosetting plastics or castable thermoplastics for production of various articles. This field is being actively developed now on the basis of the suggested principles of cocarbonization of polymers [60], whose essence consists in performing thermochemical reactions in the temperature range of the maximal thermal activity of the components. In this case, the temperature boundaries of the thermal stability of the components should be close, and the process is performed under diffusion control, with prolonged heat treatment in the isothermal mode.

These studies were initiated by reports devoted to cyclization and carbonization of polyimides and their blends with nitrogen-containing poilymers

[62–66]. These studied revealed the occurrence of thermochemical reactions of intermediates formed by degradation and cross-linking of prepolymers with components of the polymer blend. Further development of cocarbonization studies is associated with an attempt to avoid technological and economic problems in the synthesis of polyimides and their compositions. For this purpose, we chose PAN as the most mastered and the cheapest heat-resistant synthetic polymer, meeting the cocarbonization requirements in a number of parameters. As the second component we used natural polymers whose resources are renewable or which are large-tonnage wastes from various branches of process industry.

In the PAN–natural polymer combination, synthetic heat-resistant PAN can act as a modifier of a natural polymer, improving its physicochemical characteristics. These studies were started with an analysis of the thermal compatibility of PAN with chitin and chitosan [68, 69]. It was shown that PAN interacts most efficiently with chitin and chitosan in the temperature range 150–350°C. In this range, PAN undergoes thermal oxidative dehydrogenation and cyclization via nitrile groups, and the acetamido- and aminodeoxyglucopyranose rings in chitin and chitosan undergo active thermal degradation to give a wide range of low-molecular-weight oxygen- and nitrogen-containing compounds. It is difficult to follow in such reaction mixture the formation of new structures and to identify them. However, indirect evidence was obtained for certain changes in the thermochemistry of the forming composite system, relative to the initial components.

Experiments with cyanoethyl cellulose ethers as model compounds showed that the structure of the forming carbon residue is different from that of the residue formed from the initial polymers, and its amount exceeds the amount corresponding to the coke number of PAN. It was also found that, to improve the compatibility of the components, it is desirable to perform the thermochemical cocarbonization in blend films prepared from combined solutions of the components in an aprotic polar solvent. Preliminary joint solvation based on the formation of interpolymeric complexes in the temperature range of PAN cyclization (230–300°C) gives cocarbonization products in 70–80% yield at 800°C. The composite films have high strength, well comparable with that of PAN (breaking stress 48–65 MPa, breaking elongation 1.5–2.7, Young's modulus 3000–3500 MPa) [69]. As for cocarbonization with PAN of certain grafted cellulose ethers [59, 70], the role of PAN consists in an appreciable enhancement of the heat resistance of the composite and in an increase in the coke number as compared to the cellulose ethers taken separately. In turn, the products of the initial thermal degradation of cellulose derivatives make the onset temperature of PAN cyclization lower by 50–60°C. The gas medium also plays an important role in the cocarbonization of PAN with hydroxyethyl, allyloxyethyl, and allyloxycarbonylmethyl cellulose ethers, affecting the thermal cross-linking in the self-generated atmosphere. The highest coke number reaching 55–60% was obtained with graft copolymers carbonized in CO_2.

Along with cellulose derivatives, it is of interest to use another natural polymer genetically closely related to cellulose, lignin. The first attempt to perform cocarbonization of lignin with PAN was made in [71]. Already the first experiments with powdered samples revealed a catalytic effect of thermal degradation products of lignin on the kinetics of thermal stabilization of PAN. Introduction of limited amounts of PAN into lignin enhanced its heat resistance in an inert atmosphere in the range 200–300°C. Carbonizates of PAN–lignin blends differ in their characteristics from carbonizates of the polymers taken separately.

CONCLUSIONS

(1) The carbonization of polyacrylonitrile is a permanent competition of the thermal degradation the and cross-linking in all the steps of thermochemical transformations.

(2) The mechanism of carbonization of macromolecular compounds and the properties of the final carbon products depend on numerous factors governing the structure and properties of carbonizates. The main of these are the procedure for preparing the initial polymer, heat treatment conditions, presence of additional compounds in the sphere of thermochemical reactions, and, as a rule, specific features of the process for preparing carbon materials.

(3) The overwhelming majority of studies have applied purposes and do not allow unambiguous conclusions on the actual mechanism of polyacrylonitrile carbonization under "pure" experimental conditions.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Chemical Stability of Beryl and of the Product of Its Mechanical Activation against Sulfuric Acid

Received May 23, 2007

Abstract—Effect of the concentration of sulfuric acid used for beryl sulfatization, degree of beryl grinding, temperature and duration of beryl sulfatization, and other technological parameters of sulfuric acid decomposition on the extent of beryl recovery was studied. The results obtained made it possible to suggest a method for preparation of beryl concentrates for sulfatization. The method is based on a mechanochemical activation of this kind of raw materials and can serve as an alternative to the conventionally employed beryl activation techniques.

DOI: 10.1134/S1070427208060025

Of all the industrially used beryllium minerals, beryl is the most resistant to sulfuric acid and other chemical reagents. Only hydrofluoric acid reacts to a hardly noticeable extent with beryl at ordinary temperatures [1]. An X-ray diffraction analysis of beryl demonstrated that it contains discrete ring ions $Si_6O_{18}^{12-}$ symmetrically surrounded by Be^{2+} ions (coordination number 4) and Al^{3+} (coordination number 6). The metal ions are fully screened by the silicate rings [3], which accounts for the chemical inertness of the mineral.

Beryl reacts with sulfuric acid very slowly, but the reaction can be noticeably accelerated under certain conditions. For example, the reaction of beryl with concentrated sulfuric acid at 400°C in an autoclave can transfer up to 50–60 wt % of beryllium into a water-soluble form in several hours [4]. The reaction is accelerated in the presence of fluoride, which presumably occurs under the action of the forming hydrogen fluoride. Because published data on the rate of the reaction between beryl and sulfuric acid and on the extent of this process are unavailable, it is impossible to assess the advisability of direct industrial sulfatization of beryl. Therefore, the rate of the reaction between beryl from beryl concentrates and sulfuric acid taken in various concentrations was studied.

Eleven batches of beryl concentrates from Malyshevskoe and Zavitinskoe deposits were used in the study (Tables 1 and 2). Analysis of the data in Table 2 shows that, compared with the Zavitinskoe concentrates (batch nos. 5 and 7), the Malyshevskoe concentrates (batch nos. 1–4, 6, and 8) contain a substantially larger amount of calcium (by a factor of ~4); a several times larger amount of iron, manganese, and chromium; a noticeably larger amount of aluminum (by ~15 wt %), and a noticeably smaller amount of silicon (by ~30 wt %).

Decomposition of the beryl concentrate with concentrated sulfuric acid. A weighed (~105 g) portion of the concentrate from batch no. 1 (Tables 1, 2) was ground in a vibration grinder for 30 min and processed by the scheme using the following technological procedure (see scheme). Sulfatization: initial weighed portion of the concentrate 100 g, expenditure of 93% sulfuric acid 0.8 ml g^{-1} concentrate (cake), T = 250–300°C, and duration 5 h (with the reaction mass agitated with a spar every 30 min in the course of sulfatization); leaching: s : l = 1 : (4–6) (in terms of the starting concentrate), T = 95°C, and duration 20 min (with the slurry volume maintained constant in the course of leaching by permanent addition of distilled water); neutralization of the slurry to pH 3.0–3.5 (with

* Batch nos. 1–4, 6, 8–11, Malyshevskoe concentrate; nos. 5 and 7, Zavitinskoe concentrate; batch no. 4 is an ore-sorting concentrate with a grain size of 5 mm (analyzed upon a preliminary grinding in a mortar), and other batches, flotation concentrates.

Scheme of laboratory processing of the Malyshevskoe concentrate.

a 8–10% ammonia solution); 1st washing of the cake with a 5% ammonium sulfate solution acidified with sulfuric acid to pH 3.0–3.5, s : l = 1 : 7 (in terms of the starting concentrate), T = 95°C, and duration 15 min; 2nd washing of the cake with a 5% ammonium sulfate solution acidified with sulfuric acid to pH 3.0–3.5 in the mode used in the 1st washing.

The results of pilot studies (Table 3) show that the sulfuric acid decomposition of the beryl concentrate provides an, on average, 23% recovery of beryllium into solution in each stage of the multistage process, with the four-stage sulfatization of the concentrate resulting in a beryllium recovery into a sulfate solution of 65.4 wt % (Table 3). Extrapolation of the dependence of the extent of beryllium recovery into solution on the sulfatization time (Fig. 1a) enables prognostication of its complete transfer into solution after a 70-h multistage sulfatization of beryl.

Decomposition of the beryl concentrate with dilute sulfuric acid. In this set of experiments, sulfuric acid solutions with concentrations of 85, 77, 73, 71, 70, 69, 68, and 61 wt % were used. Prior to sulfatization, 27–105 g of the Malyshevskoe concentrate (Tables 1, 2; batch no. 1) were ground in

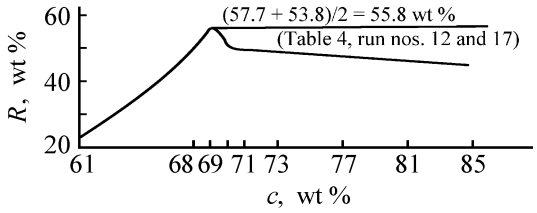

Fig. 2. Estimate of the extent R of beryllium recovery with sulfuric acid in relation to its concentration c. τ_{sulf} = 5 h.

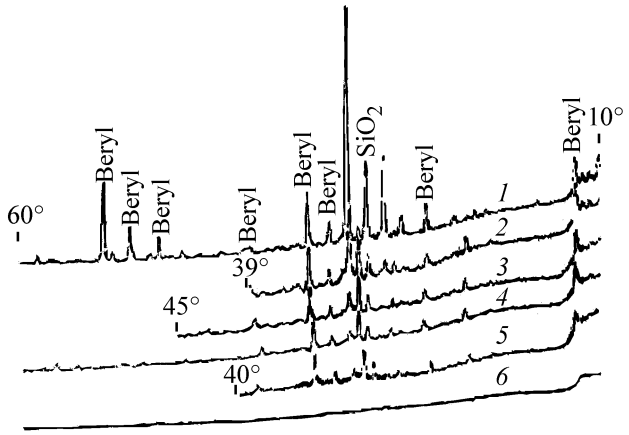

Fig. 3. X-ray diffraction patterns of a beryl concentrate (reflection angles 10°–60°) mechanically activated for varied intervals of time. (*1*) Without grinding; grinding: (*2*, *3*, *4*, *5*) in a vibration grinder for 0.5, 2.5, 5.0, and 7.5 h, respectively; (*6*) in a planetary mill for 0.5 h.

a vibration grinder for 30 min. The ground product was processed in one to five decomposition stages in the following technological mode. Sulfatization: initial weighed portion of the concentrate 20–100 g, expenditure of a sulfuric acid solution 20 ml g^{-1} concentrate (cake), and duration 5 h; further by the above scheme: leaching, slurry neutralization, 1st washing of the cake, and 2nd washing of the cake.[1] It follows from the results obtained in the experiment (Fig. 2) that the optimal sulfuric acid concentration providing the maximum decomposition rate of beryl is 69 wt % (Fig. 2). The industrially acceptable decomposition of beryl with 93% sulfuric acid requires 50–70 h (Fig. 1a), and that with 69% sulfuric acid takes only 17–25 h.

[1] The sulfatization of the concentrate (cake) was performed at the boiling point and continuous agitation of the slurry, with its initial volume maintained by addition of a sulfuric acid solution of the corresponding concentration. After the sulfatization was complete, the slurry was diluted 3-4-fold (by volume) with distilled water and filtered. The filtered-off cake was leached and processed in accordance with the technological mode.

The presently achieved extent of the sulfuric acid decomposition of beryl is 55 wt %, with the mineral sulfatized with a concentrated sulfuric acid in an autoclave during several hours. The study demonstrated that the same extent of decomposition (55.8 wt %) is reached in 5 h of sulfatization under atmospheric pressure if sulfuric acid of the optimal concentration (69 wt %) is used (Table 4, Fig. 2).

The possibility of raising the extent of beryl dissolution (Table 1, 2; batch no. 1) by preliminary mechanical activation of the beryl concentrate on a laboratory vibration grinder and a planetary mill was studied. Table 5 and Fig. 3 present results of a morphological and an X-ray structural analyses of a concentrate mechanically activated during varied time. Despite that the average particle size of the concentrate almost does not decrease after 30 min of mechanical activation on a vibration grinder, the crystal lattice of the minerals being ground progressively disintegrates during 7.5 h of mechanical activation. With the planetary mill used, the crystal lattices of the minerals in the concentrate disin-

tegrate to an even greater extent already after 30 min of its mechanical activation. A weighed portion (25 g) of a concentrate ground in a vibration grinder for 2.5 h was dissolved in boiling 69% sulfuric acid in accordance with the technological procedure described above. The results obtained are listed in Table 6 (run no. 1), which presents for comparison data (run no. 2) on dissolution of a concentrate ground in the vibration grinder for 0.5 h (see Table 4, run no. 12). On making longer the time of mechanical activation of the concentrate (from 0.5 to 2.5 h), the extent of beryl dissolution was raised by 10 wt % (from 57.7 to 67.8 wt %).

The positive effect of the mechanical activation of the beryl concentrate (Tables 1, 2; batch no. 1) on the extent of its dissolution in 69% sulfuric acid was also demonstrated in a set of experiments in which the expenditure of the acid was 375 ml g^{-1} concentrate, and the duration of its dissolution, about 13 h (Table 7). Raising the activation time of the concentrate from 2.5 to 5h, and further to 7.5 h provides an increase in the statistical-average extent of dissolution of the raw material from 73 to 78 wt %, and further to 81 wt %, respectively. It also follows from the data in Tables 6 and 7 that, by making the sulfuric acid dissolution of the concentrate ground for 2.5 h longer (from 5 to ~13 h) and the expenditure of sulfuric acid larger (from 20 to 375 ml g^{-1} concentrate), the extent of dissolution can be raised by 5 wt % (from 68 to 73 wt %).

The next state of the study consisted in testing the furnace variant of sulfatization of a mechanically activated beryl concentrate.

Use of dilute sulfuric acid. The dependence of the extent of decomposition with 69% sulfuric acid of a Malyshevskoe concentrate mechanically activated in a planetary mill on the duration of its activation was studied. The concentrate (Tables 1, 2; batch nos. 1–3, 6, and 8) was mechanically activated in the mill, with the crystal lattice of beryl disintegrated (Fig. 3). Weighed portions of the activated concentrate (18–37 g) were treated with sulfuric acid taken in an amount of 1.85 g per gram of the concentrate. The reaction mass was kept for 5 h at 250–300°C in a glassy graphite cup with a fluoroplastic cover, with a single agitation. After a high-temperature treatment, the reaction mass was processed in the standard mode (leaching, neutralization, twofold washing of the cake with an aqueous ammonium sulfate solution acidified with sulfuric acid).

Despite the conversion of the crystal lattice of beryl to the X-ray-amorphous state after 30 min of mechanical activation of its concentrate in the planetary mill (Fig. 3), the disintegration of the beryl crystal in such a short time is commonly not sufficiently complete for subsequent recovery from the concentrate of considerable amounts of beryllium with sulfuric acid. It was found that considerable amounts of beryllium contained in the concentrate (75–96 wt %) can be recovered with sulfuric acid from a mechanically activated concentrate if the duration of the mechanical treatment is no less than 50 min. Therefore, all the subsequent experiments were performed with the Malyshevskoe concentrate activated for 50–80 min.

Use of concentrated sulfuric acid. The mechanically activated concentrate was sulfatized with 93% acid, which makes lower the corrosion of the equipment. In some experiments, the mechanically activated material was separated into a fine and a coarse fractions (–10 and –45 μm) by air classification in a laboratory exhaust box. Weighed portions of the mechanically activated material (grain size –45 μm) and of its fine fraction (grain size –10 μm) isolated by air classification were treated with 93% sulfuric acid. The resulting reaction

mass was processed in the standard mode (leaching, neutralization, twofold washing of the cake).

It was found (Table 8) that the sulfatization duration strongly affects the extent of decomposition of the activated concentrate only on being raised from 0.5 to 5 h: the statistical-average Be recovery from the activated concentrate into solution increases by approximately 32 wt % (from 53 to 85 wt %). Raising the sulfatization time further, from 5 to 10 h, almost does not improve the extent of decomposition of the activated raw material at all, because the statistical-average recovery of beryllium from the concentrate into solution increases by only 0.4 wt % (from 85.3 to 85.7 wt %). Thus, the interaction of sulfuric acid with the activated concentrate nearly completely ceases after 5 h of sulfatization, which is accounted for by the formation of a layer of reaction products on the surface of particles of the activated beryl. These products are metal (beryllium, aluminum, iron, lithium, calcium, magnesium, etc.) sulfates, which hinder penetration of sulfuric acid molecules deeper into particles of the activated beryl. This conclusion is confirmed by the results of a large number of experiments on multistage decomposition of the Malyshevskoe concentrate not subjected to activation (Tables 3, 4). In these experiments, beryllium could be nearly completely recovered from cakes produced in sulfuric acid decomposition of the concentrate, because the passivating layer of sulfates was removed to a considerable extent from the reaction surface of particles of the material being decomposed.

The necessity for continuous renewal of the reaction surface of the material being decomposed in the course of its sulfatization was confirmed not only for the Malyshevskoe beryl, but also for products of its mechanical activation (Table 9). Comparison of the data in Table 9 shows that, by renewal of the reaction surface of particles of the mechanically activated beryl, the statistical-average recovery of beryllium into solution could be raised by approximately 7 wt % (from 85.8–

86.5 to 92.6–93.9 wt %). Almost the same efficiency of beryl decomposition was achieved by using the method of mechanical activation of the Malyshevskoe concentrate, which consists in combining the processes of mechanical activation and sulfatization of this raw material and provides the complete, to the maximum possible extent, renewal of the reaction surface of the activated beryl in the course of its sulfatization. The procedure used in this experiment included a mechanical activation of the concentrate in a planetary mill, followed by treatment with 93% sulfuric acid in a porcelain mortar and subsequent mechanochemical activation of the raw material (grinding of the concentrate with a porcelain pestle in the presence of the acid for 1.5 h at $T \approx 100$°C). In the process, the mixture, slurry-like at the beginning of grinding, became pasty by the end of the process, which indirectly points to a sufficiently high intensity of the sulfatization reaction. To complete the sulfatization of the concentrate, the thus activated material was kept at 250–300°C for 5 h, with agitation every 1–2 h. The resulting reaction mass was processed in the standard mode. After the 1st decomposition state, the dried cake was repeatedly decomposed in the mode used in the 1st stage of decomposition of the starting mechanically activated concentrate. The results of the two-stage decomposition of the mechanically activated concentrate with grinding of the reaction mixture are listed in Table 10.

The method used in the experiment for renewal of the reaction surface of particles of the mechanically activated concentrate provided a decomposition of the concentrate in the 1st stage by, on average, 93 wt %. After additional decomposition of the waste cake, the overall recovery of beryllium into solution increased to 94 wt %.

To further improve the extent of beryllium recovery from a mechanically activated beryl concentrate, experiments on its decomposition with a mixture of sulfuric and low-grade (as regards silicon) (waste) hydrofluoric acid were carried out. Weighed portions (30.8 g) of the concentrate were activated in a planetary mill for 70 min. The activated material (–45 μm) was treated with 93% sulfuric acid and ground with a pestle in a porcelain mortar for 1 h at $T \approx 100$°C (sulfuric acid expenditure 2.6 ml g^{-1} concentrate). Then, hydrofluoric acid was added to the reaction mass (0.2 ml g^{-1} concentrate) and the mixture was ground in a mortar at 110–120°C for 1 h. After that, the following procedure was repeated five times: the reaction mixture was kept in a porcelain mortar closed with a cover for 10 min at 200–250°C and then was ground for 10 min at 110–120°C. Further, the reaction mass was kept for 5 h at 250–300°C in a glassy graphite cup (closed with a cover), with the reaction mass ground in a porcelain mortar at 110–120°C 40 and 60 min after the beginning of the 5-h sulfatization. After 5 h of keeping, the sulfatized material was ground in a mortar for 30 min at 50–60°C, with approximately 50 ml of water added. The resulting reaction mass was processed in the normal mode. The results obtained are listed in Table 11.

CONCLUSION

The use of the mechanical activation of the beryl concentrate in the course of its sulfatization and leaching of the sulfatized material, increase in the sulfuric acid expenditure, and use of hydrofluoric acid in the sulfatization stage made it possible to raise the statistical-average recovery of beryllium into solution to 94 wt %.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Conversion of a Langbeinite Suspension to Schoenite

M. V. Karpets and I. Yu. Kostiv

Carpathian Stefanik National University, Ivano-Frankivsk, Ukraine
State Research Institute of Halurgy, Kalush, Ivano-Frankivsk oblast, Ukraine

Received October 3, 2007

Abstract—Conversion of a langbeinite suspension into a schoenite suspension was studied in relation to the preparation temperature of the former, time, and amount of added water. The optimal conditions of the process for obtaining schoenite with a K_2O content exceeding 30% and chlorite content lower than 1.5% were found.

DOI: 10.1134/S1070427208060037

Halurgic processing of polymineral potassium ores involves evaporation of an excess schoenite solution and formation of a finely dispersed langbeinite, which, contained in synthetic kainite, is separated and added to a saturated solution formed in leaching of potassium-magnesium minerals in the ore [1]. Langbeinite is also formed on mixing synthetic kainite with this saturated solution at temperatures exceeding 70°C. Because of the partial dissolution of potassium chloride and kainite, a part of NaCl precipitates from the saturated solution. This part can be separated, together with sodium chloride coming with synthetic kainite, and the finely dispersed langbeinite suspension can be used to crystallize schoenite. Synthesis of a finely dispersed langbeinite suspension from the components of the synthetic kainite and the saturated solution, with separation of the coarsely crystalline sodium chloride, and conversion of this suspension, upon cooling, to a schoenite suspension can be used as an efficient way to raise the yield of schoenite and improve its quality.

EXPERIMENTAL

The effect of various factors on the conversion of langbeinite to schoenite was studied. This process occurs in accordance with the equation

$$K_2SO_4 \cdot 2MgSO_4 + 13H_2O \rightarrow K_2SO_4 \cdot MgSO_4 \cdot 6H_2O + MgSO_4 \cdot 7H_2O.$$

A mixture of a saturated solution formed in dissolution of a polymineral potassium ore in water [2] and a synthetic kainite of composition (wt %): kainite 65.6, sylvite 12.2, and halite 22.2, was heated under permanent agitation to 90–110°C for 30 min. In this case, the components of kainite are converted to give finely dispersed langbeinite by the equation

$$2[KCl \cdot MgSO_4 \cdot 3H_2O] + MgSO_4 \rightarrow K_2SO_4 \cdot 2MgSO_4 + MgCl_2 + 6H_2O.$$

The conversion results in binding of magnesium sulfate from the liquid phase into langbeinite and in an increase in the solubility of potassium chloride. Sodium chloride remains undissolved in the suspension of finely dispersed langbeinite and can be easily separated from this suspension by hydroseparation. The langbeinite suspension synthesized at 90–110°C was decanted from the NaCl precipitate and cooled to 20°C under permanent agitation, with the liquid and solid phases sampled at certain intervals of time and the samples analyzed by using the procedures accepted in halurgy [3]. The mineral composition of the solid phases was determined on a personal computer (PC) by special software. The results obtained in calculation of the mineral composition of the solid phases are shown in Fig. 1.

It can be seen in Fig. 1 that the conversion is practically complete in 30 min. At 100°C, the content of schoenite in the solid phase of the suspension is lower than that at 90°C, which is due to the transfer of a part of sulfate compounds into the precipitate separated by decantation. This precipitate contains (wt %): sylvite 0.9, kainite 27.5, and halite 71.6 at 100°C; and sylvite 1.3, kainite 22.1, and halite 76.6 at 90°C. The content of sulfate ions in the liquid phase at 100°C is lower than that at 90°C: 7.69 and 10.41%, respectively. On cooling the langbeinite suspension obtained at 90°C to 20°C, the composition of the liquid phase of the schoenite suspension in 120 min was as follows (wt %): K^+ 3.66, Mg^{2+} 3.92, Na^+ 3.21, Cl^- 15.11 and SO_4^{2-} 6.22. For the langbeinite suspension produced at 100°C, this composition was the following (wt %): K^+ 3.92, Mg^{2+} 4.06, Na^+ 2.83, Cl^- 14.9 and SO_4^{2-} 6.59. This points to a more complete recovery of K^+, Mg^{2+}, and SO_4^{2-} ions into schoenite from solution. At 90°C, a larger amount of NaCl can be separated, compared with 100°C, and the solution contains in this case a larger amount of sulfate. Consequently, the content of schoenite in the precipitate formed on cooling to 20°C will be higher.

It should be noted that, on cooling the langbeinite suspension synthesized at 110°C to 20°C, the solid phase contains no schoenite: in 120 min, the solid phase of the suspension is composed of 6.7 wt % sylvite and 93.3 wt % halite. This occurs because the langbeinite suspension formed at 110°C is rapidly clarified, langbeinite is separated together with the NaCl precipitate, NaCl and KCl dissolve in the resulting clarified solution owing to the low concentration of sulfates, and predominantly potassium chloride crystallizes from this solution upon cooling.

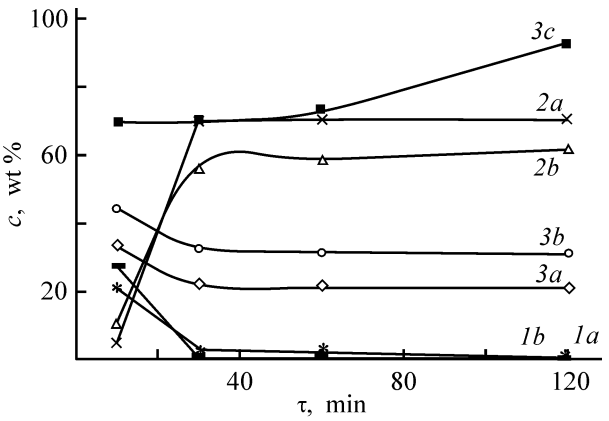

Fig. 1. Mineral composition c of the solid phase of the schoenite suspension vs. the process duration τ for different temperatures of synthesis of the langbeinite suspension. Temperature (°C): (*a*) 90, (*b*) 100, and (*c*) 110. (*1*) langbeinite, (*2*) schoenite, and (*3*) halite.

Table 1 lists the degrees of recovery of the main components of the langbeinite suspension into schoenite. The degree of recovery, α, was calculated from the material balance data obtained with a PC, using the formula

$$\alpha = \frac{m_1 c_1}{m_2 c_2 - m_3 c_3}.$$

Here m_1 is the mass of the precipitate after the precipitation and conversion; c_1, concentration of a component in question in the solid phase; m_2 and m_3, masses of the solid and liquid phases of the langbeinite suspension; and c_2 and c_3, concentrations of the component in the solid and liquid phases of the langbeinite suspension, respectively.

It can be seen from Table 1 that a higher recovery of the components into schoenite is achieved for the langbeinite suspension obtained at 100°C.

Table 1. Degree α of recovery into schoenite of the components of the langbeinite suspensions obtained at different temperatures

τ, min	α, wt %, at indicated temperature, °C					
	90			100

60	43.7	18.6	51.4	47.9	20.2	48.8
120	46.6	20.0	50.6	48.8	20.4	50.4
180	42.6	17.9	51.3	51.2	21.7	53.9

Table 2. Changes in the mineral composition of the solid phase obtained on cooling the langbeinite suspension

Composition	Content, wt %, at indicated temperature, °C					
	100	60	50	40	30	20
Langbeinite	54.7	19.2	3.1	0.2	1.8	1.1
Sylvite	–	–	–	34.5	26.2	21.6
Halite	3.7	78.9	96.5	64.0	39.6	30.3
Leonite	–	–	0.4	1.4	–	–
Schoenite	–	–	–	–	32.5	47.0
Kainite	41.6	1.9	–	–	–	–

Therefore, the langbeinite suspension for further studies was produced at this temperature.

To reduce the energy expenditure, the possibility of synthesizing langbeinite at lowered temperatures was studied. The suspension was produced by mixing a saturated solution obtained upon dissolution of the ore with synthetic kainite at 50°C, agitating the mixture for 30 min, and separating by decantation of a coarsely crystalline precipitate of the following mineral composition (wt %): kainite 14.2, halite 84.7, and sylvite 1.1. The finely dispersed solid phase obtained has the composition (wt %): kainite 37.5, leonite 1.3, and halite 61.3. This means that the temperature of 50°C is insufficient for conversion of the components of synthetic kainite to langbeinite, with leonite produced and the suspension containing a large amount of kainite separated together with sodium chloride in decantation. As a result, the separated NaCl precipitate is contaminated by impurities.

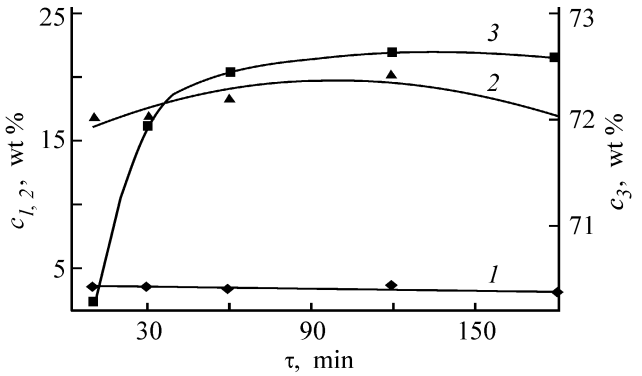

Fig. 2. Mineral composition c vs. the time τ in which the schoenite suspension is obtained after the separation of NaCl at 50°C. (*1*) Schoenite, (*2*) halite, and (*3*) langbeinite.

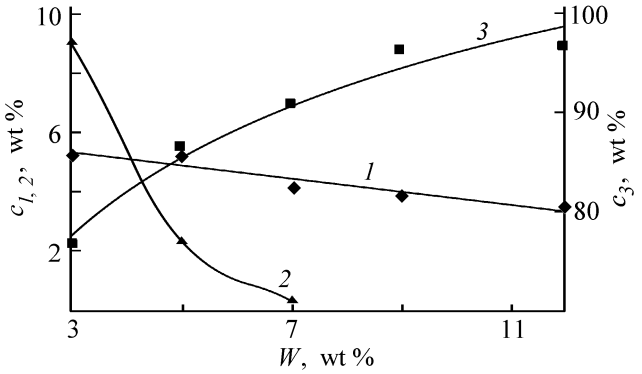

Fig. 3. Contents of langbeinite (c_1), halite (c_2), and schoenite (c_3) in the schoenite suspension vs. the amount W of water added. (*1*) Langbeinite, (*2*) halite, and (*3*) schoenite.

To find the optimal temperature for the conversion of the langbeinite suspension to a schoenite suspension and to reach the maximum yield of schoenite, the process was studied at 60–20°C, with the mineral composition determined with a PC (see Table 2).

It can be seen from the data presented that, when the suspension is cooled to 50–40°C, a small amount of leonite crystallizes, with a stable solid phase, schoenite, crystallizing at lower temperatures. At 50°C, the concentration of halite is the highest and, because it is a coarsely crystalline mineral, it is easily separated by decantation. Therefore, the langbeinite suspension synthesized at 100°C was cooled stepwise, with separation of NaCl at 50°C and subsequent cooling to 20°C. In this way, the NaCl content of the precipitate can be reduced to 16.7 wt %, with its schoenite content raised (Fig. 2).

In synthesis of schoenite, water is bound from solution into a crystal hydrate, which favors additional crystallization of NaCl. To obtain schoenite without an admixture of sodium chloride, water was added in an amount of 3 to 12 wt % to the suspension from which NaCl was separated and the mixture was agitated at 20°C for 120 min. The results obtained are shown in Fig. 3. It can be

seen that, upon addition of water, the content of halite decreases from 9.06 to 3 wt % as the content of water increases from 0.3 to 7 wt %. To obtain schoenite without admixture of chlorides, 7–9 wt % water should be added in the course of crystallization to the suspension after the separation of NaCl, with the content of K_2O, MgO, and chlorine in terms of dry substance being 30.4, 14.1, and 1.4%, respectively.

CONCLUSIONS

(1) The highest degree of conversion of the components of the langbeinite suspension to the schoenite suspension in the range 90–110°C is achieved at 100°C.

(2) On cooling the langbeinite mixture, the highest content of halite in the coarsely crystalline phase is observed at 50°C, and it can be easily separated by decanting.

(3) Addition of 9 wt % water to the langbeinite suspension after the separation of NaCl yields schoenite with 96.2 wt % main substance (or 30.4% K_2O, 14.1% MgO, and 1.4% chlorine in terms of dry substance).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Interaction of Sulfate Solutions of Zinc with Natural Calcium Carbonates

A. M. Zhizhaev and E. N. Merkulova

Institute of Chemistry and Chemical Technology, Siberian Branch, Russian Academy of Sciences, Krasnoyarsk, Russia

Received July 5, 2007

Abstract—Precipitation of zinc from sulfate solutions onto carbonate rock was studied. The residual concentrations of zinc and the capacity of the precipitating agent were measured, and the mineral forms of zinc in the precipitate under various process conditions were determined.

DOI: 10.1134/S1070427208060049

Precipitation of zinc from waste water poses certain difficulties because of the low formation rate of its poorly soluble compounds. As a rule, alkalization of solutions to pH ≥ 8.5 (commonly 10–12) fails to provide parameters required by water protection regulations [1]. Reagent methods, e.g., precipitation of carbonates in treatment with carbon dioxide can diminish the residual concentration of the metal to 1–5 mg l^{-1} [2]. However, these methods yield strongly hydrated amorphous precipitates difficulty separated from solutions, with their subsequent peptization and dissolution possible, similarly to the case of hydroxides [1, 2]. The expensive and toxic reagents pose the question as to whether their use, additional purification of solutions, and utilization of precipitates are complete [3]. Because of the comparatively high cost of the reagents, use of inexpensive mineral raw materials or industrial wastes for precipitation is of large interest [3, 4]. For this purpose, various materials that form, when reacting with metals, compounds with low solubility products: phosphates, silicates, carbonates, have been studied [4–12]. Nevertheless, zinc is precipitated with the lowest efficiency, compared with other heavy metals, when wastewater is purified using, e.g., natural phosphates [5–7]. Natural calcium carbonates are widely used to treat wastewater [8–12], primarily for controlling its acidity. Also, their sorption capacity for heavy nonferrous metals has been noted [4, 9–14].

The precipitation on calcite was mostly studied on compact monomineral samples (Iceland spar) from dilute solutions saturated with CO_3^{2-}, i.e., in an alkaline medium under nearly equilibrium conditions [8, 9, 12, 13, 15, 16]. It was assumed that, at low zinc concentrations in a solution, the sorption is due to a direct exchange interaction Zn^{2+}/Ca^{2+} and to incorporation of zinc ions into the crystal lattice of calcite. As the concentration increases to the solubility limit, independent zinc carbonate phases are formed on the surface: smithsonite ($ZnCO_3$) or hydrozincate [$Zn_5(OH)_6(CO_3)_2$] [4, 9, 15, 16]. However, formation of these compounds or their hydrates has not been confirmed instrumentally because of their low concentrations, high dispersity, and low ordering of new formations [4, 9, 12]. The solubility of precipitates of this kind is lower than that of hydrozincate, but higher than that of smithsonite, which is also attributed to the disorder of their crystal lattice [9, 12, 13].

The aim of this study was to examine the precipitation of zinc and the composition of precipitates formed on carbonate rock at comparatively high concentrations of starting solutions, characteristic of wastewater from galvanic shops, and at predominance of the concentration of ions of the salt balance over the equilibrium concentrations of carbonate ions.

EXPERIMENTAL

To 1 l of a zinc sulfate solution was added, under permanent agitation in a glass vessel with a magnetic stirrer, a weighed portion (4, 6, or 10 g) of limestone or marble ground to 100% of the –0.074-mm fraction. The chemical composition

of the carbonatites is presented in the table. An analysis was made on a Siemens SRS-300 X-ray spectrometer (Germany). Solutions of prescribed concentration were prepared from $ZnSO_4 \cdot 7H_2O$ of analytically pure grade. The duration of an uninterrupted experiment was as long as 30 h. Samples of the solution (5 ml) were periodically taken for analysis. The content of zinc and calcium in the liquid phase was determined using a Perkin–Elmer AAnalyst-400 atomic-absorption spectrometer. An X-ray phase analysis of the precipitates was performed on a DRON-3 X-ray diffractometer (LOMO, Russia, $Cu_{K\alpha}$ radiation, point-by-point scanning with a step of 0.02 deg, accumulation time 1 s). Reflections in the X-ray diffraction patterns obtained were identified using the JCPDS file of reference powder spectra. The starting samples of carbonate rock are mostly composed of calcite ($CaCO_3$, JCPDS, 47-1743) with a minor admixture of quartz (SiO_2, JCPDS, 5-490).

Composition of carbonate rock used to precipitate zinc from sulfate solutions

Component	Content, wt %	
	marble	limestone
CaO	50.2	52.3
MgO	1.4	0.22
SiO_2	3.97	1.62
Al_2O_3	0.4	0.7
P_2O_5	0.5	0.25
Fe_2O_3	0.17	0.2
SO_3	0.0017	0.002
K_2O	0.057	0.052
MnO	0.017	0.009
Ni	0.001	0.002
Cu	0.0018	0.0015
Zn	0.0012	0.001
Sr	0.02	0.01

Figure 1a shows kinetic curves of zinc precipitation from aqueous sulfate solutions on limestone. The residual concentration of zinc in solution reached a value of 20–22 mg l^{-1} in 20 h and did not become lower even after 30 h of agitation in contact with limestone. An increase in the fraction of the solid precipitating agent does not lead to fuller precipitation of zinc. The time in which the limiting concentration is reached becomes somewhat shorter, but its value fluctuates

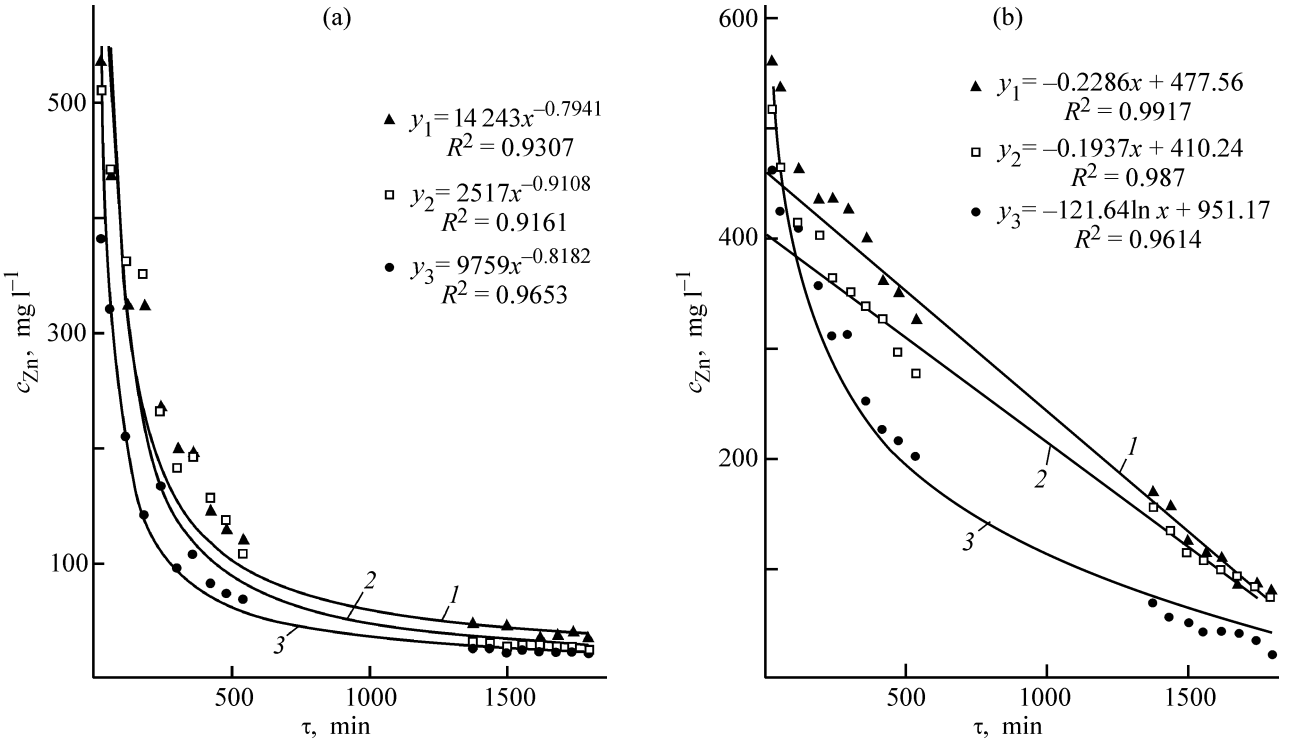

Fig. 1. Kinetic curves of zinc precipitation from a sulfate solution on (a) limestone and (b) marbled limestone. Initial concentration of zinc 1 g l^{-1}. (*c*) Metal ion concentration and (τ) time; the same for Fig. 2. Amount of the precipitating agent (g): (*1*) 4, (*2*) 6, and (*3*) 10; the same for Fig. 2.

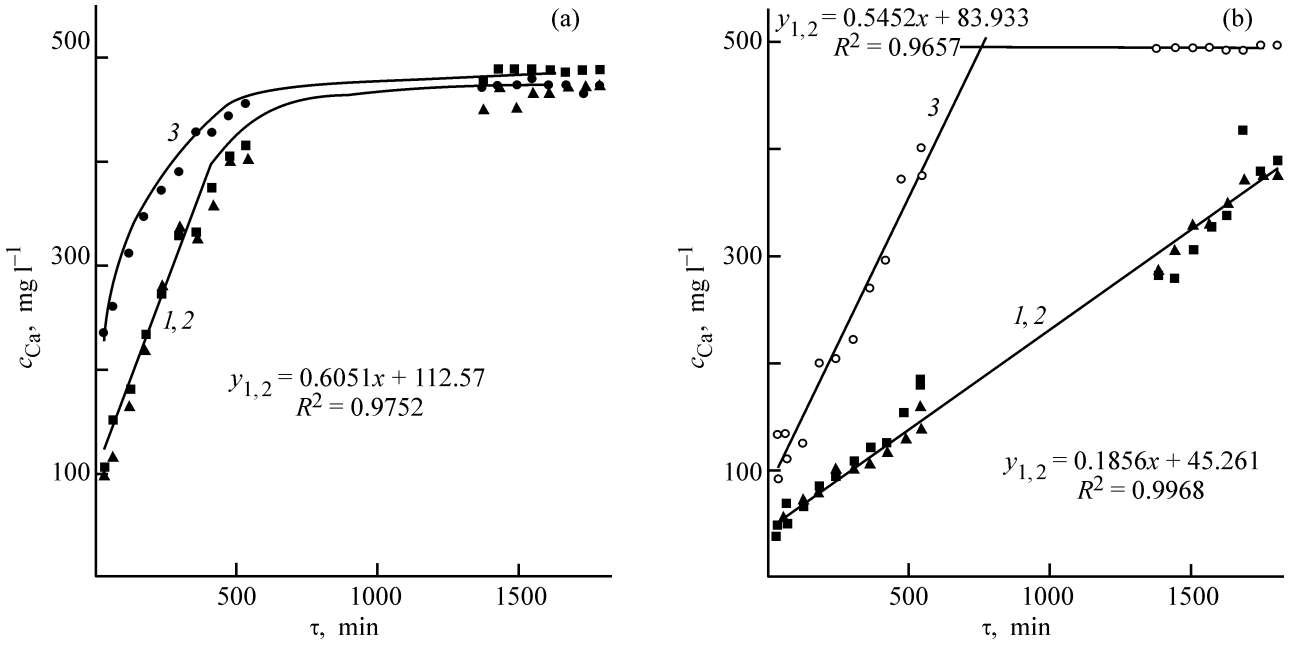

Fig. 2. Kinetic curves of calcium transfer into solution in zinc precipitation from sulfate solutions on (a) limestone and (b) marbled limestone.

within the same range, 18–20 mg l^{-1}. In the process, the concentration of calcium in solution rapidly grows to 400 mg l^{-1} during the first 10 h and then slowly increases to 450–480 mg l^{-1} and stabilizes at this level (Fig. 2a).

The precipitation on marbled limestone is substantially slower. For the weighed portions of 4 and 6 g, the process kinetics is practically linear after stabilization during the first 10 min (Fig. 1b). The residual concentration of zinc in solution is high (~100 mg l^{-1}). The concentration of calcium in solution also shows a nearly linear dependence on the keeping time and does not level out during the entire experiment (30 h) (Fig. 2b). Only when the weighed portion of the precipitating agent is raised to 10 g, a residual (after 30 h) zinc concentration of about 20 mg l^{-1} is reached. The calcium concentration in solution linearly increases during the first 10 h and reaches the limiting value of 495–498 mg l^{-1}.

The decomposition of calcite in solution neutralization or zinc precipitation in the exchange reaction yields large amounts of gypsum:

$$Zn^{2+} + SO_4^{2-} + CaCo_3 \xrightarrow{H_2O} ZnCO_3\downarrow + CaSO_4 \cdot 2H_2O\downarrow, \quad (1)$$

$$CaCO_3 + H_3O \xrightarrow{H_2O,\ SO_4^{2-}} CaSO_4 \cdot 2H_2O\downarrow + CO_2\uparrow. \quad (2)$$

The strong lines associated with gypsum are commonly recorded in X-ray diffraction patterns of precipitates (interplanar spacing d 7.56, 4.27, 2.86 Å; JCPDS, 6-46) in precipitation from solutions with sufficiently high concentrations (Fig. 3). At a more or less complete precipitation of zinc by the exchange reaction (1), the concentration of calcium in solution should, according to the salt balance conditions, approach 1 g l^{-1} or somewhat exceed this value with account of the neutralization of the acidity of the starting sulfate solution. However, the solubility of gypsum in water at room temperature (at an excess of gypsum in the solid phase) is not higher than 2 g l^{-1} [17]. It is this parameter that determines that the concentration of Ca^{2+} in solution does not exceed 0.5 g l^{-1} in a rather wide range of residual concentrations of zinc (19.4–120.7 mg l^{-1}). In this case, the acidity stabilizes at a level pH 6.75–6.8 and remains nearly unchanged till the end of the experiment, which is possibly due to formation of a gypsum carbonate buffer solution in the system during the first 10 h of tests [18].

A decrease in the initial concentration of zinc solutions to the solubility limit of gypsum results in that the line associated with gypsum disappears from X-ray diffraction patterns. However, the low concentrations of new formations and the strong lines of calcite taken in an excess hinder identification of weak, amorphous peaks of precipitation

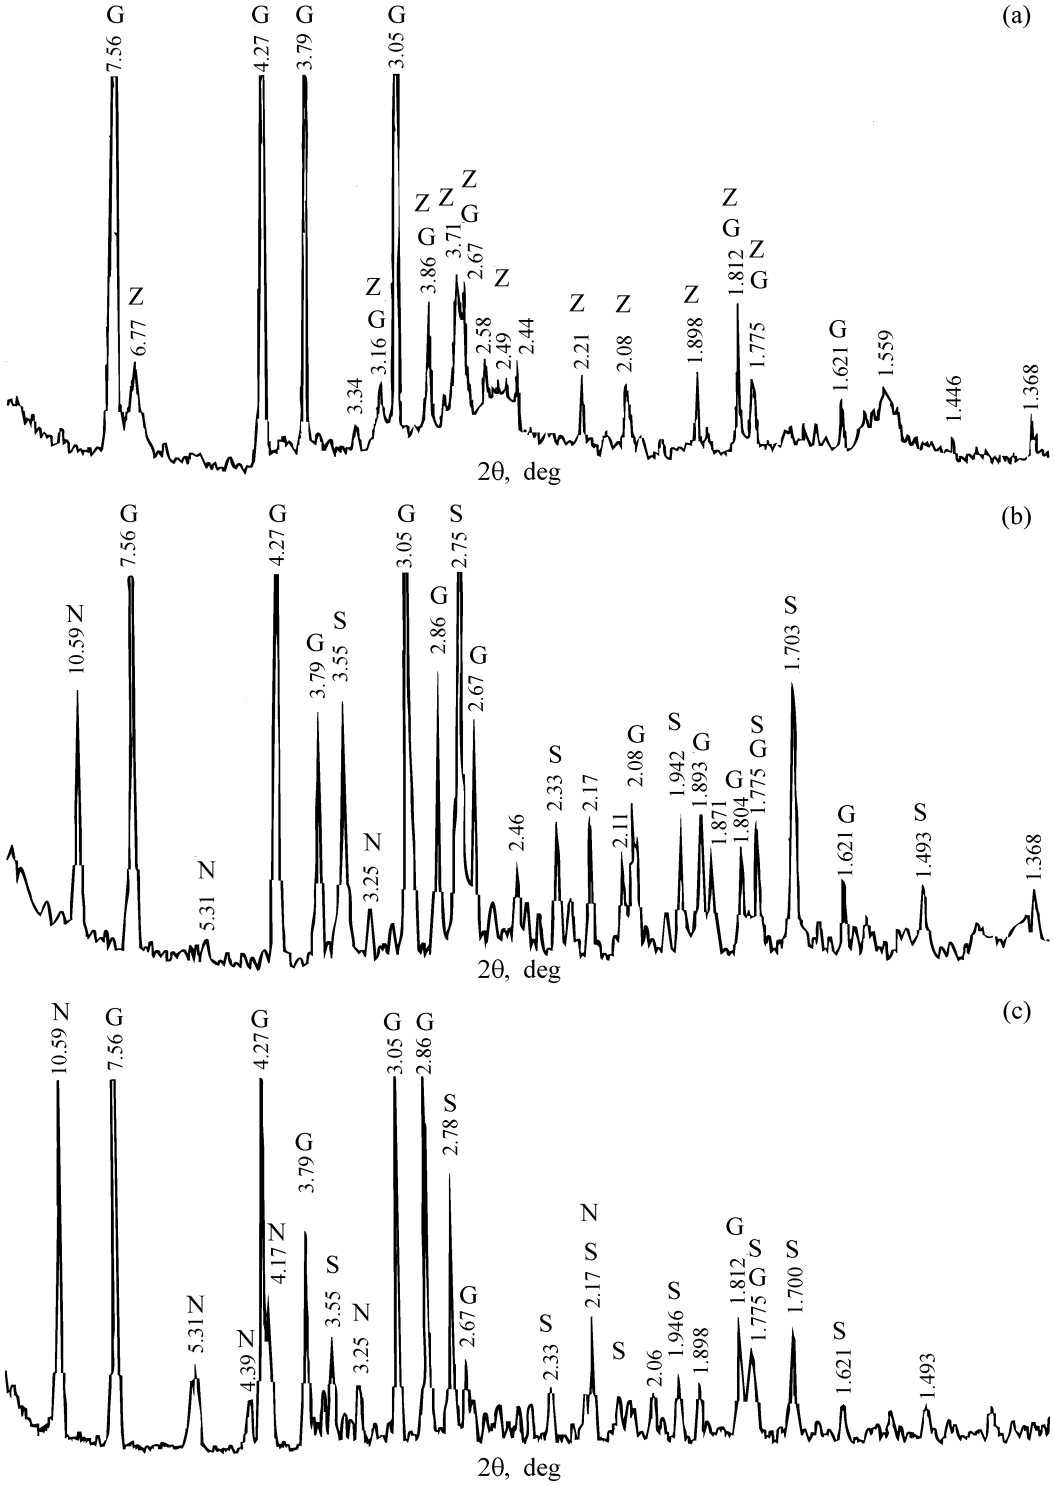

Fig. 3. X-ray diffraction patterns of products formed in precipitation of zinc from a sulfate solution on (a, c) limestome and (b) marble. Mineral phase: N, namuwite; Z, hydrozincate; G, gypsum; and S, smithsonite. (2θ) Bragg angle; interplanar spacings are given in angstroms. Initial concentration of zinc (g l^{-}): (a) 0.1 and (b, c) 1.0.

products. A detailed study of products of this kinds was performed using solutions with a comparatively high concentration of zinc (1 g l^{-1}), with an attempt to achieve a fuller use of the precipitating agent and accumulation of an as large as possible amount of new phases. The capacity of the precipi-

tating agent for zinc was as high as 0.7 g per gram of the starting calcite. However, it is more correct to speak about the coefficient of zinc fixation in the solid phase, rather than about the capacity, because calcite is nearly completely consumed in experiments aimed at the maximum degree of precipitation: its lines are not observed in the X-ray diffraction patterns of the products formed. The high value of this parameter points to the reagent mechanism of precipitation, rather than to ion exchange or simple sorption of zinc on calcite.

The X-ray diffraction patterns of the products formed in precipitation from dilute solutions or at low concentrations of the precipitating agent contain, in addition to lines of gypsum, broadened and "amorphized" lines of hydrozincite [$Zn_5(CO_3)_2(OH)_6$, *d* 6.77, 3.16, 2.71 Å; JCPDS, 19-1458] (Fig. 3a). In most cases, zinc is precipitated from dilute solutions to give just this mineral phase, in agreement with published data [4, 9, 13]. An increase in the content of the precipitating agent leads to precipitation of smithsonite ($ZnCO_3$, *d* 3.55, 2.75, 1.703 Å; JCPDS, 8-449) in a larger or smaller amount (Figs. 3b, 3c). Simultaneous presence of hydrozincate and smithsonite in noticeable amounts was not recorded in experiments. Zinc precipitates by one or the other pathway, without mixing of the mechanism of precipitate formation. Smithsonite is formed directly on calcite (topochemical reaction, large content of the latter) because of the close values of the lattice constants of these minerals (trigonal lattice with planar-axial symmetry). Hydrozincate is in all probability formed from solution similarly to gypsum, which can provide its crystals as nuclei of the new phase, because both the minerals are also crystallized in the same monoclinic crystal system. An indirect evidence that hydrozincate grows on gypsum is that the peaks common to these minerals, simultaneously present in precipitates (*d* 2.86, 2.67, 2.08 Å), are "amorphized" and their intensity decreases on the background of strong unoverlapped lines of gypsum (*d* 4.27, 3.79 Å) (compare Figs. 3a and 3b).

In addition, strong lines of a new phase with *d* 10.58, 5.31, 4.17, 3.25 appear in the X-ray diffraction patterns of precipitates. These lines best correspond to basic zinc sulfate, namuwite [$Zn_4SO_4(OH)_6 \cdot H_2O$, JCPDS, 35-528] (Figs. 3b, 3c). This phase is only formed when zinc precipitates as smithsonite and appears in amounts occasionally comparable with those of smithsonite. Not even trace amounts of this phase were found in the case of hydrozincate crystallization. The formation of basic sulfates has been observed in interaction of copper sulfate solutions with limestone [19]. Previously, formation of compounds of this kind has not been observed for zinc, and it has been disregarded in kinetic calculations [2, 9, 12, 13], although there have been reports that mineral associates of this composition are periodically found in oxidized zones of sulfide deposits of zinc. The infrequent occurrence of basic zinc sulfates is due to the lower solubility products of its carbonates [17] and, accordingly, to their predominant formation at lower CO_3^{2-} concentrations, compared with copper. Only under the conditions of rapid binding of the carbonate ion by zinc, the concentrations of the sulfate ion and the pH value become more favorable for formation of $ZnSO_4 \cdot 3Zn(OH)_2$, compared with $2Zn(CO_3)_2 \cdot 3Zn(OH)_2$. The precipitation of hydrozincate makes lower both the concentration of carbonate ions and the pH value, and, accordingly, the conditions favorable for namuwite formation are not created.

CONCLUSUIONS

(1) Calcite, the main component of natural calcium carbonates, can be successfully used to strongly diminish the concentration of zinc in wastewater. However, the residual concentrations of the contaminant after its interaction with carbonatites (18–22 mg l^{-1}) exceed the maximum permissible concentrations established by regulations for water of open water reservoirs, and additional treatment is necessary for final purification.

(2) Zinc is precipitated on calcite on the background of formation of considerable amounts of gypsum. Zinc is fixed in the solid phase as smithsonite $ZnCO_3$ or hydrozincate $2Zn(CO_3)_2 \cdot 3Zn(OH)_2$. Simultaneous presence of these minerals in noticeable amounts is not observed. In the case of smithsonite precipitation, considerable amounts of basic zinc sulfate $Zn_4SO_4(OH)_6$ are formed, which should be taken into account in calculations of the solubility of precipitates in the system constituted by a zinc sulfate solution and calcite.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Fluorination of Germanium Concentrates with Ammonium Fluorides

A. N. D'yachenko and R. I. Kraidenko

Tomsk Polytechnic University, Tomsk, Russia

Received September 20, 2007

Abstract—New method for processing of germanium-containing raw materials to obtain germanium oxide was suggested and studied. The method is based on the fluorination of germanium-containing raw materials with ammonium fluorides, followed by a sublimation isolation of ammonium hexafluorogermanate, its dissolution, and precipitation of germanium oxide from solution. The thermodynamics of the process was calculated and its thermogravimetric analysis was made. The kinetics of germanium oxide fluorination by ammonium hydrodifluoride was experimentally studied. A technological scheme for processing of germanium-containing raw materials with ammonium fluoride was suggested.

DOI: 10.1134/S1070427208060050

Proper minerals of germanium are very rare and form no commercial deposits. Germanium is obtained from the products formed in processing of zinc, copper-zinc, or lead sulfide ores, and also from coal combustion ash [1]. The technologies employed for germanium production are cost-intensive and ecologically unsafe. Pyrometallurgical processing of germanium-containing raw materials is commonly carried out at 800–1800°C in a reducing atmosphere. Germanium passes into the gas phase, from which a pure germanium product is further isolated [2]. There exists a hydrochloride acid method for processing of the germanium concentrate [3]. The resulting germanium tetrachloride is evaporated and further subjected to secondary distillation.

In this study, a new method for recovery of germanium oxide from germanium-containing raw materials with ammonium fluorides was suggested and analyzed. Previously, these have been reports [4–8] devoted to the fluoroammonium processing of certain types of mineral raw materials: zircon, ilmenite, beryl, etc. The fluoroammonium technologies for processing of mineral raw materials become increasingly topical because of the possibility of nearly complete regeneration of ammonium fluorides. It seems possible to create a completely closed cycle of fluoroammonium processing of raw materials, with recycling of the main and only reagent, ammonium fluoride or hydrodifluoride. The similarity of some physicochemical properties of germanium and silicon enables prediction of the behavior of its fluoroammonium complexes.

The thermodynamic probability of reactions between germanium dioxide and ammonium fluorides was calculated. Because of the absence of published thermodynamic data for the fluoroammonium complex of germanium, we assumed in the calculation that the fluorination of germanium dioxide by ammonium fluorides proceeds to give germanium tetrafluoride:

$$GeO_2 + 4NH_4F = GeF_4 + 4NH_3 + 2H_2O, \quad (1)$$

$$GeO_2 + 2NH_4F \cdot HF = GeF_4 + 2NH_3 + 2H_2O. \quad (2)$$

The results of the thermodynamic calculation are listed in the table.

Change in the Gibbs energy in the fluorination of germanium dioxide with ammonium fluorides

T, K	ΔG, kJ mol^{-1}, reactions	
	(1)	(2)
298	256.8	196
400	144.2	120.5
600	–75	–10.1
800	–292.8	–124.1
1000	–509.4	–225.7
1200	–725.2	–317.4

The calculated Gibbs energies suggest that the fluorination of germanium dioxide by ammonium fluorides at temperatures higher than 600 K proceeds in the forward direction. This reaction onsets already at 540 K and proceeds more completely as temperature increases further.

We carried out a thermal study of the hydrofluorination of germanium dioxide with ammonium fluorides. The experiments were performed on an SDT Q600 combined TGA/DSQ/DTA analyzer-derivatograph, with the data processed using the TA instruments Universal v4.2E software. Samples were heated at a rate of 5 deg min^{-1} in an air flow.

The thermograms of the reactions of germanium(IV) oxide with ammonium fluoride and hydrodifluoride are shown in Figs. 1a and 1b, respectively. Ammonium fluoride and hydrodifluoride were taken in a twofold excess with respect to the stoichiometry for the case in which ammonium hexafluorogermanate is formed in the reaction.

The reactions of germanium dioxide with ammonium fluoride and hydrodifluoride begin at 45°C to give a fluoroammonium complex of germanium, with gaseous ammonia and water released. In the case of the reaction with ammonium fluoride, peaks of its melting with decomposition are observed at 138°C, whereas in the case of ammonium hydrodifluoride, the peak of melting is observed at 126°C. These results completely agree with published data [8].

Upon further heating, ammonium fluoride and hydrodifluoride react with germanium dioxide. In this case, the DTA peaks coincide, with the difference in temperatures being less than 1%. All the processes occurring in the GeO_2–NH_4F and GeO_2–$NH_4F \cdot HF$ systems are identical. Heating of the mixture results in that the original fluoroammonium complex of germanium, $(NH_4)_2GeF_6 \cdot nNH_4F$, is formed and decomposes to $(NH_4)_2GeF_6 \cdot 2NH_4F$ at 170°C. Further, at 221°C, $(NH_4)_2GeF_6 \cdot 2NH_4F$ decomposes to $(NH_4)_2GeF_6$, which, in turn, decomposes to NH_4GeF_5 at 285°C. At 340°C, NH_4GeF_5 decomposes with evolution of gaseous ammonia, hydrogen fluoride, and germanium tetrafluoride. In all probability, the unsublimated part of germanium reacts with water vapor at 368°C to give germanium oxyfluoride.

The reactions of GeO_2 with NH_4F and $NH_4F \cdot HF$ are exothermic; the reactions of dissociation of germanium fluoroammonium complexes are endothermic.

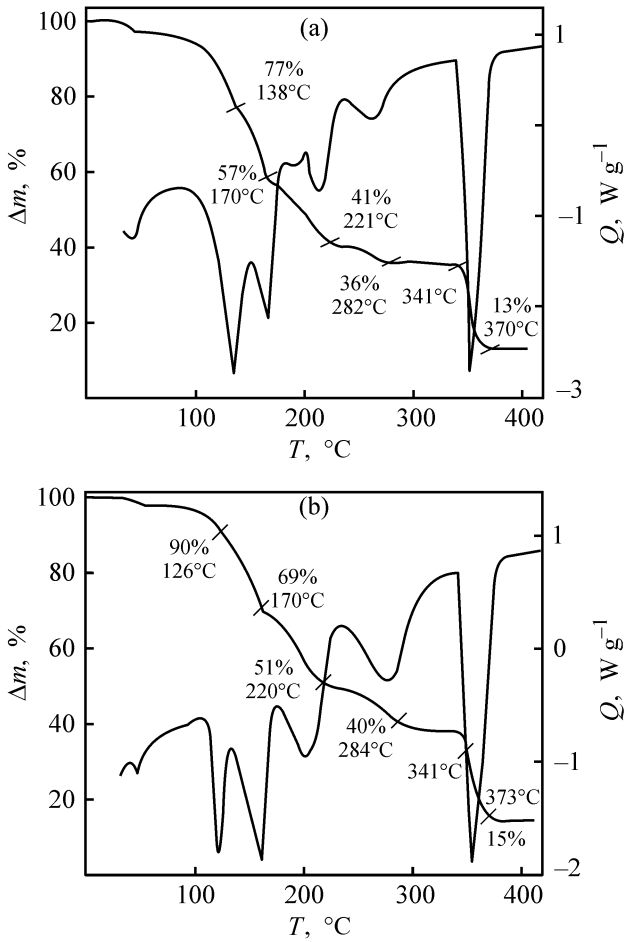

Fig. 1. TG and DTA curves for the reaction of germanium(IV) oxide with (a) ammonium fluoride and (b) ammonium hydrodifluoride. (m) Weight loss, (Q) heat flux, and (T) temperature.

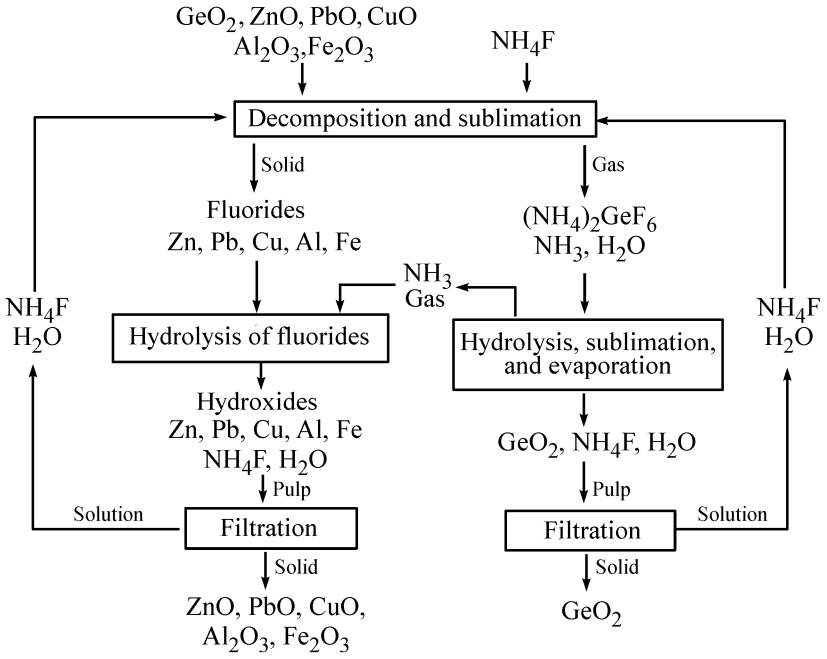

The stoichiometric composition of complex germanium fluorides was confirmed by quantitative analysis. A mixture of germanium oxide and ammonium hydrodifluoride was kept for 1 h at temperatures found by thermogravimetry, and the content of germanium in the resulting samples was determined.

The result of thermogravimetric measurements and quantitative chemical analysis suggest the following sequence of transformations:

$$GeO_2 + NH_4F \xrightarrow{126^\circ C} (NH_4)_2GeF_6 \cdot nNH_4F$$

$$\xrightarrow{170^\circ C} (NH_4)_2GeF_6 \cdot 2NH_4F \xrightarrow{220^\circ C} (NH_4)_2GeF_6$$

$$\xrightarrow{282^\circ C} NH_4GeF_5 \xrightarrow{341^\circ C} GeF_4 \xrightarrow{370^\circ C} GeF_2.$$

Scheme of the fluoroammonium cycle for processing of germanium-containing raw materials.

A kinetic study allowed us to determine the rate of germanium oxide transformation to ammonium hexafluorogermanate in a melt of ammonium fluoride. The experiment was carried out by the method of continuous weighing of the reacting mixture:

$$GeO_2 + 3NH_4F \cdot HF = (NH_4)_2GeF_6 + NH_3 + 2H_2O.$$

The conversion was determined from the weight loss caused by the formation of gaseous ammonia and water. Preliminarily, we experimentally determined the rate of ammonium fluoride decomposition at the same temperatures and the corresponding corrections were introduced into the final results.

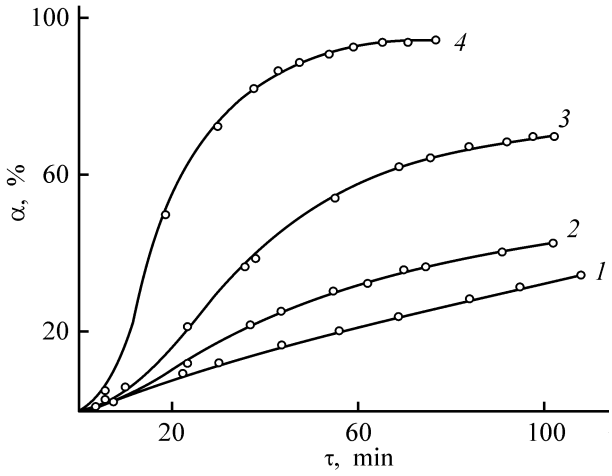

Fig. 2. Kinetic curves for the reaction of germanium dioxide with ammonium hydrodifluoride. (α) Conversion and (τ) time. Temperature (°C): (*1*) 140, (*2*) 160, (*3*) 190, (*4*) 240.

The time dependence of the degree of germanium oxide hydrofluorination by ammonium hydrodifluoride (Fig. 2) is described by the "contracting sphere" equation:

$$\alpha = 1 - \left(1 - 1.28\, e^{\frac{37\,800}{8.31T}}\tau\right)^3. \qquad (3)$$

The rate constant of the chemical reaction is 1.28 s^{-1}. The activation energy of the process is 37.8 kJ mol^{-1}. The process occurs in the transition region of reacting. The process rate is affected by temperature and stirring.

The thermodynamic, thermal, and kinetic analyses of the system under consideration, which confirmed the theoretical and laboratory possibility of performing the process, allowed us to pass to development of its technological scheme. Products formed in processing of copper-zinc ores were used as the starting germanium-containing raw material. The fluoroammonium cycle for processing of germanium-containing raw materials to germanium oxide, with recycling of ammonium fluoride, is shown in the scheme.

The starting germanium-containing ore concentrate was mixed with ammonium fluoride and

heated to 230°C. The germanium-containing concentrate entered into a reaction to give ammonium hexafluorogermanate, Cu(II), Zn(II), Pb(II), Al(III), and Fe(III) fluorides, with release of gaseous ammonia and water. When the hydrofluorination was complete, the resulting mixture of the fluorides was heated to 360°C. At this temperature, gaseous ammonium hexafluorogermanate $(NH_4)_2GeF_6$ and excess ammonium fluoride are distilled off. Thus, germanium oxide is removed from the mixture in the form of ammonium hexafluorogermanate.

The sublimated ammonium hexafluorogermanate was subjected to ammoniacal hydrolysis:

$$(NH_4)_2GeF_6 + 4NH_4OH = GeO_2 \cdot 2H_2O + 6NH_4F.$$

The resulting germanium oxide hydrate was filtered and dried. Thus, the aim of the study, specifically, GeO_2 isolation, was achieved.

The solution of ammonium fluoride can be used for fluorination of the following batch of a germanium-containing raw material. A solid residue formed upon fluorination, constituted by Cu(II), Zn(II), Pb(II), Al(III), and Fe(III) fluorides, can be subjected to ammoniacal hydrolysis for regeneration of ammonium fluoride. An important economical factor of the process is the possibility of regeneration of a larger part of ammonium fluoride.

CONCLUSIONS

(1) Thermodynamic calculations demonstrated that the reaction of hydrofluorination of germanium(IV) oxide by ammonium fluorides can be carried out at 600 K.

(2) Thermal analyses showed that germanium tetrafluoride is produced via stages of formation of fluoroammonium complexes, which successively decompose.

(3) It was demonstrated that the time dependence of the conversion for this process is described by Eq. (3).

(4) A technological sequence of the fluoroammonium cycle for processing of germanium-containing raw materials to germanium oxide was suggested.

Abstract—Mechanism of formation, nature of activity, and properties of species active in hydrogenation catalysis in systems based on $Pd(acac)_2$ and $LiAlH_4$ were studied. The effect consisting in activation of catalytic systems was observed and reasons for the modifying action of water were considered.

DOI: 10.1134/S1070427208060062

Catalysts of the Ziegler type [1] exhibit activity in various organic synthesis processes, among which the best known are poly-, oligo-, and dimerization of olefins and dienes [2–6], isomerization of alkenes [6–8], and hydrogenation of unsaturated compounds [6–11]. In our previous study of Ziegler-type systems based on $Pd(acac)_2$–$AlEt_3$, we revealed the microheterogeneous nature of the catalyst in hydrogenation of unsaturated compounds and demonstrated that the extremal type of the dependence of the specific activity, observed as the Al/Pd molar ratio grows, is due to a rise in the dispersity, increase in the fraction of reduced palladium, and change at the nature of the ligand shell [12]. The reason for the inhibition at large Al/Pd ratios is the adsorption of triethylaluminum on palladium nanoparticles. To obtain palladium nanoparticles exhibiting activity in hydrogenation catalysis it is necessary that, on the one hand, Pd(II) complexes should be reduced at a high rate and, on the other hand, the stabilizing ligands precluding growth and coagulation of particles should be sufficiently labile and be easily substituted by substrates in the course of the catalytic process.

Inorganic compounds, alumino- and borohydrides of alkali metals [13–15] are widely used as reducing agents, together with the conventional coreagents of Ziegler systems, organoaluminum compounds. It should be noted here that, in contrast to $NaBH_4$, lithium tetrahydroaluminate is more frequently used for selective reduction of organic compounds. Data on its use in hydrogenation catalysis and on properties of these catalysts are rather scarce [15, 16]. To find out how the nature of a reducing agent affects properties of palladium catalysts for hydrogenation, we studied here the catalytic system based on $Pd(acac)_2$ and $LiAlH_4$.

EXPERIMENTAL

We purified solvents (benzene, THF) and substrates by the standard procedures used for organometallic substances [17]. For deeper drying, benzene was subjected to an additional distillation over $LiAlH_4$ in a rectification column and stored in the atmosphere of argon in sealed ampules over 4A molecular sieves. Tetrahydrofuran was successively distilled, after removal of peroxides, over sodium, $LiAlH_4$, and benzophenone ketyl and stored in the atmosphere of argon in sealed ampules. The concentration of water, found by the Fisher method [18], was 1.1×10^{-3} M in benzene and 1.6×10^{-3} M in THF.

Palladium bisacetylacetonate was prepared by the procedure described in [19]. ^1H NMR spectrum (δ, ppm; solvent C_6D_6): 5.04 (s, 1H, CH), 1.76 (s, 6H, CH_3). IR spectrum (ν, cm^{-1}; solvent benzene): ν(C=O) + ν(C=C) 1560, 1516; UV spectrum (solvent benzene): ε_{330} = 10630 $M^{-1}\,cm^{-1}$.

Lithium tetrahydroaluminate $LiAlH_4$ (commercial) was used without preliminary recrystallization. A weighed portion of $LiAlH_4$ was dissolved in THF and the resulting solution was filtered in an inert atmosphere through a Schott filter. The $LiAlH_4$ concentration, found from the amount of hydrogen released in hydrolysis was about 95–98% of the theoretical value. ^{27}Al NMR spectrum (δ, ppm; solvent THF): 98 (quintet, $^1J_{Al-H}$ 173 Hz).

The catalytic hydrogenation was performed in a thermostated glass vessel of the "bedpan" type at 30°C and initial hydrogen pressure of 1 atm in the presence of a catalytic system formed in situ. To a solution of 0.01522 g (5×10^{-5} M) of $Pd(acac)_2$ in benzene, placed in a thermostated vessel, was added dropwise, in a flow of hydrogen, a $LiAlH_4$ solution in THF, and the reaction mixture was agitated for 5 min. The $LiAlH_4$/Pd ratio was varied from 0.5 to 30. The total volume of the solution was 10 ml. To the resulting black-brown "solution" was added a substrate hydrogenated under vigorous stirring at an initial hydrogen pressure of 1 atm, with monitoring by volumetry and GLC.

We studied the interaction of bisacetylacetonate with $LiAlH_4$ at different ratios of the starting components in dry deoxygenated argon in a thermostated vessel whose design envisages preliminary evacuation and filling with argon. The reaction was monitored by NMR (^{27}Al, ^7Li, ^1H) and UV spectroscopies, volumetry, and X-ray phase analysis.

The molecular hydrogen released in the reaction between the components of the catalytic system was quantitatively determined in a special thermostated vessel having an additional internal "pocket" for the second component. We placed a solution of 0.1522 g (5×10^{-4} M) of $Pd(acac)_2$ in 20 ml of benzene in a preliminarily evacuated, and filled with argon, thermostated vessel, and a solution of $LiAlH_4$ inTHF, in the internal "pocket" of the vessel. The vessel was closed with a Teflon stopper and the $LiAlH_4$ and $Pd(acac)_2$ solutions were mixed under vigorous agitation. The hydrogen formed was determined by volumetry. The solution was analyzed by UV spectroscopy: the amount of the reacted $Pd(acac)_2$ was calculated from the absorption band at 330 nm (ε_{330} =10630 $M^{-1}\,cm^{-1}$), and that of the forming $Al(acac)_3$, from the absorption band at 288 nm (ε_{290} = 43600 $M^{-1}\,cm^{-1}$). After the reaction was complete, the solvent was evaporated in a vacuum (two thirds of the volume) and pentane was added until a precipitate was formed. The black-brown precipitate was washed successively with THF and benzene in the atmosphere of argon and dried in a vacuum (30°C, 1 mm Hg). The samples obtained were stored in sealed ampules in argon.

We calculated the material balance of the reaction of $Pd(acac)_2$ with $LiAlH_4$ as follows. The reduction of $Pd(acac)_2$ involves two reducing agents, $LiAlH_4$ and aluminum formed in the course of the reaction. Knowing the concentration of $Al(acac)_2$ formed in the redox process

$$3Pd(acac)_2 + 2Al \rightarrow 3Pd + 2Al(acac)_2, \quad (1)$$

we can calculate the amount of Pd(0) reduced by Al(0). The difference between the total amount of reduced palladium and Pd(0) formed in the reduction by aluminum corresponds to the amount of palladium formed by the reaction

$$Pd(acac)_2 + 2LiAlH_4 \rightarrow Pd(0) + 2Li(acac) + 2/n[AlH_3]_n + H_2. \quad (2)$$

The volume of hydrogen evolved can be used to find the fraction of decomposed alane and the amount of aluminum involved in the formation of a substitutional solid solution with palladium.

The NMR spectra were recorded on a Varian VXR-500S pulse spectrometer. The chemical shifts of the ^{27}Al and ^7Li signals were measured relative to the external standards, 0.1 M solutions of $Al(NO_3)_3$ and LiCl. The chemical shifts of ^1H are given relative to tetramethylsilane. To prevent hydrolysis when recording ^{27}Al and ^7Li spectra, we sealed a solution under study in a quartz ampule 5 mm in diameter, preliminarily evacuated and filled with argon.

The X-ray phase analysis of the samples was made on a DRON-3M diffractometer with Cu_{K_α} radiation.

The reduction of $Pd(acac)_2$ by a freshly prepared solution of lithium tetrahydroaluminate at room temperature occurs in 1–2 min to give a black-brown solution exhibiting a comparatively low activity in hydrogenation catalysis. Even at the optimal reagent ratio $LiAlH_4$/Pd = 2, the catalytic activity of the system under consideration in hydrogenation of styrene does not exceed 30 moles substrate per mole of Pd per minute, which is considerably lower than that of palladium nanoclusters

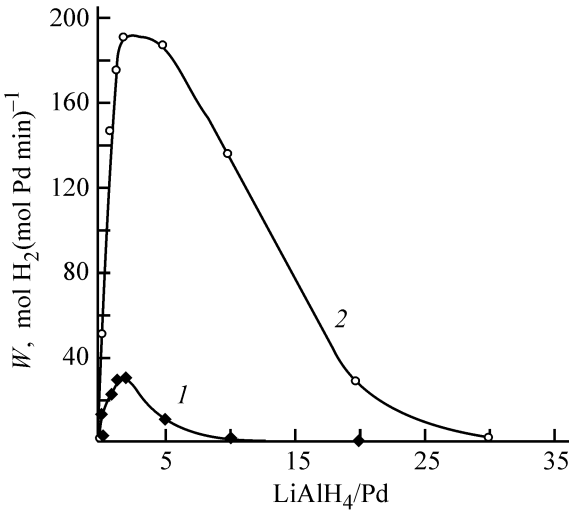

Fig. 1. Hydrogenation of styrene in the presence of the $Pd(acac)_2$–$LiAlH_4$ catalytic system (*1*) with a freshly prepared $LiAlH_4$ solution and (*2*) with that stored in an inert atmosphere for 24 h. c_{Pd} = 5 mM, [substrate]/$Pd(acac)_2$ = 170, solvent benzene, T = 30°C, P_{H_2} = 1 atm. (W) Catalytic activity.

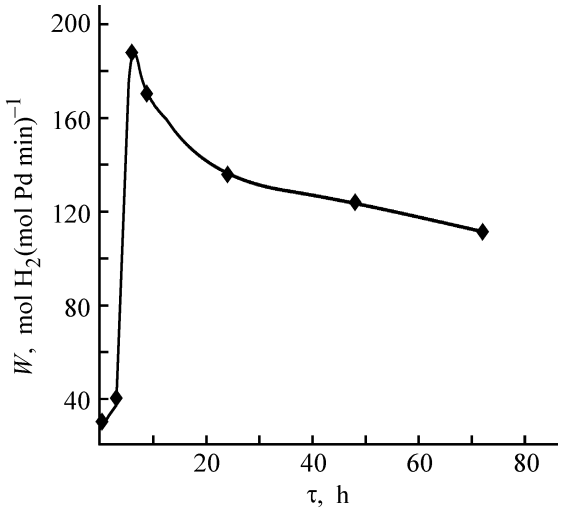

Fig. 2. Catalytic activity W of the system $Pd(acac)_2$–$LiAlH_4$ in styrene hydrogenation vs. the storage duration τ of a solution of the reducing agent. c_{Pd} = 5 mM, [substrate]/$Pd(acac)_2$ = 170, $LiAlH_4$/[Pd] = 1.5, solvent benzene, T = 30°C, P_{H_2} = 1 atm. (W) Catalytic activity.

formed in systems of the Ziegler type, including those promoted with phosphines [12] (Fig. 1).

The dependence of the specific activity on the ratio between the starting reagents is of an extremal nature, and, at $LiAlH_4/Pd \geq 10$, the hydrogenation rate falls to zero.

A study of the catalytic properties of the system $Pd(acac)_2$–$LiAlH_4$ revealed an interesting fact: the catalytic activity depends on the time during which a solution of a reducing agent is stored in the inert atmosphere in the reaction vessel (Fig. 2).

Using a $LiAlH_4$ solution 5–6 h after its preparation resulted in a steep rise in the activity of the $Pd(acac)_2$–$LiAlH_4$ catalytic system in hydrogenation of styrene (Figs. 1, 2) and other unsaturated compounds (Table 1). To find out the reason for the activation of the $Pd(acac)_2$–$LiAlH_4$ system and purposefully synthesize efficient palladium catalysts for hydrogenation, we studied the interaction between the starting components in an inert atmosphere.

In the reduction of $Pd(acac)_2$ with lithium tetrahydroaluminate, molecular hydrogen is released in an amount exceeding that calculated by Eq. (2) (Table 2).

The stoichiometric equation (2) reflects the most frequently occurring case of reduction of transition metals by $LiAlH_4$, in which the redox process comprises two stages: (i) exchange of the acido ligand for the AlH_4^- anion to give tetrahydroaluminates of transition metals and (ii) decomposition of tetrahydroaluminates of transition metals because of their instability at temperatures higher than –50°C

Table 1. Catalytic hydrogenation in the presence of the system $Pd(acac)_2$–$LiAlH_4$ (Pd concentration 5 mM, $LiAlH_4/Pd$ = 1.5, solvent benzene, T = 30°C, P_{H_2} = 1 atm)

to give the metal, alane, and molecular hydrogen [15]:

$$MX_n + nLiAlH_4 \rightarrow M(AlH_4)_n + nLiX, \quad (3)$$

$$M(AlH_4)_n \rightarrow M + nAlH_3 + n/2H_2. \quad (4)$$

It should be noted that no significant differences were observed between the volumes of hydrogen evolved with the use of a freshly prepared $LiAlH_4$ solution and that stored in an inert atmosphere for 24–28 h (Table 2). The supraequimolar release of molecular hydrogen in the reduction of $Pd(acac)_2$ with lithium tetrahydroaluminate indicates that alane formed in reaction (2) decomposes. Alane is a comparatively unstable compound, which quntitatively decomposes into elements at temperatures exceeding 100°C [20]. This process probably occurs at room temperature because of being catalyzed by the palladium clusters (nanoparticles) formed in the reduction:

$$[AlH_3]_2 \xrightarrow{Pd} 2Al + 3H_2. \quad (5)$$

It is known that highly dispersed powders of transition metals catalyze the decomposition of alane [15]. The catalytic decomposition of boranes by nanosize particles of transition metals in reduction with tetrahydroborates of alkali metals has been studied and described in the literature in sufficient detail [13, 14].

The reaction of $Pd(acac)_2$ with $LiAlH_4$ yields Pd(0) in an amount that exceeds, at $LiAlH_4/Pd \le 1$, the value calculated by Eq. (2) by nearly a factor of 2 (Table 2). Consequently, other reducing agents are involved in the redox process, together with lithium tetrahydroaluminate.

A monitoring of the reaction of $Pd(acac)_2$ with lithium tetrahydroaluminate by UV spectroscopy demonstrated that, together with a decrease in the intensity of the absorption band at 330 nm ($\pi \rightarrow \pi^*$ electron transitions in palladium complexes with chelate-bound $acac^-$ ligands), a strong absorption band peaked at 288 nm appears in the UV spectrum (Fig. 3).

* X-ray-amorphous substance.

It should be noted that the absorption band at 288 nm was recorded in the UV spectra of the $Pd(acac)_2$–$LiAlH_4$ reaction system at $LiAlH_4$/Pd = 0.5–2. At $LiAlH_4$/Pd = 5, 10, or 20, no absorption band at 288 nm was observed in the UV spectra. This absorption band is characteristic of acetylacetonate ligands of both lithium acetylacetonate (ε_{288} = 21 160 M^{-1} cm^{-1} in ethanol) and aluminum trisacetylacetonate (ε_{288} = 43600 M^{-1} cm^{-1} in benzene) [21]. However, assignment of the absorption band at 288 nm to lithium acetylacetonate is unlikely in the case in question, because this compound is insoluble in a benzene–THF mixture. If the given band corresponded to Li(acac), it would appear at any reagent ratio. Therefore, it was assumed that the absorption band at 288 nm belongs to acac ligands in $Al(acac)_3$. To verify this hypothesis, we subjected the white powder recovered from solution to analysis by NMR spectroscopy. The resonance signals of a solution of a sample under study in benzene-d_6 in the ^{27}Al (δ = 0 ppm) and ^1H spectra [δ = 5.38 ppm (s, 1H), 1.88 ppm (s, 6H)] correspond to $Al(acac)_3$ [22].

Thus, the reaction of $Pd(acac)_2$ with lithium tetrahydroaluminate yields $Al(acac)_3$ in addition to the products in Eq (2). The identification of $Al(acac)_3$ in the reaction system enables us to understand and explain the set of processes occurring in the reaction of palladium bisacetylacetonate with lithium tetrahydroaluminate by the following scheme: the first stage of the reaction of $Pd(acac)_2$ with lithium tetrahydroaluminate involves exchange of acac ligands for the AlH_4^- anion to give an unstable intermediate, $Pd(AlH_4)_2$ [Eq. (6), which decomposes to Pd(0), $[AlH_3]_n$, and molecular hydrogen [Eq. (7)]. The forming Pd(0) nanoparticles catalyze the decomposition of alane to give reduced aluminum [Eq. (8)]. Aluminum is, in turn, involved in a redox reaction with unreacted $Pd(acac)_2$ [Eq. (1)] at small $LiAlH_4$/Pd ratios ($LiAlH_4$/Pd ≤ 2), with the fraction of palladium in the reduced state increasing:

$$Pd(acac)_2 + 2LiAlH_4 \rightarrow Pd(AlH_4)_2 + 2Li(acac), \quad (6)$$

$$Pd(AlH_4)_2 \rightarrow Pd + 2/n[AlH_3]_n + H_2, \quad (7)$$

$$[AlH_3]_n \xrightarrow{Pd} nAl + (3n/2)H_2. \quad (8)$$

At high $LiAlH_4$ concentrations, mostly lithium tetrahydroaluminate acts a reducing agent.

Based on the above scheme and experimental data on $Pd(acac)_2$ conversion, hydrogen evolution, and $Al(acac)_3$ formation, we can calculate the degree of catalytic decomposition of alane and the fraction of aluminum involved in the redox process. The material balance data demonstrate that aluminum is not fully consumed in the redox reaction in accordance with Eq. (1), with a part of the metal remaining unreacted. For example, with a freshly prepared $LiAlH_4$ solution, the calculated amount of "free" Al(0) after the reduction of $Pd(acac)_2$ is 0.28×10^{-4}, 1.63×10^{-4}, and 2.3×10^{-4} mol of Al at $LiAlH_4$/Pd of 1, 2, and 5, respectively. The remaining aluminum can interact with Pd(0) to give palladium aluminides of various compositions [23] or solid solutions. To verify this assumption, we subjected catalyst samples produced as a result of $Pd(acac)_2$ interaction with a freshly prepared $LiAlH_4$ solution and that stored in an inert atmosphere for 24 h to an X-ray phase analysis (Table 3).

96	46	7	430	90	1 : 3.8

* Ratio of integral signals with δ = 98 (S_1) and 55 ppm (S_2).

The peaks in the X-ray diffraction patterns of the samples studied do not correspond to individual substances, palladium or palladium aluminides [24]. The reflections characteristic of palladium are shifted to smaller Bragg angles, toward reflections of aluminum. Because palladium and aluminum have close atomic radii (r_{Pd} = 1.37 Å, r_{Al} = 1.43 Å) and the same crystal lattice type, the increase in the interplanar spacings hkl of palladium (Table 3) may indicate that aluminum is incorporated into the palladium lattice to give a substitutional solid solution.

For catalyst samples produced by reduction of $Pd(acac)_2$ with a freshly prepared $LiAlH_4$ solution, the coherent-scattering region (CSR) calculated by the Selyakov–Scherrer formula [25] is somewhat larger that that in the case of a $LiAlH_4$ solution stored in an inert atmosphere. In both cases, an increase in the $LiAlH_4$/Pd ratio favors formation of finer catalyst particles.

It is known that addition of a second metal (Group 1B) to hydrogenation catalysts commonly improves their selectivity, but impairs the specific activity of the catalysts [26]. Probably, it is the presence of aluminum that is the main reason for the low catalytic activity in reduction of Pd(II) with a freshly prepared solution of $LiAlH_4$. It, however, remains unclear why the catalytic system is activated in storage of a solution of the reducing agent in an inert atmosphere.

To obtain additional information about the state of $LiAlH_4$ in solution and changes in this solution in the course of time, we used NMR spectroscopy on aluminum ^{27}Al and lithium ^{7}Li nuclei.

The ^{27}Al NMR spectrum of a $LiAlH_4$ solution in THF contains a single resonance signal with a chemical shift of 98 ppm, which is a quintet with a spin–spin interaction constant $^{1}J_{Al-H}$ of 173 Hz and lines with full width at half-maximum ($\Delta\nu_{1/2}$ ^{27}Al, FWHM) of 47 Hz (Fig. 4).

The region of the chemical shift observed is characteristic of the AlH_4^- anion (95–102 ppm) [27–29]. The multiplet structure of the spectrum is due to the scalar spin–spin interaction of equivalent protons with the aluminum isotope. It indicates that the tetrahedral configuration of the AlH_4^- anion is preserved in the THF solution. In the ^{7}Li spectrum, lithium tetrahydroaluminate is characterized by a singlet resonance signal with a chemical shift δ = –0.2 ppm. A ^{27}Al and ^{7}Li NMR monitoring of a solution of $LiAlH_4$ in THF in an inert atmosphere in a sealed ampule for 48 h did not reveal any changes (Table 4). At the same time, it can be seen from the ^{27}Al NMR spectra of a solution of $LiAlH_4$ in THF, stored in an inert atmosphere in

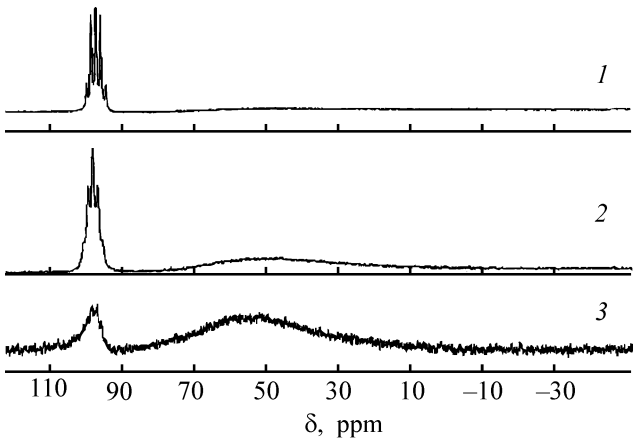

Fig. 4. ^{27}Al NMR spectra of a $LiAlH_4$ solution in THF stored in an inert atmosphere in an unsealed vessel for (*1*) 30 min, (*2*) 24h, and (*3*) 4 days. (δ) Chemical shift.

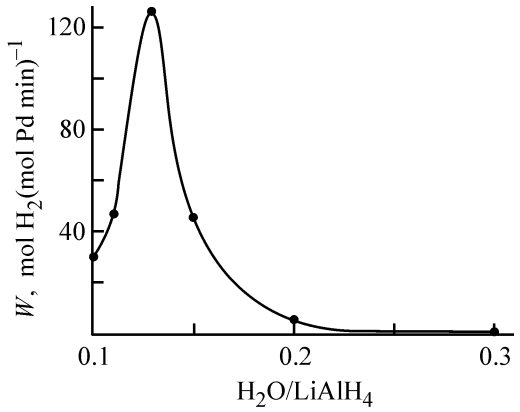
	$\Delta\nu_{1/2}$ ^{27}Al, Hz (δ = 98 ppm)	$S_1 : S_2^*$
0.1	77	1 : 0.2
0.5	108	1 : 0.3
2.0	120	1 : 0.4
24.0	291	1 : 1.6

* Ratio of the integral intensities of signals with δ = 98 (S_1) and 55 ppm (S_2).

the reaction vessel that, in the course of time, the FWHM of the lines ($\Delta\nu_{1/2}$ ^{27}Al) becomes narrower, intensity of the resonance signal with a chemical shift δ = 98 ppm decreases, and a new broad resonance signal with a chemical shift of 55 ppm appears and grows in intensity (Fig. 4, Table 4). An increase in FWHM ($\Delta\nu_{1/2}$ ^{7}Li) was also observed in the ^{7}Li spectrum. These facts indicate that the changes in the $LiAlH_4$ solution may be due to its interaction with reagents slowly diffusing from the environment, e.g., water and(or) oxygen. A contact with the $LiAlH_4$ solution with oxygen affects the spectral characteristics of the solution only slightly, whereas introduction of even small amounts of water (1/50 of the initial concentration of $LiAlH_4$) leads to observable changes in the NMR spectra (Table 5). In view of the aforesaid, we attributed the broad resonance signal with a chemical shift of 55 ppm to products of partial hydrolysis of $LiAlH_4$.



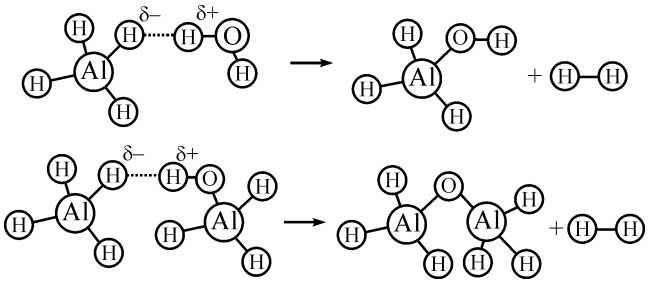


Fig. 5. Effect of water on the specific activity W of the $Pd(acac)_2$–$n$$LiAlH_4$ catalytic system in hydrogenation of styrene. c_{Pd} = 5 mM, [substrate]/$Pd(acac)_2$ = 170, $[LiAlH_4]/[Pd]$ = 2, solvent benzene, T = 30°C, P_{H_2} = 1 atm.

The width of the lines in the central component of the multiplet is affected by the following factors: distortion of the T_d symmetry of the AlH_4^- anion because of the nonequivalence of Al–H bonds in the tetrahedron in the formation of ion pairs, electric fields of the cations and dipoles of the solvent, and overlapping of the wave functions of AlH_4^- anion and other species [27]. If a ligand in the AlH_4^- anion is different in nature from the others, a multiplet structure from the EH_4^- anion will not appear in the ^{27}Al spectrum [28]. The observed increase in the FWHM ($\Delta\nu_{1/2}$ ^{27}Al) of the lines in the ^{27}Al spectrum of the $LiAlH_4$ solution is probably due to a distortion of symmetry in the environment of the aluminum atom, which may be due to its interaction with water or products of partial hydrolysis of $LiAlH_4$, followed by formation of polyoxo anions:

(the negative charge of the AlH_4^- anion and $Al_2H_6O^{2-}$ dianion is not shown in the scheme). The formation of complex compounds between the EH_4^- anion (E = Al, B, Ga) and proton-donor compounds was described in [30].

Catalytic experiments performed with preliminary addition of water to the lithium tetrahydroaluminate solution confirm the modifying effect of water on the properties of the $Pd(acac)_2$–$LiAlH_4$ system (Fig. 5).

Thus, it is the partial hydrolysis of $LiAlH_4$ that is the main reason for the observed differences in the behavior of the $Pd(acac)_2$–$LiAlH_4$ catalytic system. In the presence of small amounts of water, the reaction system simultaneously contains both $LiAlH_4$ and products of its partial hydrolysis, polyoxo anions. In this case, $LiAlH_4$, aluminum formed in decomposition of alane, and products of partial hydrolysis of $LiAlH_4$ will act as reducing agents. It is known that the reducing capacity of alkoxy

derivatives of lithium tetrahydroaluminates decreases as the number of substituted hydrogen atoms grows [31]. Therefore, on the one hand, with a partly hydrolyzed $LiAlH_4$ used, a larger part of aluminum formed in alane decomposition is consumed in the redox reaction (1). This is indicated by the increase in the $Al(acac)_3$ concentration in the case when a $LiAlH_4$ solution stored in an inert atmosphere is used (Table 2), i.e., a smaller part of reduced aluminum will be incorporated in the catalyst composition and will have an inhibiting effect. On the other hand, the redox reaction between $Pd(acac)_2$ and partly hydrolyzed $LiAlH_4$ will yield compounds of the type $[AlH_{3-x}(OH)_x]_n$:

$$Pd(acac)_2 + 2LiAlH_{4-x}(OH)_x \rightarrow Pd + 2Li(acac) + 2AlH_{3-x}(OH)_x + H_2, \quad (9)$$

rather than alane.

The catalytic decomposition of $[AlH_{3-x}(OH)_x]_n$ compounds in the presence of palladium can be represented as

$$2AlH_2(OH) \xrightarrow{Pd} H_2 + H(OH)Al{-}O{-}AlH_2. \quad (10)$$

In contrast to aluminum, the compounds being formed cannot poison the palladium catalyst because aluminum contained in these compounds is bound with oxygen.

One more reason for the promoting effect of water should be noted together with those already considered. The decrease in the particle size, observed, according to XPA, in the case when partly hydrolyzed $LiAlH_4$ is used, indicates that the polyoxo anions formed can effectively stabilize Pd particles by precluding their growth and coagulation.

CONCLUSIONS

(1) The formation and properties of the $Pd(acac)_2$–$LiAlH_4$ catalytic system in hydrogenation of unsaturated compounds was studied. It was shown that the reduction of $Pd(acac)_2$ with lithium tetrahydroaluminate is accompanied by catalytic decomposition of alane into hydrogen and aluminum. The aluminum formed reacts both with $Pd(acac)_2$, being converted to $Al(acac)_3$, and with Pd(0) particles to give a substitutional solid solution.

(2) It was demonstrated that the steep increase in the activity of the $Pd(acac)_2$–$LiAlH_4$ catalytic system in hydrogenation in storage of a solution of a reducing agent in an inert atmosphere is due to partial hydrolysis of $LiAlH_4$ and to a decrease in the fraction of the inhibitor, reduced aluminum, in the catalyst.

Abstract—Effect of modification of a layered aluminosilicate, montmorillonite, and rigid-structure kaolinite activated by sulfuric acid with solutions of magnesium chloride was studied in order to obtain sorbents for wastewater treatment to remove organic compounds.

DOI: 10.1134/S1070427208060074

Because of the wide use of adsorption technologies in the present-day development and modernization of various industries, it becomes an increasingly urgent task to create inexpensive and readily available sorbents. A problem that remains topical for extending the application range of sorption materials is the possibility of purposefully controlling the chemical structure of their surface layer and thereby of widely varying the adsorption-structural characteristics of adsorbents and improving their selectivity and multifunctionality.

The set of physicochemical properties of natural mineral sorbents is improved by their activation and modification. By the activation is commonly understood [1] the improvement of the sorption activity under any treatment of a material, and by modification, changes in the properties of sorbents, with their original structure preserved. In the present study, the adsorption properties of minerals were improved by activating samples with 20% sulfuric acid and modifying the activated samples with a magnesium chloride solution.

EXPERIMENTAL

As objects of study served two samples of natural silicates from a deposit in Lipetsk oblast, in which the rock-forming minerals are montmorillonite and kaolinite. Montmorillonite is a layered silicate material with an expanding structural unit. In montmorillonite, silicon in the tetrahedral layer is substituted by aluminum, and aluminum in octahedral positions is partly substituted by magnesium [2]. As a result, there appears charge deficiency compensated by interlayer ions having an exchange capacity. In natural montmorillonites, these are, as a rule, Na and Ca. The general crystallochemical formula of montmorillonite is $(Ca,Na)(Mg,Al,Fe)_2(OH)_2[Si,Al_4O_{10}] \cdot nH_2O$ [3, 4]. The montmorillonite clay used in the study contained 65 wt % rock-forming mineral, with halloysite (20 wt %) and vermiculite (15 wt %) the rest.

Kaolinite is composed of two-layered packets: one silica-oxygen tetrahedral layer of composition $[Si_{2n}O_{5n}]^{2n}$ and one aluminum–oxygen–hydroxyl octahedral layer of composition $[Al_{2n}(OH)_{4n}]^{2+}$. Both layers are combined into a packet by a hydrogen bond formed by oxygen ions of the silicon–oxygen layer and OH groups of the octahedral layer [3, 4]. The structural unit is "rigid," incapable of swelling. The composition of the sample under study was as follows (wt %): kaolinite 75, silicite 10, illite 5, and goethite 10 (with a trace amount of montmorillonite).

The acid treatment of the natural samples was performed by the following scheme: montmorillonite (kaolinite) with a grain size less than 0.5 mm was dried at a temperature of 130°C for 2 h. The dried material was mixed with 2.33 M sulfuric acid in a mass ratio of 1 : 3 and activated under permanent agitation and heating on a water bath. The resulting slurry was filtered with a vacuum pump through a filter made of synthetic fibers. The filter cake was washed with distilled water to pH 4 and dried

Table 1. Chemical composition of natural minerals

Component	Natural (native) mineral, wt %		Samples activated with 20% H_2SO_4,* wt %			
	montmorillonite	kaolinite	montmorillonite		kaolinite	
			MN_1	MN_6	MN_1	MN_6
SiO_2	56.2	49.0	60.2	69.7	55.4	59.4

* Time of treatment with sulfuric acid (h): $MN_1$and KN_1, 1; MN_6 and KN_6, 6.

to constant mass. As is known [5, 6], the duration of acid treatment is of key importance for the formation of adsorption properties and composition of the surface layer. Therefore, the samples used in the study were produced by treatment for 1 h (MN_1, KN_1), which provides an increase in the total exchange capacity, and for 6 h (MN_6, KN_6), which leads to a deeper structural transformation of the minerals and to an increase in the specific surface area and porosity of the material.

Samples subjected to the acid activation (MN_1 and KN_1) were treated with a 1 N magnesium chloride solution to obtain cation-substituted forms (MMg, KMg). The cation-substitution was performed at 55°C for 2 h, the filter cake was washed to trace amounts of Cl^- in the filtrate in terms of AgCl, with the Mg-form of the clayey mineral accordingly obtained.

The chemical composition was determined by X-ray fluorescence analysis on an SRM-25 multichannel X-ray spectrometer. The content of the exchange cations in the structure of the silicates was found using procedures described in [7, 8].

The adsorption-structural parameters of the minerals in the native and cation-substituted states were determined by the pycnometric [9, 10] and desiccator methods [9]; the capacity of the monolayer was measured using the procedure described in [9–11] and calculated by formulas reported in [9, 10].

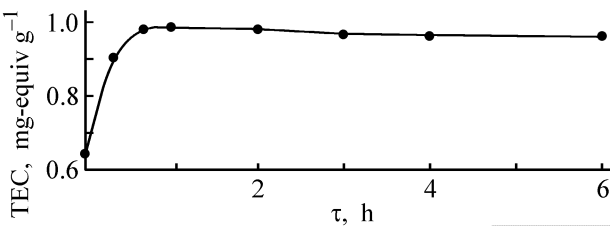

Fig. 1. Total exchange capacity of the samples, TEC, vs. the duration τ of acid activation.

The sulfuric acid treatment is a widely known method for activation of natural aluminosilicates. In numerous publications [1, 2, 5, 12], results obtained in a study of the influence exerted by the sulfuric acid concentration and treatment conditions on the surface adjustment of the minerals were reported. In the present study, the sulfuric acid activation of montmorillonite and kaolinite is only the first stage of preliminary treatment of the minerals to reach the total exchange capacity and obtain the homo-ion H-form. The modification process is the second stage, in which the unstable H-form obtained as a result of activation (for 1 h) is treated with a magnesium chloride solution to give a Mg-modified mineral (MMg, KMg). The adsorption-structural parameters of the Mg-forms of kaolinite and montmorillonite were compared with those of the minerals upon an activation for 6 h, which is the optimal duration for raising the adsorption activity of layered silicates [2, 12].

The kinetic dependence of the total exchange capacity of montmorillonite treated with a 2.33 M sulfuric acid solution is shown in Fig. 1. According to the data obtained, the optimal duration of the sulfuric acid treatment of the mineral is 1 h, in which case the TEC increases from 0.64 to 0.98 mg-equiv g^{-1}. A more prolonged treatment of the mineral with sulfuric acid leads to a slight decrease in TEC, by 0.03 mg-equiv in 6 h, which may be due to a certain instability of the H-form of aluminosilicates [5, 13]. Consequently, 1 h is the optimal time for activation of montmorillonite and synthesis of the homo-ion H-form.

The chemical composition of the minerals under study strongly changed on making longer the acid activation (Table 1). The content of free silicic

acid increases by 15–20%, and the amount of aluminum oxide decreases in montmorillonite by 17.6% as a result of ion exchange, and that of iron oxide, by 24% in montmorillonite and by 16% in kaolinite. The content of calcium oxide decreases by 55% in montmorillonite and 89% in kaolinite. The content of calcium oxide decreases more strongly in kaolinite, compared with montmorillonite, because calcium is situated in the interlayer space in montmorillonite and at the surface in kaolinite, which facilitates it reaction with the acid. The increase in the content of magnesium oxides (by 7% in MN_6) is due to the isomorphous substitution of aluminum in the octahedral network by magnesium [14].

The salt treatment of the H-forms of the minerals was performed with an excess of the magnesium chloride solution at a temperature of 40°C, with the modifier concentration varied from 0.003 to 0.5 M. The contents of the main components of the resulting forms of Mg-montmorillonite are listed in Table 2. An analysis of the results demonstrated that, at a concentration of the modifying solution equal to 0.003 M, the content of magnesium oxide in the structure of the mineral increases by 33.3%, and that of iron oxide, by 165%, with the amounts of aluminum and calcium oxides decreasing by 26 and 81%, respectively. An increase in the concentration of the $MgCl_2$ solution has nearly no effect on the content of Al_2O_3, SiO_2, and Fe_2O_3 in the mineral. The amount of CaO decreases by 58%, with the content of magnesium in the mineral increasing by 32% via ion-exchange processes whose intensity becomes lower as the concentration of the modifying solution is raised.

To study the adsorption-structural parameters, isotherms of water vapor adsorption-desorption at 25°C were experimentally obtained and the pore volume, monolayer capacity, and specific surface area were calculated (Table 3). The specific surface area increases to the maximum extent upon modification with $MgCl_2$, whereas the largest limiting sorption volume is formed upon a prolonged acid treatment of aluminosilicates. Thus, the higher sorption activity is indicated by a rise in the monolayer capacity, micropore volume, and specific surface area for Mg-samples, and by an increase in the mesopore volume for H_6-samples. Consequently, the maximum capacity is characteristic of MMg at low relative pressures, and of MN_6 at $p/p_s > 0.5$. A similar increase in the sorption activity is observed for kaolinite.

Table 2. Chemical composition of modified forms of montmorillonite

Modifier, M	Content, %				
	MgO	Al_2O_3	SiO_2	CaO	Fe_2O_3
MN_1	0.53	19.6	60.2	0.62	1.97
$MgCl_2$:					
0.003	1.77	16.47	54.65	0.12	3.25
0.03	1.92	16.61	54.09	0.08	3.71
0.1	1.97	17.07	53.39	0.09	3.71
0.3	2.05	15.92	51.72	0.07	3.03
0.5	2.07	16.13	53.74	0.07	3.23

Table 3. Adsorption-structural properties of activated (MN_1, MN_6, KN_1, KN_6) and modified (MMg, KMg) mineral*

Sample	V_s	V_{mic}	a_m, mmol g^{-1}	S_{sp}, m^2 g^{-1}
	cm^3 g^{-1}			
Montmorillonite	0.12	0.037	2.07	159
MN_1	0.16	0.036	2.00	153
MN_6	0.19	0.034	1.93	148
MMg	0.17	0.046	2.58	199
Kaolinite	0.08	0.018	1.05	80
KN_1	0.11	0.022	1.21	111
KN_6	0.12	0.017	0.94	114
KMg	0.11	0.027	1.51	114

* V_s is the limiting adsorption volume; V_{mic}, volume of micropores; a_m, monolayer capacity for water vapor at 25°C; and S_{sp}, specific surface area found from the isotherm for water vapor at 25°C by the BET method.

A characteristic feature of sorption isotherms on layered silicates (Figs. 2, 3) is their irreversibility in the whole range of relative pressures; the desorption curve does not coincide with the adsorption curve even at low p/p_s. The degree of irreversibility of the adsorption process on kaolinite is substantially lower because of the rigid structure of the rock-forming material and the smaller amount of ion-exchange cations in the structure.

The hysteresis at low pressures occurs because of the hindered desorption of water from the interpacket space, which is due to the hydration of the exchange cations and to the presence of narrow slitlike pores that hinder removal of water molecules.

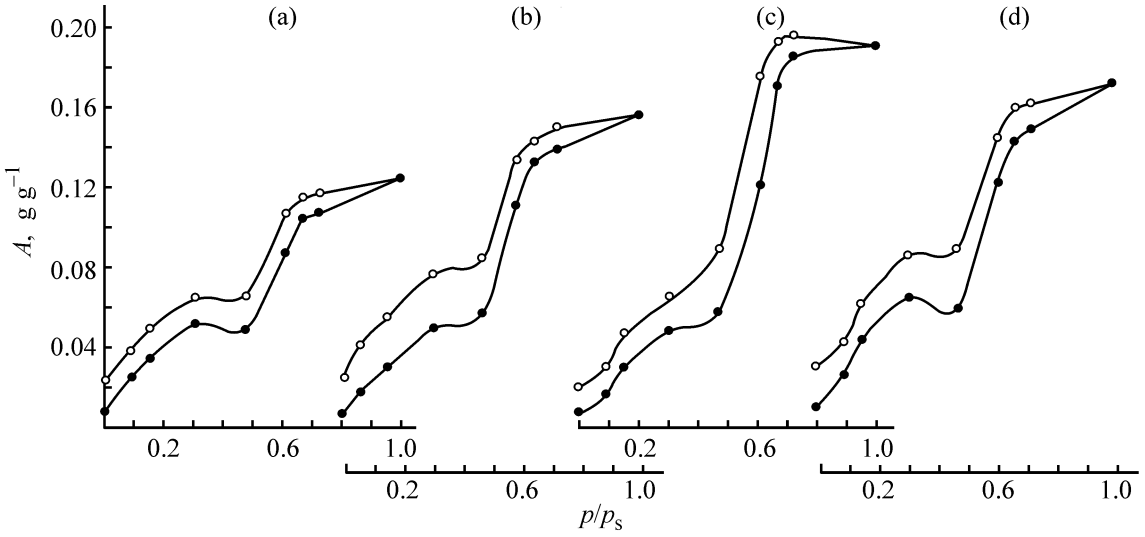

Fig. 2. Isotherms of sorption-desorption of water vapor at 25°C on natural and cation-substituted montmorillonite samples. (A) Adsorption capacity and (p/p_s) relative pressure; the same for Fig. 3. Form of montmorillonite: (a) starting M, (b) MN_1 (treatment with H_2SO_4 for 1 h), (c) MN_6 (treatment with H_2SO_4 for 6 h), and (d) MMg (treatment with a $MgCl_2$ solution).

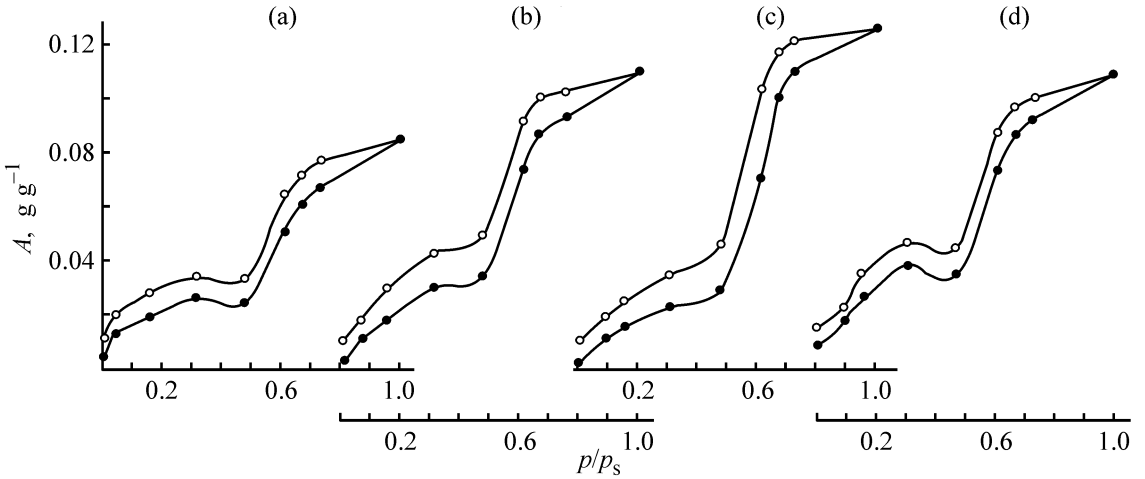

Fig. 3. Isotherms of sorption-desorption of water vapor at 25°C on natural and cation-substituted kaolinite samples. Form of kaolinite: (a) starting K, (b) KN_1 (treatment with H_2SO_4 for 1 h), (c) KN_6 (treatment with H_2SO_4 for 6 h), and (d) KMg (treatment with a $MgCl_2$ solution).

To assess the possibility of using the materials obtained in wastewater detoxication, their adsorption capacity for phenol from water was experimentally determined to be 4.8 and 6.5 mg g^{-1} adsorbent for MN_6 and MMg, respectively.

CONCLUSIONS

(1) It was found in a study of the surface properties of modified natural minerals (montmorillonite and kaolinite) that their acid activation and the subsequent salt modification improves the adsorption-structural parameters of mineral samples: V_s, by 27–39%; V_{mic}, by 20–33%; a_m, by 20–30%; and S_{sp}, by 3–20%.

(2) An analysis of the adsorption-structural parameters demonstrated that the highest sorption capacity is observed upon modification of acid-treated minerals with a 0.3 M $MgCl_2$ solution.

(3) The adsorption-structural parameters of Mg-forms of montmorillonite and kaolinite are for the most part better than those of the minerals activated for 6 h.

(4) The sorption materials obtained can be used to purify wastewater to remove phenol.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

On Calculation of the Distribution Coefficient from the Results of Continuous Gas Extraction of a Volatile Component from a Liquid Mixture

A. N. Marinichev

St. Petersburg State University, St. Petersburg, Russia

Received December 24, 2007

Abstract—Distribution coefficient of a volatile component among the liquid and gas phases was calculated from equidistant data on continuous gas extraction by using an equation generalizing the relations available in the literature.

DOI: 10.1134/S1070427208060086

Gas chromatography is widely used to solve a number of analytical and physicochemical problems (preparing gas mixtures with constant, varying in a prescribed way, concentration of a volatile analyte [1]; determining the distribution coefficient [2]; vapor pressure over a solution [3]; etc.). Similar tasks are accomplished by vapor-phase gas-chromatographic analysis, a variant of which is based on continuous gas extraction (CGE) and consists in that bubbles of an extracting gas are blown through a solution containing volatiles, with their concentration subsequently recorded by gas-chromatography.

Originally, CGE was used to prepare gas mixtures of strictly defined concentration [4]. For this purpose, it was suggested to calculate the mass-volume concentration c of the volatile analyte in the gas flow emerging from the solution as a function of the volume of the gas passed, by the formula [5]

$$c = c_G^0 \exp\left(-\frac{V}{KV_L + V_G}\right). \quad (1)$$

Another model [6] of the CGE process is characterized by the relation

$$c = \frac{c_L^0/K}{1-\left(\frac{V_G}{KV_L}\right)^2}\left[\exp\left(-\frac{V}{KV_L}\right) - \frac{V_G}{KV_L}\exp\left(-\frac{V}{V_G}\right)\right]. \quad (2)$$

In these expressions, V_L and V_G are the volumes of the solution and the gas space over its surface (so-called "dead" space) in the extractor vessel; c_L^0 and c_G^0, initial concentrations of the analyte in the solution L (at $V = V_G = 0$) and in the V_G volume, respectively; and K, ratio of the mass-volume concentrations of the volatile in the solution and in the gas phase, named the distribution coefficient. This coefficient characterizes the interphase distribution and is assumed to remain unchanged during the entire extraction process.

The volume V of the gas passed can be expressed in terms of the product of the volumetric flow rate W of the extracting gas through the solution by the extraction time t. As follows from the mass balance equation [6], the concentrations c_L^0 and c_G^0 are related by

$$c_G^0 = \frac{V_L c_L^0}{KV_L + V_G}. \quad (3)$$

Equations (1)–(3) can be combined into a general formula

$$H(t) = C_1\exp(-at) + C_2\exp(-bt), \quad (4)$$

where $a = W/(KV_L + \xi V_G)$ and $b = W/V_G$ are nonnegative exponents having dimension of inverse time; $H(t) \equiv c/c_G^0$; and the pre-exponential factors C_1 and C_2 are defined by the expressions $C_1 \equiv [1 - (1 - \xi)V_G/(KV_L)]^{-1}$ and $C_2 \equiv 1 - C_1$.

Apparently, the dimensionless parameter ξ combines the above equations as follows: Eq. (4) transforms to Eq. (1) at $\xi = 1$ and to Eq. (2), with ac-

count of (3), at $\xi = 0$. In real experiments, this parameter characterizing certain specific features of the interphase mass exchange (e.g., inertia of the substance migration into the gas phase, deviation from the equilibrium distribution) may take any real (even negative) value. Because it impossible to know a priori which of the formulas, (1) or (2), describes a particular CGE process the most adequately, it seems to be optimal to process experimental data by formula (4).

The aim of our study was to analyze the potentialities of formula (4) for describing the CGE process and calculating the distribution coefficient K and parameter ξ. So far, no sufficiently detailed and systematic data on CGE, on which the validity of Eqs. (1), (2), or (4) could be verified, have been published.

In the study [7], devoted to determining the distribution coefficients of volatile sulfur-containing substances among an aqueous solution and the gas phase, an experimental procedure for CGE was described, detailed experimental data were presented in the tabulated form, and these data were used to calculate K for dimethyl disulfide by relation (1). However, the authors did not report particular values of certain quantities necessary for calculating the distribution coefficient: only $V_L = 100$ ml is known, whereas only the range 15–25 ml min^{-1} is given for the volumetric flow rate W of the extracting gas, and no data at all, for the "dead" volume V_G. This makes difficult calculation of the coefficient K.

Let us make an attempt to find W and V_G. We assume that the concentration ratio $H(t)$ can be replaced with the corresponding ratio of peak areas in the chromatogram [7]. Results of sample batching, ordered in the integer parameter n, are listed in Table 1 as $A(n)$, peak area corresponding to time $t(n)$, for the initial instant of time (at $n = 0$) and at approximately equal time intervals (~4.67 min), beginning with 32.17 min (at $n = 1$). Let us calculate the ratio $S \equiv t/\ln(A(0)/A(n))$ for each $t > 0$. The average value of S is 87.44 (standard deviation 1.33). It follows, in particular, from Eq. (1) that

$$KV_L = WS - V_G. \quad (5)$$

Table 1 lists values of S and those of the coefficient K (column K_I), calculated using formula (1). Just the coefficients of the linear regression equation for $K_I V_L$ with respect to S are the sought-for parameters W and V_G. Their estimates by the least-squares method are $W = 25.03$ (±0.05) and $V_G = 32$ (±5), with a high (0.99991) coefficient of determination (here and hereinafter, the standard deviation of a quantity is given in parentheses to the right of its estimate).

Thus, we take to be known the parameters $W = 25$ ml min^{-1}, $V_G = 30$ ml, and $V_L = 100$ ml (just these values were probably used by the authors of [7] to calculate the distribution coefficient) and find K and ξ as unknowns from CGE data by Eq. (4).

Let us consider how the behavior of the experimental data in Table 1 affects the calculation of K. It is noteworthy that the differences between the closest values of time, succeeding, $t(n + 1)$, and preceding, $t(n)$, are approximately the same, $\Delta t = 4.67$ min, with a standard deviation of 0.11 min. Thus, the areas $A(n)$ can be considered to form at $n \geq 1$ an equidistant set with close $A(n + 1)/A(n)$ ratios having an average value of 0.946 (standard deviation 0.009). If, however, we determine this ratio by the least-squares method with a single-parameter linear equation having no free term, $A(n + 1) = uA(n)$, then we obtain that $u = 0.947$ with a standard deviation of 0.002 (coefficient of determination 0.99993). This illustrates the known concept that, of all the possible estimates of the parameter u, just the least-squares estimate is effective, i.e., it has the smallest standard deviation. It can be readily shown that, in accordance with formula (1), the parameter u has the form

$$u = \exp\left(-\frac{W\Delta t}{KV_L + V_G}\right). \quad (6)$$

It follows, in particular, from relation (6) that $K = 21.0$ (±0.9), in agreement with the value 21.1, reported in [7].

We have a somewhat different situation if Eq. (4) is used. It is noteworthy that Eq. (4) is a solution to a second-order difference equation of the form

$$A(n + 2) + pA(n + 1) + qA(n) = 0, \quad (7)$$

where p and q are parameters whose least-squares estimates can be easily found by using a linear regression.

The procedure to be employed to find the parameters of (4) with the use of (7) was described in detail in [8]. We only note that, for the data from Table 1 at n in the range from 1 to 22, the parameters p and q and the roots of the characteristic equation $z^2 + pz + q = 0$ are the following: $p =$

* Data from [7].

0.68567, $q = -0.24693$, $z_1 = 0.9465$, and $z_2 = -0.2609$. Therefore, for the calculated peak areas A_{calc}, equation of the type (4) with a "coded" argument $n = (t - 27.5)/\Delta t$ has the form

$$A_{calc} = 15\,380 \exp(-0.0549n) + (-1)^n 18 \exp(-1.343n). \quad (8)$$

Calculations show that, in Eq. (8), the contribution from the second alternating-sign term containing an exponential function is negligible. Therefore, the final relation can be written as

$$A_{calc} = 21\,249 \exp(-0.01176\,t). \quad (9)$$

The average value of the difference $|A_{calc} - A|$ is 80 (±50) for at $t \geq 32.17$. Because the coefficient $C_1 = 21\,249/A(0) = 21\,249/20\,852 = 1.019$ and $a = 0.01176$, we obtain from the relations

$$K = \frac{C_1(W - aV_G)}{aV_L}, \quad \xi = \frac{W(1 - C_1)}{aV_G} + C_1$$

by substituting the values of the constituent quantities that $K = 21.35$ and $\xi = -0.329$. Thus, the fact that the parameters C_1 and ξ are different from unity indicates that Eq. (1) is inadequate to the experimental data being discussed.

Table 1 lists the areas $A(n)$ for 23 instants of time, spaced by approximately equal intervals Δt. Let us consider how the basic parameters K and ξ will change if we use, e.g., different sets of peak areas. The results of the corresponding calculations are listed in Table 2, and we can conclude that there was no need at all to obtain 24 equidistant values of the peak areas $A(n)$ and 18, or even 12 values would be sufficient. The average value of

Table 2. Basic parameters of the CGE process, calculated from different sets of data in Table 1

Interval of n	z_1	C_1	a	K^*	$-\xi$
1–24	0.9465	1.019	0.01176	21.35	0.329
1–18	0.9468	1.016	0.01170	21.41	0.114
1–12	0.9469	1.016	0.01169	21.42	0.102
6–24	0.9448	1.055	0.01215	21.40	2.723
6–18	0.9452	1.049	0.01208	21.40	2.337
12–24	0.9442	1.074	0.01229	21.52	3.924
18–24	0.9422	1.141	0.01276	22.00	8.036

* Average value K = 21.50 at a standard deviation of 0.23.

the coefficient K is 21.50 (±0.23), which is somewhat overrated as compared with the value obtained earlier with Eq. (1).

A similar result can also be obtained by minimizing a nonnegative target function having the form of a sum of squared differences:

$$OF = \Sigma\{H[t(n) + \Delta t]/H[t(n)] - A(n + 1)/A(n)\}^2$$

with respect to the unknown values of the parameters K and ξ.

CONCLUSION

Application of Eq. (4) makes it possible not only to refine the sought-for value of the distribution coefficient K, but also to obtain the process parameter ξ whose numerical value validates or rejects use of formulas (1) and (2) for processing and interpretation of data on continuous gas extraction.

Abstract—Shrinkage of porous glasses on heating from 20 to 800°C was studied and temperature dependences of the viscosity in the range of 10^{11}–10^{13} P were determined for quartzoid (sintered) glasses based on five glasses with different compositions in the Na_2O–B_2O_3–SiO_2 system. The shrinkage of porous glasses and the viscosity of quartzoid glasses were analyzed in relation to their composition and temperature of preliminary thermal treatment.

DOI: 10.1134/S1070427208060098

A promising medium for optics and laser technology is porous glass (PG), which is a high-silica nanostructure system [1]. The advantages of PG over other materials used as solid matrices are their high thermal and chemical stability, mechanical strength, and laser resistance, combined with controllable structural characteristics. Porous glasses are used in optical technologies as a basis for composite materials produced by impregnation of PG with various substances and their subsequent sintering [2], and also for fabrication of microscopic optical elements by sintering of PG under the action of laser light [3]. Glasses based on the liquating system Na_2O–B_2O_3–SiO_2 are widely used as a starting material for production of PG of this kind.

To obtain prescribed characteristics of basic PG matrices, the information is required about the behavior of PG in a wide temperature range, depending on their composition and thermal treatment mode. The possibility of using dilatometric techniques to obtain such an information was demonstrated in [4].

The present study continues those [4, 5] devoted to changes in the size of two-phase and porous glasses based on the system Na_2O–B_2O_3–SiO_2.

EXPERIMENTAL

The compositions and porous structure parameters of PGs chosen as objects of study are listed in Table 1. The porous glasses were prepared from two-phase glasses by leaching of samples (plane-parallel polished plates of size 20 × 20 × 2 mm) in a 3 M HCl solution at 100°C.

Table 1. Compositions and pore sizes of the porous glasses studied

Starting glass	PG composition (analytical data), wt %								Pore radius, nm

NKS-1	3.3	2.9	33.2	58.5	1.2	0.95	–	–	500	24	432

Table 2 lists designations, compositions, and thermal treatment modes of the starting glasses, as well as the glass-transition temperatures T_g of the two-phase glasses.[1] To be separated into two phases, the glasses under study were thermally treated at 500 or 550°C.

The following methods were selected: for a porous glass, measuring the shrinkage, i.e., the change in the linear sample size Δl, related to the initial sample size l_0 ($\Delta l/l_0$), on heating at a rate of 7 deg min^{-1}; for a quartzoid (sintered) glass, measuring the temperature dependence of the viscosity. The shrinkage and the viscosity were measured on a general-purpose quartz dilatometer–viscometer of the Chernousov–Klyuev system [6].

The measurement errors were the following: linear sample size ±1 μm, viscosity ±0.04 log η (P), temperature ±1°C, heating rate 7 ± 0.3 deg min^{-1}; the lag of the sample temperature behind the thermocouple temperature did not exceed 5–7°C.

The temperature dependences of the shrinkage $\Delta l/l_0$ of PG samples with different initial porous glass compositions and temperatures of preliminary thermal treatment are shown in Figs. 1 and 2, respectively. The temperature dependences of the vis-

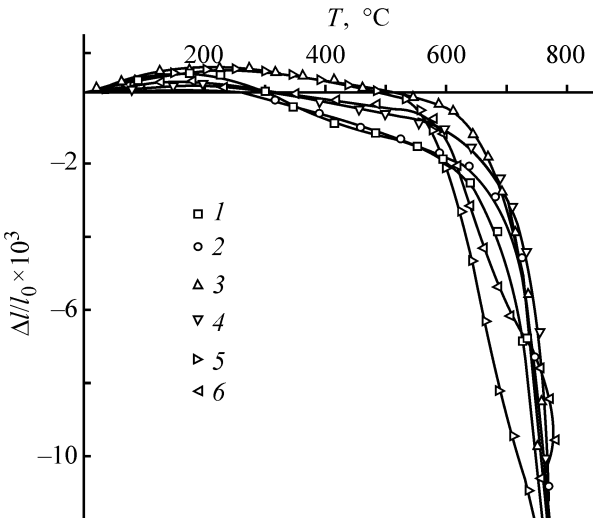

Fig. 2. $\Delta l/l_0$ of 8B PG plates vs. temperature T at a heating rate of 7 deg min^{-1} for different modes of preliminary thermal treatment of samples. Thermal treatment duration at each temperature was 1 h. Temperature of preliminary thermal treatment (°C): (*1*) 120, (*2*) 385, (*3*) 596, (*4*) 648, (*5*) 720, and (*6*) 750.

[1] The two-phase glasses were prepared from industrial glasses synthesized at the Vavilov State Optical Institute.

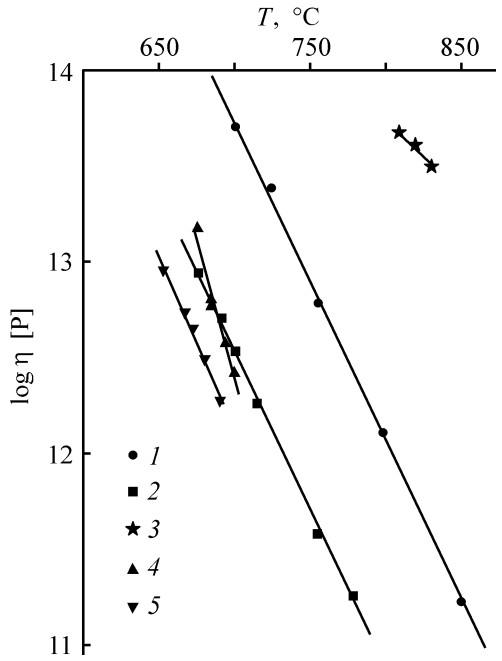

Fig. 3. Viscosity of quartzoid glasses, log η, vs. temperature T for different compositions of the starting two-phase glass.

cosity of quartzoid glasses sintered at 900–950°C are shown in Fig. 3.

Appreciable changes in the $\Delta l/l_0$ values of PG samples occur upon heating in the temperature ranges 20–250, 300–550, and 600–800°C (Figs. 1 and 2). A small expansion of the PG in the range 20–250°C results from the removal of moisture that was adsorbed in pores of the samples in storage in air before measurements. The shrinkage of the PG at higher temperatures is due to surface dehydroxylation and rearrangement (sintering) of secondary silica particles in the range 300–550°C and to softening of the skeleton of the silica phase at 600–800°C [7, 8]. In heating of PG samples at temperatures lower than the onset temperature of viscous flow in the skeleton, their linear shrinkage is the larger, the lower the Na_2O/B_2O_3 molar ratio in the starting two-phase glass and the higher the B_2O_3/SiO_2 ratio. When these quantities are equal, the PG shrinkage is the greater, the smaller the radius of the PG pores whose size is determined by the particle size of secondary SiO_2 and by the density of their packing. The weak shrinkage effect at temperatures of up to $T \le 600$°C gives no way of judging with certainty about the absolute extent to which the shrinkage of PG samples decreases as the temperature of their preliminary thermal treatment is raised (Fig. 2). However, such a tendency, presumably associated with the PG dehydration and also with the dehydroxylation resulting in stabilizations of the inner surface of pores in preliminary thermal treatment of Gs at higher temperatures, is observed. The PG shrinkage at $T > 700$°C, when skeleton softening begins, must be determined by the viscosity of the silica skeleton of PGs.

It is seen from Fig. 3 that an increase in the B_2O_3/SiO_2 molar ratio in the starting two-phase glass results in that a less viscous PG skeleton is obtained (Fig. 3). At the same B_2O_3/SiO_2, value the presence of fluoride ions in a glass considerably reduces the PG viscosity. The lower viscosity of the PG produced from FF glass (compared with the basic 8B glass) is, in all probability, due to loosening of the silicon-boron-oxygen PG skeleton upon the introduction of fluoride ions [9]. The presence of even small amounts of Al_2O_3 in the PG produced from the NKS-1 glass considerably raises its viscosity as compared with the basic NK-1 glass. The increase in the viscosity of quartzoid glasses upon introduction of Al_2O_3 into a glass is the greater, the higher the R_2O content (R = Na, Na–K) at a constant SiO_2 content of the starting two-phase glass and the larger the amount of Al_2O_3 added.

It can be assumed that it is the lower viscosity of the silica skeleton of the PG prepared from the NK-1 glass that is responsible for the onset of pore collapse in this glass at lower temperatures, compared with the PG produced from 8B glass. In a similar way can be explained the experimental data on the shrinkage of PG plates at $T \ge 700$°C (for the pair of PGs prepared from NK-1 and NKS-1 glasses) or at $T \ge 750$°C (for that prepared from 8B and NFF glasses) (Fig. 1). It is seen that the lower the viscosity of the PG skeleton (which can be judged from the viscosity of a quartzoid glass, Fig. 3), the lower the temperature (for each pair of glasses) of the onset of a sharp increase in the PG shrinkage, indicative of the onset of the viscous flow in the sample [10].

CONCLUSIONS

(1) It was found that the shrinkage of porous glasses and the viscosity of quartzoid glasses depend on the composition of the starting Na_2O–B_2O_3–SiO_2 glass and on the temperature of its thermal treatment.

(2) Three temperature regions (20–250, 300–550, and 600–800°C) of appreciable changes in

the shrinkage of porous glasses were revealed. Temperature dependences of the viscosity of quartzoid glasses were determined. These dependences can be attributed to structural transformations that occur upon sample dehydration, surface dehydroxylation, and recondensation in pores, and also as a result of thermal expansion (contraction) and viscous flow.

Abstract—Electrolytic thin-film iron sulfide compounds were studied in prototype lithium batteries with gel electrolytes based on poly(vinyliden fluoride) and its derivatives by the method of galvanostatic cycling at room temperature. A discharge capacity of 200–280 mA h g^{-1} in 80–180 cycles was obtained.

DOI: 10.1134/S1070427208060104

Transition-metal sulfides (M = Mo, Ni, Fe, etc.) are widely used owing to their electrical, magnetic, optical, catalytic, and other properties. Depending on the intended use, M-sulfides are obtained as micrometer or submicrometer particles, which may be rod-like, spherical, and other amorphous or crystalline formations and films [1–3]. Films of M-sulfides are attractive because they can provide efficient electrochemical conversion in electrodes of thin-film lithium and lithium-ion batteries [4, 5]. The demand for batteries of this kind is growing because of the miniaturization of power sources necessary for portable means of communication, electronic devices, and other power consumers.

Among the numerous known film-formation methods (magnetron, laser, and RF sputtering, thermal evaporation in a vacuum, and electrodeposition), the electrolytic method was chosen for synthesis of thin-film electrode materials for lithium chemical power cells (CPC) [6].

Electrolysis has been used to obtain thin-film molybdenum sulfides [7] and Fe sulfide compounds (e-Fe,S) with a thickness of 3–20 μm [8]. Until recently, iron sulfides (FeS, FeS_2) have been used in cathodes of lithium cells and in lithium batteries of high-temperature type with a LiCl–KCl eutectic and of medium-temperature type with solid polymeric electrolytes [9, 10]. It has been shown that a reversible electrochemical transformation of natural pyrite is possible in gel electrolytes [11]. At the same time, only a minor fraction of the theoretical specific energy of natural pyrite (FeS_2) can be obtained in cycling in a lithium CPC in pair with a solar cell at room temperature [12]. At the same time, iron sulfide products of electrolysis (e-Fe, S) can be considered suitable electrode materials for low-temperature lithium batteries [4]. Their reversible capacity in electrochemical conversion in an electrolyte composed of propylene carbonate (PC), dimethoxyethane (DME), and 1 M $LiClO_4$ is 200–300 mA h g^{-1} (in 40–50th cycles). Because gel electrolytes are preferable to liquid electrolytes for thin-film lithium batteries for environmental safety reasons, studies of the thin-film e-Fe,S system were continued on prototype lithium CPC with gel-like polymeric electrolytes.

EXPERIMENTAL

The e-Fe,S compounds were deposited as compact formations with a mass of 1.5–7.0 mg cm^{-2} on 10 × 10 × 0.1-mm aluminum alloy (AMG-6) substrates by cathodic reduction of solutions containing iron sulfate, sodium thiosulfate, and stabilizing additives. The synthesis conditions have been described in detail previously [4]. The structure of the compounds synthesized was determined by an X-ray diffraction analysis (DRON-2.0 diffractometer, LiF single crystal as monochromator, Co_{K_α} radiation). The radiation intensity was measured in the range 2θ = 10°–80°.

Table 1. PE compositions and characteristics

PE	Polymer brand	Plasticizing solution		PE state	L, μm	σ, mS cm^{-1}	Solvent
		solvent	salt				
PE1(1)	PVdF-CTFE	EC : PC = 1 : 1 (vol.)	$LiClO_4$	Gel		1.08	THF, N-MPD
PE2(1)	PVdF-HFP	EC : DMC = 1 : 1 (vol.)	$LiPF_6$	″		2.04	THF
PE3(2)	PVdF-CTFE	Activating solution EC : DMC = 1 : 1(vol.), $LiPF_6$		Film	100–150	0.46	DMF
PE4(1)	PVdF	EC : DMC = 1 : 1 (vol.)	$LiN(CF_3SO_2)_2$	″	30–60		THF, acetone

The gel electrolytes were prepared from the following reagents supplied by the Solvay Group: (i) Poly(vinyliden fluoride) PVdF Solef 21 508 and its copolymers PVdF–CTFE Solef 32008/1001, PVdF–HFP Solef 20 508, (ii) lithium salts $LiClO_4$ ("Iodobrom", Saki, Ukraine), $LiPF_6$ (Merck), $LiN(CF_3SO_2)_2$ (Aldrich, USA), and (iii) solvents EC (ethylene carbonate, Merck), DMC (dimethyl carbonate, Merck), PC (polycarbonate, Angara Plant of Chemical Reagents, Russia), TGF (tetrahydrofurane, Labscan, Ireland), acetone (Merck), and N-MPD (*N*-methyl pyrrolidone, Labscan, Ireland). Polymer electrolytes (PE) were prepared by two different casting procedures. According to procedure (1), the PE constituents (solvents, lithium salts, and polymer) were mixed in a certain ratio and order, with heating when necessary. The solution obtained was poured onto a thin-layer e-Fe, S cathode to form a polymer film of thickness 30–60 μm or a gel-like mass. In this case, all the procedures were performed in a glove box in dry argon. In method (2), a solution of polymer in an organic solvent was poured onto a smooth glass surface in air. Then the microporous polymer film was activated with a lithium-containing organic electrolyte in the dry atmosphere of the box.

The electrical conductivity of the electrolytes was measured in a cell with 12Cr18Ni9Ti steel electrodes by the method of electrolytic impedance spectroscopy on a Voltalab PJZ301 analytical radiometer.

The electrochemical characteristics of the e-Fe,S system were studied in 2325 prototype lithium chemical power cells at room temperature. Lithium plates with an excess mass and a thickness of 0.3–0.5 mm served as anodes. The prototypes were assembled in a glove box in dry argon. The galvanostatic cycling of the prototypes was carried out at voltages of 2.8–1.1 V on a computerized stand at discharge current densities of 25 to 280 mA g^{-1}.

It has been shown previously [4] that mostly iron sulfides (FeS, FeS_2, Fe_3S_4, and Fe_2S_3) with admixtures of iron oxide (γ-Fe_2O_3, γ-Fe_3O_4) and sulfur are formed in the electrolytic Fe-containing deposits. The component ratio in the deposits depends on the $FeSO_4$ and $Na_2S_2O_3$ concentrations in the deposition electrolyte. Most of Fe sulfide formulations exhibit high electrochemical activity in reactions with lithium in prototype CPC with liquid electrolytes at room temperature. Some formulations were examined in this study in prototypes with gel-like polymer electrolytes. The PE compositions in the e-Fe, S/Li prototypes and their characteristics are listed in Table 1, in which the symbol *L* designates the film thickness, and σ, the electrical conductivity of the PE. The number of PE formulations actually tested in the prototypes exceeds that listed in Table 1. For example, it was shown in [13] that the use of an electrolyte composed of PVdF, TGF, dioxolane, and 1M $LiN(CF_3SO_2)_2$ is no less successful.

The open-circuit potentials of the prototype e-Fe,S/PE/Li systems vary within 2.90–3.15 V. The general feature of the discharge characteristics of prototype with both PE and a liquid electrolyte is the considerable difference between the discharge capacity Q_d in the first cycle and those in the subsequent cycles. In the first cycle, Q_{d1} exceeds 500 mA h g^{-1} and occasionally reaches values of 800 mA h g^{-1}. Q_d decreases in cycling and stabilizes after 15–20 cycles. The specific features of cycling of e-Fe, S/PE/Li prototypes in subsequent cycles are described in relation to the PE composition.

Satisfactory charging-discharge characteristics of the e-Fe,S system are obtained with PE1(1) electrolyte prepared by procedure (1). The change

in the charging–discharge curves of a prototype in which the active cathode material (FeS_2 marcasite, FeS_2 pyrite, and γ-Fe_2O_3) is characterized by the X-ray diffraction pattern in Fig. 1a is reflected in Fig. 2. The charging–discharge profile of the prototype varies only slightly in cycling between the 40th and 86th cycles (Fig. 2). It exhibits horizontally inclined voltage plateaus at around 1.65–1.40 V in discharge and at about 1.85–1.95 V in charging. The discharge capacity decreases in cycling to reach a value of 260 mA h g^{-1} by 86th cycle. The loss of the discharge capacity is 0.2% per cycle. The temperature dependence of the discharge capacity of a prototype with PE1(1) was determined (Fig. 3). As the prototype is cooled in the temperature range 17...–7°C, the discharge capacity decreases by almost a factor of 2, which undoubtedly exceeds that upon heating from 17 to 40°C. It was found in cycling of e-Fe,S/PE1(1)/Li prototypes that the decrease in the discharge voltage to 0.35 V by the 16th cycle (inset in Fig. 4) provokes an increase in its discharge capacity in the subsequent cycles (Fig. 4). This effect should be attributed to electrochemical intercalation of Li^+ into the Al substrate of the cath-

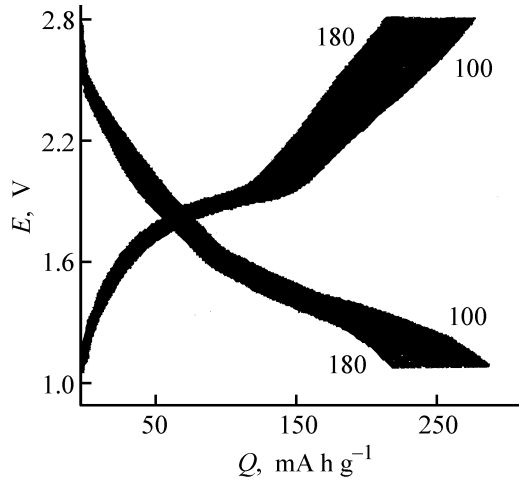

Fig. 5. Discharge-charging profile of a prototype with PE2(1) in the 100th–180th cycles. Phase composition of the cathode material: FeS, FeS_2,S; m = 1.5 mg cm^{-2}; i_{dis} = 0.05 mA cm^{-2}, i_{char} = 0.03 mA cm^{-2}. (E) Voltage and (Q) capacity; the same for Figs. 6, 7.

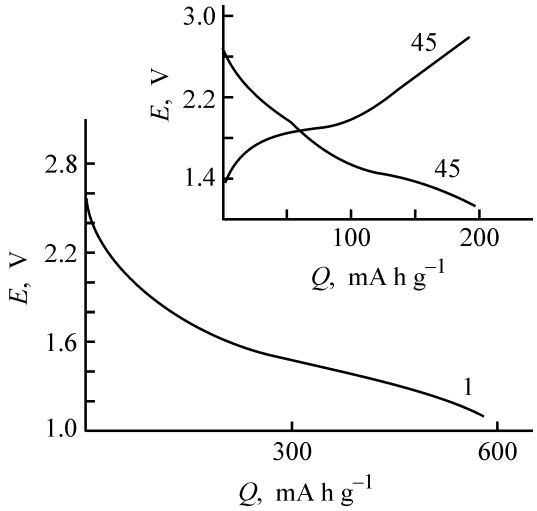

Fig. 6. Discharge curve of the prototype system constituted by FeS_2 pyrite, FeS_2 marcasite, and γ-Fe_2O_3/PE3(2)/Li in the first cycle and the discharge-charging profile in the 45th cycle (inset). m = 1.8 mg cm^{-2}, i_{dis} = 0.05 mA cm^{-2}, i_{char} = 0.03 mA cm^{-2}.

ode, in which, first, a solid α-solution $AlLi_x$ and then an intermetallic compound are formed [14, 15]. As is known, the lithiation of aluminum affects its surface and bulk properties and makes the electrode impedance lower, which exerts a positive influence on the Al/e-Fe,S interface.

The discharge characteristics of the e-Fe, S/PE2(1)/Li prototypes compare well with those of the PE1(1) prototypes. The discharge capacity of the prototypes with a PE2(1) electrolyte and a cathode material composed of FeS_2 pyrite, FeS, and S (Fig. 1b), which is 730 mA h g^{-1} in the first cycle, decreases to 280 mA h g^{-1} by the 110th cycle at a current density of 0.05 mA cm^{-2} (Fig. 5). In prolonged cycling, the loss of the discharge capacity is 0.2% per cycle in the 100th–180th cycles. The dependence of the discharge capacity on the discharge current density was determined at the end of cycling (Table 2).

Table 2. Discharge capacity at varied discharge current density in the prototype system constituted by FeS_2-pyrite, FeS, and S/PE2(1)/Li

i_{dis}, mA m^{-2}	Q_{dis}, mA h g^{-1}	Cycle no.
0.05	282	110
0.1	270	101
0.3	208	114
0.5	190	116
0.95	140	115

As follows from the data of Table 2, a discharge capacity of about 200 mA h g^{-1} can be attained at the end of prolonged cycling at a high discharge rate (300 mA g^{-1}).

In prototypes with PE3(2) electrolyte prepared by procedure (2) from the electrolytic Fe sulfide formulation (FeS_2, FeS, γ-Fe_2O_3), the discharge capacity decreases from the initial value of about 600 mA h g^{-1} (Fig. 6) to about 200 mA h g^{-1} by the end of cycling. The values of the discharge capacity for separate cycles are as follows: Q_{d20} = 201 (I_{dis} = 1.05 mA cm^{-2}), Q_{d40} = 196 mA h g^{-1} (I_{dis} = 0.2 mA cm^{-2}). The charging-discharge curves of a prototype with PE3(2) by the 45th cycle are demonstrated in Fig. 6 (inset).

Prototypes with dimensions of a flat-type lithium battery were tested in the final stage of the study. For this purpose, iron sulfides were deposited onto a 30–50-mm aluminum substrate. A PE4(1) film of thickness 30–40 μm was formed on the surface of the resulting Fe sulfide cathode and the cathode was assembled with a lithium counter electrode in a package made of laminated aluminum foil. Then, the package was sealed by hot pressing. The results obtained in cycling of the prototype battery are shown in Fig. 7. The discharge capacity of the prototype remains at a level of 200 mA h g^{-1} during 125 cycles.

The results obtained using the electrochemical impedance spectroscopy show that the conductivity of PE decreases in cycling. For example, σ of

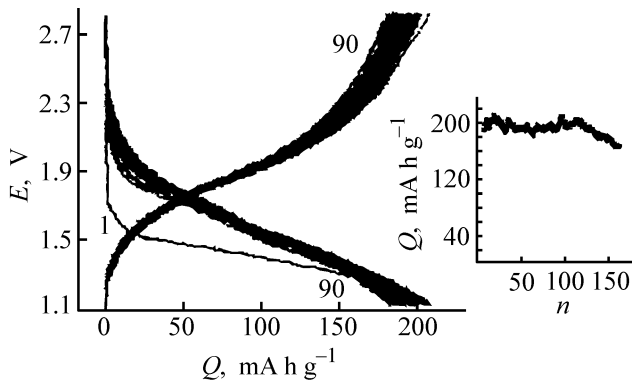

Fig. 7. Discharge-charging curves for the first 90 cycles and the variation of the discharge capacity Q with the number of cycles n (inset) of the prototype system constituted by e-FeS_2, FeS, γ-Fe_2O_3/PE4(1)/Li of size 30 × 50 mm. I_{dis} = 1.5 mA, I_{char} = 1.0 mA.

PE2(1), equal to 2.04 mCm cm^{-1} before cycling, decreases by an order of magnitude and more after the discharge capacity decreases in cycling to Q_d < 50 mA h g^{-1}. In this case, a microinjection of a liquid electrolyte into the prototype makes σ and Q_d higher. This result is accounted for by the properties of the PE composed of two macroscopic phases, a polymer and a porous space filled by the solution whose properties are close to those of the bulk solution. The polymer phase also contains ions and molecules of the solvent, but their individual properties are modified by the interaction with the polymer matrix. To factors predetermining the degradation of the e-Fe,S/PE/Li system can be attributed consumption of the liquid electrolyte in the PE pores and accumulation of electrically nonconducting products formed in interaction with the cathode material.

Thus, it was demonstrated that, as in [16–18], PVDF and its derivatives are compatible with, and swell in, liquid electrolytes and can be used together with e-Fe,S. The final result of the electrochemical conversion of the e-Fe,S/PE/Li system is determined by the nature of the cathode and the polymer materials and by the working conditions. The discharge capacity, service life, and discharge rate of the e-Fe,S/PE/Li system with PVDF electrolytes compare well with those of the system with liquid-phase electrolytes [4, 8].

CONCLUSION

Iron sulfide formulations produced by cathodic reduction of solutions containing $FeSO_4$ and $Na_2S_2O_3$ in prototype lithium chemical power cells with gel poly(vinyliden fluoride) electrolytes are capable of an electrochemical conversion in the range 2.8–1.1 V and exhibit a capacity of 200–280 mA h g^{-1} in 80–180 cycles.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Composition of Gas-Diffusion Carbon Black Electrodes on Electrosynthesis of Hydrogen Peroxide from Atmospheric Oxygen

G. A. Kolyagin, I. S. Vasil'eva, and V. L. Kornienko

Abstract—Electroreduction of oxygen to H_2O_2 on gas-diffusion air electrodes made of A 437-E acetylene black and its mixture with P 702 and P 268-E furnace blacks with various particle sizes and wettabilities by an alkaline aqueous electrolyte with 8 and 20 wt % polytetrafluoroethylene was studied.

DOI: 10.1134/S1070427208060116

Air electrodes are widely used in chemical power cells [1]. Studies are underway, intended to enable their application in new areas and, in particular, for electroextraction of oxygen from air [2] and use in hybrid power sources with simultaneous production of H_2O_2 [3].

It is known that air electrodes are less active than oxygen electrodes because the concentration of oxygen in the electrolyte becomes lower via a decrease in its partial pressure and via an increase in the resistance to diffusion of oxygen molecules across a gaseous nitrogen layer formed after atmospheric oxygen contained within electrode pores is consumed. That is inert gases create a diffusion barrier to oxygen transport to the reaction zone. However, an important advantage of air electrodes is the unlimited stock of oxygen in Earth's atmosphere at a place of its consumption without its preliminary recovery from air. This circumstance is also important for developing a process for the extensively studied electrochemical synthesis of H_2O_2 from oxygen [4–7]. In this case, it is required that the electrode structure should provide not only oxygen supply to the reaction zone across the diffusion barrier created by inert gases, but also discharge of the hydrogen peroxide obtained from the electrode volume to prevent its further reduction to water or chemical decomposition. Thus, the structure of an air electrode is even more important than that of an electrode working on pure oxygen.

Porous gas-diffusion electrodes are mostly used as air electrodes. Studies devoted to development and use of air electrodes for manufacture of H_2O_2 are only being commenced and the related published evidence is scarce. For example, an acid solution with a H_2O_2 concentration of 0.03 g l^{-1} has been obtained at a current density of 0.2 mA cm^{-2} [5], and a H_2O_2 solution with a concentration of 0.45 g l^{-1} has been produced with the use of a gas-diffusion air electrode [6].

One of methods affecting the structure of gas-diffusion electrodes is that changing their hydrophobic-hydrophilic properties by varying the content of a waterproofing agent [4, 8–11] or using carbon blacks with different wettabilities by an aqueous electrolyte [12]. For example, the use of a mixture of blacks with various properties for optimizing a gas-diffusion layer with a porosity of 70 vol % for a hydrogen-air fuel cell with a proton-exchange membrane yielded a positive effect in [13]. A mixture of acetylene black with carbon nanotubes as a carbon support for the catalytic layer of a gas-diffusion electrode for metal-air batteries was studied in [14], and the effect of a mixture of blacks on the electrosynthesis of H_2O_2 from oxygen, in [7].

The aim of the present study was to find how changes in the content of a waterproofing agent in a gas-diffusion hydrophobized electrode based on acetylene black and admixtures of a hydrophilic electrocatalyst, furnace blacks with various particle sizes, affect parameters of hydrogen peroxide synthesis from atmospheric oxygen in an aqueous electrolyte: current efficiency, electrode polarization, and kinetics of H_2O_2 accumulation. Also, the in-

Table 1. Physicochemical parameters of carbon blacks

Carbon black brand	Particle size, nm	Specific surface area, $m^2 g^{-1}$		pH of aqueous suspension	Ash content, %
		external	adsorptional		
A 473-E	30–39	101	110	9.2	0.2

P 268-E	19–35	158	265	7.8	0.1

fluence exerted by the supply rate of atmospheric oxygen to the electrode surface was analyzed. To elucidate the effect of the electrode structure on the delivery of atmospheric oxygen to the reaction zone, experiments with pure oxygen were carried out.

EXPERIMENTAL

The experimental conditions, electrolyzer design, and electrode fabrication technique are similar to those previously used in electrosynthesis of hydrogen peroxide from oxygen [4, 7, 15].

The following carbon black brands were chosen for the study: hydrophobic acetylene black of A 437-E brand and more hydrophilic furnace blacks of P 702 and P 268-E brands. The physicochemical properties of the blacks are listed in Table 1 [16]. 4D-fluoroplastic (FT-4D) served as a waterproofing agent.

The electrode material was prepared by joint coagulation of an aqueous suspension of fluoroplastic and a suspension of carbon blacks in a vessel equipped with a stirrer [17]. The mixture of carbon blacks was prepared in a 1 : 1 ratio. The material was filtered off, washed with water, dried in a drying box to constant mass at 120°C, ground in a blade mill, and screened through a sieve with 0.25-mm mesh. Further, the material was heated at 300°C for 1 h. The electrodes were formed in a mold with a piston stroke limiter as planar discs 33 mm in diameter and 0.8–0.9 mm thick, with a 0.1-mm-thick nickel grid in the middle of the electrode. The amount of the electrode material necessary for fabricating electrodes of certain porosity was calculated by the known formula [18]. The electrodes were sintered in air at 360°C for 10 min. To diminish limitations on the supply of oxygen into the electrodes, they were fabricated with a high total porosity (65 vol %). The electrolyte porosity of the electrodes was found by hydrostatic weighing [19]. Prior to experiments, the electrodes were impregnated with an electrolyte (0.5 M aqueous solution of NaOH) in the galvanostatic mode at a current density of 40 mA cm^{-2} for 1 h.

The electrolysis was performed in a three-chamber glass electrolyzer-cell [15]. A carbon black electrode (cathode) was placed between the cathode and gas chambers. The catholyte and anolyte (1 M H_2SO_4) were separated by an MF-4SK-100 cation-exchange membrane. A platinum plate served as the anode. The preparative electrolysis was performed in 0.5 M NaOH (~20 ml) at 20°C in the galvanostatic mode at an overall current density of 50 mA cm^{-2} for 5–7 h. The current density was calculated per unit apparent frontal surface area of the electrode (5 cm^2). The electrode potential was measured relative to a saturated silver chloride reference electrode (EVL-1M1). Oxygen and air were continuously fed into the electrode through its backside from the 20-ml gas chamber under atmospheric pressure. Oxygen was delivered in a small excess, discharged into the atmosphere. Air was delivered at flow rates of 0, 20, 50, and 100 ml min^{-1}. The fraction γ of current expended for synthesis of hydrogen peroxide was determined by gasometry in an electrolysis with oxygen. Potentiodynamic polarization curves were measured at a potential sweep rate of 4 mV s^{-1}. The concentration of hydrogen peroxide in solution was determined by permanganatometry. Prior to being sampled, the electrolyte was agitated by bubbling with air. The results obtained are listed in Table 2. It should be noted that by the term hydrogen peroxide are understood all forms of H_2O_2 existence in an alkaline solution, i.e., molecules and ions.

As can be seen in Table 2, a decrease in the fluoroplastic content and introduction of a hydrophilic carbon black make larger the volume of pores filled by the electrolyte. The influence exerted by replacement of oxygen with air and variation of the rate of its delivery into the gas chamber on the polarization dependence is illustrated for electrode no. 2

Table 2. Influence exerted by the electrode composition in reduction of pure oxygen, by atmospheric oxygen, and by the rate of its supply on parameters of H_2O_2 electrosynthesis (electrolysis time 7 h)

* Electrode potential, current efficiency, and H_2O_2 concentration by the end of electrolysis.

** Results obtained when passing a small excess of pure O_2.

*** Electrolysis duration 5 h.

(Table 2, Figs. 1 and 2). At an air flow rate of 100 ml min^{-1}, the best results were obtained, with the dependence of the current on the air feed rate nearly leveling-off (Fig. 2). Therefore, experiments at higher rates were not performed. Figures 3 and 4 demonstrate for electrode no. 2 the effect of electrolysis duration on the H_2O_2 concentration and current efficiency. The run of these dependences is the same as that in experiments with pure oxygen [4]. The H_2O_2 accumulation curves tend to show a plateau at which the synthesis rate is equal to the decomposition rate of H_2O_2 and the differential current efficiency is zero (Figs. 3 and 4, curve *4*).

It can be seen that, as it should be, the replacement of oxygen with air makes more pronounced the electrode polarization. Varying the air feed rate has nearly no effect on the electrode polarization up to a current density of 40 mA cm^{-2}, i.e., the electrode structure manages to feed the required amount of oxygen to the reaction zone. However, at higher currents, outer-diffusion limitations become important. The electrode polarization varies in inverse proportion to the air feed rate, and, at zero rate, the polarization curve reaches the limiting current (Fig. 1). Raising the air feed rate from 20 to 100 ml min^{-1} leads to an increase in the current

Fig. 1. Fig. 4. Current efficiency by H_2O_2, η, vs. the electrolysis duration τ in 0.5 M NaOH for gas-diffusion carbon black electrodes.

efficiency and H_2O_2 concentration obtained by 13–41%, depending on the electrode composition. The theoretical air flow rate at a current density of 50 mA cm^{-2} and a 100% current efficiency by H_2O_2 is 8.3 ml min^{-1}. As the volume of the gas chamber, and specifically its thickness, decreases, the air flow velocity along the electrode increases, and, consequently, the air feed rate can be lowered to the corresponding extent. Raising the pressure in the gas chamber by 55 cm of water at an air feed rate of 100 ml min^{-1} results in that the electrode polarization becomes stronger and the current efficiency by H_2O_2 and its concentration decrease.

In electrolysis with oxygen, electrode nos. 1, 2, and 4 demonstrated nearly the same current efficiency by H_2O_2. The fraction of current expended for the H_2O_2 electrosynthesis is 95–98% at a concentration of 36–37 g l^{-1}, but the polarization of these electrodes is approximately inversely proportional to their electrolyte porosity and increases in order no. 2 < no.4 < no. 1. The same dependence is observed in electrolysis with air, but the current efficiency by H_2O_2 and its concentration are lower, and this decrease depends on the electrode composition, which indicates that the electrode structure affects just the delivery of atmospheric oxygen. The best results were obtained with electrodes composed of a mixture of carbon blacks A 437-E and P 702. Depending on the electrolysis duration, H_2O_2 solutions with concentrations of 8–35 g l^{-1} were obtained, with the corresponding current efficiencies of 99–63% (Figs. 3, 4). This means that changing the hydrophilic properties and the structure of an electrode by introduction of furnace black with a medium wettability is more effective than making lower the fluoroplastic content. Introduction of a hydrophilic furnace black P 268-E leads to a sharp increase in the hydrophilic porosity and to a decrease in the volume of gas pores. This results in that the inner-diffusion hindrance increases, the area of the three-phase boundary between air, carbon black, and electrolyte becomes smaller, the polarization grows, and the current efficiency by H_2O_2 decreases. The fraction γ of the current is also smaller for this electrode: 50% at a H_2O_2 concentration of 13 g l^{-1}. The size of carbon black particles is also important. Addition of larger particles (P 702) to the electrode material makes it possible to create larger pores, which facilitates oxygen delivery to the reaction zone. By contrast, introduction of a carbon black with smaller particles (P 268-E) hinders this process.

The effect of the electrode composition on the H_2O_2 electrosynthesis from atmospheric oxygen is due to the diffusion hindrance to oxygen delivery into the electrode at a comparatively low content of oxygen in air. Because of this circumstance, the diffusion component of the electrode polarization increases and the zone of H_2O_2 generation shifts to the back (gas) side of the electrode, which is in contact with air. As a result, the way to be traversed by H_2O_2 to leave the electrode volume across the front side of the electrode into the electrolyte and the residence time of H_2O_2 in the electrode become longer, which leads to an increase in its concentration and decomposition rate, with

the current efficiency decreasing. This effect becomes more pronounced as the H_2O_2 concentration in the electrolyte increases. This occurs because the rate of H_2O_2 diffusion from the electrode decreases due to the lower H_2O_2 concentration gradient between the pore volume of the electrode and the electrolyte (Fig. 4). Consequently, the farther the H_2O_2 generation zone from the front side of the electrode, the lower the H_2O_2 concentration in the electrolyte and the current efficiency. The reaction zone can also be shifted by varying the air feed rate.

Thus, in the case under consideration, the electrosynthesis parameters are affected both by the electrolyte porosity (via changes in the ohmic polarization) and by the conditions of oxygen delivery to the reaction zone (via changes in the inner- and outer-diffusion components of the electrode polarization).

CONCLUSIONS

(1) Gas-diffusion air electrodes can be successfully used for electrosynthesis of hydrogen peroxide. The best results are obtained on electrodes composed of a 1 : 1 mixture of a hydrophobic acetylene black A 437-E and a semihydrophobic furnace black P 702, with addition of 20 wt % fluoroplastic. Alkaline H_2O_2 solutions are obtained with concentrations of 8–35 g l^{-1} at the corresponding current efficiencies of 99–63%.

(2) Raising the air feed rate into the gas chamber from 20 to 100 ml min^{-1}, which corresponds to a fivefold change of the air volume in the gas chamber in 1 min, makes higher the current efficiency and the H_2O_2 concentration obtained by 13–41%, depending on the electrode composition, and lowers the electrode polarization by 0.07–0.2 V.

Abstract—Electrocatalytic activity of gold and a gold–iridum binary system electrodeposited onto the surface of a glassy carbon in oxidation of cysteine was studied. A method for flow-through-injection determination of cysteine was developed.

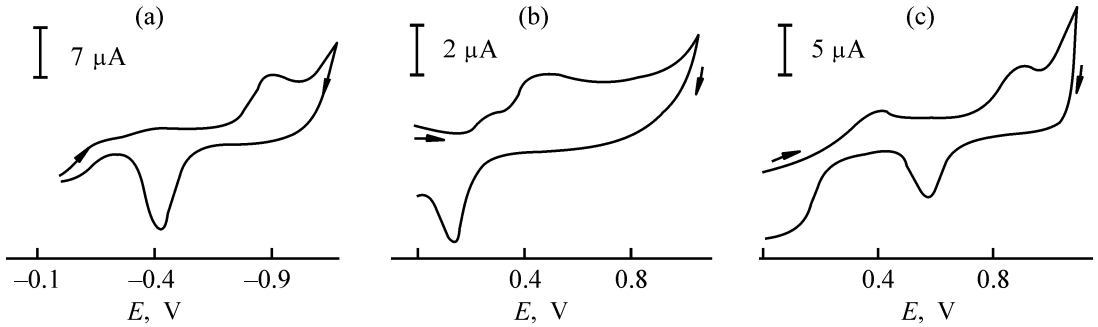
DOI: 10.1134/S1070427208060128

L-Cysteine (2-amino-3-mercaptoproponic acid) is an important biomedical compound, because it is involved in numerous biochemical processes in living systems [1, 2]. This amino acid is used in pharmaceutical industry, is applied (in combination with some antibiotics) for curing of damaged skin, and can serve for protection from radio radiation. Disturbance of its normal concentration in the human body is a reason for appearance and development of nervous, mental, and other diseases. Therefore, the development of high-sensitivity methods for determination of cysteine in various objects is an important task for analytical chemistry.

Sulfur-containing amino acids are commonly determined by spectrophotometry [3], fluorimetry [4], electophoresis [5], high-performance liquid chromatography [6], and electrochemical methods [7, 8]. As disadvantages of the spectral and chromatographic methods should be mentioned the prolonged sample preparation and analysis itself, insufficient sensitivity, and use of an expensive equipment. The electrochemical methods are distinguished by simplicity, high determination sensitivity, and use of inexpensive and readily available instruments. The polarographic determination of sulfur-containing amino acids employs dropping mercury electrodes. This method is based on the formation of mercury mercaptide and its reduction at nearly zero potentials [9]. A considerably lower detection limit is demonstrated by inversion polarography with a dropping mercury electrode. In this case, the dependence of the current on the concentration is linear in the range 2×10^{-8}–5×10^{-7} M [10]. However, the toxicity of mercury hinders wide use of mercury-based electrodes in laboratory practice. Solid (metallic or carbon) electrodes cannot provide a low detection limit of cysteine and its derivatives because of the adsorption on the electrode surface of products formed in the electrochemical reaction involving amino acids.

Recently, chemically modified electrodes (CME) possessing catalytic properties have found application for voltammetric determination of sulfur-containing amino acids. For example, cysteine is determined with such CME mediators as metal oxides [11], transition-metal phthalocyanines [12–14], and inorganic films produced from hexacyanometallates [15]. The catalytic response of CME enables a considerable lowering of the detection limit of cysteine, e.g., to 5×10^{-7} M [15]. Introduction of CME into flow-through methods of analysis improves the analytical and metrological characteristics and raises the throughput of analysis.

In this study, the electrocatalytic activity of gold and the gold–iridum binary system electrodeposited onto glassy carbon (GC) electrode in oxidation of cysteine was examined and a method for flow-through injection determination of cysteine was developed.



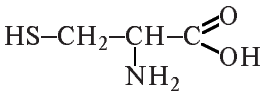


Fig. 1. Cyclic voltammograms obtained on (a) Au–GC, (b) Ir–GC, and (c) Au–Ir–GC electrodes in 1 M H_2SO_4 supporting solution. (E) Potential; the same for Figs. 2, 3c.

EXPERIMENTAL

In the experiments, dc voltammograms were recorded with a PU-1 polarograph, and cyclic voltammograms, with a PI-50-1.1 potentiostat. In a three-electrode cell, a glassy-carbon (GC) electrode with an apparent surface area of 0.1 cm^2 and Au–GC, Ir–GC, and Au–Ir–GC modified electrodes served as the working electrode. A saturated silver chloride electrode served as reference, and a platinum wire, as an auxiliary electrode. The voltammograms were recorded at a potential sweep rate of 20 mV s^{-1}.

As object of study served cysteine having the structural formula

A cysteine solution was prepared by dissolving a precisely weighed portion in an aqueous solution. Solutions of lower concentrations were prepared by successive dissolution of the initial solution immediately before the measurements. As supporting electrolyte served 0.1 M solution of H_2SO_4. The pH value was adjusted with NaOH and monitored using a pH-150 pH meter.

Measurements under the conditions of a flow-through injection analysis (FIA) were made using a setup including a peristaltic pump, injector, flow-through electrochemical cell, and recording device [16]. The solutions were delivered and discharged through pipes made of silicone tubes with an inner diameter of 2.0 mm. The injection was done with a microsyringe through the sealing membrane. Preliminarily, the electrochemical behavior of gold, iridium, and gold–iridum binary system electrodeposited on the GC electrode was studied.

The electrochemical behavior of gold electrodeposited on GC (Au–GC) is rather complex and includes formation on the CME surface of oxo and hydroxo compounds of the metal in different oxidation states: Au(OH), $Au(OH)_3$, or Au_2O_3 [17]. A cyclic voltammogram obtained on (Au–GC) electrode in 0.1 M H_2SO_4 supporting solution is shown in Fig. 1a. One pair of cathodic-anodic peaks is recorded at $E > 0.6$ V as the potential is shifted to the anodic region. The peaks can be assigned to oxidation of gold to the oxidation state +3 by the scheme [18]:

$$2Au + 3H_2O \rightleftarrows Au_2O_3 + 6H^+ + 6e. \quad (1)$$

The reverse branch of the cyclic voltammogram shows a narrow peak at $E_p \sim 0.40$ V which corresponds to formation of Au. On the subsequent anodic branch, a small current peak is recorded at $E \sim 0.40$ V, which is probably due to oxidation of Au nanoparticles. As is known [18], the electrochemical properties of single atoms of a metal and those of the atoms in the bulk are different: the absence of the crystal lattice stabilization energy in nanoparticles leads to a decrease in the oxidation overvoltage of the metal.

The cyclic voltammogram obtained on GC with an iridium deposit (Ir–GC) in a 0.1 M H_2SO_4 buffer solution is shown in Fig. 1b. The anodic branch of this voltammogram exhibits a wave at $E_{1/2} = 0.45$ V, and the cathodic branch, a peak at $E_p = 0.15$ V. Metallic iridium oxidizes to Ir(IV) via the stage of formation of the intermediate compound $Ir(OH)_3$, which immediately oxidizes to $IrO_2 \cdot H_2O$. The prewave observed at $E \sim 0.4$ V corresponds to the formation of hydrated Ir(III) oxide (hydroxide) [19]. The overall electrode process can be represented as:

$$Ir + (n + 2)H_2O \rightleftarrows IrO_2 \cdot nH_2O + 4H^+ + 4e. \quad (2)$$

Table 1. Characteristics* of voltammograms obtained on GC and CME in cysteine oxidation in a 0.1 M H_2SO_4 supporting solution (cysteine concentration 5×10^{-3} M)

Electrode	E_s, V	i_s, μA	E_{mod}, V	i_{mod}, μA	E_{cat}, V	i_{cat}, μA	i_{cat}/i_{mod}
CУ	1.05	2.5	–	–	–	–	–

Au–Ir–GC	–	–	0.45	3.1	0.45	3.1	–
			0.90	7.5	0.90	360	48.0

* E_s, i_s, E_{mod}, i_{mod}, E_{cat}, i_{cat} are potentials and peak currents of oxidation of a cysteine substratum on GC, those of oxidation of a modifier, and those of catalytic oxidation of cysteine on CME, respectively.

On passing from the deposits of individual metals to binary systems, the form of the recorded cyclic voltammograms becomes more complex. In this case, both the individual properties of metals constituting the system and the bifunctional effects can be manifested. The cyclic voltammogram obtained on GC modified with a gold–iridium binary system (Au–Ir–GC) contains two pairs of cathodic-anodic peaks, which may be due to oxidation of individual metals constituting the bimetallic system (Fig. 1c).

The good reproducibility of the cyclic voltammograms obtained in 0.1 M H_2SO_4 supporting solution confirms the high chemical and electrochemical stability of the Au–Ir binary system.

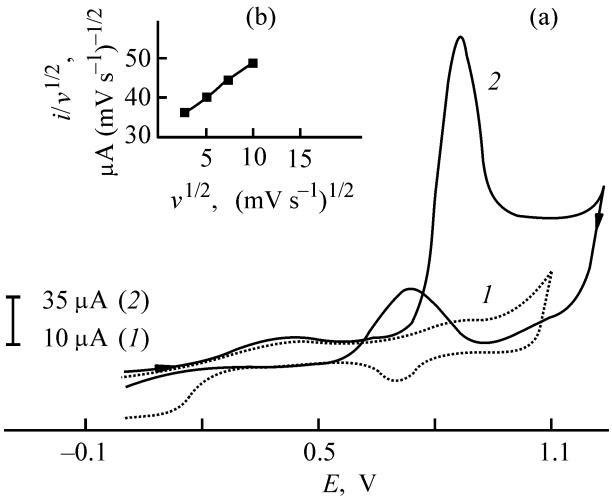

Fig. 2. (a) Cyclic voltammograms obtained on the Au–Ir–GC electrode in 0.1 M supporting solution of H_2SO_4 (*1*) without and (*2*) with cysteine and (b) dependence of the current peak of cysteine oxidation on the Au–Ir–GC electrode on the potential sweep rate *V*. Cysteine concentration 5×10^{-3} M; the same for Fig. 3. (*i*) Current strength; the same for Fig. 3.

The metrological characteristics of the electrode response remain unchanged during a month.

Cysteine oxidizes on GC irreversibly and with a large overvoltage, e.g., $E \sim 1.0$ V in an acid medium in a 0.1 M H_2SO_4 supporting electrolyte (Table 1). The oxidation wave recorded in this case is poorly reproducible because of the adsorption of products of substratum oxidation on the graphite support. Therefore, it is not appropriate to use a graphite electrode for direct voltammetric determination of cysteine.

In oxidation of cysteine on the Au–GC electrode, a manyfold increase in the current is observed at a potential of 1.0 V (Table 1), typical of the oxidation of a modifier in the absence of a substratum. On the Ir–GC electrode, two steps are recorded at potentials of 0.45 and 1.05 V (Table 1). At potentials of the first step, the modifier is oxidized, because the height of this step does not change in the presence of cysteine. The potentials of the second step correspond to oxidation of the amino acid under study, because cysteine is oxidized on unmodified GC in the same range of potentials. Thus, a change in the voltammetric characteristics of cysteine is recorded only on the Au–GC electrode. Compared with CME, the electrode with an electrodeposited Au–Ir film shows a stronger rise in the modifier oxidation current in the presence of a substratum under study (Table 1). This is due to the occurrence of the synergetic effect in cysteine oxidation on the electrode modified with a bimetallic system. Therefore, the oxidation of cysteine on Au–Ir–GC was studied in more detail.

The cyclic voltammograms obtained on the Au–Ir–GC electrode with and without cysteine are shown in Fig. 2 (curves *2* and *1*, respectively). The anodic branch of the cyclic voltammogram of

0.9	3.6	105	29.2	0.0...0.5	210	5.5	38.2

cysteine oxidation exhibits two steps. The first step at E = 0.45 V reproduces the wave corresponding to mediator oxidation, and the second step at E = 0.90 V is preceded by a current peak whose height exceeds that of the modifier oxidation peak in this range of potentials in the absence of a substratum.

The process occurring at the Au–Ir–GC electrode can be identified as an electrocatalytic process. This is so because the modifier oxidation current i_{mod} increases manyfold in comparison with the current of cysteine oxidation on CME i_{cat} (i_{cat}/i_{mod} = 48.0), the overvoltage of substratum oxidation (E_{cat}) decreases as compared with the overvoltage of its oxidation on GC E_s ($E_{cat} - E_s$ = 150 mV), and the peak current at E_p = 0.90 V linearly depends on the cysteine concentration. The plot $i/v^{1/2}$–$v^{1/2}$ has a positive slope (Fig. 2b), which points to the adsorption contribution to the electrooxidation of cysteine at the Ir–Au–GC electrode by the scheme:

$$6RSH + Au_2O_3 \rightarrow 3RSSR + 2Au + 3H_2O. \quad (3)$$

Probably, electrogenerated oxo particles of gold in the oxidation state +3, formed by reaction (1), act as a catalyst. Noteworthy is the unusual shape of the cathodic branch of the cyclic voltammogram of cysteine oxidation, which is manifested as a rise in the anodic current at the potentials of metal reduction (Fig. 2a). This may be due to oxidation of cysteine on electrogenerated particles of the catalyst.

It was found that the electrocatalytic response of CME depends on the method used for electrochemical deposition of metals onto GC. The peak current of cysteine oxidation was studied in relation to the electrodeposition conditions of the binary system the time and potential of electrolysis in the case of potentiostatic deposition or the range and rate of cyclic variation of the potential in the case of potentiodynamic deposition. As can be seen from Table 2, a stronger catalytic effect (i_{cat}/i_{mod} = 48) is observed when the bimetal is deposited by cyclic variation of the potential in the range –0.3...–0.5 V. The rise in the current in the voltammogram of cysteine oxidation on the Au–Ir–GC electrode also depends on the time of electrodeposition of the binary system. The maximum catalytic effect is observed in the case of a potentiodynamic deposition on Au–Ir at potentials of –0.3...–0.5 V in three cycles.

The results obtained were used to develop a method for voltammetric determination of cysteine on a CME based on the Au–Ir binary system. A 10-ml volumetric flask was charged with a fixed volume of the standard solution of cysteine, 5 ml of a 0.2 M solution of H_2SO_4 was added, and the mixture was brought to the mark with distilled water. The solution was transferred into an electrochemical cell containing chemically modified, auxiliary, and silver chloride electrodes. A voltammogram was recorded in the range 0.0–1.0 V and the peak current of cysteine oxidation at E_p = 0.90 V was determined.

The peak current is proportional to the cysteine concentration over a wide concentration range 5×10^{-7}–5×10^{-3} M. This dependence is described by the equation (i_p, μA; c, M):

$$i_p = (5.4 \pm 0.3) + (7.09 \pm 0.02) \times 10^4 c, \quad (4)$$

$$r = 1.000.$$

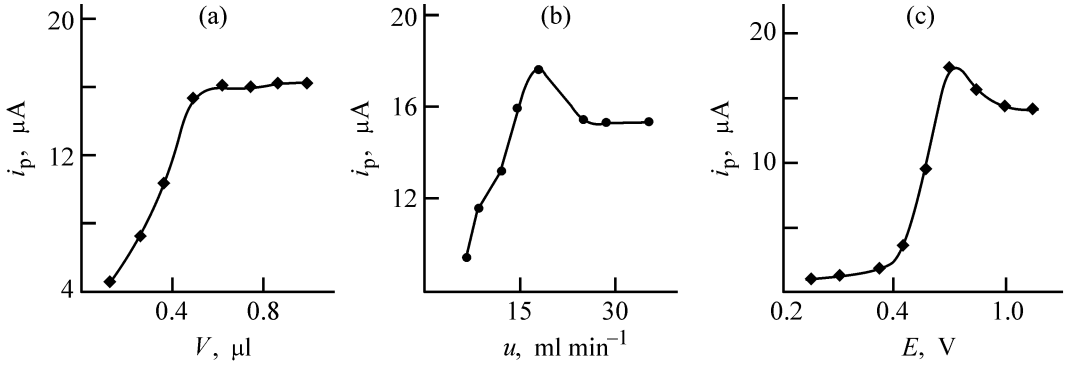

Fig. 3. FIA signal i_p obtained in cysteine oxidation on Au–Ir–GC in 0.1 M H_2SO_4 supporting electrolyte (pH 2.0) containing cysteine vs. (a) injected sample volume, (b) flow rate, and (c) applied potential. (V) Injected sample volume and (u) flow rate.

The adequacy of the procedure was assessed by the introduced–found method (Table 3).

A chemically modified electrode based on the Au–Ir binary system was used to determine cysteine under conditions of a flow-through injection analysis. The FIA signal was recorded in the potentiostatic mode. Preliminarily, the influence exerted by the hydrodynamic parameters of the system on the intensity of the analytical signal recorded under the FIA conditions was studied. The dependence of the current on the injected sample volume V and on the flow rate u was examined. The maximum FIA signal was observed at V = 0.75 ml (Fig. 3a). The i–u dependence passes through a maximum at u = 18 ml min^{-1} (Fig. 3b).

The dependence of the current on the applied potential was studied at the given hydrodynamic parameters. The maximum of this dependence was observed in cysteine oxidation on the Au–Ir–GC CME at 0.80 V (Fig. 3c). Based on the dependences obtained, the following working conditions for recording the FIA signal were chosen: V = 0.75 ml, u = 18 ml min^{-1}, and E = 0.80 V.

Table 3. Results obtained in determining cysteine on the Au–Ir–GC electrode (n = 6, P = 0.95)

* (S_r) signal reproducibility.

Cysteine was determined by the flow-through injection method on the Au–Ir–GC electrode as follows. The flow of a carrier (0.01 M H_2SO_4 solution) was passed at a rate of u = 18 ml min^{-1} through silicone pipes with an inner diameter of 2 mm. The pipes were hermetically connected to a flow-through electrochemical cell with chemically modified, auxiliary, and silver chloride electrodes. The FIA signal was recorded at 0.80 V after a sample of volume V = 0.75 ml was injected. The dependence of the FIA signal on the cysteine concentration is linear in the range 5×10^{-3}–5×10^{-8} M, which is an order of magnitude lower than that under the stationary conditions, and is described by the equation i_p, μA; c, M)

$$\log i_p = (1.22 \pm 0.09) + (0.50 \pm 0.01)\log c, \quad (5)$$
$$R = 0.9995.$$

The detection limit calculated by the 3s criterion is 2×10^{-8} M [20]. An analysis of the metrological characteristics demonstrated that the reproducibility of the analytical signals in voltammetric determination of cysteine in a flow-through system is better than that under the stationary conditions (Table 3). This occurs because the substratum and products of its oxidation are not sorbed on the CME surface.

The method suggested for voltammetric detection of cysteine with a CME based on the Au–Ir binary system under conditions of the flow-through injection analysis is characterized by simplicity, high sensitivity, and rapidity. The use of the cat-

alytic response in FIA makes it possible to achieve cysteine detection limits comparable with the values obtained for inversion voltammetry [10].

CONCLUSIONS

(1) It was shown that particles of gold and the gold–iridium binary system deposited on a glassy carbon electrode exhibit an electrocatalytic activity in cysteine oxidation. The most pronounced catalytic effect is observed for the electrode with a bimetallic system. The catalytic current is recorded in the range of oxidation potentials of Au(III) oxo particles at 0.95 V.

(2) The conditions in which an electrode based on the gold–iridium binary system is formed and the maximum catalytic current of cysteine oxidation is recorded on this electrode were determined. This modified electrode was used for voltammetric determination of cysteine under the steady-state conditions. The dependence of the catalytic current on the cysteine concentration is linear within the range 5×10^{7}–5×10^{-3} M.

(3) The possibility of using a modified electrode for amperometric detection of cysteine under the conditions of a flow-through injection analysis was demonstrated. Using the catalytic response of the modified electrode in a flow makes it possible to reduce the detection limit of cysteine by an order of magnitude to 5×10^{-8} M.

ACKNOWLEDGMENTS

The study was supported by a joint grant from CRDF (U.S. Civilian Research & Development Foundation) and Ministry of Education and Science of the Russian Federation, BRHE (Basic Research and Higher Education Program) (REC-007).

Abstract—Fundamental aspects of electrodeposition of PbO_2-based composites containing titanium dioxide particles were studied. The content of the dispersed phase in the composite depends on the electrolyte composition and deposition conditions. Incorporation of titanium dioxide particles into PbO_2 leads to significant changes in the morphology and structure of the deposit.

DOI: 10.1134/S107042720806013X

Oxide composite materials find wide use in various reactions as catalysts and photo- and electrocatalysts, in electrochemical synthesis of strong oxidizing agents, and in disintegration of organic and inorganic contaminants of water and air [1–12]. Various ways to produce materials of this type are known, e.g., sol–gel techniques, plasmochemical method, etc. The electrochemical method should be distinguished as one of the most promising, which enables wide control over the composition and properties of composites because of its simple implementation and possibility of smoothly varying the technological parameters of the process [3–12].

Lead dioxide is a promising electrocatalyst widely used in practice [1–8]. Composite materials based on lead dioxide are known, which additionally contain various oxides and, in particular, Al_2O_3, Co_3O_4, RuO_2, and TiO_2 [3, 5, 8]. Despite this circumstance, the problem of directed synthesis of materials of this kind remains unsolved, because the influence exerted by the nature of the electrolyte on the composition and physicochemical properties of the resulting materials is insufficiently well understood. In this study, the fundamental aspects of electrodeposition of oxide composites PbO_2–TiO_2 and the physicochemical properties of these materials were examined.

EXPERIMENTAL

The composites were deposited in the galvanostatic mode onto pretreated platinum-plated titanium electrodes of area 4 cm^2. The deposition electrolyte contained (M): $Pb(NO_3)_2$ 0.1 and HNO_3 0.1. Additionally, TiO_2 was introduced into the electrolyte in the form of a finely dispersed powder, together with an anionic surfactant, sodium dodecyl sulfate ($C_6H_{12}SO_4Na$). Solutions were prepared from reagents of chemically pure grade and twice-distilled water. The deposition was performed in most cases at a temperature of $20 \pm 2°C$ and anode current density of 5 mA cm^{-2}; the coating deposition time was 30 min. To study the physicochemical properties of the composites, thicker coatings were deposited (at a deposition time of 2 h). It should be noted that the composite materials under study had a composition independent of the coating thickness.

The adsorption of the anionic surfactant (sodium dodecyl sulfate) on a TiO_2 powder was studied in 0.1 M HCl [13]. The content of the surfactant in the composite was determined by the procedure described in [14]. The colloid-chemical properties of the suspension electrolyte were studied by the sedimentation method with the use of a torsion balance. The electrokinetic potential was measured using the electrophoretic technique [15]. The point of zero charge (pH_0) was measured in 0.1 M KCl.

To determine the composition of the composites, the materials were dissolved in a 1 : 1 mixture of 5 M HNO_3 and 30% hydrogen peroxide. The excess of H_2O_2 in the resulting solutions was removed by boiling with a platinum catalyst. The amount of

PbO_2 was calculated from the Pb^{2+} content of the solution, found by amperometric titration with diethylthiocarbominate [16].

The surface morphology of the materials obtained was studied by scanning electron microscopy (SEM) with a LEICA S360 microscope. X-ray diffraction patterns were recorded with a PHILIPS PW3710 diffractometer (Cu_{K_α} radiation).

Accelerated resource tests of anodes with an active layer of a PbO_2–TiO_2 composite were performed in 1 M H_2SO_4.

The composition of a composite may depend on various factors, including the nature and the colloid-chemical properties of the suspension electrolyte. The main characteristics of the colloid system are the particle size of the dispersed phase, electrokinetic potential, and point of zero charge (pH_0) of the oxide. To determine the disintegration time of the suspension and the particle size of the dispersed phase, sedimentation measurements were made. It was found that the system is actually monodisperse and contains TiO_2 particles with a diameter of approximately 0.35 μm. The composite materials were deposited in the course of 30 min, during which time the suspension did not disintegrate. It should be noted that coatings for physicochemical studies of the composites should be deposited in a longer electrolysis (2 h), with the suspension partly disintegrating. Therefore, the composites were in all cases deposited under agitation in order to stabilize the electrolyte. This made it possible to obtain deposits under identical conditions, irrespective of the electrolysis duration.

When the anionic surfactant is introduced into the deposition electrolyte, the surfactant is adsorbed on TiO_2 particles, with the process satisfactorily described by the Frumkin isotherm. The adsorption parameters were calculated: limiting adsorption of 1.75×10^{-5} mol g^{-1}, reached at a sodium dodecyl sulfate concentration of 3.8×10^{-4} M; and adsorption constant of 673.81 M^{-1}. The adsorption of sodium dodecyl sulfate on the TiO_2 powder is of specific nature, which is indicated by the rather low value of the adsorption interaction energy $\Delta G = -25.6$ kJ mol^{-1} [13].

One of the factors affecting the supply rate of the inert oxide to the electrode surface is the charge of particles of the dispersed phase. According to potentiometric data, pH_0 for TiO_2 is 6.36, and, therefore, dispersed phase particles are positively charged in the suspension electrolyte. Upon the adsorption of a surfactant on TiO_2, the point of zero charge of the oxide is shifted to the alkaline region, which confirms the conclusion about the specific nature of sodium dodecyl sulfate adsorption on particles of the dispersed phase. Measurements demonstrated that the electrokinetic potential of titanium dioxide in 0.1 M HNO_3 is 0.064 V. This also points to a small positive charge on titanium dioxide particles in the suspension electrolyte. The so low value of the ζ potential is due to the high concentration of the supporting electrolyte. Upon addition of sodium dodecyl sulfate, the electrokinetic potential substantially changes to become –0.18 V. The change in the sign and magnitude of the electrokinetic potential upon addition of sodium dodecyl sulfate indicates that the electric double layer of particles of the dispersed phase is recharged because of the adsorption of the surfactant. In the presence of the anionic surfactant, particles of the dispersed phase acquire a negative charge and can move in the course of electrolysis toward the positively charged anode surface via electrophoresis.

ization measurements were performed. The polarization curve at low polarizations (Fig. 1a, region *I*), plotted in the Taffel coordinates (E–log J), is linear, which points to the kinetic control over the lead dioxide deposition [17]. At potentials more positive than 1.4 V (Fig. 1a, region *II*), the partial current starts to approach the limiting value, which indicates that the process occurs under diffusion control. Upon the introduction of TiO_2 and sodium dodecyl sulfate into the solution, the polarization somewhat increases and the current of PbO_2 electrodeposition decreases. The results obtained can be attributed to inclusion of particles of the dispersed phase into the coating and to adsorption of the surfactant on lead dioxide [18], which leads to partial blocking of the electrode surface. It should be noted that the run of the polarization curves obtained in colloid electrolytes is nearly the same as that in true solutions. Therefore, the electrodeposition of PbO_2 from suspension electrolytes can be satisfactorily described by the kinetic scheme [18].

As follows from the total polarization curves (Fig. 1b), several processes simultaneously occur at the electrode [at high anodic potentials, the total current exceeds the partial current of lead dioxide electrodeposition (Fig. 1a)]. According to published data [18], the process of PbO_2 formation occurs simultaneously with the reaction of oxygen evolution. The current efficiency (CE) by lead dioxide will be determined by the relative contributions of the two electrode processes. At the anode current density of 5 mA cm^{-2}, the CE_{PbO_2} from the true solution was 98%. Upon addition of TiO_2 to the deposition electrolyte, CE_{PbO_2} decreases to 84%, which agrees with the results of polarization measurements (Fig. 1a) and points to a certain inhibition of the electrodeposition process via partial blocking of the electrode surface by particles of TiO_2, which is a low-conductivity semiconductor.

Particles of the dispersed phase are incorporated into the growing PbO_2 deposit to give a composite material. The content of TiO_2 in the composite will, in all probability, be determined by the stages in which particles of the dispersed phase are delivered from the electrolyte bulk to the electrode surface via diffusion and(or) migration. Because the potential of zero charge of lead dioxide in 0.1 M HNO_3 is 0.91 ± 0.1 V (relative to the standard calomel electrode) [19] at the deposition potentials (>1.5 V), the electrode surface will be positively charged. Despite the positive charge on TiO_2 in the electrolyte, particles of the dispersed phase are, nevertheless, incorporated into the growing coating, which may indicate that the contribution of the migration component is insignificant.

It follows from the data in Fig. 2a that, as the content of titanium dioxide in the deposition

electrolyte decreases to 2 g dm^{-3}, the probability of particle capture by the growing deposit increases, which results in that the amount of TiO_2 in the composite material grows to 5 wt %. This effect is probably observed because the gradient of the partial concentration of the oxide in the dispersed phase grows with its content in the electrolyte. The coating composition also depends on the solution pH. For example, an increase in the HNO_3 concentration leads to a decrease in the TiO_2 content of the coating (Fig. 2a), which is, in all probability, due to a rise in the positive charge of particles of the dispersed phase and to an increase in the rate of migration of TiO_2 particles into the cathode space.

As the current density increases, the content of the inert oxide in the composite material grows (Fig. 2b). The curve describing the content of the dispersed phase in the composite as a function of the current density can be conditionally divided into two portions. In the first of these, as the deposition rate of lead dioxide grows, the probability of capture of TiO_2 particles becomes higher and the content of the inert oxide in the composite increases to 13 wt % (Fig. 2b). In the second, the content of TiO_2 in the coating remains nearly constant as soon as the deposition rate reaches its limiting value (Fig. 1a).

Introduction of a surfactant into the deposition electrolyte results in that the surface of particles of the dispersed phase is recharged. In this case, negatively charged TiO_2–surfactant particles move under the action of electrophoretic forces toward the positively charged anode, to be incorporated there into the growing coating [12]. In the presence of the surfactant, the content of particles of the inert oxide in the composite material also grows with the current density (Fig. 2b), but the concentration of titanium dioxide in the coating does not approach the limiting value. In this case, TiO_2 is delivered not only by diffusion, but also via migration whose rate steadily increases as the polarization becomes more pronounced.

As the deposition temperature is raised, the content of particles of the dispersed phase in the coating decreases (Fig. 2c). Presumably, this occurs because of a decrease in the viscosity of the electrolyte, which, in turn, results in that the partial concentration in the suspension becomes lower because of the sedimentation [20].

It should be noted that, in most cases (Fig. 2), in the presence of the surfactant in the suspension electrolyte, the content of titanium dioxide in

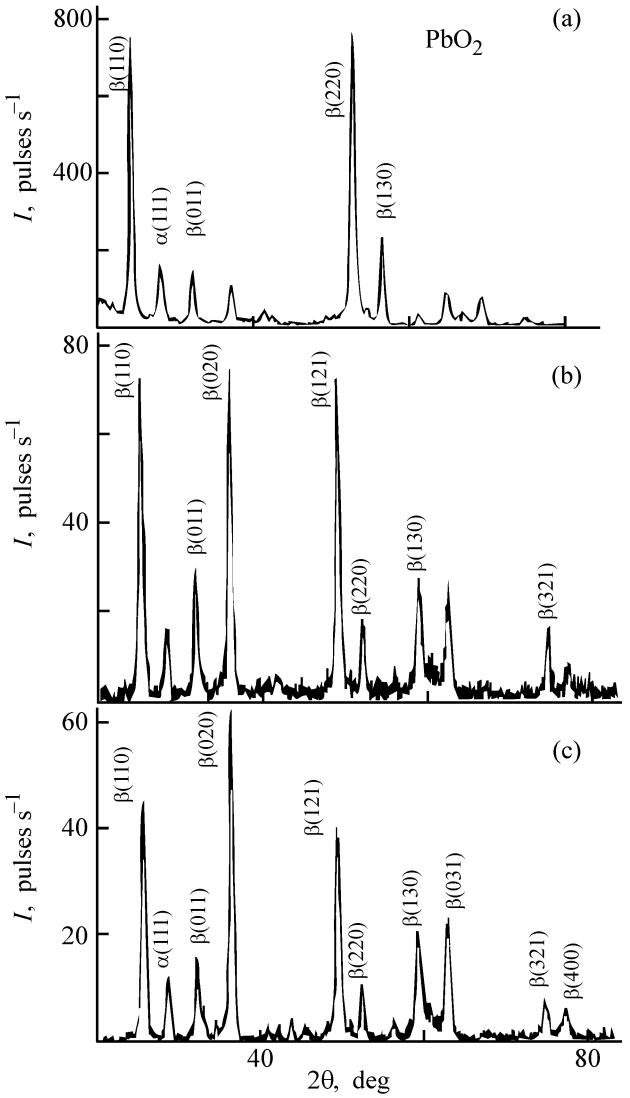

Fig. 3. X-ray diffraction patterns of composite materials deposited from different electrolytes (i_a = 5 mA cm^{-2}). (I) Intensity and (2θ) Bragg angle. (a) 0.1 M $Pb(NO_3)_2$ + 0.1 M HNO_3, (b) a + 2.0 g dm^{-3} TiO_2, and (c) b + 1 × 10^{-3} M surfactant; the same for Fig. 4.

the composite increases because of the additional supply of negatively charged particles to the electrode surface by electrophoresis. At the same time, the fact that the type of the dependence is preserved indicates that, even in the presence of the surfactant, particles are for the most part delivered to the electrode surface via diffusion.

Lead dioxide deposited from nitrate solutions is a polycrystalline formation composed of a mixture of α- and β-phases with various crystallographic orientations, with the predominance of the latter phase (Fig. 3a) [18]. As follows from the X-ray diffraction patterns in Figs. 3b and 3c, the presence of TiO_2 and a surfactant strongly affects the struc-

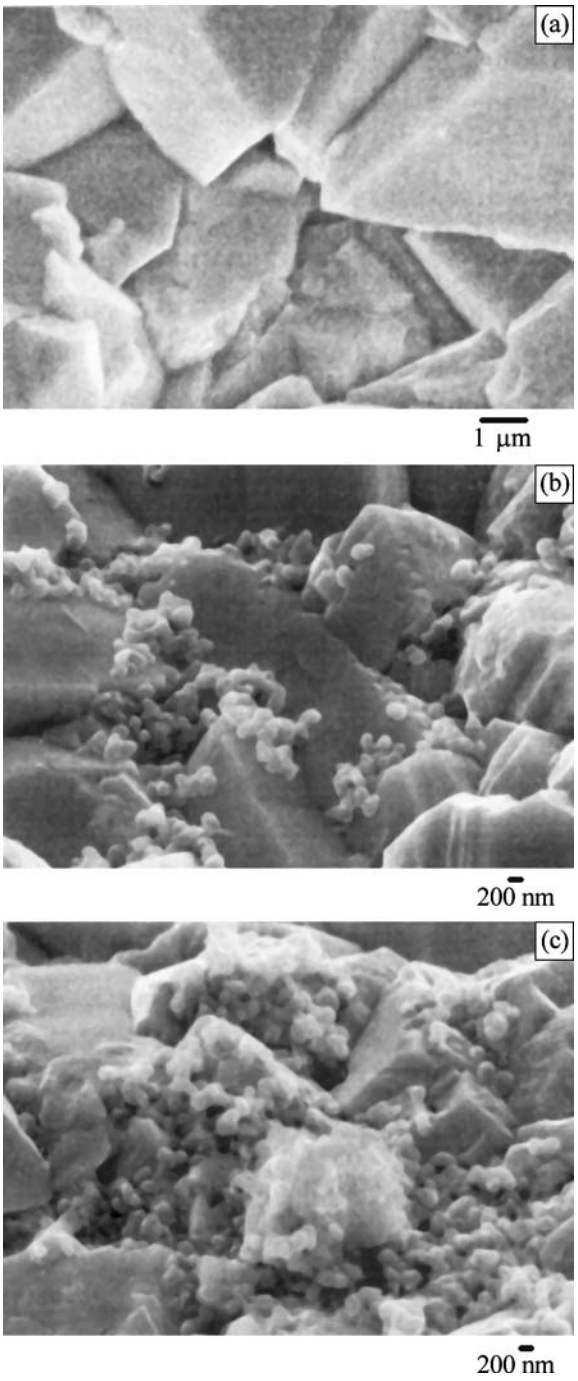

Fig. 4. SEM micrographs of materials deposited from different electrolytes (i_a = 5 mA cm^{-2}).

ture of PbO_2-based materials. The crystallographic orientation of lead dioxide in the composite material substantially changes and new faces appear: β (020), β (121), and β (031). For deposits containing particles of the inert oxide and the surfactant, the intensity of the peaks substantially decreases, which may indicate that the size of lead dioxide crystals decreases as the fraction of X-ray-amorphous phases in a sample increases. It should be noted that the X-ray diffraction patterns show no peaks of titanium dioxide. As follows from the results of sedimentation measurements, the average size of TiO_2 particles is only 0.35 μm, and, therefore, they are X-ray amorphous under the measurement conditions.

To obtain additional information, the surface morphology of the materials obtained was studied by SEM. In electrodeposition of lead dioxide from true solutions (Fig. 4a), the coatings are composed of a set of coarse polycrystalline blocks with a poorly pronounced predominant orientation of separate faces. As follows from the data obtained (Fig. 4), incorporation of titanium dioxide particles into PbO_2 results in that the morphology of the deposit significantly changes. The composite is a heterogeneous system with locally separated zones with different surface morphologies. The regions with coarse crystals are composed of lead dioxide particles, and those with fine crystals, of titanium dioxide partly or completely covered with fine crystals of lead dioxide. The disappearance of coarse crystals and polycrystalline blocks, characteristic of lead dioxide, indicates that the number of crystallization centers grows as the TiO_2 content of the composite increases and the surfactant is adsorbed on the electrode. Thus, the composite materials have the form of a PbO_2 matrix with submicrometer and nanosize crystals, into which TiO_2 crystals are incorporated.

Accelerated resource tests of anodes with an active layer of the PbO_2–TiO_2 composite were performed in 1 M H_2SO_4 at an anode current density of 200 mA cm^{-2}. The service life of the electrodes is determined by the time of uninterrupted polarization during which the potential remains nearly unchanged. A steep rise in the potential points to failure of an electrode, even though no mechanical damage to the active coating is visually observed. Such an electrode cannot be used because of the substantial increase in the electrolyzer voltage. As follows from the data obtained, electrodes containing 5 wt % titanium dioxide could operate during 207 h, and lead dioxide electrodes, during only 105 h at the same current density. Thus, the service life of the composite materials increases approximately twofold, compared with the conventional PbO_2 anodes. It should be noted that lead dioxide electrodes are commonly used at current densities of 20–50 mA cm^{-2}. In these modes, the service life of the electrodes will be 10–100 times longer than

that in the accelerated tests. As follows from a tentative comparative estimate of the electrocatalytic activities of the anodes in electrochemical disintegration of 4-chlorophenol, the composite materials are, at least, not inferior to the conventional lead dioxide electrodes. Thus, the composite materials obtained can be recommended for use as electrocatalysts with a prolonged service life in electrochemical disintegration of toxic organic substances.

CONCLUSIONS

(1) Use of suspension electrolytes makes it possible to obtain composite materials of prescribed composition, which have the form of a lead dioxide matrix into which an inert oxide is incorporated. Particles of the dispersed phase can be delivered to the electrode surface both by their diffusion and by migration. The amount of TiO_2 in the composite can be varied from 1 to 20 wt % by changing the deposition conditions and the electrolyte composition.

(2) The physicochemical properties of the composites significantly differ from those of lead dioxide and are determined by the composition of these materials. The composite has the form of a PbO_2 matrix with submicrometer and nanosize crystals, into which TiO_2 particles are incorporated. Owing to this circumstance, the composites have a large effective surface area.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

A Study of the Complex Composition of Sulfamate Ruthenium-Plating Electrolytes

S. M. Karabanov and O. G. Lokshtanova

Ryazan Plant of Metal-Ceramic Devices Open Joint-Stock Company, Ryazan, Russia

Received October 11, 2007

Abstract—Varying-with-time complex composition of a sulfamate ruthenium-plating electrolyte was studied. Recommendations are given concerning the working modes and adjustment conditions in prolonged operation of the electrolyte.

DOI: 10.1134/S1070427208060141

The sulfamate electrolyte is the most widely used industrial ruthenium-plating electrolyte [1–4]. It is prepared from a complex salt, ammonium μ-nitridobisaquatetrachlororuthenate $(NH_4)_3[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]$. In a prolonged use of the ruthenium-plating electrolyte, it is necessary to maintain its technical characteristics (e.g., the deposition rate, within the prescribed limits) and the stability of characteristics of electroplated coatings. To accomplish this task, it is necessary to know the variation dynamics of the complex composition of both the electrolyte and the adjusting solutions in prolonged storage and use during accumulation of products of chemical and electrochemical reactions.

The aim of this study was to examine the varying-with-time complex composition of ruthenium-plating electrolytes and adjusting solutions.

EXPERIMENTAL

In the study, IR spectroscopy, powder X-ray diffraction analysis, electronic absorption spectroscopy (EAS) of aqueous salt solutions, and gel-chromatography of aqueous solutions on Sefadex gels were employed.

The commonly used ruthenium-plating electrolyte has the following composition ($g\,l^{-1}$) Ru 10–20 (in terms of the metal) and ammonium sulfamate 30–80. The pH value was maintained in the range 1.5–2.0. The electrodeposition was performed at a temperature of 60–70°C and cathode current density of 1–2 A dm^{-2} with the use of Pt/Ti anodes.

Originally, the starting complex salt of ruthenium was studied. IR spectroscopy revealed the following absorption bands (cm^{-1}): 1060, vibrations of the Ru–N–Ru bond; 1450, vibrations of NH_4^+ bonds; 1543, vibrations of uncoordinated water; and 1040, vibrations of coordinated water, which is trans to the bridging nitrogen.

The complex salt was subjected to X-ray diffraction analysis. The resulting X-ray diffraction pattern is in good agreement with published data for $(NH_4)_3[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]$ [5]. It was found that the ruthenium compound used to prepare electrolytes fully corresponds to this formula, but contains hydration water: $(NH_4)_3[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]\cdot nH_2O$ (according to a calculation, $n < 1$).

It was of interest to check whether the composition of the complex changes when the electrolyte and adjusting solutions are prepared by dissolving the starting salt in water. The EAS spectra of aqueous solutions of the salt, measured immediately after the substance is dissolved, contain four absorption bands at 205, 290–292, 350, and 435 nm, in full agreement with published data [5, 6].

Solutions of the complex ruthenium salt in water and a 0.1 M solution of hydrochloric acid were subjected to chromatography on a column packed with Sefadex G-15 gel. Chromatograms of the freshly prepared aqueous and hydrochloric acid solutions are shown in Fig. 1. The chromatograms contain only a single broad brown zone containing ruthenium. The EAS spectrum of separate fractions of the zone coincides with that of the starting com-

plex (Figs. 2, 3a). The minor hypsochromic shift (up to 5–8nm) of bands of separate fractions indicates that hydrolytic processes involving the complex occur when the solution of the complex passes through the complex. In all probability, in aqueous solutions of $[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]^{3-}$, the inner-sphere chloride ions are replaced by water molecules, with the subsequent acid dissociation.

The hydrolytic process begins immediately after the salt is dissolved in water. In 24 h, the starting complex form is not found in the solution: the absorption band at λ_{max} = 435 nm, characteristic of the $[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]^{3-}$ complex, is not observed in the EAS spectra of the aqueous solution and those of separate fractions isolated by chromatography (Fig. 3b). At the same time, there appear absorption bands associated with monomeric and dimeric aqua complexes of ruthenium(III), ruthenium(IV), and ruthenium(III,IV) [7–10].

The transformations of the starting nitrido-aqua chloride complex of ruthenium(IV) in water occur rather rapidly and end in disintegration of the nitrido bridge. In 24 h, nearly only a mixture of monomeric and dimeric aqua-hydroxo chloride complexes of ruthenium(III) and ruthenium(IV) is present in the solution.

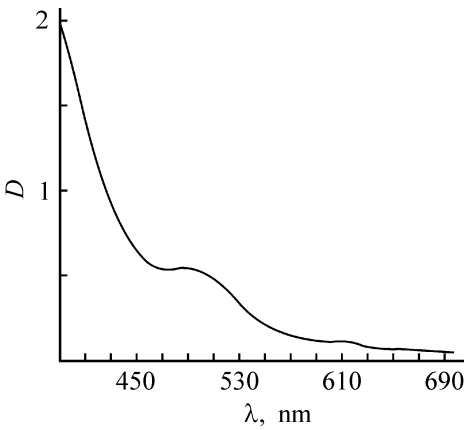

Fig. 4. EAS spectrum of an industrial adjusting solution.

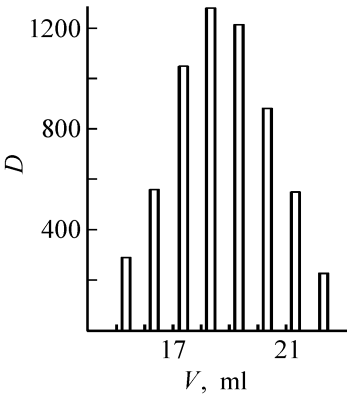

Fig. 5. Gel-chromatogram of the adjusting solution. Fourfold dilution with a 0.1 M HCl solution. (*D*) Optical density and (*V*) retained volume.

The industrially used adjusting solution with a storage life exceeding one month has an EAS spectrum shown in Fig. 4. In the spectrum, there is no absorption band at 435 nm, characteristic of the nitride complex of ruthenium, $[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]^{3-}$, whereas the band at λ_{max} = 490 nm, associated with aqua-hydroxo complexes of ruthenium(III, IV) is, by, contrast, present. This is also confirmed by the gel-chromatogram of the adjusting solution (Fig. 5). Thus, the $(NH_4)_3[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]$ salt used to prepare ruthenium-plating electrolytes and adjusting solutions is unstable in the course of time in aqueous solutions. Hydrolysis, inner-sphere dissociation of water molecules, partial reduction of the central ruthenium atom, and reactions of substitution of chloride ions result in that the starting complex is converted into a mixture of aqua and aqua-hydroxo chloride complexes of ruthenium(III,IV).

It was found that variation of the concentration of hydrochloric acid in the adjusting solution (within the technologically acceptable limits) and introduction of the sulfamate ion into this solution do not lead to any significant stabilization of the starting form of the ruthenium complex.

The behavior of a freshly prepared industrial ruthenium-plating electrolyte was studied. The composition of the electrolyte was as follows (g l^{-1}): ruthenium 18 (in terms of the metal), ammonium sulfamate 50, sulfate ions 60, and chloride ions 20.

The EAS spectra contain three absorption bands characteristic of the nitride ruthenium(IV) complex $[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]^{3-}$, peaked at 205, 290, and 435 nm. However, the intensity of the bands steeply decreased in the course of time, so that, in three days, the spectrum contained in the visible range only a weak shoulder at 430 nm (characteristic band of the nitride complex) and a new band at 490 nm [characteristic band of aqua-hydroxo chloride complexes of ruthenium(III,IV)]. This nature of the spectrum indicates that the industrial electrolyte contains a small amount of complex forms $[Ru_2(\mu\text{-}N)(OH)_m2Cl_{8-n-m}]^{k-}$, where $2 < n + m \leq 8$, and a certain amount of aqua-hydroxo complexes of retention(III,IV), whereas the main complex forms of ruthenium in solution are aqua-hydroxo complexes of ruthenium(III). Presumably, these latter predominate in the solution as a result of electrochemical and inner-sphere reduction of ruthenium(IV) to ruthenium(III) in the course of electrodeposition from the electrolyte.

Ruthenium-plating electrolytes used for a long time were studied. The following two electrolytes were examined. The first was used for two years, with fresh portions of the adjusting solution introduced at regular intervals of time, and contained (g l^{-1}): ammonium sulfamate 60, sulfate ions 250, and chloride ions 30. The second was used for about three years, exhibited an exceedingly low deposition rate, and contained (g l^{-1}): ruthenium 21, ammonium sulfamate 55, and chloride ions 35.

The EAS spectrum of electrolyte no. 1 shows a weak shoulder at 420 nm. In the EAS spectrum of electrolyte no. 2, there are no absorption bands in the visible spectral range. The nature of the EAS spectra indicates that the content of the active form of the nitrido complex $[Ru_2(\mu\text{-}N)(H_2O)_2Cl_8]^{4-}$ is nearly zero, and just this circumstance accounts for the exceedingly low rates of ruthenium deposition from this electrolyte. Apparently, adjustment of long-used electrolytes by addition of fresh portions of a solution containing the nitrido complex of ruthenium and sulfamate ions can maintain a certain content of the electrochemically active form of the ruthenium complex in electroplating baths.

An important role in the adjustment of ruthenium-plating baths is played by sulfamate ions, which form a sulfamate complex with aqua chloride complexes of ruthenium. The sulfamate complexes of ruthenium are unstable. As a result of combined internal transformations involving hydrolytic and redox reactions, the sulfamate complex is converted into a nitrido complex. A necessary condition for this reaction, in which a dimeric structure is formed, is a high concentration of ruthenium in solution. Therefore, the degree of conversion of aqua chloride complexes of ruthenium into dimeric nitrido chloride complexes in industrial electrolytes cannot be high, i.e., only a part of ruthenium is converted into the electrochemically active form of the nitrido complex in adjustment of electrolytes.

At the same time, the reaction of chloro complexes of ruthenium with the sulfamate ion is accompanied by accumulation of sulfate ions in solution. The increase in the concentration of sulfate ions in solution shifts the equilibrium of the complexation reaction toward the initial complexes of ruthenium (sulfamate and aqua-chloro complexes of ruthenium) and thereby also diminishes the concentration of the electrochemically active complex.

Thus, a stable working capacity of ruthenium-plating electrolytes is possible when the electrochemically active form of the nitrido complex of ruthenium is preserved in solution. Introduction of ammonium sulfate into the electrolyte partly solves this problem. However, the accumulation of sulfate ions as a result of multiple adjustments of the electrolyte impairs the regeneration of nitrido complexes from aqua chloride complexes of ruthenium.

Many years' practice of industrial use of ruthenium-plating electrolytes has shown that sulfate ions are accumulated to a concentration of 300–350 g l^{-1} without any deterioration of the quality of electroplated coatings. However, a substantial decrease in the ruthenium deposition rate in electroplating in the optimal modes recommended in the literature ([3, 4] j_c = 1–2.5 A dm^{-2}) was observed because of the electrolytes were depleted of the nitrido complex. In the process, other forms of ruthenium, aqua-hydroxo complexes of ruthenium(III,IV) and ruthenium(III), were accumulated in solution. The only possible way to improve the working capacity of industrial ruthenium-plating electrolytes was to perform deposition at higher cathode current densities, 3.5–4.5 A dm^{-2}. In this case, the coating quality was not impaired. Also, the ruthenium deposition rate could be raised and stabilized. In all probability, the potentials of ruthenium electrodeposition from aqua-hydroxo complexes of ruthenium, previously believed to be electrically inactive, could be reached at these current loads.

CONCLUSIONS

(1) The varying-with-time complex composition of the sulfamate ruthenium-plating electrolyte and adjusting solutions was studied. It was found that dissolution of the nitrido-aqua chloride complex of ruthenium(IV) in water is accompanied by hydrolysis, with the nitrido bridge disintegrated and a mixture of monomeric and dimeric aqua-hydroxo chloride complexes of ruthenium(III) and (IV) formed.

(2) It was shown that, to stabilize ruthenium-plating electrolytes in their prolonged use, it is necessary to perform a systematic adjustment of the electrolyte by addition of a freshly prepared adjusting solution of ammonium μ-nitridoaquachlororuthenate(IV) and ammonium sulfamate.

(3) It was demonstrated that, to maintain high performance characteristics of sulfamate ruthenium-plating electrolytes, the electrolysis should be carried out at cathode current densities of 3.5–4.5 A dm^{-2}, at which the ruthenium is electrodeposited from aqua-hydroxo chloride complexes.

Abstract—The mechanism of thermal oligomerization of hexafluoro-1,3-butadiene was examined using RHF, ROHF, and GVB/DH, and by B3LYP/6-31G* and /6-311G* quantum-chemical methods. The energies of highly reactive excited states of the monomer and of intermediate biradical species were estimated. Isomeric biradicals (excited monomers and dimers) with the free valences localized on two carbon atoms were shown to coexist in the reaction mixture. Recombination of such biradicals and their reactions with neutral stable molecules give rise to diverse products, depending on the reaction temperature.

DOI: 10.1134/S1070427208060153

Oligomerization of hexafluoro-1,3-butadiene (HFBD, **I**) at 130–300°C, experimentally studied in [1–3], is a convincing example of the occurrence of thermal reactions via biradical electronically excited states of the starting molecules and intermediates. The involvement of such states in thermochemical reactions has been studied previously for the examples of dimerization of perfluoroolefins [4–6] and polymerization of bicyclobutanes [7]. It was shown that the key step of these reactions is thermal excitation of a monomer molecule to a low-lying (~1 eV) electronic state, accompanied by degradation of the double bond or cleavage of a single C–C bond. The arising monomeric biradicals are highly reactive and readily recombine or undergo addition to monomer molecules to give stable dimers or biradical intermediates further yielding oligomers and polymers.

The role of thermally excited electronic states in polymerization reactions was considered in [8]. Such reactions are quite common in organic chemistry. Polymerization reactions initiated by free radicals naturally fall into a series of other polymer reactions that occur by the radical mechanism, but differ in the nature and properties of intermediates. One of the principal features of radical reactions is the full localization of an unpaired electron on a separate atom of a reaction center, in contrast to other reactions, such as, e.g., anionic polymerization in which an unpaired electron in the excited state of the reaction center is delocalized over several atoms.

Hexafluoro-1,3-butadiene has been extensively studied as a monomer in radical and anionic polymerization. It is nonreactive in the common radical polymerization, but readily polymerizes by the anionic mechanism under initiation with cesium or rubidium fluoride, cesium or rubidium *tert*-butylate, and other typical anionic initiators [9–11]. Poly-HFBD with the polyvinylene chain structure is highly crystalline and heat-resistant (360°C) [9].

The primary products of thermal reactions of HFBD in the gas phase are, depending on temperature, hexafluorocyclobutene, [2+4]-cycloadduct, and a pair of stereoisomeric [2+2]-cycloadducts [1, 2]. The reaction of [2+4]-cycloadduct with hexafluoro-1,3-butadiene yields three structurally isomeric trimers, whereas [2+2]-cycloadducts undergo thermal rearrangements with the formation of tricyclic saturated dimers or of a polymer. Kazmina et al. [1, 2] believe that the difference in the chemical behavior of 1,3-butadiene and its perfluorinated analog is due to their structural features. The planar structure of the carbon skeleton of the C_4H_6 mol-

ecule favors conjugation of the double bond and imparts electron-donor properties to the molecule, whereas nonplanar HFBD exhibits electron-acceptor properties typical of fluoroolefins.

EXPERIMENTAL

Quantum-chemical calculations were performed by the RHF, ROHF, GVB, and B3LYP methods in the 6-31G*, 6-311G*, and DH basis sets, using GAMESS program [12, 13]. The methodological features of quantum-chemical calculations of molecules in the ground and excited (S_1, T_1) states are described in [6]. The calculated total energies were corrected for the zero-point vibration energies.

The hexafluoro-1,3-butadiene molecule in the ground electronic state has a nonplanar *s-cis* structure [14, 15]. The CCCC dihedral angle determined by electron diffraction is 47.4° [14]. An ab initio ROHF/DH calculation also gives preference to the *s-cis* conformation (ΔE = 0.5 kcal mol^{-1}), with the dihedral angle ∠CCCC equal to 55.8°. The same energy difference, ΔE = 0.5 kcal mol^{-1} in favor of the *s-cis* form, and similar dihedral angle ∠CCCC = 54.0° are given by B3LYP/6-311G* calculations. The nonplanarity of the carbon skeleton of the hexafluorobutadiene molecule is accounted for by the repulsion of fluorine atoms [16].

Under electronic excitation, the hexafluoro-1,3-butadiene molecule can pass into several equilibrium biradical states, which is confirmed by calculation of the indices of the free atomic valence F_A in quasidegenerate singlet and triplet states $(S \cdot T)_n$ (Fig. 1). The indices F_A, whose sum in each molecule is 2.00, are close to unity only for two carbon atoms and are negligible for the remaining atoms of the molecule. This fact, along with the closeness of the geometric parameters, energies, and indices F_A, calculated for the singlet and triplet components of the $(S \cdot T)_n$ state, confirms its biradical character.

The stereoisomeric *trans*- and *cis*-1,4-**I*** states in which the free valences are concentrated on the terminal carbon atoms C^1 and C^4 (Fig. 1) have the lowest energy. The energy of the excited state *s-trans*-1,2-**I*** in which the free valences are localized on the adjacent C^1 and C^2 atoms is only slightly higher. Due to localization of the excitation on one degraded double bond and steric proximity of the radical centers, the singlet–triplet splitting of the energy level in this case (3.2 kcal mol^{-1}) is appreciably larger than in the previous case (0.3 kcal mol^{-1}).

It is important that the above-indicated energies of the biradical states of monomer **I** molecule are sufficiently low for these states to be efficiently populated at the experimental temperatures, 130–300°C [1, 2]. The excitation energies for the other species considered below are also low. Therefore, the mech-

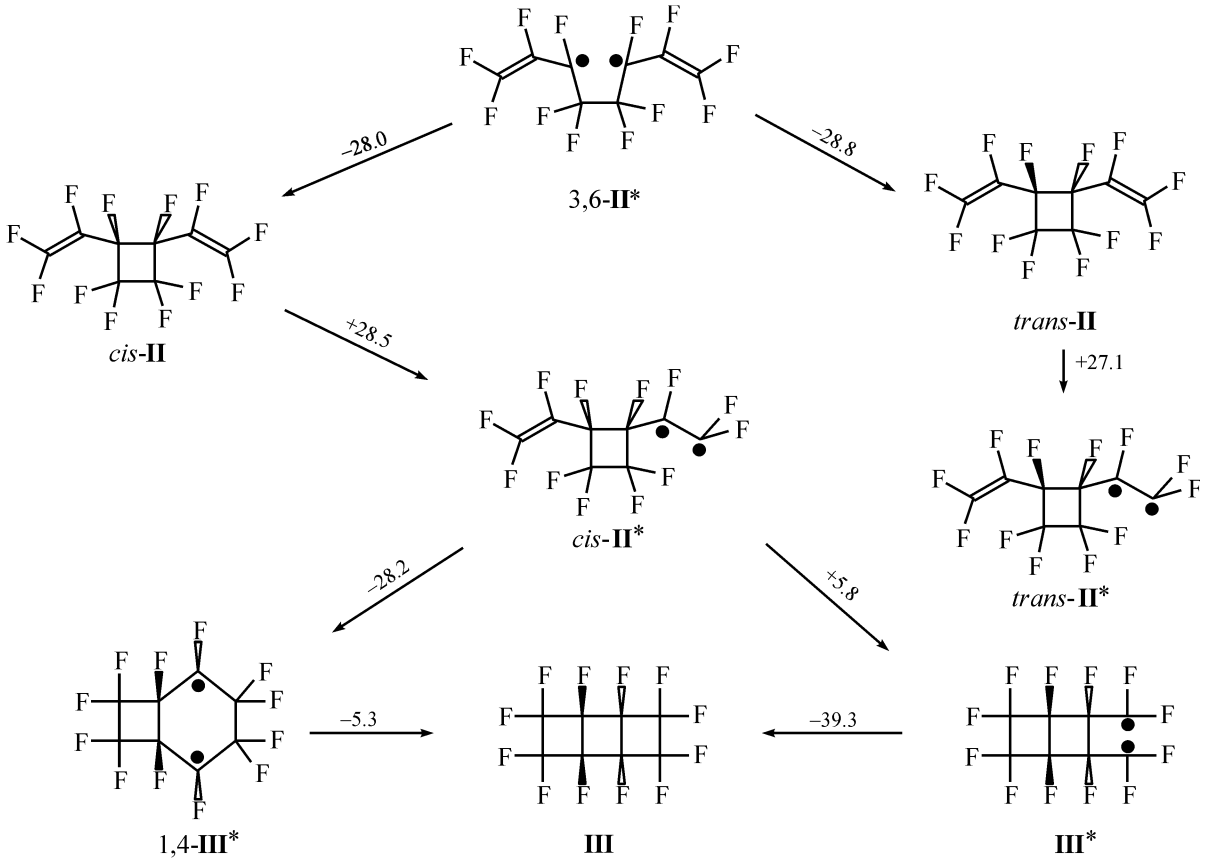

Fig. 2. Structure of hexafluorobutadiene dimers in the ground and excited triplet states. The calculated (RHF, ROFH/DH) heats of transitions with the release (–) and absorption (+) of energy are indicated over arrows.

anism of HFBD transformations on heating in the gas phase can be regarded as thermal excitation of the initial molecules and the intermediates formed to low-lying biradical states.

The excited states of hexafluoro-1,3-butadiene, discussed in this paper, have a nonplanar equilbrium structure, which is strongly different for the 1,4- and 1,2-biradicals. The presence of several excited states of HFBD with close energies, but different distributions of the free atomic valences is responsible for the occurrence of several pathways of radical reactions, involving generation of diverse structures: four-membered rings with an exocyclic vinyl group, six- and eight-membered rings, ladder-shaped molecules, etc. Some of these structures are shown in Fig. 2, with the calculated heats of transition (positive for heat absorption and negative for heat release) indicated over the arrows. The 1,4-biradical states are responsible for the formation of hexafluorocyclobutene by intramolecular recombination of free valences and of perfluorinated substituted cyclohexene as a product of the Diels–Alder-type (Lebedev) reaction. The 1,2-biradical states are involved in the formation of dimers *trans*- and *cis*-**II** with four-membered saturated rings.

The biradical states 3,6-**II*** can be populated not only by thermal excitation of these dimers, but also by the reaction of two monomer molecules, at least one of which is in the excited 1,2-biradical state. For some structures, e.g., 1,4-**III*** and **III**, the energies differ insignificantly (Fig. 2), suggesting the possibility of thermal excitation of the ladder structure to a biradical state at room temperature. Two radical structures *cis*-**II*** and **III***, differing in energy by only 5.8 kcal mol^{-1}, are also shown in Fig. 2. In the first case, the exocyclic C=C bond is excited, and in the second, the radical centers arise from cleavage of one of the single bonds of the four-membered ring.

One of the dimers, dodecafluorotricyclo[4.2.0.0^{2,5}]-octane **III** consisting of three four-membered rings in the chair conformation, is of particular interest, because it was actually isolated from the reaction mixture formed by heating of dimer *cis*-**II** (150°C)

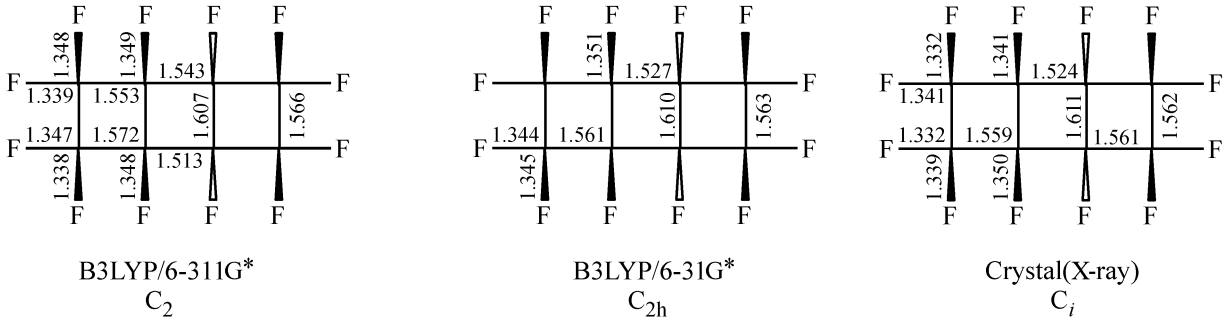

Fig. 3. Structure of hexafluorobutadiene dimer **III** in the ladder conformation, according to the results of a single-crystal X-ray diffraction analysis and to B3LYP/6-311G* and B3LYP/6-31G* calculations.

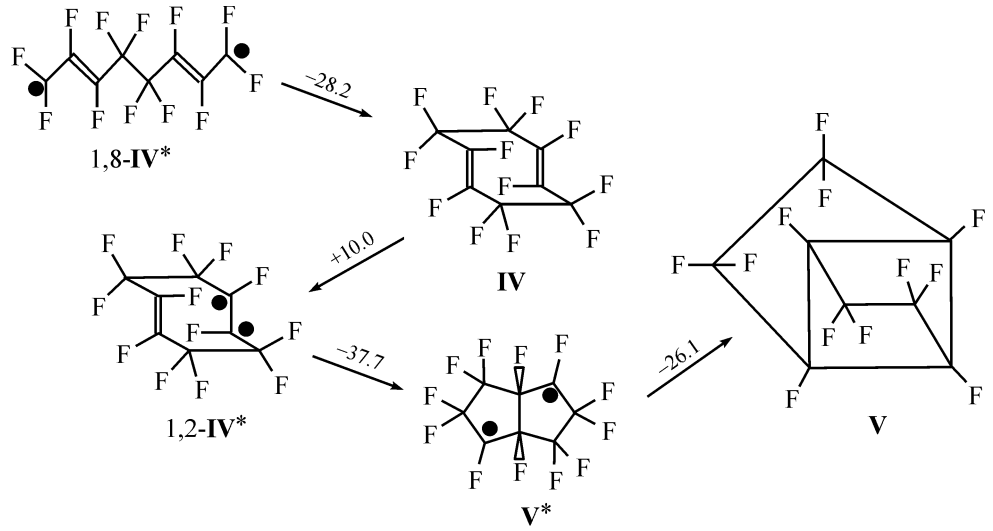

Fig. 4. Scheme of formation of a stable highly symmetric hexafluorobutadiene dimer of globular structure **V**.

and was subjected to single-crystal X-ray diffraction analysis [1]. In our calculations, the best agreement between the calculated (C_i) and experimental structural parameters is provided by the B3LYP/6-31G* method (Fig. 3). In the symmetrical (C_{2h}) molecule **III**, the presence of the symmetry center implies an ideally planar structure of the middle four-membered ring. In the extended basis set, B3LYP/6-311G*, the optimal configuration is characterized by the C_2 symmetry, but fixation of the C_{2h} symmetry leads to an increase in the energy by only 0.4 kcal mol^{-1}. The lower symmetry, C_i, of molecule **III** in the crystal, compared to the theoretically possible symmetry C_{2h}, is naturally attributable to features of molecular packing in the crystal.

Another unusual structure formed upon high-temperature heating of dimer *trans*-**II** (200°C) is dimer **V** (Fig. 4). According to [1], both dimers **III** and **V** are secondary products of thermal transformations of primary dimers *trans*-**II** and *cis*-**II** (Fig. 2). Being one of the most stable products, product **V** exists up to 300°C, in contrast to **III** which transforms at 150°C into **V** via a certain undetectable intermediate **IV**. It has been suggested [1] that intermediate **IV** is an eight-membered ring with two double bonds, namely, *trans,trans*-dodecafluoro1,5-cyclooctadiene (Fig. 4). The calculation results confirm the possibility of existence of **IV** in the chain of radical transformations of the starting hexafluorobutadiene, but the energy of excitation (**IV** → 1,2-**IV***) of this species is low (10 kcal mol^{-1}), and hence it cannot be detected at temperatures exceeding 150°C because of the fast thermochemical transformations.

Along with the above-noted products, thermal transformations of hexafluorobutadiene also yield other dimers and trimers of various structures. One of the most stable products **VI** containing a six-membered ring with an exocyclic double bond is formed from biradical 3,4-**VI*** by intramolecular recombination with a considerable heat release

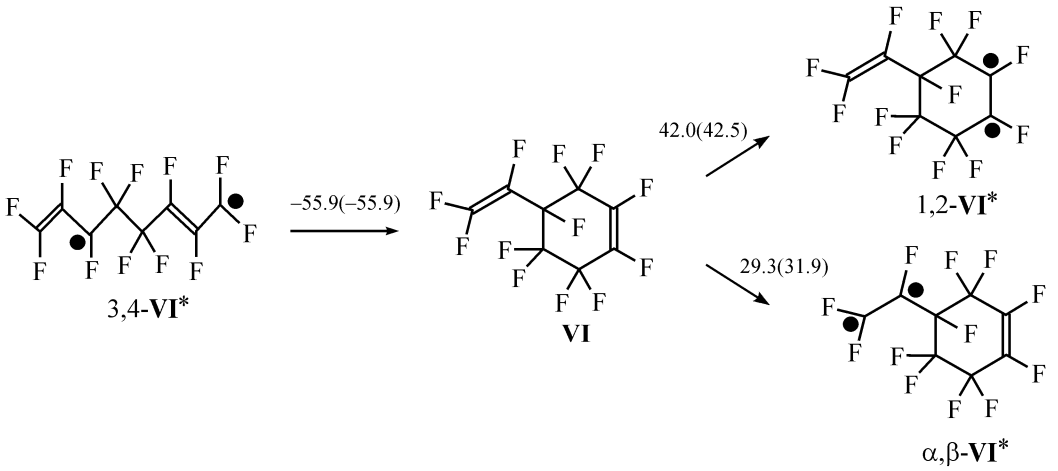

Fig. 5. Excited state of the stable dimer, 4-trifluorovinylnonafluorocyclohexene **VI** (RHF, ROHF/DH).

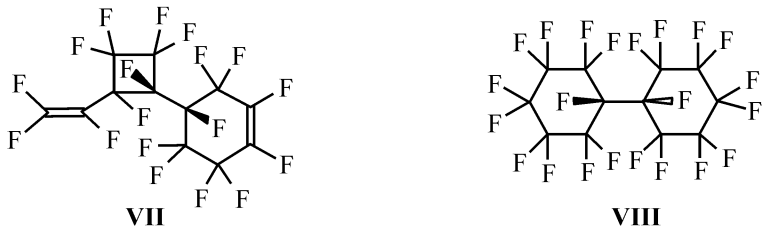

Fig. 6. Structures of hexafluorobutadiene trimers **VII** and **VIII**.

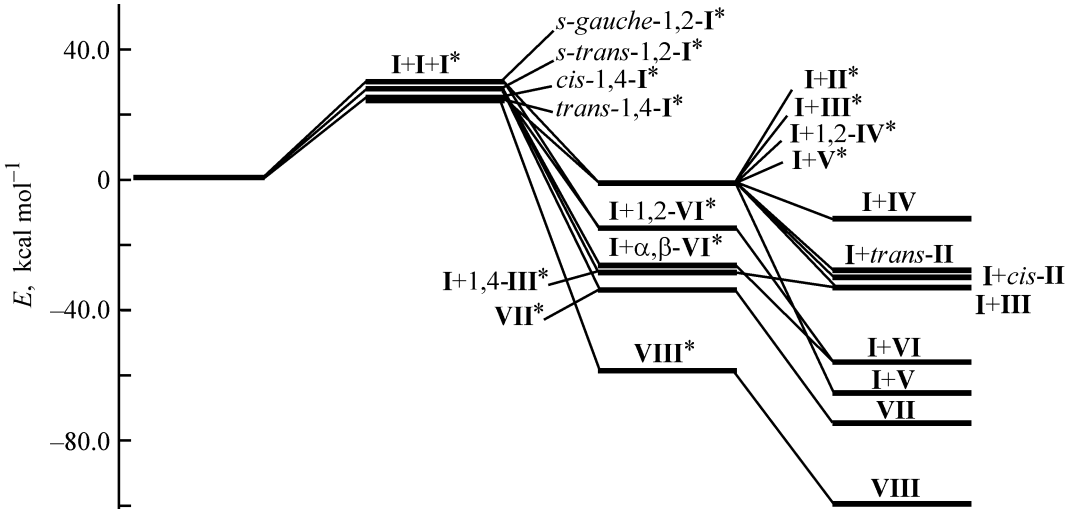

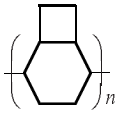

Fig. 7. Energy diagram of thermal reactions of 1,3-hexafluorobutadiene, according to RHF, ROHF/DH ab initio calculations.

(–55.9 kcal mol^{-1}, Fig. 5). Two trimers, **VII** and **VIII**, are shown in Fig. 6. Their formation by ternary collisions of C_4F_6 molecules is improbable, and the main trimerization pathway is the reaction of monomers with dimers at high temperature (>150°C).

The polymeric product formed in a small amount is the final product of thermochemical transformations of a dimer, *cis*, *trans*-dodecafluoro-1,5-cyclooctadiene **IX**, an isomeric analog of intermediate **IV**. At the same time, the polymer consisting of

units may be a product of intermolecular recombination of biradicals 1,4-**III*** [1] (Fig. 2). The latter variant of the reaction seems to be more

probable because of the low energy of excitation of dimer **III**, 5.3 kcal mol^{-1}, and full structural matching between biradical 1,4-**III*** and the elementary unit of the polymer. Dimer **IX** was not isolated pure, but its complex with (acetylacetonato)dicarbonylrhodium was prepared and studied. The excitation energy of **IX**, 9.3 kcal mol^{-1}, is close to that of the *trans*, *trans* analog, 10.0 kcal mol^{-1}.

Finally, it is appropriate to give a summary energy diagram of thermal reactions of dimerization and trimerization of hexafluorobutadiene (Fig. 7). It is of particular importance that, according to our concept, the thermal reactions in all the steps occur via electronically excited biradical states of molecules. From this standpoint, we can rationalize the main experimentally found relationships [1, 3]. In particular, structures requiring higher temperatures for their activation should have higher excitation energies. Indeed, chemically unstable dimer **III** [1] characterized by a low excitation energy (ΔE = 5.3 kcal mol^{-1}) in the biradical form involved in a number of chemical transformations, and the final product in the chain of its radical reactions is the most stable compound **V**. In contrast to **III**, dimer **V** is very stable and does not decompose up to 300°C. This compound should be characterized by high excitation energies, which is confirmed by calculations (Fig. 7).

Thus, the concept of the thermal electronic excitation is very fruitful in studying chemical transformations of unsaturated organofluoric compounds. On the whole, these data give grounds to state that, in all the steps, thermochemical reactions of hexafluorobutadiene occur via electronically excited biradical states. The molecular nature of the electronic excitation of perfluorobutadiene and related compounds consists in deformation of the carbon skeleton by a turn about the C=C bonds, with the radical centers localized on two carbon atoms. The biradical mechanism of thermal reactions of hexafluorobutadiene was suggested in experimental studies [1–3], but their authors assume the occurrence, along with the biradical mechanism, of other mechanisms (concerted, zwitterionic), impossible in our opinion.

CONCLUSIONS

(1) Thermal oligomerization of hexafluoro-1,3-butadiene in the gas phase at 130–300°C occurs via electronically excited biradical states $(S \cdot T)_n$.

(2) The existence in the reaction medium of a mixture of isomeric biradicals with close energies of $S_0 \rightarrow (S \cdot T)_n$ excitation and high free valence indices on the carbon atoms is responsible for the diversity of the reaction pathways and products: saturated polycyclic dimers with the ladder and globular structure and saturated four-membered and unsaturated six-membered rings linked by single bonds in trimers.

Abstract—Composites based on anionic polyacrylonitrile and carbon nanofibers were studied by X-ray diffraction, differential scanning calorimetry, thermal gravimetric analysis, and electron microscopy. The effect of carbon nanofibers on the specific features of cyclization and carbonization of anionic polyacrylonitrile at temperatures of to 550°C was studied.

DOI: 10.1134/S1070427208060165

Studying the cyclization and carbonization of polyacrylonitrile (PAN) in the presence of various modifiers and fillers is a topical task, because PAN-based composites and their carbonization products are widely used in many fields of engineering and industry [1, 2].

It is known that PAN carbonizates and PAN-based composites occupy a leading place among polymeric carbon materials because of the high carbon residue, reaching 60% [3]. In the initial step of carbonization of PAN and its composites in the temperature range 400–550°C, the major pathway of thermal transformations is cyclization. It is accompanied by a large heat release, frequently leading to the polymer degradation and carbon loss. The magnitude of the exothermic effect and the cyclization temperature can be decreased by using PAN copolymers or by introducing various modifying additives [4, 5].

Studies of the mechanisms of cyclization and carbonization of PAN are performed with polymer samples synthesized by both radical and anionic polymerization [6, 7]. It was shown in [8] by thermal analysis, IR spectroscopy, and mass spectrometry that PAN synthesized on anionic initiators (a-PAN) is a convenient model for studying the initial step of carbonization, as it does not contain residual amounts of the catalyst, oxidants, and other components present in PAN prepared by radical polymerization. Previous studies of a-PAN in the temperature range 20–300°C have shown the absence of impurities and volatile low-molecular-weight cyclization products [9].

Carbon nanoadditives (nanofibers, carbon nanotubes, fullerenes, shungite, etc.) find growing use for modification of polymeric materials. These additives have high specific surface area and exhibit unique mechanical and conducting properties. Introduction of carbon nanoadditives into polymers can improve their physicomechanical characteristics, enhance the heat resistance, and raise the carbon residue [10–12].

The goal of this study was to examine in more detail specific features of the cyclization and carbonization of composites of anionic polyacrylonitrile with carbon nanofibers.

EXPERIMENTAL

As object of study we used powdered a-PAN synthesized with anionic catalysts by the procedure described in [9]. For thermochemical tests we took samples with a molecular weight M_w ~20000. For the modification of a-PAN, we used carbon nanofibers (CNFs) prepared by pyrolysis of methane, using NiO as catalyst [13].[1] Composites of a-PAN with CNFs were prepared by

[1] Carbon nanofibers were prepared at a laboratory of Tambov State Technical University.

grinding in an agate mortar to obtain a uniform blend.

To assess structural changes occurring in the course of cyclization and carbonization of a-PAN, we used combined thermal analysis with simultaneous recording of the TG and DTA curves. Measurements were performed with an MOM derivatograph (Hungary) in an open crucible at a heating rate of 10 deg min^{-1}. The microstructure of carbon fibers was studied by transmission electron microscopy on a BS-500 electron microscope (Tesla, Czechia). X-ray diffraction patterns were obtained with a DRON-II device (Burevestnik Research and Production Association, Russia) using Ni-filtered Cu_{K_α} radiation (λ = 1.54 Å) in the scattering angle range $2\theta = 4°–36°$. The cyclization of a-PAN and its composites with nanofibers was monitored with a DSM-2M differential scanning calorimeter (Specialized Design Office of Instrument Making, Pushchino, Russia) at scanning rates of 8 and 16 deg min^{-1}. The temperature was calibrated using In and Sn references.

Figures 1a and 1b show, respectively, the TG and DTA curves of a-PAN, a-PAN–CNF composites (80 : 20 and 50 : 50 by weight), and CNFs. The weight loss of a-PAN (Fig. 1a, curve *1*) on heating to 270°C is 4%, which may be due to the release of adsorbed moisture. In the temperature range 270–308°C, the sample suffers a sharp weight loss (~12%) due to the release of residual low-molecular-weight polymerization products. Further heating to 330°C is not accompanied by weight loss, and at higher temperatures (up to 800°C) the TG curve reflects a typical carbonization process with gradual dehydrogenation of the formed heterochain polymer. The yield of the carbon residue at 800°C is 44%.

In contrast to a-PAN, the CNF sample (Fig. 1a, curve *4*) exhibits throughout the examined temperature range a monotonic TG curve reflecting the gradual loss of the pyrolysis products on heating. After heating the CNF sample to 800°C, the carbon residue is 66%. The TG curves of a-PAN–CNF composites reflect the superposition of thermochemical reactions characteristic of a-PAN and CNFs. Comparison of composites with various component ratios shows that a stepwise weight loss in the temperature range 160–190°C is more pronounced in curve *2* (Fig. 1a), whereas in curve *3*, the initial weight loss is complete at 260°C. The run of these curves on further heating to 350–370°C also depends on the component ratio. However, at still higher temperatures, the rates of the weight loss

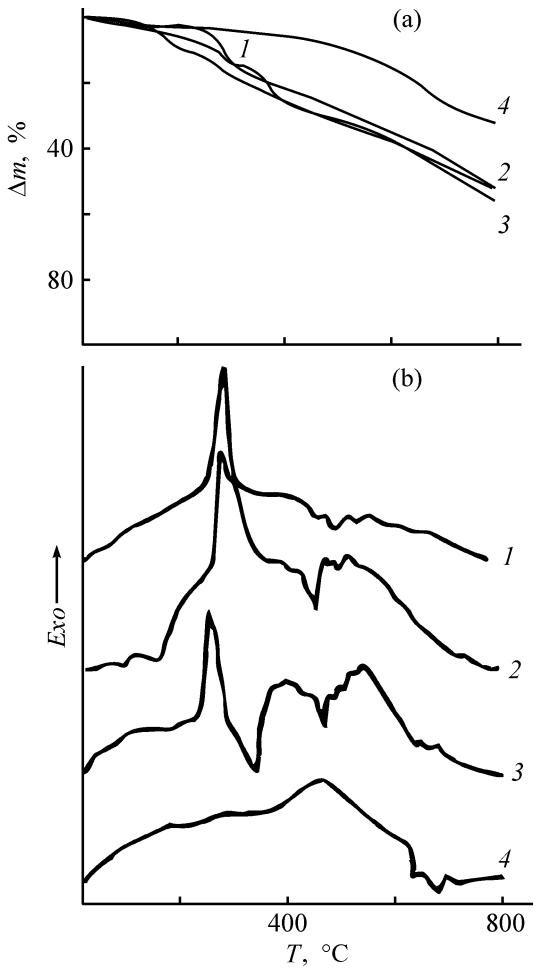

Fig. 1. (a) TG and (b) DTA curves of samples of (*1*) straight a-PAN, (*2*) 50 : 50 a-PAN–CNF composite, (*3*) 80 : 20 a-PAN–CNF composite, and (*4*) CNFs. (Δm) Weight loss and (T) temperature.

for both composites become similar. After heating to 800°C, the carbon residue for the 80 : 20 and 50 : 20 composites is 43 and 45%, respectively.

In all the DTA curves (Fig. 1b) in the temperature range 200–300°C, there are exothermic effects associated with the cyclization of a-PAN and its composites. Peaks of avalanche-like exothermic processes are observed in the range 225–250°C. The noticeable shift of the cyclization temperature, observed for the 50 : 50 a-PAN–CNF composite, may be due to the catalytic effect of CNFs on the PAN cyclization. This effect can be attributed to the presence of polyconjugated systems in CNFs, which, according to [14], accelerate condensation processes in carbonization of various compounds.

As we have found previously [15], the cyclization is followed, starting from 400°C, by carbonization

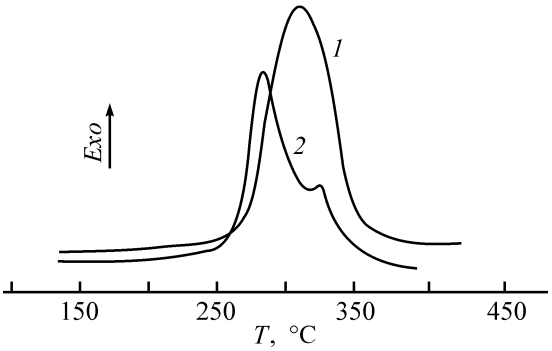

Fig. 2. DSC curves of samples of (*1*) straight a-PAN and (*2*) 50 : 50 a-PAN–CNF composite. (*T*) Temperature.

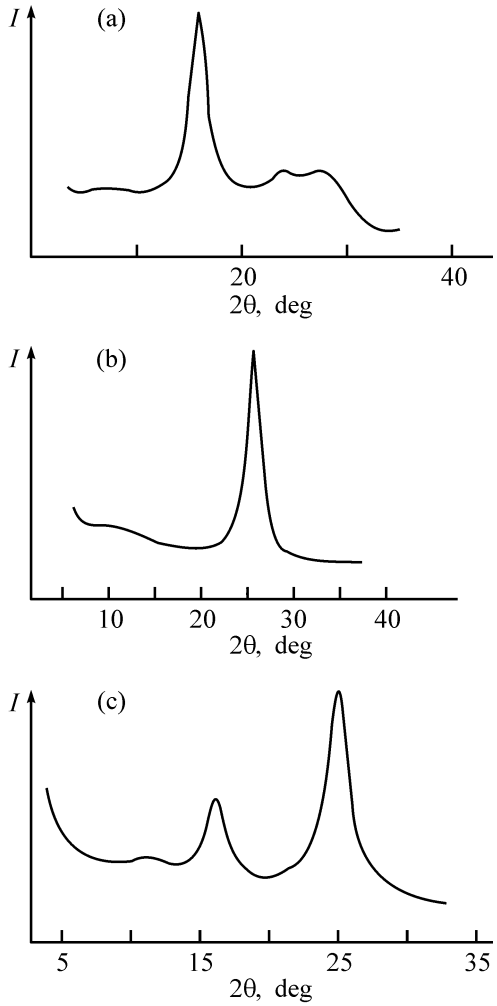

Fig. 3. X-ray diffraction patterns of samples of (a) a-PAN, (b) CNFs, and (c) 50 : 50 a-PAN–CNF composite. (*I*) Intensity and (2θ) Bragg angle; the same for Fig. 4.

of a-PAN, accompanied by slow release of volatile products. The rearrangement of the primary cyclic structure of the carbonizate in the temperature range 400–550°C is a complex process. In the DTA curve of straight a-PAN, there are ill-defined asymmetric endothermic peaks with maxima at 456, 470, and 537°C (Fig. 1b, curve *1*). In the thermograms of a-PAN–CNF composites (Fig. 1b, curves *2*, *3*), the endothermic effects in the range 400–550°C are more pronounced. As we showed in [15], the cyclization of a-PAN is accompanied by the formation of 3*D*-ordered aggregates of a-PAN macromolecules with a definite set of cyclic sequences whose fragments have a crystalline structure. These fragments were synthesized and characterized in [16]. The results of [15, 16] show that the ordering of macromolecules, in the course of a-PAN cyclization is a basis for the formation of a carbonized structure of a-PAN and a-PAN–CNF composites.

To evaluate the effect of nanofibers on the character of the occurring transformations, we examined the cyclization of the straight a-PAN powder and of the 50 : 50 a-PAN–CNF composite by DSC. Figure 2, curve *1* shows a thermogram of the cyclization of the a-PAN powder at a scanning rate of 8 deg min^{-1}. The exotherm of the cyclization of straight a-PAN is characterized by a half-width of ~50°C and a maximum at 310°C, with the onset at 250°C.

For the 50 : 50 a-PAN–CNF composite, the exotherm corresponding to the cyclization (Fig. 2b), along with the main maximum, has a high-temperature shoulder. The exothermic peaks at a scanning rate of 8 deg min^{-1} are observed at 280 and 330°C. At a higher scanning rate (16 deg min^{-1}), the peaks become better resolved. According to [15], in a-PAN prepared in DMF by the procedure described in [9], the syndiotactic configuration prevails, but the isotactic configuration is also present. The cleavage of the double bond of linear a-PAN in the course of cyclization generates active radicals capable of reacting with carbon nanofibers. The presence of two conformations in the a-PAN samples examined may be responsible for the bimodal shape of the cyclization exotherm in the presence of carbon nanofibers. It should be noted that the energy of a-PAN cyclization in the presence of CNFs is several times lower (600 J g^{-1} interms of a-PAN) than the cyclization energy of the unfilled a-PAN (2200 J g^{-1}). Furthermore, in the composite the cyclization is facilitated, as follows from the 30°C shift of the main exothermic maximum.

Figure 3 shows the X-ray diffraction patterns of (a) a-PAN, (b) CNFs, and (c) 50 : 50 a-PAN–CNF composite. In the diffraction pattern of a-PAN, there is a strong reflection at 2θ = 17°, which corre-

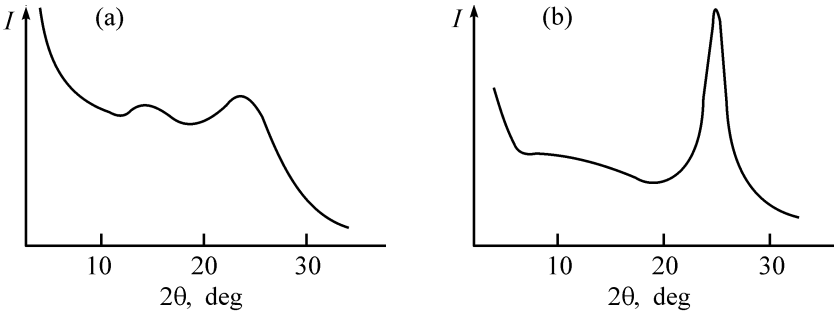

Fig. 4. Diffraction patterns of samples of (a) a-PAN and (b) 50 : 50 a-PAN–CNF composite, heated at 400°C for 3 h.

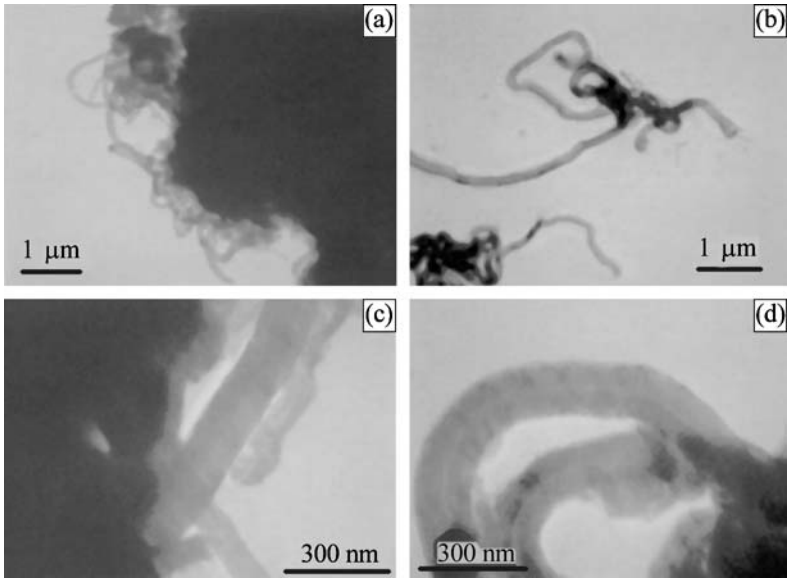

Fig. 5. Electron micrographs of CNFs at various magnifications.

sponds to the interplanar spacing d = 5.2 Å, and two weak broad reflections at 2θ = 25°30′ (d = 3.5 Å) and 29° (d = 3.1 Å), in agreement with the data reported in [17]. In the diffraction pattern of CNFs, there is a strong narrow reflection at 2θ = 26°15′ (d = 3.4 Å) corresponding to the graphite structure. In the diffraction pattern of the a-PAN–CNF blend in the initial state, there are narrow reflections at d = 5.2 Å, characteristic of a-PAN, and at d = 3.4 Å, characteristic of CNFs. That is, a superposition of the reflections of a-PAN and CNFs is observed, i.e., the composite is a mechanical blend of the components.

After heating straight a-PAN at 400°C for 3 h, the reflections characteristic of the initial a-PAN disappear (Fig. 4a), and only a weak halo at 2θ = 15° (d = 5.9 Å) is observed and a new reflection at 2θ = 25° (d = 3.55 Å) appears, which indicates that the crystal structure of the initial a-PAN is broken down and the turbostratic carbon structure is formed.

Heating of the 50 : 50 a-PAN–CNF composite at 400°C for 3 h also leads to the breakdown of the initial crystal structure of a-PAN. Only one reflection at 2θ = 26°15′ (d = 3.4 Å) remains in the X-ray diffraction pattern (Fig. 4b), and its angular width at the base is larger than that of the related CNF reflection in the unheated composite (Fig. 3c). This means that the reflection from the turbostratic carbon structure of heat-treated a-PAN overlaps with the CNF reflection.

Our results suggest the formation of ordered areas with the turbostratic carbon structure after the completion of cyclization of a-PAN and its composites, which undergo phase transitions in the range 400–550°C.

Figure 5 shows electron micrographs of carbon nanofibers used for preparing composites with a-PAN. It can be seen that the major part of the filler consists of nonfractionated nanofibers tightly linked in coarse agglomerates. A fragment of one of them is shown in Fig. 5a. Along with coarse (tens

of micrometers) agglomerates, there are also separate strongly twisted nanofibers forming submicrometer-sized globules (Fig. 5b).

An electron-microscopic examination of the agglomerates at various magnifications demonstrated that they are formed by nanofibers 60 to 150 nm thick (Figs. 5c, 5d). At larger magnifications, the fine structure of the nanofibers can be seen: a hollow channel along the nanofiber axis, 15 nm in diameter, and kinks resulting from bending [18] and suggesting high rigidity of the nanofibers (Fig. 5d). Thus, the nanofibers used in this study are hollow graphitic structures with developed surface area. It is known [19, 20] that such carbon nanofibers have high sorption capacity. Therefore, in the course of cyclization they can actively adsorb reaction products and hence shift the temperatures of cyclization peaks.

CONCLUSIONS

(1) The energy of cyclization of anionic polyacrylonitrile in a composite with carbon nanofibers is an order of magnitude lower than that of the straight polymer. Also, introduction of carbon nanofibers into anionic polyacrylonitrile decreases the cyclization temperature by 30°C.

(2) The turbostratic carbon structure is formed in anionic polyacrylonitrile and in the examined 50 : 50 composite of anionic polyacrylonitrile with carbon nanofibers in the initial step of carbonization.

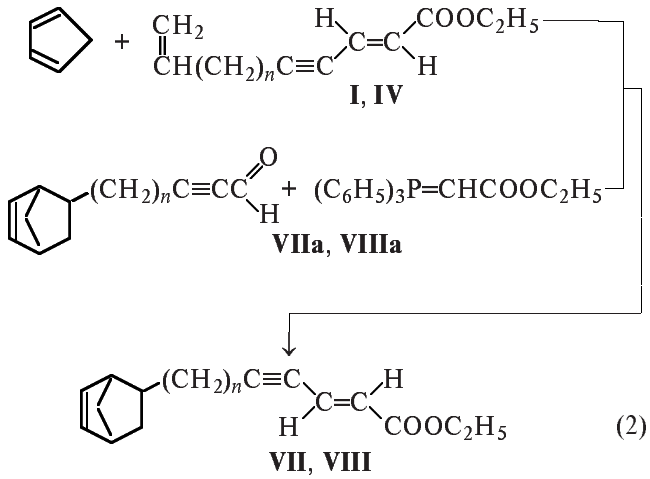
Abstract—Esters of the dienyne series with a *trans*-ethylene bond were prepared in 70–80% yield by reactions of enyne aldehydes with ethoxycarbonylmethylenetriphenylphosphorane. The compounds were studied by IR and ^{1}H NMR spectroscopy, and their modifying effect on ED-20 epoxy–4,4'-isopropylidenediphenol resin was revealed.

DOI: 10.1134/S1070427208060177

Highly unsaturated compounds containing double and triple bonds (enynes, diynes, enediynes, dienynes) offer vast synthetic possibilities for preparing various carbocyclic, heterocyclic, and polyunsaturated structures that are fragments of molecules many natural biologically active substances [1–7]. Diyne and dienyne derivatives isolated from plants and microorganisms exhibit strong fungicidal, antimicrobial, and insecticidal effects [8, 9]. Among highly unsaturated functional compounds, including esters, there are also modifiers of various polymeric materials [10–14].



Proceeding with the search for new highly unsaturated compounds of the dienyne series as high-performance modifiers for polymers, we prepared in this study new dienyne esters and examined their modifying properties. We found that esters **I**–**VI** are formed in 65–75% yield by condensation of unsaturated aldehydes with ethoxycarbonylmethylenetriphenylphosphorane in 1 : 2 molar ratio for 6 h in benzene in a nitrogen stream [scheme (1)]:

Ia–**VIa** **I**–**VI** (1)

where n = 0, X = H (**Ia**, **I**), CH_3 (**IIa**, **II**), Cl (**IIIa**, **III**); n = 1, X = H (**IVa**, **IV**), CH_3 (**Va**, **V**), Cl (**VIa**, **VI**).

We found that the dienyne esters prepared are very reactive. In particular, they enter into the Diels–Alder reaction with cyclopentadiene (CPD) at 155–160°C through the terminal double bond to form within 8 h the corresponding norbornene esters **VII** and **VIII**. Esters **VII** and **VIII** were also prepared by an independent route, reaction of appropriate norbornene-substituted aldehydes with ethoxycarbonylmethylenetriphenylphosphorane [scheme (2)].

The physicochemical characteristics of esters **I–VIII** are listed in Table 1. The compositions and structures of **I–VIII** were confirmed by GLC, TLC, and IR and ^{1}H NMR spectroscopy (Table 2) [15].

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer in the range 400–4000 cm^{-1} from thin films. The ^{1}H NMR spectra were measured on a Tesla BS-487B spectrometer (80 MHz) from CCl_4 solutions, internal reference HMDS. The purity of the products was confirmed by TLC on Silufol UV-254 plates, using various solvent systems.

The heat resistance of epoxy compounds was examined by thermal analysis on a Q-1500D derivatograph (MOM, Hungary). All tests were performed in air with 200-mg samples at a heating rate of 5 deg min^{-1}.

The starting unsaturated aldehydes **Ia–VIIIa** were prepared by oxidation of the corresponding primary alcohols with a mixture of aqueous sulfuric acid with chromic anhydride [16–19].

Ethyl hepta-2,6-dien-4-ynoate I. A solution of 2 g (0.025 mol) of pent-4-en-2-ynal in 50 ml of benzene was added to a solution of 17.4 g (0.05 mol) of ethoxycarbonylmethylenetriphenylphosphorane in 100 ml of benzene. The mixture was refluxed in a nitrogen atmosphere for 6 h. Then, benzene was distilled off, the residue was treated with petroleum ether, the undissolved residue of triphenylphosphine oxide was filtered off, and the solvent was distilled off. The residue was distilled in a vacuum to obtain compound **I**.

Compounds **II–VI** were prepared similarly from the corresponding aldehydes.

Ethyl 5-(norborn-2-en-5-yl)pent-2-en-4-ynoate VII. A mixture of 1.7 g (0.025 mol) of cyclopentadiene and 3.7 g (0.025 mol) of **I** was heated for 8 h at 150–160°C in a sealed ampule in the presence of 0.05 g of hydroquinone. After the reaction completion, the mixture was subjected to fractional distillation in a vacuum. After distillation of the unchanged starting compounds, adduct **VII** was isolated.

Compound **VIII** was prepared similarly from **IV**.

Independent synthesis of VII and VIII. Adducts **VII** and **VIII** were prepared as described above for **I**, from 0.05 mol of ethoxycarbonylmethylenetriphenylphosphorane and 0.025 mol of the corresponding bicyclic aldehyde.

Table 3. Thermal parameters of compounds based on ED-20 resin modified with acetylenic esters **I**, **II**, and **IV–VI** (ester : resin proportion 20 : 100 by weight)

Modifier	Activation energy of thermal oxidative degradation, kJ mol^{-1}	Half-life $\tau^{1/2}$, min	Thermogravimetric index, °C
I	205	60	117
II	200.3	56.4	119
IV	194.92	62	119
V	237	64	133
VI	202.7	57.2	121
None	190.5	59.8	120

Compounds **I–VI** were tested as modifiers for ED-20 epoxy–4,4'-isopropylidenediphenol resin, and compounds **I**, **III**, and **V**, as modifiers for granulated low-density polyethylene (LDPE) of 15803-020 grade.

As investigation objects we prepared compounds from ED-20 resin, polyethylenepolyamine (PEPA) curing agent taken in a stoichiometric ratio, and modifying additives **I–VI**. The weight proportion of the modifier to ED-20 was varied from 10 : 100 to 30 : 100. Along with examining the modifying properties, we also attempted to reveal a correlation between the structure of **I–VI** and their modifying effect on the epoxy compound (Table 3).

The effect of modifier on the thermal properties of the epoxy compound can be readily monitored by variation of the activation energy of degradation

Table 4. Physicomechanical parameters of modified polyethylene

Modifier	Ultimate tensile strength σ, MPa	Relative elongation ε, %	MFI, g/10 min
I	123	615	5.8
III	135	630	6.5
V	120	610	8.0
None	115	600	4.5

and the thermogravimetric index of the compound (measurement accuracy ±2–3°C, Table 3). The modifier also appreciably affects the heat resistance of cured epoxy compounds (measurement accuracy ±2°C).

Table 3 shows that replacement of the hydrogen atom (**I**, **IV**) by the methyl group (**II**, **V**) enhances the thermal parameters of the epoxy compounds, with the highest values attained with **V**. Replacement of the hydrogen atom by chlorine in **VI** affects the heat resistance of the epoxy compound insignificantly.

It should also be noted that the modifier structure does not affect the course of curing of the epoxy compound. In all the cases, curing occurs in the range 70–120°C, as indicated by exothermic peaks of curing, manifested in the DTA curve.

The effect of modifiers on the thermal properties of cured compounds was evaluated from the thermograms.

To examine the effect of **I**, **III**, and **V** on the physicomechanical properties of polyethylene, we prepared polymer compounds. The processing was in two steps: (1) compounding (polyethylene : monomer = 100 : 3 by weight) on rollers at 120–125°C for 10–15 min and (2) compaction on a hydraulic press at 170°C. We determined the physicomechanical properties of the films obtained (1 mm thick) and the melt flow index (MFI) of the compounds, as MFI is one of the most important parameters for processing. The results are listed in Table 4.

As can be seen from Table 4, ester **III** is the most efficient as modifier: it enhances the physicomechanical parameters and improves the processability (MFI) of the PE compound.

CONCLUSIONS

(1) Esters of the dienyne series were prepared by adding a benzene solution of unsaturated aldehyde to ethoxycarbonylmethylenetriphenylphosphorane at 80–85°C in a nitrogen atmosphere. The ester molecules contain a trans-ethylene bond.

(2) It was shown that dienyne esters can act as modifiers for an epoxy resin (ED-20) and polyethylene. They enhance the physicomechanical and thermal parameters and improve the processability of polyethylene compounds.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Plasticized Polyurethanes

V. V. Bestuzheva, S. A. Dushenok, F. A. Zheltikov, and A. N. Lysov

Abstract—Polyurethane formulations containing 10 to 75% tris(azidomethyl)nitromethane as a plasticizer were synthesized.

DOI: 10.1134/S1070427208060189

Plasticizing additives are widely used in practice of synthesis and processing of polyurethanes to improve the rheological properties of the reaction mass and raise the elasticity of the cured material. As a rule, polyurethanes have a complex 3*D* structure produced not only by chemical cross-links, but also by strong physical interactions via hydrogen bonds. To organic liquids used in the polymer technology belong compounds of three kinds: (i) comparatively indifferent substances, causing no profound changes in the polymer structure (dibutyl and dioctyl phthalate, dioctyl sebacate); (ii) those partly decross-linking the polymer matrix (toluene, cyclohexanone); and substances that can, under certain conditions, completely disintegrate the network of both hydrogen and chemical bonds (tetrahydrofuran and aprotic compounds: dimethyl sulfoxide, dimethyl formamide, and dimethyl acetamide).

However, the effect of each of the plasticizers even on polyurethanes with the same oligomeric base can be widely varied by changing the type and concentration of a diisocyanate and a cross-linking agent involved in the reaction. The ability of polyurethanes to widely vary their properties with synthesis conditions and structure and relative amounts of the starting reagents is a consequence of their pronounced tendency toward cross-linking; conformation transitions; change in the geometric, thermodynamic, and kinetic parameters; and combination of strongly ordered crystalline and disordered amorphous microscopic regions in the same macroscopic space. This opens up opportunities for their use in directed synthesis of products that are modified with a prescribed plasticizer and have required physicomechanical properties.

A particular place among the widely diverse functions of polyurethanes is occupied by their use as combustible binders for energetic condensed systems. One of the most serious problems to be solved when using polyurethanes in systems of this kind is that their efficiency should be improved [1]. This can be done by introducing placticizers with high enthalpy of formation and density, e.g., nitro, nitrato, and azido compounds [2, 3], into polyurethane binders.

The aim of our study was to examine the preparation conditions and determine the main characteristics of thermodynamically stable and mechanically strong polyurethane formulations that are placticized with the maximum possible amount of tris(azidomethyl)nitromethane, and can be used as binders in energetic condensed systems (ECS).

EXPERIMENTAL

We tested as a hydroxyl-containing component intended to form the hydrocarbon backbone of the polyurethane elastomer the P6-BA polyester, oligoethylene butylene glycol adipinate according to TU (Technical specification) 38-103-288–78, described by the formula

$$HO\left[(CH_2)_2OCO-(CH_2)_4-COO(CH_2)_4-OCO-(CH_2)_4-COO(CH_2)_2\right]_5OH.$$

Table 1. Effect of the plasticizer content on the properties of polyurethanes

Plasticizer content, %	σ_t, MPa	ε_{te}, %	γ, kg m^{-3}	ΔH, kJ kg^{-1}
0	12.00	160	1200	–4070
10	4.05	250	1215	–3310
20	2.80	290	1230	–2554
30	1.75	350	1245	–1796
40	1.10	435	1260	–1038
50	0.70	535	1280	280
60	0.40	630	1295	478
70	0.25	750	1315	1236
75	0.20	820	1320	1615

The choice of P6-BA is justified by its wide use in domestic industry and the high level of physicomechanical parameters of polymers produced on its base. The polyester we used had a molecular mass of 2000, density γ = 1200 kg m^{-3}, and enthalpy of formation ΔH = –4300 kJ kg^{-1}.

We used the following distillation-purified coreagents in urethane formation reactions: aliphatic hexamethylene diisocyanate (HMDI) $OCN(CH_2)_6NCO$, aromatic 2,4-toluylene diisocyanate (TDI) $CH_3C_6H_3(NCO)_2$, and alkyl aromatic 4,4'-methylene bisphenyl diisocyanate (MDI) $CH_2(C_6H_4NCO)_2$.

Because the starting polyester and diisocyanates are bifunctional, their interaction yields linear polymers that can be destructively affected by organic liquids, including the chosen plasticizer. To form a strong macromolecular matrix capable of retaining the maximum volume of a plasticizer, with a high level of physicomechanical properties preserved, the reaction of polyurethane synthesis was performed in the presence of trifunctional hydroxyl-containing substances providing formation of cross-links. Preliminarily dried (over phosphorus pentoxide) triols: glycerol $HOCH_2CHOHCH_2OH$ and trimethyl propane (TMP) $C_2H_5(CH_2OH)_3$, served as cross-linking substances, and tin dibutyl dilaurinate, as a catalyst (TU 6-02-818–73).

We studied as a plasticizer a compound having experimental-industrial resources of raw materials, tris(azidomethyl)nitromethane $(N_3CH_2)_3$–C–NO_2, conforming to TU 08015232–89 (SKTB Tekhnolog). The product is chemically and thermally compatible with other components, has low glass transition temperature, low viscosity, and low volatility, which predetermines its importance in assessment of this compound as a component of energy-saturated systems. We used the substance upon its chromatographic purification with activated carbon of OU A brand. The product had the following parameters: refractive index at 20°C 1.5255, density 1367 kg m^{-3}, bp 90°C at 0.04 mm Hg, flash point at a 5-s delay 240°C, onset temperature of intense decomposition 212°C (according to DTA), and calculated enthalpy of formation 3510 kJ kg^{-1} [4].

Plasticized polyurethanes were synthesized in a vacuum installation with a heated reactor and high-speed stirrer. Moisture and air inclusions, which can cause defect formation in cured samples, were removed from the polyester at 110°C and a residual pressure of 1 mm Hg. The weighed portion was cooled to 60°C and required amounts of a diisocyanate, triol, and catalyst were introduced. After the ingredients were mixed, a plasticizer was added and the mixture was kept under the same conditions for 15–20 min. The final curing was performed in hermetically sealed fluoroplastic molds at 60 ± 2°C.

The tensile strength of a cured polymer suitable as a binder for ECS should be no less than 0.1 MPa, and the relative tensile elongation, ≥700%. The enthalpy of formation and the density, which characterize the energetic efficiency of a polyurethane, grow as the concentration of tris(azidomethyl)nitromethane in the polyurethane increases. Consequently, the goal of our study was to carry out a directed synthesis of formulations that can withstand, at the maximum content of the plasticizer, an irreversible deformation at sufficiently high chemical, thermal, and mechanical loads.

To achieve such a result, we had to determine the component and concentration composition of the polymeric part of elastomers at which an as strong as possible 3*D*-cross-linked skeleton capable of retaining the maximum amount of the azide plasticizer would be formed. To assess the influence exerted by the introduced amount of tris(azidomethyl)nitromethane on the tensile strength σ_t (MPa), relative tensile elongation ε_{te} (%), enthalpy of formation ΔH (kJ kg^{-1}), and density γ (kg m^{-3}) of plasticized polyurethane, we obtained elastomers containing P6-BA polyester and hexamethylene diisocyanate at a 1.0 : 1.1 ratio between hydroxy and isocyanate groups. As a cross-linking substance was introduced trimethylol propane whose mole fraction in the reaction mixture was 0.3. As a catalyst served tin dibutyl dilaurinate , taken in an amount of 0.03% relative to the mass of the polymeric component. The physicomechanical parameters and the density were found in accordance with OST (All-Union Standard) V-84-434–71

Table 2. Influence exerted by the ratio between the reaction groups on the physicomechanical parameters of TDI-based polyurethane (plasticizer content 75%, mole fraction of trimethylol propane 0.30)

OH : NCO ratio	σ_t, MPa	ε_{te}, %
1.0 : 1.0	0.20	820
1.0 : 1.1	0.25	860
1.0 : 1.2	0.25	860
1.0 : 1.25	0.25	850
1.0 : 1.3	0.30	850

Table 3. Influence exerted by the mole fraction of glycerol on the physicomechanical parameters of TDI-based polyurethane (plasticizer content 75%, OH : NCO = 1.0 : 1.1)

Mole fraction of triol	Σ_t, MPa	ε_{te}, %
0.20	0.20	810
0.25	0.20	840
0.30	0.25	860
0.35	0.25	880
0.40	0.35	880

and GOST (State Standard) 267–73, respectively; the enthalpy of formation was calculated. The results obtained are listed in Table 1.

Combined with a diol and a triol, hexamethylene diisocyanate provides formation of chemical cross-links yielding a polymer matrix that can retain up to 75% low-viscosity fluid in the cured material without phase stratification. As can be seen from the data presented, raising the concentration of a plasticizer in the formulation of a polyurethane being synthesized results in that its strength steadily decreases as the elasticity, density, and enthalpy of formation become higher. This type of behavior is preserved when hexamethylene diisocyanate is replaced with toluylene diisocyanate or 4,4'-methylene bisphenyl diisocyanate, even though the strength parameters are somewhat higher upon such a replacement, and the elasticity is slightly lower (Figs. 1, 2). This is accounted for by the limited possible rotation of aromatic rings and the resulting increase in the rigidity of polymer chains.

Among the polyurethanes synthesized and tested, of particular interest, as regards the whole set of its energy-related (ΔH = 1625 kJ kg^{-1}, γ = 1320 kg m^{-3}) and physicomechanical parameters (σ_t = 0.25 MPa, ε_{te} = 860%), is the sample based on toluylene diisocyanate, with a plasticizer content of 75%. We studied the possibility of improving its properties by varying the content of the diisocyanate and the type and amount of the cross-linking substance. The data characterizing the role played by the ratio of the reaction groups involved in the reaction of the diisocyanate and oligoester are listed in Table 2.

It can be seen that, by lowering the amount of the diisocyanate to the stoichiometric value or raising it to a 30% excess, the strength of the polyurethane can be varied within ±20%. In this case, the elasticity remains nearly unchanged. Presumably, the increase in the diisocyanate content favors a fuller completion of the reaction. However, this does not improve the physicomechanical properties to any noticeable extent.

If we take glycerol as a cross-linking substance, instead of trimethylol propane, the parameters of polyurethane remain the same within the determination error. The effect of the ratio between the diol (P6-BA) and triol (glycerol) components in the polyurethane structure is illustrated by the data in Table 3.

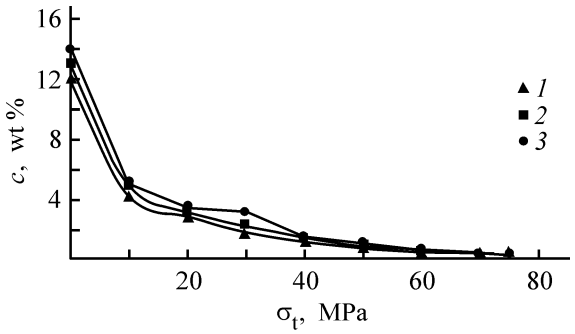

Fig. 1. Dependence of the tensile strength σ_t on the plasticizer content c for polyurethanes based on (*1*) HMDI, (*2*) TDI, and (*3*) MDI. OH : NCO = 1 : 1.1 mole fraction of TMP 0.30; the same for Fig. 2.

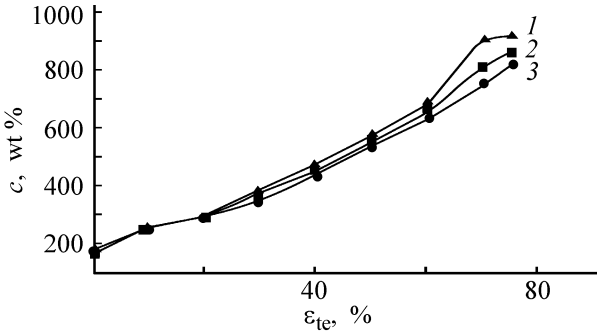

Fig. 2. Dependence of the relative tensile elongation ε_{te} on the plasticizer content c for polyurethanes based on (*1*) HMDI, (*2*) TDI, and (*3*) MDI.

As follows from the results obtained, the increased content of the trifunctional component makes higher the density of cross-linking of the material and thereby provides a certain improvement of the strength and elasticity of the polymers, all other conditions being the same.

The impact sensitivity of cured polyurethanes (according to GOST 4545–80) is 20–30%, and the friction sensitivity (GOST 50835–95), is not lower than 300 MPa. The onset temperature of intense decomposition, found by differential-thermal analysis on a Vulkan measuring-and-computing complex, is 210°C. Thus, the values of the main energy-related and performance parameters of the plasticized polymers obtained suggest that their use in energetic condensed systems is advisable.

CONCLUSIONS

(1) Polyurethanes plasticized with 10–75% tris(azidomethyl)nitromethane were obtained in a single technological cycle via directed formation of a 3*D* network (by varying the content of the plasticizer introduced and choosing the nature and concentration of a diisocyanate and a triol).

(2) It was shown that the cured elastomers have a tensile strength of 0.2–4.0 MPa, relative tensile elongation of 200–800%, and high enthalpies of formation (up to 1615 kJ kg^{-1}).

(3) It was demonstrated that the high-strength elastic polyurethane matrix provides the set of physicomechanical parameters, required for energetic condensed systems, and use of an azido-containing plasticizer leads to an increased density and enthalpy of formation, which makes the polyurethanes synthesized promising binders for energetic condensed formulations.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Modified Polyisoprene with a High Adhesion Strength

N. I. Kurbanova, N. Ya. Ishchenko, and A. M. Kuliev

Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgaiyt, Azerbaijan

Received November 2, 2007

Abstract—Modification of polyisoprene with trichloroacetic acid was studied, and the strength, adhesion, and thermal properties of vulcanizates obtained from the modified polyisoprene were determined.

DOI: 10.1134/S1070427208060190

One of efficient methods for preparing polymers with improved properties is chemical modification usually consisting in treatment of an already formed polymer molecule with a low-molecular-weight reagent. The most widely used modification route is introduction of functional groups into a polymer chain by addition or substitution reactions [1–4].

Introduction of functional groups into a polymer macromolecule affects its properties. This can be seen, e.g., from comparison of the properties of commercial synthetic isoprene rubber SKI-3 with those of semicommercial carboxylate isoprene rubber SKI-3K [5]. Rubber stocks based on SKI-3 exhibit decreased cohesion strength, and their vulcanizates show poor adhesion to metal surfaces, whereas SKI-3K is characterized by high strength of rubber stocks and high adhesion of vulcanizates to metals.

A known method for improving the SKI properties is modification by introduction of functional groups and, in particular, carboxy and hydroxy groups or chlorine atoms [5–7].

Previously, we have examined the modification of unsaturated elastomers with chloroacetic acids and their derivatives. Their introduction into rubber macromolecules noticeably improved the physicomechanical parameters of vulcanizates, such as the tensile, tear, and adhesion strength [8].

The goal of this study was to prepare modified SKI with improved physicomechanical properties, high adhesion, and high heat resistance by modification of rubber with trichloroacetic acid (TCAA).

EXPERIMENTAL

As object of study we used SKI-3 rubber with 96 mol % unsaturation and Mooney viscosity of 61 min (100°C); the modifier was TCAA (mp 58.7°C), and the initiator, benzoyl peroxide (BP).

To perform SKI modification, a 0.25-l flask equipped with a stirrer, reflux condenser, and dropping funnel was charged with a 2-g portion of rubber. The rubber was dissolved in 125 ml of benzene, and 5–10 wt % of the modifier (relative to rubber) was added. Then the initiator (0.1–1.0 wt % relative to rubber) was added, and the reaction was performed at 60–80°C for 1 h. In the process, 1-ml samples were taken at 5-min intervals, the rubber was precipitated with methanol, and the reaction mixture was analyzed for the residual modifier content. The precipitated rubber was washed with methanol and dried in a vacuum desiccator at room temperature.

The IR spectra were recorded on a UR-20 spectrophotometer. Samples were prepared as films on NaCl plates by complete evaporation of the solvent from 3% solutions of the rubber in benzene. The chlorine content and unsaturation were determined using the procedure described in [9].

The modification kinetics was studied at 60–80°C on a pH-673 device equipped with an electrode pair: a glass indicator electrode and an immersed silver chloride reference electrode. The content of the unchanged modifier was determined using a calibration plot.

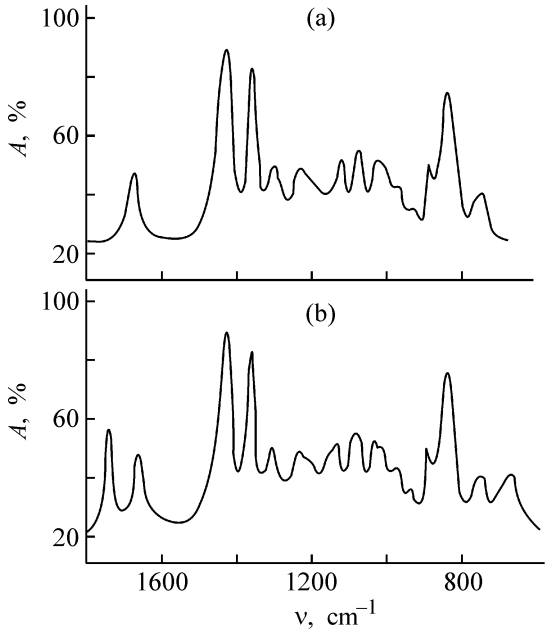

Fig. 1. IR spectra of (a) initial SKI and (b) SKI modified with trichloroacetic acid. (*A*) Absorption and (ν) wavenumber.

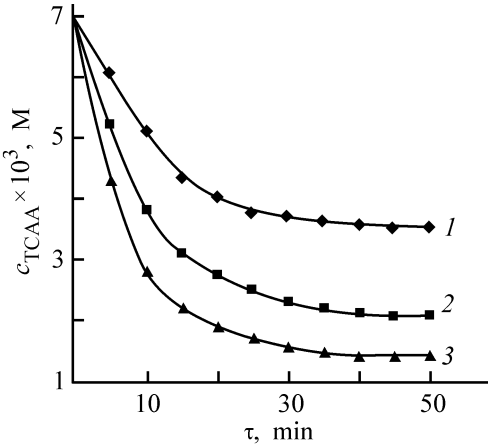

Fig. 2. Kinetic curves of trichloroacetic acid consumption in modification of polyisoprene in benzene in the presence of benzoyl peroxide at 60–80°C. Initial concentrations: $c_{BP} = 0.5 \times 10^{-4}$, $c_{TCAA} = 7 \times 10^{-3}$ M. (τ) Time. *T*, °C: (*1*) 60, (*2*) 70, and (*3*) 80.

Rubber stocks based on the modified SKI sample were prepared with standard formulations used for the straight SKI rubber. The compounding was performed on laboratory rolls whose temperature did not exceed 80°C. The vulcanization was carried out at 143°C for 25 min.

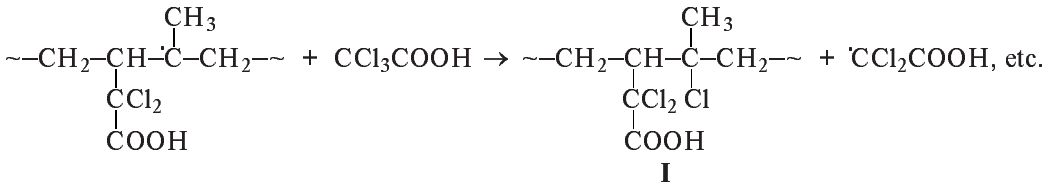
The physicomechanical tests were made on an RMI-250 tensile-testing machine at room temperature.

Derivatographic studies of vulcanizates were performed in air in the dynamic mode at a heating rate of 5 deg min^{-1} (sample weight 100 mg; sensitivities: DTA 250 μV, TG 100, DTG 1 mV) on a Q-1500D derivatograph (MOM, Hungary). The weight loss and half-life $\tau_{1/2}$ of the rubber sample on heating from 20 to 500°C were determined.

Figure 1 shows the IR spectra of the initial and modified SKI samples. Analysis of the IR spectra shows that all the absorption bands characteristic of the initial rubber are clearly pronounced in the spectrum of the modified rubber: a band of the *cis*-C=C bond at about 1130 cm^{-1}, a strong band of the methyl group at 1380 cm^{-1}, and bands of the trisubstituted double bond at 840 and 1665 cm^{-1}. In the course of modification, the intensity of the absorption band at 1665 cm^{-1} decreases, and additional bands appear at 680 (C–Cl bond) and 1160 cm^{-1} (C–O stretching vibrations). The band at 1775 cm^{-1} can be assigned to the carbonyl group of the saturated γ-lactone formed by modification.

Figure 2 shows the kinetic of the TCAA consumption in the course of SKI modification at 60–80°C. From the slope of the kinetic curves of the modifier consumption we determined the reaction rates, and from their temperature dependence we calculated the overall activation energy. The kinetic parameters of the SKI modification with TCAA are as follows: reaction rate $W \times 10^5$ = 0.378, 0.447, and 0.623 mol l^{-1} s^{-1} at 60, 70, and 80°C, respectively; apparent activation energy E_a = 27.16 kJ mol^{-1}.

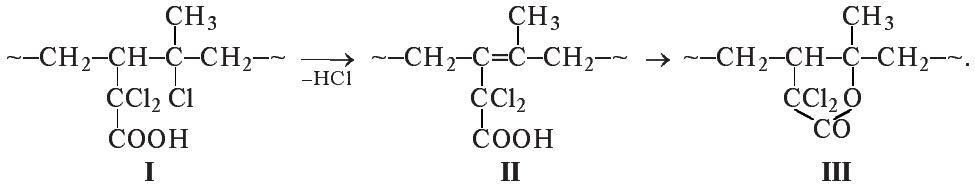
The results of the kinetic study and the spectra of the modified rubber samples suggest the following scheme of the reaction of TCAA with a rubber macromolecule in the presence of BP [10]:



$$\mathrm{I} \xrightarrow{\Delta} 2\mathrm{R}^{\cdot},$$

$$\mathrm{R}^{\cdot} + \mathrm{CCl_3COOH} \rightarrow \mathrm{RCl} + {}^{\cdot}\mathrm{CCl_2COOH},$$

$$^{\cdot}\mathrm{CCl_2COOH} + \sim\!\!-\mathrm{CH_2}-\mathrm{CH}=\overset{\displaystyle\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}-\mathrm{CH_2}-\!\!\sim$$



$$\rightarrow \sim\!\!-\mathrm{CH_2}-\underset{\displaystyle\mathrm{CCl_2}}{\underset{|}{\mathrm{CH}}}-\overset{\displaystyle\mathrm{CH_3}}{\overset{|}{\mathrm{C}}}-\mathrm{CH_2}-\!\!\sim,$$

$$\mathrm{COOH}$$

I

The initiator decomposes under the action of heat into radicals which, in turn, detach a chlorine atom from TCAA to form RCl. The $^{\cdot}CCl_2COOH$ radicals generated in the process undergo addition to the double bond of the rubber. This is followed by detachment of a Cl atom from TCAA by the macroradical to give product **I**. However, the reaction is accompanied by HCl evolution. Apparently, product **I** can eliminate HCl with the formation of product **II**, which subsequently undergoes lactonization under ionic conditions to give dichloro-γ-butyrolactone **III**:

I **II** **III**

To confirm this assumption, we studied the reaction of TCAA with 3-methyl-2-pentene, which is an analog of the polyisoprene unit. The reaction was performed under the conditions similar to those of SKI modification: in benzene in the presence of BP at 80°C. As a result, we isolated 2,2-dichloro-3,4-dimethyl-4-ethyl-γ-butyrolactone (bp 105–107°C/1 mm Hg) in a yield of up to 95%. The product structure was confirmed by IR and NMR spectroscopy. The IR spectrum contains the following absorption bands, cm^{-1}: 660, 710, 770 (C–Cl); 2960, 1460, 1380 (CH_3); 1250 (acetate group); 1755 (saturated γ-lactone). The following signals are observed in the NMR spectrum: 0.9 t (3H), 1.25 s (3H), 1.5 s (3H), 2.2 q (2H), and 4.9 (1H).

The addition of α-polychlorocarboxylic acids to olefins occurs similarly [11] and yields α-chloro-γ-butyrolactones.

A comparative study of the physicochemical properties of the initial and modified SKI samples revealed a change in the Mooney viscosity from 61 to 57 min and in the unsaturation from 96 to 93.2 mol %; the content of chlorine atoms in the modified SKI was 1.8%. By varying the component ratio, we found the optimal modification conditions (weight proportion): rubber : modifier : initiator = 100 : 7 : 0.5. From the modified SKI, using the standard formulation, we prepared vulcanizates and studied their physicochemical properties.

As can be seen from Table 1, the stress at 300% elongation and the tensile strength of vulcanized rubbers based on modified SKI samples are almost identical to those of the vulcanizate of the initial rubber. At the same time, the adhesion increases by a factor of 4, compared to SKI-3K.

Table 1. Physicomechanical properties of vulcanizates based on the initial and modified SKI

Elastomer	Stress at 300% elongation, MPa	Ultimate tensile strength, MPa	Elongation, %		Ultimate tear strength, kN m^{-1}	Adhesion strength to steel, MPa
			relative	residual		
SKI	14.2	28.5	490	22	70	0.05
SKI modified with TCAA	15.8	32.1	470	20	80	4.0
Carboxylate SKI-3K	15.3	30.2	460	21	72	1.0

Table 2. Weight loss of vulcanizates based on the initial and modified SKI

Elastomer	$\tau_{1/2}$, min	Weight loss, %, at indicated temperature, °C					
		150	200	250	300	350	400
SKI:							
initial	61	0	4	10	25	70	–
modified with TCAA	76	0	1	4	11	18	44

The results of a thermal analysis of the vulcanizates derived from the initial and modified SKI are listed in Table 2. It can be seen that the modification enhances the heat resistance: The weight loss of the vulcanizates derived from the initial and modified SKI is low (1–4%) up to 200°C, and at 300°C the weight loss is 25 and 11%, respectively. At still higher temperatures, the sample derived from the initial SKI rapidly degrades, whereas the weight loss of the sample derived from the modified SKI at 400°C is moderate, 44%. The half-life of the modified sample is also longer: 76 min against 61 min.

THe enhancement of the adhesion strength and thermal properties of vulcanizates prepared from modified SKI, compared to those prepared from the initial SKI, is apparently due to the fact that macromolecules of modified SKI contain butyrolactone groups and chlorine atoms, involved in the formation of the vulcanization network structure by forming labile bonds. Apparently, the best physicomechanical properties are exhibited by vulcanized rubbers with the optimal ratio of various types of cross-links [12]. Chemical cross-links of high energy provide preservation of the 3*D* network of the vulcanizate at large strains, whereas weak and readily rearranging vulcanization bonds favor relaxation of local overstrains.

CONCLUSIONS

(1) Modification of polyisoprene with trichloroacetic acid in benzene solution using a radical initiator occurs at the double bond of the polymer via an intermediate that transforms into γ-butyrolactone.

(2) The modified polyisoprene exhibits high adhesion strength and heat resistance, which allows its application fields in various branches of industry to be expanded.

Abstract—The temperature dependence of the tangent of the mechanical loss angle tan δ–T and the nature of the relaxation transitions were examined for model blends of polyvinyl chloride with butadiene-acrylonitrile elastomers.

DOI: 10.1134/S1070427208060207

The phenomena occurring at the interface of components in multicomponent polymer systems are of great importance in the formation of their macroscopic properties [1–3]. The structure of the components and the transition layer in polymer blends is determined by the mode of preparation and the number of polar units in the polymer chain [4, 5]. We have shown previously [6, 7] that changing the preparation conditions (pressure, temperature) strongly modifies the morphology of polymer blends [6], which is essential for formation of their physical properties [7]. For blends of compatible elastomers SKN-18 and SKN-40, there is one maximum in the temperature dependence of the mechanical loss factor, which is intermediate between those of the starting components, and its temperature position depends on the concentrations of the components. Bartenev and Zelenev [8] reported that, in particular, it shifts to higher temperatures with increasing SKN-40 proportion. This change of the temperature position of the maximum adheres to a linear (SKN-18 + SKN-40) or nonlinear [SKN-40 + polychloroprene rubber (PCPR)] law. In blends with over 50 wt % PCPR, the glass transition point T_g sharply decreases. Bartenev and Zelenev [8] reasoned that, because of the difference in the nature of the polar nitrile and chloroprene groups, the properties of the SKN40–PCPR blends differ from those of compatible and incompatible systems.

We examined here the relaxation transitions in elastomer–rigid-chain polymer systems in relation to the component ratio, taking polyvinyl chloride (PVC) and SKN butadiene-acrylonitrile elastomers as model systems. By varying the polarity of SKN, we controlled the strength of interaction of the macromolecules of different components, and by varying the mode of preparation, the mutual diffusion of the segments of the macromolecules. This yielded polymer systems with different ratios of the volume proportions of three types of structural elements, i.e., those of the initial components and of the transition layer [9].

EXPERIMENTAL

We blended PVC with SKN containing 18, 26, and 40 mol % polar acrylonitrile groups in the polymer chain on laboratory rollers in two modes. In the first mode, the elastomer was introduced into molten PVC (T_g ~90°C) in the viscoelastic state (at 145°C) (blending at $T > T_g$ of PVC; a liquid–liquid blend). In the second mode, powdered PVC with a particle size of ca. 100 μm was introduced into the elastomer mass at 30°C (blending at $T < T_g$ of PVC; a liquid–solid blend). The standard glass transition points for SKN-18, SKN-26, and SKN-40 are –40, –30, and –20°C, respectively. The structure of the blends was fixed by subsequent cross-linking of the chains by addition of sulfur (3 wt %) at

Table 1. Average PVC particle diameter R_0 and number N_c in relation to the mode of preparation, polarity of the elastomer, and component ratio

Blend composition, wt %	Blending at $T > T_g$ of PVC		Blending at $T < T_g$ of PVC	
	R_0, μm	$N_c \times 10^3$	R_0, μm	$N_c \times 10^3$
50 PVC + 50 SKN-40	0.58	26	75	2
50 PVC + 50 SKN-26	2	4.5	83	1.8
50 PVC + 50 SKN-18	8	1.8	91	1.7
20 PVC + 80 SKN-40	–	–	60	2.5
80 PVC + 20 SKN-40	–	–	90	1.7

145°C and 100 atm on a vulcanization press. The relaxation processes were examined by the method of forced (nonresonance) oscillations at a frequency $\nu = 2.5 \times 10^{-2}$ Hz on a modified Aleksandrov–Gaev instrument [10–12]; the samples were shaped as cylinders with diameter and height of 10^{-2} m. The experiments were carried out at the relative compression strain of 10%.

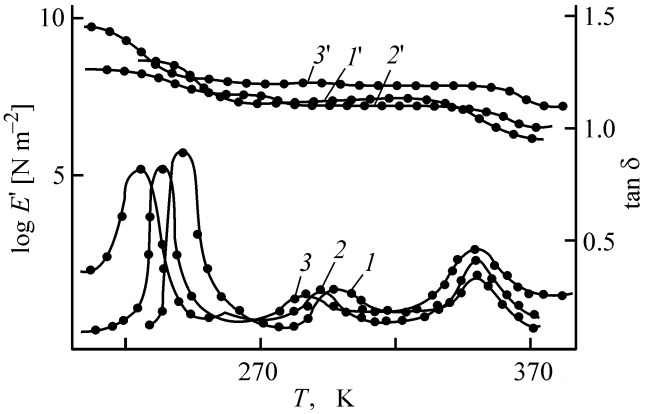

Fig. 1. Temperature dependence of (*1'–3'*) E' and (*1–3*) tan δ for blends of PVC with (*1*, *1'*) SKN-40, (*2*, *2'*) SKN-26, and (*3*, *3'*) SKN-18, obtained by blending at $T < T_g$ of PVC and 1 : 1 component ratio.

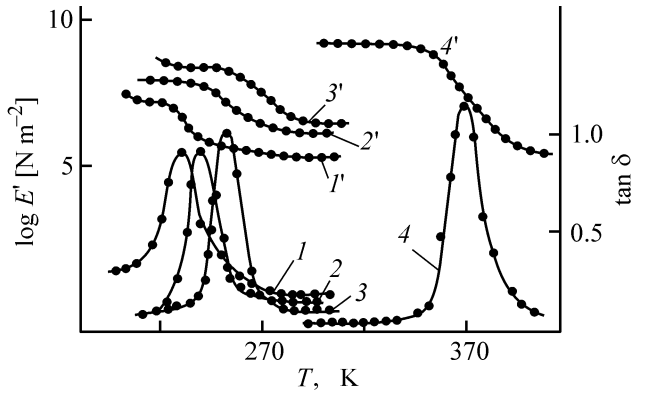

Fig. 2. Temperature dependence of (*1'–4'*) E' and (*1–4*) tan δ for (*1*, *1'*) SKN-40, (*2*, *2'*) SKN-26, (*3*, 3') SKN-18, and (*4*, *4'*) PVC.

The most important parameters of the morphology, correlated with the properties of polymer blends, are the bulk phase composition and the particle size distribution [13, 14]. We employed the Kaplan's technique [15] using the structural data, to analyze the uniformity of the morphology of the polymer blends, which is determined by the number N_c:

$$N_c = K/R_0,$$

where K = 150 Å is the characteristic dimension, the length of the segment involved in glass transition, and R_0, average diameter of the particles in the system, determining the average length corresponding to one component.

The average R_0 values were calculated using the results of an optical and electron microscopic examination of the structure of the PVC–SKN blends. At $N_c \to \infty$, the system is homogeneous, and at $N_c \to 0$, heterogeneous. The results are presented in Table 1, which suggests that an increases in the polarity of the elastomer and in the blending temperature cause the particle size to decrease.

These morphological features of the PVC–SKN blends affect their macroscopic properties, in particular, the relaxation processes.

Figure 1 shows temperature dependences of the tangent of the mechanical loss angle, tan δ, and of the dynamic modulus of elasticity, E', of the PVC–SKN-40 (curves *1*, *1'*), PVC–SKN-26 (curves *2*, *2'*), and PVC–SKN-18 (curves *3*, *3'*) blends at the 1 : 1 weight ratio of the components. There are three maxima in these dependences. The low-temperature (α_1) and high-temperature (α_2) maxima correspond to the glass transition areas of the elastomer and PVC, and the intermediate maximum α' is associated with the mobility exhibited by the kinetic segments in the transition layer [16]. Comparison of Figs. 1 and 2 shows that the high- and low-temperature maxima differ from the cor-

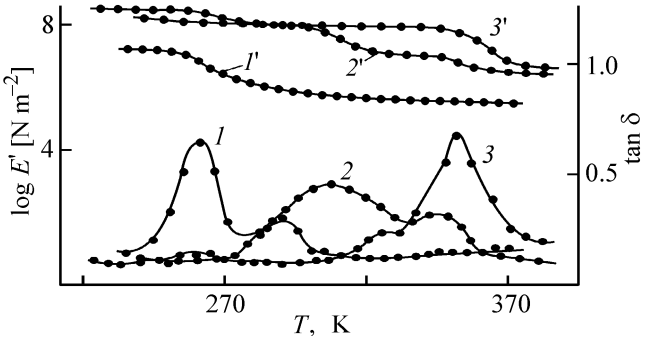

Fig. 3. Temperature dependence of (*1'–3'*) E' and (*1–3*) tan δ for the PVC–SKN-40 blends obtained by blending at $T > T_g$ of PVC. Weight ratio of the components: (*1*, *1'*) 1 : 4, (*2*, *2'*) 1 : 1, and (*3*, *3'*) 4 : 1.

Weight ratio of the components: (*1*, *1'*) 1 : 10, (*2*, *2'*) 1 : 9, (*3*, *3'*) 1 : 4, (*4*, *4'*) 1 : 1, (*5*, *5'*) 3 : 2, (*6*, *6'*) 4 : 1, and (*7*, *7'*) 7 : 3.

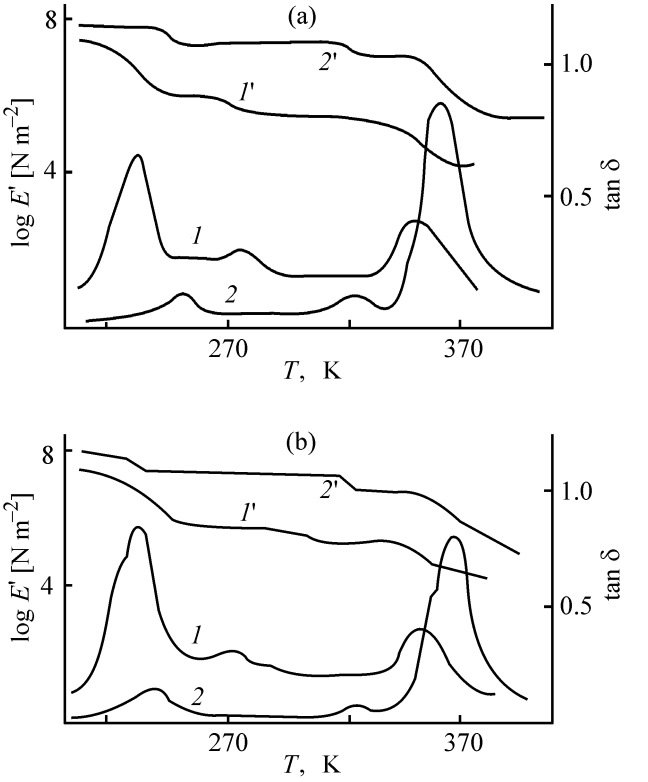

Fig. 5. Temperature dependences of (*1'–3'*) E' and (*1–3*) tan δ for PVC–SKN-18 blends obtained by blending at temperatures (a) below and (b) above T_g of PVC. Weight ratio of the components: (*1*, *1'*) 1 : 4 and (*2*, *2'*) 4 : 1.

responding α maxima of the individual components both in the height and temperature position. The low-temperature maxima are slightly shifted to higher temperatures, and the high-temperature maxima, by ca. 8 K to lower temperatures. The shift of the low-temperature maximum (α_1 process) to higher temperatures is caused by the hindrance to the segmental mobility of the elastomer molecules by the rigid-chain PVC (like in the case of carbon black filled elastomers [17]), and the shift of the high-temperature maximum, by the plasticizing action of the elastomer on PVC [18, 19]. Reznikova et al. [18] reasoned that the polar nitrile groups are responsible for the compatibility of the components in the blend, and nonpolar butadiene groups, for the plasticizing action confined to shielding of the polar groups of the polymer. The optimum effect is observed in the copolymer having two butadiene groups per nitrile group.

A decrease in the number of nitrile groups of the elastomer causes the intermediate maximum to shift to lower temperatures because of the weakening of the intermolecular interaction of different components. Simultaneously, the maximum corresponding to the glass transition range of PVC grows in height because of the change in the environment of the relaxing kinetic segments, associated with the change in the strength of interaction of the molecules of different components (a change in the number of nitrile groups in the elastomer). The difference in the conditions at which segments in the PVC–SKN blends exhibit mobility and a change in the size of the relaxing units occurs is also suggested by the changes in the height and half-width of the intermediate α' maxima in the temperature dependence of tan δ (Fig. 1, curves *1–3*).

The concentration ratio of the components strongly affects the temperature position, height, and half-width of the tan δ maxima (Figs. 3–5). A decrease in the SKN concentration causes the corresponding α_1 maximum to decrease in height and all the three (α_1, α', and α_2) maxima to shift to higher temperatures. With increasing proportion of the elastomer, the α_2 process is observed at a lower temperature, which may be due to an increase in the plasticizing influence exerted on PVC

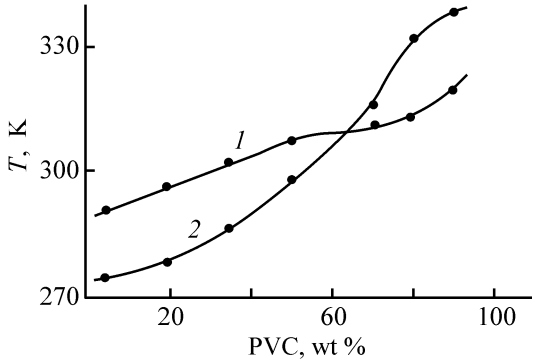

Fig. 6. Temperature position T of the intermediate maximum vs. PVC content for (*1*) PVC–SKN-26 and (*2*) PVC–SKN-18 blends. Blending at a temperature above T_g of PVC; the same for Figs. 7–9.

by the elastomer [19]. The change in the temperature position of the α' process ("floating" intermediate maximum) may be associated with that in the ratio of the components in the intermediate phase. The nature of the change in the mechanical loss background in the tan δ–T plot in Figs. 3–5 still remains to be elucidated.

The parameters of the α_1, α', and α_2 maxima are strongly affected by the strength of interaction of the molecules of different components and by the composition and mode of preparation of the blend (Figs. 6–8). The variation of the maxima in the tan δ–T plot with the concentration (Fig. 7–9) are evidently associated with the change of the conditions at which the kinetic segments of the α_1, α', and α_2 processes exhibit mobility. Similar dependences were obtained for the PVC–SKN-26 and PVC–SKN-18 blends (Table 2).

The temperature position of the intermediate maximum (Fig. 6) does not vary with the PVC content by a linear law; rather, it is approximately S-shaped, which is evidently due to the difference in the nature of the polar groups of the contacting polymers.

The intermediate maxima in the tan δ–T curve for the PVC–SKN blends can be interpreted similarly to the α' process, revealed for elastomers filled with a reactive filler in [8, 20, 21] and attributed to the mobility of the kinetic segments in the polymer layer adsorbed on the filler. However, the transition layer of the macromolecules of the components in the PVC–SKN blends has a different nature. The segmental mobility of the elastomer is manifested in the environment of the PVC segments. An increase in the PVC concentration in its blends with SKN-18 and SKN-26 causes the dynamic modulus of elasticity to grow (Fig. 9).

Table 2. Temperature position T, half-width ΔT, and height tan δ of the maxima in the tan δ–T curve at different component ratios in the PVC–SKN-26 and PVC–SKN-18 blends (blending at $T > T_g$ of PVC, $\nu = 2.5 \times 10^{-2}$ Hz)

The anomalies in Fig. 9 are due to phase inversion. The specific features of the relaxation transitions in the PVC–SKN blends strongly affect other macroscopic characteristics [3]. In particular, the temperature dependences of the tensile strength σ_t exhibit maxima corresponding to the absorption areas [3, 22].

Tkhakakhov et al. [23] examined the structure and the dynamic mechanical properties of the PVC–SKN blends and described their morphology in terms of a model comprising three phases (Fig. 10). Indeed, the shift of the α_1 and α_2 maxima along the temperature scale (their approximation) for the PVC–SKN blends suggests the formation of

a true solution of one component in the other, and the occurrence of an intermediate maximum, the existence of a developed transition layer.

CONCLUSIONS

(1) The system consisting of polyvinyl chloride and SKN butadiende–acrylonitrile elastomer, obtained by mechanical blending of the components, is characterized by three maxima in the temperature dependence of the tangent of the mechanical loss angle, which correspond to three relaxation transitions.

(2) Among these relaxation transitions, two α-transitions are associated with the segmental mobility of the macromolecule of the initial components, and the intermediate relaxation transition, with the segmental mobility in the transition layer.

(3) The temperature positions of all the three maxima vary with the concentration of the components, strength of interaction of the macromolecules of the contacting polymers, and mode of preparation of the blends, which is responsible for the "floating" character of the corresponding maxima.

ACKNOWLEDGMWNTS

Received March 13, 2008

Abstract—New cobalt(II) vinyl-β-diketone–benzoyl peroxide [or azobis(isobutyronitrile)] binary systems were studied as initiators of polymerization of styrene and methyl methacrylate.

DOI: 10.1134/S1070427208060219

The decomposition of hydroperoxides and hydrogen peroxide in the presence of β-diketonates as activators has been extensively studied [1, 2]. However, no data on the systems containing diacyl peroxides have been reported. Previously, we have studied the degradation of benzoyl peroxide (BP) as influenced by the type of the metal and ligand in the acetylacetonate complexes and the polymerization in the presence of these initiating systems and determined the yield of the radical reaction products [3, 4]. We have also studied in detail the thermolysis of a BP-iron(III) trifluoroacetylacetonate system [5]. We found that the rate of BP thermolysis increased by three orders of magnitude. Under these conditions, the acetylacetonate complex rapidly degrades. The polymerization of styrene, vinyl acetate, and methyl methacrylate (MMA) in the presence of this system was studied. We found that the polymerization of styrene and vinyl acetate in the presence of this system is significantly faster that that initiated by its components. However, the polymerization of these compounds decelerates with an increase in the conversion owing to the inhibiting effect of the acetylacetonate [6]. This system is ineffective in the case of the MMA polymerization.

Previously, we have prepared β-diketones containing reactive double bonds [7]. Their metal complexes can initiate the radical polymerization of vinyl monomers [7]. The presence of a double bond in the ligand allows incorporation of the β-diketonate fragment into the polymeric chain. Therefore, the polymerization initiated by vinyl-β-diketonate complexes yields branched polymers and macromolecular initiators [8]. However, the polymerization in the presence of pure vinyl-β-diketonaes is not always fast. In addition, these chelates can inhibit polymerization [9]. It was of interest to study mixtures of vinyl-β-diketonates with peroxide and dinitrile initiators, since no data on these systems have been reported.

The aim of this study was to examine mixtures of BP or azobis(isobutyronitrile) (AIBN) with cobalt(II) vinyl-β-diketonate as initiators of the radical polymerization of styrene and MMA.

EXPERIMENTAL

We used cobalt(II) 3-allylpentanedionate [APD(Co)] and cobalt(II) 5-methyl-5-hexene-2,4-dionate [MHD(Co)]. In [MHD(Co)], the double bond is conjugated with the chelate ring, whereas in [APD(Co)], this conjugation is absent. A BP-cobalt(II) acetylacetonate system, in which the chelate ligand has no vinyl substituent, was studied for comparison.

Vinyl-β-diketones and their cobalt complexes were prepared by the procedures described in [7] and [10], respectively. The initiators BP and AIBN were reprecipitated from chloroform solutions with ethanol. The bulk copolymerization of styrene and MMA was performed at the equimolar ratio of the monomers. The polymerization kinetics was studied dilatometrically and gravimetrically. The initial (V_0) and average (V_{av}) polymerization rates were measured. In all cases, V_{av} was determined at a ~10% conversion. The cobalt content of the polymers, w_{Co}, was determined on a Saturn atomic absorption spectrophotometer.

BP	1.0		0.36	0.36	375	9.1	0	0	
MHD(Co)–BP	0.5		0.58	0.45	650	18.0	38	0.11	
MHD(Co)	0.5		0	0	1300	0	–	–	
BP	0.5		0.25	0.25	700	13.0	0	0	
Co(acac)$_2$–BP	0.5		0.94	0.68	720	23.0	270	0.03	

We studied the MMA polymerization initiated by [APD(Co)]–BP and [MHD(Co)]–BP systems and their individual components at 70 and 40°C. The cobalt(II) acetylacetonate–BP [Co(acac)$_2$–BP] system was studied for comparison. The concentrations of the initiating systems containing APD(Co) and MHD(Co) were 1×10^{-2} and 0.5×10^{-2} M, respectively. The concentration was determined by the solubility of the cobalt complexes in the monomer. In addition, it was necessary to take into account that the dependence of V_0 on the initiator concentration is nonlinear owing to the inhibiting effect of the complexes [9].

As can be seen from Table 1, V_0 and V_{av} are higher in the presence of [APD(Co)]–BP system by a factor of more than 3 than the additive values. It should be noted that V_{av} for the system is close to V_0, whereas V_{av} for pure APD(Co) is higher by a factor of 3 than V_0. Hence, the inhibiting effect of the chelate is weak. At 40°C, the initiation efficiency by the system is higher by a factor of 10 than that by its components. It should be noted that methyl methacrylate does not polymerize at this temperature in the presence of pure [APD(Co)]. The apparent activation energy of polymerization in the presence of this system (54 kJ mol^{-1}) is significantly lower than that in the presence of BP (75 kJ mol^{-1}). It should be noted that the MMA polymerization initiated by pure [APD(Co)] is characterized by a long induction period (IP), which is also typical of other Co(II) vinyl-β-diketonates. Once the color of the polymerizing system changes from pink to green, the polymerization starts. Previously, we have shown [11] that this is due to oxidation of Co(II) to Co(III). There is no induction period in the presence of [APD(Co)]–BP system, and the color of the systems changes instantaneously after the dissolution of BP.

In the polymerization initiated by the [MHD(Co)]–BP system, the pattern is different. First, V_0 and V_{av} for this system are close to the additive values. The main difference between [APD(Co)] and [MHD(Co)] is that the double bond is not conjugated with the chelate ring in [APD(Co)]. This probably causes different types of behavior of these complexes in the course of the polymerization. Second, the cobalt content of the polymer prepared in the presence of [MHD(Co)] is higher by an order of magnitude than that of the polymer prepared in the presence of [APD(Co)]. This is probably due to the significantly higher reactivity of [MHD(Co)] in the course of polymerization, which is confirmed by the results of a study of the MHD copolymerization with vinyl monomers [12]. In addition, MHD and its metal complexes readily homopolymerize [13], whereas APD does not form homopolymers. Therefore, [MHD(Co)] copolymerizes with MMA. The apparent activation energy of the polymerization initiated by the [MHD(Co)]–BP system (E_{app} = 68 kJ mol^{-1}) is significantly higher than that for the [APD(Co)]–BP system.

Table 2. Kinetic parameters of styrene polymerization initiated by [APD(Co)]–BP and [MHD(Co)]–BP systems ($c_{chel} = c_{BP} = 1 \times 10^{-2}$ M, $T = 85°C$)

Initiating system or initiator	$V_0 \times 10^5$	$V_{av} \times 10^5$	τ, min	S, %	w_{Co}, wt %
	mol l^{-1} s^{-1}				
APD(Co)–BP	103.2	38.5	38	10.7	0.10

BP	29.0	29.0	46	9.9	0
MHD(Co)–BP	64.5	12.4	323	29.7	0.15
MHD(Co)	38.0	12.4	110	10.1	0.47
Co(acac)$_2$–BP	24.4	17.2	240	30.5	0.04

Table 3. Kinetic parameters of MMA and styrene polymerization initiated by [APD(Co)]–BP and [MHD(Co)]–BP systems ($c_{chel} + c_{BP} = 0.5 \times 10^{-2}$ M, $T = 60°C$, 10% conversion)

Monomer	Initiating system	$V_0 \times 10^5$	$V_{av} \times 10^5$	IP, min	w_M,* wt %
		mol l^{-1} s^{-1}			
MMA	APD(Co)–AIBN	80.6	80.6	13	0
	APD(Cu)–AIBN	70.2	70.2	0	0
	AIBN	77.6	73.9	0	0
Styrene	APD(Co)–AIBN	29.7	18.4	0	0.10
	APD(Cu)–AIBN	18.6	16.7	0	0.10
	AIBN	15.3	15.3	0	0

* w_M is the weight fraction of the metal in the polymer.

The kinetic parameters of the MMA polymerization initiated by the Co(acac)$_2$–BP system, in which the cobalt complex contains no double bond, are significantly inferior to those for the [APD(Co)]–BP system. The cobalt content of the polymers prepared in the presence of the Co(acac)$_2$–BP system is low, probably due to the termination of the propagating radicals by the chelate and to the impossibility of copolymerization of Co(acac)$_2$ with the monomer.

We also studied the styrene polymerization initiated by these systems. The results are listed in Table 2. As can be seen, V_0 is significantly higher in the presence of the [APD(Co)]–BP system than that in the presence of its components. The average polymerization rate V_{av} for the system is close to the sum of the polymerization rates in the presence of [APD(Co)] and BP, taken separately. A similar deceleration of styrene polymerization was observed in the presence of pure [APD(Co)], [MHD(Co)], and Co(acac)$_2$ and various metal β-diketonate–BP systems [6]. This may be due to poisoning of the metal complex by radical reagents. Styrene polymerizes without an induction period. It should be noted that a solution of the metal chelate in the monomer instantaneously becomes greenish even in the absence of BP. The small cobalt content of the polymer prepared in the presence of a Co(acac)$_2$–BP system is caused by termination of propagating radicals by the chelate. The cobalt content of the polymer prepared in the presence of the [APD(Co)]–BP system is also low because the allyl-β-diketonate ligand does not copolymerize with styrene. Our previous ^{13}C NMR study has shown the absence of chelate fragments in the polymers prepared by initiation with the iron(III) trifluoroacetylacetonate–BP system [14]. Probably, only BP radicals initiate polymerization in this case and the metal chelate activates the BP decomposition. Metal-containing polymers can also be formed by termination of propagating radicals by the chelate to form irreversibly metal complexes that are inactive in BP degradation. The crucial role is played in this case by the polarity. It is known that propagating styrene radicals are donors (Alfrey–Price e-factor is –0.8), MMA radicals are acceptors ($e = +0.4$), and the metal in a chelate complex is always an acceptor. Therefore, the polarity factor favors the reaction of styrene radicals with the metal chelate and prevents their reaction with MMA. This is confirmed by the cobalt content of the styrene and MMA polymers.

We studied the polymerization of styrene and MMA in the presence of [APD(Co)]–AIBN and [APD(Cu)]–AIBN systems with the equimolar ratio of the components. The results are listed in Table 3. As can be seen from Table 3, the rates of the MMA polymerization initiated by the systems are similar to that provided by AIBN taken separately, i.e., the chelates do not activate the initiator decomposition and behave as inert additives. The styrene polymerization initiated by these systems is characterized by a small increase in the initial polymerization rate. However, at a 10% conversion, the rate of the styrene polymerization initiated by these systems is virtually equal to that in the case of initiatition by pure AIBN. Hence, the metal chelate–AIBN initiating systems are inefficient. This is due to the fact that the metal chelate cannot form a primary complex with AIBN.

Thus, the behavior BP and AIBN in the presence of metal β-diketonates in the course of radical polymerization varies. Metal β-diketonates form complexes with BP, which promotes the BP decomposiiton and accelerates the polymerization. Experimental results supporting the formation of these complexes were reported in our previous paper [15]. In the case of AIBN, no complexes between the metal chelate and the initiator are formed and metal β-diketonates do not accelerate the initiator decomposiiton. In this case, the polymerization is initiated by AIBN. Thus, [APD(Co)]–BP system can be used as an efficient initiator of the MMA polymerization. In the presence of this system, the polymerization is fast. The low activation energy of polymerization initiated by this system allows fast polymerization at low temperatures. We studied the thermal oxidative degradation of poly(methyl methacrylate) prepared in the presence of [APD(Co)], [APD(Co)]–BP, and BP at $c_{chel} = 1 \times 10^{-2}$ M and 70°C. The termeratures of the onset and end of the thermal oxidative degradation (T_{on} and T_{end}) were calculated by the procedure described in [16]. The values of T_{on} (numerator) and T_{end} (denominator) (T, °C) for the chelate, system, and BP are 280/405, 254/418, and 250/392, respectively. Thus, T_{on} for the system is close to that for BP, and T_{end} for the system is higher by 26°C than that for BP.

CONCLUSIONS

(1) The radical polymerization of methyl methacrylate and styrene initiated by equimolar amounts of Co(II) vinyl-β-diketonate and benzoyl peroxide involves the formation of a chelate–peroxide complex, activating the benzoyl peroxide decomposition.

(2) The [APD(Co)]–azobis(isobutyronitrile) system is an inefficient initiator, since in this case, this complex is not formed and AIBN does not decompose.

(3) The metal chelate can be incorporated in the polymer chain by copolymerization with the monomer.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

New Oligomeric Surfactants Based on Ethylene Glycol and Epichlorhydrin

G. A. Akhmedova

Institute of Petrochemical Processes, Azerbaijan National Academy of Sciences, Baku, Azerbaijan

Received August 14, 2007

Abstract—Oligomeric chloroxypropylates with varied contents of epoxy groups were synthesized from ethylene glycol and epichlorhydrin. The resulting oligomers were modified with phosphoric acid, diethylamine, piperidine, pyridine, and triethanolamine. The structure and composition of the products were confirmed by ^{1}H NMR and IR spectroscopy. Their physicochemical characteristics, surface activity, and ability to reduce the gasoline loss through evaporation from storage tanks are examined.

DOI: 10.1134/S1070427208060220

Environmental pollution is among the most pressing global problems. Evaporation of oil and petroleum products from reservoirs leads to their loss, quality loss, and pollution of the environment with light hydrocarbons. A lot of variously designed systems exist for reducing the evaporation of petroleum products. Even being highly efficient, these systems have some drawbacks, such as the high cost and complicated design and control system, etc. An alternative method for solving the problem consist in use of colloidal-chemical systems. The key point in this method is applying a film-forming reagent to the surface of a petroleum product. Such reagents form a stable microemulsion layer on the surface [1–10].

In this study, we synthesized and characterized oligomeric surfactants based on epichlorhydrin (ECH) and ethylene glycol (EG), having various numbers of epoxy groups, and examined their capability to retard gasoline evaporation from storage tanks.

EXPERIMENTAL

In the experiments, we used the following chemicals: 99.97–99.98% pure commercial epichlorhydrin [Orgsintez Plant (Sumgait, Azerbaijan)]; ethylene glycol (analytically pure grade, Russia); sodium hydroxide (analytically pure grade) [Chemapol (Czech Republic)]; 86.4% phosphoric acid (pure grade, Russia); diethylamine (pure grade) [Cherkassy Chemical Plant, Cherkassy (Ukraine)]; piperidines and triethanolamine (TEA) (pure grade) [Olaine Chemical Plant, Olaine (Latvia)]; pyridine (analytically pure grade) [Nizhny Tagil Metallurgical Combine, Nizhny Tagil (Russia)] distilled over KOH; $AgNO_3$ (analytically pure grade) [Urals Plant of Chemical Reagents (Russia)]; and gasoline (A-92 grade) [Aliyev Oil Refinery (formerly Azerneftyanadzhag), Baku (Azerbaijan)].

The chloroxypropylation of EG was carried out in an autoclave at 120–140°C for about 28 h, using NaOH (3 mol % relative to EG) as a catalyst. The unreacted ECH was removed by heating the product at a moderate temperature (water bath) to constant weight. The conversion of ECH and the degree of chloroxypropylation, n (ECH to EG molar ratio), were determined gravimetrically. The resulting chloroxypropylates were modified with amines in a glass reactor with a refluxer at 55–60°C (water bath) for 18–20 h. The phosphatization of the oligomers based on ECH and EG was carried out with orthophosphoric acid at 27°C.

The ^{1}H NMR spectra were recorded on a Tesla Model BS-487 instrument (Czech Republic), and IR spectra, on an UR-20 spectrometer (Germany).

The refractive index n_D was measured on a IRF-22 refractometer (Russia); extinction coefficient ε of 0.5 wt % aqueous solutions, on a AOM-102 turbidimeter (Georgia); and conductivity χ of these solutions, on an OK 102/1 conductometer (Hungary). The density ρ_4 was determined pycnometrically, and the hydroxyl and acid numbers, as in [11]. The surface activity of the aqueous solutions at the kerosene/water interface was

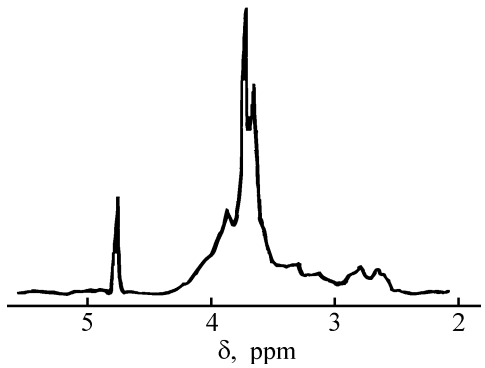
studied by the stalagmometric method, and that at the water/air interface, by the droplet counting method [12]. The hydrophilic–lipophilic balance (HLB) was estimated using the procedure described in [1].

The ability of the oligomers to retard the gasoline evaporation was estimated on the basis of laboratory tests [13]. Three identical volumetric beakers were filled with 100 ml of gasoline. A 5 wt % aqueous solution of additive tested and undiluted additive were introduced into the first and second beakers, respectively. No additive was introduced into the third beaker, which served as reference. The rate of gasoline evaporation was monitored by the lowering of the gasoline level in the beakers.



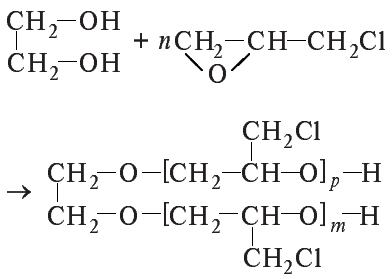


Fig. 1. ^{1}H NMR spectrum of the chloroxypropylate (n = 38.0). (δ) Chemical shift.

The retardation of evaporation E (%) was estimated as

$$E = [(V_0 - V)/V_0] \times 100,$$

where V_0 is the gasoline loss through evaporation in the blank experiment, and V, that in the experiments with the reagent.

Catalytic chloroxypropylation of EG with EPC was performed by the reaction

where $n = p + m$ is the degree of chloroxypropylation.

The reaction parameters and physicochemical characteristics of the products are summarized in Table 1.

Figure 1 shows the ^{1}H NMR spectrum of the chloroxypropylate of EG with a mean degree of chloroxypropylation of 38.0. The spectrum contains signals of the protons of the OCH_2-groups of

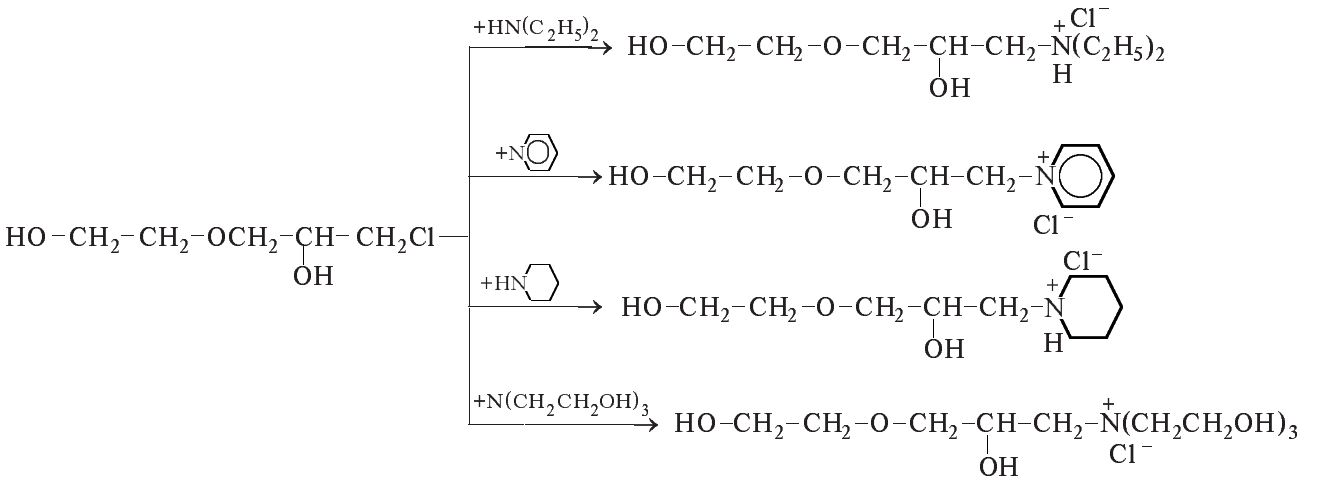
the initial EG at 2.80 ppm; protons of the OCH_2-, OCH-, and CH_2Cl-groups of the epoxy fragments at 3.40–4.20 ppm; and resonance signals of the OH group at 4.77 ppm.

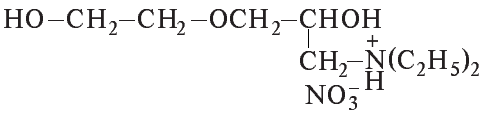
The IR spectrum of the oligomer with a mean number of monomeric units of 4.53 shows a broad band at 3100–3700 cm^{-1} due to stretching vibrations of the hydroxy group, a band at 2840–3000 cm^{-1} due to C–H stretching vibrations in the CH_2- and CH- groups, a band at 1400–1490 cm^{-1} due to C–H bending vibrations of these groups, a band at 1090 cm^{-1} due to stretching vibrations of the C–O–C etheric group, a band at 1057 cm^{-1} due to C–O stretching vibrations of the C–OH fragment, a band at 963 cm^{-1} due to out-of-plane deformation vibrations of the C–H group of the heterochain, and a band at 760 cm^{-1} due to C–Cl vibrations.



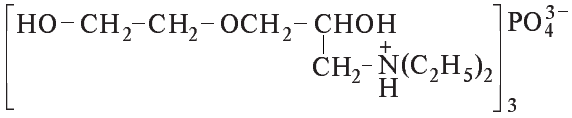
Data on the interfacial tension of variously concentrated aqueous oligomer solutions at the water/kerosene and water/air interfaces are listed in Table 2. It can be seen that these products are surfactants. The maximal surface activity at the kerosene/water interface was observed with the chloroxypropylate with a degree of chloroxypropylation of 0.95 at a concentration of 10 wt %. In this case, the surface tension decreased from 46.0–46.5 in the system without surfactant to 3.7 mN m^{-1}. The surface tension of a series of chloroxypropylates was also measured by the droplet counting method (without surfactant, the surface tension was about 72.7 mN m^{-1}).

To raise the hydrophilicity of the oligomers with the degree of chloroxypropylation of 4.53 and 37.80, we modified them with phosphoric acid:

There is a possibility of formation of diethers. The phosphatized ethers demonstrate an increased viscosity. The first phosphatized product is gold yellow. Its density at 25°C is 1.520; refractive index at 21°C, 1.4670; extinction coefficient, 49.29 $l\,mol^{-1}\,cm^{-1}$; and acid number, 709.0 mg KOH/g. The second phosphatized product is reddish brown; $\rho_4^{25} = 1.563$; $n_D^{25} = 1.4692$; and acid number, 661.6 mg KOH/g. The surface tension of 5% aqueous solution of this product at 24°C is 5.3 and 36.7 mN m^{-1} at the kerosene/water and air/water interfaces, respectively. In the case of the second phosphatized product, the phosphatization decreased the surface tension of 5 wt % aqueous solution at the water/kerosene interface from 14.1 to 5.3 mN m^{-1}.



To increase the hydrophilicity of the oligomers, we also modified them with diethylamine, piperidines, pyridine, and triethanolamine. As a result, we obtained quaternary salts and protonated nitrogen salts:



The resulting salts were liquids with refractive indices of 1.4640, 1.4555, 1.4535, and 1.5290, respectively at 20°C.

The IR spectrum of the diethylamine derivative of the oligomer ($n = 0.95$) shows a band at 3100–3700 cm^{-1} due to stretching vibrations of the hydroxy group, a band at 2860–3020 cm^{-1} due to C–H stretching vibrations in the CH_2 and CH groups, a band at 2520 cm^{-1} of the NH^+ group, a band at 1390–1510 cm^{-1} due to C–H bending vibrations in the CH_2 and CH groups, a band at 1095 cm^{-1} due to C–O stretching vibrations of the C–O–C etheric group, and a band at 1050 cm^{-1} due to C–O stretching vibrations of the C–OH group.

To confirm the formation of the salts, we performed exchange reactions of the products with $AgNO_3$ and H_3PO_4. In the case of the chloroxypropylate modified with diethylamine, the reaction with equimolar amount of aqueous $AgNO_3$ immediately afforded a white precipitate of AgCl and the salt

In this case, the chloride anion is replaced by the more bulky nitrate anion. In the exchange reaction of the same product, but with phosphoric acid (no solvent, salt : H_3PO_4 = 3 : 1), we observed liberation of HCl gas insoluble in the reaction mixture, confirming the possibility of replacement of the chloride anion for more bulky phosphate anion PO_4^{3-} to give the salt

The chloroxypropylate modified with pyridine is a yellow liquid, and that modified with piperidines, a two-phase liquid system consisting of a yellow lower layer and a pale yellow upper layer.

The IR spectrum of the chloroxypropylate (n = 47.71) modified with triethanolamine shows a broad band at 3100–3700 cm^{-1} due to stretching vibrations of the OH group, a band at 2820–3010 cm^{-1} due to C–H stretching vibrations in the CH_2 and CH groups, a band at 1350–1510 cm^{-1} due to C–H bending vibrations in the CH_2 and CH groups, bands at 1250–1260 and 1150 cm^{-1} due to antisymmetrical and symmetric stretching vibrations of the C–O–C etheric group, a band at 1060–1080 cm^{-1} due to C–O stretching vibrations in the C–OH fragment, and a band at 950–960 cm^{-1} due to C–H out-of-plane bending vibrations in the chain. The absence of the band due to C–Cl stretching vibrations confirms the formation of the salt.

The chloroxypropylate modified with triethanolamine is a homogeneous viscous yellowish brown product. The degree of conversion of triethanolamine is 90–92%. An aqueous solution of this salt demonstrates a high electrolytic conductivity (the conductivity of 0.5 wt % aqueous solution of this reagent is 0.1275 Ω^{-1} m^{-1}, while that of distilled water is 0.006 Ω^{-1} m^{-1}). The surface tension of 0.5 wt % aqueous solution at 24°C is 3.8 and 35.2 mN m^{-1} at the kerosene/water and air/water interfaces, respectively. The stalagmometric data reveal that this salt has a higher surface activity than the initial chloroxypropylate, decreasing the surface tension from 16.3 to 3.8 mN m^{-1}.

The chloroxypropylates synthesized as well as those modified with amines reduced the gasoline loss through evaporation. The reagents were tested as prepared and in the form of 5 wt % aqueous solutions.

The chloroxypropylate with one ECH unit demonstrates the effect only in the form of undiluted reagent (its efficiency was 12.5% in 11 days). The oligomer with a degree of chloroxypropylation of 2.66 is more efficient (16.3–19.2% in 11 days). For all the three chloroxypropylates (n 0.95, 2.66, and 4.53), the efficiency in the first two days was fairly high (19.0–26.5, 20.7–35.0, and 18.5–32.9%, respectively).

The chloroxypropylates with n 9.17, 14.13, and 28.92 were tested at 18–23, 25–30, and 27–30°C, respectively. The first of them demonstrate an intermediate efficiency: 13.8 and 12.4% in 26–27 days for 100% and aqueous reagents, respectively. The highest efficiency (23–43.8%) was observed in the first day. For the reagent with n = 28.92, the efficiency was 9.1 and 22.8% in 13 days for the aqueous and 100% reagents, respectively. In the undiluted form, this reagent demonstrates 48.3–57.9% efficiency in the first 5 h. The reagent with n = 14.13 has a low efficiency (3.6–4.9%).

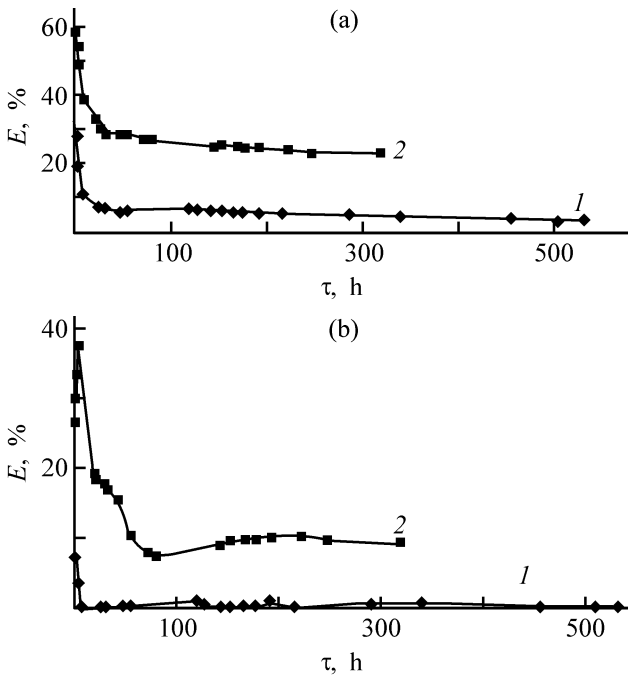


Fig. 2. Effect of chloroxypropylate (n = 28.92) on the gasoline loss through evaporation, E, vs. time τ: (a) undiluted reagent and (b) 5 wt % aqueous reagent. T (°C): (*1*) 12–15 and (*2*) 25–30.

For the chloroxypropylates with a longer heterochain (n 37.80, 47.51, and 57.75), the retardation efficiency of 5% aqueous solutions increases with n, and, vice versa, for these regents in the undiluted form, the effect decreases with increasing n.

The chloroxypropylate (n = 4.53), modified by phosphatization with phosphoric acid, taken in the undiluted form, reduces the gasoline loss by 12.6% in 18 days at 18–20°C, and, taken as 5% solution, by 13.5%. The phosphatization caused a positive effect in the first 8 days for both test forms of the reagent (compared to the unmodified chloroxypropylate): the effect increased from 11.1 to 15.3% and from 14.4 to 15.3% for 100% and 5% reagents, respectively.

The second phosphatized reagent, prepared from the chloroxypropylate with n = 37.80, also demonstrated a positive effect in both undiluted and dilute forms (gasoline loss decreased by 6.62 and 5.23%, respectively, in about 20 days). Generally, introduction of the phosphate group increased the efficiency of the reagent.

On passing from the chloroxypropylate with $n = 0.95$ to that modified with diethylamine, the efficiency of the aqueous reagent in 11 days increased by 5.1%, while that of the 100% reagent decreased from 12.5 to 8.7%.

The chloroxypropylate ($n = 47.71$) modified with triethanolamine also reduces the gasoline loss through evaporation. However, its efficiency is lower than in the unmodified product.

The effect of the temperature on the reduction of the gasoline loss through evaporation was studied for two reagents. First, we used the chloroxypropylate with $n = 28.92$ over the temperature range 12–15 and 25–30°C (Figs. 2a, 2b), and, second, the chloroxypropylate ($n = 4.53$) modified by phosphatization over the range 12–18 and 18–20°C. In both cases, the efficiency of the reagents increased with temperature.

CONCLUSIONS

(1) Oligomeric chloroxypropylates form a film on the surface of petroleum products, thus protecting them from evaporation loss.

(2) The protective efficiency could be improved through modification of the chloroxypropylates with orthophosphoric acid, diethylamine, piperidine, pyridine, and triethanolamine.

Abstract—Fundamental aspects of the interaction between the bentonite clay and self-structuring polysaccharides, agar-agar and sodium salt of carboxymethyl cellulose, were studied. The possibility of using the resulting composite gels as drug carriers was examined.

DOI: 10.1134/S1070427208060232

At present, of particular interest is preparation and study of composite materials based on mineral and organic polymers. Natural self-structuring polymers, such as agar-agar, cellulose, and gelatin, used as continuous phase in composites with clays, are promising drug carriers. Introduction of the bentonite clay into composites can improve their mechanical properties. The clayey particles incorporated into the composites also acquire new valuable properties [1].

In this context, the possibility of obtaining composites based on natural polysaccharides, agar-agar and sodium salt of carboxymethyl cellulose (NaCMC), and bentonite clay from the Manrak deposit (Eastern-Kazakhstan oblast) and using these composites as drug carriers was studied. The choice of the bentonite clay and the polysaccharides was due to their ability to swell and form gels. In addition, they are nontoxic and allowed for use in medical practice.

EXPERIMENTAL

The Endo agar-agar [TU (Technical Specification) 0515088] and Na-CMC $[C_6H_7O(OH)_{3-x} \times (OCH_2COONa)_x]_n$ of pure grade (TU 2231-00250277563–00) were used without additional purification.

Alchidine, a biologically active complex produced as an extract from Kyrgyz camel's thorn (*Alhagi Kirgisorum Shrenk*) (Zhantak sirup) manufactured by Khimfarm Joint-Stock company (Shymkent). This preparation, exhibiting anti-inflammatory, styptic, wound-healing, and astringent properties, has the following composition (%, no less than): polymeric proanthocyanidins 30, amino acids 10, polysaccharides 25, flavonoids 2, microelements 10, and moisture 10; it was used without additional purification [2]. Polymeric proanthocyanidins are believed to be the active substance in alchidine.

The bentonite clay was purified by the Salo technique [3]. The sedimentation analysis was made by the Figurovskii method [4]. The degree of gel swelling was determined by the equilibrium-swelling technique [5].

Alchidine-containing composite gels based on the bentonite clay and polysaccharides were prepared as follows: a calculated amount of the bentonite clay and polymers was added to an aqueous-glycerol solution of alchidine under agitation and allowed to stay at room temperature till solidification. To determine the amount of a medicinal substance freed from the gel, a weighed portion of the gel was placed in 50 ml of distilled water and the aqueous fraction was analyzed for the content of alchidine components in the course of 24 h. The concentration of proanthocyanidins and amino acids was determined by UV spectroscopy (SF-26) at wavelengths λ = 272 and 206 nm, respectively. The amount of polysaccharides was found using the Hagedorn–Jensen microscopic method [2] based on iodometric titration.

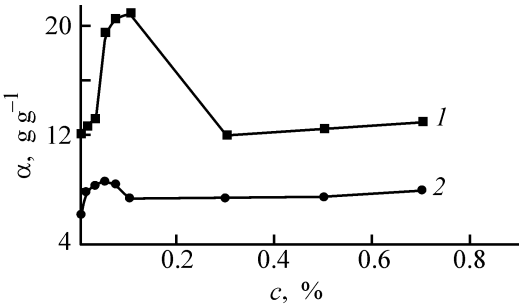

Fig. 1. Degree of swelling, α, of the bentonite clay in solutions of Na-CMC vs. its concentration *c*. (*1*) Water and (*2*) physiological solution; the same for Fig. 2.

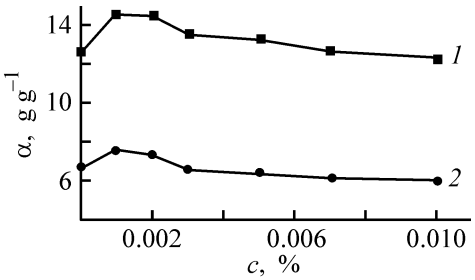

Fig. 2. Degree of swelling, α, of the bentonite clay in solutions of agar-agar vs. its concentration *c*.

The electrophoretic mobility of polymer mixtures was measured in a somewhat modified Rabinovich–Fodiman device by the mobile-boundary method [6]. The electrical conductivity of the mixtures and side liquid was measured at a constant temperature (298 K) on an R-356 installation. The electrokinetic potential ξ (V) was calculated by the Smoluchowski formula

$$\xi = \frac{4\pi\eta}{H\varepsilon} U \times 300^2,$$

where η is the viscosity of the medium (Pa s); *H*, potential gradient (V cm^{-1}); ε, dielectric constant; and *U*, electrophoretic velocity (V s^{-1}).

A study of the swelling capacity of the bentonite clay in aqueous solutions of Na-CMC and agar-agar demonstrated that the effects of polysaccharides on the swelling capacity of the bentonite clay differ both in kinetics and in nature. For example, the equilibrium swelling of the bentonite clay is attained in 20–30 min, whereas in agar solutions, the degree of swelling of the bentonite clay steadily increases. This may be due, first, to the different strengths of the polyelectrolytes: weak in the case of Na-CMC (because of the carboxy group) and strong in agar (because of the sulfo group), and, second, to the different structure-forming capacities of the polymers. In both cases, being likely charged, clayey particles and polysaccharides can interact only via hydrogen bonds. Presumably, the same circumstance can account for the different types of the concentration dependences of the swellability. For example, Na-CMC solutions show a pronounced extremal dependence of the degree of swelling of the bentonite clay on the polysaccharide concentration, whereas in agar solutions, only a slight increase is observed in the degree of swelling, irrespective of the concentration (Figs. 1, 2). At a low Na-CMC concentration (0.1%), a substantial increase in the swellability of the clay is observed. As the polysaccharide concentration increases further, the degree of swelling of the bentonite clay decreases: by almost a factor of 2 at a concentration of 0.3%.

Such a behavior of the bentonite clay in Na-CMC solutions can be understood as follows: at low concentrations, the surface of clayey particles is hydrophilized because of single contacts with polysaccharides via hydrogen bonds, which leads to an additional swelling of the bentonite clay. The tendency to form hydrogen bonds can be explained with account of the nature of the starting components. It was noted in [3] that the main mechanism by which the surface of bentonite clay particles interacts with water and other compounds is that via hydrogen bonds. At higher Na-CMC concentrations, particles of the dispersed phase aggregate and become coarser by the flocculation mechanism. In the case of agar, the strongly charged polyelectrolyte chain can exhibit an ionic strength, with the result that the swellability does not increase.

Rather interesting is the effect of polysaccharides on the stability of the bentonite clay in the presence of an electrolyte and, in particular, physiological solution (0.15 M NaCl) [7]. It can be seen in Figs. 1 and 2 (curves *2*) that the degree of swelling in the NaCl solution is almost two times lower than that in aqueous solutions. In contrast to the case of aqueous solutions, the increase in the swellability at low Na-CMC and agar concentrations in a salt solution is insignificant. This can be attributed to the high ionic strength in the NaCl solution, in good agreement with published data [3].

A characteristic feature of dispersed systems is their aggregative and sedimentation stability. It is known that the complexation processes occurring in dispersed systems are accompanied by noticeable changes in their stability [7]. It should be noted that the sodium forms of montmorillonite show high aggregative stability and can be stored in the sus-

pended state for several months to 2–3 years [3]. Therefore, a sedimentation analysis of the bentonite clay in water and Na-CMC and agar-agar solutions was performed. The results obtained agree with data on the swellability of clayey composites. Two fractions are formed in Na-CMC solutions, which correspond to the range of hydrophilization of bentonite clay particles and to the flocculation range (Fig. 3). Comparison with the swellability data shows that the range $r = 0.5 \times 10^{-5}$ m corresponds to the range of hydrophilization of clayey particles. An increase in the Na-CMC concentration leads to a decrease in the swellability of the bentonite clay, i.e., to a higher density of lyophobic parts of the dispersed phase. Similar data were obtained for composites constituted by agar and the bentonite clay. It should, however, be noted that, in the given case, there is a tendency toward a shift to a lower dispersity. Presumably, this is due to presence of bentonite clay particles bound and unbound to the polymer. This assumption is confirmed by the fact that, as the polysaccharide concentration increases, only the finely dispersed phase remains. The lyophobic parts of clayey particles act as coagulation centers and as the reason for an anomalous viscosity in dispersed systems [8, 9]. In the case in question, this leads to an insignificant coarsening of bentonite clay particles. The acceleration of the sedimentation of the clayey suspension can be favored by densification of the unit cell packing as a result of complexation.

To obtain additional information about the nature of the interaction between bentonite clay particles and polysaccharides, the variation of the electrokinetic potential in systems constituted by the bentonite clay and Na-CMC and by the bentonite clay and agar-agar was studied by means of macroelectrophoresis. The data obtained confirm to a sufficient extent the suggested mechanism of binding of Na-CMC and agar with the bentonite clay (see table).

First, the negative ξ-potential of the suspension somewhat decreases in magnitude and stabilizes at larger n. On the whole, the negative potential of the bentonite clay does not change significantly. The reason is the non-Coulomb nature of polymer binding with the bentonite clay. The observed change in the ξ-potential can be attributed to a shift of the sliding boundary of the electric double layer as a result of complexation.

To assess the possibility of using the composites as drug carriers, alchidine-containing composite gels were prepared and the release of alchidine components from these gels was studied. The kinetic curves of desorption of alchidine components into water are shown in Fig. 4. It can be seen that

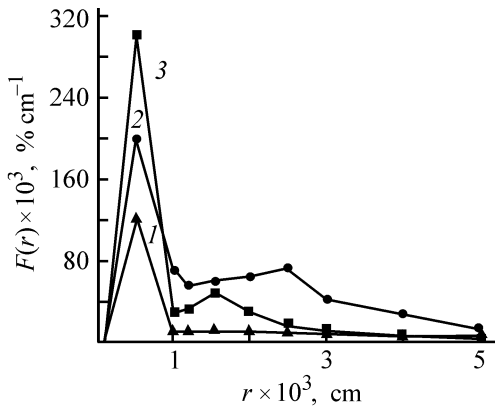

Fig. 3. Differential sedimentation curves $F(r)$–r of the bentonite clay in Na-CMC solutions. (*1*) Water; [Na-CMC] (%): (*2*) 0.05 and (*3*) 1; m_{cl} = 2.5 g.

the rate and degree of release from composite gels are the highest for polysaccharides. For example, the release of polysaccharides, proanthocyanidins, and amino acids from composite gels with 75% Na-CMC in 24 h is 40, 10, and 2%, respectively. This type of release of the alchidine components is presumably associated with differences in the sizes of their molecules. In this regard, macromolecules of polysaccharides and proanthocyanidins are of approximately the same size and can be bound only with the surface of bentonite clay particles. However, the affinity of proanthocyanidins to the gels is possibly higher due to their more pronounced ability to form hydrogen bonds because of the presence of numerous hydroxy groups. The released amount of amino acids is possibly small because, owing to the small size, their molecules are sorbed, together with water molecules, by internal pores of the crystal lattice in the course of swelling of the bentonite clay, and, as a result, they are desorbed to an insignificant extent.

The release of amino acids from gels constituted by the bentonite clay and Na-CMC is 2–3%, irrespective of the composition of these gels. At the same time, the release increases for polysaccharides and proanthocyanidins as the amount of the bentonite clay in the composites grows. This indicates that the polymeric component is responsible to a greater extent for the binding of the alchidine components.

The release of polysaccharides, proanthocyanidins, and amino acids from composites constituted by the bentonite clay and agar, with the agar-agar content of 75% in 24 h is 95, 40, and 4%, respectively. Analysis of these data suggests that the content of agar-agar and the bentonite clay has nearly no effect on the release of the alchidine components.

CONCLUSIONS

(1) The polysaccharides studied interact with bentonite clay particles via hydrogen bonds. The type of interaction and the properties of the dispersed phase depend on the nature and concentration of a polysaccharide.

(2) The bentonite clay forms with polysaccharides, sodium salt of carboxymethyl cellulose and agar-agar, a homogeneous composite with good aggregative stability and component compatibility.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Pore Structure of Activated Carbons Prepared from Polyethylene Terephthalate Waste Preliminarily Impregnated with Sulfur Compounds

N. V. Sych

Institute for Sorption and Problems of Endoecology, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received October 15, 2007

Abstract—Preparation of activated carbons from a powdered polyethylene terephthalate waste preliminarily impregnated with sulfur compounds ($Na_2S_2O_3$, Na_2S) was studied. The pore structure of the resulting sorbents was examined.

DOI: 10.1134/S1070427208060244

Production of polyethylene terephthalate (PET) steadily grows. This compound is widely used for preparing fibers, press molds, films, composites, various containers for liquids, powders, and pastes, etc. In most cases, PET articles are disposable. As a result, large amounts of spent PET in solid domestic wastes are a serious environmental problem [1–3].

Depending on particular conditions and technical feasibility, various procedures are used for utilization of spent containers, and its disposal is the main procedure for waste management [4]. PET wastes are frequently incinerated or used as secondary polymer resources. Most frequently, this packaging waste is incinerated in special installations equipped with filters for absorption of hazardous exhaust gases. These filters are rather complex in production and operation, which in some cases hinders complete sorption of the hazardous gases. As a result, processing of PET waste into a secondary polymer material seems rather promising [5–9]. This problem can be probably solved by using the following processes: depolymerization to monomers and oligomers [10–12], utilization of a powdered compound as an additive to a new polymer [13–15], and mechanical reprocessing into new articles [16–18]. It should be noted, however, that reprocessing of the PET waste into new commercial products for domestic yields new solid domestic wastes in one or two years, which does not decrease the increasing volume of wastes and only simulates their utilization [19].

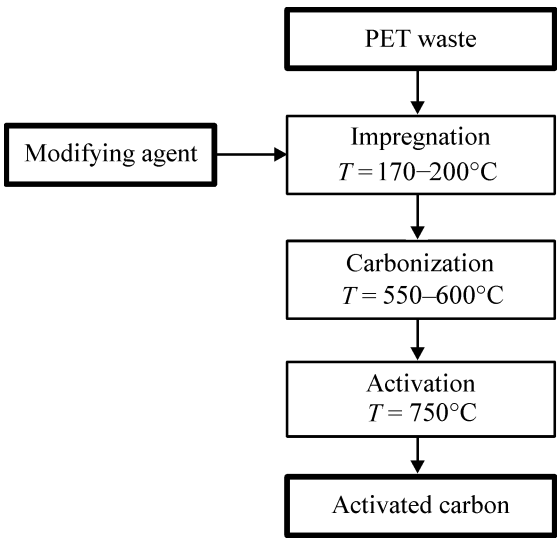
An alternative solution to the above problems of reprocessing of spent containers is to prepare of noval products, namely, cheap carbon adsorbents. In our previous studies [20, 21], we prepared using pretreatment of PET waste with concentrated sulfuric acid and subsequent steam activation, carbon sorbents whose porometric and service properties (S_{BET} 1030 $m^2 g^{-1}$, V_Σ 0.50 $cm^3 g^{-1}$, A^{MB} 350 mg g^{-1}) are competitive with those of activated carbons of KAU and SKN brands.

In the context of the steady growth of PET container industry, we assume that the high-temperature chemical activation with chemical modifying agents is the most appropriate procedure for PET waste reprocessing.

In this study we examined the activation of PET waste preliminarily impregnated with sulfur compounds and the formation of activated carbons as influenced by the degree of modification of the polymer matrix.

EXPERIMENTAL

As the initial material we used a crumb (2–3 mm) prepared from spent polymer containers. The composition of the initial PET is listed below:



Element	O	C	H
Content, %	1.2	96.6	1.8

As can be seen, the carbon content of the material is very high, which is important for production of activated carbons.

The treatment of PET waste is illustrated by the scheme. Sodium thiosulfate and sulfide were used as chemical modifying agents. The modification was performed by impregnation of polymer crumb with above reagents on heating to 170–200°C. Then the modified samples were carbonized in an argon atmosphere at 550–600°C. The resulting carbons were activated with steam at 750°C. The final product is a black powder with a bulk density of 0.11–0.13 g cm^{-3}, which can be used for preparing pellets and as aerogel.

The performance of a modifying agent was preliminarily determined from the sorption pore volume for benzene [22]. A more detailed information on the development of the pore structure was derived from the isotherms of nitrogen adsorption at –196°C on a NOVA 2200 apparatus (Quantachrome, USA). The pore size distribution was calculated using the BJH method. Before measurements, the samples were degassed at 180°C for 2 h at a pressure of 1×10^{-4} torr.

Data on the porosity (sorption pore volume for benzene) and yield of products in the course of carbonization and activation of PET samples modified with sulfur compounds are listed in Table 1. As can be seen, modification improves the porosity and yield in the stage of carbonization and activation as compared to physical activation of PET. The porosity developed in the carbonization step is characterized by the sorption pore volume for benzene of 0.15–0.18 and 0.28 $cm^3\ g^{-1}$ for the samples modified with Na_2S and $Na_2S_2O_3$, respectively. In the activation step, this parameter remains nearly constant for the samples modified with $Na_2S_2O_3$, but in the case of the Na_2S modifying agent it increases from 0.15–0.17 (carbonization) to 0.33 $cm^3\ g^{-1}$ (activation). The yield of the final product is 14.7 and 14.4%, respectively. Taking into account the sorption pore volume for benzene in

1	336	141	181	0.289	0.076	26.0
3	349	155	194	0.309	0.084	27.2
5	434	203	230	0.374	0.100	27.0
PET–Na_2S, %:						
1	576	178	397	0.347	0.158	45.5
3	594	174	420	0.424	0.164	38.7
5	449	113	336	0.349	0.133	38.1
7	348	85	263	0.312	0.102	32.6
PET	218	54	164	0.195	0.064	32.8

the case of $Na_2S_2O_3$ modifying agent, it is advisable to perform in this case only carbonization, which raises the yield of the final product to 19.8%. The yield of the product in reprocessing of the PET crumb without pretreatment with sulfur compounds is as low as 9–10%.

Our experimental data also show that the sorption properties of the resulting activated carbons depend on the content of sulfur compounds in the polymer matrix. With $Na_2S_2O_3$, the maximal porosity is attained upon addition of 3% sulfur, whereas with Na_2S the optimal porosity is observed at a sulfur content of 5%. With the content of impregnated sulfur increasing above these values, the yield of the final product upon carbonization decreases, which is inappropriate.

As can be seen from our data, Na_2S is a more efficient modifying agent than $Na_2S_2O_3$. This is probably due to the presence of oxygen in the $Na_2S_2O_3$ molecule, which can initiate combustion in the course of activation of the carbon matrix prepared from the PET waste.

Data on the porosity of the resulting activated carbons are listed in Table 2. The procedure of PET treatment combining a preliminary modification of the polymer matrix, heat treatment in Ar, and subsequent steam activation yields sorbents with a specific surface area ranging from 300 to 600 $m^2\ g^{-1}$. It should be noted that modification with $Na_2S_2O_3$ allows preparation of sorbents with almost constant V_{micro}/V_{Σ} ratio, whereas in the case of modification with Na_2S, this parameter varies withthe content of impregnated sulfur.

The isotherms of nitrogen sorption–desorption by the samples of activated carbons prepared by impregnation of the PET crumb with sulfur compounds, followed by carbonization and steam activation, are shown in Figs. 1a and 1b. The isotherm shape suggests that the activated carbons

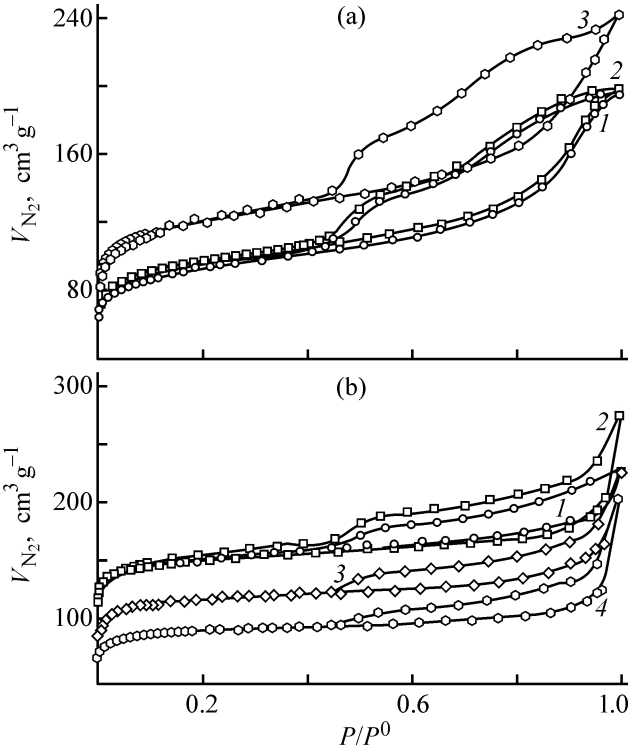

Fig. 1. Isotherms of nitrogen sorption by activated carbons prepared from the PET crumb modified with (a) $Na_2S_2O_3$ and (b) Na_2S. (V_{N_2}) Volume of adsorbed nitrogen and (P/P^0) relative pressure. Sulfur content, %: (*1*) 1, (*2*) 3, (*3*) 5, and (*4*) 7; the same for Fig. 2.

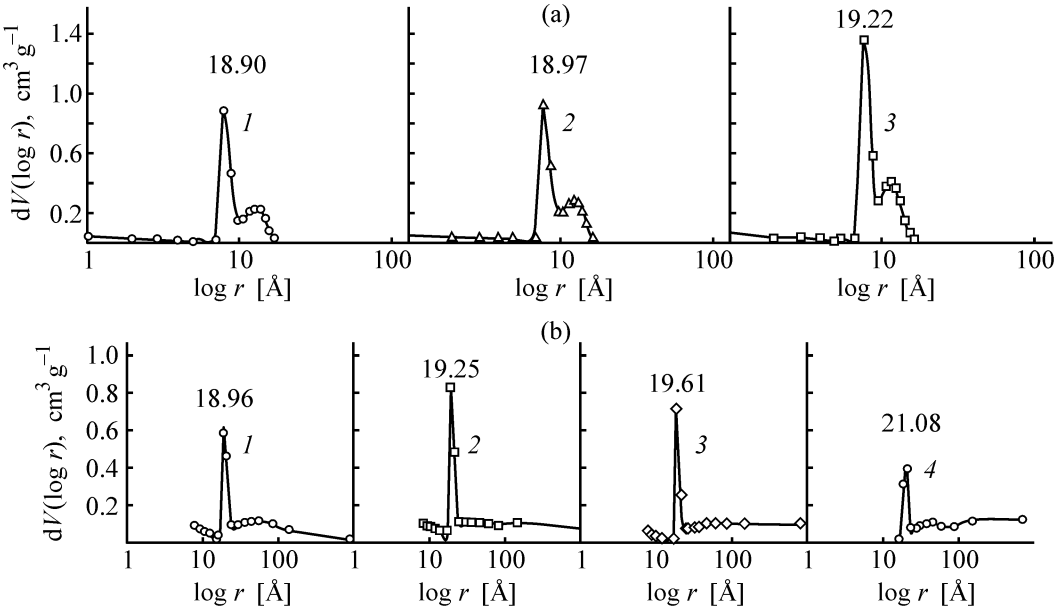

Fig. 2. Differential curves of distribution of the pore volume V with respect to the pore radius r for activated carbons prepared with (a) $Na_2S_2O_3$ and (b) Na_2S modifying agents.

prepared from PET have a polymodal pore structure, which obviously expands their application areas. The maximal volume of adsorbed nitrogen is 250 and 280 $cm^3\ g^{-1}$ for activated carbons prepared with $Na_2S_2O_3$ and Na_2S modifying agents, respectively. The $Na_2S_2O_3$ modifying agent provides formation of activated carbons with predominantly mesoporous structure, which is confirmed by the broad hysteresis loops in Fig. 1a. In the case of Na_2S modifying agent, the V_{micro}/V_{Σ} ratio can be varied depending on the content of impregnated sulfur, which allows preparation of activated carbons with controlled porosity.

Analysis of the pore size distribution (Figs. 2a, 2b) shows that the effective pore radius depends on the content of sulfur introduced into the polymer matrix and shifts toward mesoporosity. In the case of the $Na_2S_2O_3$ modifying agent, this parameter changes from 18.90 (sulfur content 1%) to 19.22 Å (sulfur content 5%). The same trend is observed with the Na_2S modifying agent. The effective pore radius shifts toward formation of mesopores from 18.96 to 21.08 Å, which suggests that the fraction of mesopores and their size increase.

Our studies are of applied importance. The alternative procedure we developed allows recycling of the valuable waste material and preparation of cheap sorbents from spent polymer containers, thus solving the problems of utilization of this type of waste. The important result of reprocessing of such waste materials into sorbents is that the environmental situation is improved, i.e., such treatment provides double positive effect. On the one hand, the problem of utilization of the large amount of PET wastes is solved and, on the other hand, the activated carbons are prepared, which, in turn, can be used to solve the problems of environmental pollution.

These results are of particular importance for the development of the resource-saving environmentally clean procedures for reprocessing of PET materials, which opens up prospects for their use in such areas of adsorption technologies as water treatment. Since the resulting sorbent is a powdered material, pelletized sorption materials can be prepared and used for gas absorption.

CONCLUSIONS

(1) Preliminary modification of the polyethylene terephthalate matrix with sulfur compounds raises the porosity and yield of the final sorbent as compared to similar treatment of unmodified polyethylene terephthalate crumb. The resulting activated carbons are characterized by the developed polymodal pore structure (S_{BET} 500–600 $m^2\ g^{-1}$ and V_{Σ} 0.37–0.42).

(2) The degree of development of the pore structure depends on the content of sulfur, and the adsorption properties of the resulting activated car-

bons depend on the amount of sulfur introduced into the polymer matrix. In the case of the $Na_2S_2O_3$ and Na_2S modifying agents, the optimal porosity is observed at 3 and 5% sulfur content, respectively.

(3) The $Na_2S_2O_3$ modifying agent provides formation of predominantly mesoporous activated carbons. The use of Na_2S modifying agent makes it possible to vary the V_{micro}/V_{Σ} ratio depending on the content of the introduced sulfur and, thus, to prepare a set of activated carbons with controlled porosity.

Abstract—Spontaneous variation of the linear size (elongation-contraction) of acetate fibers in a vapor of dimethyl sulfoxide, which is a mesophasogenic solvent, i.e., a solvent forming a liquid crystal phase with the polymer, is described. A mechanism of the interaction of the polymer with the solvent vapor is suggested.

DOI: 10.1134/S1070427208060256

It has been shown previously [1–8] that some solvents, such as nitromethane and trifluoroacetic acid, in the vapor state initiate orientation processes in cellulose acetates. It is well known that cellulose acetates in these mesophasogenic solvents form a liquid crystal (LC) phase [8–12]. Sorption of vapors of such solvents is accompanied by anomalous shape of the sorption kinetic curves [3, 5], suggesting that a structural rearrangement occurrs in the polymer matrix [13]. Under the action of vapor, the acetate fibers undergo a spontaneous cyclic deformation (elongation-contraction), and a spontaneous elongation of cellulose acetate films is observed [1, 7, 8], which confirms the formation of LC phase [14]. In films modified with vapor of these solvents, a persistent induced optical anisotropy arises [4], the intensities of reflections in the X-ray patterns increase [8], and the physicomechanical characteristics of the films and fibers are significantly improved [2, 6].

In this study, we examined the effect of dimethyl sulfoxide (DMSO) vapor on the structure of cellulose acetates. The choice of DMSO is caused by the fact that cellulose acetates form an anisotropic phase in this solvent [15, 16], and also by its wide use in production of cellulose acetate items for various purposes (hollow fibers, filters, membranes) [17, 18].

EXPERIMENTAL

As objects of the study served commercial acetate filaments formed by a dry procedure (Khimvolokno Joint-Stock Company, Engels) from cellulose diacetate (CDA) with 54.5% content of bound acetic acid and viscosity-average molecular weight of 8.0×10^4. The physicomechanical characteristics of the sample were as follows: linear density 6.7 tex, number of elementary single filaments n approximately 23, effective diameter 0.11 mm, strength 9.8–10.0 gf tex^{-1}, strength 8.8 cN tex^{-1}, and relative elongation at break 24.8–25.4%.

We used DMSO of analytically pure grade, ρ 1.1 g cm^{-3}, bp 189.0°C, mp 18.5°C, μ 3.96 D, and ε 48.9. DMSO is an aprotic dipolar protophilic solvent [19].

Acetate filaments were treated in a DMSO vapor medium in a hermetically sealed glass vessel filled with a liquid medium to one fifth of the volume. The fiber in the freely stretched state was horizontally fixed in a vessel at a distance of approximately 4 cm from the liquid surface. This experimental procedure allows visual observation of the sample deformation through the transparent vessel walls. The sag value in both direct and inverse processes was measured using a millimeter scale fixed on the back wall of the vessel. The experimental procedure and the algorithm used to calculate the variation of the linear size of the sample were described in detail in [7]. No less than 5–10 replicate measurements were performed under the same conditions, and the average values at the same instants of time were used for calculations. The experiments were performed at 19–60°C.

In the course of spontaneous deformation, we determined the degree of sorption of the solvent vapor by the fiber, C_s, by the gravimetric method using an E. Mettler analytical balance (Zürich, Switzerland) with a specially designed unit for sample fixation. The fiber was arranged so that it could be freely elongated. The experiments were performed with continuous weighing of the fiber in the course of swelling in the sorbate vapor. The weighing accuracy was ±0.0001 g.

For structural studies, the modified samples were removed from the vapor medium in various stages of spontaneous deformation, and the linear size in air was measured. Strain–temperature curves were obtained by linear dilatometry, by measuring the filament length on heating to 300°C. A load not exceeding 0.1% of the tensile strength was applied to the filament. The heating rate was 2–2.5 deg min^{-1}, measurement error 0.1%. X-ray diffraction patterns were recorded on a DRON-3 diffractometer with Cu_{K_α} radiation at U = 22 kV and I_a = 20 mA.

Our study showed that treatment of acetate fibers with a DMSO vapor is accompanied by their spontaneous elongation (Fig. 1). The elongation value depends on temperature. For example, in the range 20–30°C, the largest elongation L (with respect to the initial length taken as 100%) is 125–175% (curves *1*, *2*), and it is reached in 15–30 min. An increase in the temperature of the filament treatment to 35–60°C decreases the effect of self-elongation, and the process occurs in a shorter time interval (curves *3*–*5*).

This effect serves as direct experimental confirmation of the transition of the polymer system to the nematic phase [14]. Taking into account these concepts, published data [1–8, 20–22] in which spontaneous elongation of polymer bodies based on cellulose esters was observed, and also the fact of formation of an anisotropic phase in solutions of cellulose acetates in DMSO [15, 16], we conclude that the orientation processes occur in the polymer matrix under the action of vapor.

The feature of spontaneous elongation of CDA fibers in DMSO vapor is practically complete kinetic reversibility of the process. The fiber placed in the DMSO vapor after reaching the maximum elongation starts to contract, approaching the initial linear size (Fig. 1). The contraction of the acetate filament takes more time than elongation. For example, the direct process occurs at 20°C within approximately 25 min, and the reverse process, within approximately 70 min. In the reverse process, the fiber does not reach the initial linear size and remains slightly deflected; in this case, the sample subjected to cycles of elongation and partial contraction can remain slightly deflected in the DMSO vapor medium at room temperature for more than 90 days (Fig. 1, curve *1*). In addition, at some temperatures the sample swollen in vapor undergoes a slight secondary elongation and then is ruptured (Fig. 1, curves *2*–*4*).

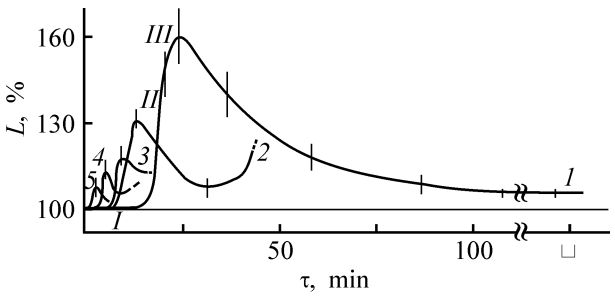

Fig. 1. Kinetic curves of spontaneous deformation (elongation-contraction) of the acetate fiber in a DMSO vapor at (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, and (*5*) 60°C. (L) Elongation and/or contraction and (τ) time. *Dotted line*: instant of fiber rupture.

Until now, the spontaneous cyclic deformation (elongation–contraction) has been observed in only a single system, acetate filament–nitromethane vapor [1, 7, 8]. As mentioned in these papers, the term shrinkage is inadequate for describing the fiber contraction, since the initial point in variation of the linear size is not the length of the initial sample but that of the spontaneously elongated sample. Contraction of the elongated sample results from neither a temperature effect nor a relaxation response to deformation stretching when forces arising in a polymer are directed opposite to motion. Both the elongation and contraction are spontaneous processes and occur in a period of time convenient for monitoring (duration of a complete cycle is 95 min at 20°C, 30–35 min at 30°C, 15–20 min at 40°C, 10–15 min at 50°C, and less than 10 min at 60°C) and, which is the most important, under the same conditions: at the same temperature and pressure and in a hermetically sealed vessel in the presence of a sorbate vapor.

The fiber removed from the solvent vapor medium in any stage of deformation (both in the course of elongation and contraction) keeps the size in air for a long time. It should be noted that the fiber becomes thinner and more even after elongation in vapor. The elongated sample can be stretched under a load by 180–230% more.

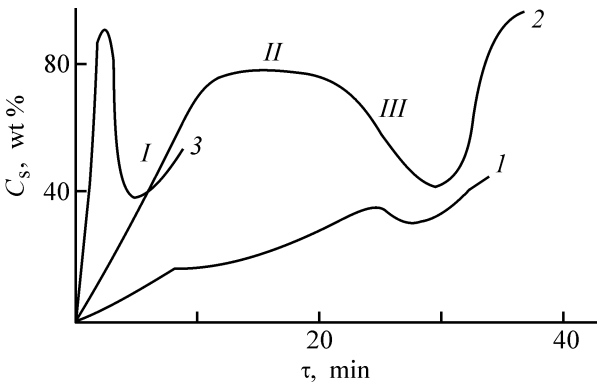

Fig. 2. Kinetic curves of sorption of the DMSO vapor by the acetate fiber in the course of spontaneous deformation at (*1*) 19, (*2*) 22, and (*3*) 60°C. (C_s) Degree of absorption of the DMSO vapor by the CDA fiber and (τ) time. (*I–III*) For comments, see text.

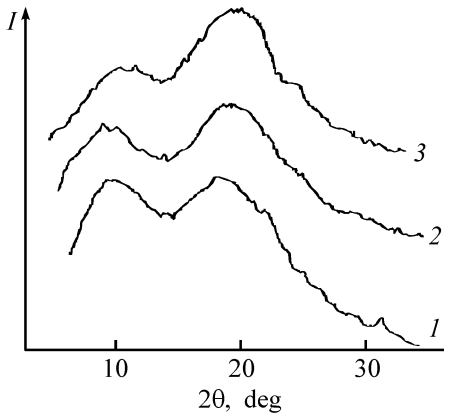

Fig. 3. X-ray diffraction pattern of acetate filaments. (*I*) diffraction intensity and (2θ) diffraction angle. Filament: (*1*) commercial (control), (*2*) elongated to the maximum extent in DMSO vapor, and (*3*) contracted after elongation and kept in this state in the sorbate vapor for 3 days.

The kinetics of sorption of the DMSO vapor by the CDA fiber in the course of spontaneous deformation is shown in Fig. 2. It can be seen that the swelling is a two-stage process. The first stage can be arbitrarily divided into several substages. For example, in the first substage of sorption at 22°C (Fig. 2, curve *2*, substage *I*) corresponding to an induction period preceding the self-elongation (Fig. 1, curve *1*, *I*), the fiber absorbs 70–75 wt % vapor within approximately 10 min (sorption rate $V \sim 7$ wt % min^{-1}). In the second substage (Fig. 2, curve *2*, *II*), the degree of sorption varies insignificantly (is practically constant); in the process, the filament length actively increases (Fig. 1, curve *1*, *II*). Then, the swollen filament desorbs 35–40 wt % of the previously absorbed vapor (Fig. 2, curve *2*, *III*; desorption rate $V \sim 5$ wt % min^{-1}) and continues to elongate (Fig. 1, curve *1*, *III*). In the second stage of swelling, a reverse effect is observed: the elongated fiber slowly contracts, approaching the initial linear size and absorbing vapor in a larger amount at a higher rate ($V \sim 15$ wt % min^{-1}). Finally, the filament ceases to absorb the sorbate vapor and, as mentioned above, remains in the deflected state in the DMSO vapor medium for a long time.

An unusual fact should be taken into account. When keeping the sample subjected to cyclic self-deformation in the DMSO vapor medium in a closed vessel, uniformly distributed small drops are formed on its surface. All drops are similar in shape and size and hang on the fiber for a long time (more than 70 days). No effect of this kind was observed in keeping an acetate filament, e.g., in a water vapor or in a vapor of other mesophasogenic (nitromethane, trifluoroacetic acid) and process (acetone, methylene chloride) solvents. This kinetic stability may be caused by various factors: surface phenomena at the phase boundary, surface energy of liquid in drop, equality of the energies of interaction of solvent vapor with polymer, and gravitational force.

The nonmonotonic sorption kinetics, squeezing of the solvent from the swollen sample, and also abrupt increase in the absorption rate (by a factor of more than 2) in the final stage of swelling are criteria of the orientation rearrangement of chains or their domains in the polymer matrix in the course of diffusion of a low-molecular-weight liquid or its vapor [5, 7, 13]. It is likely that, in this case, the DMSO vapor plays a role of a kinetic stimulant of the phase transition from the amorphous to anisotropic state [14, 22]. After removal of the kinetic hindrance, macromolecules in the swollen sample, due to their natural rigidity, are elongated to acquire the equilibrium, more straightened, conformation, become unfolded, and undergo spontaneous orientation ordering. In the macroscopic sense, this is manifested in an increase in the linear size of the fiber. In this case, the filament structure becomes compact, which results in squeezing of the solvent from the polymer matrix. It should be noted that the plateau and fall in the sorption curves (Fig. 2, curve *2*, substages *II* and *III*) correspond to the period of filament elongation (Fig. 1, curve *1*, substages *II* and *III*).

Data obtained by direct methods for studying the polymer structure suggest that the ordered state of the polymer matrix attained in the course of spontaneous deformation of the fiber in DMSO vapor. For example, X-ray diffraction patterns of the treated fiber (Fig. 3, curves *2*, *3*) have strong

reflections particularly pronounced at 2θ 18° –20° and 9°–11°. In addition, for these samples, the height and area of the peak in the range of 2θ 18°–20° increases, and those of the peak at 9°–11° decrease. In this case, the area of the peaks for the samples that underwent self-deformation in the DMSO vapor does not change noticeably in comparison with control (curve *1*). This additionally confirms that the structural rearrangements occurring in the polymer matrix under the action of the DMSO vapor are caused by orientation of macromolecules [6, 23].

The orientation ordering in the polymer matrix is confirmed by the results of a thermal deformation analysis of modified fibers (Fig. 4). For the initial sample prepared under industrial conditions by dry forming, we observed only the shrinkage (curve *1*), which suggests a weakly oriented structure of the polymer in finished acetate filaments. Contrary to the control sample, for all modified filaments, the strain–temperature curves have a different shape and are typical of preoriented polymers [3, 8, 20, 24]. The most pronounced effect of self-orientation was observed for the samples elongated in the DMSO vapor (curves *3*, *4*) and corresponding in the strain value to the middle of the strong elongation stage ($L \sim 130\%$) and to the maximum self-elongation ($L \sim 160\%$) (Fig. 1, curve *1*). The sample that sorbed the DMSO vapor before the onset of elongation (Fig. 1, curve *1*, $L \sim 101$–102%) is also characterized by orientation ordering but has a smaller peak of self-orientation (Fig. 4, curve *2*) in comparison with the more elongated samples. For the sample subjected to spontaneous cyclic deformation (i.e., the stages of elongation and subsequent partial contraction in vapor), self-ordering under the action of temperature is also observed (Fig 4, curve *5*). Contrary to the initial and other modified fibers, this sample has a higher glass transition point and, accordingly, the abrupt increase in the fiber length with linear heating occurs at higher temperatures. In addition, this sample showed virtually no contraction observed for all the other samples at $T > 230°$ and caused by the onset of thermal degradation of the polymer.

Thus, initiation of orientation processes in cellulose esters under the action of DMSO vapor takes place even in the induction period of self-elongation (Fig. 1, curve *1*, stage *I*), i.e., in the initial stage of intensive swelling of polymer in the vapor of an active medium (Fig. 2, curve *2*, stage *I*), and develops in the stages of elongation and contraction of the fiber.

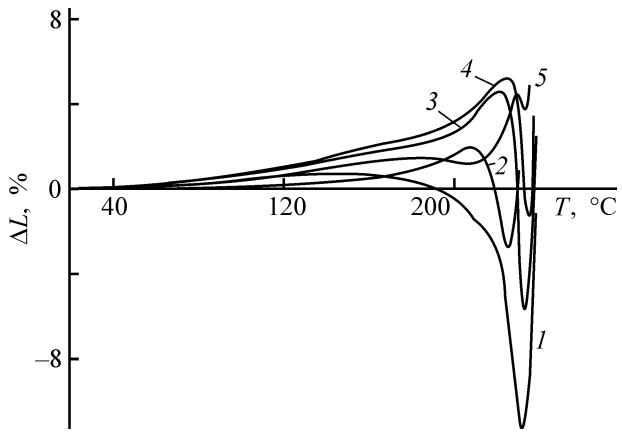

Fig. 4. Strain-temperature curves of diacetate filaments. (ΔL) Change in the sample length and (T) temperature. (*1*) Control industrial filament; samples subjected to spontaneous deformation in DMSO vapor at 20°C: (*2*) fiber swollen in vapor before beginning of self-elongation, (*3*) in the middle of the strong elongation stage, (*4*) filament elongated to the maximum, and (*5*) fiber after shortening.

It should be noted in conclusion that the ability of acetate fibers to undergo spontaneous elongation and orientation ordering under the action of DMSO vapor and also their ability to show additional stretching after removal from the sorbate vapor medium enables production of thin strong filaments with a linear density of less than 3–4 tex. It is well known that the modern industry does not produce so thin filaments by the dry forming procedure. Taking into account that DMSO is widely used in manufacture of cellulose acetate items of medical and biochemical purposes [18, 25] and also as drug [26, 27]; modified acetate filaments can be used in medicine and allied fields.

CONCLUSIONS

(1) Spontaneous variation of the linear size (elongation–contraction) of cellulose diacetate fibers in the vapor of a mesophasegenic solvent, dimethyl sulfoxide, is accompanied by initiation of orientation phenomena in the polymer matrix.

(2) The sorption of sorbate vapor with the polymer in the course of self-deformation of the fiber is described by nonmonotonic curves of swelling, rather than by Fick law , which points to the multistage mechanism of interaction of the sorbate vapor with the polymer.

(3) Treatment of acetate fibers with solvent vapor allows production of thin strong filaments for

not only textile, but also medical and biochemical purposes.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Oxidative Ammolysis of Wood under the Conditions of Cavitation Treatment

Abstract—Effect of the composition of the lignocarbohydrate vegetable raw material, treatment duration, amount of ammonium persulfate, and concentration of free ammonia on the yield of the target product and on its content of nitrogen, carboxy groups, and lignin upon oxidative ammonolysis of vegetable waste with ammonium persulfate in aqueous ammonia under the conditions of cavitation treatment was examined. The agrochemical tests of the products as nitrogen-containing fertilizers were performed.

DOI: 10.1134/S1070427208060268

The most promising line in applied chemistry of vegetable raw materials is integrated chemical processing of the whole biomass with the aim to obtain polymeric compounds with prescribed properties. An important but poorly studied pathway of vegetable waste utilization is its use as a raw material for preparing fertilizers and sorbents [1, 2].

To obtain a nitrogen-containing fertilizer from tree bark, it was suggested to treat a vegetable raw material with oxygen in an aqueous ammonia solution (oxidative ammonolysis) [1, 3]. The drawbacks of the existing process are elevated temperature (75–200°C), high oxygen pressure (up to 8 MPa), and relatively low nitrogen content of the fertilizer obtained (1.0–3.5%).

The oxidation of lignocarbohydrate materials with ammonium persulfate in ammonia under mild conditions has yielded valuable nitrogen-containing derivatives which can be used as nitrogen-containing organic fertilizers and ion exchangers [4]. Practical use of this procedure is limited by the high cost and large consumption of ammonium persulfate.

A promising procedure of wood preactivation with the aim to enhance its reactivity in chemical modification is cavitation treatment in aqueous medium in rotary cavitation dispersers [5]. Wood subjected to cavitation treatment in various media changes its chemical composition, which leads to partial breakdown of its supramolecular structure. Cavitation treatment favors fast impregnation of lignocarbohydrate materials with solutions of modifying agents, and also leads to hydrolysis of wood polysaccharides and oxidation of lignin [5].

This treatment allows activation of lignocarbohydrate materials for chemical modification directly in the course of treatment with chemical modifiers (oxidant, alkalis, aqueous ammonia, etc.) in a reactor of a rotary cavitation disperser in the zone of intense action of hydroacoustic cavitation. For example, cavitation treatment of peat in aqueous NaOH solution increases the yield of humic substances by 50% on the average, owing to the more efficient base hydrolysis of the organic matter of the vegetable substrate [6].

There are no published data on oxidation of vegetable raw materials with ammonium persulfate in aqueous ammonia under the conditions of cavitation treatment.

In this study, we examined how the conditions of oxidative ammonolysis of lignocarbohydrate materials with ammonium persulfate in aqueous ammonia under the action of hydroacoustic cavitation affect the yield and properties of nitrogen-containing derivatives.

Table 1. Influence of the time of cavitation treatment at 60°C on the content of carboxy groups and lignin in nitrogen-containing derivatives of pine wood [$(NH_4)_2S_2O_8$ content 0.2 g g^{-1} raw material, NH_3 solution concentration 0.5%]

Treatment time, min	Product yield, %	Content, %	
		COOH groups	lignin
Initial pine wood	–	2.4	27.6
15	98	2.9	26.1
30	95	3.5	24.8
45	92	4.2	23.2
60	90	4.9	22.1

EXPERIMENTAL

As the raw material we used air-dry pine sawdust (fraction 1 mm). The raw material and treatment products were analyzed for bound nitrogen after Kjeldahl [7], for lignin after Komarov [8], and for carboxy groups by conductometric back-titration [9].

The oxidative ammonolysis was performed as follows. A 350-g portion of sawdust was placed in a 50-l temperature-controlled reactor connected to a rotary cavitation apparatus with a rotor rotation frequency of 3000 rpm. The sawdust was treated with ammonium persulfate (0.2–0.8 g g^{-1} wood) in 0.5–2.0% aqueous ammonia in an aqueous suspension at 60°C for 15–60 min. The target product was a solid residue insoluble in the reaction medium. It was filtered-off on a filter cloth, washed to negative reaction for ammonium ion with the Nessler reagent, and dried in air to constant weight, after which the yield (wt % relative to the raw material) and the content of bound nitrogen, lignin, and carboxy groups were determined. The results are given in Table 1.

Agrochemical tests of the products as nitrogen-containing organic fertilizers for pea were performed by the method of vegetation experiments, with the plant height and dry matter weight measured [10].

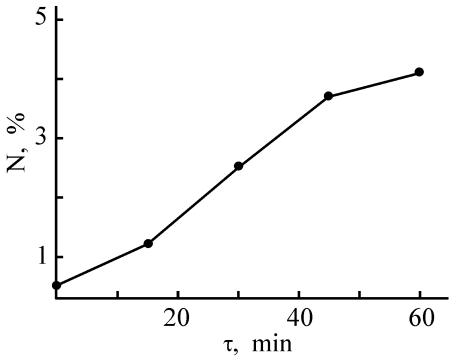
Table 1 and the figure show how the duration of the cavitation treatment at 60°C affect the composition of nitrogen-containing pine wood derivatives. The experiments show that a longer cavitation treatment of wood at 60°C in the presence of ammonium persulfate in aqueous ammonia results in steadily increasing content of bound nitrogen and carboxy groups, i.e., oxidative binding of nitrogen takes place.

After oxidative cavitation treatment for 60 min, up to 4.1% of bound nitrogen is introduced into the wood (see figure). With an increase in the process duration, the product yield decreases, probably because of increased oxidative base degradation of wood in aqueous ammonia. To evaluate the strength of nitrogen binding, samples of oxidized products were subjected to hydrolysis in 1 N H_2SO_4 at 100°C for 1 h (Table 2).

The acid hydrolysis under such conditions leads to active elimination of nitrogen in the form of ammonium ions from products of oxidative ammonolysis of wood. The nitrogen content of the hydrolyzed samples proportionally decreases. It is known [9] that, under such conditions, ammonia is eliminated from the $RCOONH_4$ and $RCONH_2$ groups with the formation of free carboxylic acids. Hence, if ammonia is eliminated from these functional groups, the content of carboxy groups in the hydrolyzed products should increase, which is

Table 2. Effect of hydrolyzing reagent on products of oxidative ammonolysis of pine wood

Treatment time, min	Hydrolysis conditions	Yield of solid residue, %	Characteristics of hydrolyzed product, %			
			nitrogen content	decrease in nitrogen content	content of COOH groups	gain in content of COOH groups
15	–	–	1.2	–	2.9	–
	1 N H_2SO_4, 100°C, 1 h	72.5	0.9	25	3.7	27
60	–	–	4.1	–	4.9	–
	1 N H_2SO_4, 100°C, 1 h	70.8	3.4	17	5.7	18



the case. The relative content of readily hydrolyzable forms of bound nitrogen in the nitrogen-containing pine wood derivatives is 17–25%, with the remaining nitrogen (75–83%) being strongly bound. A Longer oxidative ammonolysis leads to accumulation of difficultly hydrolyzable organically bound nitrogen in the wood oxidation products, whereas the content of labile nitrogen somewhat decreases.

We examined how the amount of the oxidant (ammonium persulfate) affects the functional composition of nitrogen-containing pine wood derivatives (Table 3).

The experimental results show that, with an increase in the amount of ammonium persulfate per gram of wood, the product yield decreases. This is apparently due to oxidative hydrolytic degradation of wood. With an increase in the oxidant amount from 0.2 to 0.8 g g^{-1} raw material, the content of carboxy groups and nitrogen grows from 2.9 to 6.8 and from 1.2 to 3.5%, respectively, i.e., oxidation of wood accompanied by nitrogen binding is accelerated.

We also examined the influence of the ammonia concentration on the properties of nitrogen-containing pine wood derivatives (Table 4). We found that an increase in the ammonia concentration in the aqueous suspension also leads to a certain decrease in the yield of nitrogen-containing wood derivatives, probably because of degradation (ammonolysis). An increase in the ammonia content leads to a regular increase in the content of bound nitrogen and carboxy groups in products of oxidative ammonolysis of pine wood.

The presence of various functional forms of bound nitrogen is confirmed by the IR spectra of products of oxidative ammonolysis of aspen wood. The spectra contain absorption bands characteristic of carboxylate ions in the form of ammonium salts (1595 cm^{-1}), amide groups (1625 cm^{-1}), and heterocyclic nitrogen (1680 cm^{-1}).

Bound nitrogen content in products of oxidative ammonolysis of pine wood vs. the time τ of its oxidation under the conditions of cavitation treatment.

Thus, oxidation of pine wood with ammonium persulfate in aqueous ammonia under the conditions of cavitation treatment yields macromolecular products containing up to 4.3% organic nitrogen and up to 6.8% carboxy groups. About 17–25% of the bound nitrogen is eliminated in the course of hydrolysis, and the remaining amount (75–83%) is strongly bound.

The content of lignin in products of oxidative ammonolysis of pine wood decreases with an increase in the duration of cavitation treatment and in the amounts of ammonium persulfate and ammonia (Tables 1, 3, 4), suggesting the occurrence of oxidative hydrolytic degradation of lignin in the course of oxidative ammonolysis of pine wood. That is, the process is actually delignification.

Table 3. Influence of the amount of ammonium persulfate on the properties of nitrogen-containing pine wood derivatives (duration of cavitation treatment 15 min, temperature 60°C, NH_3 concentration 0.5%)

Amount of $(NH_4)_2S_2O_8$, g g^{-1} wood	Product yield, %	Content, %		
		N	COOH groups	lignin
Initial pine wood	–	0.5	2.4	27.6
0.2	98	1.2	2.9	26.1
0.4	92	2.5	4.2	24.1
0.6	86	3.2	5.9	22.3
0.8	82	3.5	6.8	20.5

Table 4. Influence of the ammonia concentration on the properties of nitrogen-containing pine wood derivatives (duration of cavitation treatment 15 min, temperature 60°C, $(NH_4)_2S_2O_8$ amount 0.2 g g^{-1} wood)

NH_3 concentration, %	Product yield, %	Content, %		
		N	COOH groups	lignin
Initial pine wood	–	0.5	2.4	27.6
0.5	98	1.2	2.9	26.1
1.0	94	2.7	3.4	25.6
1.5	91	3.8	3.9	24.8
2.0	89	4.3	4.5	23.9

To evaluate the effect of the nitrogen-containing products obtained as growth stimulants or inhibitors for various crops, 30-day wheat acrospires of Altaiskaya-50 strain were sowed with these fertilizers. We found that the influence exerted by the products of oxidative ammonolysis of pine wood on the plant height increased with the nitrogen content of the products and the fertilizer dose. The gain in the total biomass per plant (absolutely dry weight) was 21–37%. Hence, nitrogen-containing pine wood derivatives are plant growth stimulants and can be used as nitrogen-containing organic fertilizers for crops.

CONCLUSIONS

(1) Oxidative ammonolysis of pine wood with ammonium persulfate in aqueous ammonia under the conditions of cavitation treatment yields nitrogen-containing fertilizers with a bound nitrogen content of 1.2–4.3%.

(2) Products of oxidative ammonolysis of pine wood contain, depending on the oxidation conditions, up to 4.3% organically bound nitrogen and up to 6.8% carboxy groups. The relative content of labile nitrogen is 17–25%, and the remaining 75–83% is strongly bound.

(3) With an increase in the duration of the cavitation treatment and in the amount of ammonium persulfate in aqueous ammonia, the degree of delignification of pine wood grows.

(4) The products of oxidative ammonolysis of wood stimulate the growth of the biomass of cereals and can be used as nitrogen-containing organic fertilizers.

Abstract—Carboxymethyl cellulose ethers were prepared from flax fibers of various degrees of ripeness. The influence exerted by the degree of ripeness of flax fibers on their reactivity in carboxymethylation was examined. The rheological properties of aqueous solutions of the synthesized carboxymethyl cellulose were studied.

DOI: 10.1134/S107042720806027X

Recently a trend has been outlined toward the use of nonwood cellulose-containing raw materials. This can be seen from papers concerning the development of procedures for production of cellulose from nontraditional sources: soybean and pea pod, ambary, jute, rice and wheat straw, cane, perennial grasses, agricultural wastes, and cotton, flax, and hemp pedicels [1].

Cellulose ethers are widely used in various fields of human activity. They are used for production of adhesives, chemical fibers, varnishes, paints, and also in other fields. For example, hydroxyethyl cellulose is used as swelling inhibitor for water-sensitive clays in well-drilling; carboxymethyl cellulose (CMC) is widely used in oil-and-gas-extracting industry as a component of viscoelastic systems in secondary treatment of oil wells. The main raw material for production of cellulose ethers is wood and cotton cellulose. A possible alternative source of cellulose for producing its derivatives is large-tonnage waste from flax production: short fibers and lignified part of flax pedicels (boon).

Flax growth and ripening are accompanied by changes in the physical and physicochemical properties of fibers, in their chemical composition, and in the molecular characteristics of cellulose and supramolecular structure of the polymer. The reactivity of flax fiber cellulose in polymer-analogous transformations depends on the above factors. The preferable period of flax collection is the early yellow-ripeness phase [2], providing collection of the maximal harvest of high-quality fibers. Before this phase, cellulose is accumulated in the fibers, and by this time fiber bundles become compact and dense, and technical ripeness of flax is attained. In this step of ripening, the lignification of shells of single fibers is insignificant [3–5]. Flax fibers in the green ripeness phase contain less lignin, so that the fibers are thinner and more flexible. After the early yellow ripeness phase is attained, lignin is accumulated up to the full ripeness phase, and the fibers become rough and rigid, losing the elasticity. As flax fibers of different degrees of ripeness are used in textile industry for different purposes, flax production wastes are formed: boon and short fibers.

It is of scientific and practical interest to compare the reactivities of cellulose from flax of various degrees of ripening in the CMC synthesis and to study the rheological properties of aqueous solutions of the ethers obtained.

EXPERIMENTAL

As starting materials we used fibers of flax of Orshanskii 2 strain, picked out in various stages of growth (budding, green ripeness, early yellow ripeness), and of Tomsk 18 strain (early yellow ripeness). Dry flax straw was soaked in distilled water for 5 days and dried in air for 24 h. From flax straw of various degrees of ripeness, fibers were picked out manually. Fiber samples were taken

Table 1. Chemical composition of flax fibers taken in various stages of ripening

Stage	Moisture content	Ash	Fats, wax	Pectins	Hemicelluloses	Lignin	Cellulose
	%						
Budding	5.66	1.13	2.67	10.07	8.97	4.80	66.70
Green ripeness	5.06	1.07	1.30	9.00	8.60	5.40	69.57
Early yellow ripeness	5.04	1.26	0.80	6.10	10.40	6.00	70.43

Table 2. Variation of DP_η and DS_{Na} of NaCMC samples in the course of carboxymethylation

Sample	Reaction time, h	Budding		Green ripeness		Early yellow ripeness	
		DP_η	DS_{Na}	DP_η	DS_{Na}	DP_η	DS_{Na}
Flax fibers*	–	3700	–	3980	–	4470	–
NaCMC	1	740	0.33	898	0.31	1080	0.39
NaCMC	2	720	0.36	810	0.35	1050	0.42
NaCMC	3.5	693	0.44	790	0.46	860	0.51
NaCMC	5	620	0.51	700	0.45	893	0.52

* After treatment with cooking solution.

from the middle part of plant pedicels. For fibers of various degrees of ripeness, we initially determined the chemical composition (Table 1). It can be seen that, with the progress of ripening, the content of cellulose and lignin in fibers increases and that of pectins and fats decreases. The concomitant substances affect the reactivity of cellulose.

Carboxymethyl cellulose samples were prepared in isopropanol [6]. First the flax fibers were pretreated with a cooking solution ($NaOH–Na_2S_2O_3–H_2O$, fiber : $NaOH$: $Na_2S_2O_3$ ratio 1 : 1.2 : 0.7) in a nitrogen flow. Such treatment allows removal of the major part of concomitant substances (hemicelluloses, pectin, lignin) with only a minor decrease in the degree of polymerization (DP_η).

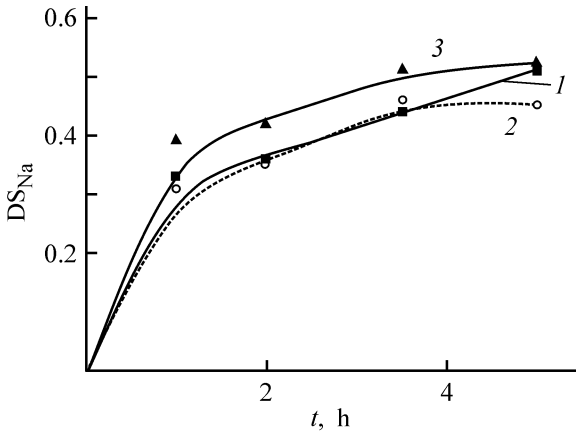

Fig. 1. Variation of DS_{Na} in the course of carboxymethylation of flax fibers of various degrees of ripeness: (*1*) budding, (*2*) green ripeness, and (*3*) early yellow ripeness; the same for Fig. 2. (t) Reaction time.

The degree of substitution with respect to carboxy groups was calculated by the formula [7]

$$DS_{Na} = \frac{162n}{2300 - 80n}, \quad (1)$$

where n is the Na content of the polymer (wt %).

The Na content of the samples was determined by conductometric titration with 0.1 N HCl. The degree of polymerization of NaCMC samples was determined viscometrically in 6% aqueous NaOH and calculated by the formula [7]

$$[\eta] = 7.3 \times 10^{-3} M^{0.93}.$$

Table 2 shows that the carboxymethylation is accompanied by a decrease in DP_η, suggesting the occurrence of oxidative degradation of the polysaccharide macromolecules. On the whole, the DP_η values of the synthesized CMC samples (based on flax fibers) are considerably higher than those of the commercial NaCMC sample (cotton linter) which was further used as a reference. For the commercial NaCMC, DP_η = 450 and DS_{Na} = 0.57. The dependences of DS_{Na} of CMC on the reaction time for fibers of flax with different degrees of ripeness are plotted in Fig. 1. Table 2 and Fig. 1 show

that the degree of ripeness of flax fibers does not appreciably affect the carboxymethylation kinetics. Apparently, pretreatment of flax fibers with the cooking solution to remove concomitant substances eliminates the effect of impurities on the cellulose reactivity. It should also be noted that preactivation of fibers with a concentrated (30%) aqueous NaOH solution before carboxymethylation also leads to partial removal of hemicelluloses, pectins, and lignin from the fibers.

Because NaCMC is widely used as aqueous solutions, we performed comparative studies of the rheological properties of moderately concentrated (wt %) aqueous solutions of NaCMC with different DS_{Na}.

Studies of the rheological properties of polymer solutions reveal specific features of the behavior of concentrated polymer solutions, gel-like systems, pastes, and suspensions, depending on the shear rate and stress, temperature, concentration, and other factors affecting the properties of these systems in the course of operation or reprocessing. Figure 2 shows the flow curves of aqueous solutions of NaCMC prepared from flax fibers of various degrees of ripeness. Similar flow curves were obtained for all the NaCMC samples represented in Table 2. The flow curves for all the systems are incomplete flow curves of non-Newtonian fluids, characteristic of strongly structured systems, such as physical thermally reversible gels [8, 9] and chemically crosslinked systems, hydrogels [10].

From the temperature dependences of the viscosity in the range 20–40°C, we calculated the activation energies of viscous flow, E_a, of the solutions. For all the solutions, the E_a values appeared to be similar, varying in the range 30.0–40.0 kJ mol^{-1}.

Table 3. Characteristics of carboxymethyl cellulose prepared by double carboxymethylation of flax fibers (Tomsk 18 strain, early yellow ripeness)

Sample	DS_{Na}	DP_η	Solubility, %
CMC (fiber):			
first etherification	0.52	950	89
second etherification	0.8	500	92
Commercial CMC	0.57	450	99

With increasing DS_{Na}, E_a tended to decrease, which is indicative of an increase in the solubility of NaCMC in water.

To raise DS_{Na}, flax fibers (Tomsk 18 strain, early yellow ripeness) were subjected to two successive carboxymethylations. The characteristics of the ethers obtained are listed in Table 3. After the first carboxymethylation of flax fibers and preparation of 1% solutions of NaCMC in water, gel particles were observed in the solution. This is caused by nonuniform carboxymethylation of flax fibers, so that fiber fragments with a low degree of substitution remain in the bulk of the material. After the repeated carboxymethylation of the same sample, DS_{Na} and the polymer solubility in water increased and the amount of gel particles decreased. The rheological properties of aqueous solutions of NaCMC samples prepared from flax fibers and of a commercial sample prepared from cotton linter are compared in Fig. 3. It is seen that aqueous solutions of NaCMC prepared from flax are more viscous than those of commercial NaCMC, which is due to the higher molecular weight of the cellulose

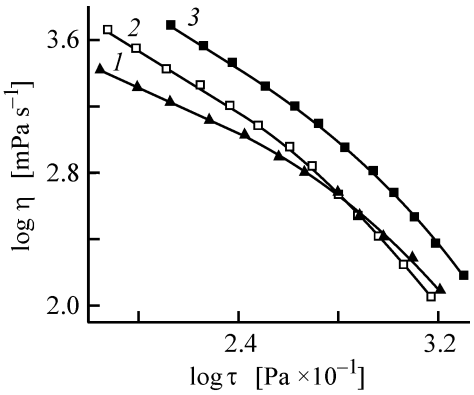

Fig. 2. Flow curves at 20°C of 1% aqueous solutions of NaCMC prepared from flax fibers of various degrees of ripeness. Reaction time 5 h. (η) Viscosity and (τ) shear stress; the same for Fig. 3.

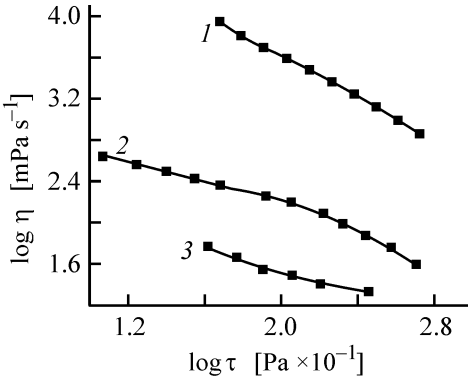

Fig. 3. Flow curves at 20°C of 1% aqueous solutions of (*1*, *2*) NaCMC prepared from flax fibers (Tomsk 18 strain, early yellow ripeness) and (*3*) commercial NaCMC (cotton). (*1*) DS_{Na} = 0.52, DP_η = 950; (*2*) DS_{Na} = 0.8, DP_η = 500; and (*3*) DS_{Na} = 0.57, DP_η = 450.

derived from flax fibers. The NaCMC prepared from flax fibers can be used as effective thickener of aqueous media in various fields of human activity.

Thus, we prepared NaCMC with various degrees of substitution from flax fibers of various degrees of ripenes.

CONCLUSIONS

(1) Pretreatment of fibers with a cooking solution to remove lignin eliminates the differences in the reactivity of flax fibers of various degrees of ripeness.

(2) Aqueous solutions (1%) of the synthesized carboxymethyl cellulose samples are more viscous than those of commercial carboxymethyl cellulose, which is caused by the considerably higher molecular weight of cellulose recovered from flax fibers.

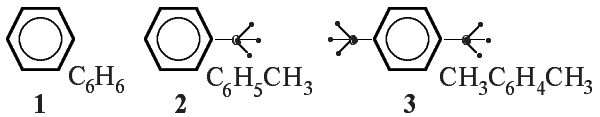
Received February 18, 2008



Abstract—The concentration dependences of densities of fullerene C_{70} solutions in benzene, toluene, and *p*-xylene were determined pycnometrically.

DOI: 10.1134/S1070427208060281

Previously we have determined the concentration dependences of the densities of C_{60} fullerene solutions in benzene, toluene, and *p*-xylene [1]. These dependences are nonmonotonic: The density initially decreases, passes through a minimum, and then again increases to reach values exceeding the density of the pure solvent. This trend correlates with the concentration dependences of the intensities of small-angle X-ray scattering [2–4].

It should be noted that aromatic liquids of the above type are relatively good solvents for C_{70} fullerene [5], although its solubility is lower than that of C_{60}. Nevertheless, just toluene and xylene are used for recovering C_{60} and C_{70} from the fullerene soot [6]. They are also used for preparing mixed solutions of fullerenes and polymers, or solutions of fullerenes with grafted polymer chains for subsequent construction of various fullerene–polymer systems. Thus, the behavior of fullerenes in aromatic solvents is of not only scientific, but also applied interest.

In this study, we determined the concentration dependence of the density of C_{70} fullerene solutions in benzene **(1)**, toluene **(2)**, and *p*-xylene **(3)**:

1 **2** **3**

EXPERIMENTAL

C_{70} fullerene prepared by the Kratschmer–Huffman method [6] (99.7% purity) and chemically pure grade benzene, toluene, and *p*-xylene (after their single distillation) were used. Initially a mother liquor with the known maximal fullerene concentration c_{max} (%) was prepared. Then solutions with intermediate concentrations were prepared by its dilution in appropriate volume or weight ratios. The concentration interval was varied from $c = 10^{-4}$% to concentrations close to saturation.

The error in determination of low concentrations was about 1–2%, and that for the highest concentrations, 0.1–0.2%.

The densities of solvents and solutions were determined pycnometrically. A standard Pyrex glass pycnometer (Czechia) with a ground-glass stopper and a mark corresponding to a liquid volume of 6.9 ml was used. Weight measurements were performed on a VLR-20g analytical balance with an error of 5×10^{-5} g in a temperature-controlled volume. The temperature of 24°C was maintained constant with an error of ±0.5°C. However, direct temperature measurements performed with an error of ±0.01°C showed that, during measurements of the solution density of a given concentration, the temperature does not change noticeably, and in going to other concentrations it changes by no more than 0.1°C. The error of pycnometric measurements of the density was ±0.0001 g cm^{-3}. For solutions of a given concentration, three to five measurements were performed, and the arithmetic mean was determined. The error of the density measurement for a solution of a given concentration did not exceed 0.01%.

Estimation of errors in measurements of pure solvent densities

Solvent	Density, g cm^{-3}				Relative error, %
	d, [7]	standard, corrected d_{st}^{*}	experimental, d_{exp}	$d_{exp} - d_{st}$	
Benzene	0.8790	0.8788	0.8880	+0.0092	1
Toluene	0.8669	0.8667	0.8776	+0.0099	1
p-Xylene	0.8611	0.8609	0.8665	+0.0056	0.5

* In [7], somewhat overestimated densities were reported, which were related to water density at 4°C. It is not equal to 1, but is close to 0.9998 [8]. Therefore, the d_{st} values obtained by multiplication by 0.9998 of d values presented in [7] are listed in the table. In all cases, the overestimation is 0.0002 g cm^{-3}.

The results of measurements are shown in Fig. 1. It should be noted that the accuracy in measuring the absolute values of the densities of the pure solvents was relatively high: deviations from the standard tabulated points did not exceed 1% (0.01 g cm^{-3} in absolute values, see table).

The concentration dependence of the density of C_{70} fullerene solutions in toluene and carbon disulfide has been measured previously by Tomiyama et al. [9]. In [9], the density of toluene was determined as 0.8619–0.8622 g cm^{-3}, i.e., deviation from the standard value was observed already in the third decimal place, and the minimal C_{70} concentration was 0.05 mg ml^{-1}, which corresponds to approximately 5.8%. This value substantially exceeds the concentrations we examined in this study, which explains why no density minima were observed in [9].

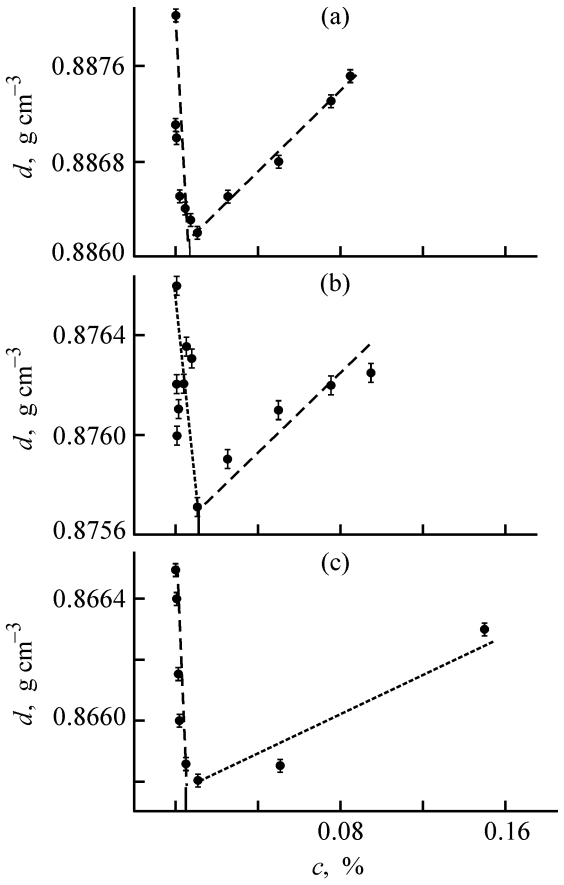


Fig. 1. Concentration dependences of densities d of C_{70} fullerene solutions in (a) benzene, (b) toluene, and (c) *p*-xylene. Temperature 24°C, pressure 697 mm Hg.

However, the main result of our study consist in revealing the specific nonmonotonic concentration dependence of the solution density, rather than in determining the absolute values of the density of C_{70} solution. For all the solvents studied, as the C_{70} concentration increases, the solution density initially sharply decreases and then, after passing through a minimum, nearly linearly grows, but does not reach the density of the pure solvent.

As can be seen from Fig. 1, each density curve is well approximated by two linear portions. Similar broken lines were observed in [10] for C_{60} solutions.

Thus, the reliability of the specific shape of the above dependences is confirmed by the following facts: (1) similarity of the dependences for three solvents, (2) similarity of the dependences for C_{60} and C_{70} solutions, and (3) correlation with data of wide-angle X-ray measurements [11].

We should note that the density, initially decreases, despite that the density of neat fullerene is approximately two times the densities of the solvents. The initial decrease in the density may be due to formation of shells with decreased density around fullerene molecules or their aggregates, and the subsequent increase in the density may be due to solvent structuring [2–4], i.e., to certain suppression of thermal fluctuations of the den-

sity and to ordering on the molecular level, which is also manifested in small- and wide-angle X-ray diffraction patterns.

It follows from Fig. 1 that the density minimum is reached at a C_{70} fullerene concentration of about 0.005–0.01% and is practically independent of the solvent, in contrast to C_{60} [1]. This is in agreement with approximately the same C_{70} solubility in the solvents examined (benzene 1.3 and toluene 1.4 mg ml^{-1} [5]). Apparently, the character of the changes in the supramolecular structure of C_{70} solutions, namely, formation of shells with decreased density and solvent structuring, should affect the solution properties.

CONCLUSION

At low C_{70} fullerene concentrations (starting from 10^{-4}%) in the aromatic solvents studied, the solution density varies nonmonotonically as the fullerene concentration increases: initially it sharply decreases and then, after passing through a minimum, sharply grows.

Sb_2S_3–SiO_2 Nanocomposite Layers Synthesized Using the Layer-by-Layer Technique

V. P. Tolstoi and L. B. Gulina

St. Petersburg State University, At. Petersburg, Russia

Received December 27, 2007

Abstract—Possibility of layer-by-layer synthesis by colloidal layering of Sb_2S_3–SiO_2 nanocomposite layers from colloid solutions of $\{[H_xSb_2S_5]^{m-}\}mNa^+$ and SiO_2 was studied. The composition of the layers synthesized was examined by Raman spectroscopy, transmission spectroscopy in the UV and visible spectral ranges, energy-dispersion microanalysis, and scanning electron microscopy.

DOI: 10.1134/S1070427208060293

As is known, a prominent place in preparative chemistry of nanolayers is occupied by methods of layer-by-layer synthesis. These techniques are based on performing successive acts of adsorption or adagulation of low-dimension precursors, with obligatory removal of their unreacted excess. As a result, a nanolayer of a substance being synthesized, i.e., a layer with a thickness of several nanometers or fractions of a nanometer, is formed on the surface. Upon a multiple repetition of the adsorption reactions, the thickness of this layer increases in proportion to the number of treatment cycles.

A method for synthesis of this kind is the colloidal layering (CL) technique, which consists in successively performing multiple reactions of adagulation of colloid particles at substrate surfaces in reagent solutions. Previously, two pathways have been suggested for synthesis of oxides by this method. The first [1] is based on formation of difficultly soluble compounds by performing on the substrate surface successive reactions of adagulation of $Sn(II)(OH)_xF_y^-$ colloid particles, with their subsequent oxidation to $Sn(OH)_4$. Upon the oxidation reaction, the $Sn(II) \rightarrow Sn(IV)$ transition occurs and, in the pH range of the reagent solutions used, the negative surface charge changes to positive. As a result, the reaction of adagulation of $Sn(II)(OH)_xF_y^-$ colloid particles can again proceed at the surface and a reversible cyclic growth of the layer thickness becomes possible. The second pathway [2] is based on successive treatments of a substrate with colloid solutions containing positively (ZnO) and negatively (Mg–Al-silicate) charged colloid particles yielding a layer of the nanocomposite when interacting at the surface.

The aim of this study was to examine specific features of synthesis by the CL method of Sb_2S_3–SiO_2 nanocomposite layers. As is known, Sb_2S_3 is a semiconductor and it would be expected that the quantum-confinement effect should be manifested in the electrical and optical properties of its nanoparticles. At the same time, layers of nano- and mesoporous composite can find use as inorganic membranes and ion-exchange materials.

Upon multiple successive treatments, a layer characterized by a spectrum in the UV and visible spectral ranges (Fig. 1) is formed on the surface. The intensity of the broad absorption band at

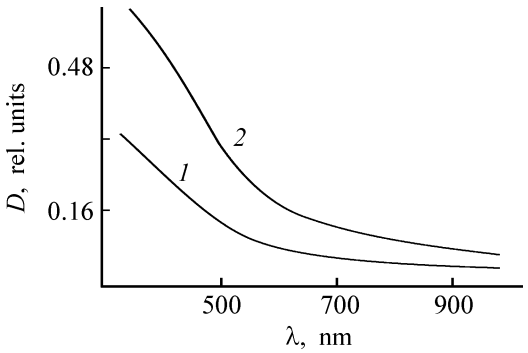

Fig. 1. Transmission spectra of Sb_2S_3–SiO_2 nanolayers synthesized on the surface of fused silica upon (*1*) 6 and (*2*) 12 CL cycles. c_{SiO_2} = 0.02 M, $c_{N_2H_4}$ = 0.01 M, $c_{Na_3SbS_4}$ = 0.01 M; the same for Figs. 2, 3. (*D*) Optical density and (λ) wavelength.

300–600 nm in this spectrum increases in proportion to the number of CL cycles. The composition of this layer was found from the Raman spectra in Fig. 2 and from results of an X-ray fluorescence microanalysis for a sample synthesized on the surface of aluminum. The Raman spectrum of this layer shows a band peaked at 300 cm^{-1}, characteristic of Sb_2S_3 [3], and, according to the X-ray data, the ratio of the element concentrations in the layer is Si : Sb : S = 1.0 : 1.0 : 1.5, which confirms the Raman data.

A SEM study of the morphology of the layers demonstrated (Fig. 3) that the layer is composed of nanoparticles 10 to 30 nm in size.

The results obtained can be accounted for by the following sequence of reactions occurring at the surface in the course of synthesis. In the first stage, after lead cations are adsorbed on the silica surface and their excess amount is removed by washing in water, ≡Si–OPbOH groups are formed on the surface and serve as centers of adsorption of $[H_xSb_2S_5]^{m-}$ colloid particles from the Na_3SbS_4 solution. Further, after a treatment in a SiO_2–$N_2H_4 \cdot HCl$ solution, the reduction $Sb^{5+} \rightarrow Sb^{3+}$ is observed and Sb_2S_3 nanoparticles are formed. These particles presumably have a positive charge on the surface and serve as adsorption centers for SiO_2 colloid particles. Thus, the subsequent cyclic treatment in solutions of the chosen reagents leads to a cyclic reproducible growth of a Sb_2S_3–SiO_2 layer.

EXPERIMENTAL

As substrates for synthesis of nanolayers were chosen polished single-crystal Si <100> wafers of KDB-40 brand (*p*-Si : B with a resistivity of 40 Ω cm), fused silica of KV brand, and electrolytic aluminum (99.99% purity). The procedure used to prepare the substrates for synthesis was described in [4].

The synthesis was performed as follows. After a standard pretreatment, the substrates were treated with a 0.01 M $Pb(NO_3)_2$ solution for 30 min, washed with water to remove the excess amount of the salt, mounted on the holder of the automated installation, and successively treated with Na_3SbS_4 solutions, water, a SiO_2–$N_2H_4 \cdot HCl$ solution, and again water. One treatment of this kind constituted a single cycle of CL, which was repeated many times. The time of treatment with each reagent was 30 s.

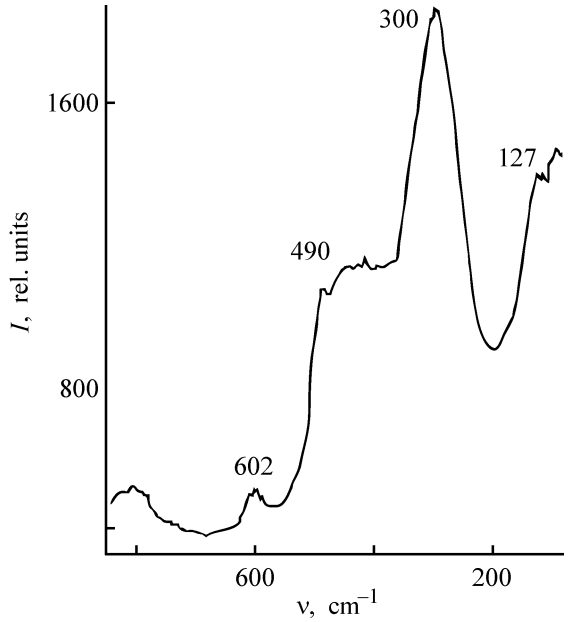

Fig. 2. Raman spectrum of a Sb_2S_3 layer synthesized on the surface of fused silica upon 10 CL cycles. (*I*) Intensity and (ν) wave number.

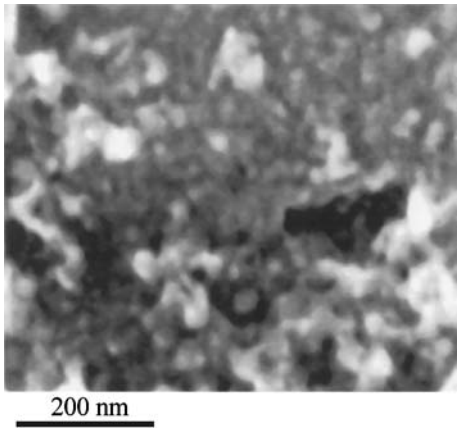

Fig. 3. SEM micrograph of the surface of a Sb_2S_3–SiO_2 layer synthesized on the surface of silicon. The layer was synthesized upon 15 CL cycles.

The colloid solution of SiO_2 was prepared by acidifying a freshly prepared 0.02 M solution of Na_2SiO_3 with HCl to pH 7. The synthesis was performed from solutions kept for 24 h at room temperature. According to the data of [5], colloid particles in a solution of this kind are 4–10 nm in size. Immediately before synthesis, $N_2H_4 \cdot HCl$ was introduced into this solution to a concentration of 0.01 M. The colloid solution of Na_3SbS_4 was prepared by dissolving the salt in water and adjusting its pH to 8.5 by addition of CH_3COOH.

It was found that, at this pH value, a light yellow colloid solution of Sb_2S_5 is formed and remains stable for 24 h.

Transmission spectra in the UV and visible spectral ranges were recorded on a Perkin–Elmer Lambda-9 spectrometer at a scanning rate of 50 nm min^{-1} and 2-nm slit program. Images of the sample surface were obtained using a Zeiss EVO40EP electron microscope with a LaB_6 cathode. An X-ray fluorescence microanalysis was performed on this microscope at an accelerating voltage of 20 kV with an Oxford Instruments INCA 350 energy-dispersion analyzer. The Raman spectra were recorded using a Bruker SENTERRA instrument, with laser excitation at a wavelength of 785 nm.

Electrical Conductivity of Porous Glasses Saturated with Sulfuric Acid Solutions

M. V. Lyubavin, Yu. Yu. Gavronskaya, and V. N. Pak

Hertzen Russian State Pedagogical University, St. Petersburg, Russia

Received December 27, 2007

Abstract—Electrical conductivity of porous glasses saturated with sulfuric acid solutions was studied. At impregnating solution concentrations in the range 20–40 wt %, the glasses have high conductivities $\sigma > 0.1\ \Omega^{-1}\ cm^{-1}$. The dependences of the electrical conductivity on parameters of the porous structure of membranes are considered.

DOI: 10.1134/S107042720806030X

The current literature pays increasing attention to development of proton-conducting membranes intended for use in fuel cells and devices for detection and generation of hydrogen. A considerable part of studies in this area are devoted to sulfo polymers and polymeric media impregnated with sulfuric and phosphoric acids [1–6]. Also, potentialities of sol–gel methods are intensively studied in order to obtain composite materials with proton conductivity, including porous oxides, polymeric fillers, and inorganic acids [7–12]. In particular, it has been found recently that the electrical conductivity of mesoporous silicas impregnated with sulfuric acid reaches high values on the order of 0.1 $\Omega^{-1}\ cm^{-1}$ [12]. In this context, it seems promising to use membranes made of porous glass (PGs) as proton-conducting media. To indubitable advantages of PGs belong the widely controllable parameters of the porous structure, narrow pore size distribution, mechanical strength, and stability in acid media [13, 14]. In this study, the electrical conductivity of a number of PG membranes saturated with sulfuric acid solutions was examined.

EXPERIMENTAL

Experiments were carried out with porous glasses in the form of 10 × 10-mm square plates with a thickness of 1 mm, which had structural parameters listed in the table. The procedures used to fabricate PG membranes of the series specified have been more than once described in the literature [13–15]. In impregnation of the membranes with sulfuric acid solutions, it is necessary to provide the maximum possible and reproducible filling of the space of through channels. The actually reached content Q of encapsulated electrolyte in a PG plate of mass m_0 is linearly related to the density ρ of the impregnating solution and the pore volume V_p of the glass by the expression

Pore radius r_p, pore volume V_p, porosity ε, and degree γ of filling of the internal space of PG membranes by sulfuric acid solutions with concentrations of 20–40 wt %

r_p, nm	V_p, cm^3	ε, %	γ at indicated c, wt %				
			20	25	30	35	40

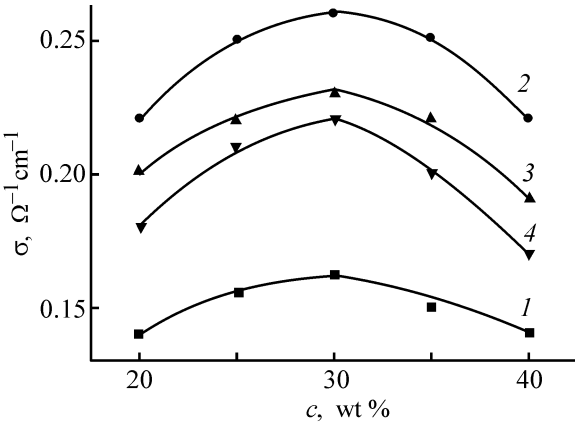

Fig. 1. Electrical conductivity σ of impregnated PGs vs. the concentration c of impregnating sulfuric acid solutions. Pore radius (nm): (*1*) 4.5, (*2*) 9, (*3*) 19, and (*4*) 74; the same for Fig. 3.

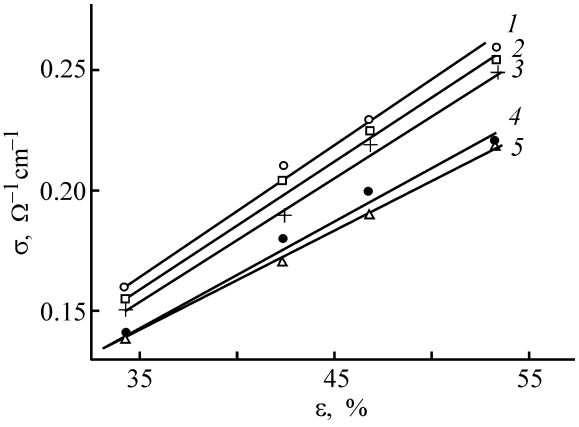

Fig. 2. Electrical conductivity σ of PG saturated with H_2SO_4 solutions vs. the volume porosity ε. H_2SO_4 concentration (wt %): (*1*) 20, (*2*) 25, (*3*) 30, (*4*) 35, and (*5*) 40.

$$Q = m_0 \rho V_p \gamma, \quad (1)$$

where $\gamma < 1$ is a dimensionless coefficient reflecting the deviation from the ideal (limiting) filling.

PGs were most fully and reproducibly impregnated via the capillary rise of the liquid in through pores. In this case, the solution was absorbed through one of the plane-parallel surfaces of a plate, with air allowed to be freely displaced through the other. As a result of impregnation in this mode, the γ defined as the ratio between the experimentally measured mass Q of the solution in PG and its limiting value was close to 0.9 in all cases, and a weak tendency was observed for γ to increase with the radius of membrane channels (see table). To reduce the contact resistance of a plate, PGs impregnated with H_2SO_4 solutions with a concentration of 20–40 wt % were coated with a layer (~1 mm thick) of graphite with an average particle size of 10–20 μm. Then, the samples were placed between planar polished graphite pressure contacts with a constant compression force of 200 g cm^{-2}. The electrical resistance was measured at 293 K in the ac mode (1 kHz) with an E7-11 multimeter. The recorded resistance was recalculated to electrical conductivity σ with account of the real dimensions of the PG plates.

Figure 1 shows how σ of impregnated PG membranes depends on the concentration of the acid introduced into the pores. In all cases, considerable values $\sigma > 0.1$ Ω^{-1} cm^{-1} are reached, with the expected maximum corresponding to an impregnating solution concentration c = 30 wt %. A strongly nonmonotonic dependence of the PG pore radius is observed on the background of pronounced differences between the electrical conductivities of different samples (Fig. 1). At the same time, it can be noted that the highest values of σ, obtained for the membrane with a channel radius of 9 nm, correspond to the maximum porosity ε = 53.3% (see table), which exceeds the volume fraction of the nonconducting silica skeleton. Comparison of the values of σ and ε for the PG membranes studied shows (Fig. 2) that an increase in the internal space filled by the acid provides a nearly linear rise in the electrical conductivity for all concentrations of the solutions used. The specific features revealed in the behavior of the PG–acid systems indicate that the pore radius itself is not an important factor affecting the electrical conductivity of impregnated glasses. Indeed, the role of a compressed electric double layer (EDL) in charge transport is at a minimum at high concentrations of acid solutions in through pores of the membranes. Thus, even at a considerable decrease in the pore radius in the set of the systems studied, the EDL is not overlapped and, as a result, the electrical conductivity is not limited.

Thus, there is reason to believe that the intrinsic electrical conductivity of strong sulfuric acid solutions remains the same in the set of the PG membranes, i.e., it is independent of their porous structure. To verify this assumption, the measured values of σ for PG–H_2SO_4 systems should be recalculated taking into account the following factors: the real free cross-section of the membranes, which provides the electrical conduction, and the degree of filling of the pore space by the electrolyte:

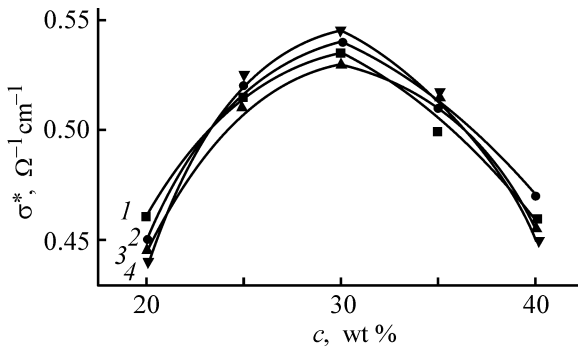

Fig. 3. Electrical conductivity σ^* of sulfuric acid in PG membranes vs. its concentration c.

$$\sigma^* = \sigma\varepsilon\gamma. \quad (2)$$

The closeness of the concentration dependences of σ^* (Fig. 3) confirms, on the whole, the assumption made: the maximum differences between the electrical conductivities of sulfuric acid for the set of membranes do not exceed 0.03 Ω^{-1} cm^{-1}, which is comparable with the measurement error. Here, it should be noted that σ^* is, on the whole, substantially lower than that of free H_2SO_4 solutions. Most likely this occurs because a contact resistance exists in the measuring system used. Nevertheless, the results obtained reliably confirm the high level of the proton electrical conductivity of the systems suggested, compared with the known published values.

CONCLUSION

Porous-glass membranes saturated with sulfuric acid solutions have a high proton electrical conductivity reaching values of 0.2 Ω^{-1} cm^{-1}. At impregnating solution concentrations in the range 20–40 wt %, the electrical conductivity of impregnated membranes is proportional to their volume porosity.

Abstract—Behavior of silver sulfide in the system Ag_2S–$Fe(NO_3)_3$–HNO_3–H_2O was studied at 25, 55, and 80°C using the method of the simplex-lattice experiment design. The quantitative dependences of Ag_2S oxidation on the concentrations of the acid and Fe^{3+} were determined. The isoconcentration diagrams were obtained.

DOI: 10.1134/S1070427208060311

The main amount of silver is extracted from complex ores and concentrates in which silver is in the form of silver sulfide, argentite, one of the most widespread minerals. Argentite is contained in gravitational and flotation concentrates produced in processing of gold- and silver-containing ores and, in particular, lead-zinc ores, and in secondary raw materials.

Hydrometallurgical procedures for recovery of silver, including that in the form of silver sulfide, employ cyanide [1, 2], thiocyanate [3], thiourea [4], and thiosulfate [5] solutions. However, it is necessary to use in such cases oxidizing agents, e.g., O_2 or Fe^{3+}, which involves additional expenditure.

A technology for processing of sulfide lead-zinc ores and concentrates and, in particular, those from the Gorevo deposit with the use of nitric acid and iron(III) nitrate solutions has been developed. The behavior of silver sulfide in systems of this kind has not been studied.

Nitric acid is a strong oxidant ($E^0_{NO_2/HNO_3}$ = 0.80 V) and, therefore, it oxidizes silver sulfide without introduction of any additional oxidizing agent into a system. However, it is of interest to study the effect of Fe^{3+} additives on the process of argentite oxidation. This is due to the composition of technological solutions, because, in most cases, the concentration of Fe^{3+} ions is appreciable when nitrate acid-salt solvents are used for processing of silver-containing ores and concentrates.

EXPERIMENTAL

To obtain information about the oxidation of silver sulfide in complex systems with various mineral forms in industrial processing of silver-containing ores and concentrates, we studied Ag_2S–$Fe(NO_3)_3$–HNO_3–H_2O systems with a high content of silver. The silver sulfide synthesized was identified by X-ray phase analysis. The behavior of Ag_2S in the systems under study was judged from the variation of the total silver concentration in solution and from the composition of insoluble precipitates. The concentration of silver in solution was determined by titration analysis and atomic-absorption spectrophotometry [6, 7], and that of HNO_3, by titration analysis [7]. The mathematical data processing was carried out by the method of simplex-lattice experiment design [8].

The experiments were performed in thermostated cells at 25 ± 0.1, 55 ± 0.1, and 80 ± 0.1°C in the course of 2 h, with mechanical stirring at s : l = 1 : 5. Preliminary experiments demonstrated that making longer the time of contact of phases does not change the silver concentration in solution. After the completion of the experiments, the solution was analyzed for the content of silver and nitric acid. The solid phase was filtered and washed with water and ethanol to remove the solution,

dried, and subjected to an X-ray phase analysis. The data obtained were processed by the method of simplex lattices, whose application to systems of this kind yielded good results in [9, 10]. The simplex-lattice design for an incomplete cubic model employed in the study is presented in the table.

Using the data obtained, we calculated the coefficients of polynomials of incomplete third order, which describe the dependence of the degree of silver sulfide oxidation on the reactant concentrations. The equations were used to construct composition–property diagrams (see Figs. 1a–1c).

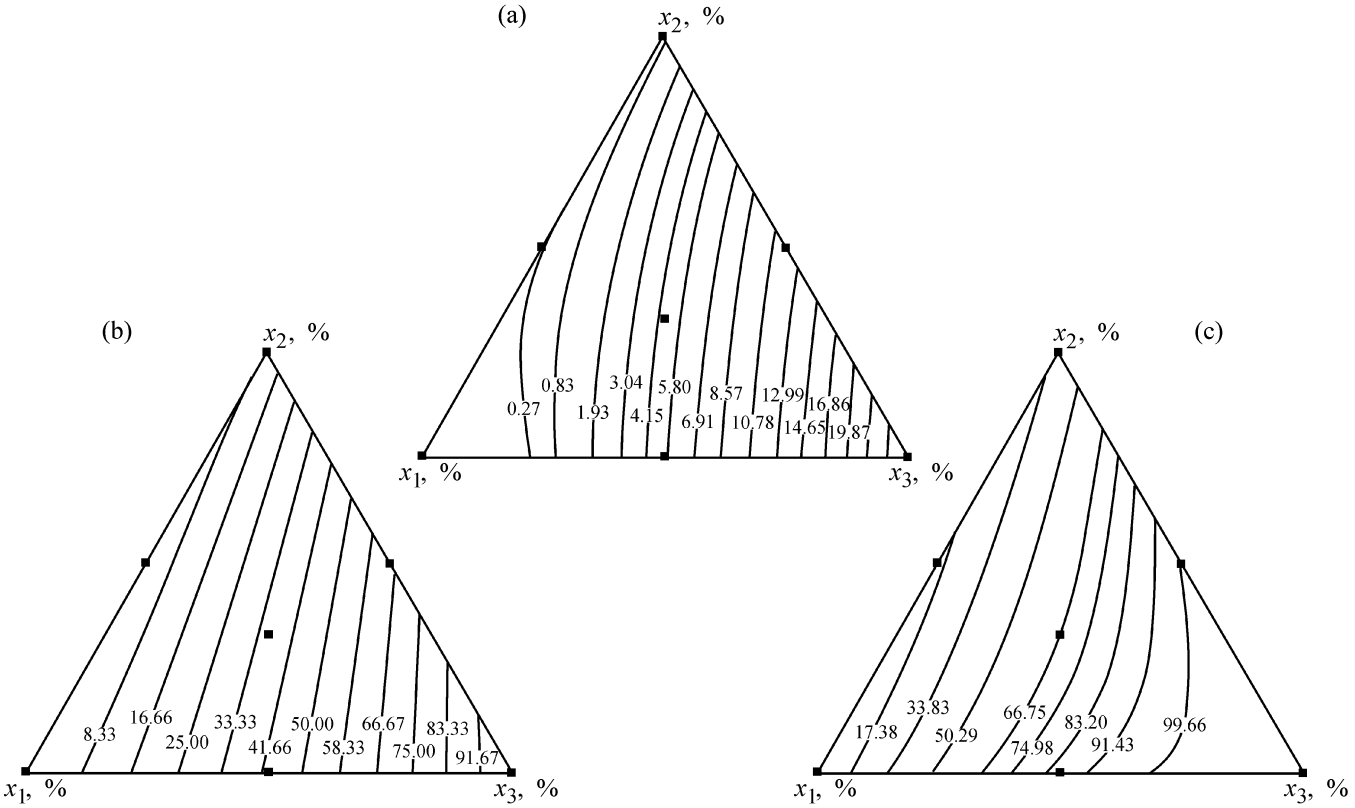

Fig. 1. Diagram of the Ag_2S oxidation (%) in the Ag_2S–$Fe(NO_3)_3$–HNO_3–H_2O system at different temperatures. Temperature (°C): (a) 25, (b) 55, (c) 80.

The oxidation of silver sulfide in the system Ag_2S–$Fe(NO_3)_3$–HNO_3–H_2O can be described by the following reaction equations:

$$Ag_2S + 4HNO_3 \rightarrow 2AgNO_3 + 2NO_2 + S^0 + 2H_2O, \quad (1)$$

$$Ag_2S + Fe(NO_3)_3 + H_2O \rightarrow 2AgNO_3 + Fe(OH)_2 + NO_2 + S^0, \quad (2)$$

$$Ag_2S + Fe(NO_3)_3 + 2HNO_3 \rightarrow 2AgNO_3 + Fe(NO_3)_2 + NO_2 + S^0 + H_2O, \quad (3)$$

$$Ag_2S + 2Fe(NO_3)_3 + 2HNO_3 \rightarrow Ag_2SO_4 + 2Fe(NO_3)_2 + 3NO_2 + NO + H_2O. \quad (4)$$

The experiments we performed demonstrated that the maximum transfer of silver into solution at 25°C (see Fig. 1a) reaches 26.8% at a HNO_3 concentration in solution of 3.0 M. Addition of iron(III) nitrate to the solution hardly affects the oxidation of silver sulfide.

The X-ray data show the presence of a significant amount of unoxidized sulfide. As the content of nitric acid in solution increases, the amount of elementary sulfur in the precipitate grows.

Based on the experimental data, we derived the regression equation relating the degree of Ag_2S oxidation to the concentrations of nitric acid and iron(III) nitrate at a temperature under consideration. A verification against the data of control run nos. 8–10 demonstrated that the equation adequately describes the process with a confidence probability of 97%. The root-mean-square error in the determination of Y values was 3%.

Raising the temperature to 55°C (see Fig. 1b) does not change the general pattern of silver sulfide oxidation in the acid–salt system under study, but only favors an increase in its transfer to solution. The maximal value (~100%) is reached at the point with the highest concentration of nitric acid. The X-ray data show the same trend toward formation of elementary sulfur in precipitates as that at 25°C. This suggests that reaction (3) predominates as the nitric acid concentration increases to 3.2 M.

For this temperature, we also derived a regression equation. To verify its adequacy, a series of control experiments were carried out. The root-mean-square deviation was 3% at a confidence probability of 97%.

At 80°C, the same behavior as that at 25 and 55°C is observed (see Fig. 1c). Only the quantitative characteristics of the process change: the whole amount of silver passes into solution even at an HNO_3 concentration of about 2.3 M.

The regression equation describing the behavior of silver sulfide in the system under consideration at 80°C was obtained. The results of control experiments show that this equation adequately describes the process with a confidence probability of 97%. The root-mean-square error in the determination of Y values was 3%.

It is necessary to note that temperature affects the possibility of occurrence of reactions (1)–(4). Reactions (1), (3), and (4) proceed in the whole temperature range under study, whereas reaction (2), only upon heating. For example, reaction (2) does not proceed at 25°C even at a Fe^{3+} concentration of 1.8 M; at 55°C, changes occur in solution beginning at a Fe^{3+} concentration of 0.744 M; and at 80°C, reaction (2) proceeds at even lower Fe^{3+} concentrations.

It was found that, in a mixture of silver and lead sulfides, produced by their coprecipitation from nitrate solutions with hydrogen sulfide, and also in mechanical mixtures of silver sulfide with elementary sulfur and lead sulfide, Ag_2S is oxidized in the same way as pure silver sulfide. An increase in HNO_3 and $Fe(NO_3)_3$ concentrations results in that the degree of silver recovery into solution becomes higher. Temperature strongly affects the process. For example, the fraction of oxidized silver sulfide was 20–30% at 25°C and 100% at 80°C. The nature of the starting solid mixtures has no effect on the degree of silver sulfide oxidation.

CONCLUSIONS

(1) A study of the effect of the concentration of nitric acid and iron(III) nitrate on the oxidation of silver sulfide in the systems Ag_2S–$Fe(NO_3)_3$–HNO_3–H_2O at various temperatures revealed that nitric acid strongly affects the oxidation of Ag_2S, which reaches the maximal value (100 %) at an HNO_3 concentration of 3.2 M.

(2) The chemical mechanism of the oxidation of Ag_2S in nitrate media to give elementary sulfur at 25 and 55°C and sulfate sulfur at 80°C was elucidated.

(3) Diagrams describing the dependence of the degree of silver sulfide oxidation on the HNO_3

and $Fe(NO_3)_3$ concentrations were constructed on the basis of the experimental data.

Abstract—The hydrolysis of acetylsalicylic acid in the anolyte under the conditions of electrolysis was studied.

DOI: 10.1134/S1070427208060323

Acetylsalicylic acid (ASA, Aspirin®) is one of the most popular drugs which, together with other drugs, gets into wastewater, and hampers operation of biological sewage treatment plants [1, 2]. It is known that the biological activity of ASA-containing aqueous solutions can be decreased by more than an order of magnitude by their electrooxidation [3]. However, it remains unknown whether ASA itself or its hydrolysis product, salicylic acid (SA), undergoes electrooxidation. To answer this question, we compared in this study the ASA anodic oxidation kinetics, on the one hand, and the ASA hydrolysis kinetics under electrolysis and without it, on the other hand.

EXPERIMENTAL

The ASA hydrolysis was studied in 0.1 N aqueous H_2SO_4 at room temperature. The ASA and SA anodic oxidation was carried out at 25°C in a two-electrode electrochemical cell with a membrane separating the anode and cathode chambers. A smooth platinum plate was used as anode. The current density was 10 mA cm^{-2}. The anolyte was analyzed by high-performance liquid chromatography (HPLC) and UV spectroscopy.

We found that, on keeping ASA in aqueous H_2SO_4 without electrolysis, the absorption band in its UV spectrum at 227 nm is shifted to 235 nm. This means that, under these conditions, ASA is hydrolyzed to form SA. This conclusion is consistent with Fig. 1 showing that, as the SA/ASA ratio in their mixtures increases, the absorption band at 227 cm^{-1} linearly shift to longer wavelengths. From this correlation, we determined the SA content of the ASA–SA mixtures in the course of ASA hydrolysis. We found that the ASA hydrolysis is relatively slow and a 90% degree of hydrolysis is reached only in 16 days (Fig. 2). The time dependence of the SA content of the reaction mixture

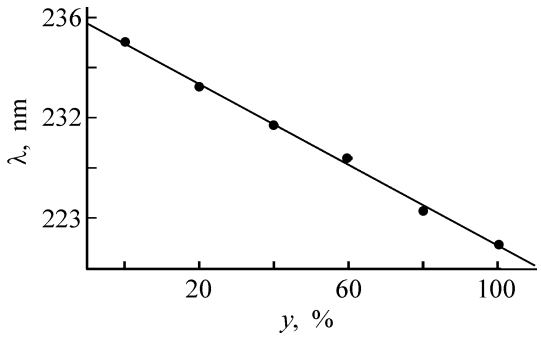

Fig. 1. Position of the maximum of the absorption band in the UV spectrum of ASA–SA solutions in 0.1 N H_2SO_4 vs. ASA content y

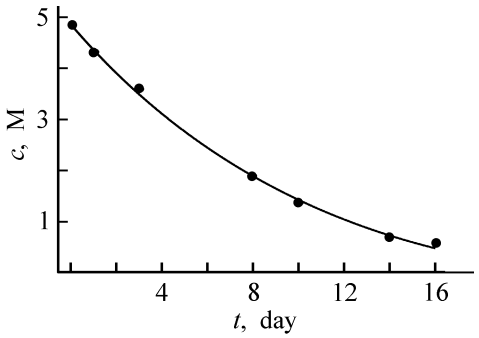

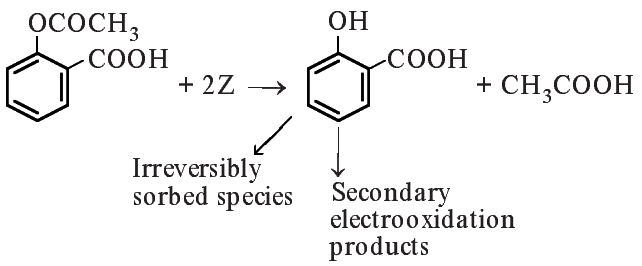

Fig. 2. Dependence of the ASA concentration c on hydrolysis time t in aqueous H_2SO_4.

showed that the ASA hydrolysis kinetics is described by a first-order rate equation with a rate constant of 0.0059 h^{-1}.

A chromatographic analysis of ASA solution subjected to electrolysis showed that the overall process of the ASA electrochemical conversion involves two successive stages. First, ASA is hydrolyzed to form SA and then, after accumulation of salicylic acid, the products of SA anodic oxidation appear in the anolyte. We found that, under the conditions of electrolysis, the rate of ASA hydrolysis is several times that under electroless conditions. Owing to the high rate of ASA hydrolysis under the conditions of electrolysis, the total ASA oxidation rate is comparable with that of the SA oxidation.

Figure 3 shows the dependence of the SA and ASA concentrations in the anolyte (M) on the electrolysis time. It is seen that the electrochemical conversion of ASA appreciably decelerates with time. It is believed [4] that this effect is caused by the fact that the SA formed by the ASA hydrolysis is irreversibly sorbed on the platinum surface and, as a result, the platinum surface becomes less accessible to ASA adsorption and its subsequent hydrolysis. Assuming that ASA hydrolysis occurs on two neighboring surface platinum atoms of the electrode, we can suggest that the ASA hydrolysis rate is proportional to the product of the ASA concentration in solution by the $(1 - \theta)^2$ factor, where θ is the fraction of platinum surface covered by irreversibly sorbed SA molecules. If the rate of the irreversible sorption of SA is proportional both to its concentration in the anolyte and to the free anode surface area $1 - \theta$, we can formulate a system of equations describing the ASA hydrolysis kinetics under the conditions of electrolysis. These equations take into account that, on the one hand, SA partially inactivates the platinum surface via its irreversible sorption, and, on the other hand, it is itself subject to anodic oxidation. The overall process of the electrochemical conversion of ASA on Pt anode can be represented by the following scheme (Z is an active center):

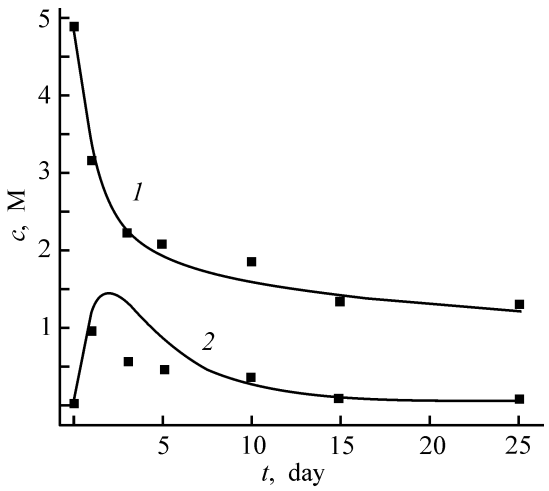

Fig. 3. Dependence of (*1*) ASA and (*2*) SA concentrations c in the anolyte (0.1 M H_2SO_4) on the electrolysis time t.

The kinetics of the processes in this scheme are described by the following equations:

$$dc_1/dt = -k_1 c_1 (1 - \theta)^2,$$

$$d\theta/dt = k_2 c_2 (1 - \theta),$$

$$dc_2/dt = k_1 c_1 (1 - \theta)^2 - k_3 c_2,$$

where c_1 and c_2 are, respectively, the ASA and SA concentrations in a time t after starting the electrolysis and k_1, k_2, and k_3 are, respectively, the rate constants of SAA hydrolysis, accumulation of irreversibly sorbed SA species, and SA oxidation.

The quantity k_3 was taken to be 0.37 h^{-1} as reported in [5]; k_1 and k_2 (0.4 and 0.17 h^{-1}, respectively) were determined from our experimental data by least-squares fitting. Figure 3 shows that the ASA hydrolysis kinetics is fairly well described by the system of the above rate equations.

Our experiments showed that the rate constant of ASA hydrolysis under the conditions of electrolysis exceeds that in the absence of current by a factor of 42. Taking into account that hydrogen peroxide promotes the ASA hydrolysis [6], we can suggest that the acceleration of ASA hydrolysis under the conditions of electrolysis is caused by adsorbed oxygen species containing O–O bonds.

In the course of ASA hydrolysis under the conditions of electrolysis, the electric current is consumed only for generation of catalytically active

oxygen adsorbed on the platinum surface. Therefore, we can suggest that, at a lower current density, the SA oxidation rate will decrease and ASA hydrolysis will become the main process. This assumption was completely confirmed by our experiments. We found that, with the current density decreasing to 0.5 mA cm^{-2}, the SA oxidation is virtually suppressed and the ASA hydrolysis becomes essentially the only process.

CONCLUSIONS

(1) Acetylsalicylic acid is not subjected to direct anodic oxidation on platinum electrode.

(2) The hydrolysis rate of acetylsalicylic acid under the conditoins of electrolysis in acidic solutions in the range of oxygen evolution potentials exceeds that in the absence of current by an order of magnitude. This phenomenon can be used to accelerate the hydrolysis of acetylsalicylic acid and other esters.

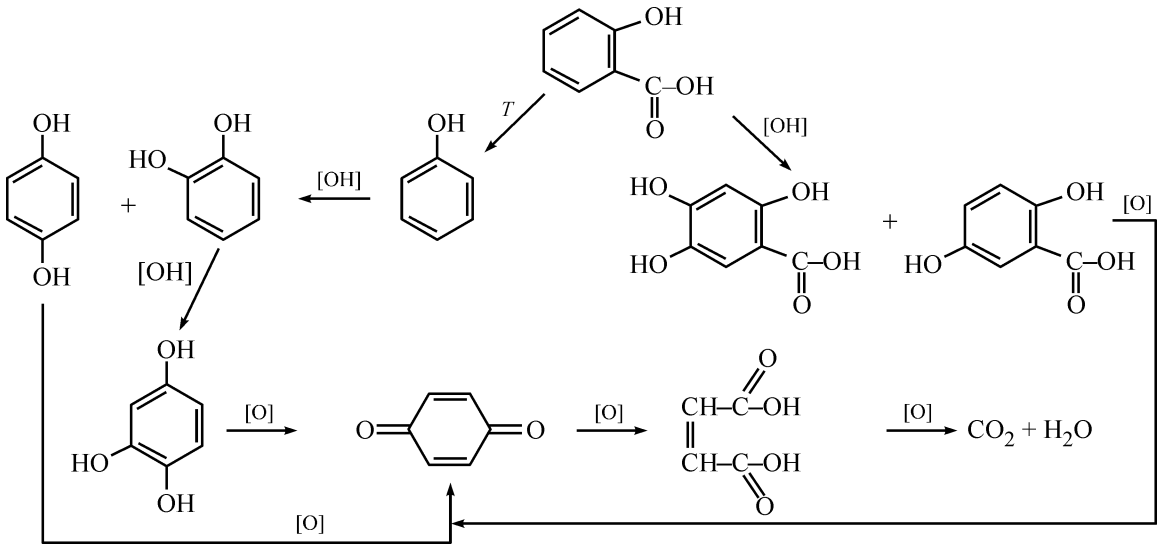
Abstract—Degradation of salicylic acids under the action of oxidants generated by electrolysis of sulfuric acid was studied. In the course of oxidation, salicylic acids decompose to simpler and nontoxic substances.



DOI: 10.1134/S1070427208060335

THe production of drugs has led to the accumulation of rejected or expired batches of pharmaceuticals, which should be eliminated for environment protection [1]. It is known [2] that pharmaceuticals are difficultly biodegradable. Therefore, the most promising ways of rendering pharmaceutical wastes harmless are thermal neutralization [3], plasma treatment [4], and liquid-phase oxidation [5]. High temperatures and the need for off-gas treatment complicate and make expensive the thermal procedure for detoxication of organic substances. Large power consumption and complexity of problems associated with plasmochemical technology restrict its applications. The main drawback of liquid-phase oxidation is the incomplete oxidation of certain substances and the high cost of the equipment.

Recently the interest in indirect oxidation of organic substances has increased. In this context, our goal was to study degradation of salicylic (SA) and sulfosalicylic (SSA) acids in the liquid phase under the action of electrolytically generated oxidants [6]. Electrolysis was performed on a laboratory installation consisting of a reactor equipped with lead electrodes, a jacket, a stirrer, a dc source, and a thermostat. Spectrophotometric measurements were performed on SF-26 and KFK-2 devices. The chemical oxygen demand (COD) was monitored throughout the process with an Ekotest-120 ion meter.

It has been found previously [7] that the current efficiency by oxidants on lead electrodes in electrolysis of aqueous solutions of sulfuric acid is the highest at 40 wt % concentration, 20–50°C, and anodic current density of 0.6–0.85 A cm^{-2}. Therefore, further experiments were performed under these conditions.

Degradation of hydroxybenzoic acids can occur both in the reaction volume and partially by an electrochemical mechanism. The composition of SA and SSA degradation products is virtually independent of the oxidation conditions. For example, deep oxidation of SA and its derivatives induced in the presence of a catalyst by ascorbic acid [8], leads, like anodic oxidation [9], to the formation of such intermediates as α- and β-resorcylic acids, gallic acid, pyrocatechol, and hydroquinone. This is followed by the formation of benzoquinone. The subsequent cleavage of the aromatic ring yields succinic, maleic, oxalic, and other acids. The common steps of the decomposition of SA and SSA are hydroxylation of the aromatic core and decarboxylation. THe hydroxylation or oxidation of side chains occurs in the *o*- and *p*-positions relative to the carboxy group with the formation of isomeric dihydroxybenzoic acids. The decarboxylation of salicylic acids occurs on their heating and yields phenols. This is followed by the formation of diketones and their subsequent oxidation via di- and monocarboxylic acids to carbon dioxide and water. Thus, the possible scheme of destructive oxidation of salicylic acids is as follows:

Scheme of oxidation of salicylic acid.

Apparently, the degradation of SA and SSA in electrochemically activated sulfuric acid solution occurs similarly. The multistep nature of these processes is confirmed by color variation in the course of oxidation of sulfuric acid solutions of hydroxybenzoic acids: colorless → yellow → orange → brown → colorless, i.e., the reaction occurs via a series of intermediates. A new absorption peak appearing at ~380 nm (Fig. 1) suggests the formation of a stable intermediate, *p*-benzoquinone [10]. The content of *p*-benzoquinone increases in the first 90 min of the reaction and, after reaching a maximum, starts to decrease as a result of further oxidation to carboxylic acids.

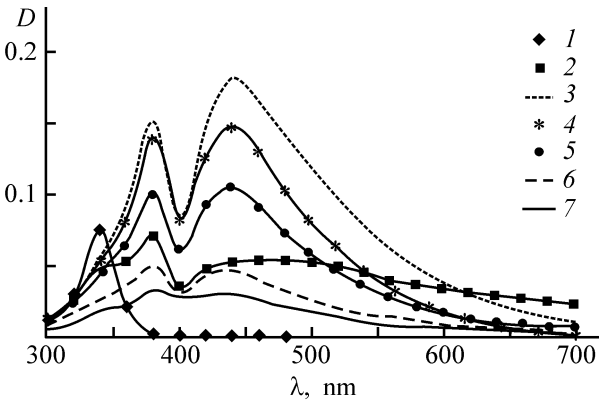


Fig. 1. Absorption spectra of a solution of sulfuric and salicylic acids, recorded after electrolysis for different times. (*D*) Optical density and (λ) wavelength; the same for Fig. 2. Electrolysis time, min: (*1*) 0, (*2*) 10, (*3*) 90, (*4*) 150, (*5*) 210, (*6*) 270, and (*7*) 330.

Salicylic acids in sulfuric acid solutions have pronounced absorption peaks at 210 and 235 nm. Therefore, variation of the optical density at these wavelengths also characterizes the oxidation of SA and SSA (Fig. 2).

In the course of electrolysis, the intensity of UV absorption of salicylic acid solutions decreases, suggesting a breakdown of the aromatic ring as a conjugated system with the formation of acetic and oxalic acids. Qualitative color reactions with Fe^{3+} showed that the initial salicylic acid fully decomposes within the first 15–20 min to give 4-hydroxysalicylic, trihydroxybenzoic, and 2,5-dihydroxybenzoic acids. The results of COD determination show that exhaustive oxidation of SSA and its degradation products at 50°C and a current density of 0.6 A cm^{-2} occurs within 80 min:

Oxidation time, min	COD_{SSA}, mg dm^{-3}
0	3500
20	2600
40	1400
60	500
80	30

Because the sulfuric acid solution after the oxidation contains no organic compounds (judging from COD) and the exit gas contains CO_2, it can be naturally assumed that the acids are oxidized to CO_2 and H_2O.

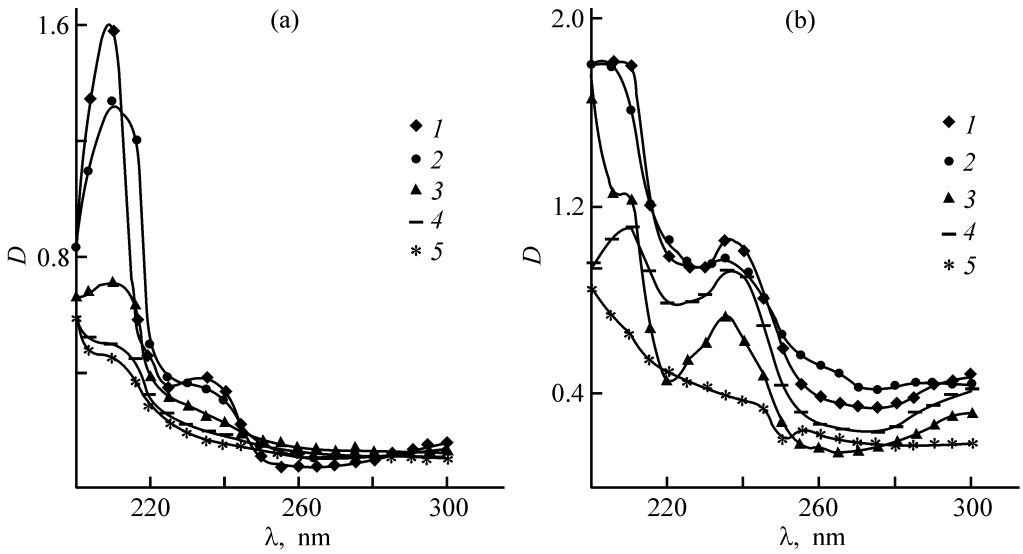

Fig. 2. Absorption spectra of sulfuric acid solutions containing (a) sulfosalicylic and (b) salicylic acids, recorded after electrolysis for different times. Electrolysis time, min: (a) (*1*) 0, (*2*) 15, (*3*) 30, (*4*) 45, and (*5*) 60; (b) (*1*) 0, (*2*) 20, (*3*) 40, (*4*) 60, and (*5*) 80.

CONCLUSIONS

(1) Indirect electrochemical oxidation is a fairly efficient method for decomposing such biologically active substances as salicylic and sulfosalicylic acids.

(2) The process yields no secondary pollutants.

Sedimentation of Carbon-Clay Dispersions with Polyacrylamide Modified with Tetraethylene Glycol

G. A. Mandrov and E. L. Schastlivtsev

Institute of Coal and Coal Fuel Chemistry, Siberian Division, Russian Academy of Sciences, Kemerovo, Russia

Received April 24, 2007

Abstract—Sedimentation of carbon-clay dispersions with polyacrylamide modified with tetraethylene glycol was studied. The concept of the formation of a binary structure of the modified polymer in a structured ternary system was formulated.

DOI: 10.1134/S1070427208060347

Improvement of the flocculation activity of domestic flocculants is still a topical problem for clarification of recycled water at coal-cleaning plants. As shown previously [1], modification of polyacrylamide (PAA) with α-propylene chlorohydrin (polymer concentration 0.4 mg dm^{-3}) raises the rate of sedimentation of carbon-clay dispersions (mean particle size 2.25 μm) by approximately a factor of 1.7.

In this study, we examined the possibility of enhancing the flocculation activity of domestic PAA.

EXPERIMENTAL

Taking into account that the flocculation activity of a PAA increases with its molecular weight, it was of particular interest to study the flocculation activity of PAA as influenced by the monomer chain length in the course of its modification with tetraethylene glycol (TEG). For dilute solutions, it was important to estimate changes in the specific viscosity on passing from the straight polymer solution to the binary system:

$$\eta_{sp} = (\eta - \eta_0)/\eta_0,$$

where η and η_0 are the viscosities of the polymer solution and solvent, respectively.

First, the viscosities of the polymer solutions were determined from their outflow time using a capillary viscometer, and then their intrinsic viscosities [η] were graphically determined and used to calculate the viscosity-average molecular weight of the polymer from the Mark–Kuhn–Houwink equation:

$$[\eta] = KM^a,$$

where K and a are constants for a given polymer–solvent system.

For the PAA–water system, $K = 0.63 \times 10^{-4}$ and $a = 0.8$ [2]. Using known K and a, [η] was determined from the intercept on the ordinate axis (Fig. 1).

As the parameters characterizing the size and shape of macromolecules, we estimated the mean distance between the ends of the polymer molecular chain h and the polymer flexibility Γ, i.e., the h/M ratio. The quantity h characterizes the reactivity of macromolecules in the course of flocculation. The mean statistical distance between the ends of

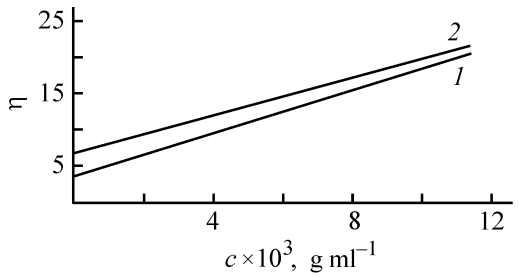

Fig. 1. Relative viscosity of flocculant solutions η vs. their concentration c. (*1*) PAA and (*2*) PAA + TEG; the same for Fig. 2. (η) Relative viscosity, $\eta = \eta_{sp}/c$.

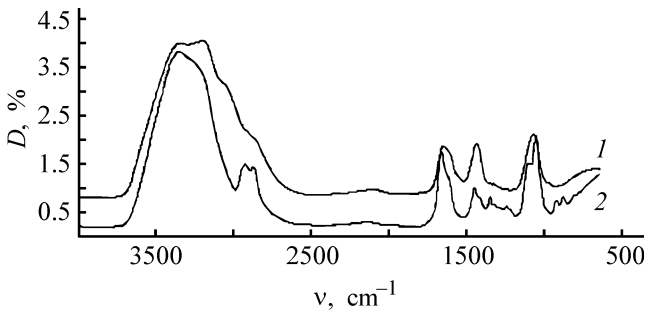
the polymer chain, h (cm), was determined from the Flory equation:

$$[\eta] = \Phi\beta h^3/M,$$

where Φ is the Flory constant and β is the swelling coefficient equal to the ratio of [η] in the given solvent to [η] in the ideal solvent; for the majority of polymers $\Phi\beta = 2.1 \times 10^{21}$ [3]. The results of our calculations are listed in the table.

The observed difference in the molecular weights of polymers allows evaluation of their relative flocculation activity toward carbon-clay suspensions prepared from the mixture of K, KO, and KS coking coals obtained at the hydrosizer outlet. The performance of PAA modified with TEG was evaluated by analyzing the size distribution of the solid phase particles in a thickener. This distribution in the clarified recycled water was characterized by the geometric-mean diameter of 1.3 μm and weight-average geometric diameter of 4.2 μm, with standard geometric mean deviation of 1.8. The concentration of the carbon-water suspension supplied to the thickener was 5 g dm^{-3}. In the case of the PAA–TEG binary system, the concentration of the solid phase in the clarified water at the thickener outlet decreased to 0.7 g dm^{-3}. The flocculation activity of PAA at a polymer concentration of 0.4 mg dm^{-3} was lower than that of the PAA + TEG system by a factor 3. The balance of the solid phase distribution in the thickener showed that the flocculation primarily involved coarse particles of the dispersed phase, whereas fine particles, poorly captured by the PAA–TEG binary flocculant in the flow mode, remained in the clarified water.

To reveal the nature of intermolecular interactions in formation of the PAA–TEG binary structure in the ternary system (PAA + TEG + H_2O), we recorded the IR spectra of the initial and modified PAA, using a TENSOR-27 unit (Bruker). As can be seen from Fig. 2, all the spectra have a strong absorption band at 3420 cm^{-1}, which is commonly assigned to the absorption of water molecules and stretching vibrations of hydroxy groups.



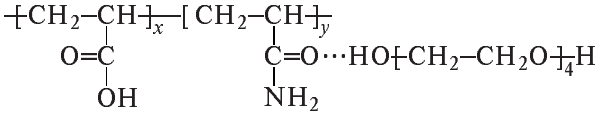


Fig. 2. IR spectra of flocculant hydrogels. (D) Optical density and (ν) wavenumber.

We also observe the absorption of the carbonyl group C=O in primary amide [4] at 1640–1650 cm^{-1}. The modified PAA has new absorption bands at 800–1350 cm^{-1}. In accordance with [5], the absorption bands in this range are typical of polyethylenimines and polyglycols and are absent in the spectrum of the initial PAA. Two bands at 800–1000 cm^{-1} belong to the C–C stretching vibrations, and the C–N and C–O stretching bands are observed at 1050–1390 and 1250 cm^{-1}, respectively.

The appearance in the PAA–TEG binary structure of absorption bands typical of polyglycols gives insight into the nature of intermolecular interactions upon the formation of the binary system in the aqueous medium. Some molecules in the structured ternary system attain the optimal energy states and occupy certain spatial positions favorable for hydrogen bonding. One of such processes is the formation of a hydrogen bond between the TEG hydroxy group and carbonyl oxygen of partially hydrolyzed PAA, which favors preservation of the open conformation of PAA, which on the whole makes higher the viscosity of the binary flocculant, its viscosityaverage molecular weight, and flocculation activity. One of the ways of hydrogen bonding between partially hydrolyzed PAA and TEG is as follows:

Polymer properties

Polymer	[η], g dl^{-1}	M	h, cm	$\Gamma = hM$
PAA	3.3	~8×10^5	1.08×10^{-5}	0.135×10^{-10}
PAA + TEG	7.0	~20×10^5	1.88×10^{-5}	0.094×10^{-10}

CONCLUSION

Modification of polyacrylamide and tetraethylene glycol makes higher the viscosity of the binary flocculant, its viscosity-average molecular weight, and the flocculation activity and can be used for clarifying the recycled water in concentration of coal slack with a hydrosizer.

Synthesis of Cellulose Esters with Aliphatic Hydroxy Acids from Aspen Wood

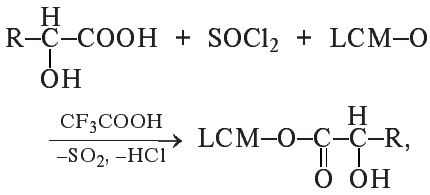
N. V. Knyazeva, V. V. Kon'shin, N. A. Chemeris, and M. M. Chemeris

Polzunov Altai State Technical University, Barnaul, Russia

Received December 27, 2007

Abstract—Synthesis of cellulose esters with aliphatic hydroxy acids from aspen wood was studied in relation to the reaction and isolation conditions.

DOI: 10.1134/S1070427208060359



Polymers prepared from aliphatic hydroxy acids are promising materials combining various properties of plastics (thermoplasticity, capability to imitate various polymers after appropriate plasticization, etc.). At the same time, an important practical property of such polymers is the capability to degrade under definite conditions to environmentally harmless products: CO_2 and H_2O [1]. The starting materials for preparing such polymers are cellulose esters with aliphatic hydroxy acids.

In a known procedure [2], cellulose esters with aromatic carboxylic hydroxy acids are prepared by treatment of cellulose with an acylating mixture containing trifluoroacetic anhydride and aromatic hydroxy acids as acylating agents [2]. The reaction is performed with addition of dichloromethane and methanol. However, the process is multistep and involves expensive solvents.

The previously developed [3, 4] procedure for preparing cellulose esters expands the possibilities of the synthesis of practically important cellulose-based polymers containing bound carboxylic acids. In the process, it is possible to use prehydrolyzed aspen wood instead of pure cellulose.

EXPERIMENTAL

The reaction of prehydrolyzed aspen wood (lignocellulose material, LCM) containing 64.8% cellulose (Kürschner's method) and 35.2% lignin (Komarov's method [5]) with carboxylic hydroxy acids of the general formula RCHOHCOOH (R = H, CH_3) in trifluoroacetic acid (TFAA) was performed in the presence of thionyl chloride (TC), following the procedure described in [6]:

where R = H or CH_3.

After the reaction completion, the product was precipitated into a polar solvent (water, acetone, ethanol, isopropanol), washed, and dried to the air-dry state. The lignin content was determined using concentrated mineral acids [5], and the amount of bound carboxylic hydroxy acids, by potentiometric titration [6]. Qualitative tests of the products for halogens gave negative results.

One of the most important aspects of the synthesis of cellulose esters from chemically modified wood is the choice of a precipitant that would provide the optimal yield of the target product with a fairly high content of bound carboxylic acid and a low lignin content. The experiments showed that isopropyl alcohol is a suitable precipitant for isolating the cellulose ester (Table 1). Isopropyl alcohol ensures the maximal yield of cellulose hydroxyacetate with a high content of bound glycolic acid and relatively small amount of lignin. With water, ethanol, or acetone as precipitant, the product yield is considerably lower. The highest lignin content was observed with water used as precipitant.

Table 1. Characteristics of cellulose esters isolated using various precipitants (synthesis temperature 40°C, time 6 h)

Cellulose ester	Polar solvent	Yield of cellulose ester,* %	Content of bound carboxylic hydroxy acid, %	Degree of substitution with carboxylic hydroxy acid	Content of lignin in cellulose ester, %
Cellulose hydroxyacetate	Isopropyl alcohol	95	27.2	0.73	9.9
	Water	75	27.8	0.75	15.7
	Ethanol	77	27.9	0.76	7.2
	Acetone	84	28.3	0.77	6.5
Cellulose α-hydroxypropionate	Isopropyl alcohol	86	33.8	0.83	7.2
	Water	93	22.4	0.49	8.7
	Ethanol	70	23.3	0.52	8.6
	Acetone	76	35.2	0.88	8.8

* Based on the initial weighed portion of wood.

Table 2. Influence of synthesis conditions on the properties of the isolated cellulose hydroxyacetate

Conditions of LCM acylation		Characteristics of cellulose hydroxyacetate		
T, °C	τ, h	yield, %	degree of substitution with glycolic acid, %	lignin content, %
30	3	85	0.63	–
40	3	97	0.79	9.8
50	3	90	0.52	11.2
40	2	92	0.72	9.9
40	4	90	0.75	–

Table 3. Influence of synthesis conditions on the properties of the isolated cellulose α-hydroxypropionate

Conditions of LCM acylation		Characteristics of cellulose α-hydroxypropionate		
T, °C	τ, h	yield, %	degree of substitution with lactic acid, %	lignin content, %
20	3	83	1.24	–
30	3	85	1.32	7.1
40	3	75	0.32	10.6
30	2	76	1.30	7.5
30	4	75	1.30	–

In the synthesis of cellulose lactate (α-hydroxypropionate), isopropyl alcohol also appeared to be a good precipitant. It ensured the highest yield of the target product with a high content of bound lactic acid.

The other factors affecting the properties and characteristics of the cellulose esters obtained are the conditions of LCM acylation. Table 2 shows how the temperature and time of LCM acylation with a glycolic acid–TC–TFAA mixture affect the characteristics of the isolated cellulose hydroxyacetates.

The reaction temperature of 40°C and time of 3 h are optimal for preparing cellulose hydroxyacetate. At higher temperatures and shorter reaction times, the yield of cellulose hydroxyacetate decreases and the lignin content increases.

The characteristics of cellulose α-hydroxypropionates prepared by acylation of LCM with a lactic acid–TC–TFAA mixture are listed in Table 3.

The highest yield of cellulose α-hydroxypropionate containing the maximal amount of bound lactic acid is provided at the reaction temperature of 30°C and time of 3 h. Deviations from these conditions lead to an increase in the residual lignin content.

CONCLUSIONS

(1) Cellulose esters were prepared by treatment of prehydrolyzed aspen wood with the acylating mixture RCHOHCOOH (R = H or CH_3)–thionyl chloride–trifluoroacetic acid.

(2) The most appropriate precipitant providing the highest yield of the desired product, a high content of bound hydroxy acid, and a low lignin content is isopropyl alcohol.

Received September 4, 2007

Abstract—Carbon modifications (anode matrices) were produced from renewable vegetable raw materials, agricultural crop waste, by pyrolysis in a quartz reactor without access of oxygen at 900°C, as well as by mechanical synthesis, and their characteristics were examined.

DOI: 10.1134/S1070427208060360

Hydrocarbon raw materials, including oil, natural gases, coals, lignites, peat, oil shales, and natural graphite [1], are conventionally used for production of anode matrices. However, natural stocks of hydrocarbon raw materials are known to be depleted worldwide, which inevitably raises their cost. In addition, many countries suffer from shortage of hydrocarbon resources or from inefficient techniques of their extraction and processing. This stimulates researchers in a number of countries and, in particular, in China and Japan, to attempt the use of vegetable (renewable) alternatives to hydrocarbon raw materials [2–4].

We prepared here carbon materials promising for production of anodes for chemical cyclable power sources from vegetable (renewable) raw materials, agricultural waste, and examined them.

EXPERIMENTAL

As initial raw materials we used wheat, oats, and buckwheat waste, as well as rice grains, sunflower seeds, corn grains, coffee beans, tea leaves, and beet sugar.[1] The dried raw material (moisture content 1.25%) was freed from impurities with a separation sieve and ground to powder on a mechanical mill. To accelerate the heating and make it more uniform [5, 6], the purified powder was placed in a special desiccator and dried at 49°C for 43 min, which yielded a material with a 0.21–0.23% moisture content. The dried and milled raw material samples were placed successively into a quartz reactor and pyrolyzed at 900°C without access of oxygen [5]. The termination of pyrolysis was ascertained from the gas evolution cessation. The pyrolysis time of 35–72 min was chosen experimentally, depending on the weight of the initial raw material loaded into the reactor. Upon termination of the pyrolysis, the reactor was left to cool together with the furnace to 25°C, whereupon the pyrolysis products were taken out of the reactor.

The resulting carbon modifications were subjected to mechanical synthesis on an energy-intensive vibration mill[2] to prepare finely dispersed carbon particles [7]. The grinding bodies in the vibration mill were ShKh15 steel spheres 15 mm in diameter. The mechanical reactor was a hermetically sealed container with an inner diameter of 50 mm and height of 125 mm. The experimental conditions were as follows: reactor vibration frequency 12 Hz; air atmosphere; intensity (weight ratio of the initial materials and grinding spheres) 1 : 20; degree of filling of the reactor with the steel spheres 30% of its volume; and synthesis time 12 min.

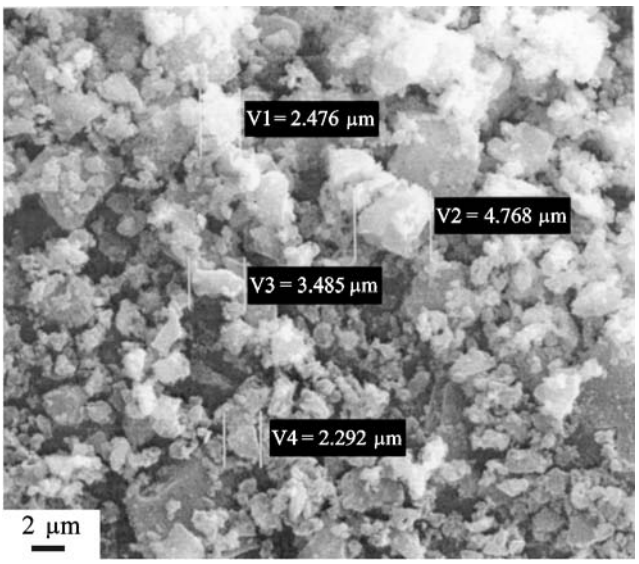
[1] The experiments on production of anode matrices from renewable raw materials were carried out at the Laboratory of Fluorinated Materials, Institute of Chemistry, Far-Eastern Branch, Russian Academy of Sciences, and at the Laboratory of Synthesis of Inorganic Substances, Kuibyshev Far-Eastern State University.

[2] The energy-intensive vibration mill was designed at the Kuibyshev Far-Eastern State Technical University.

Thus, experimental carbon modifications (anode matrices) were obtained from renewable plant raw material by pyrolysis in a quartz reactor without access of oxygen at 900°C, as well as by mechanical synthesis. A scanning electron microscopic examination showed that the particle shape and size and the texture of the material depend on the nature of the plant raw material. The resulting carbon powders are mainly polydisperse; also, irregularly shaped particles and agglomerates were formed due, most likely, to the specific conditions of preparation (pyrolysis) and mechanical activation of the carbon powders. We found that the carbon particles obtained from beet sugar (see figure) are shaped as grain fragments 0.3–11 μm in size, with most of particles (about 70%) having a size of 1–3.5 μm. The 20000 × magnification reveals globular particles 12 μm in size.

According to the results of an X-ray phase analysis, the carbon modifications prepared at 900°C from wheat, oats, and buck-wheat waste, as well as from corn and rice grains, sunflower seeds, and beet sugar have an X-ray-amorphous structure with iron inclusions. The carbon modifications obtained from coffee beans and tea leaves also have an X-ray-amorphous structure with inclusions of various phases. For example, the modifications obtained from coffee beans contain Fe_2O_3, Fe_3O_4, MgO, and CaS phases, and those prepared from tea waste, $CaCO_3$ and iron impurities. The X-ray-amorphous structure is associated with the specific temperature mode of preparation of the carbon modifications. The occurrence of the Fe_2O_3, Fe_3O_4, MgO, CaS, and $CaCO_3$ phases in the carbon modifications is most likely due to specific features of organic and mineral compositions of these vegetable raw materials.

The measured bulk and physical densities of the carbon modifications synthesized (see table) are close to those of commercial anode materials: The bulk densities are within 0.90–1.10 g cm^{-3}, and physical densities, within 2.02–2.14 g cm^{-3}, depending on the type of the vegetable raw material.



The ash content of the carbon modifications (see table) is within 0.45–0.77%. Hence, the resulting carbon materials are characterized by a high carbon yield, which is an important characteristic of anode matrices.

The specific surface area of the carbon modification obtained from beet sugar (heating to 200°C, 30 min) by pyrolysis in a quartz reactor without access of oxygen at 900°C is as follows, $m^2\ g^{-1}$: one-point BET method 217.238 and Gregg–Sing comparative method 243.133; the specific pore volume for the ultimate degree of filling is 0.103 $cm^3\ g^{-1}$, the micropore volume is 0.017×10^{-9} nm^3, and the average pore size is 1.904×10^{-9} m.

Ash content and bulk and physical density of the carbon modifications obtained from plant (renewable) raw materials by pyrolysis in a quartz reactor without access of oxygen at 900°C

Raw material	Density, g cm^{-3}		Ash content, %
	bulk	physical	
Wheat waste	0.93	2.05	0.45
Oats waste	0.90	1.99	0.41
Corn grains	1.8	2.11	0.55
Buckwheat waste	1.04	2.05	0.67
Sunflower waste	1.10	2.14	0.77
Coffee beans	1.02	2.03	0.53
Beet sugar	1.05	2.12	0.39
Tea leaves	0.97	2.02	0.48
Rice grains	1.01	2.07	0.59

Examination of the specific surface area of the powder and of the structure of the particle surface shows that the resulting carbon powders have a developed surface and are suitable as anode materials for lithium-ion (polymer) batteries.

Shape and size of particles of carbon obtained from beet sugar at 900°C by pyrolysis in a quartz reactor without oxygen access (SEM image; bar: 2 μm).

CONCLUSIONS

(1) Carbon modifications were obtained from renewable vegetable raw materials (agricultural waste, coffee beans, tea leaves) by pyrolysis in a quartz reactor at 900°C.

(2) The resulting carbon materials are finely dispersed powders with a highly developed surface.

(3) The maximal ash content (0.67%) is exhibited by the carbon samples obtained from buckwheat waste, and the minimal (0.39%), by the samples obtained from beet sugar. An X-ray phase analysis showed that the resulting structures are X-ray amorphous.

(4) A scanning electron-microscopic examination showed that the resulting carbon materials are polydisperse powders whose particles have a size of 0.1–12 μm, with most of particles (about 70%) having a size of 1–3.5 μm. The shape, size, and size distribution of the particles depend on the nature of the vegetable raw materials and preparation procedure.

(5) The resulting carbon modifications are suitable as anode materials for lithium-ion (polymer) batteries.

Abstract—Effect of ingredients of the light sensitive composition of registering layer on the photographic parameters of halosilver photographic materials for recording holograms is considered.

DOI: 10.1134/S1070427208060372

The modern materials for recording holograms are extremely diversified. They include electron-optical crystals, photoresists, photopolymerized layers, layers of chrominated gelatin, semiconductor layers, diazotype materials, systems semiconductor – metal, metallic and thermoplastic films. However, the most widespread remain halo-silver photographic materials featured by reliability, accessibility and high sensitivity.

Practically all characteristics of the quality of these materials including sensitometric ones in a great extend depend on either the mode of hologram recording, or on technology of manufacturing the registering layer photosensitive composition, or on the procedure of treatment of the material after registering exposition.

In this publication we present results of the study of influence of the photosensitive composition registering layer on the photographic parameters of the halo-silver photographic material used for recording of holograms.

EXPERIMENTAL

As is known, properties of any system are defined by essence and quantitative relation of its components.

Registering layers composed of the halo-silver photo-graphic material regardless their function are complex by composition disperse polycomponent systems on polymeric base. As the binding polymer, for the modern photographic materials the most often is used gelatin, a poymer of natural origin produced by acid or alkaline hydrolysis of collagen [1]. The binding polymer provides stability of the layer and essentially forms matrix for various active components; ratio of the latter ones defines mainly the parameters of the resulting material. Besides binding polymer, the registering layer photosensitive composition can include up to 50 ingredients varied by content in a wide enough range. Choice of the functional components is defined by the purpose of the material and always takes into account possible side effects. The main material for photosensitive compositions consists of micro crystals of silver halide formed directly in the binding polymer bulk in the process of inorganic synthesis. All other components are introduced after formation of disperse phase. They should either modify surface of photosensitive micro crystals to admit them certain photographic characteristics, or modify the matrix by chemical reaction with the binding polymer for changing physico-chemical structure of the layers to be prepared.

We studied effect of potassium bromide, 5-methyl-7-hydroxy-1,3,4-triazoindolycine (F-1) and spectral orthochromic sensitizer, the dye KR3698 on the halosilver composition including binding polymer (high viscous inert gelatin) and sensitive to light fine disperse microcrystals AgHlg.

The method of preparation of the composition includes the following steps:

– direct instant one-jet emulsifying at 40 ± 0.5°C

with silver halide at excess of silver ions pAg = 2.3 ± 0.1;

– keeping the formed dispersion under conditions identical with those of emulsifying for 10 sec (physical ripening of solid phas);

– one time freezing out the composition followed by washing – decanting with salt free water;

– introducing the modifying additive;

– coating to achieve silver content 1.6 g /m^2.

The photosensitive compositions were tested according to common sensitometric tests of the Russian standard GOST 10691.1–84, the section concerning materials with high resolution. The results are listed in Tables 1 and 2.

Comparative analysis of the obtained results (Tables 1 and 2) allows to reveal the most appropriate composition for the holography purposes.

For example, we can affirm that for the photosensitive compositions with the same filler – binding weight ratio

Table 1. Effect of photosensitive composition on sensitometric characteristics of photographic layers containing AgBr

Composition	Sensitometric characteristics			
	$S_{0.9}$, GOST units	D_0	D_{max}	γ
Gelatin // AgBr//	0.004	0.07	3.20	7.0
Gelatin // AgBr//KP3698	0.012	0.18	6.00	6.8
Gelatin // AgBr // KP3698 // F-1	0.005	0.05	3.35	5.6
Gelatin // AgBr // KP3698 // F-1 // KBr	0.020	0.04	3.20	2.5

Table 2. Effect of photosensitive composition on the sensitometric characteristics of photographic layers containing AgBrI

Composition	Sensitometric characteristics			
	$S_{0.9}$, GOST unit	D_0	D_{max}	γ
Gelatin // AgBrI //	0.008	0.08	3.58	5.2
Gelatin // AgBrI // KP3698	0.020	0.15	5.30	5.0
Gelatin // AgBrI // KP3698 // F-1	0.010	0.10	3.68	3.5
Gelatin // AgBrI // KP3698 // F-1 // KBr	0.012	0.14	2.80	3.2

polymer but differ by chemical composition of the filler, presence of microcrystals with small, ~ 3 mol %, content of iodide (≤ 6 mol % [2]) leads to substantial increase in the sensitivity of the material. Therewith, the constrastness factor γ falls significantly. The iodide most likely affects sensitometric characteristics of the material due to its presence in the disperse medium in the step of formation of solid phase. Due to lower solubility of AgBrI micro crystals as compared with AgBr, the iodide doped in a small amount is built into the lattice of conceived micro crystals and the latter become more stable than the micro crystals without iodide. Therefore the crystals are less prone to the process of ripening along the Ostwald mechanism [3]. Eventually this leads to formation of the composition with the significant scattering by sensitivity of the particles in its solid phase. High sensitivity of such compositions is stipulated by higher defectiveness of the surface of the mix based micro crystals.

As is known, sensitometric characteristics of compositions in a great extend are affected by modifying additives. As the obtained data show, their effect depends on the chemical composition of filler. For example, introducing of spectral sensitizer affects much more the sensitometric characteristics of composition with AgBr micro crystals: photosensitivity grows triple and maximal optical density is duplicated.

Introduction of potassium bromide in the step of formation of registering layer affects sensitometric characteristics only of the material containing a composition with AgBr. Potassium bromide introduced in excess behaves as a solvent of AgBr micro crystals and induces prolonged Ostwald ripping of solid phase in the process of the layer formation. This leads to not controlled grow of micro crystals resulting, on the one hand, in the increase of total sensitivity of the halosilver photographic material in account of increase in sensitivity of growing micro crystals, and, on the other hand, to decrease in the contrastness coefficient due to increase in the scattering by photosensitivity of the micro crystals differ by size. Mix based AgBrI microcrustals are less soluble than AgBr, therefore the effect of introducd potassium bromide on the compositions with AgBrI filler is much less.

Introducing to the composition the sensitizer 5-methyl-7-hydroxy-1,3,4-triazoindolycine leads to decrease in photosensitivity by a half and decreases image contrastness regardless the solid phase composition.

CONCLUSION

The optimal composition for registering layers of holographic halo-silver photographic materials from the viewpoint of sensitometric characteristics should be recognized the composition with AgBrI as a filler, containing, besides a spectral sensitizer, also a mixed stabilizer – potassium bromide with 5-methyl-7-hydroxy-1,3,4-triazoindolycine.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Appication of Ethylene–Vinyl Acetate Copolymers as a Polymeric Base of Concentrated Pigments for Coloring Polyvinyl Chloride Plastics

D. V. Merezhko, A. O. Grigorov, and S. S. Mnatsakanov

St. Petersbutg State University of Cinema and Television, St. Petersburg, Russia

Received November 2, 2007

Abstract—Physico-mechanical characteristics of compositions of polyvinyl chloride with ethylene – vinyl acetate copolymer (PVC–EVAC) are investigated. The data obtained show that these components are well compatible in the region of high content in the composition of EVAC. This result allow to conclude that EVAC can be used for producing concentrated compositions with a pigment for coloring PVC insulation of electric cables.

DOI: 10.1134/S1070427208060384

INTRODUCTION

For colorization of thermoplastic polymeric materials in bulk at the process of their transformation into a product it is reasonable from the viewpoint of economy to apply granulated concentrated pigments with polymeric base identical with the colorized polymer or technologically compatible with the latter [1, p. 50]. For colorization of plasticized polyvinyl chloride (PVC-plastic) intended for producing cables are produced granulated concentrates based on PVC only [2], which are well compatible with the cable compounds, but have certain disadvantages: low thermal stability and bad dispersing in them of organic pigments with high covering ability [3]. In recent study was shown [4] that PVC-plastic is restrictedly compatible with EVAC (ethylene and vinyl acetate copolymer), in particular, with the copolymer with high content of vinyl acetate links. It seems interesting to study a possibility of application EVAC as a polymeric base for the pigment concentrates applicable to colorization of cable PVC-plastics and displaying both colorizing and modifying action on the parent plasticized PVC.

EXPERIMENTAL

We used industrially produced PVC-plastics for cables responding to GOST 5960-72, with a sharp difference in the content of plasticizers: I40-13A (content of plasticizers 30%) and IO45-12 (content of plasticizers 70%) manufactured by Closed Join Stock Co. "Kaustik" (Sterlitamak). For modification of these PVC-plastics we used two types of EVAC with a high content of vinyl acetate (VA) links: EVAC 11507-070 (content of VA links 22%) and 12306-020 (content of VA links 18%) produces by Open Join Stock Co. "NefteKhimSevilen" in correspondence with Technical Requirments TU-6-05-1636-97. These types of EVAC as well as the types of PVC-plastics differ mutually by the viscosity of melt. As is known [5], for producing homogenous mixture of the melts of two polymers in an extruder their viscosities should differ insignificantly, therefore for the modification of rather rigid PVC-plastic I40-13A it was reasonably to apply more viscous EVAC 12306-020, while for rather soft IO45-12 more appropriate is EVAC 11507-070. We studied compositions with the content of EVAC introduced to PVC-plastic varied from 0 to 10%.

The mixtures of PVC-plastics with EVAC were prepared in a laboratory two-auger pug mill of "Thermo PRISM" firm (United Kingdom) TSE-24-TC at the temperature 130–140°C, rate of augers rotation 60 rpm, the augers configuration is for providing effective mixing.

The samples for physico-mechanical tests of PVC-plastics with EVAC varied by ratio were prepared by rolling – pressing procedure on a laboratory roller and a Scamia press (France), according to GOST 5960-72. The pressed samples had thickness 1 ± 0.1 mm.

Physico-mechaniical parameters: tensile strength and breaking relative lengthening for the samples of mixed compositions were measured on a "HOUNSFIELD" H10KT machine along the GOST 11262-80.

RESULTS AND DISCUSSION

Study of physico-mechanical characteristics in respect of the tensile strength of PVC-plastic – EVAC mixed samples for two pairs revealed that dependence of their strength on EVAC content is ambiguous.

From Figs. 1 and 2 is seen that relative elongation and tensile strength dependence of the compositions on the content of EVAC in them are differ noticeably for the different pairs of the polymers and do not obey additivity law. Physico-chemical characteristics of mixtures of PVC-plastic I40-13A with EVAC 12306-020 show an extremum in the region of 2–4 wt% of EVAC 12306-020, although tensile strength (σ_p) of individual EVAC 12306-020 is 12.5 MPa, that is, below than that of individual PVC-plastic I40-13A, and breaking elongation (ε_p) is 600%, that is, on the contratry, much higher than that of I40-13A, and then these characteristics vary insignificantly up to 10% EVAC content. Simultaneously, strength characteristics of PVC-plastic IO45-12 mixture with EVAC 11507-070 fall down monotonically and at 10% content of EVAC the sp and ε_p values of the composition fall to a half although elongation at breaking of individual EVAC 11507-070 is even higher than for EVAC 12306-020, it equals 65%. It is reasonable to assume that increase in strength and relative breaking elongation for more rigid and viscous PVC-plastic I40−13A at introducing EVAC 12306-020 in the range 2–4 wt% indicates a possibility of formation of a net of donor – acceptor type hydrogen bonds, as shown in Fig. 3.

Seems valid an assumption that dispersion of EVAC in the PVC-plastic looks in this case as follows. The particles of non-polar EVAC fragments push out polar fragments to surface, and the polar fragments on the phase interface develop donor–acceptor interaction between positively charged proton of α-methylene group and negatively charged carbonyl of vinyl acetate group. In the case PVC-plastic IO45-12 with EVAC 11507-070 the low effect of such interaction is due to high content of plasticizer (~70%) in the plastic. The plasticizer molecules surround polar groups in PVC and therefore formation of stable donor–acceptor bonds with active groups in EVAC is not

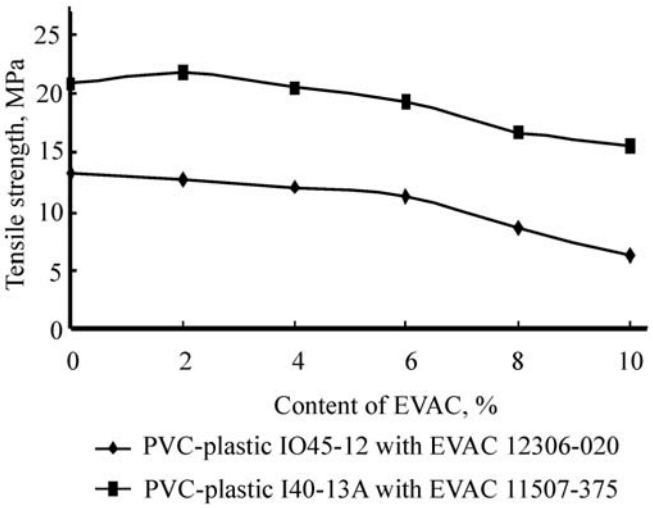

Fig. 1. Plots of tensile strength of the compositions PVC-plastic IO45-12 with EVAC 115-375 and PVC-plastic I40-13A with EVAC 12306-020 on the EVAC content.

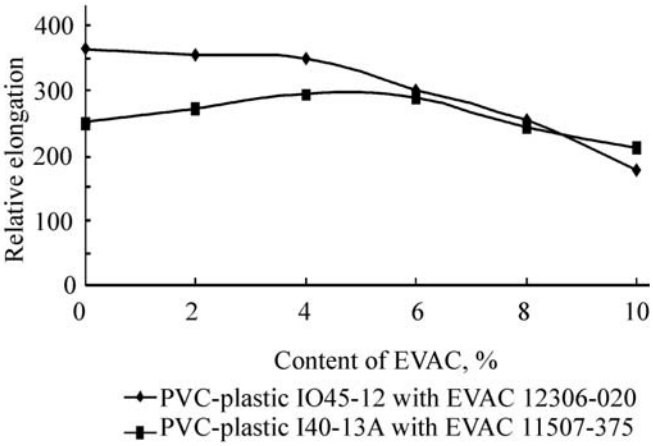

Fig. 2. Plots of relative elongation at break of the compositions PVC-plastic IO45-12 with EVAC 115-375 and PVC-plastic I40-13A with EVAC 12306-020 on the EVAC content.

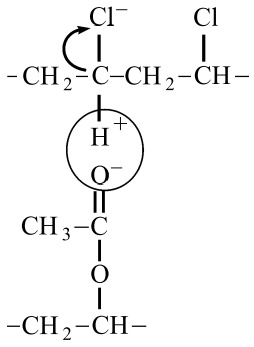

Fig. 3. Mechanism of formation of donor–acceptor bond between EVAC and PVC.

so effective due to pure sterical hindrances. Nevertheless, we can resume that at mixing EVAC with PVC-plastic can be found conditions when physico-mechanical properties of PVC-plastic are retained and even improved, at low content of EVAC in the mixture.

Taking into account that for quality colorization of cable PVC-plastics commonly the pigment concentrate is introduced to the melt in amount 1–2%, and the concentrate contains 30–80 wt% of polymeric base, it is logically to assume that creation of such concentrates based on EVAC owing to interaction of the latter with PVC can lead not only to good distribution of 1–2% of the concentrate in the colorized polymer but also can improve physico-mechanical characteristics of the colorized cable insulator.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Mixing of Polyvinylchloride Plastics with Ethylene–Vinyl Acetate Copolymer

D. V. Merezhko, A. O. Grigorov, and S. S. Mnatsakanov

St. Petersbutg State University of Cinema and Television, St. Petersburg, Russia

Received November 17, 2007

Abstract—Rheological behavior of several types of polyvinyl chloride (PVC) plastics and ethylene – vinyl acetate copolymer (EVAC) is studied. The plots of flow obtained allows to conclude that principally is possible to create quality pigment concentrates based on EVAC for application at the colorization of PVC plastics.

DOI: 10.1134/S1070427208060396

INTRODUCTION

Colorization of cable PVC-plastics commonly is carried out in melt in the process of covering copper cable core by insulant. It is reasonable economically to use together pigment and modifying additive concentrate [1]. Obviously reasonable to use concentrates based on PVC: they are absolutely compatible with the colorized plastic. However, several steps of the process (at preparation of the concentrate and colorization) can be critical for such unstable polymer as PVC and can lead to its destruction, via splitting hydrogen chloride off in particular. We propose another solution: as a binder in the concentrate composition can be used stable, available and not expensive ethylene – vinyl acetate copolymer (EVAC). Application of this polymer as a base for the pigment concentrate is advantageous in several respects. First, its low cost that is comparable with that of polyethylene, much lower than the cost for PVC-plastics. Second, EVAC is thermally stable and therefore is appropriate for high shear stress defining in a great extent the pigment effective dispersing in the concentrate. Third, EVAC possess a high wettability, that is, reveals effective adsorption on the particles of pigment and filler, which, together with ability to high shear stress, provides best quality at dispersing the concentrates for cable colorization. A disadvantage of this system is relatively low compatibility of the PVC–EVAC system [2].

By recent investigations has been established [2] that PVC-plastic is well compatible with EVAC in a certain range of EVAC concentration and at the high content of vinyl acetate links (above 20%) in the copolymer. But at mixing two polymers with restricted compatibility attention should be paid to the viscosity of components. In [3] was noted that the less viscous material while is passing extruder canal will mostly wet the canal internal surface. This simple observation was well described in [4, 5] in respect of petroleum transfer through pipes. It can be concluded that, the best conditions of pigment and additive dispersion in the polymeric product will be achieved when viscosity of components at certain conditions (temperature and shifting tension) are close together. Therefore it seems interesting to compare rheological characteristics of EVAC and PVC main types at the conditions typical for a real processing.

EXPERIMENTAL

For the study were used industrially produced PVC-plastics GOST 5960-72 for cable insulation, that differ from others by the content of plasticizer: I40-13A (30% of plasticizer) and IO45-12 (70% of plasticizer) produced by Closed join stock company "Kaustik" (Sterlitamak). For modifying the chosen PVC-plastics was applied EVAC with substantial number of vinyl acetate (VA) links of two types: EVAC 11507-070 (fraction of VA links 22%) and 12306-020 (18% of VA links) produced by Open

join stock company "NefteKhimSevilen" according to technical requirements TU-6-05-1636-97. These types of EVAC as well as the types of PVC-plastics differ in pairs significantly by the melt viscosity.

High temperature and shear stress occurred in extruder lead to little changes in the properties of PVC-plastics. This results not only from thermal cross-linking, but also with possible loss of plasticizer due to sweating [8]. Therefore before rheological investigations we passed the plastics through a TSE-24-TS extruder. The procedure was intended to modeling changes in the plastic properties at processing on extruder apparatuses.

Rheological characteristics of the samples were measured in a capillary constant pressure viscosimeter.

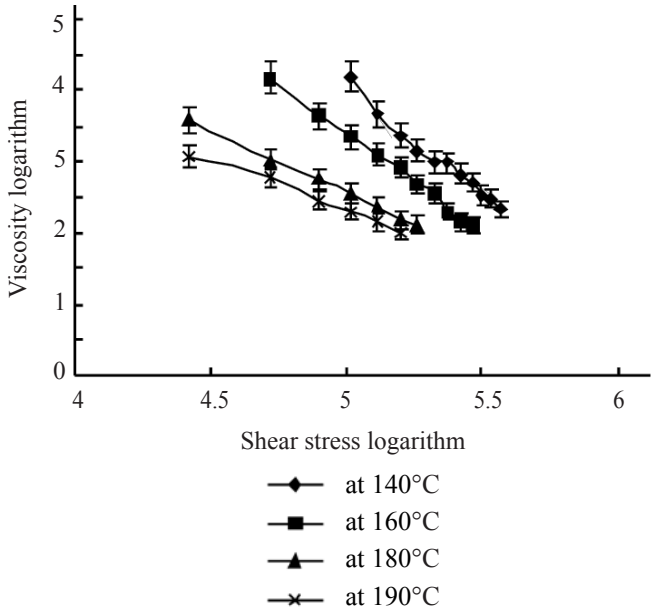

Fig. 1. PVC-plastic I40-13A.

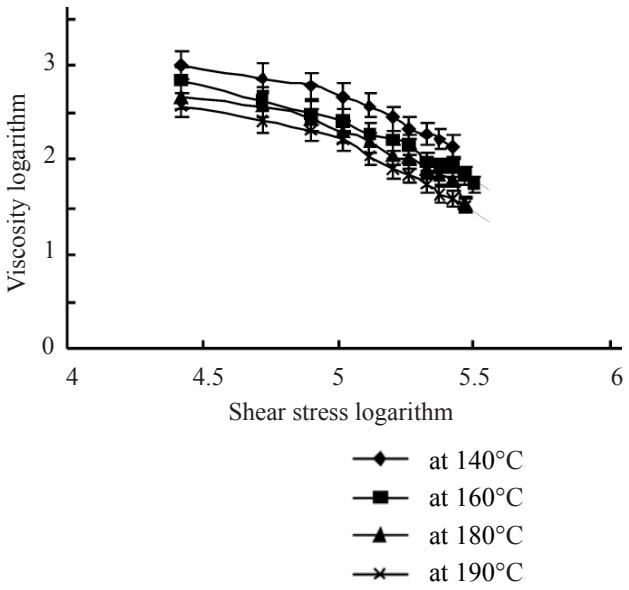

Fig. 3. Flow curves of EVAC 11507-375.

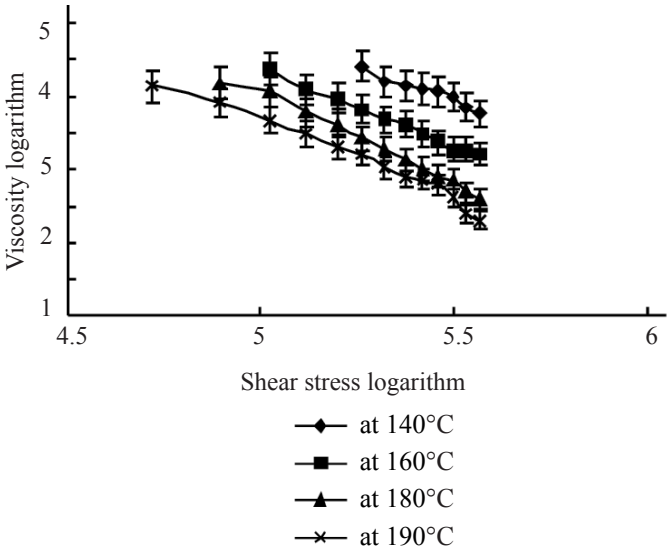

Fig. 2. Flow curves of PVC-plastic IO45-12.

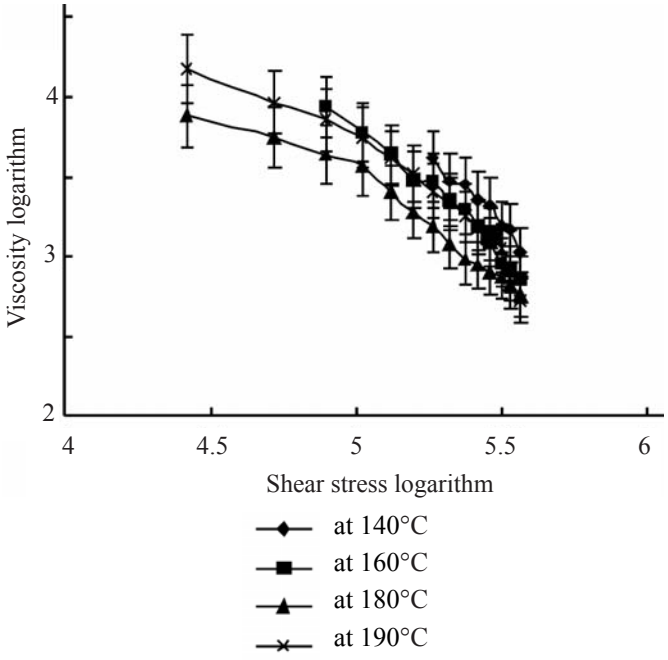

Fig. 4. Flow curves of EVAC 12306-020.

Principal scheme of the instrument and methodology of measuring viscosity are described in [6]. The measuring cycle reeated at different temperatures (160°C, 170°C, 180°C, 190°C) and shear stress (from 26 to 367 kPa). The data obtained are represented as plots [log η (log τ, T)] in Figs. 1–4.

RESULTS AND DISCUSSION

Analysis of the at 140°C shows that both EVAC 12306-020 and PVC-plastic I40-13A flow begins at high enough shear stress and therefore these data reflect the interval of shift rate not completely. For the complete description of rheoligical behavior of the material it would be logically to carry out rheological investigations at higher temperature. As seen from Figs. 3 and 4, at high enough temperatures 180 and 190°C the curves run exert change at relatively high shear stress values (clearly seen in Fig. 4). The inflection of logarithmic dependence of viscosity on the shear stress points to the possible process of destruction of the fractions with high molecular weight. Therefore we suggest that allowed temperature of the investigation is 160°C. This is even more reasonable because this value is close to the temperature of PVC processing by the cable technology [7].

Fig. 5 depicts all flow curves of samples studied at 160°C. Slope of flow curve for PVC-plastic IO45-12 differ significantly from those of the curves characterizxing PVC-plastic I40-13A and both types of EVAC, while both the EVAC samples despite the difference in content of VA links and in the melt flow index (MFI) show very similar slope in a wide range of sift tension. Therefore this investigation does not allow select universal polymeric base for the concentrate which would provide equally good mixing with any sort of PVC-plastic. Note that values of viscosity of EVAC 11507-375 and PVC-plastic IO45-12 are similar at high shear stress and flow cdurves of both EVAC12316-020 and PVC-plastic I40-13A are at near positions in the plot at wide enough range of shear stress. Seems logical to use for colorization of IO45-12 plastic the concentrate based on EVAC 11507-375 and for colorization of I40-13A plastic the concentrate based on EVAC 12316-020 or EVAC 12316-020 and EVAC 11507-375 mixture. At the development of formulation of the concentrates it is allowed to estimate rheological chatracteristics of the melts using values of their melt

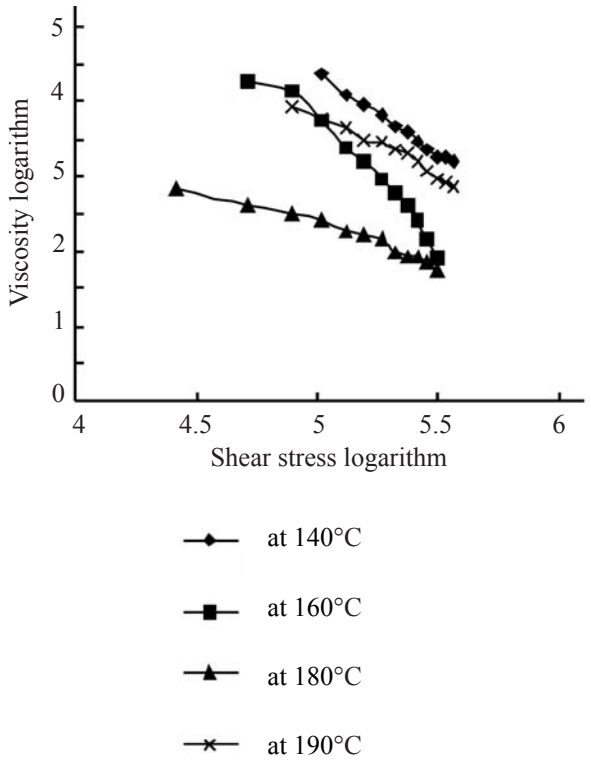

Fig. 5. Flow curves of PVC-pastics and EVAC at 160°C.

flow indices, as far as curves of flows of the EVAC sorts studied in this work are analogous in the whole range of shear stress, that is, "dot" measuring of viscosity like the melt flow index measurement defines position of flow curve of EVAC relatively to the analogous curves for the colorized PVC-plastics enough accurately.

Thus, this study showed principal possibility of creation of pigment concentrates based on EVAC with high content of vinylacetate links which by their rheological characteristics are appropriate for obtaining qualitatively colorized products using process of extrusion of PVC-plastic mixed with 1-2% of pigment based on EVAC 11507-375 and EVAC12316-020.

Abstract—The results are displayed of measuring hardness of the ammonium nitrate granules when the preceding melt is doped at 180°C either with ordinary powdered phosphorite, or with dust fraction, or with mineralized mass of the Central Kyzylkum Phosphorite in amount from 0.5 to 5.0% of P_2O_5.

DOI: 10.1134/S1070427208060402

Ammonium nitrate is the most widespread nitrogen fertilizer [1]. In Uzbekistan, three big intustrial enterprises, the Open join stock company "Electrochimprom" in Chirchik, Open join stock company "Navoiazot" and Open join stock company "Azot" in Fergana produce ammonium nitrate for agricultural application. The total productivity of these plants is above one million ton of ammonium nitrate per year. But the product is disadvantageous by two characteristics: caking at keeping and explosion hazard [2, 3]. While the caking can be diminished by introducing to the ammonium nitrate some additives, the problem of explosion hazard is not solved yet. To avoid caking, commonly are used sulfate, sulfato-phosphate or sulfato-phosphato-borate additives, caustic magnesite and other substances [4]. It is expected that the problem of explosion hazard can be solved by application of phosphorus-containing additives. In [5–7] has been described technology of manufacturing complex nitrogen-phosphate fertilizer containing 32.3% N and 5.2% P_2O_5 by adding to the ammonium nitrate melt of liquid complex fertilizer with composition 11% N and 37% P_2O_5 based on superphosphoric acid. This additive increases temperature of decomposition beginning by 22–24°C, reduces rate of its thermal decomposition, increases hardness of granules, decreases the product porosity, increasesd stability of the product to multiple phase transformations and, the most important, decreases its ability to detonation. The Open join stock company "Cherepovetskii Azot" firs applied this technology at the technological line with productivity 1000 ton per day. The plant staff noted that explosion hazard of this product is lower that that of pure ammonium nitrate, but at mixing the ammonium nitrate solution with the liquid complex fertilizer a precipitate is formed that generates problems at the steps of evaporation and granulation [7].

Russian plants "Azot" in Kemerovo, chemical mill in Kirovo-Chepetsk, Open join stock company "Minudobreniya" in Rossosh town and Open join stock company "Akron" in Novgorod decided to produce stabilized ammonium nitrate with phosphorus-containing additives. We do not know which compounds are assumed.

We decided to produce stabilized ammonium nitrate by adding to the melt the phosphorite raw material from Central Kyzylkum, namely, ordinary powdered phosphorite, or dust fraction, or mineralized mass. Two last substances are by-products at manufacturing of powdered phosphorite by the process of phosphorite ore dry enriching. Chemical and dispersion compositions of the parent ore are listed in Tables 1 and 2.

Table 1. Phosphate raw material composition

Raw material	Content of components, wt%							$\frac{P_2O_{5assim}}{P_2O_{5total}}$, %

In [8] we have studied composition of the products obtained at introduction of the Central Kyzylkum phosphate raw material to the ammonium nitrate melt in amount to acieve content 0.5 to 5% of P_2O_5 in the product. The mixture was stirred for 30 min at 180°C. Analysis showed that the ammonium nitrate melt activates phosphate raw material, that is, converts P_2O_5 to assimilating form. The product with 5% content of P_2O_5 obtained by adding ordinary powdered phosphorite contains 25.24% N and contains P_2O_5 in the form that plants assimilate by 88.29% of the total P_2O_5 content. The product containing 5% of P_2O_5 obtained by adding dust fraction contains 26.01% N and 88.20% P_2O_5 of the total P_2O_5 content in the form appropriate for assimilation. The product from mineralized mass with 5% of P_2O_5 contains respectively 23.94% N and fraction of P_2O_{5assim} 55.75%. More phosphate material introduced to the ammonium nitrate melt, less fractions of assimilating forms of P_2O_5 and CaO and less degree of decarbonization are obtained. Presence of CaO (water) in the product with 5% of P_2O_5 in amounts 1.61% in the case of powdered phosphorite, 1.40% for dust fraction and 1.71% for mineralized mass indicates that at 180°C proceeds reaction between ammonium nitrate and calcium carbonate contained in the phosphate material leading to formation of calcium nitrate:

$$2NH_4NO_3 + CaCO_3 \rightarrow Ca(NO_3)_2 + 2NH_3 + CO_2 + H_2O$$

In this publication we present results of measurements of granules hardness of ammonium nitrate doped with phosphate raw material of Kyzylkum birthplace. Hardness of granules is one of the most significant characteristics of stabilized ammonium nitrate. The granulation was carried out along the following technology. Ammonium nitrate was melted at 180°C, to the melt was loaded a given amount of phosphate raw material, the mixture was stirred carefully for 30 min. The melt was then passed to granulator – a metallic receiver with perforated bottom, the holes diameter was 1 mm. In the upper part of the receiver by a pump was created a pressure, and the melt was sprinkled from 9-th flour of building on polyethylene film at ground. After that was measured the formed granules hardness.

Note that when granulatuion is carried out just after mixing the ammonium nitrate melt with phosphate material without 30 min stirring, the granules formed are unconsolidated and absolutely not hard. This probably is a result of above written reaction of ammonium nitrate with calcium catbonate at 180°C, gas phase evolved from the mixture destroys the granules.

The granules hardness of the granules 1–3 and 2–3 mm size was measured on a MIP-10-1 instrument [9]. On the instrument scale was fixed hardness (kg) at which the granules damaged. Static of granules was calculated by averaging 20 measurements:

$$X = \frac{P_1 + P_2 + P_3 + \ldots + P_{20}}{20},$$

where P_1, P_2, P_3, ····· P_{20} are the values of power for damaging the granules (kg).

Static hardness of granules Y (kg/cm^2) was calculated along the formula:

$$Y = \frac{\sum_{i=1}^{i=20} P_i}{20\,S} = \frac{\sum_{i=1}^{i=20} P_i}{20\,\frac{\pi d^2 cp}{4}} = 0.063\,\frac{\sum_{i=1}^{i=20} P_i}{d^2 cp},$$

where Pi is the power needed for damaging one granule (kg); S is area of the granule section, cm^2; d_{av} is average diameter of granules, cm.

To convert the results obtained to MPa scale the values obtained were divided by 10.2. These data are listed in Tables 3–5.

As seen from the Tables, introducing of grinded phosphorite in amount providing P_2O_5 content from 0.5 to 5.0% to the melt increases hardness of the granules with diameter 1–3 mm from 3.18 to 7.75 MPa, of those with diameter 2–3 mm from 3.2 to 7.8 MPa. Adding the same amount of dust fraction increases hardness of granules with diameter 1–3 mm from 3.15 to 7.69 MPa, and of granules with diameter 2–3 mm from 3.16 to 7.74 MPa. Effect of mineralized mass of the Central Kyzylkum phosphorites is maximal: hardness of granules

10	48.0	100	23.94	4.95	4.49	90.51	8.87

with diameter 1–3 mm increases from 3.89 to 8.80 MPa, that of granules with diameter 2–3 mm from 3.91 to 8.87 MPa.

Increased hardness of ammonium nitrate granules corresponds to decrease in their porosity and internal specific surface and, hence, leads to retarding penetration of the granules with diesel fuel and decreased detonation hazard.

Abstract—A new electrophysical method is proposed for liquid products rapid diagnosis of quality and identification. The method is widely prospective for practical application.

DOI: 10.1134/S1070427208060414

In this publication we consider a method of revealing *state* of liquid substance for its identification or for diagnosis of its quality. Advantage of the proposed method is elucidation of earlier unknown laws for a great variety of liquid substances differ by conductivity, dielectric permeability and featured by very low magnetic susceptibility [7, 8]. The work is based on fundamental investigations [1, 2] and practical experience in the military-industrial complex.

On the basis of measurements of electrical conductivity of solutions at different affecting factors [2] we first propose generalized theoretical concept of *measuring* that includes, in conjunction, knowledge about accumulation and scattering energy in substance described by two equations of state (Maxwell equations), knowledge about mechanism of mutual influence of conductivity and mixing currents, about interface phenomenon (electrode – solution), about principles of matching parameters of cell and of measuring instrument. Owing to identity in distribution of steady current and electrostatic potentials between electrodes we succeeded in revealing conditions for measuring dielectric permeability of liquids including electrolytes and of specific electrical conductivity of liquids including dielectric ones.

This all gave a basis for creation of new methods, of reference and commonly used tools for analysis (testing) of substance composition and quality [3], and promoted revealing properties of liquids to retain independent from temperature electrical conductivity at characteristic frequency F_x of surrounding electromagnetic field.

We completed development of basic computer system of analysis (CSA) for revealing quality and for identification of liquid substances [4], which provides operations of the whole complex of devises of which each can be used separately as a basis for design lots of portable units and exploitation of the latter with various objects.

The computer system of analysis is designed as explosion-proof unit and includes following elements (Fig. 1):

– capacity probe capable of operating in chemically aggressive and dangerously explosive environment [5];

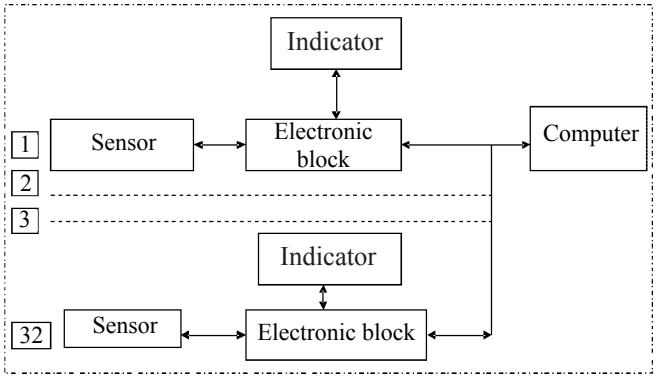

Fig. 1. CSA block-scheme.

Fig. 2. CSA general view.

– electronic block providing action of electromagnetic field with frequency from 1 kHz to 10 MHz on the substance in the operation space of the probe, obtaining responses and transformation of the latter to the form of specific electrophysical characteristics;

– indicator of the electrophysical characteristics and of their dependence on frequency;

– computer for registration and displaying frequency plots of the characteristics and for saving database.

Besides computer, the CSA includes modern portable systems based on microelectronics connected and matched with the probe at the distance up to 1.5 m by means of coaxial cables.

The system allow information acquisition and processing at the distance up to 1200 m, from 32 objects simultaneously.

Block scheme of CSA is depicted in Fig. 1, general view in Fig. 2.

The main parameters of the computer analytic system (CSA) for revealing quality and identification are:

– operating frequency: 1 kHz to 10 MHz;

– measured active conductivity: from 10 nCm to 1 mCm;

– measured capacity: 0.01 nF to 0.01 mF;

– relative error of operating frequency: 10^{-5};

– error at measuring in the frequency range from 1 kHz to 2 MHz: active conductivity from 1 S m^{-1} to 1 mS m^{-1} ± 0.5 %; capacity from 1 nF δ_O 1 000 nF ± 0.5 %;

– maximal number of points of scan frequency: 1024;

– error in measuring temperature: ± 0.05°C;

– type of interface: RS-232 and RS-422;

– power consumed by one canal: from 50 Hz electric line 85–240 W, from 5 – 12 V source 5 W.

The method used is based, first, on the Maxwell theory of electromagnetic field allowing determination of distribution and scattering of electromagnetic energy in a substance at different frequencies accounting for the fact that magnetic permeability of liquids in this field $\mu \leq 1$, and, second, on the introduction to the process of experiment a certain complex (code) of electrophysical characteristics – the new quantitative characteristics which simultaneously characterize quality of liquid and its belonging to a certain group of liquids, e.g., to a given sort of fuel and lubricant, oil from certain birthplace or mixtures of oils, to propellants, to genetic solutions, to alcohol solutions (vodka), to food, etc.

Conditions are revealed where can be commensurable the components of active conductivity stipulated by two inseparable processes of motion of "free" and bound ions and ionic associates. This is extremely needed for measuring characteristic frequency F_x at different temperatures when active conductivity remains unchanged.

In a liquid, molecules are always in the state of specific intimate collision.

Only recently were successfully realized experiments concerning the process of action of electromagnetic field at different frequency on fuel-lubricant materials and were detected characteristic frequencies F_x which are of specific value for each product depending on the chemical state (composition) of the latter. Therewith, active conductivity does not depend on the variations in temperature up to boiling point. Undoubtedly, these properties of a liquid are connected with its structure.

This situation can be adequately described as the action in the liquid of two inseparable types of the components of active current, of which one is stipulated by the motion of so-called "free" ions and another by the motion of bound ions (charges).

When molecular structure of a liquid is of multi-dimensional type (molecular associates), e.g., in the case of oil with a certain content of low boiling fractions, residual fuel oil, dark diesel fuel, nutritional vegetable oil, F_X falls to the low frequency region of spectrum (Table 1):

10 kHz –sunflower oil "Zolotoe semechko" refined;

12.6 kHz – sunflower oil "Natura", refined, GOST P524-2005;

17.4 kHz – sunflower oil "Dary Kubani", not refined,

GOST P52465-2005;

144.5 kHz – motor oil "King Oil", 5W50;

300 kHz – petroleum of West Siberian birthplace;

400 kHz – petroleum of Ukhta birthplace;

1 500 kHz – petroleum of Kaliningrad birthplace with high content of kerosene.

In the case of liquids with low electrical conductivity the F_x value is much larger. For example, a batch of propellant unsymmetrical dimethylhydrazine is characterized by F_x value 3 800 kHz, while a batch of binary mixture propellant TG-02 has F_x = 4 000 kHz [1].

At characteristic frequency of electromagnetic field F_x two types of active current have equal but of opposite signs increments. F_x belongs to the most important structural characteristics of a liquid.

The essence of electrophysical *method of states* is as follows.

At the action of electromagnetic fields differ by frequency (e.g., in the range from 1 kHz to 10 MHz or even higher) at a given temperature and pressure can be registered *responces* in the form of standard electrophysical characteristics (code of characteristics) which can be obtained experimentally and calculated theoretically:

– specific acitive conductivity ж, including that at high frequency 1 MHz, in the range from 0 to 5×10^{-6} S m^{-1} and higher and at low frequency 1 kHz in the range from 0 to 20×10^{-9} S m^{-1} and higher;

– ratio of specific active conductivities at all frequencies to specific active conductivity at 1 kHz, including ratio of specific active conductivities at the frequencies 1 MHz and 1 kHz (criterion of identity) in the range from 1 to 10 000 and higher;

– dielectric permeability ε, including measured at the frequency 1 kHz (ε_{1kHz}) and 1 MHz (ε_{1MHz}), and gain $\Delta\varepsilon_f = \varepsilon_{1kHz} - \varepsilon_{1MHz}$;

– characteristic frequency F_x in the range of few kHz to 10 MHz and higher;

– spectrum of plots of ж and ε against frequency in the range from 1 kHz to 10 MHz;

– higher specific heat of combustion Q_s^a, kJ kg^{-1} for fuels and lubricants [6].

These responses (codes) of electrophysical characteristics allow to identify belonging of a substance to certain product and to estimate its quality (composition).

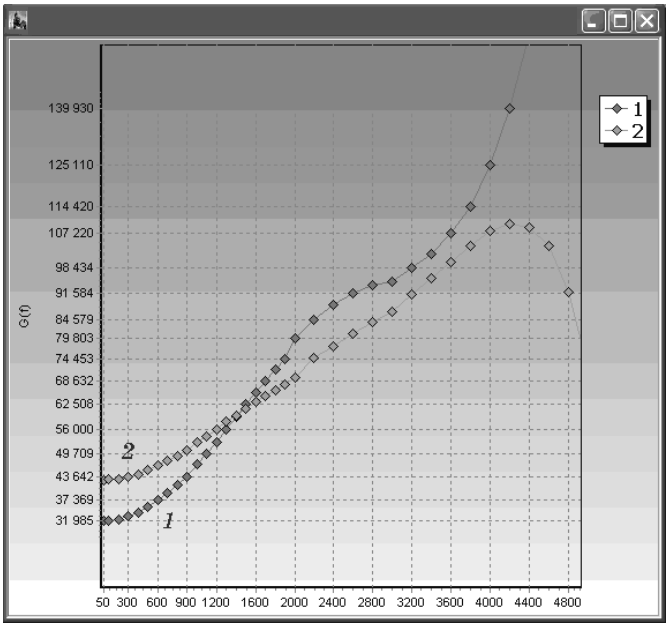

Fig. 3. Pronit (batch 1): (1) at 19.5°C; (2) at 34.0°C.

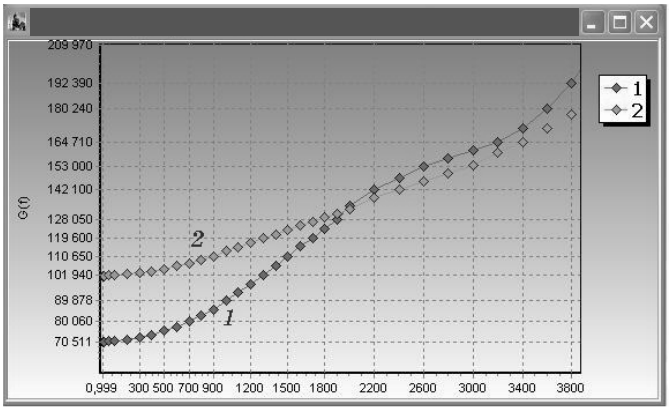

Fig. 4. Pronit (batch 2): (1) at 20.5°C; (2) at 37.0°C.

Any given product has its own values of characteristics (code). The characteristics include:

æ$_f$, æ$_{1MHz}$, , æ$_{1kHz}$, ε_f, ε_{1kHz}, ε_{1MHz}, n, Q_s^a, F_x.

They all are measured simultaneously at the same influencing factors (temperature, frequency, etc.) Applying this *computer system of quality analysis and identification* (CSA) for measuring characteristics takes 2 min or less.

Number of characteristics decreases in the cases of simple technological processes.

A significant supplement to the characteristics of products is dependence (relief) of the characteristics on frequency. This is an original spectral characteristic of electrophysical characteristics in respect of quality of

solutions. First in world practice appears real perspective for estimation of frequency dependence of electrophysical characteristics for solutions of any class and their connection with chemical state, hence, for creation of extra new technologies for estimation quality and identification of substances.

Whole, the complex of electrophysical characteristics obtained using CSA simultaneously and undert certain conditions and their dependence on frequency (spectrum) is specific for each product. Any deviation in the state (composition) of the substance can be registered promptly. This complex of electrophysical characteristics is imperative and adequate, a set of values of these characteristic constitute *code* of a substance. The identification and quality code is a set of normalized values of specific electrophysical characteristics measured simultaneously.

As examples, Tables 1 and 2 and Figs. 3 and 4 display experimental data characterizing corrspondence between liquid products and their codes and quality of products in correspondence with the values of characteristics.

These technologies for diagnosis of quality and identification are protected by patents. There are perspectives of further paten application which can create a basis for technological renewing many branches of industry, chemical industry first of all, branches of agriculture and for development of analytical technologies.

Market of application of the electrophysical method of states is impressive. Any respectful business owner realizing this technology will meet a great success. The authors can represent marketing data in the process of negotiation.

To conclusion, let us note the following. The characteristic frequency F_X with high resolution corresponds to retention of initial state of a product and exerts changes at even small deviation from this state. An important factor also is identity criterion *n*. Application of the proposed method of states will result in great diminishing of failures and accidents with "Proton" rockets, airplanes, ships and other transport means that use components of propellants and fuels.

Abstract—Solving the problem of oxygen dozing optimization (relatively to methanol mass flow) in the process of formalin producing is achieved by maximization of the metric of final product obtaining. In the solution of the optimization problem is attention is paid to the period of catalyst renewing.

DOI: 10.1134/S1070427208060426

1. INTRODUCTION

Optimization of the process of producing formalin can be achieved at consideration the process quality determining factors: the process material balance and the criterion of the commercial product maximal yield of the possible from stoichiometry [3]. We assume common system levels structure [12]. Within the commonly used 6-level structure of the Automatic System of Technological Process Control (ASTPC) the problem is decomposed into the following automatization – information tasks over the levels:

1-st level (means for the measuring and control) should provide the technological parameters measuring: mass flows of raw materials including methanol, water (for mixing with methanol), air (air oxygen for oxidizing methanol), the mass flow of final product, technological parameters such as temperature of apparatuses, water mass flow for absorption, height of methanol – water mixture in evaporator, and others.

2-nd level (controllers, schemes of local automatics): providing control over local tuning contours, that is, maintaining the values of mass flows of raw materials (methanol, water, air) defined by 3-d and 4-th ASTPC levels, other mass flows (water for absorption), temperature regimes of apparatuses, height of methanol-water mixture in evaporator, etc.

3-d level (electronic databases): providing ability to observe the scope of technological parameters both in real time and as plots; acquisition and saving external data (digitalization of the results of analysis of raw material, mass percentage of methanol in the methanol – water mixture, content by volume of oxygen in air and fraction of commercial formalin in the final product of the process, together with registration of sampling time).

4-th level (optimization of the process in real time at partial modeling): providing the automatic calculation of methanol – water ratio at dozing to evaporator of methanol – air mixture, providing automatic calculation of the degree of air dozing on stoichiometry with certain coefficient of extension (excess depending on the probable yield of final product), providing automatic calculation of the yield of final product relatively to the yield possible from sctoichiometry, at the organization of computer-based acquisition of statistical data on calculated and measured parameters (with APM program for personal computers, see below).

5-th level (record saving and internal planning): providing saving records in real time and for the reported periods (labor shift, month, quarter, year) on the flows of raw material, final (commercial) products and side products, record of labor consuming (this is a separate problem, not within the automatization), accounting for correspondence to planes in agreement with requirements of the process uniformity and matching the planes on producing and shipping, acquisition and saving records on the data of the product net cost calculations.

6-th level (tying to external economic situation): providing accounting for external prices and prognoses for calculation of optimal releasing price (assuming 30%, 36%, …, etc. profit [13]) and determination of the metric of possible internal investment.

2. RESTRICTIONS IN APPLICATION OF MATHEMATIC METHODS

The process basic reactions are [3, 5, 6]:

1. $CH_3OH + 0.5O_2 \leftrightarrow CH_2O + H_2O + 159098.4$ J

2. $CH_3OH \leftrightarrow CH_2O + H_2 - 83738$ J

3. $H_2 + 0.5O_2 \rightarrow H_2O + 242834.4$ J

Side reactions:

4. $CH_3OH + 1{,}5\ O_2 \rightarrow CO_2 + 2H_2O$

5. $CH_3OH + O_2 \rightarrow CO + 2H_2O$

6. $CH_2O \rightarrow CO + H_2$

7. $CH_3OH + H_2 \rightarrow CH_4 + H_2O$

Another side reaction can proceed, in part:

8. $CH_4 + O_2 \rightarrow CH_2O + H_2O$

9. $CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O$

Reaction (8) forms cycle with (6) and (7), therefore little possible to identify exactly the process with the model described by linear differential equations embarrassing first seven reactions. This is connected also with the fact that a system of reactions containing reaction cycles (of side products) is not describable by a system of differential equations because in such a case the continuous function argument related to the substance molar concentration is in turn a function, therefore description of processes is impossible due to natural restrictions of mathematic functional means.

This impossibility of applying a function itself as an argument of continuous (capable of differentiation in time measure parameter) function should not be mixed with the case of discrete recursive (of course appropriate for calculation) functions applied at computation programming.

In more details, the following restrictions of applying mathematic methods to the description of complex chemical processes should be accounted for. At the description of algorithmic possibility of calculation of the control parameters in real systems of process control (in the processes of chemical technology) appear additional requirements. This leads to the restrictions which do not allow algorithmic calculation of the result of (physico-chemical) process from known initial (metrics of dosing substances) and boundary (temperature, pressure) parameters of the process measured in real time scale.

Method of identification of a system and attempts of building complete model of a process (of chemical technology) are little applicable to description of real systems, as was established practically earlier in 60th of 20 century [11]. The identification was found to be partially applicable only to calculation of contours of the control parameters (2-nd level) but not for stabilization of the process quality because of omitting many factors. There is natural difference between the practice and theory in the case of complicated chemistry of the process even icluding simple inorganic reactions. (In addition, it is methodologically incorrect at the identification of a process to consider the latter as a "black box" with unknown contents despite the fact that something about the process chemistry is known).

Besides, when a system of chemical reactions includes reaction cycles, description of such system by a set of differential equation is not applicable because the function describing concentration of a component can not be taken as an argument of itself (the obvious mathematic postulate), e.g., for the cycle $A \rightarrow B \rightarrow C \rightarrow A$ the function describing concentration of substance A should be written as $v_A = v_A(v_B(v_C(v_A)))$, that is, $v_A(\ldots v_A)$, where v_A is function of concentration of substance A depends on itself and is used incorrectly. The process of producing formalin is practically of this type, and many other processes of complex chemical technology are similar (e.g., the process of reduction of titanium tetrachloride with magnesium). Therefore the only appropriate remain statistical methods of determination of the process control parameters considered below.

It is quite obvious that practically this restriction follows theoretically from the known since 20th century middle theorems about insolubility of the problem of identity of words in the semi-groups and associative systems [7, 10, 8, 2] (this restriction is also considered in [12,14]).

Let a word $a_1 \ldots a_n$ to denote left part of a chemical reaction, and $b_1 \ldots b_n$, its right part, where a_i, b_i are chars in the alphabet sequence of the names of chemical elements. Then description of chemical reaction consists in the finding identity of the words: $a_1 \ldots a_n = b_1 \ldots b_n$ for a set of reactions in a real process, the identity for a set of k words. To these words can be added sub-words F_1 (to left part) and G_1 (to right part) characterizing physico-chemical component of reaction: thermal effects,

changes in enthalpy, etc., that can be found from boundary conditions of the process. Such a set of equations forms an associative system: words are not commutative – the chars can not be replaced within alphabet – but are associative: tentative including of parentheses into the word does not changes its meaning. To such record can be applied the theorem of algebraic insolubility of the problem of words identity (A.I. Mal'tsev, see in [9, vol. 1, p. 215, line "algorithmic problem"] without evidencing), interpreted as impossibility of algorithmic calculation of results of a process of chemical technology proceeding from its initial and boundary conditions, hence, impossibility of stabilization of the process (product) quality, as has been noted by practical specialists in 60-th as absence of required mathematic methods [11]. Therefore (from practical viewpoint and due to above restrictions) control over the quality of final product is needed and appears a necessity in qualitative definition of the space of states of control system for emphasizing (besides the parameter of product quality) a parameter of control and a parameter of optimization [14], in conjunction with the known results of the theory of ability of measuring and calculating an immovable dot [4, 15].

Therefore for optimal control over the process, application of the methods of statistically optimal control described below is rather correct.

3. DESCRIPTION OF THE PROCESS MODEL

According to the main reactions of the process (1–3) at the ideal stoichiometry 1 mole of methanol affords 1 mol of formaldehyde. Practically the yield of final product is less than unity and depends (all other conditions the same) on the measure of oxygen flow into the reactor. Therefore for maximizing the final product yield should be maintained certain ratio of methanol and oxygen flows into reactor. The degree of optimality of this ratio can be judged indirectly from the data of analysis of exhaust gas that contains products of side reactions.

From the viewpoint of modeling, the process remains indefinite: the number of equations (reacting components and reaction intermediates) is greater than the number of dozed substances, and the system of linear equations at the attempted model description by the methods of linear algebra would have unknown values more than equations. Application of procedures of object identification is valuable within restricted function-space area of experiment and do not accounts for unpredictable "aging" of catalyst (decrease in activity). Therefore remains applicable only the methods of direct measuring at the co-definition of information flows and elucidation of statistical (correlation) relations of meaningful factors of the process quality (on the material balance) and control (ratio of dozing oxygen and methanol).

The more precise instrument for the determination of optimal methanol – oxygen mole ratio is providing ability of registration in the real time of the coefficient of material balance on the final product (relatively to the stoichiometric maximum). Therefore the system of the process control for the optimization toward the maximum of obtaining the product should be supplemented with revealing (in real time, during the control) the correlation between the measure of the fraction of the product obtained relatively to the maximum possible, and methanol – oxygen ratio, aimed at the optimization of the measure of air feeding into reactor. Hence, should be arranged continuous measuring of final product flow.

Similarly, from the measure of the final product as a fraction of maximally available can be determined state of catalyst, but by means of longer statistics.

Let us consider a mode. Let $m(CH_3OH)(t)$, g/s, is a measure of mass flow of methanol to the installation;

$M(CH_3OH)(t)$, mol/s, is a measure of molar flow of methanol to the installation;

$M(CH_3OH)$, g/mol, is molar mass of methanol,

$$M(CH_3OH)(t) = m(CH_3OH)(t) / M(CH_3OH). \quad (1)$$

The maximally available molar flow of the final product (according to the reactions 1–3, see above) is:

$$M_0(CH_2O)(t) = 1 \cdot M(CH_3OH)(t), \quad (2)$$

where 1 is stoichiometric coefficient in the reactions (1) and (2).

Actual flow of the final product is an object of measuring:

$m(CH_2O)(t)$, g/s, is a measure of mass flow of formaldehyde from the installation;

$M_1(CH_2O)(t)$, mol/s, is a measure of molar flow of formaldehyde from the installation;

$M(CH_2O)$, g/mol, is molar mass of formaldehyde,

$$M_1(CH_2O)(t) = m(CH_2O)(t) / M(CH_2O). \quad (3)$$

The relative measure of obtaining the product $\mu(CH_2O)$ is the ratio of real molar flow to the maximally possible from stoichiometry [ratio of the formulas (3) and (2)]:

$$\mu(CH_2O) = M_0(CH_2O)(t) / M_0(CH_2O)(t) \quad (4)$$

$$\mu(CH_2O) \in [0, 1].$$

Relative measure of dozing air oxygen relatively to methanol flow is defined by measurable relation:

$$\mu(O_2 \mid CH_3OH)(t) = M(O_2) / M(CH_3OH)(t), \quad (5)$$

where $M(O_2)$, mol/sec, is a measure of air oxygen flow determined from the results of measuring with ASTPC of the measure of air flow and calculated (with accounting for the analyses of oxygen content in air).

For the optimization of dozing air it is sufficient to arrange statistical procedure for reflecting the data on the relative dozing for determination (from sliding average values) of the measure of correlation (regression) connection between the measure of obtaining final product and the measure of the ratio of oxygen dozing:

$$regr(\ldots)(t) = regr(\mu(CH_2O); \mu(O_2 \mid CH_3OH)(t)) \quad (6)$$

with determination of oxygen dozing optimum for approaching the maximum of the final product yield (Fig. 1).

4. CONCERNING OPTIMIZATION OF THE PERIOD BEFORE RENEWING CATALYST

Measuring fraction of final product relatively to maximum available (according to stoichiometry of the process) allows determination of optimal time for renewing catalyst for the process of producing formalin and for other catalytic processes, e.g., the process of producing methanol, as described in [1], where had been noted that using the ASTPC system for the process of control of methanol manufacturing allows calculation on the 4-th level of "an estimation of the apparatuses productivity on crude methanol", and "the calculated data can be taken as a base for estimation of 'chemical activity' of the catalyst of synthesis".

As far as existing ASTPCs for producing a product (formalin or methanol) give the data for the calculation, in real time, of the fraction of practically obtained product as a part of theoretically possible, continuous statistical registration of this fraction allows solving the problem of state of catalyst and determining the time of its renewing (see Figs. 1 and 2).

Let $v_m(t)$ is a coefficient of effectiveness of transformation raw material into product (100% = 1). Obviously, the maximal period of using this catalyst is defined by the moment when the cost of not obtained product $C_i(t)$ (dashed area) becomes comparable with the cost for renewing the catalyst. With the data of the product cost it is ease to arrange calculation of the integral $C_i(t)$ in real time in the APM of ASTPC:

$$c_i(t) = \int_{t_0}^{t} \left(v_m(t_0) - v_m(t)\right) m(t)\, c(t)\, dt\,, \quad (7)$$

where $v_m(t_0) - v_m(t)$ is a difference between maximal initial (at preceding renewing) value of efficiency index and its current in time value (the measure of the product

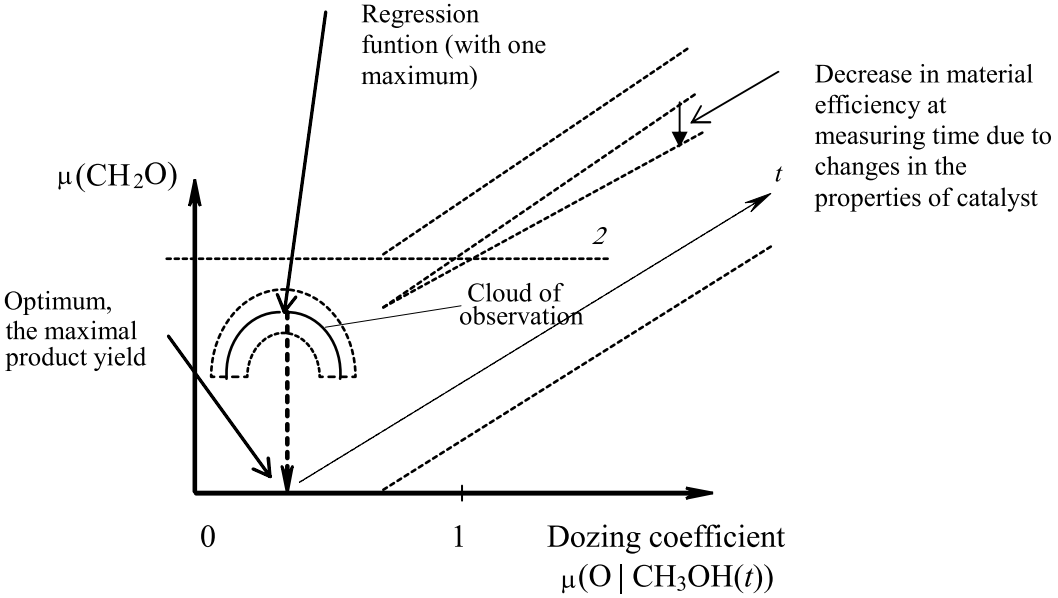

Fig. 1. Optimization diagram of the process.

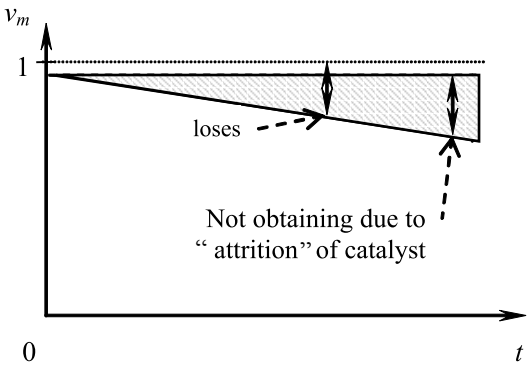

Fig. 2. Diagram of the state of catalyst.

"not obtaining"), $m(t)$ is function of measure of mass flow of final product, $c(t)$ is function of measure of the product cost (it can vary in time due to varying in prices), t_0 is the moment of beginning of use the formerly renewed catalyst.

As soon as the integral estimation of the measure of the cost of not obtained product becomes comparable with the measure of cost of the catalyst renewing (the catalyst price + cost for its mounting + product loss due to pause in the installation work), C(*catalyst renewing*),

$$C_i(t) > C(\textit{catalyst renewing}) \Rightarrow t(\textit{catalyst renewing}), \quad (8)$$

the catalyst should be renewed from the economical viewpoint (early renewing leads to extra expenses for catalyst and more product loss due to the pause for renewing; late renewing leads to increased expenses for the process due to low conversion of raw material into the product at ineffective catalyst).

Thus, calculations according to the proposed model with statistical treatment of data flows allows optimizing the process in respect of the period before renewing catalyst.

5. CONCLUSION

The problem of optimization of the process of producing formalin based on the commonly used principle of computability of unmovable point of the process control operator [14] differs from other analogous problems by complicated form of regression function, nevertheless, the method of calculation of optimal period before renewing catalyst is meaningful for this and other catalytic processes.

PROCESSES AND DEVICES OF CHEMICAL MANUFACTURES

Perfecting Construction of Metallic Packing for Random Dumping

Abstract—Problems of further development of metallic packing for mass and heat transfer units are considered.

DOI: 10.1134/S1070427208060438

Hydraulic and mass transfer characteristics of packing affect determinately efficiency of packed columns for the processes of absorption, rectification and other.

One can resume that further development of packing design will proceed with inevitable but unbiased decrease in gaining efficiency and other characteristics of new packings. Therefore every new packing that provides gain ever in only one characteristic leaving intact others is welcome. For example, diminishing hydraulic resistance ΔP provides decrease in energy consuming and increase in carrying capacity, and therefore allows to diminish diameter of column and hence to decrease weight of metal for whole unit. The same effect would be achieved at diminishing height of packing blocks and respectively of the column. Of course, it is desirable for a new packing being of the same cost to provide enhancing of two or, more so, of three characteristics. Such situation occurred in 80-th at creation in Russia of industrial packing GIAP-N3 for random dumping which was better in all characteristics than the most widespread at that time industrial packing known as Pall's rings.

Aforesaid stimulates activity in creation of new packings.

Which direction is preferable at the development of new constructions of packung?

For providing high technological characteristics, a packing should contain as high as possible pores, that is, a fraction of free volume ε needed for achieving high hydrodynamic characteristics (low ΔP, large carrying capacity), and extended geometric surface a. The last characteristic is a mandatory condition of achieving high mass transfer characteristics. However, this is just a problem, because construction of packing should satisfy two contradicting requirements: high characteristics on mass transfer that is provided by extended surface, and high turbulization of contacting phases at or near the front of their contact that inevitably deteriorates hydrodynamic characteristics, and vice versa. Therefore at the development of new packing design one should attempt to achieve optimal ε–a ratio. The problem is confirmed by the history of development of packing constructions: the way from early industrial packing, the Raschig rings [1] invented in 1914 to the modern industrial packing, the Pall rings [2] took over 40 years, therewith the mass transfer characteristics were improved by 20% only. Therefore providing 1% gain in efficiency (not deteriorating therewith other characteristics) is undoubtedly a very complicated challenge.

Experience shows that it is reasonably to work along the following directions.

Analysis of known constructions of the packing for random dump ensures [3–5] that basic form of a packing should be ring or saddle that are the most favorable from hydrodynamics viewpoint. Therefore perfecting this form packing (some of them are depicted in Fig. 1) is the most prospective. A possibility of extension the packing surface is restricted due to unavoidable complication of their construction, therefore for achieving high mass transfer characteristics should be provided effective (close to limiting) wettability of geometric surface by contacting flows. While estimating efficiency of surface wetting of a ring packing one has to pay attention to orientation of rings in a layer. According to the data of [6], chaotic

(random) loading the packing results in vertical or aslant orientation of 45% of the rings and horizontal orientation of 55% (for the rings with height equal to diameter). At vertical orientation of ring axes the rings form a structure open for flows and thus better conditions are provided for flowing over the packing element surface and for higher carrying capacity of column. However, the flow turbulization that promotes efficiency of mass transfer capacity falls down. At horizontal orientation of ring axes the mass transfer efficiency per unit of wetted surface slightly grows, but simultaneously falls fraction of using surface a, grows ΔP and falls carrying capacity.

This analysis shows that the simplest ring packing, the Raschig rings, at random packaging principally can not provide high mass transfer characteristics with high carrying capacity and low ΔP. As is known, in a layer of Raschig rings occur screening of some of elements, low accessibility of their internal surface for liquid flowing over, significant shift of liquid flow to the column walls at moving along the packing layer regardless initial distribution.

Perforation as an instrument for perfecting packing improves many features, first of all hydrodynamic characteristics and internal flowing over the ring surface. However, perforation decreases value of specific surface. The Pall rings that known as the Raschig rings with rectangle perforation and lobes bent inside the rings, retain a value and display intense mass transfer in the packing internal cavity owing additional flow turbulization by the lobes. As a result, as was mentioned above the mass transfer characteristics increase by 20%, and ΔP exerts average two-fold decrease. Nevertheless, the last characteristic remains higher than with perforated Raschig rings not bearing the lobes.

The characteristics even higher than with Pall rings were achieved with principally new construction of ring packing, the paking GIAP-N3 [7, 8]. The elements of this packing are constructed of two half-rings joined by squire separator and mutually turned by 90°C. A gap in the middle of the half-rings and, in particular, perforation of the half-rings and separator shaped as round holes provides better than the Pall rings conditions for flowing over the packing internal surface. Due to practical coinciding of ε and a values for Pall rings and GIAP-N3 the latter show by ~ 15% higher efficiency and by 20–25% lower ΔP value.

The aforesaid can be resumed that better distribution of liquid and gas phases, more complete use of the packing geometric surface, and better renewing the front of phase contact leading eventually to enhanced efficiency in mass transfer can in a great extent be provided with perforated packing elements. At the moment knowledge concerning optimal area of perforation, size of the holes and their location is practically absent (the investigations were carried out for the GIAP-N3 packing only [9, 10]), therefore it seems that further investigations in this direction is very important.

Various swirling components, lobes, projections and other construction details promote turbulization of liquid, its dispersing, and gas flow swirl. However, they unavoidably lead to increase in hydraulic resistance and decrease in maximal efficiency. Therefore investigations should be extended to searching optimal construction solutions for maximization of intensity of the mass transfer processes and minimization of ΔP grow.

To the same direction is reasonable to extend such construction features as crimping surface of packing element or rifling it for elongation of flow route, that is, for developing the surface of phase contacts and additional turbulization of the flows.

Such practice as supplementing the packing elements with separators and other additional internal surfaces increases strength of elements and expands surface of phase contact. As a rule, this lead to increase in ΔP and decrease in carrying capacity. Increase in efficiency can be achieved only in the case of high enough coefficient of use of the internal surface. The latter should be the main task in this direction of research and development.

At the development of new forms of packing constructions a special attention should be paid to creation a possibility of the most effective flowing over the internal packing surface of both flows and the most effective using the internal surface regardless orientation of the element to the column axis. Besides perforating, other methods should be found and applied, e.g., sectioning the packing surface into separate bands and bending the latter inside the packing, like in the case of metallic saddles Inatloks (Fig. 1). The mentioned above example of the Raschig rings shows how much would be efficiency loss when effective flow over the internal surface is not provided.

We suggest also that certain attention should be paid to the problem of raising strength of the packing elements. This can lead to decrease in possibility of their damage at loading and due to hydraulic shocks and to increase their running time. For metallich packing elements this can be achieved by means of bead forming at their stamping (with possible decrease in thickness of the metal, that is,

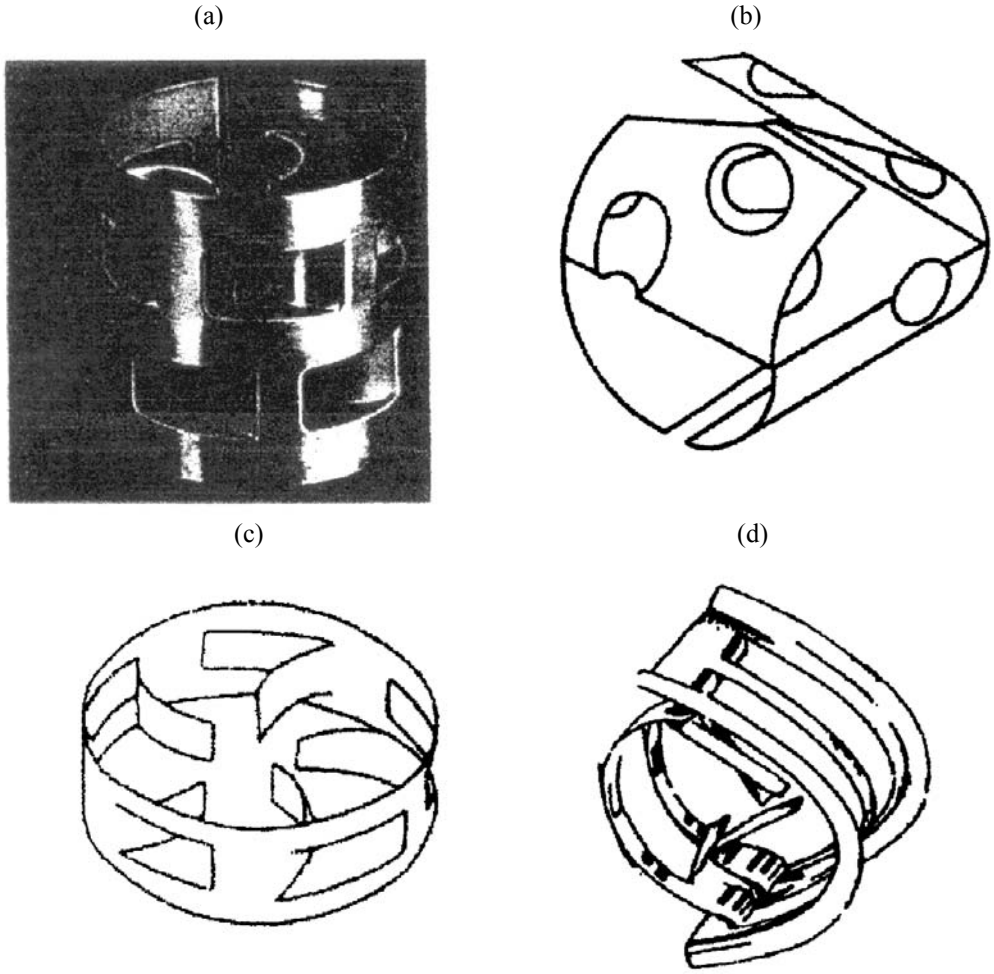

Fig. 1. Metallic packing for random dumping (a) Pall rings; (b) half-ring packing GIAP-N3; (c) miniring packing; (d) INTALOX saddles.

decrease in the packing weight per volume unit) or by means of application another technique.

An important problem for packing is increase their corrosion resistance.

For decreasing cost of metallic packing there is valuable possibility of electrochemical covering carbon steel with stainless steel [11]. Thanks to diffusion of molecules to the body bulk of a ring made of carbon steel they form cover of high strength. This excludes damage of the cover due to mutual friction of elements at their loading to column and at transportation.

Finally, an important is economical aspect, the packing cost. Therefore it seems significant now to search for new design solutions that would provide high technological efficiency and the lowest cost at the wholesale producing while retaining or enhancing main characteristics of packing. In part, metallic residues of certain profiles can be used for manufacturing.

Experience shows that expenses for consuming time and materials at the development of each new packing design or for improving an existing packing design can be reduced significantly when the fist step of investigation is blowing and study of aerodynamic characteristics of selected elements of experimental packing in a wind tunnel [12]. After introducing required corrections and achieving optimal characteristics using one element of packing can be prepared experimental batch and carried out hydrodynamic and mass transfer examination in a pilot plant installation.

PROCESSES AND DEVICES OF CHEMICAL MANUFACTURES

Separation of Various Electrolyte Mixtures by Unilateral Capillary Isotachophoresis

O. V. Oshurkova

Ioffe Physico-Technical Institute, St. Petersburg, Russia

Received October 3, 2007

Abstract—A new electrophysical method is proposed for a rapid diagnosis of liquid products relating quality and identification. The method is widely prospective for practical application.

DOI: 10.1134/S107042720806044X

Experiments on the replacement of common ion by the other ion of the same sign in the mixture of two electrolytes were realized within capillaries of a device with optic determination of boundaries by unidirectional isotachophoresis (ITP). In the work we also studied a separation on the pure electrolytes of aqueous solutions of two dyes and of several saline mixtures containing anions of organic acids. Besides we separated mixtures of the electrolytes within capillary columns using two portions of the same solution of various concentrations as catholyte and anolyte.

Acquisition of pure solutions by separation of electrolyte solutions within capillary columns in the field of direct current according to mobility of ions was first described in [1] and underlie establishment of microanalysis of complex electrolyte mixtures by ion mobility [1, 2]. The authors of [1, 2] were pioneers in developing the devices that enable the separation of electrolytes within capillaries on the zones of pure electrolytes and rendering the obtained results onto photofilm. Later the investigations in this direction were started by Martin and Everaerts [4].

Diverse solutions of electrolytes in wide range of concentrations can be studied in the capillary column can be studied. Electromigration technique for electrolyte separation within capillary developed by the authors of [1, 2] includes a quartz capillary (a separating column), high voltage power supply, electrode reservoirs for auxiliary solutions, and an arrangement for filling the capillary with sample and auxiliary solutions using at separating. It includes an optic detector to monitor the separation. Besides there is a device for recording the separation results onto a paper (shooting the obtained isotachophoregram with a photopaper). Reading the information from the photopaper is fulfilled by the measuring microscope [5].

At present large number of diverse techniques was designed for the capillary ITP with transparent and opaque capillaries of different diameters, various rearrangements for input of a sample in the capillary and plenty of sensors to record the separation of electrolyte solutions [6].

Under the influence of an electric field over the capillary length filled with solutions positively-charged particles (cationic constituents) move to cathode and negatively-charged ones (anionic constituents) move respectively to anode.

Cationic and anionic constituents of various electrolyte solutions are of different mobility. This feature of ions underlies separation of solutions. Two auxiliary solutions are used to separate the mixture of electrolytes with ITP. One of the auxiliary solutions is taken as catholyte and other, as anolyte. Since 1970 this direction has been named isotachophoresis. If the electromigration separation by the ion mobility within the capillary columns is performed with the help of one auxiliary solution possessing buffer properties then such separation is called capillary electrophoresis. Let us assume that separation of mixture of two salines containing four different ions is studied with ITP. Let it be a mixture of aqueous solutions of NaCl and $LiNO_3$. In this case it is not possible to obtain at the same time within the column two given solutions as two bordering zones of pure electrolytes NaCl and $LiNO_3$. After the separation of the mixture by ITP only

two zones can be obtained of pure electrolyte solutions with different cations and the same anion. Or on the contrary at a proper match of the auxiliary solutions the zones of pure electrolytes with different anions and the same cation can be obtained. Thus this mixture can be separated both by the difference in the mobility of cations (cationic ITP) or by the difference in the mobility of anions (anionic ITP).

For separation the studied mixture is put in the capillary column between the auxiliary solutions (between the catholyte and the anolyte). At the mixture separation according to the cation or anion mobility the different auxiliary solutions are used. At cationic separation the solution with the most mobile cation in the mixture is accepted as catholyte and then the solution with the least mobile cation in the mixture is matched as the anolyte. In the case of anionic separation the solution with the most anion mobility in the mixture is used as the anolyte and then the catholyte is the electrolyte solutions with the least anion mobility in the mixture. The matching of the auxiliary electrolytes for the solutions of the high concentrations is fulfilled according to the values of equivalent electroconductivity of solutions [8]. Suitability of the solution matching in ITP is checked experimentally. At the suitable matching the mixture of the studied ions under the electric current running through the capillary is found within capillary between the catholyte and anolyte and will be separated in the zones of the pure solutions. Each solution acquires in the column at the electrolysis one common ion coming in the solution zone from the leading solution. A place of the boundaries within capillary is defined with the detector. Correspondence of the zones to a target solution is found by comparing the primary isotachophoregram and the isotachophoregram obtained at the second separation of the mixture of the same composition by considerably increased concentration of the target constituent in the mixture. Thus the length of the single zone is largely increased. The increased zone is appropriated to the added constituent.

Cationic ITP

Before electrolysis

(catolyte) K_lA	$K_1A + K_2A$	K_tA (anolyte)
leading	mixture	terminating

After electrolysis

(catolyte) K_lA	K_1A	K_2A	K_tA (anolyte)
leading	$area_1$	$area_2$	terminating

$$u_l > u_{area1} > u_{area2} > u_t$$
$$F_l < F_{area1} < F_{area2} < F_t$$
$$\chi_l > \chi_{area1} > \chi_{area2} > \chi_t$$

Anionic ITP

Before electrolysis

(anolyte) KA_l	$KA_1 + KA_2$	KA_t (anolyte)
leading	mixture	terminating

After electrolysis

(anolyte) KA_l	KA_1	KA_2	KA_t (catolyte)
leading	$area_1$	$area_2$	terminating

$$v_l > v_{area1} > v_{area2} > v_t$$
$$E_l < E_{area1} < E_{area2} < E_t$$
$$\chi_l > \chi_{area1} > \chi_{area2} > \chi_t$$

Fig. 1. The scheme of the capillary part with the solutions before and after electrolysis at the cationic and anionic ETP, and relation of the mobility of ion constituents, the electric field strengths, and the specific electroconductivities of the pure solutions after the mixture separation on the zones of the pure solutions.

The general scheme of the location in the column of the studied mixture of two solutions, leading and terminating, before and after electrolysis in the considered types of ITP is presented on Fig. 1. A relation of the cation (u) and anion (v) mobility of the pure solutions in dependence on a solvent is denoted on the Fig. 1. Also in this figure a relation of electric field strength (E) on the parts of the pure solution and a relation of the specific electroconductivities of solutions of the pure electrolytes (χ) in the capillary in steady state [9] are appeared. A movement direction of the boundaries between electrolytes towards the walls of the separating column in the absence of electroosmotic flow and of counterflow is noted with arrows on Fig. 1. In the steady state motion velocities of the boundaries of the pure solutions acquired in result of the studied mixture separation and moving towards the column on the same direction are equal.

On Fig. 1 indexes u, v, χ, E in the bottom of the letters denote the proper solution. Index l denotes a value appropriated to leading solution. Index $area_1$ specifies a solution of the zone adjacent to the leading solution, and Index $area_2$ specifies the second solution placed between the first area and terminating solution. Letter t denotes terminating solution. The velocity of the boundary motion of the two solutions with a common ion relative to the column depends on mobility of uncommon ion, electric field strength, counterflow, and electroosomotic flow.

Counterflow, solution flow relative to the column, is the factor that allows keeping immobility of the boundaries between solutions within capillary column. Counterflow and electroosmosis, directed towards boundaries movement under the action of current promote decrease of the capillary column length. Electroosmosis as well as counterflow causes moving of the entire solution within the capillary column. Velocity of movement of the boundary between two solutions with common anion at the movement under action of current in cationic isotachophoresis is equal:

$$u_1 E_1 = u_2 E_2, \quad (1)$$

where u_1 and u_2 are different cations mobility of the solutions forming boundary ($cm^2 V^{-1} s^{-1}$); E_1 and E_2 are electric field strength in the solutions forming boundary ($V cm^{-1}$).

The boundary velocity under action of current in anionic isotachophresis respectively is

$$v_1 E_1 = v_2 E_2, \quad (2)$$

where v_1 и v_2 are uncommon anion mobility of the solutions forming boundary ($cm^2 V^{-1} s^{-1}$); E_1 and E_2 are electric field strength in the zones of pure solutions ($V cm^{-1}$).

In the steady state which is set spontaneously in isotachophoresis the solution concentrations meet to the regulating ratio of Kohlrausch [9] that is written as

$$C_l / C_{area} = T_l / T_{area}, \quad (3)$$

where C_l and C_{area} are concentration of leading solution and proper concentration of the pure electrolyte area (g.equiv/l); T_l and T_{area} are a transfer number of uncommon ionic constituents of the leading solution and the area solution within the capillary column.

The boundary between two solutions within a vertical capillary column without a filler unlike the columns of large diameters is not stirred even when solution of larger density is placed above a solution of lesser densities.

The velocity of the boundary movement between the solutions relative to the column in isotachophoresis does not coincide with velocities of boundary movement relative to the solvents of each solution.

In an experiment the transfer numbers of the ionic constituents are determined in the pure solutions relative to the solvent of this solution. Earlier such transfer numbers were called apparent.

In isotachophoresis on the solutions boundary the solvent velocity changes at solvent moving relative to the boundary from one solution into another. The solvent relative to the boundary movement moves in isotachophoresis in the strong field direction [10].

The solvent flow from leading solution to terminating solution relative to the boundary equals to [11]

$$G = g_l (W - V_l) = g_{area\,1} (W - V_{area\,1}) = g_{area\,2} (W - V_{area\,2}), \quad (4)$$

where G is the solvent flow relative to boundary ($g\ cm^{-2}\ s^{-1}$); g_l, $g_{area\,1}$, $g_{area\,2}$ are partial densities of the solvent in the leading solution and solution areas; respectively, $g\ cm^{-3}$; W is the boundary movement velocity relative to the column ($cm\ s^{-1}$); V_l, V_{area1}, V_{area2} are the solvent movement velocity of the leading first and second area solutions relative to the column.

Solvent amount coming during electrolysis from the leading solution into terminating was used for the transfer number measurement [12].

A transfer numbers sum of cationic and anionic constituents for each solution equals unity. Experimentally the transfer numbers of the ionic constituents were measured only for the leading solutions [12, 13].

It should be noted that in unidirectional isotachophoresis the common ion in the solution of all zones will be changed at replacement of this ion in the leading solution because the common ion of all the other electrolytes following the leading solution is governed by one of the leading solution ions. We use this property to form new solutions of electrolytes differing from the taken electrolyte or mixture of electrolytes by one ion.

Besides in this work the mixtures of solutions belonging to various classes of chemicals were separated to pure electrolytes. At the separation attention should be payed to the boundary between the solutions since an acquisition of the clear boundaries between the pure electrolytes and the mixture of electrolytes [14] reveals expediency of their use in electrochemical investigations as well as in works on electroseparaton and electrosynthesis.

EXPERIMENTAL

Experiments reported here were performed in U-shaped capillary column with inside diameter ranging

from 0.1 to 0.2 mm and outside diameter ranging from 0.2 to 0.4 mm. A boundary definition between the solutions was done by optical method [2, 15]. The optical method of the boundary definition is used in devices of various design and described in [2, 5, 15]. On the device [5] a capillary can be used with horizontal part of length 20–24 cm, and on the device [2] the capillary with horizontal part of length ranging from 10 to 40 cm. Length of the vertical part of U-shaped capillary used in this work was from 1 to 7 cm.

Replacement in the electrolyte solution of one ion for the other ion was carried out in the aqueous solution of $NaNO_2$ and $NaNO_3$ by anionic isotachophoresis. Mixture of $NaNO_2$ and $NaNO_3$ solutions was studied. Ion of sodium in the mixture was substituted for ion of potassium. In the study 1.0 N KCl was used as leader (anolyte) and 0.5 N $KC_7H_5O_3$ as terminator. Mixture of $NaNO_2 + NaNO_3$ solutions with chlorine concentration 1.0 g equiv/l was placed in horizontal part of U-shaped capillary between the catholyte and the anolyte (the solution column length about 6 cm) that was reached by following sample of anolyte, mixture, and catholyte in the capillary. Then we installed the capillary in the device. The ends of the U-shaped capillary put into the electrode vessels of the device. Then on the electrodes put into anolyte and catholyte voltage from a high-voltage rectifier was given. At electrolysis the boundary was kept in the horizontal part of capillary by counter flow. Theoretically the amount of electricity passed through the column should be equal to that required for deposition on the electrode of a number of gram equivalent of sodium equal to that contained in the mixture of $NaNO_2 + NaNO_3$ in the column, namely

$$It/F = CU_p, \quad (5)$$

where: I is current passing through the capillary (A); t is time (s); F is Faradey number (C/g equiv); C is concentration of the mixture (g equiv/l); U_p is the mixture volume (l).

Taking into account that at filling the capillary the solutions could mix partly with each other and also desiring in the experiment to achieve full separation of the mixture of nitrite and nitrate ions we passed through the column the larger amount of electricity than it was required for the replacement of the ions. In the experiment the current was equal to 0.5 mA and electrolysis proceeded for 2 hours. It resulted in acquisition between the catholyte and anolyte of clear zones of KNO_2 and KNO_3 solutions. Anolyte solution had a boarder with KNO_2 and catholyte, with KNO_3. Between the obtained zones of solutions of potassium nitrite and nitrate the boundary was sharp. The obtained solutions of potassium salts again were converted in solutions of sodium salts by replacement of anolyte by 2.0 N solution of NaOH. The order of passing of ions of nitrites and nitrates to an electrode at replacement of the leading solution has not changed. The zone of nitrite also concentrated ahead of a zone of nitrate.

In the work also with anionic ITP the separation of solutions of organic acid salts (formic, carbonic, acetic, propionic, salicylic, and citric acids) in the mixture onto areas of the pure solutions was studied. As leading solution (anolyte) aqueous 3.0 g equiv l^{-1} NaCl was used. A saturated borex solution was catholyte (the terminating solution). Separation results of the mixture with anions of the noted acids under 0.45 mA current during 1.5 hour electrolysis are showed on Fig. 2. On Fig. 2 a wide of a refraction picture changes in an area of the two solution interface. A dark band on the figure in the middle of the refraction picture appropriates to a parallel beam.

In this case an arrangement of the areas obtained between the leading and terminating solutions on the refraction picture corresponds to an order of the moving anions on the studied solutions when 5.0 N NaOH was used as the leading solution [16].

Beside the noted mixture we studied some solutions of dyes. At their studying with anionic ITP as leading solution an aqueous 1.0 N NaOH was used, and 0.05 N $Na_2B_4O_7$ as the terminating solution. On Fig. 3 we presented refraction picture that we observed on the device screen when only Congo red solution was in the capillary column between the leading and terminating solutions. Current run through the column was 0.025 mA. Time of the current running was about an hour. A formed dye area on the photo corresponds to a gap between two refraction pictures obtained by the beam passing through the leading and terminating solutions. The gap in the figure is caused by impenetrability of the studied dye for the beam falling on the capillary column. As shown in the Fig. 3 the dye area on the photo is clearly defined. Congo red and murexide separation is shown in Fig. 4. Two areas between anolyte and catholyte are shown on the figure: The light area of Congo red, and more dark area of the murexide solution. It is not unreasonable that light absorption by dyes can be used for defining the boundaries between the areas of solutions if their refraction pictures do not differ by size. Evidently in this case a dye flow

from one electrode solution to other is required. Then each area on the screen will have different darkening.

We like to draw attention to the width of the refraction pictures on Figs. 2–4 and to note that the width of the refraction pictures on the screen depends on a series of factors. It was shown in [17] that the width of the picture on the screen depends on solution nature and concentration. An increase in the solution concentration causes its refractive index increase that in its turn results to an extension of the refraction picture width on the device screen. In [15] the picture enlargement relative to geometric capillary parameters was studied. Both works were performed in order to increase a difference between width of the refraction pictures that reveal various areas of the pure electrolytes. However it should be noted that the most enlargement of the refraction picture it can be reached increasing the distance between the capillary column and the screen. It is shown on the figures. Figs. 2–4 were obtained when the distance between the capillary column and the screen was ranged from 5 cm to 7 cm. Fig .5 was recorded by cationic ITP separation of the mixture of cobaltous chloride and nickel chloride solutions using 7.2 N LiCl as the leading solution (catholyte and 5.0 N $CdCl_2$ as terminating solution. In this case the distance between the capillary column and the screen was increased in 2–3 times. On Fig. 5 was shown only about half of the recorded refraction picture. Entire refraction picture was not placed on the screen. If we shell observe an image obtained from the capillary column on the large screen placed on the large distance form the capillary column then on the screen the refraction picture increased would be dozens and more times in width. A factor of enlargement of the refraction picture with respect to increase of the distance between the capillary column and the screen must be studied in more detail in future. Similar investigation can widen capability of the optic boundary recording.

Except the reported experiments in the work separation of the solutions of various chlorides was studied the application of two portions of a solution of different concentrations both as catholyte and anolyte. We performed experiments according to the following method. 6.0 g equiv l^{-1} NaCl was used as catholyte, and 0.6 g equiv l^{-1} NaCl as anolyte. A solution of a mixture of lithium, copper and zinc chlorides was the separation mixture. Each salt concentration in the solution were about equal. Chlorine mixture concentration was about 6.0 g equiv l^{-1}. We put an about 1 cm of solutions mixture in the capillary column between the catholyte

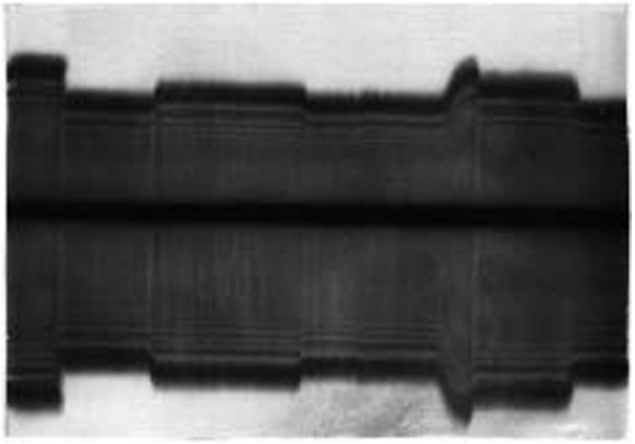

Fig. 2. The refraction picture recoded after separation of the mixture containing solutions of the organic acids salts. An order of location of the solutions in the refraction picture is from left to right: NaCl, $NaHCO_2$, Na_2CO_3, $NaC_2H_3O_2$, $NaC_3H_5O_2$, $NaC_7H_5O_3$, $Na_3C_6H_5O_7$, $Na_2B_4O_7$.

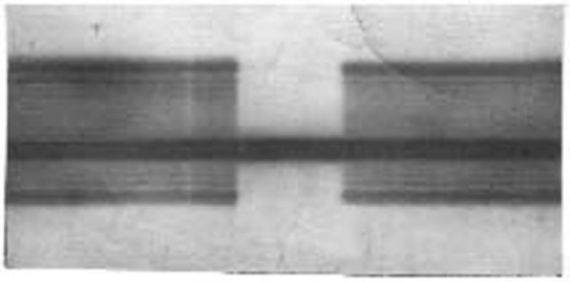

Fig. 3. Refraction picture obtained by Congo red solution study. A white bar on the figure denotes Congo red solution, on the left NaOH solution, on the right $Na_2B_4O_7$ solution.

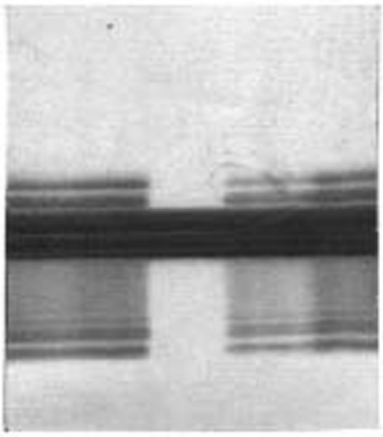

Fig. 4. Refraction picture obtained after separation of the mixture solutions of Congo red and murexide, NaOH solution is on the left, $Na_2B_4O_7$ solution is on the right, between them there are the areas of the solutions of Congo red and murexide.

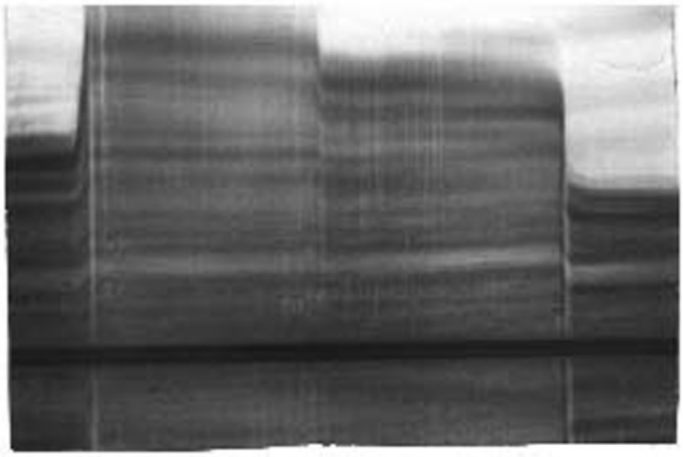

Fig. 5. The refraction picture part recorded with the separation of the cobaltous chloride and nickel chlorides solutions. LiCl solution is on the left, $CdCl_2$ is on the right, between them there are the areas of $CoCl_2$ and $NiCl_2$ solutions.

and anolyte. In the course of the electrolysis current was 0.5 mA. Time of the mixture separation was about 4 h. During this time three areas formed. A middle one was colored area of copper chloride solution, ahead of this solution was lithium chloride area, and after, was zinc chloride solution. We could not reach the steady length of the areas. In the course of the experiment the areas of solutions always changed their length. The boundaries between the solutions were not sufficiently clear. Due to decrease in the refraction picture width of areas and the unclear boundaries we assumed that the mixture constituents gradually diffuse in an anode space. Hence we carried out the following experiment. In the capillary column between the catholyte and the anolyte (6.0 N and 0.6 N HCl, respectively) we installed 4.0 N of cobaltous chloride solution. A length of the solution column in the capillary column was about 3 cm. Under running of current first we observed tuning of cobaltous chloride solution. During the experiment in course of the tuning width and length of the refraction picture from cobaltous chloride solution area ever changed. The boundary between cobaltous chloride solution and dilute HCl solution constantly moved relative to the boundary of concentrated HCl solution towards anode. Because $CoCl_2$ solution column considerably increased a device detector did not record at once both boundaries of the $CoCl_2$ solution column. Therefore in an hour of the electrolysis we removed from the capillary column HCl solution of lesser concentration and the most part of $CoCl_2$ solution. As result in the capillary column there are 6.0 N HCl and $CoCl_2$ solution column of about 1 cm of length. Then instead of removed solutions we put in the capillary column 0.6 N HCl, installed the capillary column in the device, and run current through it. First the boundaries of the small $CoCl_2$ solution column were shown sufficiently clear due to different color of the adjacent solutions. With time the area length of $CoCl_2$ solution always increased and color of $CoCl_2$ solution always turned pale. The boundaries between $CoCl_2$ solution column and 0.6 N HCl stirred. With time this results in disappearence of $CoCl_2$ solution from the capillary column. In the capillary column there was only one concentration boundary: the boundary between the catholyte (6.0 N HCl) and the anolyte (0.6 N HCl). Thus the experiments with use of two portions of different concentrations of the same solution both as catholyte and anolyte for separation of the mixture constituents revealed that at the mixture separation an amount of the mixture constituents in the capillary column constantly decreased.

CONCLUSION

The obtained results are of interest both for practical use and for development of a theory about strong solutions of electrolytes. Our experiments reveal that the study of the separation of electrolytes by electric current in the capillary columns can be carried out in a wide range of concentrations. Also the experiments prove capability of the studying substances to electrosynthesis and electroseparation, allow the recognizing of arrangement in the motion decrease of different ions of the studied solutions in comparison with the motion of different ions of the leading and terminating solutions, and the estimating of relation between the motions of ions of the mixture constituents (greater or lesser). According the experiments can be extended the recording of the boundaries on the refraction picture by the different light absorption of solutions. A considerable increase of the refraction picture width was shown at increase of the distance between the capillary column and the screen. It is not unreasonable that the increase of distance enables to improve of the recording of boundaries on refraction pictures in transparant capillary columns. However it should be noted that we did not obtain the steady state area (see [18]) using two portions on the same electrolyte of different concentrations both as catholyte and anolyte. The separation on areas conducts without reaching the steady state in these areas. Therefore application for separation of the mixture of two different solutions as catholyte and anolyte is without doubt more promising

than the use of two concentrations of the same solution. However use of two portions of the same solution of different concentrations as catholyte and anolyte allows the observation of the unsteady boundaries in the capillary columns between pure solutions of electrolytes and mixtures that expands experimental base for study of the steady and unsteady boundaries between the solutions of electrolytes and their mixtures.

MODELLING AND CALCULATION OF TECHNOLOGICAL PROCESSES

Simulation of Optimum Thickness of Acceleration Blades of a Rotary Centrifugal Grinder

A. A. Garabazhiu

Belarussian State Technological University, Minsk, Belarus

Received March 19, 2007

Abstract—We developed a method of optimum thickness simulation for the acceleration blades of the rotary centrifugal grinder. We also deduced an empirical relation that sufficiently exactly determines a minimum thickness of the acceleration blade in dependence on a currents grinder radius.

DOI: 10.1134/S1070427208060451

The energy-saving rotary centrifugal grinder with continuously flow-through classification of a product was developed in the Belarussian State Technological University ten years ago and was still in great demand in various branches of industry of Belarus. Today research workers of the university under Prof. E. I. Levdanskii developed a line of energy-saving rotary centrifugal devices of analogues operation principles and of various applications [1, 2].

Design features and principle of operation of the energy-saving rotary centrifugal grinder with continuously flow-through classification of product were set out in [2–5].

At developing the industrial sample of this grinder a simulation of the optimum thickness of the main (or the most important) design elements arouse great practical interest. An algorithm and results of a strength design of a grinder rotary disk and a bearing plate were presented in [6]. Estimation of the optimum thickness of the main design elements of the rotary centrifugal grinder allows acquisition of high reliability and wear life of the device as a whole.

A rotor of the energy-saving grinder with continuously flow-through classification of a product [2–5] has eight acceleration radial blades that are firmed to the rotary disk of the grinder at a right angle to its upper end surface

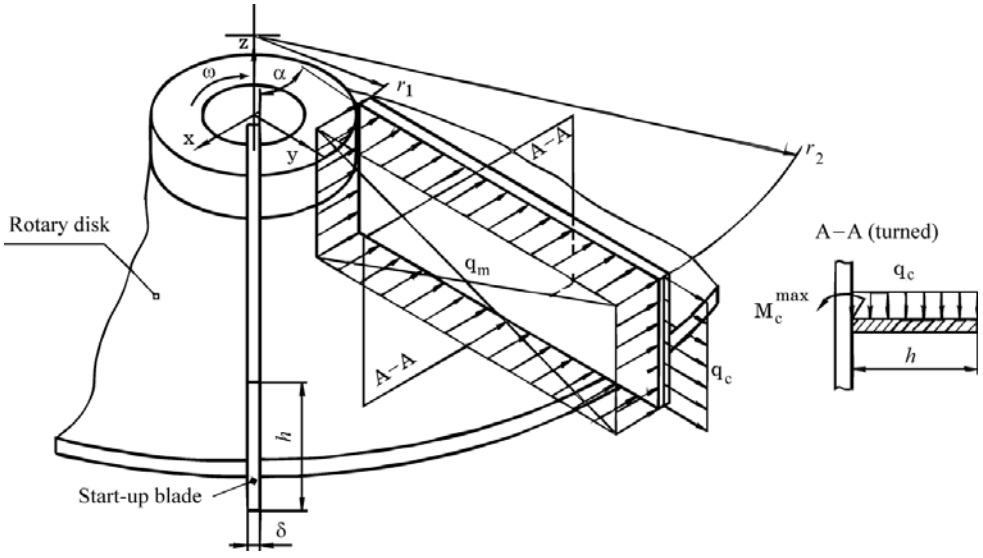

Fig. 1. A scheme for the strength design of the acceleration blade of the rotary centrifugal ginder. r_1 = 0.12 m, r_2 = 0.3 m, δ = 0.005 m, h = 0.08 m, ω = 314 rad s^{-1}, α = 45°.

(Fig. 1). The acceleration blades are made of wear-resistant steel (eg., Steel 35G2 GOST 4543-71) supplied as a sheet rolled metal.

The strength design of the grinder acceleration blade can be done according to [7] assuming the blade as an outrigger of rectangular section loaded by forces of the processed materials (P_m) in the space between the blades of the grinder rotary and by a centrifugal force (P_c).

A scheme for a computation of the acceleration blade of the rotary centrifugal grinder is presented on the Fig. 1.

For defining the maximum bending moment effected on the acceleration blade it is first required to estimate the centrifugal force values P_c and the force P_m.

The centrifugal force P_c, acting on the acceleration blade is calculated with the following equation:

$$P_c = m_b \omega^2 r_i, \quad (1)$$

where m_b is the mass of one acceleration blade, kg; ω is radial velocity of the grinder rotor, rad s^{-1} (ω = 314); r_i is the current radius of the acceleration blade, m ($r_i \in [r_1; r_2]$); r_1 is a start radius of the acceleration blade, m ($r_1 = 0.12$); r_2 is a finish radius of the acceleration blade, m ($r_2 = 0.3$).

The acceleration blade mass may be obtaines as:

$$m_b = h \delta_j r_i \rho_b, \quad (2)$$

where ρ_b is the density of the blade material, kg/m^3 (ρ_b = 7790 kg/m^3 for steel 35G2 GOST 4543-71); h is the acceleration blade height, м ($h = 0.08$); δ_j is the current blade thickness, m.

The centrifugal force P_c is evenly distributed over the whole blade height with intensity q_c (Fig. 1)

$$q_c = \frac{P_c}{h}, \quad (3)$$

The maximum bending moment (M_c^{max}) of the centrifugal force P_c in a place of the acceleration blade fixing to the rotary disk of the grinder is computed by the following equation:

$$M_c^{max} = \frac{1}{2} q_c h^2. \quad (4)$$

After appropriate substitutions the equation (4) was transformed in:

$$M_c^{max} = \frac{1}{2} \delta_j \rho_b \omega^2 r_i^2 h^2. \quad (5)$$

It is assumed that in course of the rotary centrifugal grinder operation [2–5] the processed material entirely fills the rotor space between the blades (a boundary case) and presses down with the force P_m on the flat surface of the acceleration blades. In this case the force P_m is defined according with equation (6).

$$P_m = m_m g, \quad (6)$$

where m_m is the mass of processed material (eg., gypsum) filling the rotor space between two adjacent blades, kg; g is gravitational acceleration, m s^{-2}.

The processed material mass can be computed with

$$m_m = V_m \gamma_p, \quad (7)$$

where V_m – is the processed material volume filling the rotor space between two adjacent blades, m^3; γ_p is poured density of the processed material, kg/m^3 (γ_p = 1200 kg/m^3 for gypsum).

It is assumed that the processed material fills the rotor space between two adjacent blades in a form of right trapezoidal prism of a height h and with angle between its two sides a (Fig. 1). Then after appropriate trigonometric transformations the processed material volume V_m is calculated as

$$V_m = \frac{1}{2} (r_2^2 - r_1^2) h \sin \alpha, \quad (8)$$

where α is an angle between internal longitudinal surfaces of two adjacent blades of the grinder rotor, deg (α = 45°).

The processed material force P_m is evenly distributed over the whole blade height with intensity q_m (Fig. 1)

$$q_m = \frac{P_m}{h}. \quad (9)$$

The maximum bending moment (M_m^{max}) of the force P_m in a place of the acceleration blade fixing to the rotary disk of the grinder is computed by the following equation:

$$M_m^{max} = \frac{1}{2} q_m h^2. \quad (10)$$

After appropriate substitutions the equation (10) was transformed in:

$$M_m^{max} = \frac{1}{4} (r_2^2 - r_1^2) h^2 \gamma_p g \sin \alpha. \quad (11)$$

A resultant bending moment M_{bend} from the action of the centrifugal force P_c and the force P_m will equal

$$M_{bend} = \sqrt{(M_c^{max})^2 + (M_m^{max})^2} \quad (12)$$

For the outrigger of rectangular section a bending stress is expressed by the equation:

$$\sigma_{bend} = \frac{M_{bend}}{W_r}, \quad (13)$$

where W_r is the resultant moment from a resistance of the acceleration blade cross-section area, cm^3. For our case

$$W_r = \sqrt{W_x^2 + W_y^2}, \quad (14)$$

where W_x, W_y are the resistance moments of the acceleration blade cross-section area with respect to axis x and axis y, cm^3.

For the acceleration blade of the rectangular section we have (Fig. 1) [8]:

$$W_x = \frac{\delta_j (r_2 - r_1)^2}{6}, \quad (15)$$

$$W_y = \frac{(r_2 - r_1)\delta_j^2}{6}. \quad (16)$$

After substitution and appropriate transformations an equation (13) will look as:

$$\sigma_{bend} = \frac{3h^2}{\delta_j (r_2 - r_1)} \times \sqrt{\frac{\delta_j^2 r_i^4 \rho_b^2 \omega^4 + \frac{1}{4}(r_2^2 - r_1^2)^2 \gamma_p^2 g^2 (\sin\alpha)^2}{\delta_j^2 + (r_2 - r_1)^2}}. \quad (17)$$

The largest tangential stress (a shear stress) for the outrigger of the rectangular section is calculated by the following equation [8]

$$\tau_{sh}^{max} = \frac{3}{2}\frac{Q_p}{F}. \quad (18)$$

where Q_p the resultant cross force acting on the outrigger in the considered rectangular section, N, F is an area of the outrigger cross section, m^2.

In our case

$$Q_p = \sqrt{P_c^2 + P_m^2}, \quad (19)$$

and

$$F = (r_2 - r_1)\delta_j. \quad (20)$$

Then after substitution and appropriate transformations equation (18) will look as

$$\tau_{sh}^{max} = \frac{3h}{2} \times \frac{\sqrt{\delta_j^2 r_i^4 q_b^2 \omega^4 + \frac{1}{4}(r_2^2 - r_1^2)^2 \gamma_p^2 g^2 (\sin\alpha)^2}}{(r_2 - r_1)\delta_j}. \quad (21)$$

Equivalent stresses acting on the acceleration blade of the grinder rotor can be defined according to equation (22) [9]

$$\sigma_{equiv}^{III} = \sqrt{\sigma^2 + 4 \cdot (\tau_{sh}^{max})^2} \le [\sigma]. \quad (22)$$

The comprehensive analysis of the Eqs. (17), (21), and (22) suggests that a dependence of the equivalent stresses σ_{equiv}^{III} on the acceleration blade thickness δ_j is of quadratic character. Hence a minimum permissible thickness of the acceleration blade of the grinder can obtained by equation (23) [10]

$$[\delta_j] = \sqrt{\frac{\sigma_{equiv}^{III}}{[\sigma]}}\,\delta_j, \quad (23)$$

where $[\sigma]$ is the assumed value of the blade material stress, MPa ($[\sigma] = 180$).

The main results of a simulation of the acceleration blade optimum thickness are presented on Figs. 2, 3.

Approximating the curve $[\sigma] = f(r)$ (Fig. 3) we obtained an empirical dependence $[\sigma] = -2 - 15r^3 - 7.34 / \ln r$ that quite exactly allows estimating the minimum permissible thickness of the acceleration blade in dependence in its current radius.

Methods presented in this work and in [6] of the optimum thickness computation for the rotory disk, the bearing plate, and the acceleration blades of the rotory

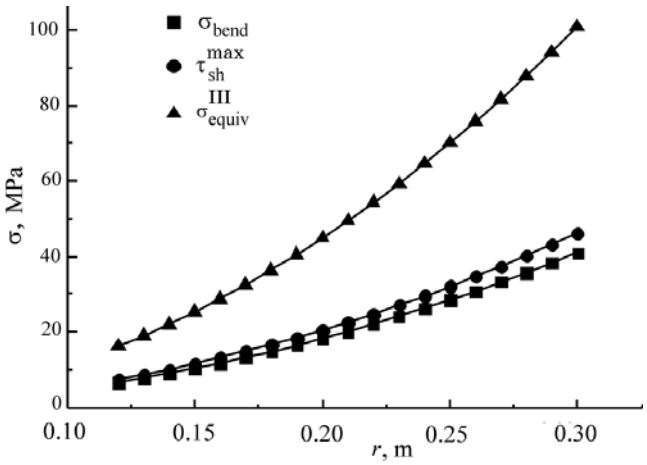

Fig. 2. The dependence of the bending stresses, the section, and equivalent stresses on the current radius of the grinder acceleration blade.

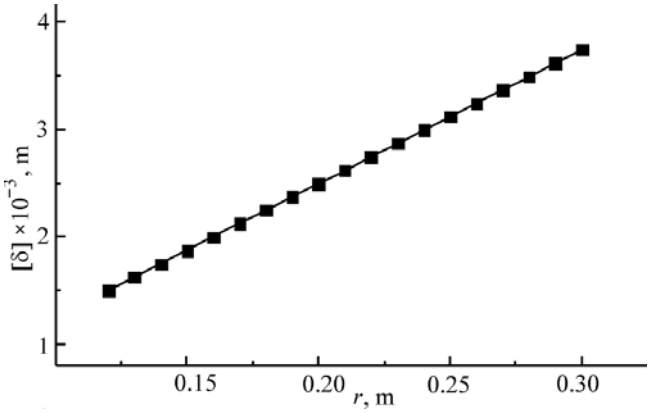

Fig. 3. The dependence of the minimum permissible thickness of the grinder acceleration blade on its current radius.

centrifugal grinder should be used for the strength design of appropriate machine elements and devices with the same operation principle.

INDUSTRUAL ECOLOGY

Effect of Nitrocalcuumphosphate Fertilizer on the Potato Yield and Quality

M. K. Abdurakhmanov

Samarkand State University, Samarkand, Uzbekistan

Received November 9, 2007

Abstract—This report lists results of testing a new fertilizer, nitrocalciumphosphate (NCF) produced by open join stock company "Samarkandkimye", on the grow, develop and yield of potato under conditions of Golodnaya Step' area of Uzbekistan. From the experimental results is defined year norm of the fertilizer on typical gray desert soil of low salinity: 20 ton of semi-rotten manure + $N_{220}P_{165}K_{125}$ kg per hectare. For soils of moderate salinity is recommended to apply 40 ton of semi-rotten manure + $N_{220}P_{165}K_{125}$ kg per hectare. It is confirmed that application of organic and mineral fertilizers for potato at optimal norm improves feeding regime of soil, increases yield and quality of tubers and improves significantly meliorative situation in solanized soil.

DOI: 10.1134/S1070427208060463

In correspondence with the Entrustment of Government of the Republic Uzbekistan No. 3057-xx of June 13, 2005, on the Samarkand chemical plant (open join stock company "Samarkandkimye") in 2005 started exploitation of experimental industrial installation producing nirocalcuimphosphate fertilizer with productivity 50 000 ton per year.

Technology of the nirocalcuimphosphate fertilizer is absolutely free of by-product. The fertilizer contains totally more feeding components ($N + P_2O_5 = 22–23\%$) than traditional ammonized superphosphate (13–14%). More so, while superphosphate contains 50% of gypsum as a ballast, the nirocalcuimphosphate fertilizer instead contains assimilable calcium nitrate. That is why the nirocalcuimphosphate fertilizer is very active on the soils of any type, the salinizated ones in particular. It is substantially more effective for the plants needed continuous inflow of calcium to the zone of growing stem, root and fruit elements.

By the investigation we revealed that on soddy podzolic soil with light granulometric composition it is economically profitable to apply organomineral fertilizers that promote high yield of potato with high quality and keeping ability of the product, increases biological activity of soil and affects positively further crop rotation and the soil fertility characteristics [1].

Effect has been studied of increasing dozes of potassium fertilizers on the dynamics of exchangeable potassium in the irrigated chestnut soil. Their influence on the yield, biochemical and mineral composition of potato was revealed [2]. In Uzbekistan were tested the sorts Sante, Condor and Licariya on the background of 20 ton of manure + $N_{200}P_{160}K_{100}$ at the density of the plants 71400 units. The testes showed that early yield can be obtained at least 25 ton per hectare [3]. Manure and other organic fertilizers for potato should be introduced only in autumn at fall plowing or to preceding culture [4].

Current investigations were aimed at the study of potato feeding regime under the conditions of the soil in Golodnaya Step' and revealing the fertilizer optimal year norm. We studied the following:

– Yield of potato without a fertilizer in account of precursors and the soil natural fertility;

– Yield and quality of potato tubers at growing them with mineral fertilizers;

– Effect of organic and mineral fertilizers on the potato yiels;

– Effect of organic and mineral fertilizers on the meliorative state of salinizated soils.

From the results of experiments the following optimal schedule of introducing fetrilizers is revealed. Before autumn plowing to the low salinizated soil should be introduced 20 ton per hectare, to strongly solinated 40 ton per hectare of semi-rotten manure and year norm of potassium. A half of year norm of phosphate fertilizers should be introbuced before plowing and a half at

first feeding. A half of the year norm of nitrogen fertilizers should be introduced at appearing of sprouts and the rest at abundant budding of plants..

The influence of organic and mineral fertelizers on the growing and development of potato is shown in Table 1.

From the data of Table 1 follows that increase in the fertilizers norm affects positively on the potato plant height, and this regularity is continuous.

At growing potato without fertilizers the plants height at the end of vegetation was 50.3 cm, with mineral fertilizers only it was from 65.3 to 74.8 cm.

At introducing to the soil 20 ton of semi-rotten manure the plant height was 71.7 cm. With 20 ton of semi-rotten manure + N_{220} P_{165} K_{125} kg per hectare the plant height was 78.4 cm, number of stems 3.8, number of leafs 180.4, number of axillary shoots 8.9, duration of vegetation period 87 days. At introducing 40 ton of semi-rotten manure + N_{220} P_{165} K_{125} the related values are, respectively: 81.9; 3.8; 194.7; 14. 2; 89.0.

At growing potato without fertilizers the height, development and yield depend both on te soil natural fertility and fertilizers introduced with preceding cultures.

The highest plant grow, leaf surface and biological mass of potato were achieved at introducing 20 and 40 ton per hectare of semi-rotten manure with year norm of mineral fertilizers N_{220} P_{165} K_{125}. When potato grows without fertilizers, its haulm turns yellow at 82th day after coming up; at introducing fertilizers according to year norm the vegetation period duration is 87–89 days.

At growing potato without fertilizers (Table 2) the characteristics of biochemical composition of tubers falls, but this characteristics in a great extent depends on genetic features, therefore it depends insignificantly on the agricultural technology.

Feeding regime affects significantly the potato yield. In the experiments of growing without fertilizers the yield is 5.6 ton per hectare, commercial part of tubers is 80 %. On the experimental fields the highest yield was achieved with 40 ton of semi-rotten manure + N_{220} P_{165} K_{125} kg per hectare, and with 40 ton of semi-rotten manure + N_{300} P_{224} K_{170} kg per hectare, the yield was 17.0 and 17.4 ton per hectare, respectively.

When mineral fertilizers are introduced according to higher norm, N_{300} P_{224} K_{170} kg per hectare, the tubers contain more nitrates affecting negatively the tubers, reducing their keeping and foodstuff quality. Application of fertilizers according to the high norm in Golodnaya Srep' detiorates significantly aero-ecological situation in the soil.

Table 1. Influence of organic and mineral fertilizers on the potato growing and development (2004–2006)

No.	Experiment mode	Griwing and development of plants				
		Height, cm	Number of stems, units	Number of leafs, units	Number of sprouts, units	Vegetation period duration, days

Table 2. Effect of organic and minerql fertilizers on the potato biochemical composition and yield (2004-2006)

No.	Experiment mode	Content in tubers			Yield of quality tubers, %	Yield, ton per hectare	Extra yield over control, ton per hectare
		Starch, %	Protein, %	Vitamine C, mg/100 g			
1.	Control (no fertilizer)	13.1	1.3	15.2	80	5.6	0.0
2.	$N_{150}\,P_{112}\,K_{85}$	13.5	1.3	15.4	84	9.1	+3.5
3.	$N_{220}\,P_{165}\,K_{125}$	13.5	1.4	15.5	85	9.4	+3.8
4.	$N_{300}\,P_{224}\,K_{170}$	13.6	1.4	15.5	85	9.5	+3.9
5.	20 ton per hectare semi-rotten manure	13.7	1.4	16.6	86	10.6	+5.0
6.	20 ton per hectare semi-rotten manure + $N_{150}\,P_{112}\,K_{85}$	13.6	1.4	15.6	87	12.2	+6.6
7.	20 ton per hectare semi-rotten manure + $N_{220}\,P_{165}\,K_{125}$	13.7	1.3	15.7	87	12.6	+7.0
8.	20ton per hectare semi-rotten manure + $N_{300}\,P_{224}\,K_{170}$	13.7	1.4	15.7	89	13.1	+7.5
9.	40ton per hectare semi-rotten manure	13.2	1.4	15.5	89	13.6	+8.0
10.	40 ton per hectare semi-rotten manure + $N_{150}\,P_{112}\,K_{85}$	13.7	1.4	15.8	90	16.2	+10.6
11.	40 ton per hectare semi-rotten manure + $N_{220}\,P_{165}\,K_{125}$	13.8	1.5	15.8	92	17.0	+11.4
12.	40 ton per hectare semi-rotten manure + $N_{300}\,P_{224}\,K_{170}$	13.8	1.5	15.9	93	17.4	+11.8

Difference in yield for the cases 11 and 12 is within the experimental error. Therefore we recommend to apply 40 ton of semi-rotten manure + $N_{220}\,P_{165}\,K_{125}$ kg per hectare at scaled growing.Then yield is 17.0 ton per hectare, by 11.4 ton per hectare higher than in the control experiments. Our experiments showed that introducing in autumn 20 and 40 ton per hectare of semi-rotten manure leads to decrease in spring of negative influence of soil salinization and improves soil melioration.

We recommend to introduce year norm of the fertilizer in the following order. 125 kg of potassium is introduced to fall-plowed field in autumn. A part of phosphoric fertilizer (80 kg) should be given to the fall plowed field and remaining 85 kg at first top dressing. Of nitrogen fertilizer, 110 kg is added before full sprouts appearing and the rest (110 kg) at second top dressing, that is, at full budding.

Thus, by our experiments we revealed year norm of the fertilizer for typical low salinizated gray desert soil: 20 ton of semi-rotten manure + $N_{220}\,P_{165}\,K_{125}$ kg per hectare. For the merely salinizated soil under the conditions of Golodnaya Step' we recommend to apply 40 ton of semi-rotten manure + $N_{220}\,P_{165}\,K_{125}$ kg per hectare. The experiments confirmed that application of these organomineral fertilizers for potato according to the optimal norm improves feeding regime of the soil, increases yield and quality of tubers and simultaneously improves considerably melioration state of the salinizated ground

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Process for Production of Granulated Soluble Glass in Ore-Thermal Furnaces

Abstract—A process for production of soluble sodium glass in electric-arc ore-thermal furnaces with three graphite electrodes was suggested and tested on the industrial scale. Fusion of sand with sodium carbonate, followed by rapid cooling of the fusion cake with cold water, yields finely grained sodium metasilicate with a developed network of microcracks as a result of a thermal impact in the course of aqueous granulation of the fusion cake.

DOI: 10.1134/S107042720807001X

Salts of silicic acids (silicates) are mostly insoluble in water, with the exception of sodium and potassium metasilicates (Na_2SiO_3 and K_2SiO_3). Owing to the outward similarity with glass and to their solubility in water, these two compounds are named soluble glass. Its aqueous solutions (liquid glass) are widely used in building, chemical, glassware, petroleum, petrochemical, ore-dressing, metallurgical, paper, textile, soap, and other industries.

There exist several methods for preparing soluble glass [1], of which the most widely used is the carbonate technique based on the reaction of sodium and potassium carbonates with silicon oxide at the melting point (1400–1500°C):

$$M_2CO_3 + SiO_2 = M_2SiO_3 + CO_2\uparrow, \quad (1)$$

where M stands for sodium or potassium.

The most important characteristic of a soluble glass, which predetermines its consumers' properties, is its silicate ratio M, defined as the weight ratio between silicon oxide and sodium (potassium) oxide in the glass:

$$M = [SiO_2]/[M_2O]. \quad (2)$$

The industry manufactures the soluble glass as silicate lumps, which are crushed and subjected to autoclave dissolution in a NaOH solution to give liquid glass. The process in which a liquid glass is obtained from a silicate lump has rather high cost and low output capacity, because it involves energy-intensive stages of crushing of silicate lump and its subsequent autoclave dissolution (during several hours) with expensive sodium hydroxide. To improve the economic efficiency of the process for producing sodium liquid glass from soluble glass, we suggest a process for fusion of soda with sand in an ore-thermal furnace, followed by rapid cooling of the fusion cake with water. The process we suggested and tested can produce granulated sodium metasilicate, whose processing to liquid glass is economically more attractive, compared to processing of silicate lumps.
