We used natural silica containing 98.0–98.8 wt % SiO_2 (Table 1) as a silica-containing raw material for production of a silicate granulate [2]. Data on the quality of soda used to prepare a stock with sand are listed in Table 1. To obtain a silicate granulate, commercial sodium metasilicate, we mixed sand and soda to obtain a prescribed silicate ratio of the stock. The stock was charged into a graphite crucible and fused in an ShP-1 furnace for 30 min at a prescribed temperature. The fusion cake was granulated in water with an initial temperature $T \approx 20$°C at s : l ≈ 1 : 15 (no "pops," vapor discharges, or other dangerous events were observed in fusion cake granulation). The silicate granulate was separated from water and analyzed for the content of oxides of silicon, sodium, and impurities.

Table 1. Chemical composition of stock components

Component	Content, wt %

	SiO_2	Na_2O	$Al_2O_3 + Fe_2O_3$	CaO + MgO	
Silica 1	67.2	28.1	<1.1	0.2	2.39
Silica 2	71.6	26.4	<0.49	<0.05	2.71
GOST 13079–73:	from 70.8 to 73.4	from 25.3 to 28.1	≤0.9	≤0.4	2.6–3.0

The results of experiments in which the silicate granulate was obtained demonstrate (Table 2) that the product nearly satisfies the requirements of GOST (State Standard) [3]. The fusion cakes become more fluidized as the silicate ratio is lowered from 3 to 2 and the fusion temperature is raised from 1350 to 1450°C. It was found that the fusion temperature of 1400–1450°C provides satisfactory fluidization of the fusion cakes if the stock used has a silicate ratio of 2–3.

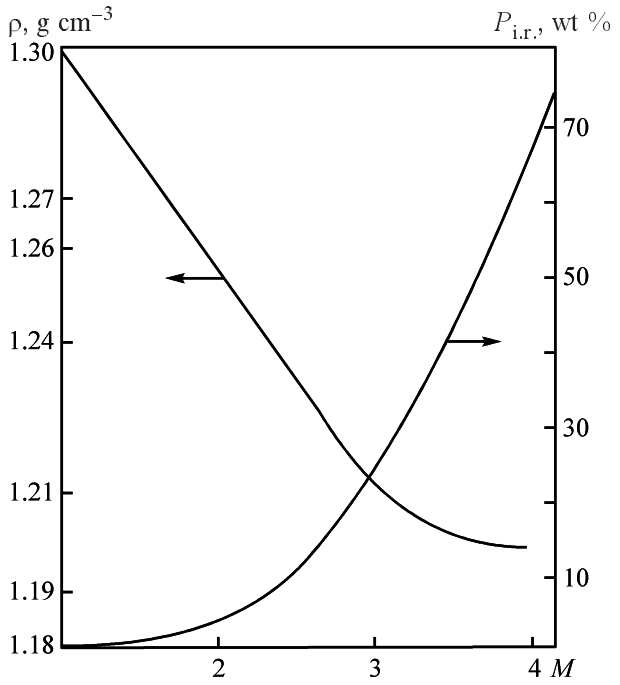

Fig. 1. Predictive estimate of how the density ρ of liquid glass and yield of the insoluble residue, $P_{i.r.}$, depend on the silicate ratio M of the silicate granulate (based on the results of 6–7 runs).

We assessed the possibility of preparing the liquid glass [2] from the silicate granulates and the silicate lump, obtained in the mode being tested (the production of silicate lump ended in cooling of the sodium metasilicate melt in air).

The solubility of sodium metasilicate, one of the most important technological properties of this compound, should provide production of solutions with a density of 1.36–1.52 g cm^{-3} [4]. To find out how the density of a liquid glass depends on the silicate ratio of the starting stock, we dissolved silicate granulate samples with different silicate ratios under the same conditions. The dissolution was performed in the course of 4 h at s : l = 1 : 2 under boiling. The results obtained are shown in Fig. 1. In the mode tested for dissolution of the silicate granulate, a decrease in the silicate ratio from 3–4 to 1 makes it possible to raise the liquid glass density from 1.18–1.21 to 1.30 g cm^{-3}, which is, however, lower than the standard value (1.36–1.52 g cm^{-3}). The required density of solutions was only achieved by their evaporation, which is economically inefficient

under industrial conditions. Positive results were obtained after preliminarily crushing the granulates to a grain size of less than 0.1 mm and raising the dissolution duration to 5 h (Table 3). However, a noticeable amount of an insoluble residue remained in this case (14 wt % relative to the initial amount of the silicate granulate), which required that the dissolution mode should be improved. Nevertheless, the experiments performed demonstrated that the liquid glass can be, in principle, obtained from a silicate granulate with a minimum expenditure for diminution of the raw material, without an autoclave and sodium hydroxide. This makes this kind of raw materials more promising than the silicate lump dissolved under industrial conditions (after its energy-intensive crushing) in autoclaves under a pressure of 5 atm in the course of 3 h with the use of sodium hydroxide. The high promise of processing of sodium metasilicate in the form of the silicate granulate, compared to the conventionally used silicate lump, was confirmed by comparative tests (Fig. 2).

The higher solubility of the silicate granulate, compared to the silicate lump, is due to the finer grain of the raw material and presence of a large number of microcracks in grains as a result of the thermal impact in the course of aqueous granulation of the molten glass. The higher dissolution rate of the silicate granulate, compared to silicate lumps, made it possible to diminish the expenditure of the alkali and steam in its autoclave dissolution under industrial conditions, which is one of the most important advantages of the silicate granulate. This was done in the course of industrial tests without grinding of the silicate granulate.

In industrial tests of the method for production of the silicate granulate, we perfected the technology of fusion of the silica–soda stock in electric-arc ore-thermal furnaces with three graphite electrodes (Fig. 3) at UMZ Joint-Stock Company [2]. In the tests, we manufactured two pilot batches of the silicate granulate (approximately 90 t each) from the raw material presented in Table 4. Both batches of the silicate granulate were industrially processed into liquid glass at Vostokmashzavod Joint-Stock Company (Ust-Kamenogorsk).

When producing the pilot batches of the silicate granulate, we used the following raw materials: stock no. 1 in the first stage of the study and stock no. 2 in the second stage (Table 4). The stock was melted at $T \approx 1400$°C. The melt was poured from the furnace into a granulator filled with water, with fine grains of the silicate granulate obtained. The product was transported in containers to Vostokmashzavod Joint-Stock Company to be processed into liquid glass.

Table 3. Effect of the duration τ of dissolution of a ground silicate granulate on the completeness of its dissolution. Silicate ratio of the starting stock 2.5

Run no.	τ, h	Solution density, g cm^{-3}	Yield of insoluble residue, wt %
1	1	1.24	–
2*	3*	1.36	25
3	5	1.41	14

* In run no. 2, the slurry formed upon 1 h of dissolution was kept for 16 h without heating and agitation, after which the product was additionally dissolved in the course of 2 h under heating and agitation.

Table 5 lists the results of analyses of the first and second pilot batches of the silicate granulate. In the first stage of the tests, the silicate granulate failed to conform to the existing regulations because of the poor quality of soda (Table 5); in the second, the product satisfied the requirements of GOST 13079–73.

It was shown in further processing of the silicate granulate batches at Vostokmashzavod Joint-Stock Company that they are suitable for manufacture of casting molds and mold cores.

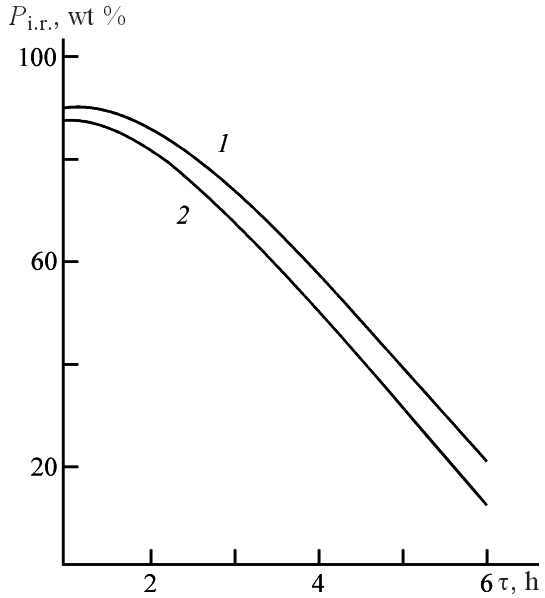

Fig. 2. Yield $P_{i.r.}$ of the insoluble residue vs. the dissolution time τ of (*1*) silicate lump and (*2*) silicate granulate.

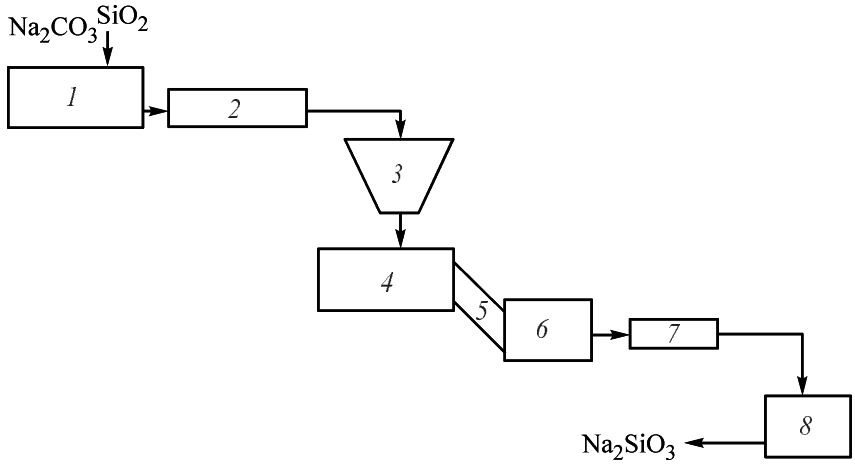

Fig. 3. Schematic of the apparatus for production of the silicate granulate: (*1*) stock scale, (*2*) belt conveyor, (*3*) furnace bunker, (*4*) ore-thermal furnace, (*5*) overflow gutter, (*6*) granulator, (*7*) vibration transporter, and (*8*) container.

The pilot batches of the silicate granulate were subjected to an autoclave treatment with addition of a sodium hydroxide solution. In contrast to the silicate lump case, this was done without preliminary crushing of the silicate granulate. The resulting liquid-glass solution was used to fabricate casting molds and mold cores. Table 6 lists data on the content of the insoluble residue in the liquid glass produced from the first and second batches of the granulate and on the chemical composition of the insoluble residue and presents the amount of the insoluble residue formed in processing of the silicate lump from Salavat-steklo plant (Bashkortostan). A considerable decrease in the content of the in-

		SiO_2	Na_2O	Al	Fe	Ca
1	20	68.5	12.2	0.98	1.65	0.6
2	3.5	36.1	16.4	2.1	0.06	0.25
Silicate lump	2.6	–	–	–	–	–

soluble residue was observed when processing the second batch of the granulate, which is due to the use of purer soda in stock formulation (Table 6). The insoluble residues are strongly contaminated with aluminum, iron, and calcium impurities and, therefore, cannot be completely recycled into the stage of sand fusion with soda. The mass of the insoluble residue can be reduced by using purer sand and soda, which will make it possible to lower the amount of the residue to that obtained when processing the silicate lump manufactured by Salavatsteklo Company (Table 6).

During the industrial tests aimed to obtain a liquid glass, we monitored its quality after each dissolution of the second batch of the silicate granulate (Table 7).

The data in Table 7 indicate that a liquid-glass batch satisfying the foundry requirements was obtained from the second batch of the silicate granulate. Compared to the conventional processing of the silicate lump, the processing of the silicate granulate does not require its crushing before dissolution, the dissolution rate of the material increases, and, simultaneously, the expenditure of steam noticeably decreases and the consumption of sodium hydroxide in dissolution becomes two times smaller.

Table 7. Quality of liquid glass produced at Vostokmashzavod Joint-Stock Company

Liquid-glass sample no.	Density, g cm^{-3}	Silicate ratio
1	1.49	2.41
2	1.50	2.56
3	1.52	2.56
4	1.50	2.56
5	1.53	2.56
6	1.46*	2.68*
7	1.50	2.41
8	1.50	2.56
Foundry requirements	1.48–1.52	2.20–2.50

* The quality satisfies the requirements of the chisel shop.

CONCLUSIONS

(1) The possibility of using electric-arc ore-thermal furnaces with three graphite electrodes for manufacture of a silicate granulate of sodium metasilicate was demonstrated.

(2) It was shown that such a silicate granulate has improved technological properties in manufacture of liquid glass, compared with the conventionally used silicate lump, and use of the silicate granulate in production of liquid glass creates prerequisites for raising the economic efficiency of this process.

Abstract—Recovery of Rb^+ ions from highly mineralized solutions with a granulated composite sorbent of the composition $K_{0.92-1.0}Cu_{1.50-1.54}[Fe(CN)_6]\cdot 4.9SiO_2$ in the multiple-cycle mode was studied.

DOI: 10.1134/S1070427208070021

Rubidium salts are obtained in industrial practice as a by-product in processing of potassium and magnesium salts by multiple fractionated crystallization, and metallic rubidium, by reduction of rubidium chloride with calcium at 700–800°C in a vacuum [1]. The high production cost of rubidium and its salts hinders wide use of the metal in technology.

The techniques employed to obtain rare-earth (REE) and scattered elements widely use extraction and sorption methods [2, 3]. REEs are recovered from solutions formed in processing of mineral raw materials with selective inorganic ion-exchange materials or organic polymeric resins. To isolate REEs, the sorbent is dissolved or subjected to thermal degradation (ashing) [2].

It is advisable to use sorption methods to recover rubidium from industrial brines (spent electrolytes, aqueous solutions of chlorides of alkali and alkaline-earth metals) formed in production of magnesium.

It is known that ferrocyanides [hexacyanoferrates(II)] of transition metals (copper, nickel, zinc) can selectively absorb ions of rubidium, cesium, and thallium(I) from solutions of various compositions, with high separation coefficients achieved for ion pairs Rb^+ and K^+, Rb^+ and Na^+ ($K_d = 10^2$–10^3), Cs^+ and K^+ ($K_d = 10^5$–10^6) [4, 7]. Granulated sorbents are commonly used in sorption techniques. To improve their mechanical properties, ferrocyanide sorbents are synthesized as composites, e.g., with silica gel [5].

Use of granulated composite ferrocyanide sorbents makes it possible to organize the process by the sorption–desorption–regeneration scheme, but the lack of an efficient method for Rb^+ desorption from the sorbent hinders application of the sorption technique to production of rubidium salts.

Ion-exchange and redox methods for desorption of alkali metal ions from the ferrocyanide phase are known. The ion-exchange techniques use concentrated solutions of ammonium chloride or nitrate, with ammonium ions substituting alkali metal ions in the solid phase. The desorption yields solutions of alkali metal chlorides or nitrates with a large excess of ammonium ions, which hinders their further processing.

The redox methods for desorption of alkali metal ions are based on the reaction

$$M^I_1M^{II}_{1.5}[Fe^{II}(CN)_6] + Ox = M^I + M^{II}_{1.5}[Fe^{III}(CN)_6] + Red,$$

where M^I stands for the ion of an alkali metal (Rb^+, Cs^+), and M^{II}, for Cu^{2+} or Ni^{2+}.

The oxidation of a ferrocyanide is accompanied by release of alkali metal ions from the sorbent phase. In [4, 5, 7], 12 M H_2SO_4 and 6 M HNO_3 are used as oxidizing agents for desorption of Rb^+, Cs^+, and Tl^+ ions from the ferrocyanide sorbent. The difficulty of further processing of highly concentrated acid solutions with a low content of the target component hinders application of this technique.

The goal of the study was to develop a sorption method for recovery of rubidium ions from highly mineralized solutions to obtain a rubidium salt of reagent grade.

EXPERIMENTAL

An FS-10 granulated composite sorbent, which is a mixed copper–potassium ferrocyanide (FOC Cu–K), and silica gel were used in the study. The choice of FOC Cu–K was due to its high selectivity with respect to Rb^+ ions and stability.

The Cu–K ferrocyanide was obtained by precipitation upon mixing of potassium ferrocyanide and copper sulfide solutions in the presence of sodium silicate at pH 4. The resulting paste was dried in air and granulated by decrepitation. The composition of the sorbent obtained is described by the empirical formula $K_{0.92-1.0}Cu_{1.50-1.54}[Fe(CN)_6]\cdot 4.9SiO_2$.

The concentration of alkali metal ions in solutions was determined by the atomic-absorption method with a Perkin–Elmer atomic-absorption spectrometer. Rb^+ ions were recovered from a model solution containing rubidium and potassium chlorides in a molar ratio $Rb^+ : K^+ = 1 : 150$ (the concentrations of Rb^+ and K^+ ions were 0.2–0.25 and 13.8–14.5 g l^{-1}, respectively).

The experiments were performed using ion-exchange column chromatography: column diameter 0.7 cm, sorbent bed height 20 cm, sorbent mass 5 g, column volume 7.7 ml, and filtration rate 1.0–1.2 m h^{-1} (25–30 ml h^{-1}).

The total ion-exchange capacity for the Rb^+ ion was 70–73 mg g^{-1} (0.82–0.85 mmol g^{-1}), or 0.51 mmol mol^{-1} $[Fe(CN)_6]^{4-}$, with a separation coefficient of 1.3×10^2 reached for Rb^+ and K^+ ions.

To obtain a rubidium salt of reagent grade, the problem of separate selective desorption of K^+ and Rb^+ ions from the sorbent was solved in the study. As a desorbing agent for recovery of K^+ ions we chose 1 M HCl. On passing 6–8 column volumes of the eluent (50–60 ml) through the sorbent bed, nearly complete desorption of K^+ ions (98%) was achieved, with the extraction of Rb^+ ions into solution being lower than 2.0%.

Rb^+ ions were extracted from the ferrocyanide sorbent by the redox method. It is the most appropriate to use chlorine or its compounds as an oxidizing agent because they have a high oxidizing capacity ($E^0_{Cl_2/Cl^-}$ = 1.36 V, $E^0_{OCl^-/Cl^-}$ = 1.63 V) and are readily available, being formed in the course of electrochemical processing of potassium and magnesium salts.

Rb^+ ions were desorbed from the ferrocyanide phase with an aqueous solution of Cl_2 (concentration of active chlorine 0.05 M) and a 0.1 M NaClO solution as oxidizing agents. The desorption curves of rubidium ions are shown in Fig. 1.

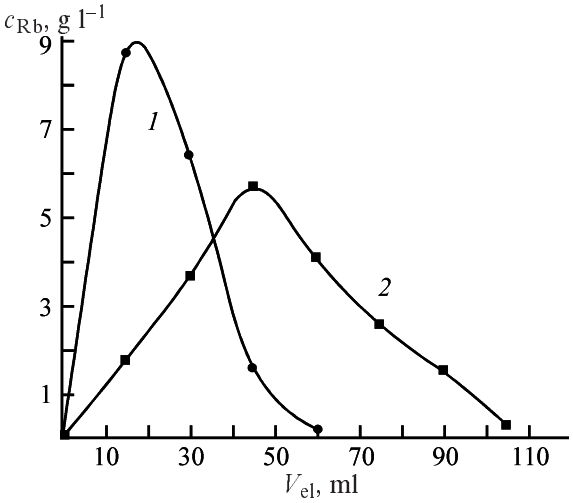

Fig. 1. Desorption curves of rubidium ions. (c_{Rb}) Concentration of rubidium ions in eluate and (V_{el}) eluent volume. Solution: (*1*) 0.1 M NaClO and (*2*) 0.05 M Cl_2 (aq).

These data show that considerable amounts of solutions with low concentration of Rb^+ ions are formed when chlorine water is used, which further leads to high energy expenditure in crystallization of rubidium chloride by evaporation of the eluates. Use of a sodium hypochlorite solution complicates further processing of eluates: a stage of purification to remove Na^+ ions is required for obtaining reagent-grade RbCl.

Raising the concentration of the oxidizing agent can considerably improve the efficiency of desorption of Rb^+ ions from the sorbent phase. Because of the low solubility of Cl_2 in water (0.1 and 0.06 M at 20 and 40°C, respectively) [8], organic liquids were chosen as solvents for chlorine. For example, it is known that gaseous chlorine is highly soluble in halogen-containing organic solvents: its solubility in carbon tetrachloride is 0.6 M at 20°C.

A solvent for chlorine should satisfy the following main requirements: low volatility, incombustibility, high chemical inertness (stability against oxidizing agents), nontoxicity, and low solubility in water. In accordance with the requirements developed, the F-13 fluorochlorocarbon liquid used in industry in lubricants and hydraulic oils was chosen for dissolution of Cl_2. The composition of F-13 is described by the chemical formula $(CF_2CFCl)_4X$, where X stands

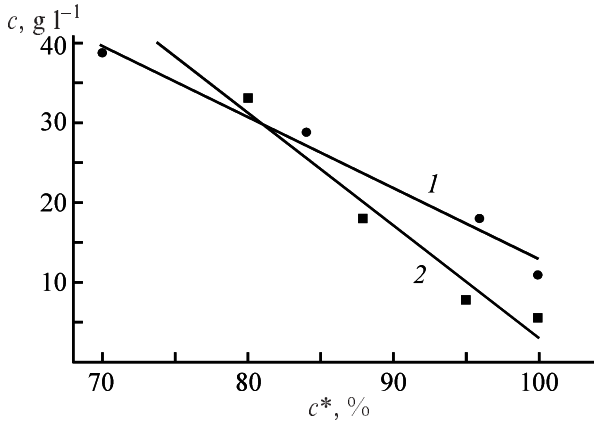

Fig. 2. Effect of the alcohol concentration c^* on the solubility of rubidium chloride in aqueous–alcoholic solutions. (c) Concentration of RbCl solution; the same for Fig. 3. (*1*) C_2H_5OH and (*2*) C_3H_7OH.

C_2H_5OH concentration, %: (*1*) 0, (*2*) 70, (*3*) 84, and (*4*) 96. C_3H_7OH concentration, %: (*1*) 0, (*2*) 80, (*3*) 88, (*4*) 95, and (*5*) 100.

for F or Cl. The average molar mass is 519 g mol^{-1} [9]. The equilibrium room-temperature concentration of chlorine in the organofluorine solvent is 0.5–07 M.

The expenditure of the eluent with a chlorine concentration of 0.7 M, passed through a sorbent bed at a rate of 1.0–1.5 m h^{-1}, for complete oxidation of Cu–K FOC is two column volumes. The reaction progress was monitored by the content of active chlorine in eluents at the column outlet. The spent organofluorine liquid was again saturated with chlorine and again used for oxidizing the sorbent. In the study, a single portion of the solvent was used in eight working cycles of the ion-exchange column.

In oxidation of the sorbent, rubidium chloride remains in the solid phase, because it is not dissolved in the fluorinated liquid. The study demonstrated that extraction of Rb^+ ions with distilled water yields low-concentration solutions of rubidium chloride, whose evaporation involves a gross energy expenditure.

It is known that rubidium chloride can be dissolved in monohydric alcohols. For example, its solubility in methanol (99.8%) is 1.4% or 13.2 g l^{-1} [1]. The high toxicity of methanol restricts its application areas. The possibility of using aqueous solutions of ethanol and isopropanol for desorption of Rb^+ ions was analyzed. Because of the lack of information about the solubility of RbCl in the alcohols, these values were found experimentally. The results obtained (Fig. 2) show that the solubility of RbCl in the anhydrous alcohols (ethanol and isopropanol) is 11.0 and 5.5 g l^{-1}, respectively, i.e., it decreases as the molar mass of the alcohol increases. Addition of water leads to a substantial increase in the solubility of rubidium chloride in the alcohols. Experiments on elution of RbCl from a column packed with the oxidized form of the ferrocyanide sorbent were performed in the dynamic mode. The eluate was sampled in 20-ml portions, in which the concentration of Rb^+ ions was determined. The first portions of the eluates, with the maximum concentration of rubidium ions, were processed to give RbCl.

The subsequent portions were taken separately and were repeatedly used to recover Rb^+ in a next working cycle of the column. The curves of elution of rubidium ions from the oxidized phase of the sorbent with water and aqueous–alcoholic solutions are shown in Fig. 3.

An analysis of the results obtained demonstrated that the best results in elution of RbCl are attained with an 80–85% aqueous solution of ethanol or an 80–88% aqueous solution of isopropanol, with more than 85% of Rb^+ recovered with first portions of

Content of rubidium chloride in solutions after evaporation of an alcohol

Concentration of aqueous–alcoholic solutions, vol %			RbCl concentration after evaporation of an alcohol, g l^{-1}

* Solid RbCl was obtained.

the eluate (2–3 column volumes). When distilled water is used, the salt concentration in the eluates formed is 1.5–1.8 times lower than that in aqueous–alcoholic solutions. First portions of the eluate were processed to obtain rubidium chloride, and subsequent portions were reused in the multiple-cycle process.

To enable its multiple use, the sorbent was regenerated, after desorption of K^+ and Rb^+, with a solution of a reducing agent of the following composition (g l^{-1}): Na_2SO_3 20 and KCl 20; pH 4. The pH value was adjusted using an acetic acid solution. It was shown that ferrocyanide retains its sorption activity in 8–12 sorption–desorption–regeneration cycles.

Evaporation of alcohols yielded saturated RbCl solutions (bp C_2H_5OH 78°C, C_3H_7OH 82°C) (see table). As indicated by the data in the table, use of ethanol and isopropanol solutions with concentrations lower than 70 and 80%, respectively, makes lower the content of rubidium chloride in the concentrates, which leads to an increase in the energy expenditure in their further processing. RbCl was isolated from the resulting solutions by evaporation. The finished salt was calcined at 250°C. It was found that the content of K^+ ions in the rubidium chloride obtained did not exceed 1% and the product satisfied the requirements to rubidium chloride of reagent grade.

CONCLUSIONS

(1) A sorption technique was developed for recovery of rubidium chloride from highly mineralized solutions with multiple use of a granulated ferrocyanide sorbent.

(2) Separate desorption of K^+ and Rb^+ ions was performed by the ion exchange $H^+ \rightarrow \underset{\leftarrow}{} K^+$ and oxidation of ferrocyanide with a solution of Cl_2 in an organofluorine solvent, followed by extraction of the RbCl formed with aqueous–alcoholic solutions. The process can yield RbCl of reagent grade.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of $(Ni_{1-x}Co_x)_2P$ ($0 \le x \le 0.65$) Substitution Solid Solution

V. N. Viter and P. G. Nagornyi

Shevchenko Kiev National University, Kiev, Ukraine

Received December 6, 2007

Abstract—The phosphides $(Ni_{1-x}Co_x)_2P$ ($0 \le x \le 0.65$) crystallizing in the hexagonal system, space group $P\bar{6}2m$, were synthesized in two steps starting from the continuous solid solution $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$. The initial phosphates were first completely dehydrated at 800°C and then reduced with hydrogen at 900–1000°C for 1–2 h.

DOI: 10.1134/S1070427208070033

Nickel, cobalt, and iron phosphides and related compounds are of appreciable interest in many fields. In particular, they catalyze hydrogenolysis of C–S, C–N, and C–O bonds [1–5]. These processes are important for the removal of sulfur, nitrogen, and oxygen organic compounds from petroleum products. Coatings of nickel and cobalt phosphides exhibit good anticorrosive properties [6, 7]. In addition to individual phosphides, solid solutions on their basis are also known. In particular, $(Ni_{1-x}M_x)_2P$ (M = Co, Fe, Mn, Cr) phases were studied by neutron diffraction [8].

Nickel phosphides and related compounds can be synthesized by various methods, e.g., by direct reaction of the elements, action of phosphine on metals and oxides, and reaction of hypophosphite solutions with nickel or cobalt salts. Phosphides of some metals can also be prepared by reduction of the corresponding phosphates with hydrogen [9, 10]. In the case of the Ni_2P synthesis, the latter method is preferable. Its advantages become still more pronounced if it is necessary to obtain not pure Ni_2P, but analogous phosphides with two or more cations. In this case, it is appropriate to use phosphates containing simultaneously nickel and the corresponding metal as starting substances. For example, hydrated cobalt and nickel phosphates form with each other continuous substitution solid solutions $Ni_{1-x}Co_x(H_2PO_4)_2 \cdot 2H_2O$ (monoclinic system, space group $P2_1/n$), $Ni_{1-x}Co_xHPO_4 \cdot 1.5H_2O$ (rhombic system, space group $Pbca$), and $(Ni_{1-x} \cdot Co_x)_3(PO_4)_2 \cdot 8H_2O$ (monoclinic system, space group $P2/m$), where $0 \le x \le 1.00$ [11]. The parameters and volumes of the unit cells of these solid solutions decrease as the degree of nickel substitution for cobalt increases. In the case of $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$ ($0 \le x \le 1.00$), a linear dependence is observed. The IR spectra within the limits of each of these solid solutions are very similar [11]. Taking into account the P/(Ni + Co) molar ratio in the above phosphates, it is the most appropriate to prepare the phosphides $(Ni_{1-x}Co_x)_2P$ starting from the solid solution $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$ ($0 \le x \le 1.00$).

Here we report on the synthesis of cobalt–nickel phosphides $(Ni_{1-x}Co_x)_2P$ from $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$ ($0 \le x \le 1.00$) by its dehydration followed by reduction with hydrogen.

EXPERIMENTAL

The starting phosphates $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$ ($0 \le x \le 1.00$) were synthesized by the reaction between $CoSO_4$ and $NiSO_4$ solutions (total concentration in reaction mixture 0.1 M) and a Na_2HPO_4 solution. The P/(Ni + Co) molar ratio in the starting reactants was 0.67, and the Co/(Ni + Co) molar ratio was varied from 0 to 1.00. The reaction time was 1–5 days, and temperature, 90°C [11]. The resulting products were filtered off, washed with water, and dried. Their composition (Table 1) was determined by standard methods of chemical analysis. Then the phosphates were heated in air at 800°C up to complete dehydration. The dehydrated products were used for preparing the phosphides.

The reduction of phosphates in hydrogen was carried out in quartz boats at 900–1000°C for 1–2 h. The chemical composition of the synthesized phosphides was calculated on the basis of the composition of phosphates and the weight loss of samples during their reduction with hydrogen. Preliminarily X-ray phase and IR spectroscopic examination showed that the synthesized samples were free of

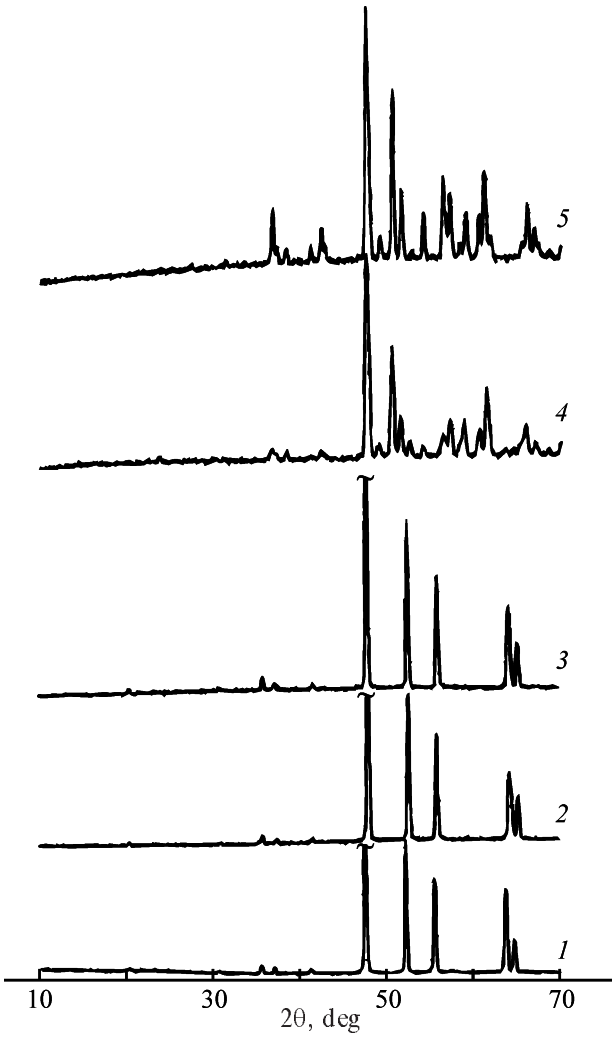
oxygen-containing compounds (phosphates and oxides). Hence, the weight loss during the reduction of anhydrous cobalt and nickel phosphates is caused by the removal of the whole amount of oxygen and a part of phosphorus:

$$M_3(PO_4)_2 + H_2 \rightarrow M_yP_z + P_4 + H_2O$$

(M = Ni, Co).

The X-ray phase analysis was carried out with a DRON 4-07 diffractometer (CoK_α radiation, scanning step 0.01°). The IR spectra were taken in KBr pellets on a Thermo Nicolet Nexus 670 spectrophotometer in the wavenumber range 400–4000 cm^{-1}.



The reduction of phosphates with hydrogen yielded grey products, with appreciable weight loss. In most cases, after calcination for 1 h in a hydrogen flow, practically no further weight loss was observed with the exception of pure cobalt phosphate.

The chemical composition of the synthesized samples is given in Table 2, which shows that the P/(Ni + Co) molar ratio for phosphides with the Co/(Ni + Co) molar ratio from 0 to 0.85 is close to 0.50. This value is stoichiometric for the compounds M_2P (M = Ni, Co). In the case when pure cobalt phosphate [Co/(Ni + Co) = 1.00] was used as the starting compound, the P/Co ratio was 0.65. Thus, according to the chemical analysis, the product synthesized at Co/(Ni + Co) = 1.00 is a phase with the composition different from M_2P (or a mechanical mixture of different phases).

The X-ray phase analysis showed that the phosphides with the cobalt content Co/(Ni + Co)

X-ray diffraction patterns of phosphides synthesized at various Co/(Ni + Co) ratios. (2θ) Bragg angle. Co/(Ni + Co) molar ratio: (*1*) 0, (*2*) 0.55, (*3*) 0.65, (*4*) 0.85, and (*5*) 1.00.

from 0 to 0.65 have similar X-ray diffraction patterns (see figure) and consist of one crystalline phase. The X-ray data for pure Ni_2P agree well with the data of [12]. The unit cell parameters of these phosphides are also close to each other (Table 3). Absorption bands characteristic of $Ni_3(PO_4)_2$ and $Co_3(PO_4)_2$ are absent from the IR spectra of all the synthesized samples. The above data unambiguously point to the formation of the substitution solid solution $(Ni_{1-x}Co_x)_2P$ ($0 \le x \le 0.65$), hexagonal system, space group $P\bar{6}2m$. The X-ray diffraction patterns of phosphides with the molar ratios Co/(Ni + Co) = 0.85 and 1.00 (see figure, curves *4* and *5*) differ essentially from those for the phosphides of the previous group. Some of reflections in these X-ray patterns cannot belong to a phase isostructural with Ni_2P. This fact suggests the formation of a phase (or several phases) of another type. The phosphide Co_2P, unlike Ni_2P, crystallizes in the rhombic system [13]. However, neither the composition nor the X-ray pattern of the sample synthesized at Co/(Ni + Co) = 1.00 coincide with those for Co_2P. It was noted previously that the reflections of the initial phosphates are absent from the X-ray patterns of the synthesized phosphides. The absorption bands of the initial $Co_3(PO_4)_2$ are also absent from the IR spectrum of this sample. Apparently, the sample is a mixture of cobalt phosphides (most likely, Co_2P and CoP).

CONCLUSIONS

(1) The limited solid solution $(Ni_{1-x}Co_x)_2P$ ($0 \le x \le 0.65$) was prepared by dehydration and subsequent reduction with hydrogen of the phosphates $(Ni_{1-x}Co_x)_3(PO_4)_2 \cdot 8H_2O$ ($0 \le x \le 1.00$).

(2) The phosphides synthesized at the molar ratios Co/(Ni + Co) = 0.85 and 1.00 contain other crystalline phases. In particular, the reduction of individual normal cobalt phosphate with hydrogen under the examined conditions yields not the individual phosphide, but a mechanical mixture of phosphides, most probably Co_2P and CoP.

Abstract—Samples of a precursor for an alumina ceramic reinforced by zirconium dioxide were synthesized. The samples have a uniform structure and are characterized by high ratios of the tetragonal and monoclinic modifications of ZrO_2, *t/m*, after a thermal treatment (1250°C). The structure of samples in the system Al_2O_3–ZrO_2 is formed under conditions favorable for deposition of products of hydrolysis of Al(III) ions on the surface of ZrO_2 sol particles in decomposition of urea. The coating of ZrO_2 sol particles by products of hydrolysis of Al(III) salts was confirmed by electrophoresis. The size distribution of particles of the individual ZrO_2 sol was determined by small-angle X-ray scattering. The structure of the products formed in thermal treatment of samples of mixed oxides Al_2O_3–ZrO_2 was characterized by X-ray phase analysis and scanning electron microscopy. The porosity and specific surface area of a thermally treated sample was determined by measuring nitrogen absorption isotherms.

DOI: 10.1134/S1070427208070045

The oxide system Al_2O_3–ZrO_2 is a basis for fabrication of a number of structural materials with enhanced strength and cracking resistance and, in particular, for the ZTA ceramic (alumina ceramic reinforced by zirconium dioxide). The microscopic structure of this ceramic material corresponds to that of dispersion-reinforced composites: reinforcing particles of the ZrO_2 phase (5–45%) are uniformly dispersed in the finely grained Al_2O_3 matrix [1–3]. The unique mechanical properties of the ZTA ceramic, predetermined by the phase transition t-$ZrO_2 \rightarrow m$-ZrO_2, are due to the action of a number of mechanisms of reinforcement, in particular, transformation mechanism, deviation (branching) of cracks, and modular load transfer [1, 2]. To improve the mechanical characteristics of this material, it is necessary that zirconium dioxide particles should be preserved in the form of a metastable tetragonal modification [2].

The t-ZrO_2 phase can also be stabilized by introducing modifying additives, e.g., Y_2O_3 and CeO_2 [1, 4–6], into the system of the starting components and by homogeneous mixing of highly dispersed Al_2O_3 and ZrO_2 nanocrystalline powders with a narrow particle size distribution [2]. It is known that the structure of composite materials can be controlled already in the stage of synthesis of their precursors [7]. A search for efficient technologies for obtaining a precursor for the ZTA ceramic as a basis for a ceramic material with prescribed structure and dispersity is an important task to be carried out by modern studies in the field of structural materials.

In this study, we examined the possibility of synthesis of samples in the system Al_2O_3–ZrO_2 with a t-ZrO_2 phase, stabilized by uniform distribution of zirconium dioxide in a finely dispersed α-Al_2O_3 matrix, by deposition of products formed in hydrolysis of aluminum sulfate [8] on the surface of ZrO_2 sol particles from solution, followed by drying and thermal treatment of the Al_2O_3–ZrO_2 samples synthesized at 1250°C.

EXPERIMENTAL

Al_2O_3–ZrO_2 samples were synthesized from aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ of chemically pure grade and a ZrO_2 sol with a ripening time τ_{rip} of 7 days. Aluminum sulfate $Al_2(SO_4)_3 \cdot 18H_2O$ was chosen as the starting reagent in accordance with the recommendations made in [8].

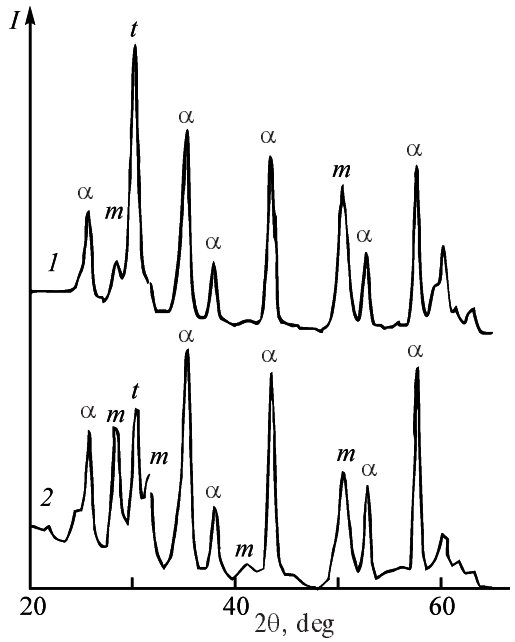

Fig. 1. X-ray diffraction pattern of Al_2O_3–ZrO_2 samples synthesized by mixing the starting components (*1*) with and (*2*) without urea. (*I*) Intensity and (2θ) Bragg angle. (α) α-Al_2O_3, (*t*) *t*-ZrO_2, and (*m*) *m*-ZrO_2.

The concentration of $Al_2(SO_4)_3 \cdot 18H_2O$ in the aqueous solution (in terms of Al_2O_3) and the ZrO_2 concentration in the liquid phase of the sol were 2.5 wt %.

The ZrO_2 and γ-AlOOH sols were synthesized by precipitation–peptization from products formed in hydrolysis of $ZrOCl_2 \cdot 8H_2O$ and $AlCl_3 \cdot 6H_2O$, respectively. Nitric acid solutions served as a peptizing agent. The molar ratios NO_3^-/Zr(IV) and NO_3^-/Al(III) were strictly fixed at 1.00 for the ZrO_2 sol and 0.33 for the boehmite sol. The concentration of the γ-AlOOH sol was also 2.5 wt % in terms of Al_2O_3.

A mixture of an aluminum sulfate solution and the ZrO_2 sol was thermostated on a water bath at 90°C for 2 h in the presence of urea $CO(NH_2)_2$ added to the solution of the starting components in a twofold excess with respect to the amount necessary for products of aluminum hydrolysis to be formed [8].

A sample was obtained in the system Al_2O_3–ZrO_2 under similar temperature conditions by mixing an aluminum sulfate solution with a zirconium dioxide sol without addition of urea. The masses of the starting components were chosen in such a way that thermally treated samples contained 75% Al_2O_3 and 25% ZrO_2. This ratio was taken in accordance with the recommendations [2].

The samples obtained were dehydrated by evaporation, dried in an SNOL-1,6.2.5.1/9-IZ chamber furnace at 105±5°C for 48 h, and calcined in a VTP low-inertia furnace at 1250°C for 2 h. The rate at which the temperature was raised to a prescribed value was 10 deg min^{-1}.

The electrophoretic behavior of mixed samples of AlOH–ZrO_2 sols, products formed in hydrolysis of aluminum sulfate in the presence of a ZrO_2 sol, and individual ZrO_2 and γ-AlOOH sols was studied by the macroelectrophoresis method with a Ken device.

An X-ray phase analysis was made on a DRON-2 diffractometer (CuK_α radiation, quartz monochromator in the primary beam path) at a counter rotation rate of 2 deg min^{-1}. The ratio between the *t*- and *m*-ZrO_2 phases in thermally treated samples was found from the ratio between the intensities of the reflections from (111) planes for *t*-ZrO_2 and (111) and ($11\bar{1}$) planes for *m*-ZrO_2 [9]. The dispersity of α-Al_2O_3 was evaluated indirectly by the half-width-to-height ratio of the peak at d = 3.48 Å [10].

The particle size distribution of ZrO_2 sols synthesized with different ripening times was analyzed by small-angle X-ray scattering.[1] A 200-μm-wide beam of CuK_α X-ray radiation was collimated by the Kratky scheme. The scattered X-ray radiation was recorded with a multiple-position detector, accumulated as a number of pulses, and processed with a computer by special software. The processed results are presented numerically and graphically in the coordinate system particle radius–volume fraction of particles.

The microscopic structure of thermally treated Al_2O_3–ZrO_2 samples was examined with a DSM 962 Leo Zeiss electron microscope (accelerating voltage 20 kV, magnification up to 20000). The grain size was evaluated using a special software of the instrument.

The porosity and specific surface area of a thermally treated Al_2O_3–ZrO_2 sample synthesized with addition of urea was found by measuring nitrogen adsorption isotherms at –176°C on a Carlo Erba Sorbtomatik 1800 installation.

The results of the X-ray phase analysis of Al_2O_3–ZrO_2 samples synthesized by mixing the starting components with and without urea $CO(NH_2)_2$ are presented in Fig. 1 in the form of X-ray diffraction patterns. Quantitative data characterizing the uni-

formity of component distribution for synthesized and thermally treated Al_2O_3–ZrO_2 samples are listed in Table 1.

In the course of calcination, both the components in samples with mixed oxides undergo polymorphic transformation. It follows from the results of X-ray phase analysis that all of the samples obtained contain Al_2O_3 in the high-temperature α-form and zirconium dioxide in the tetragonal and monoclinic modifications. No chemical interaction is observed between the oxides. A criterion of uniformity of the component distribution in the Al_2O_3–ZrO_2 system is the intensity ratio between the tetragonal and monoclinic modifications of ZrO_2, t/m. The higher this ratio, the larger fraction of ZrO_2 particles uniformly distributed in the alumina matrix retain their tetragonal structure, and their size is smaller than the critical value of 0.45 μm [11]. A necessary requirement for ZrO_2 to remain in the tetragonal modification in thermally treated samples in the Al_2O_3–ZrO_2 system is that the alumina matrix should be formed from α-Al_2O_3 particles in the finely dispersed state, which is characterized by increased values of $b_{1/2}/h$ of the line with d = 3.84 Å of the α-Al_2O_3 phase.

According to the results of X-ray phase analysis of calcined Al_2O_3–ZrO_2 samples (Table 1, Fig. 1), the tetragonal phase of ZrO_2 is stabilized and α-Al_2O_3 particles are preserved in the finely dispersed state in the sample synthesized with addition of urea.

In thermal treatment of samples of mixed oxides in the Al_2O_3–ZrO_2 system, structures with different degrees of uniformity are formed, depending on the conditions in which the "aqueous" stage of synthesis occurs. To improve the structural uniformity of the synthesized samples of the precursor for the ZTA ceramic, it is necessary to restrict the size of primary particles being formed and provide the most homogeneous mixing of the components and thereby make lower the probability of recrystallization of the t-ZrO_2 phase in thermal treatment.

To hinder the phase transition t-$ZrO_2 \rightarrow m$-ZrO_2 and preserve ZrO_2 particles in the tetragonal modification in the calcined Al_2O_3–ZrO_2 material, certain requirements are imposed upon the ZrO_2 sol. A study of the electrophoretic mobility of ZrO_2 sol particles by macroelectrophoresis revealed a certain increase in positive values of the ζ-potential and a shift of the isoelectric point (IEP) to higher pH values, dependent of the sol ripening time. An indication of the aggregative stability of ZrO_2 sols with different ripening times and of the stability of the surface charge of their particles are high values of the potential ψ (~100 mV), which vary only slightly in the pH range 1.25–4. The aggregative stability of ZrO_2 sols was attributed in [12] to existence of developed boundary layers of water at the particle surface.

An analysis by small-angle X-ray scattering of the particle size distribution of the ZrO_2 sols synthesized demonstrated that the average size of ZrO_2 sol particles is 25 nm at a ripening time of 7 days.

The significant difference of the pH values used in synthesis of precursors for ZrO_2 sols from the pH of the isoelectric point and the high stability of the given colloid system are an important condition for precluding coarsening of ZrO_2 sol particles in the stage of formation of the initial structure of mixtures in the Al_2O_3–ZrO_2 system.

The hydrolysis of urea $CO(NH_2)_2$ added to the mixture of the starting components (sample S7) occurs in solution at 85–100°C and is described by the equations

$$2CO(NH_2)_2 + 5H_2O = 2NH_3 + (NH_4)_2CO_3 + CO_2,$$

$$NH_3 + H_2O = NH_4^+ + OH^-.$$

A specific feature of this process is that the precipitating agent is not poured into a solution containing ions being precipitated, but is gradually released in decomposition of urea $CO(NH_2)_2$

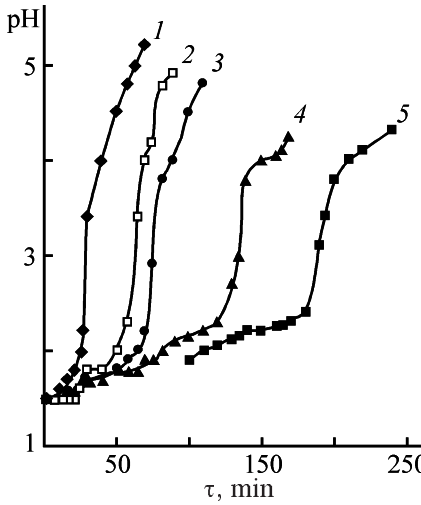

Fig. 2. Kinetic curves of joint hydrolysis of 1 M $CO(NH_2)_2$ and 0.1 M $AlCl_3$. (τ) Time. Process temperature, °C: (*1*) 98, (*2*) 95, (*3*) 90, (*4*) 85, and (*5*) 80.

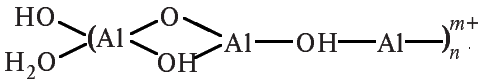
because of the occurrence of its hydrolysis uniformly throughout the solution volume [13]. This favors an increase in the uniformity and a finer dispersion of the forming nuclei of the phase being precipitated in the subsequent thermal treatment of samples of mixed Al_2O_3–ZrO_2 oxides.

The hydrolysis of Al(III) salts occurs to give a number of hydrolyzed species [12, 14], of which the most typical are the following:

$$Al^{3+} \rightleftarrows Al(OH)^{2+} \rightleftarrows [Al_2(OH)_2]^{4+} \rightleftarrows [Al_7(OH)_{16}]^{5+} \rightleftarrows Al(OH)_3.$$



The positive charge per aluminum atom decreases in the order of the successively formed hydrolysis products.

At Al(III) concentrations in salt solutions exceeding 0.1 M, hydroxo complexes are formed at pH < 4.0 and $Al(OH)_3$ precipitates as pH values increase further [14], which is confirmed, e.g., by a description of the joint hydrolysis of a solution of $AlCl_3$ and $CO(NH_2)_2$ by kinetic curves (Fig. 2) [8].

Table 2. pH values at the isoelectric points for an Al_2O_3–ZrO_2 sample synthesized in the presence of urea and mixed and individual sols of γ-AlOOH and ZrO_2

Sample	pH at IEP
S7	8.8
γ-AlOOH freshly prepared	8.2
γ-AlOOH (τ_{life} = 15 days)	9.0
ZrO_2	6.5

Hydrolysis of Al(III) salts yields oligomeric and polymeric charged polynuclear hydroxo complexes with various structures. Their composition is described by the general formula

Aluminum is an element exhibiting a pronounced tendency to form bridging bonds –O– and –OH–, which, presumably, enables aluminum to enter into a covalent interaction with surface OH groups of particles of the zirconium dioxide sol [15].

The formation of Al(III) hydrolysis products on the surface of ZrO_2 sol particles in the aqueous stage of precursor synthesis in the presence of urea can be confirmed by studying the electrophoretic behavior of the mixed sample S7.

For comparison, the IEPs were determined for boehmite γ-AlOOH sols with various lifetimes and an individual ZrO_2 sol with a ripening time of 7 days. The experimental results obtained are listed in Table 2. The γ-AlOOH sol shows a sligt shift of the IEP to higher pH values in the course of time. The IEP of sample S7 fall within the range of the IEPs of individual γ-AlOOH sols. For all of the samples studied, positive values of the ζ-potential of the particle surface were observed at low pH values of the liquid phase.

The coincidence of the electrokinetic data for the individual γ-AlOOH boehmite sol and for sample S7 confirms that, when aluminum sulfate is hydrolyzed in the presence of urea at temperatures above 90°C, the forming Al(III) hydroxo complexes are deposited onto the surface of ZrO_2 sol particles and completely cover this surface. This occurs because OH^- ions formed in hydrolysis of urea favor (in the absence of local supersaturations with OH^- groups in solution) hydrolysis of Al(III) ions and formation of bridging bonds –O– and –OH– involving hydroxy groups localized on the surface of ZrO_2 sol particles.

Thus, a heterophase finely dispersed mixture of nanosized particles in the system Al_2O_3–ZrO_2 is synthesized, with urea $CO(NH_2)_2$ serving as a precipitating agent, via coating of ZrO_2 sol particles with products of Al(III) hydrolysis, which hinders growth of ZrO_2 particles in the aqueous stage of synthesis of precursor samples and decreases the

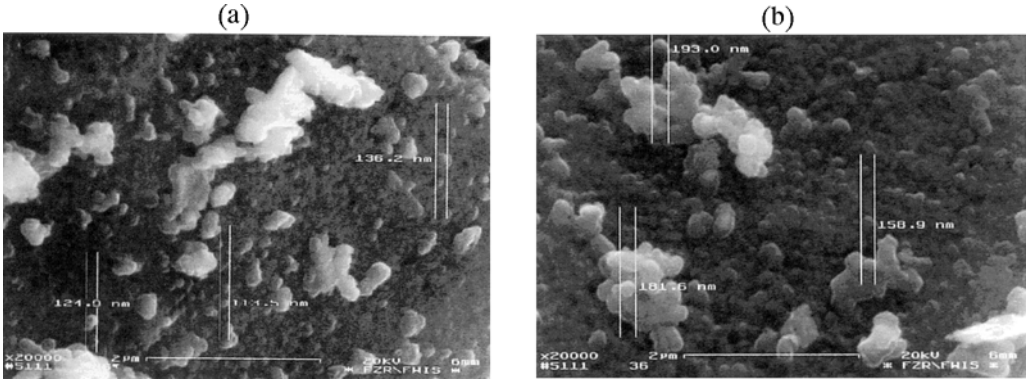


Fig. 3. SEM micrographs of surface fragments of (a) S7 and (b) S7* samples.

probability of the t-$ZrO_2 \rightarrow m$-ZrO_2 phase transition in thermal treatment of the material because of the isolation of ZrO_2 particles from each other by particles of the alumina phase.

The efficiency of using urea for synthesis of samples of a precursor for the ZTA ceramic in order to form their highly uniform finely grained structure is also confirmed by a study of the microscopic structure of thermally treated Al_2O_3–ZrO_2 samples by scanning electron microscopy (SEM). Figures 3a and 3b show micrographs of surface fragments of S7 and S7* samples, respectively. Comparison of the micrographs shows that the samples have similar structure. However, the micrograph of a surface fragment of sample S7 synthesized with addition of urea clearly shows fine individual uniformly distributed grains and medium-size regions of their agglomeration. The surface fragment of sample S7* shows larger agglomerates and coarser individual grains (their sizes are indicated in the micrograph). These facts show that the structural uniformity of S7* material synthesized without urea is considerably lower. It follows from the micrographs of the Al_2O_3–ZrO_2 samples that the average size of individual grains is 126 nm for sample S7 and 179 nm for sample S7*. Consequently, particles of the α-Al_2O_3 phase formed by thermal treatment of sample S7 stabilize the size of zirconium dioxide grains and make lower the probability of the t-$ZrO_2 \rightarrow m$-ZrO_2 phase transition.

The thermally treated Al_2O_3–ZrO_2 sample synthesized with urea (S7) has low specific surface area (S_{BET} = 4.4 $m^2\,g^{-1}$) and pore volume (W_s = 0.03 $cm^2\,g^{-1}$). Small pores (micropores) comparable in size with adsorbate molecules are not found in the sample.

CONCLUSIONS

(1) The efficiency of using urea $CO(NH_2)_2$ for hydrolysis of Al(III) on heating a solution containing aluminum sulfate and ZrO_2 sol for synthesis of Al_2O_3–ZrO_2 samples as a precursor for the ZTA ceramic was demonstrated.

(2) A study of the electrokinetic behavior of individual ZrO_2 and γ-AlOOH sols and samples of a precursor for the ZTA ceramic, obtained with the use of urea, demonstrated that, in hydrolysis of aluminum sulfate under the conditions of urea decomposition at $T \geq 90$°C, the forming products of Al(III) hydrolysis are deposited onto the surface of ZrO_2 sol particles and completely cover this surface.

(3) The results of an X-ray phase analysis and scanning electron microscopy of samples of mixed oxides Al_2O_3–ZrO_2 synthesized using urea confirm that the coating of the surface of ZrO_2 sol particles by products formed by hydrolysis of aluminum sulfate is a factor that effectively prevents coarsening of ZrO_2 particles distributed in the alumina matrix and hinders the t-$ZrO_2 \rightarrow m$-ZrO_2 phase transition in thermal treatment of Al_2O_3–ZrO_2 samples.

Abstract—Generation and properties of a catalytic system for hydrogenation, based on $Pd(acac)_2$ and $LiAlH_4$ and modified with *n*-BuOH and *t*-BuOH, were studied. The promoting and inhibiting effects of the alcohols were revealed, and their causes were discussed.

DOI: 10.1134/S1070427208070057

Palladium nanoclusters show catalytic activity in various transformations of unsaturated hydrocarbons, including hydrogenation [1]. One of the most widely used procedures for preparing metal nanoparticles is chemical condensation consisting in reduction of metal complexes in the presence of stabilizers [2]. Previously we studied how the properties of palladium hydrogenation catalysts depend on the reductant used ($AlEt_3$ [3], $LiAlH_4$ [4], NaH_2PO_2 [5], H_2 [6]) and found that the catalytic properties are influenced not only by the metal dispersity and nature of stabilizing ligands. Generation of catalytically active species is usually accompanied by a number of side reactions (degradation of phosphines taken as stabilizing ligands; catalytic decomposition of the reductant $LiAlH_4$, NaH_2PO_2, etc.), which can exert both promoting and inhibiting effect on the catalyst properties. In particular, for the system $Pd(acac)_2$–$LiAlH_4$ it was found that partial hydrolysis of lithium tetrahydroaluminate leads to a sharp (by a factor of 6) increase in the specific activity in hydrogenation of alkenes [4].

To develop efficient synthetic routes to high-performance palladium hydrogenation catalysts, in this study we examined the generation and properties of catalytic systems based on palladium bisacetylacetonate and lithium tetrahydroaluminate, modified with alcohols.

EXPERIMENTAL

Solvents (benzene, THF) and substrates were purified by standard procedures used in organometallic chemistry [7]. For more exhaustive drying, benzene was additionally distilled from $LiAlH_4$ on a distillation column and stored under argon in sealed ampules over 4A molecular sieves. Tetrahydrofuran after removal of peroxides was distilled successively from sodium, $LiAlH_4$, and benzophenone ketyl and was stored under argon in sealed ampules. The concentration of water, determined by Fischer titration [8], was 1.1×10^{-3} in benzene and 1.6×10^{-3} M in THF.

Palladium bisacetylacetonate was prepared according to [9]. ^{1}H NMR spectrum (δ, ppm, solvent C_6D_6): 5.04 (s, 1H, CH), 1.76 (s, 6H, CH_3). IR spectrum (ν, cm^{-1}, solvent benzene): ν(C=O) + ν(C=C) 1560, 1516; UV spectrum (solvent benzene): ε_{330} = 10630 l mol^{-1} cm^{-1}.

Commercial lithium tetrahydroaluminate $LiAlH_4$ was used without preliminary recrystallization. A weighed portion of $LiAlH_4$ was dissolved in THF, and the solution was filtered in an inert atmosphere through a glass frit. The $LiAlH_4$ concentration determined by the volume of hydrogen released in the course of hydrolysis was 95–98% of the theoretical value. ^{27}Al NMR spectrum (δ, ppm, solvent THF): 98 quintet ($^1J_{Al-H}$ 173 Hz).

Alcohols (*n*-butanol, *tert*-butanol) were refluxed over calcium oxide, distilled from it in an Ar atmosphere, and stored in sealed ampules under Ar.

The reactions of $LiAlH_4$ with alcohols at various component ratios were performed under dry deoxygenated argon in a temperature-controlled vessel whose design allows initial evacuation and filling with argon. The vessel connected to a volumetric system was charged with a solution of $LiAlH_4$ (2.7×10^{-3} M) in 5 ml of THF. The vessel was stoppered with a Teflon stopper, and a definite amount of an alcohol dissolved in THF (ROH : $LiAlH_4$ = 1, 2, 3) was introduced with a syringe under vigorous stirring with a magnetic stirrer. The amount of hydrogen released in the course of $LiAlH_4$ alcoholysis was determined volumetrically. The solution was transferred into a quartz ampule 5 mm in diameter, which had been preliminarily evacuated and filled with argon, and then was analyzed by ^{27}Al NMR spectroscopy. The NMR spectra were recorded on a Varian VXR-500S pulse spectrometer. The ^{27}Al chemical shifts were measured against an external reference, 0.1 M solution of $Al(NO_3)_3$. Solutions of $LiAlH_4$–ROH in THF for catalytic experiments were prepared similarly.

The reactions of palladium bisacetylacetonate with $LiAlH_4$ hydrolysis products were performed as follows. To a solution of $Pd(acac)_2$ (2.5×10^{-4} mol, 0.0761 g) in 8 ml of benzene, placed in a temperature-controlled vessel, we added dropwise with vigorous stirring under Ar a freshly prepared (as described above) solution of $LiAlH_4$–ROH in THF (ROH/$LiAlH_4$ = 1, 2, 3). The total volume of the solution was 10 ml. An aliquot of the resulting dark brown solution was transferred in an inert atmosphere into an all-sealed quartz cell and analyzed by UV spectroscopy. The palladium bisacetylacetonate concentration was calculated from the absorption band at 330 nm (ε_{330} = 10630 l mol^{-1} cm^{-1}); the concentration of acetylacetonate ligands bound to Al [$Al(acac)_3$, $Al(acac)_2$(*tert*-BuO)], from the band at 288 nm (ε_{288} = 14470 l mol^{-1} cm^{-1} per acetylacetonate group; for $Pd(acac)_2$, ε_{288} = 3090 l mol^{-1} cm^{-1}). The UV spectra were recorded on a Specord UV VIS spectrometer in the range 280–430 nm.

Catalytic hydrogenation was performed in a duck-shaped temperature-controlled glass vessel at 30°C and initial hydrogen pressure of 1 atm in the presence of the catalytic system generated in situ. A solution of $LiAlH_4$–ROH in THF was added dropwise in a hydrogen stream to a solution of 0.01522 g (5×10^{-5} mol) of $Pd(acac)_2$ in 8 ml of benzene, and the mixture was stirred for 5 min. The Red/Pd ratio was varied from 2 to 50. The total solution volume was 10 ml. To the resulting black-brown "solution," we added styrene. Its hydrogenation was performed with vigorous stirring at the initial hydrogen pressure of 1 atm. The reaction progress was monitored volumetrically and by GLC with a Chrom-5 chromatograph equipped with a packed column (3.6 m, Carbowax-20M stationary phase) and a flame ionization detector. The column temperature was 100°C, and the carrier gas was N_2.

It was shown previously that, for systems of the type $Pd(acac)_2$–Red (Red = $AlEt_3$, $LiAlH_4$), the dependence of the catalytic activity in hydrogenation of α-alkenes on the component ratio passes through a maximum [3, 4]. Studies of the formation and nature of hydrogenation-active palladium species in these reactions showed that an increase in the activity in the initial portion of the curve is due to an increase in the fraction of Pd(0) and a decrease in the size of palladium nanoparticles. The poisoning effect of excess reductant is different. Triethylaluminum acts not only as reductant, but also, when in excess, as stabilizer of palladium nanoparticles, forming surface compounds with intermediates of the catalytic cycle. Its effect as catalytic poison can be eliminated by adding alcohols which convert $AlEt_3$ into aluminum alkoxy derivatives [10]. With $LiAlH_4$, the catalytic poison is aluminum reacting with palladium to form a substitution solid solution [4]. Aluminum can arise in the reaction system $Pd(acac)_2$–$LiAlH_4$ from catalytic decomposition of alane formed by reaction of the components [4]:

$$Pd(acac)_2 + 2LiAlH_4 \rightarrow Pd(AlH_4)_2 + 2Li(acac), \quad (1)$$

$$Pd(AlH_4)_2 \rightarrow Pd + 2/n[AlH_3]_n + H_2, \quad (2)$$

$$[AlH_3]_n \xrightarrow{Pd} nAl + (3n/2)H_2. \quad (3)$$

It should be noted that, in contrast to palladium hydrogenation catalysts based on $Pd(acac)_2$ and $AlEt_3$ [3], the specific activity of the catalytic system $Pd(acac)_2$–$LiAlH_4$ is low because of the inhibiting effect of aluminum and does not exceed 30 ml of substrate per mole of Pd per minute (Fig. 1).

The above facts suggest that, to prepare high-performance palladium hydrogenation catalysts, it is appropriate to use as reductant not $LiAlH_4$ but its alkoxy derivatives. To check this hypothesis, we studied the generation and properties of catalytic

systems $Pd(acac)_2$–$LiAlH_4$–ROH (R = *n*-Bu or *tert*-Bu) in hydrogenation reactions.

The catalytic properties of the $Pd(acac)_2$–$LiAlH_4$–ROHs system in hydrogenation depend on both the Red/$Pd(acac)_2$ (Red = $LiAlH_4$–ROH) and ROH : $LiAlH_4$ molar ratios. In particular, the $Pd(acac)_2$–$LiAlH_4$–*n*-BuOH system exhibits catalytic activity in styrene hydrogenation at [*n*-BuOH]/[$LiAlH_4$] = 1 (Fig. 1). At *n*-BuOH/$LiAlH_4$ = 2 or 3, $Pd(acac)_2$ is not reduced, and the rate of styrene hydrogenation is zero. The dependence of the catalytic activity of the $Pd(acac)_2$–$LiAlH_4$–*n*-BuOH system ([*n*-BuOH] : [$LiAlH_4$] = 1) on the Red/$Pd(acac)_2$ ratio passes through a maximum (130 mol of substrate per mole of Pd per minute) at Red/Pd = 10. This activity exceeds by a factor of 4 the specific activity of the palladium catalyst prepared by reduction with lithium tetrahydroaluminate. Poisoning of the catalytic system $Pd(acac)_2$–$LiAlH_4$–*n*-BuOH ([*n*-BuOH] : [$LiAlH_4$] = 1) with excess reductant is observed at higher Red/Pd ratios compared to the $Pd(acac)_2$–$LiAlH_4$ system (Fig. 1).

With *tert*-BuOH used as modifier, the pattern somewhat changes. The catalytic system $Pd(acac)_2$–$LiAlH_4$–*tert*-BuOH ([*tert*-BuOH]/[$LiAlH_4$] = 1, 2, 3) exhibits activity in hydrogenation of styrene on adding *tert*-butyl alcohol to $LiAlH_4$ not only in 1 : 1, but also in 2 : 1 and 3 : 1 ratios (Fig. 2). The *tert*-BuOH : $LiAlH_4$ molar ratio affects the shape of the dependence of the catalytic activity on the Red/Pd ratio. At *tert*-BuOH/$LiAlH_4$ = 1, the inhibiting effect of the reductant is observed at its 50-fold excess. At *tert*-BuOH/$LiAlH_4$ ratios of 2 and 3, in the range of Red/Pd ratios from 2 to 50, no poisoning of the catalytic system $Pd(acac)_2$–$LiAlH_4$–*tert*-BuOH with excess reductant is observed.

It is well known that $LiAlH_4$ reacts with alcohols at room temperature to form lithium alkoxyalumohydrides, with the number of substituted hydride ions depending on the alcohol used [11–13]. In particular, di-, tri-, and tetraalkoxy derivatives $LiAlH_2(OR)_2$, $LiAlH(OR)_3$, and $LiAl(OR)_4$ can be readily prepared by the reaction with methanol [11]:

$$LiAlH_4 + (4 - m)ROH = LiAlH_m(OR)_{4-m} + (4 - m)H_2, \quad (4)$$

where m = 0–3.

Similar reaction occurs with *tert*-BuOH, but, because of steric hindrance, only three hydride ions are substituted with three *tert*-BuO groups. The fourth *tert*-BuO group can be introduced only upon prolonged refluxing of the solution of $LiAlH_4$ in THF [11, 12].

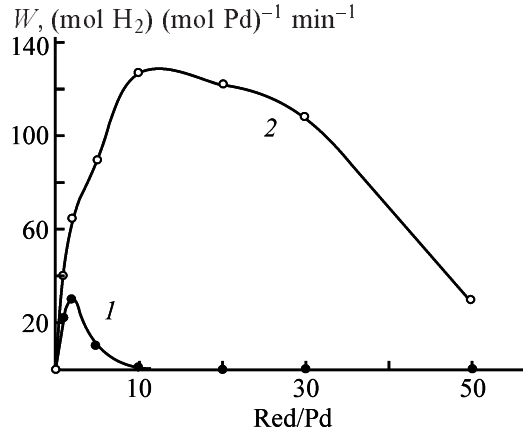

Fig. 1. Hydrogenation of styrene in the presence of the catalytic system $Pd(acac)_2$–Red. Red: (*1*) $LiAlH_4$ and (*2*) $LiAlH_4$–*n*-BuOH. c_{Pd} = 5 mM, [substrate]/$Pd(acac)_2$ ratio 170, solvent benzene, 30°C, P_{H_2} = 1 atm); the same for Fig. 2. (*W*) Catalytic activity; the same for Fig. 2.

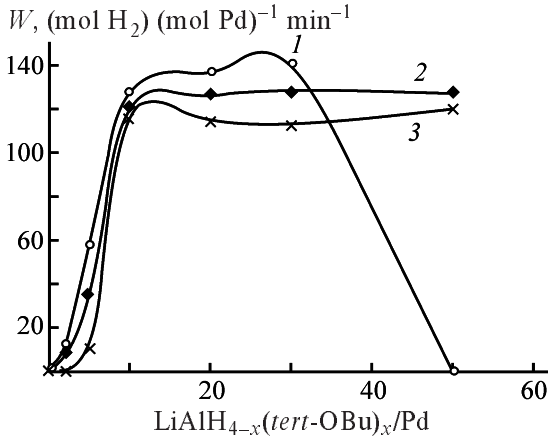

Fig. 2. Hydrogenation of styrene in the presence of the catalytic system $Pd(acac)_2$–$LiAlH_4$–*tert*-BuOH at *tert*-BuOH/$LiAlH_4$ ratios of (*1*) 1, (*2*) 2, and (*3*) 3.

With secondary alcohols, the major alcoholysis products are $LiAl(OR)_4$, apparently, owing to fast disproportionation of alkoxyhydride derivatives [12]

$$2LiAlH_2(OR)_2 \rightarrow LiAlH_4 + LiAl(OR)_4. \quad (5)$$

The formation of a mixture of $LiAlH_4$ and $LiAl(OR)_4$ (R = Et, *iso*-Pr) in partial alcoholysis of lithium tetrahydroaluminate (ROH/$LiAlH_4$ = 1–3) was also suggested by Turova et al. [13].

Since the available data on the composition of products formed by alcoholysis of lithium tetrahy-

Reaction between the components of the $Pd(acac)_2$–$LiAlH_4$–ROH systems. $c_{Pd(acac)_2} = 5 \times 10^{-3}$, $c_{LiAlH_4} = 0.54$ M, solvent benzene, 25°C

* Freshly prepared $LiAlH_4$–ROH solution was used.
** In alcoholysis of lithium tetrahydroaluminate.

droaluminate with various alcohols are ambiguous, in our study aimed to elucidate the main steps of formation of the catalytic system $Pd(acac)_2$–$LiAlH_4$–ROH we first examined the reaction of $LiAlH_4$ with *n*-BuOH and *tert*-BuOH. The results of volumetric determination of molecular hydrogen in the reaction of $LiAlH_4$ with *n*-BuOH and *tert*-BuOH are given in the table.

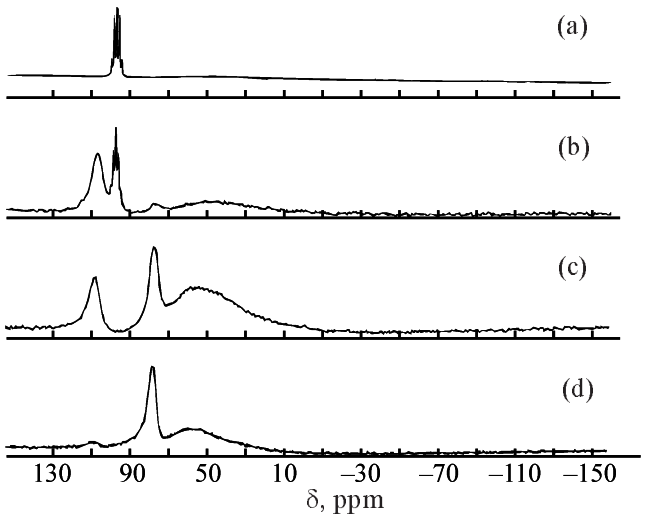

Fig. 3. ^{27}Al spectra of (a) solution of $LiAlH_4$ in THF and (b–d) products of its reaction with *tert*-BuOH at *tert*-BuOH/$LiAlH_4$ ratios of (b) 1, (c) 2, and (d) 3. c_{LiAlH_4} = 0.54 M; the same for Fig. 5. (δ) Chemical shift; the same for Figs. 4 and 5.

With *n*-butanol, alcoholysis of $LiAlH_4$ is complete in 1–2 min (c_{LiAlH_4} = 0.54 M), with an equmolar (with respect to alcohol) amount of hydrogen released. With *tert*-BuOH, the equimolar amount of hydrogen (with respect to alcohol) in alcoholysis of $LiAlH_4$ is released onlt at *tert*-BuOH/$LiAlH_4$ ratios of 1 and 2. The alcoholysis is complete in 1–2 and 60 min, respectively ($LiAlH_4$ concentration 0.54 M). At a *tert*-BuOH/$LiAlH_4$ ratio of 3 and a $LiAlH_4$ concentration of 0.54 M, even in 2 h the amount of the released hydrogen did not exceed 2 mol per mole of $LiAlH_4$, i.e., the alcoholysis did not go to completion. To gain more detailed information on the products of the reaction of $LiAlH_4$ with alcohols, we used ^{27}Al NMR spectroscopy.

The ^{27}Al NMR spectrum of a solution of $LiAlH_4$ in THF consists of one quintet at 98 ppm, with the coupling constant $^1J_{Al-H}$ = 173 Hz and line width at half maximum ($\Delta\nu_{1/2}$ ^{27}Al) of 47 Hz (Fig. 3a).

The chemical shift observed is typical of the AlH_4^- anion (95–102 ppm) [14, 15]. The multiplet structure

of the spectrum is caused by scalar spin–spin coupling of the equivalent protons with the Al isotope. It indicates that, in THF solution, the tetrahedral configuration of the AlH_4^- anion is preserved.

On adding *tert*-butanol to a $LiAlH_4$ solution ($ROH/LiAlH_4$ = 1), the spectral pattern changes. The ^{27}Al spectrum contains four signals with chemical shifts of 108.0, 98.0, 78.0, and 55.0 ppm (Fig. 3b). According to the ^1H NMR data, the reaction mixture contains no *tert*-butanol [expected signals, δ, ppm: 3.54 s (1H, OH), 1.17 s (9H, CH_3)]. The quintet at δ = 98 ppm, observed in the ^{27}Al spectrum, indicates that the $LiAlH_4$ conversion is incomplete. The relative content of unchanged $LiAlH_4$ is about 30%. In contrast to the quintet at δ = 98 ppm, the signals at 55.0, 78.0, and 108.0 ppm are broadened singlets. It is known that, if one of the ligands in the AlH_4^- anion is replaced by another ligand, the multiplet structure of the ^{27}Al signal is not manifested [15]. Hence, alcoholysis of $LiAlH_4$ with *tert*-butanol yields not one, as it could be expected from the stoichiometry of reaction (4), but three reaction products characterized in the ^{27}Al NMR spectrum by signals at 55.0, 78.0, and 108.0 ppm. Incomplete conversion of $LiAlH_4$ shows that lithium *tert*-butoxyalumohydrides are no less reactive than $LiAlH_4$ and also react with the alcohol. The products of complete alcoholysis of lithium tetrahydroaluminate with various alcohols, $LiAl(OR)_4$, are insoluble in THF, and their formation is usually judged by precipitation of a colorless product [11, 12]. The absence of the precipitate in the reaction of $LiAlH_4$ with *tert*-BuOH suggests that the reaction does not yield $LiAl(tert\text{-}BuO)_4$.

At the *tert*-$BuOH/LiAlH_4$ ratio of 2, the ^{27}Al NMR spectrum contains signals at δ 55.0, 78.0, and 108.0 ppm (Fig. 3c). At *tert*-$BuOH/LiAlH_4$ = 3, the ^{27}Al NMR spectrum consists of the same signals (δ 55.0, 78.0, and 108.0 ppm), but the ratio of their integral intensities changes (Fig. 3d). At the molar ratio *tert*-$BuOH/LiAlH_4$ = 3, the spectral pattern varied with time: In 9 days, the ^{27}Al NMR spectrum consisted of only two signals at δ 55.0 and 78.0 ppm (Fig. 4b). The relative intensity of the signal at δ 78.0 ppm decreased, and that of the signal at δ 55.0 ppm increased (Fig. 4c). In the process, the ^1H NMR signals of free *tert*-butanol decreased in the intensity.

Analysis of the NMR data allows the following assignment of signals in the ^{27}Al NMR spectrum. The signal at δ 55.0 ppm, characterizing the final

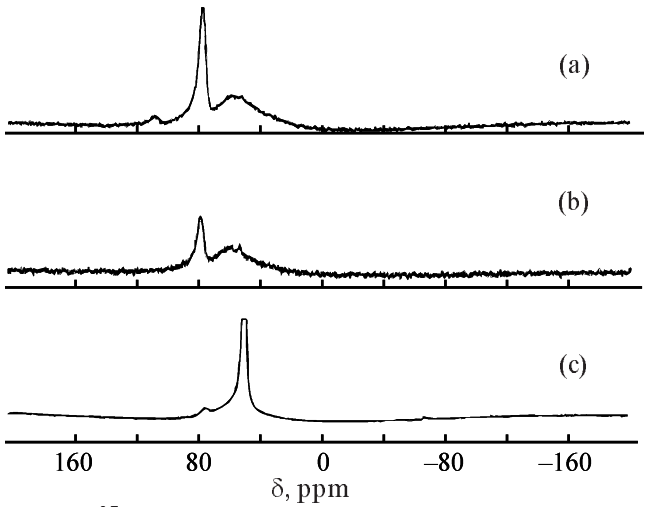

Fig. 4. ^{27}Al NMR spectra of alcoholysis products in the $LiAlH_4$–3*tert*-BuOH system in THF. Time after mixing: (a) 2 h, (b) 9 days, and (c) 3 days. c_{LiAlH_4}, M: (a, b) 0.54 and (c) 1.08.

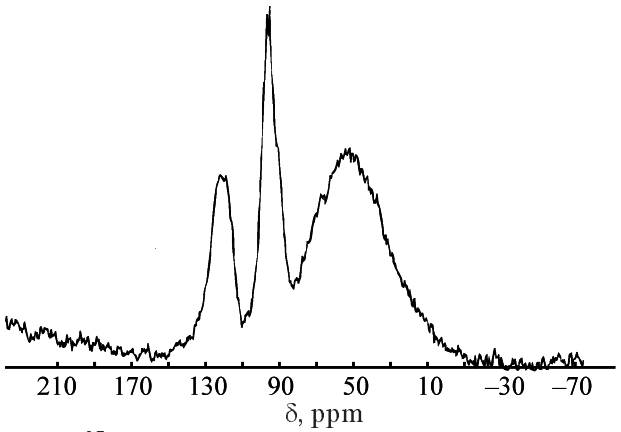

Fig. 5. ^{27}Al NMR spectrum of the $LiAlH_4$–*n*-BuOH solution in THF. $ROH/LiAlH_4$ = 1.

alcoholysis product, belongs to $LiAlH(tert\text{-}BuO)_3$; the signal at δ 78.0 ppm, to $LiAlH_2(tert\text{-}BuO)_2$; and the signal at δ 108.0 ppm, to $LiAlH_3(tert\text{-}BuO)$.

Thus, alcoholysis of $LiAlH_4$ with *tert*-butanol yields a mixture of lithium alkoxyalumohydrides $LiAlH_3(tert\text{-}BuO)$, $LiAlH_2(tert\text{-}BuO)_2$, and $LiAlH\cdot(tert\text{-}BuO)_3$ in the ratio depending on the amount of *tert*-BuOH. At *tert*-$BuOH/LiAlH_4$ = 1, about 30% of lithium tetrahydroaluminate remains unchanged.

In the reaction of $LiAlH_4$ with *n*-butanol at *n*-$BuOH/LiAlH_4$ = 1, according to the ^{27}Al NMR data, the reaction system contains both unchanged $LiAlH_4$ (δ 98.0 ppm) and products of its partial alcoholysis: $LiAlH_3(n\text{-}BuO)$ (δ 122.0 ppm), $LiAlH_2\cdot(n\text{-}BuO)_2$ (δ 71.0 ppm), and $LiAlH(n\text{-}BuO)_3$ (δ

53.0 ppm) (Fig. 5). At *n*-BuOH/$LiAlH_4$ = 3, the only transformation product is $LiAlH(n\text{-}BuO)_3$.

Hence, with $LiAlH_4$–ROH used as reductants, the system actually contains not individual compounds but a mixture of alcoholysis products and even a part of unchanged $LiAlH_4$. The composition of the reaction mixture depends not only on particular alcohol, but also on the ROH/$LiAlH_4$ ratio. Both $LiAlH_4$ and lithium alkoxyhydroaluminates $LiAlH_3(OR)$, $LiAlH_2(OR)_2$, and $LiAlH(OR)_3$ can participate in the reduction of $Pd(acac)_2$ in accordance with the equation

$$Pd(acac)_2 + 2LiAlH_{4-m}(OR)_m = Pd + 2Liacac + 2AlH_{3-m}(OR)_m + H_2, \quad (6)$$

where m = 0–3.

It should be noted that, in the $Pd(acac)_2$–$LiAlH_4$–*n*-BuOH system at *n*-BuOH/$LiAlH_4$ = 2 or 3, containing lithium alkoxyalumohydrides $LiAlH_2(OR)_2$ and $LiAlH(OR)_3$, Pd(II) is not reduced (see table, run nos. 4–9). A similar pattern was observed with the $LiAlH_4$–3*tert*-BuOH at the moment when, according to the ^{27}Al NMR data, it did not contain $LiAlH_4$ and $LiAlH_3(OR)$ (Figs. 4c, 4d), i.e., the reducing power of lithium alkoxyalumohydrides decreases in the order $LiAlH_4$ > $LiAlH_3(OR)$ > $LiAlH_2(OR)_2$ > $LiAlH(OR)_3$, so that $LiAlH_2(OR)_2$ and $LiAlH(OR)_3$ do not reduce $Pd(acac)_2$ under mild conditions. Thus, among the above reagents, only $LiAlH_4$ and $LiAlH_3(OR)$ act as reductants in the $Pd(acac)_2$–$LiAlH_4$–ROH system. At the same time, almost quantitative reduction of $Pd(acac)_2$ with a freshly prepared $LiAlH_4$–ROH solution (ROH/$LiAlH_4$ = 1, R = *n*-Bu, *tert*-Bu) at the Red : $Pd(acac)_2$ ratio of 2 (see table, run nos. 1, 10) indicates that some additional reagent, along with $LiAlH_4$ and $LiAlH_3(OR)$, participates in the Pd(II) reduction.

According to the UV data, in all the cases when $Pd(acac)_2$ was reduced, a decrease in the intensity of the absorption band at 330 nm in the UV spectrum (electronic transitions in palladium complexes with chelatingh $acac^-$ ligands) was accompanied by the appearance of a strong absorption band with a maximum at 288 nm. A previous study of the catalytic system $Pd(acac)_2$–$LiAlH_4$ by a set of spectroscopic methods (UV; ^{27}Al and ^1H NMR) showed that this band belongs to acac ligands bound to Al in $Al(acac)_3$ [4], whose formation is described by the equation

$$3Pd(acac)_2 + 2Al \longrightarrow 3Pd + 2Al(acac)_3, \quad (7)$$

or in its other derivatives, e.g., $Al(acac)(OR)_2$, $Et_2Al(acac)$ [16]. The molar extinction coefficient of this band depends on the number of chelating acac ligands at Al and is 14 470 l mol^{-1} cm^{-1} per acetylacetonate group. Hence, at the ratio *tert*-BuOH : $LiAlH_4$ > 1, when the system contains no unchanged lithium tetrahydroaluminate and hence formation of $Al(acac)_3$ is impossible, the band recorded in the UV spectrum at 288 nm can be assigned to acac ligands at Al in $Al(acac)_2$(*tert*-BuOH):

$$Pd(acac)_2 + AlH_2(OR) \rightarrow Pd + Al(acac)_2(OR) + H_2. \quad (8)$$

Thus, in generation of a hydrogenation catalyst in the $Pd(acac)_2$–$LiAlH_4$–ROH system, not only the fraction of $LiAlH_4$ unchanged in alcoholysis and lithium monoalkoxytrihydroaluminate $LiAlH_3(OR)$, but also Al and $AlH_2(OR)$ formed by redox reactions participate in the reduction of $Pd(acac)_2$. The contribution of each component will depend on the ratio of the rates of the redox processes.

The use of alcoholysis products instead of $LiAlH_4$ resulted in generation of palladium hydrogenation catalysts that were four times more active than the $Pd(acac)_2$–$LiAlH_4$ system. The promoting effect of alcohols can be caused not only by a decrease in the inhibiting effect of aluminum relative to the unmodified system. Other possible factors are the effect of the ligand surrounding and, probably, stronger ability of alkoxy anions to stabilize reduced Pd species, compared to that of AlH_4^- anions.

CONCLUSIONS

(1) A high-performance hydrogenation catalyst based on the $Pd(acac)_2$–$LiAlH_4$–ROH system was suggested.

(2) As shown by ^{27}Al NMR spectroscopy, the reaction of equimolar amounts of $LiAlH_4$ and ROH (R = *n*-Bu, *tert*-Bu) yields a mixture of lithium alkoxyalumohydrides consisting of $LiAlH_3(OR)$, $LiAlH_2(OR)_2$, and $LiAlH(OR)_3$, with a part of $LiAlH_4$ remaining unchanged.

(3) A promoting effect of alcohols on the properties of the $Pd(acac)_2$–$LiAlH_4$–ROH catalytic system in hydrogenation of unsaturated compounds was revealed. This effect is associated with two

factors: a decrease in the amount of Al acting as inhibitor owing to formation of a substitution solid solution and increased ability of alkoxy anions, compared to AlH_4^- anions, to stabilize reduced Pd species.

(4) The difference in the effects of *n*-butanol and *tert*-butanol at the ratio $ROH/LiAlH_4 > 1$ on the properties of the palladium hydrogenation catalyst is associated with the composition of the alcoholysis products and their reductive ability with respect to $Pd(acac)_2$. The inhibiting effect of *n*-butanol at $ROH/LiAlH_4 > 1$ is due to low reductive ability of lithium alkoxyalumohydrides $LiAlH_2(OR)_2$ and $LiAlH(OR)_3$.

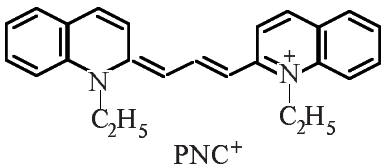
PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Effect of Surfactants on Homo- and Heteroassociation of Pinacyanol Cation in Aqueous Solution

S. A. Shapovalov



Karazin Kharkov National University, Kharkov, Ukraine

Received May 16, 2007

Abstract—The aggregative properties of pinacyanol in aqueous solution and the capability of its ionic associates to interact with surfactants were studied. The possibility of using pinacyanol associates for quantitative determination of cationic surfactants in aqueous solution and for estimation of the critical micelle concentration of anionic surfactants was examined.

DOI: 10.1134/S1070427208070069

Association between ions of various classes of dyes (heteroassociation) in solutions strongly affects the light absorption and is of both theoretical and applied interest [1, 2]. Heteroassociation in aqueous systems deserves particular attention. Water is a medium in which the interacting protolytic and aggregative species exhibit unique spectral and luminescence properties [1, 3]. Under definite conditions, a dye associate can act as analytical reagent, color marker, or bioprobe. These properties of dye associates find use in quantitative analysis, biochemistry, biomedicine, and in high technologies such as, e.g., solar power engineering and optoelectronics [4]. Cyanines exhibit particular tendency to heteroassociation. They are characterized by intense color and by capability to form stable ionic species in solutions. For a long time, much attention was given to pinacyanol {PNC, single-charged cation 2-ethyl-2-[3-(1-ethyl-1*H*-quinolin-2-ylidene)propenyl]quinolinium}:

PNC^+

Initially PNC was synthesized and tested as a standard of black-and-white photographic material in the beginning of the XX century [5, 6]. The subsequent studies concerned spectroscopic examination of PNC in liquid media of various kinds: organic solvents [7, 8], solutions with salt additions [9–11], premicellar and micellar systems [12–14], and photoemulsions [15, 16]. Pinacyanol is used, in particular, in studies of properties of biopolymers [17], steroids [18], and dendrimers [19–21], in development of metal-sensitive golographic sensors [22], and in studies of oligomeric surfactants [23] and lipopolysaccharides of complex structure [24–26].

Previously [27–30] we found that the PNC cation Ct^+ and its structural analogs interact with a series of organic anions to form in aqueous solutions ionic associates of various stoichiometric compositions. However, the dimerization and heteroassociation of PNC in solutions were studied inadequately.

In this study the aggregative properties of PNC and interaction of its heteroassociates with ionic surfactants were examined in more detail. Such studies may be useful, in particular, for the development of new procedures for determining surfactants in solutions and for estimating the critical micelle concentration (CMC) of ionic surfactants.

EXPERIMENTAL

Pinacyanol was used as chloride (Sigma). The salts and other chemicals (except dyes) were of chemically pure grade and were used without additional purification. The purity of dyes was checked spectrophotometrically from the known molar extinction coefficients at the wavelengths of the absorption maxima (λ_{max}) of the strongly colored protolytic forms. As surfactants we used anionic sodium dodecyl sulfate (SDDS) and cationic cetylpyridinium bromide (CPB), with the main substance content of no less than 98%. The solution acidity

was adjusted with phosphate, borate, and acetate buffer solutions, and also with additions of hydrochloric acid and sodium hydroxide. We found that the components of the buffer solutions in the amounts used do not noticeably affect the association processes. The pH was monitored with a glass electrode. The absorption spectra were measured at room temperature immediately after preparing the solutions on a Hitachi-U3210 or SF-46 spectrophotometer.[1] The λ_{max} values were determined with an accuracy of ±0.5 nm. From the optical densities we calculated the dimerization equilibrium constant β_{20}. The observance of the Bouguer–Beer law was checked. The measurement procedure was described elsewhere [27, 28, 30, 31]. In separate experiments[1] we found that, at the dye concentrations used, inorganic anions do not affect the molecular association of PNC.

In aqueous solutions in the pH range 3.5–9.5, PNC exists predominantly in the form of a single-charged cation appreciably protonated at pH < 2.5 and noticeably hydrolyzed at pH > 10.5. The formation of the dication, $Ct^+ + H^+ \rightleftarrows HCt^{2+}$ (for the double-charged cation, pK_a 3.5 [32]), or of the carbinol form, $Ct^+ + OH^- \rightleftarrows CtOH$, is accompanied by the break of the conjugation system of the chromophore and therefore results in decolorization of the solution. The light absorption of PNC in water depends on its concentration, because the dye shows pronounced tendency to homoassociation [33]. Figure 1 shows how the absorption spectrum changes with increasing PNC concentration. The light absorption increases throughout the examined range (curves *1–9*). However, in spectra *1–6* the major band is the α-band (ν_{max} = 16670 cm, or λ_{max} = 600 nm), and in spectra *8* and *9*, the β-band (ν_{max} = 18180 cm^{-1}, or λ_{max} = 550 nm). This redistribution of the absorption intensities is attributed to the transformation of the PNC monomer (Ct^+) into a dimer (Ct_2^{2+}) [22]. Since aggregation of a dye is of principal importance for its applications, we examined its features in more detail.

The aggregation of PNC cations can be represented by the scheme monomer → dimer → ... → H-aggregate (*n*-mer with ν_{max} = 19610 cm^{-1}, or λ_{max} = 510 nm). The dimerization of PNC is described by the equilibrium $2Ct^+ \rightleftarrows Ct_2^{2+}$ with the thermodynamic constant $\beta_{20} = a_{Ct_2}a_{Ct}^{-2}$, where a_{Ct} and a_{Ct_2} are the activities of the monomer and dimer, respectively (here and hereinafter, the charges are omitted; the dimension of the constant is l mol^{-1}). At concentrations of 5×10^{-7}–1×10^{-5} M, the ionic strength of the solutions is low, and β_{20} can be considered to be equal to $[Ct_2][Ct]^{-2}$, where the brackets denote the equilibrium concentrations (molar scale) of the species. Under these conditions, the content of higher associates Ct_n, where $n > 2$, can be neglected, then $c = [Ct] + 2[Ct_2]$, where c is the initial PNC concentration. The optical density of the solution at a given wavelength A_λ is expressed as

$$A_\lambda = \varepsilon_{Ct}[Ct]l + \varepsilon_{Ct_2}[Ct_2]l,$$

where ε_{Ct} and ε_{Ct_2} are the molar extinction coefficients of the monomer and dimer at wavelength λ; l is the layer thickness (cm).

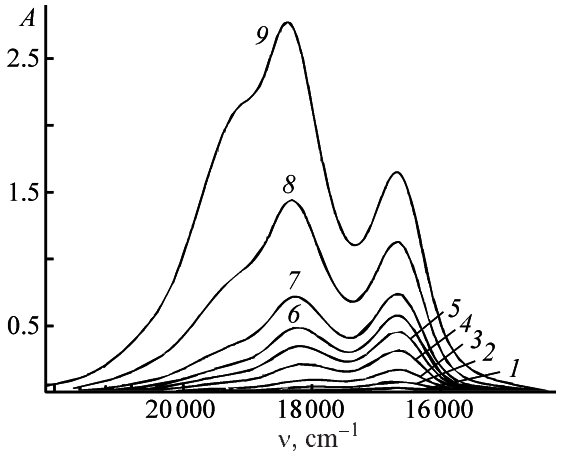


Fig. 1. Light absorption of an aqueous solution of PNC (pH 9.2). Reference solution water; the same for Figs. 3 and 4. Layer thickness 1.00 cm; the same for Figs. 3 and 5. (*A*) Optical density and (ν) wavenumber; the same for Fig. 4. c_{PNC}, M: (*1*) 5.0×10^{-7}, (*2*) 1.0×10^{-6}, (*3*) 2.0×10^{-6}, (*4*) 4.0×10^{-6}, (*5*) 6.0×10^{-6}, (*6*) 8.0×10^{-6}, (*7*) 1.0×10^{-5}, (*8*) 2.0×10^{-5}, and (*9*) 4.0×10^{-5}.

Hence, the dimerization constant $\beta_{20} = (A_\lambda - \varepsilon_{Ct}cl)(\varepsilon_{Ct_2}l - 2\varepsilon_{Ct}l)(c\varepsilon_{Ct_2}l - 2A_\lambda)^{-2}$. If l = 1 cm, we obtain $\beta_{20} = (A_\lambda - \varepsilon_{Ct}c)(\varepsilon_{Ct_2} - 2\varepsilon_{Ct})(c\varepsilon_{Ct_2} - 2A_\lambda)^{-2}$. The calculation based on solution of the system of two equations with unknown β_{20} and ε_{Ct_2} gave for two series of measurements (seven concentration points in each series) $\log\beta_{20} = 4.79 \pm 0.06$ at 297 K. Note that PNC in water shows stronger tendency to dimerization than do other cationic dyes {Rhodamine 6Zh ($\log\beta_{20} = 3.35 \pm 0.01$), Methyl Violet ($2.66 \pm 0.01$), Safranin T ($2.41 \pm 0.01$), Methylene Blue ($3.70 \pm 0.01$) [34], Rhodamine B ($2.98 \pm 0.03$) [35]}. In the series of structural analogs, in the

[1] Cand. Sci. (Chem.) T.V. Sakhno participated in the measurements and experiments.

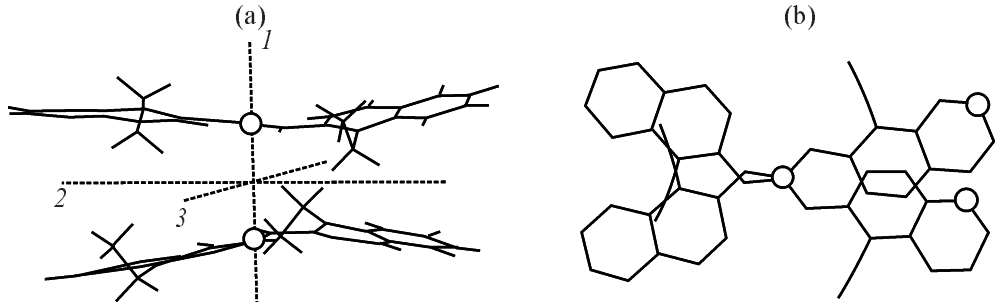

Fig. 2. Structure of PNC *trans* dimer: (a) with hydrogen atoms shown, distance between atoms denoted as circles 3.9 Å; (b) with hydrogen atoms omitted, view perlendicular to axis *1*, angle between the atoms denoted as circles (with the apex on the atom in the center of the polymethine chain) 33.9°.

tendency to dimerization PNC is inferior to some thiacarbocyanine dyes (for example, the dimerization constant of 3,3'-diethylthiatricarbocyanine is 2.4×10^5 [36]).

The dimer Ct_2^{2+} in which the ethyl radicals of the interacting cations are oriented in opposite directions (*trans* dimer, Fig. 2) appears to be more favorable energetically compared to the *cis* dimer (the ethyl radicals of the two cations are oriented in the same direction). This is indicated by the results of quantum-chemical calculations using the MOPAC 2000 software [37, 38] (AM1 semiempirical method; specific features of the calculations as applied to the dyes and their ionic associates are described in [39]). In the *trans* dimer, the cation planes are essentially coplanar. The heat of formation of this dimer is ΔH = 1325 kJ mol^{-1}, and ΔH of the Ct^+ cation is 1070 kJ mol^{-1}. For the *cis* dimer, there is no predominant mutual arrangement of the cations; ΔH of the *cis* dimer is no less than 1980 kJ mol^{-1}. Therefore, *trans* dimerization of PNC is preferable (energy gain $1070 \times 2 - 1325 = 815$ kJ mol^{-1}) over the *cis* dimerization (energy gain only $1070 \times 2 - 1980 = 160$ kJ mol^{-1}). The experimentall observed H-aggregation of PNC in solution can be represented as successive (one over another) *trans* association of the dye particles, when the π-electron interactions favoring the association are the strongest and prevail over the electrostatic repulsion of similarly charged particles.

Higher aggregates are not observed experimentally because of insufficient solubility of PNC. However, detailed analysis of the complex shape of the dye spectrum reveals their presence even at a dye concentration of 5×10^{-5} M. Deconvolution of the normalized spectrum of PNC reveals four overlapping bands [Fig. 3; the deconvolution model is equal-slope Gaussian; the maxima are sought for using the second derivative (curve *8*)]. The hypothesis of the existence of four bands is confirmed by virtual coincidence of the experimental spectrum (curve *1*) with the total calculated light absorption curve *2*: The difference between curves *1* and *2* (curve *7*) lies within a narrow corridor, from −0.039 to +0.032. The characteristics of the absorption bands of the normalized spectrum are given in the table (bands I, II, III, and IV correspond to curves *3*, *4*, *5*, and *6* in Fig. 3). The table shows that, at the indicated concentration, the PNC solution contains species more aggregated than dimers. Bands III and IV

account for approximately 1/3 of the total light absorption of PNC, whereas the relative contribution of the α-band is as low as ~23%. These data supplement the observations made in [32, 33] and allow estimation of the fraction of the PNC monomer in solution from the shape of the light absorption curve.

Cationic and anionic surfactants exert different effects on the dye. The PNC spectra at a dye concentration of 1×10^{-6}–5×10^{-5} M do not appreciably change the shape even at micellar concentrations of cationic CPB {CMC of CPB $(6.6–9.0) \times 10^{-4}$ M [40]}. This fact indicates that the dye cation forms no compounds with CPB, apparently because of electrostatic repulsion of the particles. On the contrary, interaction of PNC with SDDS is characterized by a complex pattern. At premicellar concentrations of the surfactant {CMC of SDDS is 8.5×10^{-3} M at 293 K [40]}, the dye forms with the surfactant a compound $PNC^+ + DDS^-$. This fact is consistent with data on interaction of dye ions with surfactant counterions [41]. However, at micellar (or close) concentrations of SDDS, these compounds are broken down because of solubilization of the cyanine on the surface of homomicelles. This pattern is observed irrespective of the initial concentration of PNC. Figures 4a and 4b show similar patterns of spectrum variation in PNC solutions of concentrations 2.7×10^{-6} and 1.5×10^{-5} M. In the first case, the monomeric form of PNC prevails in solution, and in the second case the fraction of the PNC

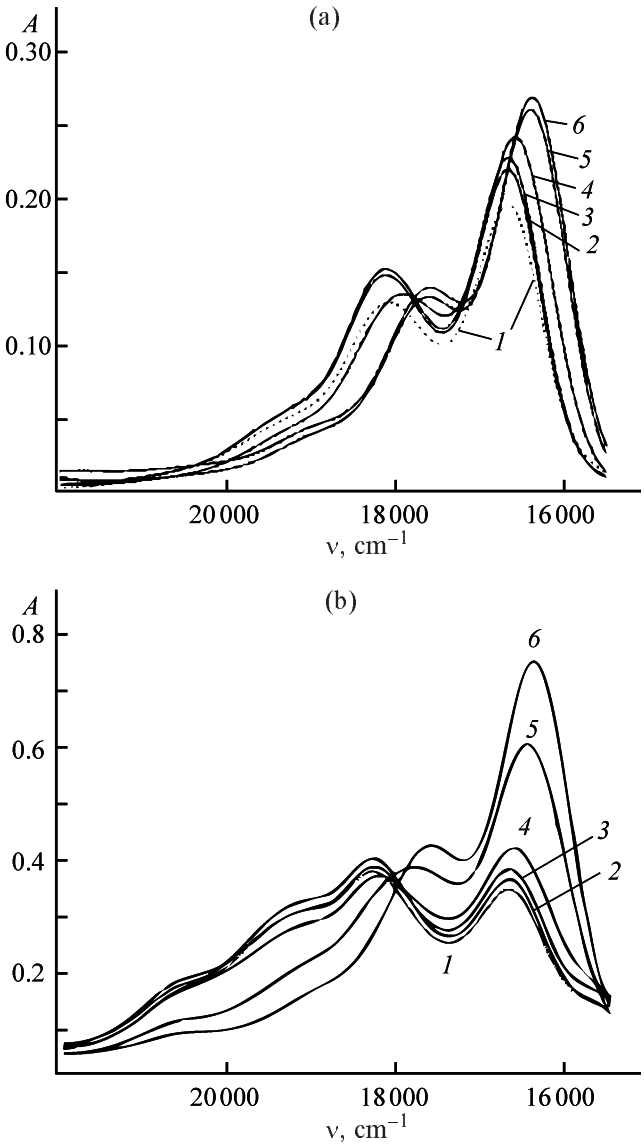

Fig. 4. Absorption spectra of the system PNC + SDDS (pH 5.9). c_{PNC}, M: (a) 2.7×10^{-6} and (b) 1.5×10^{-5}. Layer thickness, cm: (a) 1.00 and (b) 0.20. c_{SDDS}, M: (a) (*1*) 0, (*2*) 3.0×10^{-4}, (*3*) 4.0×10^{-4}, (*4*) 5.0×10^{-4}, (*5*) 6.0×10^{-4}, and (*6*) 9.5×10^{-4}; (b) (*1*) 0, (*2*) 5.0×10^{-4}, (*3*) 9.0×10^{-4}, (*4*) 2.0×10^{-3}, (*5*) 2.0×10^{-2}, and (*6*) 4.0×10^{-2}.

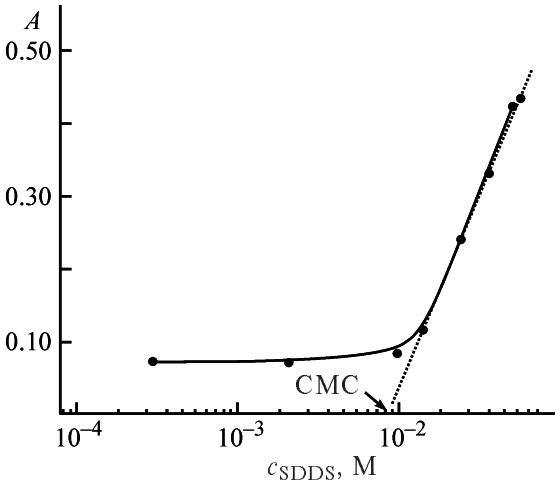
dimer is comparable with that of the monomer (cf. curve *1* in Fig. 4b and curves *6* and *7* in Fig. 1). However, despite different initial concentrations, the shapes of the spectra of PNC solutions at $[SDDS] \geq CMC_{SSDS}$ essentially coincide (Figs. 4a and 4b, curves *6*). The trend in the spectral changes is also similar: With a gradual increase in the SDDS content, the intensity of the long-wave α-band of PNC increases (Fig. 4b, curves *4–6*). Thus, the spectrum of PNC in micellar solutions of SDDS is similar to



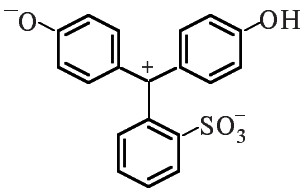


Fig. 5. Light absorption of a solution containing PNC, PR, and SDDS as a function of SDDS concentration c_{SDDS}. The reference solution contains 3.95×10^{-5} M PR and 4.86×10^{-6} M PNC; pH 9.2; λ = 608 nm. (A) Optical density.

the spectrum of the single-charged PNC cation, with a certain bathochromic shift.

It was found previously that PNC interacts with oppositely charged anions of various dyes to form ionic associates of various stoichiometries depending on the charges and concentrations of the counterions. In particular, the formation of sulfophthalein and oxyxanthene associates of the compositions $Ct^+ \cdot HAn^-$ and $(Ct^+)_2 \cdot An^{2-}$ (where HAn^- and An^{2-} are single- and double-charged dye anions), differing in the stability, has been reported [27, 29, 30]. Notably, additions of CPB of SDDS to the above associates break them down, as indicated by restoration of the shapes of absorption bands of each dye. Among sulfophthalein associates of PNC, nontrivial pattern of spectral changes is observed in the system PNC + Phenol Red (PR) + ionic surfactant:

PR^-

As this phenomenon is of practical interest, it was studied in more detail for associates of PNC^+ with single- and double-charged PR anions: $PNC^+ \cdot PR^-$ and $(PNC^+)_2 \cdot PR^{2-}$, respectively. In these experiments, the component concentrations were varied in the following ranges: cyanine, from 5×10^{-7} to 1×10^{-5} M; sulfophthalein, from 1×10^{-6} to 1×10^{-4} M; and surfactant, from 1×10^{-6} and higher. Like PNC proper, the heteroassociates show different responses on additions of cationic and anionic surfactants.

Cationic CPB breaks down the associate $PNC \cdot PR^-$ at low surfactant concentrations, from 3×10^{-6} to 2×10^{-5} M. In other words, the associate is fairly sensitive to the CPB content. The optical density at a fixed wavelength A_λ and constant concentrations of both dyes sharply increases with an increase in the surfactant concentration, c_{CPB} (M), showing a functional dependence on c_{CPB}. For example, at constant concentrations of PNC (4.9×10^{-6} M) and PR (7.1×10^{-5} M), at λ = 600 nm, the dependence is described by the equation $A_\lambda = (0.032 \pm 0.010) + (2.31 \pm 0.09) \times 10^4 c_{CPB}$. Such dependences can be used for quantitative determination of cationic surfactants in solution with a high sensitivity.

Additions of anionic SDDS break down the associate $(PNC^+)_2 \cdot PR^{2-}$ only at surfactant concentrations close to the micellar level. Figure 5 shows an example of the dependence of A_λ on the SDDS concentration. At $c_{SDDS} < CMC_{SDDS}$, variation of c_{SDDS} does not noticeably affect A_λ (linear portion virtually parallel to the abscissa). However, at $c_{SDDS} \approx CMC_{SDDS}$, A_λ at λ = 608 nm starts to sharply increase because of the release of PNC from the associate. We found that the extrapolated ascending portion (Fig. 5, dotted line) intersects the abscissa at c_{SDDS} close to CMC. Thus, it is principally possible to estimate CMC of an anionic surfactant from the experimental dependence of A_λ on c_{SDDS}.

As found previously [28], different behavior of PNC heteroassociates toward the examined surfactants can be due to different stability of the forming compounds of the cationic dye with the DDS^- anion and of the anionic dye with the CP^+ cation. Therefore, to attain the maximal effect in determination of cationic surfactants in solution and to estimate CMC of anionic surfactants, it seems important to use an associate of definite stability (in our case, associates of PNC with PR, but the use of heteroassociates of other dyes is also possible). These procedures will be characterized by high sensitivity and high contrast of the analysis. This is provided by the presence in solution of two dyes having well-resolved absorption bands in the spectrum (e.g., λ_{max} = 430 nm for PR^- and 600 nm for PNC^+). The latter fact favors not only instrumental but also visual detection of changes occurring in the solution and hence can be used in the development of test

procedures for determining cationic surfactants and/or for estimating CMC of anionic surfactants.

CONCLUSIONS

(1) The pinacyanol cation dimerizes in aqueous solution even at low concentrations. The dimerization constant was estimated from the spectroscopic data: $\log\beta_{20} = 4.79 \pm 0.06$ (at 297 K and $I \to 0$). The dimeric particle Ct_2^{2+}, most probably, has the *trans* structure.

(2) Specific features of the interaction of pinacyanol with cationic and anionic surfactants were elucidated. Ionic surfactants, when in micellar concentrations, cause solubilization of the dye, irrespective of its initial concentration and degree of dimerization.

(3) It was demonstrated by the example of heteroassociates of PNC^+ with single- and double-charged Phenol Red anions that the properties of pinacyanol associates can serve as basis of new procedures for determining the content of cationic surfactants in aqueous solutions and for estimating the critical micelle concentrations of anionic surfactants.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Adsorption Properties of Carbon Materials Produced by Thermolysis of Brown Coal in the Presence of Alkali Metal Hydroxides

Abstract—Activated carbons produced by thermolysis of brown coal impregnated with an alkali metal hydroxide MOH (M = Li, Na, K) at an MOH/coal ratio $R_{MOH} \le 80$ mol kg^{-1} were studied. Dependences of the adsorption capacities for iodine and Methylene Blue dye, specific surface area, and yield of activated carbons on the ratio R_{MOH} were obtained.

DOI: 10.1134/S1070427208070070

Thermolysis of fossil coal in the presence of hydroxides of alkali metals is a method for "chemical" activation [1–3] yielding activated carbons (ACs) with a large fraction of micropores, which occasionally exceeds 90% [4]. The high microporosity of materials of this kind predetermines their specific adsorption characteristics.

The chemical activation method is employed to produce ACs from fossil coals with different degrees of metamorphism, from brown coals to anthracites [2, 4–6]. Just brown coals (BCs) exhibit the highest activity in interaction with alkali metal hydroxides (MOH, where M stands for an alkali metal) because of the high content of OH-acid and other functional groups. In addition, the 3D skeleton of BC is conformationally labile, which allows MOH molecules and M^+ and OH^- ions to penetrate into the coal skeleton and form intercalation compounds of coal [7].

The mechanism by which MOH react with functional groups of coals is independent of the nature of M^+, whereas the specific surface area of ACs strongly varies depending on particular alkali metal cation [8]. It would be expected that the adsorption properties of ACs may also depend on the nature of an alkali.

The aim of the present study was to examine the adsorption characteristics of ACs produced by thermolysis of brown coal mixed with various alkali metal hydroxides and to assess the influence exerted by the nature of a cation.

EXPERIMENTAL

We used the most available alkalis (LiOH, NaOH, KOH) and brown coal from the Aleksandriiskoe deposit (particle size 0.5–1.0 mm) with the following characteristics (%): $W^a = 12.4$, $A^d = 11.7$, $V^{daf} = 57.6$, $C^{daf} = 70.4$, $H^{daf} = 6.0$, $S^{daf} = 3.8$, $N^{daf} = 2.0$, and $O^{daf}_{dif} = 17.8$.

The alkali metal hydroxide MOH was introduced into the carbon skeleton by impregnation with an aqueous–alkaline solution, followed by drying. A weighed portion of BC (20 g) was brought in contact with a 50% solution of MOH, kept there at 20 ± 2°C for 24 h, and dried. The coal impregnated with MOH was conventionally named BC–MOH compound. The thermolysis was performed in a vertical tubular stainless steel reactor. The reactor was purged with argon (~2 dm^3 h^{-1}) dried by bubbling through concentrated (≥96%) sulfuric acid. The heating of the reactor was switched on 10 min after the beginning of argon supply. The temperature mode of thermolysis was similar to that used in [9] and included a period of nonisothermal heating (4 deg min^{-1}) to 800°C, isothermal heating for 1 h, and rapid cooling in a flow of argon to $T \le 50$°C. An AC sample was washed with water to remove

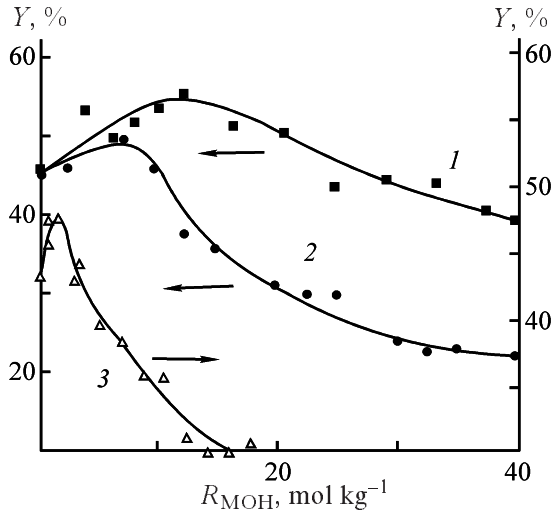

Fig. 1. Yield Y of adsorbents (based on the organic mass of coal) from BC–MOH compounds vs. the MOH/coal ratio R_{MOH}. MOH: (*1*) LiOH, (*2*) NaOH, (*3*) KOH; the same for Figs. 2–5.

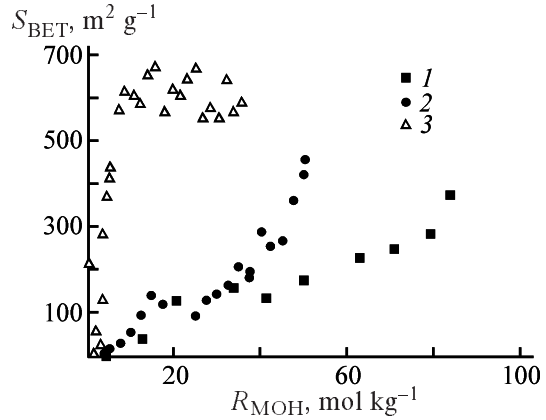

Fig. 2. Specific surface area S_{BET} of the adsorbents produced from BC–MOH compounds vs. the MOH/coal ratio R_{MOH}.

the alkali, with a 0.1 HCl solution, and again with water to negative reaction for Cl^- (with $AgNO_3$). The resulting AC sample was dried at 105±5°C to constant weight. The yield Y (%) was determined per dry coal mass, with determination errors within ±1%. The AC obtained was powder-like, with particle size of 0.05–0.25 mm and ash content A^d = 3.5–4%.

The specific surface area S_{BET} ($m^2 g^{-1}$) was found by low-temperature adsorption of argon. The determination error of S_{BET} was ±10 rel %.

As testing methods for evaluating the adsorption characteristics were chosen the adsorption capacity for Methylene Blue (MB) dye, A_{MB} (mg g^{-1}), used to evaluate the quality of clarifying carbons [10], and the adsorption capacity for iodine, A_I (mg g^{-1}) [11]. Iodine molecules are small and are adsorbed over the entire surface of AC, including the surface of micropores. On the basis of this property, a method for determining the specific surface area has been suggested [12]. The MB molecule has a considerably larger size (1.97 nm^2) and, therefore, can hardly penetrate into micropores [13]. Therefore, the quantity A_{MB} responds to changes in meso- (2–50 nm) and macropores (>50 nm) and is weakly sensitive to changes in the microporosity (≤2 nm).

For adsorbents produced by thermolysis of the chosen BC sample and BC–MOH compounds, the specific surface area and the adsorption parameters depend on the MOH/coal mass ratio and nature of an alkali.

As R_{MOH} increases, the AC yield first grows and then starts to fall (Fig. 1). The initial increase in the yield is the most pronounced for BC–LiOH compounds: from 45 to 55% at R_{LiOH} = 13 mol kg^{-1}. For BC–NaOH compounds, this effect is also well noticeable: the yield increases from 45 to 49% at R_{NaOH} = 7.5 mol kg^{-1}. In the case of KOH, the effect of an increase in yield is manifested at small alkali : coal ratios ($R_{KOH} \leq 2$ mol kg^{-1}).

On passing the maximum value, the AC yield decreases, with the yield the lower, the larger the alkali metal cation. For example, at R_{MOH} = 30 mol kg^{-1}, the AC yield is 44 (BC–LiOH), 24 (BC–NaOH), and 20% (BC–KOH).

As R_{MOH} increases, S_{BET} decreases to a minimum at R_{KOH} = 1–3 mol kg^{-1} and then increases at $R_{KOH} \rightarrow 15$ mol kg^{-1} (Fig. 2). Further increase in the amount of the alkali within the range R_{KOH} = 15–40 mol kg^{-1} does not lead to any development of the surface: it remains approximately constant within the experimental error and varies within the range S_{BET} = 550–680 $m^2 g^{-1}$.

The dependences of S_{BET} on R_{MOH} for the compounds BC–NaOH and BC–LiOH differ from that for BC–KOH. An increase in the parameter R_{NaOH} also leads to a decrease in S_{BET} to the minimum value at R_{NaOH} = 5±0.3 mol kg^{-1}. Then S_{BET} steadily increases with R_{MOH}, but the dependence does not level-off in contrast to the case of BC–KOH compounds (Fig. 2). The maximum value of S_{BET} (450 $m^2 g^{-1}$) is observed at R_{NaOH} = 50 mol kg^{-1}. A rise in the S_{BET} of solid products formed in thermolysis of BC–NaOH compounds over that of AC produced from the starting brown

coal is noticeable at $R_{NaOH} \geq 40$ mol kg^{-1}. That is, sodium hydroxide suppresses an increase in the specific surface area of brown coal under study in the range R_{NaOH} = 2.5–40 mol kg^{-1}. For ACs produced from BC–LiOH compounds, the initial decrease in the specific surface area and its subsequent increase are also observed (Fig. 2). However, on the whole, the development of the surface is less pronounced for LiOH, compared to NaOH and KOH.

The process of surface development apparently depends on the nature of an alkali metal cation. At small R_{MOH}, S_{BET} decreases for all the alkalis as the alkali/BC ratio grows, but this occurs in different ways for different alkalis (Fig. 2). As regards the development of the surface, the activity of the alkalis grows in the order LiOH < NaOH < KOH. For example, obtaining an adsorbent with S_{BET} = 400 m^2 g^{-1} requires thermolysis of a BC–MOH compound containing 80 mol kg^{-1} LiOH, or 50 mol kg^{-1} NaOH, or 5 mol kg^{-1} KOH, i.e., a 16 : 10 : 1 ratio is observed. In other words, the activity of KOH in the development of the AC surface is 10 times that of NaOH and 16 times that of LiOH. In the range R_{MOH} = 5–10 mol kg^{-1}, S_{BET} increases for LiOH and NaOH and approaches a plateau for KOH. A difference in the behavior between LiOH and NaOH is only observed at $R_{MOH} \geq 40$ mol kg^{-1}: the development of the AC surface becomes more noticeable for BC–NaOH than for BC–LiOH compounds.

The adsorption capacity for MB increases with R_{MOH} for ACs produced with all the alkalis (Fig. 3). The dependences of A_{MB} on R_{MOH} are similar for adsorbents produced from BC–LiOH and BC–NaOH compounds: the adsorption capacity steadily increases from 61 to 94 mg g^{-1} for BC–LiOH and from 58 to 157 mg g^{-1} for BC–NaOH. At the same time, the rise in A_{MB} is considerably more pronounced for ACs produced from BC–KOH compounds: A_{MB} reaches values of 300 mg g^{-1}.

The dependences of the adsorption capacity of ACs for iodine on the amount of an alkali in BC–MOH compounds are qualitatively similar (Fig. 4) to the dependences of S_{BET} on R_{MOH} (Fig. 2). For all of the alkalis, A_I decreases at small R_{MOH} and then the adsorption capacity of ACs increases and does so to a greater extent for BC–KOH compounds. For ACs obtained at R_{KOH} = 15 mol kg^{-1}, values as high as A_I = 1000–1200 mg g^{-1} are reached. For ACs produced from BC–LiOH and

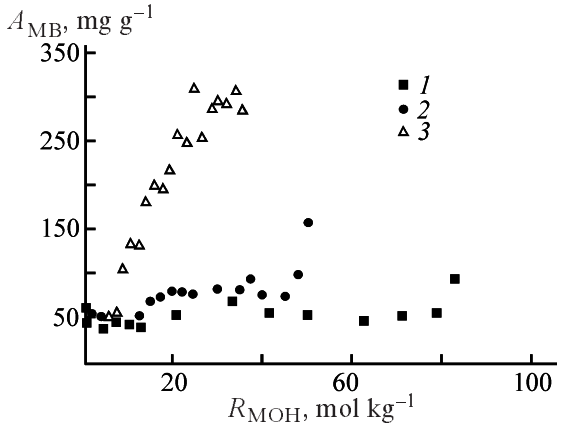

Fig. 3. Adsorption capacity for MB, A_{MB}, of adsorbents produced from BC–MOH compounds vs. the MOH/coal ratio R_{MOH}.

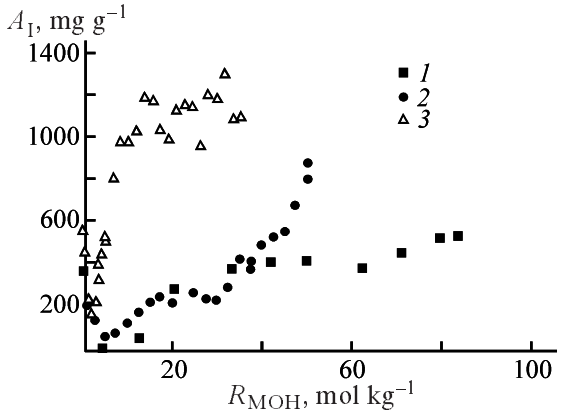

Fig. 4. Adsorption capacity for iodine, A_I, of adsorbents produced from BC–MOH compounds vs. the MOH/coal ratio R_{MOH}.

BC–NaOH, the adsorption capacities for iodine are lower (A_I = 860 mg g^{-1} for BC–NaOH and A_I = 520 mg g^{-1} for BC–LiOH), although the alkali : coal ratio is larger. For example, producing an AC with A_I = 600 mg g^{-1} requires a BC–MOH compound containing 5 mol kg^{-1} KOH, or 45 mol kg^{-1} NaOH, or no less than 100 mol kg^{-1} LiOH.

Figure 5 shows adsorption characteristics of ACs as functions of the specific surface area. As can be seen, A_{MB} changes only slightly, from 40 to 100 mg g^{-1}, as the specific surface area increases to approximately 500 m^2 g^{-1}. In the surface area range 500–800 m^2 g^{-1}, A_{MB} is independent of S_{BET}; this region is nearly entirely formed by adsorbents produced by thermolysis of BC–KOH compounds. For these adsorbents, A_{MB} increases with R_{MOH} (Fig. 3).

The adsorption capacity for iodine is directly proportional to S_{BET} (Fig. 5b), depends only slightly

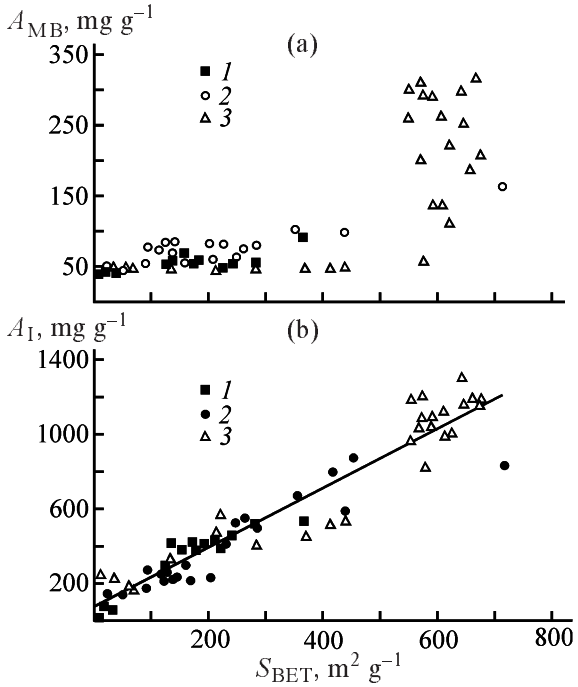

Fig. 5. Adsorption capacity for (a) MB, A_{MB}, and (b) iodine, A_I, vs. the specific surface area S_{BET} for adsorbent samples produced from BC–MOH compounds.

on the nature of a cation, and can be described by a linear dependence $A_I = 74 + 1.57S_{BET}$ ($R^2 = 0.92$). This means that only the specific surface area of the adsorbent is an important factor for the adsorption capacity for iodine, whereas the nature of an alkali is of almost no importance.

The adsorption capacity for MB ($A_{MB} \leq$ 310 mg g^{-1}) of adsorbents obtained in this study by thermolysis of BC with KOH exceeds that of carbons of OU-A and OU-B brands (A_{MB} = 210–225 mg g^{-1}), used to purify food and pharmaceutical products and process solutions [GOST (State Standard) 4453–74]. The adsorption capacity for iodine of these same adsorbents (A_I = 1000–1300 mg g^{-1}) also markedly exceeds the parameters of industrially manufactured carbons of BAU-A and BAU-MF brands (A_I = 600–700 mg g^{-1} according to GOST 6217–74).

CONCLUSIONS

(1) Thermolysis (800°C, 1 h) of brown coal impregnated with an alkali MOH (M = Li, Na, or K) yields adsorbents with high adsorbing capacities for iodine (up to 1300 mg g^{-1}) and Methylene Blue dye (up to 300 mg g^{-1}), which exceed the parameters of industrially manufactured activated carbons.

(2) The specific surface area and adsorption parameters of the adsorbents are governed by the alkali–coal ratio and increase in the order LiOH < NaOH < KOH.

(3) The dependences of the adsorption capacity for iodine on the specific surface area of the adsorbents are linear and the same for different alkalis.

Received December 25, 2006

Abstract—The effect of humates isolated from peat on the state in solution of the leuco acid of Vat Brilliant Green C dye was examined spectrophotometrically and compared with the effect of dispersants traditionally used in textile-chemical processes: disodium methylenebis(naphthalenesulfonate) and triethanolamine.

DOI: 10.1134/S1070427208070082

Peat humates (PHs) are the salt form of humus acids, specific polymeric organic compounds synthesized in the nature from plant residues under the action of soil microorganisms and abiotic factors of the medium. Humus acids are irregular copolymers of polyhydroxycarboxylic acids, containing also diverse other fragments (both aliphatic and aromatic) and functional groups (carboxy, hydroxy, phenolic, quinone, keto, hydroxymethyl, amino, imino, etc.) [1, 2]. Therefore, PHs participate in ionic and donor–acceptor interactions, hydrogen bonding, and formation of complexes with metals and adducts with various classes of organic compounds [2–5]. For living bodies, peat humates are nontoxic and nonteratogenic. They exhibit high physiological activity, primarily as strong adaptogens [6].

Peat humates are used in plant and animal breeding [7, 8], in medicine [9–11], in technologies of soil remediation and wastewater treatment [6, 12, 13], in mining [14], in building [15], and in other branches of economy.

The environmental safety of PHs makes them very attractive for applications to any fields of human activity, especially if they can replace less environmentally friendly synthetic chemicals. The processes for recovery of humates from peat are safe and waste-free.

This work continues our studies aimed to substantiate the feasibility of using PHs in textile finishing processes. Previous studies revealed the capability of humates to modify structurally and chemically starch sizing gels [16], to catalyze the reduction of vat dyes in the course of fabric printing [17, 18], and to improve the parameters of fabric dyeing with vat dyes (intensity and uniformity of dyeing), especially in the leuco acid process [19].

In accordance with this process, a vat dye in the ionic form, reduced in an alkaline solution, is converted to a nondissociated leuco acid by weak acidification. The leuco form of the dye forms an unstable colloidal solution whose stability is provided by adding special compounds, dispersants. Interaction of the dye with the dispersant determines not only the stability of the colloidal solution, but also the course of sorption of the dye with a fiber and of the subsequent diffusion in the fiber.

The dispersants traditionally used in dyeing of fabrics with the leuco acid of a vat dye are disodium methylenebis(naphthalenesulfonate) (NF, DNF) and triethanolamine (TEA).

In this study we compared the effects of DNF, TEA, and PHs on the state in aqueous solution of the leuco acid of Vat Brilliant Green C dye (VBGC) with the aim to substantiate the dispersing effect of PHs exerted on nonionic forms of vat dyes.

EXPERIMENTAL

Colloidal solutions of VBGC leuco acid were prepared by mixing two components: alkaline solution of sodium salt of leuco compound of the vat dye and aqueous solution of acetic acid [20] into which the required amount of a dispersant (DNF, TEA, PHs) was additionally introduced. The pH of the colloidal solutions prepared was 6.0.

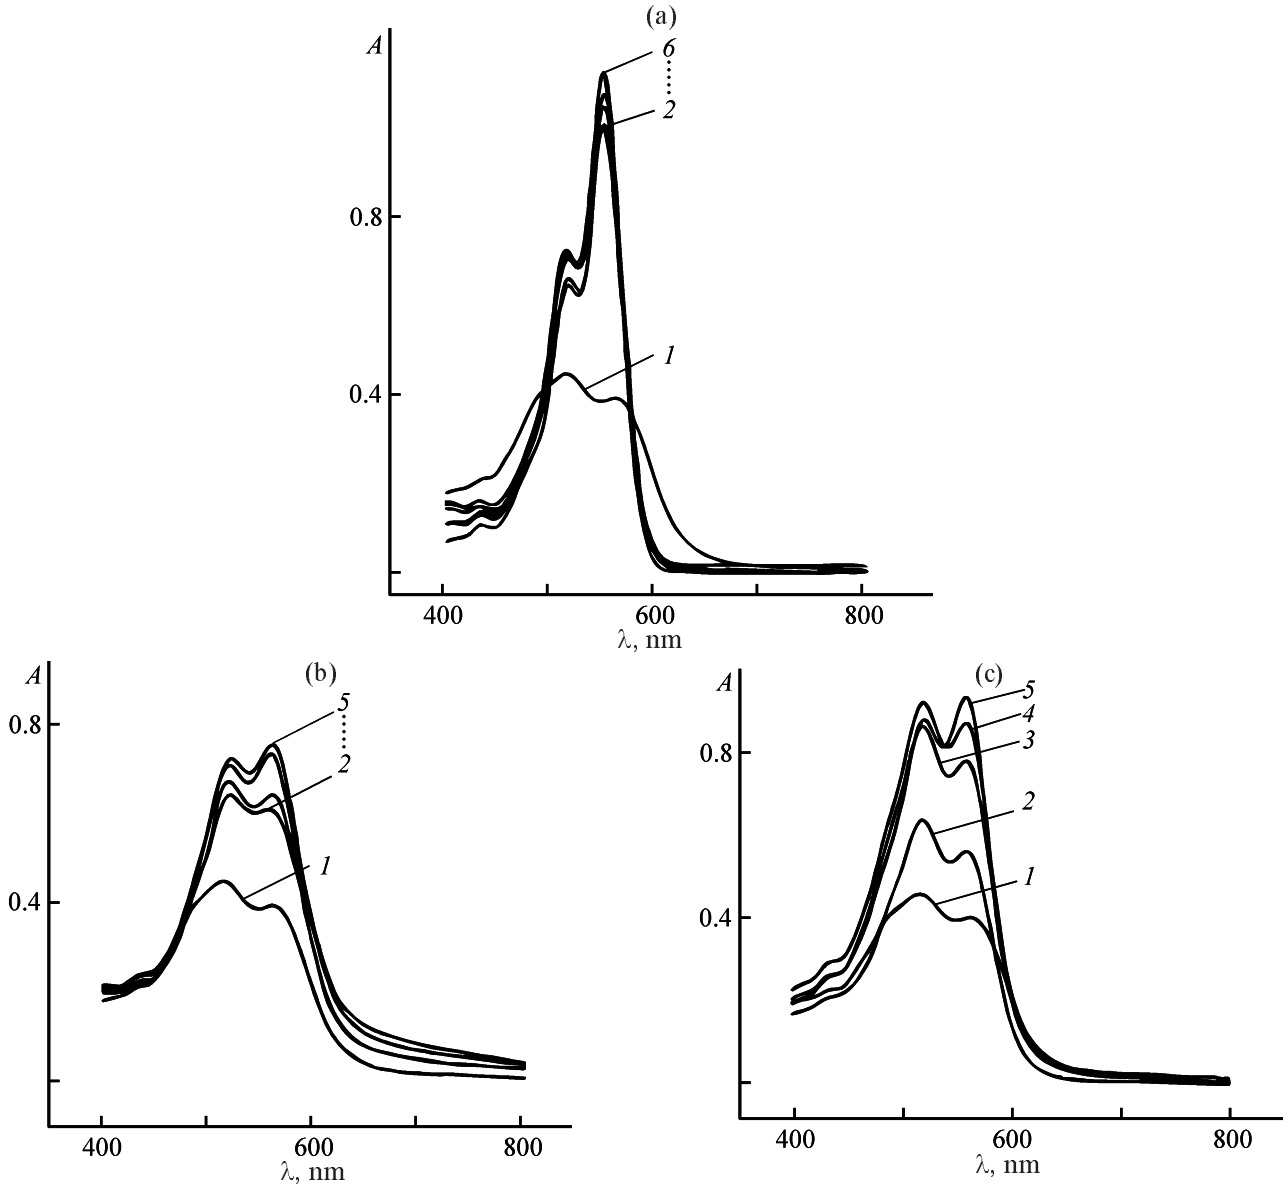

Fig. 1. Effect of the concentration of (a) DNF, (b) TEA, and (c) PHs in solution on the absorption spectra of VBGC leuco acid. (*A*) Optical density of VBGC solution and (λ) wavelength; the same for Fig. 2. [VBGC] = 8.32×10^{-5} M; 25°C. (a) [DNF], g l^{-1}: (*1*) 0, (*2*) 0.5, (*3*) 2, (*4*) 5, (*5*) 10, and (*6*) 50; (b) [TEA], g l^{-1}: (*1*) 0, (*2*) 1, (*3*) 5, (*4*) 10, and (*5*) 20; (c) [PHs], g l^{-1}: (*1*) 0, (*2*) 0.05, (*3*) 0.1, (*4*) 0.2, and (*5*) 0.5.

In the experiment we used VBGC dye as a pigment containing no additives of auxiliary textile substances.[1] The PH preparation was obtained from valley peat of the wood–sedge group by alkaline extraction [21] in the form of an aqueous solution with pH 8.2. Under these conditions, humates exhibit properties of anionic polyelectrolytes owing to dissociation of all carboxy groups and a part of phenolic groups.

[1] Submitted by Krasitel' Open Joint-Stock Company (Rubezhnoe, Ukraine).

In each series of experiments, the dye content was kept constant, and only the concentration of the additive was varied. The absorption spectra were recorded on a Specord M 400 spectrophotometer. The reference cell was filled with the solution of the dispersant of the same concentration as in the working cell and with the same pH.

The obtained series of absorption spectra of VBGC are shown in Figs. 1a–1c. As can be seen, the spectra of colloidal solutions of the leuco acid of the dye undergo noticeable changes. In all the

cases, the absorption appreciably increases (in the presence of DNF, by a factor of approximately 2.9; in the presence of TEA, by a factor of 1.6; in the presence of PHs, by a factor of 2.2). Also, DNF additions cause strong narrowing of the bands.

It is well known that, in solutions of ionic dyes, formation of disordered associates is accompanied by broadening of the absorption spectra and by a decrease in the extinction, which is the more pronounced, the larger the fraction of the dye involved in associates and the coarser the associates [22]. On the contrary, decomposition of the associates causes an increase in the optical density of the dye solution and narrowing of the spectrum. Hence, the spectral manifestations of the dispersing effect of the agents tested (DNF, TEA, PHs) toward the limitedly soluble leuco form of the vat dye coincide with the spectral manifestations of the decomposition of associates of ionic dyes into monomers.

In addition, we evaluated the effect exerted on the spectra of colloidal solutions of VBGC leuco acid by factors that a fortiori cause coagulation of the dye. In the first experiment, coagulation was induced by heating the solution, and in the second experiment, by adding an inorganic electrolyte (NaCl) acting as a salting-out agent [23]. The experimental data obtained are shown in Figs. 2a and 2b. They show that, in the course of coagulation (coarsening of dye particles in solution as a result of their aggregation, up to phase separation), the intensity of the light absorption by the dye decreases and the spectrum is broadened.

Thus, we can conclude that the dispersants tested cause disintegration of particles of the leuco acid of the vat dye in solution.

As already noted, an important feature of DNF is that even its first portions added to aqueous colloidal solutions of VBGC leuco acid cause significant narrowing of the absorption spectra of the dye. This fact indicates that the light absorption in the regions corresponding to the main electronic transition in the dye molecule becomes more efficient. From this standpoint, the observed narrowing of the spectrum can be considered as a consequence of weakening of the dye–solvent interaction on adding DNF. Hence, DNF additions cause resolvation of dye molecules, suppressing their vibrations.

This effect is not observed on adding the other two substances, TEA and PHs, to solutions of VBGC leuco acid, although the resolvation undoubtedly does take place, because the solutions are

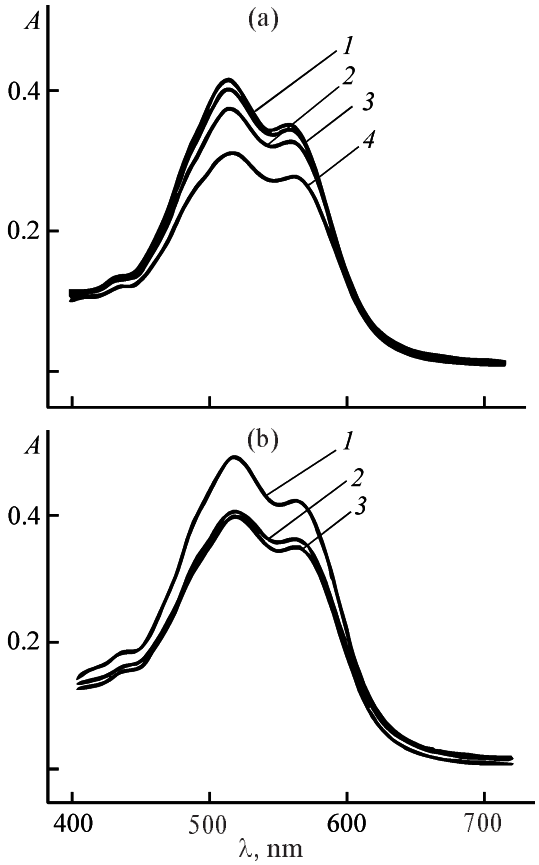

Fig. 2. Effect of (a) temperature and (b) NaCl concentration on the absorption spectra of solutions of VBGC leuco acid. [VBGC], M: (a) 6.7×10^{-5} and (b) 7.8×10^{-5}. (a) Temperature, °C: (*1*) 20, (*2*) 30, (*3*) 40, and (*4*) 50. (b) [NaCl], $g\ l^{-1}$: (*1*) 0, (*2*) 10, and (*3*) 20.

stabilized. For example, whereas without dispersants the dye coagulation starts within 30–40 min after preparing the solution, in the presence of small additions of PHs it starts in 10–12 h.

Presumably, different effects of DNF, TEA, and PHs on the absorption spectra of aqueous colloidal solutions of VBGC leuco acid are due to different nature of dye–additive interactions, which, in turn, are associated with specific features of the molecular structure of the additives. With DNF, naphthalene fragments of the dispersant molecule can interact with planar chromophores of the polycyclic vat dye molecule, which is accompanied by displacement of a part of the solvent from the solvation shell of the dye. With TEA, interaction of the dye occurs, most probably, via hydrogen bonding between hydroxy groups of the amino alcohol and functional groups of the dye. Peat humates contain in their molecules both aromatic structures and functional groups capable of hydrogen bonding.

Thus, humates recovered from peat can be recommended as adequate substitutes of synthetic dispersants. Their advantages are environmental safety, full absence of toxicity, and relatively low cost.

CONCLUSIONS

(1) In the presence of dispersants (DNF, TEA) and peat humates, the light absorption by the dye increases.

(2) In the dispersing performance, peat humates are intermediate between DNF and TEA.

Abstract—Effect of plasma modification on the sorption properties of short flax fibers for Zn(II) ions was studied.

DOI: 10.1134/S1070427208070094

Of interest in development of resource-saving technologies are sorption methods for purification of various aqueous solutions to remove heavy metal ions, with natural polymeric materials of vegetable origin as sorbents. Owing to their availability and low cost [1–3], agricultural wastes are promising sorbents for recovery of heavy metal ions from aqueous media. However, sorbents of this kind, as a rule, have low sorption capacity for the target component. Therefore, an important area in the development of new sorbents is modification of natural cellulose-containing polymers to raise their sorption capacity. There have been reports [4–9] in which various methods for processing of cellulose-containing sorbents were suggested, including mechanical, physical, mechanochemical, chemical, physicochemical, and biotechnological kinds of treatment. A promising area of modification of polymeric sorbents is application of environmentally safe plasma techniques [10, 11].

The aim of this study was to examine the effect of plasma modification of a natural cellulose-containing polymer, short flax fibers, on its sorption properties with respect to Zn(II) ions.

EXPERIMENTAL

We used in the study short flax fibers, a secondary product obtained at flax mills and having the following composition (%): cellulose 75–78, hemicellulose 9.4–11.9, lignin 3.8, pectin substances 2.9–3.2, waxy substances 2.7, nitrogen-containing substances 1.9–2.1 (in terms of proteins), and mineral substances 1.3–2.8 [12]. We also used $ZnSO_4 \cdot 7H_2O$ and NaOH of chemically pure grade.

The sorbents were modified using two kinds of discharge. The laboratory installations used to treat a sorbent with an atmospheric-pressure-discharge plasma and low-pressure gas-discharge plasma were similar to those described in [13]. The short flax fibers was modified with the atmospheric-pressure-discharge plasma in a glass cell equipped with two metallic electrodes and a magnetic stirrer. One of the electrodes (cathode) was submerged in a solution, and the other (anode) was situated over the surface of the electrolyte solution at a distance of 5 mm. The sorbent was placed in the cell and poured over with a NaOH solution with a concentration of 0.5 g l^{-1} at a solution : sorbent ratio of 80. A voltage of about 1 kV was applied to the electrodes, which resulted in that an atmospheric-pressure glow gas discharge appeared between the electrode in the gas phase and the surface of the aqueous electrolyte solution. The discharge current I was varied from 15 to 30 mA, with the treatment time τ_{tr} in the range 5–30 min. After the treatment, the sorbent was extracted from the cell and dried in air at room temperature to constant mass.

Modificaiton of short flax fibers with low-pressure gas-discharge plasma was performed in a plasmochemical reactor designed as a glass tube with metallic electrodes arranged in side arms. The sorbent was placed in the reactor evacuated to a residual pressure of 1 Pa. Then air was fed at a velocity of 5 cm s^{-1} with continuous pumping. The sorbent was treated with a glow discharge under the following conditions: working pressure 100 Pa, discharge current 15 and 30 mA, electrode voltage about 1 kV, treatment time 5–30 min.

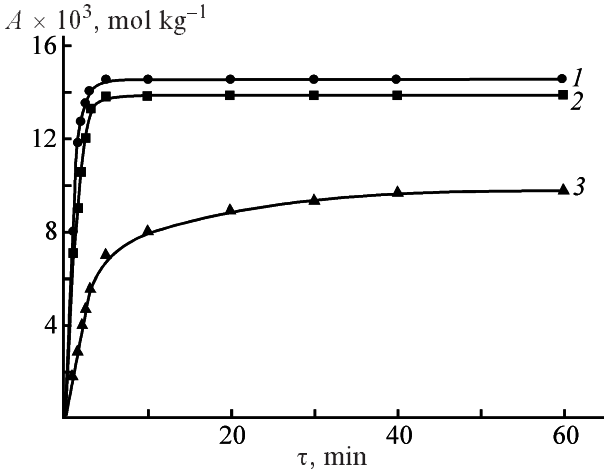

Fig. 1. Kinetics of sorption of Zn(II) ions (*1, 2*) by short flax fibers modified at I = 30 mA and τ_{tr} = 30 min with (*1*) atmospheric-pressure-discharge plasma and (*2*) low-pressure gas-discharge plasma and (*3*) by native flax fibers. (A) Sorption capacity and (τ) sorption time.

The sorption of Zn(II) ions from aqueous solutions of zinc sulfate was studied under static conditions with stirring and thermostating (293 K). The sorption kinetics was analyzed by the limited-volume method [14]. To obtain kinetic curves of sorption, weighed portions (m = 0.1 g) of native or plasma-modified flax fibers were placed in a set of test tubes, poured over with 10 ml (V) of an aqueous zinc sulfate solution with an initial concentration $c_0 = 1.5 \times 10^{-4}$ M, and kept for 30 min to 24 h. After certain intervals of time, the solution was separated from the sorbent and the current concentration of zinc ions, c_τ, in solution was determined by atomic-absorption spectroscopy on a Saturn instrument. The sorption capacity A_i of the sorbent at any given instant of time was calculated by the formula

$$A_i = \frac{c_0 - c_i}{m} V.$$

Under the conditions of an equilibrium attained by the system, we determined the equilibrium concentration of metal ions in solution, c_{eq}, and calculated the equilibrium sorption capacity of the sorbent, A_{eq}:

$$A_{eq} = \frac{c_0 - c_{eq}}{m} V.$$

The degree of recovery (%) was determined as follows:

$$\alpha = \frac{c_0 - c_{eq}}{c_0} \times 100.$$

To obtain sorption isotherms, weighed portions (0.1 g) of short flax fibers were placed in a set of test tubes, poured over with 10 ml of an aqueous zinc sulfate solution with initial concentrations of 1.5×10^{-4}–8×10^{-3} M, and kept until the equilibrium was attained. Then we separated the solution from the sorbent by filtration and determined the concentration of metal ions.

The relative experimental error was calculated using data of equilibrium and kinetic experiments in which each point is an average of the results of three parallel runs [15]. The accuracy of the Saturn instrument in determining the concentration of metal ions is 3%. The experimental error did not exceed 10%.

Important parameters of polymeric sorbents are the sorption capacity and the time in which the sorption equilibrium is attained [16]. Kinetic studies demonstrated that, in sorption of Zn(II) ions by native short flax fibers, the equilibrium in the system is attained in 40 min. The sorption capacity of the native polymer is 9.7×10^{-3} mol kg^{-1} (Fig. 1, curve *3*). The results obtained indicate that the native sorbent has good kinetic properties at a low sorption capacity.

Natural flax is composed of a set of polymers containing various functional groups exhibiting donor properties: carboxy, ether, and hydroxy groups. These groups can adsorb metal ions. Flax fibers also contain hydrophobic components, lignin and waxy substances, which hinder wetting of the natural sorbent and interfere with the sorption process. Consequently, to improve the sorption properties of flax fibers, it is necessary to remove hydrophobic substances from fibers or modify them. In addition, it is necessary to form new sorption-active groups in the sorbent. Therefore, we studied the effect of plasma treatment on the equilibrium and kinetic characteristics of short flax fibers with respect to Zn(II) ions.

The results of kinetic experiments on sorption of Zn(II) ions by short flax fibers modified by low-pressure gas-discharge and atmospheric-pressure-discharge plasmas are shown in Fig. 1 (curves *1, 2*). These data indicate that both the modification methods lead to an increase in the sorption capacity of short flax fibers by a factor of approximately 1.5. The strongest effect is obtained in activation of the sorbent by the atmospheric-pressure-discharge plasma. Simultaneously, the time of sorption of zinc ions by plasma-modified short flax fiber samples is 40 to 5 min shorter than that for the native sample.

The influence exerted by the modification time on the sorption capacity of short flax fibers is illustrated

by Fig. 2 for two kinds of discharge, with currents of 15 and 30 mA in each case. It should be noted that the duration of the modifying treatment noticeably affects the extent to which the sorption capacity of the polymer increases. Figure 2 shows that the effect of the plasma activation on the sorption properties of short flax fibers is observed already after 5 min of discharge treatment. The growth of the discharge capacity of the sorbent occurs during the entire modification process, becoming somewhat slower by its end. Upon activation for 30 min at a discharge current of 30 mA, the degree of recovery of zinc ions by modified sorbents is 1.4 and 1.5 times that of native flax fibers for low-pressure gas-discharge and atmospheric-pressure-discharge plasmas, respectively. Somewhat poorer results are observed at a discharge current of 15 mA.

To determine the optimal parameters of the plasma activation of the natural sorbent, we studied the effect of various methods and modes of modification on the kinetic and sorption characteristics of the polymer. The table presents the results obtained in modification of the short flax fibers with atmospheric-pressure-discharge and low-pressure gas-discharge plasmas in comparison with the native sorbent and short flax fibers treated with a NaOH solution with a concentration of 0.5 g l^{-1}. The treatment with such an alkali solution was chosen because, in accordance with the procedure employed, it is used for activation of the sorbent in the plasma–solution system. Therefore, it was necessary to estimate the contribution of each kind of modification to the integral effect of enhancement of the sorption capacity of short flax fibers. As seen from the table, modification of the sorbent with a NaOH solution leads to a 10% increase in the degree of recovery of zinc ions and to a decrease in the sorption time by a factor of approximately 2.5, compared to the natural fiber. This can be attributed to the following: alkaline treatment results in removal of hemicelluloses and partial removal of hydrophobic waxy substances and lignin, which hinder adsorption of aqueous solutions of reagents (zinc ions) and decelerate their penetration into the fiber. As a result, the porosity and hydrophilicity of flax fibers increases and the functional groups capable of binding heavy metal ions become more accessible.

The data in the table indicate that the plasma modification substantially improved the sorption-kinetic properties of the natural sorbent. In sorption of Zn(II) ions on sorbents modified with atmospheric-pressure-discharge and low-pressure gas-discharge plasmas, the time in which equilibrium is attained in the heterogeneous system becomes 4–8 times shorter and, depending on the treatment duration, is 5–10 min.

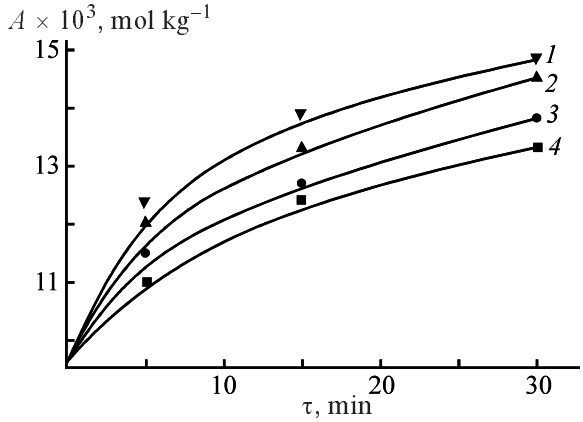

Fig. 2. Effect of the time τ of modification with (*1, 2*) atmospheric-pressure-discharge plasma and (*3, 4*) low-pressure gas-discharge plasma at I of (*1, 3*) 30 and (*2, 4*) 15 mA on the sorption capacity of short flax fibers. (*A*) Sorption capacity.

The effect observed is accounted for by simultaneous occurrence of several processes. First, these are oxidation and removal of incrusting substances:

Plasma activation parameters and characteristics of the natural sorbent in various modification conditions

Modification method	τ_{eq},* min	c_{eq}, mg l^{-1}	α, %	$A \times 10^3$, mol kg^{-1}
Unmodified sorbent	40	3.8	62	9.7
NaOH solution, 0.5 g l^{-1}	15	2.8	72	11.3
Low-pressure gas-discharge plasma				
I = 15 mA, τ_{tr}, min:				
5	10	2.2	78	12.2
15	7	1.9	81	12.7
30	5	1.5	85	13.3
I = 30 mA, τ_{tr}, min:				
5	10	2.0	80	12.5
15	7	1.7	83	13.0
30	5	1.2	88	13.8
Atmospheric-pressure-discharge plasma:				
I = 15 mA, τ_{tr}, min:				
5	8	1.6	84	13.1
15	6	1.2	88	13.8
30	5	0.7	93	14.5
I = 30 mA, τ_{tr}, min:				
5	8	1.4	86	13.4
15	6	1.0	90	14.1
30	5	0.5	95	14.8

* τ_{eq} is the equilibration time.

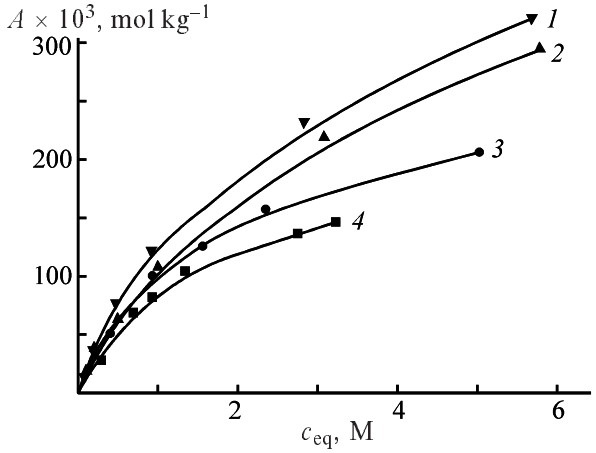

Fig. 3. Isotherm of sorption of Zn(II) ions by short flax fibers modified at I = 30 mA, τ_{tr} = 30 min with (*1*) atmospheric-pressure-discharge plasma and (*2*) low-pressure gas-discharge plasma. (*A*) Equilibrium sorption capacity and (c_{eq}) concentration of metal ions in solution. (*3*) Flax fibers treated with a NaOH solution and (*4*) native flax fibers.

hemicelluloses, waxy and pectin substances, and lignin. Second, these are partial depolymerization and oxidation of cellulose as the main component of flax.

Thus, the plasma treatment leads to chemical changes in the surface layers of flax fibers (~5 nm). Treatment in a low-pressure glow discharge makes lower the molecular weight of cellulose and oxidizes it to give mostly aldehyde groups [13]. Also noted is the formation of low-molecular-weight fractions of cellulose, which can be removed by washing in water. This accounts for the smaller increase in the degree of recovery of zinc ions by short flax fibers upon their modification with low-pressure gas-discharge plasma, compared with that upon modification of the fibers with atmospheric-pressure-discharge plasma.

Modification with the atmospheric-pressure-discharge plasma is also accompanied by depolymerization and oxidation. However, the material being processed is subjected in this case to a milder treatment, the degradation processes do not have such a deep impact on the polymer, and the resulting effect is preserved in the course of time.

The main difference between the two kinds of plasma modification of the polymer consists in the qualitative and quantitative dissimilarity of the active species being generated and of their effect on the polymer. In the atmospheric-pressure-discharge plasma, the concentration of atomic oxygen is comparable with that in the low-pressure plasma, whereas the concentration of singlet oxygen is considerably lower, and that of ozone, several orders of magnitude higher. Passing to humid air results in a substantial decrease in the concentrations of ozone and atomic oxygen, but oxidizing agents with other properties, OH and HO_2 radicals, appear instead [13].

To determine parameters characterizing the sorption capacity of unmodified and modified short flax fibers, we measured isotherms of sorption of Zn(II) ions from aqueous $ZnSO_4$ solutions (Fig. 3). The experimental data can be described by Langmuir adsorption isotherm equation:

$$A = A_\infty K c_{eq}/(1 + K c_{eq}),$$

where K is the concentration constant of the sorption equilibrium, which characterizes the intensity of the sorption process (M^{-1}).

Linearization of the sorption isotherms by the equation

$$\frac{1}{A} = \frac{1}{A_\infty} + \frac{1}{A_\infty K}\frac{1}{c_{eq}}$$

enabled graphical determination of the limiting sorption A_∞ in the Langmuir equation for native flax fibers and for flax fibers modified with an alkaline solution, low-pressure gas-discharge plasma, and atmospheric-pressure-discharge plasma: 0.15, 0.20, 0.45, and 0.53 mol kg^{-1}, respectively.

CONCLUSIONS

(1) The time τ_{eq} in which sorption equilibrium of flax fibers with respect to Zn(II) ions is attained in the system constituted by an aqueous zinc sulfate solution and plasma-modified short flax fibers is 4–8 times shorter than τ_{eq} for unmodified fibers: 5–10 min depending on the treatment duration.

(2) Plasma modification of short flax fibers leads to an increase in their limiting sorption capacity by a factor of approximately 3–3.5. The strongest effect is observed in the case of modification of flax fibers with an atmospheric-pressure-discharge plasma.

(3) The improvement of the equilibrium-kinetic characteristics of the natural polymer is accounted for by the following: occurrence of degradation and oxidation processes leading to removal of hydrophobic substances from the fibers; increase in their hydrophilicity, porosity, and internal surface area; better accessibility of the available functional groups; and formation of new sorption-active groups in the polymer being modified.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodeposition of Iron from Sulfate Solutions in the Presence of Aminoacetic Acid

Abstract—The kinetics and technology of iron electrodeposition from sulfate solutions containing various amounts of aminoacetic acid at pH 1.65, 1.95, and 2.50 in the temperature range 20–50°C were studied.

DOI: 10.1134/S1070427208070100

Amino acids are widely used in various branches of science and engineering [1–8], including electrolytic deposition of metals. Use of amino acids in electroplating is caused by the fact that electrolytes based on carboxylic acids and their derivatives can replace toxic electrolytes [2], allow preparation of alloys having preset physicochemical properties with a high current efficiency [3], and are relatively noncorrosive [6–8]. Furthermore, amino acids undergo biodegradation in sewage, which can be enhanced by adding chemical oxidants. As a result, amino acids lose the ability to bind metal ions [5]. Reactions of amino acids with metal cations result in the formation of various highly stable cyclic structures (chelates) [5]. Depending on temperature, pH of solution, ligand concentration, and some other factors, various complexes species can be formed:

It is also well known that organic acids exhibit buffer properties [4]. Their use in the deposition of electronegative metals provides the maintenance of constant pH in the cathode region. In particular, when iron group metals are electroplated, with the aim to improve the quality of the coatings, it is recommended to add certain amounts of aminoacetic acid to the electrolyte [2]. However, its role in the course of electrode reactions during the electrolysis of metal salts is poorly understood, and the choice of its optimal concentration is not substantiated.

The aim of this work was to study the kinetics of electrode reactions of iron deposition from sulfate solutions containing various amounts of aminoacetic acid (glycine) and to determine conditions for obtaining high-quality iron coatings.

EXPERIMENTAL

To prepare solutions, we used chemically pure grade $FeSO_4 \cdot 7H_2O$ and analytically pure grade NH_2CH_2COOH. The required pH was adjusted with sulfuric acid (analytically pure grade). Solutions with a constant $FeSO_4$ concentration of 0.2 M and the aminoacetic acid concentration varied within the range 0.05–0.4 M were studied. The experiments were carried out at pH 1.65, 1.95, and 2.50, at 20–50°C. The concentration of iron(II) ions and the total iron content were determined by volumetric permanganate titration [9]. The current efficiency by iron was determined gravimetrically. The electrolysis was carried out in the galvanostatic mode, using a B5-47 stabilized power source. Each experiment was repeated no less than three times on conditions that smooth deposits evenly covering the cathode working surface were obtained. Polarization curves were taken in the potentiostatic mode using a temperature-controlled three-electrode glass cell. The working electrode was a plate of electrolytic iron of 1 cm^2 area, auxiliary electrodes were made of transformer iron, and the reference electrode was a saturated silver chloride electrode. The buffer capacity was determined by potentiometric titration [10] with a 0.5 M NaOH solution. In so doing, the acidity was measured with a 150M pH-meter.

The current efficiency by iron in relation to the current density and pH of the solution is given in Table 1. These data show that the current efficiency increases in the whole pH range examined as the current density increases. The addition of glycine to the electrolyte first leads to an increase in the current efficiency, but at glycine concentrations higher than 0.1 M it decreases. For example, at a concentration of 0.4 M, practically only hydrogen is evolved (Table 1). In pure sulfate solutions, iron is deposited from simple iron ions, whereas, when glycine is added, iron ions partially or completely form complexes. However, the observed character of the dependence of the current efficiency by iron on the aminoacetic acid concentration cannot be attributed to the kinetics of the discharge of iron complex ions. According to the kinetics of electrode reactions, the rate of metal ion discharge from complex compounds should be less than or equal to that from simple ions, as determined by the reaction mechanism. Similar dependences were obtained at 40 and 50°C.

The addition of glycine affects not only the kinetics, but also the quality of the deposits. For example, without glycine, grey coatings with pitting are obtained; they begin to crack as the current density increases (over 30 mA cm^{-2}). Addition of glycine allows us to expand the range of working current densities to 50 mA cm^{-2} and to obtain lustrous smooth deposits. The best coatings are obtained at glycine concentrations of 0.1–0.15 M. Similar dependences were obtained at 40–50°C.

To determine the kinetics of electrode processes in the electrolytes under the above-given conditions, we recorded the cathodic and anodic polarization curves. The results obtained at 20°C and pH 1.95 are shown in Figs. 1 and 2. It can be seen that the rate of the cathode process decreases as the concentration of glycine in the electrolyte and pH decrease. The same trend is observed at 40–50°C.

We calculated the partial curves on the basis of the total polarization curves and current efficiencies by iron. The partial curves of discharge of iron ions are presented in semilog coordinates in Fig. 3. It is seen that the experimental points for all the considered variants are well fitted by straight lines with a slope corresponding to the discharge of iron ions in steps, with addition of the first electron being the slow step. Certain deviation from such

(*i*) Cathode current density and (*E*) potential (vs. saturated silver chloride electrode). Acid concentration, M: (*1*) 0, (*2*) 0.1, and (*3*) 0.2.

dependence of straight line *1* can result from the narrow range of obtaining high-quality deposits. We calculated the apparent activation energies of the discharge of iron ions, which are equal to 45.73, 32.24, and 34.30 kJ mol^{-1}, respectively, from the temperature dependence of the rate of the cathode process in solutions with different glycine concentrations of 0, 0.1, and 0.2 M. The values obtained also confirm that the electrochemical process is slow.

For the reaction of hydrogen evolution, we recorded the polarization curves in solutions similar in composition to those under study, but free of iron ions (Fig. 4). The data obtained at 20°C and pH 1.95 show that the presence of glycine in the electrolyte decreases the discharge rate of hydrogen ions, which may be due to glycine adsorption on the negatively charged electrode surface. It is known that, at the electrolyte acidity under study, glycine in solution is in the form of the $^{+}NH_3CH_2COOH$ cation [11], and the zero-charge potential of iron is −0.35 V [12]. Thus, the addition of glycine to the electrolyte affects the kinetics of both processes, but to a different extent. It is this fact that may be responsible for the observed maximum in the dependence of the current efficiency by iron on the amino acid concentration. At low glycine concentrations (up to 0.1 M), when iron is partially involved in complex formation, the current efficiency by iron grows owing to the inhibition of the parallel reaction to a greater extent. As the glycine concentration increases and iron becomes completely involved in the complex formation, the discharge rate of iron ions decreases to a greater extent than that of hydrogen ions, with the result that the current efficiency decreases.

The examination of the anode curves shows that the addition of glycine to the electrolyte does not affect the iron dissolution in the entire range of temperature and solution acidity. We found equilibrium potentials from the discharge curves of iron. For the amino acid concentrations of 0, 0.1, and 0.4 M these potentials are −0.488, −0.556, and −0.648 V, respectively. The shift of the equilibrium potential toward the negative values suggests the formation of complex species; however, these data are insufficient to make a conclusion on the structure of the complexes. The buffer capacities of the electrolyte, given in Table 2, were determined by potentiometric titration. It can be seen that the addition of glycine to the electrolyte in an amount of 0.2 M increases the buffer capacity by a factor of almost five. Furthermore, the addition of aminoacetic acid positively affects the electrolyte stability. We

Table 2. Buffer capacity of iron-plating electrolytes at various concentrations of aminoacetic acid

Electrolyte	c, M	Buffer capacity, mole of alkali per liter of electrolyte, at indicated pH			
		20°C		40°C	
		1.65–2.65	1.95–2.95	1.65–2.65	1.95–2.95
$FeSO_4 \cdot 7H_2O$	0.20	0.030	0.036	0.033	0.037
$FeSO_4 \cdot 7H_2O$, NH_2CH_2COOH	0.20, 0.10	0.075	0.090	0.096	0.102
$FeSO_4 \cdot 7H_2O$, NH_2CH_2COOH	0.20, 0.20	0.135	0.142	0.150	0.153

found that iron(III) is not accumulated in the electrolyte in the course of the six-month operation in the presence of glycine.

CONCLUSIONS

(1) Examination of the partial polarization curves of the discharge of iron and hydrogen ions during the electrolysis of sulfate solutions with various concentrations of aminoacetic acid shows that the presence of glycine in the electrolyte inhibits both processes. However, under the conditions studied, the electrochemical reaction is the limiting step of both processes.

(2) The dependence of the current efficiency by iron on the glycine concentration passes through a maximum. The influence of other factors (pH and temperature) on the coating quality was revealed. The following conditions are recommended for obtaining high-quality deposits: sulfate electrolyte containing 0.1–0.15 M glycine, pH 1.9±0.1, 20°C, and current density i_c = 20 mA cm^{-2}.

(3) The addition of glycine to the sulfate electrolyte increases its buffer capacity and also its stability in operation.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Production of Composite Electroplated Nickel–Fullerene C_{60} Coatings

V. N. Tseluikin, N. D. Solov'eva, and I. F. Gun'kin

Abstract—Kinetic relationships of the deposition of composite electroplated coatings based on nickel with a disperse phase of C_{60} fullerene were studied. The composition of the coatings was determined by secondary-ion mass spectrometry.

DOI: 10.1134/S1070427208070112

Composite electroplated coatings (CECs) are widely used for modifying metal surfaces. The CEC formation is affected by the nature of dispersed particles [1, 2]. Fullerenes can become a promising dispersible material for composite coatings, as they have unique chemical properties [3]. The majority of studies in the field of the electrochemistry of fullerenes are devoted to the determination of redox potentials of their derivatives [4]. However, the electrodeposition of fullerenes with metals is studied poorly.

The aim of this study was to prepare nickel–C_{60} fullerene CECs, to examine the kinetic relationships of this process, and to determine the composition of the coatings.

EXPERIMENTAL

A colloidal dispersion of C_{60} fullerene in water free of organic solvents was prepared according to [5]. By adding this dispersion to a nickel-plating electrolyte, we obtained a solution with the following concentrations of components (g l^{-1}): $NiSO_4 \cdot 7H_2O$ 220, $NiCl_2 \cdot 6H_2O$ 40, CH_3COOK 30, and C_{60} 0.05; pH 5.0. The nickel–fullerene C_{60} CEC was electrolytically deposited on a steel support (steel 45) at 25°C with continuous stirring of the electrolyte. To increase the content of the dispersed phase particles in coatings, we placed the cathode at an angle of 45° to the anode. "Pure" nickel was precipitated from the electrolyte of the same composition but without C_{60} addition.

The nickel–C_{60} fullerene CEC deposits were analyzed by secondary-ion mass spectrometry (SIMS) [6] on an MI-1305 magnetic mass spectrometer equipped with a universal unit for studying solids. The coatings intended for the analysis were deposited on a copper support.

Electrochemical measurements were carried out on a P5848 potentiostat with a KSP-4 automatic potentiometer. Potentials were set against saturated silver chloride reference electrode and recalculated to the hydrogen scale.

We have plotted the partial curves of nickel deposition (Fig. 1) on the basis of the initial currents of the deposition of nickel coatings and nickel–C_{60} CECs. In the presence of fullerene particles in the nickel-plating electrolyte, the cathode curves are shifted toward the positive potentials. The i_c–E

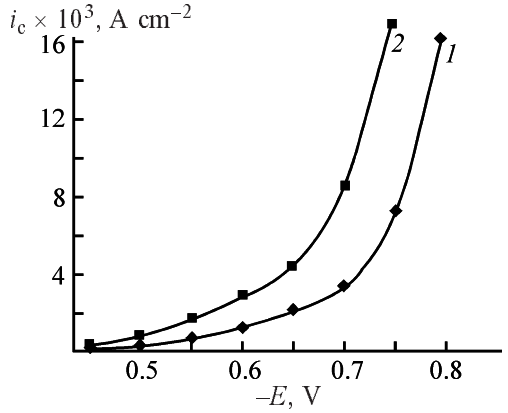

Fig. 1. Partial polarization curves of nickel deposition: (*1*) without additions and (*2*) with C_{60} fullerene addition. (i_c) Initial deposition current and (E) potential.

dependences show that the addition of C_{60} fullerene to the electrolyte makes easier the precipitation. In the presence of disperse particles, nickel is deposited at less negative potentials E in the whole examined range of potentials. The increase in currents on the CEC deposition relative to "pure" nickel coating suggests that the electrodeposition rate increases.

It is believed [7] that the transfer of dispersed phase particles to the cathode can proceed through the adsorption on their surface of cations of the metal being deposited. In the process, the particles acquire charge, are transferred to the cathode, and are discharged there, being overgrown with the metal. The ions adsorbed on particles participate in binding the dispersed phase with the cathode surface, which enhances the adhesion. Presumably, fullerene C_{60}, being an electron acceptor, gains a negative charge in the electrolyte solution on passing current and adsorbs nickel cations on its surface, which promotes the migration of dispersed particles to the cathode and their incorporation in the crystal lattice of the deposit.

In the case of the deposition in the galvanostatic mode, when fullerene is added to the nickel-plating electrolyte, the potentials are shifted toward positive values (Fig. 2). We calculated the polarization capacity of the electrical double layer from the data of the galvanostatic experiments using the expression

$$C = \frac{i}{\partial E/\partial t},$$

where i is the current density (A dm^{-2}); E; potential (V); and t, time (s).

The polarization capacity decreases on passing from nickel coatings to nickel–C_{60} fullerene coatings (see table). This is attributable to the fact that dispersed fullerene particles are relatively coarse and their incorporation in the electrical layer double increases its size.

The SIMS analysis of the composition of the nickel–C_{60} fullerene CECs revealed the presence of carbon and C–H bonds in the deposits. The content of carbon in coatings is about 1.5 wt %. The presence of C–H bonds in the structure of the deposits is caused by the fact that fullerene particles are hydrogenated before being incorporated in the coating. Probably, the hydrogenation takes place in the step of H_{ads} formation. The possibility of the electrochemical hydrogenation of C_{60} fullerene during the cathodic reduction in aqueous solutions was proved in [8]. It should be noted that the largest amount of dispersed phase particles is contained in surface layers of the composite coatings, as indicated by the fact that the intensity of secondary ions decreases when moving in depth of the deposit (Fig. 3,

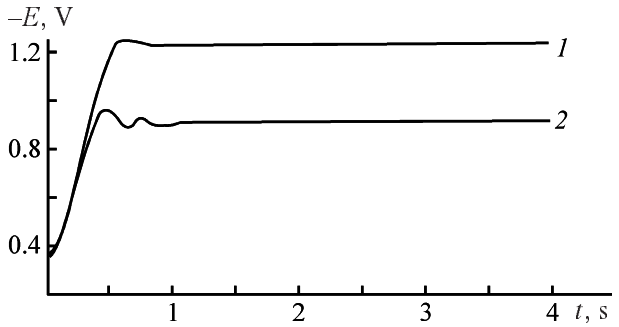

Fig. 2. Galvanostatic curves of nickel deposition at i_c = 8 A dm^{-2}: (*1*) without additions and (*2*) with addition of C_{60} fullerene. (*E*) Potential and (*t*) time.

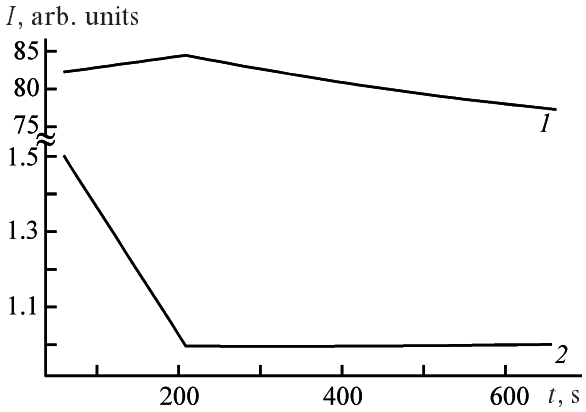

Fig. 3. (*1*) Nickel and (*2*) carbon concentration profiles in the composite nickel–C_{60} fullerene coating. (*I*) Intensity and (*t*) time.

Polarization capacity in deposition of nickel and Ni–C_{60} CECs

i_c, A dm^{-2}	$C \times 10^3$, F cm^{-1}	
	Ni	Ni–C_{60}
2	22.3	11.6
3	40.1	14.9
4	52.9	23.2
5	67.4	24.1
6	79.7	29.9
7	92.8	34.9
8	107.3	46.5
9	119.9	52.3
10	133.2	66.4

curve *2*). The content of nickel, on the contrary, increases in this direction (Fig. 3, curve *1*).

CONCLUSION

The addition of C_{60} fullerene dispersion into nickel-plating electrolyte promotes the formation of composite coatings. Fullerene particles are hydrogenated during the deposition. The largest amount of the dispersed phase is contained in surface layers of the deposits.

Abstract—Changes in electrochemical properties and surface morphology of carbon fibrous materials upon modification with manganese oxides under various conditions of their deposition were studied. The composition of manganese oxides was determined. The capacitances of the electrical double layer of manganese oxide carbon fibrous materials in sodium chloride solutions of various concentrations were found. Charging parameters of the modified electrodes were determined.

DOI: 10.1134/S1070427208070124

Manganese oxides and hydroxides are an object of comprehensive studies, because materials of this class are widely used as high-performance sorbents, catalysts, and materials for chemical power cells. Manganese oxide hydrate can be used as a sorbent in the form of grains produced by various methods [1–3], as a collector [4–6], or upon deposition on the developed surface of a porous support. Activated carbons [7, 8] or activated carbon fibers (ACFs) [9] are widely used as supports, which makes it possible to obtain manganese dioxide directly formed within pores of the carbon material via its interaction with the surface of the carbon support. In the last decade, much attention was given to the development of materials for electrochemical capacitors and power cells based on finely dispersed carbon powders coated with thin films of transition metal oxides, including manganese oxides [10].

The manganese oxides being deposited have a nonstoichiometric composition dependent on the synthesis methods and type of cations contained in the solution used [4, 6]. It can be assumed that finely dispersed manganese oxides are deposited as compounds that have a layered or pseudolayered structure and differ in the structure of these layers or interlayer spaces suitable for accommodation and mutual diffusion of exchange ions, similarly to natural manganese oxides [11].

As shown by the practice of studies of natural manganese oxides, determination of their structural features has been an exceedingly complicated task until recently. Reliable identification of manganese minerals requires using the whole set of modern investigation techniques (analytical electron microscopy, electron diffraction analysis, X-ray spectroscopy and diffraction analysis, X-ray photoelectron spectroscopy, etc.) [11]. Naturally, a study of surfaces on which nanosize metal oxide particles are situated within pores of the carbon matrix requires a long time and gross expenditure of material resources [12].

A large number of manganese oxide modifications differing in the composition and structure are known. Presence of these substances on the surface or within pores of the carbon matrix predetermines specific properties of a modified material. The use of manganese oxide carbon materials as sorbents or electrodes is efficient when their surface is the most accessible to molecules or ions of electrolytes. Changes in the surface properties of modified carbon materials can be analyzed by the electrochemical method [13, 14] from changes in the capacitance of the electrical double layer, whose formation depends on structural and surface properties of carbon-containing materials.

The aim of this study was to assess the possibility of using the electrochemical method for characterizing the surface changes upon modification of the carbon material and to reveal a relationship between the structure and surface composition determined by other methods.

EXPERIMENTAL

As starting matrices for study we chose Aktilen B activated carbon fiber (ACF_{st}) and the starting ACF oxidized with nitric acid at 90°C (ACF_{ox}).

ACF_{st} fibers were modified by deposition of active manganese oxide by the reaction of potassium permanganate with Mn(II) salts, following the method described in [15], in the presence of a carbon support. The resulting modified carbon fibrous material ACF–Mn(chem) was washed with water and dried in air. ACF_{ox} fibers were modified by the electrochemical method by deposition of oxygen-containing manganese compounds from a NaCl solution containing a Mn(II) salt under permanent aeration of the electrolyte [9], with an ACF_{ox} carbon support as the cathode. The resulting ACF–Mn(el.chem) composite material was also washed with water and dried.

The electrochemical measurements were made in a standard three-electrode cell by the methods of cyclic voltammetry and charging curves. As electrolytes served 0.9 and 3.5% NaCl solutions. The solutions were vigorously agitated and bubbled with inert gas. Samples of the carbon materials under study were placed in a gold basket serving as an inert current lead. A silver chloride electrode was used as reference. The auxiliary electrode fabricated from a porous carbon material was separated from the working electrode by an MB-2 bipolar membrane.

Potentiodynamic curves were measured near the electrical double layer (EDL) at the submergence potential of the working electrode within the range ±50 mV [16] with a P-5848 potentiostat. The EDL capacitance C (F g^{-1}) was calculated by the formula [16, 17]

$$C = I/(mv) = (I_a + I_c)/(2mv), \quad (1)$$

where I_a and I_c are the anode and cathode polarization currents (A); m, electrode mass (g); and v, potential sweep rate (V s^{-1}).

The degree (fraction) of utilization of the electrode surface, α, was calculated by the formula

$$\alpha = C/C_{max}, \quad (2)$$

where C and C_{max} are the electrode capacitances at the prescribed and minimum potential sweep rates (F g^{-1}).

The results of the potentiodynamic measurements were processed by the least-squares method to find the characteristic charging time of the EDL, τ, and the ohmic resistance of the electrolyte within pores ($R = \tau/C$) by the formula [18]

$$I = Cv\left[1 - 2\pi^{-2}\sum_{n=0}^{\infty}\frac{1}{(n+0.5)^2}e^{-\pi(n+0.5)^2 t\tau^{-1}}\right], \quad (3)$$

where I is the current (A); v, potential sweep rate (V s^{-1}); t, time (s); C, capacitance (F g^{-1}); and n, summation index.

When measuring galvanostatic charging curves, the polarizing current density was chosen experimentally. The current beginning from which the position of the polarization curve remained unchanged defined the boundary between the equilibrium and nonequilibrium currents. In all cases, the equilibrium charging current density was varied within the range 10^{-11}–10^{-10} A cm^{-2}. The linear portion of the charging curve was used to calculate the EDL capacitance C (F g^{-1}) by the formula

$$C = (I\Delta t)/(m\Delta E), \quad (4)$$

where I is the polarization current (A); Δt, electrode charging time (s); m, electrode mass (g); and ΔE, shift of the electrode potential (V).

All the values of the electrochemical parameters calculated are listed in the table.

Electron-microscopic studies were performed on an EVO 50 XVP scanning electron microscope equipped with an INCA 350 energy-dispersion spectrometer for determining the chemical composition of the surface. X-ray diffraction patterns of samples were measured on a Bruker D8 ADVANCE diffractometer. An X-ray phase analysis was made using an EVA search program with a PDF-2 powder database.

Depending on the deposition technique and on the composition of solutions from which manganese oxides were deposited, deposits differing in structure and nature are formed on the surface of the carbon support. This is confirmed by electron microscopy (SEM). Figure 1 shows SEM images of the surface of modified fibers. The surface of ACF–Mn(chem) is covered with a finely dispersed scaly phase (Fig. 1a), and that of ACF–Mn(el.chem), with manganese oxide crystals or aggregates of these. The results of a microprobe analysis (Figs. 1c, 1d) indicate that metal ions contained in mother liquors are incorporated into manganese oxides deposited onto the

substrate surface. Analysis of the deposits formed on the surface in electrochemical deposition of manganese oxides reveals impurity ions, which are possibly contained in the starting salts used to prepare the electrolyte solution and are codeposited with the active manganese oxide because of the electrochemical concentration in the deposit [9].

Analysis of the X-ray diffraction patterns of the materials under study, produced by different methods, suggests that different phases are probably present in the deposited manganese oxides and hydroxides. An analysis of the X-ray diffraction patterns of the ACF–Mn(chem) sample revealed two phases belonging to synthetic K-birnessite represented by two compounds $K_{0.46}Mn_{0.54}Mn_{0.46}O_4(H_2O)_{1.4}$ [19] and $K_{0.5}Mn_2O_{4.3}(H_2O)_{0.5}$ [20] with nearly coinciding unit cell parameters (two diffuse halos with peaks corresponding to 002 and 111 reflections with interplanar spacings d 3.56 and 2.418 Å). The compound $K_{0.5}Mn_2O_{4.3}(H_2O)_{0.5}$ con-

tains the exchangeable potassium ion. In addition, an α-Mn phase [21] is recorded (one diffuse halo with d = 2.09 Å), probably originating from reduction of manganese salts on the carbon matrix.

In electrochemical deposition of manganese oxides, a manganese oxide phase with a small oxygen deficiency, $MnO_2/Mn_{1.937}$ [22] (d 4.64 and 2.001 Å, 111 and 400 reflections), is formed on the surface. Also observed is synthetic ramsdellite MnO_2 (diffuse halos with maxima at d 4.01 and 2.06 Å, 110 and 410 reflections), which belongs to minerals with tunnel structure. It is known that the structure of ramsdellite is formed by identical ribbons constituted by double chains of MnO_6 octahedra [11]. The ribbons of octahedra, which form sides of the tunnels, are arranged in the structure with their wide sides approximately parallel to each other. In the tunnels in ramsdellite, there are no cations or water molecules [11]. On the whole, the powder X-ray diffraction patterns of the sample studied contain a small number of weak and diffuse reflections, which can be hardly used for reliable identification of manganese oxide compounds formed within pores of the carbon matrix. Indeed, as reported in [11], use of only such widely accepted methods as X-ray diffraction and microprobe analyses in studies of natural manganese oxides and hydroxides fails to provide reliable identification of manganese minerals. These minerals are distinguished by an exceedingly low degree of structural ordering and form finely dispersed mixtures; many of them have not been reliably identified by diffraction techniques.

The presence of manganese oxides of different compositions on the ACF surface changes the pore structure of the carbon material, which can be, in turn, evaluated by the electrochemical method of cyclic voltammetry [14] on submerging the fiber in an electrolyte solution. An electrical double layer is formed at the boundary between the solid and liquid phases, and its characteristics depend on the state of the surface and on the electrolyte concentration.

The differences in the charging and structural features of modified carbon materials can be judged from the variation of their capacitance in the EDL region with the potential sweep rate. At a slow polarization of the porous electrode, its surface is more involved in the electrochemical process because the supply rate of ions to the electrode surface is comparable with the formation rate of the EDL within which charge is transferred. As the polarization rate of the electrode is raised, the rates of ion delivery to the surface and EDL formation become strongly different because of the appearing ohmic and diffusion hindrances in the porous structure of the carbon material. As a result, the EDL capacitance decreases because the measured value of this capacitance corresponds only to that part of the working surface which is involved in the electrochemical process and has enough time to be charged during a potentiodynamic cycle. Figure 2 shows the dependences $C_1 = f(v)$ (Fig. 2a) and $\alpha = f(v)$ (Fig. 2b) obtained in a 0.9% NaCl solution for the starting and modified ACF. Analysis of these dependences suggests that the method used to deposit manganese oxides onto carbon fibers affects the extent to which the electrochemical properties of the materials obtained are changed. This is due to changes in the surface properties of the modified

ACF as a result of formation of manganese oxide phases in the carbon matrix.

If the polarization rate is raised when charging fibrous materials in a 0.9% NaCl solution, the EDL capacitance of the ACF–Mn(chem) sample steeply decreases and reaches rather small values (Fig. 2a, curve *3*). In the case of chemical deposition of manganese oxide onto the carbon matrix, the fiber surface is covered with a layer of birnessite, one of whose phases contains potassium ions in the exchangeable form. It is possible that, in charging of such an electrode, the EDL formation is accompanied by exchange of potassium for ions from the electrolyte, and the incommensurate rates of these simultaneously occurring competing processes lead to a considerable decrease in the capacitance of ACF–Mn(chem) upon an increase in the load on the electrode. It is not improbable that the birnessite film partly covering the fiber surface (Fig. 1a) diminishes its accessibility to ions from the dilute electrolyte. As seen from the table, the charging of ACF–Mn(chem) in a 0.9% NaCl solution occurs with a substantial resistance of the electrolyte in the pore space and, in contrast to other samples, requires a considerably longer time.

A less steep decrease in the EDL capacitance is observed for ACF–Mn(el.chem) (Fig. 2a, curve *4*). One of reasons why high capacitance values are retained by this electrode in the whole range of potential sweep rates used in the study is the lability of the fiber. The lability effect is manifested in that the porous structure of ACF changes upon polarization because likely charged fibrils of the fiber move apart and transport pores become larger. This makes weaker the hindering effect of the porous medium and favors preservation of high flow and mass-transfer rates in polarized carbon fibers [24]. It is known [11] that the tunnels in the ramsdellite structure are inaccessible to electrolyte cations and water molecules. Therefore, the better polarizability of ACF–Mn(el.chem) is in all probability due to changes in the porous structure of the carbon substrate as a result of deposition of manganese oxides.

It was noted in [25] that hydrated manganese oxide α-$MnO_2 \cdot nH_2O$ has low electrical conductivity and capacitance. However, use of carbon substrates with a highly porous structure, e.g., single-layer nanotubes, for deposition of α-$MnO_2 \cdot nH_2O$ yields a composite material with high capacitance, which exceeds severalfold the similar value for the starting carbon material. In this case, the texture characteristics of the composite material change in such a way that penetration of electrolyte ions into the bulk of the active material is facilitated and the resistance of an electrode fabricated from this material decreases [25]. Possibly, aggregates formed in the resulting ACF–Mn(el.chem) sample change the pore structure in such a way that the charging of this electrode occurs with a considerably lower electrolyte resistance in the pore space, compared with ACF–Mn(el.chem) (see table). It should be noted that, in the case when electrodes are polarized in a more concentrated solution (3.5% NaCl), their capacitance does not decrease substantially and the fraction of their surface involved in the electrochemical process remains rather large. This is favored by the considerable increase in the concentration of charged species causing faster formation of an EDL in the electrode in its charging.

A mathematical processing by Eq. (3) of the dependence of the electrode capacitance on the polarization rate made it possible to calculate the electrolyte resistance within pores, R, and the characteristic time of electrode charging, τ. The table lists the calculated values, which can be used to assess the efficiency with which carbon materials are used under polarization conditions. Analysis of the data obtained suggests that the method employed for deposition of manganese oxide onto a carbon matrix strongly affects the charging conditions of modified ACF. The strongest difference in the electrochemical characteristics of manganese oxide fibers is observed in polarization of these materials in a dilute electrolyte solution (0.9% NaCl). For effective charging of a porous electrode (especially in a solution with low concentration of charge carriers), it is necessary that the electrode should contain in its structure pores with a size comparable with the EDL thickness [14, 16], which provides supply of ions from the electrolyte to the surface of the solid and formation of an electrical double layer. Presumably, the electrochemical deposition of manganese onto a fibrous matrix (combined with the lability of the fiber itself) affects the surface and structural properties of the carbon material ACF–Mn(el.chem), providing rapid charging with a lower resistance of the electrolyte within pores, in contrast to ACF–Mn(chem). It should be noted that an increase in the electrolyte concentratrion eliminates differences between the charging parameters of modified ACF. This effect is probably due to an increase in the number of charge carriers weakening the diffusion and ohmic hindrances to the charging of the porous electrode.

CONCLUSIONS

(1) The composition of manganese oxides deposited under different conditions onto a carbon matrix was determined. Two phases of K-birnessite are formed in chemical deposition on the fiber surface. In electrochemical deposition of manganese oxide, ramsdellite and manganese oxide $MnO_2/MnO_{1.937}$, are deposited on the surface of an activated carbon fiber.

(2) The deposition conditions of manganese oxides affect the electrochemical properties of modified fibers. The properties of the manganese oxide material obtained by electrochemical deposition of manganese oxides make this material more suitable for use as an electrode.

(3) Cyclic voltammetry can be used to assess the structural changes in modified fibers, which was confirmed by scanning electron microscopy and X-ray phase analysis.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Alloying Component MnO_2 on the Type of V_2O_5 Electrocrystallization

Abstract—The methods of polarization curves E–$\log I_a$ and atomic-force microscopy were used to study the mechanisms by which the alloying component MnO_2 affects the electrocrystallization of V_2O_5 in electrolysis from mixed solutions of salts of these metals.

DOI: 10.1134/S1070427208070136

In [1], the electrolysis conditions and nature of anodic processes in electrolytic deposition of V_2O_5 in the presence of Mn^{2+} from mixed sulfate solutions were studied. The mixed V–Mn oxides obtained exhibit better specific electrochemical characteristics and are more promising as compared to the individual components [2]. However, the possible mechanisms of anodic processes in electrolytic deposition of the V–Mn double oxide from aqueous solutions of a mixture of oxovanadium(IV) and manganese(II) sulfates remained insufficiently understood. Therefore, it seemed appropriate to continue these studies in order both to optimize and improve processes of electrolytic formation of complex multiphase systems and to extend the available concepts about their nature.

The study was performed using the procedure described in detail in [1]. Polarization curves were plotted in the coordinates E–$\log I_a$ using data on the conditional current efficiency (CE_{cond}) on the assumption that the whole amount of useful current is expended for V_2O_5 formation [1].

The possibility of performing the anodic process with quantitative deposition of the V–Mn double oxide in electrolysis of an aqueous solution of a mixture of VO^{2+} and Mn^{2+} sulfates is demonstrated by the standard potentials of the electrode reactions [3]

$$2VO^{2+} + 3H_2O - 2e \rightarrow V_2O_5 + 6H^+, \quad E^0 = 1.10 \text{ V}; \quad (1)$$

$$Mn^{2+} + 2H_2O - 2e \rightarrow MnO_2 + 4H^+, \quad E^0 = 1.23 \text{ V}; \quad (2)$$

$$2Mn^{2+} + 3H_2O - 2e \rightarrow Mn_2O_3 + 6H^+, \quad E^0 = 1.48 \text{ V}; \quad (3)$$

$$Mn_2O_3 + H_2O - 2e \rightarrow 2MnO_2 + 2H^+, \quad E^0 = 0.98 \text{ V}. \quad (4)$$

Reactions (1)–(4) can occur at the anode simultaneously with the oxygen evolution

$$2H_2O - 4e \rightarrow O_2 + 4H^+ \quad (5)$$

and with the possible redox reactions, e.g.,

$$2VO^{2+} + Mn_2O_3 + 2H_2O \rightarrow V_2O_3 + 2MnO_2. \quad (6)$$

Reaction (5) occurs in steps with the formation of a layer of chemisorbed oxygen atoms [4], which is rather important for the mechanism of anodic processes.

For energetic reasons, reactions (1)–(5) can hardly be performed at anodic polarization in aqueous solutions. It can be assumed that reactions occurring by the single-electron mechanism are preferable and thermodynamically substantiated. For example, it was noted in [5] that reaction (1) may occur in two steps in the case of the reaction with chemisorbed oxygen:

$$M + H_2O - 2e \rightarrow (M\text{–}O) + 2H^+, \quad (7)$$

$$VO^{2+} + (M\text{–}O) - e \rightarrow VO_2^+ + M, \quad (8)$$

$$VO_2 + VO_2^+ + H_2O \rightarrow V_2O_5 + 2H^+. \quad (9)$$

A similar mechanism was considered in [6]. Apparently, such a pathway is also justified for reactions (2) and (3) of anodic deposition of manganese oxides, which can be represented as a set of successive reactions

Current efficiency by V_2O_5 and MnO_2 in electrolysis from their individual solutions and CE_{cond} by V_2O_5 in its joint deposition with MnO_2 from mixed solutions of various concentrations. Average solution concentrations 0.35–0.4 M, T = 85°C, pH 2.0

I_a, mA cm^{-2}	CE, wt %		CE_{cond}, %, at indicated V : Mn ratio		
	V_2O_5	MnO_2	3 : 1	1 : 3	1 : 3 recalculated to E(MnO_2) = 1.62 g (A h)$^{-1}$
7.5	37	69	13.8	7.0	21
10	33.5	65	9.7	10.2	19.8

$$Mn^{2+} + (M–O) - e \rightarrow MnO^+ + M, \quad (10)$$

$$MnO^+ + (M–O) - e \rightarrow MnO_2 + M, \quad (11)$$

$$2MnO^+ + (M–O) \rightarrow Mn_2O_3 + M. \quad (12)$$

Apparently, the reactions of discharge of VO^{2+} and Mn^{2+} ions are the most energy-consuming. In these cases, the electron transfer is possibly facilitated via reaction with adsorbed oxygen, which can serve as a mediator. The subsequent reactions occur spontaneously and may be accompanied by release of the formation energy of V_2O_5 and MnO_2 molecules (the corresponding reactions are exothermic). The mutual influence of the above reactions in their parallel occurrence at the anode changes their relative rates in the overall process, which is characterized by a steep fall of the current efficiencies by both the main and alloying components, compared to their separate recovery from their individual solutions. This is confirmed by the current efficiencies

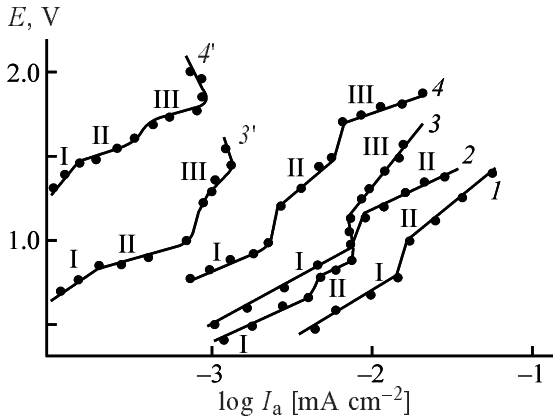

Fig. 1. (*1–4*) Overall and (*3'*, *4'*) partial anodic polarization curves obtained in sulfate solutions of (*1*) oxovanadium (0.3 M) and (2) manganese (0.4 M) and in mixed solutions with a mean concentration of 0.35–0.4 M at various V : Mn concentration ratios. Temperature 85°C, pH 2.0. (*E*) Potential and (I_a) current density. V : Mn concentration ratio: (*3*, *3'*) 3 : 1 and (*4*, *4'*) 1 : 3.

(CE) by V_2O_5 and MnO_2 in electrolysis from their individual sulfate solutions and by CE_{cond} by the V–Mn double oxide at V to Mn concentration ratios of 3 : 1 and 1 : 3 in solution (see table). It can be seen that the CE by V_2O_5 sharply decreases in the presence of Mn^{2+} even at its comparatively low concentrations in solution. The same behavior is observed for MnO_2 [in this case, CE_{cond} is formally calculated from its electrochemical equivalent E = 1.62 g (A h)$^{-1}$]. Thus, the conjugated anodic reactions are mutually decelerated, with a simultaneous increase in the rate of oxygen evolution.

Figure 1 shows the dependences E–logI_a for the overall processes of V_2O_5 and MnO_2 deposition with simultaneous evolution of oxygen from their individual solutions and for the overall and partial processes of joint deposition of V_2O_5 with MnO_2 from solutions with V : Mn concentration ratios of 3 : 1 and 1 : 3. The dependences of V_2O_5 and MnO_2 deposition from their individual solutions (curves *1*, *2*) form two ascending rectilinear branches connected by an intermediate portion. The lower branch (curve *1*) is mostly determined by the V_2O_5 deposition accompanied by discharge of oxygen. When the diffusion of VO^{2+} ions to the surface is decelerated, the anodic potential increases (intermediate portion) and reaches values corresponding to accelerated evolution of O_2. This latter becomes predominant at potentials of the upper branch of the curve [5].

Curve *2* describes the electrolytic deposition of MnO_2 from the sulfate solution [6] and reflects the step-by-step oxidation $Mn^{2+} \rightarrow Mn^{3+} \rightarrow Mn^{4+}$, with simultaneous evolution of oxygen. Comparison of curves *2* and *3* shows that curve *2* lies at higher anodic potentials. This means that manganese is oxidized at a higher anodic overvoltage.

The general shape of the overall E–logI_a dependences becomes considerably more complex in the

case of V_2O_5 deposition in the presence of Mn^{2+} (curves *3*, *4*). The dependences comprise three stepwise-arranged rectilinear portions (zones I–III) determined by the corresponding steps of the anodic process. The steps are connected by transition portions. The lower portions of curves *3* and *4* lie parallel to lower portions of curves *1* and *2* and are, apparently, mostly related to deposition of V_2O_5 under weak influence of the concomitant reactions of Mn^{2+} and oxygen discharge.

A decrease in the VO^{2+} concentration in the surface layer leads to an increase in the anodic polarization and the anodic process passes to the stage (zone II) in which joint deposition of V_2O_5, Mn_2O_3, and MnO_2 becomes possible. In this case, the rates of the competing reactions are redistributed, with a simultaneous increase in the rate of O_2 evolution (zone III). The slope of the portion of curve *3* in zone III is noticeably larger than that of the corresponding portion of curve *4*. This may be due to still higher rates of V_2O_5 and MnO_2 formation processes which hinder evolution of O_2 in the first case, and to its dominating role in the second case, which predetermines the corresponding decrease in the anodic overvoltage.

The partial E–$\log I_a$ dependences for V_2O_5 deposition in the presence of Mn^{2+} (curves *3'*, *4'*) have less pronounced transition portions. Comparison of the slopes of the corresponding steps clearly shows that the relative concentrations of the main and alloying components in solution affect the kinetics of the anodic processes. For example, steps I and II are longer at a lower Mn^{2+} concentration in solution (curve *3'*), compared to the case of its higher concentration (curve *4'*). This points to a predominant rate of V_2O_5 deposition in the first case and to a weaker influence of the reaction of manganese oxide formation, which is confirmed by the smaller slope of the corresponding portion of curve *3'*.

The smaller slope of the last branch, compared to that of the similar step in curve *4'*, is determined by processes considered above for similar portions of the overall curves *3* and *4*.

The linearity of the portions (steps) of the overall and partial E–$\log I_a$ curves under study enables analysis of the corresponding anodic processes in terms of electrochemical kinetics. However, the pronounced anomaly of the slopes of the corresponding portions of the curves in the interval 0.27–1.45 V points to their strong dependence on diffusion hindrances, which is substantiated by generalization of relationships of electrochemical and diffusion kinetics [7]. This is also indicated by the low level of limiting diffusion currents, which do not exceed 1.0–1.5 mA cm^{-2}.

Analysis of the data presented here shows that, in the anodic processes under consideration, the alloying additive hinders the efficiency of the processes in which both V_2O_5 and double V–Mn oxide are formed. It can be assumed that this is due to competition of VO^{2+} and Mn^{2+} ions in the double-layer zone. Because of the absence of electrostatic migration of the competing ions toward the anode, the electrical double layer, which is also formed by water molecules and adsorbed oxygen, is rather diffuse. Therefore, at rather close standard formation potentials of V_2O_5 and MnO_2, the smaller Mn^{2+} ions more easily penetrate to the anode and are better retained there than bulky VO^{2+} ions and thereby block the access of these latter into the reaction zone. Apparently, this leads to an increase in the overvoltage of their discharge and simultaneously stimulates the O_2 evolution. It can be seen from Fig. 1 that curve *4'* is shifted with respect to curve *3'* in the positive direction by 0.7 V. Possibly, a certain contribution to this shift is made by a change in the overvoltage of VO^{2+} discharge on changing the V : Mn concentration ratio from 3 : 1 to 1 : 3. It is difficult to determine this contribution because of the masking influence of accompanying factors and, in particular, by decelerated diffusion of ions, discharge–adsorption of oxygen, and multiple-stage nature of the main anodic processes. The contribution can be roughly estimated by the difference between the averaged shift of the potential difference upon a change in the V–Mn concentration ratio (curves *3'* and *4'*) and the difference of the onset potentials of anodic deposition of V_2O_5 and MnO_2 from their individual solutions. This difference is 0.24 V, which is a reasonable value.

The effect of the alloying MnO_2 additive in the processes under study is clearly manifested in the fundamental change in the nature of V_2O_5 electrocrystallization. Vanadium pentoxide is deposited from individual oxovanadium sulfate solution in the form of finely dispersed amorphous-crystalline conglomerates forming a pronounced relief on the surface of deposits in the form of interlacing ridges (Fig. 2a). This structure is mostly due to continuous degeneration of the nucleating crystals in the initial stages of their development. The weakened intermolecular bonding between these crystals or separate crystalline aggregates (grains), which impairs

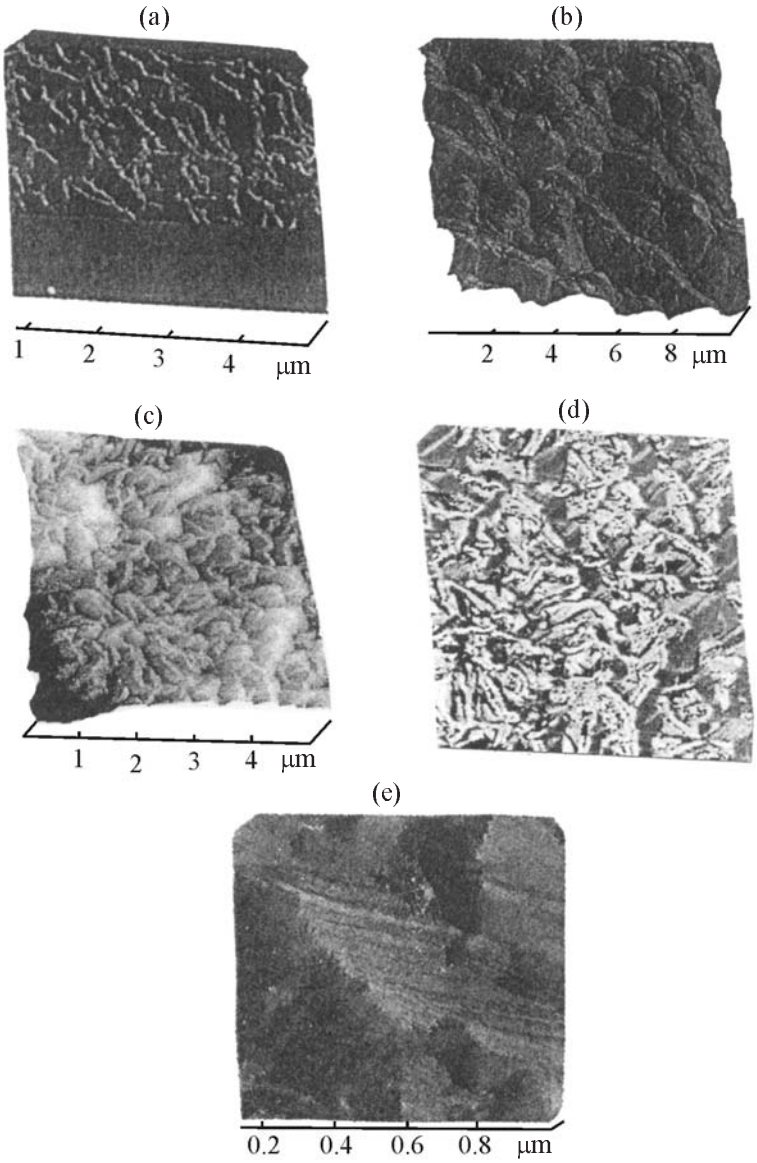

Fig. 2. Surface morphology of electrolytic deposits of (a) V_2O_5, (b) MnO_2, and (c–e) V–Mn double oxide from a mixed solution. V : Mn ratio: (c) 3 : 1, (d) the same at a height of 2500 nm from the substrate surface, and (e) 1 : 3.

the compactness of the deposit formed at the anode, may be a consequence of the high sorption activity and ability of V_2O_5 to absorb H_2O, which disrupts the intravolume intermolecular binding. A certain role can also be played in this regard by partial corrosion of the oxide, associated with the solution acidification.

The "pure" anodic MnO_2 deposit (Fig. 2a) formed from the sulfate solution is constituted by coarsened petallous grains with a rounded frontal face. The presence of crystal growth steps points to the probability of their formation by the mechanism of layer-by-layer packing of 2D crystalline aggregates (nuclei). The certain symmetry in the mutual arrangement of the grains indicates that twinned formations can exist. In the presence of Mn^{2+} (V : Mn = 3 : 1), V_2O_5 is formed at the anode as ridge-like crystalline deposits constituting a complex surface relief replicating to a certain extent the profile of pure V_2O_5 deposits (Fig. 2c). This gives reason to suggest that the forming, originally chaotically arranged, chains of amorphous-crystalline V_2O_5 deposits are covered with growing MnO_2 crystals, which is confirmed by the structure of the corresponding deposit formed at a height of 2500 nm from the substrate surface (Fig. 2d). The

deposit is a conglomerate of alternating crystalline MnO_2 deposits in the form of broken ridges (light bands) and dark areas of indefinitely crystalline V_2O_5 with a rather uniform distribution throughout the volume. Hence, the anodic deposits of the binary V–Mn oxide, obtained at concentration ratios V : Mn = 5 : 1 to 2 : 1 in solution, can apparently be regarded as sufficiently homogeneous mechanical mixtures with intravolume binding on the molecular level. Their two-phase composition is confirmed by X-ray phase analysis [1].

If the concentration of manganese in solution is substantially raised (V : Mn ≤ 1), the structure of the deposits fundamentally changes (Fig. 2e). The deposits are composed of irregularly growing coarsened MnO_2 grains of block type, with spaces between these grains filled with finely grained V_2O_5 agglomerates. This structure of the deposits is presumably due to the stimulating effect of lateral faces and separate fragments of MnO_2 crystals growing with a certain advance on the electrocrystallization of V_2O_5. This, in turn, makes higher the growth intensity of MnO_2 crystals at insignificant energy expenditure.

Thus, the electrodeposition of V_2O_5 at the anode in electrolysis from a mixed sulfate solution containing an alloying $MnSO_4$ additive yields a two-phase V–Mn oxide whose composition is determined by the V : Mn concentration ratio in the solution. Analysis of the experimental data shows that of practical importance, as regards the specific electrochemical characteristics and quality (compactness, homogeneity, adhesion), are V–Mn deposits with MnO_2 content of 5–15 wt %, formed at the ratio V : Mn = 5 : 1 to 2 : 1 and current densities of 7.5–10 mA cm^{-2}.

CONCLUSIONS

(1) The kinetics of the anodic processes occurring in electrodeposition of V_2O_5 in the presence of an alloying manganese additive from a sulfate solution at V : Mn concentration ratios of 3 : 1 to 1 : 3 was considered by analyzing the corresponding E–log I_a dependences.

(2) A stage-by-stage mechanism of the anodic processes of V_2O_5 and MnO_2 formation in their joint deposition via interaction with chemisorbed oxygen was suggested.

(3) It was shown that, in deposition of V_2O_5 in the presence of an alloying additive, the anodic polarization, including those of the concentration and chemical types, grows in proportion to the increase in the concentration of this additive in solution and to the rate of MnO_2 codeposition at the anode.

(4) An analysis of the surface morphology of anodic V_2O_5 and MnO_2 deposits produced by electrolysis from their individual solutions and by joint deposition demonstrated that, in the latter case, the structure is fundamentally different from that of the individual deposits because of the change in the nature of electrocrystallization of the components.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of 4-Aminotoluene with Ozone in Acetic Acid Solution

A. G. Galstyan, A. S. Bushuev, and R. N. Solomyannyi

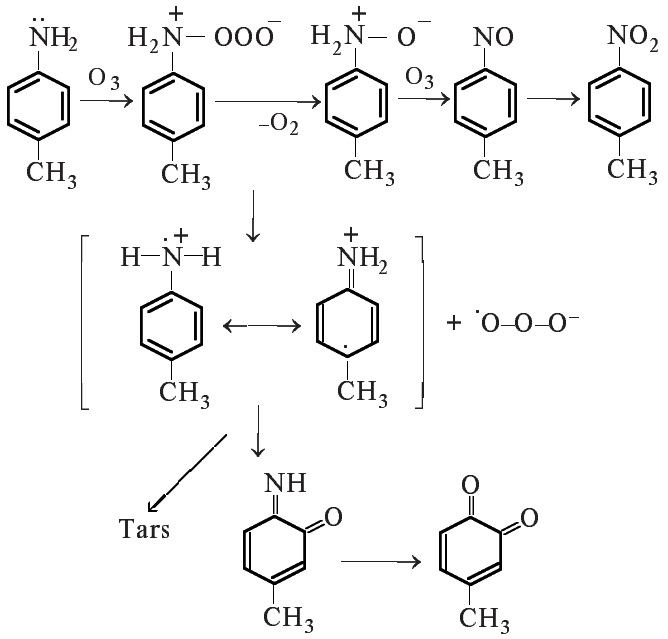
Abstract—The possibility of preparing 4-aminobenzoic acid by oxidation of 4-aminotoluene with ozone in acetic acid in the presence of cobalt(II) acetate and potassium bromide was examined. The optimal oxidation conditions were found.



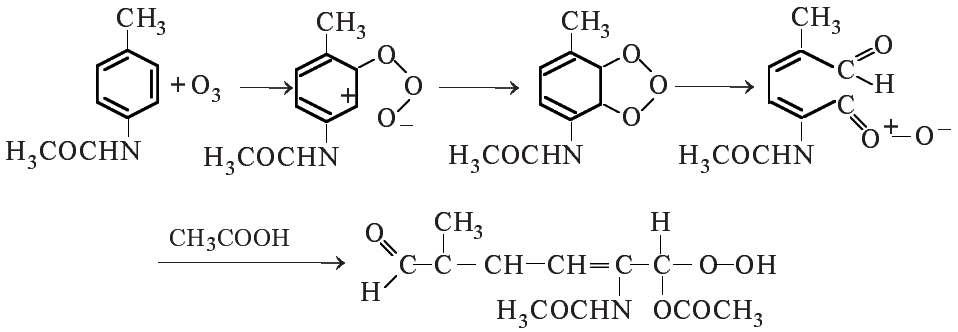
DOI: 10.1134/S1070427208070148

4-Aminobenzoic acid (4-ABA) is widely used in pharmaceutical industry, in particular, as an intermediate in production of anesthetics [1]. It is prepared by oxidation of 4-acetylaminotoluene (4-AAT) either with potassium permanganate or with atmospheric oxygen, followed by hydrolysis of the resulting 4-acetylaminobenzoic acid (4-AABAc) [1, 2]. The drawback of the first procedure is formation of large amounts of toxic, difficultly utilizable substances, and that of the second procedure is cumbersome implementation. A good choice may be the use of ozone, an environmentally friendly oxidant reacting under mild conditions with virtually all classes of organic compounds [3, 4].

The known method for oxidation of methylbenzenes with ozone in acetic acid [5] is unsuitable for preparing benzoic acids from methylbenzenes containing in the aromatic ring substituents with one or more lone electron pairs (–OH, $–NH_2$, etc.). It is known that methylanilines are oxidized with ozone at a high rate at the lone electron pair of the nitrogen atom with the formation of the molecular adduct $Ar\overset{+}{N}H_2–O_3^-$. Products of methyl group oxidation are not formed under these conditions [4, 6].

To examine the possibility of oxidative synthesis of aminobenzoic acids from methylanilines and develop low-waste processes, we studied the liquid-phase reaction of ozone with 4-aminotoluene (4-AT) in an acetic acid solution.

Preliminary studies [6] showed that ozone in an acetic acid solution reacts with 4-AT at a high rate ($k_{app} = 2.5 \times 10^3$ l mol^{-1} s^{-1}, 20°C). The major reaction products are tars. Also, 4-nitrosotoluene, 4-nitrotoluene, and traces of toluquinone are formed. The product composition is essentially similar to that described in the literature [4, 6] and corresponds to the scheme suggested for the reaction of ozone with aromatic amines [6]:



The scheme suggests fast attack of ozone at the lone electron pair of the nitrogen atom with the formation of an ion–radical pair which, depending on the structure of the amine, transforms into various products, the majority of which are unidentified polymeric tars. The absence of products of methyl group oxidation is due to the fact that the reactivity of 4-AT along this pathway is almost three orders of magnitude lower than that of the amino group [8].

To prevent the reaction of the amino group with

ozone, we protected it by acylation. 4-Acetylaminotoluene was dissolved in glacial acetic acid, and an ozone–air mixture with an ozone concentration of 4.5×10^{-4} M was passed through the solution. Kinetic studies showed that the reactivity of acylated 4-AT toward ozone decreases considerably. The rate constant of the reaction is $k_{app} = 28.7$ l mol^{-1} s^{-1} at 20°C. Drastic decrease in the rate constant of the reaction of ozone with 4-AAT suggests a change in the reaction mechanism.

Apparently, ozone under these conditions attacks not the NH group but mainly double bonds of the aromatic ring (85%) and, to a lesser extent, the methyl group (15%) (see figure). In accordance with the results of the study, 1.36 mol of ozone is consumed at 20°C per mole of 4-AAT. At such ozone consumption, the reaction with the aromatic ring, presumably, follows the scheme [9]

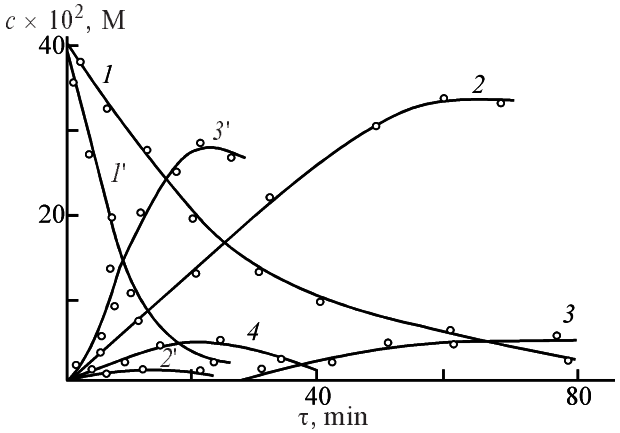
Among the methyl group oxidation products, 4-acetylaminobenzaldehyde (4-AABAl) prevails in the early reaction steps, and 4-AABAc, in the late steps (see figure).

The rate and selectivity of 4-AAT oxidation at the methyl group increase with temperature and on adding a catalyst, cobalt(II) acetate. The reaction becomes fast, and its major product is 4-AABAc. At 4-AAT concentration of 0.4 M, cobalt(II) acetate concentration of 0.14 M, and temperature of 95°C, the oxidation is complete in 40 min, and the selectivity with respect to the methyl group is 52%.

Addition of KBr increases the rate and selectivity of oxidation at the methyl group. The 4-AABAc yield reaches 75%. Among methyl group oxidation products, we also detected 4-acetylaminobenzyl bromide (4-AABB) and traces of 4-AABAl.

Selective oxidation at the methyl group in the presence of cobalt(II) acetate and potassium bromide becomes possible owing to two-step oxidation with ozone. Ozone predominantly reacts with Co^{2+} ($k_1 = 9.3 \times 10^2$, $k_{(AcNHArCH_3 + O_3)} = 28.7$ l mol^{-1} s^{-1}, our data) with the formation of Co^{3+} active species [reaction (1)]. The subsequent reaction (2) yields the complex $Co^{2+}Br^{\bullet}$ [10], which involves 4-AAT into fast and selective oxidation at the methyl group [reaction (5)]:

$$Co^{2+} + O_3 + H^+ \rightarrow Co^{3+} + HO^{\bullet} + O_2, \quad (1)$$



$$Co^{3+} + Br^- \rightarrow Co^{3+}Br^- \rightleftarrows Co^{2+}Br^{\bullet}, \quad (2)$$

$$Br^- + O_3 + H^+ \rightarrow Br^{\bullet} + HO_3^{\bullet}, \quad (3)$$

$$AcNHArCH_2^{\bullet} + Br^{\bullet} \rightarrow AcNHArCH_2Br, \quad (4)$$

$$AcNHArCH_3 + Co^{2+}Br^{\bullet} \rightarrow AcNHArCH_2^{\bullet} + Co^{2+} + Br^- + H^+. \quad (5)$$

To provide the occurrence of reaction (1), ozone should be continuously fed to the reaction system.

Variation of the concentrations c of components of the reaction mixture in oxidation of 4-AAT with ozone–air mixture at (*1–4*) 20 and (*1'–3'*) 95°C in the presence of cobalt(II) acetate and potassium bromide. $[4\text{-AAT}]_0 = 0.4$, $[O_3]_0 = 4.5 \times 10^{-4}$, $[Co(OAc)_2]_0 = 0.1$, $[KBr]_0 = 0.1$ M, $\nu_{air} = 8.3 \times 10^{-3}$ l s^{-1}. (τ) Time. (*1*, *1'*) 4-AAT, (*2*) peroxides, (*2'*) 4-AABB, (*3*, *3'*) 4-AABAc, and (*4*) 4-AABAl.

Interruption of the ozone supply leads to deceleration and complete termination of the process. This fact additionally confirms the formation of active catalyst species mainly by reactions (1) and (2). Under the experimental conditions, the concentration of molecular oxygen in the gas mixture is 15 times higher than that of ozone. Therefore, the acetylaminobenzyl radical formed in the system reacts predominantly with the oxygen molecule [reaction (6)] to form acetylamino peroxy radical which subsequently yields the final products [reaction (7)]:

$$AcNHArCH_2^{\bullet} + O_2 \rightarrow AcNHArCH_2O_2^{\bullet}, \quad (6)$$

$$AcNHArCH_2O_2^{\bullet} \rightarrow \text{products}. \quad (7)$$

4-AABB can appear in the system owing to the occurrence of reactions (3) and (4).

An increase in the rate and selectivity of 4-AAT oxidation in the presence of KBr is due to accumulation of the active complex $Co^{2+}Br^{\bullet}$, which involves the substrate in oxidation at a higher rate than does the oxidized form of cobalt [10].

EXPERIMENTAL

In the experiments we used analytically pure grade glacial acetic acid purified by vacuum distillation from potassium permanganate. Crystalline 4-AT was purified by repeated recrystallization from water. Cobalt(II) acetate and potassium bromide (analytically pure grade) were used without additional purification.

The calculated amount of 4-AT was dissolved in acetic anhydride in a flask at 20°C. The mixture was stirred for 15 min. After the acylation completion, the mixture was poured into ice-cold water. The 4-AAT precipitate was separated, washed with a 5% NaOH solution and water, and dried in a vacuum desiccator. Yield 94%.

A glass column equipped with a porous partition for dispersing an ozone–air mixture was loaded with 10 ml of acetic acid, 0.4 M of 4-AAT, and calculated amount of the catalyst, after which the unit was thermostated and, after attainment of the steady-state mode of ozonizer operation, an ozone–air mixture containing 4.5×10^{-4} M ozone was passed at a rate of 30 l h^{-1}. After the oxidation completion, the mixture was poured into a glass beaker filled to 2/3 with finely crushed ice, after which the mixture was diluted with cold water to a total volume of 50 ml. The precipitated 4-AABAc was filtered off, washed with cold water, and dried. Then 10 ml of concentrated HCl, 20 ml of water, and 4 ml of alcohol were added, and the mixture was refluxed for 1 h with stirring. After cooling, the precipitated 4-ABA was filtered off. Yield 68% based on the loaded 4-AAT.

The ozone concentration in the gas phase was determined spectrophotometrically from the absorption at 254–290 nm. The oxidation products were identified and quantitatively determined in solution by GLC on a chromatograph equipped with a flame ionization detector. The column, 2 m long and 4 mm in diameter, was packed with Chromaton N-AW impregnated with SE-30. Chromatographing conditions: vaporizer temperature 250°C, column temperature 180°C; flow rates, l h^{-1}: carrier gas (nitrogen) 1.8, hydrogen 1.8, and air 18. 4-Nitrochlorobenzene was used as internal reference.

The running concentration of 4-AABAc was determined by alkali titration. A 0.5-ml sample was taken from the reaction mixture, the solvent was distilled off, and the dry residue was dissolved in 30 ml of 50% ethanol. The solution was titrated with 0.05 N NaOH using phenolphthalein as indicator.

CONCLUSIONS

(1) Ozone reacts with 4-aminotoluene in acetic acid at a high rate, mainly at the nitrogen atom. Products of methyl group oxidation are not formed under these conditions. The direction of the ozone attack can be changed to the methyl group and benzene ring by amino group acylation; however, under these conditions, the yield of aromatic products does not exceed 15%.

(2) The selectivity of oxidation of 4-acetylaminotoluene increases to 52% with increasing temperature to 95°C and on adding a catalyst, cobalt(II) acetate. Addition of potassium bromide leads to a further increase in the rate and selectivity of the methyl group oxidation. The yield of 4-acetylaminobenzoic acid reaches 75%.

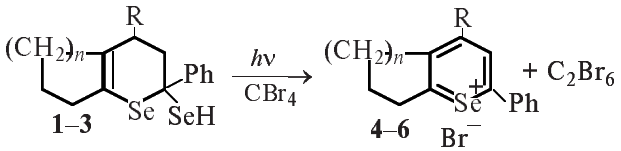
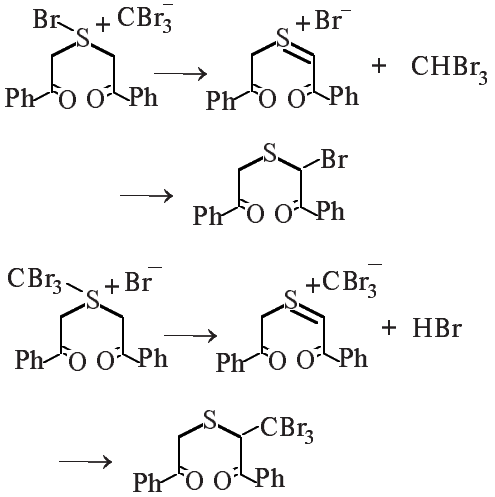
Abstract—Photochemical transformations of 2,4,6-triphenylthiacyclohexane, 2,6-dimethoxyphenyl-4-phenylselenacyclohexane, 2,4,6-triphenylselenacyclohexane, 2,6-diphenyl-4-methoxyphenylselenacyclohexane, and 2,4,6-trimethoxyphenylselenacyclohexane in diisopropyl ether and ethanol under initiation with CBr_4 were studied.



DOI: 10.1134/S107042720807015X

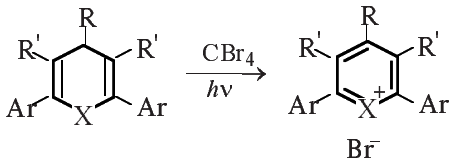
Selenopyrylium salts and selenopyrans are of importance as components of optical recording media, photovoltaic cells, photomaterials, photopolymerization initiators, electrophotographic materials, photoconducting materials in measuring devices, and materials for fast-relaxing passive laser gates. 4*H*-Selenopyrans and their condensed analogs show promise for medicine and veterinary.

Known methods for preparing arylaliphatic 4*H*-selenopyrans [1] are based on reactions of gaseous hydrogen selenide with 1,5-diketones. This route appeared to be applicable to polysubstituted diketones only, and the reactions yielded mixtures of selenopyrylium salts and selenacyclohexanes.



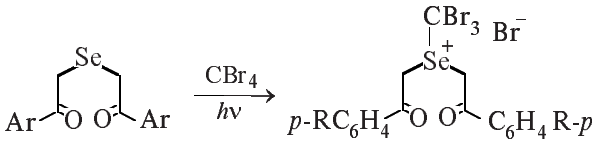
This study is aimed at search for new synthetic routes (in particular, photochemical) to selenopyrylium salts and selenopyrans and at elucidation of mechanisms of photochemical processes involving chalcogen-containing, and primarily selenium-containing heterocycles, which are used as drugs.

It is known [1] that, when irradiated with polychromatic UV light in the presence of CBr_4, hydroseleno derivatives of dihydroselenopyrans **1**–**3** transform into the corresponding selenopyrylium bromides **4**–**6** in 39–50% yield:



where R = Ph, n = 2 (**1**, **4**); R = $C_6H_4OCH_3$-*p*, n = 2 (**2**, **5**); R = Ph, n = 1 (**3**, **6**).

In the previous studies we prepared [2, 3] 9-phenyloximes of octahydrochalcogenoxanthenes, halogenated at the chalcogen atom, which spontaneously transformed into the corresponding heteroaromatic cations. The results of the previously performed [3] GC–MS analysis suggested that the reaction mechanism involves elimination of the hydrogen atom from the C^4 position of the heteroring, followed by aromatization and disproportionation of adducts formed by the reaction at the heteroatom. The first data on photochemical oxidation of some thiacyclohexanes are given in [4, 5]. It was found that, in chlorination of sulfur-containing 1,5-diketones, the reaction occurs at the heteroatom with the subsequent rearrangement similar in the mechanism to the Pummerer rearrangement [6]:



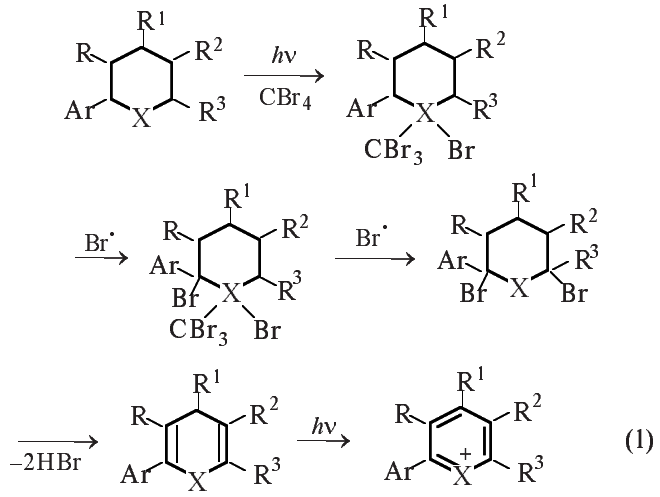
It is known that 4*H*-thio(seleno)pyrans undergo photochemical oxidation to form the corresponding

thio(seleno)pyrylium salts [7]. Therefore, a reaction scheme involving the C^4 atom of the heteroring was suggested:

where X = Se, Ar = R = Ph, R' = H; X = Se, Ar = Ph, R = R' = H; X = S, Ar = Ph, R = $C_6H_4OCH_3$-*p*; X = Se, Ar = $C_6H_4OCH_3$-*p*, R' = CH_3, R = H.

The analogous reaction with 1,5-diaryl-3-selenapentane-1,5-diones occurs by a different mechanism [8]:

In this study we examined the specific features and mechanism of photochemical oxidation of selena(thia)cyclohexanes.



EXPERIMENTAL

Initially we prepared 1,5-diketones in accordance with [9]: 1,3,5-triphenylpentane-1,5-dione, 1,5-diphenyl-3-methoxyphenylpentane-1,5-dione, and 1,3,5-trimethoxyphenylpentane-1,5-dione, which were the starting compounds for preparing thia(selena)cyclohexanes by known procedures [1, 9].

Photochemical oxidation was performed in CCl_4 under UV initiation [10, 11]. The reaction mixture was placed in a quartz reactor, and the initiator (CBr_4) was added. The reactants were stirred with a power-driven stirred under irradiation with a polychromatic UV source (λ = 200–380 nm) arranged on the level of the reaction vessel. The irradiation was performed until the starting compound fully disappeared. The reaction progress and purity of the compounds obtained were monitored by TLC and gas chromatography with a mass-selective detector (GC–MS).

We studied the photochemical oxidation of 2,4,6-triphenylthiacyclohexane, 2,6-dimethoxyphenyl-4-phenylselenacyclohexane, 2,4,6-triphenylselenacyclohexane, 2,6-diphenyl-4-methoxyphenylselenacyclohexane, and 2,4,6-trimethoxyphenylselenacyclohexane in the presence of CBr_4.

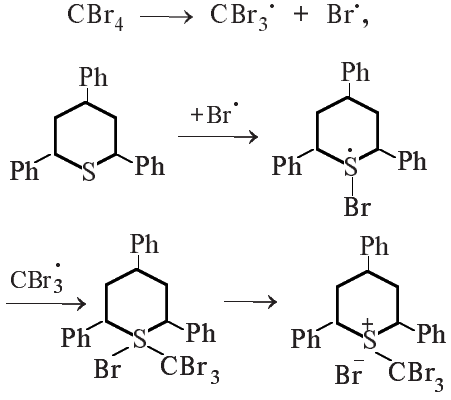


Figure 1 shows the chromatogram and mass spectrum of 2,4,6-triphenylthiacyclohexane. It can be seen that its retention time is 27 min. Figure 2 shows the chromatogram and mass spectrum of 2,4,6-triphenylselenacyclohexane. Its retention time is also 27 min. The content of the starting diketone is very low, which shows that the photochemical reaction goes virtually to completion. Analysis of the mass spectra of other components of the reaction mixture containing 2,4,6-triphenylselenacyclohexane shows that the strongest peaks belong to compounds with molecular ions with *m*/*z* 284 and 209. It could be suggested theoretically that photochemical oxidation of 2,4,6-triphenylthia(selena)cyclohexanes in the presence of CBr_4 occurs as a result of hydrogen halide elimination. In photochemical oxidation of 2,4,6-triphenylthiacyclohexane, we detected the formation of the corresponding thiopyrylium salts, which were identified as perchlorates. The mass spectra suggest the following scheme of transformations:

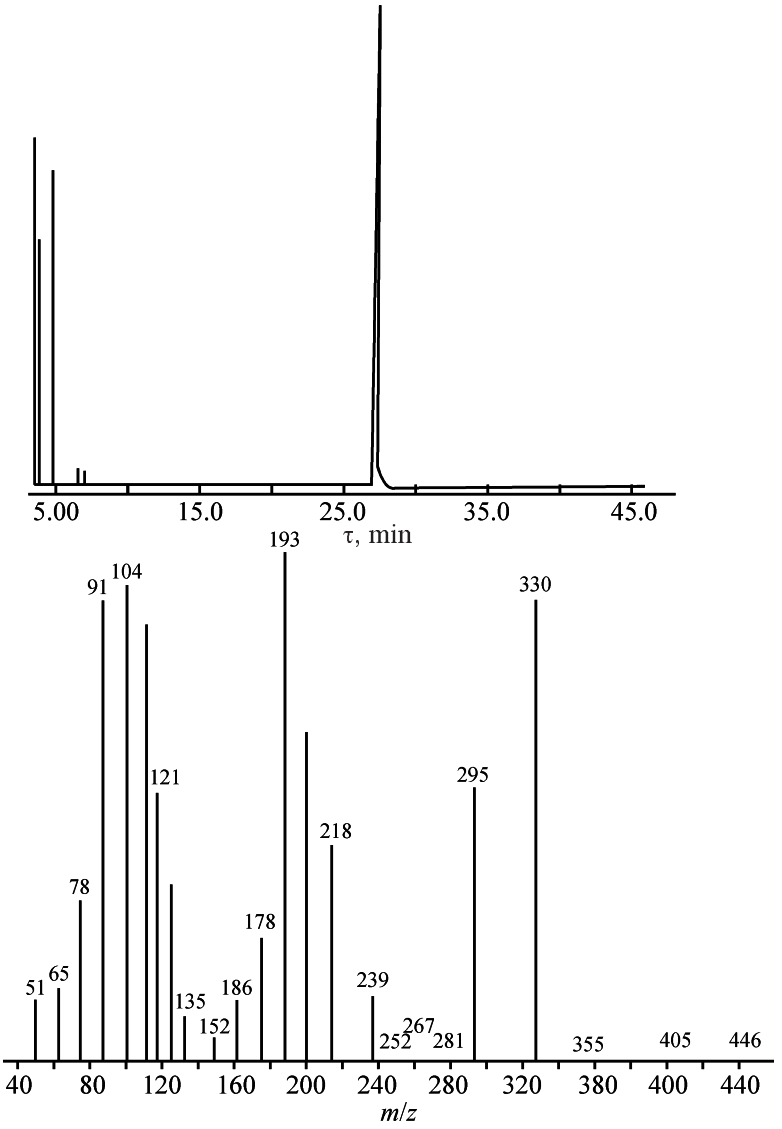
(1)

where X = S or Se.

The mechanism of this reaction can be described by the following scheme:



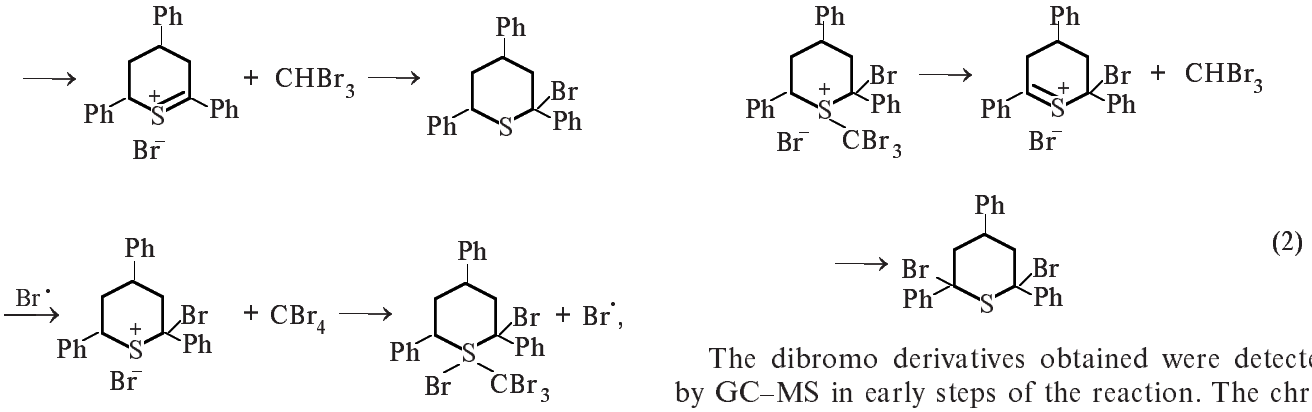


Fig. 1. Chromatogram and mass spectrum of 2,4,6-triphenylthiacyclohexane. (τ) Retention time; the same for Fig. 2.

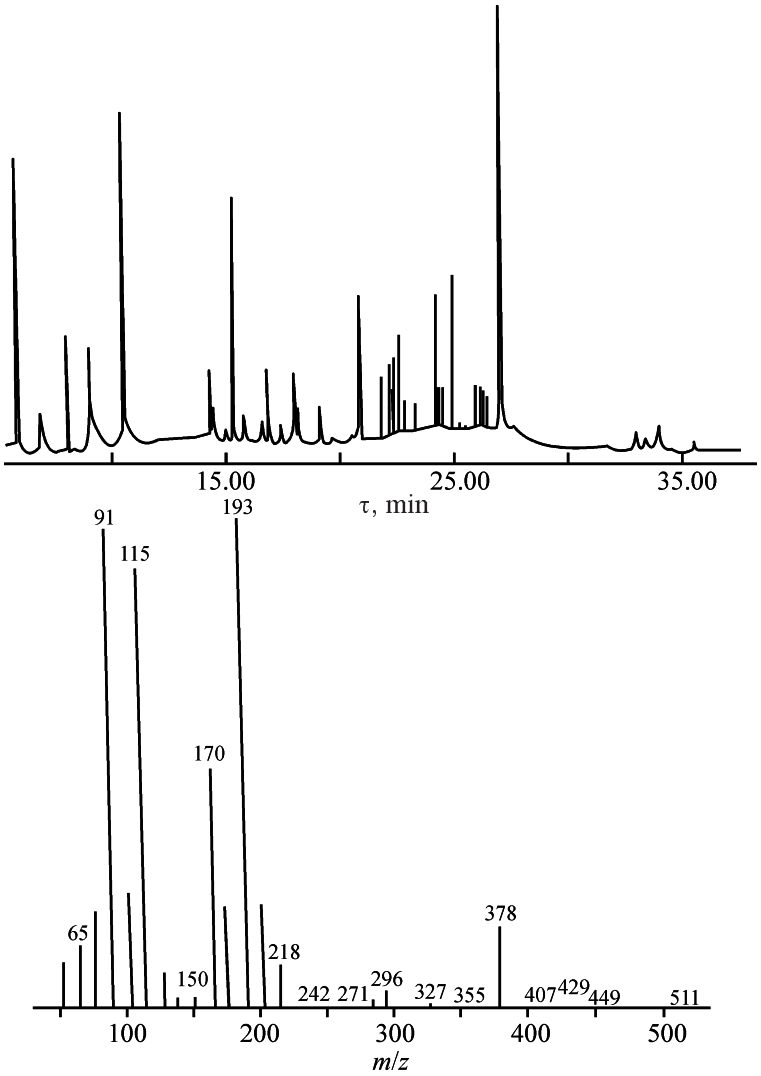
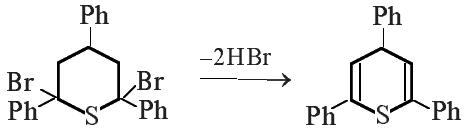
(2)

The dibromo derivatives obtained were detected by GC–MS in early steps of the reaction. The chro-





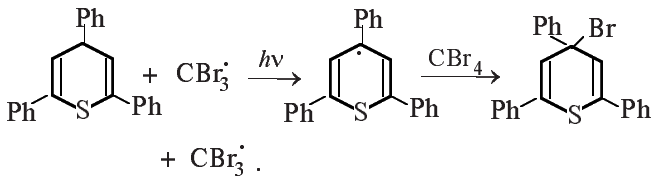


Fig. 2. Chromatogram and mass spectrum of 2,4,6-triphenylselenacyclohexane.

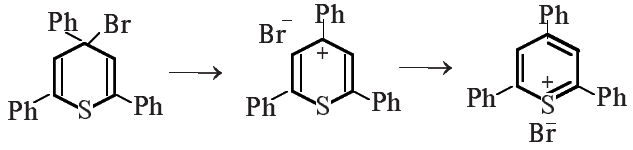


matogram of the photochemical oxidation products shows the formation of 2,4,6-triphenylthiacyclohex-2-ene. Apparently, the dibromide obtained subsequently eliminated hydrogen bromide.

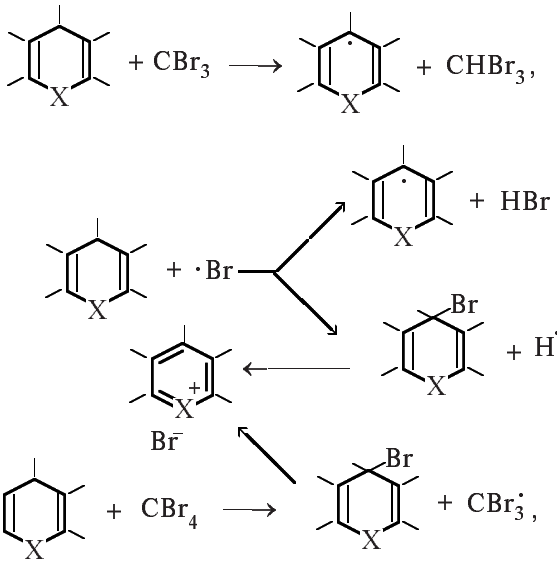
The reaction product, 2,4,6-triphenyl-4*H*-thiopyran, detected by GC–MS, subsequently underwent photochemical oxidation:

The product is thermodynamically unstable and undergoes the following transformations:

The latter structure is more favorable thermodynamically. We found that 4*H*-seleno(thio)pyrans under the conditions of photochemical oxidation transform into the corresponding heteroaromatic cations. Along with the corresponding chalcogenopyrylium salts, among the reaction products we detected by GLC hexabromoethane and bromoform, which confirms the free-radical mechanism of the reaction.

Apparently, the chalcogenopyrylium salt (CP)

absorbs a visible light quantum and in the excited state transfers the energy to the complex of chalcogenopyran (HP) with CBr_4, which decomposes into chalcogenopyrylium bromide and bromoform:



$$CP \xrightarrow{h\nu} CP^*,$$

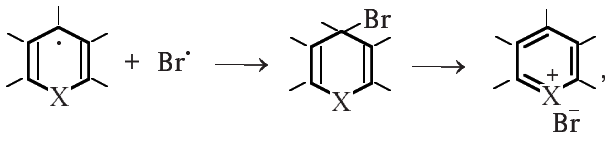
$$CP^* + CBr_4 \cdot HP \longrightarrow CP + CBr_4 \cdot HP^*,$$

$$CBr_4 \cdot HP^* \longrightarrow CP + CHBr_3.$$

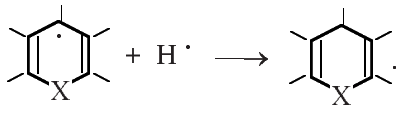
The selenopyrylium salt apparently acts as a sensitizer in this reaction, because, out of all the forming salts, only this compound exhibits strong absorption in the visible range. The following transformation scheme can be suggested:

$$CBr_4 \longrightarrow CBr_3^{\bullet} + Br^{\bullet},$$

$$CBr_4 + H^{\bullet} \longrightarrow CHBr_3 + Br^{\bullet}.$$



Several schemes of the chain termination in the free-radical reaction are possible:



$$CBr_3^{\bullet} + CBr_3^{\bullet} \longrightarrow C_2Br_6,$$

$$CBr_3^{\bullet} + H^{\bullet} \longrightarrow CHBr_3,$$

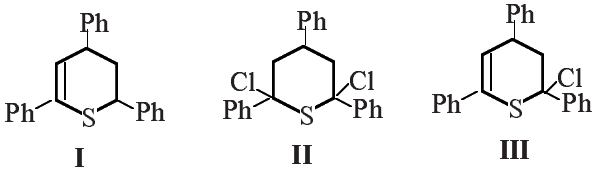
$$CBr_3^{\bullet} + Br^{\bullet} \longrightarrow CBr_4,$$

$$Br^{\bullet} + H^{\bullet} \longrightarrow HBr,$$

Thus, the forming thio- and selenopyrans can undergo photochemical oxidation by the free-radical mechanism with the formation of the corresponding heteroaromatic cations.

Similar results were obtained in the photochemical reaction with 2,6-dimethoxyphenyl-4-phenylselenacyclohexane in CCl_4.

We attempted to perform photochemical oxidation of substituted thiacyclohexanes in CCl_4. The intrinsic absorption of CCl_4 in this range is relatively low, but it may act as sensitizer for aromatic substituted chalcogenacyclohexanes which are simultaneously the reactants. According to our experimental data, the occurrence of photochemical reactions by the free-radical chain mechanism is characteristic of all chalcogenacyclohexanes (CC):



$$CC \xrightarrow{h\nu} CC^*,$$

$$CC^* + CCl_4 \longrightarrow CC + CCl_4^*,$$

$$CCl_4^* \longrightarrow CCl_3^{\bullet} + Cl^{\bullet}.$$

For the homolytic cleavage of the CCl_3–Cl bond, the light quantum with $\lambda < 330$ nm is sufficient. This wavelength correspond to absorption of the aryl substituent at $\lambda = 240–330$ nm. However, thio- and selenopyrylium salts have very high molar extinction coefficient and high quantum yield when used as sensitizers. Therefore, the reaction is autocatalytic.

In photochemical oxidation of 2,4,6-triphenylthiacyclohexane, the following products were detected in the reaction mixture by GC–MS:

I **II** **III**

The corresponding thiopyran could not exist under these conditions for a long time, because it readily transforms into the salt. In this case, the limiting step of the reaction is formation of dichloro- and dihydro derivatives of triphenylthiacyclohexanes. The major components of the reaction mixture were 2,4,6-triphenyl-2,3-dihydrothiacyclohexane **I** and 2,4,6-triphenyl-6-chlorothiacyclohex-2-ene **III**.

The latter product could be formed both in the reaction mixture and by dehydrochlorination on the adsorbent in the course of chromatographic analysis.

Thus, we developed a new procedure for preparing thio(seleno)pyrans by photochemical oxidation of thia(selena)cyclohexanes, which is of practical interest.

CONCLUSIONS

(1) Chalcogenacyclohexanes can undergo photochemical oxidation in the presence of CCl_4 and CBr_4 to form heteroaromatic cations. Chalcogenacyclohexanes can act as sensitizers in photochemical oxidation.

(2) The most thermodynamically stable products of oxidation of 4*H*-selenopyrans are the corresponding aroylselenophene derivatives.

(3) Photochemical oxidation of selenopyrans can occur both at the C^4 atom of the heteroring and at the heteroatom.

(4) The new modification of the Pummerer rearrangement is accompanied by elimination of the reagent with the formation of the corresponding unsaturated compound.

(5) Photochemical oxidation of selena(thia)cyclohexanes is a new route to seleno(thio)pyrans and seleno(thio)pyrylium salts.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Peat Humus Acids as Catalysts of Reduction of Quinone Groups in Vat Dye Molecules

Abstract—The redox titration of peat humus acids was carried out. The effect of humic acids on the reduction kinetics of an anthraquinone dye as a model of water-soluble vat dyes with sodium hydroxymethanesulfinate was examined.

DOI: 10.1134/S1070427208070161

One of biospheric functions of natural humus acids (HA) is catalysis of redox decomposition of organic ecotoxicants, first of all, pesticides [1–4]. Currently the areas of application of catalysts based on humus acids is limited to coal fuel chemistry and such processes as purification of gaseous and solid compounds and water [3, 5–9].

It is known that many textile-chemical processes such as dyeing of textile materials with vat dyes are based on redox processes [10, 11]. For example, water-insoluble vat dyes after reduction of their quinone groups become water-soluble and acquire affinity for cellulose materials. After the subsequent reoxidation, these dyes lose solubility and are strongly fixed on the textile material. The reduction of vat dyes is accelerated in the presence of redox catalysts, e.g., anthraquinone derivatives [11]. The mechanism of functioning of these catalysts involves stepwise redox reactions. In this reaction chain, the reductant first reacts with catalyst molecules to transform them into the hydroquinone form, which reduces the dye more readily than does the reductant itself and is oxidized in the process to the initial form [11].

The accelerating effect of peat humus acids on fixation of vat dyes on cotton fabric in its printing by the rongalite–potash technique was reported in [12]. Then we further examined this effect with Chrome Green Anthraquinone dye (CGA) as analog of the vat dye [13]. This compound has the following formula:

We suggested that humus acids catalyze the reduction of the quinone groups in the dye molecules by the mechanism typical of anthraquinone compounds. In these systems, the catalytically active centers can be both the quinone (carbonyl) groups of humus acids and transition metal ions coordinated with humus acid functional groups. In this study we attempted to verify this hypothesis.

EXPERIMENTAL

The chemicals used in this study were as follows. Sodium hydroxymethanesulfinate HMS (rongalite) (standard reducing agent used in textile industry) was recrystallized two times from water by the procedure reported in [14]. Aqueous solution of humus acids in the form of sodium salt was prepared by alkaline extraction from peat by the standard technique [15]. $FeSO_4 \cdot 7H_2O$ and sodium ethylenediaminetetraacetate (Na_2EDTA) were of chemically pure and analytically pure grades, respectively. The commercial Chrome Green Anthra-

quinone acid dye CGA was purified by the method reported in [16] to attain a constant extinction coefficient.

The redox titration curves of humus acids were obtained by two-step titration. First humus acids were reduced with rongalite in alkaline medium (pH 12.7) to constant redox potential, and then the reduced form of humus acids was reoxidized with aqueous potassium ferricyanide. The redox titration involved two cycles of reduction and oxidation of humus acids. The redox titration was performed under argon at 85°C in a temperature-controlled glass cell equipped with a magnetic stirrer. The redox potentials were measured on a laboratory digital OP-211/1 pH-meter with platinum and silver chloride electrodes.

The transition metal content in HA was determined by an atomic-absorption technique [17]. The content of the quinone and carbonyl groups in HA was determined by potentiometric titration [18].

The reaction rate of CGA with excess of sodium hydroxymethanesulfinate was determined by change in the optical density of solutions of this dye at the absorption maximum of the oxidized form (λ_{max} = 612 nm, ε = 10870 l mol^{-1} cm^{-1}), which is well resolved with the absorption maximum of CGA in the reduced form. The CGA concentration in solutions was in the range of observance of the Lambert–Bouguer–Beer law. The kinetic measurements were carried out on a Specord M-400 spectrophotometer.

Taking into account that the dyeing of cotton fabric with vat dyes is commonly carried out in alkaline media, the reversibility of oxidation and reduction of HA was studied at pH 12.7, typical of industrial conditions. The redox curve of humus acids, $-E = f(V)$ (Fig 1a), has a dome-like shape. Its ascending and descending branches reflect the reduction and reoxidation of humus acid functional groups, respectively. It is seen that each of these branches has two inflection points marked with arrows. This means that both the reduction of humus acids and their subsequent reoxidation are two-step processes. We believe that this multistep character of the process is caused by successive reduction (or oxidation) of two kinds of redox-active functional groups contained in humus acids.

The reduction and oxidation potentials of these functional groups were determined by differentiating the titration curve. Figure 1b shows the differential form of the redox titration curve. In this curve, the maxima and minima correspond to the reduction and reoxidation potentials of the redox-active functional groups, respectively. These potentials are listed in Table 1.

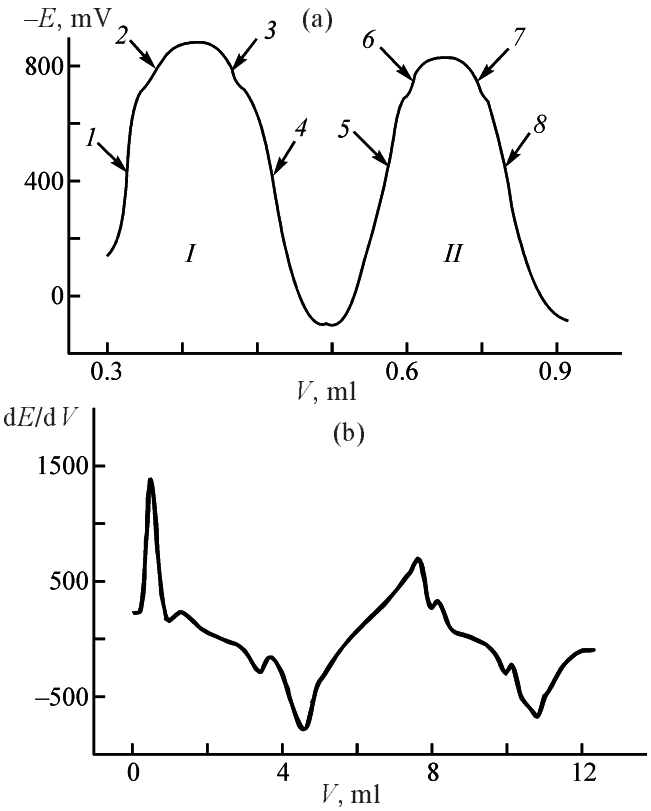

Fig. 1. (a) Redox titration curves of humus acids and (b) their differential form. c_{HA} = 0.1 g l^{-1}, c_{HMS} = 0.11 M, c_{NaOH} = 0.1 M, $c_{K_3[Fe(CN)_6]}$ = 0.24 M. 65°C. OP	–420	–779
Fragments of second kind		
RP	–448	–750
OP	–441	–744

Table 2. Content of reducible functional groups in humus acids

Main fragments	Concentration, g-equiv g^{-1}
Functional groups:	
carbonyl	$(112 \pm 8.3) \times 10^{-4}$
quinone	$(10.5 \pm 0.5) \times 10^{-4}$
total	122.5×10^{-4}
Transition metals:	
Fe	$(4.25 \pm 0.758) \times 10^{-4}$
Mn	$(0.027 \pm 0.0015) \times 10^{-4}$
Cu	$(0.02 \pm 0.001) \times 10^{-4}$
total	4.297×10^{-4}

The fact that the ascending and descending branches in the titration curve are symmetrical (the oxidizing and reducing agents are consumed in equal amounts) shows that the identical functional groups of humus acids participate in the reduction and reoxidation reactions. It should be noted that the maximum height in the second redox cycle is somewhat lower than that in the first cycle. The similar trend is observed for the inflection points in the titration curves. This is apparently caused by the fact that a part of functional groups in humus acids (~10%) are reduced irreversibly in the first redox cycle.

We believe that the catalytic centers of humus acids capable of reversible reduction are, firstly, transition metal ions strongly coordinated with humus acids, whose bonds with humus acid functional groups are not broken on changing metal valence. The other redox-active centers contained in humus acids are the carbonyl and quinone groups. The concentration of these functional groups in humus acids is given in Table 2. This table shows that iron accounts for 98% of the variable-valence metals contained in humus acids. The reversible redox reactions of iron without break of its coordination bonds with humus acid functional groups were analyzed in [3, 18, 19].

The standard electrode potential of the half-reaction $Fe^{3+} + e \rightarrow Fe^{2+}$ varies in the range 360–500 mV depending on the kind of ligand and solvent [20, 21]. As seen from Fig. 1a, this potential range covers the reduction potential corresponding to the first inflection point in the redox titration curve of humus acids. The half-reaction potentials of reduction of the aldehyde, ketone, and quinone functional groups, corresponding to the second inflection point in the redox titration curve, are in the range 770–970 mV [22].

Thus, the reduction and oxidation potentials determined from the redox titration curve of humus acids allowed determination of both the kind of reducible functional groups and the order of their reduction. These results showed that the transition metal ions coordinated with humus acids are reduced first [(reaction (1)], and this is followed by the reduction of the carbonyl and quinoid groups [(reaction (2)].

$$HA(Fe^{3+}) + HOCH_2SO_2^- + 2OH^- \rightleftarrows HA(Fe^{2+}) + SO_3^{2-} + CH_2O + H_2O \quad (1)$$

$$HA(C{=}O) + SO_2^{2-} + 2OH^- \rightleftarrows HA(C{-}O)^- + SO_3^{2-} + H_2O. \quad (2)$$

We attempted also to elucidate whether both kinds of the redox-active centers in humus acids contribute to catalytic reduction of the quinone groups in CGA molecules. The contribution of particular active centers of humus acids to the total catalytic effect was also examined. Taking into account that 98% of the varible-valence metals contained in humus acids are coordinated iron ions, we chose the Fe(II)–EDTA complex as a model of the metal-containing catalytic center. The stability constants of complexes of iron cations with both EDTA and humus acids have the same order of magnitude [13, 23]. The reduction and oxidation of metals in such strong complexes is not accompanied by their breakdown.

Figure 2 shows the kinetic curves of CGA dye reduction with sodium hydroxymethanesulfinate under the following conditions: (*1*) without catalyst, (*2*) in the presence of Fe(II)–EDTA complex, and (*3*) in the presence of humus acids. The iron concentration in both Fe(II)–EDTA complex and humus acids was equal. The rate constants obtained in these experiments are listed in Table 3.

Table 3 shows that, in the presence of both the Fe(II)–EDTA complex and humus acids, the rate constant of CGA reduction with sodium hydroxymethanesulfinate increases by a factor of 1.4 and 11, respectively. The considerably higher catalytic effect of humus acids as compared to Fe(II)–EDTA complex is caused by the fact that humus acids contain two kinds of catalytic centers: metal ions and organic groups (quinone, carbonyl). Due to the catalytic

Table 3. Rate constants of reduction of CGA dye with sodium hydroxymethanesulfinate in the presence of various catalysts at 65°C

Catalyst	Concentration of catalytic centers, mg-equiv g^{-1}	Rate constant $k \times 10^3$, s^{-1}
None	–	3.7

Quinone and carbonyl functional groups in humus acids (calculated values)	12.25	29.2

activity of quinone (carbonyl) groups, the rate constant of CGA reduction increases by a factor of 7.9. The necessary condition for humus acid functioning as a catalyst is the lower activation energy E_a of reduction of its functional groups as compared to that for the quinone groups in vat dye molecules. The E_a of reduction of humus acid functional groups with sodium hydroxymethanesulfinate, determined by the Arrhenius equation, was 28.6± 1.1 kJ mol^{-1}. At the same time, the activation energy of reduction of CGA anthraquinone dye is higher by a factor of approximately 5 (E_a = 138 ± 5.9 kJ mol^{-1}) [13].

CONCLUSIONS

(1) According to the results of redox titration, peat humus acids contain two kinds of successively reducible catalytic centers: variable-valence metal ions strongly coordinated with humus acids and organic (carbonyl, quinone) groups. The reduction potentials of these groups were determined and the reversibility of their reduction was established.

(2) In reduction of vat dyes catalyzed by humus acids, the catalytic centers are both the organic (quinone, carbonyl) groups and the coordinated variable-valence transition metal ions.

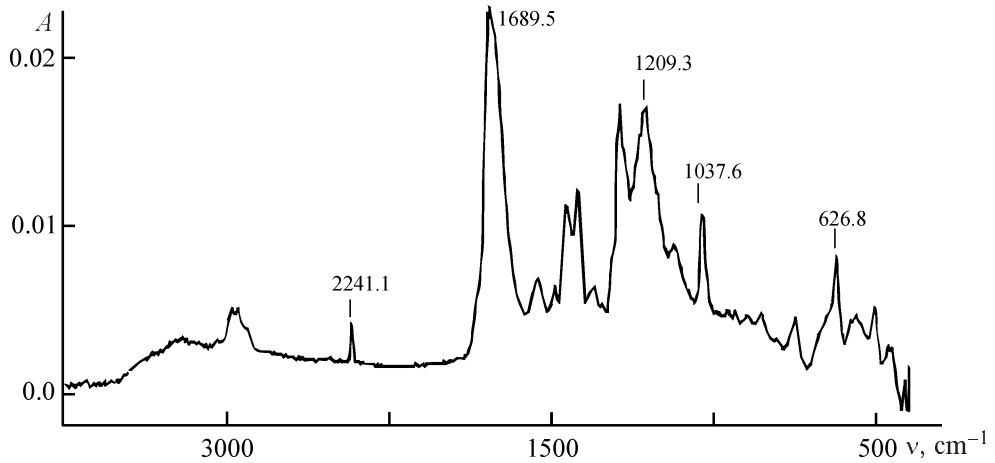
Abstract—Preparation of proton-conducting polymeric composites via copolymerization of multicomponent monomeric systems using the interpenetrating polymer network preparation procedure is studied. The products are characterized by the protonic conductivity, water-retaining capacity, and mechanical properties. The approach used allows fabrication of membranes with a reasonable protonic conductivity over the temperature range 20–90°C. A possibility of modification of the proton-conducting materials with small additions of hydrolyzable organosilicon comonomers is analyzed. The structure of the resulting systems is examined by small-angle neutron scattering.

DOI: 10.1134/S1070427208070173

Currently one could say that the principal types or classes of proton-conducting polymeric membranes for fuel cells take a clear shape [1]. Primarily these are perfluorinated polymers of the Nafion type and composition- and structure-related polymeric composites [1–5], polycondensation membranes based on poly(benzimidazoles), polyester–ester ketones, etc. [5, 6].



Recently data on proton-conducting polymeric membranes based on hybrid polymeric systems were reported [7–9]. In this relation, patents and developments from the recently founded ITM Power Ltd. are of particular interest [10–14]. The original development of this company proposes fabrication of not only a membrane, but also a membrane electrode assembly (MEA) consisting of electrodes and an ion-exchange polymeric membrane (PM) made of a hydrophilic polymer bearing a strong ionic group. Such an aggregate is prepared by γ-radiation-induced in situ copolymerization of a mixture of hydrophobic and hydrophilic comonomers, including a monomer containing a strong ionic group. As the authors asserted, such PMs demonstrate high protonic conductivity, controlled hydrophilicity, and capability of recycling of the platinum catalyst from MEA. Furthermore, the authors declare the possibility of reducing cost of PM and exploitation of the system by an order of magnitude as compared to Nafion membranes. They pointed out that cross-linked polymeric membranes could be prepared through not only radiation, but also chemical cross-linking. The description of the invention includes no data on the performance characteristics of the membrane materials under different exploitation conditions.

In this study, we examined the possibility of implementation of the method for fabricating polymeric membranes, proposed in [10–14], including the effect of the composition of the monomer mixture on properties of the resulting PMs and their performance characteristics as components of fuel cells (FSc).

EXPERIMENTAL

In synthesis of hydrophilic polymers containing an ionic group, we used such monomers as acrylonitrile (AN), *N*-vinylpyrrolidone (*N*-VP), vinyltrimethoxysilane (VTMS), vinyltriethoxysilane (VTES), 3-(trimethoxysilyl)propyl methacrylate (TMSPMA), 2-acrylamido-2-methyl-1-propanesulfonic acid (AMPSA), and ethylene glycol dimethacrylate (EGDM), all from Sigma Aldrich.

The hydrophilic ionic polymers were synthesized by copolymerization of three- or four-component

IR spectrum of PM (for chemical composition of PM, see Table 1, sample no. 2).

monomer mixtures in the presence of a cross-linking agent using ammonium persulfate as an initiator in an aqueous solution at room temperature for 24 h. Because of high adhesive capacity of the materials synthesized, polymeric membranes were fabricated in sealed built-up fluoroplastic molds.

The water content of PMs was determined after keeping samples in water at 25 or 90°C (equilibrium swelling conditions). From this data, we additionally determined the parameter λ defined as the amount of water in moles per $-SO_3H$ group. One more parameter used was $\Delta H_2O^{90°C}$ representing the water loss of a membrane in the equilibrium swelling state in 1 h at 90°C. Parameter λ reflects the hydrophilicity of PM, and $\Delta H_2O^{90°C}$ characterizes the stability of hydrophilic properties under heating.

Mechanical properties of hydrated PMs in the equilibrium swelling state were examined on a UTS 10 multipurpose mechanical testing machine (Germany) at 20°C. The samples represented 0.5–1.0-mm-thick spatulas with the size of the working part of 20 × 3.5 mm. The extension rate was 10 mm min^{-1}. In these tests, we determined the ultimate tensile strength σ_u, elastic modulus E, and relative elongation at break ε.

Since measurement of the elongation for highly swollen samples at 90°C is a difficult task, we determined the ultimate compression strength σ_u, elastic modulus E, and failure strain ε under uniaxial compression using the same testing machine. In this case, samples were 5-mm-high flat cylinders 12 mm in diameter. The compression rate was 1 mm min^{-1}.

The conductivity of the hydrated films at 20 and 90°C was measured in a cell with platinum electrodes using the four-probe method.

Infrared reflection spectra of dry samples were recorded on a Shimadzu FTIR-8300 instrument using Kramers–Kroning transformation.

The structure of the membranes (pore and channel distribution) was studied by small-angle neutron scattering on a Membrana-2 diffractometer at the Konstantinov Institute for Nuclear Physics using a beam of neutrons with a wavelength of 0.3 nm.

First we reproduced the procedures for preparing polymeric membranes by copolymerization of monomer mixtures of AN, *N*-VP, and AMPSA according to [10] using the chemical initiator and EGDM as a cross-linking agent.

The figure shows the IR spectrum of the polymeric membrane (Table 1, sample no. 2), suggesting that the copolymer contains the AN, *N*-VP, and AMPSA units (bands at 2240; 1690; and 625, 1040, and 1210 cm^{-1}, respectively).

The study of the films of the synthesized partially cross-linked hydrophilic ionic copolymers capable of equilibrium and reversible swelling in water showed that they are polymeric hydrogels [15]. Such hydrated materials demonstrate reasonable protonic conductivity (σ_H > 0.05 S cm^{-1} at 20°C) at an AMPSA content in PM of 16.5–23.5 wt % (Table 1, sample nos. 2–5), which is well comparable with that of Nafion membranes. Data on the effect of the chemical composition of the copolymer on the characteristics of PMs revealed that decrease in the AMPSA content in the copolymer below 15 wt % abruptly decreases the protonic conductivity of the material as a result of significant decrease in parameter λ (Table 1, sample no. 1). There is an optimal concentration of the sulfonate groups in

the copolymer (15–20 wt %) at which the material exhibits a reasonable protonic conductivity. Too high AMPSA concentration (above 25 wt %) in the copolymer does not allow preparation of PMs stable under the exploitation conditions. Even at the optimal AMPSA content, the resulting PMs do not exhibit high mechanical strength. As seen from Table 1, with increasing AMPSA content, i.e., with increasing concentration of the sulfonate groups in the copolymer, from 16.5 to 23.5 wt %, λ increases from 101 to 770 (at 25°C), and σ_u decreases from 1.94 to 0.35 MPa. At elevated temperature (90°C), PMs fabricated according to the procedure described in [10] exhibit unsatisfactory mechanical characteristics, making them unsuitable for use at this temperature. The attempt to improve the mechanical strength of PMs through adding hydrophobic monomers such as methyl and *n*-butyl methacrylate failed.

Strengthening of such PMs through increasing cross-linking density in the copolymer resulted in micro- and macrocracking in formation of the membrane and in its breakdown upon hydration. It was demonstrated that the cross-linking agent content in the copolymer should be below 3 wt %. Above this critical value, cracking of PMs takes place in its formation in the course of copolymerization.

Therefore, we failed to prepare PMs with reasonable characteristics, especially at elevated temperatures, which can be attributed to the fact that the authors of [10] employed radiation copolymerization, or to some other know-how.

For polymeric hydrogels, several approaches to formation of the structure of materials can be used to impart desired properties to the polymeric system. In synthesis of polymeric hybrid hydrogels, the optimal approach is accepted to be that based on formation of interpenetrating polymer network (IPN) [16, 17].

To fabricate PMs with satisfactory characteristics, we used the IPN formation approach in which one of the networks is proton-conducting, and the other network provides reasonable mechanical strength and barrier characteristics with respect to components of the working medium of the fuel cell (oxygen, hydrogen). In the first stage, we synthesized cross-linked copolymers with ionic sulfonate groups. Their compositions and characteristics are presented in Table 1.

In the second stage, to the polymer network prepared previously, a mixture of monomers of another, more hydrophobic composition, was added, which was followed by copolymerization using the cross-linking monomer. The water-retaining and mechanical characteristics of the IPNs can be controlled over a wide range by varying the ratio of AN and *N*-VP monomers used in synthesis of the second network and the network weight ratio.

Table 2 (sample nos. 1–7) shows characteristics of IPN-based PMs. As can be seen, this method allows preparation of PMs with high protonic conductivity, exhibiting good mechanical characteristics in the hydrated state up to 90°C. It was found that, to maintain mechanical strength in IPN-based PMs at elevated temperatures, the amount of the second

polymer network should be at least 10–15% of the weight of the first (ionic) network. Variation of the composition and weight fraction of the second network in PM allows control of not only the water-retaining and mechanical characteristics, but also the protonic conductivity of PM. Naturally, the protonic conductivity decreases with increasing weight fraction of the second network (Table 2, sample nos. 1 and 3). Thus, it was demonstrated for PMs containing the second network with relatively high AN content (Table 2, sample nos. 5 and 6) that the resulting membranes are more rigid, having lower protonic conductivity.

Unexpectedly, IPN-based PMs appeared to have higher protonic conductivity than ionic polymer networks formed in the first stage, despite the decrease in the total concentration of the sulfonate groups in the composite material, suggesting a complex dependence of the protonic conductivity on the concentration and degree of hydration of the sulfo-

nate groups, including the effects of the PM structure and transfer conditions of hydrated protons across the membrane. Many researchers [18, 19] pointed out that the membrane morphology is controlled by the nature of monomers and membrane fabrication procedure, which affect the distribution and concentration of acid groups in nanosized structural elements of PMs, limiting water-retaining properties of membranes and transport of hydrated proton across the membrane, thus controlling its protonic conductivity.

To check this hypothesis, we studied the PM structure by small-angle neutron scattering. Prior to experiment, the membranes were swollen in D_2O, which allowed examination of the system of nanosized pored filled with water. It was demonstrated that, in the initial polymer network (Table 1, sample no. 2), the clusters are nonuniform, consisting of large-sized (24–26 nm) blocks with small (about 3 nm in size) cavities inside them. Interpenetrating polymer networks (table 2, sample no. 3) prepared on the basis of the initial network have more complex structure (in this case, network 2 additionally forms water-retaining blocks up to 70 nm in size). Evidently, such an hierarchical structure favors formation of channels connecting the clusters, thus causing the increased protonic conductivity of IPN-based PMs.

It was shown that IPNs exhibit a protonic conductivity σ_H = 0.12–0.31 and 0.019–0.095 S cm^{-1} at 20 and 90°C, respectively, which is condiderably higher than in the previously fabricated structures (0.055–0.083 S cm^{-1} at 20°C). In this study, we managed to significantly improve mechanical characteristics of the hydrated IPN-based membranes

(σ_u = 2.04–2.54 MPa; elastic modulus increased to 3.52–4.85 MPa), making these membranes suitable for use at temperatures of up to 90°C. The drawback of the IPN-based PMs is in slight deterioration of the water-retaining properties, as demonstrated by the parameter $\Delta H_2O^{90°C}$.

Therefore, the way to improve performance characteristics of PMs based on ionic copolymers is the formation of interpenetrating networks in their structure.

Another possible way to improve mechanical properties of PMs is to form additional cross-linked structures in the membranes using a sol–gel process. We analyzed the effect of additions of such hydrolyzable comonomers as alkoxysilanes (VTMS, VTES, and TMSPMA) (Table 3) in the first stage of synthesis of ionic copolymers.

In hydrolytic treatment of such copolymers, the alkoxysilane groups hydrolyze into the silanol groups, which is followed by their partial condensation at elevated temperatures [20, 21]. In the case in hand, hydrolysis of the alkoxysilane groups is acid-catalyzed without adding some additional acid, since the copolymer contains the sulfonate groups, and pH of the aqueous phase in contact with the polymer hydrogel is close to 3.0.

Because of low concentration (0.3–1.7 mol %) of organosilicon fragments in the structure of PMs, the matter concerns not the formation of hydrophilic organo–inorganic clusters, but rather some additional randomly distributed cross-linked domains in the already cross-linked and swollen copolymeric system. Furthermore, after hydrolysis, cross-linking involves only a small part of the silanol groups, while the remaining silanol groups improve the water-retaining characteristics of PMs.

It was demonstrated that introduction of VTMS, VTES, or TMSPMA into the ionic copolymer allows improvement of the mechanical strength and protonic conductivity of PMs. For the ionic copolymers modified with organosilicon comonomers of VTMS and TMSPMA, parameter λ at 25°C ranges from 70 to 90, which is probably close to the optimal value (at 16.5 wt % AMPSA content in the copolymer). This causes a reasonable protonic conductivity of the material (σ_H = 0.10–0.32 S cm^{-1}, which is considerably higher than for the unmodified membranes (σ_H = 0.055 S cm^{-1}). For all the PMs studied, increase in the additive (VTMS, VTES, or TMSPMA) content at constant AMPSA concentration in the copolymer results in increasing protonic conductivity of the membranes at low temperatures, which can be attributed to both additional randomly distributed cross-links, changing the distribution of the ionic sulfonate groups in the copolymer, and also to increase in the amount of undercondensed silanol groups improving the water-retaining characteristics of the copolymer and optimizing the transport of hydrated protons across the membrane. Introduction of the modifiers also allowed fabrication of PMs mechanically stable at elevated temperatures (90°C), as in the case of IPN-based membranes, even though with slightly lower protonic conductivity.

Modification with organosilicon monomers appeared to be most effective for IPN-based PMs. The effect of hydrolyzable organosilicon fragments of networks 1 or 2 on characteristics of interpenetrating networks is ambiguous. Modification of network 1 of PM with the organosilicon additives allows preparation of IPN-based PMs with better mechanical properties (Table 2, sample nos. 8–14; σ_u = 2.24–2.59 MPa, E = 4.50–9.58 MPa) and high protonic conductivity preserved (σ_H = 0.087–0.21 S cm^{-1} at 20°C and σ_H = 0.025–0.078 S cm^{-1} at 90°C), which is caused by enhanced mechanical characteristics of the first network. The use of organosilicon additives as components of network 2 deteriorated both mechanical and proton-conducting properties of the resulting PMs.

CONCLUSIONS

(1) A novel method is developed for fabricating proton-conducting materials as a hybrid ionic hydrated copolymer, using the interpenetrating network approach.

(2) The hydrophilicity and structure of interpenetrating polymer networks can be controlled, allowing improvement of the mechanical characteristics of the polymeric membranes at ambient and elevated (90°C) temperatures, with the satisfactory protonic conductivity of the material preserved.

(3) Structural elements of the ionic copolymers proved to be nanosized; the size changes upon formation of interpenetrating networks.

Abstract—Films of polyacrylonitrile and lignin cast from dimethylformamide were studied by dynamic thermal analysis in a self-generated atmosphere and in a vacuum. The occurrence of a thermochemical reaction of the components on heating was demonstrated. The optimal conditions of the reaction between polyacrylonitrile and lignin were determined.

DOI: 10.1134/S1070427208070185

In our previous study [1], the possibility of polyacrylonitrile (PAN) carbonization with lignin (LG) was demonstrated for powder mixtures of these compounds. It was found that, in the course of thermochemical reaction of the components, the heat resistance of LG increases owing to the reactions starting with PAN cyclization. The observed features of cocarbonization of PAN and LG suggest the necessity of closer contact of the starting reactants by their preliminary homogenization in the form of solutions or suspensions. In the case of chitin and chitosan [2], cocarbonization with PAN is strongly accelerated by thermal treatment of films prepared from solutions of these polymers. From the experimental results, the role of interpolymer complexes of PAN with chitin and chitosan in a common solvent was revealed, which allowed preparation of cocarbonized composites with properties different from that of the initial polymers.

In this study we attempted to combine polymers through interpolymer complexes using PAN to impart new properties to lignin in the course of combined thermal treatment of a mixed solution of these polymers.

EXPERIMENTAL

As starting compounds we used ND-1 PAN fibrous copolymer produced by the Khimvolokno Joint-Stock Company (Svetlogorsk, Belarus) with molecular weight of 130 000 and an LG powder recovered by base hydrolysis using the procedure given elsewhere [3], forming suspensions in dimethylformamide (DMF). The express analysis of the ND-1 fiber and films cast from its solutions in DMF on a derivatograph and on a unit for thermovolumetric analysis (TVA) showed no differences in the thermochemical behavior of this copolymer and of PAN prepared in the laboratory. A dry PAN–LG mixture was prepared by mixing finely cut ND-1 PAN fiber and LG powder sifted through a sieve (0.04 mm mesh size). The films were prepared by casting of PAN solutions and PAN–LG suspensions in DMF (5% concentration) onto glass supports with subsequent drying at room temperature in a vacuum. Based on our previous results [1], we used the weight ratio of the starting components of 1 : 1, because this ratio allows evaluation of the thermochemical parameters typical for both polymers and their changes in the course of carbonization, especially using DTA. The dynamic thermal analysis of the PAN–LG films in the self-generated atmosphere (SGA) was carried out on an MOM C derivatograph at a heating rate of 10 deg min^{-1} using ceramic crucibles (sample weight 50 mg). The dynamic analysis of the PAN–LG films in a vacuum was carried out on a TVA unit with manometric recording [4] with heating to 900°C at a rate of 7 deg min^{-1} (sample weight 50 mg). The thermal degradation kinetics was studied on a NETZSCH STA 429 device in open crucibles in air at a heating rate of 7 deg min^{-1} (sample weight 10 mg). The PAN–LG composites with a high content of LG were prepared by pouring of a PAN–LG suspension in DMF into a burnt clay mold and evaporation of the solvent on a sand bath with gradual addition of a thick suspension of LG in DMF. Then the mold was dried for 4 h in a vacuum (10^{-3} mm Hg) in the TVA device to constant weight, after which the sample was heated

to 1000°C. Similar procedure was simultaneously performed with individual PAN.

The TG curves of the weight loss on heating of the samples to 1000°C are shown in Fig. 1a, and the thermal effects accompanying thermochemical transformations of the samples in the same temperature range are illustrated by Fig. 1b (DTA curves). As seen from the TG curve (Fig. 1a, curve *4*), thermal degradation of the film samples in the oxidative atmosphere in the entire temperature range studied proceeds more smoothly than that of the initial compounds. Starting from 120°C, the rate of the weight loss is slightly smaller than in the 300–400°C range, and above 400°C the pattern of thermal degradation of the mixed films strongly differs from that of the LG degradation. Above 600°C, the rates of the weight loss of samples 1–4 are similar, although the coke number of LG is noticeably lower than that of the modified samples.

Comparison of the thermal effects of the samples studied allows certain assumptions on the mechanism of thermal reaction of LG and PAN. Curve *1* (Fig. 1b) primarily illustrates thermal cyclization of PAN with a maximum at 244°C, complicated by subsequent oxidation reactions (300–380°C). This pattern is typical for a series of various PAN samples and can be used as reference for comparison with modified samples. As for curves *3* and *4* (Fig. 1b), it should be noted that the maximum of the exothermic effect is shifted toward higher temperatures, especially for the film sample (shift by 43°C). Moreover, the DTA curve of the film sample exhibits an endothermic effect at 400°C. Comparison of these parameters with those of curves *1* and *3* suggests that the thermal treatment of the PAN–LG mixed film leads to noticeable reaction of the components. The shift of the temperature maximum of the exothermic effect toward higher temperatures and a decrease in the peak area as compared to straight PAN and mixed powder samples are indicative of a certain decrease in the rate of PAN cyclization. Changes in the shape and temperature of the maximum of the endothermic effect at 400°C suggest formation of the carbonized compound with more ordered structure as compared to samples 1 and 3. The mechanism of this phenomenon was discussed previously in a study of low-temperature PAN carbonization [5].

In contrast to our previous measurements of thermochemical parameters [1], in this work we primarily studied the kinetic parameters of cocarbonization of PAN and lignin and attempted to minimize the

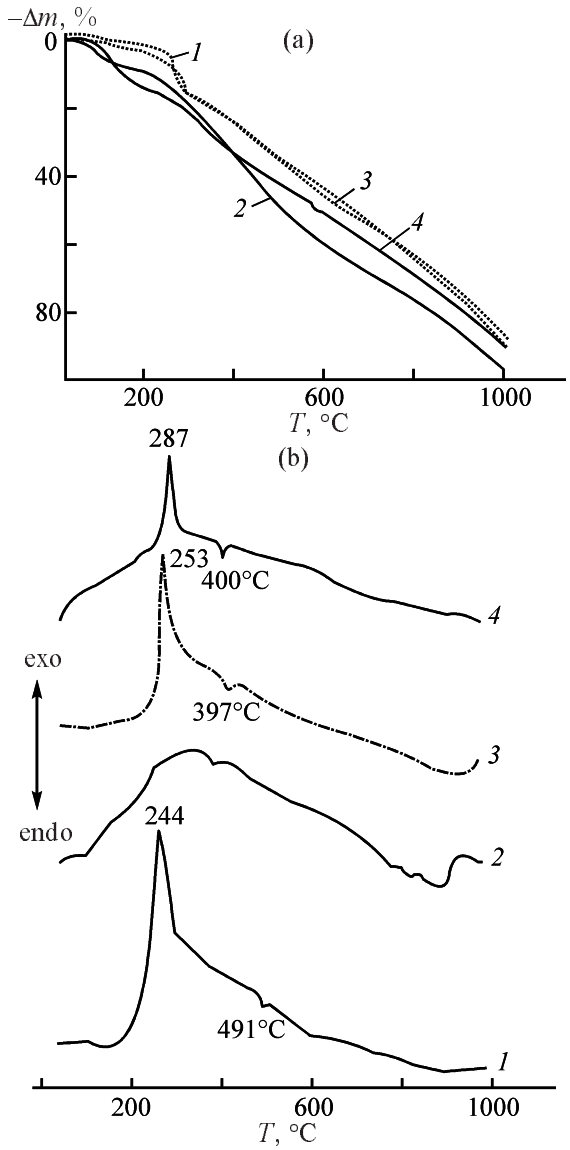

Fig. 1. (a) TG and (b) DTA curves of the LG, PAN, mixed samples, and PAN–LG (1 : 1) film, recorded in the course of dynamic heating in air at a rate of 10 deg min^{-1} (sample weight 50 mg). (Δm) Weight loss and (T) temperature. (*1*) PAN film, (*2*) LG powder, (*3*) PAN–LG (1 : 1) dry powder mixture, and (*4*) PAN–LG (1 : 1) film; the same for Fig. 2.

effect of the diffusion factors. For this purpose, the measurements were performed on a NETZSCH STA 429 device using small samples (10 mg), with a heating rate of 7 deg min^{-1}. The decrease in the sample weight to 10 mg decreases the probability of the majority of secondary reactions in the sample, which are initiated by gaseous products of thermal degradation passing through the composite layer in the case of larger samples (50–100 mg). This approach allows studying processes that are masked by the diffusion factor in large samples.

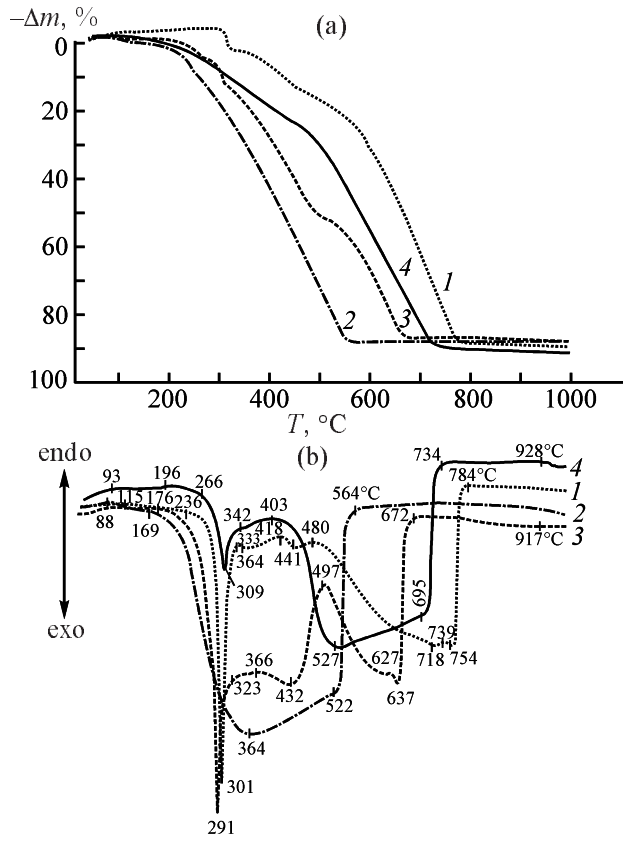

Fig. 2. (a) TG and (b) DTA curves of LG, PAN, mixed samples, and PAN–LG (1 : 1) film, recorded in the course of dynamic heating in air at a rate of 7 deg min^{-1} (sample weight 10 mg).

The TG curves shown in Fig. 2a strongly differ from those recorded on a derivatograph. As seen from the shape of these curves, oxidative atmosphere strongly affects all the process, especially in the 400–450°C range. The observed changes in the weight with temperature indicate that, in the 550–750°C range, the degradation reactions leading to complete combustion of the samples prevail. The TG curves of the initial samples correspond to the thermal degradation processes observed in the previous studies. We should note the behavior of the PAN–LG dry mixture (Fig. 2a, curve *3*). The shape of the TG curve of this sample reflects separate microreactions of the components, suggesting the absence of reaction of the components under the experimental conditions studied. As for the film sample (Fig. 2a, curve *4*), in the course of heating, after passing the range 300–350°C in which specific differences in the thermal degradation pattern are observed, the TG curve of the film becomes comparable with that of PAN. This fact suggests that more intimate and prolonged contact between the components is observed in the PAN–LG film sample as compared to the dry mixture. This assumption is confirmed by strong difference in the thermal effects at temperatures of the PAN cyclization (270–360°C, Fig. 2b). For example, the temperature peaks of cyclization of straight PAN and powdered mixed sample differ by 10°C, although the total thermal effect is proportional to the component ratio in the initial mixture.

The shape of the curve for sample 4 is quite different. The thermal effect of PAN cyclization in the mixed film is lower, compared to samples 1 and 3, by a factor of almost 5, and the peak temperature is shifted toward higher temperatures by 8°C (309°C) relative to the dry mixture. Thus, we observed changes in the thermochemical transformations of PAN whose cyclization is suppressed by LG and, probably, by its reaction with the nitrile groups in the step of their activation. This process should provide formation of new structures whose subsequent degradation is accompanied by prolonged exothermic effect in the 403–695°C range. The same specific effects are observed for dry mixed samples, for which the TG curve after 323°C exhibits the endothermic effect with a maximum at 497°C at significant heat release (Fig. 2b, curve *3*). In this sample, the cyclization of PAN proceeds completely and the exothermic effect corresponding to cyclization overlaps with an extensive exothermic effect of the LG thermal degradation.

As for the PAN–LG film prepared using DMF solution (Fig. 2b, curve *4*), the thermal peaks are smoother and shifted toward higher temperatures, and all the exothermic effects are significantly lower. The shape of the TG curve in the exothermic range 527–695°C is close to that of LG, but the effect is smaller and shifted upward in the temperature–time scale by 163 (start) and 170°C (end), as compared to LG. These facts suggest certain similarity in processes occurring in both exothermic ranges (PAN–LG film and LG), such as free-radical cleavage of bonds between the LG phenylpropane groups with the release of low-molecular-weight products of thermal degradation, followed by carbonization. This temperature range is wide and "monolithic," probably because the reaction products are diverse (low-molecular-weight aromatics, simple organic and inorganic compounds) and elimination of low-molecular-weight compounds occurs uniformly in time, which is typical for network polymers such as lignin. Whereas LG in the 180–520°C range actively degrades, the film is relatively stable in the 180–403°C range. Thus, the thermal degradation processes in the film are shifted toward higher tempera-

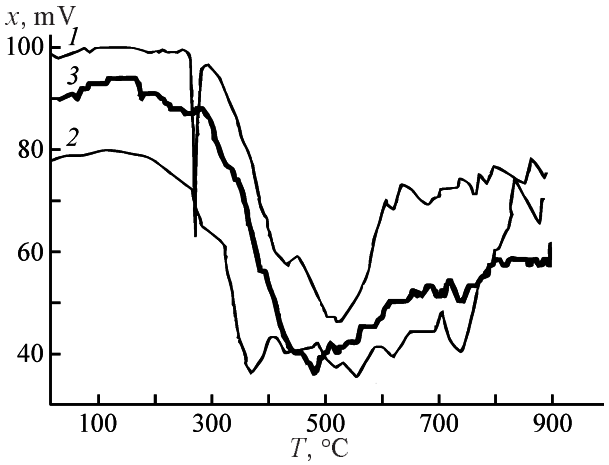

Fig. 3. TVA curves recorded in the course of dynamic heating at a rate of 7 deg min^{-1} (sample weight 50 mg). (x) Parameter of vacuum and (T) temperature. (*1*) PAN film, (*2*) LG powder, and (*3*) PAN–LG (1 : 1) film.

tures with simultaneous decrease in their intensity (inhibition of thermal degradation and deceleration of the weight loss in the course of the film pyrolysis). As a result, the thermal stability of the carbon product of thermal degradation of the mixed film increases by 60°C (as compared to the PAN–LG dry mixture) and, apparently, the carbon product of a new structure is formed.

Thermal treatment in a vacuum allows monitoring of the polymer degradation under the conditions maximally free of the effect of oxidizing atmosphere and concomitant thermal oxidative degradation of the gaseous products, which additionally complicate the pattern. As seen from the TVA data (Fig. 3), lignin in the film, apparently, hinders cyclization of the nitrile groups (absence of peak at 270°C), and the coke number of the carbonized residue formed from the PAN–LG film after its final thermal treatment is higher by 16% as compared to the theoretical value calculated assuming no thermochemical reactions of the components (Fig. 3, curve *3*). In contrast to straight LG, whose treatment at temperatures of up to 900°C yields a black powder, heating of the mixed film yields a film with a smooth lustrous surface. Thus, LG as a component of films, when heated in a vacuum, prevents cyclization of PAN and reacts with it in a wide temperature range, which decreases the carbonization onset temperature. This is confirmed by the relatively low temperature (470°C) of the end of the maximum of the gas release in the TBA curve recorded for the PAN–LG film (Fig. 3, curve *3*) and by observed stabilization of the product, which is characterized by smoother and more uniform decrease in the gas release. As for PAN film (Fig. 3, curve *1*), the maximum of the gas release is shifted by 100°C toward higher temperatures (530°C) as compared to the mixed film. In the case of LG (Fig. 3, curve *2*), the gas release decreases for a short time at 270°C, but at higher temperatures it is periodically resumed up to complete explosion-like degradation.

Thus, preparation of the LG suspensions, their mixing with PAN solutions, and subsequent film casting provide more intense interaction of the components as compared to dry mixtures. The highest possible content of LG in the PAN–LG film composites is 50–60%. Nevertheless, along with films, PAN–LG block carbon composites with a higher content of LG can be prepared from DMF solutions. The resulting PAN–LG carbonized product retains the shape and exhibits no shrinkage (in contrast to PAN carbonized in a vacuum) and is characterized by the fine-grain surface, opaque metallic luster, and strength.

CONCLUSIONS

(1) The kinetic parameters of cocarbonization of polyacrylonitrile and lignin under the conditions of minimization of the effect of the diffusion factors were studied.

(2) Thermal treatment of the film composites in a vacuum yields carbonized products without changes in the shape, which exhibit metallic luster and are characterized by the coke number higher by 16% as compared to the additive value.

(3) Cyclization of polyacrylonitrile in the film samples is partially inhibited by the products of lignin thermal degradation.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Modification of Polymeric Composites with Electric and Magnetic Fields

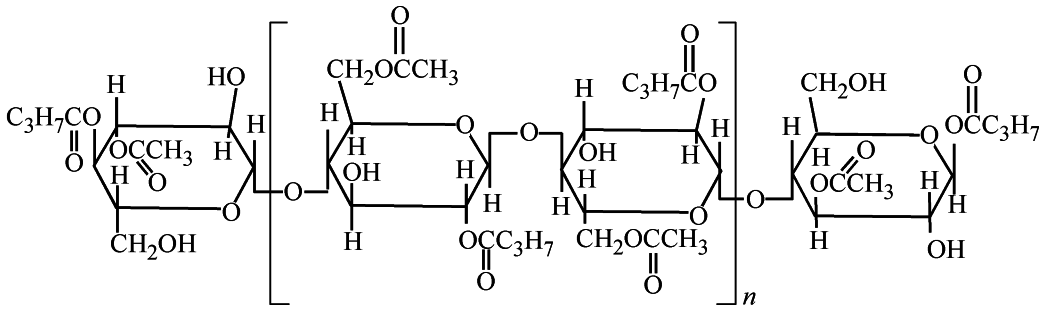
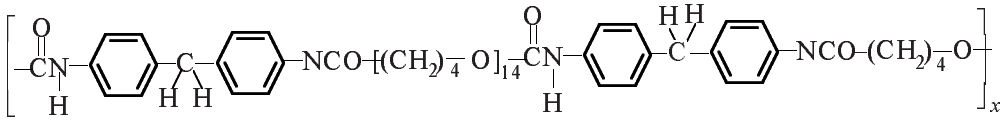
Abstract—Effect of the component composition and magnetic and electric fields on the structure and dielectric and electromechanical properties of composites constituted by incompatible polymers, cellulose acetobutyrate and segmented polyurethane, was studied.



DOI: 10.1134/S1070427208070197

Use of biopolymers and their derivatives for preparing composites is a topical area of the development of the modern polymer science and technology. At present, physical methods for modification of polymeric systems are also being actively sought for. In our previous studies [1–3], we determined specific features of formation of the structure of polymers produced by a polyaddition of hydroxy groups of cellulose derivatives to diisocyanate groups of oligourethanes. It was also shown in a series of studies [4–7] devoted to the effect of magnetostatic (MSF) and electrostatic (ESF) fields on polyurethane modified by addition of cellulose acetobutyrate (CAB) that these physical fields weaken the microphase segregation in the composites and not only improve the thermal and thermomechanical properties of the starting polymers and their blends, but also impart new properties (higher conductivity and dielectric constant) to the materials, which expands their application field.



EXPERIMENTAL

In this work we continue these studies of composites in which the role of the matrix is played by a polysaccharide (CAB), and that of the modifying additive, by segmented polyurethane (PU) whose concentration was varied in the order 0.5, 1, 2, 5, 10, 15, and 25 wt % (Schemes 1, 2).

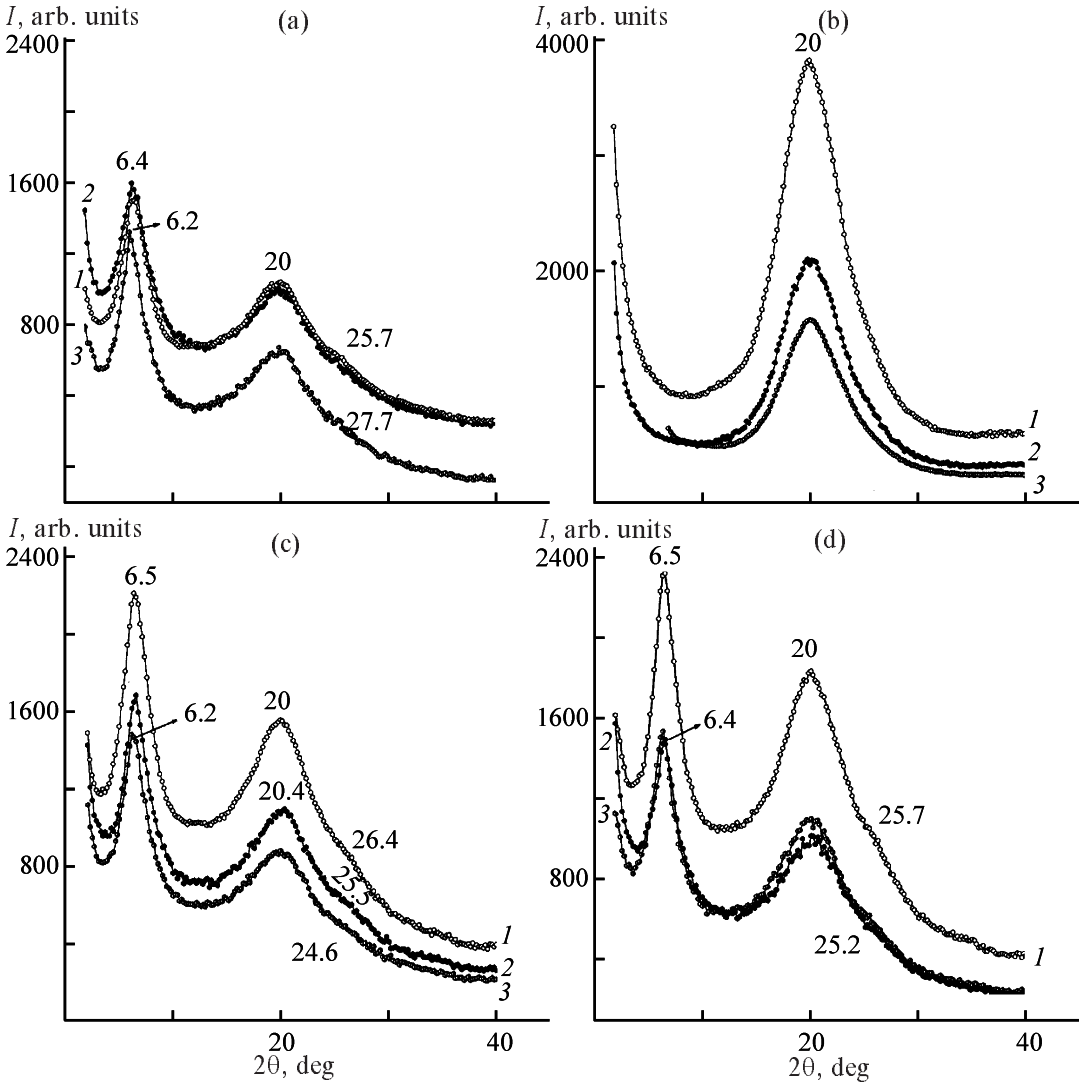

Fig. 1. X-ray diffraction patterns of (a) CAB, (b) PU, and composites (c) CAB + 0.5% PU and (d) CAB + 25% PU: (*1*) initial samples and (*2, 3*) those subjected to the action of (*2*) MSF and (*3*) ESF. (*I*) Intensity and (2θ) Bragg angle.

The procedures used to obtain the blends and treat them with physical fields were described in [2]. The effect of PU additives on the crystal structure of CAB was studied by wide-angle X-ray diffraction analysis on a DRON-4-07 installation with CuK_α radiation monochromated with a Ni filter. The diffraction patterns were normalized to the scattering volume of a sample and to the attenuation of the primary beam by the sample. The error in measuring the scattering interval did not exceed 3%.

The conductivity of the samples was studied at room temperature with a P5083 ac bridge in sandwich-type cells [8]. A pellet was placed between planar polished fluoride bronze electrodes with a pressure of 0.1 MPa applied to the sample. The time during which the dielectric characteristics were measured at each point in the frequency range 0.1–100 kHz did not exceed 4 s at a measurement error of up to 3%. The thermomechanical properties were studied on a versatile thermomechanical installation in the mode of axial compression of samples under a pressure of 2.56 MPa in the temperature range 20–250°C. Samples in the form of pellets 0.008 m in diameter and 0.005 m thick were heated at a rate of 2.5 deg min^{-1}; the error in measuring the strain ε (%) = $f(T, °C)$ was 5%.

Here we consider two extreme compound compositions: CAB + 0.5% PU and CAB + 25% PU. The choice of these composite samples is governed by the fact that they are in different thermodynamic states: the first blend is a dispersion of separate PU particles in the polysaccharide matrix; these particles

serve as centers of secondary crystallization of tie CAB molecules connecting the amorphous and crystalline parts of the polymer. In the second case, it would be expected that the microphase segregation of incompatible polymers should affect the thermodynamic structure at the phase boundary between the "like" and "foreign" molecules.

It can be seen in Schemes 1 and 2 that the polymers under consideration differ in the chemical structure. It is known [10] that CAB is partly crystalline, whereas the PU structure is characterized as topological [11]. It was shown in [1, 2] that these polymers strongly differ in polarity (0.55 for the repeating unit of CAB and 0.36 for PU) and in equilibrium flexibility of macrochains. Therefore, it could be assumed that the effect of the magnetic and electric field on the packing of macromolecules of the chosen polymers would be different. It is known [12] that the ability of a substance to scatter X-rays directly depends of the packing density of the constituent molecules. Therefore, it can be stated that samples of individual polymers have different scattering capacities.

Comparison of the intensities of X-ray scattering by CAB (Fig. 1a) and PU samples (Fig. 1b) shows that the packing density of macromolecules in the topological structure of polyurethane is more sensitive to the action of physical fields than the heterophase structure of CAB. The effect of MSF as a means of orientation of the dipoles of polar groups was not observed for the crystalline CAB phase, which is indicated by the constant angular positions of the main reflections (Fig. 1a, curves *1, 2*) of the polymer and preserved intensities of X-ray scattering by CAB. At the same time, the effect of ESF, i.e., the change in the bulk polarization of the CAB insulator, affects constituents of its structure. It can be seen from Fig. 1a (curve *3*) that the scattering power of the polymer decreased and the angular positions and intensity of the reflections changed. The interplanar spacings d (nm) corresponding to the reflections at $2\theta = 6.4°$ and 25.7° of the initial CAB and that modified with physical fields were calculated using the Bragg equation [13] (see table). These changes suggest that the bulk polarization of macrochains of the polysaccharide is accompanied by spatial displacements of the crystallite planes in the crystalline phase and of kinetic segments in the intercrystallite (amorphous) regions.

It is clear that the selective action of physical fields on PU and CAB inevitably affects the structure of their composites, which is confirmed by the X-ray diffraction patterns in Figs. 1c and 1d. The scattering on blends is considerably stronger, compared to the initial CAB sample; the reflection at $2\theta = 6.4°$ is steadily shifted to larger scattering angles, and part of the reflections, e.g., those at $2\theta \approx 20°$ and 26.4°, have angular positions dependent on the composition of the composite. The decrease in the interplanar spacings in CAB, resulting from the presence of minor additions of PU, can be attributed to plasticization of the rigid heterocyclic chains of CAB by oligoether fragments of the macrochains of PU, which was demonstrated previously in [9]. Also, the polar groups of PU, which have acceptor properties (Schemes 1, 2), can interact with the donor groups of CAB. Hence follows that minor additions of PU to the mixtures make closer, by the structural plasticization mechanism [9], the packing of macromolecules of the polysaccharide in amorphous regions, with the result that the crystallites grow in size. However, the reflections at $2\theta = 20°$ and 26.4° from the CAB + 25% PU composite are sensitive to the density of the matrix polymer, as indicated by the change in their intensity. It is clear that the phase segregation of the blend is accompanied by partial removal of foreign macromolecules from the interaction regions and, accordingly, by restoration of the spatial characteristics of the crystal lattice of CAB.

It is known that the magnetostatic and electrostatic fields differ in the mechanism of interaction

with charge dipoles primarily in that the former orients the dipoles along the magnetic force lines, whereas the latter polarizes (shifts) electric charges in the directions opposite to the sign of the charges. Being polar insulators, the polymers under study were subjected to the action of MSF and ESF in a state close to that of a viscous flow, which provided relative freedom of the polar groups of hydrogen bonds, which are in fact bound dipoles. The following conclusions can be made on the basis of the X-ray diffraction patterns of the composites subjected to MSF or ESF. First, the changes in the structure of the polymer blends formed under the action of physical factors and in the intensity of X-ray scattering by these blends (Figs. 1c, 1d) demonstrate that choosing the composition of a blend and the type of a field exerting an orienting or polarizing effect on the initial structure is an effective way to create composites with the necessary set of properties. Second, on bringing the composition of a blend closer to the phase segregation range, its structure becomes incapable of orientation under the action of ESF. These conclusions are in agreement with the results of a study of how these factors affect the secondary crystallization of CAB in a blend. The longitudinal sizes L (nm) of the crystallites, calculated by the Scherrer formula [13], are listed in the table.

Analysis of the data in the table makes it possible to evaluate the influence of each factor on the secondary crystallization of CAB in the composite. The concentration component shows that the influence of small amounts of PU is within the experimental error. At the same time, the increase in the area of the surface of contact between the components in the course of their phase segregation affects the efficiency of the structural plasticization of the amorphous phase of CAB, with the result that the crystallites of the polymer matrix become longer. The situation significantly changes under the action of MSF on the dipoles of the polar groups of PU. Their orientation in the CAB medium favors secondary crystallization, with values of L increasing. An increase in the concentration of polar groups of PU in the composite also causes further development of secondary crystallization processes. However, the opposite effect is observed under the action of ESF, whose mechanism consists in the bulk polarization of polymer macrochains. It appears that the bulk polarization of heterocycles of the individual CAB is an active factor in the development of secondary polarization processes (see the value of L in relation to the nature of a field). It can

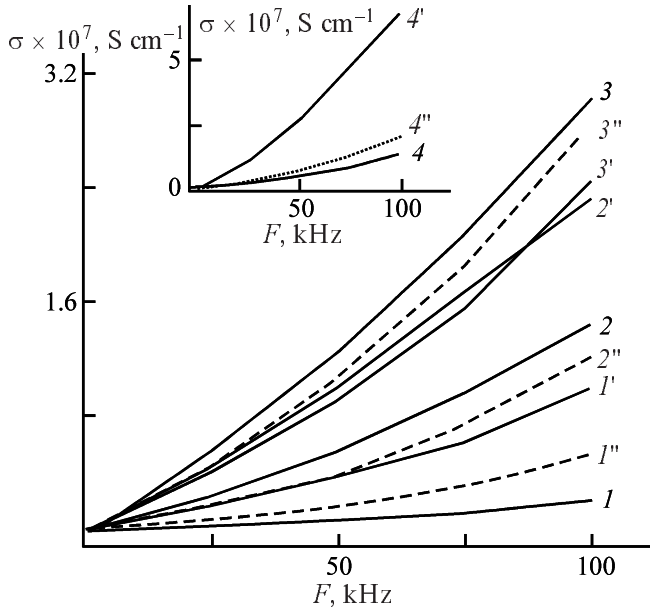

Fig. 2. Conductivity σ of the initial samples of (*1*) CAB, (*2*) CAB + 0.5% PU, (*3*) CAB + 25% PU, and (*4*) PU and those subjected to the action of (*1'–4'*) MSF and (*1"–4"*) ESF, as a function of frequency F.

be assumed that, when macrochains with different sensitivities to the action of ESF are mixed, this leads to redistribution of the front of the bulk polarization; as a result, CAB crystallization processes are inhibited (see table).

These results agree with data on the influence of physical fields on the conductivity σ of the composites. It can be seen in Fig. 2 that, under the action of MSF, the conductivity of PU dramatically increases over the entire frequency range (curves *4, 4'*). This is due to the orientation of polar groups in the specific volume of the repeating unit of the polymer and to the partial structural homogenization because of the mutual penetration of rigid and flexible segments of macrochains. Addition of PU also makes higher the conductivity of the composites; this means that the fraction of traps for free carriers becomes smaller because of the secondary crystallization of tie CAB molecules, initiated by the flexible-chain component. The effect of MSF eliminates structural differences between the composites, caused by microphase segregation processes, which is also reflected on the conductivity (Fig. 2; curves *2, 3* and *2', 3'*). The possible explanation is that the orientation of the polar groups of the elastic PU under the action of MSF induces stronger alignment of segments of the chains of unlike constituent polymers. Thus, composites with strongly different compositions and states of structural phase segrega-

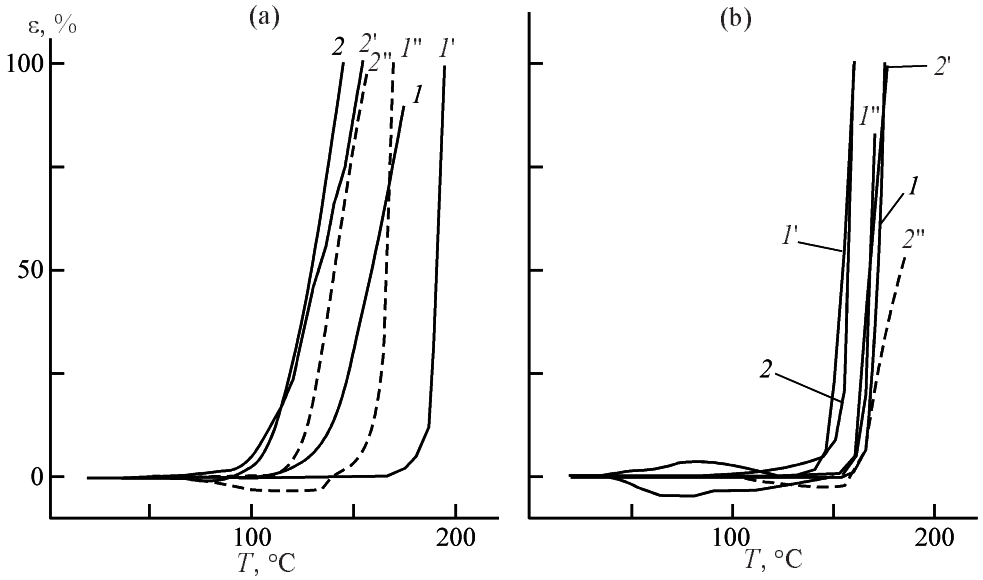

Fig. 3. Thermomechanical curves for the samples: (a) (*1*) CAB and (*2*) PU; (b) (*1*) CAB + 0.5% PU and (*2*) CAB + 25% PU. (ε) Strain and (*T*) temperature. Samples: (*1, 2*) initial and subjected to the effect of (*1'*, *2'*) MSF and (*1"*, *2"*) ESF.

tion acquire close conductivity characteristics. The effect of ESF on the conductivity of the polymers and composites is considerably weaker as compared not only with MSF, but also with the formation of a current-conducting structure under the conditions of a microphase segregation in blends.

To conclude, let us compare the effects of physical fields on the thermomechanical properties of the starting polymers and the composites. Figure 3a confirms the conclusion that physical fields strongly affect the properties of the starting polymers and, in particular, their thermomechanical properties. It can be seen that the use of these fields makes it possible to extend the range of transition to the viscous-flow state from 100 to 180°C and to change the very process of this transition from that characteristic of a partly crystalline polymer to that for the crystalline polymer. On passing to modification of the composites (Fig. 3b), it can be seen that the effect of the fields is not so pronounced as that in the case of the individual components, which is probably due to the internal compensation of the polar groups of both the components.

CONCLUSIONS

(1) The results obtained in a study of composites based on incompatible polymers, cellulose acetobutyrate and segmented polyurethane, demonstrate that integrated use of different factors (varying the concentrations of the constituents, changing the type of the physical field) affecting the structure and properties of the blends is an effective method for development of composites with predicted characteristics.

(2) Minor additions of polyurethane create a structurally plasticizing effect in the cellulose matrix, as a result of which macromolecules from amorphous regions become capable of secondary crystallization, the fraction of the crystalline phase increases, and crystallites grow in size. Samples of this kind are very sensitive to the action of physical fields.

(3) In the phase segregation region ($c_{PU} \geq 25\%$), the effect of the physical fields on the component phases is equivalent to the action on the individual polymers, polysaccharide and segmented polyurethane.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Nanoporous Carbon Powders Prepared from Phenol–Formaldehyde Resin

T. V. Smyshlyaeva, I. A. Borisova, and Yu. D. Khramtsov

Institute of Technical Chemistry, Ural Branch, Russian Academy of Sciences, Perm, Russia

Received November 28, 2007

Abstract—Formation of the pore structure of nanoporous carbon materials and their physical properties were studied in relation to the composition of stocks of phenol–formaldehyde resin and starch. The dependences of the specific surface area, resistivity, interplanar spacing d_{002}, and crystallite size on the degree of thermolysis during activation were determined.

DOI: 10.1134/S1070427208070203

Supercapacitors or electrochemical capacitors and double-layer capacitors are intermediate between batteries and common "electronic" capacitors. The main parts of supercapacitors are porous electrodes with a highly developed surface. The electrode material should meet the following requirements. Since the capacity of supercapacitors linearly depends on the surface area, the particle size of the powder electrodes should be smallest. The pore size distribution of the electrodes should provide the maximal specific surface area S_{sp} at minimal internal resistance of the electrolyte. The other requirements are chemical and electrochemical stability of the electrode material, mechanical strength, and good wettability of the electrode surface with the electrolyte [1]. These electrodes are usually prepared from activated carbon.

High capacity of supercapacitors is believed to be provided by either nanopores of the electrode [2] or interlayer spacing d_{002} of the graphite electrode [3]. Alekseeva and Amirkhanov believe [4] that the microporosity and hence the specific surface area S_{sp} are determined by the spacing between the disordered blocks of graphite-like layers of the amorphous structure.

The capacity of supercapacitors may be increased by using nanoporous powders and new carbon forms, fullerenes and nanotubes [5]. Practical application of nanotubes is restricted by their high cost. The price of 1 g of single-wall carbon nanotubes (SWCNT) ranges from \$300 to \$700 depending on their purity [6]. Therefore, development of cheap nanoporous carbon materials is an urgent problem. In this study we examined the specific surface area, density, porosity, resistivity, and structural parameters of carbon materials prepared from phenol–formaldehyde resin (PFR) in relation to the composition of the stock of phenol–formaldehyde resin and starch and to the process parameters of its thermolysis.

EXPERIMENTAL

Activated carbon powders were prepared from BZh-3 PFR containing starch as a blowing agent. The starch content in the initial stocks was 4.5, 10, 16.7, 24.5, and 45.6 wt %. The carbon powders were prepared by polymerization of the initial stock at temperatures lower than 130°C, followed by carbonization at 600°C. Under these conditions, carbon with maximal open porosity [4, 7] and maximal radical content [8] is formed. The carbonized material was ground and activated in an atmosphere of humid nitrogen at 700°C. Activation is high-temperature steam–gas or chemical treatment of carbon materials to develop their porous structure.

The specific surface area of the powders was measured on a GKh-1 gasometer from the peak area of nitrogen desorption. X-ray diffraction studies were performed on a DRON-3 diffractometer using monochromated CoK_α radiation. The X-ray diffraction patterns were recorded in the discrete scanning mode with a step of $\Delta 2\theta = 0.2°$. The interplanar spacings were determined from the center of gravity of the reflections.

* (V_s) Volume of pores smaller than 100 nm, (γ_{pr}) powder density corresponding to ρ_{min}, and (γ) apparent density.
** Natural polymerization.
*** Thermal curing.

The average size of coherent scattering areas (CSAs) was calculated from the integral width of the reflections by the Selyakov–Scherrer equation for graphite [9]

$$L_c = 0.89\lambda_{Co}/\beta\cos\theta,$$

where L_c is the size of coherent layers of carbon planes parallel to the c direction of the graphite lattice and β is the reflection width (rad).

The pore size and micropore volume of carbonized materials were determined by mercury porosimetry on a Pore Sizer-9305 device (Micromeritics, USA). The resistivity of the carbon powder compositions was measured by the two-point loading scheme [10].

The properties of the carbonized materials are presented in the table. The amount of the carbon residue decreases with increasing starch content, except for the concentration range 10–15 wt %. This nonmonotonic behavior is due to formation features of the porous structure of the composites. Carbonized PFR is almost nonporous (Fig. 1a). The carbonization products of PFR–starch stocks contain mainly 10–20-μm spherical pores (Fig. 1b, 1c).

The porous structure is formed in the course of polycondensation and carbonization. The precursor is BZh-3 resol resin. PFR undergoes polycondensation in the course of curing by the reaction

$$2(\text{–}C_6H_3CH_2(OH)\text{–})_n + H_2CO$$

$$= (\text{–}C_6H_3CH_2(OH))_{n1}\text{–}CH_2\text{–}(C_6H_3CH_2(OH)\text{–})_{n2} + H_2O.$$

Cross-linking of PFR polymeric chains by this reaction increases the viscosity of the mixture and yields a branched three-dimensional polymer network. Water formed in the process is partially released into the environment and partially remains in the polymer as bubbles which form the primary pore system.

In the presence of water, starch grains are gelatinized at 55–60°C and higher temperatures, and the system consists of liquid resin and paste inclusions. At temperatures above 100°C, steam is formed and steam bubbles diffuse in the viscous medium. The final step is resin curing. The volume of the polymerized samples significantly increases owing to formation of gas cavities.

Carbonization involves pyrolysis of PFR and starch to form the carbon residue, volatile degradation products (H_2, CO, CO_2, CH_4), and unsaturated compounds [11]. The gaseous products increase the porosity and promote cracking and breakdown of the carbonization product.

Variation of the total pore volume and volume of mesopores smaller than 100 nm, determined by

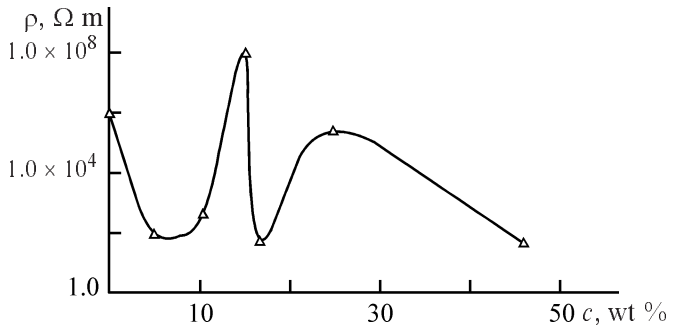

Fig. 3. Resistivity ρ of carbonized PFR–starch stocks as a function of the starch content c.

porosimetry, is shown in Fig. 2. The maximal total porosity (curve *1*) is observed in the samples containing 10% starch and is determined by relatively coarse pores (50–100 μm). The weight loss in the course of curing (Fig. 2, curve *3*) is proportional to the total volume of meso- and macropores.

The specific surface area is the parameter that is the most sensitive to the presence of micropores smaller than 6 nm, which cannot be determined by mercury porosimetry. The S_{sp} of carbonized samples shows that the number of micropores increases with increasing starch concentration. The decrease in the specific surface area of the carbonizates at a starch content of 10% is due to densification of the resin owing to vapor phase formation (Fig. 1b). In this case, the fraction of meso- and micropores sharply decreases (Fig. 2, curve *2*). Starch particles present in the resin are the sites of water vapor formation. At the starch content higher than 15%, the partially permeable porous structure is formed. These samples have a continuous contact between pores. Once the percolation threshold is reached [12], the mechanism of pore formation changes and the fraction of macropores (up to several millimeters) and mesopores (~100 nm) decreases (Fig. 2, curve *2*). Uniform contraction and water absorption by starch can result in encapsulation of the second phase, which is the case at a starch content of 16.7%. The polymerized sample with 16.7% starch content is characterized by the maximal amount of water. In the course of carbonization of these samples, additional weight loss is observed and the specific surface area increases (see table).

The dependence of the resistivity of carbonized samples on the starch content is shown in Fig. 3. The resistivity of the samples containing 15% starch is maximal. Comparison of Figs. 2 and 3 shows that the resistivity correlates with the volume of micro- and mesopores (smaller than 100 nm). The higher the content of micro- and mesopores, the higher is the resistivity. The probability of contacts of conducting clusters in nanoporous systems decreases, and the chain is disconnected. Thus, high resistivity of the carbonized material is partially caused by its nanoporosity.

The X-ray diffraction patterns of the carbonization product contain only one reflection assigned to the 002 plane of the graphite lattice.

The calculated interplanar spacings d_{002} of the carbonization products are significantly higher than that of graphite (d_{002} = 0.336 nm). The carbonization products of PFR–starch stocks meet the "large interplanar spacing" criterion [3]. The structural parameters of the carbonized material insignificantly change after introduction of starch. L_c increases or decreases depending on the degree of polymerization, and the interplanar spacing slightly increases (see table). Calculated d_{002} and L_c, as a whole, are consistent with published X-ray diffraction data for carbonization products of resins [7].

Activation of carbon materials is aimed at developing the porous structure with the maximal specific surface area. The dependence of S_{sp} of activated carbon on the weight loss (combustion loss) in the course of activation is shown in Fig. 4a. All dependences of the specific surface areas of carbonized PFR–starch stocks on the combustion loss have an inflection in the range 40–50%. In the case of the straight resin, this dependence flattens out, which is clearly due to attainment of a quasi-equilibrium between the growth of graphite crystallites and oxidation. As the activation time increases, S_{sp}

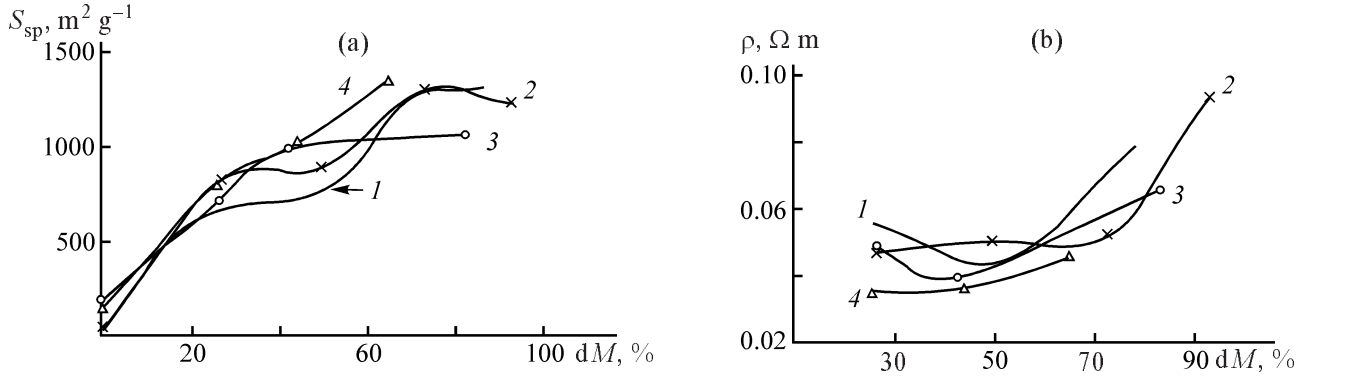

Fig. 4. Variation of the (a) specific surface area S_{sp} and (b) resistivity ρ of PFR–starch compositions containing (*1*) 0, (*2*) 10.5, (*3*) 16.7, (*4*) 24.7 wt % starch in the course of their activation. (dM) combustion loss; the same for Fig. 5.

decreases owing to burning of small particles of carbon powder. Maximal S_{sp} (1350 m^2 g^{-1}) was observed at 24.7% starch content in the stock (Fig. 4a, curve *4*).

The electrical resistivity of all compositions varies similarly in the course of their activation. In the first activation step, ρ sharply decreases. The maximal conductivity is observed at the combustion loss from 30 to 60%. The samples with high starch content are characterized by the lowest resistivity (Fig. 4b, curve *4*). The minimum in the resistivity corresponds to the inflection in the S_{sp}–dM curves (Fig. 4a).

We studied the change in the fine carbon structure during the activation with PFR–16.7% starch stock and straight phenol–formaldehyde resin as examples. The dependences of the interplanar spacing d_{002} and crystallite size L_c on the combustion loss are shown in Fig. 5.

Our experimental data show that activation of carbon powder is accompanied by the following structural transformations. At the activation temperatures, which exceed carbonization temperatures, the growth of graphene planes is accelerated (as compared to carbonization), their number in a crystallite increases (growth of L_c), and a topologically connected network within carbon particles is formed. As a rule, the interplanar spacing d_{002} decreases in this activation step. At the same time, carbon powders are activated in the presence of an oxidizing agent and less stable carbon forms (amorphous carbon etc.) burn out, thus facilitating the contact between the conducting planes. These structural transformations decrease the resistivity of the activated powder (Fig. 4b).

The activation continues owing to oxidation of graphite planes, and average L_c decreases (Fig. 5b). The shape of the 002 reflection changes simultaneously: an additional reflection with d = 0.39 nm appears and the total intensity of the reflections decreases. The changes in d_{002} of both reflections are shown in Fig. 5a. An increase in d_{002} indirectly suggests a decrease in the block size (number of layers) along crystallographic axis c [13].

The decrease in the block size in the course of combustion increases the specific surface area in the final activation step. In this step, the resistivity of the powders increases owing to changes in the morphology and the particle size of the activated powder and a sharp decrease in the apparent density, which is as low as 0.7 g cm^{-3} at 70% degree of combustion.

The properties of activated powders prepared from the straight resin significantly differ from those prepared from the starch-containing stocks: the block size L_c is larger and the interplanar spacings

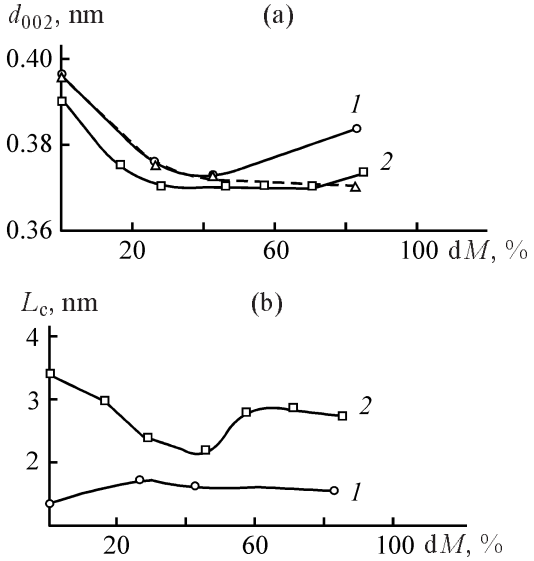

Fig. 5. Variation of the (a) interplanar spacing d_{002} and (b) size of blocks L_c of carbon powders in the course of their activation. (*1*) PFR + 16.7% starch and (*2*) PFR.

d_{002} are small in all the activation steps. Introduction of starch decreases the block size, thus increasing the density of interblock boundaries per unit length. As a result, nanopores between blocks are formed [4]. In the presence of starch, the activation time decreases by a factor of 1.5 owing to development of the porous structure.

The specific surface area S_{sp} of activated PFR–starch compositions is higher than the maximal specific surface area of activated carbons and is comparable to that of nanotubes [6]. The resulting powders have the nanoporous structure and can be used in production of supercapacitors.

CONCLUSIONS

The macro- and mesoporous structure of carbons prepared from phenol–formaldehyde resin is mainly formed in the course of polycondensation. High resistivity of the carbonization product is caused, in particular, by the presence of micropores. The block size L_c increases and the interplanar spacing d_{002} decreases in the first activation steps. In the subsequent steps, the particles are burn out and the interplanar spacing increases. The minimal resistivity observed during activation corresponds to the minimal interplanar spacing. Introduction of starch into phenol–formaldehyde resin increases the porosity of the carbonization products, decreases the block structure, increases the interplanar spacing d_{002}, and accelerates the activation. The specific surface area and resistivity of activated carbon powders prepared from phenol–formaldehyde resin in the presence of starch is 1350 $m^2 g^{-1}$ and 0.05–0.03 Ω m, respectively.

Abstract—The kinetics of the bulk radical polymerization of methyl methacrylate and the structure and properties (physicomechanical and thermomechanical, as well as diffusion and sorption) of the polymers were examined in relation to the amount of low-molecular-weight poly(methyl methacrylate) added.

DOI: 10.1134/S1070427208070215

Published data on polymerization of monomer–polymer blends, in particular, those of methyl methacrylate (MMA) with poly(methyl methacrylate) (PMMA) additions, are scarce. They are mostly focused on the polymerization kinetics. For example, Barton et al. [1] showed that, upon introduction of PMMA into the reaction system, the initial polymerization rate decreases, and the maximal polymerization rate is not significantly affected. O'Driscoll and Capek [2] demonstrated that the stereoregularity of PMMA affects the MMA polymerization kinetics. In the presence of isotactic PMMA, the MMA polymerization is accelerated. Kandyrin et al. [3] found that, upon thickening of MMA with PMMA additions, the gel effect is observed in an earlier time.

We examined here the kinetic features of radical polymerization of MMA in the presence of the modifying additive, PMMA, as well as the structure and properties of the resulting polymers in relation to the content of the additive.

EXPERIMENTAL

We used MMA available from Lancaster without additional purification and low-molecular-weight PMMA with $M_n = 7 \times 10^3$, synthesized by radical polymerization in toluene (80 wt %) at $T = 80°C$ in the presence of 2×10^{-2} M azobis(isobutyronitrile) (AIBN) as initiator.

The MMA polymerization kinetics was examined by high-precision isothermal calorimetry on a DAK-1-1 instrument at $T = 60°C$ in the presence of 0 to 40 wt % low-molecular-weight PMMA; AIBN (1×10^{-2} M) served as initiator. The technique of sample preparation for examining the polymerization kinetics consists in the following. The necessary amount of the formulated reaction mixture was charged into glass ampules and degassed by repeated freeze–pump–thaw cycles, after which the evacuated ampules were sealed. The conversion of the C=C bonds C and the reduced polymerization rate $w/[M]$ were calculated for MMA characterized by the specific heat of polymerization of 58.82 kJ mol^{-1}.

The structure of the polymers synthesized with and without different amounts of PMMA was examined by the diffusion and sorption probing (in water and benzene vapor at atmospheric pressure and $T = 20°C$). The mechanical characteristics were measured in the uniaxial compression mode at low strain rates (1×10^{-4} s^{-1}) with a high-precision lever arm testing machine intended for examination of small samples (~0.1 g).

The thermomechanical curves for the polymers modified with additions of low-molecular-weight PMMA were obtained on a UIP-62-M setup at a heating rate of 2.5 deg min^{-1} and a constant load σ, in particular, in the dilatometric mode ($\sigma \approx 0$). The thermal expansion curves of the polymers, measured in the dilatometric mode, were used for correction of the apparent strain ε' by the formula $\varepsilon_\sigma = \varepsilon'_{\bar{\sigma}} - \varepsilon'_\sigma = 0$. For T_g we took the temperature corresponding to the maximum of the differential curves $d\varepsilon/dT$. The integrated curves $\varepsilon = f(T)$ were differentiated, and from the resulting $d\varepsilon/dT$ curves we determined for

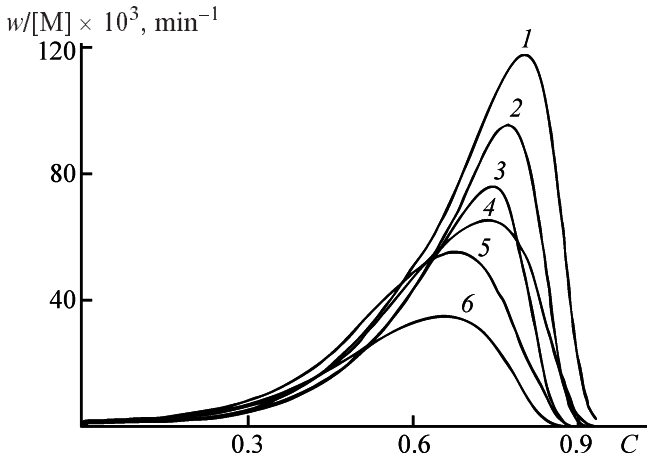

Fig. 1. Kinetic curves of MMA polymerization in the presence of low-molecular-weight PMMA. T = 60°C, [AIBN] = 0.2 wt %. (w/[M]) Reduced polymerization rate, and (C) conversion of the C=C bonds. PMMA, wt %: (*1*) 0, (*2*) 5, (*3*) 10, (*4*) 20, (*5*) 30, and (*6*) 40; the same for Figs. 2 and 3.

each load the upper (T'_{g1}) and lower (T'_{g2}) limits of the temperature range for α-transition. The temperature corresponding to the maximum of the curves was taken as T'_g at which the inflection point is observed in the integrated curves. When T'_{g1}, T'_{g2}, and T'_g depended on the load, we carried out extrapolation to the zero load to determine the T_{g1} and T_{g2} parameters and the glass transition point T_g. If such dependence was not observed, we took the average T'_{g1}, T'_{g2}, and T'_g values as T_{g1}, T_{g2}, and T_g, respectively.

For the sorption, thermomechanical, and physicomechanical measurements we used cylindrical polymer samples 5 mm high and 3 mm in diameter. The residual stress was removed by annealing of the polymers at $T \sim 120$°C. The conversion of the C=C bonds in them was determined by IR spectroscopy; the absorption band corresponding to the stretching vibrations of the C=O bond at 1725 cm^{-1} was taken as the internal reference. As analytical band served the absorption band of the bending vibrations of the H atom in the $C=CH_2$ group at 812 cm^{-1}. The conversion of the C=C bonds C was calculated by the formula

$$C = [1 - (D_{812}/D_{1725})_p/(D_{812}/D_{1725})_m] \times 100,$$

where D_{812} is the optical density of the absorption band of the bending vibrations of the H atom in the $C=CH_2$ group of the polymer (subscript p) and monomer (MMA, subscript m), and D_{1725}, optical density of the absorption band corresponding to the stretching vibrations of the C=O bond in the polymer and monomer (MMA).

The conversion of the C=C bonds in the polymers examined was 90–95%.

A gel-permeation chromatographic analysis [4] showed that the PMMA used as the modifying additive has $M_n = 7 \times 10^3$ and is characterized by a broad MWD (M_w/M_n = 2.6). This suggests that the disproportionation substantially contributes to termination of the polymer chains in MMA polymerization in toluene. This process gives rise to terminal C=C bonds in the polymer macromolecules. They were revealed by ozonolysis and IR examination. Ozonolysis showed that the content of the C=C bonds in low-molecular-weight PMMA is ca. 0.1 mol kg^{-1}. Because of a high concentration of the ends with enhanced molecular mobility, the glass transition point T_g of the low-molecular-weight PMMA is 108°C, as shown by DSC. The intrinsic viscosity measured in toluene with an Ubbelohde viscometer at T = 20°C is 0.117 dl g^{-1}.

The structure of low-molecular-weight PMMA was elucidated by spectral analysis of the conformation assumed by the ester group. Along with the band corresponding to the *cis* isomer (1192 cm^{-1}), the spectrum of PMMA contains a shoulder at 1174 cm^{-1} belonging to the *gauche* isomer. The less favorable energetically *gauche* conformation results from rotation of the $O–CH_3$ group around the C–C bond by 60° [5]. This means that PMMA is characterized by a planar conformation typical for *syndio* addition, which does not sterically hinder the *gauche* conformation of the COOR groups. The IR spectrum of the polymer of interest contains bands at 749 and 1060 cm^{-1} and does not contain bands at 1290 and 759 cm^{-1}, which also suggests *syndio* addition of methacryl groups in PMMA.

Figure 1 presents the kinetic curves of radical polymerization of MMA with and without different amounts of low-molecular-weight PMMA, plotted as the reduced polymerization rate w/[M] ([M] is the running concentration of the monomer) vs. the conversion of the C=C bonds in the monomer. Without additions, the MMA polymerization is accompanied by gel effect (Fig. 1, curve *1*) due to increase in viscosity of the reaction medium with increasing conversion of the monomer. This hinders the termination of the propagating macroradicals and causes the rate constant of the polymer chain termination to decrease. Additions of low-molecular-weight PMMA (Fig. 1, curves *2–6*) cause the

maximal reduced rate of MMA polymerization to significantly decrease via decreasing the magnitude of the gel effect and shift its onset to lower conversions. For example, with increasing PMMA content in the reaction mixture to 40 wt %, $w/[M]_{max}$ decreases approximately threefold. Low-molecular-weight PMMA, apparently, inhibits radical polymerization of MMA, which suggests formation of a polymer whose molecular weight is lower than that of the PMMA obtained without additions. In the presence of high concentrations of PMMA (≥ 20 wt %), in some cases the kinetic curves exhibited two maxima, evidently associated with microphase segregation of the reaction system.

Valuable information about the structure of the MMA polymers modified with various amounts of low-molecular-weight PMMA was derived from examination of sorption of vapors of benzene and water differing not only in the size of the molecules but also in the degree of thermodynamic affinity. Figure 2 presents the kinetic curves of water vapor sorption by the MMA polymers obtained with and without low-molecular-weight PMMA, plotted in the Fick's equation coordinates. As known, in the case of water, the diffusion and sorption properties of the polymer are determined by the structural defects like microcracks due to internal stress, as well as by possible H-bonding with ester groups. Figure 2 shows that, in the water vapor sorption, the examined polymers exhibit mostly pseudonormal kinetics, as suggested by the lack of linear portions in the $S = f(t^{1/2})$ curves. Abnormal sorption is apparently due to the relaxation phenomena accompanying the water vapor diffusion into the polymers of interest [6].

Figure 2 shows that the diffusion and sorption properties of the examined polymers depend on the content of low-molecular-weight PMMA in them. The rates of water sorption into unmodified PMMA and that obtained in the presence of 5% low-molecular-weight polymer are close (Fig. 2, curves *1*, *2*). With the content of low-molecular-weight PMMA in the polymer increasing to 10–30%, the kinetic plots of water vapor sorption are transformed into S-shaped curves (Fig. 2, curves *3*–*5*). The water diffusion rates and sorption limits decrease relative to unmodified PMMA and the polymer obtained with 5% low-molecular-weight PMMA. This suggests a decrease in the number of structural defects like microcracks due to internal stress in the polymer. A probable reason for a decrease in the internal stress level in the polymer being formed is that the rates of chemical shrinkage and the polymerization reaction get equal [7]. At the same time, Fig. 2 (curve *6*) suggests acceleration of the water vapor sorption into the polymer obtained with 40 wt % low-molecular-weight PMMA. Apparently, MMA polymerization with and without modifying addition yields a polymer characterized by a high level of internal stress responsible for numerous structural defects.

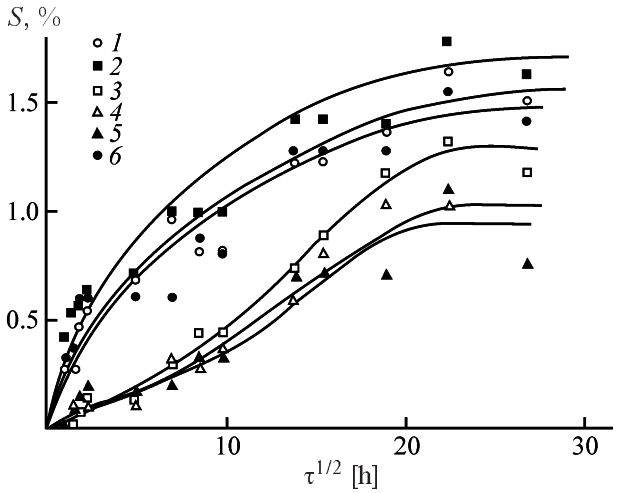

Fig. 2. Kinetic curves of water vapor sorption S by the polymers obtained from MMA in the presence of low-molecular-weight PMMA. (τ) Time; the same for Fig. 3.

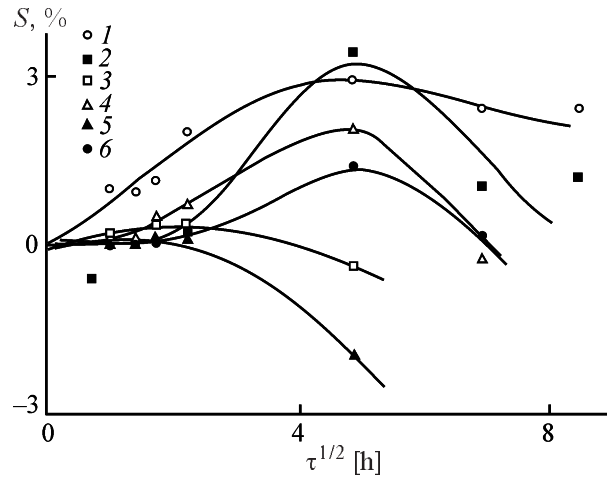

Fig. 3. Kinetic curves of benzene vapor sorption S by the polymers obtained from MMA in the presence of low-molecular-weight PMMA.

Figure 3 demonstrates the kinetics of benzene vapor sorption by the polymers obtained from MMA with and without low-molecular-weight PMMA. It is seen that benzene vapor sorption by unmodified PMMA and the polymer synthesized in the presence of various additions of low-molecular-

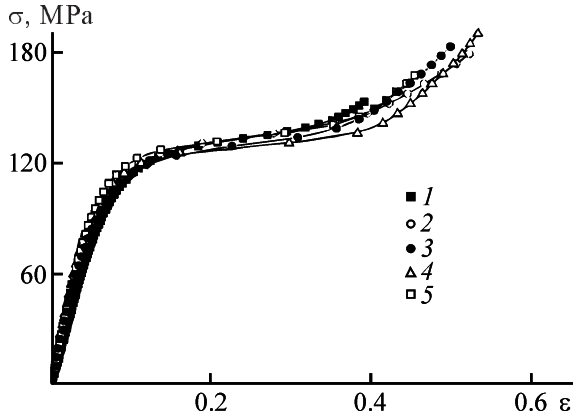

Fig. 4. σ–ε diagrams for the polymers obtained from MMA in the presence of low-molecular-weight PMMA. PMMA, wt%: (*1*) 0, (*2*) 10, (*3*) 20, (*4*) 30, and (*5*) 40.

weight PMMA proceeds in the unlimited swelling mode with subsequent dissolution and mass loss.

The polymers obtained from MMA in the presence of low-molecular-weight PMMA exhibit a strong mutual correlation of the benzene vapor diffusion rate, sorption limit, and content of the additive in the polymer (Fig. 3). With increasing amount of the additive, the benzene vapor diffusion tends to decelerate, probably due to an increase in the molecular packing density. A decrease in the sorption limit suggests that the polymers modified with low-molecular-weight PMMA additions, compared to unmodified PMMA, have a lower molecular weight and a higher thermodynamic affinity for the solvent.

Figure 4 shows the typical stress (σ)–strain (ε) diagrams of the polymers examined. The strain of the polymers is comprised of elastic strain and forced elasticity. At a certain stress σ the sample undergoes transition from the glassy state with the elastic modulus E_1 to the forced elasticity state characterized by the modulus $E_2 \ll E_1$. The parameter E_1 represents the contribution to the properties of the polymer, made by the physical network resulting from intermolecular interaction of the polar (ester) groups of the neighboring polymer chains [8]. The transition from the glassy state to the forced elasticity state is associated with breakdown of the physical network cross-links. The modulus E_2 in PMMA is determined by the number of the physical cross-links preserved after the transition [8]. Such stable physical cross-links originate from cooperative intermolecular interactions of the complementary segments of the chain, yielding *n*-unit *iso*- and *syndio*-regular sequences with n = 2–4 (adducts, stereo complexes formed from addition of such *iso* blocks to *syndio* blocks [9]).

Figure 5 presents the plots of the elastic moduli E_1 and forced elasticity E_2 vs. content of low-molecular-weight PMMA additive, calculated from the slopes of the first and second linear portions of the $\sigma = f(\varepsilon)$ curves. It is seen that the additions cause the elastic modulus E_1 to increase (Fig. 5, curve *1*) due to intensification of the intermolecular interactions in the polymer. For the polymers obtained in the presence of low-molecular-weight PMMA, the forced elasticity modulus E_2 is lower than that in the unmodified polymer (Fig. 5, curve *2*). In the presence of low-molecular-weight PMMA, short-lived physical cross-links are evidently formed, and they decrease in number upon transition of the polymer from the glassy state to the forced elasticity state.

Thus, low-molecular-weight PMMA introduced into the reaction mixture modifies the physicochemical properties of the resulting polymers, the magnitude of the modifying effect being dependent on the content of low-molecular-weight PMMA.

The table presents the glass transition point T_g and the transition width ΔT_g for the polymers con-

taining 0, 20, and 40 wt % low-molecular-weight PMMA, calculated from the thermomechanical curves. The experimental data suggest that T_g of the polymer with 20 wt % PMMA remains virtually unchanged relative to unmodified PMMA, while ΔT_g decreases approximately threefold. The latter fact suggests a decrease in the number of relaxants, elementary moieties of the polymer chain, whose unfreezing is necessary for transition from the glassy to hyperelastic state. Further increase in the PMMA content in the polymer to 40 wt % causes T_g to decrease by 10°C, while ΔT_g remains unchanged (see table). Thus, a high content in the polymer of the macromolecules of low-molecular-weight PMMA, characterized by enhanced molecular mobility, causes T_g of the polymer being formed to decrease. A decrease in T_g and an increase in the elastic modulus E_1 upon introduction into the polymer of 40 wt % low-molecular-weight PMMA suggests antiplasticization effect. The rigidity and brittleness of the polymers increased and T_g decreased upon introduction into the linear amorphous PMMA of phosphoric acid esters [10]. The magnitude of this effect was straightly related to the intrinsic volume of the plasticizer molecules: The larger the molecule, the larger the increase in the elastic modulus of the system.

The antiplasticization effect observed upon addition of 40 wt % low-molecular-weight PMMA can be due to heterogeneous structure of the polymer being formed and the associated heterogeneous distribution of the polymeric addition in it. The macromolecules of low-molecular-weight PMMA get into loosely packed domains in the polymer being formed, in which fairly loose chains assume a more extended conformation and get more rigid upon interaction with the plasticizer.

CONCLUSIONS

(1) Introduction of poly(methyl methacrylate) into the reaction system causes the maximal reduced rate of methyl methacrylate polymerization to substantially decrease and shifts the gel effect to lower conversions.

(2) The number of structural defects like microcracks depends on the content of the modifying addition in the polymer.

(3) Benzene vapor sorption by the polymers modified with low-molecular-weight poly(methyl methacrylate) additions proceeds in the unlimited swelling mode and is accompanied by dissolution and mass loss. The benzene vapor diffusion rate and the sorption limits vary with the content of the modifying additive in the polymer.

(4) Low-molecular-weight poly(methyl methacrylate) additions cause the rigidity of the polymer being formed to increase [the elastic modulus E_1 increases relative to unmodified poly(methyl methacrylate)]. The glass transition point T_g of the polymer containing 40% low-molecular-weight poly(methyl methacrylate) decreases by 10°C due to the antiplasticizing effect exerted by this additive.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Viscoelastic and Surface Properties of Polymer Complexes with Fillers of Different Nature

L. M. Trufakina

Institute of Oil Chemistry, Siberian Branch, Russian Academy of Sciences, Tomsk, Russia

Received November 29, 2007

Abstract—Rheological and surface properties of polymer blends based on aqueous solutions of polyacrylamide and polyvinyl alcohol were studied by viscometry and methods of penetration of a spherical indenter and detachment of a metal plate from a polymer body. The work of adhesion was examined in relation to the filler type and the time of formation of the polymer composites.

DOI: 10.1134/S1070427208070227

Interpolymer complexes based of polyacrylamide (PAA) and polyvinyl alcohol (PVA) have been studied in sufficient detail by now [1, 2]. Polymer matrices often need modification to acquire new properties. The advantages offered by polymer fillers include a low specific surface area which affords a high degree of filling, as well as improved rheological properties and high insulation and mechanical characteristics of the filled composites [3]. Polymer complexes with fillers in the presence of adhesion bond cause the viscosity and Young modulus of compositions to increase. Modification of the properties of polymer complexes has always been of much practical significance.

At the same time, large-scale worldwide polymer production generated another major problem: waste utilization. Scattered polymer waste under exposure to environmental factors such as microorganisms, light, water, heat energy, etc. can degrade and be assimilated by the environment. Among these processes, biodegradation of polymer waste affords the most reliable, prompt, and environmentally safe utilization of polymers. At the same time, light and water exposure, as well as other factors, often also promote their degradation. One of the ways to solve the problem of polymer waste utilization consists in the use of highly biodegradable fillers in manufacture of polymer materials.

At present, the development of this kind of materials goes along the following lines: synthesis of new polymer structures, introduction into macromolecules of photo- and hydrodegradable fragments; and use of polymer blends comprising at least one easily degradable component (natural polymer, plasticizer).

The use of polymer blends for preparing various materials with the desired set of properties is an advanced method. Biodegradable polymer blends are typically prepared by addition to a synthetic polymer of a different biopolymer (natural or synthetic). Natural substances used for this purpose are mostly represented by polysaccharides, above all starch and cellulose [4, 5].

We elucidated here the trends in variation of the rheological and surface properties of the filled complexes comprised of a polymer matrix and fillers imparting different properties to the polymer complex. For example, quartz sand is introduced to increase the efficiency of abrasion of synthetic and natural fibers; peat, to decrease the gas permeability; and sawdust and starch, to provide rapid utilization of polymer complexes.

The polymer complex for examinations was prepared by mixing aqueous solutions of PVA and PAA.

EXPERIMENTAL

We used PAA (Obninsk) samples with the molecular weight $M = 4.8 \times 10^5$, as calculated by the formula $[\eta] = 3.73 \times 10^{-4} M^{0.66}$ at 30°C [6]. The molecular weight of PVA (Nevinnomyssk), $M = 2 \times 10^5$, was calculated by the formula $[\eta] = 8.86 \times 10^{-4} M^{0.72}$ at 20°C.

From the dependence of the logarithm of the intrinsic viscosity on the volume concentration of aqueous solutions of the polymers we estimated the

critical concentrations of the crossovers c_{cr} at 1.35 and 7 wt% for PAA and PVA, respectively.

The dynamic viscosity and shear stress of the solutions of polymers were measured on a Rheotest-2 rotary viscometer with a cylinder–cylinder working unit. The measured data are summarized in Table 1.

The polymer blends were prepared by the procedure described in [7]; the dynamic viscosity and shear stress of the filled polymer complexes were measured on a cone–plate viscometer. To prepare polymer complexes with fillers, the calculated amount of the filler was introduced into an aqueous solution of PVA with stirring on a mechanical stirrer, whereupon a PAA solution was added. The resulting blend was stirred for another 10 min, and after 1 h its viscosity, elasticity, and work of adhesion were measured.

The polymer composite materials (PCMs) comprised of polymers and inorganic or organic substances of different nature are widely used in many areas. The properties of PCMs are determined by the diversified chemical and physical processes involved in interaction of the components at the interface, rather by the sum of the properties of the components [8]. We used the following materials as fillers:

(1) Poly(ethylene terephthalate) (PET) fiber with the diameter d = 0.05–0.1 mm. This is a reinforcing filler, whose main advantages are high strength and rigidity; the blends are superior in their properties to unfilled polymers.

(2) Quartz sand (QS) with the particle diameter d = 0.1 mm, imparting stability to the dispersion, having insulation properties, and exhibiting increased wear resistance and chemical stability. It does not contain hydration water and provides higher degrees of filling of the compositions.

(3) Moss, a rootless perennial sporophyte containing triterpene compounds and a phenol-like substance sphagnol preventing degradation of the structure.

(4) Cellulose (pine wood) with 4–5-mm-long fibers, the main component of cellular walls of plants. Wood exhibits high strength and elasticity combined with a low density, it is insoluble in water and organic solvents and is easily processed. The wood tissues contain 40–44% cellulose (linear polysaccharide), and lower plant tissues, 10–25%.

(5) Plant-originated peat containing both organic (carbohydrates, phenols, lipids, humic acids, and polysaccharides) and inorganic components.

Table 1. Dynamic viscosity and shear stress of the aqueous solutions of PAA and PVA at T = 20°C

c_{PAA}, wt %	η, Pa s	τ, Pa	c_{PAA}, wt %	η, Pa s	τ, Pa
0.5	0.16	26.34	4	0.14	22.76
1.0	0.27	41.45	5	0.21	34.14
2.0	0.38	66.31	6	0.31	51.21
3.0	0.47	78.12	7	0.42	68.28
			8	0.56	91.04

(6) Mechanically activated peat yielded by peat treatment in an APF-4 planetary ball mill operating in the batch mode; the acceleration of stainless steel milling balls, 10 mm in diameter, was 200 m s^{-2}; the treatment time was 2 min at 20°C.

(7) Starch, a polysaccharide of plant origin, comprised of 15–25% linear amylose and 75–86% branched amylopectin. Amylose precipitates from starch paste.

Starch is an amorphous product, insoluble in cold water, alcohol, and ether; it forms gel with hot water and undergoes biological and oxidative degradation. We used corn starch [GOST (State Standard) 7697–82)], either dry (starch 1) or as a suspension made with boiled water on a water bath at T = 90°C for 10 min (starch 2).

Figure 1 shows how the dynamic viscosity of the polymer matrix and that of the complexes with different fillers varies with the formation time. It is seen that sand, PET, and moss cause the viscosity of the polymer matrix to significantly increase with time, and peat, to increase insignificantly; with starch hydrogel, the viscosity increases substantially, which causes rapid degradation of the polymer complex (the filler concentration in all cases was 10%). Upon addition of dry starch. the viscosity remained virtually unchanged with time. The viscosity of the polymer composite with cellulose initially exceeds that of the polymer matrix, but further sharply decreases to minimal values.

The elastic modulus was measured by the method of penetration of a spherical indenter, i.e., via measuring the depth of indentation under load into an elastic body, which yields actually the modulus [9–11]. The indenter had the radius R = 7 mm. The PCM specimens were shaped as cylinders of the diameter D = 40 mm and height H = 40 mm. The

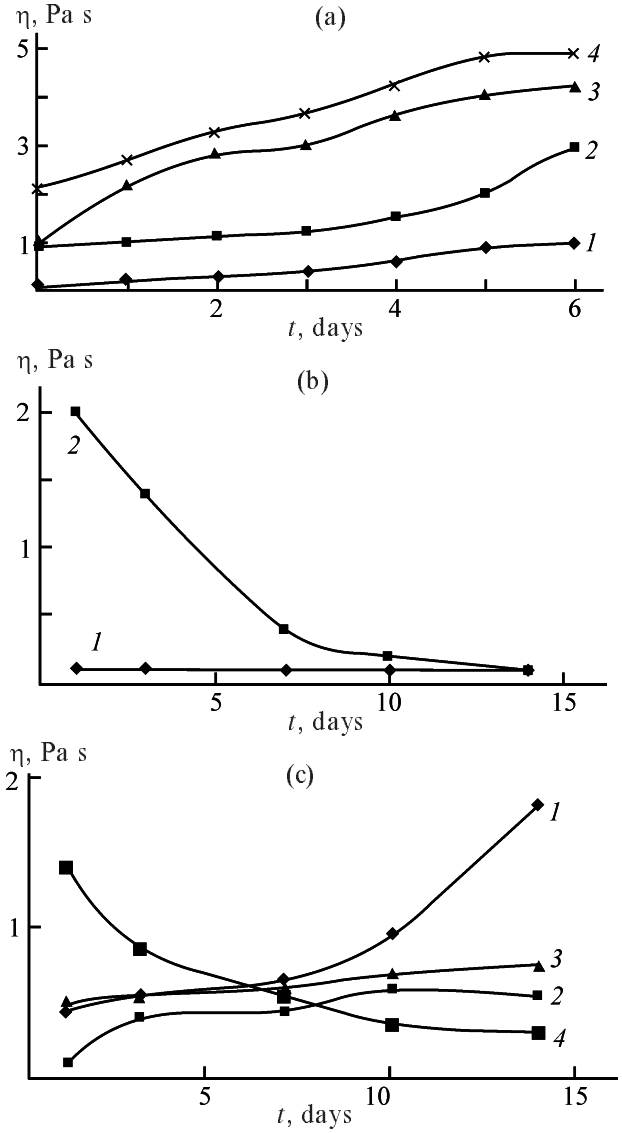

Fig. 1. Dynamic viscosity η vs. time of structure formation t of the polymer complexes. Initial concentration of PAA and PVA 1.35 and 7 wt %, respectively; temperature 20°C; the same for Figs. 2, 3. (a) (*1*) Polymer matrix, (*2*) PET, (*3*) moss, and (*4*) QS; (b) (*1*) starch 1 and (*2*) starch 2; (c): (*1*) polymer matrix, (*2*) mechanically activated peat, (*3*) plant-originated peat, and (*4*) cellulose.

elastic modulus was calculated by the formula

$$E = 3F/(16h^{3/2}R^{1/2}),$$

where F is the force acting on the indenter, and h, depth of penetration of the spherical indenter with the radius R into the flat surface of the sample.

For all the PCMs prepared we examined the elastic modulus in relation to the type of the filler.

Figure 2 shows how the elastic modulus of PCMs

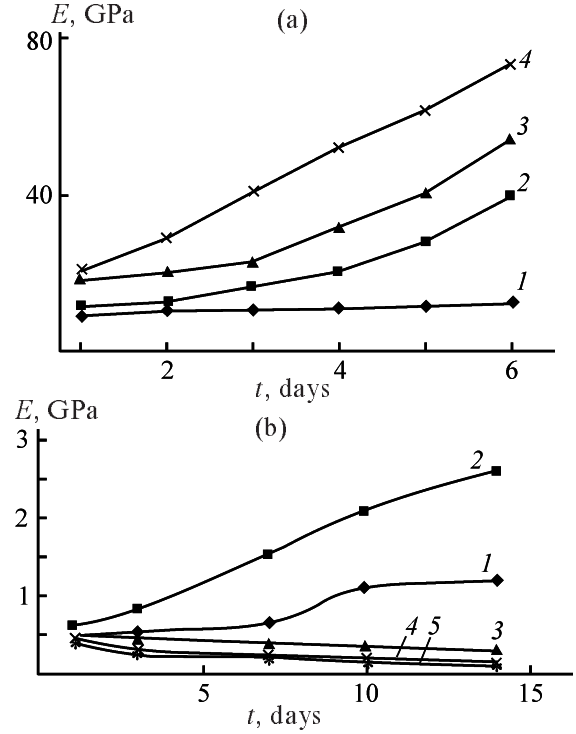

Fig. 2. Elastic modulus E vs. time of structure formation t of the polymer complexes: (a) (*1*) polymer matrix, (*2*) PET, (*3*) moss, and (*4*) QS; (b) (*1*) mechanically activated peat, (*2*) plant-originated peat, (*3*) cellulose, (*4*) starch 1, and (*5*) starch 2.

varies with the formation time at 20°C. It is seen that, among the fillers utilized, moss, sand, and PET cause the elastic modulus to significantly increase, peat affects it insignificantly, and the elastic properties of PCMs filled with starch and cellulose are negligible.

Thus, rheological examination of the PCMs with various fillers showed how the latter affect the properties of the polymer matrix based on aqueous solutions of PAA and PVA.

The method of uniform detachment of a flat metal plate from a polymer body surface, which estimates both the strength and degradation mechanism for the adhesion joint, was applied to examine the surface properties of the PCMs in relation to the type of the filler. The adhesive strength was estimated from the work of detachment of the metal plate from the polymer complex when exposed to an external force [12]:

$$W = W_{det}/S,$$

where S is the adhesive–substrate contact area.

Figure 3 demonstrates how the work of adhesion

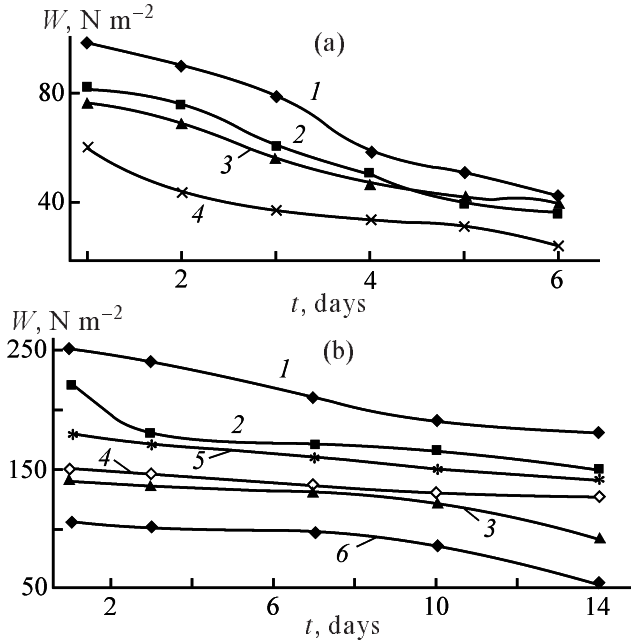

Fig. 3. Variation of the work of adhesion W with the time of structure formation t of the polymer complexes. (a) (*1*) Polymer matrix, (*2*) PET, (*3*) moss, and (*4*) QS; (b) (*1*) polymer matrix, (*2*) plant-originated peat, (*3*) mechanically activated peat, (*4*) cellulose, (*5*) starch 1, and (*6*) starch 2.

for different fillers varies with the time of formation of the polymer complex. The work of adhesion of the polymer complexes with sand, PET, and moss is lower than that of the polymer matrix. The surface layer buildup is, evidently, affected not only by formation of supramolecular structures but also by the type of filler. In the case of peats, starches, and wood, the work of adhesion is much higher. The PCMs with solid starch exhibit adhesive breakoff, in contrast to those with starch hydrogel, for which cohesive breakoff is observed. Probably, the polymer matrix degrades as a result of cleavage of swollen grains in starch hydrogels into smaller grains [13]. Also, the hydrogels exhibit enhanced concentration of the terminal reducing groups due to cleavage of the glucoside bonds in the macromolecules. The dynamic viscosity and elastic modulus of mechanically activated peat is lower than that of untreated peat. The reason is that mechanical treatment of peat causes the yield of polysaccharides, polyphenols, and humic and fulvic acids to increase [14]. Acids, most likely, cause a decrease in the number of interpolymer hydrogen bonds in the matrix.

Table 2. Initial dynamic viscosity, elastic modulus, and work of adhesion of the PVA + PAA polymer matrix and its complexes with various additives

Additive	η, Pa s	E, GPa	W, N m^{-2}
–	0.21	8.9	103
Sand	1.23	23.8	62
PET	0.87	12.2	84.1
Moss	0.29	19.8	78
Cellulose	1.34	0.42	149.6
Peat	0.46	0.63	225.3
Mechanically activated peat	0.45	0.55	144.7
Starch 1	0.11	0.41	174.2
Starch 2	2.05	0.36	250.1

Table 2 lists the measured initial dynamic viscosity, elastic modulus, and work of adhesion; it shows how the fillers modify the properties of the polymer matrix. Upon introduction of starches and cellulose, the dynamic viscosity of the polymer composites increases insignificantly, the elastic modulus decreases, and the trends in the work of adhesion suggest that supramolecular structures are not formed in the polymer composites.

CONCLUSIONS

(1) Directed modification of the polymer matrix based on polyacrylamide and polyvinyl alcohol via introduction of quartz sand, moss, and poly(ethylene terephthalate) improves its rheological and surface characteristics.

(2) Filling with starch and sawdust enables prompt utilization of the polymer matrix.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Dependence of Composition and Characteristics of Lignosulfonates on the Procedures of Their Recovery and Purification

N. V. Shul'ga, L. A. Gomolko, and N. P. Krut'ko

Institute of General and Inorganic Chemistry, National Academy of Science of Belarus, Minsk, Belarus

Received December 11, 2007

Abstract—Composition and characteristics of lignosulfonic acids recovered from technical-grade lignosufonates were studied by IR spectroscopy, viscometry, and elemental and chemical analyses. The dependence of the chemical composition and characteristics of lignosulfonic acids on the procedures of their recovery and purification was examined.

DOI: 10.1134/S1070427208070239

Integrated processing of all types of raw materials, including those of plant origin, and by-products based on them is an urgent problem.

Lignosulfonates are formed in sulfite cooking of wood and are large-tonnage wastes from pulp-and-paper industry. Certain amount of these wastes is used in building and in woodworking and oil-refining industries or is chemically reprocessed for vanillin production; however, the major part of these wastes is incinerated [1–3]. At the same time, lignosulfonates as derivatives of a natural polymer, lignin, proved well as soil land-reclamation agents and also as cheap adjuvants in production of preparative forms of pesticides and nontoxic complexones in production of preparations for plant leaf treatment [4, 5]. There are extensive data on compositions and characteristics of lignins; however, data on lignosulfonic acids and their derivatives are practically lacking.

EXPERIMENTAL

Technical-grade lignosulfonates (ILSs) produced by the Sokol Pulp-and-Paper Combine according to TU (Technical Specification) 13-0281036-029 were used as raw materials for synthesis of lignosulfonic acids (LSAs). The main characteristics of ILSs were as follows: density 1235 kg m^{-3}, weight fraction of dry substances 49.1%, ash content 15.5%, pH of 20% aqueous solution 4.5, and Na base of cooking acid.

Lignosulfonates were recovered from the technical-grade product with simultaneous purification to remove concomitant impurities by two procedures.

In purification with organic salting-out agent, the initial material was dissolved in hot distilled water (60–70°C). The resulting solution with the content of dry substance of about 20–25 wt % (density 1.08–1.10 g cm^{-3}) was passed through a textile filter and cooled to room temperature. After settling for 4–5 days, the solution was separated from the precipitate and evaporated at 50–60°C to 40–45% content of dry substance. Acetone and ethanol, both of chemically pure grade, were successively added to the concentrated solution with continuous stirring. The expenditure of each organic salting-out agent was equal to the volume of the initial aqueous solution of lignosulfonates. The resulting viscous pulp was separated from the mother liquor, dried in air until it solidified, and then dried in an oven at 60°C for 1 day to completely remove residual amounts of moisture and organic solvent. The resulting product was milled, passed through a sieve, and kept in an oven at 60°C for several hours with intermittent mixing, after which the chemical composition of the purified lignosulfonates (PLSs) was determined.

In purification with an inorganic precipitant, a saturated solution of the precipitant, hexaamminecobalt(III) chloride $[Co(NH_3)_6]Cl_3$ (7.5 g of salt per 100 ml of water), was added to a solution of ILS with a concentration of 40–45%. The precipitant expenditure was approximately 4.5 g of anhydrous

* Absolute error of determination is less than 0.02 (N), 0.05 (C), and 0.08 wt % (S); 0.03 mg-equiv g^{-1} (H^+).

salt per 20 g of dry ILSs. After the precipitation completion, the mother liquor became orange. The resulting suspension was settled for 1 day, after which the precipitate was transferred onto a Buchner funnel (blue band paper filter) and thoroughly washed with distilled water. The resulting product, insoluble lignosulfonic complex (LSC), was dried in air and then in an oven at 65°C and analyzed.

The nitrogen, carbon, and sulfur content in the ILS, PLS, and LSC samples and also in the preparations obtained from them was determined on a C–H–N–O–S Vario EL-3 analyzer (Elementat, Germany).

The content of soluble sulfates in the samples was determined gravimetrically by precipitation of sulfate ions with calcium chloride solution taken in a threefold excess with respect to stoichiometry.

Lignosulfonic acid LSA1 was synthesized by the ion-exchange procedure with passing of a 20% solution of PLSs through a column packed with KU-2 cation exchanger in the H^+ form.

In synthesis of acid LSA2, the LSC complex was pretreated with concentrated NaOH solution, and the filtrate was separated and passed through an H^+ cation exchanger. In all cases, in synthesis of lignosulfonic acids the amount of lignosulfonates passed through a column did not exceed 20% of its calculated capacity. The purity of the resulting products (residual content of Na^+ ions) was monitored with an Iris Intrepid IIX DL atomic-emission spectrometer (Intertech, the United States). The sample preparation involved their mineralization.

For additional purification of the PLS sample to remove low-molecular-weight impurities of organic and inorganic origin, we used ultrafiltration. The initial product was separated into two components (permeate and concentrate) using an ultraporous membrane with a cutting limit of 100 000 amu. In subsequent experiments the concentrate was used for synthesis of lignosulfonic acid LSA3.

Lignosulfonic acid LSA4 was synthesized after preoxidation of an LSA1 sample with manganese dioxide taken in an amount of 43% of the LSA1 weight in the solution, separation of the filtrate, and passing of the filtrate through a cation exchanger in the H^+ form.

The IR spectra of the samples were recorded on a Protégé 460 IR Fourier spectrometer (Nicolette, the United States). Samples were pelletized with dried KBr powder to obtain thin discs 10 mm in diameter. The weighed portion of the sample was 1 mg. The spectrometer resolution was 4 cm^{-1}, number of scans 128.

The content of labile protons in the synthesized lignosulfonic acids was determined by potentiometric titration of aqueous solutions of LSA. In determination of the dynamic viscosity of LSA solutions we used a VPZh-3 glass capillary viscometer with a capillary diameter of 1.2 mm.

The chemical compositions of the initial ILSs and of intermediates and final products recovered from them are presented in Table 1. These results show that lignosulfonates are complicated mixtures of components having different degrees of sulfonation. In extraction with an organic solvent, the C : S ratio in the purified product is lower than that in the initial ILSs. Apparently, enrichment of the salted-out product with sulfur is caused by transfer of nonsulfonated extracted substances (resins, tanning agents, etc.) into the organic phase and coprecipitation of

sulfates with lignosulfonates under the action of an organic salting-out agent. The found content of sulfate ions is approximately 0.66 mg-equiv g^{-1} of dry ILSs and 0.67 in the salted-out product, which does not noticeably affect the position and intensity of the bands in the IR spectra of LSAs (Fig. 1).

On the contrary, treatment of an ILS solution with concentrated $[Co(NH_3)_6]Cl_3$ gives a product with noticeably increased C : S ratio. This is apparently caused by predominant precipitation of higher-molecular-weight fraction of ILS in formation of the cobalt lignosulfonate complex. In addition, lower-molecular-weight and more soluble fractions of the product can be lost in washing of the complex salt to remove excess unchanged precipitant. Similar to the products obtained from PLS by ion exchange, the sample recovered from ILS by salting-out contains nitrogen (Table 1). The largest amount of nitrogen was found in low-sulfonated poorly soluble precipitate formed by dilution and settling of ILS solution. It is likely that amino acids, precursors of lignin, are the source of nitrogen. A high content of amino acids was also found in young wood or wood that grew under unfavorable environmental conditions [6, 7].

The amorphous nature of lignin and its derivatives, complicated structure of monomeric units, and variety of bonds make impossible application of the group theory to analysis of IR spectra of these compounds. Therefore, we used an empirical approach in interpretation of the IR spectra of lignosulfonic acids and its salts (Fig. 1, Table 2).

At first glance, the IR spectra of the resulting LSA1–LSA4 samples and lignin precursor are practically identical (Table 2). In particular, this is due to the fact that the chemical reactions occurring in the course of sulfite cooking, both main (sulfonation, hydrolysis, condensation) and secondary (oxidation, reduction, dehydration, rearrangement), affect the ratio between functional groups of the initial polymer, but their main types are preserved [11].

Introduction of sulfonic group into the structural unit of lignin (nucleophilic substitution) does not give rise to new absorption bands in the IR spectra of lignosulfonates, because the frequencies of symmetric and antisymmetric vibrations of this functional group coincide with the frequencies of vibrations of lignin functional groups (Table 2). The result of this coincidence is noticeable increase in the integral intensity of absorption in the regions of

1030 and 1140 cm^{-1} in lignosulfonates in comparison with lignins (Fig. 2).

IR spectroscopy allows elucidation of the source of lignins and furnishes preliminary data on their structural features. It is well known that, in conifer-

ous lignins, the main structural unit is guaiacylpropane unit. For this type of lignins, the band at approximately 1600 cm^{-1} is typically weaker than the band at 1500 cm^{-1}. These bands in the IR spectrum correspond to stretching modes of the aromatic ring. The bending band of methoxyls of guaiacylpropane unit (approximately 1460 cm^{-1}) has lower intensity, and the band maxima of bending modes of the CH group of the benzene ring are observed at about 860 and 815 cm^{-1} (Fig. 2) [11, 12].

Sulfite cooking does not alter the structural type of the initial natural polymer, as it affects guaiacylpropane and syringylpropane units to a significantly lesser extent than other segments of the lignin molecule. The ratio of intensities of the absorption bands and their positions in the IR spectra of the resulting LSA samples (Figs. 1, 2) suggest that ILSs used in this study are the product of processing of coniferous wood. Coniferous lignins contain smaller amounts of methoxyls in the aromatic nucleus and are sulfonated more readily than deciduous lignins [6, 11].

Industrial lignins always contain certain amount of impurities. In their purification with organic salting-out agents there is no way to avoid coprecipitation with the main product of inorganic sulfates and

also sugars, aldonates, uronates, and sulfocarbonates having low solubility in organic solvents. Ultrafiltration is considered to be an efficient procedure allowing separation of low-molecular-weight impurities. However, it is well known that even the most narrow-porous membranes are permeable to lignins and do not fully prevent penetration of lignins of low and even intermediate molecular weight into the filtrate (permeate) [13].

In an attempt to apply this procedure to purification of not PLS sample but lignosulfonic acid LSA1 prepared from this sample, we ran into problems. Attempts to separate low-molecular-weight impurities from the main product using an ultraporous membrane failed, since a large amount of lignosulfonic acid passed into the filtrate. This can be caused by changes in the conformation of polymer molecules in an acid medium (linear form instead of globular form).

To attain more complete separation of low-molecular-weight impurities from lignosulfonates PLSs, the permeate was concentrated and subjected to repeated filtration.

The dried permeate was a hygroscopic brown mass with numerous whitish platelike inclusions, had light-beige color after grinding, and noticeably differed from the other samples in the chemical composition, having high degree of sulfonation (Table 1). This is apparently caused by passing of the most sulfonated low-molecular-weight fractions of the main substance and inorganic sulfates into the filtrate. The presence of inorganic sulfates in the filtrate is confirmed by an increase of the intensity of the bands at 1130 and 616 cm^{-1}.

Contrary to the filtrate, the membrane concentrate obtained by ultrafilration of the PLS sample did not have pronounced hydrophilic characteristics, was readily dehydrated, and after drying turned brown, which is typical for lignosulfonates. After dissolution it was used for synthesis of lignosulfonic acid LSA3. As expected, removal of the low-molecular-weight fraction of the technical-grade product resulted in a decrease in the degree of sulfonation of the residue (concentrate) and in the content of acid groups in the residue (Table 1). Chemical analysis and IR measurements show that the major organic components of the filtrate are lactones and also derivatives of uronic and sulfocarboxylic acids: after purification by ultrafiltration, the intensities of the absorption bands at 1780 and 1740 cm^{-1} noticeably decrease (Figs. 1, 3). These bands correspond to vibrations of carbonyl group in γ-lactone and open-chain forms of uronic acids [14].

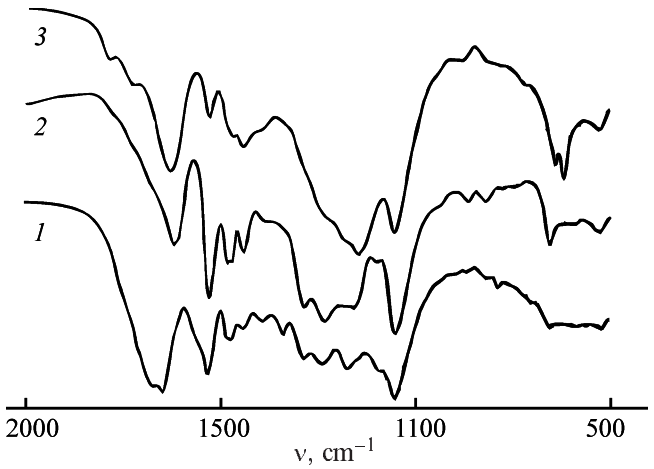

Fig. 3. IR spectra of (*1*) insoluble residue, (*2*) concentrate, and (*3*) permeate.

The band at approximately 1780 cm^{-1}, especially strong in the IR spectra of LSA1 and LSA4 (Fig. 1), can be assigned to stretching vibrations of the C=O bond in anhydrides of organic acids. Their amount can be considerable due to condensation of hydroxyls of sulfonic and carboxy groups in drying of lignosulfonic acids [15]. Dry lignosulfonic acids are practically insoluble in water, which is typical for condensed products.

A fairly strong absorption band at approximately 1717 cm^{-1} in the spectra of lignosulfonic acids (Fig. 1) can be assigned to stretching vibrations of carbonyl groups of nonconjugated keto and aldehyde groups and also of carboxy groups bonded to aromatic ring. In the spectra of salts of lignosulfonic acid, the intensity of this band noticeably decreases (Fig. 1). A weak band preserved as a shoulder at approximately 1660 cm^{-1} cannot be assigned to only carbonyls of carboxy groups. The vibrations of β-keto esters, alkenes, quinones, some aldehydes, and also nitrogen-containing functional groups also fall into this range. The presence of nitrogen-containing groups in lignosulfonates is beyond question (Table 1). The strong bands at approximately 1630 and 1660 cm^{-1} in the IR spectra of the insoluble residue presumably belong to amide functional groups (Fig. 3). It should also be noted that, under certain treatment conditions, gaseous ammonia is released from the insoluble precipitate, which is typical for hydrolytic rupture of amide bonds.

The vibrations in the range 520–650 cm^{-1} are

Table 3. C : S ratio in complex salt at various synthesis conditions

Precipitation conditions		Content, wt %		Atomic ratio	
ILS concentration in solution, wt %	precipitate treatment procedure	C	S	C	S
0.5	Settling	45.13	5.91	204	10
1.25	Washing with water	46.26	5.96	207	10
1.25	Washing with water–ethanol mixture	42.47	6.60	173	10
10.0	Without washing	44.65	6.24	191	10
10.0	Washing with water–ethanol mixture	46.44	6.14	202	10
10.0	Washing with water	46.71	5.82	214	10
40.0	Washing with water	49.74	5.80	229	10

usually assigned to sulfoxyl groups [12]. The bands at 1140–1150 and 1030–1036 cm^{-1} also belong to these groups since, according to data obtained, their positions in the above range vary depending on the nature of lignosulfonate cation or coordination of the complex cation relative to the sulfonate anion.

Purification of ILSs with complex precipitants precludes the possibility of coprecipitation of any low-molecular-weight impurities (sulfates, sugars, lactones, etc.) with the main product [16]. However, the study showed that this procedure does not allow recovery of lignosulfonates with chemical composition similar to that of lignosulfonates in the initial technical-grade product. In washing of the precipitate to remove the residual unchanged precipitant, the precipitate is peptized and the fractions enriched with strongly acidic sulfonic groups, i.e., the lowest-molecular-weight and most hydrophilic fractions (Table 3), are lost. Settling of the precipitated complex is accompanied by its progressing hydrolytic decomposition resulting in the loss of the substance. The results obtained agree well with published data showing that, with complex precipitants, no more than 60% of lignosulfonates can be recovered from a solution [8]. It is not improbable that the inorganic precipitant $[Co(NH_3)_6]Cl_3$ binds into a stable insoluble complex only less sulfonated polymer fractions having definite steric orientation.

Table 4. Dynamic characteristics of lignosulfonic acids LSA1 and LSA2

Sample	Density, g cm^{-3}	Concentration in solution, wt %	pH	Dynamic viscosity, mPa s
LSA1	1.077	23.2	0.33	1.79
LSA2	1.075	20.4	0.70	4.94

Purification of lignosulfonates to remove low-molecular-weight impurities noticeably alters not only their chemical composition but also rheological characteristics (Table 4).

It is well known that low-molecular-weight lignosulfonates enter into the composition of the solvate shell of significantly coarser molecules [6]. It can be expected that this is also true for other low-molecular-weight impurities. Participating in formation of hydrogen bonds with functional groups of macromolecular fractions of lignosulfonic acid LSA1, low-molecular-weight compounds stabilize a finely dispersed colloid. This type of structure of colloidal solution provides high mobility of individual components and, correspondingly, low viscosity.

It is likely that, in LSA2 solutions purified to remove the low-molecular-weight component, a 3D network is formed by interaction of side chains of polymer molecules, which noticeably decreases the fluidity of the colloid.

CONCLUSIONS

(1) Chemical composition and characteristics of lignosulfonates depend on the procedure of their recovery from the industrial product.

(2) The presence of the low-molecular-weight fraction in lignosulfonates significantly affects their physical characteristics.

Abstract—Organic–inorganic composites of poly(methyl methacrylate) with alkoxysilane hydrolyzates form transparent films. Their thermal and oxidative thermal degradation were studied by differential scanning calorimetry and thermogravimetric analysis.

DOI: 10.1134/S1070427208070240

Poly(methyl methacrylate) (PMMA) is a large-tonnage commercial product. Transparent PMMA glasses are widely used in various fields of economy. However, the heat resistance of PMMA is poor. Its thermal degradation starts on heating above 150°C.

Modification of polymer properties with the aim to improve the quality and prolong the service life was and remains an urgent theoretical and applied problem. Diverse methods are used today to inhibit polymer degradation. These include choice of proper processing conditions, addition of antioxidants or oxidation inhibitors to the polymer, and control of the supramolecular structure of polymeric materials.

Active efforts have been made recently to develop polymeric nanocomposite materials. To prepare nanocomposites, an ultrafine silica sol is introduced into a polymer dispersion [1]. Nanocomposites can also be prepared by simultaneously performing polymerization of a monomer and hydrolysis of alkoxysilanes [2]. Ivanchev et al. [3] reported on preparation of a nanocomposite material based on polypropylene (PP) by hydrolysis of alkoxysilanes directly in a polymer matrix in the solid state or in a melt.

It was interesting to examine the possibility of preparing PMMA films filled with inorganic particles by introducing into a polymer solution hydrolyzates of various alkoxysilanes and to study how the hydrolysis conditions and composition of the blends affect the properties of the films obtained.

EXPERIMENTAL

PMMA(I) samples were prepared in sealed ampules by bulk polymerization of MMA with various concentrations of azobis(isobutyronitrile) (AIBN), following the standard procedure [4]. Before polymerization, MMA was purified by vacuum distillation and deoxygenated by threefold freezing–pumping–thawing. Also, PMMA(II) samples were prepared by bulk polymerization of MMA in air without initiator under UV irradiation. Emulsion PMMA was prepared as described in [5].

Tetraethoxysilane (TEOS), γ-aminopropyltriethoxysilane (APTEOS), and phenyltrimethoxysilane (PTMOS) were purified by vacuum distillation.

Hydrolysis of siloxanes was performed at room temperature in a flask. The mixture was stirred with a magnetic stirrer at a rate of 500 rpm. Water was added in an amount of 1 mol per each hydrolyzable bond in alkoxysilane. Hydrochloric acid was used as catalyst. The hydrolysis time was about 30 min. The hydrolyzate was diluted with acetone in a volume ratio of 1 : 20.

The solution of the hydrolyzate in acetone was mixed with a solution of PMMA in methylene chloride and poured onto a Petri dish. The films obtained after solvent evaporation were dried in a vacuum oven at 60–70°C to remove the solvent completely. The film thickness was about 100 μm.

IR measurements were performed with an FSM 1201 IR Fourier spectrometer, and DSC measurements, with a DSK 204 F1 Phoenix differential scan-

ning calorimeter (Netzsch, Germany) with linear heating from 20 to 450°C at a rate of 10 deg min^{-1}.

Thermogravimetric analysis of samples in the dynamic mode in a nitrogen atmosphere (thermal degradation) or in air (thermal oxidative degradation) was performed with a Perkin–Elmer Pyris 6 TGA device, with linear heating from 20 to 450°C at a rate of 10 deg min^{-1}.

The rate of thermal oxidative degradation (TOD) at a constant temperature (302°C) was evaluated by the weight loss on an installation equipped with a quartz spring balance at an oxygen pressure of 200 mm Hg.

According to published data [6], hydrolysis of alkoxysilanes occurs in several steps during which the initial two-phase liquid mixture of the reactants after stirring for a definite time transforms into a single-phase liquid. Further stirring leads to the formation of a two-phase mixture transforming into a suspension of solid silica microspheres.

In this study, the hydrolysis was stopped at the step of transformation of the two-phase system into the single-phase system by diluting the hydrolyzate with acetone. The composition of alkoxysilane hydrolysis products was examined by IR spectroscopy [7].

On mixing TEOS hydrolyzate with a PMMA solution, after removing the solvent and drying, a transparent film was obtained. Its IR spectrum contained, along with PMMA bands, also a band at 1091 cm^{-1} belonging to C–O vibrations in the Si–O–C fragment of partially hydrolyzed TEOS.

In the spectrum of the film obtained from PMMA and PTMOS hydrolyzate, a shoulder at 1030 cm^{-1} appears on the band with a maximum at 1067 cm^{-1}. These frequencies are characteristic of Si–O–Si stretching vibrations, confirming the presence of silicon compounds in PMMA films. In addition, the spectra of samples containing PTMOS hydrolysis products contain an absorption band of the phenyl group (1595 cm^{-1}).

In the spectrum of the film obtained from PMMA with APTEOS hydrolyzate, there is a strong band with a maximum at 1064 cm^{-1} and a weak band at 1030 cm^{-1}, characteristic of the Si–O–Si group in linear oligosiloxanes and in cyclic trisiloxane. A slight increase in the absorption at 1580 and 3400 cm^{-1} suggests the presence of NH groups.

The mechanism of poly(methyl methacrylate) degradation at elevated temperatures has been

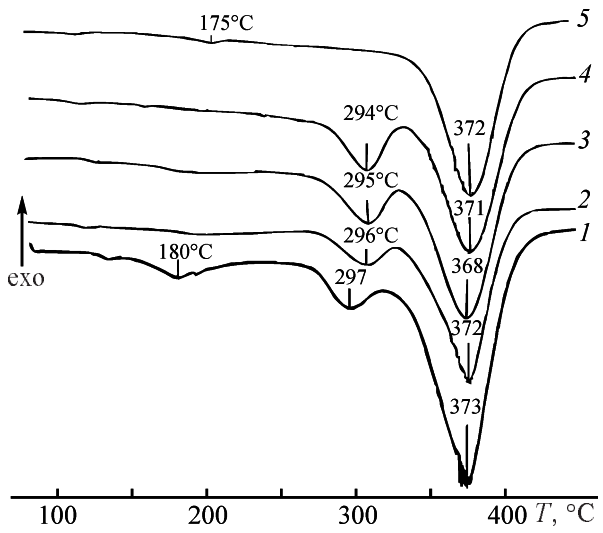

Fig. 1. DSC curves: (*1*) emulsion PMMA, (*2–4*) PMMA(I) prepared in the presence of AIBN, and (*5*) PMMA(II). (*T*) Temperature; the same for Fig. 2. AIBN concentration, wt %: (*2*) 0.1, (*3*) 0.2, and (*4*) 0.5.

studied in detail [8]. Thermal degradation of PMMA occurs by the mechanism of radical nonbranched chain reactions. The major process is depolymerization. The monomer is virtually the only product of thermal degradation of PMMA (99%) [8].

To compare the thermal properties of PMMA and organic–inorganic composites prepared by adding hydrolysis products of various alkoxysilanes into the polymer, we studied by DSC in an inert atmosphere the PMMA samples prepared in emulsion or in the bulk in the presence of an initiator and without it. The DSC curves of PMMA samples prepared by the above procedures differ in the number and positions of endothermic peaks.

The DSC curve of emulsion PMMA (Fig. 1, curve *1*) has three endothermic peaks. The total area of the peaks is proportional to the total thermal effect of processes occurring in the polymer on heating. At a heating rate of 10 deg min^{-1}, the first peak with a minimum at 180°C is observed in the temperature range 160–210°C; the second peak with a minimum at 297°C, in the range 280–315°C; and the third peak with a minimum at 373°C, in the range 315–420°C.

Kashiwagi et al. [9] studied by TG at a heating rate of 2 deg min^{-1} the thermal degradation of PMMA samples prepared by anionic (sample A) and radical (sample B) polymerization. In the DTG curve of sample A, there is only one peak at 360°C. In the DTG curve of sample B prepared in the bulk

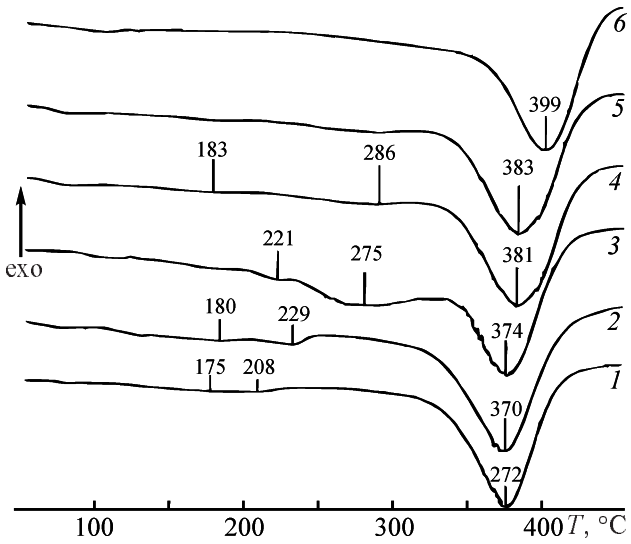

Fig. 2. DSC curves of PMMA(II) composites with hydrolyzates of various alkoxysilanes. Alkoxysilane, %: (*1*) 1 TEOS, (*2*) 10 TEOS, (*3*) 1 PTMOS, (*4*) 10 PTMOS, (*5*) 1 APTEOS, and (*6*) 7 APTEOS.

in the presence of AIBN, there are three peaks at 165, 270, and 360°C. Taking into account the data they obtained for model oligomers, Kashiwagi et al. assigned the peaks in the DTG curve of sample B to degradation initiated by unstable head-to-head grouos (165°C), unsaturated terminal bonds (270°C), and random cleavage of the macromolecular backbone (360°C). For sample A containing no unstable structures, the only peak observed in the DTG curve at 360°C is apparently due to initiation by random cleavage of the backbone. The same conclusions were made later by Shibaev et al. [10, 11].

The temperature intervals of the endothermic peaks in the DSC curves of various PMMA samples suggest that these peaks are related to the three steps of thermal degradation described in [9–11].

The first peak in the DSC curve of emulsion PMMA (Fig. 1, curve *2*) corresponds to the degradation of macromolecules initiated by cleavage of weak head-to-head bonds formed when the MMA polymerization is terminated by recombination of the macroradicals. The second peak in the DSC curve is due to initiation of the degradation by cleavage of terminal double bonds of polymer macromolecules, formed by disproportionation of the macroradicals in the course of polymerization. The largest thermal effect is associated with the last step of the degradation, initiated by random cleavage; it is proportional to the area of the third peak.

In the DSC curves of PMMA(I) samples prepared by bulk polymerization in the presence of AIBN (Fig. 1, curves *2–4*), there are only two endothermic peaks. One of the peaks (294–296°C) is apparently associated with degradation of macromolecules initiated by cleavage of terminal double bonds. Initiation by weak terminal double bonds leads to only 10–15% degradation of PMMA, as judged from the ratio of the peak areas, and it depends on the initiator concentration: The higher the initiator concentration, the larger the area of the first peak. The second peak with a minimum at about 370°C, whose relative area is 85–90%, corresponds to processes initiated by random cleavages of macromolecules.

In the DSC curve of the PMMA(II) sample prepared without initiator (Fig. 1, curve *5*), there are also two peaks, but the curve differs in shape from the previously discussed curves (Fig. 1, curves *2–4*). Namely, the first peak is observed at 174.6°C. The lower temperature of the degradation onset, apparently, suggests initiation of the degradation by cleavage of weak head-to-head bonds. As judged from the area of the first peak, the amount of such bonds is relatively low. Initiation of the degradation by cleavage of such bonds leads to only 1% degradation of the polymer. The second peak in the DSC curve of the PMMA(II) sample (about 370°C), as in the previous samples, is due to degradation initiated by random cleavages of the backbone.

The DSC curves of composites of PMMA(II) with hydrolysis products of alkoxysilanes (Fig. 2) differ from that of straight PMMA and from each other. First, in these curves the degradation processes initiated by cleavage of weak head-to-head bonds and terminal double bonds are manifested very weakly. Second, in the DSC curve of the composite with 10% TEOS, an endothermic peak appears at 229°C, absent in the PMMA(II) curve. This peak is apparently attributable to cleavage of the residual siloxane fragments in the component. In addition, the major peak is shifted toward higher temperatures. Below are given the additives to PMMA, their percentage, and the temperature of the major DSC peak: none, 372°C; 1% TEOS, 372; 10% TEOS, 375; 1% PTMOS, 374; 10% PTMOS, 385, 1% APTEOS, 383; and 7% APTEOS, 399°C, i.e., the additives enhance the heat resistance of the polymer.

In contrast to DSC, the TGA method allows not only determination of the temperature intervals of PMMA degradation, but also measurement of the weight loss rate in these intervals (see table). The

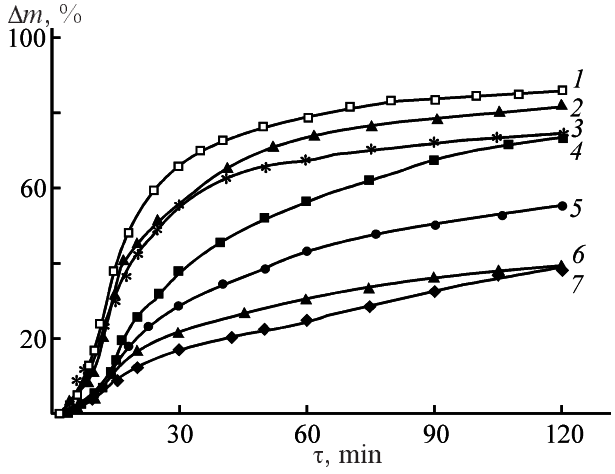
temperature intervals of degradation acceleration, observed in the DTG curve of the PMMA(II) sample in a nitrogen atmosphere, correspond to the endothermic peaks in the DSC curve.

In the DTG curves recorded in the course of heating in a nitrogen atmosphere the PMMA(II) samples and composites of PMMA with TEOS and PTMOS hydrolyzates (see table), steps of degradation acceleration are observed in the range 100–300°C. Additions of PTMOS and TEOS cause in this range a small additional weight loss (26.5% for PTMOS and 21–24.5% for TEOS) compared to PMMA (19.5%), apparently due to occurrence of



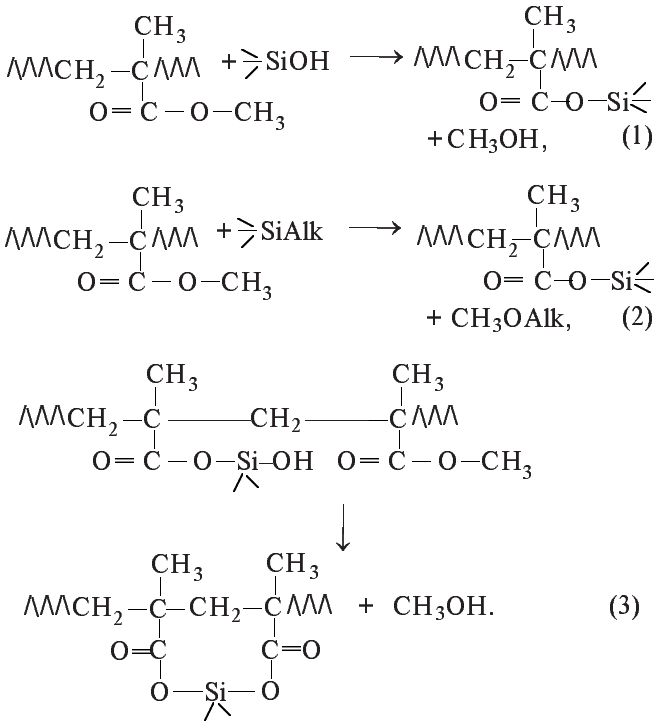


Fig. 3. Curves of the weight loss Δm in thermal oxidative degradation of (*1*) PMMA(II) and (*2–7*) composites of PMMA(II) with hydrolyzates of various alkoxysilanes. Temperature 302°C, O_2 pressure 200 mm Hg. Alkoxysilane, %: (*2*) 1 TEOS, (*3*) 10 TEOS, (*4*) 1 PTMOS, (*5*) 10 PTMOS, (*6*) 1 APTEOS, and (*7*) 7 APTEOS.

the reactions

The PMMA degradation in composites, initiated by random bond cleavage in macromolecules, in the presence of additives of alkoxysilane hydrolysis products occurs more slowly than that of straight PMMA (see table). As the rate of the chain reaction of macromolecule depolymerization is determined by the product of the initiation rate by the chain length, it can be assumed that additives do not affect the initiation rate but decrease the depolymerization

chain length by terminating it in sites of silicon addition to PMMA chain [reactions (1)–(3)].

In the degradation of PMMA in air, monitored by TG in the dynamic mode (see table), the weight loss starts at 100°C. As in thermal degradation in a nitrogen flow, three steps of the polymer degradation are observed. However, the degradation rate sharply increases already above 211°C. In the DTG curve, sharp oscillations of the weight loss rate are observed in the range from 250 to 330°C, suggesting intense release of volatiles from the sample. The polymer fully degrades below 430°C.

Additions of APTEOS hydrolysis products increase the degradation temperature and inhibit the PMMA degradation to a greater extent than do the TEOS and PTMOS hydrolyzates, both in a nitrogen flow and in air (see table). The degradation rate reaches a maximum at 400–420°C in nitrogen and 375–380°C in air, which is 60–65°C higher than the temperature of the maximal weight loss rate for straight PMMA.

Studies of the thermal oxidative degradation of blends of PMMA with alkoxysilane hydrolyzates at a constant temperature of 302°C in oxygen (Fig. 3) showed that the kinetics of their decomposition depends on the amount and kind of the additive. We found that the weight loss in them is slower than in the PMMA sample without additives. The strongest deceleration of the degradation is observed for blends of PMMA with APTEOS hydrolyzate (Fig. 3, curves *6*, *7*), as in the dynamic experiment.

Thus, it follows from the above DSC and TGA data that introduction of alkoxysilane hydrolyzates into PMMA stabilizes the polymer with respect to thermal degradation. Modification of the macromolecule with silicon-containing fragments leads to a decrease in the length of the depolymerization chain. Blends of PMMA with APTEOS hydrolysis products are the most heat-resistant. Additional stabilizing effect on the polymer in this case is exerted by the presence of the amino group in the alkoxysilane. The reaction of the amino group with the ester group of the monomer unit of PMMA, occurring on heating the polymer above 150°C, yields six-membered imide rings. This was proved by appearance of an absorption band at 1657 cm^{-1}, characteristic of imide rings, in the IR spectrum of a film of the PMMA–10% APTEOS composite after heating in a vacuum at 200°C for 30 min. Previous studies showed [12, 13] that such fragments decelerate the degradation of PMMA and its copolymers.

CONCLUSIONS

(1) Thermal and oxidative thermal degradation of poly(methyl methacrylate) is inhibited by introduction of alkoxysilane hydrolysis products into the polymer.

(2) In organic–inorganic composites of poly(methyl methacrylate), among three alkoxysilanes studied (tetraethoxysilane, γ-aminopropyltriethoxysilane, phenyltrimethoxysilane), γ-aminopropyltriethoxysilane exerts the strongest stabilizing effect.

ACKNOWLEDGMENTS

The authors are grateful to O.V. Kuznetsova for recording and discussing the IR spectra.

Abstract—Corona electrets based on composites of shockproof polystyrene and starch were studied.

DOI: 10.1134/S1070427208070252

Utilization of spent polymer electrets is a topical problem because of their wide use in various converters, air filters and individual respirators, tribotechnical and sealing systems, etc. [1–3]. In Russia, polymer items are usually disposed of with solid domestic wastes. However, since polymers are extremely resistant to degradation, studies should be carried out to develop new biodegradable polymers. One of the ways to impart biodegradability to polymers is addition of fillers, which can act as a source of food for bacteria and fungi and simultaneously promote degradation of polymer chains to oligomeric fragments easily assimilated by the same microorganisms [4, 5].

Our previous studies [6–8] showed that, from polymers and dispersed fillers, it is possible to prepare electrets considerably surpassing in characteristics those based on unfilled polymers. However, as shown in [9], electric fields negatively affect the vital activity of various microorganisms. In this case, electret as a material producing an electrostatic field cannot undergo biodegradation even when modified with various fillers.

In this work we studied biodegradation of electrets based on polymers and fillers.

EXPERIMENTAL

In our studies we used shockproof polystyrene (SPPS) of 0801 brand [GOST (State Standard) 20250–89E] and potato starch (GOST 7699–78).

The polymer and filler were mixed in a Brabender blender at 190±2°C for 5 min. The composite plates with a thickness of 0.8 mm were pressed in accordance with GOST 12019–66 at 190±5°C for 5 min. Then, the resulting plates were heated at 100°C for 10 min and cooled in the field of the negative corona discharge. The corona discharge was obtained with an electrode of 196 needles uniformly distributed over the square area (7 × 7 cm). The polarization voltage and time were 35 kV and 60 s, respectively.

The electret and straight polymer plates were stored in paper envelops at ambient temperature and humidity. The electret characteristics were measured every day on an IPEP-1 meter whose operation is based on intermittent shielding of the measuring probe located at some distance from the electret surface. The measurement errors of the surface potential V_s, electric field strength E, and surface density of the electric charges σ_{sp} were no more than 3%.

To perform the biodegradation studies, the plate was placed into a Petri dish with the Saburo model culture medium containing spores of *Aspergillus niger* mycelial fungi. The biodegradation was monitored by the outward appearance and weight loss of the plates.

Shockproof polystyrene is one of the most widely used structural polymeric materials. However, its electret properties are analyzed only in a few studies [10, 11]. At the same time, corona electrets based on polystyrene, exhibiting high electret properties, were studied fairly extensively [6–8, 12, 13]. Electrets with a stable external electric field are prepared by corona discharge using specifically nonpolar polymers, which are characterized by the presence of the energy trap of charge carriers (impurity ions), free polymer volume, and specific surface defects formed in the course of oxidation. It should be noted that shockproof polystyrene has a two-phase structure typical for composites in which the matrix phase of polystyrene incorporates microgel particles

of a graft copolymer, butadiene rubber. The phase boundary also acts as an efficient trap of charge carriers. Addition of a filler into the polymer gives rise to new levels of charge carrier trapping at the polymer–filler boundary and changes the energy depth of the existing levels, which significantly alters the electret properties [6–8, 14–16].

To evaluate the effect of starch on the properties of shockproof polystyrene, we prepared composites of the polymer and filler of various compositions (Figs. 1, 2). As can be seen, as the starch content is increased, the surface potential, electric field strength, and specific surface density of the electric charges of the polystyrene composites increase. This is due to the appearance of the Maxwell–Wagner polarization at the phase boundary, which noticeably affects formation and transformation of the electret state in heterogeneous systems.

The observed increase in V_s, E, and σ_{eff} of the shockproof polystyrene with increasing filler content can probably be explained as follows. The starch dipole molecules act as traps of the injected charges, attracting and holding them owing to the Coulomb forces, i.e., starch is the source of traps of the injected charge carriers. Shockproof polystyrene, exhibiting low electrical conductivity and forming a dispersion medium, hinders depolarization and determines high stability of the electret properties of the polystyrene composites. The above mechanism is typical for blends of polar and nonpolar polymers [17].

Thus, addition of starch as a filler promoting biodegradation of polymers improves the electret properties of shockproof polystyrene. However, as shown previously, the electric fields of the polymer corona electrets can negatively affect the biodegradation processes. To study these processes, plates of the straight and electret polystyrene composites were placed in a medium simulating soil and containing spores of *Aspergillus niger* mycelial fungi. The biodegradation was monitored by the outward appearance and weight loss of the plates. For this purpose, at 1-month intervals the sample was taken from the Petri dish, washed, and examined visually with an optical microscope, and the weight changes were measured with an analytical balance (see table).

The outward appearance of shockproof polystyrene and its composites with starch noticeably changes in the course of biodegradation. Before the experiment, all the plates were smooth. After a certain time, roughness and dark small spots appeared

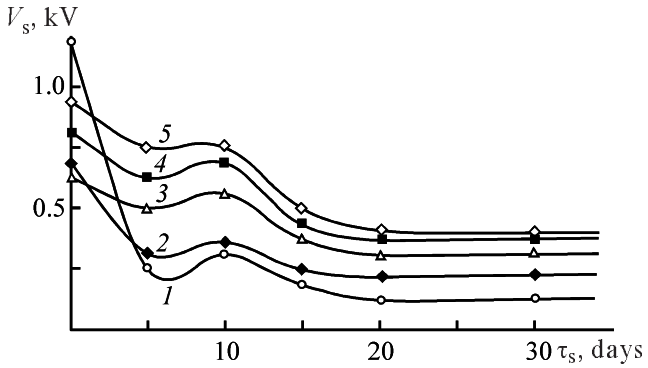

Fig. 1. Surface potential V_s of corona electrets based on (*1*) polystyrene and (*2–5*) its composites as a function of the storage time τ_s. Starch content, %: (*2*) 3, (*3*) 6, (*4*) 9, and (*5*) 12.

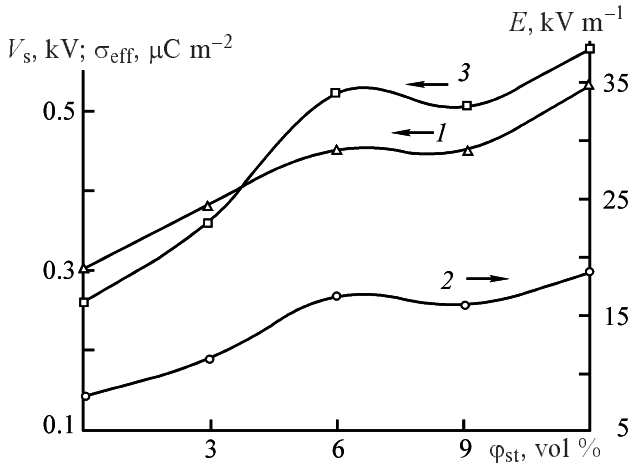

Fig. 2. (*1*) Surface potential V_s, (*2*) electric field strength E, and (*3*) effective surface density of electric charges σ_{eff} of corona electrets based on polystyrene and starch on the 20th day of storage, as functions of the filler content φ_{st}.

on the surface of the polystyrene plates with a high starch content (more than 6 vol %), and their edges became uneven. Then the plates became porous and dark and in some cases were broken on removal from the model system. However, no complete degradation of the composites in the Saburo medium was observed even after storage for 9 months.

It should be noted [18] that biodegradation of polymer composites with starch proceeds by the following mechanism. In the presence of soil moisture, starch nuclei swell. In the process, the polymer surface area increases, it is hydrolyzed and coated with glucose, which promotes formation of peroxides and hydroperoxides initiating degradation of the polymer chains. Moreover, observed increase in the volume of starch nuclei can initiate mechanical degradation of the polymer macromolecules. This is

Relative changes in the weight of polystyrene plates Δm and their outward appearance in the course of storage in the Saburo model culture medium

Composition	Straight plates				Electret plates			
	Δm, % after storage for indicated period, months							
	0	3	6	9	0	3	6	9
SPPS	100	101	101	101	100	100	99	98
SPPS + starch, %:								
3	100	100	97	95	100	99	95	92
6	100	94	86	79	100	94	82	70
9	100	91	83	70	100	91	69	60
12	100	91	71	61	100	89	74	53

especially important for polystyrene whose macromolecules are characterized by low flexibility. The bacteria and fungi feeding on starch also assimilate the resulting oligomer molecules.

As seen from the experimental data on changes in the plate weight after storage in the Saburo solution (see table), the electric field of corona electrets did not affect biodegradation. On the contrary, the rate of biodegradation of the corona electrets was significantly higher. This is probably due to the fact that certain oxidation and even slight breakdown of the polymer macromolecules occur in the course of treatment of shockproof polystyrene composites in a corona discharge. As shown previously [19], the molecular weight of polymers decreases with increasing duration of treatment in an electric field. This phenomenon can strongly facilitate assimilation of the materials studied by soil microorganisms.

The electret charge of the polystyrene composites after storage in wet media (such as the Saburo system) is rapidly relaxed, which is due to an increase in the surface electrical conductivity of the polymers and preferable relaxation of the homocharge in the surface and near-surface electret layers [12]. Hence, the effect of the electric field of the electret decreases and even disappears with time. Our studies suggest that, after storage of the electret plates in the Saburo medium for 1 month, V_s, E, and σ_{eff} decrease to zero, i.e., the electret state of the polystyrene composite does not prevent their assimilation by microorganisms.

CONCLUSIONS

(1) The surface potential, electric field strength, and specific surface density of the electric charges of the corona electrets based on composites of shockproof polystyrene with starch increase with increasing filler content, which is due to the appearance of the Maxwell–Wagner polarization at the phase boundary.

(2) Composites of shockproof polystyrene with a starch content exceeding 6 vol % are biodegradable. With increasing content of the filler, the biodegradation rate increases.

(3) Biodegradation of polystyrene corona electrets proceeds at a high rate owing to the degradation of the polymer macromolecules under treatment of the composites in a corona discharge. This phenomenon strongly facilitates assimilation of the polymer materials by soil microorganisms.

(4) The electret charge of the polystyrene composites does not affect their assimilation by microorganisms, because it is rapidly relaxed on storage of the corona electrets in a wet medium.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Organosilicon Chain-Transfer Agents on the Heat Resistance of Vinyl Polymers

S. A. Zhil'tsov, S. A. Bulgakova, and Yu. D. Semchikov

Research Institute of Chemistry, Lobachevsky Nizhni Novgorod State University, Nizhni Novgorod, Russia

Received November 28, 2007

Abstract—The effect exerted on the resistance of polymers to thermal oxidation degradation by organosilicon hydrides used as chain-transfer agents in polymerization of styrene, methyl methacrylate, and vinyl acetate was examined.

DOI: 10.1134/S1070427208070264

The function of chain-transfer agents is not restricted to a decrease in the molecular weight (MW) of polymers to a level sufficient for their processing through melts. Modification of polymers at terminal functional groups can impart to them new valuable properties. For example, with such functional chain-transfer agents as organosilicon hydrides (OSHs), the radiation sensitivity of poly(methyl methacrylate) as positive radiation resist was increased by a factor of 2 [1]. OSHs also affect the physical properteis of polymers such as the glass transition point and density [2]. Furthermore, multifunctional OSHs open the possibility of preparing block and graft copolymers [3]. Assuming that OSHs can cause morphological changes in the polymer structure and thus affect their heat resistance, which is very sensitive to such changes, we examined in this study the effect of OSHs on the thermal oxidative degradation of vinyl polymes: PMMA, polystyrene (PS), and poly(vinyl acetate) (PVA).

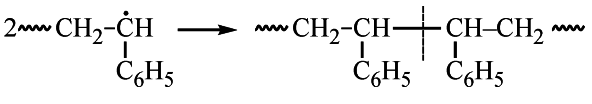
EXPERIMENTAL

For thermal oxidative degradation experiments, we prepared samples of PMMA, PS, and PVA in the presence of OSHs indicated below.

OSH formula	Designation
(*t*-BuO)$Me_2SiSiMe_2H$	DS-1
$H_2MeSiSiMeH_2$	DS-2
$(Me_3SiO)_2SiMeH$	DS-3
$H_3SiCH_2CH_2SiH_3$	DS-5
$Me_3SiSiMe_2H$	DS-9
$(HMe_SiO)Me_2SiSiMe(OSiMe_2H)_2$	DS-11
$(Me_3Si)_3SiH$	DS-15
$(Me_3Si)_2SiMeH$	DS-18
H(*i*-Pr)$_2$SiOSi(*i*-Pr)$_2$H	DS-20
$(Me_3SiO)_3SiH$	DS-21
$MePhSiH_2$	DS-23
$PhSiH_3$	DS-24
$(Me_3SiCH_2)_3SiH$	DS-26
Ph_3SiH	DS-27

Methyl methacrylate was purified by vaporization–condensation in a vacuum. Styrene was washed with an alkali solution to remove hydroquinone, dried over calcium chloride and then over calcium hydride, and vacuum-distilled. Vinyl acetate was purified by distillation at atmospheric pressure. The initiator, azobis(isobutyronitrile) (AIBN) was recrystallized from ethanol. The OSHs used as chain-transfer agents were prepared by published procedures [4]. The polymers were prepared by radical polymerization in the bulk to high conversions at 60°C in the presence of 0.005 M AIBN in sealed deoxygenated ampules. The OSH concentration in the monomers was varied from 0 to 2.5 wt %. The polymers were purified by triple reprecipitation from acetone (PVA, PMMA) and chloroform (PS) into petroleum ether and dried in a vacuum at 30°C to constant weight.

The molecular weight of the polymers was determined with an Ubbelohde viscometer using the Mark–Kuhn–Houwink equation $[\eta] = K_\eta M_\eta^\alpha$ with the constants K_η and α taken from a reference book [5]. Thermal oxidative degradation was studied at



290 ± 5 (PS) and 280 ± 5°C (PMMA, PVA) by thermal gravimetric analysis in the isothermal mode on an installation consisting of a furnace, a torsion balance, and a contact thermometer. The degree of degradation was determined by graphical differentiation of the curves of weight loss vs. time in the time point of 30 min.

Pyrolysis of PS samples was performed at 290°C for 1 h in evacuated sealed glass ampules with a branch in which the decomposition products were condensed at liquid nitrogen temperature. The products were analyzed by gas chromatography–mass spectrometry (GC–MS) on a GC 8000/MD 800 device at an injector temperature of 250°C. The temperature of the chromatographic column HP 5MS, 60 m long and 0.32 mm in diameter, was raised from 70 to 250°C at a rate of 8 deg min^{-1}. The carrier gas was helium of M60 brand. The mass chromatograms were recorded in the range of *m*/*z* 33–350. The substances were identified using the NIST and Wiley databases and the MASSLAB software.

The ^1H NMR spectra of 2% solutions of PMMA in $CDCl_3$ were recorded at 50°C on a Tesla BS-567A NMR Fourier spectrometer operating at 100 MHz. The probability of *meso* addition in the course of MMA polymerization was calculated from the ratio of the areas of CH_3 signals belonging to the hetero- and syndiotactic triads in PMMA.

Figure 1 shows the dependence of MW of polystyrene samples prepared with DS-2 additive and without it on the thermal degradation time. It can be seen that, at similar shape of the curves, the extent to which the MW of the polymer decreases depends on the preparation conditions. The decrease in MW is more pronounced for the PS sample prepared without chain-transfer agent (curve *1*). For the polymer modified with the chain-transfer agent, the limiting MW is considerably higher (curve *2*).

The results obtained can be readily accounted for on the basis of concepts of the recombination mechanism of bimolecular termination of macroradicals in radical polymerization of styrene, with the formation of weak bonds in polymer macromolecules:

According to classical concepts [6], a sharp decrease in MW of the polymer in the initial step of the process, followed by stabilization, indicates that the decomposition of PS macromolecules is initiated by weak bonds. The chain transfer in polymerization

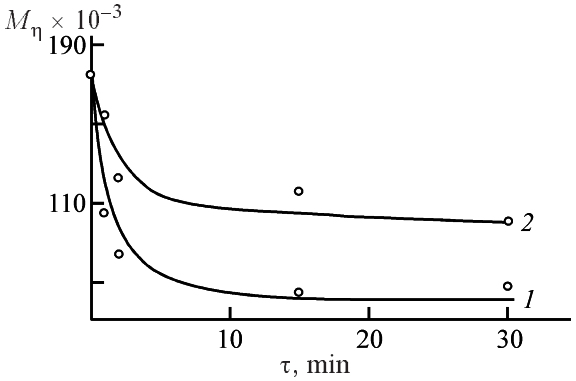


Fig. 1. M_η of polystyrene as a function of the time τ of thermal oxidative degradation at 290°C for the samples prepared by bulk polymerization in the presence of (*1*) 0.05 M AIBN and (*2*) 0.005 M AIBN + 0.4 wt % DS-2.

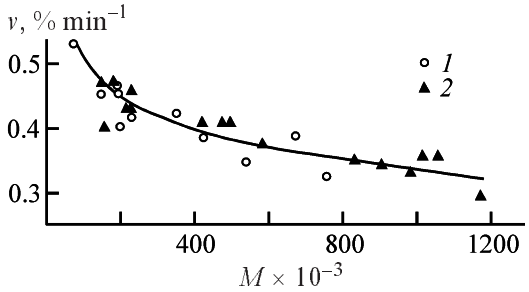

Fig. 2. Rate *v* of thermal oxidative degradation at 290°C as a function of the initial *M* of the polymer for PS samples prepared in the presence of (*1*) various concentrations of AIBN and (*2*) hydrides Et_3SiH, DS-2, DS-5, DS-11, DS-20, DS-23, DS-26, and DS-27.

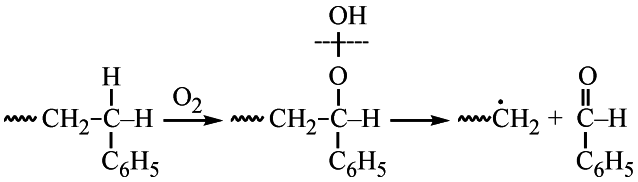
leads to a decrease in the contribution of bimolecular termination involving two propagating styrene radicals and hence in the number of weak head-to-head bonds. As a result, the concentration of radicals initiating the depolymerization decreases.

Figure 2 shows how the rate of thermal oxidative degradation of PS correlates with its MW for the samples prepared at various concentrations of the initiator and chain-transfer agents. It can be seen that, in both cases, with an increase in MW of the polymer the rate of formation of volatiles decreases to an equal extent. Thus, in thermal oxidative degradation of PS, the stabilizing effect exerted by OSHs with respect to variation of MW is not noticeably manifested in the degradation rates. This is apparently due to the fact that in macromolecules modified with OSH, depending on the chemical structure of the chain-transfer agent, one more type of terminal bonds appears: Si–Si, Si–C, or Si–H. These bonds are less strong than C–C bonds [7, 8]. Therefore, the relative content of weak bonds is close in both cases, and hence the total amount of volatile

Table 1. Yield of major pyrolysis products from PS samples prepared in the presence of chain-transfer agent and without it



PS pyrolysis product	Yield of pyrolysis products, %	
	PS without additive	PS + Et_3SiH
Styrene	78	76
Benzaldehyde	7.5	21
Styrene dimer	2.6	0.22

Table 2. Microstructure of PMMA samples prepared in the presence of various silicon hydrides

		syndio	*iso*	*hetero*
None	0.22	0.6084	0.0484	0.3432
DS-1	0.24	0.5776	0.0576	0.3648
DS-2	0.24	0.5576	0.0576	0.3648
DS-9	0.23	0.5881	0.0543	0.3576

degradation products is also close. However, weak bonds of the second type lead to chain cleavage at its termini, which does not appreciably affect the MW of the polymer. Therefore, as noted above, decrease in MW in the course of thermal degradation is more significant for PS prepared without OSH.

The GC–MS studies of volatile pyrolysis products of PS samples prepared without additives and in the presence of triethylsilane showed that the presence of fragments of organosilicon chain-transfer agents in the polymer chain strongly affects the composition of these products. As seen from Table 1, the yield of benzaldehyde noticeably increases in this case. This may be due to increased content on chain termini of units with secondary carbon atom, formed by chain transfer. Therefore, specifically these radicals primarily participate in oxidation leading to the formation of benzaldehyde:

High yield of benzaldehyde is also certainly favored by the chain transfer in the step of thermal degradation involving a Si–H bond of polyfunctional OSHs. Furthermore, the chain microstructure can also affect the occurring reactions, especially intramolecular reactions such as chain transfer in the course of PS degradation with the participation of the hydrogen atom bonded to the tertiary carbon atom in the backbone:

Specifically this reaction determines the yield of styrene dimers in degradation of the polymer: The yield of the dimers is the higher, the higher the probability of intramolecular chain transfer. According to Table 1, for the modified chains this reaction is less characteristic, which may be due to lesser accessibility of the hydrogen atom as a result of changes in the polymer microtacticity. The latter fact was revealed in NMR studies of PMMA samples prepared in the presence of OSHs of various structures (Table 2).

A study of the thermal degradation of PMMA revealed a similar correlation of the degradation rate with MW of the polymer as for PS samples (Fig. 3). According to [6], the thermal degradation of PMMA occurs by the mechanism similar to that of thermal degradation of PS. The reaction starts with cleavage of weak bonds, which is followed by depolymerization of the free-radical fragments. In this case, the weak bonds are terminal allyl groups formed by disproportionation of radicals in synthesis of the polymer. A decrease in the number of events of bimolecular termination due to chain transfer, on the one hand, leads to a decrease in the amount of allyl groups on the chain termini and, on the other hand, gives rise to another type of labile bonds responsible for PMMA depolymerization. As a result, the rate of PMMA degradation increases with a decrease in MW. It is interesting that data for such chain-

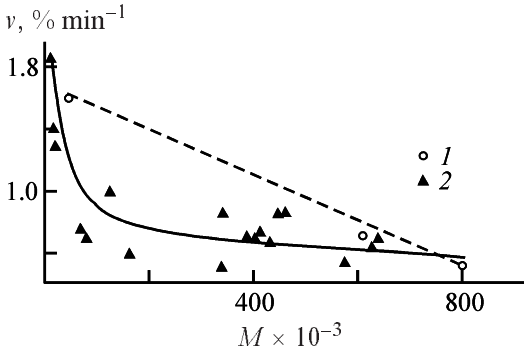

Fig. 3. Rate v of thermal oxidative degradation at 280°C as a function of the initial M of the polymer for PMMA samples prepared in the presence of (*1*) various concentrations of AIBN and (*2*) chain-transfer agents Et_3GeH, Et_3SiH, $C_{12}H_{23}SH$, DS-2, DS-3, DS-5, DS-15, DS-18, DS-20, DS-23, DS-24, and DS-26.

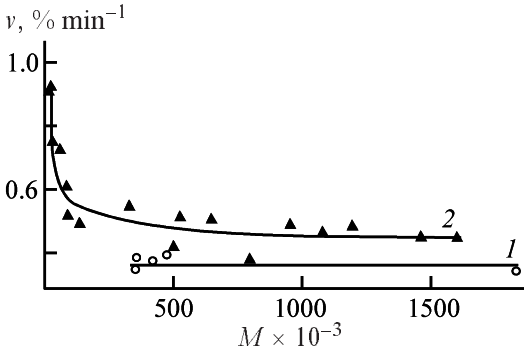

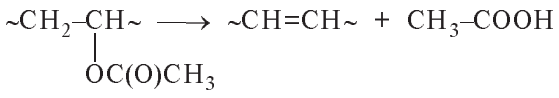

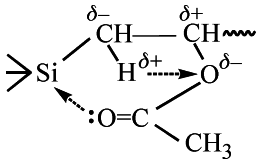

Fig. 4. Rate v of thermal oxidative degradation at 280°C as a function of the initial M of the polymer for PVA samples prepared in the presence of (*1*) various concentrations of AIBN and (*2*) chain-transfer agents Et_3SiH, DS-5, DS-9, DS-11, DS-15, and DS-21.

transfer agents as Et_3GeH and $C_{12}H_{23}SH$ also fall on the common curve. This fact can be readily accounted for, taking into account that the forming covalent bonds C–Ge and C–S are less strong than the C–C bonds in the backbone, because of longer interatomic distance. Along with the strength of terminal bonds, increased fraction of *iso* triads in PMMA samples prepared in the presence of OSHs (Table 2) can give rise to additional strain in the polymer chain and thus decrease the heat resistance.

Thermal degradation of PVA, in contrast to the cases considered above, occurs not via cleavage of the C–C bonds in the backbone but via elimination of pendant substituents by the molecular mechanism with practically 100% yield of acetic acid:

According to the known concept [6], this reaction is not random but is initiated on the macromolecule terminus and propagates along the chain toward the other terminus. Having studied in detail the kinetics of thermal degradation of PVA in a vacuum, Grassie showed [6] that all terminal groups of the polymer, both saturated and unsaturated, formed by disproportionation and chain transfer, participate in the degradation to an equal extent. Therefore, we can expect a decrease in the degradation rate with increasing MW of PVA, due to a decrease in the concentration of terminal groups initiating the degradation. As seen from Fig. 4 (curve *2*), the rate of thermal deacetylation of PVA samples modified with silicon hydrides, indeed, decreases with an increase in MW of the polymer, but only up to M ~200000, and at higher MW the degradation rate becomes essentially independent of MW. Comparison of curves *1* and *2* in Fig. 4 allows an important conclusion that, at equal MW, the polymers prepared in the presence of the chain-transfer agents are less thermostable than those prepared without modifiers. This result can be attributed only to the fact that electrophilic organosilicon fragments activate the PVA degradation via formation of complexes

with the formation of a terminal unsaturated bond and release of acetic acid. In the presence of the latter, the thermal degradation of PVA becomes autocatalytic [7, 8]. This hypothesis is well consistent with the available data [9] that thermal degradation of PVA is accelerated by electrophilic agents.

CONCLUSIONS

(1) Organosilicon chain-transfer agents introduced into polymers accelerate formation of volatile degradation products in thermal oxidative degradation of poly(vinyl acetate) and poly(methyl methacrylate) at 280°C. At the same time, modification of polystyrene chains with organosilicon hydrides does not affect the rate of formation of volatile products in thermal oxidative degradation, but noticeably increases the yields of styrene dimers and benzaldehyde.

(2) Chain-transfer agents can alter the polymer microstructure, thus affecting its heat resistance.

Abstract—The properties of asphalt binder modifiers prepared by dissolving butadiene–acrylonitrile rubbers and their production waste in liquid products of heat treatment of various brands of coal were studied.

DOI: 10.1134/S1070427208070276

The durability of asphalt pavings is mainly determined by their crack resistance. This parameter, especially in Siberia and northern Russia, depends on low-temperature properties of asphalt, i.e., on its frost resistance. The low-temperature properties can be considerably improved by modifying asphalts with additions of synthetic polymers. Synthetic rubbers are widely used as structuring modifiers of asphalts [1–3].

A specific feature of rubbers distinguishing them from other polymers used for modifying asphalts is the capability for large elastic strains. Rubbers consist of macromolecular chains in which thousands of monomeric units are linked in series by covalent bonds. High elasticity of rubbers is due to intrinsic mobility of the system, provided by weak intermolecular interaction of the chains and low crystallinity [4, 5]. Additions of rubbers improve the physicochemical properties of asphalt, making it less brittle, more crack-resistant, and more elastic [6–10].

In polymer–asphalt composites, butadiene–styrene, polyisoprene, polybutadiene, and other rubbers are widely used [1–3, 11–13]. It is well known that the group composition of asphalts determines their properties. Asphaltenes are responsible for the hardness and high softening point; resins, for elasticity and penetration; oils are a medium in which the resins are dissolved and asphaltenes swell [14]. The polymer amount in a polymer–asphalt binder should be thoroughly balanced, because certain amount of asphaltenes is required for forming an associate with the polymer, which increases the yield resistance and softening point. The aromaticity of malthenes (sum of resins and oils) is also important. Increased aromaticity predetermines decreased softening point of the polymer–asphalt binder [15].

An important aspect of modification is the way of introducing rubber into asphalt. In some procedures, synthetic rubbers or their production wastes are added directly to asphalts [4–6]. Along with advantages, such binders also have certain drawbacks: nonuniformity of the composition and low stability in the hot state. Furthermore, the use of nitrile brands of rubber for asphalt modification is limited by their practical insolubility in asphalts [16]. This fact is of particular importance when considering the problem of utilizing wastes from rubber production. In some studies, to eliminate these drawbacks, rubbers are initially dissolved in organic solvents such as kerosene, diesel fuel, black oil, shale oil, or toluene [7, 17, 18], with the subsequent addition of the resulting mixture to petroleum asphalt.

In this study we examined the properties of asphalt binder modifiers prepared from butadiene–acrylonitrile rubbers. As solvents for these rubbers we used liquid products of heat treatment of coals of various brands.

EXPERIMENTAL

To prepare the modifier, we chose a commercial sample of SKN-40 ASM-E butadiene–acrylonitrile rubber [TU (Technical Specification) 38.30313–98] and waste (coagulum) from production of BNKS-28

Table 1. Characteristics of solvents

BND 90/130 asphalt	81.6	18.0	0.4

AMN rubber (TU 38.30313–98) from the Krasnoyarsk Plant of Synthetic Rubber. As solvents we used coal semicoking tar of D brand (TU 2453-001-22931414–96) from the Leninsk-Kuznetskii Semicoking Plant and a high-boiling (>350°C) liquid product of thermal dissolution of V2 brand brown coal from the Kansk–Achinsk coal fields. The coal was subjected to thermal dissolution in petroleum residues at 400°C in an autoclave. The experimental procedure is described elsewhere [19]. Some characteristics of solvents are given in Table 1.

Rubber samples were preliminarily crushed to a particle size of 10–20 mm and dissolved at 100–120°C with continuous stirring. The resulting rubber-containing component was used as modifier for BND-90/130 petroleum asphalt products by the Achinsk Oil Refinery, Joint-Stock Company. The physicochemical characteristics of the modifiers, initial asphalt, and asphalt–rubber binders obtained were determined by standard procedures applied to petroleum asphalts [20–23]. The aging resistance of organic binders was determined as resistance to heating at 163°C for 5 h [24], evaluated by the weight loss and changes in the penetration and softening point.

The IR spectra were recorded with a Bruker Vektor 22 spectrometer in the range 500–3500 cm^{-1} from thin films.

Studies of the solubility of the chosen rubbers in liquid products of thermal transformations of coals showed that the optimal concentration of the polymers in solution is 30 wt %. At this concentration, the process occurs within less than 1 h, and a homogeneous mixture readily miscible with petroleum asphalts at 100–120°C is formed.

The group composition of bitumen modifiers is given in Table 2. Data for BND 90/130 petroleum asphalt, obtained by averaging the results of laboratory tests of commercial batches of BND 90/130 asphalt produced during a period of 2 years, are given for comparison.

Typical IR spectra of the asphalt and three samples of the modifiers are shown in Fig. 1. The spectra of all the modifiers contain an absorption band in the range of stretching vibrations of the C≡N group at 2240 cm^{-1}, characteristic of nitrile rubbers. The spectra show that all the modifiers, in contrast to petroleum asphalt mainly consisting of paraffin hydrocarbons, are complex mixtures of organic substances with a high content of aromatic compounds. This is confirmed by high intensity of absorption bands in the range of stretching vibrations of C–H bonds in aromatic structures at 3050 cm^{-1} and of out-of-plane bending vibrations of C–C bonds in aromatic rings at 1590 cm^{-1}. The high content of aromatic compounds in the modifiers is well

consistent with the results of group analysis (Table 2) and is, apparently, the consequence of using products of heat treatment of coals and lignites as solvents in preparing the modifiers. One more significant difference of the modifiers from the asphalt is the high content of oxygen-containing compounds giving rise to strong bands in the ranges of absorption of hydroxy and carbonyl groups (3600–2100, 1700–1550 cm^{-1}) and at 1000–1300 cm^{-1} (phenolic hydroxyls, ethers, alcohols).

Comparison of the spectra of various modifiers with each other suggests considerably higher content of oxygen-containing compounds (alcohols, acids) in M-3 modifier. This is apparently associated with the procedure and temperature conditions of preparation of coal solvents for modifiers.

The results of tests of BND 90/130 asphalt with additions of modifiers are given in Tables 3 and 4. These data show that M-1 and M-2 modifiers considerably decrease the brittle point of asphalt and increase the extensibility, especially at 0°C. The use of such modifiers allows preparation of asphalt concrete resistant to cracking in the winter period. The effect of M-3 modifier on brittle point is insignificant, but this modifier increases to a greater extent the extensibility of the asphalt, making it more plastic.

Measurements of the ring-and-ball softening point (Table 4) showed that its change for the initial asphalt after heating, compared to the value before heating, is beyond the limit prescribed by GOST (State Standard), 6°C, i.e., the asphalt used in the study does not pass the aging test. Samples of the composite binder with the modifier content exceeding 5 (M-1, M-2) and 2.5 wt % (M-3) are also unstable in this test. Samples containing 5 wt % M-1 or M-2, or 2.5 wt % M-3 showed the change in the softening point by 2.5, 5.5, and 5.5°C, respectively. These data show that the modifiers inhibit oxidative aging of the organic binder. Measurements of the change in the penetration upon aging (Table 4) show that heating of composite binder samples containing no more than 5 wt % modifiers does not affect this parameter significantly.

Figure 2 shows the time dependence of the weight loss of composite binders modified with products of thermal dissolution of coal, lignite, and synthetic elastomers, monitored in the course of aging tests at 163°C. As seen from Fig. 2, additions of M-2 and especially M-3 modifiers cause larger weight loss upon heating, compared to the initial asphalt.

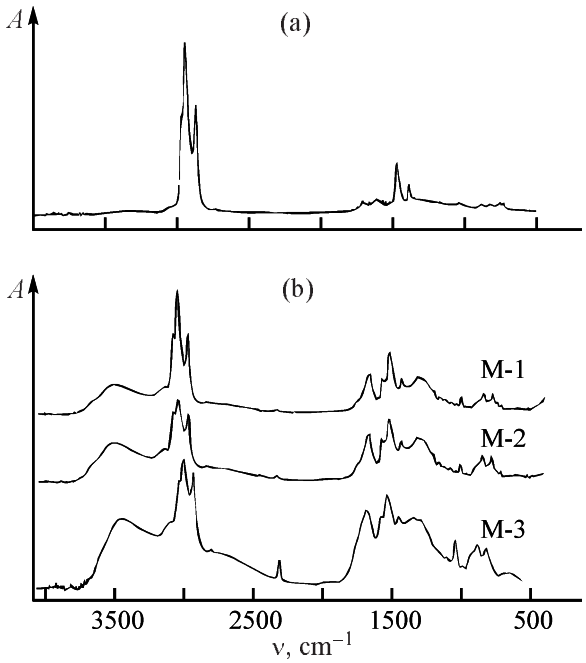

Fig. 1. IR spectra of (a) BND 90/130 asphalt and (b) M-1, M-2, and M-3 modifiers of the asphalt–rubber binder. (*A*) Absorption and (ν) wavenumber.

Apparently, addition of 7.5 wt % modifiers and more lead to thinning of asphalt, and evaporation of low-boiling fractions of both the asphalt and modifiers becomes the prevalent process. This means that the optimal content of additives in the modified asphalt should not exceed 5 wt %.

Among the modifiers obtained, M-3 is the most

* (P_{25}) Penetration at 25°C; (T_s) softening point.
** Binder: asphalt + additives 100; M-1, 30 wt % coagulum; M-2, 30 wt % nitrile rubber.

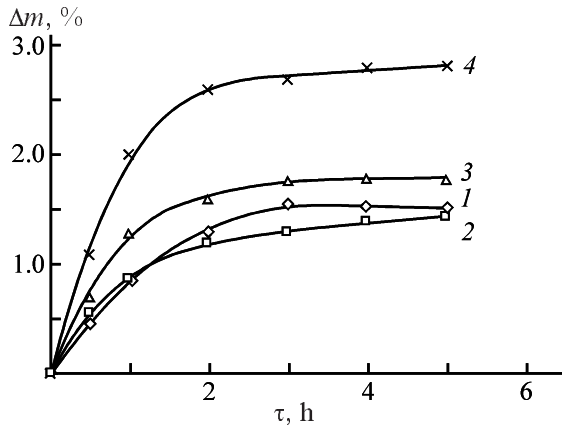

Fig. 2. Weight loss Δm (%) of composite binders modified with products of thermal dissolution of coal, lignite, and synthetic elastomers, monitored in the course of aging tests (163°C). (τ) Heating time. (*1*) Initial BND 90/130 asphalt and (*2–4*) asphalt containing 7.5 wt % modifier: (*2*) M-1, (*3*) M-2, and (*4*) M-3.

fluid (T_s <28°C, P_{25} 250). Therefore, its addition causes pronounced thinning of the asphalt, and the asphalt containing this modifier in an amount of 10% passes to the BND 130/200 grade, which is undesirable for upper layers of the pavement.

CONCLUSIONS

(1) Road asphalt modifiers were prepared by dissolving butadiene–acrylonitrile rubbers and their production waste (coagulum) in liquid products of thermal transformation of coals, characterized by increased aromaticity as compared to products of petroleum origin.

(2) Additions of 2.5–5.0 wt % modifiers obtained to BND 90/130 asphalt decrease its brittle point and enhance the aging resistance.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Polymeric System Based on Wastes from Production of Butyl Alcohols and KORS Copolymer

O. N. Filimonova and M. V. Enyutina

Voronezh State Academy of Technology, Voronezh, Russia

Received May 23, 2007

Abstract—A polymer system based on KORS copolymer and RS solvent prepared from wastes from production of butyl alcohols was studied. The RS solvent can replace butyl acetate and xylene, with improvement of the physicomechanical properties of the coatings obtained.

DOI: 10.1134/S1070427208070288

Polymeric materials are multicomponent systems based, in the overwhelming majority of cases, on solutions in organic solvents. The preparation conditions and quality of polymeric coatings largely depend on propeties of the starting materials, which should meet the following requirements: possibility of distribution on the substrate surface as a thin layer, capability for film formation, and formation of coatings with the desired properties [1].

Production and use of polymeric materials involves consumption of enormous amounts of organic solvents [2]. Virtually the whole amount of them is irretrievably lost in the course of coating application, giving rise to environmental and economical problems. Powder and water-dispersible polymeric coatings used today solve these problems, but powder polymeric materials are unsuitable for domestic use because they require special equipment for application, and their decorative properties are poor. Water-dispersible polymeric formulations can be efficiently applied only in the warm period of year, and water-soluble surfactants present in them reduce the protective properties of the coatings. Therefore, one of the main avenues of the progress of the varnish-and-paint industry today is the development of polymeric formulations with decreased content of organic solvents, search for new solvents of low toxicity and for new sources of raw materials, and development of new processes for their production [3–5].

The dissolution of film-forming substances is determined by the chemical composition and structure of the film-forming agent and by the chemical nature and thermodynamic characteristics of the solvents used [6, 7].

EXPERIMENTAL

RS solvent can be prepared from wastes from production of butyl alcohols [8]. Its composition was determined by functional analysis and gas–liquid chromatography. The composition and characteristics of major components of RS solvent are given in Table 1. The main component is isobutyl acetate used in the formulations instead of butyl acetate and cyclohexanone. The content of isobutyl acetate in RS solvent reaches in some batches 75 wt %.

Formic and acetic acid esters entering into the composition of RS solvent dissolve cellulose esters, chlorinated rubber, vinyl polymers, and carbinol and other resins; they are well miscible with many solvents used in production of nitrocellulose varnish-and-paint materials (VPMs) [9].

Isomers of butyl alcohols, whose content in the solvent reaches 4.5 wt %, in a mixture with ethanol are used for dissolving urea–formaldehyde oligomers and polyvinylbutyral, and in a mixture with xylene, for dissolving polyacrylates. They are added to the majority of mixed solvents to enhance their solvency, improve the adhesion of coatings owing to a decrease in the surface tension, prevent the films from becoming turbid or white, and facilitate pouring of lacquers and enamels by decreasing their viscosity.

RS solvent contains large amounts of butyl ethers, mainly of dibutyl ether. Butyl ethers are used as solvents for certain film-forming agents [9], mainly

Table 1. Characteristics of components of RS solvent

Component	Weight fraction of component, %	Heat of vaporization, kJ mol^{-1}	Solubility parameter, $(MJ\ m^{-3})^{1/2}$
Isobutyl acetate	50.0–75.0	39.25	16.62
Butyl acetate	3.0–15.0	40.56	17.02
Isobutyl alcohol	0.5–3.0	50.83	22.97

Weight fraction of water after Fischer, %, GOST 14870–77	0.2	0.7	0.2–0.8

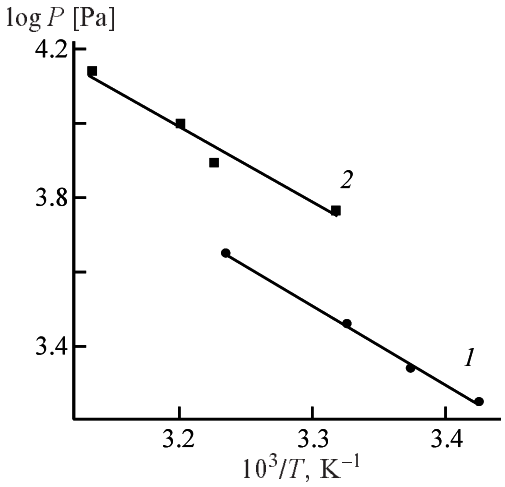
as components of mixed solvents. To evaluate the structure and properties of polymeric systems, it is necessary to study the main physicochemical properties of RS solvent as applied to (co)polymer solutions. Both individual and mixed solvents should have certain properties prescribed by state standards. According to GOST (State Standard), the following solvent parameters should be regulated: acid number, weight fraction of water after Fischer, volatility with respect to diethyl ether, and coagulation number. The physicochemical properties of RS solvent in comparison with those of butyl acetate and R-5 solvent are given in Table 2.

As follows from Table 2, RS solvent is characterized by a wider range of volatility values compared to butyl acetate and R-5 solvent. However, as RS solvent is a mixture of components, it is possible to provide, if necessary, the same volatility as that of butyl acetate or R-5 by varying the composition. This can be ensured by technological organization of the process for RS production. The coagulation number of RS solvent considerably exceeds the level prescribed for R-5, which is an advantage. The acid number and weight fraction of water after Fischer for RS solvent meet the requirements formulated for R-5 solvent.

Thus, RS solvent can replace butyl acetate as a component of R-5 solvent. It can also serve as a component of a mixed solvent or as a solvent itself. Meeting the existing requirements, RS solvent can be used for preparing solutions of (co)polymers.

According to published data [9], an efficient characteristic of the solvent and dissolved (co)polymer is the "three-dimensional" solubility parameter δ. To estimate the solubility of a film-forming agent in a solvent, their solubility parameters are compared. The closer these parameters, the higher the solvency of the given solvent with respect to the polymeric material. The parameter δ of a solvent is estimated from its heat of vaporization. In so doing, δ is deter-

Table 3. Composition of samples of RS solvent, wt %



Component	Composition, wt %	
	sample 1	sample 2
Isobutyl acetate	72.3	52.1
Butyl acetate	2.6	8.8
Isobutyl alcohol	1.4	0.9

Unidentified components	0.3	0.5

mined either by calculation from the heats of vaporization ΔH of the mixture components, taking into account their mole fractions, or from the experimentally determined ΔH. In our study we used the second approach.

Experimental determination of the heat of vaporization ΔH, required for calculating the solubility parameter δ, was performed for two RS samples (Table 3) characterized by the isobutyl acetate content close to the lower (52.1 wt %, sample no. 1) and upper (72.3 wt %, sample no. 2) limits of the range. The temperature dependence of the saturated vapor pressure P is described by the equation

$$\ln P = -\Delta H/(RT) + B \text{ or } \log P = -A/T + B, \quad (1)$$

$$A = \Delta H/(2.303R) = \Delta H/(2.303 \times 8.314) = \Delta H/19.147, \quad (2)$$

Logarithm of the saturated vapor pressure $\log P$ as a function of reciprocal temperature for RS solvent sample nos. (*1*) 1 and (*2*) 2.

where ΔH is the heat of vaporization, J mol^{-1}; P, saturated vapor pressure, Pa; T, temperature, K; and B, integration constant.

Equation (1) corresponds to the linear dependence of $\log P$ on $1/T$. The heat of vaporization can be calculated from the coefficient A determined by the least-squares method: $\Delta H = A \times 19.147$. The saturated vapor pressure was determined by the dynamic method. The installation consisted of a vessel placed in a thermostat with distilled water and connected to a vacuum system through a condenser in which the vapor of the liquid being studied was condensed. To measure the vapor pressure, the installation was evacuated until the liquid started to boil. After that, the system was connected with the atmosphere. In 5 min, the readings of the thermometer and open manometer were recorded. Measurements were performed at 4–5 K steps starting from room temperature. The experimental results for the two samples were plotted on the scale of $\log P$ vs. $1/T$ (see figure). The dependences are clearly linear and are described by the regression equations of type (1):

$$\log P_1 = 10.75 - 2189.59(1/T), \quad (3)$$

$$\log P_2 = 10.63 - 2064.30(1/T). \quad (4)$$

In both cases, the equations are characterized by the sample correlation coefficient $r \approx 1.00$.

The heat of vaporization ΔH calculated by formula (2) is 41 920 J mol^{-1} for sample no. 1 and 39 530 J mol^{-1} for sample no. 2, which may be due to higher content of more volatile ethers in sample no. 2. As the difference between the heats of vaporization of sample nos. 1 and 2 was insignificant, in what follows we used the mean value, ΔH = 40 725 J mol^{-1}. The linear character of regression equations (3) and (4) allows the experimental heat of vaporization of RS solvent to be used in the subsequent calculations by analogy with individual substances. From the experimentally determined ΔH, the solubility parameter is calculated by the formula [9]

$$\delta^2 = (\Delta H - RT)/V,$$

namely,

$$\delta = [(40\,725 - 8.3144 \times 298)/135.12]^{1/2}$$

$$= 16.82 \text{ (MJ m}^{-3})^{1/2}.$$

The results of experimental determination of the

solubility parameter of RS solvent are consistent with the results obtained by calculation [δ_m = 16.72–16.94 $(MJ\ m^{-3})^{1/2}$], so that both calculated and experimental data can be used in further studies of the properties of RS solvent.

Comparison of the solubility parameter of RS solvent with those of butyl acetate and isobutyl acetate [δ = 17.02 and 16.62 $(MJ\ m^{-3})^{1/2}$, respectively] suggests the possibility of replacing butyl acetate and isobutyl acetate in polymeric systems by RS solvent.

According to the Hildebrand–Scatchard theory, the components are infinitely mutually soluble if the molar enthalpy of mixing ΔH is low:

$$\Delta H = (\delta_1 - \delta_2)^2 V_1 \varphi_1 \varphi_2,$$

where δ_1 and δ_2 are the solubility parameters of the components $[(MJ\ m^{-3})^{1/2}]$; V_1 is the mixture volume (m^3); and φ_1, φ_2 are the volume fractions of the components.

According to the Flory–Huggins theory [6], the solute–solvent interactions and miscibility are characterized by an empirical parameter x defined as

$$x = x_s + V(\delta_1 - \delta_2)^2/RT,$$

where x_s is the parameter taking into account entropy phenomena and varying from 0.05 to 0.20; V is the molar volume of the solvent; δ_1 and δ_2 are the solubility parameters of the film-forming agent and solvent.

The maximal value of x corresponding to full miscibility of a (co)polymer and a solvent with the formation of a homogeneous solution should not exceed 0.5 at any ratios. For polymers of relatively low molecular weight, mixing is also possible at somewhat higher values of x (usually at $x \le 0.55$). Taking into account the solubility parameter of the polymers, we determined the values of x in the polymer–solvent systems for certain polymers (Table 4). It can be seen that the parameters x of RS solvent with these copolymers are close to those of butyl acetate. Hence, RS solvent can be recommended for replacement of butyl acetate in complex polymeric systems.

One of the parameters characterizing the polymer–solvent system is the intrinsic viscosity. It is related to the molecular weight of the dissolved polymer M by the formula

$$[\eta] = KM^{\alpha}, \quad (5)$$

Table 4. Solubility parameters of polymers and parameters x in various polymer–solvent systems at x_s = 0.1 and T = 298 K

Film-forming agent	Solubility parameter, $(MJ\ m^{-3})^{1/2}$	Parameter x	
		RS solvent	butyl acetate

Poly(methyl methacrylate)	18.3	0.20	0.19
Fatty alkyd	19.2	0.36	0.35
Vinyl chloride (40 wt %) copolymer	18.9	0.31	0.29

where K and α are constants for the given polymer–solvent system.

The better the solvent, the higher α and the lower K [9]. Comparison of the constants α and K for the systems of a (co)polymer with various solvents allows evaluation of the solvent quality with respect to the given (co)polymer. To determine α and K, it is appropriate to take the logarithm of Eq. (5):

$$\log[\eta] = \log K + \alpha \log M. \quad (6)$$

The intrinsic viscosity [η] was measured in the systems KORS copolymer–xylene and KORS copolymer–RS solvent, with KORS copolymer samples of various average molecular weights. KORS copolymer is one of the kinds of petroleum polymeric resins widely used in formulations for preparing corrosion-protective coatings. It was prepared from styrene distillation bottoms by thermal copolymerization with maleic anhydride. KORS copolymer is a random atactic copolymer of styrene with maleic anhydride containing about 3.0 wt % maleic anhydride. The content of residual styrene monomer does not exceed 0.1 wt % [10].

The average molecular weight was calcuated from the molecular-weight distribution of the copolymer, determined on a (UONTRS-200)-POLISTIROL device. The molecular weights M_v of copolymer samples were calculated by the formula

$$M_v = \sum_{i=1}^{n} P_i M_i / \sum_{i=1}^{n} P_i,$$

where P_i is the content of the polymer with the

Table 5. Mean molecular weights of KORS copolymer

Sample no.	Molecular weight M_v	$\log M_v$
1	15 400	4.1875
2	17 500	4.2430
3	23 600	4.3729
4	34 100	4.5328

Table 6. Calculated intrinsic viscosities for the systems KORS copolymer–xylene and KORS copolymer–RS solvent

Molecular weight of KORS copolymer M_v	Intrinsic viscosity $[\eta]$	$\log[\eta]$
KORS copolymer–xylene		
M_1 = 15 400	0.2180	–0.6635
M_2 = 17 500	0.2480	–0.6055
M_3 = 23 600	0.3054	–0.5151
M_4 = 34 100	0.3988	–0.3992
KORS copolymer–RS solvent		
M_1 = 15 400	0.4589	–0.3389
M_2 = 17 500	0.4818	–0.3171
M_3 = 23 600	0.6065	–0.2172
M_4 = 34 100	0.8728	–0.0591

molecular weight within the given interval in the polymer mixture (%); n, number of intervals of molecular weights; and M_i, molecular weight M_v for the ith interval of molecular weights of the polymers.

The calculated average molecular weights of copolymer samples, calculated by formula (7), are given in Table 5. From these samples of KORS copolymer, we prepared solutions of five concentrations in xylene and RS solvents and measured, using an Ostwald–Pinkevich viscometer, the average outflow times of the pure solvent (τ_0) and polymer solutions (τ). From the experimental results, we calculated the relative viscosity $\eta_{rel} = \tau/\tau_0$, specific viscosity $\eta_{sp} = (\tau - \tau_0)/\tau_0 = \eta_{rel} - 1$, and reduced viscosity $\eta_r = \eta_{sp}/c$, where c is the concentration of the polymer solution, g (100 cm^3)$^{-1}$.

The intrinsic viscosity is determined by the formula

$$[\eta] = \lim_{c \to 0} \eta_{sp}/c$$

by extrapolation of the experimental dependence of η_{sp}/c to zero concentration (Table 6).

Having transformed Eq. (6) to the form

$$Y = a_0 + a_1 x$$

($Y = \log[\eta]$; $x = \log M_v$; $a_0 = \log K$; $a_1 = \alpha$), we determined by the least-squares method the unknown parameters a_0 and a_1 and, from these quantities, the constants K and α.

For the KORS copolymer–xylene system, $K = 1.61 \times 10^{-4}$, $\alpha = 0.75$; for the KORS copolymer–RS solvent system, $K = 1.56 \times 10^{-4}$, $\alpha = 0.83$.

The differences between the values of K for polymer solutions in xylene and RS solvent do not exceed 5% of the minimal values, i.e., the values of K for KORS copolymer in xylene and RS solvents are essentially similar. The constants α in these systems differ to a greater extent, by more than 10% of the minimal value. The constant α for the KORS copolymer–RS solvent system is higher than that for the KORS copolymer–xylene system, suggesting higher solvency and performance of RS solvent compared to xylene [9]. The use of RS solvent allows the solvent assortment to be expanded and the physicomechanical properties of coatings to be improved [11].

CONCLUSIONS

(1) RS solvent prepared from wastes from production of butyl alcohols meets the requirements to solvents for varnish-and-paint materials.

(2) A comparative estimation of the solubility of (co)polymers in RS solvent and butyl acetate, based on the solubility parameters, was made, and the possibility of replacing butyl acetate by RS solvent in polymeric systems was assessed.

(3) A polymeric system based on KORS copolymer (waste from styrene production) and RS solvent was studied, and RS solvent was shown to exhibit higher performance compared to the commonly used xylene.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Potentiometric Titration of Lignosulfonic Acids

N. V. Shul'ga, L. A. Gomolko, and N. P. Krut'ko

Institute of General and Inorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received December 11, 2007

Abstract—The conditions of potentiometric titration of lignosulfonic acids allowing quantitative determination of strongly and weakly acidic functional groups in lignosulfonates were determined.

DOI: 10.1134/S10704272080702 9X

Lignosulfonic acids (LSAs) are complex and poorly studied compounds. The analytical procedures existing today allow fairly accurate determination of the majority of functional groups in lignins, precursors of lignosulfonates [1]. Differentiation of acid groups in lignin and its derivatives is complicated because of wide range of their ionization constants and of certain specific features related to macromolecular structure of lignin, such as accessibility of acid functional groups [2, 3].

In this study we made an attempt to find potentiometric titration conditions that would furnish evidence for the existence of acid groups of different strenghths in lignosulfonates and allow their quantitative determination.

EXPERIMENTAL

As starting material for preparing LSAs we used technical-grade lignosulfonates (LSTs) from the Sokol Pulp-and-Paper Combine. Their characteristics and the conditions for their purification and synthesis of LSAs are described in detail in [4].

In potentiometric titration of LSAs, we used as solvents distilled water, mixed aqueous–organic solvent (water, ethanol, and acetone taken in 35 : 21 : 4 volume ratio), and dimethyl sulfoxide (DMSO) of chemically pure grade. As base titrant we used an aqueous or aqueous–alcoholic (1 : 19) NaOH solution (0.06–0.75 N).

When choosing the solvent, we took into account the fact that the apparent strength of acids and bases depends on the extent of their interaction with the solvent. In aqueous medium, the leveling effect of the solvent smears the inflection points in potentiometric titration curves because of close ionization constants of acids of different strengths in water and hydrolysis of the forming salt of a weak acid. However, this factor does not prevent determination of the total amount of acidic protons.

In nonaqueous titrations (in DMSO), we did not make special efforts to remove residual water (about 1 wt %) from the mixture being titrated. It is known that glass electrodes in many organic solvents give unstable data, and small amounts of H_2O stabilize the pH-meter readings [5]. Furthermore, an experiment showed that dry LSA is practically insoluble in water and DMSO. Therefore, in some cases in titration of more saturated (~2%) solutions of lignosulfonic acid in DMSO, to decrease the water content of the mixture being titrated, a sample of LSA aqueous solution containing 20–23 wt % dry matter was transferred into a titration beaker and carefully evaporated at 35–40°C to a resinous state, after which the organic solvent (60–80 ml) was added and the titration was started.

Titration was performed at room temperature wich continuous stirring in a flow of an inert gas (He or N_2) after its passing through a column packed with KOH. As indicator electrode we used an ESL 43-07 electrode. The reference electrode was an EVL-1-M3 silver chloride electrode filled with a saturated aqueous KCl solution. According to the existing experience [6], the glass electrode is preferable in titration of model lignin compounds in DMSO and DMSO–water mixtures.

The EV-74 pH meter was calibrated using standard buffer mixtures. The correctness of readings was checked every time before the measurements.

The base titrant was added to an LSA solution in

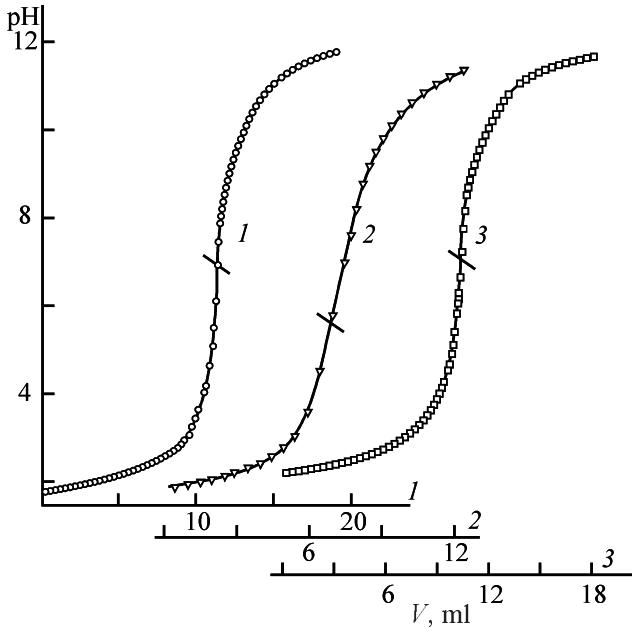

Fig. 1. Potentiometric titration curves of (*1*) LSA1, (*2*) LSA2, and (*3*) LSA4 in aqueous medium. Acid amount in solution, mg: (*1*) 200, (*2*) 223, and (*3*) 151. Titrant concentration, g-equiv l^{-1}: (*1*, *2*) 0.060 and (*3*) 0.068. (*V*) Titrant volume; the same for Figs. 2 and 3.

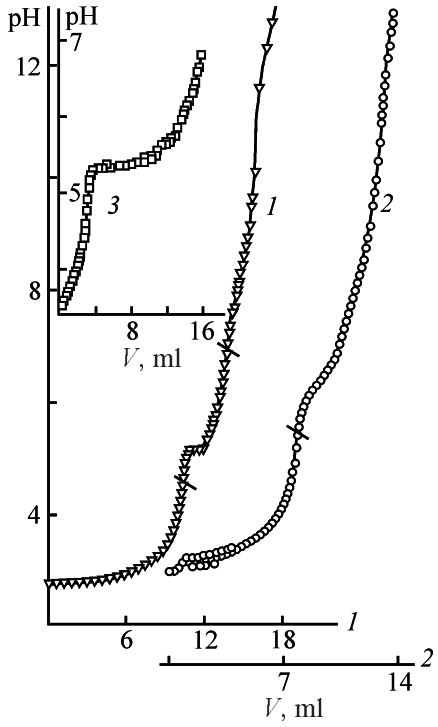

Fig. 2. Potentiometric titration curves of (*1*, *3*) LSA1 and (*2*) LSA4 in DMSO. Acid amount in solution, mg: (*1*) 248, (*2*) 192, and (*3*) 991. Titrant concentration, g-equiv l^{-1}: (*1*, *3*) 0.060 and (*2*) 0.068.

0.1-ml portions, and in the vicinity of the neutralization point, in 0.025-ml portions. Each subsequent portion of the titrant was added only after attainment of the equilibrium in the system and stabilization of the pH-meter readings. Usually this took 6–8 min.

The data obtained show that a mixed aqueous–organic solvent containing alcohol or acetone cannot be used for titration of lignosulfonic acids. Although the starting LSA readily dissolves in ethanol, the neutralization product, sodium lignosulfonate, is salted-out even in cases when the fraction of the organic component in the mixed aqueous–organic solvent does not exceed 40 vol %. The oily product deposited on the electrodes does not allow correct pH measurements.

The problem is easily solved with DMSO. This is an aprotic bipolar solvent (pK_S 18, $\varepsilon = 40$) [7]. The experimental data show that it does not enter into undesirable side reactions with lignosulfonates, and no precipitation is observed even in titration with an aqueous–alcoholic (1 : 19) NaOH solution.

It should be noted that the titration conditions chosen (electrode type, titrant, presence of small amounts of water in the mixture being titrated) do not allow determination of the concentration of phenolic hydroxyls, functional groups exhibiting weakly acidic properties.

Figures 1 and 2 show the potentiometric titration curves of samples LSA1, LSA2, and LSA4 in aqueous solution and in DMSO. In all cases, the equivalence point was found from the differential plots $\Delta pH/\Delta V–V$, where V is the spent titrant volume.

Titration in an aqueous medium (Fig. 1) allows determination of the total amount of strongly and weakly acidic functional groups in lignosulfonates (Table 1). The results obtained are well consistent with the content of metals (Zn^{2+}, Mn^{2+}, Co^{2+}, etc.) in lignosulfonic acid salts prepared by ion exchange or neutralization of LSAs with the corresponding carbonates. For example, in LSA1 salts we found (mg equiv g^{-1}) 3.44 Na^+, 3.37 Mn^{2+}, 3.41 Co^{2+}, and 3.46 Fe^{3+}, which is well consistent with the content of mobile protons (3.49 mg-equiv g^{-1}) in lignosulfonic acid sample LSA1 (Table 1).

Calculations based on data of [6] show that the activity (concentration) of H^+ ions in an aqueous–organic solution containing 90% DMSO and a weak carboxylic acid decreases by a factor of no less than 300 compared to the aqueous solution. Dissociation

Table 1. Chemical composition of lignosulfonic acids*

Sample	N	C	S	S, mg-equiv g^{-1}	H^+, mg-equiv g^{-1}		Atomic ratio			
	wt %				total	strongly acidic	N	C	S	H^+
LSA1	0.433	40.465	8.693	2.72	3.49	2.62	1.14	124.15	10.00	12.85
LSA2	1.110	52.925	6.009	1.88	1.88	1.88	4.22	234.82	10.00	10.01
LSA4	0.374	43.445	8.779	2.74	4.61	2.67	0.97	131.99	10.00	16.8

* The absolute determination error is less than 0.02 wt % for N, 0.05 wt % for C, 0.08 wt % for S, and 0.03 mg-equiv g^{-1} for H^+.

of strongly acidic groups in an organic solvent is suppressed to a considerably lesser extent. As follows from Table 2, the concentration of free protons in a 1% solution of LSA1 in DMSO decreases, compared to aqueous solution, by a factor of less than 10.

Replacement of water by DMSO affects the character of interaction of lignosulfonates with the solvent and suppresses dissociation of weakly acidic groups. As a result, no less than two inflection points corresponding to neutralization of strongly and weakly acidic functional groups become resolved in the potentiometric titration curve (Fig. 2).

In some cases, to attain clear separation of portions of the potentiometric titration curve as an indubitable evidence of the presence of weakly acidic groups in lignosulfonic acids, an LSA sample (~1 g in terms of dry matter) after preliminary evaporation was neutralized to pH ~3–4 with a concentrated alkali solution, and the mixture was kept in a hermetically sealed vessel for several days, after which it was titrated with a dilute alcoholic solution of the titrant (Fig. 2, curve *3*).

By varying the titration conditions (LSA weighed portion, LSA and titrant concentrations), it is possible to attain good separation of portions of the potentiometric titration curves and estimate the content of strongly acidic groups in lignosulfonates (Table 1, Fig. 2). It should be noted that in LSA1 and LSA4 samples about 0.67 mg-equiv g^{-1} of labile protons are bound to the sulfate anion. It was shown previously [4] that salting-out with organic solvents leads to precipitation of sulfates simultaneously with lignosulfonates.

Table 2. pH of LSA1 solutions in aqueous and organic solvents

Solvent	ω_{LSA}, wt %	pH	$c_{H^+} \times 10^3$, M
Water	1.0	1.72	19.1
Water–alcohol–acetone	1.0	2.06	8.7
DMSO	1.0	2.70	2.0
	2.4	2.47	3.4

In titration of the LSA2 sample, the shape of the potentiometric curve remained unchanged irrespective of the solvent (water or DMSO, Fig. 1, curve *2*). Titration of large LSA2 portions by the procedure described above revealed no changed in the monotonic shape of titration curves, either, and the content of acid groups found (~1.88 mg-equiv g^{-1}) strictly corresponded to the sulfur content (Table 1). The data obtained indicate that LSA2 contains no acid groups other than sulfonic acid groups. This, however, does not mean that the initial lignosulfonates could not contain carboxy groups. It was shown previously [4] that the chemical composition of lignosulfonates depends on the procedure of their recovery from the crude product.

Experiments on assessing the possibilities of potentiometric titration as applied to LSA analysis showed that titration in a mixed aqueous–organic medium gives the best results. The optimum is 10% water content in DMSO in the final steps of titration. In this case, acids of different strengths are well resolved, the pH-meter readings are stable, the titration can be performed with a fairly high accuracy, and reliable data on the nature and amount of acid groups in lignosulfonates can be obtained. The positive effect of small water additions is attributable to the following processes.

It is known that, for dissociation and neutralization processes to occur, a solvent is required. The ease of ionization of acid groups in inorganic and low-molecular-weight organic compounds is largely determined by the basic character of the solvent as proton acceptor and by its dielectric constant. The degree of ionization of an acid and its dissociation constant depend on the solvent, its chemical composition, and size and configuration of the molecules.

When macromolecular compounds of network structure, with complex mutual orientation of molecular fragments and substituents, are concerned, it is also impossible to eliminate the effect of steric factors on the results of quantitative analysis. Apparently, neutralization of acid groups in LSAs occurs in cases when they are readily accessible to solvated ions of the titrant. In this sense, water can be considered as universal solvent, but with DMSO the pattern is apparently different. Molecules of this compounds have the size comparable with that of structural units and substituents in LSA, and solvation of titrant ions with DMSO molecules gives rise to additional hindrance. As a result, steric hindrance may arise in titration of the most difficultly accessible acid groups of LSA.

Another factor that can prevent dissociation of weaker carboxy groups can be insufficiently high, compared to water, proton-acceptor power of DMSO. Furthermore, replacement of aqueous medium by an organic medium can appreciably affect the colloidal properties of LSA solutions, including the molecular conformation in solution, density of coils, and accessibility of functional groups.

Figure 3 confirms the above assumptions. The experimental results were obtained under static conditions. In the first step of titration, to a mixture containing an aliquot of DMSO and a portion of LSA1 dehydrated to a resinous state, we addded the required amount of an alcoholic solution of the titrant. The vessel was hermetically stoppered, and its contents were thoroughly mixed and kept for a long time with intermittent pH measurements. With an increase in the neutralization time, the potentiometric curve portion corresponding to titration of weakly acidic groups shifted toward lower pH values (Fig. 3, curves *1*, *2*). In the step of titration of sulfonic acid groups, the equilibrium pH value was attained considerably faster.

On adding portions of water (~12% of the liquid volume) to the mixtures being titrated, the pH-meter readings in the step of titration of sulfonic acid groups quickly stabilized (Fig. 3, curve *3*) and then remained unchanged. However, in the step of titration of weakly acidic groups, certain time was required to attain the equilibrium pH values. The ascending portion of the potentiometric curve, corresponding to the titration of a weak acid, shifted toward lower pH values. This means that addition of a more polar solvent favored "opening" of the weakest acid groups and titration completion.

Specific features of potentiometric titration in

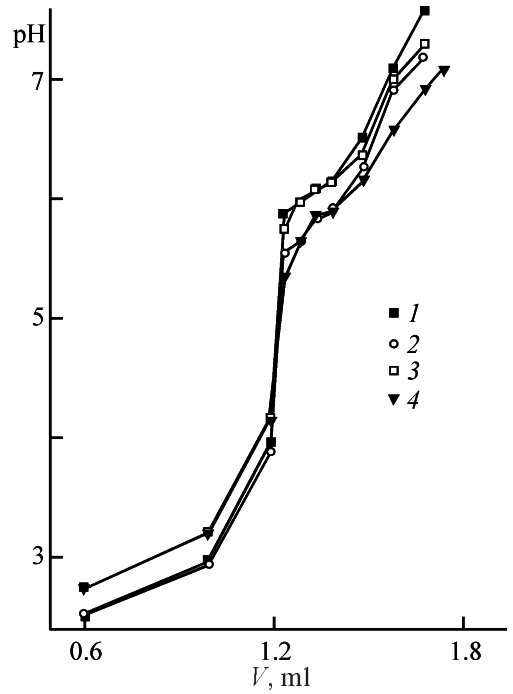

Fig. 3. Potentiometric titration curves of LSA1 in (*1*, *2*) organic and (*3*, *4*) aqueous–organic solutions. Acid amount 375 mg, titrant concentration 0.75 g-equiv l^{-1}. Storage time, days: (*1*) 2, (*2*) 20, and (*4*) 30.

DMSO (properties of electrodes and organic solvent) do not allow the titration to be performed to completion, with flattening out at pH > 11 as in titration in an aqueous medium (Figs. 1, 2), which somewhat complicates determination of the position of the equivalence point and of the total content of acids of different strengths in the sample, but does not prevent determination of strongly acidic groups (Fig. 2). Their amount corresponds to the sulfur content of the samples (Table 1). This means that practically the whole amount of sulfur in lignosulfonates (96–100%) is incorporated in strongly acidic groups.

Comparison of the results of potentiometric titration of LSA in water and DMSO shows that the content of weakly acidic (mainly carboxy) groups depends on the procedure for isolating lignosulfonates from the crude product for their further processing, ranging from 0 (LSA2) to 1.9 mg-equiv l^{-1} (LSA4).

In accordance with data of [8], lignosulfonates of high molecular weight contain no acid groups other than sulfonic acid groups. As the weight fraction of such lignosulfonates in the sulfite liquor after separating soluble inorganic impurities is about 50 wt % [8], it is difficult to imagine that the remaining part

of the liquor consists exclusively of nonlignin impurities.

Presumably, low-molecular-weight lignins as intermediates of organic transformations of amino acids are sulfonated in the course of wood cooking without breakdown of carboxy groups, which appreciably increases the solubility of their sulfonated derivatives. Furthermore, lignosulfonates of low molecular weight, in contrast to macromolecular compounds, have less branched structure and show stronger tendency to association in aqueous solutions [9]. Apparently, such properties in combination with high solubility do not favor formation of a stable organomineral complex on treatment of lignosulfonate solutions with the complex salt $[Co(NH_3)_6]Cl_3$, which leads to the loss of carboxyl-rich fractions of the main substance.

Salting-out with organic solvents, on the contrary, increases the content of carboxylated nonlignin impurities in the isolated lignosulfonate because of their low solubility in organic solvents.

We should probably agree with the opinion of Gardon and Mason [8] that there are no rigorous analytical criteria for estimating the degree of removal of concomitant nonlignin organic compounds from lignosulfonates. Also, there are apparently no ideal methods for complete separation of lignosulfonates and nonlignin impurities without loss of each component.

CONCLUSIONS

(1) Conditions were found for potentiometric titration of lignosulfonic acids in an organic solvent, dimethyl sulfoxide, allowing determination of the content of strongly acidic groups in lignosulfonic acids.

(2) The presence of small amounts of water in a mixture being titrated or in a titrant does not interfere with the separate titration of acid groups of different strengths in lignosulfonic acids and increases the neutralization rate.

(3) The amount of acid groups in lignosulfonic acids and their qualitative composition depend on the procedure for recovering lignosulfonates from the crude product.

Abstract—Results obtained in a study of the desulfation of the active paste from lead battery scrap with the use of an aqueous ammonium carbonate solution are presented.

DOI: 10.1134/S1070427208070306

In recent years, considerable attention has been paid in all the economically developed countries to utilization of worked out lead batteries. Year by year, this problem becomes increasingly economically and environmentally important [1–3]. By now, more than a half of world's output of lead is produced from secondary raw materials, mainly from lead battery scrap. In a number of leading countries, the share of secondary lead constitutes 65–85% of its total output [3].

Lead battery scrap is a specific kind of secondary raw materials whose processing must considerably differ in the apparatus and technological regards from the ore processing. The most appropriate is the technology including preliminary processing of battery scrap into the metallic (grids), oxide–sulfate (active paste of the positive and negative plates), and organic fractions. On average, after being washed with water, the oxide–sulfate fraction contains (wt %): Pb 73.5, Sb 0.3, As up to 0.04, Cu 0.1, Fe 0.05, and SO_4^{2-} 16.7 [4]. Its main components are $PbSO_4$ and PbO_2, and to a lesser extent PbO and other compounds (Fig. 1). Direct pyrometallurgical processing of the sulfate–oxide fraction in furnaces of any design leads to transfer of the whole amount of sulfur into the gas phase and necessitates its catching [5, 6]. The most appropriate in environmental and economical regards is conversion of lead sulfate to lead carbonate by a simple hydrometallurgical procedure, desulfation (desulfurization). This enables full utilization of sulfur, which passes into the aqueous phase in the form of a soluble sulfate. Physicochemical and technological studies of the desulfation process were considered in detail in the review [7]. The most appropriate reagents for desulfation are sodium or potassium carbonate and sodium hydroxide. The reaction not subject to any considerable kinetic hindrance is based on the substantially lower solubility products of lead(II) carbonate or hydroxide, compared to lead sulfate.

Previously, results of experimental studies of the desulfation with aqueous solutions of NaOH, KOH, Na_2CO_3, $NaHCO_3$, and K_2CO_3 have been presented [7–10], the possibility of using calcium hydroxide has been discussed [11], and the thermodynamics and mechanism of processes occurring in solid-phase reduction of the oxide–carbonate cake obtained upon desulfation have been studied in detail [12]. Even at 600°C, all lead compounds are converted into lead(II) oxide, which is easily reduced by carbon or any carbon-containing material at 720–740°C. Similarly to the desulfation, the reduction is relatively safe environmentally, does not require intricate apparatus, and can be performed under small-scale production conditions.

Here we report the results of studying the desulfation of the active paste from lead battery scrap with ammonium carbonate. As the starting material served active paste from batteries of various brands, including those of foreign make, after manual disassembly (total mass 25 kg). The sulfate–oxide materials were washed and dried first in air (72 h) and then in an oven at 110°C for 4 h. Further, the active paste was ground in a porcelain mortar and screened through a set of sieves with a mesh of 0.25 to 3.0 mm. The fraction with a particle size

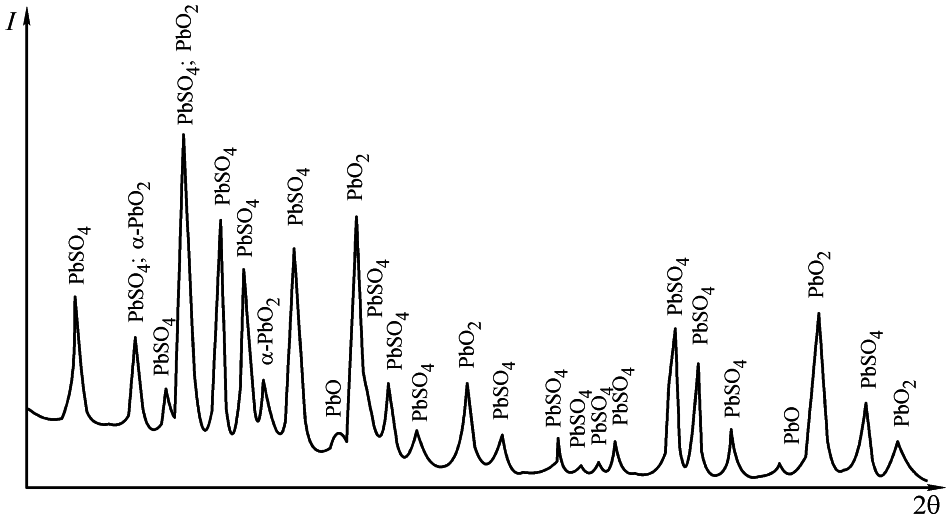

Fig. 1. X-ray diffraction pattern of the starting oxide–sulfate fractions (active paste from positive and negative plates of lead batteries). (*I*) Intensity and (2θ) Bragg angle; the same for Figs. 2 and 3.

smaller than 0.25 mm was used for desulfation (total weight of the fraction 7 kg). An analysis for the content of SO_4^{2-} was made by two methods, gravimetric and turbidimetric [13, 14], with consistent results obtained. The content of SO_4^{2-} in the sample was 16.66 wt %, which corresponds to 52.6 wt % $PbSO_4$.

The necessary theoretical amount of $(NH_4)_2CO_3$ was calculated using the reaction equation

$$PbSO_4 + (NH_4)_2CO_3 = PbCO_3 + (NH_4)_2SO_4.$$

Ammonium carbonate of analytically pure grade was used. The weighed portion of the oxide–sulfate fraction was 25 g in all the experiments, and the amount of water, 200 g. The reaction mixture was agitated with a magnetic stirrer, with the temperature and solution pH measured in the course of an experiment (duration 50 min). It was found in preliminary experiments that the extent of the desulfation process is affected by the solution pH. In the experiments, the pH value was maintained at no less than 9.5 by adding an NH_4OH solution. The temperature of the experiments was 25±2°C; raising the temperature to 45°C had no effect on the results of desulfation. The forming oxide–carbonate cake was separated by filtration, washed with a double (compared to that of the primary filtrate) volume of distilled water, and dried at 110°C. The primary filtrate and the solid phase were analyzed for the content of SO_4^{2-} ions. The results obtained are listed in the table. On the average, 94% of SO_4^{2-} contained in the starting oxide–sulfate fraction passes into the aqueous phase in the course of desulfation. The content of SO_4^{2-} in the forming oxide–carbonate cake is within 0.7–1.1 wt % (0.9 wt % SO_4^{2-} on average). As can be seen in Fig. 2, PbO_2 and $PbCO_3$ are the main components of the desulfated paste. After annealing at 600°C, virtually the only component of the oxide–carbonate cake is rhombic lead(II) oxide (Fig. 3).

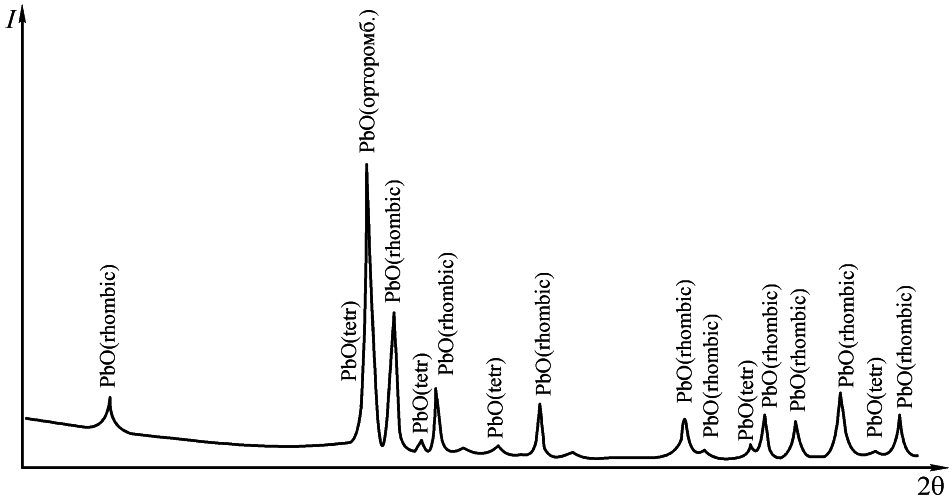

Fig. 3. X-ray diffraction pattern after annealing of the oxide–carbonate cake at 600°C.

CONCLUSIONS

(1) Ammonium carbonate can be used, together with sodium or potassium carbonate, in desulfation of the active paste from lead battery scrap.

(2) To achieve a high degree of recovery of SO_4^{2-} ions into the aqueous phase (94–95%) in desulfation, it is advisable to maintain a solution pH of no less than 9.5 by addition of NH_4OH.

(3) PbO_2 and $PbCO_3$ are the main components of the desulfated paste (oxide–carbonate cake).

(4) Upon annealing of the oxide–carbonate cake at 600°C, PbO_2 and $PbCO_3$ are converted to rhombic lead(II) oxide.

Abstract—Applicability of the Zdanovskii rule to melts of the systems Fe–Ni–S and Cu–Ni–S was studied.

DOI: 10.1134/S1070427208070318

Zdanovskii [1] established, based on a study of a large number of aqueous solutions, a law that became known as the Zdanovskii rule: The activity of water remains unchanged on mixing isopiestic solutions of different electrolytes that do not interact chemically with each other. Later, it was demonstrated [2–4] that the above rule can also be applied to ternary systems of varied nature, in which the interaction of two of three components with each other is minimal.

In this study we considered the applicability of the Zdanovskii rule to melts of the sulfide systems iron–nickel–sulfur and copper–nickel–sulfur, which contain less than 50 mol % sulfur ($x_S \le 0.50$, x_S is the mole fraction of sulfur). Published data on the phase diagrams and thermodynamic properties of the above systems have been considered previously in detail [5, 6].

Iron–nickel–sulfur system. In the boundary binary systems iron–sulfur and nickel–sulfur, the components actively interact to form a number of compounds (FeS, FeS_2, Ni_3S_2, NiS) [7, 8]. The thermodynamic properties of melts of the metal–sulfur systems are described within the associated solution model [9, 10].

The phase diagram of the Fe–Ni system shows formation of a continuous series of solid solutions, with the interval between liquidus and solidus temperatures as small as 5–6 K. The thermodynamic properties of liquid iron–nickel alloys have been considered in detail in [11, 12]. The system exhibits slight negative deviations from the ideal behavior at 1873 K.

The applicability of the Zdanovskii rule to the ternary system Fe–Ni–S was checked along the hypothetical sulfur isoactivity lines, which were constructed from data on the sulfur activity in Ni–S and Fe–S melts (Fig. 1). The compositions of the boundary binary systems with the same values of sulfur activities and the equations of lines connecting these compositions are given in the table. This made it possible to calculate the dependence of the sulfur activity on the composition of the ternary system along secants with constant ratios of mole fractions of iron and nickel ($x_{Fe} : x_{Ni}$) and to compare the values obtained with the available experimental data for each section of the ternary system (Fig. 2). At a calculated temperature of 1573 K, all the compositions considered lie in the homogeneity region.

It should be noted that, in the previously made

* M is Fe or Cu.

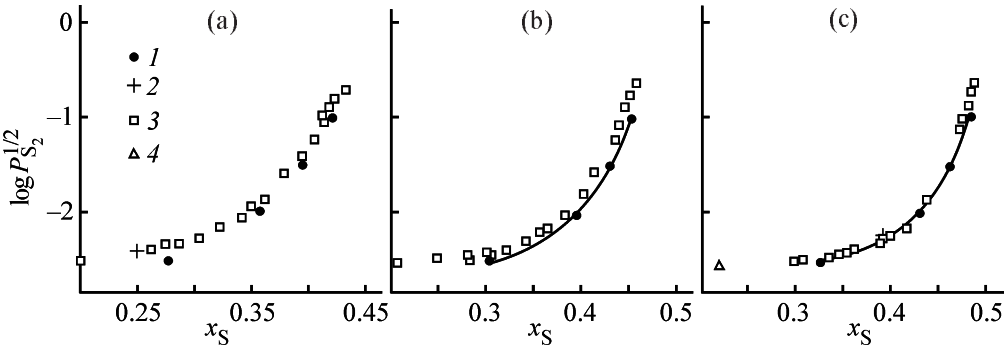

Fig. 2. Plots of $\log P_{S_2}^{1/2}$ vs. x_S for the Fe–Ni–S system along secants with varied $x_{Fe} : x_{Ni}$ ratio at 1573 K. $x_{Fe} : x_{Ni}$: (a) 1 : 4, (b) 1 : 1, and (c) 4 : 1. (*1*) calculation; data from (*2*) [13], (*3*) [14], and (*4*) [15].

experimental studies of the thermodynamic properties of melts of sulfide systems, approaches to choosing the standard state of sulfur are diverse [6]. This is due to the fact that, in metallurgical practice, copper–nickel sulfide ores are processed at relatively high temperatures. At the same time, sulfur melts at 388.36 K and its boiling point is 717.82 K. The gaseous phase has a complex composition S_n, and n varies with temperature ($1 \le n \le 8$). In [14, 15], sulfur activity is identified with a value of $P_{S_2}^{1/2}$ (P_S is the partial vapor pressure of sulfur, which is considered as ideal diatomic gas at experimental temperatures). While comparing results of the calculation with the experimental data, we used the same procedure.

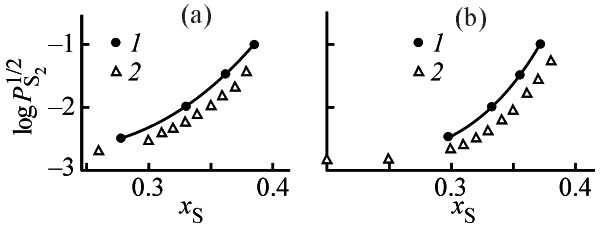

Fig. 3. Plots of $\log P_{S_2}^{1/2}$ *vs.* x_S for the Cu–Ni–S system along secants with varied $x_{Cu} : x_{Ni}$ ratio. $x_{Cu} : x_{Ni}$: (a) 1 : 3 and (b) 1 : 1. (*1*) Calculation, T = 1523 K; (*2*) data from [15], T = 1473 K.

Copper–nickel–sulfur system. In the boundary binary system copper–sulfur, the interaction of components is especially complex [16]. In the composition range considered ($x_S \le 0.50$), the phase separation region (between Cu and Cu_2S) is found, along with the compounds Cu_2S and CuS. Applicability of the associated solution model to melts of the Cu–S system has been considered in a Sharma and Chang's study [17]. In the Cu–Ni system, the component solubility in both liquid and solid state is unlimited. According to data of different authors,

the activity isotherms of the components have moderate deviations from ideality [18]. For the Cu–Ni–S system, the sulfur isoactivity lines were constructed by the same way as for the Fe–Ni–S system. The compositions of the boundary systems and the equations for the isoactivity lines are given in the table. In this system, both the sections considered lie in the homogeneity region at a calculated temperature of 1523 K. Agreement with the experimental data is satisfactory (Fig. 3).

CONCLUSION

The sulfur isoactivity lines in the Fe–Ni–S and Cu–Ni–S systems at 1573 and 1523 K, respectively, within the homogeneity region can be described by data on the boundary binary sulfide systems with the application of the Zdanovskii rule.

Received December 11, 2007

Abstract—The possibility of preparing two series of solid solutions in the system $Ba_{3-x}Sr_xEr(BO_3)_3$ ($0 \le x \le 3.0$), crystallizing in different structural types, was examined. Samples of the phases of variable composition were synthesized by the method of solid-phase reactions, and their X-ray phase analysis was done. The X-ray diffraction characteristics of the phases synthesized were determined.

DOI: 10.1134/S107042720807032X

Double barium borates of the composition $Ba_3R(BO_3)_3$, where R is an yttrium-group rare-earth element (REE), are interesting objects of study, because they have noncentrosymmetrical hexagonal structure (space group $P6_3cm$) and exhibit properties making them promising for nonlinear optics and for pyro- and ferroelectrics [1, 2]. At the same time, compounds with the above structure are few. The phases of the above composition with cerium-group lanthanides (La–Dy) and isoformular strontium borates crystallize in another structural type (space group $R\bar{3}$). Structures with a center of symmetry are hardly to possess the required properties. Varying the composition of cations makes it possible to purposefully synthesize phases with the required structure and properties.

As known, crystalline substances can form solid solutions or phases of variable composition. The isomorphic substitutions can occur if cations have the same charge and close radii and polarizabilities [3, 4].

In this study, we synthesized solid solutions $Ba_{3-x}Sr_xEr(BO_3)_3$, determined their X-ray diffraction characteristics, and established the solubility regions of strontium atoms in the acentric barium structure.

EXPERIMENTAL

Samples for study were synthesized by the method of solid-phase reactions. The reaction mixtures were prepared by thorough mixing of stoichiometric amounts of the starting components, which were then annealed in platinum crucibles in air and repeatedly ground. As started components we used preliminarily calcined barium and strontium carbonates (both ultrapure grade), erbium(III) oxide (99.9% pure), and boric acid (chemically pure grade). The mixtures of the starting components taken in stoichiometric amounts (x 0, 0.1, 0.4, 0.5, 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, 1.8, 2.0, 2.5, 3.0) were annealed at 500–1000°C for 70–80 h. The phase composition of powders was monitored by X-ray phase analysis [DRON UM1 diffractometer (CuK_α radiation) and D8 Advance Bruker AXS diffractometer (CuK_α radiation, graphite monochromator, $10° < 2\theta < 60°$, 0.02° interval). The unit cell parameters of the synthesized phases were refined by the least-squares method using a specially developed program. The analysis showed that in the range of $0.1 \le x \le 0.4$, rich in barium, the diffraction patterns of the samples resemble the diffraction pattern of the double borate $Ba_3Er(BO_3)_3$: both the reflection positions and relative intensities are the same. The diffraction patterns of samples of the above compositions were identified using X-ray diffraciton characteristics of double barium and erbium borate by assuming their being isostructural. The results of identification of the powder diffraction pattern of $Ba_{2.9}Sr_{0.1}Er(BO_3)_3$ are listed in Table 1.

The reflection positions in the diffraction pattern of the samples of composition $0.5 \le x \le 3.0$ are close to those of double strontium erbium borate. The diffraction patterns of the phases in this region of

with the similar character of chemical bonds, makes possible formation of the substitution solid solutions of double borates in a wide concentration range.

According to XPA, the solubility region of strontium atoms in the acentric barium structure in the concentration range studied is narrow: $0 \le x \le 0.4$. In this concentration range, the borate $Ba_3Er(BO_3)_3$ of the hexagonal structure (space group $P6_3cm$) is stable. On the contrary, the substitution solid solutions of the $Sr_3Er(BO_3)_3$ trigonal structure (space group $R\bar{3}$) are formed in a wide range of concentrations: $0.5 \le x \le 3.0$. The unit cell parameters of double barium strontium borates and solid solutions based on them are listed in Table 2. As can be seen, the unit cell parameters of the synthesized phases within regions wherein structures of trigonal and hexagonal modifications are formed monotonically decrease as x grows. Change in the unit cell parameters and volumes confirmed formation of two series of solid solutions over the entire concentration range.

CONCLUSIONS

(1) Phases of variable composition in the system $Ba_{3-x}Sr_xEr(BO_3)_3$ ($0 \le x \le 3$) were synthesized by the method of solid-phase reactions in the range 500–1000°C.

(2) According to X-ray phase analysis, the ternary phases synthesized form two series of substitution solid solutions.

Abstract—Triple molybdates of compositions $M_5(Li_{1/3}Hf_{5/3})(MoO_4)_6$ (M is K, Rb, or Tl) and $M_3LiHf_2 \cdot (MoO_4)_6$ (M is Na, K, Rb, or Tl) were synthesized by solid-phase reaction, and their conductivity in the temperature range 200–550°C was studied.

DOI: 10.1134/S1070427208070331

Advances in the field of synthesis and study of oxygen-containing compounds are due to the development of modern materals science [1, 2]. Recent studies [3, 4] showed that some oxygen-containing molybdenum compounds exhibit ferroelastic and luminescent properties, and the majority of them are characterized by ionic conductivity. Owing to increasing production of devices and equipment that use chemical power sources (CPS), a need is evident for materials with high ionic conductivity [5]. Under the conditions of increasing demand for lithium–ion solid electrolytes [6], a search for novel functional materials with ionic conductivity becomes urgent.

In the study, we prepared triple molybdates $M_5(Li_{1/3}Hf_{5/3})(MoO_4)_6$ (M is K, Rb, or Tl) and $M_3LiHf_2(MoO_4)_6$ (M is Na, K, Rb, or Tl) and examined their conductivivty. As starting compounds we used carbonates of univalent metals (chemically pure grade) and analytically pure grade hafnium dioxide. Before syntheses, hafnium dioxide was calcined at 800–850°C for 6–8 h, and carbonates, at 400–500°C.

The molybdates were synthesized by the solid-state reaction in air. The starting carbonates in the form of a mixture of oxides and carbonates of univalent metals were thoroughly ground in an agate mortar and subjected to stepwise thermal annealing at 400–450, 450–500, and 500–550°C. The time of each step was 10–20 h. Stepwise heating of the products alternated with grinding. The reactant ratios corresponded to the given stoichiometry. The phase compositions of the starting and annealed mixtures were monitored by X-ray phase analysis. The diffraction patterns of the powders were recorded on a DRON-UM1 diffractometer in CuK_α radiation. The phase analysis of the annealed $M_5(Li_{1/3}Hf_{5/3}) \cdot (MoO_4)_6$ (M is K, Rb, or Tl) and $M_3LiHf_2(MoO_4)_6$ (M is Na, K, Rb, or Tl) samples showed that the compounds obtained were individual and contained no impurities [7, 8].

The unit cell parameters were calculated and refined by the least-squares method (LSM). To do this, we used unambiguously identified lines of the powder diffraction patterns and the POLIKRISTALL program [9]. The density in toluene was measured pycnometrically at 25°C using a 5-ml pycnometer.

Triple molybdates $M_3LiHf_2(MoO_4)_6$ (M is K or Rb) are classed with the known structural type $KAl \cdot (MoO_4)_2$ (trigonal crystal system, space group $P\bar{3}m1$, $Z = 1$) [10]. The diffraction pattern of $Tl_3LiHf_2 \cdot (MoO_4)_6$ was indexed assuming formation of a superstructure of the $KIn(MoO_4)_2$ type (rhombic crystal system, space group $Pnam$, $Z = 4$) [11], with trebling of the smallest parameter. Sodium–lithium–hafnium molybdates $Na_3LiHf_2(MoO_4)_6$ are isostructural to $NaIn(MoO_4)_2$ (triclinic crystal system, space group $P\bar{1}$, $Z = 4$) [12]. The crystallographic characteristics and the temperatures of incongruent melting of the synthesized compounds are given in Table 1. The molybdates $M_5(Li_{1/3}Hf_{5/3})(MoO_4)_6$ (M is K, Rb, or Tl) are isostructural to $K_5Mg_{0.5}Zr_{1.5}(MoO_4)_6$ (trigonal crystal system, space group $R3c$, $Z = 6$) [9] (Table 2). This is in line with the previously obtained results [8].

The differential thermal analysis (DTA) was done

$Tl_3LiHf_2(MoO_4)_6$	2.29×10^{-3}	7.25×10^{-3}	1.95×10^{-2}	0.60
$Na_3LiHf_2(MoO_4)_6$	3.83×10^{-6}	–	–	0.59
$Na_3LiZr_2(MoO_4)_6$	1.93×10^{-6}	–	–	0.58

on an OD-103 derivatograph (MOM) and a specially designed thermal analytical installation allowing recording of heating (cooling) curves and thermal effects at temperatures of up to 1000°C. The substance weight was 0.3–0.5 g. The triple molybdates prepared melt incongruently and crystallize in four different structural modifications (Table 1).

The temperature dependence of the conductivity σ for samples of the synthesized compounds was studied by the Vest–Tallan polarization method. For this purpose, we used dense ceramic pellets 10 mm in diameter, 4–5 mm thick. The measurements were performed with an E8–4 ac bridge, to which a P5025 capacity box was connected. The frequency was 10^3 Hz. The dc current at a preset voltage of 30–60 mV was recorded wiht an E6-13A teraohmmeter. The electrodes were formed by firing a platinum paste into the surface of pellets. The experimental conductivity activation energies E_a (eV) and specific conductivities σ of the triple molybdates are given in Table 3.

The temperature vs. conductivity curves for molybdates of the compositions $Na_3LiHf_2(MoO_4)_6$ and $Rb_3LiHf_2(MoO_4)_6$ are shown in the figure. The temperature dependence for the zirconium analog $Na_3LiZr_2(MoO_4)_6$ [8] is given for comparison. The conductivity activation energies are 0.43–0.6 eV. Analysis of the conductivity values at various temperatures showed that, in the temperature range studied (400–500°C), the samples exhibit mixed conductivity (ionic and electronic), with the ionic conductivity dominating.

The conductivity values (10^{-3}–10^{-2} S cm^{-1} at 450–500°C) allow the triple molybdates to be classed with solid electrolytes.

Conductivity σ vs. temperature T curve for (*1*) $Na_3LiHf_2(MoO_4)_6$, (*2*) $Na_3LiZr_2(MoO_4)_6$, and (*3*) $Rb_3LiHf_2(MoO_4)_6$.

The electrical properties of triple molybdates are accounted for by the specific features of their structure [8]. Owing to voids and channels present in the structure, single-charged ions start to freely migrate in the corresponding direction upon the exposure of an electric filed.

CONCLUSIONS

(1) Triple molybdates $M_5(Li_{1/3}Hf_{5/3})(MoO_4)_6$ (M is K, Rb, or Tl) and $M_3LiHf_2(MoO_4)_6$ (M is Na, K, Rb, or Tl) were prepared from starting carbonates of univalent metals and hafnium dioxide by the solid-phase reaction.

(2) Molybdates of the composition $M_5(Li_{1/3}Hf_{5/3})(MoO_4)_6$ (M is K, Rb, or Tl) are isostructural and crystallize in the trigonal crystal system (space group $R3c$, $Z = 6$). Triple molybdates of the composition $M_3LiHf_2(MoO_4)_6$ (M is Na, K, Rb, or Tl) crystallize in three different structural modifications ($P\bar{1}$, $P\bar{3}m1$, and $Pnma$), depending on the nature of single-charged cations.

(3) Triple molybdates of single-charged lithium cations and zirconium exhibit mixed conductivity, with the ionic conductivity at 400–500°C dominating.

Abstract—The solubility products of basic salts $Cu_2(OH)_3NO_3$ and $Hg_3O_2(NO_3)_2$ were determined using dilatometric data.

DOI: 10.1134/S1070427208070343

Difficultly soluble oxo and hydroxo compounds formed by induced hydrolysis are typical of the majority of metal ions. Data on the composition and solubility products of the above compounds are necessary for quantitative evaluation of the concentration of ions in heterogeneous systems. This is especially important for the case of metals contaminating the environment.

The dilatometric method was used previously to study the volume changes that accompany induced hydrolysis of some cations and result from the shift of the equilibrium toward formation of precipitate on adding alkali. It was shown, in particular, that chemical interactions in the systems depend on the molar ratio of alkali and a cation subject to hydrolysis (N = OH/M). The above dependence was demonstrated for the $Cu(NO_3)_2$, HNO_3–$NH_3 \cdot H_2O$–H_2O and $Cu(NO_3)_2$, HNO_3–KOH–H_2O systems in [1] and for the $Hg(NO_3)_2$, HNO_3–KOH–H_2O system in [2]. It was found that basic salts $Cu_2(OH)_3NO_3$ and $Hg_3O_2(NO_3)_2$ are formed first, which is followed by formation of $Cu(OH)_2$ and HgO (the composition of the solid phases calculated from the dilatometric data was confirmed by X-ray phase analysis). Thus, it was shown that the action of an electrolyte induces metamorphization (change in composition and structure of a solid compound) in the heterogeneous system.

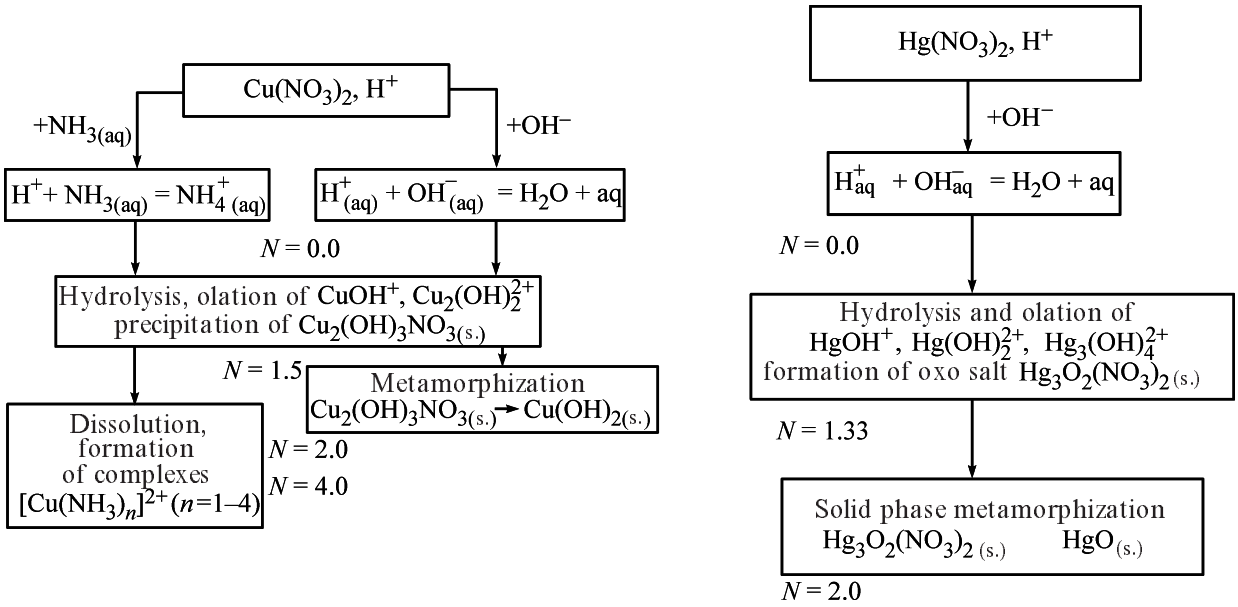
Based on dilatometric data [1, 2] and potentiometric studies [3, 4], schemes of induced hydrolysis were suggested for copper(II) and mercury(II) ions, involving transformations of aqua complexes in solution into solid oxo and hydroxo compounds.

Some data on the solubility products (SPs) of oxo and hydroxo compounds of copper(II) and mercury(II) are available from the literature. According to [5], in particular, the SP for copper hydroxo nitrate

$$Cu_2(OH)_3NO_3 \rightleftarrows 2Cu^{2+} + 3OH^- + NO_3^- \qquad (1)$$

is 3.2×10^{-32} and 5.8×10^{-33} in 2 M methylammonium nitrate and 2 M diethylammonium nitrate, respectively.

For $Cu(OH)_2$, SP is 2.2×10^{-20} and for HgO, 3×10^{-26} [6]. At the same time, data on the SP of $Hg_3O_2(NO_3)_2$ are lacking.



In this study, we applied the results of dilatometric measurements at 25°C in 1 M KNO_3 to obtain quantitative characteristics of the solubility products of basic salts $Cu_2(OH)_3NO_3$ and $Hg_3O_2(NO_3)_2$. The SPs of the basic salts under study were calculated by mathematical simulation (CPESSP program) [7, 8]. In calculating the equilibrium composition by Brinkley's method [9], the CPESSP program for heterogeneous systems sets limits for the solubility products of precipitate species in the form

$$\sum \nu_{ij} \ln b_j - \ln K_i \le 0, \qquad i = 1, 2, \ldots, m;\ i = 1, 2, \ldots, s;$$

or in the matrix form

$$\nu \ln b - \ln K \le \mathbf{O},$$

where K_i is the solubility product of the ith precipitate; m, number of precipitate species; s, number of

Steps of induced hydrolysis in the systems $Hg(NO_3)_2$, HNO_3–KOH–H_2O; $Cu(NO_3)_2$, HNO_3–$NH_3 \cdot H_2O$–H_2O; and $Cu(NO_3)_2$, HNO_3–KOH–H_2O at different molar ratios N.

starting reactants (basis species); v, stoichiometric matrix with respect to precipitate species; $\ln b$ and $\ln K$, vectors of equilibrium concentrations and solubility products of basis species in the logarithmic scale, respectively; and **O**, zero vector.

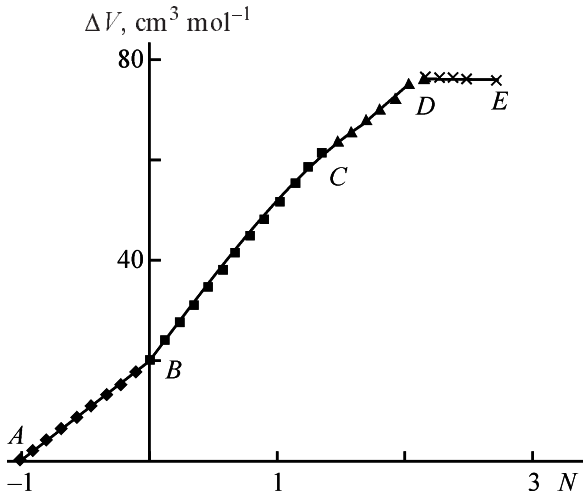
This procedure allows the equilibrium composition with respect to the soluble species and species separated from a liquid-phase system to be expressed in the same concentration units (in the program, in M), which makes it possible to use the additivity rule for processing results of dilatometric measurements. According to the additivity rule, the total value of the volume change ΔV_m observed in the reaction is the sum of contributions from single interactions ΔV_i:

$$\Delta V_m = \sum_{i=1}^{N} \alpha_i \Delta V_i, \qquad (2)$$

where ΔV_i is the change in the reduced volume or the volume change in formation of 1 mol of the ith species and ΔV_i is its fraction or concentration.

The matrix constructed in the course of the calculation includes a set of basis, complex, and precipitated species present in the system. To each of them, the initial value of property ΔV_i and the formation constant for soluble species or the SP value for precipitate species are ascribed.

The K_i constants were used to calculate α_i for each species at each titration point and, correspondingly, ΔV_{cal}. The convergence of the calculated and experimental points was checked by the Fisher test, which is calculated as the sum of the weighted squared deviations reduced to the number of the degrees of freedom m ($m = M$ is k, where k is the total number of the parameters being determined):



$$F_r = m^{-1} \sum_{j=1}^{M} (\Delta V_{exp} - \Delta V_{calc})^2 / [(\sigma \Delta V_{exp})^2 + (\Delta \Delta V)^2],$$

$$F_r \le 2, \quad m > 5, \qquad (3)$$

where σ is the relative (taken $\sigma = 0.05$), and $\Delta\Delta V$, absolute determination error (taken $\Delta\Delta V = 0.007$ cm^3).

The minimum was found by the iteration procedure using the dependence (2) and the target function F_r (3). We found the values of ΔV_i and of the unknown constant, SP of basic salt, corresponding to the minimum of the target function. In going to the global minimum in the program, the analysis block was used in each iteration to efficiently overcome local minima and "gullies" of the target function.

It is important that the CPESSP program for processing of the physicochemical responses [data of various methods in which the response can be described by Eq. (2)] allows simultaneous determination of the equilibrium constants and SP (solubility). Both the soluble species and the species separating out from a solution (in the form of precipitates and

Dilatometric titration curve for the $Hg(NO_3)_2$, HNO_3–KOH–H_2O system: (points) experimental data and (lines) calculation. (ΔV) change in molar volume, $N = (n_{OH} - n)/n_{Hg}$.

in the gaseous state) can be included into the stoichiometry matrix of the system in the course of simulation.

The initial model for the $Cu(NO_3)_2$, HNO_3–$NH_3 \cdot H_2O$–H_2O system included dissolved hydroxo complexes [$Cu(OH)^+$, $Cu_2(OH)_2^{2+}$, Cu_2OH^{3+}] (hydrolysis constants pK –7.4±0.1, –10.93±0.02, and –6.02±0.02, respectively [3]), ammine complexes {$Cu(NH_3)_n^{2+}$ (n = 1–4, $\log k_1$ = 4.31, $\log k_2$ = 3.67, $\log k_3$ = 3.04, $\log k_4$ = 2.30) [5]}, and solid compounds $Cu_2(OH)_3NO_3$ and $Cu(OH)_2$.

The best fit of the calculation results to the experimental SP values was achieved for $Cu_2(OH)_3 \cdot NO_3$, $(1.3 \pm 0.3) \times 10^{-31}$. This SP value correlates with the above-presented literature data. Some difference between the values is due to the effect of the medium.

The model for calculating SP of $Hg_3O_2(NO_3)_2$ included hydroxo complexes in solution {$HgOH^+$, Hg_2OH^{3+}, $Hg_3(OH)_4^{2+}$} [8]} and solid phases $Hg_3O_2(NO_3)_2$ and HgO.

The experimental results obtained in the dilatometric study of hydrolytic transformations of mercury nitrate and the theoretical curve calculated by the optimization method are presented in the figure as example. The best fit of the calculation results to the experimental data for the systems studied was achieved at SP values of basic mercury nitrate of $(5.2 \pm 0.1) \times 10^{-56}$ according to the equilibrium

$$Hg_3O_2(NO_3)_2 + 2H_2O \rightleftarrows 3Hg^{2+} + 4OH^- + 2NO_3^-. \quad (4)$$

CONCLUSIONS

(1) The applicability of dilatometric method to determination of quantitative characteristics, the solubility products of basic salts, was demonstrated.

(2) The solubility products of $Cu_2(OH)_3NO_3$ and $Hg_3O_2(NO_3)_2$ in 1 M KNO_3 at 25°C, calculated from data of the dilatometric measurements, are $(1.3 \pm 0.3) \times 10^{-31}$ and $(5.2 \pm 0.1) \times 10^{-56}$, respectively.

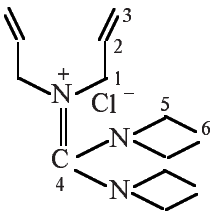
Abstract—Radical copolymerization of *N*-vinylpyrrolidone with 2,2-diallyl-1,1,3,3-tetraethylguanidinium chloride in the bulk and in dimethyl sulfoxide was studied. Kinetic parameters of the reaction were examined. The monomer activities were determined.

DOI: 10.1134/S1070427208070355

Directed synthesis of water-soluble polyfunctional polymers attracts growing attention. One of the promising procedures for preparing these polymers is copolymerization of monomers containing different functional groups. In this connection, *N*-vinylpyrrolidone (VP) copolymers attract much interest. These copolymers are widely used in engineering, medicine, cosmetic industry, pharmacy, and agriculture [1, 2].

Synthesis of polymers derived from diallyl compounds is also a topical problem. The study of radical polymerization of allyl monomers concerns mainly homo- and copolymerization of *N,N*-diallyl-*N,N*-dimethylammonium chloride. Copolymers of this compound are used as flocculants for wastewater treatment, catalysts of some chemical reactions, growth stimulants, aftertanning agents in leather manufacture, etc. [3–6]. A wide range of useful properties of nitrogen-containing allyl copolymers stimulates preparation and study of new copolymers of this type. In this connection, 2,2-diallyl-1,1,3,3-tetraethylguanidinium chloride (AGC) shows promise as an initial monomer for radical copolymerization. It is known that polymers containing guanidine groups exhibit biocidal activity [7] and can be used as antibacterial agents. Therefore, preparation of AGC–VP copolymers is an urgent problem.

The aim of this study was to examine radical copolymerization of VP with AGC in the bulk and in dimethyl sulfoxide (DMSO) solution and some properties of the resulting copolymers.



EXPERIMENTAL

N-Vinylpyrrolidone (Lancaster) was dried over KOH and distilled under reduced pressure. The fraction with bp 65°C/1.5 mm Hg and n_D^{20} = 1.5117 was collected.

2,2-Diallyl-1,1,3,3-tetraethylguanidinium chloride was prepared by the known procedure [8]. Its purity was determined by elemental analysis and ^{13}C NMR spectroscopy.

Found, %: C 62.42, H 10.67, N 14.58, Cl 12.32.
Calculated, %: C 62.61, H 10.43, N 14.61, Cl 12.35.

The chemical shifts δ (ppm) and signal multiplicities in the ^{13}C NMR spectrum are presented below

C^1	C^2	C^3	C^4	C^5	C^6
54.56	133.76	123.41	165.71	45.83	14.48
t	d	t	s	t	q

Initiator [azobis(isobutyronitrile), AIBN] and solvents were purified by standard procedures [9]. Their properties were consistent with the reference data.

Apparent copolymerization constants of VP (M_1) and AGC (AIBN, 80°C)

Medium	r_1	r_2
In bulk	0.92±0.01	1.35±0.12
DMSO	0.83±0.07	1.80±0.15

Copolymerization of VP with AGC in the bulk and in DMSO was performed under reduced pressure in the presence of AIBN in the initial steps (conversion ≤5%). The polymerization kinetics was monitored by dilatometry [10]. Once the required conversion was reached, the reaction was stopped by cooling and the copolymer was precipitated with diethyl ether. The copolymer was reprecipitated two times from a methanol solution with diethyl ether and dried in a vacuum at 40–50°C to constant weight. The copolymer composition was determined by elemental analysis.

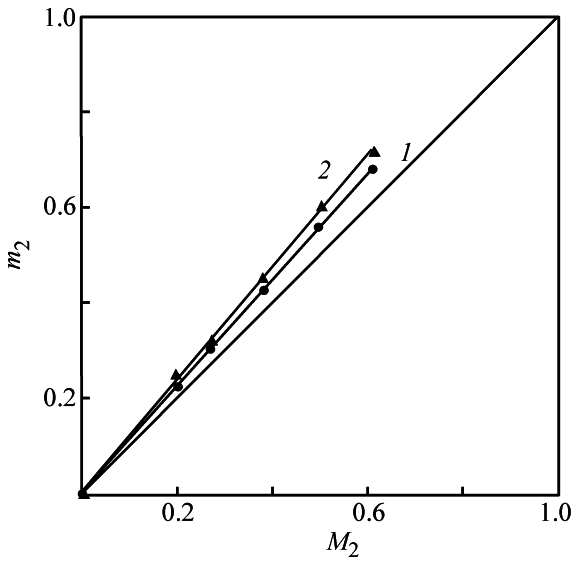


Fig. 1. Composition of VP–AGC (M_2) copolymers prepared by polymerization (*1*) in the bulk and (*2*) in DMSO solution as a function of the composition of the initial monomer mixture. [AIBN] = 1.0×10^{-2} M, T = 80°C. M_2 and m_2 are mole fractions of AGC in the initial mixture and copolymer, respectively.

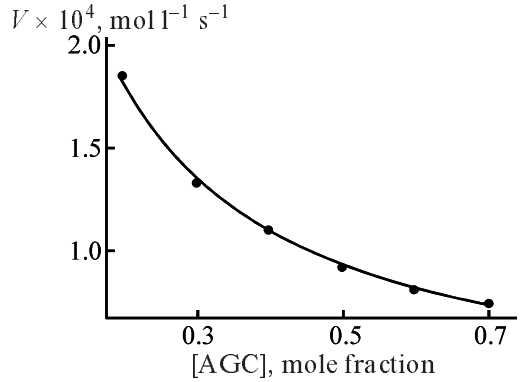

Fig. 2. Initial rate V of copolymerization of VP with AGC (M_2) as a function of the mole fraction of AGC in the initial monomer mixture. DMSO, [M_1 + M_2] = 3.2 M, [AIBN] = 1.0×10^{-2} M, T = 80°C.

The apparent copolymerization constants r_1 and r_2 were calculated by Mayo–Lewis [11], Finemann–Ross [12], and Kelen–Tudos [13] procedures.

The ^{13}C NMR spectra were recorded on Bruker AM-300 spectrometer operating at 75.5 MHz, with broad-band proton decoupling in the JMOD mode. The solvents were DMSO-d_6 and D_2O. Tetramethylsilane and 2,2-dimethyl-2-silapentane-5-sulfonic acid were used as internal references.

The intrinsic viscosity [η] was measured with an Ubbelohde viscometer.

The acute toxicity parameters of the copolymer samples were determined by the Prozorovskii express method [14].

Previously we found [8] that AGC slowly homopolymerized in the presence of radical initiators. We also showed that AGC copolymers with vinyl monomers (methyl methacrylate, acrylic acid, methacrylic acid, and VP) could be prepared. It was of interest to study copolymerization of VP with AGC in more detail. We found that VP–AGC copolymers with random distribution of monomeric units were formed. The dependence of the copolymer composition on the composition of the initial monomer mixture is show in Fig. 1. The apparent copolymerization constants of VP (M_1) with AGC (M_2) are presented in the table. It is seen that the reactivity of the allyl monomer in the system is slightly higher than that of VP. The difference is more pronounced in a DMSO solution.

Our kinetics experiments showed that the reaction order with respect to initiator was 0.5. This fact suggests bimolecular termination of the propagating chain and the absence of degradation chain transfer to the monomer, which is typical for allyl compounds. The total reaction order with respect to both monomers at their equimolar ratio in DMSO solution is 1.3. As the content of the allyl monomer (M_2) in the initial monomer mixture increases, the polymerization decelerates (Fig. 2).

The temperature dependence of the reaction rate in DMSO was studied in the range 70–90°C. The overall activation energy of copolymerization of VP with AGC is 68.3±1.5 kJ mol^{-1}.

Our previous ^{13}C NMR study [8] showed that both double bonds of AGC were involved in copolymerization to form five-membered pyrrolidinium structures. These results agree with the known data on homopolymerization of diallyl nitrogen-containing compounds, in particular, *N,N*-diallyl-*N,N*-dimethylammonium halides, and on their copolymerization with SO_2 [15].

VP–AGC copolymers are soluble in water, methanol, chloroform, dimethylformamide, and DMSO. The intrinsic viscosity of VP–AGC copolymers (80 : 20 mol %) is 0.16 dl g^{-1} (water with 0.1 N NaCl, 25°C). The molecular weight of the copolymer containing 20 mol % AGC, roughly estimated by the Levy–Frank equation for aqueous solutions of polyvinylpyrrolidone ($[\eta] = 6.76M^{0.55} \times 10^{-4}$ [16]), is 20700.

Our toxicological study shows that VP–AGC copolymers belong to the fourth hazard category.

Our study of the biocidal activity showed that the polymers exhibited pronounced antimicrobial activity with respect to gram-positive microflora (*Staphylococcus aureus*) and could be used in medicine and biotechnology.

CONCLUSIONS

(1) *N*-Vinylpyrrolidone copolymerizes with 2,2-diallyl-1,1,3,3-tetraethylguanidinium chloride to form random copolymers. The apparent copolymerization constants show that the relative reactivity of 2,2-diallyl-1,1,3,3-tetraethylguanidinium chloride is higher than that of *N*-vinylpyrrolidone.

(2) The copolymerization rate decreases with increasing fraction of the diallyl monomer in the initial monomer mixture.

(3) In the course of copolymerization, both double bonds of 2,2-diallyl-1,1,3,3-tetraethylguanidinium chloride undergo intramolecular cyclization to form pyrrolidinium rings in the macromolecule.

(4) The polymers are nontoxic in intragastric introduction, belong to the fourth hazard category, and exhibit pronounced antimicrobial activity with respect to gram-positive microflora.

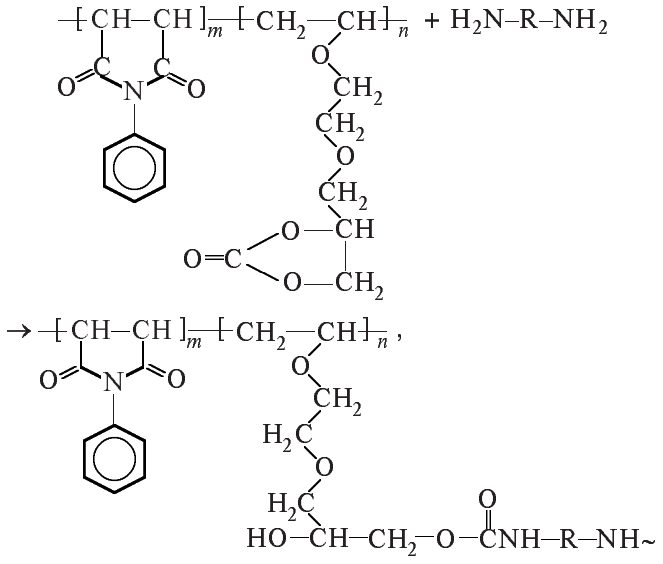
Abstract—Poly(hydroxy urethanes) and coatings based on them were prepared by ammonolysis of copolymers of 3-(2-vinyloxyethoxy)-1,2-propylene carbonate and *N*-phenylmaleimide.

DOI: 10.1134/S1070427208070367

Particular interest in polymers with cyclocarbonate groups is caused by the possibility of preparing from them polyurethanes without using toxic isocyanates. The isocyanate-free process is based on the reaction of cyclocarbonates with amines [1–3].

Copolymers containing five-membered carbonate rings in the pendant chain were prepared previously by radical copolymerization of 3-(2-vinyloxyethoxy)-1,2-propylene carbonate (VOPC) and *N*-phenylmaleimide (PMI) [4]. Here we report on preparation of poly(hydroxy urethane) coatings by modification of VOPC–PMI copolymers with amines at cyclocarbonate groups.

EXPERIMENTAL



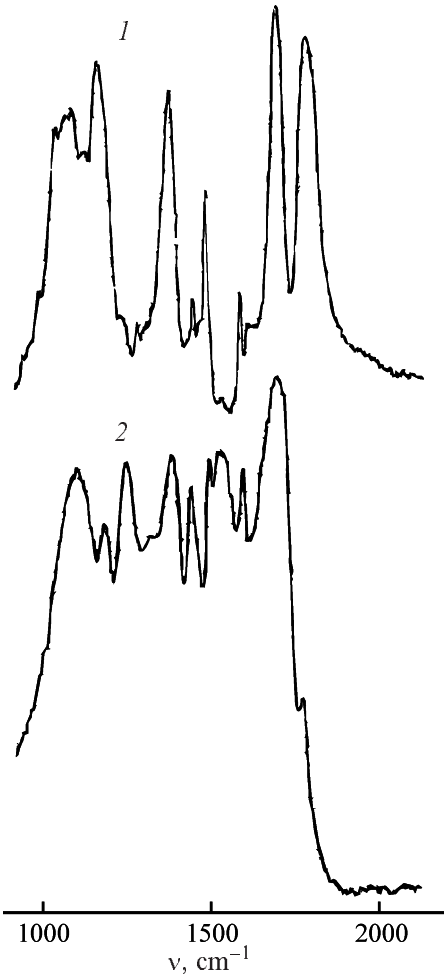
N-Phenylmaleimide was prepared by a common procedure from maleic anhydride and aniline [5]. VOPC was synthesized at the pilot plant of the Favorskii Irkutsk Institute of Chemistry, Siberian Branch, Russian Academy of Sciences [6]. VOPC–PMI copolymers were prepared by radical copolymerization in methyl ethyl ketone (MEK) in the presence of AIBN initiator [4].

Aminolysis of the copolymers was performed in DMF at room temperature for 6 h. The resulting product was precipitated with toluene and then dried in a vacuum oven at 40°C for 3 h. The copolymer has approximately equimolar composition.

Poly(hydroxy urethane) coatings were prepared as follows. VOPC–PMI copolymer was mixed with a solution of polyamine in DMF. The mixture was applied onto plates of cold-rolled 08 kp steel sheets according to GOST (State Standard) 9045–80 and dried at room temperature or at 150°C.

The IR spectra were recorded on IFS25 and UR-20 spectrophotometers in the wavenumber range 4000–400 cm^{-1}. Samples were prepared as KBr pellets. The moisture absorption was determined according to [7]. The impact strength was evaluated with a UM1 device according to GOST 4765–73. The adhesion of the coating was determined by grid notching according to GOST 15140–78.

For the modification of VOPC–PMI copolymers we used 1,2-ethylenediamine (EDA) and 1,6-hexamethylenediamine (HMDA). Aminolysis of the copolymers follows the scheme



Moisture absorption and solubility of polyurethane coatings obtained (curing at 150°C for 3 h)

where R = $-(CH_2)_2-$, $-(CH_2)_6-$; n = 1; m = 1.1–1.6.

The poly(hydroxy urethanes) obtained with HMDA and EDA are dark blue solid resins. The absence of the absorption band of the carbonate carbonyl group at 1830 cm^{-1} in the IR spectrum and the appearance of amide absorption bands (1252, 1538, 1675 cm^{-1}) is indicative of complete opening of the carbonate ring and formation of urethane groups (see figure).

IR spectra of (*1*) VOPC–PMI copolymer and (*2*) poly(hydroxy urethane). (ν) Wavenumber.

From the poly(hydroxy urethanes) synthesized, we prepared hot- (150°C) and cold-cured coatings. As curing agent we used EDA, HMDA, and polyethylenepolyamine at equimolar ratio of the copolymer and curing agent and at excess of the latter. The best adhesion to metal surfaces, 2 points according to GOST 15140–78 (1 point according to ISO 2409–72 standard) were obtained at equimolar ratio of the copolymer and curing agent. In impact strength tests of the coatings, signs of damage appeared at an impact height of 35–40 cm.

Coatings exhibiting high chemical resistance and low moisture absorption were prepared from the copolymer and 4,4'-diamino-3,3'-dimethyldiphenylmethane (see table). Such coatings do not dissolve in concentrated solutions of acids and alkalis, and their moisture absorption is below 1%. However, their adhesion to metal surfaces and impact strength are poor, probably because of the fact that aromatic amines react with cyclocarbonates without formation of urethane groups imparting the elasticity to the material [1].

CONCLUSION

Aminolysis of copolymers of 3-(2-vinyloxyethoxy)-1,2-propylene carbonate and *N*-phenylmaleimide, containing cyclocarbonate groups, allows preparation of poly(hydroxy urethane) coatings exhibiting good mechanical properties.

BRIEF COMMUNICATIONS

Synthesis of Mixed Wood Esters

M. V. Efanov, A. I. Galochkin, and V. A. Novozhenov

Research Institute of Wood Thermoplastics, Altai State University, Barnaul, Russia

Received February 5, 2008

Abstract—A new procedure was developed for preparing mixed esters of lignocarbohydrate materials. Transformations of aspen wood in the course of its acylation with a mixture of acetic anhydride with aliphatic carboxylic acid under the conditions of mechanochemical activation in the presence of ammonium sulfate as catalyst were studied.

DOI: 10.1134/S1070427208070379

Acylation of wood is a promising direction of its chemical modification. Wood acylation products are soluble in organic solvents. They exhibit hydrophobic and thermoplastic properties and are bioresistant. These physicochemical properties determine possible application fields of wood acylation products [1].

The use of acylated wood as a thermoplastic binder for preparing composite materials with a mineral or wood filler allows preparation of wood boards with good physicomechanical and hydrophobic properties. This is favored by high thermoplasticity of acylated wood and its good adhesion to mineral and especially organic substances (wood) [2].

Procedures have been developed for preparing esters from wood mechanochemically activated in the presence of catalysts by acylation with a mixture of acetic anhydride (AAn) with a carboxylic acid at 100–130°C for 4–6 h. These procedures have certain drawbacks: long synthesis time (up to 6 h), elevated temperature, and high consumption of acylating agents (up to 10 mol) [3, 4].

A more efficient mechanochemical procedure for acylation of lignocarbohydrate materials with acetic anhydride or a mixture of acetic anhydride and a carboxylic acid in the presence of ammonium sulfate as catalyst was developed previously [5, 6]. In this study we examined the composition and properties of products obtained by mechanochemical acylation of aspen wood.

EXPERIMENTAL

Mechanochemical acylation of vegetable raw materials was performed as follows: A reactor of a vibration mill (IV 98B commercial vibrator, frequency 2800 min^{-1}) with 15 steel rods (10 × 100 mm) was charged with a 2.0-g portion of air-dry sawdust of a lignocarbohydrate material, and acetic anhydride and a monobasic saturated carboxylic acid containing three to six C atoms in the molecule were added (0.3–5 mol per mole of OH groups of the raw material). The temperature in the reaction chamber was maintained at 25°C with a thermostat. The reactor was charged with 5–30% ammonium sulfate (based on the raw material), and the mixture was subjected to intense mechanical milling for 0.5–3 h. Then the products were unloaded, separated from the milling bodies, washed with water to remove the acids and catalyst, and dried to constant weight.

The content of bound acyl groups was determined by saponification of the samples of acylated lignocarbohydrate materials with a 0.5 N alcoholic solution of NaOH, followed by determination of the free carboxylic acids by GLC with an internal reference [4]. The solubility of wood acylation products in chloroform was determined by the procedure described in [7] fir cellulose acetates.

We examined how the time of the mechanochemical synthesis at an acetic anhydride amount of 1 mol per mole of OH groups of wood affects the content of bound carboxylic acids and the solubility of the acylation products in chloroform.

Experiments showed (Table 1) that, as the time of mechanochemical acylation is made longer, the content of bound acetic (AAc) and butyric (BAc) acids in the products and their solubility in chloroform regularly increase.

Table 2 shows that, with an increase in the molar

12	Propionic	17.8	8.2	61
13	Valeric	19.5	7.1	73
14	Capronic	21.5	6.3	75

ratio of the acylating agents (acetic anhyride, butyric acid) to OH groups of wood from 0.5 : 0.5 : 1 to 3 : 3 : 1, the content of bound acetic and butyric acids and the solubility of the products in chloroform increase.

The chain length of the carboxylic acid also affects the properties of mixed aspen wood esters (Table 3). With an increase in the number of carbon atoms in the carboxylic acid, the solubility of the acytlated products in chloroform regularly increases. Simultaneously the content of bound higher carboxylic acid in the products somewhat decreases, probably because of a decrease in the reactivity of carboxylic acids with increasing chain length.

The amount of the catalyst (ammonium sulfate) also affects the content of the bound acids and the solubility of the wood acylation products in chloroform (Table 4).

With an increase in the amount of the catalyst (ammonium sulfate), the content of bound carboxylic acids in the products and their solubility in chloroform increase. The best properties are attained with the amount of ammonium sulfate of 20–30 wt % relative to the raw material.

For comparison, we prepared sample 19 with

* Magnesium perchlorate catalyst.

magnesium perchlorate [4] used as catalyst. We found that comparable results are obtained with ammonium sulfate taken in amount of 5–30 wt % relative to the raw material.

CONCLUSIONS

(1) With mechanochemical treatment, the reagent consumption in acylation of lignocarbohydrate materials can be decreased by a factor of 3–10; the process time, from 4–6 to 0.5–3 h; and the reaction temperature, from 100–130°C to 25°C, with the process as a whole made cheaper.

(2) The obtained mixed esters of lignocarbohydrate materials contain up to 32.9% bound acetic acid and up to 12.1% bound butyric acid. They are soluble in chloroform to 84%, exhibit thermoplastic properties, and can be used as binders for boards of composite materials.

BOOK REVIEWS

Meretukov, M.A., *Aktivnye ugli i tsianistyi protsess* (Activated Carbons and the Cyanide Process)

Moscow: Ruda i Metally, 2007, 288 pp.

DOI: 10.1134/S1070427208070380

At present, the carbon-sorption process is used at a number of gold-mining enterprises in the Russian Federation. In accordance with the Federal Program for Development of the Gold-Mining Industry, the share of sorption processes based on activated carbons should sharply increase. The monograph by Prof. M.A. Meretukov presents for the first time in the domestic literature the history of development of the scientific foundations and technology of carbon-sorption processes, discusses the theory of sorption of various cyanide compounds on activated carbon, and considers other processes related to the technique in question.

The book comprises an introduction, twenty-three small chapters, and a supplement. Each chapter is provided with a bibliographic list, with a total of 373 references to mostly original publications in foreign journals of last years. Chapters 11 and 19 also have lists of additional references.

The introduction (pp. 3–6) briefly presents the history of application of activated carbons in hydrometallurgical processes. Chapter 1 (pp. 7–21) considers the nature of adsorption processes and their mathematical description. Chapter 2 (pp. 22–30) discusses types of activated carbons and methods for their preparation. Chapters 3 (pp. 31–47), 4 (pp. 38–41), and 5 (pp. 42–51) are devoted to the structure and properties of activated carbons. Chapter 6 (pp. 52–60) describes in the historical aspect the development of concepts of the adsorption properties of carbons. Chapter 7 (pp. 61–77) considers the nature and composition of surface groups of both acidic and basic types on activated carbons. Chapters 8 (pp. 78–84) and 9 (pp. 85–97) are devoted to electrochemical and electrical properties of carbons. Chapter 10 (pp. 89–110) contains brief evidence about the chemistry of cyanide compounds of gold and silver.

Chapter 11 (pp. 111–127) summarizes reference data on the thermodynamic properties of cyanide compounds of gold and silver. The author is mostly based on recent publications and widely uses potential–pH diagrams in analysis of the stability regions of compounds or complex ions. Chapters 12 (pp. 128–161) and 13 (pp. 162–166) are devoted to an analysis of the existing theories of gold and silver sorption on activated carbons. Chapter 14 (pp. 167–172) presents information about the effect of oxygen on the sorption of gold and silver. Chapter 15 (pp. 173–183) describes the most informative methods for study of the sorption of gold and silver. Unfortunately, even the most recent studies fail to provide a unified concept not only about the mechanism by which carbon sorbents interact with cyanide complexes of gold, but also about the composition of compounds formed in the carbon phase. The author attributes the insufficient reproducibility of the experimental results to the heterogeneous structure of activated carbons, which depends on the starting raw material and synthesis conditions. The differences are eliminated and cease to be important only when tests are performed with large batches of activated carbon.

Chapter 16 (pp. 184–199) formulates a set of problems associated with studies of the sorption of gold from cyanide solutions and once again emphasizes the difficulty of choosing a definite mechanism of this process. Chapter 17 (pp. 200–216) presents kinetic characteristics of gold sorption by activated carbon, obtained by different authors. Most of kinetic models are based on the assumption of a local equilibrium between gold contained in solution near the carbon surface and gold already adsorbed on the surface. Very small chapter 18 (pp. 217–222) is devoted to thermodynamic and chemical properties of the cyanide ion in aqueous solutions.

Chapters 19 (pp. 223–239), 20 (pp. 240–243), 21 (pp. 244–257), 22 (pp. 258–262), and 23 (pp. 263–278) describe the technology of sorption recovery of

gold and silver from solutions and slurries and characterize the apparatus employed, mostly on the basis of the experience of foreign plants.

The very brief supplement (pp. 280–282) is devoted to calculation of the activity coefficients of separate ions in solutions on the basis of the extended Debye–Hückel equation.

The monograph by Meretukov is of indubitable interest for specialists engaged in the gold-mining industry. The book covers a wide variety of theoretical and practical issues; the manner of presentation is well understandable. The large number of references to publications and the well-prepared illustrative and tabulated material make higher the information value of the book.

REVIEWS

Development and Improvement of Extraction Processes for Separation and Purification of Petroleum Products

A. A. Gaile

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received December 26, 2007

DOI: 10.1134/S1070427208080016

Processes of extraction, extractive and azeotropic rectification, absorption, and extractive crystallization, which use selective solvents, are widely used in petroleum processing and petrochemistry. As far back as 1950s–1960s, effective agents were suggested for separation and purification of petroleum products: sulfolane, *N*-formylmorpholine, and *N*-methylpyrrolidone.

At present, more than 150 industrial installations for extraction of aromatic hydrocarbons with sulfolane from products formed in pyrolysis and catalytic reforming of gasoline fractions are in use in the world. About 9 million tons of benzene, toluene, and xylene is annually produced by extractive rectification (Morphylane) and extraction (Morphylex) with *N*-formylmorpholine on 55 industrial installations [1]. Mixtures of *N*-formylmorpholine and *N*-acetyl-morpholine are also used in the Morphysorb process for absorption purification of natural gas and industrial gases with high content of hydrogen sulfide and carbon dioxide [2]. The Sulfinol process is widely used for absorption of hydrogen sulfide and other sulfur-bearing compounds from hydrocarbon gases and hydrogen. This process employs a mixed absorbent composed of a chemisorbent (diisopropanolamine), water, and sulfolane as a physical solvent [3].

Owing to a combination of high selectivity toward aromatic and unsaturated hydrocarbons, hydrogen sulfide, and a number of other gaseous components with an exceedingly high dissolving capacity, *N*-methylpyrrolidone is widely used in various separation processes. These are the following: recovery of arenes from mixtures with saturated hydrocarbons by extraction and extractive rectification; separation of 1,3-butadiene and isoprene by extractive rectification; selective purification of oil fractions to remove tars, polycycloarenes, and heteroatomic compounds; absorption recovery and purification of acetylene; absorption of hydrogen sulfide and other acid-type compounds from gas mixtures; removal of lubricants and technological coatings from the surface of metallic and optical articles.

In 1986, UOP company developed and put into industrial practice the Carom process intended for extraction of arenes with a mixed solvent based on tetraethylene glycol, which contains up to 20% cosolvent that raises the dissolving capacity [4]. Addition of the cosolvent, whose composition is not disclosed, makes it possible to lower the ratio between the extractive agent and the feed, diminish the specific energy expenditure, and improve the output capacity of installation. Four industrial installations operate by the Carom technology.

In the late XX century, GTC Technology Corporation developed a process for recovery of benzene, toluene, and xylenes by extractive rectification with a Tective-100 mixed selective solvent whose composition has not been disclosed, either [5]. Three industrial installations operate using this technology, and several installations are being designed and constructed.

In 2001, the first industrial extraction installation was put into operation in the United States for removal of sulfur-bearing compounds and aromatic hydrocarbons from the diesel fraction and for production of an ecologically clean diesel fuel [6]. The above-mentioned brief reports presented only a rough schematic diagram of the process, whence follows that an extractive agent of unspecified composition is regenerated from equilibrium phases by extraction with water.

The liquid–vapor and liquid–liquid equilibria are described using various empirical equations (Redlich–Kiester, Van Laar, Margules), semiempirical models

Wilson, NRTL, and UNIQUAC, developed by Renon, Prausnitz, Abrams, and others), and theoretical methods (ASOG, UNIFAC) [7, 8]. New or refined interaction parameters have been reported for 78 pairs of groups for the Dortmund model UNIFAC [9]. The effect of temperature on the mutual solubility data for 81 binary systems is better described by the extended UNIQUAC model [10] suggested in [11].

A major contribution to studies of the thermodynamics of solutions of hydrocarbons and other organic compounds in selective solvents have been made by J. Gmehling and coworkers (Oldenburg University, Germany). The following parameters have been determined: activity coefficients of hydrocarbons at infinite dilutions (by gas–liquid chromatography), selectivity of solvents toward aromatic and unsaturated hydrocarbons, and heats of mixing. The liquid–vapor and liquid–liquid equilibria have been studied. The results obtained and published data of other authors are represented in a number of reference books [12–19].

Studies of the thermodynamics of solutions of hydrocarbons in selective solvents have also been conducted under the supervision by Bittrich and are being continued by Lempe and Hradetzky (University of Halle, Germany) [20, 21].

The donor–acceptor properties of solvents, including a number of selective solvents, are characterized in the monographs [22, 23]. It is important to take these properties into account because the selectivity of polar (solvents toward aromatic and unsaturated hydrocarbons is mostly due to the formation of π-complexes [24].

In recent years, numerous studies have been reported, devoted to the selectivity of ionic fluids and their use as separating agents in extractive rectification and extraction for isolation of aromatic hydrocarbons and extractive purification of diesel fuel and oil fractions. It has been found that some ionic fluids are more selective toward the hexane–benzene system, than sulfolane, which is the most selective of the industrial extractive agents. These are, e.g., 1-ethyl and 1-butyl-3-methylimidazolium tetrafluoroborates [25] and 4-methyl-*N*-butylpyridinium tetrafluoroborate [26]. It is noted that the latter ionic fluid makes it possible to extract toluene from a mixture with heptane by using a rotary-disc extractor at a lower ratio to the feed, compared with sulfolane [27]. It is suggested to use ionic fluids for extraction of sulfur-containing compounds from diesel fractions (degree of recovery in a single stage, 10–30%) [28] and for selective purification of oil fractions [29]. However, the following disadvantages of ionic fluids can be noted.

(1) High viscosity, which must impair the efficiency of the contact members of extractors or extractive rectification columns. For example, the viscosity of the phenyl ammonium formate complex suggested for selective purification of oil lubricants at 50°C is 7.6×10^3 Pa s, and that of furfural, with which the extraction results are compared, is as low as 11.5 Pa s [29].

(2) Low dissolving capacity of highly selective ionic fluids. The solubility of benzene in 1-butyl-3-methylimidazolium tetrafluoroborate at 25.06 and 70.38°C is 2.3 and 18.73 wt %, respectively [30].

(3) The dramatic decrease in the selectivity of ionic fluids toward the cyclohexane–benzene system, compared with the hexane–benzene system, e.g., by a factor of 2.32 at 30°C for 1-butyl-3-methylimidazolium tetrafluoroborate [25]. At the same time, just the cycloalkane–arene systems are the key, most difficultly separable systems in isolation of arenes from mixtures with saturated hydrocarbons.

(4) Ionic fluids with high group selectivity also have selectivity in molecular masses. For example, the ratio between the limiting coefficients of heptane and hexane at 30°C in 1-butyl-3-methylimidazolium tetrafluoroborate is 1.614 [25]. Therefore, the ionic fluids must exhibit low selectivity toward the key, most difficultly separable components in extraction of arenes from fractions with broad boil-off limits.

Thus, with account of the set of requirements to selective solvents (high selectivity toward key components, high dissolving capacity with respect to the components being isolated, low selectivity in molecular mass, and low viscosity), the ionic fluids under study are inferior to the most efficient industrial extractive agents. However, ionic fluids may exhibit a higher efficiency, compared with sulfolane, in separation of close boiling hydrocarbons or narrow boiling fractions.

An important contribution to the development of theoretical foundations and technology of separation of mixtures of organic substances with selective solvents has been made by specialists from Russia and CIS countries. The review presented in a biobibliographic reference book [31] briefly characterizes Russia's main extraction schools; however, the biographic evidence about specialists is far from being complete.

Fundamental monographs and reference books including data on separation of mixture with the use of selective solvents and phase equilibria have been published [32–43].

Many years' studies of separation of multicomponent azeotropic mixtures have been carried out at Lomonosov State Academy of Fine Chemical Technology in Moscow under the supervision of Serafimov, Timofeev, and Frolkova [44–48].

The selectivity of separation of hydrocarbons with binary solvents are studied by E.I. Shcherbina, A.E. Shcherbina, and their pupils at Belarussian Technological Institute [49–51]. At Belarussian State University, S.M. Leshchev and co-authors study the dissolving capacity and the solvation and solvophobic effects of solvents with various polarities on various classes of nonelectrolytes. It has been suggested to use increments of the methylene and functional groups for calculating the distribution constants in extraction of organic substances [52].

R.G. Makitra has suggested to use polyparameter equations for evaluating the solvation effects in dissolution of gases and extraction of hydrocarbons and their derivatives by supplementing the Koppel–Palm equation with the Hildebrand solubility parameter [53].

S.Yu. Pavlov and co-workers have been developing the physicochemical foundations of separation of industrial mixtures of C_4–C_5 hydrocarbons by extractive rectification in order to isolate 1,3-butadiene and isoprene at Yaroslavl NIIMSK during many years [54]. At present, the work on isolation of unsaturated hydrocarbons and syntheses on their basis is being successfully continued together with O.S. Pavlov and D.S. Pavlov.

Zaretskii studies separation of products formed in thermal treatment of coals and shales at Zelinskii Institute of General Chemistry [55, 56]. Results of these studies and the author's review devoted to isolation of aromatic hydrocarbons and heterocyclic compounds are also of interest for solution of problems encountered in separation and purification of petroleum products.

At Ufa Petroleum Institute, many years' studies of extraction of aromatic hydrocarbons and selective purification of oil petroleum fractions have been performed under supervision of Bikkulov [57]. At present, technologies of selective purification and dewaxing of oil fractions by extractive crystallization are being developed by Ol'kov and coworkers [58, 59]. He also heads works on extractive dearomatization of diesel fractions with the use of, in particular, 1,4-dioxane [60]. At the same institute, Ziganshin and coworkers develop extractive agents with a regular packing, which are successsfully used industrially in installations for deasphalting and selective purification in manufacture of oil lubricants [61–63].

Studies of extractive purification of petroleum fractions and, in particular, of dearomatization of diesel fuels are being also conducted at the Institute of petrochemical processing of the Republic of Bashkortostan (State unitary enterprise INKhP RB), but the composition of the extractive agents studied has not been identified [64]. Of interest is a combined technology for production of diesel fuels by extractive and catalytic dearomatization [65].

At Gubkin Russian State University of oil and gas, studies deasphalting, selective purification, and dewaxing in manufacture of oil lubricants and deoiling of solid hydrocarbons are conducted under supervision of Fuks [66].

At VNIINP, Shkol'nikov and coworkers carry out studies aimed to improve processes of selective purification and deasphalting of oil raw materials [67, 68].

At Kazan State University, the selectivity of solvents toward aromatic hydrocarbons and organosulfur compounds have been studied by I.N. Diyarov and V.G. Kozin with coworkers [69].

The extraction of phenols and other aromatic oxy compounds from aqueous solutions is studied by Korenman and coworkers at Voronezh Technological Academy [70–72]. Works in the same area are being continued by Ermolaeva [73].

At the Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, the extraction of phenols, organic acids, and various biologically active substances has been studied under the supervision of Yu.E. Nikitin, Yu.I. Murinov, and N.L. Egutkin [74].

In the 1960s–1970s, processes for extraction of aromatic hydrocarbons from reforming catalyzates were being developed at the laboratory of extraction at VNIINeftekhim (V.N. Pokorskii, N.F. Grishchenko with coworkers), and those for selective purification of oil fractions and deasphalting of petroleum residues, at GrozNII (A.G. Martynenko, G.L. Potashnikov with coworkers) [75].

Many years' studies of the physicochemical foundations and technology of processes of separation of hydrocarbon raw materials with selective solvents have

been carried out at St. Petersburg State Technological Institute (SPbGTI). Ya.I. Leitman and coworkers developed the first domestic process for recovery of benzene, toluene, and xylene from reforming catalyzates by extractive rectification with an LTI solvent. In 1963–1964, this process was implemented at six industrial installations. In the last 40 years, studies in this area have been conducted by A.A. Gaile and coworkers. The results obtained are represented in 3 doctoral [76–78] and 24 candidate dissertations and in 320 publications, including a number of monographs [79–85], textbooks [86–89], reviews [90–93], and topical collections of articles [94, 95]. The present review considers results of studies carried out, for the most part, in the last five years.

In the studies, the following goals were formulated [96, 97]:

(i) development and improvement of extractive and combined processes for recovery of aromatic hydrocarbons from catalyzates produced in reforming of gasoline fractions;

(ii) extractive purification of the kerosene and diesel fractions and atmospheric gas oil to obtain motor fuels satisfying the increased ecological requirements;

(iii) extractive refinement of vacuum gas oils and mazut, which are raw materials for catalytic cracking and hydrocracking.

Review [98] contains data on the selectivity of 683 solvents toward the systems hexane–benzene, cyclohexane–benzene, and 1-hexene–benzene. Of these solvents, 506 have been studied at SPbGTI. Also presented are values of the limiting activity coefficients of benzene in the solvents, which can be used to judge about their dissolving capacity, and ratios between the limiting activity coefficients of heptane and hexane, which characterize the selectivity of the solvents with respect to molecular masses. The review presents correlation equations relating the selectivity to the σ-constants of substituents in solvent molecules and to the criteria characterizing the nonuniformity of the charge distribution. The relations that can be used to choose effective extractive agents combining high selectivity and dissolving capacity toward aromatic hydrocarbons are analyzed.

Review [99] presented patent information about 230 individual extractive agents and about mixed solvents and heterogeneous extractive systems, both those used industrially and those suggested for extraction of aromatic hydrocarbons from reformates of gasoline fractions and from medium-distillate and oil fractions.

The interaction parameters of the UNIFAC method have been refined for group pairs ACH–TMS (sulfolane) and $ACCH_2$–TMS. On the basis of parameters of binary systems, liquid–liquid equilibria have been calculated using the NRTL and UNIFAC equations for 15 three-component systems constituted by sulfolane, a saturated hydrocarbon (alkanes C_5–C_{10}, cyclohexane), and an arene (benzene and its homologues C_7–C_{10}) [100].

In 2000, the extraction unit of an LG-35-8/300B installation at Kirishinefteorgsintez Production Association Ltd. was converted from triethylene glycol (TEG) to a mixed extractive agent composed of TEG and sulfolane. At a sulfolane content of 15 wt %, the ratio of the extractive agent and recycle to the feed was reduced by 20% at the same degree of recovery. In another operation mode with the same ratios of the extractive agent and recycle to the feed, as also in the case of TEG without sulfolane, the overall degree of arene recovery increased by 2.1%, and that for toluene and xylenes, by 2.4 and 10.1%, respectively [101, 102].

At the end of 2006, the content of sulfolane in the mixture with TEG was raised to 28–30 wt % in accordance with the recommendations of [103] and the mass ratio between the extractive agent and feed was lowered to 4.9. The benzene fraction isolated by rectification from the reformate of the broad gasoline fraction was used as an additional source of feed for the extraction unit. As a result, the content of benzene in motor gasoline was diminished to below 1 vol % in conformity with Euro-4 regulations, and the daily output of commercial benzene increased from 120–140 to 240 tons. The comparatively weak intermolecular interactions in the TEG–sulfolane system lead to an increase not only in the selectivity, but also in the dissolving capacity toward hydrocarbons [104]. Positive deviations from the Raoult law facilitate regeneration of the mixed extractive agent. The stripping of arenes occurs without vacuum with the use of the 10-atm steam available at the plant.

In the initial stage of operation of the installation on the mixed extractive agent, an increased loss of sulfolane with the extract was revealed. To eliminate the problem, the unit for washing with water was redesigned, which made it possible to re-extract sulfolane and TEG from the still bottoms of the toluene column,

in which xylenes and higher-boiling extractive agents are concentrated, rather than from the extract. Because the fraction of xylenes in the extract is 3–5 wt %, the expenditure of the aromatic feed delivered to water washing became 20–30 times smaller. In addition, the extraction of polar solvents with water from xylene solutions is more efficient than that from mixtures with benzene and toluene, because the systems constituted by xylenes and sulfolane (TEG) have a higher degree of nonideality [105].

After the washing scheme was changed, the loss of the extractive agent with the extract decreased by a factor of 20–25 to become about 10 g per ton of the recovered arenes.

A dramatic decrease in the required mass ratio of selective solvents to the feed to 2.8 in recovery of arenes C_6–C_8 is achieved on replacing the extraction with the combined method of extractive rectification, followed by extraction of benzene partly finding its way into the distillate [106–111]. It was suggested to use a 30/70 wt % mixture of sulfolane with *N*-methylpyrrolidone, which exhibits a synergistic effect, as a selective solvent in the stage of extractive rectification. In the stage of benzene extraction, the optimal composition of the mixed extractive agent constituted by sulfolane and *N*-methylpyrrolidone is 90/10 wt %.

The principle of combination of mutually complementary processes of extractive rectification and extraction with mixed solvents of the same qualitative, but different quantitative compositions enables regeneration of selective solvents in the same common unit. The high economic efficiency of the suggested combined method for recovery of benzene, toluene, and xylenes from reformates has been confirmed by technical-and-economic calculations [112]. The results obtained surpass the parameters of the most efficient individual processes of extraction with sulfolane or extractive rectification with *N*-formylmorpholine.

The combined method of extraction with sulfolane and the subsequent extractive-azeotropic rectification of the extract phase with sulfolane and ethanol from the reforming catalyzate of the broad gasoline fraction containing 55.6 wt % arenes C_6–C_9 was used to obtain in 65 wt % yield the gasoline component satisfying the enhanced ecological requirements. The total content of arenes in this component is 28 wt %, including about 1 wt % benzene. Simultaneously, benzene, toluene, and C_8 and C_9 arenes were recovered with degrees of recovery of 89, 77, 69, and 24 wt %, respectively.

The overall mass ratio of sulfolane to the feed in both stages of the process is 1.88, and that of ethanol, 0.032, with recycling flows being absent. Ethanol can be used in extractive-azeotropic rectification without regeneration as a high-octane component of gasoline [113, 114].

To make lower the content of benzene in motor gasoline manufactured at Kirishinefteorgsintez Production Association Ltd., it is planned to construct an installation for extractive rectification under license from GTC Technology, Inc., with the use of Tektiv-100 mixed selective solvent [115]. The solvent composition has not been reported, but, judging from its regeneration in the vacuum striping column with high-pressure steam (as in the case of recovery of arenes by extraction with sulfolane), it contains high-boiling components. For example, it has been suggested to recover arenes by extractive rectification with mixtures of sulfolane with 3-methyl sulfolane or dipropyl sulfone [116], or with alkyl derivatives of sulfolane [117]. A number of disadvantages associated with the application of mixtures of high-boiling solvents can be noted. In particular, there are difficulties in their regeneration, the elevated temperature at plates of the extractive recombination column impairs the stability of π-complexes with arenes and the selectivity of solvents. The high viscosity of the solvents leads to a decrease in the plate efficiency.

These shortcomings can be overcome by addition of a comparatively low-boiling low-viscosity solvent with an increased dissolving capacity, e.g., *N*-methylpyrrolidone, which promotes homogenization of the system with hydrocarbons being separated and makes higher the efficiency of extractive rectification [109], to the highly selective solvent (sulfolane, *N*-formylmorpholine).

Raising the content of sulfolane in the mixture with TEG to 57 wt % makes it possible to reduce the mass ratio of the mixed extractive agent to the reformate of the fraction containing arenes C_6–C_8 to 3 and the expenditure of the recycle from 80–100 to 30 wt % relative to the feed. The use of the pentane recycle instead of the C_6–C_8 hydrocarbons results in that toluene is excluded from its composition, the content of benzene in the recycle becomes substantially lower, and its expenditure additionally decreases [118, 119].

After a new installation of extractive rectification for recovery of benzene is put in operation in the extraction unit of the operating LG-35-8/300B installation, it

will become possible to extract toluene and sum of xylenes. The seven-stage counterflow extraction of arenes from the toluene–xylene fraction of the reformate with a mixed TEG–sulfolane–water extractive agent (48.1 : 48.1 : 3.8 wt %) at a mass ratio of 5 : 1 will provide a degree of recovery of toluene and xylenes exceeding 97% [120].

Another suggested way to use the extraction unit of the operating installation is to recover C_7–C_9 arenes from the reformate of the 95–190°C gasoline fraction by the combined method of extraction with a mixed TEG–sulfolane extractive agent (50 : 50 wt %), followed by removal of admixtures of saturated hydrocarbons from the extract phase by azeotropic rectification with ethanol without regeneration of the alcohol. The suggested method makes it possible to obtain a reformed component of gasoline, which satisfies the Euro-4 and Euro-5 regulations in the total content of arenes, at a small mass ratio between the extractive agent and the feed (2.5) and to recover commercial toluene and sum of xylenes with a degree of recovery equal to about 90 and 85%, respectively [121, 122].

A new principle was suggested for choosing extractive agents for recovery of aromatic hydrocarbons and heteroatomic compounds from medium-distillate petroleum fractions and vacuum gas oils. In accordance with this principle, the extractive agent must form heteroazeotropes with saturated hydrocarbons from the feed and must not yield azeotropic mixtures with the components being extracted. In this case, the rectification regeneration of the extractive agent from the extract phase is accompanied by additional removal of saturated hydrocarbons and an increase in the content of the components being extracted in the aromatic concentrate.

In extractive purification of the kerosene fraction, this requirement is satisfied by acetonitrile, which forms azeotropes with C_9–C_{10} saturated hydrocarbons and gives no azeotropes with arenes. As a result of the combined purification of the kerosene fraction with the extractive system composed of acetonitrile with 3 wt % water and pentane, the content of saturated hydrocarbons decreases from 16.4 wt % in the extract to 0.5 wt % in the aromatic concentrate in the remaining still bottoms. This method can be used to obtain a high-quality jet engine fuel with a content of arenes of 8.5 wt % from the hydropurified kerosene fraction, and aromatic Nefras solvents from the aromatic concentrate [123, 124].

The following extractability series was determined in extractive purification of the straight-run kerosene fraction with the same system: benzothiophenes > alkylnaphthalenes > biphenyls > alkylthiophenes > tetralines and indanes > alkylbenzenes > dialkyl sulfides. Thus, benzothiophenes, which are the most difficultly removed in hydropurification, is extracted the most easily [125].

A similar extractability series was determined in extractive purification of the straight-run kerosene fraction with the system constituted by methyl cellosolve and pentane [126]: dibenzothiophenes > phenanthrenes, fluorenes > benzothiophenes > naphthalenes > biphenyls > thiophenes > tetralines and indanes > alkylbenzenes > saturated organosulfur compounds.

Even more easily extracted are nitrogen-containing heterocyclic compounds of aromatic nature. The extraction of 1-methyl naphthalene, benzothiophene, and indole from model mixtures with hexadecane has been studied with *N*-methylpyrrolidone as extractive agent without a nonpolar solvent, in the presence of comparatively low-boiling alkanes: hexane, decane, and dodecane [127]. The following extractability series was established: indole > benzothiophene > 1-methyl naphthalene. It was demonstrated that extraction with a polar extractive agent in the presence of a nonpolar solvent is a more effective way to improve the selectivity of separation, compared with watering of the extractive agent.

The calculation methods UNIFAC and UNIQUAC have been used to analyze the effect of various nonpolar solvents (butane, pentane, hexane, cyclohexane, eicosane, benzene) on the results of the single-stage extraction of arenes from model mixtures containing alkanes and cycloalkanes with acetonitrile and *N*,*N*-dimethylformamide [128]. Introduction of alkanes and cyclohexane into the extractive system results in that the selectivity of the process increases: the content of arenes in the extract and the separation coefficients become higher. The extraction in the presence of benzene favors an increase in the degree of recovery of arenes; however, the selectivity of the separation process decreases. Arenes are more selectively extracted with polar extractive agents in the presence of pentane, hexane, or cyclohexane. With account of technological and technical-economic factors, it is preferable to use pentane as a nonpolar solvent limitedly miscible with a polar extractive agent.

The extraction of arenes from a hydropurified diesel fraction with acetonitrile with 2 wt % water in

the presence of pentane yielded a diesel fuel and an extract containing 15 and >90 wt % arenes, respectively [129]. The efficiency of the method has been confirmed on an installation with a rotary-disc extractor corresponding to 4.5–5 theoretical stages [130].

By using a five-stage counterflow extraction of a hydropurified diesel fraction with methyl cellosolve with 5 wt % water in the presence of pentane, the content of arenes can be reduced from 25 to 10–11 wt %, and that of sulfur, from 0.045 to 0.02 wt % [131–133].

Even more effective in extractive purification of the diesel fraction are extraction systems constituted by dimethylformamide (or *N*,*N*-dimethylacetamide) and pentane [134–135]. In contrast to acetonitrile and methyl cellosove, dimethylformamide and *N*,*N*-dimethylacetamide form azeotropic mixtures with saturated hydrocarbons contained in the extract phase. As a result, the content of saturated hydrocarbons decreases from 7 wt % in the extract to 2 wt % in the aromatic concentrate, which can be used as an aromatic Nefras solvent.

With the same dimethylformamide–pentane extractive system, ecologically clean waxy working fluids RZh-3 and RZh-8, whose arene content does not exceed 5–5.5 wt %, can be obtained from a dewaxed 200–320°C fraction [136].

The extractive purification of atmospheric gas oil with methyl cellosolve in the presence of pentane can yield a raffinate that can be used, on being subjected to hydropurification, as a component of the summer diesel fuel [137]. The high economic efficiency of the combined method for production of a diesel fuel component from the atmospheric gas oil by extraction followed by hydropurification of the raffinate under mild conditions to remove saturated organosulfur compounds was confirmed in [138].

Even more efficient is the extractive purification of atmospheric gas oil with *N*-methylpyrrolidone in the presence of undecane. In the case of a four-stage counterflow extraction at a mass ratio of *N*-methylpyrrolidone and undecane to the feed equal to 2 and 0.3, respectively, the raffinate yield was 77.6 wt %. The content of arenes in the raffinate decreased from 28.2 to 9.8 wt %, and that of sulfur, from 1.15 to 0.47 wt %. The cetane ratio increased from 50 to 59%. and the 90% point of the raffinate decreased, compared with the feed, by 17° [139, 140].

Various methods for extractive purification of motor fuels were considered in the reports [141, 142].

The five-stage counterflow extractive purification of the 225–290°C fraction of Troitsk-Anastasievsk petroleum containing about 23 wt % arenes with methyl cellosolve and 4 wt % water at a mass ratio of the extractive agent and nonpolar solvent (pentane) to the feed equal to 8 and 1, respectively, produced a raffinate in 69 wt % yield [143]. The content of arenes in the raffinate is decreased to 4.2 wt % and it satisfies requirements to the AMG-10 low cold-test hydraulic oil manufactured by the method of sulfatization with oleum, which fails to conform to modern ecological regulations.

Similarly, a five-stage counterflow extraction of arenes and heteroatomic compounds from the 300–350°C fraction of the Troitsk-Anastasievsk petroleum containing 30 vol % arenes and 0.16 wt % sulfur at a mass ratio of methyl cellosolve with 5 wt % water and pentane to the feed equal to 4 and 1, respectively, lowered the content of sulfatable compounds to 18 vol %. The raffinate yield was about 82 wt %; the content of arenes in the extract was 87 wt %, which points to a rather high selectivity of the extractive purification. The transformer oil produced from the raffinate obtained satisfies the requirements to TKp oil in all parameters with a large safety margin; in particular, the dielectric loss tangent is 0.24% at a required value of 2.2% [144].

To remove polycycloarenes, nitrogen- and sulfur-containing compounds, and heavy metals (which poison and coke hydrocracking catalysts) from heavy vacuum gas oil, a combined method of extraction followed by azeotropic rectification has been developed [145–147].

Aqueous *N*-methylpyrrolidone served as a polar solvent, and a mixture of 99 wt % heptane and 1 wt % toluene, which models the raffinate produced by the LG-35-8/300B benzene reforming installation, was used as a nonpolar solvent improving the separation selectivity. After nonpolar solvents were removed from the extract phase, ethylene glycol was added to the still bottoms in an amount of 10 wt % relative to the feed. Ethylene glycol forms heteroazeotropes with saturated hydrocarbons up to C_{28}–C_{30}, and, therefore, additional removal of saturated hydrocarbons from the extract phase leads to concentration of undesirable components in the aromatic concentrate, compared with the extract.

About half of polycycloarenes and approximately two thirds of organosulfur compounds are selectively removed from heavy vacuum gas oil. Simultaneously, most part of heavy metals are removed.

The use of the raffinate instead of the starting heavy vacuum gas oil as a raw material for the catalytic cracking made it possible to raise the yield of the gasoline and diesel fractions by 9.7 and 37%, respectively, and to diminish the coking by 31% [148].

Vacuum gas oil can also be upgraded by using extractive systems based on oxygen-containing solvents (furfural, methyl cellosolve) in the presence of heptane. In this case, the hazard of catalyst poisoning in the subsequent processing of raffinates by admixtures of the nitrogen-containing extractive agent is eliminated, but an increased ratio of the extractive agent to the feed is required, compared with purification with *N*-methylpyrrolidone [149].

Less selective is the extractive purification of vacuum gas oils by extraction with *N*-methylpyrrolidone in the presence of a low-boiling nonpolar solvent (e.g., heptane), without ethylene glycol as an azeotrope-forming component [150].

The most efficient is the extractive purification of vacuum gas oils with *N*-methylpyrrolidone in the presence of the undecane fraction recovered by vacuum distillation of C_{10}–C_{14} liquid paraffins on the Parex installation. Undecane forms with *N*-methylpyrrolidone an azeotrope boiling at 179°C and containing 36 wt % *N*-methylpyrrolidone. This makes it possible to lower by 25°C the temperature at which the extractive agent is regenerated and to reduce the degree of thermal and hydrolytic decomposition of *N*-methylpyrrolidone and the equipment corrosion rate. In addition, the selectivity of removal of undesirable components increasers in the presence of undecane. For example, the content of saturated hydrocarbons in the extract formed in purification of light vacuum gas oil decreases from 18 wt % in extraction with only *N*-methylpyrrolidone to 5–6 wt % in the presence of undecane. Owing to the more selective removal of undesirable components, the raffinate yield increases by 10–12 rel % [151, 152].

The same extractive system, *N*-methylpyrrolidone + undecane, has also been used for extractive purification of mazut [153].

The extractive purification of high-sulfur mazut with *N*-methylpyrrolidone in the presence of undecane or the undecane fraction yields a raffinate in 70–74 wt % yield. In this case, the content of sulfur decreases by more than a factor of 2; cokeability, by a factor of 1.5; and viscosity and ash content, by 30–35%. The extractive purification of mazut yields a low-sulfur fuel oil and enables use of the resulting raffinate as a feed for hydrocatalytic processes with an energy-intensive stage of vacuum rectification of mazut, with the raffinate yield substantially exceeding the output of vacuum gas oils from AVT installations. The capital expenditure for the construction of an installation for extractive purification of mazut with an annual output capacity of 2 million tons will constitute $50 million. The operating costs will be $10.9 per ton, net annual profit of the plant, $21.4 million, and the discounted payback period (without the construction time), 3.4 years [78, 154].

The main results of the research work conducted in the last decade at SPbGTI were represented in a report at the jubilee conference of the chair of technology of petrochemical and coal-chemical industries [155, 156].

The principles to be used when choosing extraction systems and combined methods for separation and purification of petroleum products in order to improve the selectivity and efficiency of separation can be formulated as follows [157]:

(i) use of mixtures of extractive agents that include an associated selective solvent and a close-boiling high-selectivity extractive agent and form azeotropic mixtures with the lowest boiling point and an endothermic effect in mixing (TEG–sulfolane, DEG–*N*-formylmorpholine);

(ii) use of extractive agents that form azeotropes with saturated hydrocarbons of a feed, but not with the components being extracted;

(iii) use of extractive systems that include a limitedly mutually soluble polar extractive agent and a nonpolar solvent (e.g., pentane);

(iv) use of extraction systems that include a polar extractive agent and a nonpolar solvent, which form an azeotropic mixture with the lowest boiling point (e.g., *N*-methylpyrrolidone–undecane);

(v) use of azeotropic rectification with high-octane components requiring no regeneration for recovery of arenes (e.g., sum of xylenes) and for removal of admixtures of saturated hydrocarbons from the extract phase and from C_6-C_8 aromatic extracts;

(vi) extractive rectification with mixtures of a high-selectivity extractive agent limitedly miscible with the feed and a comparatively low-boiling selective solvent with increased dissolving capacity toward the components being separated, with these mixtures exhibiting a synergistic effect;

(vii) combination of mutually complementary processes of extractive rectification and subsequent extraction, with mixed selective solvents of the same qualitative, but different quantitative compositions used in both stages: with predominance of the high-selectivity solvent in the extraction stage, and of the solvent with increased dissolving capacity in the stage of extractive recombination;

(viii) combination of mutually complementary processes for production of motor fuels: extraction, in which polycycloarenes (homologues of thiophene, benzothiophene, and dibenzothiophene) and nitrogen-containing compounds of aromatic type are the most easily removed; and hydropurification, in which comparatively poorly extractable saturated organosulfur compounds are easily removed;

(ix) use of extractive purification instead of vacuum distillation of mazut.

The results of studies performed in recent years and devoted to separation and purification of petroleum products were reported in [158–160].

CONCLUSION

Thus, extractive and combined processes of separation and purification of petroleum products can recover benzene and its homologues with low specific energy expenditure; these processes have been used to obtain motor gasolines and jet and diesel fuels satisfying modern ecological requirements and to produce low-sulfur mazut and high-quality raw materials for hydrocatalytic processes with vacuum gas oils and high-sulfur mazuts.

Abstract—Effect of conditions of hydrothermal and microwave synthesis of supported vanadium-phosphorus oxide catalysts in an aqueous medium on the physicochemical properties of the vanadyl hydrophosphate obtained was studied. The transformations occurring in the system were examined using X-ray phase and differential-thermal analyses, adsorption-structural method, and scanning electron microscopy.

DOI: 10.1134/S1070427208080028

The problem of development of physicochemically and technologically efficient heterogeneous catalysts for numerous processes remains topical. In particular, it is necessary to improve vanadium-phosphorus oxide (VPO) catalysts for oxidation of *n*-butane into maleic anhydride [1]. It seems that one of ways to solve this problem is to develop methods for deposition of the active phase, vanadyl diphosphate $(VO)_2P_2O_7$ (VDP) or its precursor, vanadyl hydrophosphate semihydrate $VOHPO_4 \cdot 0.5H_2O$ (VHP), onto an appropriate support [1, 2]. It should be noted that substances of varied nature and different physicochemical characteristics have been used as supports of this kind: silica gel, aerosil, silicas with regular porosity (MCM-41, SBA-15), zeolites, titanium and aluminum oxides, metal phosphates, silicon carbide, and silicon and boron nitrides [2, 3–8]. However, the methods reported in the scientific and patent literature have failed to raise the yield of the target product, compared with the bulk analogues.

It should be emphasized that most of the supported VPO catalysts described in the literature have been synthesized, similarly to their bulk analogues, in organic media (butanol, isobutanol, benzyl alcohol) with the use of organic reducing agents [1–9]. Therefore, it is a topical ecological task to prepare catalysts of this kind in an aqueous medium [1].

A possibly interesting class of supports for VPO systems are carbosils, which, on the one hand, combine numerous advantages of both carbon and silica materials [10] and, on the other, enable synthesis of VDP or VHP in an aqueous medium, because the carbon surface of carbosils acts as a substrate for the active phase, and surface carbon atoms, as a reducing agent for vanadium.

The aim of this study was to examine the effect of conditions of hydrothermal (HTS) and microwave (MWS) syntheses on the formation of VPO phases, and VHP in the first place, on the surface of carbosils with varied content of carbon and to analyze the physicochemical properties of the supported composites obtained. It should be added that the hydrothermal method has already been used to prepare VPO catalysts [1, 9, 11, 12], whereas use of the microwave synthesis for this purpose has not been reported.

EXPERIMENTAL

As VPO supports served carbosils produced from porous silicon dioxide, silica gel Sipernat-50, and nonporous pyrogenic silicon dioxide Aerosil-200 (both silicas manufactured by Degussa, Germany) by carbonization of potato starch in a flow of nitrogen at 500°C for 5 h in a flow-through rotating laboratory reactor [13]. Starch was deposited on the surface of the silicas from aqueous dispersions of the com-ponents. Selected characteristics of the starting silicas and carbosils prepared from these silicas are listed in Table 1.

Table 1. Selected characteristics of starting supports

Support	c, wt %	S_{BET}, $m^2 g^{-1}$	V_{N_2}	V_{mi}	d, nm	ΔT, °C
			$cm^3 g^{-1}$			
Supernat-50	0	503	1.190	0.0034	9.5	–
Carbosil 1	18.7	361	0.971	0.0357	10.8	340–585
Carbosil 2	26.4	338	0.722	0.0536	8.6	350–590
Carbosil 3	33.8	356	0.568	0.0699	6.4	340–590
Aerosil 200	0	236	–	–	–	–
Carbosil 4	8.5	245	0.030	0.024	–	350–580
Carbosil 5	31.2	265	0.025	0.021	–	345–600

* ΔT is the combustion temperature range of pyrolytic carbon (according to DTA in air), and $d = 4V_{N_2}/S_{BET} \times 10^3$, average pore diameter.

It is noteworthy that carbosils 1–3 were synthesized from porous silica, and carbosils 4 and 5, from nonporous silica. As a source of vanadium(V) served vanadium pentoxide of chemically pure grade, which is the most frequently used for this purpose [1, 2, 9, 12]. A 85% aqueous solution of orthophosphoric acid (chemically pure) was used as a source of phosphorus. The *P*/*V* ratio in the reaction mixture was 1.15 [2, 3, 9]. The amount of a support introduced into the reaction mixture was chosen in such a way that the concentration of the supported VPO phase was 10–35 wt % in terms of VHP. Supported VPO were synthesized at 175–240°C by two methods: (i) in a 45-ml stainless steel laboratory autoclave, with the reaction mixture (carbosil, V_2O_5, and 85% H_3PO_4) introduced into a Teflon test tube and 5 ml of water placed at the autoclave bottom (to create pressure), duration 6 h; and (ii) in a NANO-2000 laboratory microwave reactor (Plazmotronica, Poland), with the reagents charged in a similar way, duration 0.5–1 h.

When synthesizing supported samples based on purely silica supports, citric acid was added as a mild reducing agent.

After the hydrothermal or microwave treatment, the reaction products were washed with distilled water and dried at 110°C for 3 h.

The X-ray phase analysis (XPA) was performed with a Philips PW 1830 diffractometer (Cu_{K_α} radiation). The size of crystallites was found from the line broadening in X-ray diffraction patterns by using the Debye–Scherrer formula. The thermogravimetric analysis (DTA–TGA) was made on an MOM C derivatograph (Hungary) in the temperature range 20–700°C at a heating rate of 10 deg min^{-1} in air and in the atmosphere of argon (sensitivity 10 mg, weighed portion 20 mg). The content of the supported VPO phase was calculated from the decrease in the fraction of pyrolytic carbon in supported samples, compared with the starting carbosils.

The content of the supported VPO phase was calculated from gravimetric data on the assumption that neither carbon, nor silica from the support pass into the acid medium in the course of deposition and, consequently, their mass ratio c_C/c_{SiO_2} in the solid phase (in carbosil) remains unchanged after the reaction:

$$c_C^0/c_{SiO_2}^0 = c_C/c_{SiO_2},$$

where the concentration c^0 is related to the starting carbosil.

Thus, the mass content c_{VPO} of the supported phase can be calculated by the formula

$$c_{VPO} = 100 - c_C - c_C(100 - c_C^0)/c_C^0.$$

The concentrations of carbon in the starting carbosil (c_C^0) and in the supported sample (c_C) were found from TG curves for the corresponding samples.

The porous structure parameters were calculated for all samples from isotherms of low-temperature adsorption–desorption of nitrogen, measured with a Micromeritics ASAP 2405N analyzer as follows: specific surface area S_{BET}, by the BET method; limiting sorption volume of pores, V_{N_2}, from the amount of adsorption at a relative pressure close to unity; surface area and volume of micropores, S_{mi} and V_{mi}, by the *t*-method; and the pore size distribution, by the Barrett–Joiner–Halenda method (BJH) [14]. The total pore volume V_Σ was found by impregnation with water from the liquid phase.

The surface morphology of the deposited samples was studied by scanning electron microscopy (SEM) with a TESLA BS 301 instrument.

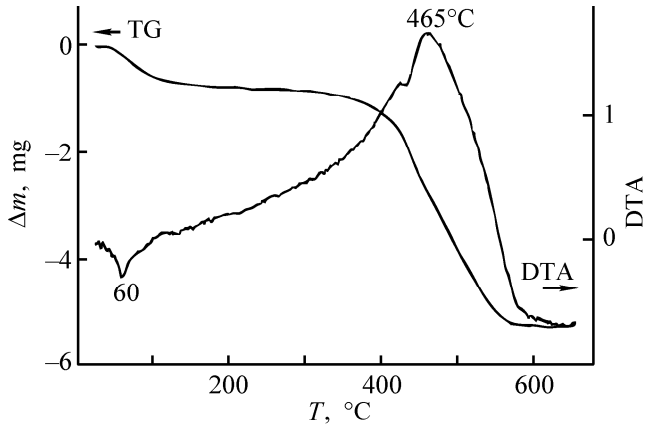

Fig. 1. DTA and TG curves for a VPO sample produced from carbosil 3 by MWS at 190°C. (Δ*m*) Change in mass and (*T*) Temperature.

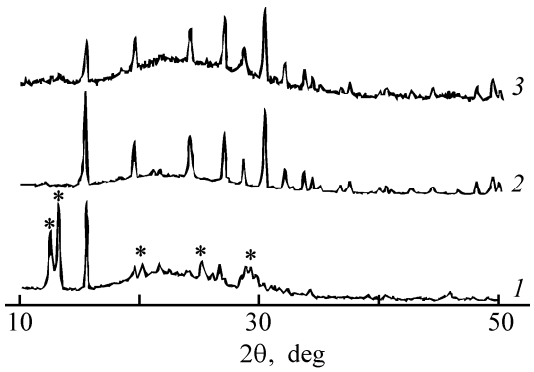

Fig. 2. X-ray diffraction patterns of supported VPO samples prepared (*1*) from the starting Sipernat-50 by MWS at 175°C and from carbosil 3 at 190°C by (*2*) MWS and (*3*) HTS.

Figure 1 shows as an example DTA–TG curves for a supported VPO sample produced from porous carbosil 3. It can be seen that the run of these curves is the same as that for the corresponding pure carbosil [13]: the loss of mass at 50–150°C, accompanied by an endothermic effect, is due to removal of adsorbed water from the surface and pore volume, and the loss of mass in the temperature range 350–650°C and the corresponding exothermic effect are due to combustion of pyrolytic carbon [10].

The results obtained in thermogravimetric measurements of supported samples are summarized in Table 2. It can be seen that, irrespective of the content of carbon in the starting carbosil, the amount of the supported VPO phase is in good agreement with the content of vanadium and phosphorus in the reaction mixture. Because VPO catalysts for oxidation of *n*-butane into maleic anhydride are active in the range 300–400°C [9, 15], an important factor is the thermal stability of carbon-containing supported composites. Table 1 lists combustion temperature ranges of pyrolytic carbon, found from DTA data obtained in air: for most of the supported samples, the combustion onset is at 360–390°C (which exceeds by at least 20–30°C that for similar starting carbosils). The highest thermal stability is observed for supported samples produced from a car-bosil with the lowest carbon content: the onset of carbon combustion for these samples is at 400–410°C. Apparently, in these samples, the minimum layer of car-bon is screened by the supported VPO phase to the max-imum extent. When estimating the thermal stability, it is necessary to take into account that VPO catalysts work in a reaction mixture containing 1.5–3 vol % *n*-butane in air [1, 3, 7–9], i.e., in the presence of a reducing agent, which may shift the combustion of carbon to higher temperatures. For example, thermographic experiments in the atmosphere of argon demonstrated that the combustion onset temperature of carbon increases by 20–30°C for supported samples, compared with the data in Table 2 for heating of these samples in air.

Table 2. Synthesis conditions and selected properties of supported VPO samples

Support	Synthesis conditions	Content, %		c_C/c_{SiO_2}	T*	ΔT*
		carbon	VPO phase		°C	
Carbosil 1	MWS, 240	14.1	24.6 (25.0)**	0.23	385	385–600
	HTS, 240	16.1	13.8 (15.0)	0.23	360	360–590

	HTS, 175	VHP	0.72	18.9	V/P-micas

Table 3 and Fig. 2 present results of XPA for supported composites prepared on starting silicas and on carbosils. The X-ray data were interpreted in accordance with the data of [16, 17]. It should be noted that synthesis from the starting silica yields, even in the presence of citric acid, not only VHP, but also other VPO phases in which the degree of vanadium oxidation exceeds 4+. For example, X-ray diffraction pattern *1* in Fig. 2 contains strong reflections belonging to the impurity phase of V/P-micas (denoted by asterisks). At the same time, a single-phase layer of VHP is formed on the surface of all carbosils. It should be noted that 0.5–1.0 h is sufficient for this to occur in the case of MWS, and no less than 6 h for HTS. The last experimental fact is in agreement with published data indicating that chemical and physicochemical transformations are strongly accelerated by microwave heating of other oxide systems [18, 19]. In addition, control over the synthesis conditions enables formation of the VHP phase with a varying intensity ratio of two principal reflections in the X-ray diffraction patterns, I_{001}/I_{220}, which correspond to different crystallographic planes: basal (001) and lateral (220). This ratio widely varies, from 0.60 to 9.56 (Table 3). The following tendency is observed in this case: in HTS, I_{001}/I_{220} markedly exceed unity in some cases (even by an order of magnitude), which points to the preferential surface orientation of the basal surface of VHP , responsible for selective oxidation of *n*-butane [9]. At the same time, MWS yields VHP with comparable surface concentrations of the basal and lateral phases. The data in Fig. 3 indicate that the VHP crystallites formed on the surface of carbosils are in the nanodispersed state and have sizes in the range 20–30 nm.

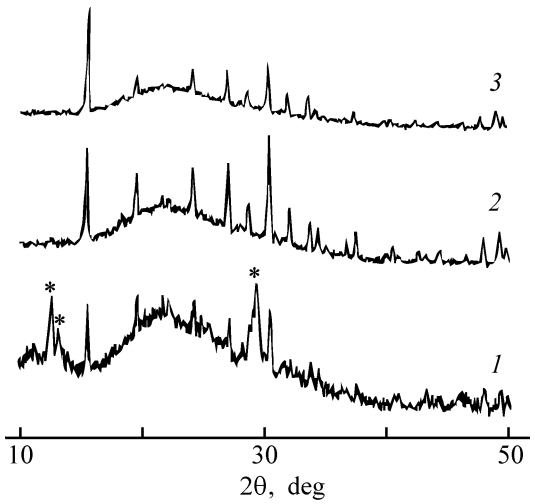

Fig. 3. X-ray diffraction patterns of supported VPO samples synthesized (*1*) from the starting Aerosil-200 by MWS at 175°C and from carbosil 4 at 200°C by (*2*) MWS and (*3*) HTS.

* d_{me} is the diameter of mesopores, found from curves of pore volume distribution over pore size by using the BJH method.

Table 4 lists porous structure parameters of the supported samples obtained. For composites prepared on porous supports (starting Sipernat-50 and carbosils 1–3), the specific surface area and the pore volume typically steadily decrease as the degree of VPO deposition increases, in agreement with the previously established fundamental aspects of their behavior [20]. The decrease in S_{BET} and V_{N_2}, observed in the case of MWS, always exceeds that for samples produced by HTS. In addition, all samples prepared on the basis of silica gel and carbosils 1–3, i.e., on porous supports, contain nearly only mesopores, with the share of micropores being as low as 1–10% of the total volume of pores. There are no macropores in these samples, which is indicated by the coincidence of V_{N_2} and V_Σ.

In synthesis of supported samples from carbosils 4 and 5, which are, as already mentioned, nearly nonporous, the crystalline VHP phase is formed (Fig. 3) simultaneously with the porous structure of the whole composite. This has been reported previously for the case of deposition of VPO phases onto a pure nonporous silica, aerosil [21]. An interesting specific feature of these samples is that the total pore volume V_Σ, found by impregnation with water from the liquid phase, substantially exceeds the limiting-sorption pore volume V_{N_2}, which confirms that the samples contain macropores unfilled in the course of capillary condensation of the adsorbate (nitrogen). At the same time, the amount of micropores in the samples is close to zero (Table 4). Thus, the supported VPO samples prepared from nonporous carbosils have a meso-macroporous structure (the macroporous component is 0.5–1.1 ml g^{-1}, or 65–85% of the total pore volume). This makes samples of this kind especially promising as catalysts, for which transport pores are necessary, because the role of these pores can be played by macropores [15].

The results obtained in an analysis of the structure of a supported VPO layer and of the morphology of its constituent particles are shown in the SEM micrographs in Figs. 4 and 5. Because a mixture of several

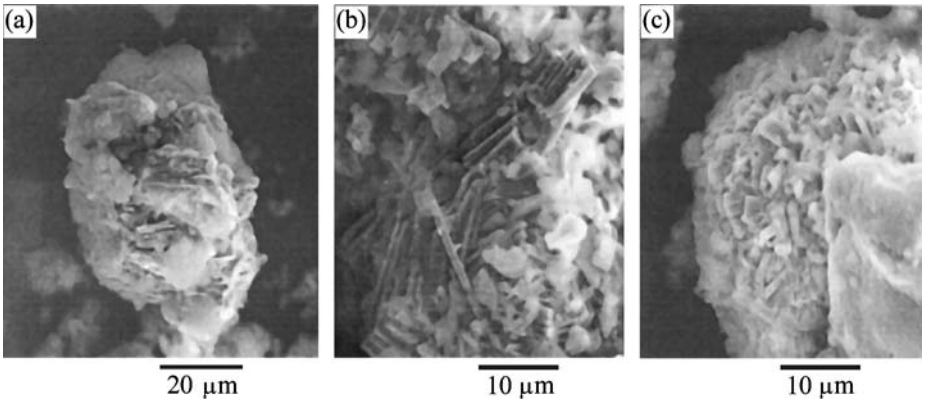

Fig. 4. SEM micrographs of supported VPO samples prepared from (a) Sipernat-50 by MWS and from carbosil 3 by (b) MWS and (c) HTS.

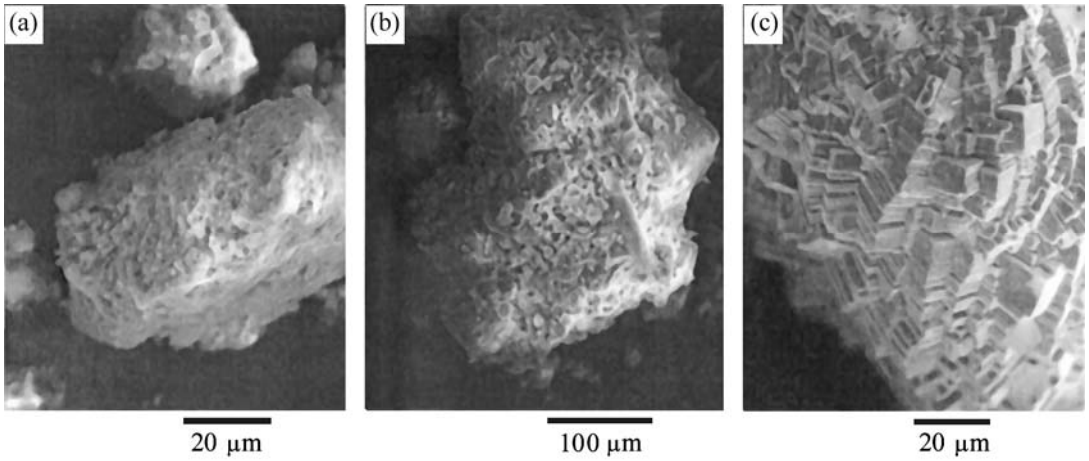

Fig. 5. SEM micrographs of supported VPO samples prepared from (a) Aerosil-200 by MWS and from carbosil 4 by (b) MWS and (c) HTS.

VPO phases is formed on pure silica supports, it is rather difficult to determine the shape of their crystals (Figs. 4a and 5a). At the same time it can well be seen that VHP crystallites are formed on the surface of porous carbosils in the form of rods 1–2 μm in diameter and 10–20 μm long after MWS (Fig. 4b) or 2–4 μm long after HTS (Fig. 4c). It can also be seen in the micrographs that not the entire surface of carbosils is covered by the VPO phase. Comparison of the pore diameters of the starting supports (6.5–11 nm, Table 1) with the crystallite size suggests that the supported phase is on the external surface of the support, rather than within its pores. The observed decrease in S_{BET} and V_{Σ} is presumably due to blocking of a part of pores by the VPO crystallites formed.

Deposition of VPO onto nonporous supports, during which the porous and crystalline structures are simultaneously formed, yields are more uniform, nearly continuous coating (including that within pores). This is indicated by the micrographs in Fig. 5. Particularly characteristic in this regard is the sample synthesized by HTS from carbosil 4 (Fig. 5c). VHP crystalites, which are nearly regular parallelepipeds with edge lengths of 5–15 μm, are aggregated on its surface into a kind of solid brickwork. The shape of VHP crystallites on the surface of carbosils strongly differs from that for bulk samples prepared by other methods. For example, the crystallites formed in organic media frequently have the shape of rosettes [1].

CONCLUSIONS

(1) A supported vanadyl hydrophosphate semihydrate, precursor of the active phase of vanadium-phosphorus oxide catalysts, was obtained on silica-carbon (carbosil) supports by hydrothermal or microwave treatment in an aqueous medium.

(2) It was shown that supported samples have an acceptable thermal stability, widely controllable parameters of the crystal and porous structure, and variable morphology of particles of the supported phase.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Phase Transformations of Amorphous Aluminum Hydroxide Produced by Ammoniation of Potassium Alum

Abstract—A novel method for neutralization of aluminum salts was suggested for the example of treatment of crystalline potassium alum with gaseous ammonia. An assumption was made that the structure of the forming primary particles is specific. The process of formation of a pseudoboehmite structure was studied in relation to the aging conditions of the aluminum hydroxide precipitate.

DOI: 10.1134/S107042720808003X

Amorphous aluminum hydroxide (AH) can be obtained by precipitation from an aluminum salt solution treated with an alkaline reagent, e.g., an ammonia hydrate solution. There is no common opinion about the phase composition of AH and factors affecting the formation and stability of various forms of AH [1–5]. The reason is that the decisive influence on the chemical and phase composition, morphology, and specific surface area of particles of the AH being formed is exerted by a set of its synthesis conditions: pH value and temperature of neutralization and aging, preliminary keeping of aluminum salt solutions, order and duration of solution mixing, agitation intensity, etc.

This communication reports results obtained in a study of the phase transformations that occur in amorphous AH produced from potassium alum (PA) in the course of aging of the precipitate and its thermal treatment.

EXPERIMENTAL

PA was chosen as a source for obtaining AH because it can be rather easily isolated in a sufficiently pure form in sulfuric acid treatment of the widely available nepheline-containing raw materials [6]. In the study, potassium alum isolated from the a sulfuric acid extract from a nepheline concentrate was used. It had the following composition (wt %): Al_2O_3 10.4, K_2O 9.9, Fe_2O_3 0.006. The specificity of obtaining amorphous AH consisted in that the salt was neutralized by direct treatment of crystalline PA with gaseous ammonia produced by slow heating of concentrated (25–27% NH_3) of an ammonia hydrate solution [7]. Melting of the alum (mp ≥ 92.5°C) leads to its balling and to an incomplete reaction. To prevent melting, the temperature was maintained in the range 50–80°C.

The neutralization process was monitored as follows: a sample of the ammoniation product was suspended in water and the pH of the suspension was measured. After a pH ≥ 7 was reached, the neutralization process was considered to be complete. The ammoniation product was treated with warm water for 5–10 min and the precipitated amorphous AH was separated by filtration from the solution containing ammonium and potassium sulfates. The AH precipitate was subjected to aging in an ammonia hydrate solution under various conditions. The treatment was carried out in hermetically sealed vessels to prevent loss of NH_3. After the process was complete, the precipitate was filtered off and washed with water to complete disappearance of the SO_4^{2-} ion from the washing water, as indicated by the absence of turbidization upon addition of a drop of a barium chloride solution. The precipitate was dried at 105°C to constant weight and examined by various physicochemical analytical techniques. The table shows how the phase composition of the samples [according to the results of an X-ray phase analysis (XPA)] and their specific surface area, determined by the BET method from low-temperature adsorption of nitrogen, depend on the aging conditions.

Effect of the aging conditions of the aluminum hydroxide precipitate on the phase composition and specific surface area of the product obtained

* (A) stands for amorphous aluminum hydroxide, and (PB), for pseudoboehmite.

As can be seen from these data, only a single crystalline phase, pseudoboehmite (PB), is formed, irrespective of the aging conditions of amorphous AH. It is known [1] that the direction of phase transformation of AH is "programmed" as early as the very first stage of neutralization. Hence follows that, in neutralization of crystalline PA with gaseous ammonia, the composition and structure of the forming primary particles are such that the subsequent phase transformations of AH occur solely via formation of the pseudoboehmite structure. In the process, the decisive influence is exerted on the crystallization process by the pH of the medium: as pH increases, the content of the pseudoboehmite phase and the specific surface area of its particles steadily grow. PB is formed the most rapidly and to the fullest extent at pH > 10, i.e., under conditions believed to be typically of the bayerite kind [1].

This fact confirms that the composition and structure of primary particles formed in neutralization of crystalline PA with gaseous ammonia are specific. Probably, this is due to the absence of a liquid phase at the instant of formation of the primary particles.

The effect of the aging temperature is substantially weaker and is manifested in that raising this temperature leads to a certain increase in the specific surface area of particles and favors earlier appearance of only a single phase, pseudobelite. The aging duration of the hydrate precipitate is mainly determined by the pH value: at pH 11, the crystallization process is almost complete already in 30 min, whereas at pH 10, is duration should be raised to 2 h.

For a more detailed study of the influence exerted by the aging pH on the course of the crystallization, the products obtained were examined by XPA, DTA, IR spectroscopy, and electron-microscopic and crystal-loptical analyses.

The X-ray diffraction patterns of the samples under study (Fig. 1) were obtained on a DRON-3 instru-

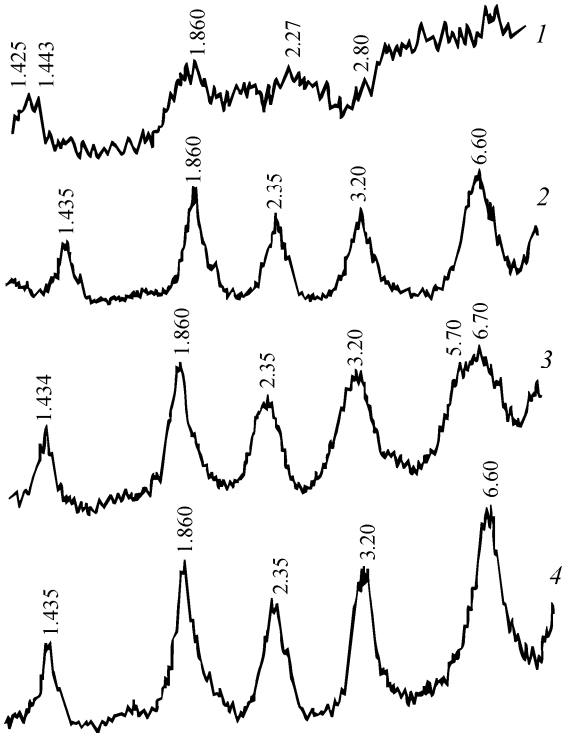

Fig. 1. X-ray diffraction patterns of aging products 1–4. Aging conditions: (*1*) pH 7, T = 75°C, τ = 4 h; (*2*) pH 9, T = 75°C, τ = 4 h; (*3*) pH 10, T = 75°C, τ = 2 h; and (*4*) pH 11, T = 75°C, τ = 1 h; the same for Figs. 2–4.

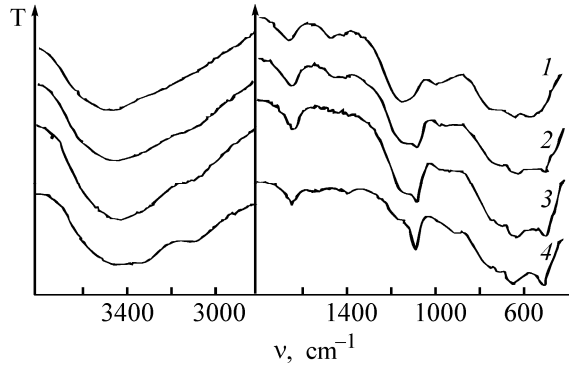

Fig. 2. IR spectra of aging products *1–4*. (T) Transmittance and (ν) wave number.

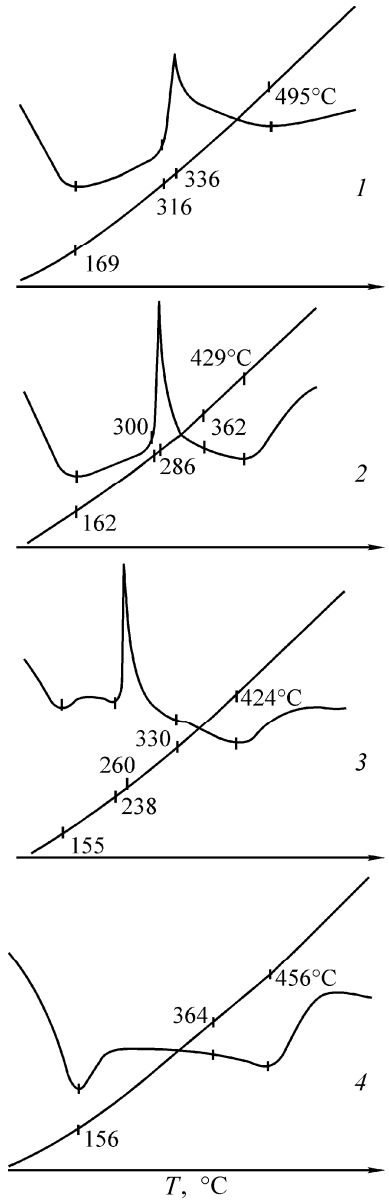

Fig. 3. Thermograms of aging products *1–4*. (*T*) Temperature.

ment with Cu_{K_α} radiation.[1] The X-ray diffraction pattern of the sample formed at pH 7 shows separate weak peaks, which gives no way of identifying any particular crystal structure of AH. The samples is mostly X-ray amorphous. As the pH is raised, increasingly intense lines belonging to the crystalline phase identified as pseudoboehmite appear in the X-ray diffraction patterns. The product obtained at aging pH 11 (sample 4) is nearly fully composed of the pseudoboehmite phase.

The IR spectra of the samples are shown in Fig. 2.[2] The absorption peaks at 3060 and 1080 cm^{-1}, associated with pseudoboehmite, are clearly seen in the spectrum of sample 4. The spectra of the samples obtained at lower pH values show a steadily decreasing intensity of the corresponding absorption bands, to the point of their complete disappearance, which suggests the total absence of pseudoboehmite in sample 1.

The XPA and IR spectral data are in good agreement with the results of a differential-thermal analysis carried out at a heating rate of 9 deg min^{-1} in air. The mass of the samples was 0.12 g. Their thermograms are shown in Fig. 3.[3] A feature common to all of the samples studied is that the differential curves of their thermograms exhibit a low-temperature endothermic effect at 155–169°C, which corresponds to removal of unbound water. As temperature is raised, a strong exothermic effect associated with crystallization of the pseudoboehmite phase appears in the DTA curves of samples 1–3. As the pH at which the samples are prepared increases, the exothermic effect is noticeably shifted to lower temperatures, from 316–336°C for sample 1 to 238–260°C for sample 3. This indicates that the "degree of readiness" to transition to the crystalline state increases as the pH of aging of the AH precipitate becomes higher. The reason for the absence of an exothermic effect in the curve for sample 4 is that the sample is originally composed of AH with a pseudoboehmite structure. Each of the differential DTA curves for samples 2–4 also shows two endothermic effects: a weak effect at 330–364°C and a more pronounced one at 424–456°C. The first of these is probably due to dehydration of pseudoboehmite.

To determine the nature of the occurring transformations, sample 4 was kept at a temperature of 365°C for 1 h and then subjected to XPA. The X-ray diffraction pattern obtained in this case is similar to that of

[1] The X-ray diffraction patterns were measured by T.I. Makarova.

[2] The IR spectra were measured by N.L. Mikhailova.

[3] The thermograms were measured by O.A. Zalkind.

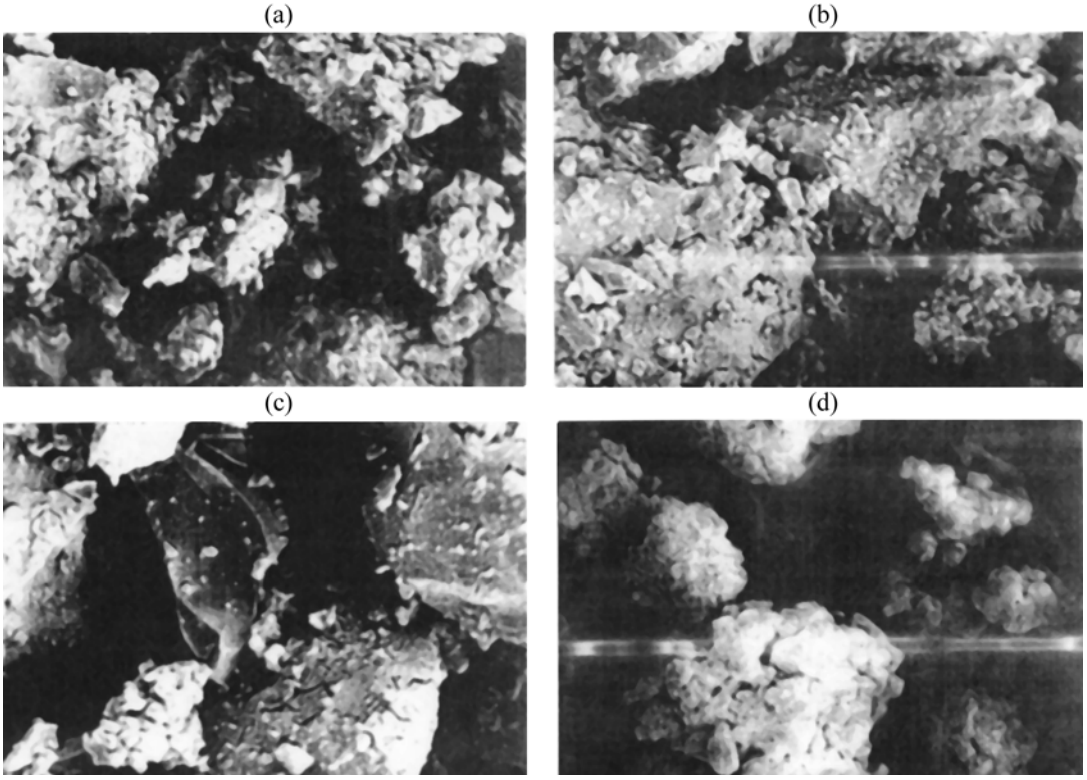

Fig. 4. (a–d) SEM micrographs of aging products 1–4.

sample 4, but has three additional low-intensity peaks with *d*/*I* 7.70, 3.64, and 1.70 Å, which indicates that a somewhat different pseudoboehmite structure is formed. These results are in full agreement with published data [1, 2, 4], according to which there exist two morphological pseudoboehmite structures with different contents of interlayer water. The second endothermic effect is due to pseudoboehmite dehydration to give γ-Al_2O_3. The first endothermic effect is not observed in the DTA curve of sample 1. This is so because, as a result of the crystallization occurring at higher temperatures as compared with samples 2 and 3, the pseudoboehmite phase with lower content of structural water is formed from the very beginning.

The morphology of the aging products was studied with a SEM LEO-420 digital scanning electron microscope. SEM micrographs of the constituent particles (5000 magnification) are shown in Fig. 4.[4] The outward appearance of particles of sample 1 is nearly the same as that of particles of amorphous AH. As the aging pH is raised, crystalline formations appear in an increasing amount and sample 4 is fully composed of conglomerates of crystallites mostly having a rounded shape.

According to the results of a crystal-optical analysis,[5] sample 1 is for the most part optically isotropic, with only a minor part of its substance exhibiting birefringence. These two phases are either cocrystallized or individual. The refractive index of one of these phases is $N \approx 1.508 \pm 0.005$, and that of the other is within the range 1.46 ± 0.01. Sample 2 is also composed of no less than two phases. A part of its substance exhibits weak birefringence (in separate areas). A characteristic feature is cocrystallization of phases in the form of both simple and more complex configurations. The refractive index of one of the phases is within the range 1.442–1.480, and that of the other is about 1.510. Sample 3 is for the most part optically isotropic and is formed by complex cocrystallization of two phases.? One of these has $N \approx 1.460$, and the other, $N \approx 1.555 \pm 0.005$. The vast majority of the substance in sample 4 is optically isotropic and has a refractive index within the range 1.556–1.564.

CONCLUSIONS

(1) A novel method for neutralization of aluminum salts was suggested for the example of potassium alum. The method consists in direct treatment of the crystalline salt with gaseous ammonia.

[4] Studied by A.T. Belyavskii.

[5] Analyzed by M.P. Rys'kin.

(2) It was suggested that neutralization by this method yields primary particles of specific structure, which is due to the absence of a liquid phase at the instant of their nucleation.

(3) It was found that, irrespective of the aging conditions of precipitated amorphous aluminum hydroxide, the crystallization proceeds exclusively via formation of the pseudoboehmite structure.

(4) It was demonstrated that pseudoboehmite is formed the most rapidly and fully under the conditions believed to be of the typically bayerite kind.

(5) The existence of two morphological pseudoboehmite structures was confirmed.

Abstract—Results of a systematic study of the chemical sensitization of cubic-faceted AgBr emulsion microcrystals with complex compounds $K_2[XY_4]$ and $Na_6[XZ_4]$ [X = Pd, Pt; Y = Br^-, Cl^-, SCN^-; Z = $(SO_3)^{2-}$] were considered. The role of secondary dissociation of complex ions during the chemical sensitizing was established. Conditions were determined in which the compounds specified can be used as chemical sensitizers of AgBr. The effect of these complexes on the basic photographic characteristics was demonstrated.

DOI: 10.1134/S1070427208080041

The efficiency of the photoprocess in silver-halide photographic materials can be raised by more intensive utilization of the energy of light, localization of the latent image (LI), and use of AgHlg microcrystals with impurity ions in chemical-photographic processing of the materials. The use of doping ions makes it possible to create centers on the surface or in the bulk of AgHlg. Most frequently, ions of heavy metals are introduced into AgHlg microcrystals for controlling their photographic properties [1].

The formation of a latent image in silver halide microcrystals has been repeatedly and comprehensively studied. The main goal has been to develop emulsion AgHlg microcrystals with prescribed properties. A large number of studies in this field have been devoted to controlled introduction of impurities into the AgHlg matrix to change the kinetics of the photochemical reaction kinetics and, specifically, to inhibit the carrier recombination. The processes occurring on the surface of microcrystals in chemical sensitization (CS) have been given less attention and, for the most part, the empirical approach has been used. The conventional methods for chemical sensitization of AgHlg microcrystals fail to always provide the required photographic characteristics. Therefore, a purposeful search for new CS methods is a topical task.

It is known that Pt(II) and Pd(II) ions introduced into AgHlg form deep electron traps [2–4]. It has been shown [5] that introduction of Pd(II) ions into the bulk of microcrystals results in that the layer desensitization, which becomes more pronounced as the concentration of these ions increases and the depth of the related trap levels decreases. Complex ions $[PdBr_4]^{2-}$ used as chemical sensitizers makethe photosensitivity higher. It becomes apparent that these ions have a positive effect because sensitivity centers become coarser in their presence. Thus, the photographic effect of these ions must depend on their state (localization) on the microcrystal surface. Therefore, it is necessary to choose conditions of chemical sensitization and compositions of Pt(II) and Pd(II) complex ions to be introduced into the surface sensitivity centers being formed during sensitization. Possibly, Pd(II) and Pt(II) ions introduced into surface clusters perform several functions, such as intensification of the catalytic activity of latent image centers (LIC) and increase in their stability during formation and further in the dark stage [6].

This study is devoted to the influence of $K_2[XY_4]$ and $Na_6[XZ_4]$ complex compounds [X = Pd, Pt; Y = Br^-, Cl^-, SCN^-; Z = $(SO_3)^{2-}$] on AgHlg microcrystals in the stage of chemical sensitization of isometric AgBr microcrystals.

The aim of the study was to raise the CS efficiency by finding conditions in which palladium(II) or platinum(II) complex ions can be introduced into LIC of isometric AgBr microcrystals and to examine the photographic properties of emulsion layers based on such microcrystals.

EXPERIMENTAL

Complex compounds $K_2[XY_4]$ (X = Pt, Pd; Y = Cl^-, SCN^-) were synthesized by the known procedures [7]. $K_2[PtBr_4]$ was obtained using the procedure described in [8], and $K_2[PdBr_4]$ was prepared similarly to $K_2[PtBr_4]$ by reacting potassium bromide with $K_2[PdCl_4]$. The complexes $Na_6[X(SO_3)_4]$ (X = Pt, Pd) were synthesized by treating the corresponding tetracido compounds $K_2[XCl_4]$ with a Na_2SO_3 solution.

The photographic emulsion containing AgBr {100} microcrystals with an average equivalent diameter d = 0.5 μm and the size variation factor C_v = 10–15% was produced by controlled two-jet crystallization. A reactor containing a required amount of a water-gelatinous solution was charged with KBr and $AgNO_3$ solutions under permanent stirring. During the synthesis, the temperature, concentration of [Br^-] ions, and feed rate of reagent solutions were controlled. After the synthesis process was complete, soluble salts were removed from the emulsion by washing and pBr 3.0 and pH 6.9 were set. During the sul-fur-gold sensitization of the resulting emulsion at 50°C, solutions of Pt (II) and Pd(II) complex compounds were added after the main sensitizers ($Na_2S_2O_3$ and $HAuCl_4$) in concentrations of 10^{-6} to 10^{-3} mol mol^{-1} Ag. The volume of the solution of the complex being added was 0.3% of the total emulsion volume, and the CS time, 60–90 min. The sensitized emulsions were poured onto a triacetate support, dried, and subjected to sensitometric tests. The samples were exposed in a UKEP-1M universal contact exposition instrument with a color temperature of the radiation source equal to 2850 K and exposure time of 0.05 s. Then, the standard photochemical processing of sensitograms at 20 ± 0.5°C was carried out using a methylhydroquinone developer and an acid fixer. The optical density of darkening in the developed sensitograms was measured on a DP-1M densitometer. The characteristic curves obtained were used to determine the photosensitivity according to the criterial density of 0.2 and 0.85 units over the fog level.

* Sensitometric characteristics after addition of Pd(II) or Pt(II) complex compounds are given in the numerator and denominator, respectively.

The nucleation of AgAuS clusters (sensitivity centers) on the surface of AgHlg microcrystals is a complex process dependent on many factors. One of these is the algorithm of sensitizer introduction. Solutions of sensitizers were introduced in the following order: sodium isobutylbenzene thiosulfate (KF-4026), $Na_2S_2O_3$, and $HAuCl_4$. During thermostating, hydrochloroauric(III) acid is reduced to metallic gold and makes coarser silver sulfide centers. It was found in a set of preliminary experiments that Pt(II) and Pd(II) complex compounds should be added after the main sensitizers, which apparently raises the probability of their incorporation into sensitivity centers.

The sensitometric characteristics of layers containing AgBr microcrystals sensitized with Pt(II) and Pd(II) complex compounds with various ligands are listed in Table 1. It can be seen that Pt(II) compounds with Cl^- and Br^- ligands cause desensitization at any concentrations, and the extent of this desensitization increases with the concentration. It is possible that, because of the lower stability of the complexes and a lower ligand-exchange rate, these compounds are the most predisposed to incorporation into the AgBr surface in the form of ions with partial or full preservation of coordinated ions, which results in the formation of deep electron traps that can irreversibly capture electrons [2, 3]. Being incorporated into the lattice, the activated ions create even deeper electron traps [3]. At a Pt (II) concentration of 10^{-3} mol mol^{-1} Ag, the sensitivity $S_{0.2}$ decreases to 0 and 0.5 units for complexes with Cl^- and Br^- ligands, respectively.

For Pd(II) complex ions with halide ligands (Cl^- and Br^-), the dependences of the sensitometric characteristics show extrema, with the sensitivity passing through a minimum in the case of Cl^- of ligands and through a maximum for Br^- ligands (Fig. 1). The depth of the electron trap created by the Pd(II) ion is 0.61 eV [4], which also results in a prolonged capture of a photoelectron in the temperature range under study.

It can be suggested that the dependences observed are determined by two competing processes. The first of these is incorporation of Pd(II) ions into the surface layer of microcrystals, which results in the formation of deep electron traps making lower the probability of LIC formation. The second is reduction of Pd(II) ions to metallic palladium, which probably occurs the impurity centers and intensifies the catalytic activity of these centers. In the end, the sensitometric characteristics are governed by the kinetics of these parallel processes. It is possible that the differences in the kinetics of the competitive processes are determined by in the cases of Cl^- and Br^- ligands differences in their chemical properties: instability constants ($pK_4([PdCl_4]^{2-})$ 12.2 and $pK_4([PdBr_4]^{2-})$ 16.1) and redox potentials ($E^0_{[PdCl_4]^{2-}}$/Pd = 0.623 and $E^0_{[PdBr_4]^{2-}}$/Pd = 0.60). The stability of the bromide complex is higher and its redox potential is lower than the corresponding parameters for the chloride complex, which promotes incorporation of Pd(II) ions into sensitivity centers and thereby makes higher the photosensitivity.

An increase in the sensitivity is also observed for thiocyanate and sulfite complexes, which is attributable to the additive sensitization by thiocyanate and sulfite ions in parallel with the processes considered above. Thiocyanate ions formed upon the secondary dissociation of complex ions interact with the surface of microcrystals and thereby accelerate the sensitization process. However, the optical density of the fog considerably increases (D_0 0.7 and 0.4 for concentrations of 10^{-4} and 10^{-5} mol mol^{-1} Ag, respectively) in this case.

Thus, we can assume that the coordination sphere affects the interaction of Pt(II) and Pd(II) complex ions with the AgBr surface. This results in qualitative and quantitative changes in LIC formation processes. Probably, it can be concluded that the coordination sphere changes the topography of platinum and palladium centers on the surface of microcrystals.

Therefore, if the secondary dissociation of complex ions is eliminated or minimized, approaches based on use of palladium and platinum complex compounds as chemical sensitizers become possible.

It is known that $[XY_4]^{2-}$ complex ions easily undergo secondary dissociation in an aqueous solution, which decreases the ion charge. The secondary disso-

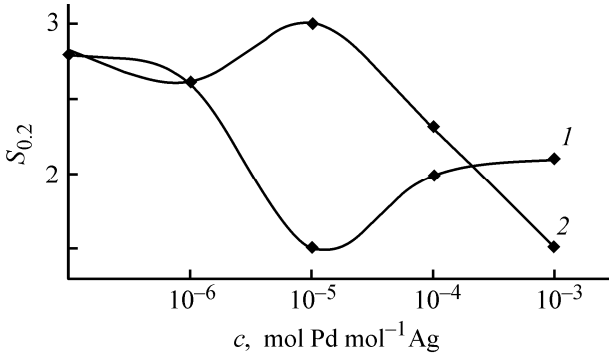

Fig. 1. Photosensitivity $S_{0.2}$ vs. the concentration c of complex ions. (*1*) $[PdCl_4]^{2-}$ and (*2*) $[PdBr_4]^{2-}$.

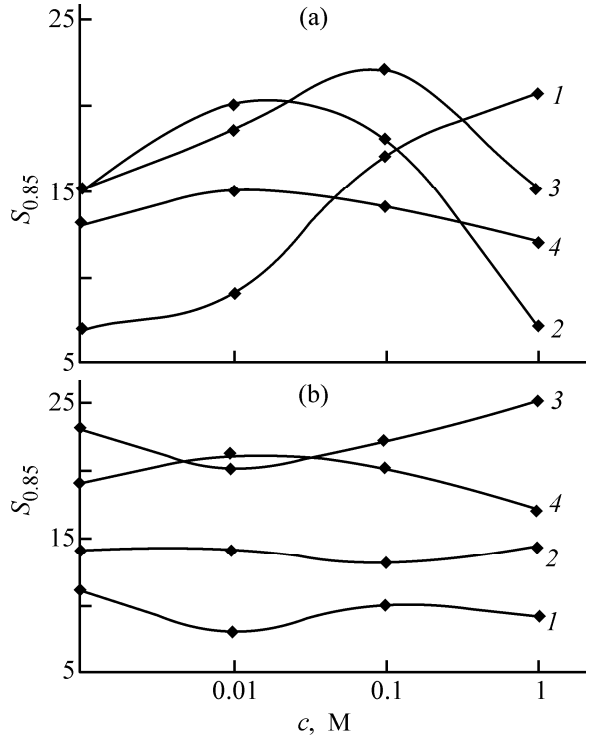

Fig. 2. Photosensitivity $S_{0.85}$ vs. the concentration c of the supporting electrolyte for compounds containing complex ions (a) Pd(II) and (b) Pt(II). Concentration of ions (mol mol^{-1} Ag): Pd(II), 10^{-4}; and Pt(II), 10^{-5}. (*1*) $K_2[XCl_4]$, (*2*) $K_2[XBr_4]$, (*3*) $K_2[X(SCN)_4]$, and (*4*) $Na_6[X(SO_3)_4]$, where X = Pt, Pd.

ciation of complex ions can be diminished by adding to the solution an electrolyte containing ligand ions[9]. Therefore, we added an electrolyte containing ligand ions (supporting electrolyte) to a solution of a complex compound used in the chemical sensitization. The effect of the supporting electrolyte is shown in Fig. 2 in the form of dependences of the photosensitivity on the concentration of the supporting electrolyte.

In the case of the palladium complex compound with chloride ligands, an increase in the sensitivity is observed when the concentration of the supporting electrolyte concentration is higher than 0.1 M. Because the stability of this complex against secondary dissociation is at a minimum, we can assume that, at concentrations lower than 0.1 M, the secondary dissociation, nevertheless, takes place. We can also assume that the driving force of the catalytic action of Pd(II) ions in this compound is the substitution of bromide ligands for chloride ligands at the surface of AgHlg microcrystals. This makes higher the probability of incorporation of Pd(II) ions into impurity sensitivity centers.

In the case of Br^- ligands, the optimal concentration of the supporting electrolyte is in the range from 0.01 to 0.1 M. A higher concentrations leads to desensitization, apparently, because of the excess of Br^- ions, which are adsorbed on the AgBr surface and hinder formation of sensitivity centers.

It follows from the results obtained that it is most appropriate to use palladium complex ions with Cl^- ligands in chemical sensitization. In this case, the solution of the complex ions should be added with no less than 1 M of the supporting KCl electrolyte.

When the concentration of the supporting electrolyte concentration is changed, compounds with SCN^- ligands make lower the sensitivity of microcrystals because of the increasing minimum optical density level. In this case, a certain rise in the sensitivity may result from an increase in the amount of SCN^- ions introduced into the reaction vessel, because this ion is known to be an AgHlg sensitizer. In this context, we performed experiments in which an equivalent amount of SCN^- ions was introduced into the emulsion under study in the course of its sensitization. The results obtained are listed in Table 2.

Table 2. Sensitometric characteristics of samples containing AgBr microcrystals sensitized with $K_2[Pd(SCN_4)]$, with various concentrations of the supporting electrolyte and equivalent amounts of KSCN

Sample no.	Chemically sensitizing additives, mol mol^{-1} Ag		Sensitometric characteristics			
	$K_2[Pd(SCN)_4]$	KSCN	$S_{0.2}$	$S_{0.85}$	D_{max}	D_0
1	–	–	2.8	11	3.5	0.04
2	10^{-5}	–	4.0	18	3.3	0.03
		5×10^{-6}	4.0	17	3.7	0.03
		5×10^{-5}	3.0	15	3.7	0.02
		5×10^{-4}	4.5	20	3.9	0.03
3	–	5×10^{-6}	2.0	10	3.5	0.02
		5×10^{-5}	1.5	12	2.0	0.02
		5×10^{-4}	1.5	10	1.8	0.02

It follows from Table 2 that addition of thiocyanate ions in the amount equivalent to their content in the complex compound $K_2[Pd(SCN_4)]$ does not increase the sensitivity. At the same time, addition of the complex compound both with and without a supporting electrolyte results in a substantial increase in the photosensitivity. Apparently, the sensitizing effect is due to palladium complex ions.

CONCLUSIONS

(1) It was found that the chemical sensitization of AgHlg microcrystals is hindered by the secondary dissociation of $[XY_4]^{2-}$ (X = Pt, Pd; Y = Cl^-, Br^-), which makes lower the charge of complex ions. The secondary dissociation of complex ions can be diminished by addition of an electrolyte containing ligand ions to the solution.

(2) It is the most appropriate to use platinum(II) and palladium(II) thiocyanate complexes as sensitizers of AgBr microcrystals. In this case, solutions of palladium complexes should be used with supporting electrolytes taken in a concentration of no less than 0.01 M. When platinum(II) compounds are used as chemical sensitizers of AgBr, the supporting electrolyte has the minimum effect.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Micellar Phases Based on Sodium Dodecyl Sulfate for Preconcentration

S. A. Kulichenko, V. A. Doroshchuk, and V. S. Starova

Shevchenko National University, Kiev, Ukraine

Received April 3, 2007

Abstract—Features of phase formation from solutions of sodium dodecyl sulfate on cooling were examined. The effect of electrolyte and phenol additions on the parameters of phase formation and distribution of model substrates was examined. Conditions were found for albumin preconcentration with phases in the system sodium dodecyl sulfate–phenol–NaCl.

DOI: 10.1134/S1070427208080053

Micellar extraction of microcomponents with phases of nonionic surfactants (NSAs) at the cloud point is considered today as an efficient alternative to common liquid–liquid extraction with organic solvents [1, 2]. The method is based on the phenomenon of phase separation of NSA aqueous solutions on heating, with the microcomponent concentrated in the forming micellar phase. The prospects for using micellar extraction in analysis are determined by high preconcentration factors with small sample volume, ability of the surfactant phase to extract hydrophobic, hydrophilic, and ionic compounds, and good compatibility with physicochemical determination methods [3–5]. An additional advantage of micellar extraction is the improved environmental safety of the analysis.

The need for heating the system is a basic limitation of the common micellar extraction, complicating preconcentration of readily hydrolyzable and volatile components [6]. This drawback can be overcome by using low-temperature versions of micellar extraction with NSAs having low cloud point, or by adding hydrotropes. In addition, the phase transition temperature in surfactant solutions is decreased on adding electrolytes, oxygen-containing block copolymers, and hydrotropic additives (urea, organic solvents, phenol) [7–9].

Phenol has proved to be the most effective hydrotrope lowering the phase transition temperature in NSA solutions owing to its breaking effect on the system of hydrogen bonds between the oxygen atoms of the polyoxyethylene chain and water molecules [9].

Heterophase transitions occurring with temperature variations are also characteristic of ionic surfactant (ISA) solutions. The formation of ISA phases can be predicted from the temperature diagram of the solubility and the Kraft point [10, 11]. Ionic surfactant phases have been used for preconcentration of metal ions [12–14], cyclic aromatic hydrocarbons [15], and microorganisms [16]. The use of ionic phases in analysis can open new possibilitites for preconcentration of diverse substrates: from highly hydrophobic electrically neutral organic compounds to charged forms of inorganic toxicants.

The efficient use of ISA phases for preconcentration and separation of microcomponents, as well as the phenomenon of phase separation in ionic surfactant solutions in the presence of hydrotropes itself, requires a systematic study. Therefore, the goal of this study was to examine the fundamental aspect of in recovery of various organic compounds with phases of an anionic surfactant (ASA), sodium dodecyl sulfate (SDDS), and to assess the possibilities of using these systems for preconcentration. To this end, we examined the conditions of formation of low-temperature phases in SDDS solutions and the effect of hydrotropic additives on the phase formation in the system.

EXPERIMENTAL

The choice of SDDS (Merck, main substance content >98.5%) was governed by its wide use in analytical practice, good knowledge of its colloid-chemical

properties, and combination of low CMC and low Kraft point with high solubilizing power. Working SDDS solutions were prepared by dissolving the corresponding accurately weighed portions in distilled water.

In the study, we used as hydrotropic additives phenol and electrolytes, which proved to be efficient in many systems based on surfactants. The chemicals were of analytically pure grade.

Aliphatic carboxylic acids are convenient objects for studying the effect of the overall hydrophobicity of a substrate on the efficiency of its recovery into the SDDS phase. We used acids of the general formula $C_nH_{2n+1}COOH$ with n = 1–15. The liquid acids were of analytically pure grade, and the solid acids were of the pure grade and were additionally purified by recrystallization from acetone–alcohol [17]. Solutions of the acids were prepared by dissolving their accurately weighed portions in SDDS solutions.

In our study, we used basic triphenylmethane dyes: Methyl Violet (MV), Crystalline Violet (CV), Methyl Green, and Malachite Green; zwitterionic dyes: Methyl Orange and reagents of the tropeolin series; sulfophthaleins: Phenol Red (PR), Bromophenol Red (BPR), Bromophenol Blue (BPB), Bromocresol Purple (BCP), and Bromothymol Blue (BTB), all of analytically pure grade. Solutions of dyes were prepared by dissolving their weighed portions in distilled water.

The absorption spectra of the solutions were measured on SF-46 and KFK-3 spectrophotometers. The solution acidity was monitored with a pH-340 pH-meter equipped with an ESL-43-07 glass electrode.

Aqueous SDDS solutions containing all the required components were placed to 10-ml volumetric cylinders, which were fastened in a stand and immersed in a water bath with ice. The temperature was monitored with thermometers immersed in the cylinders and in the water bath. The solutions were cooled at a rate of about 1 deg min^{-1}. The phase formation temperature was recorded when the solutions became opalescent. The forming ASA phase precipitated on the cylinder bottom. If necessary, the mixture was centrifuged before decanting the aqueous phase.

The distribution of carboxylic acids was monitored by pH-metric titration of their micellar solutions before and after the phase separation and by titration of the micellar phase after its dilution [18]. The distribution of organic dyes was monitored spectrophotometrically by measuring the absorption at the peak absorption wavelength of the corresponding form of the dye. The albumin distribution was monitored by the biuret reaction [19].

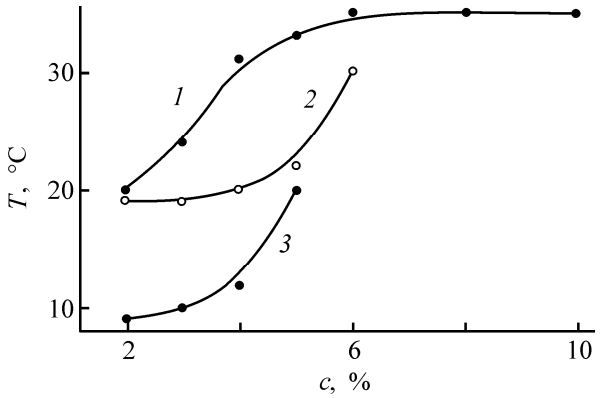

Fig. 1. Phase formation temperature T in (*1*) SDDS and (*2*, *3*) SDDS–phenol solutions vs. NaCl concentration c. c_{SDDS} = 0.1 M; c_{phenol}, %: (*2*) 1 and (*3*) 2.

The SDDS phase formation on cooling is due to the disappearance of the micellar constituent of the solubility below the Kraft point [10]. In the process, excess SDDS forms a crystallie precipitate. With an increase in the concentration, the volume of the SDDS phase linearly grows. However, the precipitation is slow, and the decantation of the precipitate is complicated by its rapid dissolution upon a small rise in the temperature. Therefore, the forming SDDS phase is unsuitable for preconcentration of microimpurities.

Upon introduction of adding electrolytes, the phase formation temperature increases and precipitates are formed already at room temperature. For example, at [NaCl] ≤ 2%, the crystalline phase of SDDS is formed at 20°C. An in-crease in the NaCl concentration in the system to $c \geq 6\%$ leads to a rise in the phase formation temperature to 35°C (Fig. 1, curve *1*). Owing to the salting-out effect, the volume of the forming phase also increases. The phase being formed in the SDDS–NaCl system is stable at room temperature, can be readily separated by centrifugation, and is convenient for preconcentration of microcomponents.

Addition of phenol to SDDS solutions raises the solubility of the ASA phase and appreciably lowers the phase formation temperature. However, the crystalline precipitate formed in the SDDS–phenol system is poorly decantable. Therefore, with an increase in the phenol concentration, the volume of the forming phase decreases, and, at a fourfold molar excess of phenol, cooling to 3°C no longer leads to formation of precipitates.

Comparative characteristics of the efficiency of recovery of various substrates with SDDS-based phases ($c_R = 4\times10^{-5}$, c_{SDDS} = 0.1 M; $c_{NaCl} = 6$, $c_{phenol} = 1\%$; $V_0 = 10$ ml)

Dye, MW	Dye form	*R*, %

* $c_{SDDS} = 0.01$ M.

Joint addition of phenol and NaCl to SDDS solutions leads to formation in the system of two types of phases: a liquid phase and a solid amorphous phase. Phenol and NaCl affect the phase formation temperature in SDDS solutions differently: phenol lowers it and NaCl, by contrast, raises (Fig. 1). Owing to the opposite and mutually compensating effect of the additives, precipitates in the SDDS–NaCl–phenol system are formed at 15°C, which is lower than the phase formation temperature in the SDDS–NaCl system and higher than that in individual SDDS solutions and in the SDDS–phenol system. With an increase in the temperature to 25°C, the initially formed solid phase transforms into a gel. Such transitions are reversible, and, upon cooling, an amorphous precipitate is again formed in the system. The phases formed in the three-component system are stable at room temperature, are readily decanted, and are convenient for preconcentration of microimpurities.

We found that, for two- and three-component systems, the volume of the forming phase increases with the SDDS concentration, and decreases with an increase in the phenol and electrolyte concentrations. The phase volume determines the preconcentration efficiency, and the volume ratio of the aqueous and "micellar" phases corresponds to the maximal absolute preconcentration factor for microimpurities, attainable under the experimental conditions. By properly choosing the ratio and the absolute concentrations of components in the SDDS–NaCl–phenol system ($c_{SDDS} = 0.1$ M, $c_{phenol} = 1\%$, $c_{NaCl} = 6\%$), we obtained a phase convenient for processing with acceptable preconcentration parameters.

With cationic, anionic, and zwitterionic dyes and carboxylic acids as examples, we assessed the possibility of using SDDS-based phases for recovering various forms of organic substrates.

Phases formed from SDDS and SDDS–phenol solutions poorly recover basic triphenylmethane dyes. At the same time, dyes are efficiently extracted in the SDDS–NaCl and SDDS–phenol–NaCl systems (see table). However, because of the virtually complete extraction of basic reagents with these phases, we could not trace the effect of the hydrophobicity and structure of the dyes on their distribution parameters. For example, the molecular weight of the dyes affects their recovery insignificantly. For the SDDS and SDDS–phenol phases, the efficiency of the dye extraction decreases with an increase in their hydrophobicity, which suggests the predominantly hydrophilic character of the takeup phase.

We found that the zwitterionic form of the substrate (pH 1) is recovered by SDDS phases better than does the corresponding monoanion (pH 10) (see table). Under the experimental conditions, the zwitterionsic form of tropeolins is recovered virtually completely ($R > 97\%$). Notably, the degree of recovery of the R^- and R^+ forms into SDDS-based phases increases with the molecular weight of dyes.

The degree of recovery of sulfophthaleins with SDDS phases increases with the hydrophobicity. The dye monoanion (pH 2) is recovered into the collector phase better than the corresponding dianion (pH 10) (Fig. 2). Although the ability of anionic surfactants to solubilize anionic reagents is known from the literature [10], the high efficiency of binding of anionic forms of sulfophthaleins with SDDS phases appeared to be somewhat unexpected. The high hydrophobicity of the substrate eliminates the mutual repulsion of similarly

charged particles of the substrate and SDDS-based phase. With an increase in the hydrophobicity of the indicators, the dependences $R = f(M_R)$ obtained for the mono- and dianions converge (Fig. 2). However, for all the dyes studied, the HR^- form is recovered better than the R^{2-} form.

The influence of the hydrophobicity of a substrate on its recovery with SDDS phases was analyzed for the example of monocarboxylic aliphatic acids. The data obtained show that the molecular uncharged forms of the substrates (pH 2) are recovered by SDDS phases more completely than the corresponding anionic forms (pH 9). A similar trend was also observed in recovery of carboxylic acids with classical micellar phases of nonionic surfactants at the cloud point [20]. For example, the degree of recovery of the molecular form of caproic acod in the SDDS–NaCl system is approximately 40% higher than that of the anionic form and reaches 74%. However, the recovery of caproic acid into the phase formed from SDDS–NaCl–phenol solutions is virtually independent of pH, with $R = 80\%$.

We found that the degree of recovery of aliphatic carboxylic acids with SDDS phases increases with the length of their hydrocarbon radical (Fig. 3). However, for moderately hydrophobic acids with $n = 3$–4 the trend is the opposite and the degree of recovery of the acids somewhat decreases. The break of the monotonic trend in the recovery of the homologs may be due to the appearance of certain "organization" of the takeup surfactant phase [1, 6]. Notably, for carboxylic acids, the shape of the $R = f(n)$ plots does not appreciably change in going from SSDS–phenol–NaCl to SSDS–NaCl phases.

The data we obtained allow ranking of the organic substrates in the following order with respect to the solubilization efficiency: cationic substrate > uncharged or zwitterionic substrate > anionic substrate. In particular, SDDS phases provide optimal parameters for the recovery of cationic substrates owing to the solubilization enhancement by the electrostatic attraction of oppositely charged particles of the substrate and takeup phase. Elimination of the electrostatic constituent leads to a decrease in the efficiency of the extraction of uncharged or zwitterionic substrates. The electrostatic repulsion of similarly charged particles leads to the weakest binding of anionic forms of the reagents. An increase in the charge of a cationic substrate enhances its recovery into the SDDS phase, whereas an increase in the charge of the anionic substrate has an opposite effect. It is important that an increase in the overall hydrophobicity within a given series of substrates enhances their extraction with the phases examined. Thus, SDDS-based phases are the most suitable for pre-concentration of highly hydrophobic positively charged substrates.

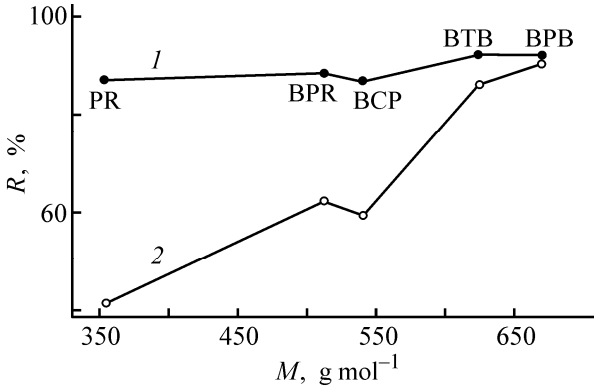

Fig. 2. Degree of recovery R of (*1*) HR^- and (*2*) R^{2-} forms of sulfophthalein indicators with the SDDS-based phase in the SDDS–phenol–NaCl system, plotted against the dye molecular weight M. $c_R = 4\times10^{-5}$ M, $c_{SDDS} = 0.1$ M, $c_{NaCl} = 6\%$, $c_{phenol} = 1\%$; $V_0 = 10$ ml. pH: (*1*) 2 and (*2*) 10.

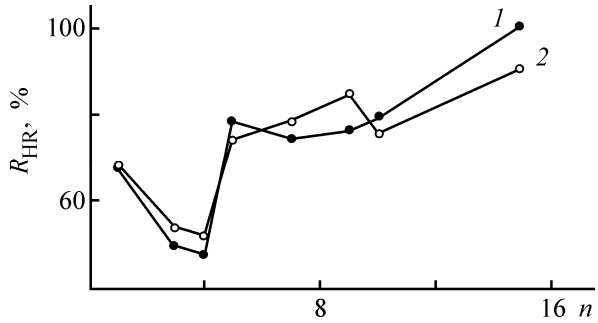

Fig. 3. Degree of recovery RHR of carboxylic acids with (*1*) NaCl–SDDS and (*2*) SDDS–phenol–NaCl phases, plotted against the number n of carbon atoms in the hydrocarbon radical of the acid. $c_{SDDS} = 0.1$ M, $c_{HR} = 1\times10^{-2}$ M, $c_{NaCl} = 6\%$, $c_{phenol} = 1\%$, pH 2, $V_0 = 10$ ml.

Analysis and comparison of our data on the recovery of various substrates allowed us to rank the SDDS-based phases in the following order with respect to the solubilization activity: SDDS–phenol–NaCl > SDDS–NaCl > SDDS–phenol > SDDS. Thus, hydrotropes favoring the phase formation proved to be efficient additives enhancing the recovery of organic substrates into the SDDS phases. The phases obtained in the SDDS–phenol–NaCl and SDDS–NaCl systems are stable at room temperatures; they are readily separated and are convenient for preconcentration of microcomponents.

By the example of albumin, we demonstrated the efficiency of low-temperature SDDS phases for pre-

concentration of cationic hydrophobic microimpurities. Development of efficient methods for preconcentration of biomolecules remains a topical task in screening of biological objects [21–24]. The micellar extraction with surfactant phases is considered to be one of the most efficient methods for preconcentration and separation of hydrophobic and hydrophilic biomaterials. Preliminary experiments showed that albumin is not recovered by nonionic surfactant phases because of the prevalence of hydrophilic properties. Therefore, micellar NSA phases are used for separating other, more hydrophobic proteins from albumin [25, 26]. In protein preconcentration with anion-active phases, the hydrophobic binding is supplemented by the attraction of oppositely charged particles. Therefore, it could be expected that albumin would be bound more efficiently by SDDS phases from acidic solutions at pH below the isoelectric point. However, such phases recover albumin to only 14% (c_{SDDS} = 0.01 M, pH 4, c_{Alb} = 10 mg ml^{-1}). Use of an electrolyte and phenol-modified phases enhances the albumin recovery. At c_{SDDS} = 0.1 M, c_{NaCl} = 6%, c_{phenol} = 1%, pH 4, and c_{Alb} = 10 mg ml^{-1}, albumin passed into the collector phase almost completely (~99%). The SDDS–phenol–NaCl is more convenient from the technological standpoint.

Based on the data obtained, we suggested a new approach to detection and determination of proteins. In the process, the solubilizing power of SDDS is used for efficient washout of protein molecules from the surface of a solid specimen (sample preparation), and the subsequent precipitation of a low-temperature anionic phase is used for the preconcentration. The procedure was tested as applied to determination of albumin on a fabric.

A sample of cotton fabric (10 × 10 cm) with preliminarily applied albumin was placed in 50 ml of a 0.1 M SDDS solution and rinsed for 20 min with a magnetic stirrer. The fabric was removed, and 0.5 g of phenol and 3 g of NaCl were successively added to the resulting solution, pH 4 was adjusted, and the mixture was cooled to 3°C. After complete phase separation and removal of the aqueous phase by decantation, the precipitate was transferred into a 25-ml volumetric flask, 5 ml of the biuret reagent (1.5 g of $CuSO_4 \times 5H_2O$ + 6.0 g of sodium potassium tartrate + 30 g of NaOH per liter) was added, and the solution was brought to the mark with distilled water. The contents were mixed and allowed to stand for 30 min, after which the optical density of the solution was measured at λ = 540 nm, l = 2 cm, against a solution from a blank experiment (without protein). The protein concentration in the sample was determined using a calibration plot.

After applying 5.0 mg of albumin to the fabric, we found 4.9 ± 0.1 mg (S_r = 0.02, n = 5, P = 0.95). These data show that the procedure is adequate and fairly accurate. The conditions suggested for the recovery and determination of protein compounds can be implemented in forensic examinations and also in analyses of solid samples for the presence of protein molecules (after washing with a surfactant solution).

CONCLUSIONS

(1) Studies of the effect of additions of electrolytes and phenol on the parameters of phase formation and distribution of model substrates allowed the phases based on sodium dodecyl sulfate to be ranked in the following order with respect to the solubilizing activity: sodium dodecyl sulfate–phenol–NaCl > sodium dodecyl sulfate–NaCl > sodium dodecyl sulfate–phenol > sodium dodecyl sulfate.

(2) Analysis of the parameters of phase distribution of various organic reagents allowed the substrate forms to be ranked in the following order with respect to the efficiency of solubilization by anion-active phases: cationic substrate > uncharged or zwitterionic substrate > anionic substrate.

(3) An increase in the charge of a cationic substrate enhances its recovery into the sodium dodecyl sulfate phase, whereas an increase in the charge of an anionic substrate has an opposite effect. An increase in the overall hydrophobicity within particular substrate groups enhances their extraction with the phases examined.

Abstract—Activated carbons produced by thermal treatment of a mixture of sunflower husks, low-grade coal, and refinery waste were studied as adsorbents of transition ion metals from aqueous solutions of various compositions. The optimal conditions and the mechanism of sorption, as well as the structure of the sorbents, were studied.

DOI: 10.1134/S1070427208080065

The possible waste processing to obtain activated carbons (AC) is aimed to solve two important ecological problems: utilization of wastes and production of carbon adsorbents for purification of aqueous solutions to remove toxic impurities. For example, it has been suggested to recover heavy metals with inexpensive ACs synthesized by processing of rice husks [1], coconuts [2, 3], bituminous carbon [4], bog moss [5], saw dust [6], and solid industrial waste [7]. It has been found that low-temperature carbonization and the subsequent high-temperature coactivation of a mixture of wastes can yield ACs whose adsorption capacity for Cr(III) and Cr(VI) substantially exceeds the values obtained for commercial ACs manufactured by Norit and Merck [8]. It has also been shown that adsorbents of this kind can recover copper and other heavy metals from multicomponent aqueous solutions, including technological mixtures [9].

The present communication reports on a study of the sorption properties of these carbons with respect to recovery of Cu(II), Fe(II), Co(II), Ni(II), Mn(II), and Pd(II) from various solutions, including washing and waste water formed in processing of palladium-containing raw materials.

EXPERIMENTAL

Carbon adsorbents were prepared from a mixture of secondary natural materials: sunflower husks (25%), refinery waste (50%), and low-grade coal (25%) from the Donetsk region by the previously described method [8, 9]. The composition of ACs and their physicochemical properties [specific surface area, pore volume, pore size distribution, presence and nature of surface functional groups (SFG)] of the adsorbents under study were determined by elemental analysis, ?Behm titration, and nitrogen adsorption at 77 K.

The structure of the ACs obtained was modeled by the PM3 quantum-chemical method [10–12]. As input structures served $C_{96}H_{24}$ carbon clusters as a model of coal, low-molecular-weight alkyl phenanthrene as a model of the refinery waste, and two fragments of a cellulose chain as a model of vegetable wastes. Successively, step by step, these clusters were stripped of hydroxy groups and hydrogen atoms, which appear in hydrolysis of organic substances and form water and hydrogen molecules as a result of the reaction. Then, the spatial structure was optimized for the system obtained. The number of steps for the dehydrogenation-dehydroxylation process was chosen so that the result-

ing carbon cluster was sufficiently close in composition to the experimentally obtained carbon materials.

Single- and multicomponent model solutions were prepared using weighed portions of commercial salts of Cu(II), Fe(II), Co(II), Ni(II), Mn(II), and Pd(II), acids of chemically pure and analytically pure grades, and distilled water. Technological solutions obtained in final stages of processing of secondary platinum-containing raw materials (washing and waste water) were provided by the near-Dnieper Plant of Nonferrous Metals State Enterprise.

The adsorption of Cu(II), Fe(II), Co(II), Ni(II), and Mn(II) ions on AC from the model and technological solutions was studied in static and dynamic modes: (i) by the method of separate weighed portions under the standard conditions at the same s : l ratio at a temperature of 21 ± 4°C (The time of contact of the solutions and the adsorbent was 24 h in most experiments, which corresponded to the time in which the adsorption equilibrium was attained.) and (ii) by the method of dynamic sorption at different solution flow rates at a temperature of 21 ± 4°C (sorption columns with a diameter d = 9 mm, bed height h = 9.5 mm, weighed portion of AC m = 1 g).

For evaluation of the adsorption equilibrium in the systems under study, the static and dynamic sorption capacities of a carbon (SEC and DEC, respectively) and the degrees of metal recovery were used.

The concentration of the metals in the starting solutions and their residual concentration in filtrates after separation of the solid phase were determined by the atomic-absorption method [13]; the concentration of palladium(II) was also found by the selective catalytic method [14].

When studying the sorption properties of ACs, it is necessary to take into account that, in each particular case, wastes with widely varying composition were used to produce the carbons. In a set of experiments, carbons differing in the nature of a single component were used, which enabled certain general assumptions and conclusions. Carbon samples produced under identical conditions from mixtures in which the agricultural waste (sunflower husks) and low-grade coal served as components with fixed nature and amount. The refinery wastes differed in the nature of hydrocarbons: AC-1, AC-2, and AC-3 were produced from predominantly aliphatic hydrocarbons, mainly aromatic hydrocarbons, and a mixture of both kinds of hydrocarbons, respectively. The sorption properties of starting samples and those oxidized with nitric acid were studied. The characteristics of different carbon samples are rather close, the structural parameters and surface group compositions are listed for some of the samples in Tables 1 and 2. As follows from these data, the ACs produced from aliphatic hydrocarbons have a larger specific surface area, and oxidation of the activated carbons leads to an increase in the number of oxygen-containing functional

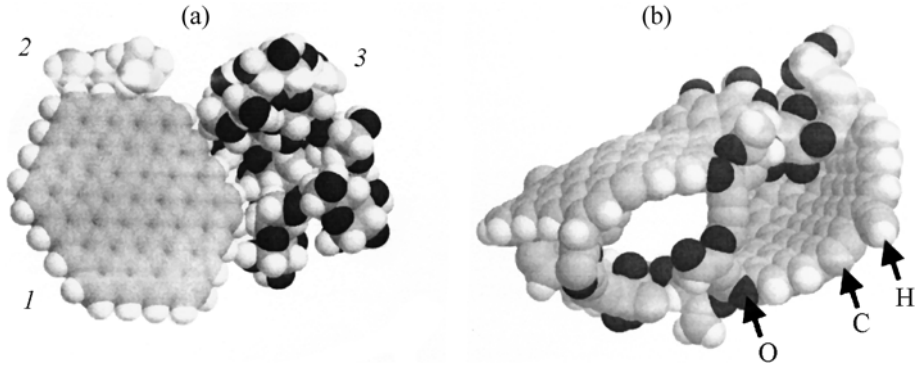

Fig. 1. Results of a quantum-chemical simulation of carbon formation from a mixture of organic materials. (a) Starting molecules: (*1*) $C_{96}H_{24}$ carbon cluster modeling the structure of a graphene plane, (*2*) low-molecular-weight alkyl phenanthrene as a model of refinery wastes, and (*3*) two fragments of a cellulose chain as a model of vegetable wastes. (b) Structure of the carbon material formed (the arrows show different types of atoms constituting the cluster).

groups on the surface, with the total surface area changing only slightly.

As follows from the model obtained in a quantum-chemical analysis, the structure of unoxidized carbon (Fig. 1) includes surface areas that differ to a certain extent in chemical nature. For example, the porous structure of the carbon is constituted by fragments of graphene planes, which are preserved in a sufficiently large size and bear no functional groups. The edges of these fragments contain doubly coordinated carbon atoms, which are the most active in oxidation are converted in this case to phenol and quinoid groups. The same atoms are possible sites of reductive sorption of noble metals.

Because of the presence of oxygen atoms in cellulose molecules in the starting mixture, the carbon material obtained contains oxygen in the form of various functional groups differing in the coordination activity and ability to undergo further transformations. Most part of oxygen is in ester groups included in the rings, so that their chemical and coordination activity must be low, and their stability against oxidation and hydrolysis, high. Also present is a rather large amount of aldehyde residues that can be coordinated and oxidized to carboxy groups providing the ion exchange properties of the oxidized carbon. Complexation processes may involve α-diketone groups in the aliphatic chain, which are preserved in a small amount, as well as ketone groups and esteric (heterocyclic) oxygen atoms whose mutual position will favor manifestation of the chelate-formation effect. Thus, the structure of the carbon material can provide both physical sorption within graphene planes and chemisorption on active groups, including the complexation and reductive sorption of noble metals.

Sorption of heavy metal ions from model solutions. To determine the time in which the adsorption equilibrium is attained under static conditions, a set of sorption measurements of the recovery of copper and compounds of other metals from solutions with a concentration of each ion in the mixture in the range 1–10 mg l^{-1}, i.e., in solutions modeling natural water whose contamination with heavy metals exceeds the maximum permissible concentrations and wastewater in technologies for processing of various metal-contain-ing secondary raw materials. The measurements were made during 1 to 72 h.

When the concentration of metals in solutions is about 1 mg l^{-1}, the mixture of ions of all metals is completely recovered on all AC samples, irrespective of the solution pH, in already less than1 h of contact in the solution–adsorbent system: the content of metal ions in the filtrate after the sorption is below the sensitivity limit of the atomic-absorption method. In multicomponent solutions with pH ≥ 3 and a concentration of each ion approximately equal to 10 mg l^{-1}, a period of time slightly longer than 1 h is required for a nearly equilibrium adsorption of Cu(II) on the starting carbon and its oxidized sample (Table 3). Similar results were obtained in sorption of Fe(II), which suggests that the sorption mechanisms of these ions are close.

Further studies of the static sorption of metal ions were based on results obtained in 24 h, i.e., under the conditions of complete attainment of the sorption equilibrium. The influence exerted by the acidity and by the nature of an acid on the sorption properties of ACs in recovery of metal ions (~10 mg l^{-1}) from single-component solutions and the role of ammonium ions commonly present in technological solutions formed in

processing of platinum-containing raw materials were examined. It was found that, as the acidity increases, the sorption decreases even in single-component solutions (Table 4), and ammonium ions additionally diminish the degree of recovery. From solutions with pH > 3.5, ions of all the metals studied are recovered completely. In acid (pH ≤ 0.1) single- and multicomponent solutions with a concentration of each of the present metal ions equal to 10 mg l^{-1}, no more than 20% of Cu(II) and Fe(II) ions and less than 10% of other metal ions is recovered in 72 h of sorption.

The decrease in the adsorption of metal ions, observed as the solution acidity increases, may be due to a shift of the reaction equilibrium in complexation of metal ions with the SFG of adsorbents via the protonation of these latter. In addition, the comparatively low capacity of ACs produced from secondary raw materials in sorption of metal ions from acid solutions can be also well understood in terms of competition in the systems for metal ions: between a ligand in the corresponding aqueous acid solution and a ligand fixed on the adsorbent surface. This is the more so because of the complex structure of ACs, which is not always accessible for approach of metal ions to the surface ligand. Ammonium ions can play a twofold role: this is competition in the formation of sufficiently stable ammonia complexes of metals in solution and the interaction of these complexes with the SFG, on the one hand, and the ion exchange of protons between the SFG and ammonium ions. In the case of multicomponent solutions with pH ≥ 3.5, the sorption capacity for each of the metal ions decreases, compared with single-com-

Mn(II)	1.82	0.52	0.38	2.1	0.04

ponent solutions (Table 5), which is especially noticeable in sulfuric acid solutions. Here, the main explanation may consist both in the low sorption capacity of the carbon itself and in the competitive complexation of each of the metal ions with SFG, whose amount is rather limited (Table 1). Under the optimal conditions (pH ~ 4), the degree of copper(II) and iron(II) recovery in 24 h of sorption is 54 and 87%, respectively, for AC-1 and 82 and 97% for AC-1(ox); the sorption of Cu(II) from single-component solution on AC-2 and AC-2(ox) is 47.7 and 94%, respectively; and that from multicomponent solutions of the same acidity, 60.3 and 89.6%.

Similar results were obtained for all the AC samples, irrespective of the nature of refinery wastes used in their production. Thus, it can be assumed that the key role is in sorption of copper(II) and, presumably, iron(II) is the possible presence and amount of SFG. In all of the systems, the sorption capacity for the metal ions studied increases in the following order: Fe(II) > Cu(II) > Co(II) > Ni(II) > Mn(II), which almost coincides with the series of stability constants of complexes of these metals with organic acids (acetate, tartrate, malonate, etc.) [15]. On the whole, it should be noted that the ACs studied are the best suitable as adsorbents for purification of aqueous solutions to remove metal impurities with concentrations not exceeding 10 mg l^{-1}, i.e., for purification of contaminated natural and certain technological washing waters.

The sorption of metal ions was studied under dynamic conditions on AC-3 produced from a mixture of refinery wastes of aliphatic and aromatic nature and solutions with a varied content of the main component, copper(II). It was shown that copper(II) and iron(II) ions are completely recovered from a model multicomponent solution containing a mixture of chlorides of divalent metals at a concentration of each of these ions close to 10 mg l^{-1} and solution flow rate through the column of 25 ml h^{-1} (Fig. 2). The degree of recovery

* Washing water contains an excess amount of alkali metals; chloride, sulfate, and nitrate ions; and an admixture of ammonium salts.

of other metal ions corresponds to the order of their sorption under static conditions. An increase in the solution flow rate through the column does not change the type of the dependence in Fig. 2a, but makes the time to breakthrough shorter and the amount of a metal absorbed by a certain instant of time smaller (Fig. 2b), which can improve the selectivity of iron(II) recovery, compared with copper(II).

It was found in recovery of copper(II) from a model single-component solution with pH 3.56 and rather high concentration of the ion that, as the concentration of copper(II) increases, its sorption to breakthrough changes only slightly (DEC for solutions with initial copper concentrations of 48.2 and 97 mg l^{-1} is 7.21 and 6.84 mg l^{-1}, respectively) and is presumably determined primarily by the adsorbent properties. The presence of ammonium ions in multicomponent solutions with pH 3.56 has no effect on the absorption of copper(II) and iron(II) and somewhat reduces that of cobalt(II),nickel(II), and manganese(II) (Table 6).

Sorption of Cu(II), Fe(II), Co(II), Ni(II), Mn(II), and Pd(II) ions from technological solutions. The possibility of using ACs produced from wastes for recovery of ions of copper(II) and other metals from technological solutions was assessed using high-salt acid (up to 1 M in terms of an acid) solutions (washing water) with a copper concentration of up to 100 mg l^{-1}. The solutions contained alkali metals, ammonium, and carbonate, sulfate, and nitrate ions in a manyfold excess and admixtures (up to 5–10 mg l^{-1}) of iron(II), lead(II), and other metals. As follows from the results obtained (Table 7), copper(II) is recovered under static conditions from washing water with complex composition in accordance with the sorption capacities of the carbons, and raising the solution pH enables a pronounced increase in copper(II) recovery. Iron is completely sorbed at its concentration of about 10 mg l^{-1}.

In sorption purification of technological solutions formed in processing of platinum-containing raw materials, the possibility of selective separation of residual amounts of target products, platinum metals, was taken into account. Previously, data on selective sorption of small amounts of platinum metals and, in particular palladium(II) from acid aqueous solutions on the activated carbons, irrespective of their nature and origin, have been obtained [16–18]. It was assumed on the basis of these data that residual amounts of palladium(II) can be recovered with a sufficient selectivity by sorption

Table 8. Sorption of metal ions from an industrial solution* on passing 175 ml of the solution at a rate of 25 ml h^{-1} (m = 1 g, V = 25 ml, bed height h = 9.5 mm, diameter d = 9 mm)

Parameter	Pd(II)	Cu(II)	Fe(II)	Co(II)	Ni(II)	Mn(II)

* In addition to the metal ions specified, the solution contains a 1000-fold excess of potassium and sodium salts, up to 10 g l^{-1} of ammonium ions, about 1 M of hydrochloric acid, and up to 0.1% nitric acid.

from acid technological solutions, and then, on changing the acidity of the medium, ions of other accessory metals. It was found that palladium(II) is completely recovered on passing a high-acidity (pH < 2) multicomponent technological solution containing an excess of ammonium salts through a column packed with an AC. It was also found that the Pd(II) : M(II) ratio on the adsorbent substantially exceeds that in the starting solution: already after passing the solution for 1 h, the Pd(II) : M(II) ratio becomes at least two times larger; after 7 h of purification, the Pd(II) : M(II) ratio is approximately 1 : 5 for iron and copper and no less than 1 : 3 for the other metals. The degree of recovery of the other metal ions is within the range 20–40% (Table 8). Alkalization of the solution after the separation of palladium enables subsequent purification of the solution: on raising the solution pH after separating palladium ions, the remaining copper and iron are completely removed and the amount of the other metal ions substantially decreases in the solution volume being purified.

CONCLUSIONS

(1) Activated carbons produced by thermal processing of a mixture of sunflower husks, low-grade coal, and refinery wastes are adsorbents for ions of copper(II), iron(II), and other metals from multicomponent solutions, including those of technological origin, irrespective of the nature of a refinery waste.

(2) A decisive stage in the interaction of metal ions with activated carbons is the ion exchange and complexation with oxygen-containing surface functional groups; additional oxidation of the carbons makes it possible to raise the content of surface functional groups and the sorption of metal ions.

(3) Activated carbons produced from waste selectively absorb palladium(II) from acid multicomponent technological solutions; dynamic adsorption makes it possible to diminish the excess amount of the accessory metals from a 20-fold in solution to a 3-fold on the adsorbent.

Abstract—Sorption of chromium(III) ions by cation exchangers based on oil residue and ED-20 epoxy resin was studied in comparison with that of KU-2 × 8 industrial cation exchanger.

DOI: 10.1134/S1070427208080077

Chromium compounds are among the most toxic contaminants of natural water [1, 2]. The find their way into the environment as a result of technological activities and can migrate in the aqueous medium during a long time. In addition to having a generally toxic effect, chromium compounds exert a mutagenic and teratogenic influence and, therefore, their penetration into water reservoirs is hazardous for people's health. Removal from wastewater and concentration of chromium ions is a topical task for environment protection services, especially for Eastern Kazakhstan, where richest deposits of chromite ores are being developed [3]. From slime stores of Aktobinsk chemical plants, which contain millions of tons of highly toxic water-soluble chromium compounds, they penetrate via underground and surface water into the Ilek and Ural rivers and further into the Caspian Sea. For water reservoirs used for sanitary and household purposes, the maximum permissible concentration (MPC) is 0.5 mgl^{-1} for Cr(III) and 0.1 mgl^{-1} for Cr(VI); near the town of Aktobe, the chromium concentration exceeds the MPC by a factor of 20.

Compared with chemical reagent purification methods, sorption techniques for recovery of chromium are more promising and ecologically and energetically favorable. However, choosing ion-exchange materials and sorbents for recovery of chromium compounds from technical, natural, and potable water is a complicated task, because removal of chromium salts from these kinds of water is difficult due to the wide variety of oxidation states of this element and to the large number of its complexes with natural compounds.

The aim of this study was to examine the sorption capacity of new cation exchangers based on oil residue and ED-20 epoxy resin for chromium(III) ions.

EXPERIMENTAL

Cation exchangers based on oil residue and ED-20 epoxy resin were synthesized by the procedure described in [4, 5] as follows: sulfo cation exchangers: K-SM, from mazut (ED-20 : mazut : H_2SO_4 = 3.0 : 1.0 : 0.5, heating at 110°C for 30 h); K-SG, from goudron (ED-20 : goudron : H_2SO_4 = 2.0 : 1.0 : 3.0, heating at 110°C for 24 h); K-SB, from bitumen (ED-20 : bitumen : H_2SO_4 = 1.0 : 1.0 : 2.5, heating at 140°C for 24 h); phosphoric acid cation exchanger K-FB, from bitumen (ED-20 : bitumen : H_3PO_4 = 1.0 : 1.0 : 2.5, heating at 140°C for 24 h). The yield of the cation exchangers synthesized was 68–88%; SEC for 0.1 N NaOH solution, 2.75–5.50 mg-equiv g^{-1}; specific volume, 1.6–3.8 $mg\,l^{-1}$; pK 2.0–3.8. In all the cases, the cation exchangers are have irregularly shaped grains with sizes of 1.0–2.5 mm (~35%) and 0.25–0.5 mm (>55%), with dust the rest (particles less than 0.25 mm in size). KU-2 × 8 industrial cation exchanger [GOST (State Standard) 20 298–74] in the H^+ form was also used for sorption.

The recovery of chromium ions from a $Cr_2(SO_4)_3$ solution was studied by the static method at a 1 : 400 ratio between a cation exchanger and solution. The contact duration was varied from 10 min to 7 days. The concentration of chromium ions in the starting and equilibrium solutions was found polarographically, because chromium can be determined from the Cr^{3+}

Sorption capacity of various cation exchangers in Cr^{3+} recovery from acodic and alkaline $Cr_2(SO_4)_3$ solutions (contact durtion 7 days)

K-SB	0.151	52.22	65.75	0.173	13.06	10.09
K-FB	0.143	54.75	68.11	0.143	28.14	22.40
KU-2 × 8	0.226	28.48	35.26	0.143	28.14	22.27

reduction wave [6]. The polarograms were measured with a PU-1 polarograph in a thermostated cell at 25 ± 0.5°C, with a dropping mercury electrode. Oxygen was removed from the solutions being analyzed by bubbling with argon for 5 min. A saturated calomel electrode served as reference. The content of Cr^{3+} ions was determined on the background of 0.5 M $CaCl_2$ ($E_{1/2}$ = –0.92 V). The amount of the sorbed metal was calculated from the difference of its concentrations in the starting solution and in the filtrate.

The purification of wastewater to remove chromium ions has been extensively studied [7–9], with a considerable attention paid to development of ion-exchange and sorption methods. Data on recovery of various chromium ions by anion and cation exchangers have been reported. The recovery of chromium from wastewater is difficult because, depending on a purification method, chromium is either reduced to the trivalent state or oxidized to become hexavalent. Of particular importance in this case is the pH value or wastewater or technological water and the chromium concentration. This study is devoted just to the influence of these factors on the sorption properties of new cation exchangers.

Cation exchangers based on oil residue (K-SM, K-SG, K-SB, and K-FB) were used for sorption of chromium ions. An industrial sample of KU-2 × 8 cation exchanger was taken for comparison, because KU-2 × 8 and KU-2 × 20 cation exchangers are the best for absorption of trivalent chromium [7].

The PH value of the starting solution is one of the most important parameters affecting the sorption and ion-exchange processes, because the pH value of the medium affects the chemical form of both the ion exchanger and the metal ion. Figure 1 shows how the sorption capacity (SC) for Cr^{3+} ions of various cation exchangers based on oil residue depends on the pH of the medium in the range 2–4. The upper limit to pH is due to the decrease in the stability of the chromium salt in the alkaline medium, and the lower, to inexpediency of performing sorption processes from strongly acidic media.

As can be seen in Fig. 1, the maximum recovery of Cr^{3+} ions is observed for all samples at pH 3.5. The sorption capacity of K-SM cation exchanger for Cr^{3+} ions from the given solution at pH 2–4 is lower than that of other resins.

It has been reported [10] that Cr(III) and Cr(VI) ions are strongly absorbed not only in the acid region at pH 2–5, but also in the alkaline region: anion exchangers adsorb Cr(III) and Cr(VI) ions to the greatest extent at pH 9.0 and 4.0, respectively. Therefore, the sorption of Cr^{3+} ions was studied not only from acid solutions, but also from an alkaline solution (pH 12.1) in which no precipitation of chromium hydroxide or a basic salt of chromium is observed (see table).

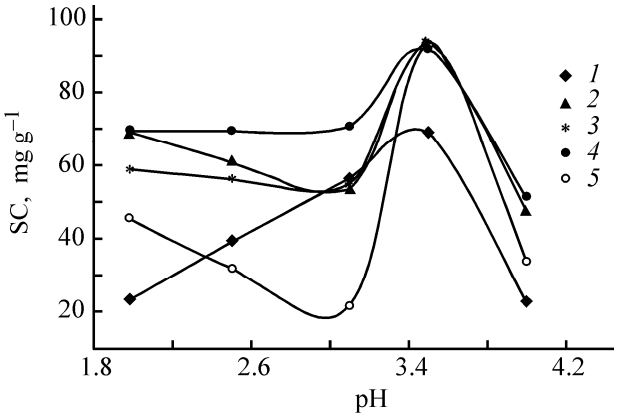

Fig. 1. Sorption capacity SC of (*1*) K-SM, (*2*) K-SG, (*3*) K-SB, (*4*) K-FB, and (*5*) KU-2 × 8 for Cr^{3+} ions vs. the pH of the medium. 0.025 N $Cr_2(SO_4)_3$ solution, 7 days.

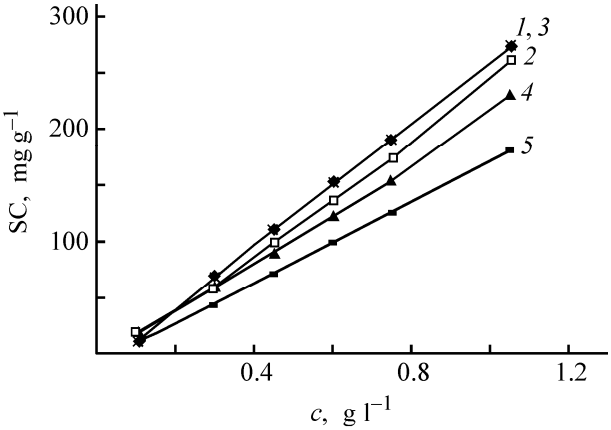

Fig. 2. Sorption isotherms of Cr^{3+} ions on (*1*) K-SM, (*2*) K-SG, (*3*) K-SB, (*4*) K-FB, and (*5*) KU-2 × 8 cation exchangers. Contact duration 7 days. (SC) Sorption capacity and (*c*) initial Cr^{3+} concentration.

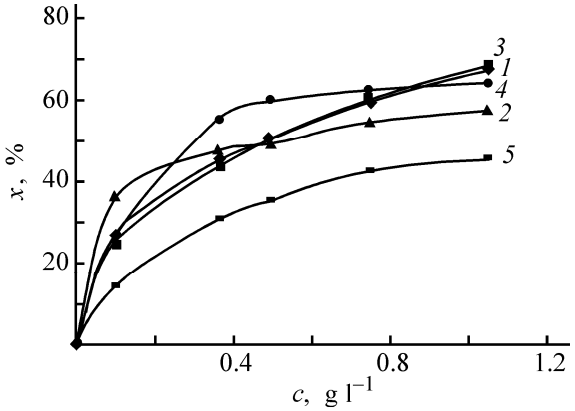

Fig. 3. Degree of recovery of Cr^{3+} ions, *x*, vs. their initial concentration *c* in a solution of $Cr_2(SO_4)_3$ on (*1*) K-SM, (*2*) K-SG, (*3*) K-SB, (*4*) K-FB, and (*5*) KU-2 × 8 cation exchangers.

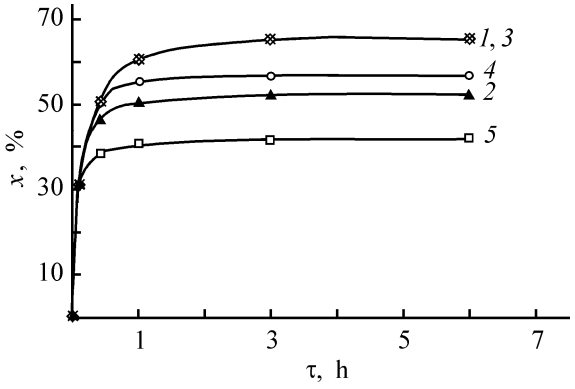

Fig. 4. Degree of recovery of Cr^{3+} ions, *x*, by (*1*) K-SM, (*2*) K-SG, (*3*) K-SB, (*4*) K-FB, and (*5*) KU-2 × 8 cation exchangers vs. the contact duration τ.

As can be seen in the table, the degree of Cr^{3+} recoery from the alkaline solution is substantially lower than that from the acid solution. Cr^{3+} ions are absorbed to the minimum extent by K-SB cation exchanger. All the ion exchangers synthesized adsorb chromium(III) ions from a solution with pH 3.1 better than the industrial sorbent KU-2 × 8 does. The highest sorption capacity for Cr^{3+} (68.11 mg g^{-1}) is observed for the phosphoric acid cation exchanger based on bitumen, K-FB. The sulfo cation exchanger K-SG is inferior to other ion exchangers based on oil residue in absorption of chromium(III) ions from acid media, and surpasses them in absorption from alkaline media.

The sorption capacity of the cation exchangers synthesized strongly depends on the concentration of $Cr_2(SO_4)_3$ solutions. At a content of chromium(III) cations in the starting solution equal to 1.04 g l^{-1}, the SC for these cations is 273 mg g^{-1} for K-SM and K-SB resins, 229 mg g^{-1} for K-SG and K-FB, and 181 mg g^{-1} for KU-2 × 8 (Fig. 2). At initial Cr^{3+} concentrations below 0.5 g l^{-1} Cr^{3+}, sulfo cation exchangers K-SM and K-SB recover chromium ions to the same extent as does phosphoric acid ion exchanger K-FB, and in solutions with higher content of chromium ions, the sorption capacity of the latter is higher.

As is known [7], the sorption isotherm provides information about the selectivity of an ion exchanger, and it follows from the slope of the dependences obtained that these cation exchangers have a rather high selectivity with respect to Cr^{3+} ions.

The solution concentration also affects the degree of recovery of Cr^{3+} cations (Fig. 3). The higher the content of Cr^{3+} ions in the starting solution, the larger the amount of ions absorbed by the cation exchangers. In the concentration range studied, the degree of recovery for K-FB resin reaches 55% for the solution with the Cr3+ ion concentration of 0.31 g l^{-1} and remains nearly unchanged as the concentration increases further. The best sorption properties are observed for K-SM and K-SB cation exchangers in absorption of Cr^{3+} ions from solutions with their concentration of 1.04 g l^{-1}. In this case, the degree of recovery is 67.5%.

At higher concentrations of Cr^{3+} ions, their recovery from solutions was not studied because it is believed [8] that the ion exchange or sorption is economically sound only for solutions containing the metal ion being recovered in a concentration not exceeding 1.0 g l^{-1}.

A no less important for development of the technology of sorption processes is analysis of the kinetic properties of ion exchangers. Figures 4 and 5 show how the degree of recovery of Cr^{3+} ions and the sorption capacity of various cation exchangers depend on

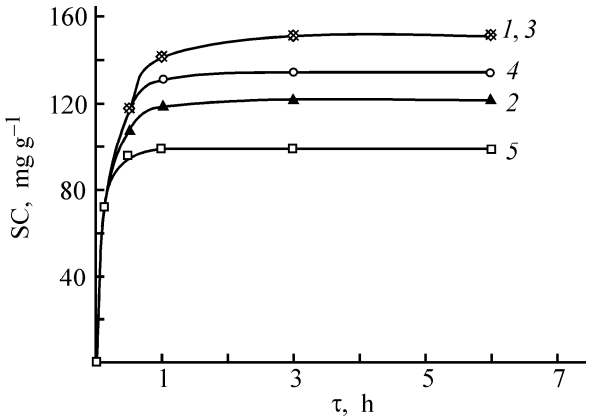

Fig. 5. Sorption capacity SC of (*1*) K-SM, (*2*) K-SG, (*3*) K-SB, (*4*) K-FB, and (5) KU-2 × 8 exchangers for Cr^{3+} ions vs. the contact duration τ.

time. The variation of these parameters with the duration of contact between the resins and the $Cr_2(SO_4)_3$ solution containing 0.6 g l^{-1} shows that the equilibrium is attained for the cation exchangers synthesized from oil residue in nearly 1 h. The industrial cation exchanger KU-2 × 8 exhibits better kinetic properties (the equilibrium state is attained in 0.5 h), although the degree of recovery by this cation exchanger and its sorption capacity for Cr^{3+} ions are lower.

CONCLUSIONS

(1) The static sorption of chromium ions by synthetic cation exchangers based on oil residue and ED-20 epoxy resin are better in the conditions studied than those of the industrial KU-2 × 8.

(2) Owing to their high sorption and kinetic parameters, it promising to use new cation exchangers for wastewater purification to remove chromium(III) ions.

Abstract—Anodic dissolution of ferroniobium in anhydrous methanol in the presence of sodium methylate was studied. The possibility of recovering pure hexamethoxyniobate from the electrolyzate and its conversion into niobium methylate with an iron content not exceeding 0.01% was analyzed.

DOI: 10.1134/S1070427208080089

The permanent need of the electronic industry in high-purity materials and, in particular, in special-purity niobium used in manufacture of bulk-porous niobium capacitors enforces a search for new methods for its production and purification. Of particular interest is recovery of niobium from the inexpensive and industrially produced ferroniobium and other alloys. Rather promising for this purpose is the electrochemical method for obtaining metal alkoxides by anodic dissolution of a metal in an aliphatic alcohol [1]. Published data on the anodic dissolution of alloys in alcohols are virtually lacking. The only exception are data on formation of tetraethoxysilane by anodic dissolution of ferrosilicon in ethanol on the background of ammonium chloride [2].

The anodic dissolution of technical-grade niobium in anhydrous methyl alcohol has been described previously [3, 4]. It was established that the mechanism of the process largely depends on the nature of a supporting electrolyte. Niobium(V) methylate was obtained in high yield by using lithium chloride as a supporting electrolyte. In this process, niobium methoxychlorides are first formed at the anode and readily interact in the solution bulk with methoxyl ions generated at the cathode. In the case of a sodium methylate supporting electrolyte, niobium cations generated at the anode are bound into a stable complex compound $NaNb(OCH_3)_6$, which is not subject to any transformation in the course of electrolysis and can be easily isolated from the electrolyzate in a nearly quantitative yield. It can serve as the starting material for preparing niobium(V) methylate by the reaction with ammonium chloride:

$$NaNb(OMe)_6 + NH_4Cl \rightarrow Nb(OMe)_5 + NaCl\downarrow + CH_3OH + NH_3\uparrow.$$

In this study, the possibility of obtaining niobium methylate and sodium hexamethoxyniobate from ferroniobium by the electrochemical method was considered and it was demonstrated that sodium hexamethoxyniobate can be converted to other niobium-containing compounds.

EXPERIMENTAL

Because the synthesis of alkoxides is sensitive to presence of moisture, methanol of chemically pure grade used in the study was subjected to additional drying by boiling with magnesium shavings [5]. The final content of water was less than 0.01%.

Sodium methylate was obtained by a direct reaction of metallic sodium (chemically puregrade) with methanol. Ferroniobium anodes were made of technical-grade ferroniobium containing (wt %): Nb 67.5, Al 0.45, Si 0.45, Ti 0.47, Ta 0.109, P 0.144, S 0.094, C 0.105, and Fe the remainder. The other reagents (lithium chloride, hydrochloric acid, and toluene) used in the study were of chemically pure grade.

Experiments were performed in a diaphragmless electrolyzer having the form of a 90-cm^3 glass cylinder with a thermostating jacket and a cock at the bottom for discharging the electrolyzate. The electrolyzer was hermetically closed with a cover into which a thermometer, gas-discharge pipe with a calcium chloride packing, and current leads to the electrodes were inserted. The ferroniobium anode was mounted below the cathode at a distance of 0.5 cm.

The working area of the anode was 10 cm^2. The cathode was made of a coiled iron wire 1 mm in diameter and had a working area of 24 cm^2. Prior to each electrolysis, the electrodes were trimmed and degreased with Vienna lime, washed with distilled water, dried, and weighed. After an experiment was complete, the electrolyzate was discharged for further processing into a flask preliminarily purged with argon. The amount of the dissolved metal was found from the loss of mass by the anode.

The residual iron(II) methylate was filtered from the electrolyzate without access of air.

To isolate niobium pentamethoxide (methylate), methanol was evaporated from the electrolyzate under a reduced pressure and then the product was extracted from the still bottoms with hexane. After the extractive agent was evaporated, a light yellow liquid that crystallized upon cooling remained in the flask. The resulting yellowish crystals had mp 61°C, in agreement with published data for niobium methylate [1].

Sodium hexamethoxyniobate was isolated from the filtrate, after the precipitated iron methylate was separated, by distilling off methanol until the onset of precipitation of crystals. After that, a fivefold amount of toluene or benzene was added to the solution and the mixture was kept at a lowered temperature until the crystallization was complete. The precipitated white needle-like crystals were filtered off and washed with toluene.

The content of sodium methylate in the still bottoms was found by their dissolution in water and titration of the resulting solution with an alkali. The content of niobium in the still bottoms was found by their dissolution in water, addition of hydrochloric acid, and gravimetric determination of the precipitated niobium pentoxide.

Dissolution of ferroniobium on the background of LiCl. Prior to electrolysis, the ferroniobium anode was thoroughly degreased and weighed. The electrolyzer was charged with an electrolyte solution [2.12 g of LiCl in 90 ml of methanol (0.5 M solution)]. The electrolysis was performed in the galvanostatic mode at a current density of 0.1 A cm^{-2} and temperature of 30–35°C. In the course of electrolysis, the solution remained transparent and the voltage was constant (9 V). The time of the experiment was 5 h, and the quantity of passed electricity, 5.0 A h^{-1}. The loss of mass by the electrode was 3.48 g, which corresponds to a 99.8% current efficiency by pentavalent niobium and trivalent iron. The precipitated iron methylate was filtered off, and methanol was evaporated from the electrolyzate under a reduced pressure (15 mm Hg). $Nb(OCH_3)_5$ was extracted (3.42 g) from the still bottoms with hexane, which corresponds to a 55% substance yield by a dissolved niobium. The content of the iron impurity in the product obtained was 0.54 wt %.

Dissolution of ferroniobium on the background of $NaOCH_3$. Prior to electrolysis, the ferro-niobium anode was thoroughly degreased and weighed. The electrolyzer was charged with an electrolyte solution [0.57 g of Na in 50 ml of methanol (0.5 M solution)]. The content of moisture in the solution was less than 0.05 wt %. The electrolysis was performed in the gal-vanostatic mode at a current density of 0.025 A cm^{-2} and temperature of 30–35°C. In the course of electrolysis, the solution remained transparent, with the electrolyzer voltage equal to 4 V at the beginning of a run and increasing to 9 V by its end. The experiment duration was 19 h 50 min, and the amount of passed electricity, 4.96 A h. The loss of mass by the electrode was 3.46 g, which corresponds to a 99.5% current efficiency by pentavalent niobium and trivalent iron. The precipitated iron methylate was filtered off and methanol was evaporated from the filtrate under a reduced pressure (15 mm Hg) before a crystalline pecipitate started to be formed. A five-fold volume of toluene was added to the resulting solution and the remaining methanol was evaporated under a reduced pressure until the precipitation of sodium hexamethoxyniobate crystals. The crystals obtained were filtered off and washed with toluene. The mass of the crystals was 7.26 g. The yield of sodium hexamethoxyniobate was 96.5% in terms of dissolved niobium. The obtained complex compound was dissolved in methanol and then a methanol solution of ammonium chloride (equimolar amount) was added to it. After the evaporation of methanol, 5.23 g of niobium methylate was isolated from the resulting residue with hexane. The substance yield was 87.5%.

Voltammetric measurements were made with an IPC-2000 computer-controlled electronic potentiostat

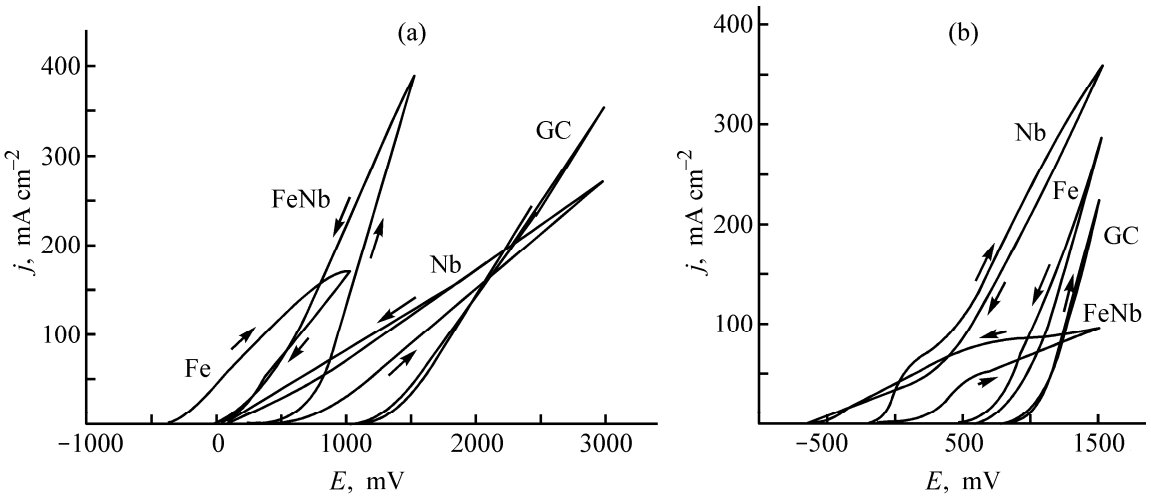

Fig. 1. Voltammetric curves obtained on iron, niobium, ferroniobium and glassy carbon (GC) in 1 M solutions of (a) LiCl and (b) NaOMe in anhydrous methanol. The potential is given relative to a silver chloride reference electrode. Temperature 25°C, potential sweep rate 0.2 V s^{-1}. (j) Current density and (E) potential.

in a 20-cm^3 cylindrical diaphragmless glass cell with a thermostating jacket. Electrodes and a gas-discharge pipe were inserted into the cell cover. The electrode system comprised a stationary working electrode with an area of 0.5 cm^2 [made of a material under study (niobium, iron, ferroniobium, or glassy carbon)], platinum auxiliary electrode, and silver chloride reference electrode. The last electrode was brought in close vicinity of the working electrode with a capillary.

To measure a voltammetric curve, the cell was charged with an electrolyte solution of the required concentration and bubbled with dry argon through the outlet tube for 0.5 h. Then, the trimmed electrode was introduced into the cell preheated to the required temperature and was polarized following the preset program.

To have a notion of the anodic behavior of ferroniobium under the above-described conditions of synthesis of niobium methylate and hexamethoxyniobate, voltammetric measurements were performed with lithium chloride and sodium methylate as supporting electrolytes. Figures 1a and 1b show sets of voltammograms obtained in anodic dissolution of iron, niobium, and ferroniobium and anodic polarization curves for glassy carbon. It can be seen that the onset potential of niobium dissolution on the background of sodium methylate is shifted to the negative region by approximately 750 mV in comparison with the corresponding potential in a lithium chloride solution. This indicates that niobium ions are bound into complexes in the presence of methylate ions. At the same time, the onset potential of iron dissolution on the background of sodium methylate is, by contrast, shifted to the positive region by 700 mV. This suggests that iron forms no complexes with methylate ions in the course of anodic dissolution and, in addition, the potential barrier of the electrode reaction for iron is higher in a solution with sodium methylate, compared with the solution with lithium chloride. In both cases, the onset potential of ferroniobium dissolution lies between the dissolution potentials of pure iron and niobium, which points to their joint dissolution.

Comparison of the slopes of the polarization curves in Fig. 1a shows that the dissolution of ferroniobium in the presence of lithium chloride is more intense than that of its individual components. It is easier than that in the case of niobium and, as the current density increases, occurs in approximately the same region of potentials as the dissolution of iron. In the presence of sodium methylate, the opposite situation is observed (Fig. 1b). Ferroniobium dissolves at the same potential as niobium. In all probability, hexamethoxyniobate is formed in both cases. Raising the potential results in the passivation of a surface.

It is seen from the results of voltammetric measurements that ferroniobium easily dissolves in methanol on the background of lithium chloride. In this case, electrolysis yields a mixture of iron and niobium methylates. It was difficult to recover niobium methylate free of iron compounds from the mixture obtained. A treatment of the electrolyzate by a verified extraction scheme

with hexane gave in low yield (≤55 %) a product rather strongly contaminated with iron.

As is known [1], niobium methylate itself exists in the form of a dimer including a four-member cycle $Nb_2(OMe_2)$. Probably, joint dissolution of niobium and iron yields a binuclear complex of Nb with Fe. The complex is poorly extracted with hexane and remains in the residue. Passing into the extractant, the compound contaminates the recovered niobium methylate with iron. Special experiments devoted to mixing of preliminarily obtained niobium and iron methylates in methanol showed that niobium methylate can be separated from the above mixtures in a considerably higher yield (up to 70%).

The situation changes profoundly when sodium methylate is used as a supporting electrolyte. In this case, niobium methylate being formed at the anode is bound into a stable complex hexamethoxiniobate anion, which forms no compounds with iron methylate. Sodium hexamethoxiniobate is easily recovered by crystallization from the mixture obtained upon electrolysis. The yield of sodium hexamethoxiniobate in terms of the dissolved metal exceeds 90 %. It was demonstrated by the spectral analysis that the con-tent of the iron impurity does not exceed 0.01 %. The thus obtained hexamethoxiniobate can be used as a starting material for preparation of pure niobium compounds. For example, niobium oxide was produced by hydrolysis of the isolated crystals with water, followed by addition of hydrochloric acid, and niobium methylate was obtained by the reaction with ammonium chloride. The results of the preparative electrolyses are listed in the table.

Thus, the attempts to separate the electrolysis products obtained in anodic dissolution of ferroniobium in a methanol solution of lithium chloride were unsuccessful. It was shown that, by contrast, the electrolysis with sodium methylate as a supporting electrolyte makes it possible to obtain a complex easily separable from iron compounds and can be considered a promising way of niobium purification.

Anodic dissolution of ferroniobium in methanol

Electrolyte	Yield, %		Substance yield, %	Fe content of final product, %
	Fe^{2+}	Fe^{3+}		
LiCl	90	10	Nb(OMe), 55	0.54
$NaOCH_3$	63	37	NaNb(OMe), 96	0.01

CONCLUSIONS

(1) A new direct way was found for separation of niobium from iron. The method involves anodic dissolution of ferroniobium in a methanol solution of sodium methylate, followed by separation of sodium hexamethoxyniobate from the electrolyzate.

(2) Sodium hexamethoxyniobate can be easily converted to niobium methylate by the reaction with ammonium chloride. In turn, the methylate can serve as a starting material for preparation of other niobium compounds.

(3) In contrast to the processes used in industry, the process of niobium separation from a ferroalloy occurs under mild conditions, with no aggressive media required.

Abstract—Indirect electrochemical oxidation of *N*-methyl-*n*-aminophenol by active oxygen species was studied. The active species were in situ generated from O_2, H_2O_2, and H_2O in aqueous solutions with various pH values by using a gas-diffusion cathode in a diaphragmless electrolyzer with anodes made of platinum, lead dioxide, and ruthenium-titanium oxide (RTO).

DOI: 10.1134/S1070427208080090

In recent years, technologies for purification of industrial wastewater by ecologically safe reagents, such as chemically bound active oxygen species, have aroused increasing interest. It is known [1–3] that electrochemical methods enable comparatively simple in situ generation of active oxygen species by conjugated processes from O_2, H_2O_2, and H_2O in the form of intermediates $HO^{\bullet}$, HO_2^-, and $HO_2^{\bullet}$ differing in oxidizing ability by 5–6 orders of magnitude.

Aromatic amines, which are typical hydrosphere contaminants [4], are widely used in industry, e.g., as starting and intermediate products in production of dyes and medicinal preparations.

Presently, the electrochemical technique of sewage treatment with highly reactive intermediates, active oxygen species in situ generated from O_2, H_2O, and H_2O_2, becomes increasingly attractive because of the ease of control, high efficiency, and ecological safety. Processes of indirect oxidation consist in the electrochemical generation at the cathode or anode (possibly, at the cathode and anode simultaneously) of intermediates of oxygen reduction and water oxidation (hetero-geneous stage) and in their subsequent in situ chemical reactions with organic substrates in an electrolyte solution (homogeneous stage).

At present, carbon-graphite gas-diffusion electrodes (GDE) are widely used in experimental practice, because these electrodes make it possible to raise the current density of O_2 reduction to H_2O_2 by 2–3 orders of magnitude, compared with smooth electrodes, which is important for practical application of such processes [5, 6].

Depending on the pH value, oxygen is reduced to hydrogen peroxide by one of the following reactions:

$$O_2 + 2H_2O + 2e = H_2O_2 + 2OH^-, \text{ pH} \geq 7; \quad (1)$$

$$O_2 + 2H^+ + 2e = H_2O_2, \text{ pH} < 7. \quad (2)$$

The oxidation reactions occur at metal-oxide anodes in diaphragmless cells:

$$H_2O \rightarrow 2HO^{\bullet} + 2H^+ + 2e, \quad (3)$$

$$H_2O_2 \rightarrow HO_2^{\bullet} + H^+ + e, \quad (4)$$

$$HO_2^{\bullet} \rightarrow O_2 + H^+ + e. \quad (5)$$

Studies of the oxidation of *N*-methyl-*n*-aminophenol by the Fenton photoreaction, UV/H_2O_2, at 60°C and its photocatalytic oxidation with TiO_2/H_2O_2 have shown [7–9] that, under these conditions, *N*-methyl-*n*-aminophenol is oxidized via formation of several intermediates: various cyclic carbonyl compounds and carboxylic acids, which are further oxidized to CO_2 and water.

The aim of this study was to examine the indirect electrochemical oxidation of *N*-methyl-*n*-aminophenol

by active oxygen species in situ generated from O_2, H_2O, and H_2O_2 in alkaline and acid electrolytes in a diaphragmless electrolyzer with carbon-black and graphite gas-diffusion cathodes and Pt, PbO_2, and RTO anodes.

EXPERIMENTAL

To obtain H_2O_2 and carry out in situ electrolyses involving hydrogen peroxide, we used temperature-controlled cells with unseparated cathode and anode spaces (two-chamber cells). The gas-diffusion cathode had the form of a planar disk with a total porosity of 65–70% and thickness of 0.8–0.9 mm, composed of a mixture of A 437-E carbon black (60 wt %) and FP-4D (40 wt %). The design of a cell of this kind was described in [10]. A platinum plate served as the anode. The volume of the electrolyte cell was 50 ml. The electrode potential was monitored on the front side of the gas-diffusion cathode relative to a silver chloride reference electrode.

N-methyl-*n*-aminophenol was oxidized at current densities of 20, 50, and 70 mA cm^{-2} at pH 2–3 and 9–10. The initial solution concentration was 1000 mg l^{-1}.

In electrolyses with a graphite cathode, we used a standard electrochemical cell with a cathode area S = 3 cm^2 and Pt, Pb/PbO_2, and RTO anodes. The PbO_2 anode was fabricated by anodic oxidation of a $2 \times 10 \times$ 25-mm lead plate in a 0.7 M solution of sulfuric acid at a current strength of 1 A within 1 h [11]. An X-ray phase analysis demonstrated that the coating formed in this way consisted of PbO–α-PbO_2 (3 : 1). Model solutions of *N*-methyl-*n*-aminophenol were oxidized at a current density of 150 mA cm^{-2}. The initial solution concentration was 500 and 1000 mg l^{-1}.

The variation of contents of *N*-methyl-*n*-aminophenol and other organic intermediates during the electrolysis was monitored by changes in the chemical oxygen demand (COD) [12]. The composition of the oxidation products was analyzed by UV spectroscopy. We used solutions of 0.1 and 0.2 M NaOH as an alkaline electrolyte, and 1 M Na_2SO_4 with addition of iron(II) sulfate ($c_{Fe^{2+}} = 0.4 \times 10^{-3}$ mg l^{-1}), acidified with 10% H_2SO_4 to pH 2–3, as the acid electrolyte; the electrolyte temperature was 30 ± 2°C.

When discussing the results obtained, we used the dependence of the Faraday efficiency on the quantity of passed electricity [13–15]:

$$\eta = \Delta \mathrm{COD} VF/(8I\Delta t).$$

Here COD is the chemical oxygen demand (mg l^{-1}); V, electrolyte volume (l); F, Faraday constant; I, current strength (A); and Δt, electrolysis duration (s).

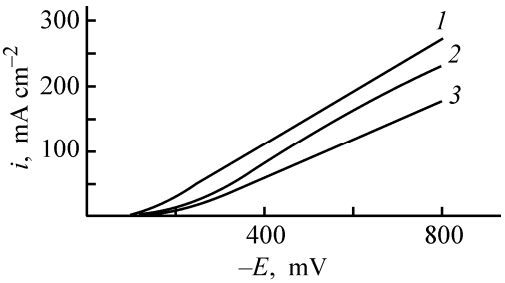

Fig. 1. Polarization curves for oxygen reduction at a gas-diffusion cathode. (*i*) Current and (*E*) potential. (*1*) 0.1 M NaOH, (*2*) 0.1 M NaOH + *N*-methyl-*n*-aminophenol (500 mg l^{-1}), (*3*) after electrolysis (5 h).

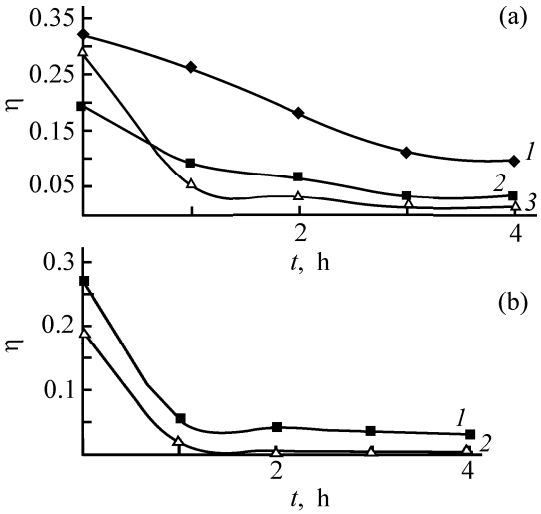

Fig. 2. Faraday efficiency η of *N*-methyl-*n*-aminophenol oxidation at pH (a) 9–10 and (b) 2–3 vs. the electrolysis duration t at various current densities at GDE. Metol concentration 1000 mg l^{-1}, Pt anode. (*i*) (mA cm^{-2}): (*1*) 20, (*2*) 50, and (*3*) 70.

To study the activity of gas-diffusion electrodes and the stability of the cathodic generation of hydrogen peroxide from oxygen, we recorded polarization curves. Figure 1 shows polarization curves of oxygen reduction at GDE in 0.1 M NaOH. Curve *1* indicates that the electroreduction of O_2 to H_2O_2 proceeds smoothly with a slight polarization. When, e.g., the current density increases from 100 to 150 mA cm^{-2}, the electrode potential shifts to the cathodic region by 100 mV. In the presence of *N*-methyl-*n*-aminophenol, the GDE potential slightly shifts to the cathodic region at all current densities, probably, due to the adsorption of the organic substrate. After performing electrolysis in the presence of Metol for 5 h, the polarization also increases further because of the adsorption of oxidation products on the cathode surface.

Figures 2a and 2b show how the Faraday efficiency of *N*-methyl-*n*-aminophenol oxidation at GDE

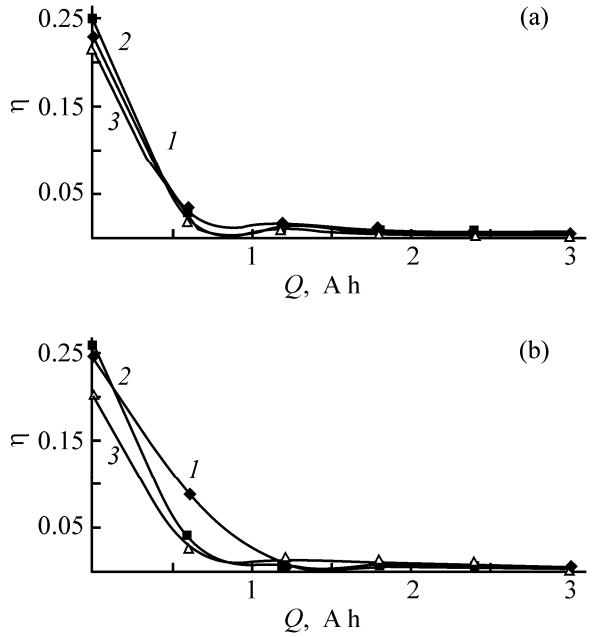

Fig. 3. Faraday efficiency η of *N*-methyl-*n*-aminophenol oxidation by oxygen vs. the quantity *Q* of passed electricity at pH (a) 2–3 and (b) 9–10. Current strength 600 mA, Metol concentration 1000 mg l^{-1}. (*1*) RTO, (*2*) Pb/PbO_2, (*3*) Pt.

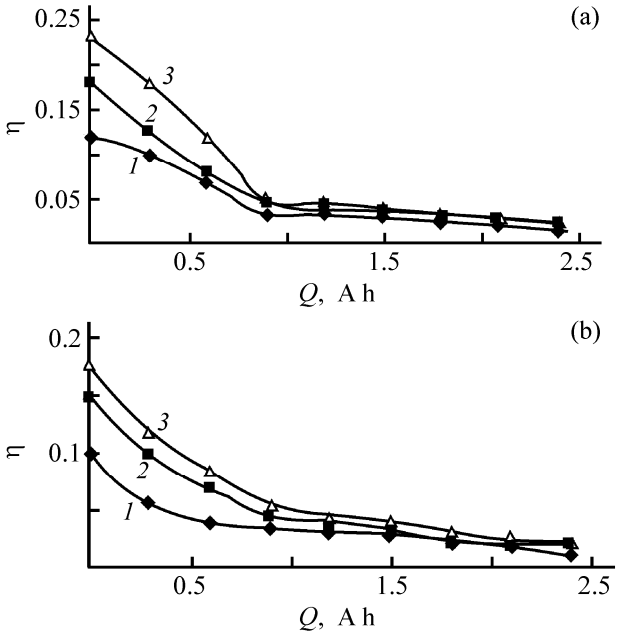

Fig. 4. Faraday efficiency η of the *N*-methyl-*n*-aminophenol oxidation by hydrogen peroxide vs. the quantity *Q* of passed electricity in (*1*) 0.1 M and (*2*) 0.2 M NaOH solutions. Current strength 600 mA, Metol concentration 500 mg l^{-1}, Pt anode. Peroxide concentration (M): (*1*) 0, (*2*) 0.1, and (*3*) 0.2.

depends on the current density at an initial Metol concentration of 1000 mg l^{-1} and pH 9–10 and 2–3. It can be seen that the Faraday efficiency increases with the current density. For example, η = 0.2 at i = 20 mA cm^{-2} and η = 0.33 at i = 70 mA cm^{-2} for the alkaline electrolyte. The oxidation is more effective in 0.1 M NaOH, compared with the acid electrolyte. This presumably occurs because hydrogen peroxide being formed is more stable in the acid electrolyte, compared with the alkaline electrolyte. Similar dependences were obtained in oxidation of phenol, with the calculated kinetic constants k found to be 1.8 h^{-1} and 1.4 h^{-1} for alkaline and acid electrolytes, respectively [10, 16].

Figures 3a and 3b show how the Faraday efficiency of *N*-methyl-*n*-aminophenol oxidation by molecular oxygen on various anode materials, with oxygen bubbled through a solution in which reactions (1)–(3) occur in this case, depends on the quantity of passed electricity. Oxygen is reduced at the graphite cathode to hydrogen peroxide, whose concentration was 0.002 M at pH 2–3 and 0.006 M at pH 9–10. The initial concentration c_{met} of *N*-methyl-*n*-aminophenol was 1000 mg l^{-1}, and the current strength, 600 mA. These dependences show that the oxidation better proceeds at pH 9–10 at Pb/PbO_2 (η = 0.27), RTO (η = 0.25), and Pt (η = 0.2) anodes, and at pH 2–3 at Pb/PbO_2 (η = 0.26), RTO (η = 0.23), and Pt (η = 0.22) anodes. Under these conditions, it is preferable to use Pb/PbO_2 and RTO anodes.

Figures 4a and 4b show how the Faraday efficiency depends on the quantity of passed electricity in direct anodic oxidation of *N*-methyl-*n*-aminophenol and in its indirect oxidation with addition of hydrogen peroxide ($c_{H_2O_2}$ 0.1 and 0.2 M) in a cell with a graphite cathode and a platinum anode in 0.1 and 0.2 M NaOH. The initial concentration of *N*-methyl-*n*-aminophenol was 500 mg l^{-1}.

In is seen from Fig. 4 that the efficiency of direct anodic oxidation is comparatively low: η = 0.12 for 0.1 M NaOH and η = 0.1 for 0.2 M NaOH, which is probably due to a low $HO_2^{\bullet}$ concentration. Addition of hydrogen peroxide leads to a rise in the oxidation efficiency due to an increase in the $HO_2^{\bullet}$ concentration via reaction (4). The Faraday efficiency is 0.23 for 0.1 M NaOH and 0.18 for 0.2 M NaOH. These data show that the oxidation in a 0.2 M alkali solution is less efficient than that in 0.1 M NaOH. Similar dependences were obtained in [16] for the phenol oxidation. The results of mineralization of *N*-methyl-*n*-aminophenol under various electrolysis conditions are listed in the table.

Results of *N*-methyl-*n*-aminophenol mineralization under various electrolysis conditions

c_{met}, mg l^{-1}; electrolysis conditions	i, mA cm^{-2}	Anode	Electrolyte, M	Mineralization efficiency, %
1000; GDE + O_2	70	Pt	0.1NaOH	98–99
	20	Pt	0.1NaOH	60–65
	20	Pt	1 Na_2SO_4 + 2H_2SO_4	25–30
1000; graphite + O_2	150	Pb/PbO_2		95–96
	150	OPTA	1 Na_2SO_4 + 2H_2SO_4	98–99
	150	Pt		89–90
1000; graphite + O_2	150	Pb/PbO_2		95–96
	150	OPTA	0.1NaOH	98–99
	150	Pt		91–92
500; graphite	150	Pt	0.1NaOH	72–73
500; graphite + H_2O_2	150	Pt	0.1NaOH + 0.1H_2O_2	95–96
	150	Pt	0.1NaOH +0.2H_2O_2	98–99
500; graphite	150	Pt	0.2NaOH	54–55
500; graphite + H_2O_2	150	Pt	0.2NaOH + 0.1H_2O_2	61–62
	150	Pt	0.2NaOH + 0.2H_2O_2	64–65

It is seen from the table that the indirect oxidation of *N*-methyl-*n*-aminophenol in a diaphragmless cell with GDE is more efficient in alkaline electrolytes, compared with acid electrolytes, and depends on the current density. In the oxidation by oxygen with the use of a graph-ite cathode at various pH, the best anode material is Pb/PbO_2: the efficiency of Metol mineralization is 99%. The indirect oxidation of *N*-methyl-*n*-aminophenol by hydrogen peroxide occurs with a 98% mineralization to CO_2 and H_2O in 0.1 M NaOH, whereas in 0.2 M NaOH, the efficiency is 65%.

The UV spectroscopic data show that the *N*-methyl-*n*-aminophenol oxidation via oxidative polymerization of the starting compounds is not predominating. The oxidation of *N*-methyl-*n*-aminophenol at various pH values proceeds by various successive oxidation pathways: at pH 2–3, intermediates of the carboxylale type are mainly formed, and at pH 9–10, products of *N*-methyl-*n*-aminophenol hydroxylation, with the subsequent conversion to aliphatic acids, which are further oxidized to CO_2 and water. A similar scheme of the *N*-methyl-*n*-aminophenol oxidation has been described in the literature [9, 17]. It is necessary to note that, when Fe^{2+} cations are present in the initial solution, the oxidation of the organic substrate is accompanied by the appearance of Fe^{3+} cations which have their own absorption bands in UV spectra. These bands are superimposed on the absorption bands of organic products and surpass these latter in intensity. Under these conditions, analysis of organic products is difficult.

CONCLUSIONS

(1) *N*-Methyl-*n*-aminophenol can be oxidized by active oxygen species generated in situ from oxygen, hydrogen peroxide, and water with the use of gas-diffusion electrodes, graphite cathodes, and various anode materials at various pH values.

(2) The indirect oxidation of *N*-methyl-*n*-aminophenol in a diaphragmless cell with gas-diffusion electrodes is more efficient in an alkaline electrolyte and depends on the current density.

(3) When oxygen is bubbled through a solution at various pH in a cell with a graphite cathode, the best anode material is Pb/PbO_2: the efficiency of *N*-methyl-*n*-aminophenol mineralization is 99%.

(4) The indirect oxidation of *N*-methyl-*n*-aminophenol by hydrogen peroxide in 0.1 M NaOH proceeds with a 98% mineralization to CO_2 and H_2O.

(5) According to UV spectroscopic data, the intermediate products of *N*-methyl-*n*-aminophenol oxidation in an acid electrolyte are various organic compounds of the carboxylate type, whereas upon addition of iron ions, mainly oxalate complexes are formed. In the case of electrochemical oxidation in an alkaline

electrolyte, the intermediate products are quinone, hydroquinone, and organic acids.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Chemical Effects of Hydroacoustic Treatment in Starch Hydrogels

I. M. Lipatova and N. V. Losev

Institute of Solution Chemistry, Russian Academy of Sciences, Ivanovo, Russia

Received December 27, 2007

Abstract—Energetic efficiency of application of a hydroacoustic treatment in a rotary-pulsatory apparatus in initiation or acceleration of chemical processes in starch hydrogels was studied. The contribution of the acoustic and shear components of this treatment to the activation of systems under study was evaluated for the example of destruction, acid hydrolysis, and oxidation of gelatinized starch.

DOI: 10.1134/S1070427208080107

The most efficient and, at the same time, less studied among the physical methods used to intensify technological processes in liquid media is the hydroacoustic treatment (HA treatment) in rotary apparatus with a pulsating flow. The main distinctive design feature of apparatus of this kind is the existence of alternating immobile and rotating revolution bodies with a common axis, which are perforated on their periphery to produce slits and openings. The most important factors affecting the structure of liquid polymeric materials being treated in hydroacoustic apparatus are ultrasonic pulsations and, accordingly, cavitation, as well as the high shear stresses to which the fluid is subjected in narrow (0.1–0.5 mm) gaps between the rotor and stator members [1, 2].

The scientific and special literature reflects the most extensively the applied and theoretical aspects of the liquid-phase hydroacoustic dispersion and homogenization [2, 3]. Comparatively recently there appeared reports devoted to application of HA apparatus for acceleration of homogeneous and heterogeneous chemical processes in systems with low-molecular-weight reagents and a low-viscosity medium [4, 5]. In the opinion of the authors of these studies, the main activating factor for systems of this kind is ultrasonic cavitation. In our previous studies, we demonstrated for the first time the possibility of using the HA treatment for initiation or acceleration of chemical processes in starch hydrogels and suggested that, in the case of viscous polymeric systems, an important contribution to the activation is made by high shear stresses [6–8].

The aim of this study was to find an approach to prognostication of the chemical effects of the HA treatment in starch hydrogels on the basis of the imparted mechanical energy, with account of the viscosity of the medium, and to evaluate the contribution of the acoustic and shear components of this treatment to the activation of the systems under study. The problem was to be solved using experimental data previously obtained in studies of the effect of the HA treatment on the dissolution [6], destruction [7], and acid hydrolysis [8] of gelatinized starch, as well as new data on mechanically activated oxidation of starch by various oxidizing agents.

EXPERIMENTAL

Corn starch served as the object of study. Starch hydrogels were prepared by thermal treatment of starch suspensions on a water bath at $T = 90°C$ for 15 min.

The starch hydrogels were treated in a laboratory rotary-pulsatory apparatus (RPA) with a set of replaceable rotors. The average gap between the rotating and immobile members of the working chamber was 0.3 mm. The rotor rotation rate was varied within the range 1000–5000 rpm, to which corresponded the shear rate gradient range $(0.5–17.4)\times10^4$ s^{-1}.

The ultrasonic treatment of the starch hydrogels was performed in a UZDN-2T disintegrator at a frequency of 22 kHz. The exposure time was varied from

5 to 60 s. The volume density of the acoustic power was 1.34 W cm^{-3}.

The amount of acoustic energy imparted to a liquid medium in its treatment in RPA or UZDN in unit time, characterized by the acoustic power, was determined by chemical dosimetry with the standard test systems [9].

The procedures for measuring the rates of mechanically initiated destruction of starch and mechanically activated acid hydrolysis were described in [7, 8]. The rate of starch oxidation reactions was measured by determining the loss of the oxidant concentration by the iodometric technique. To measure the rate of mechanically activated reactions, the reaction mixtures were prepared in number equal to that of points in the kinetic curve to be obtained. Each mixture was activated for a different time, after which a sample was immediately taken for analysis. The kinetic order of the reactions was determined graphically.

By the chemical effect of the HA treatment on polymer–solvent or polymer–solvent–reagent systems is understood either initiation of chemical processes that do not occur under ordinary conditions (mechanically initiated processes) or a change in the reaction rate, caused by mechanical activation (mechanically activated processes). As a measure of the chemical effect in the first case commonly serves the rate of the mechanically initiated process. For processes of the second group, i.e., those accelerated by the HA treatment, we use in this study the acceleration coefficients equal to the factor by which the reaction rate constant increases under mechanical activation (k_A/k).

We consider in this study reactions of oxidation of gelatinized starch as an example of mechanically activated processes. These reactions were performed in parallel in a thermostated working chamber of RPA and under ordinary conditions at the same temperature. We used potassium permanganate (6×10^{-4} M) and potassium bichromate (6×10^{-4} M) as oxidizing agents with the ionic mechanism of action, and ammonium persulfate (0.02 M) as an oxidizing agent with a radical mechanism of action.

In the oxidation of polysaccharides by the oxidizing agents used, the hydroxy groups of the glucopyranose units (mostly primary ones) are oxidized to carbonyl and carboxy groups, whose relative amounts depend on the process condition [10]. It should be noted that the oxidation of polysaccharides may also be accompanied by oxidative destruction of polymers. To estimate the extent of oxidative destruction, we measured the viscosity of hydrogels in parallel with measurements of the concentration of the oxidizing agent. In the case of potassium permanganate and bichromate, the viscosity data we obtained suggested that, under the chosen rather mild conditions (low oxidant concentrations and moderate temperatures), the oxidation occurs predominantly at hydroxy groups.

Table 1 lists values of k, k_A, and k_A/k at various starch concentrations in the hydrogels for the oxidation reactions under study. It is noteworthy that the nature of the dependence of the acceleration coefficients on the starch concentration in the hydrogels varies with the type of the oxidizing agent.

As can be seen in Table 1, the oxidation rate increases with the concentration of starch in hydrogels

under ordinary conditions when oxidizing agents with an ionic mechanism of action (potassium permanganate and bichromate) are used. However, the effect of reaction acceleration under mechanical activation, characterized by the ratio k_A/k, steadily decreases in this case.

When ammonium persulfate is used as a radical-forming oxidizing agent and the concentration of starch in hydrogels becomes higher, the reaction acceleration coefficient first decreases because of the mechanical treatment and then again starts to increase. A parallel viscometric monitoring demonstrated a substantial decrease in the viscosity of starch hydrogels in the course of the oxidation reaction. This indicates that the process occurs with predominance of oxidative destruction. The oxidative destruction is a process occurring with rupture of polymer backbones, and the probability of rupture increases under the action of deforming loads. Therefore, similarly to the case of the reaction of acid hydrolysis [8], the role of shear stresses in the chemical activation of starch increases as the polymer concentration and, accordingly, the viscosity of the hydrogels become higher.

The activation energy of the reactions under study decreased under mechanical treatment within an order of magnitude. For example, the activation energy of the reaction of interaction of starch in a 5% paste with ammonium persulfate was 86.9 kJ mol^{-1} under ordinary conditions and 17 kJ mol^{-1} under a hydroacoustic treatment.

The energy-related approach to the problem of prognostication of the chemical effects produced by HA treatment presumes that the following tasks should be accomplished. It is necessary reveal the decisive factors of the chemical activation of the system, determine the total amount of mechanical energy imparted to the reaction mixture, and, finally, to find how the chemical effect obtained depends on the amount of imparted mechanical energy.

To assess the role of the acoustic component of the HA treatment, it was appropriate to compare the mechanoacoustic yields of ultrasonic and hydroacoustic initiation of the same processes. The mechanoacoustic yield, equal to the number of initiated elementary events per 100 eV of absorbed acoustic energy, was calculated using the quantitative characteristics of processes of dissolution [6], depolymerization [7], and acid hydrolysis [8] and experimental values of the acoustic power W_{ac} (J s^{-1}) of ultrasonic and HA treatments. It was shown in [8] that, at a temperatures below 45°C and sulfuric acid concentrations in the range 0.03–0.15 M, the hydrolysis reaction does not occur under ordinary conditions, but proceeds at a measurable rate in the working chamber of RPA. Therefore, the process can be considered to be mechanically activated under the conditions specified and, consequently, its mechanoacoustic yield can be calculated by the formula

$$G = \frac{\Delta c_{RG} V N_A \times 100}{W_{ac} t \times 6.25 \times 10^{18}}, \quad (1)$$

where Δc_{RG} is the change in the concentration of terminal reducing groups in starch (M); V, volume of the working chamber of RPA (l); and t, treatment duration (s).

At higher temperatures, the process occurs even under ordinary conditions and can be regarded as mechanically activated in this case.

For a mechanically activated physicochemical dissolution process, we used the number of elementary starch units in the polymer that passed into solution, with the amount of this polymer found from the increase in the concentration of the water-soluble fraction in activated hydrogels, ΔA (wt %) [6]:

$$G = \frac{\Delta A c V N_A \times 100}{10 \times 159 W_{ac} t \times 6.25 \times 10^{18}}, \quad (2)$$

where c is the concentration of starch in the hydrogels (wt %), and 159 is the molecular mass of the elementary unit of starch.

The mechanoacoustic yield of the destruction of gelatinized starch was calculated using the experimental data of [7] by the formula

$$G = \frac{10c\left(\frac{1}{P} - \frac{1}{P_0}\right) V N_A \times 100}{159 W_{ac} t \times 6.25 \times 10^{18}}, \quad (3)$$

where P_0 and P are the degrees of starch polymerization in the starting and activated hydrogels.

The data in Table 2 show that, at starch concentrations not exceeding the critical gelation concentration c_{cr}, the mechanoacoustic yields for the ultrasonic and HA treatments are close. At higher concentrations, the effect of the HA treatment starts to substantially exceed that of the ultrasonic field. This increase begins at a concentration corresponding to c_{cr} for the starting hydrogels (c_{cr} = 23 wt %) for processes involving destruction of the primary gel structure and at a concentration corresponding to c_{cr} of mechanically disintegrated starch hydrogels (c_{cr} = 5 wt %) for the chem-ical process (hydrolysis) [11]. Thus, it was found that, at c

$< c_{cr}$, ultrasonic cavitation is the main factor initiating and accelerating chemical and physicochemical processes. At concentrations exceeding c_{cr}, the contribution of noncavitational mechanical factors becomes noticeable, and the most important among these factors is the unidirectional shear in radial gaps between the rotor and stator members.

The experimental data in Table 2 can be used to prognosticate the extent of the processes in question under ultrasonic or hydroacoustic treatment at low concentrations of starch hydrogels on the basis of the calculated or measured amount of imparted acoustic energy. As for the range of hydrogel concentrations corresponding to a joint treatment by cavitation and shear stresses, the data in Table 2 are only valid for the RPA design used in the apparatus. Of particular interest in this context was to find a correlation between the known or easily determinable characteristics of an arbitrary apparatus and a medium being treated, on the one hand, and the chemical effect produced by the treatment, on the other.

The energy-related approach to prognostication of treatment results, used in this study, is based on the assumption that the chemical effect in the case of a combined action of two basic factors, namely, ultrasonic cavitation and shear stresses in the radial gaps of the apparatus, are additively related to the total amount of mechanical energy imparted to the liquid medium in unit time. The intensity of supply of the acoustic energy in HA treatment, W_{ac}, was found in this study experimentally by the method of chemical dosimetry. The intensity of supply of the mechanical energy under shear stresses, W_τ, which is calculated as a product of the average shear stress by the shear rate, can be expressed in terms of the known RPA parameters, rotor rotation rate n (rpm), and dynamic viscosity of the medium being treated, μ (Pa s):

$$W_\tau = \frac{\pi^3 n^2 R_r^2 h(R_r + R_s)}{900\delta}\mu, \quad (4)$$

where R_r and R_s are the rotor and stator radii, respectively (m); δ, radial gap (m); and h, height of the rotor and stator slits (m).

An analysis of the experimental data demonstrated a strong dependence of the chemical effect of the HA treatment on the polymer concentration. Therefore, we studied how the magnitude of the chemical effect, g factor, depends on the intensity of supply of the total mechanical energy E_m (J) related to the starch concentration c (wt %) in a unit volume V of the hydrogel being treated (l):

$$g = \frac{E_m}{V \times 10c}. \quad (5)$$

It can be assumed that the product $V \times 10c$ is the mass of the polymer in the volume of the medium being treated, because, as the concentration of starch in the hydrogels varies from 1 to 8 wt %, the density of hydrogels varies from 1.005 to 1.036 g cm^{-3} (density of dry starch is 1.45 g cm^{-3}). Thus, the g factor describes the amount of mechanical energy supplied to unit mass of the polymer. Using expressions (1) and (2), we obtain

$$g = \frac{1}{V \times 10c}\left[W_{ac} + \frac{\pi^3 n^2 R_r^2 h(R_r + R_s)}{900\delta}\right]. \quad (6)$$

Figure 1a shows how the overall g factor calculated by Eq. (6) for the hydroacoustic treatment in RPA depends on the concentration of starch in the hydrogels being treated. At comparatively low concentra-

tions, the *g* factor decreases as the concentration increases, but at concentrations characterized by the formation of a 3*D* physical network of the starch hydrogel and a steep increase in viscosity, the situation changes. In this concentration range, the increase in the g factor because of the rapid rise in viscosity and, accordingly, in the intensity of energy supply exceeds its decrease caused by the increasing concentration of the polymer in solution. Curve *2* in Fig. 1a is the dependence of the *g* factor on the starch concentration for a hypothetic case in which only the acoustic (cavitational) component of the HA treatment is effective [here, the term "acoustic *g* factor" (g_{ac}) is used].

The concentration dependences of the chemical effects of the HA treatment of starch hydrogels, i.e., of the acceleration coefficients for the reactions of mechanically activated oxidation, are shown in Fig. 1b, and the rates of mechanically initiated destruction of starch and rate constants of the reaction of mechanically activated acid hydrolysis, in Fig. 1c.

It is noteworthy that the run of the concentration dependences for the processes occurring with rupture of skeletal bonds in starch macromolecules (mechanical destruction, acid hydrolysis, oxidative destruction) is symbate to that of the dependence of the same type for the overall *g* factor. For the concentration dependence of the rate of mechanically initiated destruction at low starch concentration, the symbasis to the concentration dependence of the *g* factor is disturbed. At concentrations of about 2 wt %, an extremal variation of the rate of mechanical destruction is observed. This can be understood as follows. In the starting hydrogel, the main part of starch is contained in swollen grains. At low starch concentrations, the efficiency of grain disintegration via collapse of cavitation bubbles decreases because of the probability factor. It is known that, for dispersions with low content of dispersed phase particles, the rate of their cavitation-induced diminution becomes lower as the concentration of these dispersions decreases [12]. The splitting of the swollen grains in starch hydrogels into finer fragments also favors the simultaneously occurring destructive processes. Possibly, it is this circumstance that is responsible for the lack of correlation between the rate of mechanical destruction and values of the *g* factor in low-concentration starch hydrogels.

A fundamentally different run is observed for the dependences corresponding to reactions between gelatinized starch and oxidizing agents with ionic mechanism of action. The conditions in which such reactions were performed were specially chosen so that the oxidation occurred at hydroxy groups. The acceleration coefficients for these reactions steadily decrease as the starch concentration grows, and the increase in viscosity with the concentration and the corresponding rise in the shear loads hardly affect the magnitude of the chemical effect. A comparative analysis of the curves in the figure demonstrated that the dependences of the chemical effects for the reactions involving pendant bonds are symbate to a similar dependence for the acoustic *g* factor.

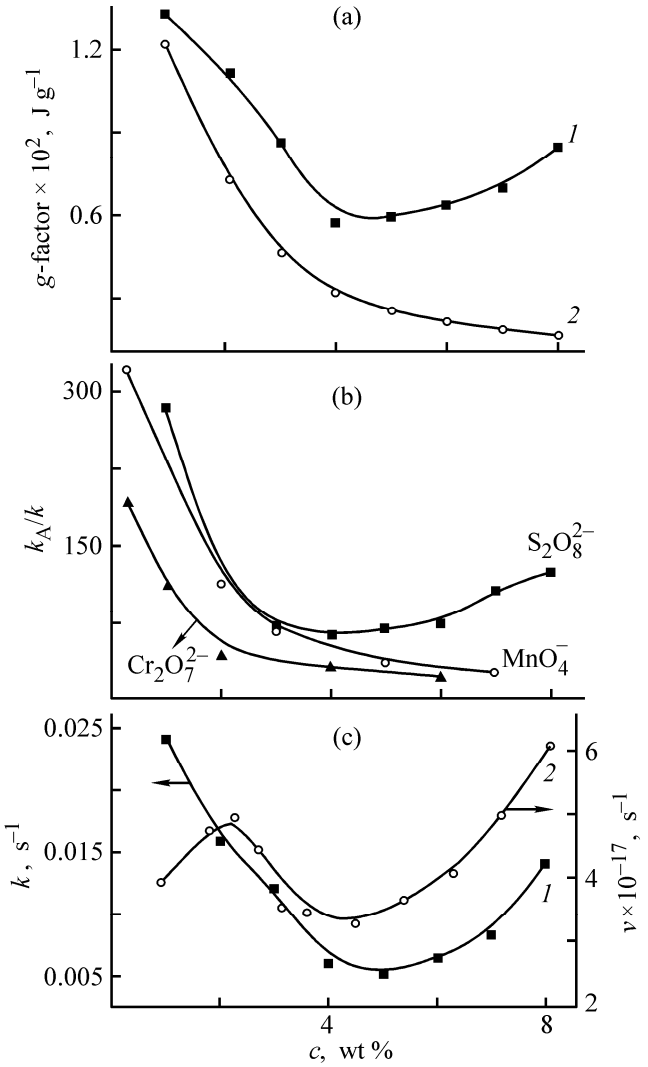

Fig. 1. (a) (*1*) Overall and (*2*) acoustic *g* factors, (b) acceleration coefficients k_A/k for reactions of oxidation by various oxidizing agents, and (c) (*1*) rate constants *k* of mechanically activated acid hydrolysis and (*2*) rate *v* of mechanically initiated destruction of gelatinized starch vs. its concentration *c* in hydrogels under a hydroacoustic treatment.

Thus, it was shown that prognostication of the chemical effects of an HA treatment in starch hydrogels is, in principle, possible. In the present stage of studies, the results obtained enable qualitative prognostication of changes in the chemical effects of an HA treatment, caused by changes in the polymer concentration or in the viscosity of the medium at a constant polymer concentration.

CONCLUSION

In the case of a hydroacoustic treatment of starch hydrogels, the rate of mechanically activated processes involving rupture of main-valence (skeletal) bonds is determined by the overall g factor (amount of total mechanical energy per unit mass of a polymer), and that of processes involving pendant groups, by the acoustic *g* factor.

Abstract—Extractive rectification of the benzene fraction of reformer naphtha with *N*-methylpyrrolidone–sulfolane mixtures exhibiting synergistic effect was studied. After benzene separation, the distillate contains less than 1 vol % benzene and can be used as component of automobile gasolines.

DOI: 10.1134/S1070427208080119

In accordance with Euro-4 European specification for automobile gasolines, valid since 2005, the benzene content should not exceed 1 vol % [1]. At the same time, the major component of Russian automobile gasolines is reformer naphtha distilled in the range from the start of boiling to 180°C and containing 3–5 vol % benzene.

For large oil refineries producing more than 1.5 million tons of reformer naphthas annually, the most efficient way to reduce the benzene content of automobile gasolines is postfractionation of reformer naphtha, followed by benzene separation from the benzene fraction by extractive rectification [2]. The following selective solvents are used in industry for extractive rectification: *N*-methylpyrrolidone (N-MP) [3], *N*-formyl-morpholine (N-FM) [4], and Tektiv-100 mixed solvent [5].

The main drawback of highly selective solvents (sulfolane, N-FM, etc.) is their insufficiently high solvency toward hydrocarbons, leading to phase separation on trays of extractive rectification tower and to decreased efficiency of benzene separation.

To prevent phase separation of the system hydrocarbon feed–selective solvent, a method has been patented for arene separation from hydrocarbon mixtures by extractive rectification with N-FM, differing in that the process is performed at elevated pressures (up to 0.5 MPa) [6]. Elevated pressures lead to an increase in the temperature in the tower and in the solubility of saturated hydrocarbons in N-FM. However, the drawback of the method suggested is that the separation selectivity decreases due to the lower stability of π complexes of arenes with polar solvents at elevated temperatures.

The solvency of *N*-methylpyrrolidone is very high, so that the system on trays of the extractive rectification tower is homogeneous. This solvent, however, is less selective to arenes than sulfolane and N-FM.

The composition of Tektiv-100 mixed solvent has not been reported. However, as judged from the use of vacuum and high-pressure steam in the stripping tower for arene distillation, it contains high-boiling selective solvents like sulfolane regenerated by a similar procedure [7].

For example, a method has been patented for separation of arenes from hydrocarbon fractions by extractive rectification using a mixture of sulfolane with a cosolvent, alkylsulfolanes containing up to eight carbon atoms in the molecules [8]. This procedure has certain drawbacks: Use of high-boiling selective solvents (the boiling point of sulfolane is 285°C, and that of alkylsulfolanes is still higher) results in a high temperature in the extractive rectification tower and in the boiler and leads to a decrease in the separation selectivity; the high viscosity of the mixed solvent impairs the efficiency of trays and make smaller the number of theoretical plates of the extractive rectification tower; problems arise in solvent regeneration (need for high-

Table 1. Physicochemical and selective properties of solvents in benzene separation from mixtures with saturated hydrocarbons

Parameter	Sulfolane [7]	N-FM [4]	N-MP [3]
Boiling point,°C	285	244	202–204

pressure steam generator and for a vacuum in the stripping tower); need for using a vacuum-producing system and a vacuum tower of increased diameter, compared to an atmospheric-ressure stripping tower, leads to larger capital outlays.

The above drawbacks can be eliminated by adding to a highly selective solvent a relatively low-boiling solvent with low viscosity and increased solvency toward hydrocarbons. As such solvent we chose N-MP, and as highly selective solvent, sulfolane.

The physicochemical and selective properties of these solvents are listed in Table 1. These data show that sulfolane is considerably more selective than N-MP toward the hexane–benzene model system, as indicated by the ratio of the limiting activity coefficients of these hydrocarbons in solvents, γ_h^0/γ_b^0. At the same time, N-MP shows higher solvency characterized by the quantity reciprocal to the limiting activity coefficient of benzene, $1/\gamma_b^0$. With respect to a combined performance criterion taking into account both the selectivity and solvency, sulfolane and N-MP differ insignificantly. The advantages of N-MP are the lower values of viscosity, enthalpy of vaporization, and congealing point.

EXPERIMENTAL

As feed we used the commercial benzene fraction 55–85°C recovered by distillation from reformer naphtha (boiling range from start of boiling to 180°C). The composition of the initial benzene fraction, determined by capillary gas–liquid chromatography, is given in Table 2.

Extractive rectification experiments were performed on a laboratory packed column operating in the batch mode, with a 15 TP efficiency. A definite amount of feed was charged into a boiler equipped with a thermometer and heated on an oil bath. In the upper part of the column we arranged a heated dropping funnel with the selective solvent. By heating the boiler and jacket, the column, was brought to the flooding state, after which the column operated for 10–15 min in the normal mode without distillate takeoff. Then we started to add dropwise the selective solvent preheated to 70–75°C and to take off distillate fractions. The rates of solvent feeding and distillate takeoff were determined by the preset solvent : feed ratio. For example, at a solvent : feed weight ratio of 2 : 1, with into account of the total con-

tent of arenes in the benzene fraction (about 31 wt%), the solvent : distillate weight ratio should be about 2.9 : 1.

In each experiment, we took several fractions of the distillate, determined their yield, and analyzed by GLC for the benzene content (the distillate fractions contained no toluene). The distillate takeoff was stopped when nearly the whole amount of nonaromatic hydrocarbons passed into the distillate (at calculated concentration of arenes in the aromatic concentrate of the bottom residue of 99.9 wt %). The aromatic concentrate was distilled-off from the bottoms with live steam.

Preliminary experiments for determining the possible synergistic effect and optimal composition of the mixed solvent were performed with technical-grade sulfolane containing 2.6 wt % water, anhydrous N-MP, and mixed selective solvents of various compositions, prepared by adding M-MP to technical-grade sulfolane. The water content of the initial sulfolane sample was determined from the congealing point, +8°C, corresponding to a water content of about 2.5 wt % [7], and then was refined by azeotropic distillation of water with benzene, using a Dean–Stark trap.

All the preliminary experiments on selective rectification were performed at the same weight ratio of the selective solvents and feed, 2 : 1 (Table 3).

The dependence of the degree of arene separation on the N-MP content of the mixed solvent, plotted according to data of Table 3, is shown in Fig. 1 (curve *1*).

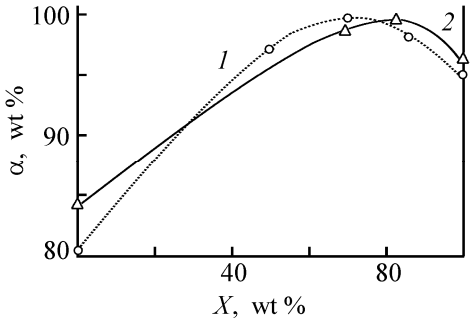

Fig. 1. Degree of arene separation α vs. N-MP content X of the mixed selective extractant, according to data of (*1*) Table 3 and (*2*) Table 4, run nos. 2–5.

As follows from Table 3 and Fig. 1, the worst results in extractive rectification are obtained with technical-grade sulfolane, despite its highest selectivity to arenes. This may be due to the insufficient solvency of sulfolane, which leads to phase separation of the liquid in the extractive rectification column. With N-MP, which provides the homogeneity of the system with the hydrocarbons being separated, the process is more efficient. The best results are obtained on adding sulfolane enhancing the separation selectivity to N-MP in an amount with which the system is still homogeneous, namely, up to 30 wt % content of technical-grade sulfolane in the mixed solvent. At this composition, a synergistic effect is observed: The degree of arene separation, equal to 99.9 wt %, is considerably higher than with individual N-MP or with technical-grade sulfolane.

Previously, when developing a combined procedure for separating C_6–C_8 arenes from the 62–105°C fraction of reformer naphtha by extractive rectification followed by extraction of the benzene that partially gets to the distillate, we suggested to use in both steps mixtures of sulfolane with N-MP [9, 10]. In the extractive rectification step, we used a mixture of these solvents containing 30 wt % sulfolane, which showed a synergistic effect.

A change in the fractional composition of the feed could lead to a change in the optimal composition of the mixed solvent. However, it actually remained the same. This may be due to the effect of two factors acting in opposite directions. On the one hand, the major components of the benzene fraction of reformer naphtha are C_6 saturated hydrocarbons, which are better soluble in polar solvents than C_7–C_8 hydrocarbons, and, for homogenization of the system, it is sufficient to add smaller amounts of N-MP to ensure the system homogeneity (provided that the process temperature is the same). However, on the other hand, in separation of relatively low-boiling C_6 hydrocarbons, the temperature in the extractive rectification tower decreases, which leads to a decrease in the solubility of saturated hydrocarbons in polar solvents.

The optimal composition of mixed selective solvents also depends on their water content. Water is added to decrease the temperature in the low sections of the extractive rectification tower and in the stripping tower. This is necessary to make lower the probability of thermal and hydrolytic decomposition of the solvent and to perform the process at a moderate (about 10 atm) steam pressure.

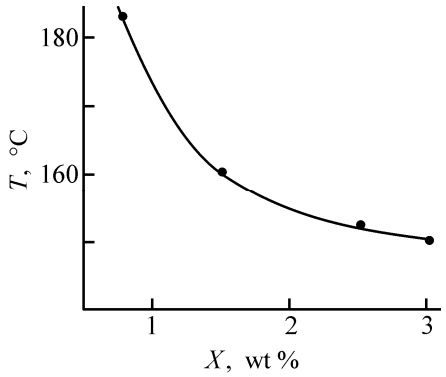

Fig. 2. Boiling point T of the mixed selective solvent sulfolane : N-MP = 30 : 70 (w/w) vs. its water content X.

The water content of the selective solvent should be chosen on the level at which the boiler temperature in the stripping tower does not exceed 165–170 °C, which corresponds to the normal boiling point of about 155 °C. To determine this level, we examined how the water content affects the boiling point of sulfolane–N-MP mixtures of the composition (30 : 70 wt %) providing a synergistic effect in extractive rectification (Fig. 2). The above condition is met at a water content as low as 2 wt %.

An increase in the water content of the mixed solvent to 2.5 wt % leads to a decrease in the degree of arene separation in extractive rectification to 96% against 98.25% at a water content of 2.0 wt % (Table 4, run nos. 1, 2). In the process, the benzene concentration in the distillate increases to 1.76 wt %, which exceeds the permissible level of 1 vol %. Thus, an increase in the water content of the mixed solvent to 2.5 wt % is undesirable, as it would require an increase in the solvent-to-feed ratio.

The synergistic effect was revealed for the mixed solvent sulfolane : N-MP = 30 : 70 wt % containing 0.78 wt % water. An increase in the water content to 2.0 wt % may somewhat alter the optimal composition of the solvent. To refine this composition, we performed experiments with solvents containing 2 wt % water, both individual and mixed with various sulfolane : N-MP ratios (Table 4, run nos. 2–5).

Figure 1 shows that the optimal composition of the mixed solvent containing 2 wt % water shifts toward a higher N-MP content (85 wt % N-MP–15 wt % sulfolane). In this case, the synergistic effect in extractive rectification is manifested to the greatest extent.

Table 5. Relative fugacity coefficients of the heptane–benzene system in the presence of selective solvents (solvent : hydrocarbons weight ratio 2 : 1)

Solvent composition, wt %			T, °C	Heptane content, mol %		Phase equilibrium constants		$\alpha = K_{hp}/K_b$
sulfolane	N-MP	water		in liquid phase, X_{hp}	in vapor phase, Y_{hp}	K_{hp}	K_b	
98.0	–	2.0	98	55.20	70.8	1.28	0.65	1.97
83.3	14.7	2.0	103	54.32	73.3	1.35	0.58	2.33
63.7	34.3	2.0	105	60.00	74.69	1.24	0.63	1.96

Experiments aimed to determine the minimal ratio of the mixed selective solvent to the feed, providing recovery of commercial benzene and its content in the distillate not exceeding 1 vol %, were performed with the solvent of the optimal composition, sulfolane : N-MP : water = 14.7 : 83.3 : 2.0 wt % (Table 4, run nos. 3, 6, 7).

At the solvent-to-feed ratio decreased to 1.5 : 1, fairly pure arenes can be obtained at the benzene content of the distillate less than 1 vol %. Further decrease in the solvent-to-feed ratio to 1 : 1 by weight (0.7 : 1 by volume) leads to a considerable decrease in the degree of benzene separation and to an increase in its content in the distillate over 1 vol %.

The individual hydrocarbon composition of the distillate and aromatic concentrate obtained by extractive rectification with the mixed selective solvent N-MP–sulfolane of the optimal composition (Table 4, conditions of run no. 3) is given in Table 2.

The total content of saturated hydrocarbons in the aromatic concentrate is as low as 0.08 wt %, and all these impurities are C_7 alkanes with boiling points higher than that of benzene. By fractional distillation of the aromatic concentrate, 99.9 wt % pure benzene and ~99 wt % pure toluene were obtained. The aliphatic distillate formed meets the modern requirements to gasolines with respect to the benzene content.

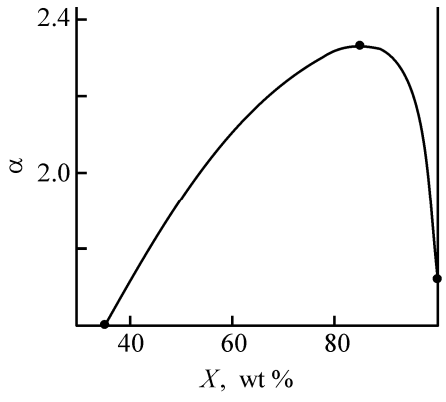

Fig. 3. Relative fugacity coefficient α of the heptane–benzene system vs. the N-MP content X of the mixed selective extractant sulfolane–N-MP–water.

The synergistic effect for the mixed selective solvent sulfolane–N-MP containing 2 wt % water was confirmed by studying the liquid–vapor equilibrium by the circulation method with a modified Othmer device [11]. At 2 : 1 weight ratio of the selective solvent and heptane–benzene model system, we determined the phase equilibrium constants for heptane (K_{hp}) and benzene (K_b) and calculated the relative fugacity coefficients (Table 5). As follows from Table 5 and Fig. 3, the relative fugacity coefficient of the heptane–benzene system is at maximum in the presence of the mixed solvent sulfolane–N-MP–water of the composition 14.7 : 83.3 : 2.0 wt%, which showed the best performance in benzene separation by extractive rectification.

CONCLUSIONS

(1) The mixed selective solvent sulfolane–*N*-methylpyrrolidone–water containing about 15–30 wt % sulfolane and 0.8–2.0 wt % water shows a synergistic effect in benzene separation from the benzene fraction of reformer naphtha by extractive rectification, which provides a higher degree of benzene separation, compared to sulfolane and *N*-methylpyrrolidone taken separately.

(2) The maximal relative fugacity coefficient of the heptane–benzene system, $\alpha = 2.33$, at the solvent to hydrocarbons weight ratio of 2 : 1 corresponds to the optimal composition sulfolane : *N*-methylpyrrolidone : water = 14.7 : 83.3 : 2.0 wt %.

(3) A decrease in the benzene content from 30–31 wt % in the benzene fraction of the reformer naphtha to the level below 1 wt % is provided at the weight ratio of the mixed selective solvent to the feed of 1.5 : 1 and 15 TP performance of the extractive rectification tower.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Water-Soluble Polymeric Additives on Energy Expenditure in Transportation of Water–Oil Systems in Turbulent Mode

S. V. Chichkanov, A. I. Shamsullin, and V. A. Myagchenkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 26, 2007

Abstract—New installation of the circulation type was used to perform a joint analysis of rheological and energy parameters of turbulent flows of water and water–oil media in the presence of polymeric additives of anionic copolymers of acrylamide. Copolymers with varied molecular mass were produced by ultrasonic destruction of a starting high-molecular-weight sample of the polymer under mild conditions. The effect of the molecular mass of the polymer additive on the specific energy expenditure in the case of circulation of water–oil media in the turbulent mode was analyzed.

DOI: 10.1134/S1070427208080120

The effect of a decrease in the hydraulic resistance of a turbulent flow of a fluid in the presence of small doses of polymer additives (<0.001%) has been known for a rather long time. The first results of experiments of this kind were reported as far back as 1948 by Toms [1]. Since that time the interest of numerous researchers has been concentrated on this unusual and, in a sense, paradoxical phenomenon. The paradoxicality consists in that, upon introduction of minor concentrations of a polymer into a turbulent flow, its velocity increases, rather than decreases (as is the case in a laminar flow). This occurs because the hydraulic resistance becomes lower, which leads to an increase in the flow velocity and fluid flow rate, decrease in the pressure difference at pipeline ends, etc. Naturally, this effect has found wide use in various industries associated with high-speed pipeline transportation of large volumes of fluids and, in particular, in the oil industry in pipeline transportation of water, oil, oil products, and oil emulsions [2].

When attempting to practically use the Toms effect in real pipeline transport objects, it is necessary to take into account a number of specific technological features. This is primarily due to the fact that, upon introduction of a polymeric additive into a turbulent flow of a fluid in real systems, the effect can be manifested in several ways [3, 4]: (i) an increase in the fluid flow rate at a constant pressure in the pipeline and constant load on the drives of transfer pumps, (ii) a decrease in the pipeline pressure at a constant fluid flow rate, and (iii) a decrease in the load on the drives of transport pumps.

In view of the fact that, in most cases, the fluid flow rate and the pumping pressure remain invariable, the expected positive effect of introduction of a polymeric additive is that the energy consumption by the transport pumps per unit volume of the fluid being transported could decrease. Now, this circumstance becomes increasingly important because of the deficiency of electric power and a steady increase in its cost and 24/7 operation of pumping stations consuming an enormous amount of electric power in oil-producing regions of Russia. Therefore, even a minor decrease in the electric power consumed in high-speed transportation of water–oil media could become an important energy-saving factor making lower the cost of products transported by pipelines.

Analysis of published data shows that, in most cases, classical studies of the Toms effect are based on considering only the rheological aspects of the process (e.g., in motion of solutions in capillaries and pipes) [5, 6] or examining the structure of various zones of

turbulent flows of polymer solutions (laser Doppler anemometry) [7]. Owing to the vast experience of application of the Toms effect in oil industry and to the topicality of the problem, of particular interest are experimental studies in which the most important technological parameters of the pipeline transportation of fluids (e.g., fluid flow rate and electric power consumed for transportation of a unit volume of a fluid) serve as the main estimation characteristics.

In this study, we evaluated the efficiency of anionic copolymers of acrylamide as additives that can be used to raise the fluid flow rate and diminish the electric power consumed in a turbulent flow of water and water–oil media.

EXPERIMENTAL

To perform the experiment, we developed an installation of the circulation type, schematically shown in Fig. 1. A distinctive feature of this installation is its bifunctionality. First, the installation makes it possible to obtain dispersed systems of ?direct and inverse? types, using unit I. Second, this system can be used to perform extended tests of polymeric additives as agents reducing the hydraulic resistance ?of turbulent flows and energy expenditure for transportation of the fluids under study (in unit II).

As already noted, a topical issue are studies of the influence exerted by polymeric additives on the hydrodynamic and energy parameters of the processes of pipeline transportation of fluids. Therefore, a double monitoring of the fluid circulation in the limiting circuit was used in unit II: the fluid flow rate and the electric power consumed by the pump were simultaneously recorded.

The experimental procedure consisted in the following. To obtain 10 vol % direct emulsions of oil, calculated amounts of water, oil, and stabilizer (nonionogenic surfactant, Neonol AF9-10 in an amount of 1 vol % relative to the volume of oil) were charged into vessel *8*. Then the mixture was circulated by pump *1* over the small circuit through grid membrane unit *2* intended for additional disintegration of particles of the dispersed phase (oil). This way to obtain direct emulsions of oil guaranteed their high aggregative and sedimentation stability in the course of further experiments. After a certain interval of time, pump *1* was switched off. To study the rheological properties of fluids and energy parameters of turbulent flows, unit II was put to use. For this purpose, pump *4* was switched on and the fluid was circulated

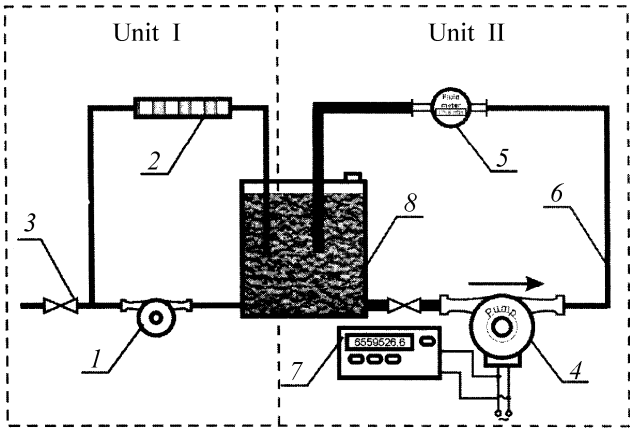

Fig. 1. Schematic of the installation used to prepare emulsions and to study the hydrodynamic and energy parameters of turbulent water and water–oil flows: (*1*) pump serving to produce emulsions, (*2*) grid membrane unit, (*3*) valve for dis-charging a spent emulsion, (*4*) centrifugal pump, (*5*) flow meter, (*6*) control pipeline (diameter 12 mm, length 15 m), (*7*) electricity supply meter, (*8*) working vessel with a fluid being analyzed.

through control pipeline *6* (inner diameter 12 mm, length 15 mm) made of reinforced polyethylene. In the course of circulation, the fluid flow rate was monitored with flow meter *5*, and the amount of electricity consumed by the pump in the course of circulation, with electricity supply meter *7*. It should be noted that the power of the pump provided a developed turbulent mode of fluid flow in the pipeline (Reynolds number for water was about 3×10^4).

It was appropriate to use as an indicator of the efficiency of a polymeric additive not simply a change in the fluid flow rate or in the electric power consumed by the pump, but a combined parameter: relative energy consumption by the pumping unit, ε, defined by

$$\varepsilon = E/E_0,$$

where E and E_0 are the specific energy consumptions by the pump [electric power consumption (kW h) in transportation of 1 m^3 of the fluid] in circulation of the fluid in the limiting circuit with and without a polymer additive, respectively.

To obtain samples of anionic copolymers of acrylamide with different values of M, we used the method of ultrasonic destruction (USD) of a starting sample of a statistical copolymer of acrylamide with sodium acrylate, with $M = 1.6 \times 10^6$ and content of ionogenic (acrylate) groups, $\alpha = 17.5$ mol%. By analogy with [8, 9], the USD of the copolymers was performed with a UZDN-1 device at a frequency of 22 kHz in

Modes of ultrasonic treatment of solutions and molecular masses of the copolymer samples being analyzed

Sample no.	Treatment duration, min	Ultrasonic power, W cm^{-2}	$[\eta p]$, cm g^{-1}	$M \times 10^{-6}$
1	–	–	662.2	1.61
2	5	1.0	561.1	1.32
3	5	4.0	504.6	1.15
4	6.5	7.9	303.9	0.62
5	7	11.8	223.3	0.42
6	8	15.2	96.7	0.15

the mild mode in a 0.2% aqueous solution, with varied power of the ultrasonic field and exposure time. The developed USD mode made it possible to obtain six copolymer samples with widely different molecular masses.

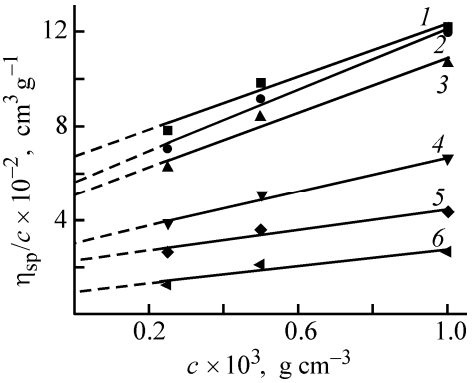

Fig. 2. Viscosity numbers η_{sp}/c in a 0.5 N NaCl solution vs. the concentration c of anionic copolymers of acrylamide (sample nos. 1–6), produced by ultrasonic destruction (see table).

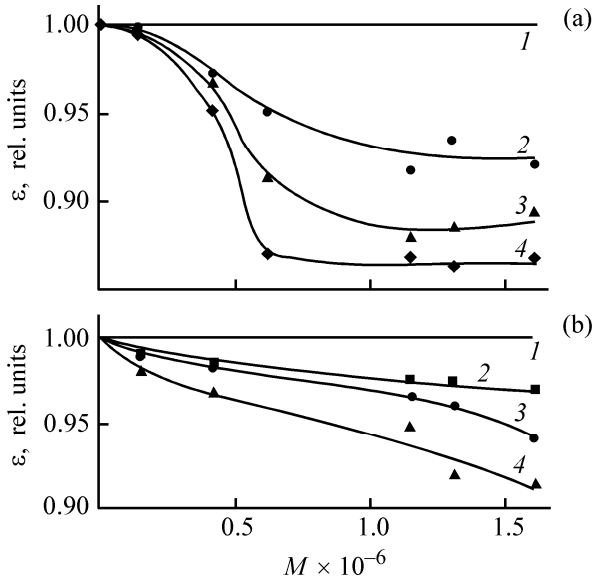

Fig. 3. Relative energy consumption ε vs. the molecular mass M of anionic copolymers in (a) water medium and (b) 10% direct emulsion of oil. Copolymer concentration c (kg m^{-3}): (*1*) 0, (*2*) 0.01, (*3*) 0.025, and (*4*) 0.05.

It should be particularly noted that the method chosen for obtaining samples with different molecular masses provided identity of all copolymer fractions in composition α and polydispersity [10, 11].

Values of the limiting viscosity numbers [η] were found by extrapolating the dependences $\eta_{sp}/c = f(c)$ in a 0.5 N NaCl solution to $c = 0$ (Fig. 2). The molecular masses M of the samples obtained were calculated using the Staudinger–Mark–Houwink equation:

$$[\eta] = KM^a,$$

where K and a are constants ($K = 0.0062$, $a = 0.81$) [12].

Generalized data on the USD process parameters and molecular masses of copolymer samples are listed in the table.

In the preliminary stage, experiments aimed to evaluate the rheological and energy parameters of turbulent flows in purely water flows were performed.

According to the data in Fig. 3a, the relative energy consumption by the pumping unit, ε, is lower than unity for all concentrations and molecular masses of the copolymers. This indicates that, in all of the experiments carried out, introduction of a polymeric additive leads to an increase in the fluid flow rate and this is not due to a rise in the electric power consumed by the pump (i.e., to an increase in the load on the pump). This circumstance is a very important argument indicating that the increase in the pipeline throughput is not due to any additional energy expenditure for maintaining the accelerated mode of fluid transportation.

It can also be seen in Fig. 3a that the parameter ε decreases as the molecular mass of the copolymer and its concentration in solution increase. In this case, the dependence $\varepsilon = f(c)$ is quite understandable [13, 14], whereas the run of the experimental dependence $\varepsilon = f(M)$ is less predictable [15] and, with account of difficulties in performing the experiments and interpreting their results, it required an additional elucidation. The point is that, with the commonly accepted procedure used to process the experimental data (effect evaluated by the gain in the fluid flow rate), the magnitude of the Toms effect gradually grows with the molecular mass [11]. At the same time, the dependences $\varepsilon = f(M)$ exhibit certain threshold values of the molecular masses of the polymers [~$(0.6–0.7) \times 10^6$], below which the polymer becomes inefficient as an agent reducing the relative energy consumption. This behav-

ior of the empirical dependences $\varepsilon = f(M)$ can be attributed to two circumstances. First, the dynamic viscosity of the solutions grows with M both in the flow core and in its near-wall zone, which leads to an increase in the energy consumption in transportation of the fluid. Second, macromolecules are subjected in the working zone of the pump and in the turbulent fluid flow in the pipeline to strong local stresses. In this mode of the fluid flow, a quite probable process is mechanical destruction of macromolecules, which is characteristic to a greater extent of polymer fractions with high molecular masses [16].

Let us now analyze the dependences $\varepsilon = f(M)$ for direct emulsions of oil (Fig. 3b). An important result can be noted for these emulsions (as also for water media): the rise in the fluid flow rate in the turbulent mode is not accompanied by any increase in the energy expenditure for circulation of the fluid.

Comparative analysis of the data in Figs. 3a and 3b suggests that, in turbulent flows and fixed values of c and M, the parameter ε for direct emulsions of oil exceeds that for purely water media. As regards the energy expenditure, these results indicate that the efficiency of the polymeric additive is lower in the oil emulsion, compared with the water medium. This is, in all probability, due to adsorption of polymer macromolecules on particles of the dispersed phase, which leads to a decrease in the real ("working") concentration of the polymer in the dispersion medium [17].

CONCLUSIONS

(1) A new experimental installation was suggested and tested. This installation makes it possible to use the volumetric flow rate of the fluid and the electric power consumed by the pump as complex estimation parameters.

(2) The method of ultrasonic destruction was used to obtain samples of anionic copolymers of acrylamide, with different molecular masses and identical composition and polydispersity characteristics.

(3) The dependence of the relative energy consumption by the pumping unit on the concentration and molecular mass of the polymer additive in both water and oil-containing media (direct emulsions of oil) was analyzed.

Abstract—Extraction of iron from aluminate-alkaline solutions was studied in relation to the concentration of the extracting reagent, 2-hydroxy-5-alkyl(C_8–C_9)benzyldiethanolamine and the volume ratio between the aqueous and organic phases. The re-extraction conditions were determined.

DOI: 10.1134/S1070427208080132

At present, extraction is the most important among the best known methods used to concentrate and separate metals from various complex compositions. The intensive manufacturing application of the extraction technique and the rather effective use of extraction processes in a number industries recovery of precious metals from industrial raw materials make profitable and cost-efficient and enable development of rational technological schemes for separation of metals with close physicochemical properties, which is now a rather topical issue for modern hydrometallurgy.

A promising field of hydrometallurgy is recovery of metals from alkaline solutions. However, concentration of metals from solutions of this kind and their further processing is rather labor-consuming and inefficient, which leads to loss of valuable components. In addition, the lack of effective and available extractants that could recover metals from strongly alkaline solutions hinders wide use of the extraction technique for recovery and concentration of metals from products with a complex salt composition and, in particular, from aluminate-alkaline solutions. This technique could simultaneously solve a no less important problem of purification of the final product (alumina) to remove iron impurities.

Thus, a search for, and synthesis of the most accessible extraction reagents and development on this basis of sufficiently efficient and selective methods for recovery and separation of metals from alkaline solutions with a complex composition constitute a rather topical task of extraction chemistry.

This communication reports results obtained in studies of extraction purification of industrial aluminate-alkaline solutions, formed in manufacture of alumina to remove iron impurities present in these solutions, to give a gallium concentrate and pure alumina. A technological scheme that provides integrated processing of solutions with complex salt composition for hydrometallurgical purposes was developed and suggested.

One of the main impurities in gallium-containing technological solutions is iron [1, 2], which is present in oxidation states II and III, or in a mixture of these. In most cases, the concentration of iron is many times that of gallium [3, 4]. In the alkaline technique for production of alumina from alunites or bauxites, there is a special technological unit for purification of aluminate-alkaline solutions to remove iron impurities. Therefore, it is necessary to briefly analyze the level of understanding of methods for purification of these solutions, produced by alkaline treatment of basic ores in manufacture of alumina.

At present, this process is performed using classical methods, which have a rather low efficiency and fail to provide the required degree of purification of

Purification of aluminate-alkaline solutions to remove iron impurities with 2-hydroxy-5-alkyl(C_8–C_9)benzyldiethanolamine in kerosene in relation to its concentration and volume ratio between the aqueous and organic phases

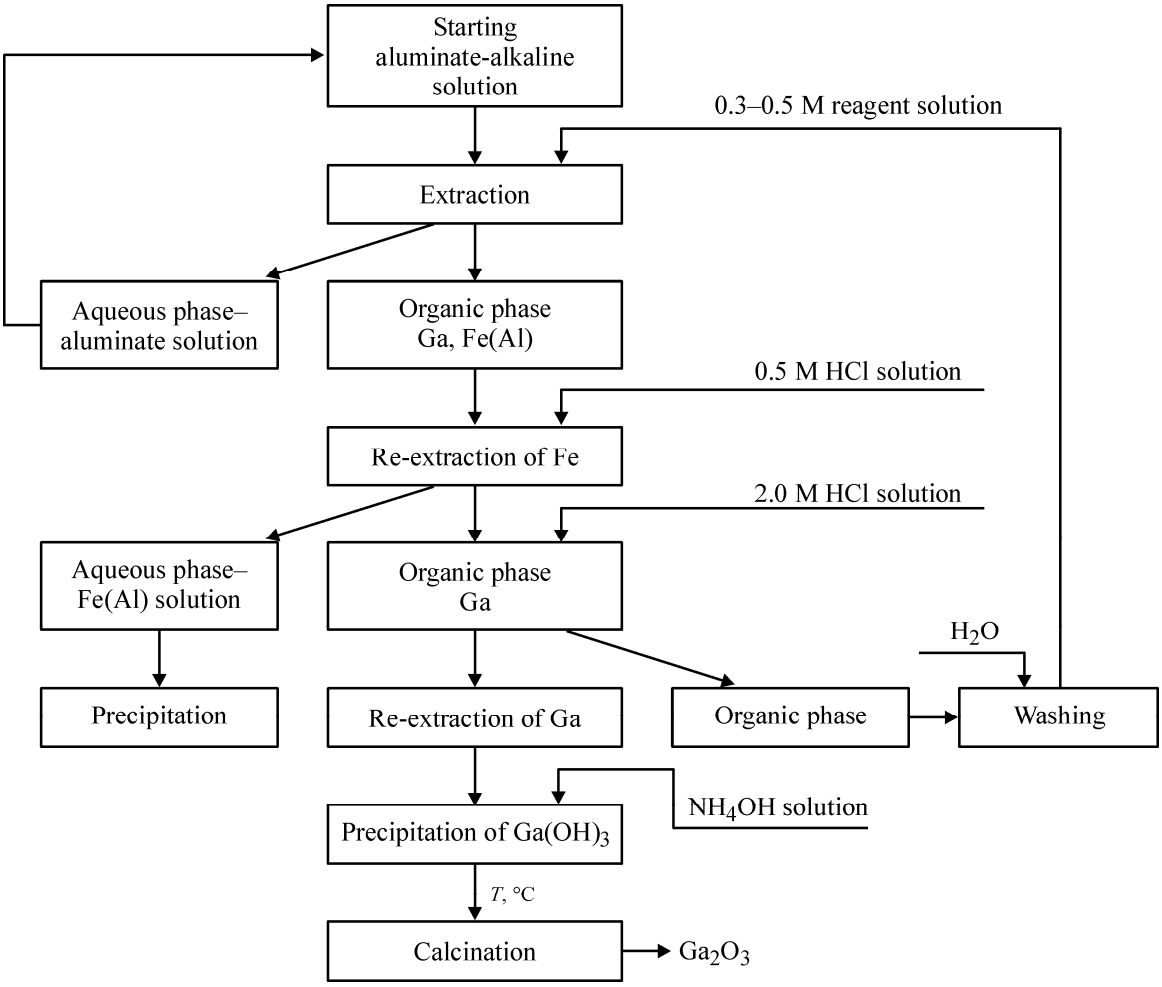
* In stages I and II of the extraction process.

aluminate-alkaline solutions, and, therefore, the quality of the final product obtained is low. One of methods for purification of aluminate-alkaline solutions to remove iron impurities is that by treatment with gas–air mixtures, e.g., by ozone, air, or ozonized air [5]. The treatment time is 3–8 h. As a result the Fe_2O_3 concentration decreases from 0.018 to 0.0018 g l^{-1}, with the degree of purification equal to 90%. A disadvantage of this method is the long duration of the process itself and the low degree of purification. In a method used to purify aluminate-alkaline solutions to remove ion impurities [6], chromium-containing materials and, in particular, chromium(III) oxide Cr_2O_3 are used as reagents. The starting aluminate-alkaline solution containing 0.018 g l^{-1} is mixed with chromium(III) oxide, taken in an amount of 1 mol per 2/3 mol Fe_2O_3, at 95°C for 20 min. After a prolonged settling, 0.002 g l^{-1} of iron remains in solution, i.e., the degree of purification is 89%.



The most widely used method for purification of aluminate-alkaline solutions to remove iron impurities is treatment with calcium oxide CaO with addition of sodium sulfite [7]. This method consists in that 2.5 g l^{-1} calcium oxide and 0.5–10.0 g l^{-1} sodium sulfite are introduced into a solution containing (g l^{-1}): Na_2O 150, Al_2O_3 0.75, and iron in the form of Fe_2O_3 0.24. As a result, the Fe_2O_3 concentration in solution decreases to 0.003 g l^{-1}, which constitutes a 94% degree of purification of the starting solution. However, this method fails to provide solutions with a required purity, and, in addition, sodium sulfite contaminates aluminate-alkaline solutions with sulfur.

Because there is no published evidence about purification of aluminate-alkaline solutions to remove iron impurities by the extraction method, the previously studied extraction systems with aminomethylene derivatives of substituted phenols, used to remove iron from alkaline solutions [8], and the revealed optimal conditions of the extraction process make it possible, in principle, to solve a number of practical tasks.

In this communication, a technological scheme for purification of aluminate-alkaline solutions, formed in alumina production, to remove iron impurities by the extraction method, with 2-hydroxy-5-alkyl(C_8–C_9) benzyldiethanolamine in a kerosene diluent as the extraction agent. As object of study served industrial aluminate-alkaline solutions produced at Gyanja aluminum plant and having, prior to a purification cycle, the following composition (g l^{-1}): Na_2O 180–210, Al_2O_3 80–105, Fe_2O_3 0.45–0.50, Ga_2O_3 0.095–0.125. The solution under study was brought in contact with a 0.3–0.5 M solution of 2-hydroxy-5-alkyl(C_8–C_9) benzyldiethanolamine in kerosene at a (1–4) : 1 volume ratio between the aqueous and organic phases for 10–20 min. The phase separation in the settler was rather distinct and occured rather rapidly in the course of no more than 10–15 min. After the distinct phase separation, the residual content of iron in the aqueous solution was monitored.

Depending on the number of stages of the extraction process, the concentration of iron in the aluminate-alkaline solution decreases to a minimum, with a full purification reached (95–100% after two treatment stages). The spent extraction agent is easily regenerated by washing with a 0.1–0.5 M solution of hydrochloric acid and can be reused for purification of aluminate-alkaline solutions to remove iron impurities. The results obtained in purification of aluminate-alkaline solutions, formed in alumina production, to remove iron impurities are listed in the table.

As can be seen in the table, use of the extraction method for purification of aluminate-alkaline solutions to remove iron impurities makes it possible to raise

Technological scheme for purification of aluminate-alkaline solutions to remove iron impurities by the extraction method.

the degree of purification of solutions of this kind to 95–100%.

It should be noted that the conditions and aqueous medium of the extraction purification of aluminate-alkaline solutions with a representative of aminomethylene derivatives of substituted phenols, 2-hydroxy-5-alkyl(C_8–C_9)benzyldiethanolamine, in kerosene correspond to recovery of gallium from these solutions. Therefore, purification of aluminate-alkaline solutions to remove iron impurities under these conditions results in that gallium contained in these solutions is extracted into the organic phase together with iron. However, differences in the stability of the iron and gallium compounds being extracted in the organic phase enable their separation in the re-extraction stage. Therefore, iron and galium are re-extracted in the organic phase in stages. First, iron is completely re-extracted by treatment of the extract with a 0.5 M solution of hydrochloric acid, and then gallium readily passes from the organic phase into the aqueous stage in the subsequent cycle of re-extraction with a more concentrated 2.0 HCl solution. Further, gallium is precipitated from the re-extract with ammonium hydroxide and, after drying, the precipitated $Ga(OH)_3$ is calcined at 20–30°C to obtain the final product, gallium oxide.

The conditions of iron re-extraction with a 0.5 M HCl solutions are almost identical to those of aluminum re-extraction, which enables separation of gallium and these metals, iron and aluminum, in the re-extraction stage. Above is presented a technological scheme of the extraction recovery of gallium and purification of aluminate-alkaline solutions to remove iron impurities with 2-hydroxy-5-alkyl(C_8–C_9)benzyldiethanolamine in kerosene. The suggested method en-

ables a steep rise in the degree of purification of the aluminate-alkaline solutions under study to 100%. The technique was tested on real industrial solutions from the alumina shop of Gyanja aluminum plant.

CONCLUSIONS

(1) The extraction purification of industrial aluminate-alkaline solutions, formed in manufacture of alumina, to remove the iron impurities they contain, with a gallium concentrate further obtained with the use of 2-hydroxy-5-alkyl(C_8–C_9)benzyldiethanolamine in a kerosene diluent, was studied.

(2) It was found that iron is extracted from aluminate-alkaline solutions at a concentration of the extraction agent equal to 0.3–0.5 M and a (1–4) : 1 volume ratio of the aqueous and organic phases, with the degree of purification of solutions of this kind to remove impurities being as high as 95–100%.

(3) The conditions of the stage-by-stage re-extraction of iron and gallium were determined and it was found that iron is completely re-extracted from the organic phase with a 0.5 M solution of hydrochloric acid, and gallium, with 2.0 M HCl.

(4) A technological scheme for purification of aluminate-alkaline solutions to remove iron impurities by the extraction method was suggested.

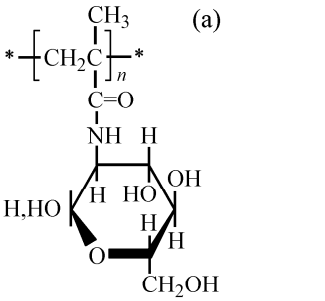
Abstract—Conjugates of polymers of 2-deoxy-*N*-methacryloylamido-*D*-glucose with ligands of various molecular sizes were synthesized. The structures and compositions of the starting polymers and conjugates were examined, and their structure in aqueous solutions was studied by viscometry .

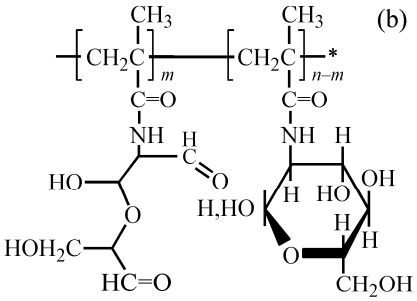
DOI: 10.1134/S1070427208080144

Water-soluble biocompatible polymers attract enormous interest today because of the possibility of using them in various biomedical technologies [1]. For example, the recently developed approach to preparation of biofunctional polymer–inorganic composites (scaffolds) for repairing bone tissues involves adsorption coating of the surface of a 3*D* mineral matrix with a polyfunctional biocompatible nonbiodegradable polymer [2]. The inorganic constituent should ensure the mechanical stability of the scaffold, and the biological polyfunctionality is provided by the covalent binding of special signal molecules with the polymer. It seems most promising to use for this purpose ligands of both low (e.g., poly-*L*-lysine) and high specificity (a peptide containing the arginine–glycine–aspartic acid sequence, i.e., an RGD peptide [3, 4] and a special protein, cell growth factor [5, 6]). Creation of such a polyfunctional polymeric vector on the surface of a mineral matrix should intensify the adhesion and 3*D* cell growth and, ultimately, the formation of a tissue structure.

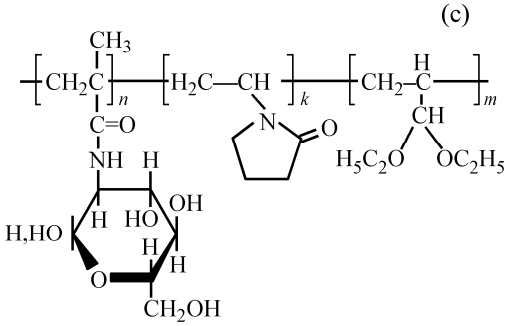
Much promise for the development of polymer–mineral scaffolds is shown by synthetic polyvinyl saccharides [7–10], carbon-chain polymers containing saccharide residues as pendant groups. For covalent linking of bioligands to polymers, it seems most appropriate to use aldehyde groups providing binding of amine-containing ligands (peptides, proteins) under mild conditions without release of toxic by-products.



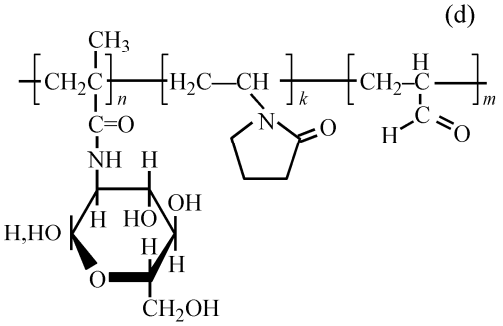
In previous studies, we developed procedures for preparing new hydrophilic aldehyde-containing polymers based on vinyl saccharides and differing in the chemical structure, composition, and molecular weight [11]. With the aim to introduce a controllable amount of aldehyde groups, we examined periodate oxidation of poly(2-deoxy-*N*-methacryloylamido-*D*-glucose) (pMAG). Aldehyde-containing polymers were also prepared by terpolymerization of MAG with *N*-vinylpyrrolidone (VP) and acrolein diethyl acetal (AcDA), followed by aldehyde deprotection. Simultaneously, procedures were developed for controllable introduction of aldehyde groups, followed by modification with the above bioligands [12]. It was also shown that the polymers and conjugates obtained exhibit high adsorption affinity for the chosen mineral materix (Sponceram®). Furthermore, the first experiments on cells showed that the composites developed do intensify the adhesion and cell growth [12].



Nevertheless, further optimization of the process for preparing the above-described polymer–inorganic composites should involve studies of physicochemical characteristics of the polymers and conjugates. In this study we made the first attempt to determine their hydrodynamic parameters from viscometric data. To this end, we measured the viscosities of solutions of both the initial polymers and those modified with low- (glycine) and high-molecular-weight (ribonuclease A-RNAase) model ligands.



EXPERIMENTAL



All the salts for preparing buffer solutions (Fluka Chemie AG, Switzerland), glycine, and RNAase (Sigma AG, Germany) were of analytically pure grade and were used without additional purification. For desalination of solutions of polymers and conjugates and removal of low-molecular-weight impurities from them, we used dialysis bags (Spectra/Pore®, USA; MWCO: 1000).

Samples of pMAG, MAG–VP–AcDA copolymer {p(MAG–VP–AcDA), [MAG] : [VP] : [AcDA] = 77 : 15 : 8 mol %}, and their activated forms, i.e., oxidized pMAG and p(MAG–VP–Ac) containing 32 and 8 mol % aldehyde groups, respectively, were synthesized as described previously [11]. The covalent binding of glycine and RNAase was performed by the previously developed procedures [12]. Samples of all the polymers and conjugates were purified by dialysis against water and stored at –20°C. The structures of the initial and activated polymers pMAG (a), oxidized pMAG (b), p(MAG–VP–AcDA) (c), and p(MAG–VP–Ac) (d) are given below:

The ^{1}H COSY NMR spectra of the polymers were recorded with a Bruker AV400 NMR spectrometer, and the IR spectra, with a Bruker IFS 88 spectrophotometer (Germany). The UV spectra were measured with an ND-1000 spectrophotometer (peQLab Biotechnologie GmbH, Germany).

The molar amount of aldehyde groups in the polymers was determined by a highly specific reaction with the Schiff reagent (fuchsinsulfurous acid) using a calibration plot preliminarily constructed with a model (glutaric) aldehyde. For this purpose, to 0.5 ml of a solution of an aldehyde-containing polymer we added 2.5 ml of a Schiff reagent solution and, on Keeping the mixture for 40 min, measured the absorption of the colored complex at λ= 550 nm. This method was also used for determining the amount of bound glycine from the amount of residual aldehyde groups.

The molar content of VP in the p(MAG–VP–Ac) copolymer was determined using the so-called "iodine test." To 0.5 ml of a sample of a polymer solution, we added 3 ml of a 0.003 M solution of iodine in 0.2 M sodium acetate buffer solution (pH 4.6). The formation of a colored complex was recorded immediately after adding the reagent. To calculate the amount of VP, we used a calibration curve constructed with poly(*N*-vinylpyrrolidone) (pVP) as reference.

The amount of RNAase bound with polymers was determined by the well-known Lowry–Folin method [13]. The intrinsic viscosity [η] of samples was measured with an Ubbelohde viscometer (chamber volume 2 ml) at 25°C. We used the following solvents: 0.1 M Na_2SO_4; 0.01 M sodium borate buffer solution, pH 9.5; borate solution, pH 7.0 (0.01 M sodium borate solution, pH 9.5, acidified to pH 7.0 by adding boric acid).

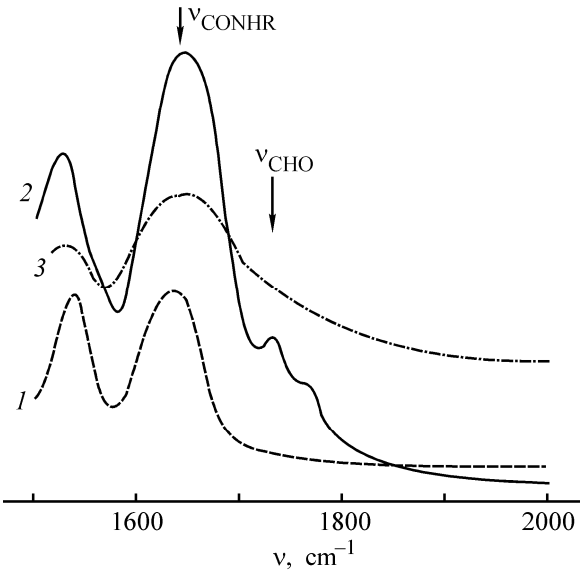

Fig. 2. IR spectra of (*1*) pMAG and (*1–3*) aldehyde-containing polymers: (*2*) oxidized pMAG and (*3*) p(MAG–VP–Ac). (ν) Wavenumber; the same for Fig. 3.

To calculate the molecular weights of pMAG and p(MAG–VP–AcDA), we used the previously derived Mark–Kuhn–Houwink equation for solutions of pMAG in 0.1 M Na_2SO_4 [7]:

$$[\eta]^{25^\circ C} = 8.29 \times 10^{-4} M^{0.49}.$$

To calculate the root-mean-square distance between the chain ends $\langle h^2 \rangle^{1/2}$ and the radius of inertia R_G, we used the well-known relationship [14]

$$[\eta] = \Phi \frac{\langle h^2 \rangle^{3/2}}{M} = \Phi \frac{\langle 6R_G^2 \rangle^{3/2}}{M}.$$

In these calculations, with the aim to compare the above parameters of the polymers and conjugates under consideration, we used for all the samples the common experimental value of the Flory parameter, $\Phi = 2.1 \times 10^{21}$ mol^{-1}.

To estimate the hydrodynamic radius R_H of macromolecules of the initial polymers and their conjugates with glycine and RNAase, we used the Einstein relationship for impermeable spheres:

$$[\eta] = \left(\frac{10\pi}{3}\right) N_A \frac{\left(R_H^{[\eta]}\right)^3}{M}.$$

where $R_H^{[\eta]}$ is the viscometric hydrodynamic radius of the equivalent sphere.

The formation of the p(MAG–VP–AcDA) terpolymer was confirmed by COSY NMR spectroscopy (Fig. 1). In the spectrum of the copolymer, we found cross signals corresponding to interaction of protons of the EtO groups in AcDA and of the lactam ring in VP.

The aldehyde groups are qualitatively detected by IR spectroscopy (Fig. 2). In the spectrum of oxidized pMAG, on the short-wave wing of the strong band of amide carbonyl groups, there are two minor peaks at 1755 and 1735 cm^{-1}, assigned to two aldehyde groups formed by oxidation of the *vic*-glycol group of glucose. In the spectrum of the activated terpolymer p(MAG–VP–Ac), on the short-wave wing of the band of the amide carbonyl group in the range corresponding to the absorption of aldehyde groups, there is a shoulder suggesting the presence of a small amount of an aldehyde.

For the synthesized activated polymers, we determined the composition, M_η, and content of aldehyde groups. The copolymer composition was determined from the results of the iodine test and the Schiff reaction (determination of the VP and Ac content, respectively; the Ac content was determined after AcDA deprotection). The MAG content was determined by subtraction of the percentage mole fractions of VP and AcDA from 100%.

The results are listed in Table 1. It can be seen that the molecular weight of the copolymers is relatively low. This is important from the standpoint of excretion of polymers from a living body in the case of their desorption from the mineral support. It is also evident that the polymers contain aldehyde groups in an amount sufficient both for ligand binding and for formation of mixed polyfunctional conjugates.

The covalent binding of glycine and RNAase to aldehyde-containing polymers was qualitatively confirmed by comparison of the IR spectra of oxidized pMAG, gly-cine, and RNAase with those of the pMAG–glycine and pMAG–RNAase conjugates (Figs. 3a, 3b). The spectrum of oxidized pMAG contains a fairly pronounced absorption band of aldehyde groups, whereas in the spectra of the conjugates, it is considerably less intense. Also, despite the prolonged (150 h) purification of the polymeric derivatives by dialysis against water, the spectra of pMAG–glycine and pMAG–RNAase contain absorption bands of carboxylate groups, ν_{COO^-}. Both these facts, i.e., the considerable decrease in the intensity of the aldehyde band and the appearance of absorption bands untypical of the initial polymer and corresponding to symmetric vibrations of carboxylate anion, along with a noticeable change in the shape of the amide carbonyl absorption band, confirm the formation of the conjugates.

A quantitative estimation of the ligand binding with the polymers was performed by chemical analytical methods. For conjugates with glycine, the degree of substitution of aldehyde groups of the polymer with the amino acid was determined from the results of quantitative determination of the residual CHO groups by the Schiff reaction. To estimate the molar amount of immobilized RNAase, we used the Lowry method. To examine the hydrodynamic parameters of mixed polyfunctional conjugates of both polymers, we synthesized samples containing both RNAase and glycine, namely, pMAG–(RNAase–glycine) and p(MAG–VP–Ac)–(RNAase–glycine). These conjugates were prepared in two steps. First we performed covalent binding of RNAase, using the same [CHO] : [RNAase] ratio as that in conjugates with a single ligand, after which we added to the reaction mixture excess glycine to substitute the residual aldehyde groups. The results are listed in Table 2.

Prior to discussing data on the viscosity of solutions of the polymers and conjugates, it is necessary to consider a procedure for preparing 3*D* polymer–inorganic composite supports of bone tissue cells, because the solvent choice was governed specifically by the strategy used. In accordance with our approach, in the first step, the aldehyde-containing polymers syn-

thesized are modified with low- and high-molecular-weight ligands. The reaction is performed in a 0.01 M sodium borate buffer solution, pH 9.5 (b/b 9.5). Therefore, the viscosities of pMAG and p(MAG–VP–AcDA) were measured specifically in this buffer solution. The second step of formation of the composite support involves adsorption of the conjugates obtained on the surface of a mineral support at physiological pH values. For this purpose, we used the same 0.01 M sodium borate buffer solution, pH 9.5, and acidified it to pH 7.0 with boric acid (borate solution, pH 7.0: b/s 7.0). In this solution, we measured the intrinsic viscosities of the conjugates and initial polymers with the aim to determine their hydrodynamic parameters in the course of adsorption.

The intrinsic viscosities of pMAG and p(MAG–VP–AcDA) were measured in 0.1 M Na_2SO_4. To calculate M_η, we used the Mark–Kuhn–Houwink (MKH) equation derived for pMAG by Klein [7]. It should be noted that, previously, Pavlov has examined in detail the hy-drodynamic characteristics of pMAG, using water as sol-vent [15]. The MKH equation obtained is as follows:

$$[\eta]^{25^\circ C} = 2.18 \times 10^{-5} M^{0.76}.$$

The choice of 0.1 M Na_2SO_4 as solvent is governed by the fact that, in this solvent, the contribution of polyelectrolytic swelling, caused by the possible presence of methacrylic acid units in the copolymer, is avoided. Furthermore, as shown by Klein [7], 0.1 M Na_2SO_4 is nearly a θ-solvent for MAG polymers ($[\eta] \sim M^{0.49}$). Thus, the hydrodynamic characteristics of the starting polymers, obtained in this solvent [Table 3, sample nos. 1 (0.1 M Na_2SO_4), 3], were taken as unperturbed values for comparison with the values for the initial polymers and their conjugates in other solvents.

Comparison of the mean contour lengths of the polymers, determined from viscometric data [pMAG ~31, p(MAG–VP–AcDA) ~25 nm], with the RH values [Table 3, sample nos. 1 (0.1 M Na_2SO_4), 3] suggests a comparatively coiled conformation of the macromolecules, despite bulky glucose pendant groups. The approximate lengths of the Kuhn segment, calculated from the general relationship $A = \langle h^2 \rangle L^{-1}$, appeared to be 4 nm for pMAG and 3.5 nm for p(MAG–VP–AcDA), in agreement with Pavlov's data [15].

As the polymers under consideration contain saccharide residues of *D*-aminoglucose, it can be presumed that their size in dilute solutions should be determined by the energy of intramolecular hydrogen bonds [16] in the chosen solvent.

In addition, introduction of aldehyde groups that are able to form intramolecular hemiacetals should give rise to additional intramolecular interactions.

Measurement of the intrinsic viscosity of pMAG in b/b 9.5 showed that [η], R_G, and R_H [Table 3, sam-

12	p(MAG–VP–Ac)–RNAase–glycine	b/s, pH 7.0	0.23	5.1	12.8	4.1

ple no. 1 (in 0.1 M Na_2SO_4 and b/b 9.5); Fig. 4a, curves *1*, *2*] increase relative to those in 0.1 M Na_2SO_4. Therefore, b/b 9.5 can be considered a good solvent for pMAG. The hydrodynamic radius determined for pMAG and b/b 9.5 from the viscometric data (Table 3, sample no. 1, b/b 9.5) coincided with that determined from light scattering, R_H^{DLC} = 3.9 nm).

A study of the concentration dependences of η_{sp}/c for activated polymers, oxidized pMAG and p(MAG–VP–Ac), in b/b 9.5 revealed a polyelectrolytic effect (Figs. 4a, 5a, curves 3). This may be due to the presence of a small amount of carboxy groups formed by partial oxidation of aldehyde groups. For oxidized pMAG, with an increase in the solution concentration,

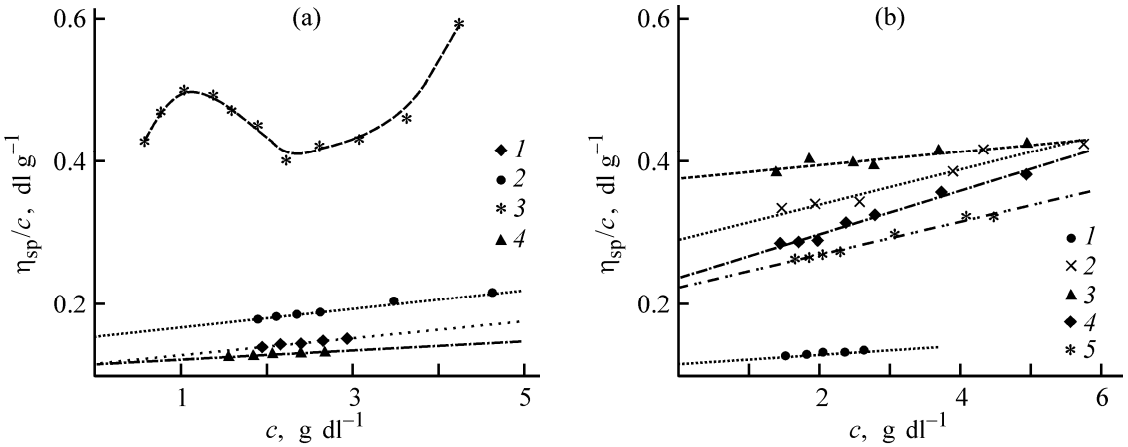

Fig. 4. Reduced specific viscosity η_{sp}/c vs. concentration c for pMAG, oxidized pMAG, and conjugates with glycine and RNAase. (a) (*1*) pMAG (sample no. 1) in 0.1 M Na_2SO_4, (*2*) pMAG (sample no. 1) in b/b 9.5, (*3*) oxidized pMAG (sample no. 2) in b/b 9.5, and (*4*) oxidized pMAG (sample no. 2) in b/s 7/0; (b) (*1*) oxidized pMAG (sample no. 2), (*2*) pMAG–glycine (sample no. 5), (*3*) pMAG–glycine (sample no. 6), (*4*) pMAG–RNAase (sample no. 7), and (*5*) pMAG–(RNAase–glycine) (sample no. 8), all in b/s 7.0.

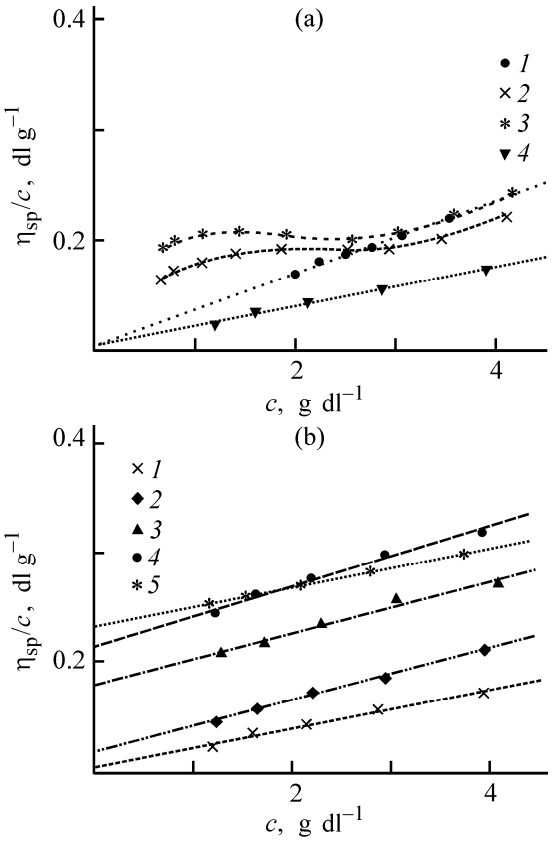

Fig. 5. Reduced specific viscosity η_{sp}/c vs. concentration c for p(MAG–VP–AcDA), p(MAG–VP–Ac), and conjugates with glycine and RNAase. (a) (*1*) p(MAG–VP–AcDA) (sample no. 3) in 0.1 M Na_2SO_4, (*2*) p(MAG–VP–AcDA) (sample no. 3) in b/b 9.5, (*3*) p(MAG–VP–Ac) (sample no. 4) in b/b 9.5, and (*4*) p(MAG–VP–Ac) (sample no. 4) in b/s 7.0; (b) (*1*) p(MAG–VP–Ac) (sample no. 4), (*2*) p(MAG–VP–Ac)–glycine (sample no. 9), (*3*) p(MAG–VP–Ac)–glycine (sample no. 10), (*4*) p(MAG–VP–Ac)–RNAase (sample no. 11), and (*5*) p(MAG–VP–Ac)–(RNAase–glycine) (sample no. 12), all in b/s 7.0.

the specific viscosity sharply grows (Fig. 4a, curve *3*) owing to the formation of associates via hydrogen bonding and possible formation of intramolecular hemiacetals. The polyelectrolytic effect is also observed with the nonactivated terpolymer p(MAG–VP–AcDA) (Fig. 5a, curve *2*), apparently due to partial removal of diethyl acetal protecting groups in the course of polymer synthesis and purification to give aldehyde groups, followed by their partial oxidation to carboxy groups. The occurrence of the polyelectrolytic effect indicates that, in these cases, conformations of the polymer macromolecules in an alkaline borate buffer solution are more unfolded, compared to their solutions in the standard solvent, 0.1 M Na_2SO_4. Along with the polyelectrolytic interaction causing an increase in the size of the macromolecules, a small contribution to the increase in the hydrodynamic size of the aldehyde-containing polymers can be made by the reversible interaction of aldehyde groups with hydroxide anions, which makes lower the degree of formation of intramolecular hemiacetals. Apparently, the hydrodynamic swelling of polymes should increase their reactivity due to an increase in the steric accessibility of aldehyde groups to ligands of different molecular sizes (amino acids, peptides, proteins). The concentration dependences of the specific viscosity of solutions of oxidized pMAG and p(MAG–VP–Ac) in b/s 7.0 (Figs. 4a, 5a, curves *4*) showed no polyelectrolytic effect.

As noted above, it was very interesting to examine the hydrodynamic parameters of oxidized pMAG, p(MAG–VP–Ac), and their conjugates with low- and high-molecular-weight ligands in the same solvent as that used for performing adsorption on the macroporous mineral matrix in the course of preparation of polymer–inorganic composites, namely, in b/s 7.0.

The concentration dependence of η_{sp}/c for solutions of pMAG and p(MAG–VP–Ac) in b/s 7.0 showed no polyelectrolytic effect (Figs. 4a, 5a, curves *4*). This result may be due to suppression of the formation of carboxylate anions by protons of boric acid added to adjust pH 7.0. It is interesting that the quantities [η], R_G, and R_H, determined for the polymers under consideration in b/s 7.0 and in 0.1 M Na_2SO_4, nearly coincide. Hence, presumably, the pH adjustment for pMAG and p(MAG–VP–Ac) solutions by the above-described procedure makes their properties close to the θ-conditions [Table 3, sample nos. 1 (0.1 M Na_2SO_4), 2–4]. This assumption, in turn, may be one more explanation for the previously found high adsorption rate and considerable amount of the adsorbed substance [11].

To determine the size of the polymer macromolecules upon modification with glycine and RNAase, we measured the viscositites and calculated the hydrodynamic parameters of the above-described conjugates (Table 2). The data obtained are listed in Table 3. The dependences of η_{sp}/c on c for conjugates with one and two ligands are shown in Figs. 4b and 5b (curves *2–5*) in comparison with the dependences for the initial aldehyde-containing polymers (Fig. 4b and 5b, curves *1*).

It can be seen that binding of glycine with oxidized pMAG leads to an increase in the hydrodynamic size of its macromolecules. This is due to the fact that modification with glycine involves introduction of a large amount of pendant carboxy groups, which leads to polyelectrolytic repulsion of the macromolecular units even at pH 7.0. Furthermore, blocking of alde-

hyde groups with the amino acid makes impossible formation of intramolecular hemiacetals, which also should lead to an increase in the hydrodynamic size of the macromolecules. We found that the swelling noticeably increases with the degree of substitution of aldehyde groups with glycine (Table 3, sample nos. 5, 6). This effect is considerably less pronounced for the terpolymer (Table 3, sample nos. 9, 10), in which the amount of aldehyde groups is smaller, and their distance from the backbone, shorter.

Covalent binding of RNAase, as expected, leads to an increase in the size R_G and R_H of the forming conjugate, compared to the initial polymer. In view of the possible cross-linking between the activated polymer as polyaldehyde and the protein as polyamine, we used strongly dilute solutions of both reactants and took the polymer in a large excess. The conditions we chose [12] allowed us to obtain water-soluble polymer–protein conjugates.

The hydrodynamic size of the pMAG–RNAase conjugate (Table 3, sample no. 7) appeared to be smaller than that of the pMAG–glycine conjugate, whereas with the terpolymer (Table 3, sample no. 11), the pattern was the opposite. This difference may be due to a different distribution of aldehyde groups in the polymers examined. Aldehyde groups formed by oxidation of pMAG are randomly distributed over the polymer chain, whereas in the course of terpolymer formation, AcDA, being an allyl-type monomer, causes degradation chain transfer accompanying the chain propagation. Hence, the aldehyde groups in p(MAG–VP–Ac) should be arranged in the copolymer structure loosely, at a long distance from each other. Thus, presumably, the binding may be multipoint with oxidized pMAG, whereas with the terpolymer, the binding with RNAase if effected by separate Ac units.

As noted above, synthesis of mixed conjugates (different ligands on one polymer chain) starts with the addition of RNAase. This fact explains why the hydrodynamic parameters of pMAG–(RNAase–glycine) (Table 3, sample no. 8) and p(MAG–VP–Ac)–(RNAase–glycine) (Table 3, sample no. 12) are close to those of the conjugates of the same polymers with RNAase.

CONCLUSIONS

(1) Macromolecules of two types of new aldehyde-containing polymers derived from 2-deoxy-*N*-methacryloylamido-*D*-glucose and of their conjugates with glycine and ribonuclease A (low- and high-molecular-weight model ligands, respectively) have a comparatively coiled conformation.

(2) The concentration dependences of η_{sp}/c of aldehyde-containing forms of both types of polymers demonstrate a polyelectrolytic effect, and oxidized poly(2-deoxy-*N*-methacryloylamido-*D*-glucose) forms associates as the concentration increases.

(3) The behavior and structure of polymer–glycine and polymer–ribonuclease conjugates in aqueous solutions depend on the chemical structure of the polymres, distribution of aldehyde groups in the polymer chain, and amount of the bound ligand.

Abstract—New silicon-containing poly(salicylidene azomethines) were prepared by polycondensation of di- or tetrasalicylidene derivatives of aromatic di- or tetraamines. The spectral data suggest the occurrence of noncovalent transannular donor–acceptor interaction N→Si providing "nonclassical" conjugation.

DOI: 10.1134/S1070427208080156

The goal of this study was to develop a procedure for preparing a new class of polymers, Si-containing poly(salicylidene azomethines) containing donor nitrogen atoms and acceptor silicon atoms in the chain, which creates prerequisites for the formation of intramolecular donor–acceptor charge-transfer complexes (CTCs) in the polymer chain. Such kind of complexation should be accompanied by effective charge transfer, which will polarize the polymers and hence impart to them specific electro- and photophysical properties.

EXPERIMENTAL

As comonomers we used *N*,*N*',*N*'',*N*'''-tetra-salicylidene-3,3',4,4'-tetraaminodiphenyl ether (M1), *N*,*N*',*N*'',*N*'''-tetrasalicylidene-3,3',4,4'-tetraaminodiphenyl (M2), 1,3-bis(salicylidenimino)-4-nitrobenzene (M3), and 2,4-bis(salicylidenimino)azobenzene (M4):

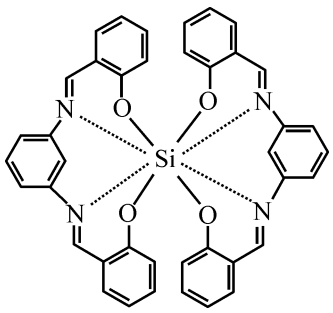
The monomers were prepared by reactions of salicylaldehyde with 3,3',4,4'-tetraaminodiphenyl and 3,3',4,4'-tetraaminodiphenyl ether in 4 : 1 molar ratio or with 4-nitro-1,3-diaminobenzene and 2,4-diaminoazobenzene in 2 : 1 ratio.

The polymers were prepared in a DMF solution by polycondensation of the corresponding salicylidene derivatives of tetraamines and diamines with tetrachlorosilane or tetraethoxysilane (Vekton, bp 57 and 168°C, respectively). Polycondensation of disalicylidene de-

Characteristics of the polymers obtained

Polymer	UV, λ, nm	IR, ν, cm^{-1}	NMR, δ, ppm	M_n
P1	236, 289, 314, 444, 461	1610 (C=N), 1597 (C_{ar}–C_{ar}), 1110 (Si–O)	9.3 (C=N), 6.9–7.6 (C_{ar}–H)	11 000
P2	230, 295, 315, 430, 455	1606 (C=N), 1596 (C_{ar}–C_{ar}), 1110 (Si–O)	9.4 (C=N), 6.9–7.6 (C_{ar}–H)	8000
P3	230, 323, 349, 421	1613 (C=N), 1595 (C_{ar}–C_{ar}), 1112 (Si–O)	9.0 (C=N), 6.9–7.5 (C_{ar}–H)	12 000
P4	242, 270, 347, 428	1603 (C=N), 1582 (C_{ar}–C_{ar}), 1100 (Si–O)	9.3 (C=N), 6.8–7.5 (C_{ar}–H)	9000

rivatives of aromatic diamines was performed with dimethyldiethoxysilane prepared from dimethyldichlorosilane and sodium ethylate. The polymers were isolated by precipitation into diethyl ether. The characteristics of the polymers are listed in the table.



Polymers P1 and P2. To a solution of 0.006 mol of M1 in 15 ml of DMF, 0.006 mol of tetrachlorosilane was added dropwise under agitation. The reaction was performed at room temperature in an inert atmosphere (dry Ar) for 8 h, after which the reaction mixture was concentrated on a rotary evaporator and the dry residue was dissolved in methanol. Polymer P1 was isolated by precipitation from methanol solution into diethyl ether. Yield 94%.

Polymer P2 was prepared similarly.

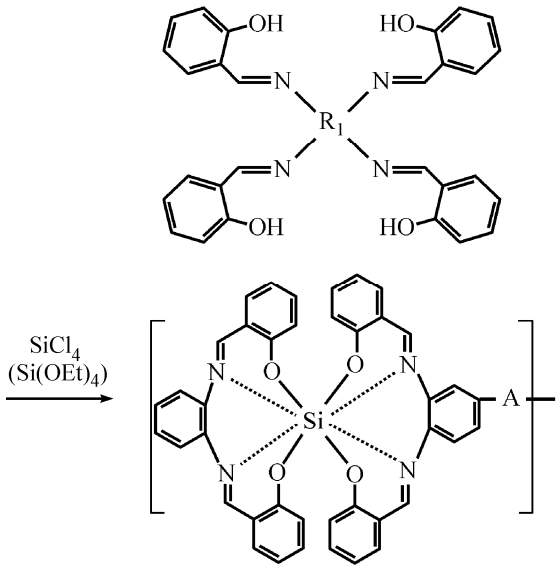
Polymers P3 and P4. To a solution of 0.011 mol of M3 in 20 ml of DMF, we added 0.011 ml of dimethyldiethoxysilane under agitation. The reaction was performed in an inert medium (dry Ar) for 6 h at 80°C, after which the mixture was concentrated on a rotary evaporator and the dry residue was dissolved in methanol. Polymer P3 was isolated by precipitation from methanol solution into diethyl ether. Yield 89%.

Polymer P4 was prepared similarly.

The model compound necessary for identifying the spectra of the synthesized polymers was prepared by condensation of 1,3-bis(salicylidenimino)benzene with tetraethoxysilane in 2 : 1 molar ratio:

An elemental analysis of the monomers was performed on a LECO CHNS(O)-932 dewvice, and consistent results were obtained.

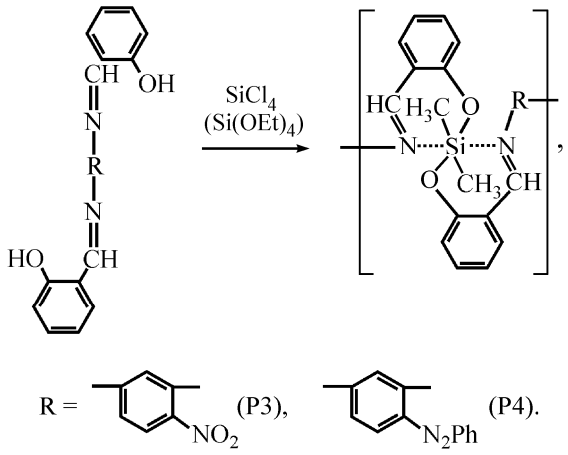
The ^1H NMR spectra of 4–5 wt% solutions of the monomers and polymers in DMF-*d*–7 were recorded on a Bruker Avance 200 NMR spectrometer operating at 200 MHz; the UV spectra, on an SF-2000 spectrophotometer in methanol or isopropanol in the wavelength range 200–700 nm; and the IR spectra, on a Vertex IR Fourier spectrometer (Bruker) from KBr pellets in the 400–4000 cm^{-1} range. The bands were assigned taking into account published data [1–3] and data obtained for the model compound.



The ESR spectra were measured at 35 GHz with the magnetic field varied in a wide range.

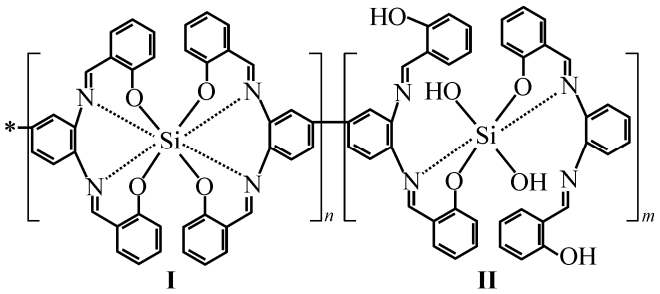
The number-average molecular weights and degrees of polymerization of the polymers were estimated by NMR spectroscopy from the ratio of the integral intensity of the signal of terminal hydroxy groups to the total integral intensity of the signals of aromatic protons or to the integral intensity of the signal of the azomethine proton.

Donor–acceptor interactions are well understood for "low-molecular-weight" reactions of silanes with various organic polydentate ligands. In particular, reactions of dialkyldichlorosilanes with salen-type ligands [salen stands for *N*,*N*'-ethylenebis(salicylidenimine)] have been reported [4–9]. These data on the synthesis of low-molecular-weight CTCs give grounds to expect that replacement of mono- with di- and tetrasalicylidene derivatives will allow synthesis of polymeric CTCs. In our case, the polycondensation should involve, firstly, nucleophilic substitution at the silicon atom and, secondly, N→Si donor–acceptor interaction with the formation of a stable six-membered ring, which should significantly stabilize the corresponding segment of the forming polymer chain.



Polymers P1 and P2 were prepared by polycondensation of salicylidene derivatives of tetraamines M1

and M2 with tetrachloro- or tetraethoxysilane in a 1 : 1 molar ratio by the following scheme:



A = –O– (P1), – (P2).

Polymers P3 and P4 were prepared from bis(salicylidenimino) derivatives and dimethyldiethoxysilane, also in a 1 : 1 molar ratio:

R = (P3), (P4).

The major factor determining the yield and molecular weight of the product is the strict observance of the equimolar ratio of the reactants. It is also important to properly choose the solvent, monomer concentration, and temperature. As solvent we chose DMF, which well dissolves the starting monomers and the forming polymer and can also serve as acceptor for the hydrogen chloride released in the reation. To prepare poly-[tetra(salicylidene azomethines)], it is appropriate to take the starting monomers as dilute (5–10%) solutions, because the probability of formation of disubstituted fragments **II,** along with the desired tetrasalicylidene fragments **I,** increases at high concentrations :

I **II**

Because chlorosilanes are highly reactive, to suppress side reactions (hydrolysis of chlorosilanes, followed by tetracyclization) and raise the probability of more complete substitution at silicon (i.e., to raise the relative content of tetrasalicylidene units **I**), the polycondensation should be performed at low temperature (20–25°C). Another way to suppress the contribution of undesirable processes, such as hydrolysis of chlorosilanes, is their replacement with ethoxysilanes, which are less reactive and less susceptible to hydrolysis. However, in the latter case, the leaving group in the polycondensation is the ethoxy group, and therefore, to ensure its complete removal, the reaction should be performed at 85–90°C.

The main spectral problem in analysis of the polymers obtained is to confirm the structure of the monomeric unit, i.e., to confirm the presence in polymer chians of a six-membered ring formed by N→Si coordination interaction. This interaction results in a shift of the electron density from the donor to the acceptor, which, in turn, should affect the spectral characteristics of the substance.

According to published data, the formation of low-molecular-weight complexes is accompanied by pronounced changes in the IR spectra of both donor and acceptor molecules [10]. The vibration frequencies of the donor are shifted toward higher frequencies, and those of the acceptor, toward lower frequencies. The intensities of the absorption bands also change. In the NMR spectra, the signals of the donor are shifted downfield [11]. In our cases, the strongest changes should be expected for the azomethine group, because this group is directly involved in the coordination bonding. Indeed, the intensity ratio of the stretching vibration bands of the azomethine groups (C=N) and aromatic rings (C_{ar} –C_{ar}) in the IR spectra of the samples examined changes upon complexation. Comparison of the intensities of the bands at 1610 and 1597 cm^{-1} shows that,

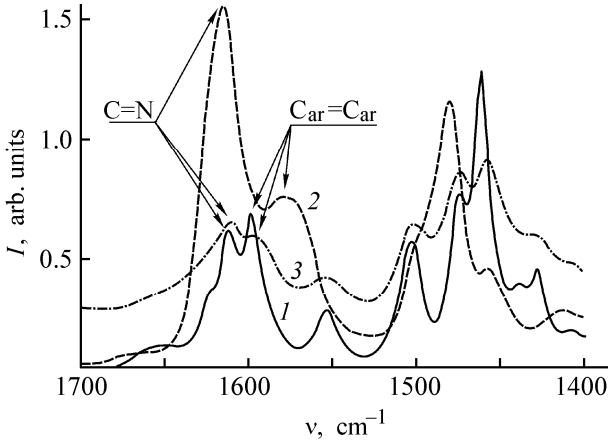


Fig. 1. IR spectra of (*1*) model low-molecular-weight compound, (*2*) M1, and (*3*) P1 (1700–1400 cm^{-1}). (*I*) Intensity and (ν) wavenumber; the same for Fig. 2.

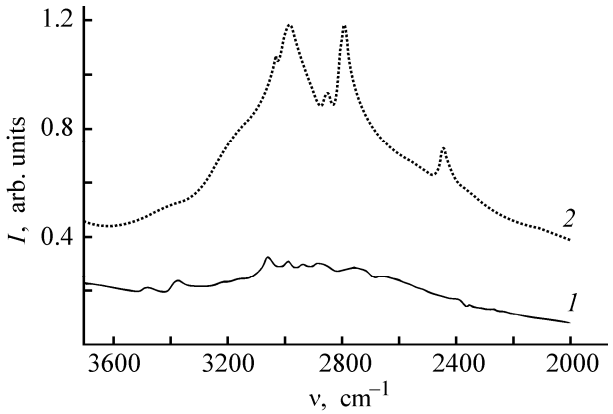

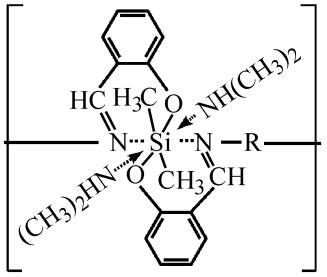

Fig. 2. IR spectra of (*1*) M2 and (*2*) P2 (3600–2000 cm^{-1}).

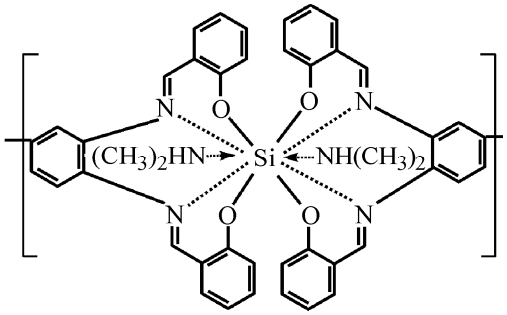

in the spectrum of the monomer, the intensity of the first band (C=N groups) is considerably higher than that of the second band (stretching vibrations of the ring), whereas in the polymer, the intensity of the first band decreases and for the model compound, it becomes even lower than that of the C_{ar}–C_{ar} band (Fig. 1).

These differences may be due to a decrease in the extinction coefficient of azomethine groups as a result of donor–acceptor interactions. Thus, the intensity ratio of these bands can serve as a criterion of the efficiency of N→Si donor–acceptor bonding.

Along with the above features, strong absorption in the range from 2000 to 4000 cm^{-1} engages attention (Fig. 2). According to the previously described polymerization scheme, the amount of OH groups directly is involved in the formation of the polymer chain should decrease in the course of the synthesis. Thus, a decrease in the absorption in the range of stretching vibrations of hydroxy groups whould be expected. However, by contrast, a series of strong bands at 2978, 2780, and 2439 cm^{-1} appear in the spectrum. These bands cannot be assigned to absorption of the polymer and suggest that DMF is involved in side processes accompanying the polymerization. In polycondensation of salicylidene derivatives and chlorosilanes, the release of hydrogen chloride favors decomposition of the solvent. The decomposition products, primarily dimethylamine, are capable of binding with the polymer by donor–acceptor interaction with vacant *d* orbitals of the Si atoms.

In the process, the N atom of the amine competes with the N atoms of azomethine groups, thereby decreasing the effective conjugation length. The forming complex is apparently so stable that the amine cannot be removed by simple reprecipitation. To eliminate the above-described side processes, eses we replaced DMF with a more inert dioxane in further synth.

Figures 3a and 3b show the absorption spectra of the monomers and the synthesized polymers. A considerable bathochromic shift (50–70 nm) accompanied by a hyperchromic effect and the appearance of additional long-wave bands in going from the monomers to the polymer suggest that multiple CTCs are formed in the polymer structure and the conjugation length increases.

The absorption spectra of 1,3-bis(salicylidenimino)-4-phenylazobenzene (M4) and its silicon-containing polymer P4 are markedly different. The strong

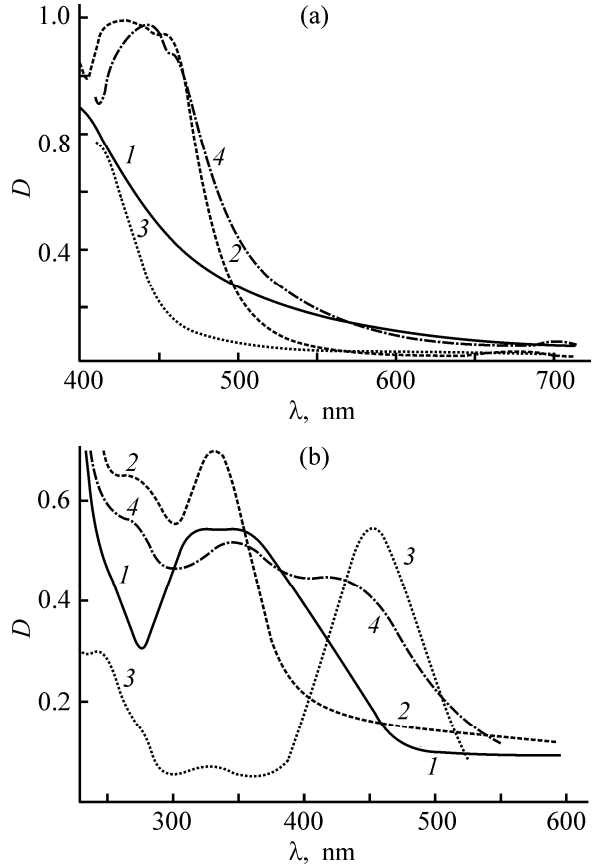

Fig. 3. UV spectra of monomers and polymers derived from (a) tetra- and (b) di(salicylidene azomethines). (*D*) Optical density and (λ) wavelength. (a) (*1*) M2, (*2*) P2, (*3*) M1, and (*4*) P1; (b) (*1*) P3, (*2*) M3, (*3*) M4, and (*4*) P4.

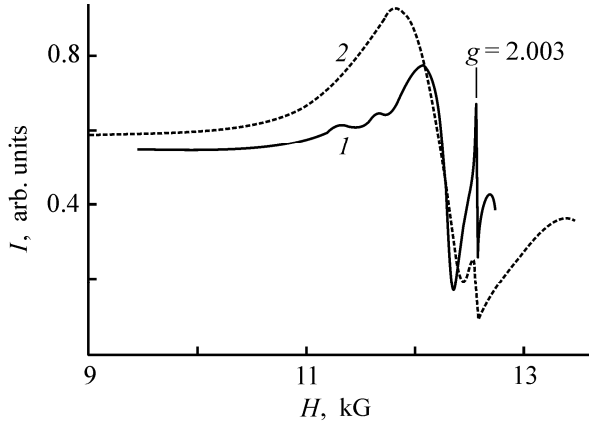

Fig. 4. ESR spectra of polymers (*1*) P1 and (*2*) P3. (*I*) Intensity and (*H*) magnetic field intensity.

absorption band of the azo group present in the spectrum of the monomer (λ = 470 nm, Fig. 3b, curve *3*) disappears in the spectrum of the polymer (Fig. 3b, curve *4*), suggesting this group is involved either in specific donor–acceptor interaction, or in a polymer-analogous transformation in the reaction with the released hydrogen chloride.

The position of the azomethine proton signal in the ^{1}H NMR spectrum also suggests a strong coordination interaction of the lone electron pair of nitrogen with the *d* orbitals of the Si atom.

Interesting information is furnished by ESR spectra. In the ESR spectra of polysalicylidene derivatives (Fig. 4), there is a narrow singlet with the *g*-factor close to that of the free electron, which suggests conjugation in the polymer chain.

CONCLUSION

In the silicon-containing poly(salicylidene azomethines) prepared, there is intramolecular donor–acceptor interaction resulting in the formation of charge-transfer complexes in the polymer backbone.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Monolithic Methacrylate Polymeric Sorbents: Development of Methods for Chemical Modification of the Surface for the Subsequent Bioaffine Functionalization

E. S. Sinitsyna, E. N. Vlasova, E. G. Vlakh, and T. B. Tennikova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 16, 2008

Abstract—Copolymers containing aldehyde, succinimidyl carbonate, and imidazolecarbamate groups were prepared by polymer-analogous transformations of epoxy groups of a macroporous monolithic polymeric support derived from glycidyl methacrylate and ethylene glycol dimethacyrlate. The effect of certain parameters on the course of the copolymer modification and immobilization of a protein on the surface of the polymeric support was studied. The possibility of using the matrices obtained for development of biorecognizing systems was examined.

DOI: 10.1134/S1070427208080168

In the late 1980s–early 1990s, novel polymeric sorbents were developed: solid macroporous polymers prepared as monoliths of various designs (continuous macroporous phases) [1, 2]. These materials are characterized by a constant pore structure which is formed and controlled directly in the synthesis step and is preserved in the dry state. The morphological and hydrodynamic properties of continuous macroporous phases allow separation processes to be performed with very high, anomalous for liquid chromatography, flow rates of the mobile phase [3]. Performing high-speed separations becomes possible owing to the nearly full absence of diffusion hindrance to the normal phase transfer of a substance.

Continuous macroporous phases are prepared by in situ polymerization directly inside an empty column or another mold of the required shape and design. The necessary condition for the pore structure formation is the presence in the polymerization mixture of an inert solvent acting as a porophore. The main criterion of a possible use of a substance as a porophore is its thermodynamic compatibility with the forming polymer [4].

Since the second half of the 1990s, the interest in continuous macroporous phases showed avalanche-like growth. Monolithic materials based on a wide range of synthetic polymers, such as polystyrene, polyacrylates, polymethacrylates, polyacrylamide, etc., have been developed and are used in practice.

The development of the ideology of modern affine separations is closely associated with the development of new support materials and new approaches to the preparation of affine sorbents. Among monolithic polymeric sorbents used to prepare affine supports are copolymers of 2,3-epoxypropyl methacrylate (glycidyl methacrylate, GMA) with ethylene glycol dimethacrylate (EDMA) [3, 5, 6]. An advantage of GMA–EDMA matrices is their mechanical strength and chemical stability. An extremely important property of these materials is that the cross-linked copolymer contains reactive epoxy groups with which diverse polymer-analogous transformations can be performed for functionalization of the sorbent surface. It is known that the procedure for covalent immobilization of a ligand on the surface strongly affects the ligand immobilization capacity and the immobilization rate. Therefore, it was interesting to use different chemical reactions for introducing a bioadsorption site into the structure of a polymer matrix.

Thus, the goal of this study was to prepare modified macroporous supports based on GMA–EDMA

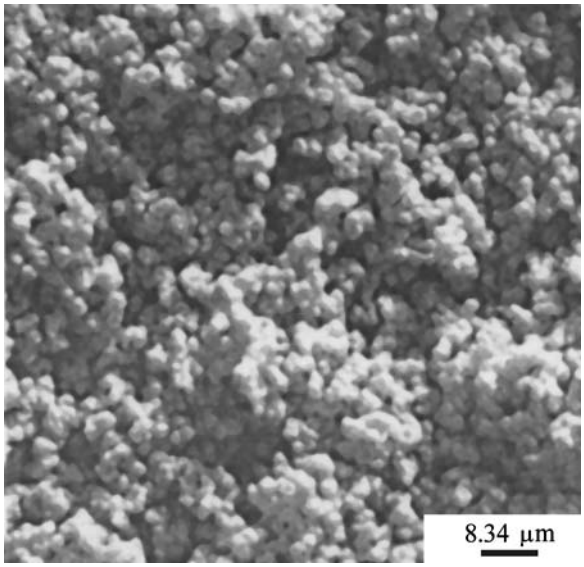

Fig. 1. Electron micrograph of the surface of GMA–EDMA continuous macroporous support prepared by radical photoinitiated copolymerization.

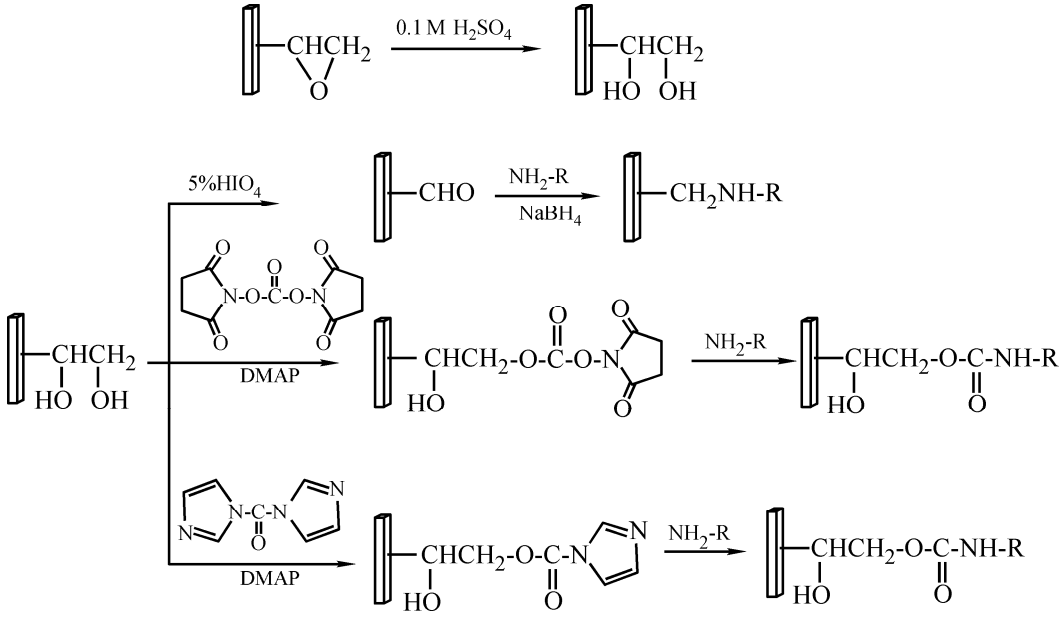
copolymer, examine the effect of various parameters on the covalent immobilization of proteins on the surface of modified matrices, and test the performance of the supports obtained with respect to a model affine pair.



EXPERIMENTAL

The most widely used procedure for preparing continuous macroporous stationary phases based on GMA–EMDA copolymer is thermally initiated radical polymerization of the corresponding monomers in the presence of porophores. However, to prepare monolithic columns with a diameter exceeding the height, or thin layers (planar analytical test systems), it is preferable to use photoinitiation, which not only requires no elevated temperatures, but also is less time-consuming. The photoinitiated free-radical polymerization of GMA and EDMA has been studied previously [7], with the suitable initiator found and optimal synthesis conditions determined. The monomers, solvent-porophore (cyclohexanol), and initiator, 2-hydroxy-2,2-dimethylacetophenone (Darocure-1173) were purchased from Merck–Schuchard (Germany). The following volume ratios of the reactants were used: GMA : EDMA = 60 : 40, porophore : monomers = 60 : 40; the initiator concentration was 1 wt % relative to the monomers. The irradiation time was 20 min, and the copolymer yield, 93%.

To perform photoinitiated copolymerization of GMA and EDMA, we used as a UV source a 125 W mercury lamp with a wide radiation spectrum and constant intensity (Philips, the Netherlands). For quantitative determination of the mean pore size and pore-size distribution, we used a Thermoquest Pascal 440, mercury porosimeter (Rodano, Italy). The weight of the sample taken for the analysis was about 100 mg. According to the data of intrusion mercury porosimetry, the mean pore radius of the sorbent obtained was 0.8 μm at a surface area of 28 $m^2 g^{-1}$ and 55% porosity. The pore characteristics obtained provide free penetration of protein molecules inside the 3*D* pore space in the course of immobilization and subsequent affine interaction of the complements, and also a high adsorption capacity of the support. According to theoretical calculations, the content of epoxy groups in the copolymer is within 3.9–4.2 mmol g^{-1} sorbent.

The morphology of the polymer samples obtained was studied with a JSM-35 CF scanning electron microscope (Japan). The thickness of the sputtered gold layer was 50–100 Å. An electron micrograph of the surface of the continuous macroporous polymeric material obtained is shown in Fig. 1. In addition, we used for this purpose the qualitative "ink test" which was performed by immersing the samples into an alcoholic solution of Methylene Blue for 1 min. The homogeneity of the pore structure was estimated from the extent of penetration of the dye into the sorbent pores. The results of our experiments show that the chosen synthesis conditions allow preparation of a polymeric support with a homogeneous structure of the pore space and a narrow pore-size distribution.

To introduce highly reactive groups into the macroporous polymeric support for the subsequent reaction with a biospecific ligand (protein), we used polymer-analogous transformations. An advantage of this approach to introduction of highly reactive groups is that of the pore structure of the starting copolymer is preserved, which is certainly very important for the subsequent analysis based on affine interactions. As such highly reactive groups we chose aldehyde, succinimidyl carbonate, and imidazolecarbamate groups. The scheme of reactions involved in the modification and immobilization of a bioligand on the surface of the GMA–EDMA copolymer is given below:

In the first step, we performed hydrolysis of native epoxy groups of GMA–EDMA copolymer to vicinal diol. The hydrolysis was performed in an excess of 0.1 M sulfuric acid at 80°C for 6 h. The degree of hydrolysis of the epoxy groups was estimated by IR spectroscopy. For qualitative and quantitative analysis, IR spectra were measured using equal weighed portions of the starting epoxy sorbent and the hydroxy sorbent obtained. Samples for IR spectroscopy were prepared by compacting a uniform mixture of 5 mg of finely ground GMA–EDMA copolymer and 600 mg of KBr. The spectra were measured in the range 200–4000 cm^{-1} with a Specord M 80 automatic spectrometer (Carl Zeiss, Germany).

The disappearance of all the characteristic absorption bands of the epoxy ring (1250, 950–810, and 840–750 cm^{-1}) and the appearance of a broad band in the range 3200–3600 cm^{-1}, corresponding to stretching vibrations of the OH groups, and a band at about 1100 cm^{-1}, corresponding to stretching vibrations of secondary hydroxy groups, are indicative of the occurrence of hydrolysis (Fig. 2a). The degree of hydrolysis was estimated quantitatively using the so-called method of internal reference [8]. We found that the conversion of epoxy groups into hydroxy groups was 80%.

An intrusion mercury porosimetric analysis of the samples obtained after hydrolysis showed that the hydrolysis somewhat affected the mean pore size. In particular, we found that the mean pore radius increased by 50 nm and the total content of pores coarser than 500 nm increased from 87 to 90%. It is also important that samples of the macroporous polymeric support obtained after hydrolysis of the epoxy groups of GMA–EDMA preserved the external appearance and mechanical properties of the monolithic matrix.

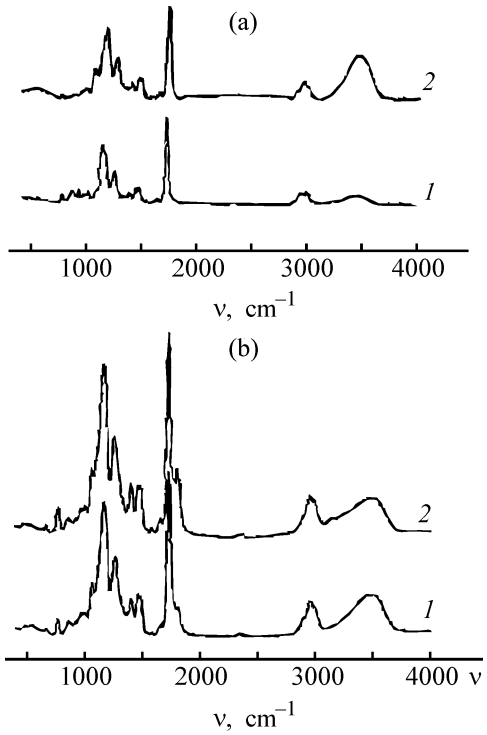


Fig. 2. IR spectra of (a) (*1*) initial GMA–EDMA copolymer, (*2*) copolymer formed upon hydrolysis of epoxy groups, and (b) copolymer modified with 1,1'-carbonyldiimidazole. (ν) Wavenumber. (b) Amount of modifying agent, % of the total amount of hydroxy groups: (*1*) 8 and (*2*) 180.

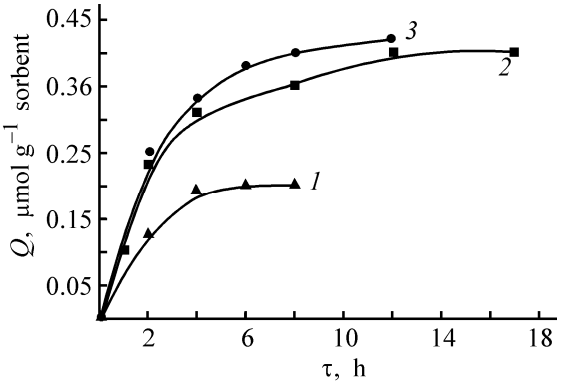

Fig. 3. Amount Q of the protein covalently bound to the surface of modified materials as a function of the time t of copolymer modification: (*1*) oxidation, (*2*) modification with 1,1'-carbonyldiimidazole, and (*3*) modification with bis(*N*-succinimidyl) carbonate; the same for Fig. 4.

With the aim to generate aldehyde groups on the surface of 2,3-dihydroxypropyl methacrylate–ethylene glycol dimethacrylate (DHPMA–EDMA) copolymer prepared by hydrolysis of epoxy groups of GMA–EDMA copolymer, we oxidized the hydroxy groups with an excess of a 5% solution of periodic acid in 90% acetic acid. The amount of periodic acid taken per 150 mg of the copolymer was 110 mg (0.48 mmol). The reaction was performed by keeping the polymeric support in the oxidant at 22°C. After the reaction completion, the sorbent was washed with distilled water for 3 h, with 2 N NaCl for 1 h, and again with distilled water for 3 h. The presence of aldehyde groups in the oxidized samples was qualitatively confirmed by the specific reaction with fuchsinsulfurous acid (Schiff reagent) [9]. The uniform lilac coloration of the polymeric support confirmed the presence of aldehyde groups in the modified copolymer. An IR analysis, however, appeared to be inefficient because the absorption bands of the aldehyde groups (1724 cm^{-1}) were obscured by bands of ester groups (1730 cm^{-1}) present in a large excess.

The modification of DHPMA–EDMA copolymer with bis(*N*-succinimidyl) carbonate (Aldrich, Germany) was performed in acetonitrile in the presence of 4-(dimethylamino)pyridine (DMAP) (Merck, Germany). Per 150 mg of the polymer, we took 44 mg of bis(*N*-succinimidyl) carbonate (0.17 mmol) and 33 mg of DMAP (0.27 mmol). The amount of the taken modifying agent corresponded to an 18% theoretical conversion of hydroxyl groups. The reaction was performed at 22°C by immersing the polymer matrix into a solution of the modifying agent. After the modification was complete, the copolymer was washed using a laboratory shaker with acetonitrile for 2 h and then with distilled water for 1 h.

The introduction of succinimidyl carbonate groups was confirmed by IR spectroscopy. A shoulder appearing at about 1790 cm^{-1} was indicative of the presence of the five-membered imide ring in the copolymer and hence of the occurrence of the modification.

The modification of DHPMA–EDMA copolymer with carbonyldiimidazole was performed in two modes. In the first mode, the amount of the modifying agent was 18% relative to hydroxy groups, and in the second mode it was 180%. For this purpose, the hydroxyl-containing sample of the copolymer was placed in a solution containing 1,1-carbonyldiimidazole (Aldrich, Germany) and DMAP. Acetonitrile was used as a solvent. The amount of 1,1-carbonyldiimidazole taken for modification of 150 mg of the copolymer was 31 and 310 mg (0.19 and 1.90 mmol), and that of DMAP, 33 and 330 mg (0.27 and 2.70 mmol). The reaction and washing conditions were the same as in the modification with bis(*N*-succinimidyl) carbonate.

The conversion of hydroxy groups was judged from the IR data. For the sample obtained at a deficiency of the modifying agent (i.e., with an excess of hydroxy groups of the polymer), a small shoulder appeared in the IR spectrum at 1804 cm^{-1}. With an excess of the mod-ifying agent, the band in the same region became more pronounced (Fig. 2b). In both cases, the characteristic bands appearing in this range correspond to the absorption of imidazolecarbamate groups.

The amount of imidazolecarbonate groups introduced into the structure of the methacrylate copolymer was estimated by elemental analysis. With the modifying agent taken in an amount of 18%, the content of imidazolecarbamate groups introduced into the copolymer structure was 5–7.5%, which corresponds to 300–450 μmol of reactive groups per gram of the sorbent. With a 180% excess of the modifying agent, the solid-phase reaction occurs with 30% conversion and the amount of imidazolecarbamate groups introduced into the copolymer structure is 15%, or approximately 900 μmol g^{-1} sorbent.

The progress of the covalent binding of proteins in time is illustrated by Fig. 3. For the aldehyde-containing copolymer, the maximal binding capacity is attained within 4 h, and for the copolymers modified with the other two agents, within 8 h. The immobilization capacities obtained were compared with the amount of the protein introduced into the structure of the GMA–EDMA copolymer by the reaction between the epoxy groups of the sorbent and the amino groups of the protein. We found that, in the latter case, the maximal capacity was 0.2 μmol of protein per gram of

the sorbent, and it was attained within 16–18 h at 35°C. At the same time, for the aldehyde-containing sample, the same immobilization capacity was attained in 4 h at 22°C. With the other two modification procedures, the same amount of the protein was bound within 1.5–2 h at 22°C.

The schemes of the reactions of covalent immobilization of proteins on the surface of supports containing aldehyde, succinimidyl carbonate, and imidazolecarbamate groups are given above. To develop and optimize a procedure for covalent binding of a proten on the surface of modified polymeric supports, we examined the effect of certain experimental parameters on the capacity of the matrices obtained. In particular, we examined the dependences of the amount of the immobilized ligand on the reaction time, initial protein concentration, pH of solution, and temperature.

The procedure of protein immobilization on the surface of a monolithic macroporous support was performed by incubation in a protein solution. In experiments on optimizing the immobilization conditions, we used bovine serum albumin (BSA) and soyben trypsin inhibitor (STRI), both purchased from Sigma–Aldrich, Germany. After the reaction completion, the polymeric support was washed with the reaction buffer solution for 40 min, with 2 M NaCl (three portions, for 15 min with each portion), and with a 0.01 M sodium phosphate buffer solution (pH 7.0) containing 0.15 M NaCl for 40 min. The amount of the immobilized ligand (mg) was determined from the difference between the ligand amounts in the initial solution (mg) and in the solution after immobilization plus wash solutions (mg). The protein content was determined by the Lowry –Folin method [10]. The optical density of solutions was determined with an SF-26 spectrophotometer (LOMO, Russia). After the immobilization, the azomethine bonds were reduced with sodium borohydride. The residual imidazolecarbamate and succinimidyl carbonate groups were blocked with ethanolamine.

The dependence of the amount of the ligand covalently linked to the surface of the polymeric matrix on the protein concentration in solution shows that, with all the modified supports, the maximum capacity is attained at a protein concentration in solution of 4.5–5.0 mg ml^{-1}. Furthermore, the ligand binding in biofunctionalization of the starting GMA–EDMA copolymer also reaches a maximum at this concentration .

The influence of pH on the covalent binding of the protein with aldehyde, succinimidyl carbonate, and imidazolecarbamate groups was studied with STRI as an example. The maximal binding of the protein with

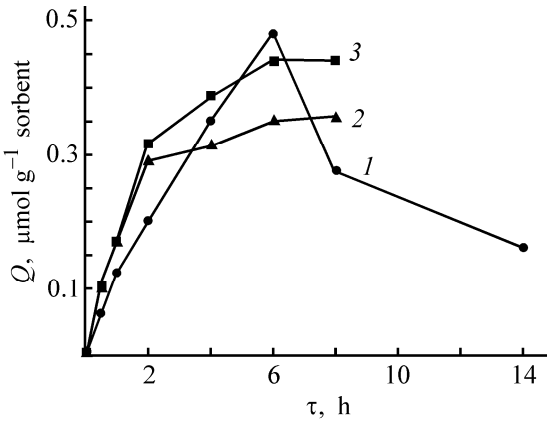

Fig. 4. Amount Q of the protein covalently bound to the surface of modified materials as a function of the reaction time τ. Initial protein concentration 5 mg ml^{-1}, pH 8.1 for the aldehyde-containing support and 7.6 for the supports containing succinimidyl carbonate and imidazolecarbamate groups.

the sorbent (15 mg g^{-1}, or 0.63 μmol g^{-1}) for the aldehyde-containing copolymer was observed at pH 8.1–9.4. For the other two reaction groups, the immobilization capacity (12 mg g^{-1}, or 0.5 μmol g^{-1}) was maximal at pH 7.6–9.4, varying in this range insignificantly.

The immobilization data allowed us to calculate the surface area occupied by the covalently bound protein macromolecules, using the equation

$$S_{surf} = \pi R^2 Q N_A,$$

where S_{surf} is the surface area occupied by the protein (m^2 g^{-1}); N_A, Avogadro number (mol^{-1}); R, radius of the protein molecule (m); and Q, amount of the substance (mol g^{-1}).

In the case of STRI immobilization, the surface area occupied by the protein was 3.5–5.0 m^2 g^{-1} for the aldehyde-containing support, which corresponds to 13–18% of the total surface area of the pores. For the supports containing succinimidyl carbonate and imidazolecarbamate groups, these values decreased to 3.5–4.0 m^2 g^{-1}, which corresponded to a 13–14% coverage of the pore surface. In the case of immobilization on the initial epoxy-containing polymeric support, the related quantity obtained for covalent binding of STRI was 2 m^2 g^{-1}, which corresponded to a 7% coverage of the surface area of the pore space of the sorbent.

To determine the optimal time of biofunctionalization of the polymeric materials obtained, we examined the dependence of the amount of the immobilized model protein, BSA, on the reaction time. As can be seen from Fig. 4, the maximal BSA binding is attained in 6 h for all the three modified forms of the polymeric

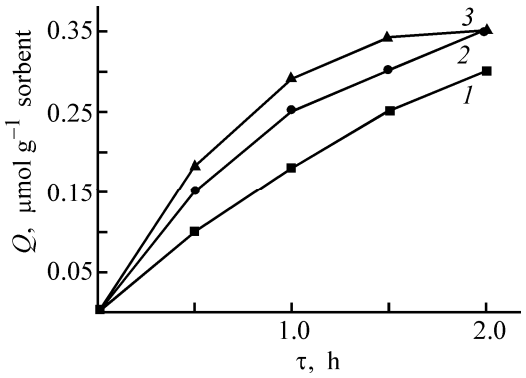

Fig. 5. Amount Q of BSA immobilized on the surface of the imidazolecarbamate-containing support vs. the reaction time τ. Temperature, °C: (*1*) 22, (*2*) 30, and (*3*) 37. Initial protein concentration 5 mg ml^{-1}, pH 7.6.

materials. In the case of aldehyde-containing supports, this is followed by a sharp decrtease in the amount of the bound protein, apparently due to instability of the azomethine bonds formed. For succinimidyl carbonate and imidazolylcarbamate supports, the maximal binding capacities were attained in 6 h and then remained virtually unchanged. As noted above, the maximal protein binding, equal to 0.2 μmol g^{-1} in the reaction of BSA amino groups with epoxy groups of the GMA–EDMA sorbent, was attained in 16 h, and in the case of aldehyde groups, it was attained in 2 h. At the same time, in the case of succinimodyl carbonate groups, the immobilization capacity of the sorbent in reached 0.3 μmol g^{-1} 2 h, and in the case of imidazolecarbamate groups, 0.28 μmol g^{-1}. Furthermore, the use of epoxy groups for the immobilization, along with the slow kinetics, does not allow the sorbent capacity to be raised, whereas for the modified copolymers, the capacity can be raised by more than a factor of 2.

With the aim to examine the effect of temperature on the ligand immobilization, with the supports containing imidazolecarbamate groups as examples, we performed experiments at 22, 30, and 37°C, with the reaction time varied from 0.5 to 2 h. The data we obtained (Fig. 5) show that, with increasing temperature, the amount of the protein bound in a given time noticeably grows. In particular, the amount of the protein bound in 2 h at 22°C is bound in 1 h at 37°C.

To confirm the possibility of using the modified supports for the development of biorecognizing systems, we used two approaches:

(1) frontal method of affinity high-performance monolithic disc chromatography (HPMDC) and (2) analysis using test systems (planar 3*D* biochips).

As HPMDC sorbent we used commercial macroporous discs based on GMA–EDMA copolymer (CIM® Epoxy Disks, BIA Separations d.o.o., Ljubljana, Slovenia, of size 12×3 mm, mean pore size 1 μm, porosity 60%. As a model affine pair we used the trypsin (TR)–STRI pair. To determine the apparent dissociation constants of the affine complex we passed trypsin solutions across a disc containing immobilized STRI as ligand, to complete adsorption saturation of the affine sorbent surface, following the procedure described in [3]. The results of our dynamic (chromatoghraphic) experiments show that all the affine matrices prepared by intermediate modification of CIM discs with aldehyde, succinimidyl carbonate, and imidazolecarbamate groups are capable of specific binding of trypsin. For all the sorbents prepared, the dissociation constants for the TR–STRI pair were commensurable, on the order of 10^{-5} mol l^{-1}, which confirms that the materials we obtained are suitable for the development of biorecognizing systems.

In parallel with the dynamic experiments, we examined the possibility of using the sorbents based on the modified polymers as static test systems. As a model of a planar biochip we used a thin layer of modified GMA–EDMA copolymer bound to a glass support [11]. Analysis on the surface of polymer layers functionalized with trypsin inhibitor was performed by the method of fluorescence densitometry. Spots were detected at λ = 365 nm. Trypsin solutions were prepared by dissolving trypsin marked with fluorescamin in 0.01 M sodium phosphate buffer solution containing 0.15 M NaCl, pH 7.0. The resulting solutions containing 0.002–2.0 mg ml^{-1} protein were applied in 0.3-μl portions onto the surface of a polymer layer containing immobilized STRI. Correspondingly, the trypsin content in the adsorption spots was in the range 0.0006–0.6 μg/spot (spot is the formed analytical zone 1.5 mm in diameter). The biochip with the applied protein spots was kept in the dark for 10 min and then successively washed with a 0.01 M sodium phosphate buffer solution containing 0.15 M NaCl for 40 min and with a 2 N NaCl solution also for 40 min. After that, the biochip was washed with distilled water for 10 min. After the washing was completie, solutions of marked trypsin of known concentration were applied onto the polymer layer surface to construct the calibration plot. We found that the sensitivity limit of the bioassay performed using aldehyde affine matrices was 0.5 ng of trypsin per spot, or 20 fmol/spot, i.e., the procedure is four times more sensitive than with the other two modified forms of the polymer.

CONCLUSIONS

(1) Macroporous methacrylate supports containing aldehyde, succinimidyl carbonate, and imidazolecarbamate groups were prepared by chemical transformations of epoxy groups of the glycidyl methacrylate–ethylene glycol dimethacrylate copolymer.

(2) It was demonstrated that the modification methods chosen do not alter significantly the pore size of macroporous supports, which is important for their subsequent applications.

(3) It was shown that affine sorbents based on modified continuous macroporous phases are capable of fast and sterically unhindered specific binding of biological partners one of which is covalently bonded to the sorbent surface.

Abstract—Organic–inorganic hybrids in the system polyhydric phenols–silica were prepared by hydrolytic polycondensation of tetraethoxysilane in the presence of di- and trihydroxy derivatives of benzene. From these materials, film coatings were prepared, and their physical properties were studied

DOI: 10.1134/S107042720808017X

One of interesting and promising fields of polysiloxane chemistry is the development of methods for constructing polymeric composites exhibiting valuable properties. Such composites surpass unmodified polysiloxanes in many technical characteristics [1].

Composites prepared as organic–inorganic hybrids combine the elasticity and flexibility of organic components with high heat resistance, mechanical strength, and chemical stability of inorganic materials [2], which expands the fields and possibilities of their application [3].

The widely used way to prepare hybrid coatings is incorporation into a polysiloxane matrix of film-forming organic polymers that form thermoplastic coatings with a set of valuable physicochemical properties (high elasticity, mechanical strength, abrasion resistance, etc.) [4, 5]. Of particular interest for designing hybrid coatings for various purposes is the use of ogranosilicon monomers and oligomers, as they are readily soluble in the majority of organic solvents. This allows preparation of solutions with a relatively high content of the main substance (>40%) [6]. The technology of forming polymeric coatings from such solutions is particularly promising because of their lower viscosity and lower surface tension (better wettability), compared to solutions of the corresponding polymers. Owing to the increased covering capacity of such solutions, they can penetrate into pores and defects of the surfaces being treated. With hybrid composites based on organosilicon monomers and oligomers, the polymeric coating is formed not only on the surface but also in pores of a material.

One of the simplest and promising methods for preparing a polysiloxane matrix is the sol–gel procedure of hydrolytic polycondensation of tetraalkoxysilanes [7]. The sol–gel process performed in the presence of organic compounds yields organic–inorganic hybrids [8].

With polyphenols, the stability and uniformity of structures formed in the process should be provided by chemical binding of the system components:

$$-\overset{|}{\underset{|}{Si}}-H + HO-Ar \rightarrow -\overset{|}{\underset{|}{Si}}-O-Ar + HX,$$

where X = OR, OH, Cl, $-C\begin{matrix}O\\ \diagdown\\ OR\end{matrix}$.

In this study, we examined the possibility of performing heterofunctional polycondensation of oligoethoxysilanes with 1,4-dihydroxybenzene (hydroquinone) or 1,3,5-trihydroxybenzene (phloroglucinol).

EXPERIMENTAL

The silicon content of the samples was determined gravimetrically by decomposition of a weighed portion of a substance with a mixture of 20% oleum with concentrated nitric acid, followed by calcination of the residue to constant weight at 800°C [9].

The density ρ (g cm^{-3}) of the solid materials obtained was measured by the Archimedean method (toluene–water system). The porosity W (%) was determined from the ethanol adsorption–desorption with a McBain vacuum spring balance [10]. The microhardness (MH) was measured with a PMT-3 microhardness meter.

All the above parameters were determined for samples that did not crack in the course of drying and measurements. The gel point was characterized by the time after which the system lost mobility.

Thermal analysis was performed with a Q-1500D derivatograph (Hungary). The samples were heated to 1000°C at a rate of 20 deg min^{-1}.

Electron-microscopic examination of xerogels was performed with an EM-125 device at an accelerating voltage of 75 kV.

To prepare hybrid coatings by the sol–gel procedure, to tetraethoxysilane hydrolyzate we added organic components: hydroquinone **I** (Vekton) or phloroglucinol **II** (Merck). We also used 1,4-bis(triethoxysilyloxy)benzene **III** and 1,3,5-tris(triethoxysilyloxy)benzene **IV** prepared by the reactions of $Si(OEt)_4$ with hydroquinone and phloroglucinol in 2 : 1 and 3 : 1 molar ratios, respectively, in the presence of CF_3COOH as catalyst, according to the general equation

$$n\mathrm{Si(OEt)_4} + (\mathrm{HO})_n\mathrm{C_6H_{6-n}} \xrightarrow{\mathrm{H^+}} [(\mathrm{EtO})_3\mathrm{SiO}]_n\mathrm{C_{6-n}H_2} + n\mathrm{EtOH},\ \ n = 2, 3.$$

1,4-Bis(triethoxysilyloxy)benzene III. A mixture of 10.0 g (0.048 mol) of tetraethoxysilane (TEOS), 1.32 g (0.012 mol) of hydroquinone, and 0.2 g of CF_3COOH was refluxed for 4 h, after which the released ethanol was distilled off. The residue was distilled in a vacuum to obtain 2.5 g (yield 48%) of **III**, bp 180–190°C (0.01 mm Hg). ^{1}H NMR spectrum ($CDCl_3$): 6.88 s (4H, H_{ar}), 3.89 q (12H, –Si–O–CH_2–), 1.23 t (18H, CH_3).

1,3,5-Tris(triethoxysilyloxy)benzene IV was prepared similarly from 10.0 g (0.048 mol) of TEOS, 1.0 g (0.008 mol) of phloroglucinol, and 0.2 ml of CF_3COOH. Yield 1.2 g (25%), bp 210–220°C (0.01 mm Hg). ^{1}H NMR spectrum ($CDCl_3$): 6.64 s (3H, H_{ar}), 3.85 q (18H, –Si–O–CH_2–), 1.24 t (27H, CH_3). Compounds **III** and **IV** are readily hydrolyzable colorless liquids with a weak odor.

To prepare a polysiloxane matrix, we used a mixture of polyethoxysiloxanes **V** and **VI** prepared by controllable hydrolytic polycondensation of tetraethoxysilane under the conditions of acid catalysis.

To prepare oligomers **V** and **VI**, we took 9.8 g (0.044 mol) of TEOS, 4.8 g (0.104 mol) of ethanol, and 1.1 and 1.2 g of 0.01 N HCl, respectively. The components were mixed in the following order: ethanol, HCl solution, TEOS. The resulting mixture was placed in polypropylene jars with screwed caps (three samples for each system) and kept for 2–4 days in a thermostat at 90°C to obtain a xerogel (Table 1).

Table 1. Gelation rate in the $Si(OEt)_4$–H_2O–EtOH–HCl system at various amounts of HCl solution

Oligomer	Amount of 0.01 N HCl, g	SiO_2 content of liquid oligomer, %	t_1*	t_2*	State of solidified gel

IX	**VI**	0.045	18	1.44	37	88
X	**VI**	0.03	21	1.48	35	96
XI	**VI**	0.03	23	1.53	32	101

* Films prepared with (**VII–IX**) hydroquinone and (**X**, **XI**) phloroglucinol.

** (t) Time of film drying at 80°C.

The formation of polymeric composites based on products of the condensation of a mixture of oligoethoxysiloxanols **V** and **VI** with hydroquinone and phloroglucinol involves the following main reactions (with hydroquinone as example):

$$2\text{–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–OH} + \mathrm{HO–C_6H_4OH} \rightarrow \text{–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–O–C}_6\mathrm{H_4}\text{–O–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–} + 2\mathrm{H_2O},$$

$$2\text{–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–OEt} + \mathrm{HO–C_6H_4OH} \rightarrow \text{–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–O–C}_6\mathrm{H_4}\text{–O–}\overset{|}{\underset{|}{\mathrm{Si}}}\text{–} + 2\mathrm{EtOH}.$$

To perform these reactions, to 0.5 g of a mixture of polyethoxysiloxanols **V** or **VI** in dimethylacetamide (DMAA) heated to 70–80°C we added a solution of hydroquinone **I** or phloroglucinol **II** in DMAA and 0.2 ml of CF_3COOH. The amount of hydroquinone was varied from 0.015 to 0.075, and that of phloroglucinol, from 0.01 to 0.04 g. The hot mixture was cast onto a glass plate and dried at 80°C in a DMAA vapor for 1–2 days. In the process, polymer films formed on the glass surface. The physicochemical parameters of some film samples are listed in Table 2.

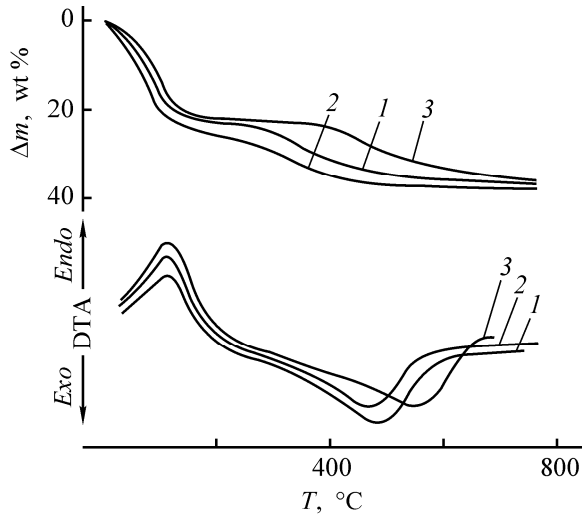

Fig. 1. DTA and TG curves of composites **VII**, **VIII**, and **X**. Film prepared with (*1*, *2*) hydroquinone (samples **VII** and **VIII**, respectively) and (*3*) phloroglucinol (sample **X**). (Δm) Weight loss and (T) temperature; the same for Fig. 2.

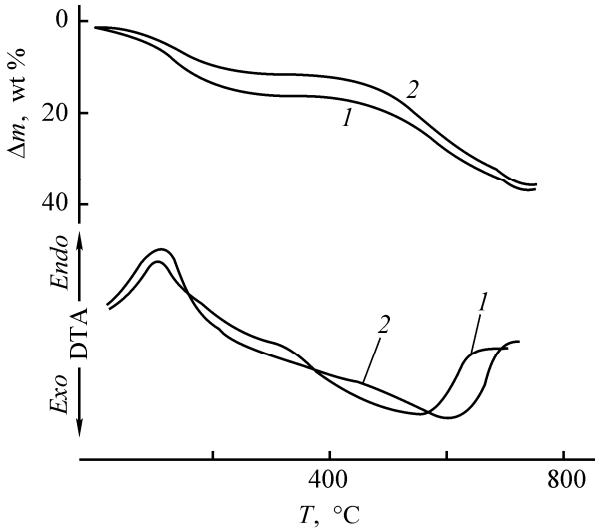

Fig. 2. DTA and TG curves of film samples **XVI** and **XVII**. Film prepared from (*1*) 1,4-bis(triethoxysilyloxy)-benzene **III** and oligomer **V** and (*2*) 1,3,5-tris(triethoxysilyloxy)benzene **IV** and oligomer **VI**.

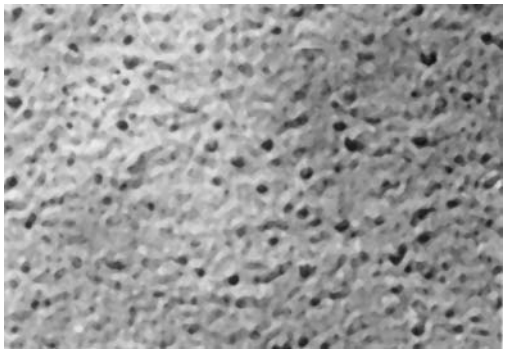

Fig. 3. Electron micrograph of a film of composite **VIII**. Magnification 80 000.

Table 2 shows that film samples **X** and **XI**, with phloroglucinol as cross-linking agent, have a somewhat higher density and microhardness, despite lower concentration of phloroglucinol in the coating, compared to systems with hydroquinone. This may be due to the fact that trifunctional hydroquinone, in contrast to bifunctional hydroquinone, binds the siloxane structures in a three-dimensional network.

In the DTA curves (Fig. 1) of composites **VII**, **VIII**, and **X**, there are two peaks. The endothermic peak at 150–180°C corresponds to the removal of sorbed ethanol and water from the composite. The exothermic peak in the range 400–600°C is due to burnout of organic components (ethoxy groups, benzene rings). The high-temperature shift of the exothermic maximum in the DTA curves of composite **X,** compared to **VII** and **VIII,** indicates that composite **X** is more resistant to thermal oxidation, which is due to its cross-linked 3*D* structure.

Replacement of hydroxy groups in hydroquinone and phloroglucinol with triethoxysilyloxy groups allows the initial content of ethoxy groups in the composites formed by reactions with $Si(OEt)_4$ hydrolyzates **V** and **VI** to be increased. Compounds **III** and **IV** are liquids that form liquid mixtures with oligomers **V** and **VI** homogeneous. The formation of composites from these mixtures is due to the occurrence of parallel-consecutive condensation (ether interchange) reactions:

$$\begin{aligned} &\text{–Si(–)–OH} + (C_2H_5O)_3SiO–C_6H_4–OSi(OC_2H_5)_3 \\ &\rightarrow \text{–Si(–)–O–Si(OEt)}_2–O–C_6H_4–OSi(OEt)_3 + C_2H_5OH. \end{aligned}$$

From triethoxysilyl ethers of hydroquinone and phloroglucinol and oligomers **V** and **VI**, the composites were prepared as follows. To 0.7 g of oligomer mixture **V** or **VI** in 0.5 g of ethanol, we added 1,4-bis(triethoxysilyloxy)benzene (from 0.05 to 0.5 g) or 1,3,5-tris(triethoxysilyloxy)benzene (from 0.2 to 0.5 g) and 0.03 g of a 0.01 N HCl solution. The resulting mixture was cast onto a glass plate, which was dried at 80°C for 1–2 days. The physicochemical parameters of some of the films are listed in Table 3.

Figure 2 shows the TG and DTA curves for film samples **XVI** and **XVII**. As in the case of composites derived from phenols (Fig. 1), there are two peaks in the DTA curve. The endothermic peak (140–180°C) corresponds to the removal of sorbed ethanol and water from the system. The exothermic peaks in the range 450–630°C for composites **XVI** and **XVII** are some-

Table 3. Physicochemical properties of polymer film samples **XII–XV***

* Films prepared with (**XII**, **XIII**) 1,4-bis(triethoxysilyloxy)-benzene and (**XIV**, **XV**) 1,3,5-tris(triethoxysilyloxy)benzene.

what shifted toward higher temperatures relative to samples **VII** and **X**.

The structures of all the synthesized composites are similar. Figure 3 shows as an example an electron micrograph of composite **VIII**. The structure is fairly uniform, with a mean pore size of 15–20 nm.

CONCLUSION

Polyethoxysiloxanes cross-linked with hydroquinone or phloroglucinol were prepared for the first time. The structures cross-linked with phloroglucinol are more resistant to thermal oxidation than those cross-linked with hydroquinone.

Abstract—Kinetic relationships in homogeneous radical copolymerization of acrylamide with sodium acrylate, initiated by potassium peroxosulfate in concentrated aqueous solutions at 60°C, were examined in relation to the ionic strength of the solution and pH of the medium.

DOI: 10.1134/S1070427208080181

Water-soluble copolymers of acrylamide (AA) with acrylates having specific molecular characteristics find application as flocculants and stabilizers of dispersed systems, thickeners, and cross-linking agents [1, 2]. Considering the high practical value of the copolymers, of much importance is the most efficient, though inadequately understood, method of their preparation: copolymerization in concentrated aqueous solutions. Our previous studies have been focused on the copolymerization of AA with sodium acrylate (SA) at pH 7 [3] and pH 8 [4] and with ammonium acrylate at pH 8 [5], as well as on the binary copolymerization of AA with SA and ammonium acrylate in relation to the nature of the cation [4].

As is known [6, 7], the radical copolymerization of ionic monomers in aqueous solutions can be substantially affected by the ionic strength of the solution, μ, and the pH of the medium. We elucidated here how these factors affect the kinetic relationships in preparation of water-soluble AA–SA copolymers with different intrinsic viscosities, molecular weights, and chemical compositions by homogeneous radical copolymerization initiated by potassium peroxosulfate in concentrated aqueous solutions at 60°C. We took into account that pH in alkaline media and the ionic strength μ of the solution affect the polymerization of acrylic acid [6, 8] and do not affect that of AA [8].

EXPERIMENTAL

We used biocatalytically prepared aqueous solutions of monomers (40% AA and 18% SA) available from Ashland Eurasia MSP Private Company, Perm, as well as pure-grade potassium peroxosulfate (PP), analytically pure grade sodium hydroxide and acetone, and high-purity helium. In all the experiments, we used distilled water.

The initial copolymerization rate v_0 was estimated at low conversions ($x < 3\%$) from the dilatometrically recorded kinetic curves. For the copolymerization technique, as well as for the technique and devices used for dilatometric, viscometric, and potentiometric analyses, see [5]. When the reaction was complete, the copolymer was precipitated from the aqueous solution into an acetone excess, after which it was washed with acetone and vacuum-dried in a desiccator at 50°C to constant weight.

The intrinsic viscosity [η] of the copolymers was determined viscometrically in 0.5 M NaCl at 30°C and used for calculating the viscosity-average molecular weight M of the AA–SA copolymers by the Mark–Houwink–Kuhn equation:

$$[\eta] = KM^{\alpha}.$$

The parameters K and α, dependent on the content of the SA units in the copolymer, were taken from [9].

The content of the SA units in the AA–SA copolymer was estimated from potentiometric data by the technique described in [10].

Copolymerization of AA (M_1) with SA (M_2) was carried out in 18% aqueous solutions at 60°C with PP as initiator ([PP] = 7.4×10^{-4} M). Maintaining pH at 10

and 12 afforded efficient initiation by PP [11] and a constant initiation rate at varied concentrations of SA and NaOH and NaCl additions, since the PP decomposition rate in alkaline media is independent of μ [12]. Under the actual experimental conditions, the copolymerization did not go without initiator, and in the presence of PP it proceeded under homogeneous conditions.

Let us analyze the AA–SA copolymerization in relation to the composition of the initial monomer mixture. The experiments were run at $M_1 + M_2 = \text{const}$, with all other conditions remaining unchanged as well; the results are shown in Fig. 1. It is seen that, with increasing SA content in the initial monomer mixture, v_0 tends to decrease at pH 10 and 12, both with and without NaCl. Comparative analysis of the data in Fig. 1 at $[M_2] = \text{const}$ (cf. curves *3*, *4* and *1*, *2*) shows that, at pH 10 and 12 over a wide range of compositions of the initial monomer mixture, v_0 increases on passing from aqueous solutions to 1% NaCl, owing to the change in μ.

Figure 1 also demonstrates a decrease in v_0 with increasing pH in the absence of NaCl, which reasonably agrees with the data on homopolymerization of acrylic acid in alkaline media [6, 8]. This decrease in v_0 is due to a decrease in the local concentration of the charged SA monomer near the macroradicals, associated with contraction of macromolecular coils in alkaline solutions.

Figure 2 shows how [η] and $\bar{M}_\eta$ of the resulting AA–SA copolymers vary with the composition of the initial monomer mixture during copolymerization. It is seen that, with increasing M_2 concentration, [η] (Fig. 2a) and $\bar{M}_\eta$ (Fig. 2b) of the copolymers tend to decrease. Similar trends in variation of v_0 (Fig. 1) and $\bar{M}_\eta$ (Fig. 2) with M_2 are characteristic of polymerization of ionic monomers [6, 7]. Figure 2 also shows that copolymerization in the monomer mixtures enriched in AA yields AA–SA copolymers with the highest molecular weights. It is also seen from Fig. 2 that both [η] (Fig. 2a) and $\bar{M}_\eta$ (Fig. 2b) tend to slightly decrease upon addition of NaCl at pH 12.

Figure 3 plots the yield of the resulting AA–SA copolymer vs. the M_2 content in the initial monomer mixture. For the copolymerization in alkaline media without NaCl, the plot exhibits a maximum at $[M_1]/[M_2] \approx 1$ (curves *1*, *2*). Comparative analysis of the data in Fig. 3 (at $[M_2] = \text{const}$) shows that the yield

Table 1. Parameters r_1 and r_2, determined by different methods for the AA–SA copolymerization in aqueous solutions

Copolymerization conditions	Method of determination	$r_1 \pm 0.03$ (AA)	$r_2 \pm 0.03$ (SA)
pH 10	Fineman–Ross	2.00	0.60
	Kelen–Tüdös	2.00	0.60
pH 10 + 1% NaCl	Fineman–Ross	1.40	0.90
	Kelen–Tüdös	1.50	0.80

Table 2. AA–SA copolymerization in relation to the NaCl concentration*

[NaCl], M	Yield, %	$[m_2]$, mol %	$[\eta]$, $cm^3 g^{-1}$
0.034	–	12.8	–
0.085	88	13.4	–
0.171	91	16.9	450
0.513	95	22.9	250
0.855	99	24.7	230

* The copolymerization conditions are identical to those for Fig. 5.

grows as pH increases from 10 to 12 (curves *1*, *2*) and upon addition of NaCl (at pH 12) (curves *2*, *3*).

Figure 4 shows how the running composition of the AA–SA copolymers (at conversions $x < 3\%$) varies with the M_2 mole fraction in the initial monomer mixture during copolymerization. It is seen that, over a wide range of compositions of the initial monomer mixture without (curve *1*) and with (curve *2*) NaCl, the copolymerization yields copolymers enriched in AA units. Using the data from Fig. 4, the apparent relative activities of the monomers $r_1 = k_{11}/k_{12}$ (AA) and $r_2 = k_{22}/k_{21}$ (SA) were calculated by the Fineman–Ross and Kelen–Tüdös methods (Table 1). The r_1 and r_2 values determined by these different methods reasonably agree. As can be seen from Table 1, $r_1 > r_2$, which indicates that AA is more reactive in copolymerization than SA. Figure 4 shows that addition of NaCl at pH 10 causes the mole fraction of the SA units in the copolymer to increase (curve *1* against curve *2*). This is associated with an increase in μ, which accelerates the reaction of SA with the macroradical of the terminal SA unit and favors enrichment of the copolymer with the SA units, thereby raising r_2 and lowering r_1 (Table 1).

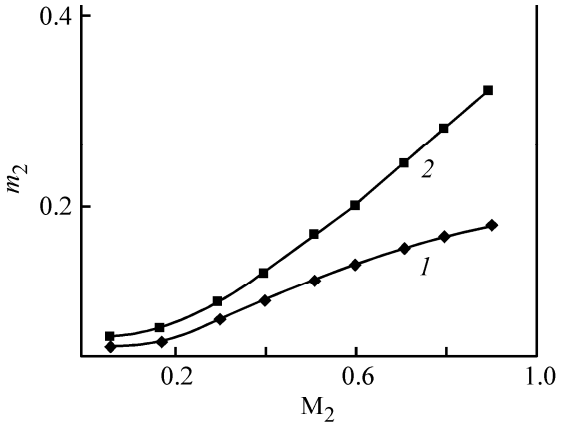

Fig. 4. Mole fraction of the SA units, m_2, in the copolymer vs. SA mole fraction in the initial monomer mixture, M_2, for AA–SA copolymerization at pH 10 (*1*) without and (*2*) with 1% NaCl. Fig. 5. Initial AA–SA copolymerization rate v_0, mol l^{-1} s^{-1}, at pH 10 vs. NaCl concentration.

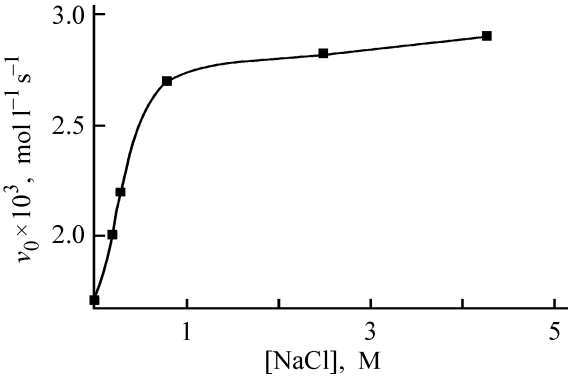

Fig. 5. Initial AA–SA copolymerization rate v_0 at pH 10 vs. the NaCl concentration. $[M_1]:[M_2] = 4:6$, $[PP] = 7.4 \times 10^{-4}$ M.

Figure 5 shows how the NaCl concentration (at pH 10) affects v_0, and Table 2 lists the characteristics of the resulting copolymers. With increasing electrolyte concentration, v_0 tends to grow and reaches a limiting value (Fig. 5); also, the yield of the copolymer and the content of the SA units in its macromolecules tend to increase, and $[\eta]$, to decrease (Table 2).

To interpret the kinetic data obtained, we will consider the ionization balance of the ionic groups in the salt solutions:

$$\underset{\text{I}}{A^+Na^-} \rightleftarrows \underset{\text{II}}{A^-} \,||\, Na^+ \rightleftarrows \underset{\text{III}}{A^- + Na^+},$$

where A^- is the anion of the monomer and macroradical; I, II, and III are contact and solvent-separated ion pairs and free ions in solution, respectively.

As is known [6], in alkaline solutions, the ionic groups of SA and its units in the copolymer macromolecules are ionized. With increasing μ (upon addition of NaCl), the ionization balance shifts to the left. This favors weakening of the electrostatic repulsion between the acrylate anions along the chain and diminishes the size of the macromolecular coils, as indirectly confirmed by a decrease in the reduced viscosity of the copolymer solution η_{sp}/c_p with increasing NaCl concen-

tration (Fig. 6). Under the copolymerization conditions, an increase in μ weakens the electrostatic repulsion between the identically charged SA monomer and macroradical with the terminal SA unit, thereby raising both the chain propagation rate constant k_{11} and v_0.

To derive an equation for the AA–SA copolymerization rate at pH 10, we carried out experiments at variable concentrations of the comonomers and the initiator, with the concentrations of the other components of the system and the reaction conditions remaining unchanged. The AA, SA, and PP concen-trations were varied within 2.2–9.5, 7.4–8.8, and $(3.9–14.8)\times 10^{-4}$ M, respectively. Figure 7a presents the experimental results. It is seen that v_0 tends to increase with increasing AA and PP concentrations and to decrease with increasing SA concentration, which agrees well with Fig. 1. From the slope of the straight lines in Fig. 7, we determined the reaction orders with respect to the components of the reaction mixture and derived the following empirical equation for the AA–SA copolymerization in aqueous solutions at pH 10:

$$v_c = k_c[AA]^{0.8}[SA]^{-1.0}[PP]^{0.5}.$$

Table 3. Intrinsic viscosity [η] of the AA–SA copolymers at different concentrations of the comonomers and the initiator

[AA]	[SA]	[PP]	[η], $cm^3 g^{-1}$
M			
2.2	7.4	7.4	125
2.8	–	–	145
4.0	–	–	150
6.5	–	–	160
8.5	–	–	185
6.5	7.4	7.4	160
–	7.9	–	330
–	8.5	–	370
6.5	7.4	3.7	440
–	–	4.9	410
–	–	7.4	160

In this equation, the reaction order with respect to the initiator suggests the bimolecular termination of the kinetic chains. The dependence of the polymerization rate on the total concentration of the monomers in the mixture was estimated at $[M_1]/[M_2] = 4:6$ (Fig. 7b); the reaction order with respect to the total concentra-

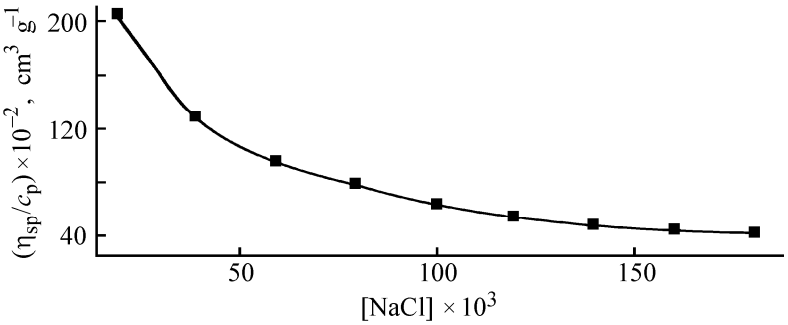

Fig. 6. Reduced viscosity of solutions, η_{sp}/c_p, of the AA–SA copolymer ($\bar{M}_\eta = 7.7\times 10^6$, content of SA units 51 mol %) vs. NaCl concentration at 25°C.

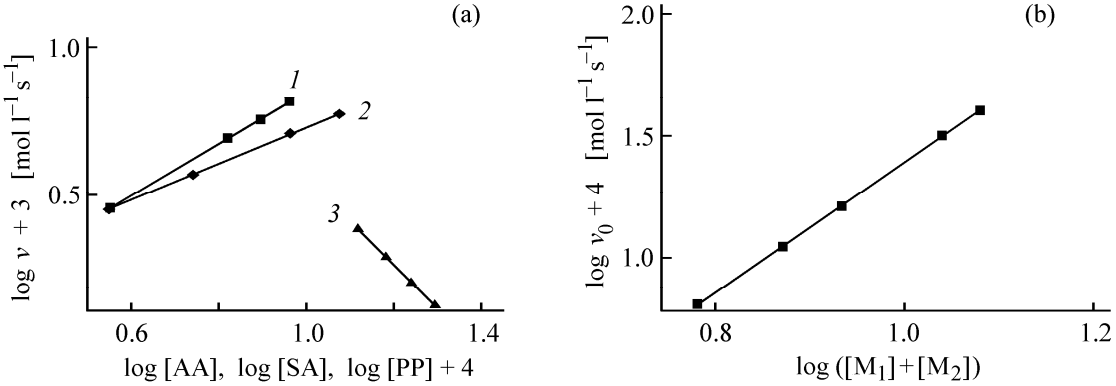

Fig. 7. Initial rate of AA–SA copolymerization, v_0, in aqueous solutions vs. concentrations of (a) (*1*) AA, (*2*) PP, and (*3*) SA and (b) $M_1 + M_2$ mixture in the log–log coordinates. (a) Concentration, M: (*1*) [SA] = 7.4, [PP] = 7.4×10^{-4}; (*2*) [AA] = 6.5, [SA] = 7.4; (*3*) [AA] = 6.5, [PP] = 7.4×10^{-4} and (b) $[M_1] : [M_2] = 4 : 6$, [PP] = 7.4×10^{-4}.

tion of the monomer mixture is 2.5. This yields the following copolymerization equation:

$$v_c = k_c([M_1] + [M_2])^{2.5}[PP]^{0.5}.$$

Table 3 lists the intrinsic viscosities [η] of the resulting copolymers in relation to the concentration of the reaction mixture components. It is seen that [η] tends to increase with increasing concentration of the AA and SA comonomers and with decreasing initiator concentration, in agreement with the general relationships in radical copolymerization.

CONCLUSION

Homogeneous radical copolymerization of acrylamide with sodium acrylate in concentrated aqueous solutions at 60°C, initiated by potassium peroxosulfate, can yield water-soluble high-molecular-weight copolymers, for which the initial rate of copolymerization, as well as the intrinsic viscosity, molecular weight, composition, and yield can be controlled by varying the pH and ionic strength.

Kazan State University of Technology, Kazan, Tatarstan, Russia

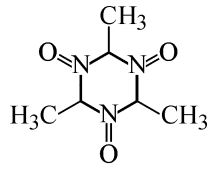
Received September 17, 2007

Abstract–Thermodynamic parameters of reactions of methyl and phenyl isocyanates with a series of compounds were determined by quantum-chemical calculations. The products of these reactions model for various functional groups present in commercial polyurethanes. The thermodynamic stability series for compounds formed from aliphatic and aromatic isocyanates were constructed.

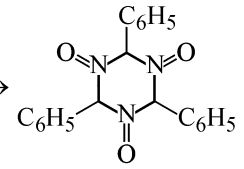
DOI: 10.1134/S1070427208080193

Production of polyurethanes based on reactions of isocyanates with polyols grows year by year [1, 2]. The main reaction of isocyanates with alcoholsto give urethanes is accompanied by side processes: formation of allophanates and isocyanurates [1–3]. When bisamines are used in synthesis of polyurethanes or when amino groups are purposefully generated from isocyanate groups, urea and biuret fragments arise in the polymer structure. The properties of the polyurethanes obtained largely depend on the ratio of these groups. Purposeful variation of the functional composition of polyurethanes is the most important way to control their physicomechanical properties. Both that urethane formation and concomitant processes are reversible [4–10]. Therefore, knowledge of the thermodynamic parameters of these reactions would allow their efficient control. In the available literature, there are only scarce data on thermochemical characteristics of particular reactions involved, and complete thermodynamic data are lacking. Experimental determination of the thermodynamic characteristics of particular reactions is complicated by the fact that the main reaction, urethane formation, is accompanied to one or another extent by side reactions [11]. To estimate the thermodynamic parameters of urethane formation and concomitant reactions, we examined quantum-chemically a series of model reactions simulating certain processes that occurr in real systems in the course of polyurethane formation:

$$\underset{\mathbf{I}}{CH_3NCO} + \underset{\mathbf{II}}{CH_3OH} \rightarrow \underset{\mathbf{III}}{CH_3NHCOOCH_3}, \quad (1)$$



$$\underset{\mathbf{IV}}{C_6H_5NCO} + \mathbf{II} \rightarrow \underset{\mathbf{V}}{CH_3NCOOCH_3}, \quad (2)$$



$$\mathbf{I} + \mathbf{III} \rightarrow \underset{\mathbf{VI}}{CH_3N(COOCH_3)CONHCH_3}, \quad (3)$$

EXPERIMENTAL

Quantum-chemical calculations were performed using the Gaussian 03 software package [12] with full geometry optimization involving determination of the most energetically favorable conformations of the compounds. Initially the molecular geometry was optimized by the PM3 semiempirical method, after which the results obtained were used in DFT calculations using the PBE1PBE/6-31G(d) hybrid method. This method was recommended for calculating thermodynamic characteristics of organic compounds [13, 14]. Initially, we calculated the Gibbs energies, enthalpies, and entropies of formation of the compounds appearing in Eqs. (1)–(12). The thermodynamic characteristics of reactions were determined as differences between the corresponding quantities for the reaction products and reactants. The entropies were calculated taking into account the translation, rotation, and vibration degrees of freedom.

Pre-isocyanate from polyethylene glycol adipate (PEA) and 2,4-toluene diisocyanate (2,4-TDI). A thoroughly dried PEA sample (M = 1874 amu, 1.79 wt % OH groups) was mixed with freshly distilled 2,4-TDI. The NCO : OH molar ratio was 2 : 1 and 1.6 : 1 in preparation of pre-isocyanates for SKU-6 and SKU-7, respectively. The reaction mixture was heated in a flow of dry nitrogen at 80°C with stirring to attain a constant concentration of NCO groups.

Castable polyurethane elastomer SKU-6. The pre-isocyanate was mixed with trimethylolpropane (TMP) and 1,4-butanediol (BD) to obtain the molar ratio PE : 2,4-TDI : TMP : BD = 1 : 2 : 0.32 : 0.24. The resulting mixture was cast into molds and kept first at 120°C for 24 h and then at room temperature for no less than 2 weeks.

Castable polyurethane elastomer SKU-7. The pre-isocyanate was mixed with MOKA melt to obtain the molar ratio PEA : 2,4-TDI : MOKA = 1 : 1.6 : 0.4. The subsequent work-up was the same as for SKU-6.

Castable polyurethane elastomer SKU-OM. The pre-isocyanate was mixed with 2,4-TDI to obtain the molar ratio PEA : 2,4-TDI = 1 : 1.25. Then 2,4,6-tris(dimethyl-aminomethyl)phenol (0.25 wt %) was added as catalyst of trimerization of isocyanate groups. The resulting mixture was cast into molds, which were kept at 80°C for 25 h and then at room temperature for no less than 2 weeks.

The tensile strength was determined with a TR-3 kN tensile-testing machine equipped with a temperature-controlled chamber. The clamp velocity was 500 mm min^{-1}.

We compared the thermodynamic functions of the model reactions involving an aliphatic isocyanate (methyl isocyanate **I**) and an aromatic isocyanate (phenyl isocyanate **IV**) to find how the π–π conjugation of the isocyanate group with the aromatic ring affects the thermodynamic functions of the transformations. The results are listed in the table.

As for the correctness of these data, the following can be noted. The enthalpy of the reaction of isocyanic acid with compound II, calculated from the enthalpies of formation in the gas phase (kJ mol^{-1}) of isocyanic acid (–104 [15]), methanol (–201 [16]), and methyl carbamate (–425 [17]), is –120 kJ mol^{-1}.

This is a reaction of a nonconjugated isocyanate with a primary alcohol. The enthalpy of the liquid-phase reaction of isocyanate **IV** with 1-butanol is –84 [18] or –105 kJ mol^{-1} [19], according to data of differ-

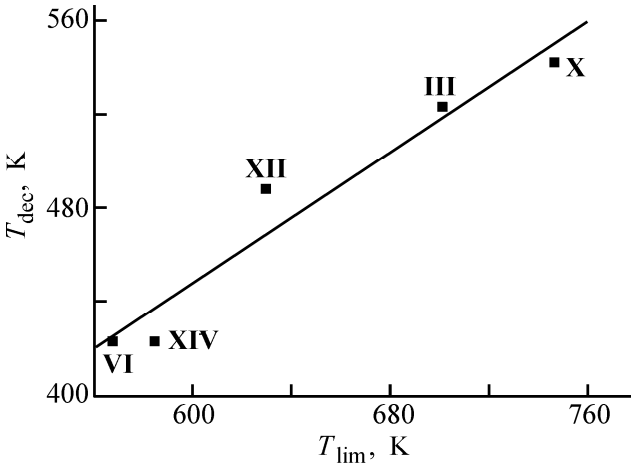
ent authors. The enthalpy of reaction (10) in 1,4-dioxane is –82 kJ mol^{-1} [20]. The heat of trimerization of isocyanate **I** in the gas phase is estimated in [21] at –278 kJ mol^{-1} [21]. All these values are close to the results of our calculations, which supports their reliability. Bonetskaya et al. [22] reported for the enthalpy of reaction (8) in diglyme the value of –52 kJ mol^{-1}. This value is apparently overestimated, as it suggests a low thermal stability of isocyanurate rings, which is in-consistent with the available experimental data [1–3].

The data we obtained show that all the reactions with methyl isocyanate **I** are more exothermic than those with phenyl isocyanate **IV**. This is primarily due to the fact that the reactions with **IV** involve break of the conjugation between the isocyanate group and aromatic ring, with a significant energy loss. The Gibbs energies of reactions involving the aliphatic isocyanate are also more negative, compared to the related reactions with the aromatic isocyanate. Therefore, urethanes derived from aliphatic isocyanates should be more thermostable than those derived from aromatic isocyanates. This is indeed the case. Urethanes derived from aliphatic isocyanates and alcohols start to dissociate at 250°C, and those derived from aromatic isocyanates, at 200°C [23]. The stronger exothermicity of reactions of alcohols with aliphatic isocyanates, compared to aromatic isocyanates, was shown in [24]. These data suggest that, to obtain polyurethanes with a higher temperature limit of operation, it is necessary to choose di- and polyisocyanates in which the isocyanate group is not conjugated with the aromatic ring.

Synthesis of polyurethanes can be accompanied by formation of *N*-alkoxycarbonylbiurets [reactions (5) and (6)]. These compounds show low stability. Therefore, involvement of these functional groups in the formation of the structure of polyurethanes is questionable. Among the products under consideration, isocyanurates **X** and **XI** are highly stable. The stability of these heterocycles is primarily due to the fact that their formation is characterized by high negative enthalpies of reactions (7) and (8).

To quantitatively characterize the thermal stability of particular functional groups in polyurethanes on the basis of thermodynamics of the model compounds, we calculated the limiting temperatures T_{lim} of their stability, i.e., the temperatures at which the Gibbs energies of the reactions of their formation become zero. The limiting temperatures were calculated as follows:

$$T_{lim} = \Delta H/\Delta S.$$



Based on the limiting temperatures (see table), we can rank structural fragments of polyurethanes in the following orders of thermodynamic stability: for reactions with aliphatic isocyanates: isocyanurates > urethanes > ureas > biurets > allophanates > *N*-alkoxycarbonylbiurets; for reactions with aromatic isocyanates: urethanes > ureas > isocyanurates > biurets > allophanates > *N*-alkoxycarbonylbiurets.

The thermodynamic functions of the reactions, given in the table, show that the transformations leading to allophanates and biurets become essentially reversible with increasing temperature. If the data obtained for model reactions adequately reflect the thermodynamic stability of various functional groups in polyurethanes, polyurethanes containing large amounts of these groups should exhibit a relatively low thermal stability. The experimental data are consistent with this conclusion. It is believed that long-term service of polyurethane items is possible only at temperatures not exceeding 80°C [25].

We supplemented the quantum-chemical calculations by experimental determination of the tensile strength in relation to temperature for a series of castable polyurethane elastomers: SKU-6, SKU-7, and SKU-OM. All these rubbers contain ester groups as main structural fragments. In addition, SKU-6 rubber contains urethane and allophanate groups; SKU-7, urethane, urea, and biuret fragments; and SKU-OM, urethane and isocyanurate groups. At 25°C, the breaking tensile stress for SKU-6, SKU-7, and SKU-OM rubbers is 38.6, 43.4, and 42.2 MPa, respectively. At 100°C, the breaking stress is 5.0, 3.0, and 13.5 MPa, respectively. As can be seen, only SKU-OM rubber exhibits an acceptable strength at elevated temperatures. These data show that the thermodynamic functions of model reactions do correlate with those of reactions yielding definite functional groups in polyurethanes. Furthermore, there is satisfactory correlation between T_{lim} in model reactions and the decomposition temperatures of separate functional groups in polyurethanes (see figure). The decomposition temperatures are characterized by a definite interval of values [26]. When plotting the diagram, we took the mean values. The correlation is described by the equation

$$T_{lim} = 27.480 + 0.70T_{dec} \quad (R = 0.973).$$

The existance of this correlation indicates that the differences in thermal stability between functional groups in polyurethanes are primarily due to differences in the thermodynamic parameters of their forma-

Decomposition temperature T_{dec} of various functional groups in polyurethanes [25] vs. the limiting temperature of stability of model compounds, T_{lim}.

tions. The thermodynamic parameters of the intermolecular interaction between polyurethane macromolecules make a contrast contribution accounted for by the free term in the equation.

The thermodynamics of dimerization of isocyanate **IV** in toluene was studied in [27]. It follows from these data that, even at low temperatures, the equilibrium of this reaction is strongly shifted toward the isocyanate. These results indicate that uretidinedione groups cannot determine the functional composition of polyurethanes to a significant extent, because their synthesis, as a rule, involves high temperatures.

All the reactions (1)–(12) are characterized by large negative entropies. The transformations we considered are models for the formation of particular functional fragments in polyurethanes. The large negative entropies of the reactions account for the low heat resistance of polyurethane items, because they lead to an increase in the Gibbs free energy with temperature. As a result, the reaction equilibria become shifted toward the reactants.

CONCLUSIONS

(1) All reactions with methyl isocyanate are more exothermic than the analogous reactions with phenyl isocyanate. All the reactions are characterized by large negative entropies.

(2) The presence of allophanate and biuret fragments in the structure of polyurethanes decreases their heat resistance.

Abstract—Alkenylation of a series of aromatic compounds with 1,3-pentadiene was studied. The oligomeric alkenylation products cured with hexamethylenetetramine were used for modifying elastic-strength properties of elastomeric compounds and improving the compatibility of the elastomers with silicic acid fillers.

DOI: 10.1134/S107042720808020X

The growing requirements to consumers' properties, service characteristics, and environmental safety of modern tires and general mechanical rubber goods call for development and application of new high-performance auxiliary ingredients, modifiers of polymer compounds considerably enhancing their strength. Phenolic compounds (resorcinol, 5-methylresorcinol) in combination with hexamethylenetetramine, widely used as modifying additives in formulations of rubber stocks and showing fairly high performance, have certain drawbacks [1].

As a continuation of previous studies [2–4] of acid-catalyzed alkenylation of shale resorcinols with 1,3-pentadiene (piperylene), it was interesting to further expand the range of aromatic compounds subject to alkylation with the aim to find new, more effective modifying additives to skimming rubber stocks based on general-purpose rubbers. Alkenylated derivatives introduced into an elastomeric matrix with the aim to improve the physicomechanical parameters of ready rubber items enhance the adhesion strength of rubber–metal cord systems under the conditions of steam and salt aging and positively affect the compatibility of rubbers with silicic acid fillers.

In this study, we examined the composition of alkylates formed by some aromatic compounds with 1,3-pentadiene under the conditions of phosphoric acid catalysis and evaluated the character and efficiency of the modifying action of the alkenylation products in polymer compounds.

EXPERIMENTAL

The following compounds were subjected to alkenylation with 1,3-pentadiene. Aromatic compounds with hydroxy group directly bonded to the aromatic ring: phenol, *p*-cresol, *p*-nonylphenol (Agidol 21, distilled, T grade), salicylic acid, a-naphthol, resorcinol, 5-methylresorcinol, and Alkirez-1 (a technical mixture of dihydric phenols mainly consisting of 5-methylresorcinol, 2,5-dimethyl-resorcinol, and their closest homologs); aromatic compounds containing no phenolic hydroxyls: styrene, a-methylstyrene, and benzoic acid.

The alkenylation was performed in the melt at 140°C. The molar ratio aromatic compound : 1,3-pentadiene : orthophosphoric acid was 1 : 2 : 0.1. The reaction was performed in two modes: (a) in the course of 5 h in a 30-cm^3 steel autoclave without forced stirring; (b) for 2–2.5 h in a 250 cm^3 glass vessel equipped with a power-driven stirrer, a dosing unit, and a reflux condenser. In the latter case, 1,3-pentadiene was added to the reaction mixture gradually in small portions.

The components were separated on a 30-m quartz capillary column coated with a nonpolar stationary phase, poly(methyl–5% phenyl)siloxane. In identification of the chromatographic peaks, we used along with the mass spectra the estimated boiling points and retention indices of the suggested compounds, obtained using the ACD Labs 4.0 and NIST MS Search 2.0 soft-

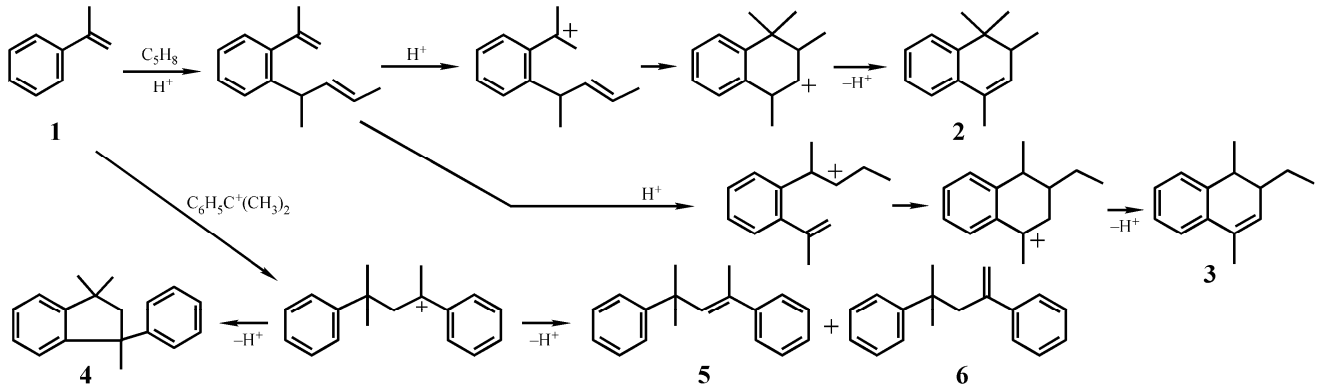
ware.The reaction products were identified by gas chromatography–mass spectrometry (GC–MS) on a Shimadzu GCMS-QP 2010 quadrupole device.



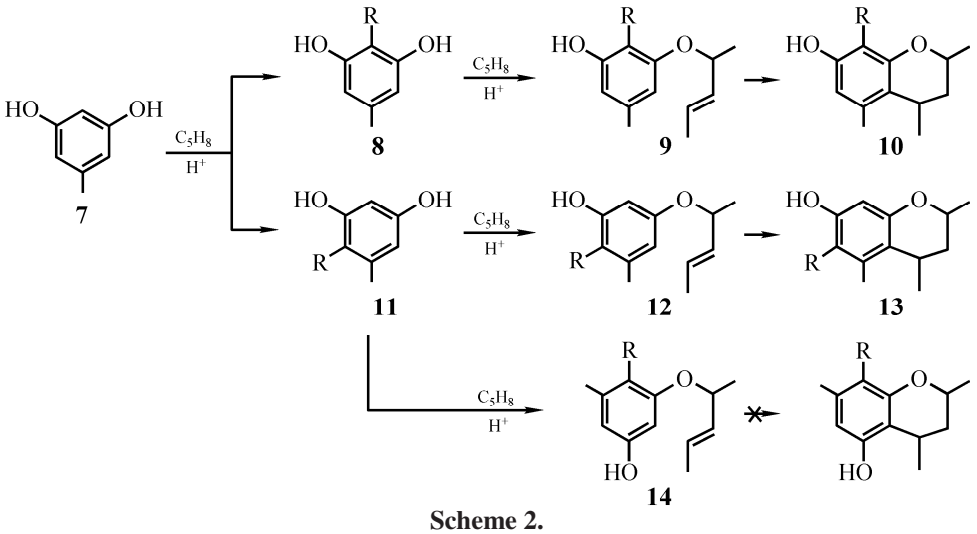
The quantitative composition of reaction mixtures was determined using a Kristall-2000M gas chromatograph equipped with a thermal conductivity detector. A 1-m steel column, 3 mm i.d., was packed with Chromaton N-AW-HMDS (0.25–0.315 mm) + 15% Apiezon L. The column was heated from 90 to 300°C at a rate of 16 deg min^{-1}. The flow rate of the carrier gas (He) was 20 $cm^3 min^{-1}$.

A TLC analysis was performed on Silufol UV-254 plates, using toluene as eluent. The component spots were developed with iodine vapor.

To convert the alkenylation products to the commercial form convenient for further use in rubber stock formulations, they were treated with hexamethylenetetramine. Transformation of the alkylate into the oligomeric form (“curing”) was monitored by the dropping point measured by the ring-and-ball method according to GOST (State Standard) 11 506. The iodine number of the products was determined in accordance with GOST 17 823.2–72.

Data on the composition of reaction mixtures obtained by alkenylation of aromatic compounds with 1,3-pentadiene are listed in the table.

A GC–MS analysis showed that the reaction of α-methylstyrene **1** with 1,3-pentadiene yields four monoalkenylation products whose structure cannot be unambiguously determined from the mass spectra because of their similarity for the suggested isomers. However, the major product of a-methylstyrene monoalkenylation (>60% of the total amount) is, presumably, compound **2** (1,1,2,4-tetramethyl-1,2-dihydronaphthalene) or **3** (1,4-dimethyl-2-ethyl-1,2-dihydronaphthalene).



Scheme 1.

The reaction mixture obtained from α-methyl-styrene contains no dialkenylation products but contains dimers of the starting α-methylstyrene: 1,1,3-trimethyl-3-phenyl-2,3-dihydro-1*H*-indene **4**, (2-methyl-4-phen-ylpent-3-en-2-yl)benzene **5**, and (2-methyl-4-phenylpent-4-en-2-yl)benzene **6** in 75 : 10 : 15 molar ratio. This composiiton of the α-methylstyrene alken-ylation products agrees with the measured iodine nu-ber, 78.0 (value of 76.7, calculated on the assumption that the major monoalkenylkation products contain no more than one olefinic or cycloolefinic double bond in the molecule).

Transformations similar to those shown in Scheme 1 are also observed in alkenylation of styrene with piperylene.

A TLC analysis showed that the alkenylation of salicylic and benzoic acids with 1,3-pentadiene occurrs at the carboxy group and yields the corresponding pent-3-en-2-yl esters. With salicylic acid, the alkenylation also partially occurrs in the benzene ring owing to the activating effect of the phenolic hydroxyl.

Specifically the alkenylation of compounds containing phenolic hydroxy groups is of most interest from the standpoint of using the products as modifiers for polymer compounds. A detailed GC–MS analysis of the alkylate obtained from 5-methylresorcinol **7** allowed us to suggest the following scheme of its alkenylation with 1,3-pentadiene.

Scheme 2.

We found that the monoalkenylated fraction is composed of approximately equal amounts of 1,3-dihydroxy-5-methyl-2-(pent-3-en-2-yl)benzene **8** and 1,3-dihydroxy-5-methyl-4-(pent-3-en-2-yl)benzene **11**, formed by introduction of the alkenyl group into position 2 or 4 of the aromatic ring of 5-methylresorcinol, respectively. Further reaction of these monoalkenylation products with 1,3-pentadiene involves phenolic hydroxyls and yields mixed C,O-dialkenylation products: 5-methyl-2-(pent-3-en-2-yl)-3-(pent-3-en-2-yloxy)phenol **9**, 5-methyl-6-(pent-3-en-2-yl)-3-(pent-3-en-2-yloxy)phenol **12**, and 5-methyl-4-(pent-3-en-2-yl)-3-(pent-3-en-2-yloxy)phenol **14**, which are present in the reaction mixture in comparable amounts.

Under the reaction conditions, the dialkenylation products undergo partial cyclization. Compounds **9** and **12** form 2,4,5-trimethyl-8-(pent-3-en-2-yl)-3,4-dihydro-2*H*-benzo[*b*]pyran-7-ol 10 and 2,4,5-trimethyl-6-(pent-3-en-2-yl)-3,4-dihydro-2H-benzo[*b*]-pyran-7-ol **13**, respectively. Compounds **10** and **13** can be considered to be products of intramolecular electrophilic substitution in the aromatic ring with alkenyloxy groups as electrophilic agents. On the whole, the fraction of dialkenylated compounds contains about 70% C,O-dialkenylation products **9**, **12**, and **14**, with the remaining 30% being chroman derivatives **10** and **13**. It should be noted that we did not detect the expected cyclization product of compound **14** in the reaction mixture in noticeable amounts.

Bringing the alkylate obtained by the reaction of 1,3-pentadiene with 5-methylresorcinol or Alkirez-1 into the subsequent reaction with hexamethylenetetramine gives an oligomeric (so-called "cured") product with a softening point of about 75°C. A special study showed that nearly the whole available amount of the monoalkenylated dihydric phenol **8** or **11** undergoes condensation to give Resorcinol–amino aldehyde resin, whereas dialkenylated compounds **9**, **10**, and **12–14** remain unchanged and control the melting point of the resulting oligomer. The cured product with a higher

degree of oligomerization would have an unacceptably high melting point, which would make impossible its further use as a modifier of elastomeric compounds because of the insufficiently uniform distribution in the rubber stock.

The piperylene alkylate of Alkirez-1 condensed with hexamethylenetetramine (AP-U resin) was tested as modifier for improving the elastic-strength properties of thermoplastic elastomers (TPEs) of the composition SKEPT Elastokam 6305–PVD 10 803-020 (50:50 ratio), filled with BS-100 white black. The TPE modification with AP-U resin enhanced the strength (by up to 75%) and raised the relative elongation (by up to 20%) relative to the unmodified formulations.

The use of a silicic acid filler in the polymer compounds without addition of a phenolic modifier, as well as the modification without silicic acid filler, has nearly no effect on the TPE strength. The use of the reinforcing filler and oligomeric phenolic modifier in a combination affords a very significant improvement of the properties, i.e., a synergistic effect is observed.

Apparently, the alkenylresorcinol oligomer interacts, on the one hand, with the surface of BS-100 filler via phenolic hydroxyls and, on the other hand, with the rubber phase of TPE via alkenyl fragments, which strongly enhances the reinforcing effect of the filler [5].

In 2007, two batches of AP-U resin (25 kg) were produced on a pilot installation at the Central Plant Laboratory of the Kauchuk Joint-Stock Company (Sterli-tamak, Bashkortostan, Russia).

CONCLUSIONS

(1) Alkenylation of 5-methylresorcinol with 1,3-pentadiene yields complex mixtures of mono- and dialkenylated products. Monoalkenylation mainly occurs at the aromatic ring, whereas introduction of the second alkenyl group yields C,O-dialkenylated derivatives subsequently undergoing partial cyclization.

(2) Introduction of AP-U resin into polymer compounds based on thermoplastic elastomers is accompanied by a considerable enhancement of the strength characteristics of the ready items owing to the synergistic effect of interaction of the hydroxylcontaining moiety of the resin with the filler and of alkenyl substituents with the elastomer matrix.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Selective Interactions of Ionic Acrylamide Copolymers on Flocculation Properties with Respect to Titanium Oxide in Aqueous Salt Solutions

Abstract—The kinetics of unhindered sedimentation of a titanium dioxide suspension (as model dispersed system) was studied, and the effect of the concentration and mode of addition of various formulations based on anionic and cationic acrylamide copolymers on their flocculation properties in aqueous salt (NaCl) solutions was evaluated.

DOI: 10.1134/S1070427208080211

The effect of macromolecular compounds [in particular, polyacrylamide flocculants (PAAFs)] and their mixtures on various physicochemical processes such as adsorption, flocculation, flotation, and filtration are still of particular importance in both theoretical and practical aspects [1–3]. As compared to individual polymer components, their mixtures provide more direct and efficient control over the properties of various model and real dispersed systems (DSs) and, thus, of the aggregation and sedimentation processes occurring in these systems. The above differences are primarily due to the specific interactions of the functional groups in various macromolecules, which change their conformation state and, as a result, make stronger or weaker the effect of copolymer mixtures with respect to certain fixed parameters of dispersed systems [4, 5].

Therefore, the kinetic studies using a relatively poorly studied model DS (titanium dioxide TiO_2 suspension) are a promising way to evaluate the effect of selective interactions in mixtures of ionic PAAFs on flocculation processes in multicomponent systems. As compared to common DSs used in Russia (such as kaolin, ocher, copper oxide), the given system exhibits more stable surface characteristics and higher surface charge density ($\zeta = -55$ mV) [6, 7]. Previously, we have studied [8] the kinetic features of hindered sedimentation of an ocher suspension in the presence of binary mixtures of ionic (anionic and cationic) PAAFs with a high content of ionic groups. It is of particular interest to study the flocculation kinetics of a TiO_2 suspension in the mode of unhindered sedimentation, using ionic [anionic (A) and cationic (C)] random polymers of acrylamide (AA) with a high molecular weight ($M > 2 \times 10^6$) and lower or similar concentrations of ionic groups β.

We emphasize that the positively and negatively charged fragments in both anionic and cationic AA copolymers are identical in chemical nature and have similar lengths of the flexible nonionic acrylamide fragments. This fact makes it a priori unnecessary to take into account various difficultly controllable specific interactions of nonionic fragments in mixtures of oppositely charged ionic copolymers, which is of particular importance for polymer mixtures in passing from aqueous to aqueous salt solutions.

EXPERIMENTAL

In our study, we examined the flocculation power of various AA copolymers, using a rutile (TiO_2) suspension [TU (Technical Specification) 24.1-05 762 329-001–2003] with an average particle radius $R = 8.7 \times 10^6$ m and density $\rho = 3.9 \times 10^3$ kg m^{-3}. The following ionic PAAFs were used: anionic (A) random copolymer of acrylamide and sodium acrylate (molecular weight $M = 6.7 \times 10^6$, content of ionic groups $\beta = 17.5\%$) and cationic (C) random copolymer of acrylamide and dimethylaminoethyl methacrylate hydrochloride ($M = 2.3 \times 10^6$, $\beta = 16.3\%$).

The flocculation kinetics of the TiO_2 suspension in the mode of free (unhindered) sedimentation in the presence of various AA copolymers was evaluated by sedimentometric analysis in a 400-ml cylinder, using a VT-500 torsion balance. In all the tests, the initial con-

(*1*) No additives; with addition of copolymer mixtures, binary: (*2*) AC, (*3*) CA, and (*4*) 2(1/2A + 1/2C); quaternary: (*5*) ACAC, (*6*) CACA, and (*7*) 4(1/2A + 1/2C); the same for Fig. 3.

centration of the dispersed phase was constant, c_d = 0.3%. The TiO_2 suspensions were clarified for 1 day before adding polymer mixtures to aqueous salt solutions with various ionic strengths (adjusted by adding various amounts of NaCl). The rutile suspension was mixed with a perforated disk stirrer (12 holes), which was slowly shifted in the cylinder 10 times in the vertical direction.

The viscometric analysis of the PAAF solutions was performed on an Ostwald viscometer (capillary diameter 0.54 mm). The correction for the kinetic energy of the flow was less than 1.5% and, thus, was neglected in the calculations of the reduced viscosity η_{sp}/c of copolymers and their mixtures by the following expression:

$$\eta_{sp}/c = (\tau - \tau_0)/\tau_0 c, \quad (1)$$

where τ and τ_0 are the flow times of the polymer solution of concentration c and the solvent, respectively.

To prepare the mixture of the ionic copolymers A and C of volume $V_A + V_C$ with fixed concentration $c = c_0$ and the ratio of the polymer components w_A =[A]/([A] + [C]), we mixed solutions of A and C (at [A] = [C] = c_0) in the following volume ratio: $V_A = w_A(V_A + V_C)$ and $V_C = (1 - w_A)(V_A + V_C)$. With this approach, the contraction in the aqueous and aqueous salt solutions of mixtures of copolymers A and C is less than 0.01%, and thus we can neglect it in treat-ment of the flocculation, viscometric, conductometric, and optical density data. The optical densities Q of the solutions of PAAFs and their mixtures were de-termined on a UNICO-1200 spectrophotometer.

The electrical conductivity of PAAF solutions was measured with an ANION-4100 conductometer with a working cell volume of 10 cm^3.

First, to evaluate the optimal charge of the flocculants in the mixtures, we studied the flocculation kinetics of a TiO_2 suspension in the presence of various concentrations of ionic polymer flocculants A and C (Fig. 1). Based on these data, we determined the optimal (standard) concentration $c = 4.98 \times 10^6$ % for all the further flocculation tests with various mixtures of copolymers A and C.

As shown in a series of papers [1, 8–10], on passing from water-soluble copolymers to binary mixtures, their effect on flocculation processes increases. Therefore, it was of interest to study the flocculation kinetics of the given model system (TiO_2), using not only binary (AC and CA), but also more complex systems of copolymers A and C (ACA, CAC, ACAC, and CACA).

Some kinetic curves of TiO_2 sedimentation with binary and quaternary systems of copolymers A and C in aqueous solution are shown as examples in Fig. 2. As can be seen, binary and quaternary systems of copolymers A and C have similar overall compositions and, thus, comparison of their flocculation properties would allow certain conclusions about the specific in-

teractions of the polymer components in various modes of their addition. Our experimental data suggest a strong dependence of the flocculation properties on the mode of addition of the polymer components to the disperse system. As can be seen, the flocculation performance decreases in the case of a simultaneous addition of the copolymers (1/2A+1/2C, Fig. 2, curves *4* and *7*) as compared to successive addition of these components (Fig. 2, curves *2*, *3* and *5*, *6*). This result unambiguously indicates that copolymers A and C, when added simultaneously as DS flocculants, show an antagonistic effect. In this paper, we show that this is due to sharp changes in the conformation state of the A and C macroions already in the stage of formation of the binary mixture (1/2A + 1/2C).

Comparison of the kinetic curves for binary (AC, CA, Fig. 2, curves *2*, *3*) and quaternary (ACAC, CACA, Fig. 2, curves *5*, *6*) systems with similar total compositions indicates that the AC and ACAC systems (when copolymer C is added second and fourth) exhibit higher flocculation properties as compared to the CA and CACA systems. On the one hand, this effect is probably due to the irreversible adsorption of macromolecules and, on the other hand, to different conformation states of macromolecules of copolymers A and C on the TiO_2 surface upon addition of a new copolymer additive.

As can be seen from published data, flocculation in the presence of macromolecular compounds may be due either to the adsorption of a macromolecule on the surface of the dispersed phase (DP) particles, or to their intermolecular binding with the previously adsorbed macromolecules to form links, interweavings, secondary structures, and aggregates [11]. It should be noted that the molecular binding is possible not only in the stage of interaction of DP particles with the already formed adsorption layer, but also in the stage of formation of the surface layer in the course of interaction of macromolecule aggregates with the TiO_2 surface [12]. Taking into account the high negative charge of TiO_2 particles ($\zeta = -55$ mV) and the kinetic data (Fig. 2), we suggested that formation of bridges in the AC and ACAC systems is more probable than that in CA and CACA systems [13]. Obviously, in such an approach the probability of formation of anchor bonds (inefficient in flocculation) changes in the opposite direction.

In treatment of the experimental kinetic data we used the procedure described previously in [14], which allows evaluation of the integral and differential characteristics of the flocculation in the presence of copolymers A and C. The integral parameters of the flocculation effect D and flocculation activity λ were calculated by the following equations:

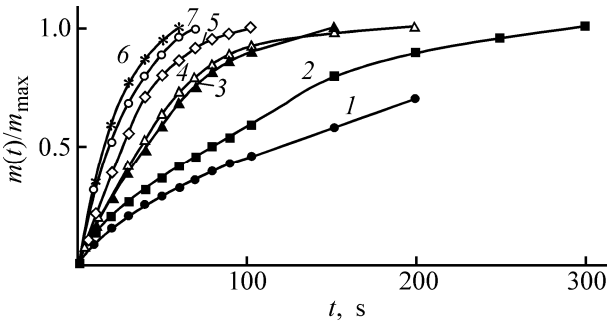

Fig. 3. Kinetic curves of sedimentation of the TiO_2 suspension at dosed charging of the A + C copolymer systems at $I = 0.05$ N.

$$D = \frac{\bar{u}_i}{\bar{u}_0} - 1, \quad (2)$$

$$\lambda = \left(\frac{\bar{u}_i}{\bar{u}_0} - 1\right)\frac{1}{c} = \frac{D}{c}, \quad (3)$$

where $\bar{u}_i$ and $\bar{u}_0$ are the average rates of the rutile sedimentation [at fixed $m(t)/m_{max}$ 0.7] in the presence of AA copolymer mixtures (concentration c) and without them, respectively.

The differential parameters of the flocculation effect D_i^* and flocculation activity λ_i^* were calculated by the equations reported in [8]:

$$D_i^* = \frac{\bar{u}_i}{\bar{u}_{i-1}} - 1,$$

$$\lambda_i^* = \frac{\bar{u}_i}{\bar{c}_i^*},$$

where $\bar{u}_i$ and $\bar{u}_{i-1}$ are the average rates of the rutile sedimentation at dosed addition of $(i - 1)$th and ith polymer doses, and $\bar{c}_i^*$ is the concentration of ith polymer dose.

It should be noted that, at dosed addition of the polymer components, the differential quantitative parameters of the flocculation D_i and λ_i allow evaluation of the contribution of each successively added polymer dose to the total flocculation effect.

In the second stage of our studies, to illustrate the potential of the kinetic analysis for finding efficient ways to control the sedimentation stability of the disperse system, we studied the flocculation of the TiO_2 suspension in aqueous salt (NaCl) solutions with various ionic strengths, using binary, ternary, and quaternary systems of copolymers A and C. Figure 3 shows as an example the kinetic curves of TiO_2 sedimentation in the presence of mixtures of copolymers A and C in the solution with $I = 0.01$ N. As can be seen from

the comparison of Figs. 2 and 3, passing from aqueous (I = 0) to aqueous-salt (I = 0.01 N) solutions causes strong changes in the flocculation parameters for similar polymer systems. The flocculation par-ameters in aqueous-salt solutions are summarized in Table 1. The values of the flocculation effect D_{calc} for the systems of copolymers A and C were calculated from the following equations:

$$D_{calc}(AC) = D_{calc}(CA) = (1 + D_A)(1 + D_C) - 1, \quad (4)$$

$$D_{calc}(ACA) = (1 + D_A)^2(1 + D_C) - 1, \quad (5)$$

$$D_{calc}(CAC) = (1 + D_A)(1 + D_C)^2 - 1, \quad (6)$$

$$D_{calc}(ACAC) = D_{calc}(CACA) = (1 + D_A)^2(1 + D_C)^2 - 1. \quad (7)$$

As can be seen from the experimental data (Table 1), the experimental D values are noticeably higher than the calculated values, which is probably due to the occurrence of selective interactions of the charged fragments of macromolecules A and C on the DP particle surface, and heterocontacts of macroions A and C appearing in the course of adsorption promote coarsening of the floccules and formation of bridges between the DP particles. This conclusion is confirmed by comparison of the experimental data on the ratio of the differential parameters λ^*_{CA}, λ^*_A and λ^*_{AC}, λ^*_C in aqueous salt solutions with systems CA, AC and CACA, ACAC, namely, $\lambda^*_{CA} \geq \lambda^*_A$ and $\lambda^*_{AC} \geq \lambda^*_C$. At dosed addition of the polymer mixture (1/2A + 1/2C) as a binary or quaternary additive, the flocculation effect D is significantly smaller as compared to the flocculation effect of the binary or quaternary systems of components A and C added to the rutile suspension successively.

Our experimental data listed in Table 1 indicate that the mode of addition of the polymer components affects the formation of floccules and, thus, such their important properties as the average size of the floccules, their size distribution, density, and shape asymmetry [15]. The observed effect of the modes of copolymers addition and differences in the structures of the resulting floccules are primarily due to the differences in the parameters of the electrical double layers at the DP particles. Since the adsorption of macromolecules on the DP particles in mainly irreversible [11], with complication of the polymer mixture, the forming more complex (e.g., ternary) floccules retain certain elements of the simpler aggregates (in our case, binary) in their modified structure [4].

Data on interactions of polymer components are necessary to understand dependences of the macroscopic sedimentation process in complex multicompo-

nent systems in the presence of copolymers A and C. Such interactions can be judged from the data of viscometric analysis [16]. To evaluate the conformational changes, we use the well-known Flory equation:

$$\eta M = \Phi(\bar{R}^2)^{0.5}, \quad (8)$$

where $[\eta] = \lim_{c\to 0}(\eta_{sp}/c)$ is the intrinsic viscosity; $(\bar{R}^2)^{0.5}$, root-mean-square radius of inertia of the macromolecule; and Φ, Flory constant.

Severe problems appear even in the step of evaluation of $[\eta]$ for electrolytes A and C and especially for their mixtures, because the dilution at concentrations $c \to 0$ is nonisoionic [16]. To overcome this problem, we used the De Gennes principle of invariance [17]. With the reduced viscosity $[\eta_{sp}/c]$ used instead of $[\eta]$ at final relatively low polymer concentrations c, the Flory equation can be transformed as follows:

$$[h_{sp}/c]^{1/3}M = \Phi'(\bar{R}^2)^{0.5}, \quad (9)$$

where Φ' is a constant.

It is not improbable that the constant Φ' is not identical to the Flory constant Φ, but this is not critical for further analysis, because the most important fact is that $\Phi' = \text{const}$ at fixed molecular weights of the (co)polymers.

Based on expression (9) for quantitative evaluation of the selective interactions between macromolecules of varied nature at a certain fixed concentration of the binary copolymer mixture (c = const), we can use the dimensionless parameter F [8, 18]:

$$F = (h_{sp}/c)^{1/3}_{exp}\,(h_{sp}/c)^{-1/3}_{calc} - 1. \quad (10)$$

On applying the rule of additivity of the contributions of copolymers A and C to the viscosity of the binary mixture, the calculated values $(h_{sp}/c)_{calc}$ can be determined as follows:

$$(h_{sp}/c)_{calc} = w_A(h_{sp}/c)_A + (1 - w_A)(h_{sp}/c)_C\,. \quad (11)$$

where w_A is the weight fraction of copolymer A in the mixture.

It is obvious that the parameter F determined by the above procedure is a reliable and convenient characteristic of the intermolecular interactions of the polymer components upon their mixing. Actually, the condition $F = 0$ [and thus $(h_{sp}/c)^{1/3}_{exp} = (h_{sp}/c)^{1/3}_{calc}$] suggests the absence of specific interactions between copolymers A and C. The other limiting case ($F = -1$) is typical of systems in which copolymers A and C form very compact interpolymer complexes (of globule type) [19]. When $F > 0$ [i.e., $(h_{sp}/c)^{1/3}_{exp} > (h_{sp}/c)^{1/3}_{calc}$], the heterocontacts being formed between the AC molecules lead to an increase in the effective size of macromolecular aggregates $(\bar{R}^2)^{0.5}_A$ and $(\bar{R}^2)^{0.5}_C$. At $F < 0$ [i.e., $(h_{sp}/c)^{1/3}_{exp} < (h_{sp}/c)^{1/3}_{calc}$], macromolecules are compacted in the presence of macromolecules of another kind, so that $(\bar{R}^2)^{0.5}_A$ and $(\bar{R}^2)^{0.5}_C$ decrease. Specifically this type of the selective interactions was observed for all the compositions of the binary mixture (A + C) because the following conditions were satisfied: $F < 0$ (Fig. 4) and $(h_{sp}/c)^{1/3}_{exp}\,(h_{sp}/c)^{1/3}_{calc} < 1$.

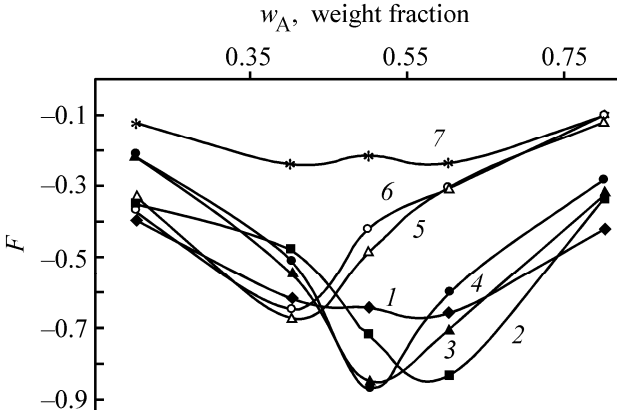

Fig. 4. Parameter F vs. the composition of A + C copolymer mixture. ([A] + [C]) × 10^2, kg m^{-3}: (*1*) 2, (*2*) 4, (*3*, *5*) 6, and (*4*, *6*, *7*) 10. I, N: (*1*–*4*) 0, (*5*, *6*) 0.01, and (*7*) 0.05.

The dependences $F = f(w_A)$ are characterized by a clearly pronounced extremum (minimum) for $w_A \sim 0.5$, which directly confirms the occurrence of strong selective interactions of the ionic fragments of macromolecules of the anionic and cationic AA copolymer. With account taken of the low density of the ionic units in copolymers A and C ($\beta < 20\%$), relatively small values of parameter $F < -0.7$ at $w_A \sim 0.5$–0.6 seem unexpected. This fact suggests that strongly compressed, close to globular, macromolecular aggregates are formed in the above range of the polymer mixture compositions.

In this context, evaluation of the effect of low-molecular-weight electrolytes on the intensity of inter- and intramolecular interactions in polyelectrolytes A and C is of particular importance [18]. We studied the dependences of parameter F on w_A for aqueous-salt solutions (I = 0.01 N) (Fig. 4, curves *5*, *6*). The dependences $F = f(w_A)$ pass through a minimum, which is shifted for curves *5* and *6* (Fig. 4) toward smaller w_A (0.4). Certain increase in parameter F for aqueous-salt solutions with I = 0.01 M, compared to the aqueous solutions, suggests weakening of the selective interactions of macroions A and C. More pronounced changes in the dependences $F = f(w_A)$ are observed as the ionic strength of the solutions increases to 0.05 N (Fig. 4, curve *7*). In this case, the probability of selective electrostatic interactions of the charged macromolecular

Table 2. Results of a conductometric analysis of aqueous solutions of copolymers A and C and their 1 : 1 mixtures

Parameter	Copolymer concentration c, %	
	0.002	0.1
χ_A, S cm^{-1}	6.13	11.7
$\chi_C \times 10^6$, S cm^{-1}	4.85	19.4
χ_{mix}, S cm^{-1}	26.02	36.9
χ_{ad}, S cm^{-1}	2.38	12.4
Y	9.63	2.73

fragments A and C sharply falls, the parameters η_{sp}/c and $(R^2)^{0.5}$ decrease simultaneously, and the parameter F strongly increases, with the minimum in the dependence $F = f(w_A)$ becoming less pronounced.

Along with the viscometric parameter F, the conductometric parameter Y is an additional sensitive characteristic of the selective interactions of the ionic PAAFs:

$$Y = \frac{\chi_{exp}}{\chi_{calc}} = \frac{\chi_{mix} - \chi_0}{\bar{\chi}_{ad}}, \qquad (12)$$

where χ_0 is the electrical conductivity of the solution (water, $\chi_0 = 3.109 \times 10^{-6}$ S cm^{-1}); χ_C and χ_A are the electrical conductivities of the solutions of copolymers A and C; and $\bar{\chi}_{ad}$ is the average electrical conductivity calculated on the assumption of additivity.

The values of Y for two fixed concentrations of the copolymers are given in Table 2. These values indicate that the interaction of macroanion A with macrocation C is accompanied by the formation of NaCl. In the process, the counterions Na^+ and Cl^- escape from "microreactors" (macroions) into the dispersion medium. As a result, χ_{exp} increases, and Y becomes greater than 1. The relationship between the parameters Y for two copolymer concentrations, Y (c = 0.002%) > Y (c = 0.01%), is also quite understandable, because at lower concentrations of A and C the macroion coils have more open conformations, and hence the charged fragments of macroions A and C interact with each other more strongly.

The intense intermolecular interactions of macroions A and C in aqueous salt solutions with the formation of compact structural elements are additionally confirmed by the optical method. The dependences of the optical density Q on the wavelength of incident light at fixed concentration of copolymers [A] = [C] = 0.006% and their 1 : 1 mixture are shown in Fig. 5. In this series of experiments, we used 1 : 1 polymer complex (1/2A + 1/2C) (Fig. 5, curve *3*) to which the calculated amounts of NaCl were added to prepare solutions with the ionic strength I of 0.002, 0.01, and 0.05 N. At low and intermediate ionic strengths, the dependence $Q = f(\lambda)$ lies slightly higher than the basis line, whereas at higher ionic strength (I = 0.05 N) a sharp decrease in the optical density is observed in the entire special range, which is due to partial degradation of compact globular aggregates formed by macromolecules of copolymers A and C. Thus, the dependences $Q = f(\lambda)$ shown in Fig. 5 qualitatively characterize the decrease in the intensity of selective interactions of macroions A and C in passing from aqueous to aqueous-salt solutions with I = 0.05 N.

To evaluate the influence exerted by the mode of addition of the active components (electrolyte and flocculants) on the flocculation properties with respect to TiO_2 suspension in aqueous-salt solutions, we performed a series of experiments at a fixed ionic strength I = 0.0025 N. The kinetic curves for the first (electrolyte and then the mixture of copolymers A and C, curves *2–4*) and second addition mode (mixture of copolymers A and C and then electrolyte, curves *2'–4'*) are shown in Fig. 6. As can be seen, changes in the addition mode significantly affect the flocculation pa-

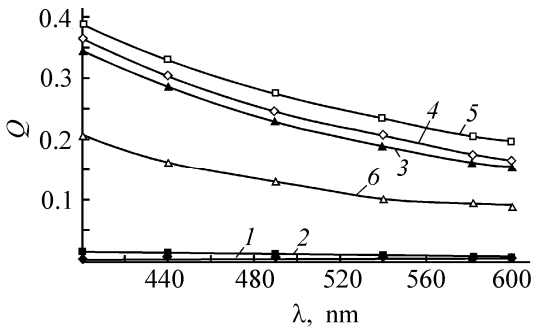

Fig. 5. Optical density Q vs. the wavelength λ of incident light for copolymers (*1*) A, (*2*) C, and (*3–6*) their 1 : 1 mixtures [1/2A + 1/2C]. I, N: (*3*) 0, (*4*) 0.002, (*5*) 0.01, and (*6*) 0.05.

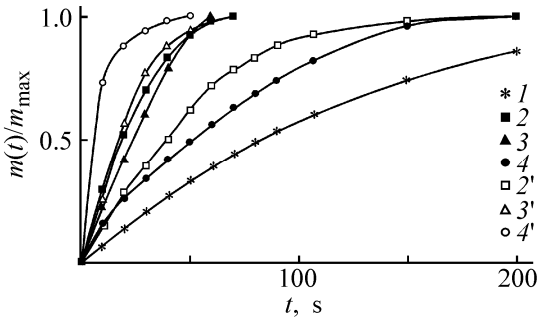

Fig. 6. Kinetic curves of sedimentation of the TiO_2 suspension (*1*) in the absence of flocculants and at dosed charging of copolymers A and C: (*2*, *2'*) ACAC, (*3*, *3'*) CACA, (*4*, *4'*) 4[1/2A + 1/2C]; I = 0.0025 N and c = 19.8 × 10^{-6}%. (*2–4*, *2'–4'*) First and second mode of addition of the copolymers and electrolyte, respectively.

rameters of the system and, thus, the resulting flocculation effect in the aqueous-salt solutions of PAAFs strongly depends on technological parameters.

The observed differences in the flocculation parameters may be due to the irreversibility of the adsorption of copolymers and to the effect of electrolyte ions Na^+ and Cl^- on the electrical properties of the surface of TiO_2 particles and, primarily, on the ζ-potential and physicochemical properties of the localized and nonlocalized adsorption centers and on the length and structure of the adsorption layers. Initial addition of the electrolyte causes strong changes in the parameters of the electrical double layer near the TiO_2 particle and makes the diffusion layer thinner and the electrokinetic potential lower. As a result, the aggregation and sedimentation stability of the disperse system decreases. With successive addition of various mixtures of the ionic PAAFs into the aqueous salt solution, the size of macromolecular globules of the A and C macroions strongly decreases and, thus, the probability of formation of bridges between the dispersed particles also falls.

Thus, the main reason for differences in the kinetics of flocculation of the TiO_2 suspension for the first and second addition modes of addition of the polymer mixtures and electrolyte is due to the differences in the structure and thickness of the electrical double layer, in the conformation of A and C macroions on the surface of dispersed phase particles, and in the size and structure of the resulting floccules.

CONCLUSIONS

(1) in the case of dosed addition of binary, ternary, and quaternary systems of acrylamide copolymers into a rutile suspension, the resulting flocculation effect strongly depends on the selective interactions of the ionic fragments of macromolecules of the anionic and cationic polyacrylamide flocculants on the surface of the dispersed phase. With increasing ionic strength of the solution, the intensity of the selective interaction between the macroions of the anionic and cationic copolymers decreases, and degradation of the polymer aggregates is observed at a higher ionic strength (I = 0.05 N).

(2) The flocculation parameters of polyacrylamide flocculants with respect to the rutile depend on the mode of addition of the polymer flocculants (simultaneously or successively) and on the mode of addition of the polymer flocculants and the electrolyte.

Abstract—The structures of polymeric complexes of chitosan with methyl cellulose, lactoserum protein, gelatin, and polyvinyl alcohol were simulated on a computer. The mechanism of metal captures in cavities of these complexes was analyzed. The conformational and geometric characteristics of polymeric complexes of chitosan were obtained. The properties and structure of complexes in solutions and in the bulk were examined.

DOI: 10.1134/S1070427208080223

Chitosan, a promising biopolymeric material of the XXI century, is characterized by a number of valuable properties, such as biocompatibility, biodegradability, biological activity without toxicity, and availability of raw materials. One of specific features of chitosan as compared to other polymers is its pronounced capacity for intermolecular interactions with other compounds [1–4]. In particular, chitosan forms polymolecular and interpolyelectrolytic complexes and associates with other biopolymers and polar synthetic polymers via hydrogen bonds [5–9]. Such modification of chitosan allows improvement of its characteristics. In this respect, complexes of chitosan with proteins, cellulose derivatives, and water-soluble synthetic polymers, e.g., polyvinyl alcohol are of particulat interest [10, 11]. The search for fields of application of these complexes and development of methods for their production are urgent problems. At present, polymeric complexes of chitosan (PCCs) are poorly studied, especially in the solid state.

EXPERIMENTAL

Chitosan (CS) with a degree of deacetylation of 0.97 was isolated from fresh-water *Branchipus Stagnalis* anthropoda branchiopodas and was used as solutions (5 wt %) in 2% acetic acid. The other chemicals were as follows: food gelatin (G) of P-11 brand [TU (Technical Specification) 9219-017-179 102 261–01); lactoserum protein (LCP) isolated as a by-product in production of pot cheese; 5% aqueous solutions of commercial methyl cellulose (MC, TU 6-9-2344–78) and polyvinyl alcohol (PVA) [GOST (State Standard) 10 779–64].

The molecular weights (MW) of polymers were determined viscometrically: that of chitosan, on an Ubbelohde viscometer in the mixed solvent 2% CH_3COOH + 0.2 M CH_3COONa under standard conditions; those of gelatin, PVA, and lactoserum protein, on a BPZh-2 viscometer in distilled water under standard conditions [12]. The molecular weights of chitosan, gelatin, PVA, and lactoserum protein were 86.9×10^3, 14.4×10^3, 36.0×10^3, 56×10^3, and 83.2×10^3, respectively.

At present, for polymers of complicated structure, some physical characteristics whose experimental determination is difficult or impossible can be determined by calculation. In this study, the physicochemical characteristics of polymers were calculated by computer simulation methods using reference structural characteristics of polymeric chains and functional groups [13–15].

The initial chitosan and its complexes with other polymers were characterized by IR spectra recorded on a Bio-Rad Win-IR spectrometer (NaBr pellets) [16].

The complexes of chitosan with polymers were prepared as follows. A solution of chitosan in aqueous acetic acid was added to a solution of a polymer (methyl cellulose, lactoserum protein, gelatin, or polyvinyl alcohol) in distilled water at a prescribed chitosan-to-polymer ratio, and the resulting mixture was stirred with a magnetic stirrer for 30 min.

The polymeric films were prepared by casting of polymer solutions onto a glass support surface, followed by evaporation of the solvent in a vacuum at 25°C.

The structural characteristics of chitosan-containing complexes were determined by thin-layer chromatography, using Silufol UV-254 plates and various solvents [17].

The particle size of complexes was determined from the "turbidity spectra." The optical density was measured on a KFK-2 photocolorimeter (TU 3-3.1766–82) [18, 19].

The concentrations of phenol and petroleum products (PPs) in wastewater samples were determined by the fluorescence technique on a Flyuorat-02 analyzer of liquids (TU 4321-001-20 506 233–94) [20].

The amounts of metals bound by polymeric complexes were determined by compexometric titration [21]. The water content of the films was determined in accordance with GOST 11 736–78 [22].

The deformation-strength characteristics of films cast from solution of polymeric complexes (tensile strength, relative elongation at break) were determined on an RT-250M-2 tensile-testing mashine (GOST 14236–81) [23].

The swelling kinetics of chitosan films in various solvents (water, acetone, oil) was studied in accordance with GOST 4650–80 [24].

The oxygen index of the polymolecular materials was determined in accordance with GOST 21 793–76 [25]. The coke number was determined thermogravimetrically on heating a weighed sample (0.05–0.5 g) at a prescribed rate in an inert atmosphere to 800–900°C [26]. The flame propagation velocity on ignition of horizontally placed films of the polymolecular complexes was determined in accordance with GOST 28 157–89 [27].

The thermal behavior of the polymeric complexes was studied by thermomechanical analysis [26, 28].

The electrical characteristics of films prepared from solutions of polymeric complexes (electrical resistance, electrical conductivity, permittivity) were measured on an Immitans E7-14 digital device (TU 2.724.013) [29].

Table 1. Calculated physicochemical parameters of chitin and chitosan structural units

Parameter	Chitin	Chitosan
van der Waals volume $\sum_i \Delta V_i$, Å	168.1	132.4
Density, ρ, g cm^{-3}	1.35	1.40
Cohesion energy, $\Sigma \Delta E_i$, J mol^{-1}	78 294	56 272
Cohesion energy density δ, (J cm^{-3})$^{1/2}$	27.8	26.6
Surface tension γ_s, dyne cm^{-1}	40.5	36.6
Permittivity ε	4.5	3.3
Temperature, K:		
glass transition T_g	289	183
degradation of polymer T_d	570	615

Table 2. Calculated characteristics of macromolecules

Macromolecule	$M \times 10^{-3}$	$V_M^h \times 10^3$, cm^3	$h \times 10^6$, cm
Chitosan	86.9	6.5	4.5
Methyl cellulose	56.0	11.5	4.2
LSP	36.0	0.2	2.0
Gelatin	14.4	2.3	2.1
PVA	83.2	1.3	3.5

Table 1 lists physicochemical characteristics of chitin and chitosan fragments, determined in this study by the computer simulation technique.

The following volume parameters of polymeric complexes were calculated: the mean statistical distance between the ends of the macromolecules h, responsible for their flocculation and sorption ability, and the hydrodynamic volume V_M^h occupied in solution by unit weight of macromolecules and determining the overall size of the macromolecule [30]. These characteristics are listed in Table 2.

The volume characteristics of macromolecules under consideration show that the distance between the terminal groups of chitosan, methyl cellulose, and polyvinyl alcohol macromolecules exceeds that for gelatin and lactoserum protein by a factor of 2–4. This fact indicates that the terminal groups of the first series of macromolecules are more active in flocculation and sorption processes.

The hydrodynamic volumes of chitosan and methyl cellulose macromolecules are considerably larger

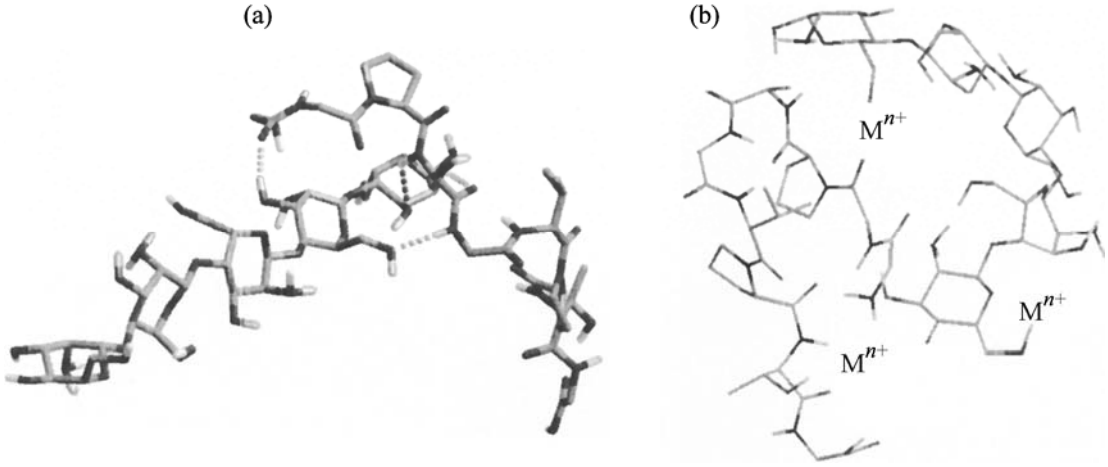

Fig. 1. Structure of (a) chitosan-gelatin and (b) chitosan-gelatin-metal complexes.

than those of the other macromolecules under consideration, i.e., their structures are bulkier and less coiled. Therefore, the functional groups of chitosan and methyl cellose are more accessible to intermolecular interactions.

Figure 1 shows the hypothetical structures of chitosan-gelatin complexes with a coordinated metal and without it. In these schemes, the intermolecular contacts are indicated by dotted lines. The calculated geometric characteristics of complexes are listed in Table 3. The number of intermolecular contacts in these structures reflects the stability of the complex.

Table 3 shows that the metal-capturing cavities are considerably larger than the metal ion size [31]. Owing to chemisorption, metal ions are strongly retained in macromolecular cativities, and the large weight of these macromolecular complexes can promote their sedimentation.

The features of structure formation in the systems under consideration can be elucidated by a computer technique allowing steric visualization of macromolecular complexes (Fig. 1) [14].

Table 3. Calculated geometric characteristics of polymeric complexes

Parameter	Parameter value
Particle size of complex, nm	80–130
Metal-capturing cavity size, nm	5–9
Metal ion size, nm	Cu^{2+} = 0.071, Fe^{3+} = 0.063, Zn^{2+} = 0.083, Cd^{2+} = 0.092, Ni^{2+} = 0.069

The size of polymeric complexes in aqueous medium was measured by turbidimetric spectroscopy. It was found that macromolecules in aqueous solutions form associates approximately 130 nm in size (macromolecular nanostructures).

We found that the macromolecular complexes are so stable that they are not separated into two components when subjected to thin-layer chromatography.

The physicomechanical and physicochemical characteristics of polymeric complexes under consideration and their constituents are poorly understood. In this study, we examined the deformation-strength, sorption, thermal, dielectric, thermomechanical, relaxation, and combustion characteristics of these polymers.

Table 4 show that treatment of water with polymeric complexes ensures a higher efficiency of its decontamination from petroleum products as compared to treatment with individual polymers (methyl cellulose, lactoserum protein, gelatin, and polyvinyl alcohol). The degree of decontamination of water with these individual polymers is as follows (%). Decontamination to remove petroleum products: gelatin 65.8, lactoserum protein 63.2, methyl cellulose 42.1, and polyvinyl alcohol 39.3. Decontamination to remove phenol: gelatin 40.3, lactoserum protein 39.2, methyl cellulose 23.6, and polyvinyl alcohol 21.6.

It has been reported previously that the sorption of metals with chitosan-containing sorbents (Fig. 2) is controlled by diffusion of metal ions into the sorbent [32]. Among polymeric complexes under consideration, a somewhat higher sorption ability toward metals is exhibited by chitosan–protein complexes containing a larger number complexing sites. These complexes also exceed straight chitosan in sorption ability.

Table 4. Degree of decontamination of wastewater to remove petroleum products and phenol by treatment with chitosan and polymeric complexes (initial content of petroleum products X_{init} PP and phenol in water 1.450 and 0.736 mg dm^{-3}, respectively; weight ratio between chitosan and a second polymer in binary polymeric complexes 1 : 1)

Composition	PP concentration in water sample, X_{PP}, mg dm^{-3}	Degree of decontamination of water to remove PP, Q_{PP}, %	Phenol concentration in water, X_{ph}, mg dm^{-3}	Degree of decontamination of water to remove phenol, Q_{ph}, %
Chitosan	0.147	98.9	0.101	86.3
CS–MC	0.155	98.7	0.130	82.3
CS–G	0.162	98.5	0.116	84.2
CS–LSP	0.163	98.3	0.105	85.7
CS–PVA	0.153	98.4	0.169	77.0

Table 5. Deformation-strength parameters of films

Film	Tensile strength σ_t, MPa	Relative elongation at break ε_b, %
Chitosan	112	31
CS–MC	102	29
CS–G	98	27
CS–LSP	96	25
CS–PVA	107	25

The increased stability of polymeric complexes is due to their polynuclear structure with multicenter bridging bonds between functional groups of neighboring macromolecules. The polymeric complexes are characterized by increased capacity for capturing not only cations, but also anions. The resulting heavy cation-anionic complexes lose solubility and undergo sedimentation from aqueous media in 30 min.

As can be seen from Table 5, the best deformation-strength properties among the complexes studied are exhibited by the CS–PVA complex. The strength of films of this complex is approximately equal to that of chitosan films. Owing to the low production cost, this complex is a commercially promising material. The hydrogen-bound water molecules present in the structure of this polymeric complex provide the elasticity of films [33].

We found that, on prolonged heating of chitosan-containing films at temperatures of up to 80°C, these materials retain water (up to 80–85%) and, therefore, do not lose their strength properties. Since water is the fireproofing agent, it imparts flame resistance to polymers and also allows introduction into the polymer and retention of additional appropriate hydrophilic fireproofing compounds, e.g., crystal hydrates.

Figure 3 shows the time dependence of swelling of chitosan-containing films in water. The first portion of this curve reflects fast swelling caused by chemical

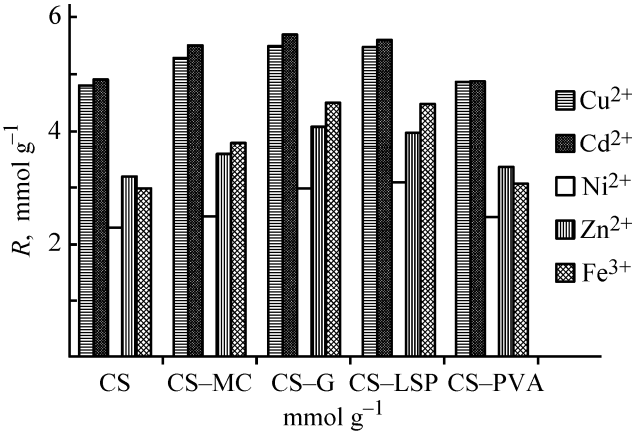

Fig. 2. Retention R of metal ions by chitosan and chitosan-containing polymeric complexes.

CS–LSP	29	52	5.6
CS–PVA	28	44	5.3

binding of water with the polymer. In going from water to acetone and oil, the degree of swelling of all the films becomes less than 3 and 0.01%, respectively. Figure 3 shows that the largest swelling is shown by the CS–MC film, which is due to the high hydrophilicity of methyl cellulose.

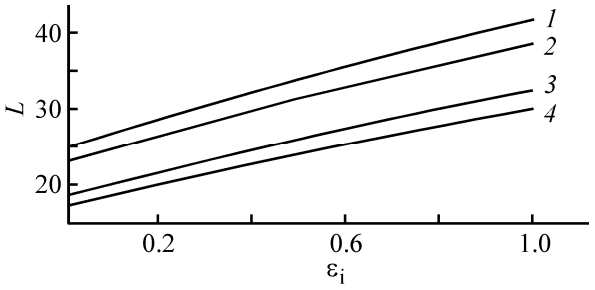

Fig. 4. Performance parameter L of (*1*, *2*) hydrated and (*3*, *4*) anhydrous CS–PVA complexes vs. the intumescence deformation ε_i at various thermal effects of pyrolysis Q and material densities ρ. (*1*) Q = 1300 kJ kg^{-1}, ρ = 1.22 kg m^{-3}; (*2*) Q = 1000 kJ kg^{-1}, ρ = 1.22 kg m^{-3}; (*3*) Q = 1300 kJ kg^{-1}, ρ = 1.32 kg m^{-3}; and (*4*) Q = 1000 kJ kg^{-1}, ρ = 1.32 kg m^{-3}.

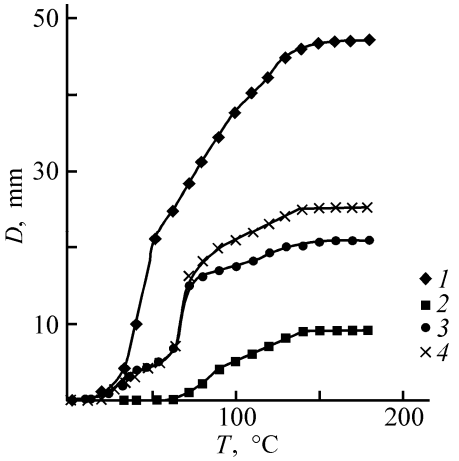

Fig. 5. Results of thermomechanical analysis of films of chitosan-containing complexes: deformation D vs. temperature T. (*1*) CS–MC, (*2*) CS–PVA, (*3*) CS–G, and (*4*) CS–LSP; the same for Fig. 6.

Table 6 lists the combustion characteristics of chitosan and chitosan-containing polymeric complexes. The oxygen index (OI), coke number (CN), and combustion rate of chitosan and chitosan-containing polymeric films show that these polymers belong to the group of self-extinquishing materials with reduced flammability and are suitable for preparing fireproofing coatings.

We believe that enhanced flame resistance of the chitosan complexes is due to the high content of bound water and to the presence of cyclic groups and nitrogen atoms.

Using a multifactorial model of heating of fireproofing and heat-shielding materials and Teplo 1 software [34], we simulated the fireproofing and heat-shielding characteristics of chitosan-containing coatings in relation to their thermolphysical parameters and heating mode, taking into account the physicochemical transformations of coatings (pyrolysis, intumescence, pore formation).

We found that the intumescence, coking, and amount of retained water determine to the greatest extent the performance characteristics of polymers. For example, the retention of 20% water in a coating increases the total endothermic effect by more than 30%. Figure 4 shows the dependence of the performance parameter L of CS–PVA complex on the intumescence strain ε_i at various thermal effects of pyrolysis Q and material densities.

After thermal treatment of coatings, the following characteristics were determined: thickness of degraded layer, δ_d; thickness of heated layer, δ_h; total thickness of heated layer, $\delta = \delta_d + \delta_h$; performance parameter L taking into account the degradation rate V_d and material density ρ, where $L = 1/(V_d\rho)$, $V_d = \xi_z/\sqrt{t}$; ξ_z, param-eter related to the temperature conductivity, intumescence deformation, and heat of pyrolysis; and t, heating time (s).

Figure 5 shows that heating causes a considerable deformation of polymeric materials. It is seen that the most deformable is CS–MC polymeric complex, and the least deformable, CS–PVA. The reinforcement of the latter polymer can be caused both by the cross-linking effect of PVA and by the formation of interpenetrating networks of PVA and chitosan.

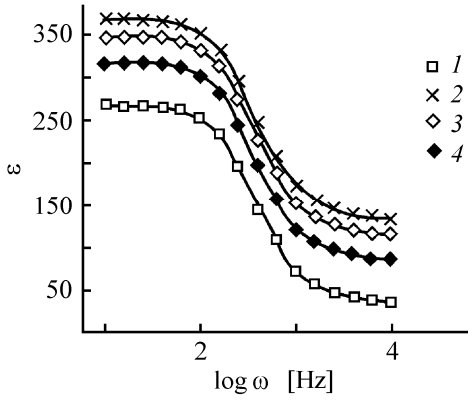

Fig. 6. Permittivity ε of chitosan-containing films vs. frequency ω.

The relaxation characteristics of polymeric complexes were obtained from the frequency dependence of their permittivity. Figure 6 shows that, for all the polymeric complexes under consideration, the mobility of macromolecules decreases with increasing frequency. A particularly sharp decrease in the permittivity is observed in the 100–1000 Hz frequency range. This behavior indicates that the polymeric complexes consist of mobile kinetic units. Among the materials tested, the CS–PVA complex has the highest permittivity and the longest relaxation time.

CONCLUSIONS

(1) Complexes of chitosan with synthetic polymers and biopolymers are characterized by increased flame resistance and high sorption ability toward metal ions and organic compounds.

(2) Accordingly to the results of a computer simulation, the sorption of metal ions and organic compounds by chitosan-containing polymers occurs by the mechanism of their capture in polymer cavities.

(3) Upon prolonged heating of chitosan-containing films at temperatures of up to 80°C, these materials retain water (80–85%). Their strength properties are not inferior to those of chitosan, and the flammability is lower than that of chitosan by a factor of 1.3.

(4) The chitosan-containing materials can be used for sorption of phenols, petroleum products, and toxic metal ions from aqueous solutions and for preparation of fireproofing and heat-shielding coatings, membranes, and films, especially in the case of stringent toxicity restrictions. These materials are characterized by such advantages as availability of raw materials, nontoxicity, and environmental safety.

Abstract—Antireflection coatings with a low refractive index (1.25–1.34) were prepared from mesoporous silicon dioxide by using carbochain polymers and statistical copolymers, instead of ionogenic and noionogenic surfactants and amphiphilic block-copolymers in a sol–gel process. The optimal concentration of the organic additive in the sol, at which a transparent film with the maximum antireflection effect is formed in the sol–gel process followed by heating of a sample, was determined.

DOI: 10.1134/S1070427208080235

Thin-film antireflection interference coatings of optical articles are widely used in optical and commercial industries (antireflection coatings of display screens, photodetectors, fiber-optic waveguides, etc.). The principal limitation of thin-film antireflection coatings is the impossibility of their deposition in a vacuum onto large-size optical articles (large-aperture optics based on optical articles fabricated from fused silica and optical glass of various brands, nonlinear water-soluble crystals, etc.).

In the general case, light is reflected at the interface between two materials, e.g., silicate glass and air. At a refractive index of glass $n \approx 1.51$, about 8.6% of light incident at a zero angle is reflected at two glass–air interfaces. Theoretically, to minimize (to 0.0% in the limiting case) the reflection of light with a wavelength λ, glass should be coated with a transparent film with a refractive index $n_t = \sqrt{n} \approx 1.23$ and optical thickness $\lambda/4$.

However, film-forming materials with such a low refractive index are nonexistent in the nature. For example, low refractive indices are observed for fluorinated compounds: magnesium difluoride (refractive index 1.38) and Teflon (1.33), but the refractive indices of these substances substantially exceed the theoretical value of 1.23.

Therefore, multilayer coatings are widely used in practice as antireflection coatings of optical articles: two-layer, three-layer, four-layer, etc. [1]. Various types of multilayer antireflection coatings on silicate glass are well known and have been considered in detail, e.g., in US patents [2–5].

The practice of deposition of thin-film antireflection coatings onto optical articles employs vacuum technologies [1] and the sol–gel method [6–10]. The vacuum technologies use expensive equipment whose cost increases with the size of optical articles. The dimensions of optical articles are limited by the size of the vacuum chamber of deposition installations. The sol–gel process is simpler experimentally and can be used for deposition of coating onto large optical articles.

In 1992, scientists of Mobil Oil Corp. (USA) made an important discovery in synthesis of new nanomaterials [11–13], they developed matrix synthesis of mesoporous silicates and aluminosilicates. A group of mesoporous materials, M41S (MCM-4, hexagonal mesophase; MCM-48, cubic mesophase; MCM-50, lamellar mesophase), with a regular, well-pronounced system of nanosize structures was synthesized for the first time by a sol–gel process in the presence of a cationic surfactant. Owing to the comparatively simple synthesis of new mesoporous materials and wide op-

Additive: (a) polyvinyl butyral, (b) polyvinyl acetate, and (c) polyvinyl methacrylate. (*1*) Coating-free glass; additive content (wt %): (a) (*2*) 0.35, (*3*) 1.0, (*4*) 1.5, and (*5*) 2.0; (b) (*2*) 1.0 and (*3*) 1.5; (c) (*2*) 1.0 and (*3*) 2.0.

portunities for their practical use in catalysis, microelectronics, optics, and sensor fabrication, this area of research has been vigorously developing since that time [14].

It should be noted that, in early studies [11–13], mesoporous silicates and aluminosilicates were produced only in the form of powders. In 1997, the EISA (evaporation-induced self-assembly) technique for deposition of nanoporous silicon dioxide films onto substrates was developed and a way was opened-up to obtain single-layer transparent coatings having a low refractive index and exhibiting a nearly theoretical antireflection effect [15]. This was done using cationactive surfactants (cetyltrimethylammonium bromide an others) as a matrix, an organic compound that predetermines self-organization of inorganic-organic nanosize structures in a forming film.

The aim of the present study was to examine the possibility of obtaining antireflection coatings with a low refractive index (1.25–1.34) on the basis of mesoporous silicon dioxide with the use of carbochain polymers and statistical copolymers, instead of ionogenic and nonionogenic surfactants and amphiphilic block copolymers [14], in the sol–gel process.

EXPERIMENTAL

A 1.0-ml portion of tetraethoxysilane (TEOS) and 5.0 ml of isopropanol were placed in a 50-ml glass flask and then water was added in a stoichiometric ratio to TEOS (4 : 1 mol/mol) [9], and hydrochloric acid, in a concentration of 3.0×10^{-3} mol per mole of TEOS. The contents of the flask were agitated at room temperature with a magnetic rabble for 1–4 h. A solution of polyvinyl butyral or polyvinyl acetate in isopropanol was introduced into the flask and the mixture was agitated for 1.0 h at room temperature. Then the mixture was diluted with isopropanol to a concentration of 1.0 wt % in terms of SiO_2.

When synthesizing sols with addition of polymethyl methacrylate (PMMA) and statistical copolymers of methyl methacrylate (MMA), tetrahydrofuran was used as organic solvent. Tetraethoxysilane and organic solvents were purified prior to use by the known procedures. Twice-distilled water was used.

Silicate glass slides (thickness 2.0 mm, length 20 mm, width 10 mm, refractive index 1.506) were used as substrates. The slides were cleaned to remove contaminations from the glass surface by submersion in a solution of an alkali with hydrogen peroxide, washed with water and distilled water, and dried in a thermostat at 150°C for 6–8 h.

Coatings were deposited onto the glass by the method of spinning at 500–2000 rpm for several minutes at room temperature. Then the glasses were kept at room temperature for 12 h. Further, the coated glasses were

placed in a thermostat at 150°C and were heated at a rate of 5 deg min^{-1} to 500°C. The samples were kept at this temperature for 5–6 h. After a slow cooling, the samples were removed from the thermostat and their optical transmission was determined in the wavelength range 200–1100 nm on a Perkin–Elmer Lambda 25 spectrometer with an accuracy of ±0.1%.

The optical thickness of the films and their refractive index were measured with an LEF-3M1 ellipsometer.

Figure 1 shows optical transmission curves for coating-free glasses and those with two-side single-layer coatings based on mesoporous silicon dioxide, deposited by the sol–gel method in the presence of various concentrations of polyvinyl butyral (Fig. 1a), polyvinyl acetate (Fig. 1b), and polymethyl methacrylate (Fig. 1c).

The optical transmission of the coating-free glass is the highest (91.1%) at wavelengths of 515–520 nm (curve *1*) and steadily decreases to 83.3% into the near-IR region. The glass is nontransparent for UV light with wavelengths shorter than 325 nm.

Transparent coatings of mesoporous silicon dioxide, deposited with polyvinyl butyral as an additive, make the optical transmission of the glass higher (antireflection effect) at wavelengths in the range 350–1100 nm (Fig. 1a, curves *2–5*). The antireflection effect depends on the concentration of polyvinyl butyral in the sol: its magnitude first increases, passes through a maximum, and further decreases as the concentration of the additive grows (Fig. 1a, curves *2–5*). The maximum transmission (97.0%; degree of antireflection, 5.9%) is observed at wavelengths of 530–540 nm at the optical concentration of polyvinyl butyral of 1.0 wt % (Fig. 1a, curve *3*). The optical thickness of the film is 120 nm, and the refractive index, 1.34.

Transparent coatings of mesoporous silicon dioxide, deposited with addition of polyvinyl acetate to the sol, also make higher the optical transmission of the glass (Fig. 1b, curves *2* and *3*). The maximum transmission (98.6%; degree of antireflection, 7.5%) is observed at a wavelength of 530 nm at a polymer concentration of 1.5 wt % (curve *3*). The optical thickness of the film is 136 nm, and the refractive index, 1.25.

The same effect is observed for coatings based on mesoporous silicon dioxide, deposited by the sol–gel method in the presence of various concentrations of polymethyl methacrylate (Fig. 1c, curves *2* and *3*). The maximum transmission (98.4%; degree of antireflection, 7.3%) is observed at wavelengths of 540–550 nm at the optimal concentration of the polymer of 1.0 wt % (curve *2*). The optical thickness of the film is 137 nm, and the refractive index, 1.26.

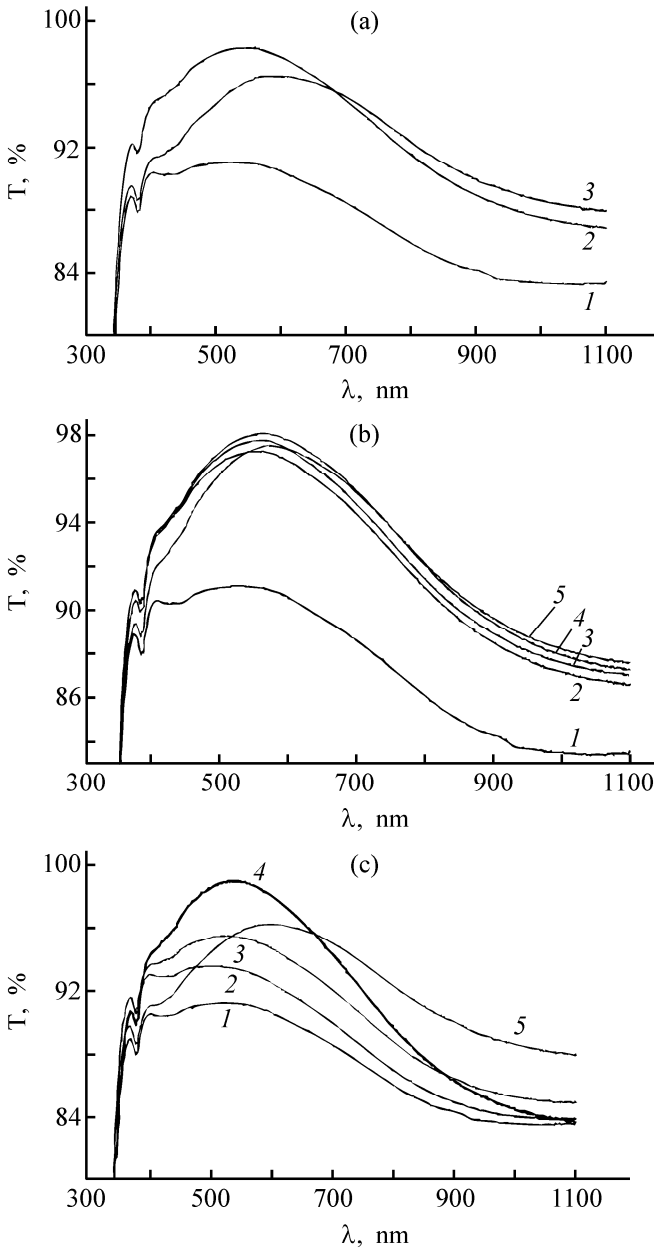

Fig. 2. Influence exerted on the antireflection capacity of single-layer two-side coatings on glass by addition of (a) copolymers of methyl methacrylate with 5.0 mol % hydroxyethyl methacrylate, (b) 20.0 mol % merhacrylic acid, and (c) 10 mol % vinylpyrrolidone. (*1*) Coating-free glass; additive content (wt %): (a) (*2*) 0.5, (*3*) 0.7, and (*4*) 1.0; (b) (*2*) 0.5, (*3*) 1.0, (*4*) 1.2, and (*5*) 1.5; (c) (*2*) 0.5, (*3*) 0.7, (*4*) 1.0, and (*5*) 1.5.

Figure 2 shows optical transmission curves for a coating-free glass (curve *1*) and glasses with two-side

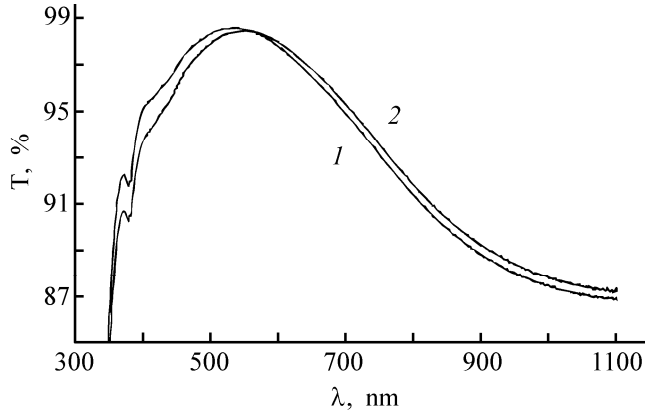

Fig. 3. Change in the antireflection capacity of single-layer two-side coatings on glass in the presence of 1.0 wt % copolymers of methyl methacrylate with (*1*) acrylamide (5 wt %) and (*2*) maleic anhydride in the sol.

single-layer coatings based on mesoporous silicon dioxide, deposited by the sol–gel method in the presence of various concentrations of methyl methacrylate copolymers with 5 mol % hydroxyethyl methacrylate (Fig. 2a, curves *2–4*), with 20.0 mol % methacrylic acid (Fig. 2b, curves *2–5*), and with 10 mol % vinylpyrrolidone in the sol (Fig. 2c, curves *2–5*).

The magnitude of the antireflection effect depends on the concentration of a copolymer in the sol: it first increases, passes through a maximum, and further decreases as the concentration of an additive increases (Figs. 2a–2c).

For films with addition of a copolymer of methyl methacrylate with hydroxyethyl methacrylate in the sol (Fig. 2a, curves *2–4*), the maximum transmission of 98.0% (degree of antireflection, 6.9%) is observed at wavelengths of 580–590 nm at the optimal concentration of the copolymer equal to 0.7 wt % (Fig. 2a, curve *3*). The optical thickness of the film is 150 nm, and the refractive index, 1.285.

For films with addition of a copolymer of methyl methacrylate with methacrylic acid (Fig. 2b, curves *2–5*), the maximum transmission of 98.1% (degree of antireflection, 7.0%) is observed at wavelengths of 580–590 nm at the optimal concentration of 1.0 wt % (Fig. 2b, curve *3*). The optical thickness of the film is 140 nm, and the refractive index, 1.28.

For films with addition of a copolymer of methyl methacrylate with vinylpyrrolidone (Fig. 2c, curves *2–5*), the maximum transmission of 98.4% (degree of antireflection, 7.3%) is observed at wavelengths of 530–540 nm at the optimal concentration of the copolymer of 1.0 wt % (curve *4*). The optical thickness of the film is 130 nm, and the refractive index, 1.26.

Antireflection effects are also observed in experiments with addition to the sol of a statistical copolymer of methyl methacrylate with 5 mol % acrylamide (Fig. 3, curve *1*) and a statistical copolymer of methyl methacrylate with 10 mol % maleic anhydride (Fig. 3, curve *2*). The maximum transmissions of 98.4% (degree of antireflection, 7.3%) and 98.5% (degree of antireflection, 7.4%) are observed at wavelengths of 540–550 nm at the copolymer concentrations of 1.0 wt %. The optical thicknesses of the films are 130 and 132 nm, and the refractive index, 1.26.

The examples presented in Figs. 1–3 indicate that the previously developed EISA technique [15] for matrix synthesis of transparent coatings based on mesoporous silicon dioxide can be modified by replacement of surfactants and amphiphilic block polymers with well-known carbochain polymers and statistical copolymers easily produced by radical polymerization. The EISA method can be conditionally divided into three stages [15]. During the first, the most important stage, after the deposition of a solution of hydrolyzed TEOS with a surfactant (starting sol) onto a substrate by its dipping or spinning, the easily volatile solvent and most part of water evaporate in the course of several seconds from the substrate and the inorganic and organic phases undergo spontaneous microseparation to give an inorganic-organic film on the substrate. The role of various classes of surfactants and amphiphilic block copolymers in the self-organization of inorganic-organic structures has been studied in detail [14] and attributed to joint formation of liquid–crystalline mesophases by a surfactant and oligosiloxanes. A mesophase serves as a matrix for synthesis of inorganic cross-linked networks. In the second stage of the EISA technique, the sample with a coating is kept at room temperature for 12 h and more. In the third stage, the sample is slowly heated in air to 500–700°C. In the process, organic nanostructures "burn-out" and a transparent film of mesoporous silicon dioxide is formed. The mesoporous structure of the film spatially reproduces the structure of the corresponding mesophase formed in the first two stages.

It should be noted that the mechanism of spontaneous microseparation of the inorganic and organic phases in sol–gel processes performed with addition of carbochain polymers and statistical copolymers that are not surfactants or amphiphilic block copolymers remains unknown. The architecture of nanopores has

not been studied, either. Probably, the microseparation of phases is due to supramolecular interactions of growing inorganic chains with fragments of macromolecules of organic polymers and statistical copolymers. This is indicated by the following experimental fact. If polystyrene is used as an additive in the sol–gel process, then only macroseparation of phases is always observed and the films obtained already in the first stage of the EISA method are turbid. The starting sol is transparent because products of partial hydrolysis of TEOS and polystyrene are well dissolved in tetrahydrofuran. Polystyrene is an aromatic hydrocarbon in which there are no functional groups. The interaction of fragments of polymer macromolecules with growing inorganic chains is weaker than that between inorganic macromolecules, and, therefore, macroseparation of inorganic and organic phases occurs in the stage of film formation.

As can be seen from the experimental data in Figs. 1 and 2, the antireflection effect of deposition of a film coating onto glass depends on the concentration of the carbochain polymer (copolymer) in the sol and is the strongest (with the minimum refractive index observed for the film) at the optimal additive concentration of 0.7–1.5 wt %. As follows from the Lorentz–Lorenz formula, the decrease in the refractive index of meso-porous silicon dioxide films is due to an increase in the volume content of air (whose refractive index is 1.0). Air can be contained only within nanopores of the material, and, consequently, introduction of a polymer additive into the sol may affect both the number of nanopores and their size in the course of formation of a mesoporous silicon dioxide film. The minimum refractive index is observed at the optimal relationship between these parameters.

CONCLUSIONS

(1) Carbochain polymers and statistical copolymers can be used as an organic additive to a silicon dioxide sol. The additive predetermines spontaneous microseparation of inorganic and organic phases in the formation of a gel in the form of a transparent thin film on the surface of a silicate glass.

(2) In "burning-out" of the organic phase at 500°C in the atmosphere of oxygen from the gel formed, a transparent film of mesoporous silicon dioxide is obtained on the glass surface. The film has a low refractive index (1.25–1.34) and produces an antireflection effect.

(3) The optimal concentration of the organic additive in the sol is 0.7–1.5 wt %. At this concentration, a transparent film of mesoporous silicon dioxide, with the maximum antireflection effect, is formed in the sol–gel process followed by heating of a sample with a coating.

Abstract–Polymer films with a dispersed liquid crystal were prepared by photopolymerization of (meth)acrylic monomers. The electrooptical properties of these films were studied. The influence exerted by the composition of the monomer mixture, cross-linking agents, and chain-transfer agent on the liquid crystal drop size and on the transmission of the polymer–liquid crystal films was examined.

DOI: 10.1134/S1070427208080247

Polymer films with a liquid crystal (LC) dispersed in them [polymer-dispersed liquid crystal (PDLC) films] are promising composite materials for use in display devices, in glasses with controllable transparency, in TV projection systems, in optical fibers, and in other electrooptical devices [1]. The use of PDLC films in these systems is based on their ability to transmit light under the action of an external electric field and to become nontransparent in the common state. As compared to liquid crystal twist cells, PDLC films have a number of advantages: higher contrast and brightness (as the use of polarizers is not required), mechanical strength and flexibility due to the polymer matrix, and simpler fabrication. Despite that PDLC films have been extensively studied by now [1–10], they have not found wide use yet because of the high control voltages.

The electrooptical properties of PDLC films depend on numerous parameters: optical constants of the LC and polymer; size, shape, concentration, polydispersity, and degree of alignment of LC groups; drop director and orientation of optical axes of the drops [2]. The major factor controlling the electrooptical properties of PDLC systems is the drop size. It has been shown [3, 4] that the best results can be obtained with the submicrometer drop size.

The strong dependence of the electrooptical properties on the drop size and geometry is due to the fact that the operation of a PDLC cell is based on the effect of electric-field-controlled light scattering, consisting in reorientation of LC drops in an external electric field. The major problem in the development and optimization of electrooptical properties of PDLC films is that these properties depend on the LC drop size oppositely. For example, it is known [5] that reorientation of coarser drops requires weaker threshold fields, but in this case, the switch-off time becomes longer and the film contrast becomes worse. When the LC drop size is decreased to the wavelength of light (e.g., visible), the light scattering by the film increases and the contrast becomes better. The electrooptical properties of polymer composites with a drop size $d \approx \lambda$ have been studied poorly. Extensive data are available only for PDLC films with a drop size $d >> \lambda$ (1–10 mm) [6–8]. In turn, the particle size, shape, and size distribution will be determined by the conditions of phase separation in curing of a polymer matrix, its composition, and component concentrations.

In this study, we examined how the composition of the polymer matrix prepared by photopolymerization of (meth)acrylic monomers affects the electrooptical properties of PDLC films.

EXPERIMENTAL

The monomers (methacrylic acid, MAA; 2-ethylexyl acrylate, EHA; acrylic acid, AA; ethylene glycol diacrylate, EGDA; ethylene glycol dimethacrylate, EGDM) and chain-transfer agent (dodecyl mercaptan, DDM) were purified in a vacuum. MAA and AA were dehydrated by triple freezing–thawing. The copolymerization of MAA and AA with EHA to construct the composition curves was performed in the bulk in the presence of 0.005 M azobis(isobutyronitrile) at 60°C. To this end, the prepared monomer mixtures were placed in glass ampules, deoxygenated by triple freezing–pump-ing–thawing, sealed, and placed in a thermostat. The polymerization was performed to 5–10% conversion. The copolymers obtained were purified by triple reprecipitation from a solution in acetone–methanol with acetonitrile–diethyl ether for EHA–AA or with hexane–diethyl ether for EHA–MAA. The acid content of the copolymer was determined by potentiometric titration of solutions of copolymers in dimethylformamide with a 0.1 N methanolic solution of KOH on TV-6L 1 device in the presence of phenolphthalein indicator with an accuracy of ±(0.3–0.7) mol %.

PDLC films were prepared by photopolymerization of monomer mixtures containing 2 wt % photoinitiator and various concentrations of a liquid crystal on an ST-301 photolithographic installation at irradiation wavelength λ = 365 nm and irradiation power of 0.3–0.5 mW cm^{-2}. For this purpose, the reaction mixture formed after mixing the starting components was placed between two glass plates. The distance between these plates was controlled with spacers (SiO_2 particles) 25–35 μm in diameter. To study the electrooptical properties of the films, the inner sides of the glass plates were preliminarily coated with an ITO layer, and indium con-tacts were soldered-on. The irradiation time was about 10 min in all the experiments. As photoinitiator we used 2,2-dimethoxy-2-phenylacetophenone (Irgacure 651 brand name). The E7 liquid crystal (Merck) was a mixture of nematic liquid crystals (4'-pentyl-4-cyanobiphenyl : 4'-heptyl-4-cyanobiphenyl : 4'-octyl-4-cyanobiphenyl : 4'-pentyl-4-[4-cyanobenzyl]-biphenyl = 51 : 25 : 16 : 8) with the refractive indices for ordinary and extraordinary beams, n_o = 1.5258 and n_e = 1.7366, respectively.

The size and polydispersity of LC particles were determined from photomicrographs obtained with an Axioscop 40 Pol optical polarization microscope (Carl Zeiss), with computer processing of the images. The microstructure of EHA–MAA films was examined by confocal Raman spectroscopy with a Ntegra Spectra NT-MDT device. To obtain a confocal image, we used the Raman line of E7 at 1600 cm^{-1} as the base line and a line at 1283 cm^{-1} as additional line to confirm the reliability of the information obtained. The excitation wavelength was 488 nm, at a power of no more than 1 mW. The dependence of the transmission factor of PDLC films on the applied voltage was determined with a spectrometer based on MDR-204 monochromator (LOMO-fotonika). To measure the response time, square pulses were modulated with an ac voltage (5 kHz).

To impart elastic properties to PDLC films, we introduced polymers with a low glass transition point into the polymer matrix. One of such polymers is poly (ethylhexyl) acrylate (PEHA), which has been studied by Roussel and Buisine as a polymer matrix for PDLC [11]. They noted that the PDLC microstructure was unstable, which was manifested in an increase in the LC drop size in time. The results of that study were confirmed in analysis the stability of PDLC films prepared by photopolymerization of a mixture of EHA with E7 liquid crystal. First, we found that, because of the high solubility of E7 in the polymer–monomer mixture, the phase separation in the system upon photocuring is observed only at LC concentrations no less than 30 wt %. Immediately after the sample preparation, the drop size showed scatter from 1 to 5 μm, and after 3 h the drop size increased to 10 μm, but the polydispersity appreciably decreased. The drop texture in crossed polarizers was typical of radial distribution of molecules, suggesting the homeotropic alignment of molecules on the drop|matrix boundary.

The instability of the LC drop size is most likely due to the fact that, owing to its low glass transition point T_g = –50ºC [12], PEHA does not prevent the mobility and coalescence of drops. One of possible ways to solve the problem is copolymerization of EHA with monomers that raise the glass transition point of the polymer. As such monomers we examined unsaturated acids AA and MAA, whose homopolymers have glass transition points of 105 and 228ºC, respectively [13].

A study of the systems EHA–MAA and EHA–AA with a liquid crystal showed that even minor concentrations of acids in copolymers not only stabilized the PDLC structure, but also decreased the LC drop size. It was found that the drops formed in the presence of MAA were coarser than those in the system with AA. In particular, in films of EHA–AA and EHA–MAA copolymers of similar composition, we detected LC

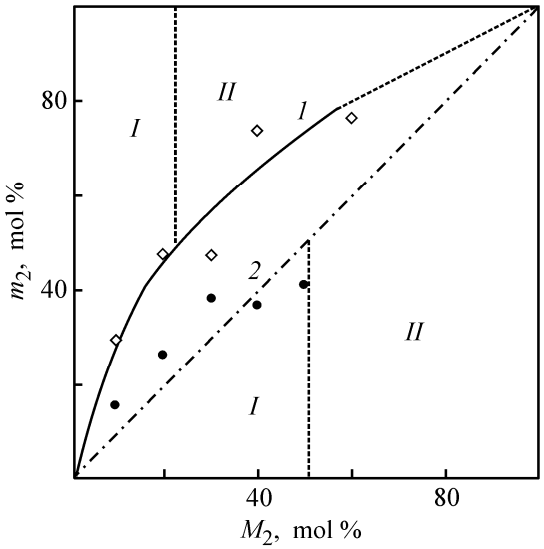

Fig. 1. Initial composition of copolymers (*1*) EHA–MAA and (*2*) EHA–AA vs. the composition of the monomer mixture. (m_2, M_2) Content of unsaturated acid units in the copolymer and of unsaturated acid in the monomer mixture, respectively. Area of copolymerization: *I* homogeneous and *II* heterophase.

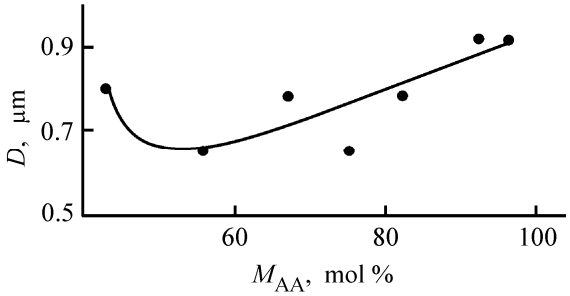

Fig. 2. The most probable LC drop size D at a concentration of 23 wt % vs. the composition of the EHA–AA monomer mixture. (M_{AA}) Acid content.

drops of size $d \le 0.8$ and 1 μm, respectively, and in the EHA–MAA copolymer, conglomerates of the size exceeding 1 μm were also formed. To account for the trends observed, it was interesting to compare these systems in substance-initiated copolymerization to low conversions.

Figure 1 shows the composition curves for the copolymers prepared by bulk polymerization in the presence of a radical initiator. It is seen that the EHA–AA copolymerization is approximately azeotropic, whereas the EHA–MAA is appreciably enriched in MAA units copolymer in the entire composition range of monomer mixtures. This fact is indicative of its high composition nonuniformity in polymerization to high conversions. Apparently, specifically the composition nonuniformity of macromolecules, arising in the course of the copolymer synthesis, is responsible for the formation of drops coarser than those in the EHA–AA system. It should be noted that the heterophase area in this system (area *II* in the diagram) is appreciably wider than that in EHA–AA copolymerization, which restricts the applicability of this systems to preparation of PDLC films.

Therefore, systematic examination of the influence exerted by the composition of the photopolymerizing mixture on the properties of PDLC films was performed with the EHA–AA system. As can be seen from Fig. 2, the phase separation in this system is primarily determined by the composition of the monomer mixture: The dependence of the LC drop size on the acid content of the reaction mixture passes through a minimum at approximately 50 mol % content of AA. Presumably, an increase in the drop size at AA content lower than 50 mol % is associated with low T_g^1 of the copolymer (lower than 27°C), when the mobility of the macromolecules is fairly high and does not prevent coalescence of the liquid crystal drops. In addition, previous data [14] suggest that, with a decrease in the AA concentration, the LC solubility in the polymer–monomer mixture increaes, and on reaching the gel point, coarser drops are formed. At AA content higher than 50 mol %, the system becomes heterophase, as can be seen from Fig. 1, and the copolymer itself forms a separate phase, preventing coalescence of the LC drops in the course of phase separation. Simultaneously, with an increase in the AA content, the LC solubility in the polymer–monomer mixture decreases, which leads to formation of coarser drops.

The properties of a copolymer are determined not only by the composition, but also by its molecular-weight characteristics. To control them, we used a chain-transfer agent (dodecyl mercaptan $C_{12}H_{27}SH$) and two kinds of cross-linking agents: EGDA and EGDM. Chain-transfer agents decrease the molecular weight (MW) of a copolymer, and cross-linking agents cause formation of a 3*D* polymer network. The effect of the additives on the formation of LC drops was examined in photopolymerization of EHA–AA mixture (25 : 75 mol %) containing 2 wt % photoinitiator and 23 wt % LC. The results obtained in studying the effect of the chain-transfer and cross-linking agents are shown in Fig. 3 as size-distribution curves for LC drops.

[1] The glass transition point of the copolymer was calculated by the additive scheme from T_g of the homopolymers.

As can be seen from Fig. 3, both a decrease in MW of the copolymer in the presence of DDM (curve *3*) and cross-linking of the chains with EGDA–EGDM (curve *2*) lead to a decrease in the size of LC drops and in the particle polysidpersity, compared to the system with-out additives (curve *1*). Proceeding from the common standpoint [15, 16] that thiols not only decrease MW of a copolymer but also make narrower its molecular-weight distribution and make the copolymer composition more uniform, we can conclude that specifically these changes are responsible for a decrease in the LC drop size. In 3*D*-cross-linked systems obtained in the presence of EGDM and EGDA, the polymer chains are less mobile, restricting the coalescence of LC drops and correspondingly their size.

It is well known [17–21] that simultaneous addition of a chain-transfer agent and a cross-linking agent leads, depending on their molar ratio, to formation of either a branched polymer or a cross-linked 3*D* network. The presence of a chain-transfer agent allows control over either the length of branchings or the length of segments between the network junctions. Therefore, we examined in this study the effect of jointly introduced additives on the LC drop size in the course of curing of the polymer matrix.

Figure 4 shows the dependence of the LC drop size on the concentration of one of MW regulators at a fixed concentration of another regulator. It can be seen (curve *1*) that, with an increase in the concentration of the chain-transfer agent, when the length of branchings (in the case of formation of a branched structure) or the length of the segment between the network junctions (in the case of formation of a 3*D* network) decreases, the LC particle size decreases. A similar trend in the LC particle size is observed at a fixed

concentration of DDM with an increase in the amount of cross-linking agents (curve *2*). In both cases, a decrease in the size of LC drops can be accounted for by strengthening of the structure of the polymer matrix due to formation of either branched or 3*D*-cross-linked structure.

Thus, our studies show that introduction of modifiers (chain-transfer and cross-linking agents) into a photocurable compound leads to a decrease in the LC drop size. This, in turn, should affect the electrooptical properties of PDLC films.

The electrooptical characteristics of PDLC films are the switching-on voltage V_{on}, switching-off voltage V_{of}, contrast ratio K, and response times: switching-on

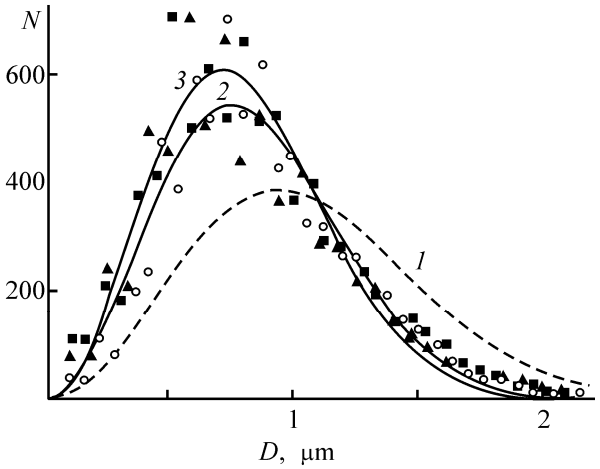

Fig. 3. Size distribution of LC drops formed in the course of polymerization of EHA : AA = 25 : 75 mol % mixture (*1*) without additives and with addition of (*2*) 0.58 mol % EGDA or 0.52 mol % EGDM and (*3*) DDM. (*N*) Number of particles and (*D*) particle size.

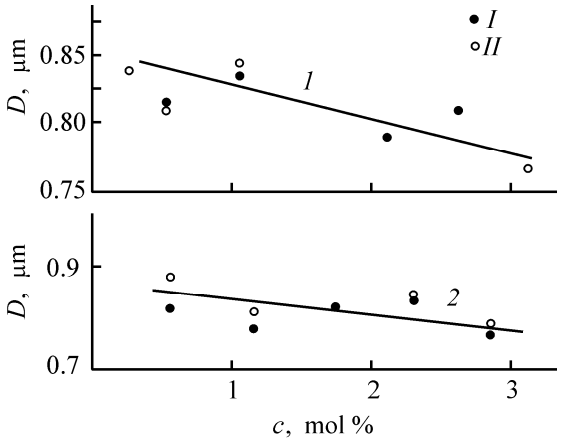

Fig. 4. Particle size *D* of LC drops formed in the EHA : AA = 25 : 75 mol % mixture vs. the concentration *c* (*1*) of chain-transfer agent DDM in the presence of *I* 0.58 mol % EGDA and *II* 0.52 mol % EGDM, and (*2*) of cross-linking agents *I* EGDA and *II* EGDM in the presence of 1.5 mol % DDM.

time t_{on} and switching-off time t_{of}. The first three parameters are determined by the formulas

$$V_{on} = 0.9(T_{max} - T_{min}),$$

$$V_{of} = 0.1(T_{max} - T_{min}),$$

$$K = (T_{max} - T_{min})/(T_{max} + T_{min}),$$

from the dependence of the transmission factor on the applied electric voltage, where T_{max} and T_{min} are the maximal transmission in the switched-on state and the minimal transmission in the switched-off state, respectively. The switching-on and switching-off times are measured by applying to a PDLC film a square

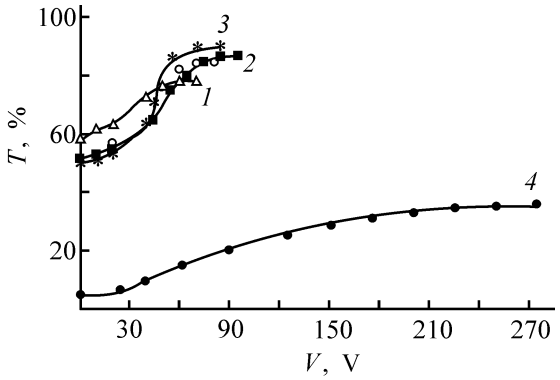

Fig. 5. Transmission factor T vs. the applied electric voltage V for 25-mm-thick PDLC films prepared by photopolymerization of the system EHA : AA = 25 : 75 mol % + 0.5 mol % EGDM + 23 wt % LC at DDM concentrations of (*1*) 0.25, (*2*) 0.5 and 1, and (*3*) 3 mol %, and (*4*) for films of EHA : MAA = 65 : 35 mol % copolymer containing 30 wt % E7 liquid crystal.

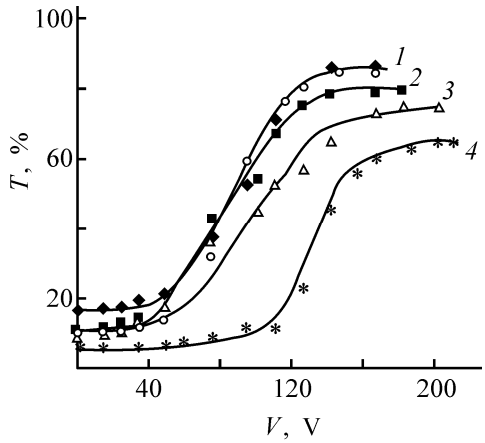

Fig. 6. Transmission factor T vs. the applied electric voltage V for 35-mm-thick PDLC films prepared by photopolymerization of the system EHA : AA = 25 : 75 mol % + 1.5 mol % DDM + 23 wt % LC at EGDM concentrations of (*1*) 0.5 and 1, (*2*) 2, (*3*) 2.5, and (*4*) 3 mol %.

voltage pulse and measuring the dependence of the transmission on time. The theoretical values of the switching-on voltage and switching-off time can be calculated through the elastic distortion energy and electric field energy by the equations [9, 11]

$$V_{on} \sim \frac{d}{R}\left[L^2 - 1\right]\left[\frac{4\pi K}{\Delta\varepsilon}\right]^{1/2},$$

$$\tau_{of} = \sim\frac{\gamma R^2}{K(L^2 - 1)},$$

where R is the mean radius of an LC drop; $L = R_1/R_2$, drop ellipticity; R_1 and R_2, major and minor radii of the elliptic drop; d, PDLC film thickness; g, viscosity; K and $\Delta\varepsilon$, elastic constant and dielectric anisotropy of the liquid crystal, respectively.

As follows from Eqs. (1) and (2), with a decrease in the drop size, the switching-on voltage increases and the switching-off time decreases. This fact indicates that, to obtain PDLC films with high electrooptical characteristics, conditions should be found for the formation of LC drops of the optimal size.

The results obtained in studying the electrooptical properties of PDLC films with polymer matrices of different compositions are shown in Figs. 5 and 6 in the form of curves of the film transmission vs. applied voltage. Comparison of the results obtained with EHA–AA and EHA–MAA copolymers shows that films of the former copolymers exhibit a considerably higher transmission in the switched-on state. As both systems are heterophase, the differences are associated with the particle size of the dispersed phase of the copolymer proper, rather than with that of LC. Apparently, EHA–MAA polymer particles coalesce in the course of the synthesis to a size exceeding the wavelength of visible light, which results in a low transmission of the PDLC films both in the switched-off and switched-on states. It is significant that the threshold voltages V_{on} in films based on EHA–AA copolymer are considerably lower than those for the EHA–MAA copolymer: 1.6–4.5 and 8 V μm^{-1}, respectively. This fact is, at first glance, unexpected, as drops formed in EHA–MAA films are coarser than those formed in the EHA–AA films and, therefore, require a lower threshold voltage for reorientation. The observed inconsistency with the theoretical expectations can be accounted for only by the higher polarity of the EHA–AA copolymer, which contains 75 mol % acid, against 35 mol % MAA in EHA–MAA copolymer. Therefore, the dielectric constant of the films in the first case will be higher, which favors a decrease in the threshold voltage.

Thus, the EHA–AA polymer matrix is more promising also from the standpoint of electrooptical properties. We optimized the composition of this matrix with respect to the content of molecular weight regulators: EGDM and DDM. Figure 5 shows that, with an increase in the DDM concentration, the transmission of samples in the switched-off state decreases and that in the switched-on state increases. With an increase in the concentration of the cross-linking agent EGDM (Fig. 6), both the lower and upper boundaries of the film transmission decrease. The film contrast grows in both cases, which is associated with an increase in the number of scattering centers due to a decrease in the LC drop size, observed as the concentrations of the chain-transfer agent DDM and cross-linking agent EGDM are raised. It was concluded from the threshold voltages

Threshold voltages V_{on} of PDLC films prepared by photopolymerization of EGA : AA = 25 : 75 mol % + 23 wt % LC mixture at various kinds and concentrations of MW regulator

c, mol %	V_{on}, V μm^{-1}	
	EGDM	DDM
0.25	–	1.6
0.5	3	2
1.0	3	2.4
2	3.4	3.2
2.5	4.2	–
3	4.5	2.1

(see table) and transmission of the films that the optimal concentrations of MW regulators in the composition of the EHA–AA polymeriz-ing mixture are 1–2 mol % DDM and 1 mol % EGDM. This corresponds to the minimal values of the threshold voltage and transmission in the switched-off state and to the maximal transmission in the switched-on state.

Along with the threshold voltage, an important characteristic of PDLC films is the switching-off time. According to formula (2), the switching-off time depends on the LC drop size. Namely, it decreases with a decrease in the particle size. The results obtained in studying the PDLC response on a square voltage pulse show that the switching-off time of films modified with additions of a cross-linking agent and a chain-transfer agent is shorter, which is consistent with the theoretical concepts. For example, for the films without additives, the switching-off time was 3–6 ms, and for the films modified with EGDM and DDM, 1–3 ms at a switching-on time t_{on} of about 0.7 ms, which opens prospects for the use of these films in electrooptical devices.

CONCLUSIONS

(1) In preparation of PDLC films by photopolymerization of the 2-ethylhexyl acrylate–acrylic acid–liquid crystal system, the size of the forming liquid crystal drops does not exceed 0.8 μm, whereas in copolymerization of 2-ethylhexyl acrylate with methacrylic acid, the liquid crystal particle size exceeds 1 μm.

(2) Analysis of the dependence of the liquid crystal particle size on the composition of the monomer mixture 2-ethylhexyl acrylate–acrylic acid shows that the smallest drops are formed at acrylic acid content of about 50 mol %.

(3) PDLC films based on 2-ethylhexyl acrylate–acrylic acid copolymer show a higher transmission in the switched-on state with a lower threshold voltage, compared to 2-ethylhexyl acrylate–methacrylic acid films.

(4) Introduction of molecular weight regulators, a chain-transfer agent and a cross-linking agent, into the photocurable compound 2-ethylhexyl acrylate–acrylic acid leads to a decrease in the liquid crystal drop size and to improvement of the electrooptical properties of PDLC films.

(5) The threshold voltage for films based on 2-ethylhexyl acrylate–acrylic acid copolymer modified with molecular weight regulators is 1.6–4.5 V μm^{-1}, the switching-off time is 1–3 ms, and the switching-on time is about 0.7 ms.

Institute of General and Inorganic Chemistry, State Scientific Institution, Belarussian National Academy of Sciences, Minsk, Belarus

Received November 15, 2007

Abstract—The volume electrical resistivity of composite films based on polystyrene, polyvinyl chloride, polymethyl methacrylate, and butadiene-styrene latex containing Ni-carbon fibers was studied in relation to the degree of filling, fiber length, and temperature.

DOI: 10.1134/S1070427208080259

Raising in the electrical conductivity of polymers is of particular importance for preparing conducting materials for various purposes: low-temperature heating elements, electrodes of chemical power cells, antistatic coatings, etc. One of ways to improve the conductivity of polymers is to conducting fillers, including carbon fillers, which, are known to be characterized by fairly high conductivity, chemical inertness, and sedimentation stability [1, 2]. The electrical conductivity of carbon-containing polymer composites strongly depends on the physical form of the fillers used [3]. It is known that fibrous carbon fillers are more efficient in decreasing the polymer conductivity as compared to powder materials [4, 5]. Appropriate carbon fibers containing various metals heve been developed at the Institute of General and Inorganic Chemistry (Belarussian National Academy of Sciences) [6].

In this study, composite polymer films based on Ni-containing carbon fibers (Ni-CF), polystyrene (PS), polyvinyl chloride (PVC), polymethyl methacrylate (PMMA), and butadiene-styrene (BS) latex were prepared and their conducting properties were examined in relation to the degree of filling, fiber length, and temperature. In some cases, Ni-free carbon fibers (CFs) and highly dispersed powder carbon (HDC) were used as fillers for comparison.

EXPERIMENTAL

The Ni-carbon fibers were prepared by carbonization of hydrated cellulose fibers (preliminarily treated with a nickel chloride solution) in an inert gas flow at 900°C [7, 8] in accordance with TU RB (Technical Specifications of the Belarus Republic) 100 029 049.020–2003.The carbonized fibers were finely divided and the fractions with an average length (l_{av}) of 0.1, 0.5, and 3 mm were taken. The nickel-free carbon fibers were prepared under the same conditions, excluding impregnation of the initial fibers with $NiCl_2$ solution. As the polymer we used the following polymers: polystyrene (PS-S), polyvinyl chloride (S 63 Zh brand), polymehyl methacrylate [GOST (State Standard) 24 234–80], and butadiene-styrene latex (BS-65 A brand). The composites were prepared by dispersion of the carbon fibers of a certain size in benzene containing PS (15%), in cyclohexanone–pentane mixture (9 : 1) containing PVC (10%), in cyclohexanone–benzene mixture (9 : 1) containing PMMA (5%), and in 50% aqueous dispersion of butadiene-styrene latex. The concentrations of the polymer solutions were determined in our preliminarily tests so as to obtain the solutions with an optimal viscosity, acceptable for preparation of films. The content of the carbon filler was varied from 5 to 33% to the composite weight. The larger amount of the filler was not added because of a strong increase in the viscosity, which hinders mixing and casting of the films. The liquid compositions were poured onto degreased glass supports (7.5 × 2.7 cm) in amounts of 0.1 ml cm^{-2} and dried at room temperature. The thickness of the films prepared from PS, PVC, and BS latex at medium degrees of filling was 120–170, and that of the PMMA films, 90–100 μm.

Changes in the volume electrical resistivity of the composite films were measured by the two–contact

method in a cell equipped with two brass clamps, using a V7-16A universal voltmeter and an E6-13A teraohmeter. The volume electrical resistivity of the films, ρ_V (Ω m) was calculated from the expression $\rho_V = (RS)/l$, where R is the measured resistivity; S, film sectional area; and l, film length. To study the temperature dependence of the electrical resistivity, the cell with a sam-ple was placed in a temperature–controlled chamber, and the electrical resistivity of the sample was measured in the course of heating to 130°C (in the case of BS latex, to 240°C) at 10°C steps.

The confidence interval of the experimental error was evaluated from the measurements of at least five samples. The relative rms measurement error increased with the length of the filler fibers and amounted to 15–20%.

The electrical resistivities of the composite films based on PS, PVC, PMMA, and BS latex filled with HDC (30–50 nm particle size), CF (l_{av} 0.5 mm), and Ni-CF of various sizes are listed in the table. These data show that all the films containing powdered fil-ler HDC exhibit relatively high electrical resistivity (2.0×10^2 Ω m) even at a 23 wt % degree of filling,

whereas ρ_V of the films containing fibrous filler CF (even at the same degrees of filling) is smaller by 2–3 orders of magnitude and amounts to 0.2–2.5 Ω m, depending on the polymeric binder. It should be noted that, in the case of the HDC filler, we failed to prepare films with a degree of filling higher than 23 wt % because of the cracking and disturbance of the film continuity.

Filling of the polymers with Ni-carbon fibers decreases ρ_V of the films studied still more strongly. For example, ρ_V of the films containing 23 wt % Ni-CF (l_{av} 0.5 mm) is 7.5×10^{-3}–2.0×10^{-2} Ω m, depending on the polymer type, which is probably due to the effect of metal contained in the fibers on the structure of carbon in the course of pyrolysis.

With increasing Ni-CF length, the resistance of the composite films decreases, and, in this case, ρ_V depends on the type of the polymer and degree of its filling. At small degrees of filling, the dependence of ρ_V of the composite films on the Ni-CF length is the most pronounced. As can be seen from the table, ρ_V of the PS films at 5% degree of filling varies from 1.0×10^8 to 3.8×10^{-2} Ω m as the length of the filler fibers increases from 0.1 to 3.0 mm. In this cases, the strongest decrease in ρ_V (by 7 orders of magnitude) is observed as the fiber length increases from 0.1 to 0.5 mm, whereas with l_{av} increasing from 0.5 to 3.0 mm, ρ_V changes by less than an order of magnitude. With increasing degree of filling, the effect of the fiber length on ρ_V decreases. At 10–17 wt % degree of filling, ρ_V decreases by less than an order of magnitude as the l_{av} increases from 0.1 to 0.5 mm, and further increase in l_{av} to 3.0 mm does not noticeably decrease the film resistivity ($\rho_V \approx$ const). At higher degrees of filling (>23 wt %), ρ_V is at all independent of the fiber filler length.

These results show that the resistivity of the polymer films can be varied in a wide range by varying the length of Ni-CFs used for filling of the polymer films. The fibrous structure of the filler provides formation of conducting chains even at small degrees of filling, which well agrees with the percolation conductivity theory [3]. In accordance with this theory, the dielectric state of composite materials containing both a low-conducting polymer phase and a highly conducting filler phase shaprly changes to the conducting state on attainment of a certain degree of filling (so-called percolation threshold, c_p). This process occurs owing to the fact that, at c_p, the filler particles form a continuous conducting cluster, which provides a sharp increase in the electrical conductivity of the system.

It was found that the percolation threshold in the composites containing needle-like filler particles is attained at lower concentrations than those in composites with spherical filler particles [3, 5]. This is due to the fact the lengthy particles (in particular, fibers) have a larger number of contacts with the neighboring particles, which facilitates formation of conducting chains. For such filler type, the percolation threshold is directly proportional to the radius of the needle-like particles and inversely proportional to their length. For the fillers studied, the ratios of the fiber radius to their length were 0.1, 0.02, and 0.003 for l_{av} of 0.1, 0.5, and 3.0 mm, respectively. In accordance with these data, the percolation threshold of the films studied decreased in the same order. In particular, c_p of the films based on PS decreased from 10 to less than 5 wt % (see table).

In the case of PVC films at 5 wt % content of Ni-CF, the percolation threshold is observed only for the filler with the fiber length of 3.0 mm. Probably, in the case of shorter fibers (l_{av} 0.1 and 0.5 mm), no continuous conducting cluster was formed, i.e., the concentration of the filler in these composite films is lower than the percolation threshold. As in the case of PS films, the strongest changes in ρ_V (by eight orders of magnitude) are observed at a 10% degree of filling as the fiber length increases from 0.1 to 0.5 mm, whereas with l_{av} increasing from 0.5 to 3.0 mm, it decreases by only an order of magnitude. With increasing degree of filling, the dependence of ρ_V on l_{av} becomes less pronounced, and, at degrees of filling greater than 17 wt %, the resistivity of the films filled with fibers with l_{av} 0.5 and 3.0 mm is essentially the same. In the case of a short-fiber filler (l_{av} 0.1 mm), the percolation threshold of the composite films based on PVC is observed at higher degrees of filling (23 wt %) as compared to the PS films.

The dependences of ρ_V of the films based on PMMA filled with Ni-CF of various lengths are similar to those for PVC films, with only difference that the films based on PMMA with a 5 wt % degree of filling did not attain the percolation threshold even at l_{av} 3 mm. With the shortest fibers (l_{av} 0.1 mm), the percolation in this polymer was attained at c_p of 17 wt %. With increasing fiber length, it decreased and, for Ni-CF with l_{av} 0.5 and 3.0 mm, c_p was 10 wt % (see table).

The composite films based on BS latex with a 5 wt % degree of filling and fiber length of 0.1–3.0 mm are conducting, i.e., their c_p is smaller than 5 wt %. Our additional experiments showed that, at l_{av} of 0.1 and 0.5–3.0 mm, the percolation threshold of the films was

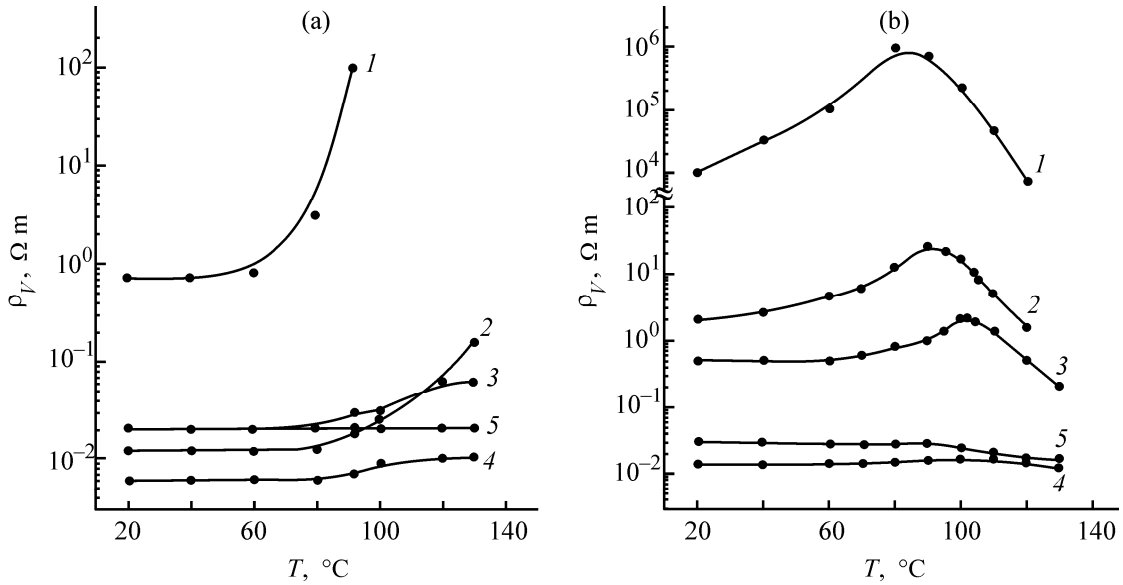

Fig. 1. Temperature dependence of the volume electrical resistivity ρ_V of the composite films based on (a) PS and (b) PVC filled with Ni-CF of various lengths. Length, mm: (*1*, *2*) 0.1, (*3*, *4*) 0.5, and (*5*) 3.0. Degree of filling, wt %: (*1*, *3*, *5*) 10 and (*2*, *4*) 23.

3 and 2 wt %, respectively. As in the case of PS films, the strongest change in ρ_V was observed at small degrees of filling with l_{av} increasing from 0.1 to 0.5 mm. A specific feature of the composite films based on BS latex is that the resistivity of the films containing fibers with l_{av} = 3.0 mm is higher at all the examined degrees of filling than that of the films filled with shorter fibers (l_{av} = 0.5 mm). This is probably due to the irregular distribution of the long fibers in the BS latex. Hence, the use of fibers with l_{av} = 0.5 mm seems to be preferable in this case.

As can be seen from our experimental data, the composite films based on PS exhibit the lowest electrical resistivity, $(7.5 \pm 1.5) \times 10^{-3}$ Ω m, at a 17 wt % degree of filling (Ni-CF, l_{av} = 0.5–3.0 mm). At the same degree of filling, the electrical resistivity of the PVC films is higher by a factor of 4, and only at a 33 wt % degree of filling their electrical resistivity reaches 7.5×10^{-3} Ω m. The composite films based on PMMA at a 17 wt % degree of filling (l_{av} = 3.0 mm) are characterized by the electrical resistivity similar to that of PS films, and at a 28 wt % degree of filling ρ_V is still lower [$(5.5 \pm 1.5) \times 10^{-3}$ Ω m]. The higher degree of filling of the PMMA films with the long fibers (l_{av} = 3.0 mm) was not attained because of the break of the continuous films due to the binder deficiency. The lowest electrical resistivities of the composite films based on PS and BS latex are attained at a 17 wt % degree of filling and l_{av} = 0.5 mm. At this relatively low degree of filling, the composite films retained their rather high physicomechanical properties.

Since data on the electrical resistivity at elevated temperatures are of particular importance in working with composite films [9], we studied the temperature dependence of the electrical resistivity of the composite films in the ranges 20–130°C for PS- and PVC-based films and 20–240°C for BS latex films. It was found that the temperature dependence of the electrical resistivity of these films strongly depends on the polymer type, degree of its filling, and length of the filler fibers.

For example, ρ_V of the PS films containing 10 wt % Ni-CF (l_{av} = 0.1 mm) remains almost constant on heating to 60°C. With a further increase to 90°C, ρ_V changes insignificantly, whereas at temperatures above 90°C ρ_V increases by several orders of magnitude (Fig. 1a, curve *1*). With the degree of filling increasing to 23 wt %, the temperature range in which ρ_V of the PS films is stable extends to 90°C, and with further heating the increase in ρ_V is less pronounced than that at a 10 wt % degree of filling (Fig. 1a, curve *2*). With increasing Ni-CF length (l_{av} 0.5 mm), the temperature dependence of ρ_V becomes smoother (Fig. 1a, curves *3*, *4*). The electrical resistivity of the films filled with the longest fibers (l_{av} 3.0 mm) remains constant in the entire temperature range studied (Fig. 1a, curve *5*).

The trends observed can be accounted for as follows. It is known that the glass–transition point of polystyrene is 93°C [10]. With the temperature increasing above this value, PS passes into the hyperelastic state, and the mobility of its molecular chains increases. Since the linear expansion coefficient of PS is

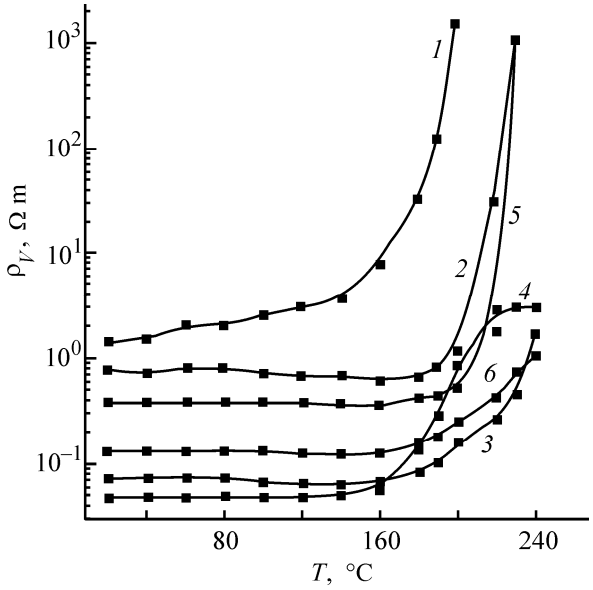

Fig. 2. Temperature dependence of the volume electrical resistance ρ_V of the composite films based on (a) PS and (b) PVC filled with Ni-CF of various lengths. Length, mm: (*1*) 0.1, (*2–4*) 0.5, and (*5*, *6*) 3.0. Degtee of filling, wt %: (*5*) 3, (*2*, *6*) 5, (*3*) 10, and (*1*, *4*) 23.

higher than that of the carbon fibers [6] by a factor of 15–20 [11], the volume fraction of the polymer in the composite film increases with temperature as compared to the Ni-CF fraction. As a result, the contact area of the fiber filler particles decreases, causing an increase in the electrical resistivity of the composite film. This factor is the most important at small degrees of filling and small particle size. With increasing fiber particle length and degree of filling, the effect of the polymer on the contact area between the filler fibers decreases and the temperature dependence of the electrical resistivity of the composite films becomes insignificant.

The temperature dependence of ρ_V of the films based on PVC is more complex. The strongest temperature dependence is observed for the films filled with the shortest fibers (l_{av} = 0.1 mm) (Fig. 1b, curves *1*, *2*). For these films, ρ_V increases as the temperature is raised from 40 to 90°C. On further heating, the electrical resistivity of the films decreases and at 120°C it becomes lower than that at room temperature. As in the case of the PS films, with the Ni-CF length increasing from 0.1 to 0.5 mm, the temperature dependence of ρ_V becomes smoother even at relatively low degrees of filling (10 wt %; Fig. 1b, curve *3*). With the degree of filling increasing to 23 wt %, changes in ρ_V become smaller than 25% in the 20–130°C range (Fig. 1b, curve *4*). A similar relatively high temperature stability of the electrical resistivity is observed for PVC films containing 10 wt % Ni-CF (l_{av} = 3.0 mm) (Fig. 1b, curve *5*).

As in the case of PS films, the electrical resistivity of PVC films filled with finely dispersed fibers increases as the temperature is raised from 40 to 90°C. This trend may be due to the difference in the linear thermal expansion coefficients of the polymer and fiber, which deteriorates the contact between the filler particles in the course of heating. This effect is strongly enhanced when the polymer passes into the hyperelastic state. The temperature of this transition in PVC is 80°C [12]. Further decrease in the electrical resistivity as the temperature is raised above 110°C may be due to transformations of the polymer itself, giving rise to conductivity of another type. It is known that, at temperatures higher than 100°C, PVC undergoes slow degradation with elimination of hydrogen chloride and formation of a system of conjugated double bonds [13–15]. As a result, the conductivity mechanism in the PVC polymer may change, with a decrease in the resistivity with increasing temperature. As in the case of PS films, the electrical resistivity of the composite films based on PVC becomes more independent of temperature with an increase in the degree of filling and in the length of the filler fibers (Fig. 1b, curves *4*, *5*).

In contrast to the composite PS- and PVC-based films, the films based on BS latex are characterized by significantly broader (20–160°C) temperature range in which ρ_V is either independent of temperature or only slightly changes with temperature (Fig. 2). At temperatures above 160–180°C, the electrical resistivity sharply increases. The onset temperature of this step and the character of ρ_V variation depend on the length of the Ni-containing fibers. The temperature dependence of ρ_V of BS latex films filled with Ni-CF (l_{av} = 0.1 mm) only slightly depends on the degree of filling within the range 10–20 wt % (Fig. 2, curve *1*). A sharp increase in ρ_V of these films is observed only on heating to temperatures higher than 160°C. At the fiber length of 0.5 and 3.0 mm, the observed increase in ρ_V depends on the content of Ni-CF in the polymer, namely, the shape of the temperature dependences of the electrical resistivity becomes smoother with increasing degree of filling. A sharp increase in ρ_V of the BS latex films containing Ni-CF (l_{av} = 0.5 mm) starts at temperatures higher than 200°C (Fig. 2, curve *2*), which is probably due to the degradation of the latex matrix.

The observed sharp increase in the electrical resistivity of the films with temperature can be of particular interest in the design of posistors (devices used to con-

trol the temperature parameters of the medium). To examine the possibility of using BS latex films for this purpose, we studied changes in the electrical resistivity of these films in the heating–cooling cycles. We found that, after cooling of the initially heated films, their resistivity increased by more than an order of magnitude as compared to the initial films. In the course of repeated heating, the onset of the sharp change in the electrical resistivity shifted toward lower temperatures, which may be due to the latex degradation at high temperatures. Therefore, these films can be used as disposable thermal sensors and indicators preventing heating of system to temperatures higher than 220°C.

Thus, by varying the degree of filling and length of the Ni-containing fibers used to prepare filled films based on PS, PVC, and BS latex, we can prepare both composite films with different temperature coefficients of resistivity (TCR) and films with stable electrical resistivity. The composite films based on PS and PVC, exhibiting constant electrical resistivity in the 20–120°C range, and the BS latex films with ρ_V stable at 20–180°C can be used as conducting elements in systems operating at elevated temperatures.

Our results show that, by using various polymers and Ni-containing fibers, it is possible to prepare conducting polymer coatings with ρ_V of 10^{-1}–10^{-2} Ω m at small degrees of filling, which would allow strength properties of the initial polymers to be preserved and the disadvantages of metallic fillers (sedimentation and oxidation) to be avoided. Moreover, the presence of a ferromagnetic metal in the Ni-containing filler provides a high specific magnetization of the resulting fibers [8, 16], which would allow direct orientation of the fibrous conducting filler in the magnetic field [17] and, thus, preparation of composites with anisotropic magnetic and conducting properties. It should also be noted that the commercial production of Ni-containing carbon fibers is mastered at the Khimvolokno Production Association (Svetlogorsk, Belarus).

CONCLUSIONS

(1) The composite films based on polystyrene, polyvinyl chloride, polymehyl meth-acrylate, and butadiene-styrene latex containing Ni-carbon fibers are characterized by the volume resistivity of $(5.5–8.0) \times 10^{-3}$ Ω m at small degrees of filling.

(2) The temperature dependence of the electrical resistivity decreases with an increase in the degree of filling of the film and in the average length of the Ni-containing carbon fibers.

Abstract—The flocculating effect of a cationic polyelectrolyte, *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–maleic acid copolymer, in the recovery of rubber from SKS-30 ARK butadiene–styrene latex at various concentrations of the dispersed phase and H_2SO_4 and at various temperatures was studied.

DOI: 10.1134/S1070427208080260

Recovery of rubbers from latexes is one of the most labor-, material-, and power-consuming process operations. It should be noted, however, that this problem is not given due attention today. It is well known that shops for rubber recovery from latexes discharge tens and hundreds of thousand tons of mineral salts and other compounds, which are not removed at wastewater treatment facilities and pollute natural water basins.

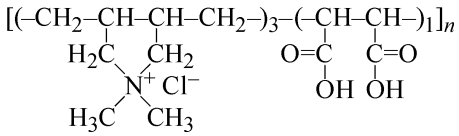
Traditional procedures for rubber recovery from latexes are based on using sodium chloride, which shows high performance and is inexpensive, as the main coagulant. However, a significant disadvantage of NaCl is its relatively high consumption for rubber recovery from a latex (up to 250 kg per ton of rubber). Furthermore, NaCl is not trapped on wastewater treatment facilities, and virtually the whole its amount is discharged with wastewater into natural basins.

Therefore, a search for new coagulants and for ingenious process designs with lower consumption of chemicals and water and the water discharge by shops for rubber recovery from latexes is an urgent problem. Alternative coagulants (proteins, Mannich base, salts of polyvalent metals, such as Ca, Mg, Al, etc.) suggested [1–4] for recovering rubbers from latexes find yet very limited use on the industrial scale and are mainly used for production of only pilot batches.

Published data show that there are numerous and diverse organic coagulants, both synthetic and natural, that can either fully replace inorganic salts or considerably reduce their consumption. Of particular interest in this respect are polymeric quaternary ammonium salts which have a set of interesting properties and can find various industrial applications [5]. As shown in a review [6], complete recovery of rubbers from latexes is attained at relatively low consumption of these agents (3–6 kg per ton of rubber). However, data on the possibility of using them in production of emulsion rubbers are fragmentary, and the influence exerted by these agents on the rubber recovery from latexes and on the properties of the rubbers obtained and of articles thereof is poorly understood. Furthermore, data on the extent of contamination and amount of wastewater discharged by shops for rubber recovery from latexes are lacking.

The available data on the use of polymeric quaternary ammonium salts for rubber recovery show that the consumption of coagulants decreases by a factor of 50–100. One more significant fact is that, with these salts, the process becomes only slightly sensitive to pH fluctuations (polymeric quaternary ammonium salts can well be used in the pH 2–5 range). An important positive factor is that polymeric quaternary ammonium

salts, being cation-active products, actively interact with soaps of carboxylic and sulfonic acids to form insoluble salts and are captured by the forming rubber crumb. This leads to a decrease in the amount of organic salt–acid fractions discharged from rubber recovery shops and provides, to some extent, solution of environmental problems. However, the presence in the rubber of polymeric quaternary ammonium salts and products of their interaction with components of the emulsion system leads to acceleration of the rubber vulcanization [7] and requires correction of the rubber stock formulation.



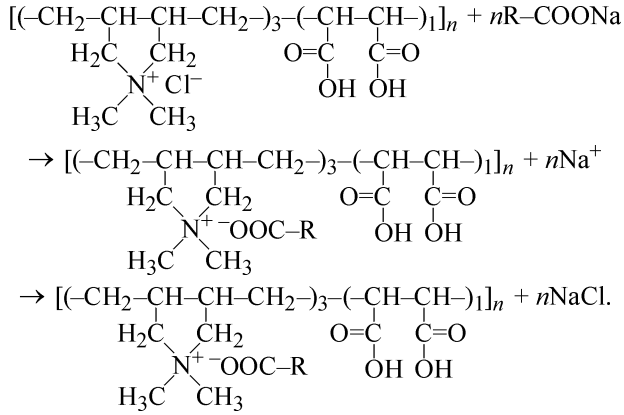
The above-noted advantages of quaternary ammonium salts make appropriate further studies of application of the known, and synthesis of new quaternary ammonium salts with the aim to evaluate their coagulating effect and prospects for their use for rubber recovery from latexes.

Here, we consider the possibility of using *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–maleic acid copolymer for rubber recovery from latexes.

A possible advantage of the suggested copolymer is that its component, maleic acid, is a by-product from production of phthalic and maleic anhydrides [8], which may reduce the cost of the polymeric coagulant and make it more competitive. This may open up new prospects for utilization of wastes from chemical industry and thus for a decrease in the environmental pollution. Furthermore, introduction into a polymer chain of units containing different functional groups will provide a tool for controlling their flocculating power by varying the chemical composition, steric structure, and charge of the chains.

EXPERIMENTAL

N,*N*-Dimethyl-*N*,*N*-diallylammonium chloride–maleic acid (DDACMA) copolymer is readily soluble in water and infinitely miscible with it. The concentration of the initial aqueous solution was about 51 wt %, pH ~2, average molecular weight $(3–8)\times 10^3$. The structure of the copolymer is as follows:



Experiments were performed with a commercial sample of SKS-30 ARK butadiene–styrene latex. As emulsifiers we used soaps derived from disproportionated rosin and tall oil resin acids. The colloid-chemical characteristics of the latex were as follows: dry residue 21.1%, pH 9.3, mean particle radius 50.8 nm, surface tension 63.7 mN m^{-1}.

The coagulation was performed as follows. A vessel placed in a thermostat was charged with butadiene–styrene rubber latex and kept at the prescribed temperature for 10–15 min, after which definite amounts of an aqueous solution of DDACMA copolymer were added. The coagulated system was acidified with a 2.0% aqueous solution of sulfuric acid in an amount of 15 kg per ton of rubber. The coagulum was separated from the serum, washed with water, and dried at 75–80°C.

The efficiency of the coagulating (flocculating) effect of DDACMA copolymer was evaluated gravimetrically (by the relative amount of the coagulum formed) and visually (from the serum transparency).

The concentration of the dispersed phase and temperature play an important role in the rubber recovery from latex, especially with organic cationic coagulants [9, 10]. Therefore, in the first step of our study we examined the effect of these factors on the completeness of rubber recovery. The experiment showed (Fig. 1) that the weight of the coagulum formed steadily increases with the amount of the coagulant added, and complete coagulation is attained at a coagulant consumption of 2.5–3.0 kg per ton of rubber (the amount of sulfuric acid added was constant, about 15 kg per ton of rubber).

In the course of coagulation of SKS-30 ARK latex, the particle charge is neutralized owing to a chemical reaction of the coagulant cation with anions of surfactants present on the surface of latex globules and entering into the composition of the adsorption layer [11]. As a result, an insoluble nondissociating complex is formed:

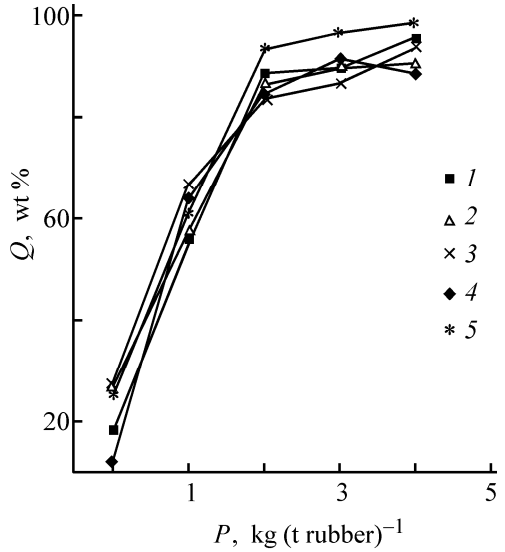


Fig. 1. Fraction Q of the polymer recovered from SKS-30 ARK latex vs. the concentration of DDACMA copolymer P at various temperatures. Dispersed phase concentration $c_{d.p}$ = 211 g l^{-1}, H_2SO_4 consumption 15 kg per ton of rubber. T, °C: (*1*) 1, (*2*) 20, (*3*) 40, (*4*) 60, and (*5*) 80.

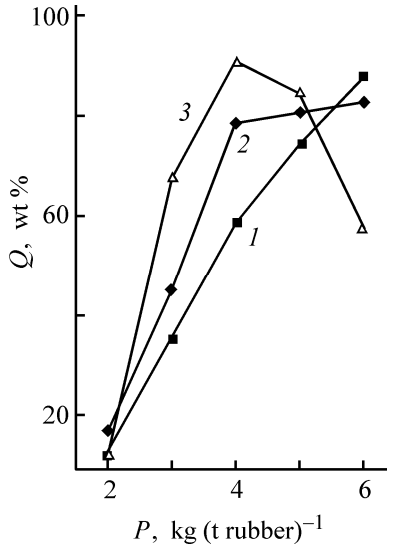

Fig. 2. Influence of the DDACMA copolymer concentration P on the degree Q of coagulation of SKS-30 ARK latex. Dispersed phase concentration $c_{d.p}$ = 52.7 g l^{-1}, H_2SO_4 consumption 15 kg (t rubber)$^{-1}$. T, °C: (*1*) 20, (*2*) 60, and (*3*) 80.

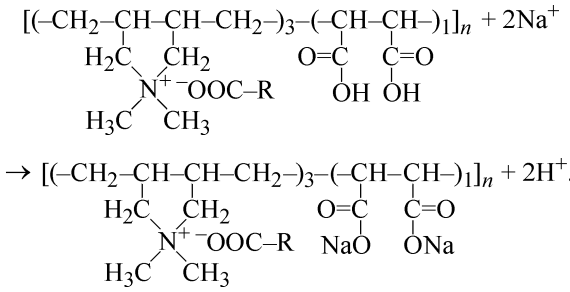

It should be noted that sodium chloride formed by this exchange reaction can also be involved in the coagulation as a salt coagulant, which is an advantage of DDACMA copolymer. It is extremely difficult to evaluate the contribution of the noticeably different components to the total coagulating effect. However, most probably, the coagulating effect is due to a combination of two factors: neutralization and bridge formation [12]. In addition, it should be emphasized that acid groups of maleic acid should cause acidification of the system and thus additionally promote its destabilization. This also positively affects the coagulation and allows its completion at a lower coagulant consumption (2.5–3.0 kg per ton of rubber, which is two orders of magnitude less than that with NaCl).

An additional advantage of the suggested coagulant is that the presence of acid groups makes the coagulating system considerably less sensitive to fluctuations of the content of the acidifying agent, which should inevitably lead to stabilization of the coagulation process. Thus, our study revealed a number of advantages of DDACMA copolymer as coagulant for rubber recovery from latex.

Our experiments show (Fig. 1) that the temperature affects the consumption of DDACMA copolymer required for complete recovery of the rubber from the latex, with the highest coagulum yield observed at low temperatures (1–20°C). An increase in the coagulation temperature led to a slight decrease in the coagulum eight, which may be due to several factors. First, the solubility of the coagulant and products of its interaction with surfactants decreases at low temperatures, and they are less readily washed out from the rubber crumb. Second, a denser coagulum is formed at low temperatures, whereas the coagulum formed at elevated temperatures is "looser," which, in turn, is accompanied by accumulation of a certain amount of finely dispersed rubber crumb in the serum. On the one hand, the presence of loose coagulum and finely dispersed rubber crumb favor a more efficient washing-out of impurities from the rubber. On the other hand, this factor increases the rubber loss with wash waters, which negatively affects the process efficiency and leads to environmental pollution. The denser coagulum is free of these drawbacks, its weight is higher because components of the emulsion system are captured by the coagulum, but its washing becomes inefficient, which may exert a negative effect on the properties of rubber stocks and vulcanizates. These trends were revealed in experiments on coagulation of the concentrated latex (21.1 wt %). A decrease in the dispersed phase concentration at 20°C (1 : 1, 1 : 2, 1 : 3 dilutions) leads to an increase in the coagulant consumption to 3–4 kg per ton of rubber (Figs. 2, 3), against starting 2 kg t^{-1} for the initial latex.

Figures 1 and 2 show that, with a decrease in the dispersed phase concentration, not only the coagulant

consumption increases (Fig. 3), but also the shape of the curves changes, especially at the maximal dilution. Namely, at a dispersed phase concentration of about 5.3 wt % (1 : 3 dilution) and temperature of 80°C, a flocculation optimum is observed, and deviation from it toward an increase in the consumption of DDACMA copolymer leads to a decrease in the coagulum weight. This may be due to adsorption of charged copolymer macromolecules on the particle surface, which makes possible both neutralization by the interaction of surfactant anions with cationic groups of the polyelectrolyte to give an insoluble complex, and formation of an oppositely charged (with excess flocculant) protective adsorption layer. The recharging phenomena have been repeatedly observed in experiments on coagulation of SKS-30 ARK latexes with poly(*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride) [13]. In addition, it is possible that, after the interaction of quaternary ammonium groups of DDACMA copolymer with surfactant anions is complete, free carboxy groups of maleic acid interact with sodium cations to form the corresponding salt, which can act as a surfactant of a new protective layer:

As noted by Pelssers et al. [14], it is also necessary to take into account the occurrence of relaxation processes in layers of adsorbing macromolecules. As a result of these processes, the number of segments contacting with the particle surface increases with time. In the process, the length of "tails" and "loops" remaining in the aqueous phase and responsible for capture of adjacent particles (bridging flocculation mechanism) decreases. The relaxation processes lead to "smoothening" of the polymer molecules and their "deactivation" (loss of the capacity for bridge formation) and favor formation of a dense adsorption layer exerting a protective effect, which is particularly manifested at low latex concentrations. As the dispersed phase concentration is raised, the frequency of particle collision increases and the time of the relaxation of the adsorption layers becomes shorter. At a certain concentration of the dispersed phase, the time intervals between the collisions become too short for the smoothening of the adsorbed molecules to occur to a significant extent, and the capacity for bridge formation is preserved. Then, even despite the recharging and the arising electrostatic repulsion, the flocculation activity of a cationic polyelectrolyte is preserved owing to the bridging mechanism.

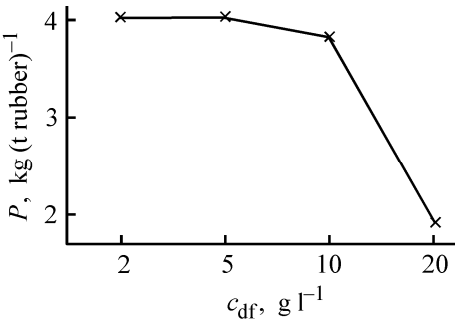

Fig. 3. Consumption of DDACMA copolymer P vs. the dispersed phase concentration $c_{d.p}$ H_2SO_4 consumption 15 kg per ton of rubber, $T = 20$°C.

Thus, at a definite concentration of the dispersed phase (latex concentration), the restabilization effect is suppressed and the degree of flocculation reaches the limiting value corresponding to complete breakdown of the dispersed phase (complete recovery of the rubber from the latex).

It is significant that, at decreased concentrations of the dispersed phase (Figs. 1, 2), an increase in the temperature leads to a decrease in the consumption of DDACMA copolymer for complete recovery of the rubber. Hence follows that dilute latexes should be coagulated at higher temperatures. This may be due to the fact that the latex particles separated from each other by a large distance due to dilution interact with each other at elevated temperatures more actively.

It is well known [1] that, in industry, rubber is recovered from a latex by adding NaCl in the presence of ~15.0 kg t^{-1} of sulfuric acid. Therefore, evaluation of the effect of sulfuric acid additions on the rubber recovery from latex is extremely important. As shown by an experiment (dispersed phase concentration 21.1 wt %, Figs. 4a, 4b), with the amount of the polyelectrolyte added of 1.0 kg per ton of rubber and the acidifying agent consumption varied from 5.0 to 30.0 kg per ton of rubber, the coagulation was incomplete. The maximal yield of the coagulum was observed at coagulation temperatures of 1–20°C and reached 80 wt % at best.

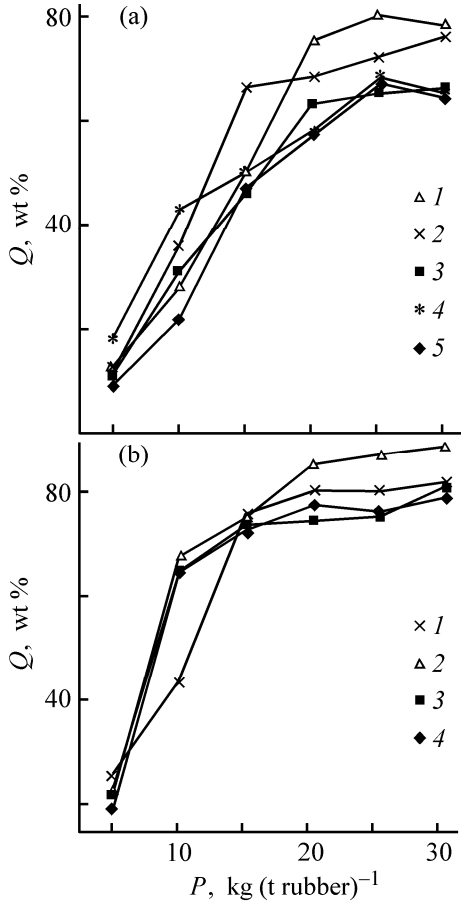

Fig. 4. Coagulum yield Q from SKS-30 ARK latex vs. the sulfuric acid consumption P at various temperatures. Dispersed phase concentration $c_{d.p}$ = 211 g l^{-1}, consumption of DDACMA copolymer (a) 1 and (b) 1.5 kg per ton of rubber. T, °C: (a) (*1*) 1, (*2*) 20, (*3*) 40, (*4*) 60, and (*5*) 80; (b) (*1*) 1, (*2*) 20, (*3*) 40, and (*4*) 80.

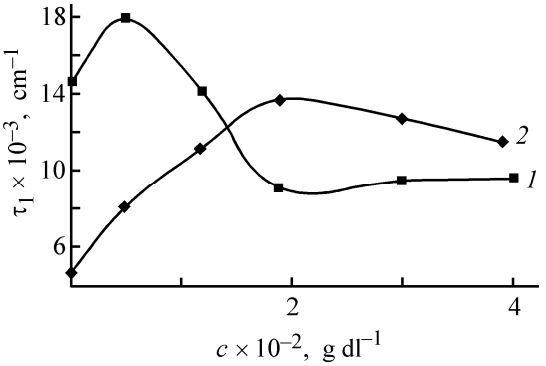

Fig. 5. Influence of the concentration of DDACMA copolymer, $c \times 10^{-2}$, on the 1-min turbidity $\tau_1 \times 10^{-3}$ of SKS-30 ARK latex at pH (*1*) 3 and (*2*) 9.

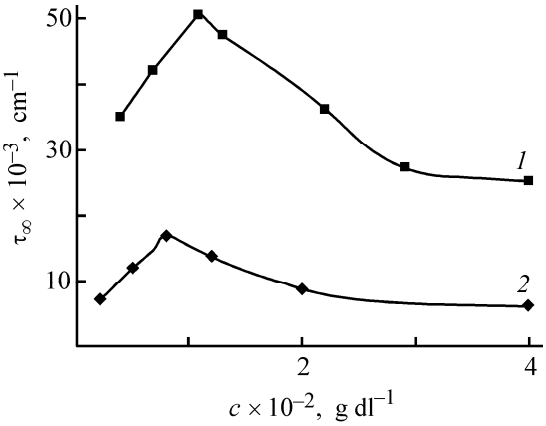

Fig. 6. Limiting turbidity $\tau_\infty \times 10^{-3}$ of SKS-30 ARK latex vs. DDACMA copolymer concentration $c \times 10^{-2}$. pH: (*1*) 3 and (*2*) 9.

Raising the coagulation temperature to 80°C led to a decrease in the coagulum weight, which can be attributed to the two factors discussed above.

With an increase in the DDACMA copolymer consumption to 1.5 kg per ton of rubber (Fig. 4b), the coagulation was the most complete (91 wt %) at the acidifying agent consumption of 30 kg per ton of rubber. An increase in the temperature led to a decrease in the coagulum yield to 70–80 wt %.

The coagulating performance of electrolytes is commonly assessed, along with the influence of their consumption on the degree of coagulation, by the initial coagulation rate. This quantity is usually evaluated nephelometrically, by measuring the 1-min turbidity [15].

To a latex diluted by a factor of 10^4, we added various amounts of the coagulant at pH 3 and 9 (adjusted with aqueous sulfuric acid). The turbidity was measured 1 min after introducing DDACMA copolymer into SKS-30 ARK latex.

Figure 5 shows the dependences of the 1-min latex turbidity τ_1 on the concentration of the polyelectrolyte added. As can be seen, both curves pass through a maximum. An increase in the initial rate of the latex flocculation in the ascending portions of curves *1* and *2* may be due to binding of emulsifier anions into an insoluble and virtually nondissociating complex. The optimum point corresponds to complete neutralization of the surface electric charge of the particles. Further decrease in the 1-min turbidity characterizes an increase in the stability of the disperse system, apparently due to recharging of the latex globules [13].

Notably, acidification of the system to pH 3 leads to a considerable enhancement of the flocculating effect of the polyelectrolyte (Fig. 5, curve *2*). The floccu-

lation optimum at pH 3 is observed at a polyelectrolyte concentration approximately five times lower than at pH 9. This fact has been noted previously in the literature [16] and is due to the pronounced coagulating effect of sulfuric acid itself, which is an efficient electrolyte-coagulant causing contraction of the electrical double layer on the surface of latex globules.

Another quantitative characteristic of the flocculating effect of the polyelectrolyte is the maximal turbidity τ_∞, which is determined from the kinetic data and characterizes the size of floccules that are not broken down in storage. The effect of polyelectrolyte additions on τ_∞ is shown in Fig. 6. As can be seen, at small additions of the polyelectrolyte, τ_∞ (and, accordingly, the mean floccule size) increases. Acidification of the system (Fig. 6, curve *1*) leads to considerable coarsening of the aggregates formed, which would be expected. Further increase in the amount of the polyelectrolyte added leads to a decrease in τ_∞, which confirms the previously found increase in the system stability. Similar results have been obtained previously [17] on polystyrene latexes coagulated with poly(*N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride). The data obtained are consistent with the data on the degree of the rubber recovery from concentrated SKS-30 ARK latex at various pH values.

The final stage of this study was to determine the physicomechanical parameters of rubber stocks and vulcanizates based on SKS-30 ARK butadiene–styrene rubber recovered from the latex with DDACMA copolymer. As control sample we used a rubber sample recovered from SKS-30 ARK latex with the traditional coagulant, NaCl. Rubber stocks were prepared on laboratory rollers, using standard ingredients, and subjected to vulcanization at 143°C for 60 min. The results are listed in the table.

The data obtained show that rubber stocks prepared from the experimental sample undergo vulcanization faster than does the control stock. The vulcanization is accelerated by DDACMA copolymer and products of its interaction with the emulsion system components remaining in the rubber after its recovery from the latex. This leads to a slight decrease in the strength characteristics. Hence, for commercial use of DDACMA copolymer for recovering butadiene–styrene rubbers from latexes, it is necessary to additionally correct the composition of rubber stocks. We also found that the experimental sample surpass the control samples in the resistance to thermal aging and to crack propagation. The other characteristics of the experimental and control samples coincided within the experimental error.

Properties of rubber stocks and vulcanizates based on SKS-30 ARK rubber

Parameter	Sample	
	experimental	control
Mooney viscosity of rubber stocks MB 1+4 (100°C)	60.5	63.0
Nominal stress at 300% elongation, MPa	6.3	6.7
Nominal tensile strength, MPa	21.9	25.1
Relative breaking elongation, %	650	690
Relative remanent strain	16	20
Rebound elasticity, %:		
at 20°C	48	46
at 60°C	50	50
Shore hardness A	51	48
Tear resistance, kN m^{-1}	61.0	58.0
Resistance to crack propagation with ≤12-mm puncture, thousand cycles	112.7	98.6
Thermal aging resistance factor (72 h, 100°C):		
for nominal strength	0.71	0.63
for relative elongation	0.43	0.38

CONCLUSIONS

(1) A decrease in the concentration of the dispersed phase from 21 to 5.3 wt % leads to an increase in the coagulant consumption to 3.0–4.0 kg per ton of rubber.

(2) An increase in the acidifying agent consumption from 15 to 30 kg per ton of rubber ensures complete rubber recovery from the latex at a consumption of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–maleic acid copolymer as low as 1.5 kg per ton of rubber.

(3) The dependences of the 1-min and maximal turbidity of the dilute latex on the amount of *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–maleic acid copolymer added pass through a maximum, which points to enhancement of the flocculating performance of the polyelectrolyte at its small additions and to an increase in the latex stability at the polyelectrolyte overdose.

(4) The *N*,*N*-dimethyl-*N*,*N*-diallylammonium chloride–maleic acid copolymer can be used in the industrial process of rubber recovery from latexes. The complete recovery is attained at its consumption of 2.5–3.0 kg per ton of rubber. Its use as coagulating agent does not significantly alter the properties of the rubber

obtained, rubber stocks, and vulcanizates. The vulcanizate strength slightly decreases, whereas the resistance to thermal aging and crack propagation increases.

Abstract—Gel-forming polyacrylamide (PAA)–aluminum pentahydroxochloride (APHC) formulaitons were studied as waterproofing agents for an oil pool. The optimal formula and the gelation rate were determined.

DOI: 10.1134/S1070427208080272

The majority of methods for raising the oil recovery from oil strata are based on flooding. Breakthrough of injected and stratal waters through areas with high filtration properties results in the formation of flooded-out regions. Water is filtered through these regions, bypassing low-permeable oil-bearing areas of a pay. The oil production decreases and water content of oil increases.

To raise the oil recovery from oil pools, chemicals that form a waterproofing shield in highly watered interlayer, which prevents water penetration in producing oil wells, are pumped in [1].

However, most of these chemicals have significant disadvantages. Among them is the high cost, contamination of underground and surface waters, poor technological properties, and short life of the protecting shields. To selectively protect strata from water, gel-forming formulations of organic, inorganic, or organomineral compounds are used and, in particular, a mixture of a polyacrylamide (PAA) solution, aluminum salt, and urea (U) [2, 3]. The resulting aluminum hydroxide gel is a polydisperse system with poor and nonuniform adhesion to the stratum rock. Although an introduction of polyacrylamide improves the adhesion, the resulting system is freely disperse and is gradually washed out from the collector by injected or stratal water.

A gel-forming formulation containing aluminum pentahydroxochloride (APHC) yields a more stable and longer-lived gel. Colloidal polymer complex (CPC) [4] is almost instantaneously formed by the reaction of APHC with polyacrylamide in the starting solution. Urea introduced in the course of preparation of the starting solution decomposes in a stratum. The hydrolysis product initiates hydrolysis of the aluminum salt [5]. As a result, a stable strong gel-in-gel (combined gel) dispersion resistant to washout is formed.

The aim of this study was to develop a gel-forming PAA-APHC formulation for water-shutoff of oil pools, to find the best formula, to determine the gelation rate, and to estimate waterproof properties of this gel toward oil pools.

EXPERIMENTAL

Aluminum pentahydroxochloride prepared by the patented procedure [6] had the following properties: Al^{3+} content 12.8 wt %, Cl^-/Al^{3+} atomic ratio 0.48, pH 4.5, $\rho = 1330$ kg m^{-3}, dry residue 46.5 wt %. PAA with molecular weight of 6×10^6 was purchased from ACROS Company (USA), and urea, from Ekros Company (Russia). The formulations were prepared by mixing an aqueous PAA solution (1 wt %) with an aqueous APHC solution and urea at room temperature.

The instant of gelation was visually determined by the absence of fluidity of the liquid and more precisely by the solution viscosity measured with a Reokinetika-M vibration viscometer with a temperature-controlled cell. The vibration frequency was 750 Hz, and amplitude, 0.02 mm.

Table 1. Dependence of the gelation time on the APHC : U ratio (temperature 75°C)

APHC : U weight ratio	Gelation	Gelation time, h*
1 : 0.25	–	–
1 : 0.50	–	–
1 : 1	–	–
1 : 2	+	13
1 : 4	+	8.5
1 : 6	+	6
1 : 8	+	5
1 : 10	–	–

* In the case of negative results, the mixture was heated for 22 h.

Table 2. Dependence of the gelation time on the concentration of APHC–U mixture in the solution (APHC : U weight ratio = 1 : 6, T = 75°C)

Concentration, %	Gelation	Gelation time, h*
5	–	–
10	+	6.0
15	+	4.2
20	+	4.0

* In the case of negative results, the mixture was heated for 34 h.

The waterproofing properties were studied in a glass column with a heated jacket in which the required temperature was maintained with the aid of a thermostat.

The bench experiments were performed on a UIPK unit. Water and oil prepared in accordance with OST (Branch Standard) 39-235–89 were used as stratal liquids. The experiments were performed under the model thermobaric conditions (stratal pressure 31 MPa, temperature 75°C).

To analyze the ability of the gel to be confined in the rock (resistance of the gel to washout), pressure differences were produced taking into account the technical possibilities of the equipment (discreteness of the filtration rate) and the fluid properties. The pressure difference during washing of oil- and water-saturated samples was 18.8–21.9 and 1.1–3.2 MPa, respectively. The waterproofing power G (%) was calculated by the equation

$$G = \frac{k_0 - k}{k_0} \times 100,$$

where k_0 the penetrability of the rock before gel injection and k is that,

$$k = \frac{Q f \mu}{ps},$$

Q is the flow rate of water passed through the bulk model ($m^3 s^{-1}$); L, height of the rock bed (m); μ, water viscosity (Pa s); p, pressure (Pa); and s, cross-section area of the bulk model (m^2).

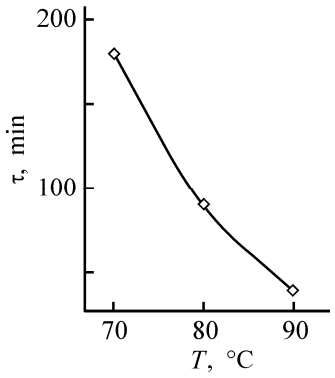

Fig. 1. Gelation time τ of APHC–U mixture vs. temperature T.

The main gelation parameters are the gelation time and the dependence of this time on the reagent ratio and temperature. To study the gelation, formulations with different component ratios and different component concentrations were placed in test tubes and heated in a thermostat at different temperatures until a gel was formed. The gel state and gelation time were determined. The results of the experiments on the influence of the component ratio on gelation in the examined system and gelation time are presented in Table 1.

As can be seen from Table 1, the gel is formed in a definite range of component ratios. No gelation was observed within the examined time at both decreased (less than 1 : 2) and significantly increased (more than 1 : 8) APHC amount. It should be noted the gel could also be formed at low APHC : U ratios in a longer time, but this possibility was not examined.

The dependence of the gelation time on the total component concentration in an aqueous solution is presented in Table 2. It is seen that no gel is formed at a total component concentration decreased to 5%. The gelation time somewhat decreases with increasing urea concentration.

The temperature is an important parameter which determines the hydrolysis rate of urea and hence the increase in the pH of the solutions to the values providing hydrolysis of the aluminum salt to form an amorphous gel of aluminum hydroxide. As can be seen from Fig. 1, the temperature is a key factor for gelation.

Table 3. Water permeability of quartz sand upon formation of an aluminum hydroxide gel in the presence of PAA in the bulk of the bed

Gel-forming system, weight proportion	Time of water drainage before treatment, min	Gelation time at 75°C, h	Time of water drainage after treatment, h	Waterproofing factor, %
APHC : U = 1 : 6	0.6	1	1.2	90
PAA : APHC : U = 0.07 : 1 : 6	3.1	6	1.3	93

To determine the gelation time and other rheological parameters of the gels more precisely, we studied the gelation kinetics of APHC–U formulations with different component ratios at 75°C. The kinetic curves (Fig. 2) show a significant dependence of gelation on the component ratio.

All the curves are characterized by a sharp increase in the viscosity due to transformation of the disperse system into gel. The shape of the curve corresponding to gelation depends on local changes of viscosity in the gel body and features of propagation of mechanical vibrations in the structurally nonuniform media. As the APHC : U ratio increases, the gelation time and the gel viscosity decrease since the amount of the reagent initiating gelation under these conditions grows and the weight of the gel-forming component (APHC) becomes lower.

These results confirm our previous assumption that the required gelation time and rheological properties of gel-forming formulations can be attained by varying the component ratio.

To study the waterproofing properties of aluminum hydroxide gels in the presence of polyacrylamide, we modeled a stratum by a bulk bed of quartz sand, since quartz is one of the natural strata of terrigenous sedimentary rocks contained in oil-saturated collectors. The main parameter used to estimate the influence exerted on the waterproofing properties of the gels was the waterproofing factor.

The time of water drainage through a bed of quartz sand at room and gelation temperature is presented in Table 3. It is seen that the time of water drainage through the sand bed sharply increases after gelation in the bed. Introduction of PAA improves the waterproofing effect.

Gel-forming formulation containing polyacrylamide, urea, and an aqueous solution of the aluminum salt was prepared by mixing a 0.1–1.0% aqueous polyacrylamide solution with a aqueous colloidal solution of aluminum pentahydroxochloride to form a colloidal polymer complex by intermolecular interaction of flexible polyacrylamide chains with the surface of colloidal APHC particles. Urea undergoes thermolysis on heating by the equation

$$CO(NH_2)_2 + H_2O \xrightarrow{T,\ ^\circ C} CO_2 + NH_3$$

and the pH solution gradually increases, reaching the threshold value (pH > 6.8) at which aluminum hydroxide gel is instantaneously formed in the bulk of the solution.

Apparently the gel–polyacrylamide system is structured with time. The formulation containing APHC was kept for a long time in a fixed bed. Water was passed through the quartz sand bed at regular intervals and the rate of water drainage was measured. The results are presented below:

Day after gelation	3	6	9	12	22	26	35	37	40	45
Time of water drainage, $V = 100$ cm^3, h	1.5	2.5	6.3	7.2	7.5	7.7	8.1	8.2	8.4	8.5

The results show that the gel strength increases and its waterproofing properties are improved with time.

We studied the influence of the gel-forming formulation containing polyacrylaamide, aluminum pentahydroxochloride, and hydrolyzing agent (urea) on

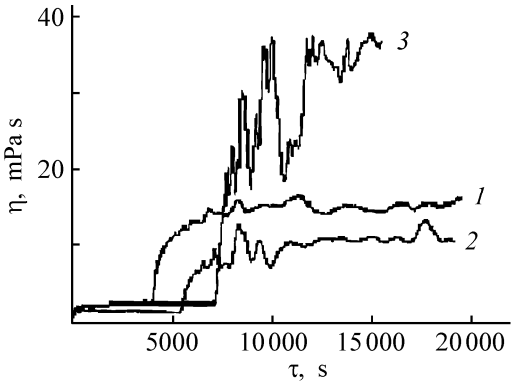

Fig. 2. Viscosity η of the formulation with APHC : U weight ratio of (*1*) 1 : 4, (*2*) 1 : 6, and (*3*) 1 : 8 vs. time τ.

Table 4. Influence of gel-forming formulation on filtration properties of deposit rocks

Sample no.	Porosity, %	Modeled saturation zone	Permeability coefficient, $K_{pm} \times 10^{-3}$, μm^2		
			initial	after injection of gel	after washout of gel
1	13.1	Water-saturated	33.6	0.034	0.084
2	10.22	Oil-saturated	0.06	0.014	0.045

the permeability of the rock saturated with stratal liquids (oil, stratal water). In these experiments, we studied core materials of oil wells. The rheological properties of collectors before and the treatment with the developed formulation were determined. The results of the bench experiments are presented in Table 4.

The permeation of water through the water-saturated samples decreased by a factor of 10^3 after treatment with the gel-forming formulation.

Analysis of gel retention in the rock (resistance of the gel to washout) showed that the permeability increased by a factor of 1.5–2.5. Thus, the gel is fairly resistant to washout.

Treatment of the water-saturated zone with the formulation developed decreases the permeability by a factor of 400 owing to plugging of the collector pores with gel particles (mudding).

The influence of the gel-forming formulation on the oil-saturated zone of the stratum was weaker. The penetrability of oil after injection of gel decreased by a factor of 4.3. The final permeability after washing (determination of the gel resistance to washout) decreased by a factor of 1.3 relative to the initial value.

CONCLUSION

Gel prepared from a polyacrylamide–aluminum pentaoxochloride-urea mixture of the optimal composition decreases the rock permeability by a factor of 400 and hardly affects the permeability of the oil-saturated zone. The gel is resistant to washout from the water-saturated zone of a stratum.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Physicochemical Properties of Ocher Used as Polymer Filler

T. N. Teryaeva, O. V. Kas'yanova, G. M. Rotova, and O. V. Kostenko

Kuzbass State Technical University, Kemerovo, Russia

Received December 27, 2007

Abstract—Principal physicochemical properties of ocher were studied in order to use it as a mineral filler for polymers.

DOI: 10.1134/S1070427208080284

Fillers produced by crushing and processing of natural minerals, such as, e.g., talc, chalk, kaolin, and mica, find wide use in manufacture of polymeric composite materials (PCM). Introduction of mineral fillers into a polymer makes it possible to solve a number of problems related to materials science (extending the raw materials base, improving the strength, rigidity, heat resistance, etc.), technology (controlling the viscosity and thermal stability of melts), and economics (lowering the production cost of PCM) [1, 2]. However, the available commercial assortment of domestically manufactured fillers used on the industrial scale for synthesis of PCM is limited and cannot satisfy the diverse and steadily growing requirements of consumers. Therefore, a search for effective fillers of natural origin, large raw material resources, and low cost is a topical task.

Rather promising in this regard for polymer filling is use of ocher, a readily available and ecologically safe mineral raw material, whose deposits are present in sufficient number on the territory of Russia, including those in Kuzbass.

Ocher is mostly used as a pigment in production of paint-and-varnish materials and its properties reported in the technical literature are the spreading capacity, light resistance, oil capacity, density, particle size, and elemental composition, which is insufficient for characterizing a mineral powder as a polymer filler [3].

There is published evidence about the possible use of ocher for polymer filling [4–6], but neither recommendations about the composition of formulations and necessity for preparation procedures, nor parameters commonly determined for dispersed mineral polymer fillers can be found in the literature.

This communication reports the results of a study of the physicochemical properties of ocher, which make it possible to assess its applicability as a polymer filler.

EXPERIMENTAL

As object of study served ocher of O2 brand [TU (Technical Specification) 301-10-019–90] from the Gavrilovskoe deposit (town of Salair, Kemerovo oblast). It had the following composition (%): Fe_2O_3 17.6, Al_2O_3 29.1, SiO_2 44.8, SO_4 0.05, K 0.26, Cu 0.03, PO_4 0.57, Cr 0.9, Ca 1.4, Ni 0.003, Mn 0.64, Mg 0.64, and Cl 0.001.

Standard procedures were employed to find the density ρ [in accordance with GOST (State Standard) 15 139], content W of water and volatiles (GOST 19 728.19), and bulk density ρ_b (GOST 11 035). The pH of a water extract, granulometric composition, particle size d, and specific surface area S_{sp} were determined using the methods described in [7].

The thermochemical properties of ocher were studied on a Q-1500D derivatograph in air.

The thermal properties of ocher (heat conductivity λ, specific heat c_p) were found using the integrated thermographic method [8].

The experimental results were processed in accordance with GOST (MI 2336–2002.GSI) [10, 11].

Ocher is a finely ground goldish yellow powder. As regards the content of iron oxide hydrate, the ocher under study is classed as ordinary clayey, with Fe_2O_3 content of about 17.6%. The outward appearance of ocher is shown in Fig. 1.

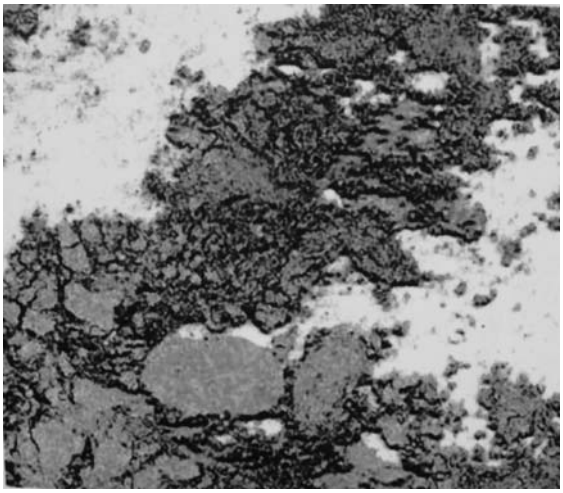

Fig. 1. Outward appearance of ocher.

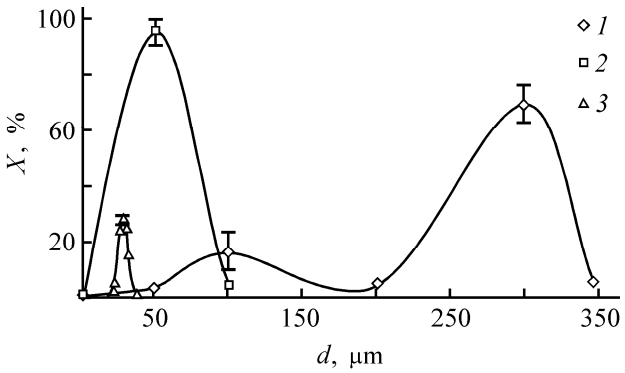

Fig. 2. Granulometric composition of ocher. (*X*) Content of a fraction and (*d*) particle size. Sieving: (*1*) dry and (*2*) wet; (*3*) sedimentation analysis.

Ocher particles have a lamellar shape, which is indicated by their form factor, found using a rheological method (Einsten coefficient k_e is 16.5), and by the accordingly stronger effect of the filler on the viscosity of, and the stress concentration in filled polymers.

The particle size and the granulometric composition of a filler largely affect the PCM properties. In the industry, the granulometric composition of powders is most frequently determined by dry or wet sieving analysis. The particle size distribution curves found for ocher by dry or wet sieving are shown in Fig. 2. In addition, the same figure presents results of a sedimentation analysis. This dependence was obtained in five parallel runs, with the plots constructed using the average values. The deviation in the content of particles of a certain size does not exceed 5% (the error is shown in the plots).

As can be seen from the curves in Fig. 2, in the case of dry sieving, the size distribution of ocher particles has two peaks, at 100 and 300 μm. In the case of wet sieving, most part of particles are 50 μm in size. The results obtained can be attributed to the tendency of ocher particles to form agglomerates, which is characteristic of the majority of dispersed fillers. This is also confirmed by the outward appearance of ocher particles (Fig. 1). Upon wetting with a liquid, coarse agglomerates disintegrate.

The particle size of ocher was found by sedimentation analysis to be 20–40 μm. This means that ocher belongs to the group of medium-dispersity fillers ($10 \le d \le 40$ μm) [1]. The results of sedimentation analysis were used to calculate the specific surface area of ocher ($S_{sp} = 0.08 \pm 0.05$ m^2 g^{-1}) and the degree of polydispersity $\delta = 1.6$.

It is rather difficult to determine the chemical composition and the nature of the surface of mineral fillers. Therefore, the common way is to evaluate the overall chemical nature and the degree of contamination by the pH of an aqueous extract of the filler. For ocher, pH 6, i.e., the particle surface of ocher under study are weakly acidic.

The true and bulk density of ocher was measured to be 2630 ± 60 kg m^{-3} and 680 ± 90 kg m^{-3}, respectively, which made it possible to find the maximum volume degree of filling, φ_{max}, to be 26 ± 2 vol %. The quantity φ_{max} is the upper limit on the filler content of the two-phase material. In the end, it determines the properties of PCM, technological parameters of the forming process, and the service characteristics of articles. The larger φ_{max}, the greater amount of the filler can be introduced without substantially impairing the technological properties, including the melt viscosity [1, 8].

The abrasiveness, or abrasion capacity, is a negative characteristic of mineral powders. In grinding, dispersion, transportation, and other technological procedures, the equipment undergoes a strong wear [4]. To preclude this phenomenon, it is recommended to use PCM fillers with low hardness (Mohs hardness ≤ 2). For ocher, the Mohs hardness (MH) is 1–2 and is approximately equal to that of kaolin, which enables processing of formulations with ocher in standard apparatus.

The thermal properties of ocher were as follows: $c_p = 0.6 \pm 0.02$ kJ kg^{-1} K^{-1} and $\lambda = 0.26 \pm 0.03$ W m^{-1} K^{-1}, which corresponds to similar characteristics of natural minerals.

The moisture content of ocher is 1.91 wt %, which necessitates drying of ocher in the case of its introduction into polymers in amounts exceeding 1 wt %. The increased moisture content of the filler will primarily affect the type of interaction between the polymeric matrix and the filler. An excessive content of moisture and volatiles (> 0.02%) leads to formation of pores and voids at the polymer–filler interface and, as a result, can impair the service characteristics of PCM (hardness, strength) and adversely affect their outward appearance (porosity, bulging). An increased moisture content of the filler may lead to arching of the material in the bunker of a processing apparatus, which disturbs the even feeding of the machine.

Moisture is commonly removed by thermal treatment at the minimum possible temperature.

To study the behavior of ocher under heating, the derivatogram shown in Fig. 3 was measured. The DTA curve obtained shows endothermic peaks at 105, 275, 502, and 700°C, accompanied by loss of mass by the sample under study. For example, ocher loses 1.91 to 5.4% of its mass at 105–300°C, and 8.17 to 12.43% at 490–740°C.

Moisture is removed via evaporation (at 100–105°C) of water adsorbed by the ocher surface and via chemical reactions at higher temperatures:

$$2FeO(OH) \rightarrow Fe_2O_3 + H_2O,$$

$$Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O \rightarrow Al_2O_3 \cdot 2SiO_2 + 2H_2O.$$

It should be noted that the color of ocher changes from goldish yellow to red-brown at temperatures higher than 150°C. At 250–300°C, ocher is nearly completely dehydrated and transformed to red-brown iron oxide. At temperatures of 490–700°C, there occurs dehydration and disintegration of the kaolin lattice [4].

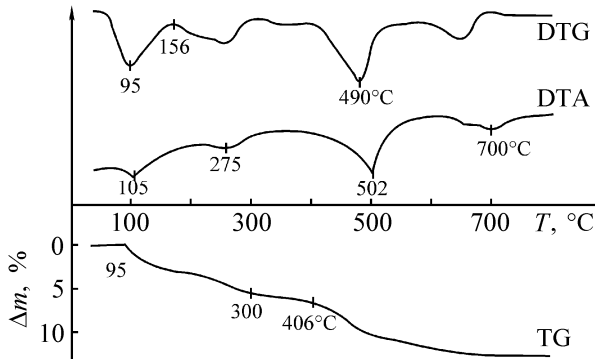

Fig. 3. Derivatogram of ocher (sample mass 402 mg). (Δm) Loss of mass and (T) temperature.

The results of the thermal analysis suggest that ocher should be treated at 300°C to remove moisture. The duration of such a thermal treatment for an ocher layer with a thickness of up to 10 mm is 90 min.

For a thermally treated ocher, the same characteristics as those for the starting ocher were determined. The results obtained are listed in the table, together with the parameters of the presently most widely used mineral polymer fillers.

Analysis of the data in the table shows that thermal treatment of ocher leads to an increase in the density, heat conductivity, specific heat, and specific geometric surface area and to a decrease in agglomeration because of the moisture removal.

Physicochemical properties of ocher and mineral fillers

Parameter	Filler				
	ocher*	talc	kaolin	chalk	mica
ρ, kg m^{-3}	2830	2800	2600	2600–2900	2830
d, μm	16–28	5–40	0.5–10	2–50	35–40
pH	4–5	9.2	4.5	8.1–9.6	7.5
j_{max}, vol %	30	31	15	34	–
λ, W m^{-1} K^{-1}	0.3	2.1	0.18	2.4	0.6–2.5
c_p, kJ kg^{-1} K^{-1}	0.75	0.87	0.89	0.82	0.87
MH, arb. units	2	1	1–2	3	2.5–3.5
W, %	0	–	–	–	–
ρ_b, kg m^{-3}	810	–	–	–	–
S_{sp}, m^2	0.1	–	–	–	–

* Thermally treated.

Comparison of the properties of the starting and thermally treated ocher with those of the conventional dispersed mineral polymer fillers shows that they are on the same order of magnitude or slightly differ, and, consequently, ocher can be used to obtain polymeric composite materials. Kaolin has parameters the closest to those of ocher.

CONCLUSIONS

(1) Preparation of ocher as a polymer filler should include thermal treatment at 300°C to remove moisture and obtain high-quality articles.

(2) As a result of thermal treatment of ocher, its density, specific heat, heat conductivity, and specific geometric surface area increase by 5–15%, the degree of its agglomeration decreases, and its color changes because of the moisture removal.

BRIEF COMMUNICATION

Effect of Mechanical Activation on the Synthesis and Electrochemical Properties of Lithium-Vanadium Bronze

S. S. Smirnov and V. A. Zhorin

Moscow Institute of Power Engineering, Moscow, Russia

Received December 11, 2007

Abstract—An original technique for production of a lithium-vanadium bronze was developed. It includes mechanical activation of a mixture of vanadium oxide with lithium hydroxide in the course of plastic flow under twisting.

DOI: 10.1134/S1070427208080296

In presently manufactured lithium-ion batteries, the positive electrodes are as a rule fabricated from lithiated cobalt, nickel, and manganese oxides [1–3]. In recent years, the technology of these conventional electrodes has been refined and novel materials have been sought for. The main way to refine the conventional materials is doping, i.e., synthesis of mixed cobaltates, nickelates, spinels and development of two-phase composites containing particles of an active material enveloped with thin films of a foreign substance.

Recently, interest has been revived in vanadium oxides, a promising material for positive electrode of secondary lithium power cells. Materials based on vanadium oxides were intensively studied in the 1980s**.** After that, however, researchers' attention has been mostly concentrated on cobalt and nickel oxides and manganese spinels, which have a more positive potential. Among vanadium compounds, the most promising materials for positive electrodes are lithium-vanadium bronzes (LiV_3O_8) [3]. A large number of both high- and low-temperature methods for their preparation have been suggested: solid-phase thermochemical method, sol-gel procedure, melt technique, and hydrothermal method [4–8].

However, lithium-vanadium bronzes obtained by the sol-gel procedure contain a large amount of water, which is then extracted into the electrolyte. In addition, such vanadium oxides absorb a considerable amount of organic solvents. The high-temperature solid-phase method has the shortcomings of multistage nature, prolonged process duration, and low dispersity of LiV_3O_8 powders, which affects the capacity and service life of the electrodes fabricated from this compound and of a battery as a whole.

At present, a considerable attention is given to preliminary treatment of precursors. The authors of [9] used the mechanical activation to synthesize cathode materials for lithium batteries. A mixture of precursors was mechanically activated in planetary centrifugal mills. The method made it possible to prepare dispersions with a required structural disordering and thus to improve the quality of the cathode material.

An effective way to affect the structure of solids is their treatment in high-pressure apparatus of the type of Bridgman anvils**.** This treatment of mixtures of powdered substances makes sizes of the heterophases considerably lower. A large number of defects are formed in the structure of single components. Owing to a sharp acceleration of mass-transfer processes, the components can be mixed at nearly a molecular level, with various chemical processes also activated in this case [10].

The previously performed studies have shown that use of high pressure and shear deformations in manufacture of cathodes for lithium power cells considerably improves their electrochemical characteristics [11, 12].

A lithium-vanadium bronze is obtained by mixing of vanadium oxide with lithium salts or hydroxide, followed by heat treatment of the mixture. Therefore, it was suggested in this study to perform mixing in high-pressure apparatus.

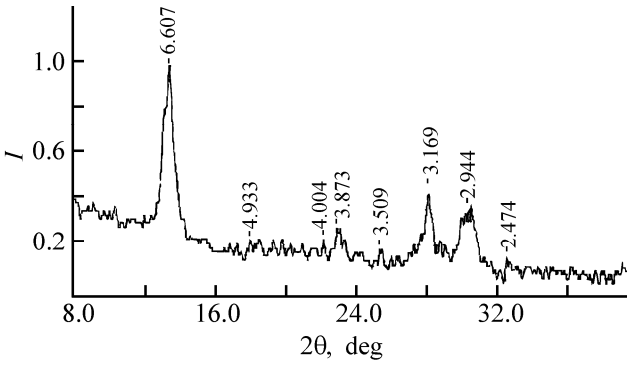

Fig. 1. X-ray diffraction pattern of a V_2O_3 + 15% LiOH sample plastically deformed under a pressure of 1.7 GPa (anvil rotation angle 500°) and then heat-treated at 200°C for 5 h. (*I*) Radiation intensity and (2θ) Bragg angle.

EXPERIMENTAL

A mixture of V_2O_3 and LiOH was poured in a ceramic bowl, gently agitated in dry state with a glassy rod for 10–15 s, and subjected to plastic deformation on a Bridgman anvil type high-pressure apparatus. Anvils made of a VK-6 hard alloy (working diameter 20 mm) were used. The treatment was performed at room temperature under a pressure of 1–2 GPa (anvil rotation angle 500°). As starting reagents served vanadium oxide V_2O_3 and lithium hydroxide (chemically pure grade). The resulting discs (2 cm in diameter) were wrapped in aluminum foil and heat-treated in a muffle furnace at temperatures of 100, 200, 300, and 400°C for 0.5–10 h.

Then, the substance obtained was washed in distilled water to remove excess OH^- ions and dried at 80–100°C to constant mass.

X-ray diffraction patterns of the electrode samples studied, fabricated from a lithium–vanadium bronze were obtained on a DRON-3 diffractometer in $Cu_{K\alpha}$ monochromatic radiation in the range 2θ 8°–40°, using automated recording programs.

To prepare the cathodes, a powdered lithium–vanadium bronze, to which an electrically conducting additive was introduced in a ratio of 85 : 10, was agitated in a mortar. Then, the mass obtained was impregnated with a solution of lithium perchlorate and polysulfone in dimethylacetamide and dried at 100°C in a vacuum. The resulting mass was ground, poured onto a current lead made of aluminum foil, and compacted in a special press mold under a pressure of 100 kg cm^{-2}. Before a model battery was assembled, the electrodes were kept in a desiccator at 100°C for 1–1.5 h.

The cathode was mounted at the bottom of a three-electrode measuring cell made of polypropylene. From above, the cell was covered with a polymer electrolyte and lithium foil. The working surface of the electrodes was 1 cm^2; their active mass, 0.07 g; and thickness, about 0.1 mm. The Li/Li^+ electrode was used as reference. The electrodes were uniformly spring-loaded. The current was collected by means of stainless steel rods pressed against tabs of the current leads. Electrochemical studies were performed with a Solartron SI 1287 Electrochemical interface potentiostat.

A high-pressure apparatus made it possible to subject the substances studied to uniaxial compression and shear forces, whose value did not exceed the yield stress of a material under a given pressure. On the apparatus of this kind, the plastic flow is observed in the case when the skin-friction force is large or equal to the yield stress of the material being processed. For the mixtures of vanadium oxide V_2O_3 and lithium hydroxide LiOH, this ratio occurs at pressures of about 1.7 GPa. At lower compression pressures, the anvil and the punch slip through the surface of a substance and the starting powdered materials remain powdered. At pressures above 1.7 GPa, the powdered materials are compacted, i.e., their constituents are subjected to plastic deformation.

The standard method for production of lithium–vanadium bronzes consists in sintering of powdered mixtures of vanadium oxide and lithium salts or hydroxide at a temperature of 700°C or higher for 24 h. It has been shown previously [13] that, if the starting mixtures of V_2O_5 and LiOH are preliminarily treated under a high pressure, then a LiV_3O_8 phase is formed even at 400°C in the course of 10 h. In this study, mixtures of V_2O_3 with LiOH were subjected to plastic deformation under a pressure of 1–2 GPa and then sintered at high temperatures.

According to the results of an X-ray diffraction analysis, the diffraction patterns of the samples treated under pressure contain reflections belonging to the LiV_3O_8 phase, for which the sizes of coherent scattering regions (CSRs), calculated from the reflections' width, were 20 nm. This means that the substance is in a highly dispersed state. Heating of such samples at 200°C for 5 h considerably raises the intensity of the LiV_3O_8 lines in the X-ray spectrum. At the same time, the width of the lines, i.e., the sizes of the CSRs do not virtually change, which confirms the high thermal stability of the ultradispersed structure formed upon the treatment under a pressure (Fig. 1). Annealing of samples at higher temperatures did not lead to any noticeable changes in the LiV_3O_8 structure obtained by annealing at 200°C.

Thus, owing to the mechanical activation of the mixture of V_2O_3 and LiOH on the Bridgman anvils, the annealing temperature at which a highly dispersed state of the substance was attained was lowered by 500°C (from 700 to 200°C). This result can be accounted for by the following processes**.** The action of pressure and a shear force results in that nanostructures are formed. In this case, a large number of structural defects (dislocations) appear in the structure of individual solids. In the course of a plastic deformation, there occurs intense mass-transfer leading to homogenization of the starting heterogeneous mixtures at a nearly molecular level. The annealing of such a system raises the solubility of lithium atoms in vanadium oxide and causes their concentration diffusion.

The study demonstrated that cathodes fabricated from a lithium-vanadium bronze can be reversibly cycled at a current density of 0.5–1.0 mA cm^{-2}. The specific capacity of the cathodes in the potential range 3.5–2.5 V is 150 mA h g^{-1}, which exceeds the capacity of high-temperature samples (120 mA h g^{-1}) by approximately 20%. The discharge-charging characteristics of the LiV_3O_8 cathodes demonstrate a high stability during 150 cycles: the loss of capacity does not exceed 5.5% (Fig. 2). A comparison of the results obtained with published data showed that the electrodes fabricated from the LiV_3O_8 prepared surpass the analogs known from the literature [4–9] in stability by, on average, 25%.

CONCLUSION

An original technique for fabrication of cathodes for lithium power cells by using a Bridgman anvil type high-pressure apparatus was developed. The technique made it possible to raise the electrode capacity by 20% and improve the electrode stability by 25%, as well as to reduce severalfold the duration of the technological cycle of their fabrication.

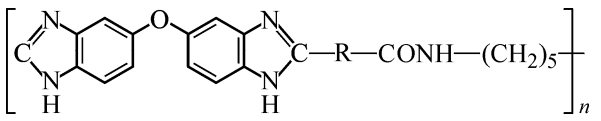
BRIEF COMMUNICATION

Manifestations of Crystallinity in Polyamidobenzimidazoles

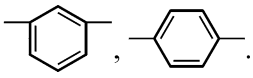
D. M. Mognonov, Zh. P. Mazurevskaya, V. V. Khakhinov, and O. V. Il'ina

Baikal Institute of Nature Management, Siberian Branch, Russian Academy of Sciences, Ulan-Ude, Buryatia, Russia

Received December 27, 2007



Abstract—Polyamidobenzimidazoles derived from 3,3',4,4'-tetraaminodiphenyl ether, diphenyl esters of aliphatic and aromatic dicarboxylic acids, and ε-caprolactam were prepared by solid-phase polycondensation. The relative degree of crystallinity, imparting the plasticity to the polymers as compared to the corresponding polybenzimidazoles, was determined by X-ray phase analysis.



DOI: 10.1134/S1070427208080302

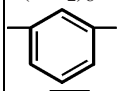
In this study, we examined the physicochemical-properties of polyamidobenzimidazoles (PABIs) prepared at various molar ratios of the starting monomers.

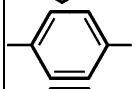
EXPERIMENTAL

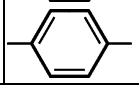
Polyamidobenzimidazoles were prepared by solid-phase polycondensation from 3,3'4,4'-tetraaminodiphenyl ether (TADPE), diphenyl esters of adipic (DPA), sebacic (DPS), isophthalic, and terephthalic (DPT) acids, and ε-caprolactam (CL) [1]. The substances are copolymers of polybenzimidazole (PBI) and polycaproamide (PCA), containing benzimidazole rings and amide groups. The unit composition depends on the starting monomers and their molar ratio in the reaction mixture and, at equimolar ratio of the comonomers, can be represented by the following formula:

where R = $-(CH_2)_4-$, $-(CH_2)_8-$,  .

The polymers were purified by reprecipitation from a solution in concentrated formic acid by dilution with a small amount of water, avoiding turbidity, followed by addition of a 0.5% solution of ammonium carbonate. The product was filtered off on a Büchner funnel, repeatedly washed with distilled water to neutral reaction, and dried in a vacuum oven at 60–70°C. The X-ray phase analysis was performed on a DRON-UM1 diffractometer using Ni-filtered Cu_{K_α} radiation. The thermal and chemical characteristics of PABIs are given in [2], and some properties of the copolymers are listed in the table.







The majority of PABIs are amorphous, but show high resistance to acid and base agents and relatively high strength preserved at elevated and low temperatures [3]. Such properties of the copolymers are due to the presence of thermally stable benzimidazole rings, and amide groups in PABI macromolecules make the copolymers soluble in amide and other available organic solvents.

The relatively high structural regularity of the PABIs containing aliphatic (sebacic acid) fragments can be judged from the swellability in organic solvents (dioxane, MEK). Experimental data show that this copolymer considerably swells (to up to 100%) and partially dissolves upon heating. The Koenig hardness of the polymer is 0.54, i.e., it has a high surface strength and increased brittleness.

An increase in the length of aliphatic fragments in the polymer (sebacic acid residues) leads to a rise in its elasticity, as judged from the low hardness (0.045); the polymer is in the hyper-elastic state. Swelling in a solvent suggests its denser regular structure. After heating, the polymer loses solubility.

In PABI, there are elements of crystallinity, particularly clearly manifested at the equimolar ratio of

the comonomers (Fig. 1). The degree of crystallinity increases upon replacement of adipic acid by sebacic acid, which is due to an increase in the chain length or, in the case of a terpolymer prepared using hexamethylenediamine along with CL as the amine-containing component, to the specific structure of the monomeric unit:

Whereas the polymer derived from 3,3',4,4'-tetraaminodiphenyl ether and diphenyl terephthalate has an amorphous structure, the copolymer prepared from the same monomers with the addition of ε-caprolactam at its mole fraction of 0.2 and above preserves, according to X-ray phase analysis, a highly organized fibrillar-crystalline structure. Moreover, in going from polycrystalline poly-ε-caproamide (degree of crystallinity ~40%) to PABI with a smaller content of lactam units, up to homopolybenzimidazole, the crystal lattice of the copolymers rearranges with the appearance of new crystalline formations (Fig. 2). The highest intensity is attained at the equimolar ratio of the starting monomers (degree of crystallinity 10–20%). Copolymers derived from diphenyl isophthalate and diphenyl phthalate are amorphous, and the degree of ordering of their molecules decreases as the mole fraction of CL units in the chain becomes smaller, as in the case of PABIs derived from aliphatic acids.

It is known that PBIs have high melting points, and some of them decompose without melting. This fact severely complicates their processing into items [4]. The appearance of crystalline areas in PABIs makes them more plastic and convenient for process-

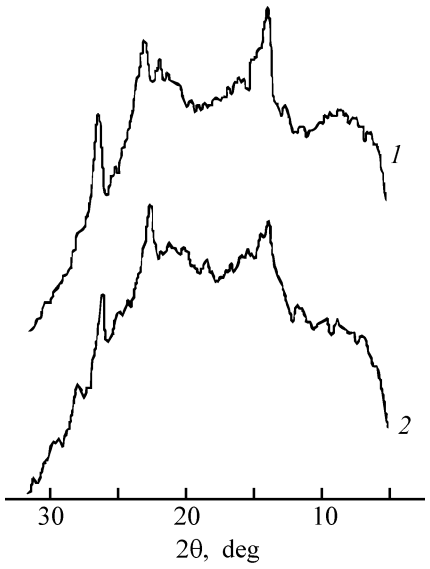

Fig. 1. X-ray diffraction patterns of PABI pre-pared at equimolar ratio of the monomers. (2θ) Bragg angle; the same for Fig. 2. (*1*) TADPE : DPS : CL and (*2*) TADPE : DPA : CL.

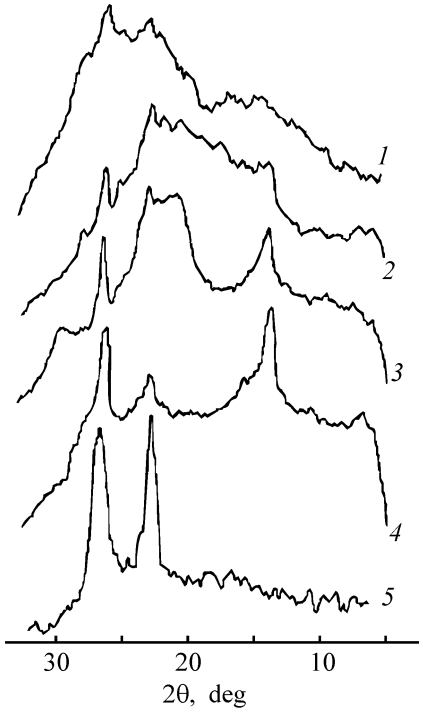

Fig. 2. X-ray diffraction patterns of (*1*) PBI TADPE : DPT, (*2–4*) PABIs TADPE : DPT : CL [molar ratios of comonomers: (*2*) 0.8 : 0.8 : 0.2, (*3*) 0.5 : 0.5 : 0.5, and (*4*) 0.2 : 0.2 : 0.8], and (*5*) PCA.

ing, compared to the corresponding PBIs. Polyamidobenzimidazoles have lower and more distinct melting points, especially the terpolymers whose macromolecule additionally contains six methylene groups. At the same time, they have relatively high decomposition points. The fabrication conditions and physicomechanical properties of compression samples based on PABI are described in [5].

CONCLUSIONS

(1) Polyamidobenzimidazoles with terephthalic acid residues in the macrochain show the highest crystallinity. They have a highly organized fibrillar-crystalline structure.

(2) In contrast to the corresponding commercial polybenzimidazoles, polyamidobenzimidazoles are more plastic and convenient in processing. At the same time, they preserve high decomposition points.

BRIEF COMMUNICATION

Oxidative Bromination of Aniline and Its Derivatives

Received December 12, 2007

Abstract—Oxidative bromination of aniline and its derivatives containing various substituents (CH_3, Cl, NO_2, COOH) in *ortho*, *meta*, and *para* positions with a brominating mixture of NaBr (KBr) and 20–22% hydrogen peroxide in 6–8% hydrochloric acid at the molar ratio aniline : NaBr (KBr) : H_2O_2 : HCl = 1 : 3.5 : 3.2 : 4.5 is described.

DOI: 10.1134/S1070427208080314

Compounds containing nitrogen and bromine are effective antipyrenes used to prepare noncombustible polymeric materials [1, 2]. To compounds of this class belongs 2,4,6-tribromoaniline (TBA), which also finds use as a constituent of biologically active preparations, pharmaceuticals [3], and herbicides [4]. A variety of methods for preparing TBA have been described [4–8]. However, all these methods [2, 5] provide only a 15–50% yield of a product that requires additional purification.

This study is concerned with the development of a wasteless method for preparation of TBA and its derivatives by oxidative bromination of aniline with a mixture containing a brominating agent (potassium or sodium bromide) and 20–22% hydrogen peroxide in 6–8% hydrochloric acid at 15 ± 5°C for 2 h [8] by the scheme:

I–V, **XI–XIV** **II–X**, **XV–XVIII**

Z = Z' = X = Y = H (**I**), Z = Z' = X = Br, Y = H (**VI**); Z = Z' = X = H, Y = CH_3 (**II**), Z = Z' = X = Br, Y = CH_3 (**VII**); Z = Z' = X = H, Y = Cl (**III**), Z = Z' = X = Br, Y = Cl (**VIII**); Z = Z' = X = H, Y = NO_2 (**IV**), Z = Z' = X = Br, Y = NO_2 (**IX**); Z = Z' = X = H, Y = COOH (**V**), Z = Z' = X = Br, Y = COOH (**X**); Z = Z' = Y = H, X = NO_2 (**XI**), Z = Z' = X = Br, X = NO_2 (**XV**); Z = Z' = Y = H, X = COOH (**XII**), Z = Z' = X = Br, X = COOH (**XVI**); Z = Y = X = H, Z' = NO_2 (**XIII**), Z = Z' = X = Br, Z' = NO_2 (**XVII**); Z = Y = X = H, Z' = COOH (**XIV**), Z = Z' = X = Br, Z' = COOH (**XVIII**).

The reaction involved aniline and its *ortho*-, *meta*-, and *para*-substituted analogues containing various substituents (CH_3, Cl, NO_2, COOH). To determine the optimal conditions of oxidative bromination**,** we studied how the concentrations of hydrogen peroxide and hydrochloric acid and the molar ratio of the reagents affect the yield of tribromoaniline (TBA) for the example of aniline and its *m*-substituted derivatives.

The reaction was performed in hydrochloric acid at 15 ± 5°C in the course of 2 h.

In studying the influence exerted by the hydrogen peroxide concentration, a 20–22% aqueous solution at the molar ratio NaBr (KBr) : H_2O_2 : HCl = 1 : 3.5 : 3.2 : 4.5 was found to be the optimal.

Under these conditions, the yield of TBA reaches 99.9%. With concentration of the H_2O_2 aqueous solution raised to 25% or lowered to 16–18%, the TBA yield decreases to 86 and 90.2%, respectively.

The yield of TBA is the highest (99.9%0) at a hydrochloric acid concentration of 6–8%. Lowering the HCl concentration to 4% or raising it to 10% leads to a decrease in the TBA yield to 86 and 90.9%, respectively.

The influence exerted by the molar ratio of the reagents on the TBA yield in oxidative bromination of aniline was studied at NaBr(KBr) : 20–22% H_2O_2 : 6–8% HCl = 1 : 3 : 3 : 3, temperature of 15 ± 5°C, and reaction time of 2 h.

It was shown that, under the above conditions, the yield of TBA is 98%, whereas at a NaBr(KBr) : H_2O_2 : HCl molar ratio equal to 1 : 4.5 : 6.5 : 8.0, the TBA yield reaches 99.9%. At the same time, to use the latter ratio is unreasonable, because the same yield of TBA is

Characteristics of the compounds synthesized

2-Nitro-4,6-dibromoaniline (**XVII**)	94.0	128	0.68	24.19 / 24.32	1.27 / 1.35	53.79 / 54.05	9.16 / 9.46	$C_6H_4Br_2N_2O_2$
2-Carboxy-4,6-dibromoaniline (**XVIII**)	95.0	76	0.76	28.10 / 28.48	1.53 / 1.70	53.87 / 54.10	4.51 / 4.74	$C_7H_5Br_2NO_2$

reached at a ratio NaBr(KBr) : H_2O_2 : HCl = 1 : 3.3 : 3.2 : 4.5.

m-Substituted TBAs containing electron-donating and electron-accepting substituents in the aromatic ring were obtained similarly. In all cases, *m*-substituted TBAs were isolated in quantitative yield and no additional purification was required. The characteristics of compounds **VI–X** are listed in the table.

The oxidative bromination of *o*- and *p*-substituted anilines differs from the bromination of *m*-substituted derivatives and depends on the electronic nature of substituents in the phenyl ring. It was found that, in *o*- and *p*-substituted anilines, substituents of the first kind (CH_3, –Cl) lead to black solid products. This shows that, in the course of oxidative bromination, molecules of *o*- and *p*-substituted anilines can take on a quinoid structure, which is facilitated by electron-donating substituents. The target products were not isolated.

With substituents of the second kind (COOH, NO_2), *o*- and *p*-substituted anilines undergo oxidative bromination under the optimal conditions without blackening of the reaction mass, with 2,4- and 2,6-dibromoanilines isolated as a target product. This confirms the decisive role of the electronic nature of the substituents in the stabilization of the aromatic nucleus in the course of oxidative bromination.

The structure of compounds **VI–X** and **XV–XVIII** was found from IR spectra, in which bands associated with stretching vibrations of the C–Br bond at 540–680 cm^{-1} were observed, and from a comparison of their physical parameters (melting point, elemental composition) with the known data [2, 3, 6, 8].

EXPERIMENTAL

The IR spectra of the compounds (suspensions in Vaseline oil) were recorded on an UR-20 spectrophotometer.

The purity R_f of the compounds was monitored by TLC on Silufol plates with spot development by UV light [9]. A mixture of benzene, dichloroethane, and acetic acid [benzene : dichloroethane : acetic acid = 4 : 1.5 : 1 (by volume)] served as eluent.

2,4,6-Tribromaniline VI. A flask was charged with 0.1 M of aniline and 0.45 M of 6% hydrochloric acid. To the reaction mixture was added dropwise under agitation 0.35 M of NaBr or KBr dissolved in 0.32 M of 20% hydrogen peroxide. The temperature was main-

tained within 15±5°C. Molar ratio aniline : NaBr(KBr) : H_2O_2 : HCl = 1 : 3.5 : 3.2 : 4.5**.** After addition of the brominating mixture was terminated, the flask was charged with 100 ml of water and the agitation was continued for another 1 h. The precipitated crystals were filtered off, washed with water to neutral reaction, and dried. The yield of TBA VI was 99.9%.

The oxidative bromination of *m*-substituted anilines **II–V** was performed similarly. *m*-Substituted tribromoanilines **VII–X** were isolated. Their characteristics are listed in the table.

Dibromo-substituted anilines XV–XVIII. The reaction was similar to that employed to obtain tribromoaniline**,** but with *p*-substituted anilines **XI**, **XII** and *m*-sub-stituted anilines **XII**, **XIV** used. The characteristics of dibromo derivatives **XV–XVIII** are listed in the table.

CONCLUSIONS

(1) Irrespective of the nature of a substituent in the phenyl ring, *m*-substituted anilines result in the formation of 2,4,6-tribromoanilines in high yield.

(2) Use of *o*- and *p*-substituted anilines with substituents of the second kind results in the formation of 2,4- or 2,6-dibromoanilines.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction of Oxalic Acid from Solutions of Electrolyte Mixtures

V. N. Lebedev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received November 8, 2007

Abstract—Extraction of oxalic acid with tributyl phosphate and triisoamyl phosphate from solutions of its mixtures with nitric, phosphoric, sulfuric, and hydrochloric acid and with ammonium nitrate and chloride was studied. In the extractability series, oxalic acid occupies the position between nitric and phosphoric acids, with sulfuric and hydrochloric acids acting as strong salting-out agents. Nitric acid salts drastically decrease the distribution ratios of oxalic acid.

DOI: 10.1134/S1070427208090012

Khibiny apatite concentrate remains the most important potential source of rare-earth elements (REE) in Russia [1]. Their concomitant recovery is possible in the nitric acid procedure for apatite processing into phosphorus fertilizers. However, involvement of this kind of raw materials into production is hampered, among other factors, by certain problems arising in processing of the recovered rare-earth phosphate concentrate. Primary purification to remove phosphorus is mainly performed by oxalate precipitation or extraction [2, 3]. The simplest variant of purification via oxalates is direct conversion into oxalates [4].

Because of high cost of oxalic acid, purification via oxalates should involve the regeneration of oxalic acid incorporated in REE oxalates by their treatment with an alkali [5]. The recovery of excess oxalic acid from mother liquors is not provided, although, along with economic aspects, one should take into account the environmental and economic consequences of the ingress of oxalate ions into production or waste solutions (MPC 2 mg g^{-1}).

In this study we examined the extraction of oxalic acid from solutions of electrolyte mixtures with the aim to evaluate the possibility of its utilization by extraction. For the extraction we used tributyl phosphate (TBP) and triisoamyl phosphate (TiAP), with dodecane as diluent. Preliminary experiments showed that oxalic acid is not noticeably extracted with higher alkanols. Extraction of oxalic acid from its straight aqueous solutions with TBP was studied by Allamuratov et al. [6]. We found no data on extraction in systems containing in the aqueous phase, along with oxalic acid, also mineral acids and their salts. Extraction of oxalic acid with triisoamyl phosphate was not studied either.

EXPERIMENTAL

Extraction was performed in a beaker at room temperature for 3 min with stirring. The phase separation in all the systems was good. Samples were taken after settling for 10 min. The salt composition of the aqueous solution was varied within the limits determined by the conditions of the conversion of phosphates into oxalates. The oxalic acid concentration was determined by titration with potassium permanganate, and the total acidity, by titration with alkali.

Experimental data on the extraction of oxalic acid with TBP and TiAP are given in Figs. 1 and 2. These data show that oxalic acid can be fully recovered with both neat and diluted extractants. The log–log plots of the distribution ratios D on the extractant concentration S (M) are straight lines with a slope close to 2, which suggests formation of the stable extractable complex $H_2C_2O_4 \cdot 2L$ (L = TiAP, TBP). The apparent extraction constant of oxalic acid is

$$K = D/([HC_2O_4^-]_{aq} S_{free}^2),$$

where $[HC_2O_4^-]_{aq}$ is the oxalic acid concentration in the equilibrium aqueous phase (M), and S_{free} is the free extractant concentration (M), which was 2–3 M in our experiments, i.e., it was by an order of mag-

* In run nos. 6 and 7, the aqueous phase also contained 1 M HNO_3.

ammonium nitrate and chloride. The distribution data are given for the binary mixtures with oxalic acid, except a ternary mixture containing phosphoric acid in a mixture with nitric acid. The extraction was performed at 1 : 1 ratio of the organic and aqueous phases.

As seen from Tables 1 and 2, relationships in the oxalic acid distribution in extraction with TBP and TiAP in the presence of electrolytes are similar. Nitric acid at its concentration of up to 1 M affects the extraction of oxalic acid insignificantly and even acts, to a small extent, as a salting-out agent. However, as the nitric acid concentration is increased, its distribution ratio increases also, and nitric acid starts to displace oxalic acid from the organic phase. Introduction of up to 3 M HNO_3 into the aqueous phase decreases the distribution ratios of oxalic acid by a factor of more than 4. Oxalic acid, on the contrary, exerted no salting-out effect on nitric acid.

Phosphoric acid only slightly affects the extraction, and in the ternary system containing 1 M H_3PO_4 and 1 M HNO_3 the distribution ratios of oxalic acid are relatively high.

Sulfuric and hydrochloric acids are poorly extracted with neutral extractants and therefore act as salting-out agents increasing the activity of oxalic acid. The distribution ratio of oxalic acid in the presence of these acids increases by a factor of more than 2.

Introduction of ammonium nitrate drastically decreases the extraction of oxalic acid because of the exchange decreasing the oxalic acid concentration:

$$2NH_4NO_3 + H_2C_2O_4 \rightleftarrows 2HNO_3 + (NH_4)_2C_2O_4,$$

with simultaneous extraction of the released nitric acid. In the presence of ammonium nitrate, the distribution ratio of nitric acid increases.

In the presence of ammonium chloride, the exchange occurs also and the concentration of oxalic acid decreases. However, the released hydrochloric acid exerts a salting-out effect, and as a result the oxalic acid extraction decreases only slightly.

Thus, oxalic acid recovery from electrolyte solutions by extraction with TBP and TiAP is quite feasible. The extracted oxalic acid can be readily

backwashed with an equivalent amount of aqueous ammonia, as ammonium oxalate is only slightly soluble in the extractant.

CONCLUSIONS

(1) The extraction of oxalic acid from a mixture of electrolytes with tributyl phosphate and triisoamyl phosphate was studied. Nitric acid at its concentration in the initial aqueous solution of up to 1 M exerts a weak salting-out effect on the extraction of oxalic acid, and at its higher concentrations nitric acid starts to displace oxalic acid from the organic phase. Phosphoric acid does not noticeably affect the extraction, whereas sulfuric and hydrochloric acids act as strong salting-out agents, increasing the distribution ratios of oxalic acid by a factor of more than 2. Nitric acid salts suppress the extraction of oxalic acid, and hydrochloric acid salts decrease its extraction slightly.

(2) The data on the oxalic acid distribution demonstrate the feasibility of oxalic acid utilization by extraction.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Kinetics of Iron(II) Oxidation in Pyrrhotine Leaching with Acid Sulfate Solutions in the Presence of Nitrous Acid

T. I. Markovich

Institute of Geology and Mineralogy, Siberian Branch, Russian Academy of Sciences, Novosibirsk, Russia

Received September 10, 2008

Abstract—Variation of the ratio between the concentrations of Fe^{2+} and Fe^{3+} ions in leaching of pyrrhotine with acid sulfate solutions containing HNO_2 was studied for the example of the oxidation of iron(II) with molecular oxygen, which widely occurs in the nature and is widely used in hydrometallurgy.

DOI: 10.1134/S1070427208090024

According to modern concepts, oxidative leaching of iron sulfides in acid media is not limited to only a topochemical reaction, but may also include multistep reaction between molecular oxygen and solutions of iron(II) salts [1, 2].

One of methods for raising the rate of this process is to use activating agents, nitrogen compounds (oxides, nitrates, nitrites, etc.) [3–6]. The mechanism of catalysis is rather complex and has not been elucidated so far. In the course of oxidation, quite a number of species (NO, N_2O_3, NO_2, N_2O_4, HNO_2, NO_2^-, HNO_3, NO_3^-, NO^+, NO_2^+) with widely different activating capacities can be formed in various amounts and disappear. According to numerous experimental studies, nitrous acid and products of its dissociation are the most kinetically reactive species. As shown in [4, 6], the activating effect of HNO_2 at low concentrations (<1 M) exceeds severalfold the catalytic activity of all other oxygen compounds of nitrogen.

Another way to accelerate the oxidation of Fe^{2+} is based on passing from the homogeneous mechanism of activation of molecular O_2 to a heterogeneous mechanism based on the capacity of a number of solid substances to absorb dissolved oxygen on active centers of their surface [7].

This study is concerned with the behavior of iron(II) in the system $Fe_{0.88}S + H_2O + H_2SO_4 + O_2 + HNO_2$ in decomposition of the solid sulfide phase that can chemisorb dissolved oxygen [8].

EXPERIMENTAL

We studied the kinetics of Fe^{2+} oxidation in sulfuric acid solutions containing nitrous acid in parallel with an analysis of the process of pyrrhotine breakdown. For this purpose, we used polydisperse samples (53–74-μm fraction) of the selective pyrrhotine concentrate from the Norilsk deposit, which contained, according to the results of an X-ray phase analysis, 93.2% $Fe_{0.88}S$, 1.5% $CuFeS_2$, and 4.5% SiO_2.

A weighed portion of the sulfide was leached under temperature control and continuous agitation with an upper drive in a closed reaction vessel equipped with a sampler with a finely porous filter, a batcher for an activating solution, and a system for delivery and discharge of gases, which provided oxygen supply to the reaction zone at a pressure of 1 atm. Nitrous acid was produced by the reaction

$$2NaNO_2 + H_2SO_4 = 2HNO_2 + Na_2SO_4, \quad (1)$$

by batching a sodium nitrite solution directly into the reaction pulp at prescribed intervals of time. The catalyst supply mode was developed with account of the occurrence of concurrent processes in the oxidizing system and made it possible to maintain the concentration of nitrous acid at a level as close as possible to the prescribed value of 0.001 M.

The initial concentration of sulfuric acid in the solution, $c^0_{H_2SO_4}$, was varied from 0.25 to 1.02 M, and the temperature of the experiment, in the range 293–333 K. The concentration of nitric acid (0.001 M), angular velocity of stirrer rotation (ω = 168 s^{-1}), and oxygen pressure ($P_{O_2} = 1.01 \times 10^5$ Pa) were maintained constant in all the experiments. The s : l ratio was 1 : 100 (2 g of the sulfide per 200 ml of the solution).

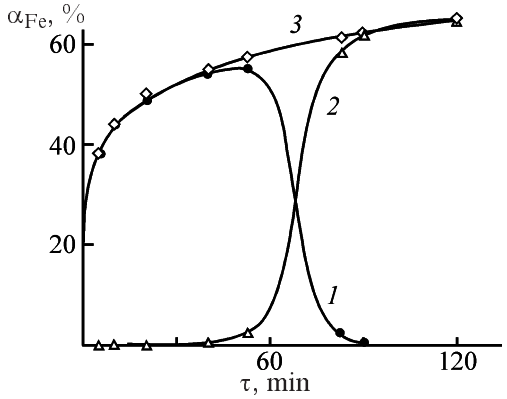

Fig. 1. Kinetic curves describing the degree of recovery, α_{Fe}, of (*1*) Fe^{2+} and (*2*) Fe^{3+} ions and (*3*) total iron (Fe^{2+} + Fe^{3+}) into solution in pyrrhotine leaching at $c_{H_2SO_4}$ = 0.51 M. T = 298 K, ω = 168 s^{-1}, P_{O_2} = 1.01 × 10^5 Pa, c_{HNO_2} = 0.001 M; the same for Fig. 2. (τ) Time.

We analyzed the solutions for the content of iron ions by complexometric titration [9]. We used standard methods for calculating the main process parameters (activation energy, reaction orders with respect to reagents) [10].

It has been shown previously [11] that pyrrhotine leaching in an acid sulfate–nitrite medium occurs in two successive steps with rapid (first step, up to 10 min) and slow (second step, from 10 to 120 min) dissolution. The observed nature of the process is possibly due to a change of the leaching mechanism from nonoxidative to give hydrogen sulfide to oxidative:

$$FeS + H_2SO_4 = FeSO_4 + H_2S, \quad (2)$$

$$FeS + 2HNO_2 + H_2SO_4 + O_2 = FeSO_4 + 2NO_2 + S^0 + 2H_2O. \quad (3)$$

The decrease in the process rate is probably due to formation of a film of difficultly soluble compounds (iron oxides, elementary sulfur) on the reaction surface [11].

The manner in which the content of Fe^{2+} and Fe^{3+} ions in solution varies in the course of pyrrhotine decomposition is shown in Fig. 1. A similar shape of kinetic curves was observed for all the experimental conditions. It should be noted that, in all the experiments, iron(III) ions appeared only in the second, slow step of sulfide leaching, after the degree of breakdown of the solid phase reached nearly 80% of its maximum value for the given conditions.

The absence of iron(III) in the system in the initial, rapid step is probably due to occurrence of competing processes

$$2FeSO_4 + 2HNO_2 + H_2SO_4 + O_2 = Fe_2(SO_4)_3 + 2NO_2 + 2H_2O, \quad (4)$$

$$H_2S + Fe_2(SO_4)_3 = 2FeSO_4 + S^0 + H_2SO_4. \quad (5)$$

Apparently, reaction (5) predominates over (4) until the main part of hydrogen sulfide is oxidized to elemental sulfur or sulfuric acid:

$$2H_2S + O_2 = 2S^0 + 2H_2O, \quad (6)$$

$$H_2S + 2HNO_2 = 2NO + S^0 + 2H_2O, \quad (7)$$

$$H_2S + 2O_2 = H_2SO_4, \quad (8)$$

$$2H_2S + 4HNO_2 + 3O_2 = 4NO + 2H_2SO_4 + 2H_2O. \quad (9)$$

According to Blyumberg and co-workers [12], the liquid-phase oxidation of hydrogen sulfide with molecular oxygen is substantially accelerated in the presence of nitric acid. A new ion–radical mechanism of catalysis is suggested, in which the nitrosonium ion NO^+ generated in the system in secondary oxidation of products formed in HNO_3 decomposition is the process-activating agent. The probability of occurrence of reactions (6)–(9) in the oxidizing system under study, which contains nitrous acid, a stronger source of NO^+ ($HNO_2 \rightleftarrows NO^+ + OH^-$), is very high.

We took as a factor characterizing the rate of Fe^{2+} conversion into Fe^{3+} the quantity inverse to the time τ_{eq} in which the concentrations of the oxidized and reduced forms of iron reached the same value: $1/\tau_{eq}$. When determining the kinetic parameters of the process (reaction order with respect to sulfuric acid and activation energy), we took into account that the following changes occur in the system during the first stage: the solution acidity decreases by reaction (1) and the Fe^{2+} concentration unevenly increases by the beginning of the second stage.

We calculated the content of sulfuric acid in the system (at τ = 10 min) for each experiment by the kinetic equation of pyrrhotine leaching, according to which the process rate linearly increases with the acidity of the medium [11] (Table 1).

Based on published data on oxidation of iron(II) salts with molecular oxygen in acid sulfate solutions

[13, 14] (including that involving nitrous acid [6] and that in the presence of a solid phase, activated carbon [7]), we suggested that, in experiments at a substantial, 2–14-fold excess of H_2SO_4, the rate of the reaction under study linearly depends on the initial content of Fe^{2+} ions in solution.

In this case, the rate equation describing the oxidation of iron(II) ions takes the form

$$1/\tau_{eq} = kc_{Fe^{2+}}c^n_{H_2SO_4}, \quad (10)$$

where $c_{Fe^{2+}}$ and $c_{H_2SO_4}$ are the concentrations of iron(II) ions and sulfuric acid, respectively, at the beginning of the second stage (τ = 10 min) (M); n, reaction order with respect to sulfuric acid; and k, an empirical constant.

The experimental results of a study of how the solution acidity affects the variation of the concentrations of oxidized (Fe^{3+}) and reduced (Fe^{2+}) forms of iron in the course of pyrrhotine decomposition are listed in Table 1. An increase in the H_2SO_4 concentration from 0.22 to 0.95 M makes the oxidation process slower and the time τ_{eq} in which equal concentrations are reached by a factor of 2.4 longer.

In the log–log coordinates, the resulting dependence (Fig. 2) has the form

$$\log(1/\tau_{eq}) - \log c_{Fe^{2+}} = -1.09\log c_{H_2SO_4} - 0.92. \quad (11)$$

Thus, the reaction order n with respect to sulfuric acid is, with account of the corrections described above, -1.1 ± 0.1.

A similar result was described in [6, 13, 14]. An analysis of a rather complex kinetic equation describing a vast body of experimental data [14] demonstrated that a higher acid concentration hinders oxidation of iron(II) in sulfate media and accelerates it in chloride media, which is due to the increased reactivity of $FeSO_4^+$ complexes.

It should be noted that the presence of activated carbon strongly changes the kinetics and mechanism of the process [7]. The decelerating effect of sulfuric acid is only manifested starting from a certain instant of time (under conditions of blocking of centers at the reaction surface by hydroxonium and hydrosulfite ions), when liquid-phase oxidation of iron(II) predominates in the heterogeneous system. At H_2SO_4 concentrations in the range from the initial concentration to 1.5–2 M (value dependent on the state of the surface of the solid phase), the topochemical reaction predominates and the process rate linearly grows with the solution acidity.

Table 1. Effect of the initial concentration of sulfuric acid, $c^0_{H_2SO_4}$, on the pyrrhotine leaching in acid sulfate–nitrite solutions* (c_{HNO_2} = 0.001 M, T = 293 K, P_{O_2} = 1.01×10^5 Pa)

$c^0_{H_2SO_4}$, M	$c_{H_2SO_4}$, M	α_{Fe}, %	$c_{Fe^{2+}}$, M	τ_{eq}, min	$1/\tau_{eq}$, min^{-1}
0.25	0.22	29	0.034	47	0.021
0.51	0.46	44	0.050	68	0.015
0.75	0.67	50	0.056	96	0.010
1.02	0.95	60	0.067	113	0.009

* $c_{H_2SO_4}$, $c_{Fe^{2+}}$, and α_{Fe} are, respectively, the concentrations of H_2SO_4 and Fe^{2+} ions and degree of recovery of total iron (Fe^{2+} + Fe^{3+}) into solution at the beginning of the second stage (τ = 10 min); τ_{eq} is the time in which equal concentrations of Fe^{2+} and Fe^{3+} are reached.

We studied the effect of temperature on the rate of Fe^{2+} conversion to Fe^{3+} in two modes at different initial H_2SO_4 concentrations of 0.25 and 1.02 M. The results obtained are listed in Table 2. Raising the temperature from 293 to 333 K accelerates the oxidation process and makes shorter the time τ_{eq} in which equal concentrations are reached by factors of 4.7 and 5.6 at the minimum and maximum solution acidities, respectively.

In the temperature range under study, the increase in the oxidation rate of iron(II) ions is described in the general form in the Arrhenius coordinates at the sulfuric acid concentrations specified

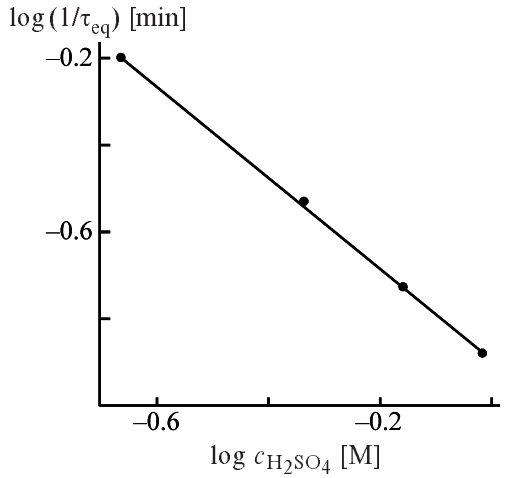

Fig. 2. Logarithm $\log(1/\tau_{eq})$ of the oxidation rate of Fe^{2+} ions (for explanations, see text) vs. the sulfuric acid concentration $c_{H_2SO_4}$. (τ_{eq}) Time in which equal concentrations of Fe^{2+} and Fe^{3+} are reached; the same for Fig. 3.

Table 2. Effect of temperature on the pyrrhotine leaching at different initial concentrations of sulfuric acid H_2SO_4 (c_{HNO_2} = 0.001 M, T = 293 K, P_{O_2} = 1.01×10^5 Pa)

T, K	$c_{H_2SO_4}$,* M	τ_{eq}, min	$1/\tau_{eq}$, min^{-1}	α_{Fe}, %	$c_{Fe^{2+}}$, M	s : l**
293	0.219/0.940	47/113	0.021/0.009	27/70	0.031/0.080	1.46 : 200/0.60 : 200

333	0.171/0.923	10/20	0.010/0.050	70/85	0.079/0.097	0.60 : 200/0.30 : 200

* Numerator, $c^0_{H_2SO_4}$ = 0.25 M; denominator, $c^0_{H_2SO_4}$ = 1.02 M.
** The s : l ratio by the beginning of the second step of leaching.

above by the equation

$$1/\tau_{eq} = k_1 c_{Fe^{2+}} (c_{H_2SO_4})^{-1.1} \exp(-E_a/RT), \quad (12)$$

where E_a is the activation energy (kJ mol^{-1}); R, gas constant (J mol^{-1} K^{-1}); T, temperature (K); and $k_1 = k/[\exp(-E/RT)]$.

Having transformed Eq. (12) to the logarithmic form, we obtained for different initial H_2SO_4 concentrations the following expressions:

$$\ln(1/\tau_{eq}) - \ln c_{Fe^{2+}} + 1.1 \ln c_{H_2SO_4} = -801.8/T + 0.7 \quad (13)$$

at $c^0_{H_2SO_4}$ = 0.25 M, and

$$\ln(1/\tau_{eq}) - \ln c_{Fe^{2+}} + 1.1 \ln c_{H_2SO_4} = -3679.0/T + 10.3 \quad (14)$$

at $c^0_{H_2SO_4}$ = 1.02 M.

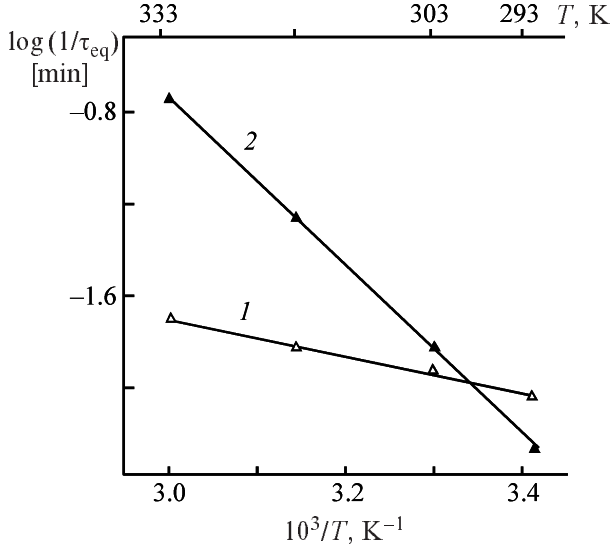

Fig. 3. Logarithm $\log(1/\tau_{eq})$ of the oxidation rate of Fe^{2+} ions vs. temperature T at different initial H_2SO_4 concentrations. ω = 168 s^{-1}, c_{HNO_2} = 0.001 M, P_{O_2} = 1.01×10^5 Pa; $c^0_{H_2SO_4}$, M: (*1*) 0.25 and (*2*) 1.02.

The thus determined effective activation energies of the process under study are 7±5 [Eq. (13)] and 31±5 [Eq. (14)] kJ mol^{-1}.

The strong differences between the E_a values obtained are possibly due to different contents of the solid phase of pyrrhotine in the system at the beginning of the second step of leaching (Table 2) (provided that the assumption of a linear dependence of the process rate on $c_{Fe^{2+}}$ is correct). The s : l ratio at $c^0_{H_2SO_4}$ = 0.25 M exceeds the corresponding value at $c^0_{H_2SO_4}$ = 1.02 M by a factor of 2.

It should be emphasized that, in the case of homogeneous oxidation of iron(II) ions under similar conditions (in acid sulfate solutions in the presence of nitrous acid), the effective activation energy of the process is even higher, 59 kJ mol^{-1} [6].

The considerable changes in the kinetics of Fe^{2+} to Fe^{3+} conversion in the presence of activated carbon in the system confirm the possibility of oxidation of iron(II) ions with molecular oxygen in sulfate media not only in solution, but also at the surface of the solid phase [7].

Thus, our experimental data indicate that the surface of the sulfide phase affects the kinetics of Fe^{2+} oxidation.

CONCLUSIONS

(1) Iron(II) ions are oxidized with molecular oxygen in pyrrhotine leaching in acid sulfate solutions in the presence of nitrous acid only in the second, slow step of the process, after the degree of decomposition of the solid phase reaches nearly 80% of the maximum value for the given conditions.

(2) The absence of Fe^{3+} ions in the system in the first step results from their reduction to the initial state with hydrogen sulfide, a product of nonoxidative leaching of pyrrhotine.

(3) In the presence of the solid sulfide phase, Fe^{2+} ions are oxidized to Fe^{3+} in the system under study with a substantially lower energy expenditure.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Zinc Cadmium Ammine Aqua Monophosphate and Its Thermal Transformations

D. A. Savchenko, V. A. Kopilevich, and L. V. Voitenko

National Agrarian University, Kiev, Ukraine

Received January 30, 2008

Abstract—Synthesis of amorphous zinc cadmium ammine aqua monophosphates $Zn_{3-x}Cd_x(PO_4)\cdot 2n(NH_3)\cdot m(H_2O)$ (x = 0.6–2.4, n = 1.3–3.1, m = 2.3–3.4) with variable molar ratio of the cations is described. The sequence of thermal transformations of compound $[Zn_{1.5}Cd_{1.5}(NH_3)_{1.4}(H_2O)_{3.2}(PO_4)_2]$ with equimolar ratio of cations is studied, and schemes of its transformation into the crystalline zinc cadmium monophosphate $Zn_{1.5}Cd_{1.5}(PO_4)_2$ are suggested.

DOI: 10.1134/S1070427208090036

Phosphates of divalent metals find expanding application as materials for modern engineering [1]. It is known that cadmium phosphates $CdHPO_4$, $Cd_3(PO_4)_2$, $Cd_2P_2O_7$, and $Cd(PO_3)_2$ and zinc phosphates $Zn_3(PO_4)_2$, $Zn_2P_2O_7$, $Zn(PO_3)_2$, $Zn(PO_3)_2\cdot Cd(PO_3)_2$, $Zn(PO_3)_2\cdot Mg(PO_3)_2$, $Zn_3(PO_4)_2\cdot 4H_2O$, and $Zn(H_2PO_4)_2$ are used for preparing phosphors, special glass, and catalysts for organic synthesis [1–14]. Their performance is frequently determined by the composition and thermal stability. Scientific statistics in the field of chemistry of phosphates [1] shows that the number of new phosphate engineering materials has noticeably increased as the nomenclature of phosphor compounds was expanded and the technology of their preparation was improved. In this connection, of special interest are crystalline and amorphous heterometallic [5] and mixed-anion phosphates which seem to have a wider spectrum of useful technological properties.

EXPERIMENTAL

Zinc cadmium ammine aqua monophosphate was isolated from an aqueous ammonia solution by precipitation with acetone [15], using as starting reactants $Zn_3(PO_4)_2\cdot 4H_2O$ synthesized according to [16] and $Cd_3(PO_4)_2\cdot 5H_2O$ synthesized according to [2].

The content of zinc and cadmium in the compounds synthesized was determined by stripping chronopotentiometry [17], that of phosphorus, by gravimetry [18], and that of ammonia, by distillation on a Seren'ev's apparatus [18]. The total content of water and ammonia was determined by the weight loss on heating to 750°C for 2 h [18].

The IR spectra were taken on a Specord 75-IR spectrophotometer. Samples of compounds to be analyzed were prepared in the form of KBr pellets in which the concentration of the substance under study was 0.2–0.3 wt %. The X-ray phase analysis was carried out on a DRON-UM1 diffractometer (CuK_α radiation). A single crystal of graphite placed in the diffracted beam was used as a monochromator. The diffraction patterns were taken in the step scanning mode in the range of angles 2θ = 4°–80°. The scanning step was 0.05°, and the exposure time in a point, 3–9 s. The measured diffraction maxima were approximated by a pseudo-Voight function, with the K_{α_1} component singled out. The unit cell parameters were calculated by the known procedure [19]. Qualitative and quantitative anionic composition of all intermediate and final products of heating was determined by paper chromatography [20].

Thermal transformations of zinc cadmium ammine aqua monophosphates were studied by thermal analysis on a Q-1500D derivatograh. Samples were heated in air in the range 15–900°C up to termination of weight loss. The experiment with the dynamic heating mode was carried out using platinum cylindrical crucibles with lids; the weighed portion of a compound was 0.500 g. Final and all intermediate heating products were obtained at a heating rate of 5 deg min^{-1}.

Table 1. Composition of zinc cadmium ammine aqua monophosphates

ZnO : CdO molar ratio in starting mixture	Content in products, %					Product composition
	ZnO	CdO	P_2O_5	NH_3	H_2O	
0.6 : 2.4	8.38	52.92	24.41	3.88	10.44	$Zn_{0.6}Cd_{2.4}(PO_4)_2 \cdot 1.3NH_3 \cdot 3.4H_2O$
1.2 : 1.8	17.46	41.31	25.37	5.76	10.15	$Zn_{1.2}Cd_{1.8}(PO_4)_2 \cdot 1.9NH_3 \cdot 3.2H_2O$
1.5 : 1.5	22.72	35.79	26.38	4.52	10.68	$Zn_{1.5}Cd_{1.5}(PO_4)_2 \cdot 1.4NH_3 \cdot 3.2H_2O$
1.8 : 1.2	27.28	28.68	26.43	8.54	9.05	$Zn_{1.8}Cd_{1.2}(PO_4)_2 \cdot 2.7NH_3 \cdot 2.7H_2O$
2.4 : 0.6	38.47	15.25	27.93	10.19	8.19	$Zn_{2.4}Cd_{0.6}(PO_4)_2 \cdot 3.1NH_3 \cdot 2.3H_2O$

To obtain zinc cadmium ammine aqua monophosphates, we took weighed portions of $Zn_3(PO_4)_2 \cdot 4H_2O$ and $Cd_3(PO_4)_2 \cdot 5H_2O$ corresponding to a specified ZnO:CdO molar ratio in the starting mixture and dissolved them in concentrated aqueous ammonia. The resulting solution was poured into acetone. In so doing, two liquid phases formed. Then the upper phase was decanted, and the bottom phase looking like a transparent oily film was left to crystallize in air at 20–25°C to constant weight.

The compositions of thus isolated compounds are given in Table 1. We found that the ZnO : CdO molar ratio in the starting mixtures of monophosphates was identical to that of the components in the synthesized products.

X-ray phase analysis shows that the initial zinc and cadmium monophosphates are crystalline, whereas zinc cadmium ammine aqua monophosphates synthesized on their basis are X-ray amorphous irrespective of their composition (Table 1).

The IR spectra of the zinc cadmium ammine aqua monophosphates under study are practically identical to each other and contain several groups of absorption bands. For example, a strong broad absorption band corresponding to stretching vibrations of water and coordinated ammonia molecules in the range 3435–2485 cm^{-1} is observed in the IR spectra of $Zn_{1.5}Cd_{1.5}(PO_4)_2 \cdot 1.4NH_3 \cdot 3.2H_2O$ (Fig. 1, curve *1*) and products of its heating to 208 and 343°C (Fig. 1, curves *2* and *3*). As the temperature and, correspondingly, the water and ammonia loss increase, the intensity of this band decreases. In the IR spectrum of the product of heating to 392°C (Fig. 1, curve *4*), this band is ill-defined, and in the final product of heating to 710°C it is absent (Fig. 1, curve *5*). The absorption bands corresponding to bending vibrations of water and ammonia molecules are located in the range 1600–1560 cm^{-1}. In the range 1485–1360 cm^{-1}, a maximum is detected, which corresponds to bending vibrations of ammonia molecules coordinated by metal ions and forming a stable hydrogen bond with presumably possible proton transfer to the phosphate anion [21]. It should be noted that maxima observed in the range 1250–1220 cm^{-1} correspond only to symmetric bending vibrations of coordinated ammonia [22]. The absorption bands corresponding to asymmetric and symmetric stretching vibrations of the PO_4^{3-} group are located in the range 1060–735 cm^{-1}. Absorption bands at 655–540 cm^{-1} in the spectra of samples taken at elevated temperatures belong to vibrations of the P–O–P and O–P–O groups.

Thus, the IR spectra suggest that the synthesized zinc cadmium ammine aqua monophosphates contain coordinated ammonia molecules rather than ammonium ions, which is also proved by the chem-

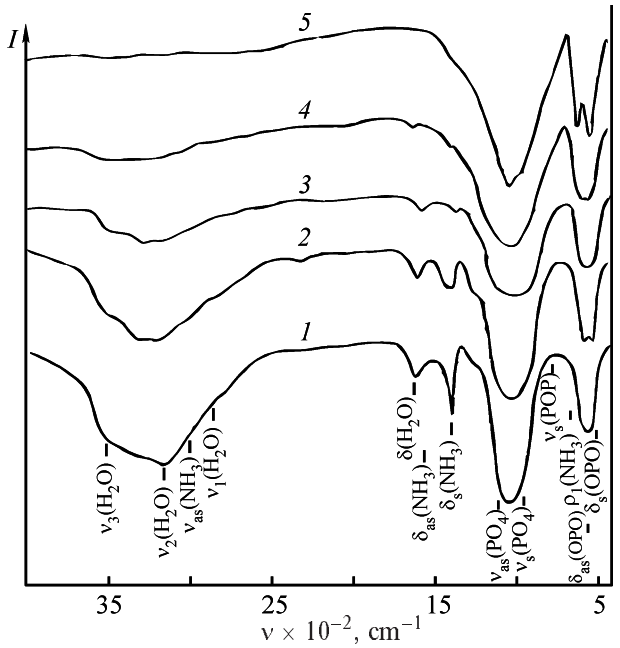

Fig. 1. IR spectra of (*1*) initial $Zn_{1.5}Cd_{1.5}(PO_4)_2 \cdot 1.4NH_3 \cdot 3.2H_2O$ and products of its heating to (*2*) 208, (*3*) 448, (*4*) 508, and (*5*) 710°C. (*I*) Intensity and (ν) wavenumber.

ical analysis including the molar ratio (ZnO + CdO) : P_2O_5 = 3 : 1.

The temperature ranges of the removal of volatile components from zinc cadmium ammine aqua monophosphates and the ranges of separate process steps, on the whole, coincide. Thermal transformations were studied in more detail for $Zn_{1.5}Cd_{1.5} \cdot (PO_4)_2 \cdot 1.4NH_3 \cdot 3.2H_2O$ (compound **I**) with an equimolar ratio of the metals as example.

Thermal analysis shows (Fig. 2) that the thermolysis of **I** proceeds in a wide temperature range (approximately 70–670°C) and, as follows from the DTA curve, is accompanied by endothermic effects with pronounced minima at 118, 268, and 478°C. At 504°C, an exothermic maximum superimposed on an endothermic effect is observed, which is proved, in particular, by a weight loss detected in the DTG and TG curves.

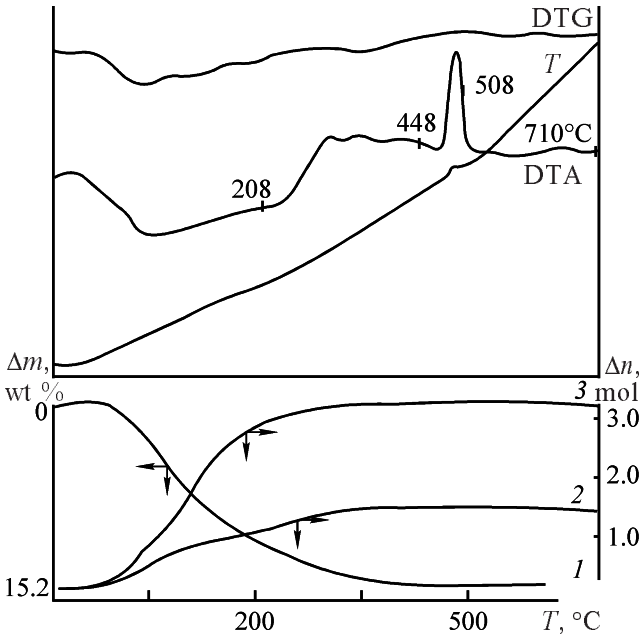

Fig. 2. Thermogravimetric curves of heating $Zn_{1.5}Cd_{1.5} \cdot (PO_4)_2 \cdot 1.4NH_3 \cdot 3.2H_2O$ at a rate of 5 deg min^{-1}. (Δm) Weight loss, (T) temperature, and (Δn) NH_3 or H_2O loss. Points in the DTA curve denote moments of sampling for X-ray diffraction analysis. (*1*) Total weight loss (TG), (*2*) NH_3 loss, and (*3*) H_2O loss.

The thermogravimetric (TG) curve shows that the weight loss of the sample is observed in the same range, 70–670°C. It was found by chemical analysis of products of heating compound **I** (Fig. 2, curves *2* and *3*) that, in the range 70–208°C, 2.6 mol of H_2O and 0.7 mol of NH_3 are removed, which corresponds to approximately half amount of ammonia and 80% of water in the initial compound. According to the chromatographic data (Table 2), phosphate in a sample taken at 208°C is entirely in the mono form PO_4^{3-}. This step of the thermolysis can be described by the overall scheme

$$[Zn_{1.5}Cd_{1.5}(NH_3)_{1.4}(H_2O)_{3.2}(PO_4)_2] \xrightarrow{60-208^\circ C} [Zn_{1.5}Cd_{1.5}(NH_3)_{0.7}(H_2O)_{0.6}(PO_4)_2] + 0.7NH_3 + 2.6H_2O.$$

Further heating of the substance to 343°C leads to the removal of certain additional amount of NH_3 and H_2O. The data of the quantitative paper chromatography (Table 2) show that, upon thermolysis performed to this temperature, monophosphate anions are partially converted to diphosphate anions. This step of transformations can be described by a combination of hydrolysis of monophosphate anion and condensation of acid monophosphate to diphosphate according to the generalized schemes

$$[Zn_{1.5}Cd_{1.5}(NH_3)_{0.7}(H_2O)_{0.6}(PO_4)_2] \xrightarrow{208-448^\circ C} [Zn_{1.5}Cd_{1.5}(NH_3)_{0.2}(H_2O)_{0.03}(PO_4)_{1.7}(P_2O_7)_{0.17}] + 0.5NH_3 + 0.6H_2O,$$

$$[Me \leftarrow OH_2 \cdots (PO_4)] \xrightarrow{208-448^\circ C} MeOH^+ + HPO_4^{2-},$$

Table 3. Crystal-chemical characteristics of final products of the thermolysis of zinc cadmium ammine aqua monophosphates

Compound	Unit cell parameters				Cell volume, Å^3
	a, Å	b, Å	c, Å	β, deg	
$Zn_{0.6}Cd_{2.4}(PO_4)_{2.0}$	9.028(6)	11.760(0)	6.113(9)	99.22	640.7(8)
$Zn_{1.2}Cd_{1.8}(PO_4)_{2.0}$	9.037(3)	11.660(7)	5.921(5)	98.88	614.7(6)
$Zn_{1.5}Cd_{1.5}(PO_4)_{2.0}$	9.044(4)	11.500(4)	5.930(0)	98.71	609.9(4)
$Zn_{1.8}Cd_{1.2}(PO_4)_{2.0}$	9.039(1)	11.517(0)	5.913(2)	98.69	608.4(9)
$Zn_{2.4}Cd_{0.6}(PO_4)_{2.0}$	8.992(9)	11.353(2)	5.934(2)	98.85	598.6(3)

$$2HPO_4^{2-} \longrightarrow P_2O_7^{4-} + H_2O.$$

On further heating to 508°C and higher temperatures, residual amounts of ammonia and water are removed from the material. The exothermic effect with a maximum at 498°C in the DTA curve (Fig. 2) coincides with the process of diphosphate decomposition (Table 2) and the onset of the zinc cadmium monophosphate crystallization (Fig. 3). In this case, the redistribution of P_2O_5 over oligomeric forms can be presented by the scheme

$$[Zn_{1.5}Cd_{1.5}(NH_3)_{0.12}(H_2O)_{0.02}(PO_4)_{1.8}(P_2O_7)_{0.1}]$$

$$\xrightarrow{508\text{–}710^\circ C} Zn_{1.5}Cd_{1.5}(PO_4)_{2.0} + 0.5NH_3 + 0.2H_2O,$$

$$[Zn_{1.5}Cd_{1.5}(NH_3)_{0.20}(H_2O)_{0.03}(PO_4)_{1.7}(P_2O_7)_{0.2}]$$

$$\xrightarrow{448\text{–}508^\circ C} [Zn_{1.5}Cd_{1.5}(NH_3)_{0.12}(H_2O)_{0.02}(PO_4)_{1.8}\cdot$$

$$(P_2O_7)_{0.1}] + 0.8NH_3 + 0.01H_2O,$$

According to X-ray phase analysis (Fig. 3), the completing stage of the thermolysis of zinc cadmium ammine aqua monophosphate, consisting in the transition from the amorphous state of the compound (20–343°C) to crystalline $Zn_{1.5}Cd_{1.5}(PO_4)_{2.0}$, requires larger energy consumption, i.e., heating to 690–710°C.

Crystal-chemical characteristics of the final products of heating the synthesized zinc cadmium ammine aqua monophosphates are given in Table 3.

All the final products of the thermolysis of zinc cadmium ammine aqua monophosphates are isostructural and crystallize in the monoclinic system. Figure 4 that their unit cell volume decreases approximately linearly (R^2 = 0.8812) with an increase in the zinc mole fraction, which agrees with the classical concept of solid solutions of substitution. This trend indirectly confirms the fact that the isolated X-ray amorphous zinc cadmium ammine aqua monophosphates are also solid solutions with practically unlimited possibility of substitution of zinc

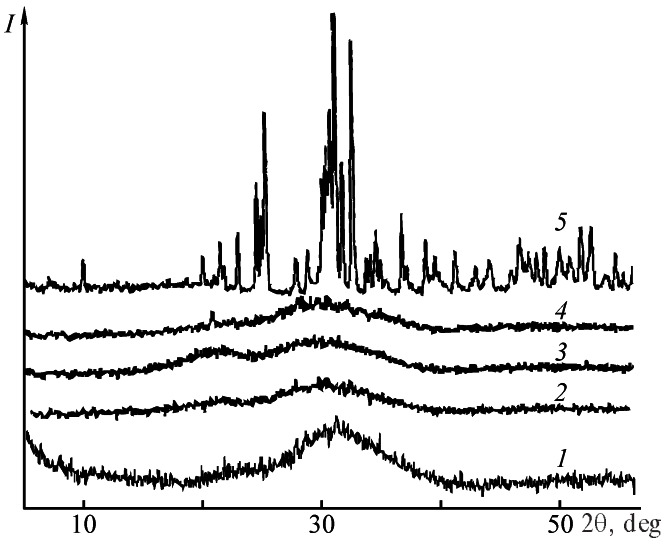

Fig. 3. Diffraction patterns of the (*1*) initial $Zn_{1.5}Cd_{1.5}\cdot(PO_4)_2\cdot 1.4NH_3\cdot 3.2H_2O$ and products of its heating to (*2*) 208, (*3*) 448, (*4*) 508, and (*5*) 710°C. (*I*) Intensity and (2θ) Bragg angle.

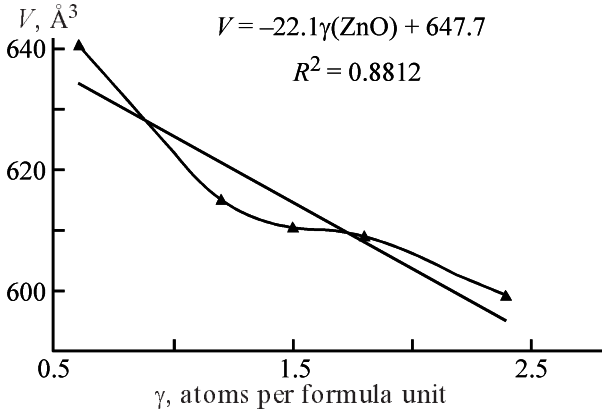

Fig. 4. Unit cell volume V of the crystal lattice of zinc cadmium monophosphates as a function of the zinc content γ.

ions for cadmium ions in equivalent crystallographic positions, as the difference in the ionic radii of the metals is insignificant (about 14%).

CONCLUSIONS

(1) The synthesized X-ray amorphous zinc cadmium ammine aqua monophosphates have the general formula $Zn_{3-x}C_x(PO_4)_2 \cdot n(NH_3) \cdot m(H_2O)$, where x = 0.6–2.4, n = 1.3–3.1, and m = 2.3–3.4. They undergo a series of thermal transformations in the temperature range 208–710°C.

(2) The compounds isolated are apparently solid solutions of substitution.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Control over Cracking of Heavy Petroleum Residue by Weak Acoustic Fields

St. Petersburg State Institute of Technology (Technical University), St. Petersburg, Russia

Received February 12, 2007

Abstract—Effect of weak periodic electromagnetically excited acoustic pulses with a repetition frequency of 100 to 1000 kHz on thermolysis of petroleum residue was studied. It was shown that weak acoustic fields affect the yield and quality of target products (gas, liquid, solid cracking residue).

DOI: 10.1134/S1070427208090048

Creation of innovation ways to intensify the existing processes of chemical industry is a topical task. The method of background control over heterogeneous processes [1], based on specific features of the media being controlled, makes it possible to shorten the production cycle and change the technical-and-economical parameters of the process both qualitatively and quantitatively without any significant capital expenditure or direct change in both the apparatus and technology employed.

Most of processes used in oil refining and treatment of petroleum residue are accompanied by phase transitions: evaporation and condensation, melting and crystallization, etc. Controlling the kinetics of phase transitions with chemical substances and physical fields allows optimization of the processing of the oil stock and enables modification of the properties of the products obtained. In contrast to chemical methods, the physical activation does not impair the production efficiency and extends the range within which the process parameters can be varied.

Acceleration of a phase transition is a favorable factor in dehydration, deasphalting, dewaxing, and in certain stages of coking. In thermal cracking, there occur high-temperature degradation of hydrocarbons and condensation of polyaromatic hydrocarbons, regarded as crystallization and glass formation from a petroleum solution. In the industrial technology for thermal cracking of black oils and petroleum tars (viscosity breaking), it is desirable to accelerate the thermal cracking of the heavy oil stock without any noticeable coking (to reduce the rate of formation of the solid phase via controlled decrease in the rate of thermal condensation processes). It is noteworthy that the residual oil stock of viscosity-breaking and delayed-coking installations starts to undergo partial cracking already in the stage of heating in coiled pipes of a tubular furnace. In view of the aforesaid, the present study was devoted to the effect of weak acoustic treatments on the thermal cracking of petroleum tar.

EXPERIMENTAL

The petroleum tar was taken from an AVT-6 installation at Kirishi petroleum refinery. Its parameters are listed in Table 1.

Table 1. Group composition of petroleum tar

Group components	Yield based on petroleum tar, wt %
Asphaltenes	6.4
Maltenes	93.6
Polar components (PCm):	16.6
Oils:	67.3*
paraffin–naphthene compounds	22.2*
monocycloaromatic compounds	18.6*
bicyclo- and polycycloaromatic compounds	26.5*
Resins:	32.7*
toluene	13.2*
alcohol–toluene	19.5*
Nonpolar components	83.4

* The yield of polar components is given relative to their sum taken as 100%.

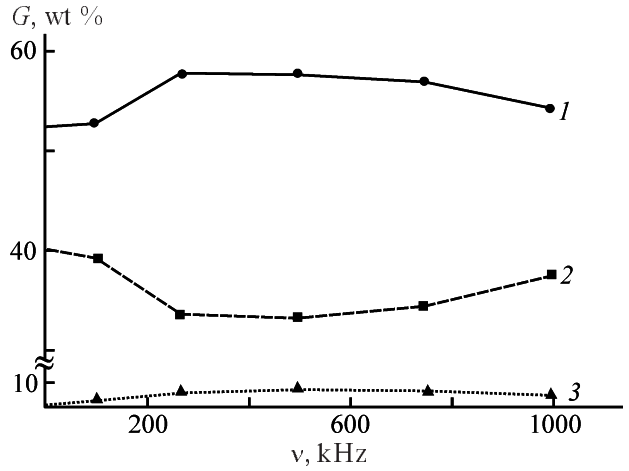

Fig. 1. Effect of weak acoustic fields on quantitative parameters of petroleum tar thermolysis. (*G*) Yield of petroleum tar thermolysis products and (ν) frequency of acoustic field. (*1*) Total yield of light distillates, (*2*) yield of the cracking residue, and (*3*) gas and loss.

The thermal cracking was performed in a heated glass reactor with mechanical agitation (ν = 45 rpm) at a thermostating temperature of 425°C and process duration of 75 min to exhaustive evaporation of the sum of liquid distillation products. A weak acoustic field with an average pulsation amplitude of 150 Pa was electromagnetically generated within the loop-antenna of a generator of electromagnetic pulses, which was brought in contact with the reactor in the zone of occurrence of petroleum tar thermolysis. The repetition frequency of weak acoustic pulses was varied in the range 100–1000 kHz [2].

The thermal cracking was performed in a heated glass reactor with mechanical agitation (ν = 45 rpm) at a thermostating temperature of 425°C and process duration of 75 min to exhaustive evaporation of the sum of liquid distillation products. A weak acoustic field with an average pulsation amplitude of 150 Pa was electromagnetically generated within the loop-antenna of a generator of electromagnetic pulses, which was brought in contact with the reactor in the zone of occurrence of petroleum tar thermolysis. The repetition frequency of weak acoustic pulses was varied in the range 100–1000 kHz [2].

The thermal cracking of petroleum tar yields gaseous and liquid products with a lower molecular mass than that of the starting raw material and solid pitch-coke-like products of thermal condensation, with a higher molecular weight. Results of balance experiments on thermal cracking of petroleum tar under the action of an acoustic field and without it are shown in Fig. 1. It is noteworthy that the most valuable product formed in thermal cracking of petroleum tar is the total liquid distillate, because its further qualified processing into motor fuel components can markedly improve the extent of petroleum processing without using high-cost methods (deasphalting and demetalation of petroleum tars) to prepare raw materials for the subsequent hydrocracking. The amount of petroleum tar formed in primary processing of West-Siberian industrial crude oil (oil distillation into fractions) is 21–23% (based on oil).

The total distillate formed in thermal cracking of petroleum tar was subjected to fractional distillation to obtain naphtha (from start of boiling to 200°C) and diesel (200–360°C) fractions. For these fractions, the density, refractive index, iodine numbers, and total sulfur content were determined by the procedures described in [3]. The qualitative composition of the fractions of the total distillate was determined by chromatography–mass spectrometry. Complex mixtures of hydrocarbons of the fractions being analyzed were separated on a 30-m-long HP-5MS capillary column coated with a nonpolar phase (polydimethylsiloxane). All the measurements were made on an Agilent 5973/6850 chromatograph–mass spectrometer.

The residence time of the raw material being cracked in the reaction zone affects, at the same temperature, the degrees of feed conversion and decomposition. It is known that competitive reactions of decomposition and condensation occur in the chosen temperature range of petroleum tar cracking. The activation energy of the condensation reactions is substantially lower than that for the decomposition reactions. Consequently, to raise the yield of decomposition products (gas, naphtha, diesel fractions) and make lower the yield of the cracking residue, it is necessary to maintain in the reaction zone a temperature sufficient for rupture of the bonds being cracked under mild process conditions as regards its duration and pressure (permanent removal of light cracking products from the reaction zone in the gas and vapor phases under atmospheric pressure).

It can be seen from Fig. 1 that the curves describing the frequency dependence of the yields of the total distillate and cracking residue show opposite trands and pass through extrema. The yield of the gas is independent, within the experimental error, of the frequency of the acoustic treatment. The optimal conditions providing the maximum yield of the total distillate (57.4%) are obtained at characteristic

frequencies in the range 270–750 kHz. In this case, the yield of light products increases by 8–10% based on the total distillate (4–5% based on converted petroleum tar). A similar behavior was observed in thermolysis of another batch of petroleum tar, taken at Kirishi refinery (repetition frequency of acoustic pulses 500 kHz, average amplitude of the sonic wave 0.15 Pa).

The acoustic pressure depends on a material chosen for the EMAP loop-antenna (copper or steel). Presumably, the optimal activated state of the system being cracked is observed in this range of sonic field frequencies. This state (which is far from the thermal equilibrium) promotes intense rupture of the weakest carbon–carbon and carbon–heteroatom (C–S, C–O, C–N) bonds of the molecules being cracked, with radicals formed. In normal alkanes with a long chain, the rupture energies of the C–C and C–H bonds somewhat decrease toward the middle of the chain. However, the former is always substantially lower than the latter. C–C bonds in cycloalkanes are less strong than those in normal alkanes. In the radical-chain process of thermal cracking of petroleum tar, paraffin, cycloparaffin, and isoparaffin hydrocarbons are easily cracked. Cracking of alkanes and cycloalkanes gives olefins in which the C–C bond in the β-position to the double bond is substantially weaker than the C–C bond in alkanes. In arenes, the C–H and C–C bonds are stronger than those in alkanes, and the bonds conjugated with the aromatic ring are weakened. In addition, weak carbon–heteroatom bonds in hybrid compounds of petroleum tar are intensely ruptured.

The ease of homolytic bond rupture in a hydrocarbon strongly depends on the stability of the radicals being formed. The final composition of the products is determined by the relative rates of interaction of the radicals being formed with the starting hydrocarbons of the feed, cracking of the radicals, cracking of the hydrocarbons, and condensation reactions yielding compounds with molecular masses exceeding those of the feed. The cracking occurs when the energy of the thermal vibration motion of molecules increases to values exceeding the bond energies. Under these conditions, there occur degradation, interaction, recombination, and condensation of fragments of the starting molecules.

The probable pathways of cracking of individual hydrocarbons belonging to different classes were analyzed in most detail in [4, 5]. Syunyaev [6] suggested that the result of cracking in a mixture of the macromolecular hydrocarbons of petroleum is

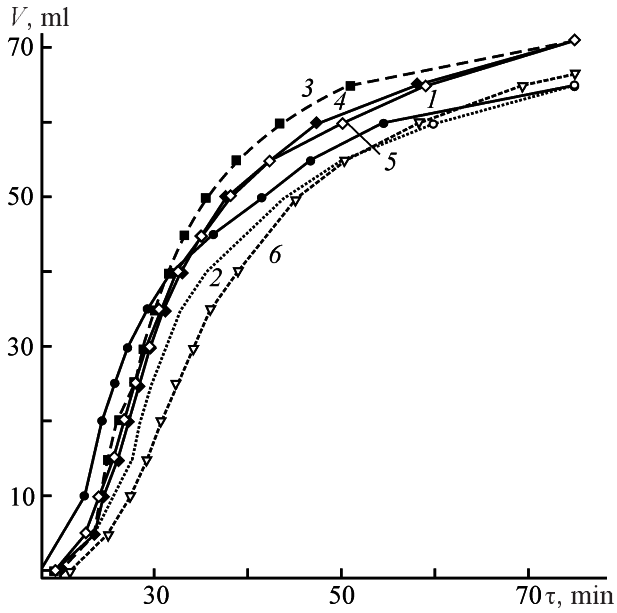

Fig. 2. Yield of the total distillate vs. the duration τ of the experiment. (V) Running volume of the total distillate. (*1*) Without acoustic treatment; (*2–6*) with acoustic treatment at a frequency (kHz): (*2*) 100, (*3*) 270, (*4*) 500, (*5*) 750, and (*6*) 1000; the same for Fig. 6.

also affected by the intermolecular interaction of molecules, a part of whose energy is expended for disaggregation of the dispersed system, rather than to cleavage of macromolecules. From this standpoint, the intensification of the thermolysis of a heavy petroleum residue is due to processing of raw materials in their active state. In this case, the optimal relationship is attained between the sizes of a solvation shell and of a complex structural unit whose core is constituted by supramolecular formations of asphaltenes. The kinetic curves representing the yield of the total distillate of the petroleum tar being cracked (Fig. 2) are S-shaped and described by the differential equation

$$d[V_i]/d\tau = k_i([V_i]_\infty - [V_i]_\tau)[V_i]_\tau, \quad (1)$$

where k_i is the constant characterizing the rate at which the limiting volume of the total distillate is reached at a fixed working frequency of the sound generator.

The whole set of experimental curves in Fig. 2 is linearized in the coordinates $\ln y$–x, where

$$y = [V_i]_\tau/([V_i]_\infty - [V_i]_\tau), \quad (2)$$

$$x = k_i[V_i]_\infty\tau, \quad (3)$$

Trend lines are plotted (Fig. 3) on the basis of

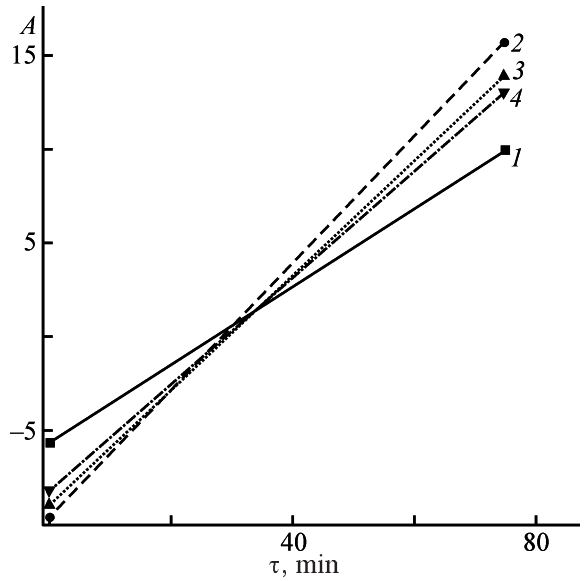

Fig. 3. Trend lines. $A = \ln [V_i/(V_{lim} - V_i)]$, where V_i is the running volume, and V_{lim}, limiting volume; (τ) time. (*1*) Without acoustic treatment; (*2–4*) with acoustic treatment at a frequency (kHz): (*2*) 270, (*3*) 500, and (*4*) 750.

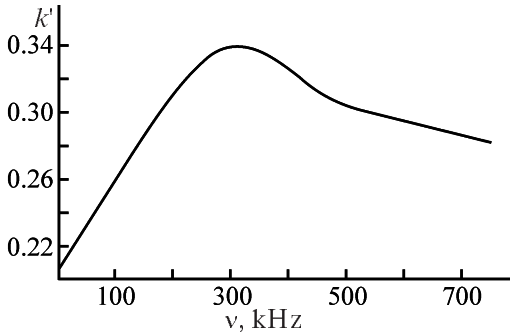

Fig. 4. Effective rate constant of thermolysis, k', vs. the acoustic treatment frequency ν.

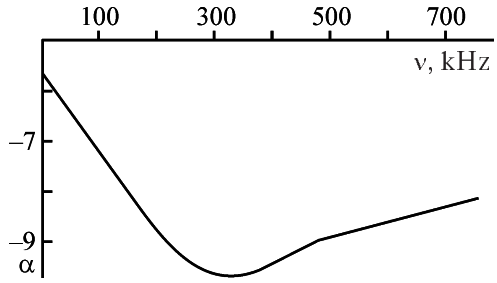

Fig. 5. Empirical parameter α as a function of the acoustic treatment frequency ν.

the converted experimental data used to find the constants of the equation

$$\ln \{[V_i]_\tau/([V_i]_\infty - [V_i]_\tau)\} = k'\tau - \alpha, \quad (4)$$

where k' is the effective rate constant of petroleum tar thermolysis (min^{-1}), and α is an empirical parameter.

Equation (4) is transformed to

$$[V_i]_\tau = \frac{[V_i]_\infty e^{k'\tau - \alpha}}{1 + e^{k'\tau - \alpha}}, \quad (5)$$

or, in the differential form, to

$$\frac{d[V_i]}{d\tau} = \frac{k'[V_i]_\infty e^{k'\tau - \alpha}}{(1 + e^{k'\tau - \alpha})^2} = \frac{k_i[V_i]^2_\infty e^{k'\tau - \alpha}}{(1 + e^{k'\tau - \alpha})^2}. \quad (6)$$

Equation (6) can be used to calculate the running volumes (concentrations) of the total distillate, gaseous products, and cracking residue and the degree of petroleum tar conversion. At an acoustic field frequency of 270 kHz, the parameters k and α (Fig. 4, 5) reach their extremal values. The empirical parameter α, which characterizes the beginning of evaporation of the total distillate, is uniquely dependent on the duration of the induction period of the radical-chain reaction by which thermolysis of petroleum tar occurs and on the related control over the nucleation of a new phase (tars start to be converted by condenation reactions to asphaltenes, and these latter, to carbenes and carboids). Presumably, it is the hindrance to this phase transition that leads to qualitative and quantitative changes in the process parameters. The thermolysis of petroleum tar involves endothermic reactions of dehydrogenation and cracking of group components, as well as exothermic reactions of synthesis, polymerization, and condensation.

During the induction period (Fig. 2), the system more actively absorbs energy (Fig. 6), with the evaporation of the total distillate beginning at higher temperatures. The effective heat conductivity of the reaction mixture varies with the controlling signal frequency, which determines the temperature mode in which the system reaches the prescribed cracking temperature.

As can be seen in Table 2, the content of total sulfur in the total distillate tends to decrease as compared with base runs of petroleum tar cracking without ultrasonic treatment. We identified 99 compounds in the naphtha fraction by chromatography–mass spectrometry. Comparative analysis of naphthas formed in thermal cracking of petroleum tar points to an increase in the content of linear alkanes (3.18%), isoparaffins (2.52%), linear olefins (1.19%), and isoolefins (1.82%) in the fraction obtained under

Table 2. Characterization of the total distillate

Parameter	Blank run	Acoustic treatment frequency, kHz				
		100	270	500	750	1000
Yield of the naphtha fraction (start of boiling–200°C), wt %	25.50	33.30	36.90	33.90	33.90	30.30
Iodine number	80.80	80.20	82.70	85.40	91.70	78.10

Iodine number	34.80	35.50	35.50	35.70	33.50	36.10
S_{tot}, wt %	0.53	0.46	0.44	0.45	0.42	0.46
Yield of light gas oil, wt %	28.80	23.60	15.70	26.70	13.50	16.40

the action of the acoustic field. The main group of compounds unidentified in detail (15%) is represented by cycloalkenes and cycloalkanes. The fraction of aromatic compounds in the ultrasonically treated (500 kHz) naphtha fraction decreases by 5.22%, with the organoleptic properties impaired (strong unpleasant odor, poor stability). As a consequence, the boiling onset temperature and iodine numbers grow. The resulting cracking residues have a higher softening point. These substances can be used as binders for modification of starting petroleum tars to obtain compounded asphalts. A sample based on a high-melting cracking residue of field-assisted (500 kHz) thermolysis of petroleum tar produced from West-Siberian crude oil with a softening point of 214°C, modified with the starting petroleum tar (50%), satisfies in all characteristics the requirements to road asphalts of BND 60/90 brand.

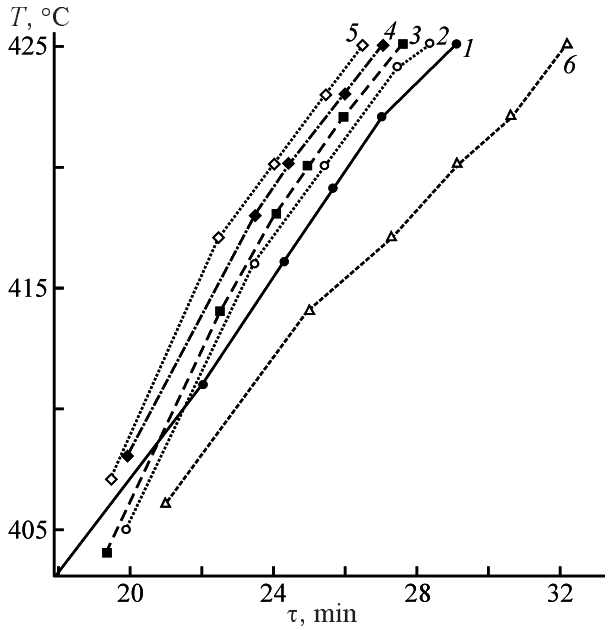

Fig. 6. Temperature T in the reaction zone as a function of time τ at fixed heating of the reactor.

The prospects for practical use of the method are quite real, and it can be implemented as a supplement to the existing technology, e.g., as an additional unit in the system for automated control over the process. There exist and are widely used ultrasonic counters–flow meters, to which an ultrasonic emitter can be added as a function. This approach does not require any additional equipment.

The induction period can be characterized at invariable output parameters of the process by an increase in the time of residence in the reaction zone. The increase in the thermal stability of an insonificated petroleum residue is a favorable factor that will make it possible to diminish coke deposits within the reaction coiled pipes of furnaces in installations for thermal cracking and delayed coking and to raise the admissible temperature of feed heating.

CONCLUSIONS

(1) Weak acoustic fields affect to a certain extent the overall process of thermal cracking of petroleum tar both in deep degradation of the starting mostly hybrid molecules of complex structure (gasification) and in their moderate decomposition.

(2) The maximum yield of the target total distillate (57.4 wt %) in thermolysis of petroleum tar at a temperature of 425°C and process duration of 75 min is obtained at an acoustic treatment frequency of 270 kHz. Under these conditions, the yields of the gas and cracking residue are 6.2 and

36.4 wt %, respectively. The yield of light products increases by 4–5%, compared to experiments on thermal cracking of petroleum tar without an acoustic treatment.

(3) The effective rate constant of formation of a liquid product in field-assisted thermolysis of petroleum tar at the optimal frequency is 1.6 times that in thermal cracking without acoustic treatment.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

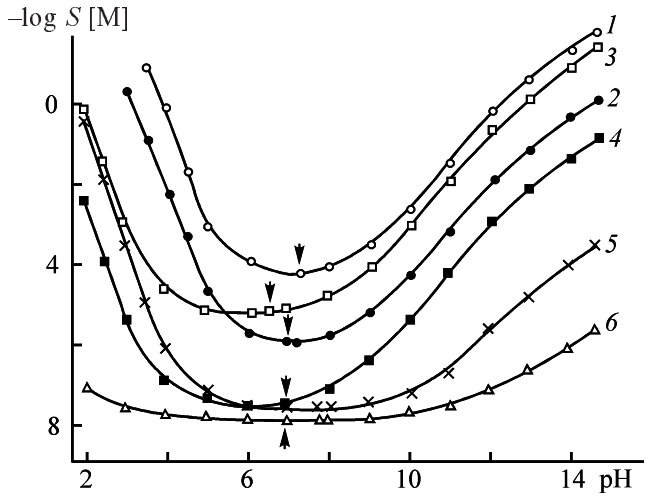
Thermodynamic Calculation of the Solubility of Solid Hydroxides of Group IIIA Elements in Water and Aqueous Media

E. V. Shkol'nikov

St. Petersburg State Academy of Forestry Engineering, St. Petersburg, Russia

Received April 10, 2008

Abstract—The effect of pH on the molar solubility of amorphous and crystalline hydroxides $M(OH)_3$ and metahydroxides MO(OH), where M is B, Al, Ga, In, or Tl, in aqueous alkaline and acidic media at 25°C was calculated thermodynamically taking into account the formation of hydroxo complexes.



DOI: 10.1134/S107042720809005X

A thermodynamic characteristic of the amphoteric properties of solid hydroxides $M(OH)_2$ in aqueous nonoxidizing media was suggested previously [1, 2]. Of interest is the thermodynamic calculation of the effect of pH on the molar solubility of hydroxides $M(OH)_3$ and metahydroxides MO(OH), where M is a Group IIIA element, in aqueous media. The calculation results can be used for the synthesis of hydroxides and oxides and for determination of conditions of their hydrolysis, practically complete precipitation, or efficient masking of cations in the form of soluble hydroxo complexes [3–7]. The hydroxides and metahydroxides of Group IIIA elements are used in production of special glasses, enamels, and cements, in chemical analysis and synthesis, and in medicine.

The amphoteric properties of $M(OH)_3$ and MO(OH) have been studied insufficiently, and quantitative data on the solubility in aqueous media are scarce and often contradictory. Thus, according to [4–8], weak acids H_3BO_3 and HBO_2 do not have basic properties and are markedly soluble in cold water, unlike practically insoluble hydroxides of other Group IIIA elements. On the other hand, boron(III) acetate, perchlorate, and hydrosulfate can exist in the crystalline form and the acid properties of $B(OH)_3$ are attributed to the formation of hydrogen (hydroxonium) cations and hydroxo complexes $[B(OH)_4]^-$ in aqueous solution [9, 10]. Colorless solid hydroxides $Al(OH)_3$, $Ga(OH)_3$, and $In(OH)_3$ are soluble in acids and alkalis, with the acid properties of $In(OH)_3$ being weak. Freshly precipitated indium(III) hydroxide readily dissolves in dilute acids, is insoluble in dilute alkalis, and forms unstable indates in concentrated alkaline solutions [9, 10]. According to [9], gallium(III) hydroxide shows almost ideal amphoteric behavior and readily dissolves in alkalis with the formation of stable gallates $[Ga(OH)_4]^-$. At the same time, according to [7], its acid properties dominate over base properties.

Reddish brown hydroxide $Tl(OH)_3$ dissolves in acids and is easily peptized with alkalis with the formation of a sol, but it is insoluble in them and does not form thallates [9]. According to a handbook [8], the hydroxide $In(OH)_3$ is difficultly soluble and $Tl(OH)_3$ is insoluble in alkalis. At the same time, in concentrated alkaline solutions the hydrate $Tl_2O_3 \cdot mH_2O$ has very weak acid properties, forming readily hydrolyzable thallates [10]. Amphoteric hydroxides of Group IIIA elements, freshly precipitated from aqueous solutions, are X-ray amorphous gels of variable composition $M_2O_3 \cdot mH_2O$ ($m > 3$). They contain excess water of hydration, which is lost on keeping and heating with the possible formation of crystalline hydroxides, metahydroxides, and oxides of definite composition [9–11].

Four crystal modifications of $Al(OH)_3$ were identified: monoclinic (γ) and triclinic (γ') gibbsite, or hydrargillite; monoclinic bayerite (α) and triclinic nordstrandite (β). There are also two AlO(OH) modifications (rhombic boehmite and diaspor). Nordstrandite is formed on aging $Al_2O_3 \cdot mH_2O$ gels [10]. Stable gibbsite is obtained by slowly feeding CO_2 into an alkaline solution, and metastable bayerite is formed by fast precipitation [11]. Boehmite and diaspor are obtained on heating of bayerite and gibbsite. All the above modifications are components of bauxites. The chemical activity decreases in the order amorphous gel → bayerite → gibbsite →

Solubility S of solid hydroxides vs. pH of an aqueous medium at 25°C: (*1*) freshly precipitated $Al(OH)_3$, (*2*) γ-AlO(OH), (*3*) $Ga(OH)_3$, (*4*) α-GaO(OH), (*5*) $In(OH)_3$, and (*6*) $Tl(OH)_3$.

boehmite → diaspor [10]. The crystalline compounds H_3GaO_3, $In(OH)_3$, and $Tl(OH)_3$ can be obtained by precipitation from alkaline solutions [11]. Heating H_3GaO_3 to approximately 400°C yields metagallic acid $HGaO_2$ [10].

In an aqueous solution saturated with a difficultly soluble hydroxide $M(OH)_3$ or MO(OH), the heterogeneous chemical equilibria

$$M(OH)_3(cryst) \rightleftarrows M^{3+}(sol) + 3OH^-(sol),$$
$$MOOH(cryst) + H_2O(l) \rightleftarrows M^{3+}(sol) + 3OH^-(sol) \quad (1)$$

are attained, whose thermodynamic constant is given by the expression

$$K_s^0 = SP^T = a(M^{3+})a^3(OH^-) = const(T), \quad (2)$$

where $a(M^{3+})$ and $a^3(OH^-)$ are the activities of the ions (M^{3+} and OH^-).

The thermodynamic calculation of K_s^0 for equilibria (1) was performed using the method from [1]. The free energies ΔG_f^0 of formation of the ions in aqueous solutions, required for the calculation, were taken from [12] and the free energies ΔG_f^0 of formation of the solid hydroxides at 298 K, from handbooks [5, 8, 13]. The molar solubility of hydroxides, except for H_3BO_3, was calculated taking into account the ionic strength of the solution and the formation of mononuclear hydroxo complexes, using the general equation

$$S = c_M = K_s^0(f_{M^{3+}}f_{OH^-}^3)^{-1}\sum_{i=0}^{n}\beta_i[OH^-]^{i-3}, \quad (3)$$

where the constant K_s^0 characterizes heterogeneous chemical equilibrium (1); $f_{M^{3+}}$ and f_{OH^-} are the molar activity coefficients of M^{3+} and OH^- ions; $\beta_0 = 1$, β_1, β_2, β_3, and β_4 are step stability constants of the hydroxo complexes MOH^{2+}, $M(OH)_2^+$, $M(OH)_3$, and $M(OH)_4^-$, found from the averaged data [3–6].

The molar solubility of the hydroxides in 1 M NaOH solution was calculated by the simplified formula $S = 1.13K_s^0\Sigma\beta_i$.

The equilibrium concentration of free OH^- anions and the pH value of saturated aqueous solutions of the hydroxides in pure water (shown by the arrows in the figure), were found by solving the system of six equations

$$3[M^{3+}] + 2[MOH^{2+}] + [M(OH)_2^+] + [H^+] = [M(OH)_4^-] + [OH^-],$$
$$[M^{3+}][OH^-]^3 = K_s^0, \quad [H^+][OH^-] = K_w,$$
$$[MOH^{2+}] = \beta_1[M^{3+}][OH^-], \; [M(OH)_2^+] = \beta_2[M^{3+}][OH^-]^2,$$
$$[M(OH)_4^-] = \beta_4[M^{3+}][OH^-]^4 \quad (4)$$

with the use of Ferrari, Cardano, or Newton method for the obtained equation

$$(1 + K_s^0\beta_4)y^4 - (K_s^0\beta_2 + K_w)y^2 - 2K_s^0\beta_1 y - 3K_s^0 = 0, \quad (5)$$

where K_W is the autoprotolysis constant of water at 25°C, $y = [OH^-]$.

For the H_3BO_3 crystals with molecular layered structure [9–11], no thermodynamic data exists on the small triply charged boron cation exhibiting high polarizing effect. The same concerns its hydroxo complexes in aqueous solutions, except for $B(OH)_3$ and $B(OH)_4^-$. Therefore, for the molar solubility of the triclinic H_3BO_3 modification in pure water at 25°C we took the intrinsic solubility of weak boric acid [4] in the form of H_3BO_3 molecules. The latter was found from the calculation, using electrochemical data of [14], of the thermodynamic constant K_s^0 for the heterogeneous equilibrium $H_3BO_3(cryst) \rightleftarrows H_3BO_3(sol)$ in saturated aqueous solution.

The results of the calculation are given in the table ($pK_s^0 = -\log K_s^0$, s^0 is the total molar solubility of solid hydroxides in pure water and $[M(OH)_3]$, the equilibrium molarity of neutral complexes in aqueous solutions of the hydroxides at 25°C). It can be seen from the table that the pK_s^0 values calculated in this study and those taken from [4, 7] are in reasonable agreement. For a number of hydroxides, the

* Freshly precipitated amorphous.
** In 0.01 M NaOH solution.

calculation was performed for the first time. Experimental solubilities of H_3BO_3 in water at 20°C differ markedly [4, 8–11]. At the same time, they are close to the calculated value of the intrinsic solubility of boric acid in the form of neutral complexes $B(OH)_3$ (see table). The dissolution of H_3BO_3(cryst) in water is an endothermic process (ΔH_s^0 = 22.6 kJ mol^{-1} [13]). The analysis of the data from handbooks [4, 8] shows that the temperature dependence of the solubility of boric acid in water can be presented by the equation

$$\ln(S_2/S_1) = \Delta H_s^0 R^{-1}(1/T_1 - 1/T_2), \quad (6)$$

where S_1 and S_2 are the solubilities at temperatures T_1 and T_2, respectively, and R is the gas constant.

The solubility of amorphous hydroxides $M(OH)_3$, like that of hydroxides $M(OH)_2$, is considerably higher [1, 2] than that of their crystalline modifications, because dehydration and crystallization of $M_2O_3 \cdot mH_2O$ precipitates are accompanied by formation of chemically inactive oxo derivatives in which the M atoms in polynuclear hydroxo aqua complexes are bound through O bridges [3, 10]. The solubility of crystalline hydroxides markedly depends on the structure, decreasing on passing to the stable modifications γ-$Al(OH)_3$ and α-AlO(OH). The solubility of hydroxides $M(OH)_3$ and metahydroxides MO(OH) (M is Al, Ga, In, or Tl) in pure water is determined by the concentration of dissolved neutral complexes $M(OH)_3$ [from 88% in aluminum hydroxides to approximately 100% in $Tl(OH)_3$].

The tables show that aqueous saturated solutions of aluminum and indium(III) hydroxides are weakly alkaline (pH^0 7.0–7.3), those of thallium(III) hydroxide, neutral, and those of gallium(III) hydroxide, weakly acidic (pH 6.2–6.9). The isoelectric point of the dispersed system was found at pH 6.8 [9], 9.2, and 9.4 [11] for $Ga(OH)_3$, bayerite α-$Al(OH)_3$, and boehmite γ-AlO(OH), respectively.

Free M^{3+} cations are practically absent in saturated aqueous solutions (mole fraction of the cations x^0, calculated as in [1], is less than 4×10^{-6}) and dominate in strongly acidic solutions (Al^{3+} and In^{3+} at pH < 3, Ga^{3+} at pH < 2, and Tl^{3+} at pH < 1), where they can be determined by potentiometric methods.

The solubility of amphoteric aluminum, gallium, and indium hydroxides passes through a minimum as pH of the medium is varied (by adding NaOH or

$HClO_4$, see figure, curves *1–5*). For $Tl(OH)_3$, the calculation yields a wide interval of pH values in which the solubility is minimal and does not vary noticeably (see figure, curve *6*). Analysis of Eq. (3) leads to a conclusion that the minimal solubility of $M(OH)_2$ precipitates is observed at the optimal concentration of OH^- ions when neutral complexes $M(OH)_2$ dominate in solution among equilibrium species. From the condition for the maximum mole fraction $x_{M(OH)_3}$, the following equation was obtained:

$$\beta_4[OH^-]^4 - \beta_2[OH^-]^2 - 2\beta_1[OH^-] - 3 = 0. \quad (7)$$

Solving this equation by the same way as Eq. (5) yielded first $[OH^-]_{opt}$ and pH_{opt} and then S_{min}. The values of $pS_{min} = -\log S_{min}$ at 25^0C are given in the table and partly in the figure. It can be seen that the negative effect of common OH^- ions on the solubility of the hydroxides under study $[M(OH)_3]$ in alkali is absent, as in the case of $Sn(OH)_2$ and HgO [1, 2]. The analysis shows that high stability constants β_3 of the neutral complexes $M(OH)_3$ and their high mole fractions in saturated aqueous solution ($x_{M(OH)_2} \geq 0.9$) are the conditions for the absence of this effect for hydroxides $M(OH)_3$ and metahydroxides MO(OH).

For comparative quantitative estimation of the amphoteric properties of hydroxides, we used, as previously, the ratio ($A > 1$) of their molar solubilities in an alkaline medium with pH 14.7 (5 M NaOH solution) and in pure water. The amphoterism parameter A markedly depends on the structure of modifications (see table) and is determined by the chemical nature of hydroxide {ratio of total stability constants of hydroxo complexes $[M(OH)_4]^-$ and $M(OH)_3$}. The calculated values of A and of the molar solubility of stable crystalline hydroxides $M(OH)_3$ in water and in alkali decrease in the order Ga → Al → In → Tl (see table). The results of the thermodynamic calculation are consistent with the experimental data on the solubility [8–11] and with the pH values corresponding to the complete precipitation of hydroxides: 3.6–7.6, 5.2–7.8, and 4.6–11 for $Ga(OH)_3$, $Al(OH)_3$, and $In(OH)_3$, respectively [4]. According to the experimental data, the solubility of H_3BO_3 in 1 M NaOH at 25°C is higher by 40% than S^0 and is controlled by the solubility of products formed by the reaction of $Na_2B_4O_7$ and $Na[B(OH)_4]$. In a solution containing excess alkali ($c \geq 5$ M), $NaBO_2$, which is a more water-soluble component, dominates [9, 10], which agrees with the experimental determination of H_3BO_3 solubility in 5 M NaOH and of A.

The molar solubility of stable hydroxides $M(OH)_3$ in acidic medium (pH 3) decreases upon the replacement of M element in the order B → Al → Ga → In → Tl, which coincides with the order in which the M^{3+} ionic radius increases and the polarizing effect of the cation decreases. In an acidic medium (pH 3), the solubility of very weak electrolytes H_3BO_3 and $Tl(OH)_3$ is intrinsic. The solubility of gallium(III) hydroxide is determined by hydroxo complexes $GaOH^{2+}$ and by Ga^{3+} cations; that of indium(III) hydroxide, by In^{3+} cations and $InOH^{2+}$ complexes; and that of aluminum hydroxide, by free Al^{3+} cations. In a strongly acidic medium (pH < 3), the solubility of a rather weak boric acid, unlike other Group IIIA hydroxides, decreases (our experimental value in 6 M HCl with pH –1.3 at 25°C is 0.16 M, i.e., 5.4 times less than the solubility in water).

CONCLUSIONS

(1) The molar solubility of hydroxides and metahydroxides of Group IIIA elements in water is largely determined by neutral complexes $M(OH)_3$ and depends on the structure and composition, considerably decreasing on passing from the amorphous to the difficultly soluble crystalline modification. Also, the solubility in water decreases on passing from difficultly soluble and rather weak acids H_3BO_3 (pH^0 3.7) and H_3GaO_3 (pH^0 6.2–6.6) to practically insoluble very weak base $Tl(OH)_3$ ($pH^0 \sim 7$).

(2) The effect of pH on the solubility of $M(OH)_3$ hydroxides and MO(OH) metahydroxides in aqueous alkaline and acidic media at 25°C was calculated by the thermodynamic method. The amphoterism parameter $A > 1$, decreasing in the order B → Tl → In → Al → Ga, was determined. The pH values of an acidic medium, below which M^{3+} ions are not bound into hydroxo complexes, were found.

(3) The minimal solubility and the values of pH corresponding to the most complete precipitation of the amphoteric hydroxides of aluminum, gallium, indium, and thallium(III) were calculated taking into account the formation of hydroxo complexes.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Simulation of Nonstationary Heat Transfer in Jacketed Apparatus

S. V. Shikhalev, S. A. Ermakov, and I. F. Reshetnikov

Ural State Economical University, Yekaterinburg, Russia

Received February 18, 2008

Abstract—Nonstationary heat transfer in jacketed apparatus was studied.

DOI: 10.1134/S1070427208090061

Chemical technology and food and pharmaceutical industries widely use jacketed vessels with steam heating without an agitating device, in which heating and cooling, extraction, crystallization, dissolution, chemical reactions, etc. are performed. In most of these processes, temperatures of both heat-transfer agents and heat transfer coefficient in the apparatus vary in the course of time, i.e., the heat-transfer process occurs under nonstationary conditions.

However, designing a jacketed apparatus by the available procedures for thermal calculations, mostly based on stationary heat-transfer models, requires a longer calculation time, impairs the output capacity, and leads to a substantial energy consumption and higher steel intensity.

In particular, it was assumed in [1, 2] that the heat-transfer coefficient k is constant and the temperature of process media varies by the exponential law, which disagrees with the actual working mode of jacketed apparatus [3]. The procedure for mathematical simulation of nonstationary temperature fields of a vessel, suggested in [4], employs partial local heat-transfer coefficients, which frequently cannot be calculated using the suggested criterion equations or can be, but with a gross error. The linearized model of the heat-up mode of jacketed apparatus makes it possible to determine in an easier way the area of the heat-transfer surface and the heat-up time [3]. However, for finding the operation parameters of a jacketed apparatus (temperature and pressure of process media), which are to be known for automation of vessels or other process purposes, the linearized model should be further refined.

The difficulties encountered in thermal calculations of this equipment initiated development of a model of nonstationary heat-transfer process that would enable thermal engineering calculations of jacketed apparatus with a sufficient accuracy.

We simulated the heat-up mode of jacketed apparatus using the nonstationary heat-transfer equation [3]

$$Q = F\int_0^{\tau_h} k(\tau)[l_m(\tau) - l_l(\tau)]d\tau, \quad (1)$$

where $k(\tau)$ is the coefficient of heat transfer from the heat-carrying agent in the jacket of the apparatus to a medium being heated (W m^{-2} °C^{-1}); $t_m(\tau)$, volume-average temperature of the steam-and-gas mixture in the jacket of the apparatus (°C); $l_l(\tau)$, volume-average temperature of the medium being heated (°C); F, area of the heat-exchange surface (m^2); τ_h, heat-up time of the apparatus (s); and Q, amount of heat transferred to the product by the heat-exchange surface with area F during a time interval τ_h (J).

To solve Eq. (1), we performed a number of experiments on heating of process media in jacketed apparatus with different capacities and found the functional dependences of the thermal parameters of the heat-up mode (temperature of process media and heat-transfer coefficients) on the process duration.

As objects of our experimental studies served electric jacketed apparatus with capacities of 0.02, 0.04, and 0.06 m^3 (Fig. 1).

The temperatures of the process media and the lid in heat-up of a jacketed apparatus were measured using Chromel–Copel thermocouples with thermal electrodes 0.2 mm in diameter and automated re-

cording by multipoint potentiometers of the KSP-4 type (accuracy class 0.25).

The working volume of the apparatus was filled with a rated amount of a product with an ambient temperature. As process media served solutions with different physicochemical properties: sugar solution with 10 to 20% dry substances and a 5% solution of table salt. The warming-up parameters of these solutions were compared with data on warming-up of a reference liquid (water). On switching-on the electric circuit with measuring devices and apparatus heaters, the temperatures of the technological media, heat-transfer surface, and steam-and-gas mixture in the apparatus jacket were simultaneously measured at regular intervals of time, $\Delta\tau$ = 180 s.

The local-in-time coefficient of heat transfer from the steam-and-vapor mixture to the contents of the boiling vessel was found using the relationship

$$k(\tau) = \frac{Q_{tot} - Q_{lid}}{F[t_m(\tau) - t_l(\tau)]\Delta\tau},$$

where Q_{tot} is the amount of heat transferred across the wall of the working vessel in a time τ (J), and Q_{lid}, the heat loss by the apparatus in a time $\Delta\tau$ (J).

We processed the experimental data in accordance with the recommendations of [5]. We presented the results of our experiments as graphical dependences $t_l = f(\tau)$, $t_m = f(\tau)$, and $k = f(\tau)$.

To generalize the experimental data on heat-up of jacketed apparatus, the graphical temperature dependences were plotted in the relative coordinates $t_{l,b} = f(\tau_b)$ and $t_{m,b} = f(\tau_b)$ (Fig. 2). We took as the relative temperature of the liquid

$$t_{l,b} = (t_l - t_{l,in})(t_{l,fin} - t_{l,in})^{-1}, \quad (2)$$

where t_l, $t_{l,in}$, and $t_{l,fin}$ are, respectively, the running temperature, that at the beginning of the heat-transfer process, and that at the end of the heat-up process (°C).

Similarly, we have for the relative temperature of

Testing of the linear model of heat-transfer in a jacketed apparatus

Process medium	Apparatus volume, m^3	Heat-up time τ_h, min		Error Δ, %	Temperature difference Δt_{fin} at the end of the heat-up, °C		Error Δ, %	Apparatus parameters*
		experiment	calculation by (10)		experiment	calculation by (10)		
Water	0.02	35	37.7	7.7	9.4	10.5	11.7	$F = 0.29$ m^2, $N = 3$ kW, $k_{fin} = 1276$ W m^{-2} °C^{-1}
	0.03	40.1	41.4	3.3	8.7	9	3.4	$F = 0.41$ m^2, $N = 3$ kW, $k_{fin} = 1289$ W m^{-2} °C^{-1}
	0.04	34.5	32.6	5.4	11.4	10.5	7.9	$F = 0.51$ m^2, $N = 9$kW, $k_{fin} = 1262$ W m^{-2} °C^{-1}
	0.06	45	45.6	1.4	8.7	8.9	2.3	$F = 0.75$ m^2, $N = 9$ kW, $k_{fin} = 1109$ W m^{-2} °C^{-1}
10% solution of sugar	0.05	33	36.5	10.6	8.9	10.1	13.5	$F = 0.62$ m^2, $N = 9$ kW, $k_{fin} = 1257$ W m^{-2} °C^{-1}
20% solution of sugar	0.05	39	43.4	11.4	7.7	8.7	12.9	$F = 0.62$ m^2, $N = 9$ kW, $k_{fin} = 1357$ W m^{-2} °C^{-1}
5% solution of salt	0.05	41	44.2	7.8	9.4	10.4	10.6	$F = 0.72$ m^2, $N = 9$ kW, $k_{fin} = 1025$ W m^{-2} °C^{-1}

* N is the power of electric heaters.

the steam-and-gas mixture:

$$t_{m,b} = (t_m - t_{m,in})(t_{m,fin} - t_{m,in})^{-1}, \quad (3)$$

where t_m, $t_{m,in}$, and $t_{m,fin}$ are, respectively, the running temperature, that at the beginning of the heat-transfer process, and that at the end of the heat-up process (°C).

We took as the relative time the ratio between the running time τ and the warming-up time τ_h of the contents of the boiling vessel:

$$\tau_b = \tau/\tau_h, \quad (4)$$

As can be seen in Fig. 2a, the family of points for jacketed apparatus is described with a certain accuracy (average relative error 2.9%) by the straight-line equation

$$t_{l,b} = 1.04\tau_b, \quad (5)$$

On substituting the dimensionless quantities $t_{l,b}$ and τ_b from expressions (2) and (4) into the straight-line equation (5), we obtained a correlation dependence of the temperature of the liquid in the working vessel on the heat-up time for jacketed apparatus:

$$t_l(\tau) = t_{l,in} + 1.04(t_{l,fin} - t_{l,in})\tau/\tau_h. \quad (6)$$

Similarly to (6), we obtained a correlation dependence of the temperature of the steam-and-gas mixture on the heat-up time, with a relative error of 7.9%:

$$t_m(\tau) = t_{m,in} + 1.04(t_{m,fin} - t_{m,in})\tau/\tau_h. \quad (7)$$

By plotting the dependence of the heat-transfer coefficient on the temperature difference Δt in the log–log coordinates (Fig. 3), we found an approxi-

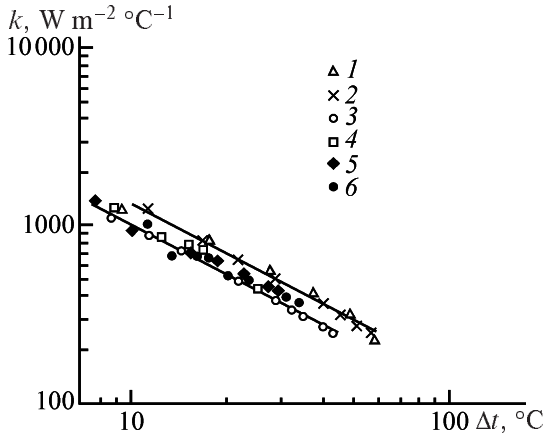

Fig. 3. Heat-transfer coefficient k vs. the temperature difference Δt. (*1*) KPE-20 (water), (*2*) KPE-40 (water), (*3*) KPE-60 (water), (*4*) KPEM-60 (10% solution of sugar), (*5*) KPEM-60 (20% solution of sugar), and (*6*) KPEM-60 (5% solution of table salt).

mate law by which k varies during the heat-up.

As can be seen in Fig. 3, the experimental data for jacketed apparatus form a family of parallel straight lines, described in the dimensionless representation by the dependence

$$k/k_{fin} = (\Delta t/\Delta t_{fin})^{-0.92}, \quad (8)$$

where k_{fin} is the heat-transfer coefficient in the final period of the heat-up (W m^{-2} °C^{-1}); Δt_{fin}, temperature difference in the final period of the heat-up (°C); and Δt, running temperature difference (°C).

The relative error of approximation of the experimental points in Fig. 3 did not exceed, on average, 5.2%.

With account of the fact that the temperature difference Δt is equal to the difference between the temperatures of the heat-carrying agents in the apparatus, dependence (8) takes the form

$$k(\tau) = k_{fin}\{[t_m(\tau) - t_l(\tau)]/(t_{m,fin} - t_{l,fin})\}^{-0.92}. \quad (9)$$

On substituting the local-in-time temperatures of media, defined by expressions (6) and (7), and the heat-transfer coefficient (9) into the nonstationary heat-transfer equation (1), we obtained a refined thermal engineering model of nonstationary heat transfer in bulk jacketed apparatus:

$$Q = 0.89Fk_{fin}\Delta t_{fin}^{0.92}(\Delta t_{in} - \Delta t_{fin})^{-1}(\Delta t_{in}^{1.08} - 1.04\Delta t_{fin}^{1.08})\tau_h, \quad (10)$$

where the subscripts "in" and "fin" correspond for all the parameters to the beginning and end of warming-up of the contents of the working vessel of the apparatus, respectively.

Our model (10) was tested against experiments on heat-up of jacketed apparatus with varied physicochemical parameters of the product and different ratios between the capacity and delivered power. The results obtained are listed in the table.

CONCLUSIONS

A nonlinear model describing the nonstationary heat-transfer process with an acceptable error was suggested. The model enables substantiated thermal engineering calculations of bulk jacketed apparatus operating in the heat-up mode.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Effect of Surfactants on Properties of Composite Sorbents Based on Fullerene Black

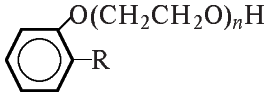
Abstract—Synthesis of composite sorbents by molding of fullerene blacks with a solution of polyacrylamide as a binder and surfactants was studied. The effect of surfactants of varied nature on the wettability of fullerene blacks and the sorption and mechanical properties of the molded products obtained was considered.

DOI: 10.1134/S1070427208090073

Composite sorbents are systems constituted by a matrix and a filler. Inorganic binders, organic polymers, metals, and carbon materials commonly serve as matrices, and both inorganic (silica gel, zeolites, active alumina) and organic (ion-exchange resins, activated carbon) sorbents, as fillers. Polymers serve as binders providing that a sorbent can be obtained as a molded product and, in particular, as pellets, blocks, and plates. Simultaneously, polymers used for molding affect the sorption and strength characteristics of the composites obtained [1, 2].

We used as a filler fullerene black (FB), which is a by-product formed in synthesis of fullerenes by combustion of graphite in an electric arc [3] and has good sorption properties [4]. In particular, the adsorption capacity for benzene from the gas phase is about 0.6–0.8 g g^{-1}, and the specific surface area determined with argon is within the range 50–250 m^2 g^{-1} and strongly depends on the conditions in which fullerenes are obtained. The content of fullerenes in the black used in the study was 4.2% ($FB_{4.2}$).

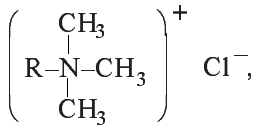
The practical use of FB as a sorbent is hindered by the fact that it is a highly dispersed material whose particle size is mostly within the range 0.5–5 μm. Therefore, it is appropriate to use this material as a component of a molded composite sorbing article. In this study, we produced a molded material from FB in the form of pellets.



We used as a binder polyacrylamide (PAA) in the form of an aqueous gel [TU (Technical Specification) 6-01-1049–92] with the following parameters: mass fraction of the main substance, 6.1%; sedimentation rate of copper oxide, 4.2 mm s^{-1}; kinematic viscosity, 4.2 (at a 0.25% mass fraction of polyacrylamide); residual content of monomers 0.004; and that of acrylamide, 0.004. The molecular mass of PAA was about 10^6 g mol^{-1}, as determined viscometrically after Staudinger [5]. The choice of the polymer was governed by environmental and economical considerations.

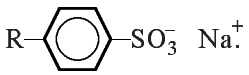
The procedure used to obtain a molded material is based on mixing FB with an aqueous solution of PAA in a certain ratio. The resulting paste was molded into pellets 3 cm in diameter and 1 cm high. The molded material was kept at 20°C for two days and then was thermally treated to remove excess amounts of moisture and surfactants providing wettability of the hydrophobic FB with an aqueous solution of the hydrophilic polymer and preventing direct interaction of PAA with the active surface of FB. Molding of FB and PAA without additives markedly impairs the sorption characteristics of the resulting molded material, and the very process of mixing and molding is hindered by the hydrophobic properties of the filler.

It has been suggested previously [1] that the decrease in the sorption capacity of sorbing materials of this kind, compared to the capacity of the starting sorbent, is primarily due to blocking of the surface of the sorbent-filler by a thin (10–50 μm) PAA film formed around its particles, which hinders diffusion of adsorbate molecules to the sorbent. In addition, in the case of the filler under consideration, the functional amide groups of the polymer interact [6] with active acid centers of FB, represented by carbonyl,



phenol, hydroxy, and other groups, whose presence is confirmed by IR spectroscopy and potentiometric titration [7]. This leads to adsorption of PAA on the FB surface and, as a result, impairs the sorption characteristics of the molded product.

To protect the surface of FB and to diminish the adsorption of the polymer on its surface in the stage of mixing of the starting products, the filler (black) is preliminarily treated with solutions of surfactants of varied structure: a nonionic surfactant (NS), Neonol-10



$R = C_9$, $n = 10$;

cationic surfactant (CS), quaternary ammonium compound

$R = C_{10}$–C_{16};

and anionic sufactant (AS), linear alkylbenzenesulfonate (LABS)

To determine the minimum necessary amount of a surfactant, we performed a set of experiments in which the effect of the surfactant concentration on the intensity of FB wetting was judged from the rate of FB sedimentation in aqueous solutions of surfactants. In accordance with the procedure, equal-weight portions of FB were placed in surfactant solutions with different concentrations and the same volume. After that, the time of complete FB sedimentation was determined as the time necessary for complete sedimentation of visually observed black particles in a surfactant solution, measured with a stopwatch. Figure 1 shows the resulting graphical dependences of the sedimentation time on the surfactant concentration.

Figure 1 shows that it is inexpedient to use surfactant solutions with concentrations lower than 0.8 wt %, because this impairs the stabilizing effect of a surfactant on the FB suspension, determined from the FB sedimentation rate in aqueous solutions of surfactants. At concentrations higher than 0.8 wt %, the sedimentation time of black particles becomes essentially constant, which suggests that optimal surfactant concentrations are reached.

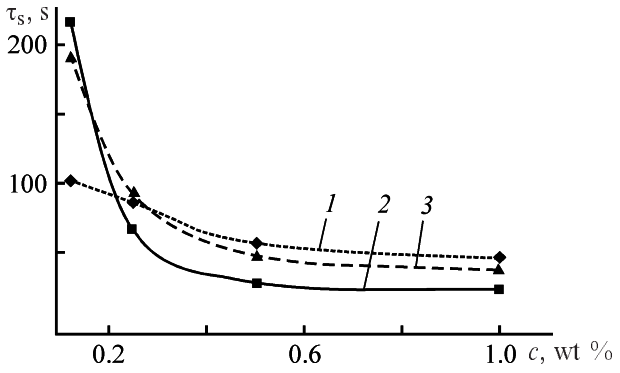


Fig. 1. Sedimentation rate of fullerene black vs. the concentration c of surfactants of varied ionic nature. (τ_s) Sedimentation time. Surfactant: (*1*) AS, (*2*) CS, and (*3*) NS.

At solution concentrations higher than 0.25 wt %, the FB sedimentation rate in a solution of the quaternary ammonium base exceeds that for other surfactants of the corresponding concentrations. This suggests that the interaction of FB with the quaternary ammonium base is more intense. At a concentration of 0.5 wt %, the time of FB wetting with an aqueous solution of CS is 1.4 and 1.5 times shorter than those for solutions of NS and CS (25, 46, and 54 s, respectively).

The interaction of a surfactant with FB is largely determined by the nature of the FB surface. It has been shown previously by means of potentiometric titration by the Boehm method [8] that the FB surface bears a large number of acid groups, whose amount substantially exceeds that for activated carbons. In all probability, the interaction of acid groups on the fullerene black surface with the quaternary ammonium groups of CS intensifies wetting processes, compared with processes associated with nonspecific interaction with AS and NS. The acceleration of the wetting of FB with CS, observed visually and recorded instrumentally, is illustrated by Fig. 1. The nature of the interaction CS groups with FB is the same as that in the FB–PAA interaction. By the nonspecific interaction we understand the adsorption due to the van der Waals interaction.

Use of surfactant solutions of concentrations higher than 2 wt % is inexpedient because such a high concentration does not make higher the wetting rate, whereas the interaction of FB with a surfactant may give rise to film effects.

In addition, surfactants affect the sorption and mechanical properties of the molded product (Table 1). The sorption properties of the materials

Table 1. Effect of surfactants on the sorption characteristics and mechanical strength of molded samples

Surfactant	W_S, $cm^3\ g^{-1}$		X, $mg\ g^{-1}$	E^{Cu}, $mg\ g^{-1}$	A_a, mg-equiv g^{-1}		S_{sp}, $m^2\ g^{-1}$	WR, %
	C_6H_6	C_2H_5OH			NaOH	$NaHCO_3$		
Initial $FB_{4.2}$	0.43	0.30	–	42	–	–	210	–
AS	0.76	0.50	141	79	5.7	5.6	185	80

NS	0.68	0.44	140	55	5.6	5.5	140	75

obtained were evaluated using standard techniques by determining the following parameters: limiting volume W_S of the sorption space with respect to vapors of organic compounds [9]; specific surface area S_{sp} of samples, measured by the method of thermal desorption of argon, with data processing in terms of the Brunauer–Emmett–Teller (BET) theory (for instrumental and mathematical description, see [10]); amount A_a of acid groups, found by potentiometric titration by the Boehm method; sorption activity with respect to dyes (Methylene Blue, X) [11]; sorption activity E^{Cu} with respect to heavy metal cations, measured with a KFK-2MP photocolorimeter. The mechanical properties of the materials were evaluated by the wear resistance WR [12].

It is noteworthy that Table 1 lists results for samples obtained in the optimal conditions. The molding conditions are identical for all the samples represented in Table 1: the time of mixing of FB with a surfactant was 5 min, and that of further mixing with a PAA solution, 10 min; the mixing was performed in a paddle mixer at a treatment temperature T = 180°C and duration of 1 h.

According to the results of the study (Table 1), the composite sorbents produced by molding exhibit a sorption capacity that surpasses, in the case when CS is used, the similar characteristics of the starting material nearly twofold for benzene and ethanol, and more than 1.5-fold for copper cations. The achievable sorption capacity for copper (79 $mg\ g^{-1}$) substantially exceeds the corresponding parameter for industrial activated carbons (40–50 $mg\ g^{-1}$), determined under similar conditions. The materials are inferior in sorption capacity for Methylene Blue dye (140–149 $mg\ g^{-1}$) to industrial activated carbons OU-A (no less than 225 $mg\ g^{-1}$).

The sorption characteristics of the composite materials molded with the use of CS are better than those obtained with NS and AS both in sorption of vapors of organic compounds from the gas phase and in sorption of the organic dye and copper cations from the aqueous medium. In addition, the specific surface area substantially increases, by factors of 1.4 and 1.8, compared to the cases of AS and NS, respectively. The possible reason for such a difference in sorption properties is that the nature of a surfactant largely determines the mechanism by which PAA interacts with the black to give the corresponding structure of the sorbing material obtained. NS and AS interact with the FB surface presumably by the dispersion interaction mechanism. In the interaction of CS with the FB surface, the most probable is the interaction with active acid groups whose amount on the surface of the material is rather large (Table 1).

Thus, in the first stage of synthesis of the molded material by treatment of the starting FB with a surfactant, the wetting of the sorbent surface by water is provided by its interaction with alkyl chains. When a surfactant is mixed with the black, a film of the surfactant is formed on the surface of FB particles. The hydrophilic groups of the surfactant are directed toward the aqueous solution and the surfactant interacts with PAA (in the second stage of synthesis of the molded material) at these hydrophilic groups. It seems unlikely that the surfactant could be reoriented with its alkyl groups looking toward PAA because the hydrophobicity of the fullerene surface is very strong and exceeds that of the alkyl chain of PAA. Thus, PAA does not directly interact with the FB surface. In the subsequent thermal treatment, the surfactant is partly removed and a free space appears in the structure of the molded material, which is confirmed by the increase in the specific surface area of the sample. Owing to this free space, the sorption capacity of FB contained in the composite material for vapors of organic substances, benzene, and ethanol somewhat increases. Because the functional groups of FB remain free, its sorption capacity for copper cations, sorbed by the ion-exchange mechanism, grows. At the same time, the blocking of the FB surface by a surfactant,

with its subsequent partial removal, diminishes the interaction of PAA with the filler, which affects the strength of the molded material.

Thus, partial removal of surfactants from the pellets is an important stage of the synthesis of composite sorbents, which determines their sorption and strength properties. The temperature at which the material was treated was maintained within the range 150–200°C, which resulted in that the surfactant content of the molded sorbing material decreased to an extent sufficient for reaching its acceptable characteristics. The thermal treatment also leads to formation of interchain bonds via interaction of the amide groups of PAA [13], which provides a sufficiently high stability of the molded material against water. On raising the temperature to above 180°C, the composite sorbent being synthesized disintegrates [1], which primarily occurs because of the decomposition of the binder (PAA) and the resulting decrease in the strength of the molded material. Thus, the optimal temperature range for performing the given stage is 165–180°C. The results obtained are listed in Table 2.

It is noteworthy that the conditions in which materials of this series were synthesized differed only in agitation intensity from those in which the composite sorbents whose properties are listed in Table 1 were obtained. The latter were produced with manual agitation of the paste. It can be seen that the absolute values of the sorption characteristics of the materials slightly change, but all the main trends noted above are preserved.

The data in Table 2 suggest that, on elevating the treatment temperature, surfactants are most effectively removed from FB and the structure of the material is transformed to a certain extent and, accordingly, both the sorption capacity of the composite sorbent for benzene and ethanol vapors and the specific surface area increase.

A rather important factor affecting the filler–surfactant interaction and the properties of the sorbing material obtained is the duration of mixing of these components. Table 3 lists sorption characteristics of samples based on $FB_{4.2}$ fullerene black and obtained at different durations of mixing with a surfactant for the example of CS. The finishing thermal treatment of the composite material obtained was performed at 150°C for 1 h.

It follows from Table 3 that, on making longer the duration of FB mixing with CS, the sorption characteristics of the materials obtained are considerably improved. Upon agitation for 25 min, the sorption capacity for benzene and ethanol increases by 20 and 44%, respectively, compared with agitation for 5 min. This points to a more homogeneous distribution of the surfactant over the FB surface. In some cases, the sorption parameters of the materials obtained surpass those of the starting FB. This occurs because, in the course of interaction of fullerene materials (fullerites, fullerene blacks) with various compounds (organic solvents, water), the structure of the fullerene materials is transformed, including an increase in the porosity and sorption capacity [14, 15].

Making the agitation duration longer also leads to a substantial decrease in strength (by 20%). In all probability, this is due to a change in the meso- and

Table 2. Effect of the treatment temperature on sample properties

macroporous structure of the composite sorbents obtained. Fig. 2 shows how the duration of FB mixing with PAA affects the pore volume distribution with respect to pore size in the composite sorbent obtained, measured by mercury porosimetry.

On raising the duration of FB mixing with CS to 15–25 min, mostly the volume of macropores (with radii of 100–30000 nm) increases, and just this circumstance impairs the strength of the product obtained. Macropores appear in the product because separate filler–binder conglomerates are formed in the course of agitation [16]. In the case in question, these are FB–PAA conglomerates whose size predetermines the size of macropores. The strength of the material decreases on passing from a homogeneous system to that constituted by a set of higher-density conglomerates.

Thus, the time of mixing of the filler and a surfactant is an important process parameter whose optimal value should be found because of its influence on the sorption and strength characteristics of the molded material.

Table 4. Sorption characteristics and strength of samples produced at different durations of FB mixing with PAA

τ, min	W_S, cm^3 g^{-1}		WR, %
	C_6H_6	C_2H_5OH	
10	0.52	0.53	70
20	0.57	0.62	65
30	0.56	0.59	60
35	0.55	0.57	50

The properties of the molded sorbents obtained are also affected by other process parameters and, in particular, by the duration of filler mixing with the binder (Table 4), which was varied in the range 10–35 min. The time of mixing with a surfactant in a mechanical paddle mixer was 5 min for all the materials; the thermal treatment was performed at 150°C for 1 h.

As follows from Table 4, the agitation duration strongly affects the strength properties of the materials obtained. As the agitation duration is raised, the wear resistance decreases from 70 to 50% (by a factor of 1.4), which is highly important for molded sorbents. On making longer the agitation duration, the sorption properties of the materials also insignificantly change, in particular, the sorption capacity for benzene and ethanol passes through a maximum. The maximum sorption capacity for ethanol was 0.62 cm^3 g^{-1} at an agitation duration of 20 min, which exceeds by 17% the same parameter for the material synthesized at an agitation duration of 10 min (at the measurement error of 3–4%). The wear resistance of this material was 65%.

Thus, it was shown that the most important stage in synthesis of composite sorbents based on FB and PAA is the additional treatment of FB with a solution of a surfactant. The strongest influence on the FB surface is exerted by the cation-active surfactant, whose use improves the sorption characteristics of the composites obtained.

Raising the thermal treatment temperature leads to an increase in the sorption capacity of the material for organic compounds from the gas phase and in the specific surface area, which possibly occurs because space is freed via partial removal of the surfactant and structural rearrangement. According to the experimental data, the optimal temperature is 160–180°C, which, on the one hand, gives a sufficiently developed porous structure and, on the other, leads to formation of a cross-linked [13] water-resistant polymer-binder.

CONCLUSIONS

(1) The possibility of obtaining high-strength molded sorbents based on fullerene black and a polymeric binder polyacrylamide was demonstrated. The key factors determining the properties of the material obtained are the conditions of mixing of the fullerene black with a surfactant and polyacrylamide and the thermal treatment of the materials.

(2) An optimization of the processes allowed preparation of composite sorbents with a wear resistance of up to 75% (relative to the initial mass of the sorbent) and a sorption capacity for organic solvent vapors of 0.7–0.8 $cm^3 g^{-1}$, which surpasses the corresponding parameters of most of industrial activated carbons.

(3) It was shown that the materials surpass commercial brands of activated carbons in sorption capacity for copper ions, but are inferior to these carbons in sorption capacity for Methylene Blue dye.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

S-Cinnamyl Esters of Thiocarbonic Acids as Additives to Lubricating Oils

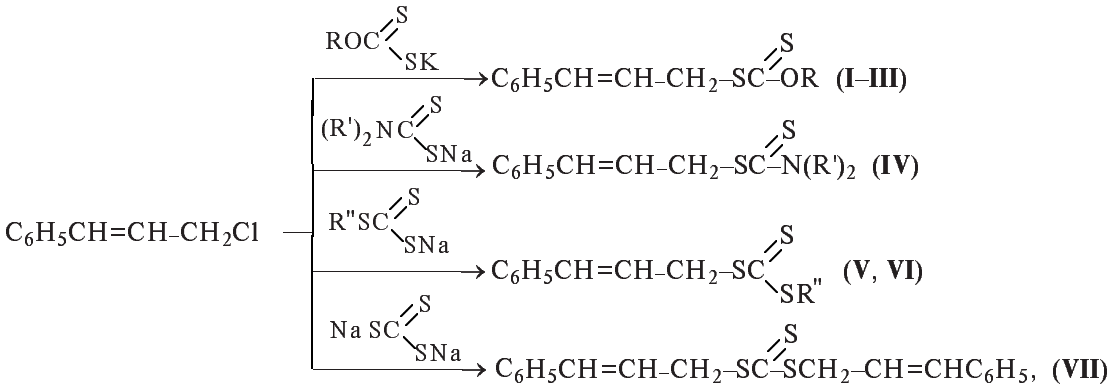
Abstract—A series of cinnamul esters of xanthic, trithiocarbonic, and dithiocarbamic acids were prepared. The optimal conditions of their synthesis were found. The cinnamyl esters were studied by thermal analysis, and the dependence of their lubricating power on the composition and structure was revealed. The tribological properties of lubricating oils with additions of cinnamyl esters of thiocarbonic acids were studied. A correlation between the structure of the esters synthesized and their antiscuff properties was found.



DOI: 10.1134/S1070427208090085

Improvement of machinery is often accompanied by posing more stringent requirements upon lubricating oils, which, in turn, requires the development of more effective additives. Despite enormous success in studies and application of various organic sulfur compounds as additives to lubricating oils, a systematic search for new, more effective representatives of this class is continued.

Numerous studies performed at the Institute of Chemistry of Additives on the synthesis and application of organosulfur compounds as antiscuff additives revealed high performance of various derivatives of thiocarbonic (TC) acids [1–4].

The goal of this study was to prepare derivatives of thiocarbonic (xanthic, trithiocarbonic, dithiocarbamic) acids by reactions of their salts with cinnamyl (phenylallyl) chloride; to study their lubricating properties in relation to the composition and structure; and to test the esters synthesized as antiwear and antiscuff additives to lubricating oils.

Our study is of interest from the viewpoint of predicting the optimal composition and structure of additives having the preset service properties. The choice of TC acid derivatives containing the fragments  ,  , and  based on cinnamyl chloride is governed by the presence in molecules of these esters of thione and sulfide sulfur atoms and of the phenylallyl group. All these fragments are responsible for the antiwear and antiscuff properties. Also, the required raw materials (styrene, xanthic and dithiocarbamic acid salts) are commercially available. Thiocarbonic acid derivatives were prepared by reactions of cinnamyl chloride with alkali metal salts of the corresponding acids by the scheme

where R = C_2H_5 **(I)**, *i*-C_3H_7 **(II)**, C_4H_9 **(III)**; R' = C_2H_5 **(IV)**; R" = C_4H_9 **(V)**, C_5H_{11} **(VI)**.

The known procedure for preparing cinnamyl chloride involves the reaction of styrene with formaldehyde and concentrated HCl in the presence of elemental sulfur [5]. The cinnamyl chloride yield in this procedure does not exceed 60–63%. It was shown that, in the presence of hydroquinone as an agent preventing styrene polymeriation, the cinnamyl chloride yield reaches 90%. Lyushin and Alekberova [6] suggested the following procedure for preparing cinnamyl chloride:

$$C_6H_5–CH=CH_2 + \overset{+}{C}H_2OH \rightleftarrows C_6H_5\overset{+}{C}H–CH_2–CH_2OH,$$

$$C_6H_5CH–CH_2–CH_2OH \underset{+H^+}{\overset{-H^+}{\rightleftarrows}} C_6H_5CH=CH–CH_2OH,$$

$$C_6H_5CH=CH–CH_2OH + HCl \rightarrow C_6H_5CH=CH–CH_2Cl + H_2O,$$

The reactions of cinnamyl chloride with potassium xanthates were performed in a polar solvent at 60°C and were complete in 4.5–5 h. The reaction with sodium diethyldithiocarbamate, as with xanthates, occurred smoothly in an aqueous or alcoholic solution with a noticeable heat release [7]. Dithiocarbamate was used as 50% aqueous solution.

Synthesis of trithiocarbonic acid esters was preceded by the synthesis of the starting alkali metal trithiocarbonates. From alkali metal trithiocarbonates and cinnamyl chloride we prepared both unsymmetrical and symmetrical esters of trithiocarbonic acid.

To prepare unsymmetrical trithiocarbonic acid esters, we initially prepared alkali metal alkyl trithiocarbonates by the reactions of mercaptans with carbon disulfide in the presence of an aqueous or alcoholic solution of alkali [8, 9]:

$$RSH + CS_2 + KOH \rightarrow RSC(S)SK + H_2O.$$

Then the corresponding unsymmetrical trithiocarbonic acid esters were prepared in 70–90% yield by reactions of aqueous solutions of alkyl trithiocarbonates with cinnamyl chloride [10, 11].

Sodium trithiocarbonate required for the synthesis of the symmetrical trithiocarbonic acid ester was prepared by the reaction of sodium sulfide with carbon disulfide in aqueous solution [12]:

$$Na_2S + CS_2 \rightarrow NaS–C(S)SNa.$$

Our studies showed that alkali metal alkyltrithiocarbonates and sodium trithiocarbonate are obtained in a higher yield with a strongly polar aprotic solvent, dimethylformamide. Furthermore, in dimethylformamide the second step, reaction with cinnamyl chloride, also occurs fairly readily, with a high yield of the target products. The characteristics of the synthesized esters are given in Table 1.

Cinnamyl esters of xanthic, trithiocarbonic, and dithiocarbamic acids are pale straw-colored liquids, and dicinnamyl trithiocarbonate is a yellow crystalline substance. All these compounds are readily soluble in organic solvents and lubricating oils.

The structures of the synthesized esters were confirmed by elemental analysis and by IR and ^1H NMR spectroscopy. The IR absorption spectra were recorded on a Specord-75 spectrophotometer (Carl Zeiss, Germany), and the ^1H NMR spectra, on a Varian T-60 spectrometer (60 MHz, CCl_4 solutions).

The IR spectra of cinnamyl esters of all the thiocarbonic acids contain absorption bands at 1645–1659 cm^{-1}, characteristic of the –HC=CH– bond conjugated with the aromatic ring. Strong bands at 1600–1610 cm^{-1} are due to stretching vibrations of the aromatic ring. The out-of-plane bending vibrations of the C–H bond give rise to a strong band at 695–739 cm^{-1}, characteristic of monosubstituted benzene derivatives.

In the IR spectra of xanthic acid esters, there are strong bands at 1250–1225, 1150–1090, and 1060–1030 cm^{-1}. Although all these bands belong to the R–O–C(S)– fragment, according to [13, 14], the bands at 1060–1030 cm^{-1} should be assigned to the C=S vibration, and the high-frequency bands, to the C–O stretching vibrations.

The stretching vibrations of the C=S groups in trithiocarbonates and *S*-cinnamyl diethyldithiocarbamate are manifested at 1040–1020 and 990–980 cm^{-1} (doublet), respectively. The other NCS bonds of *S*-cinnamyl diethyldithiocarbamate, characteristic of all the thioamides, are observed at 1570–1395 and 1420–1260 cm^{-1}.

The signals observed in the ^1H NMR spectra of cinnamyl esters of thiocarbonic acids (δ, ppm) are given in Table 2.

With the aim to examine the dependence of the lubricating power on the composition and structure of cinnamyl esters of thiocarbonic acids, we studied them by thermal analysis [15, 16]. As the additives operate at elevated temperatures, it was interesting

to study thermal characteristics of the synthesized compounds, both taken alone and in contact with metals, so as to evaluate their performance in the required temperature range. This would also allow estimation of their chemical activity toward metals and preliminary assessment of the performance of the compounds as antiwear and antiscuff additives to oils. The thermal analysis was performed on an OD-102T derivatograph (MOM, Hungary) in the dynamic mode at a heating rate of 5 deg min^{-1} in the temperature range 20–500°C.

Thermal analysis of the thiocarbonic acid derivatives shows that thermal transformations of the majority of compounds taken separately start above 170°C, i.e., above the oil temperature in transmission units. The dithiocarbamates and trithiocarbonates are somewhat more heat-resistant than xanthates. In the presence of metals, trithiocarbonates are more active than the other TC acid derivatives.

We found that all the TC acid derivatives are active toward metals, and their chemical activity in relation to the acid residue decreases in the order –S–C(S)SR > –S–C(S)N$(C_2H_5)_2$ ≥ –S–C(S)OR.

According to the common views [15–17], the lower the temperature of the interaction of a compound with metals and the lower the weight loss at this temperature, the more effective is the compound as an antiscuff additive. Correspondingly, the efficiency of the lubricating action of TC acid esters will vary in the same order.

EXPERIMENTAL

***S*-Cinnamyl isopropylxanthate.** To a mixture of 34.8 g (0.2 mol) of potassium isopropylxanthate in 50 ml of isopropyl alcohol, we gradually added 30.5 g (0.2 mol) of cinnamyl chloride and stirred at 60°C for 5 h. After cooling, the mixture was washed with water, dried, and subjected to vacuum distillation. Yield of *S*-cinnamyl isopropylxanthate 45.4 g (90%). *S*-Cinnamyl ethyl- and butylxanthates were synthesized similarly.

***S*-Cinnamyl butyl trithiocarbonate.** To 47 g (0.25 mol) of sodium butyl trithiocarbonate in a dimethylformamide solution, we added 38.1 g of cinnamyl chloride and stirred for 4–5 h. The mixture was washed with water, and low-boiling products were distilled off in a vacuum. The residue was purified by liquid column chromatography. Yield of *S*-cinnamyl butyl trithiocarbonate 63.5 g (90%). *S*-Cinnamyl amyl trithiocarbonate was synthesized similarly.

Dicinnamyl trithiocarbonate. To 22.5 g (0.1 mol) of sodium sulfide in 20 ml of dimethylformamide, we added dropwise 8 ml of carbon disulfide and stirred for 1 h, after which we added dropwise 30.4 g (0.2 mol) of cinnamyl chloride. The mixture was heated to 60°C and stirred for 3 h. The precipitated yellow crystals were filtered off and recrystallized from isopropyl alcohol. Yield of dicinnamyl trithiocarbonate 29.9 g (87.5%).

***S*-Cinnamyl diethyldithiocarbamate.** To 45.6 g (0.2 mol) of sodium diethyldithiocarbamate trihydrate in 23 ml of water, we added 30.5 g of cinnamyl chloride and stirred at 65–70°C for 4 h. The mixture was washed with water, vacuum-dried, and distilled. Yield 50.4 g (95%).

The performance of cinnamyl esters of TC acids was examined in liquid paraffin and MS-20 oil with a four-ball friction machine according to GOST (State Standard) 9490–75. The concentration of the additives was 20 mmol per 100 g in liquid paraffin and 5% in MS-20 oil (the most frequently used concentration of antiscuff additives).

The results of studying lubricating properties of thiocarbonic acid esters as additives to liquid paraffin are given in Table 3, with the data for alkyl esters of thiocarbonic acids given for comparison.

As can be seen, all derivatives of thiocarbonic acids improve the antiscuff characteristics of liquid paraffin, with the cinnamyl esters surpassing in the antiscuff performance the related alkyl esters. High antiscuff performance of cinnamyl esters of TC acids is apparently due to the negative inductive effect of the styryl group $C_6H_5CH{=}CH{-}$. Similar effect was observed previously in studies of benzyl and allyl esters of TC acids [18]. The styryl group, like phenyl and vinyl groups, being electronegative, makes the $S{-}CH_2$ bond more polar, facilitates its heterolytic cleavage, and thus favors formation of iron sulfides mitigating the seizing process.

As follows from the comparison of cinnamyl xanthates with each other, with an increase in the length of *O*-alkyl radicals the antiscuff properties of the compounds become somewhat worse, i.e., the strength of the boundary film decreases. Relatively high antiscuff performance of short-chain xanthates may be due to higher packing density of their molecules in adsorption on a metal surface, as compared to long-chain analogs.

It can be seen that thiocarbonic acid esters surpass in the antiscuff properties xanthic and dithiocarbamic acid esters. This fact may be due to specific features of interaction of these compounds with the surface.

Thiocarbonates containing an additional sulfur atom compared to dithio acid esters provide higher concentration of useful products on friction surfaces, whereas esters of the other two thio acids partially form oxygen- and nitrogen-containing products of poor performance.

The results of 1-h tests of thiocarbonic acid esters in mineral oil solution at an axial load of 392 N might suggest that these compounds exhibit no antiwear properties, becuase the index D_w of their solutions exceeds D_w of straight liquid paraffin. However, data on the critical seize load P_s are inconsistent with this conclusion: The index P_s characterizes the strength of the boundary film, and introduction

Table 4. Lubricating properties of cinnamyl esters of thiocarbonic acids in MS-20 oil

Compound	Concentration in oil, %	Scuff index I_s	Seize load P_s	Welding load P_w	Wear index D_w, mm
		N			
MS-20 oil	–	304	784	1568	0.62
I	5.0	632	1235	3685	0.77
II	5.0	615	1235	3479	0.78
III	5.0	586	1166	3283	0.78
V	5.0	671	1303	3920	0.84
VII	5.0	715	1303	4381	0.81
IV	4.0	624	1303	3550	0.80

of TC acid esters into liquid paraffin favors formation of very strong films that withstand higher loads (872–1303 N) than do adsorption films of straight liquid paraffin (549 N). Hence, the TC acid esters do exhibit antiwear properties, which, however, are not manifested at their concentration of 20 mmol per 100 g of oil and an axial load of 392 N corresponding to a specific pressure of 2.32 GPa (232 kgf cm^{-2}).

We also examined the cinnamyl esters of TC acids as additives to MS-20 oil. The results are given in Table 4.

As can be seen, the main trends revealed with liquid paraffin were also observed with MS-20 transmission oil. The most significant difference of the samples with MS-20 oil is that their antiscuff properties are better because of higher viscosity of the initial oil.

REFERENCES

(1) The optimal conditions were found for preparing cinnamyl esters of xanthic, dithiocarbamic, and trithiocarbonic acid esters by reactions of cinnamyl chloride with alkali metal salts of the corresponding acids, with increased yields of both the starting cinnamyl chloride and thiocarbonic acid esters.

(2) All cinnamyl esters of thiocarbonic acids are chemically active toward metals; dithiocarbamates and trithiocarbonates taken separately somewhat surpass xanthates in the thermal stability. In the presence of metals, however, trithiocarbonates are more reactive than dithiocarbamates and xanthates.

(3) Lubricating properties of the synthesized esters were examined, and a correlation was revealed between their structure and antiscuff performance. All the cinnamyl esters of thiocarbonic acids exhibit high antiscuff performance and surpass in this property the esters of xanthic and dithiocarbamic acids whose performance is essentially similar. With an increase in the alkyl chain length, the seize load decreases and the antiscuff properties become worse.

Abstract—Extractive rectification of the benzene fraction of reformer naphtha was studied, and the relative fugacity coefficients of the heptane–benzene system in the presence of *N*-methylpyrrolidone–*N*-formylmorpholine mixtures of various compositions were determined. A synergistic effect was revealed for a mixed selective solvent containing 29–30 wt % *N*-formylmorpholine, 68–69% *N*-methylpyrrolidone, and 2–3 wt % water.

DOI: 10.1134/S1070427208090097

Previously we suggested to use a mixed selective solvent *N*-methylpyrrolidne (*N*-MP)–sulfolane, exhibiting a synergistic effect, for separation of benzene from the benzene fraction of reformer naphtha [1]. As highly selective solvent added to *N*-MP instead of sulfolane, one can use *N*-formylmorpholine (*N*-FM) which is widely applied to separation of arenes by selective rectification (Morpholane process) or extraction (Morphylex process) [2]. Advantages of *N*-FM compared to sulfolane are lower values of the boiling point, viscosity, and enthalpy of vaporization and higher solvency toward hydrocarbons [1–4]. However, the solubility of saturated hydrocarbons in *N*-FM, especially if it contains several percents of water to decrease the temperature in the lower sections of the extractive rectification and stripping towers, is limited. For example, at 80°C the solubility of hexane and heptane in *N*-FM is about 5.2 and 3.7 mol %, respectively [5]. The critical points of solution of methylcyclopentane and methylcyclohexane in *N*-FM are 130.14 and 131.61°C, respectively [6].

Thus, on the upper trays of an extractive rectification tower at pressures close to 1 atm the *N*-FM–hydrocarbons system can undergo phase separation, which will lead to a decrease in the fugacity coefficients of saturated hydrocarbons relative to arenes. Addition of *N*-MP to *N*-formylmorpholine is characterized by the following positive effects: homogenization of the system due to considerably higher solvency of *N*-MP; decrease in the process temperature due to lower boiling point of *N*-MP, which favors stabilization of π complexes of arenes with solvents; decrease in the viscosity of the system, which leads to an increase in the efficiency of trays of an extractive rectification tower.

With the aim to determine the required content of water in a mixed solvent, we found the normal boiling points of a 50 : 50 (wt %) *N*-FM–*N*-MP mixture in relation to the water content of the ternary mixture (Fig. 1).

At this composition of a mixed solvent and steam pressure of 10 atm in the stripping tower, the water content of the solvent should be about 3 wt %.

The results of benzene recovery from the benzene fraction of reformer naphtha by extractive rectification with *N*-FM and its mixtures with *N*-MP are given in Table 1.

The procedure of extractive rectification experiments was described previously [1]. In all the experiments we detected no toluene in the distillate, i.e., the degree of separation of toluene by extractive distillation with *N*-FM and its mixtures with *N*-MP is virtually 100%. The degree of separation of benzene with *N*-FM containing 3 wt % water is low: Even at a solvent to feed weight ratio of 3 : 1, the benzene concentration in the distillate exceeds 5 wt %. *N*-MP

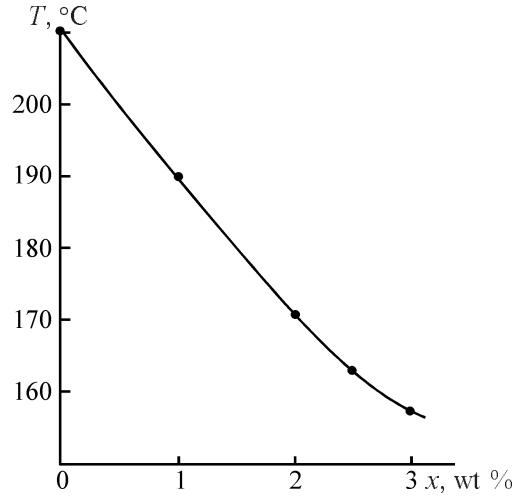

Fig. 1. Boiling point T of the mixed extractant N-FM : N-MP = 50 : 50 (wt %) as a function of its water content x.

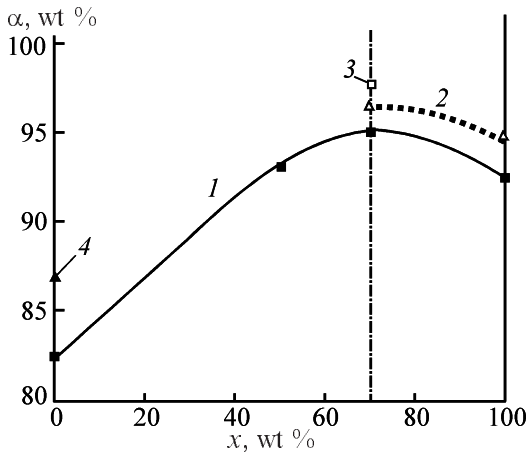

Fig. 2. Degree of arene separation α at their 99.9 wt % content in the bottoms as a function of the N-MP content in the mixed extractant. Run nos. (Table 1): (*1*) 1, 3–5; (*2*) 6, 8; (*3*) 7; and (*4*) 2.

containing 3 wt % water is more efficient, but in this case the benzene content of the distillate decreases only to 3.25 wt %. N-FM–N-MP mixtures containing 3 wt % water are still more efficient.

As seen from Fig. 2, the optimal content of N-MP in the mixed extractant at its water content of 3 wt % and extractant to feed weight ratio of 1.5 : 1 is 70 wt %.

However, even at the optimal composition of the mixed solvent, despite a synergistic effect, the arene concentration in the distillate decreases to only 2.13 wt %, or to somewhat less than 2 vol %. In principle, a decrease in the benzene concentration to this level is sufficient to meet the requirement of the maximum permissible concentration of benzene in automobile gasolines (≤1 vol %), taking into account that the distillate can be mixed with the reformer naphtha containing C_7–C_9 arenes, with isomerizates, and with other possible components containing no benzene.

In the mixed solvent of the optimal composition, relatively low-boiling N-MP prevails, which allows the water content of the ternary system to be decreased to 2 wt %. With a simultaneous increase in the mixed solvent to feed weight ratio to (2–2.5) : 1, the arene concentration in the distillate decreases to 1.65–1.07 wt % (Table 1, run nos. 6, 7). In run no. 7, the benzene concentration in the distillate decreases to a level less than 1 vol %.

The dependence of the degree of arene separation and benzene concentration in the distillate on the weight ratio of the mixed solvent of the optimal composition to the feed is shown in Fig. 3. The final temperature in the boiler of the extractive rectification tower is 160°C, which allows steam with a pressure of 10 atm to be used as heat carrier.

It should be noted that mixtures of N-MP with both N-FM and sulfolane exhibit a synergistic effect in benzene separation by extractive rectification. Addition to N-MP of approximately 15 wt % sulfolane is somewhat more efficient than addition of 30 wt % N-FM, which may be due to higher criterion of the sulfolane performance. Both recommended

mixtures of selective solvents allow the drawbacks of the process suggested by GTC company with Tective-100 solvent [7] to be avoided.

By circulation method, using the modified Othmer device [8], we determined the relative fugacity coefficients α of the heptane–benzene system in the presence of *N*-MP and its mixtures with *N*-FM containing 2 wt % water at a solvent to hydrocarbons weight ratio of 2 : 1 (Table 2, Fig. 4). The quantity α is maximal for the mixed selective solvent which showed the maximal activity in benzene separation by extractive rectification.

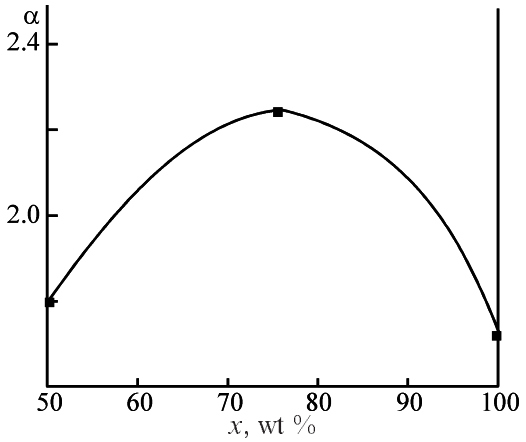

Fig. 4. Relative fugacity coefficient of the heptane–benzene system as a function of the *N*-MP content *x* in the mixed selective extractant *N*-FM–*N*-MP–water.

CONCLUSIONS

(1) The mixed selective solvent *N*-formylmorpholine–*N*-methylpyrrolidone–water containing about 30 wt % *N*-methylmorpholine and 2–3 wt % water exhibits synergistic effect in benzene separation from the benzene fraction of reformer naphtha by extractive rectification.

(2) The *N*-formylmorpholine–*N*-methylpyrrolidone mixture of optimal composition allows the benzene content to be decreased from 30–31 wt % in the feed to 1.65 wt % (about 1.25 vol %) in the distillate.

Abstract—The chromatographic behavior of previously unknown nitrogen-containing heterocyclic compounds was studied by reversed-phase high-performance liquid chromatography. The main relationships in the retention of the compounds with variation of the acetonitrile content in the mobile phase were examined. One- and multiparameter correlations between the logarithm of the retention factor and quantities characterizing physicochemical properties of the compounds were constructed.

DOI: 10.1134/S1070427208090103

Nitrogen-containing heterocycles are a promising class of organic compounds, mainly due to their medical applications. Numerous pharmaceuticals with various pharmacological properties have been developed on the basis of these compounds. Therefore, synthesis of nitrogen-containing heterocyclic compounds with the required set of properties is a topical problem.

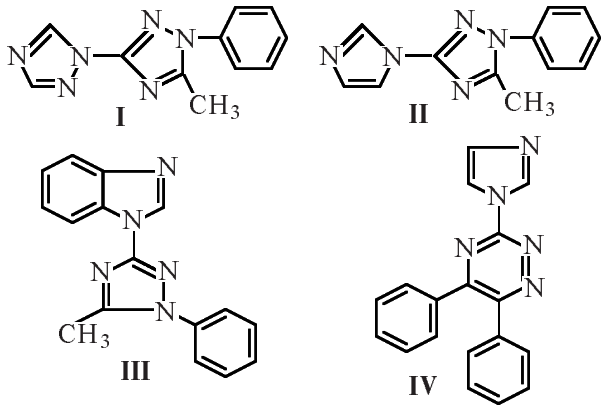
The development of methods allowing reliable prediction of both the physicochemical properties and the biological activity of compounds that have not yet been synthesized, as well as synthesis of new compounds with the required properties are one of the most important problems of the modern chemistry [1, 2]. This field of research is termed QSAR (Quantitative Structure–Activity Relationships), QSPR (Quantitative Structure–Property Relationships), or QSRR (Quantitative Structure–Retention Relationships).

The initial data for QSRR studies involve a set of molecular descriptors for the compounds under consideration and the retention factors obtained experimentally by HPLC. Based on these quantities, model equations are constructed, in which the parameters characterizing various descriptors of compounds are variables [3]. The QSRR model is used for predicting the retention parameters of sorbates belonging to the given class. The mathematical apparatus of this model is mainly based on the method of multidimensional statistical analysis, linear or nonlinear regression analysis [4, 5].

In this study we examined the chromatographic behavior of some previously unknown azoles by reversed-phase HPLC. The correlation dependences of the retention parameters of the compounds on their physicochemical properties were constructed. These dependences offer criteria for purposeful synthesis of compounds of this class.

EXPERIMENTAL

The compounds were analyzed under reversed-phase HPLC conditions on a Milichrom-1 microcolumn liquid chromatograph with a spectrophotometric detector (λ = 254 nm). We used an Ultrasep ES 100RP18 column (120 × 4 mm, particle diameter 4 μm) with grafted octadecyl groups. As stationary phase we used acetonitrile–water mixture with various volume ratios. Samples were prepared by dissolving crystalline substances in water and acetonitrile. The volume of the injected samples was 4 μl, at a flow rate of the mobile phase of 100 μl min^{-1}. As nonsorbable substance we used sodium nitrite.



The investigration objects were previously unknown nitrogen-containing heterocyclic compounds 3-(1*H*-1,2,4-triazol-1-yl)-5-methyl-1-phenyl-1*H*-1,2,4-triazole **(I)**, 3-(1*H*-imidazol-1-yl)-5-methyl-1-phenyl-1*H*-1,2,4-triazole **(II)**, 3-(1*H*-benzimidazol-1-yl)-5-methyl-1-phenyl-1*H*-1,2,4-triazole **(III)**, and 3-(1*H*-imidazol-1-yl)-5,6-diphenyl-1,2,4-triazine **(IV)**.

Table 1. Retention factors of the compounds under consideration

Compound	Retention factor k at indicated acetonitrile : water volume ratio							
	80 : 20	70 : 30	60 : 40	50 : 50	40 : 60	30 : 70	20 : 80	10 : 90
I	0.43	0.92	0.92	0.95	1.09	1.91	3.68	4.24
II	0.59	1.04	1.08	1.45	2.27	3.00	3.93	4.37

IV	1.15	1.77	2.74	4.09	8.93	–	–	–

Table 2. Physicochemical properties of compounds under consideration

Compound	V, Å^3	α, Å^3	μ, C m	RM, Å^3	SA_{grid}, Å^2	M_r, g mol^{-1}
I	677.28	24.50	9.68	63.80	423.93	226.24
II	690.38	25.21	7.06	65.11	432.58	225.25
III	811.42	31.39	6.56	81.86	487.44	275.31
IV	880.35	34.45	5.08	91.51	526.16	299.33

The retention factrors of the compounds, obtained using several mobile phases, are given in Table 1.

Using the HyperChem 7.0 program, we calculated by the PM3 semiempirical method with full geometry optimization such physicochemical parameters of the compounds as molecular volume V, polarizability α, dipole moment μ, molecular refraction RM, surface area SA_{grid}, and molecular weight M_r. The values of these parameters are given in Table 2.

In reversed-phase HPLC, the retention of compounds is determined by the competition between the dispersion interaction of sorbates with the stationary phase and by donor–acceptor interaction with the mobile phase (with acetonitrile as modifier of the mobile phase). In the course of the experiment we found that the retention of the compounds under consideration strongly depends on the mobile phase composition. An increase in the fraction of the polar solvent (water) leads to an increase in the retention, which is in agreement with the retention mechanism in reversed-phase chromatography.

It is well known that, in reversed-phase chromatography, the nature of the substrate or, more accurately, of substituents in its molecule is of no less importance. Let us consider as example the retention of the compounds under consideration at an acetonitrile : water ratio in the mobile phase of 50 : 50. For example, compound **I** is characterized by the weakest retention (k = 0.95), as it is the most polar. This compound contains two triazole rings whose nitrogen atoms can enter into dipole–dipole interactions with water or acetonitrile molecules.

Compound **III** is retained more strongly than **II** (k = 4.06 and 1.45, respectively) owing to the presence of an additional phenyl, and not methyl, substituent. Presumably, the phenyl radical introduces a new π-electron system which, in turn, causes redistribution of the electron density. As a result, the compound becomes more inclined to dispersion interactions with the mobile phase.

At the same time, compounds **IV** and **II** differing in the benzimidazole and imidazole substituents have different retention constants (k = 4.09 and 1.45, respectively). The benzimidazole substituent enhances the dispersion interactions with the stationary phase owing to π electrons of the benzene ring.

In this study we obtained the correlation dependences of the retention factor on various physico-

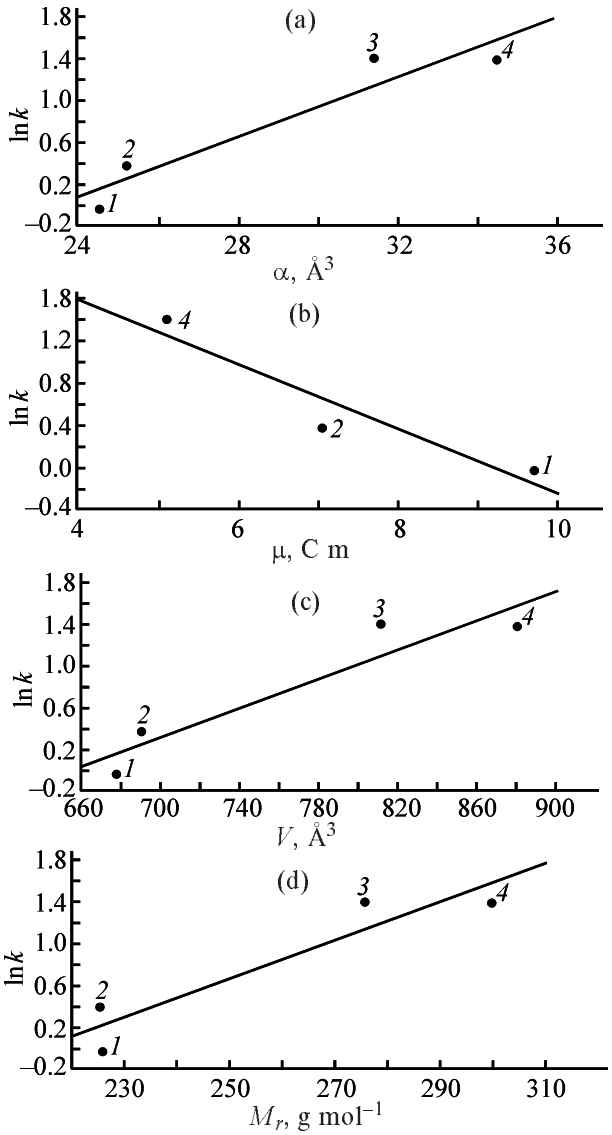

Fig. 1. Retention factor k as a function of the (a) polarizability α (r = 0.95), (b) dipole moment μ (r = –0.95), (c) molecular volume V (r = 0.94), and (d) molecular weight M_r (semilog plots). (*1–4*) Compounds **I–IV**, respectively.

chemical parameters of the compounds: polarizability, dipole moment, molecular volume, and molecular weight.

Figure 1a shows that, with an increase in the polarizability, the retention increases, which is due to enhancement of dispersion interactions with the stationary phase. Satisfactory correlation is observed between the retention of the compounds and their dipole moment (Fig. 1b). With an increase in the dipole moment of the molecule, the contribution of the orientation and induction intermolecular interactions with the mobile phase increases and hence the retention decreases. The chromatographic retention increases with an increase in the volume of the molecules (Fig. 1c). In reversed-phase HPLC, the retention increases with an increase in the molecular weight of compounds. We actually observed this trend (Fig. 1d).

Table 3. Linear multiparameter dependences for the compounds under consideration

Correlation equation	Correlation coefficient r
$\ln k = 9.14 + 1.56SA_{grid} - 0.07V$ (1)	0.98
$\ln k = 0.07 - 0.01SA_{grid} + 0.31V - 0.09E_{hydr}$ (2)	1.00
$\ln k = 0.02 + 1.18V - 0.51RM$ (3)	1.00
$\ln k = 0.07 + 0.29V - 0.06\mu$ (4)	1.00
$\ln k = 0.45 - 0.01SA_{grid} - 0.35\log P$ (5)	1.00
$\ln k = -1.29 - 0.39\alpha - 0.01M_r$ (6)	1.00
$\ln k = 0.01 + 0.66\alpha - 0.08\mu + 0.28M_r$ (7)	1.00
$\ln k = -4.91 - 0.39RM + 1.29\alpha - 0.01M_r$ (8)	1.00

Table 4. Logarithms of the calculated and experimentally obtained retention factors k ($\ln k$)

Compound	Experiment	Calculation by Eq. (1)	Calculation by Eq. (8)
I	1.41	1.32	1.31
II	0.37	0.37	0.29
III	–0.04	–0.05	–0.12
IV	1.40	1.26	1.29

The dependences we obtained have fairly high correlation coefficients. However, to enhance the predictive power of the equations in calculation of the retention factor, it is appropriate to construct multiparameter correlation dependences.

Some linear multiparameter correlations for the compounds under consideration, obtained with MS Excel 2000 program, are given in Table 3.

Low regression coefficients at some terms [e.g., –0.001 at SA_{grid} in Eq. (2)] indicate that the effect of these parameters on the retention is insignificant.

From the equations obtained, we can calculate the logarithms of the retention factors and compare them with the experimental data. The logarithms of the experimentally obtained retention factors and those calculated by Eqs. (1) and (8) are given in Table 4.

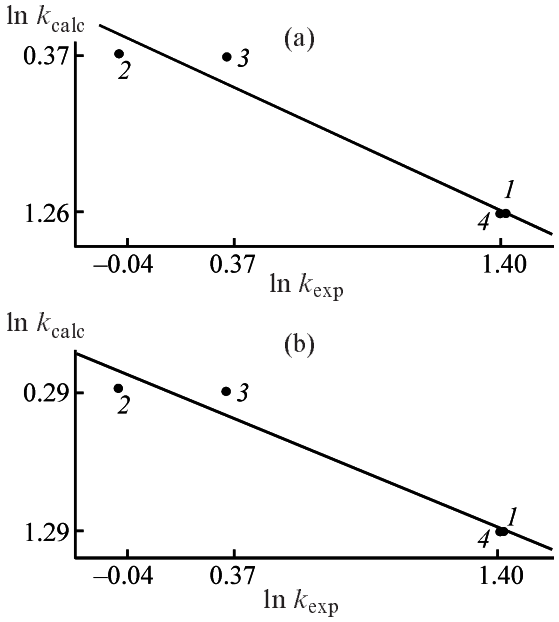

Fig. 2. Retention factor calculated by (a) Eq. (1) (r = 0.98) and (b) Eq. (2) (r = 0.99) as a function of the experimentally obtained retention factor (log–log plots).

In Figs. 2a and 2b, the experimentally obtained retention factors are plotted on the log–log scale vs. the calculated values. It can be seen that introduction of one more parameter [e.q., of V in Eq. (1)] increases the correlation coefficient. High correlation coefficients of the dependences obtained demonstrate the applicability of the QSPR approach to the compounds under consideration.

CONCLUSIONS

(1) Chromatographic behavior of previously unknown nitrogen-containing heterocyclic compounds under the conditions of reversed-phase HPLC is determined by such factors as the polarizability, dipole moment, molecular volume, and molecular weight.

(2) The linear multiparameter dependences obtained, describing the corelation between the retention and physicochemical properties of compounds, allow satisfactory prediction of the retention factors.

(3) Equations including the molecular volume, polarizability, and molecular refraction allow the most accurate prediction of the retention factors.

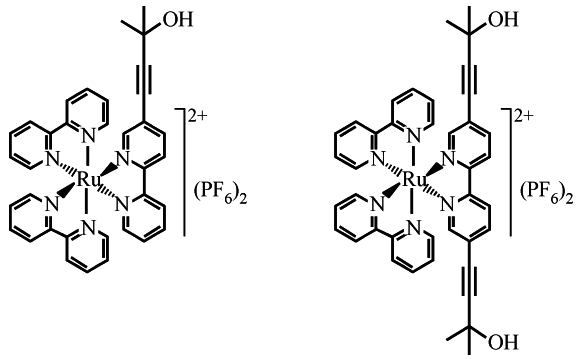
Abstract—Organo-inorganic composites consisting of mutually linked ruthenium complexes with organic ligands and an inorganic SiO_2 network were synthesized by the sol-gel method. The luminescence and photosensitive properties of the resulting compounds were studied.

DOI: 10.1134/S1070427208090115



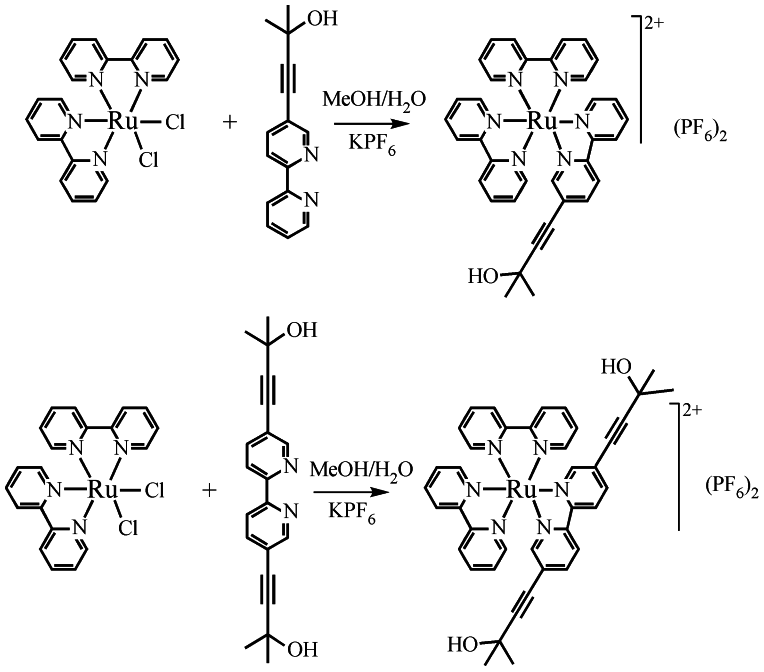
Thermally and chemically stable ruthenium(II) complexes with 2,2'-bipyridine derivatives have interesting photophysical, photochemical, and electrochemical properties. This allows them to be used for constructing photosensitive and electroluminescent devices, sensors, luminescent transducers, and catalysts [1–3]. Practical application of such structures is associated with their incorporation in a polymeric organic or inorganic matrix.

In case of organo-inorganic hybrids, the homogeneity and stability of the resulting structures is determined by the stability of the organic component of the system and by the possibility of its chemical binding with the inorganic network.

Tris(2,2'-bipyridine)ruthenium(II) complexes have unique thermal (500°C) and chemical stability: They are inert to concentrated sulfuric acid and to a 50% alkali solution [4]. The possibility of their chemical binding with an inorganic matrix by using special cross-linking agents has been shown earlier [5–8].

At the same time, further prospects for using organic complexes of transition metals, in particular, Ru^{2+}, in the form of organo-inorganic hybrids are associated with the possibility of the formation of a supramolecular organic structure based on them. In this structure, separate discrete centers of complex molecules should be connected with each other by chemical, preferentially double, bonds. An organic network synthesized in such a way opens principally new possibilities for electron movements, inaccessible for solutions of organic molecules. The most obvious method of preparing such structures is sol–gel synthesis of interpenetrating organo-inorganic hybrid networks.

To examine the basic possibility of the synthesis of such nanohybrid structures, we used ruthenium complexes containing in one of ligands substituents with triple bonds:



The goal of this study was to synthesize the above-mentioned complexes, to link them with each other by copolymerization with trimethoxysilicylacetylene (TMOSA), to incorporate the resulting structure into a silica matrix obtained by hydrolytic copolycondensation of tetramethoxysilane and TMOSA, and also to study physicomechanical and optical properties of the resulting materials.

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were recorded on a Bruker DPX-300 instrument, working frequencies 300.13 and 75.5 MHz, respectively, internal reference TMS. The absorption spectra were measured on an SF-56 spectrophotometer; the IR spectra, on a Bruker IFS-88 Fourier spectrometer; and the mass spectra, on an MKh5303 instrument equipped with an electrospraying ionization source (Institute of Analytical Instrument Making, Russian Academy of Sciences). The composition of reaction mixtures and purity of compounds were determined by thin-layer chromatography (TLC) on Silica gel 60 F254 and Armsorb TSKh-AN-UF 254 plates. In the synthesis we used Favorskii's carbinol and potassium hexafluorophosphate purchased from Aldrich. *cis*-[Bis-(2,2'-bipyridine)]ruthenium dichloride [9, 10], bis-(triphenylphosphine)palladium dichloride [11], copper(I) iodide [12], 5-bromo-2,2'-bipyridine, and 5,5'-dibromo-2,2'-bipyridine [13, 14] were prepared by the procedures described previously. The light sensitivity and quantum yields of photogeneration of charge carriers η were measured in the electrophotographic mode [15, 16] in the spectral range 400–800 nm at a field intensity $E = (0.1–1.0)E_0$, where E_0 is the limiting electric field strength for a material under study. The light sensitivity $S_{0.1}$ was determined by the criterion of a 10% decrease in the surface potential layer V in relation to the initial value ($\Delta V/V = 0.1$) for illumination both by a monochromatic light with a wavelength from 400 to 700 nm and with a KGM-300 halogen lamp (integral light sensitivity).

Stable tris(2,2'-bipyridine)ruthenium complexes containing triple bonds conjugated with the bipyridine system were prepared with 5-(2-hydroxyisopropylethynyl)-2,2'-bipyridine and 5,5'-bis(2-hydroxyisopropylethynyl)-2,2'-bipyridine:

For this purpose, a suspension of 500 mg of [bis-(2,2'-bipyridine)]ruthenium dichloride and 1.05 equiv of functionally substituted 2,2'-bipyridine in a mixture of 40 ml of water and 40 ml of methanol was refluxed for 2 h until the complex $bipy_2RuCl_2$ disappeared (monitoring by TLC on aluminum oxide). The resulting solution was cooled and filtered, and 2.1 equiv of potassium hexafluorophosphate in 30 ml of water was added to the filtrate. The precipitate formed was filtered off, dried, dissolved in 2 ml of acetonitrile, and reprecipitated into 20 ml of absolute diethyl ether.

[Rubipy$_2$(bipy–C≡C–CMe$_2$OH)](PF$_6$)$_2$, yield 58%. ^1H NMR spectrum [$(CD_3)_2SO$], δ, ppm: 1.39 s (6H, CH_3), 5.57 s (1H, OH), 7.55 m (6H, $1H^6 + 5H^{5,5'}$),

7.66–7.73 m (3H, $H^{6,6'}$), 7.78 d (1H, $H^{6'}$), 7.86 d (1H, H^{6}), 8.18 q (6H, $H^{4,4'}$), 8.83 t (6H, $H^{3,3'}$). ^{13}C NMR spectrum [$(CD_3)_2SO$], δ_C, ppm: 31.9 (CH_3), 64.6 (C–OH), 76.8 (C≡C), 104.1 (C≡C), 123.8, 125.0, 125.3, 125.5, 125.8, 128.7, 128.8, 128.9, 129.6, 138.9, 140.9, 151.9, 152.1, 152.3, 152.6, 152.8, 156.6, 156.8, 157.2, 157.4, 157.5. According to the published data [17–22], TMOSA is prepared in two steps:

$$Si(OMe)_4 \text{ (or } SiCl_4) \rightarrow Si(OMe)_3Cl \rightarrow HC{\equiv}C{-}Si(OMe)_3.$$

Despite apparent simplicity of these transformations, this synthesis involved serious problems. Initially we thoroughly tested all the three known procedures [17–21] for preparing trimethoxychlorosilane:

$$3Si(OMe)_4 + SiCl_4 \overset{AlCl_3}{\rightleftarrows} 4Si(OMe)_3Cl,$$

$$Si(OMe)_4 + CH_3COCl \overset{AlCl_3}{\rightleftarrows} Si(OMe)_3Cl + CH_3COOMe,$$

$$SiCl_4 + 3MeOH \rightleftarrows Si(OMe)_3Cl + 3HCl.$$

The boiling points and refraction indices of thus obtained samples completely corresponded to the published values [17–21], and the elemental analysis seemed to confirm the trimethoxychlorosilane formation. However, detailed examination of their structure by NMR spectroscopy and mass spectrometry showed that the synthesized samples were mixtures containing at least three compounds: $Si(OMe)_2Cl_2$, $Si(OMe)_3Cl$, and $Si(OMe)_4$.

This result can be accounted for by closeness of their boiling points, possible formation of azeotropes, and/or disproportionation of methoxychlorosilanes on heating to boiling points.

The reaction of silicon tetrachloride with methanol appeared to be practically the most convenient. Analysis by chromatography–mass spectrometry showed that this reaction yielded a mixture of methoxychlorosilanes of the following composition (%): $Si(OMe)Cl_3$ 5, $Si(OMe)_2Cl_2$ 30, $Si(OMe)_3Cl$ 50, and $Si(OMe)_4$ 15.

The replacement of chlorine by the ethynyl group according to the known procedure [22] became the second step of the synthesis:

$$Si(OMe)_3Cl + HC{\equiv}CNa \rightarrow Si(OMe)_3C{\equiv}CH.$$

Unfortunately, here again the results were poorly reproducible and the yield of the final product was low. Variation of reaction conditions did not give a positive result. Therefore, we developed a new synthesis method using ethynylmagnesium bromide, which allowed us to considerably increase the yield of the target product:

$$Si(OMe)_3Cl + HC{\equiv}CMgBr \rightarrow Si(OMe)_3C{\equiv}CH.$$

According to the data of NMR spectroscopy, gas chromatography–mass spectrometry, and elemental analysis, the product obtained was a mixture of mono-, di-, and triethynylmethoxysilanes free from chlorine.

Attempts to separate this mixture failed. We could not increase the TMOSA content in the distillate to a value over 70%. However, this fact should not influence the formation of an organo-inorganic hybrid, as all the components contain building blocks necessary for it, namely, triple bonds and

methoxy groups, allowing organic and inorganic networks, respectively, to be formed.

Polymerization via triple bonds was carried out by the modified procedure from [23]. The initial system consisted of tetramethoxysilane (0.5 equiv), a mixture of methoxysilylacetylenes (0.5 equiv), palladium chloride (0.01 equiv), and a solution of ruthenium complexes in propionitrile. The reaction mixture was left for two days at room temperature, and then the polycondensation process was carried out. For this purpose, 4 equiv of water and 0.1 equiv of trifluoroacetic acid were added to the system.

The resulting solutions were placed in sealed polypropylene test tubes and kept at 60°C for 2 days. Then hermetic stoppers to the tubes were replaced by perforated stoppers (hole diameter about 1 mm), and crude gels were dried for 10 h at 60°C, 14 h at 75°C, 24 h at 90°C, and 24 h at 110°C. The temperature was raised at a rate of 5 deg h^{-1}. After that, the gels were placed in glass test tubes with perforated stoppers, heated to 110°CC (15 deg h^{-1}), and kept for 12 h at this temperature.

The samples were synthesized in the form of monolithic structures: disks of width 3–7 mm and diameter 15–30 mm and cylinders of length 15–30 mm and diameter 4–6 mm, and also 1–2-μm-thick films on a polymeric support. The conditions for the hydrolysis of methoxy groups of the components and for polycondensation of the formed compounds were optimized by varying the acidity of the medium in the course of the sol–gel process and by simultaneously removing the formed alcohol in the form of volatile compounds [24].

The absorption spectra of the composites practically coincide with the spectra of the initial ruthenium complexes (Fig. 1).

All the synthesized samples show strong luminescence in the region of 610–630 nm (excitation with xenon lamp radiation with λ = 450 nm). The normalized luminescence spectra of the composites (Fig. 2) contain one emission band broadened as compared to solutions. Its position depends on the concentration of the ruthenium complex in the hybrid.

The light sensitivity $S_{0.1}$ of the synthesized samples (Fig. 3) is at a level of $(1–2) \times 10^4$ cm^2 J^{-1} in

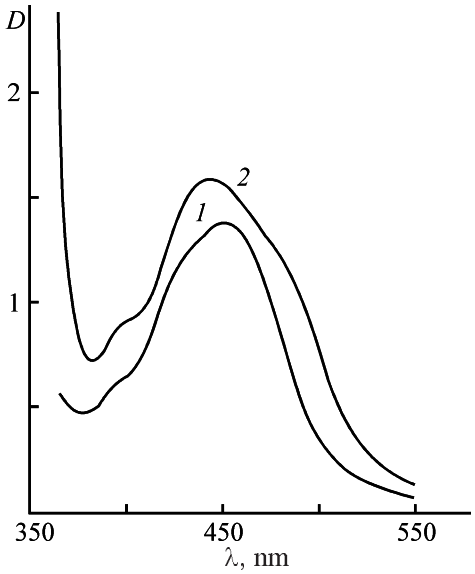

Fig. 1. Absorption spectra of ruthenium complexes. (*D*) Optical density and (λ) wavelength. Complex: (*1*) [Ru-bipy$_2$(bipy–C≡C–CMe$_2$OH)](PF$_6$)$_2$ and (*2*) [Ru-bipy$_2${bipy(C≡C–CMe$_2$OH)$_2$}](PF$_6$)$_2$; the same for Fig. 2.

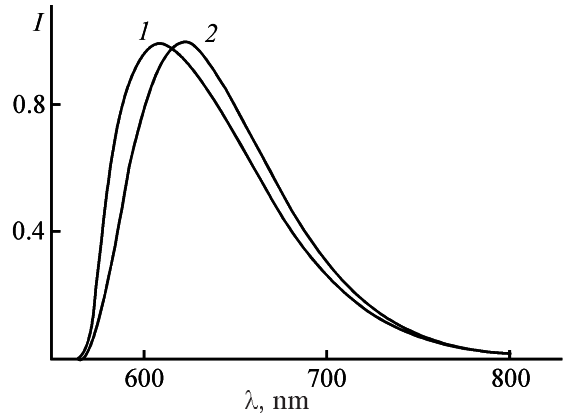

Fig. 2. Normalized luminescence spectra of composites containing various complexes. (*I*) Normalized intensity and (λ) wavelength.

the spectral range 400–550 nm; the quantum yield of charge carriers is 0.005±0.001. These values are 2–4 times higher than the analogous value found previously for composites in which ruthenium complexes are covalently bonded with the silica matrix, but are not a part of an organic network and are not bonded with each other.

An insignificant bathochromic shift in absorption spectra (~10 nm), and also a weak decrease in the intensity of absorption bands of the –C≡C– bond in the IR spectra show that the structure connecting ruthenium complexes with each other is primitive and imperfect. However, a substantial growth of

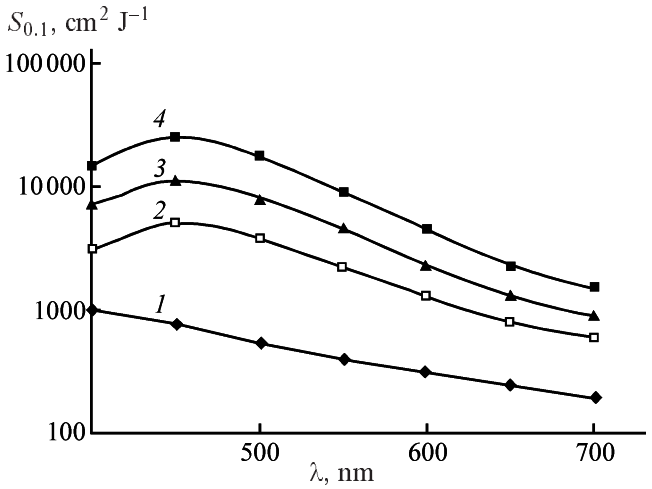

Fig. 3. Spectra of light sensitivity of composites. ($S_{0.1}$) Light sensitivity and (λ) wavelength. (*1*) Sample free of ruthenium complexes, (*2*) composite in which ruthenium complexes are not a part of a supramolecular structure [6], and (*3, 4*) composites with the ruthenium complexes under consideration: (*3*) [Rubipy$_2$(bipy–C≡C–CMe$_2$OH)](PF$_6$)$_2$ and (*4*) [Rubipy$_2${bipy(C≡C–CMe$_2$OH)$_2$}](PF$_6$)$_2$.

light sensitivity of the composites, and also a 20–40 nm long-wave shift of the emission band maximum with increasing concentration of the ruthenium complex, as compared to composites in which the components are chemically bonded with each other but are not incorporated in a supramolecular structure, suggest the formation of a supramolecular organic network linking the ruthenium complexes.

CONCLUSIONS

(1) The new organo-inorganic hybrids based on Ru(II) complexes containing substituents with triple bonds in one of ligands were synthesized.

(2) Even incomplete binding of ruthenium complexes with each other with the formation of a supramolecular structure strongly enhances the luminescence and photosensitive properties of the synthesized samples.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Determination of the Retention Characteristics in Thin-Layer Chromatography Taking into Account the Actual Position of the Mobile Phase Front

L. S. Litvinova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 21, 2008

Abstract—To reveal the actual position of the mobile phase front, corresponding to the free volume of the layer in thin-layer chromatography, it is suggested to use a nonsorbable low-molecular-weight marker. The expressions for the capacity coefficient k', equilibrium coefficient K_d, and corrected R_f values (R'_f) were obtained taking into account the correction of the position of the mobile phase front.

DOI: 10.1134/S1070427208090127

One of the most important parameters of a chromatographic process is the capacity coefficient k':

$$k' = Q_s/Q_m, \quad (1)$$

where Q_s and Q_m are the amounts of a substance in the stationary and mobile phases, respectively. The capacity coefficient in thin-layer chromatography (TLC) can be determined as follows [1]:

$$k' = t_s/t_m, \quad (2)$$

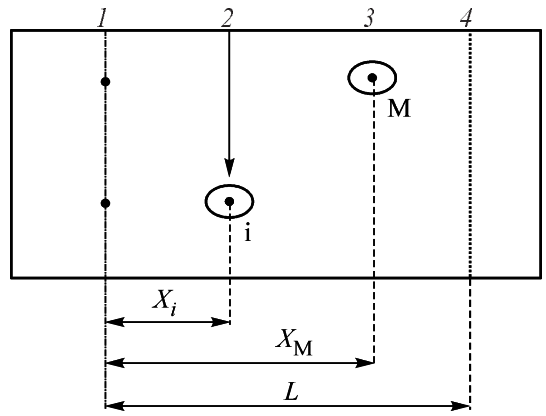
where t_s and t_m are the residence times of a substance in the stationary and mobile phases, respectively.

A characteristic feature of TLC is that the sum $t = t_s + t_m$ is equal for all the substances being separated, whereas in column chromatography all the substances being separated have equal t_m values.

The retention in TLC is characterized by the relationship

$$R_f = X_i/L, \quad (3)$$

where X_i is the distance passed by a substance from the start and L is the distance passed by the mobile phase front from the start (see figure).



Hence, the position of the mobile phase front is the starting point in TLC. The velocity of the mobile phase motion along the plate is also judged from the front motion [2–4]. If the mobile phase vaporization from the wetted area of the sorbent layer and the adsorption of the vapor on a dry sorbent layer are excluded, then [1]

$$R_f = t_m/(t_m + t_s). \quad (4)$$

It follows from (2) and (4) that

$$k' = (1 - R_f)/R_f.$$

Determination of one of basic characteristics of a chromatographic process, k', by TLC is seemingly easy. However, the necessary conditions for experi-

Schematic representation of TLC in a saturated chromatographic chamber: (*1*) start line, (*2*) chromatographic spot of the sorbate (i), (*3*) mobile phase front found from the position of the spot of a low-molecular-weight nonsorbable ($k' = 0$) marker (M), and (*4*) observed mobile phase front.

mental determination of the capacity coefficient k' in TLC and of the true value of R_f are difficult to fulfil in practice: no vaporization of the mobile phase from the wetted area of the sorbent layer and no adsorption of the solvent vapor on the dry layer. In this ideal case, the mobile phase is spent only for filling of pores and interparticle space, and thus the solvent volume fed to the plate corresponds to the free volume.

In the course of chromatography, it is difficult to avoid uncontrollable adsorption of solvent vapor, especially if a saturated N-chamber is used or the time of solvent ascent is as long as several tens minutes. Filling of the adsorbent surface and pores with solvent molecules through the vapor phase leads to changes in the volume of the mobile phase fed to the sorvent layer at equal values of L and hence to changes in R_f. In an unsaturated S-chamber, these processes do not occur, but another problem arises: A mixed mobile phase is separated into components, forming a stepwise gradient on the plate [3]. Geiss [3] emphasizes that the R_f values commonly measured in TLC are not true quantities. Geiss believes that true R_f values can only be obtained with Vario-KS or U-chambers allowing simultaneous introduction into a solvent flow of a test sample and a reference for which $R_f = 1$. The sample and reference are applied simultaneously onto adjacent tracks in the eluent flow after a sufficient amount of the solvent passes the start line. The true R_f value (R'_f) will be determined by the ratio of the distances passed by the sample and reference.

This study is also aimed to solve the problem of determining the true values of R_f (R'_f), and also of k' and K_d in TLC and thus to improve the repeatability and reliability of the analysis results. Solving the problem requires determination of the actual mobile phase front corresponding to the free volume V_0 of the adsorbent layer. In this study we suggest to use the marker of the actual position of the front and a saturated chamber. As a marker we used a nonvolatile nonsorbable ($k' = 0$) low-molecular-weight compound to which all the pores of the adsorbent are accessible.

When a chromatographic experiment is performed on a plate with the layer cross section S, dry adsorbent weight on the working area of the layer g, specific pore volume V'_p, specific interparticle volume (volume between the adsorbent particles in the layer) V'_i, and specific free volume V'_0 ($V'_p + V'_i = V'_0$), the solvent is spent for filling of interparticle channels of the dry layer ($gV'_i = V_i$) and for pore filling ($gV'_p = V_p$).

Neglecting the vaporization of the mobile phase components from the wetted layer and vapor adsorption on the dry area of the layer, the volume gV'_0 of the solvent that filled the layer will be equal to

$$gV'_0 = g(V'_p + V'_i).$$

The front will move by the following distance:

$$L = g(V'_p + V'_i)/S.$$

The sorbate spot will move by the following distance X_i:

$$X_i = g(V'_p + V'_i)/(k' + 1)S.$$

The filling of adsorbent pores through the vapor phase regularly leads to an apparent decrease in V'_p and, correspondingly, to an increase in the front motion velocity [4]. On the contrary, the solvent vaporization from the wetted layer decreases the front motion velocity. As already noted, the vaporization processes are suppressed in a saturated N-chamber. Apparently, in the case of transfer of eluent components into the layer through the vapor phase, the solvent ascending by interparticle channels by a distance L is only partially spent for the pore filling, and its volume V is smaller than the free volume gV'_0. The distance X_i passed by the sorbate spot and the quantity R_f will also decrease, because the sorbate moves only with the solvent flow. Thus, the quantity R_f determined by a common procedure depends not only on the characteristics of the sorbent, mobile phase, and sorbate, but also on processes leading to pore filling through the vapor phase. Variation of the content of the solvent vapor in a chromatographic column leads to uncontrollable variation of R_f.

The systematic error in determining the retention parameters in TLC can be eliminated by performing the chromatography in a saturated chamber and determining the actual position of the mobile phase front with a nonvolatile nonretainable low-molecular-weight compound to which the adsorbent pores are accessible (as it is done in column chromatography for determining the free volume V_0 [5]).

The true value of R_f (R'_f) should be determined as the ratio of the distance passed by the sorbate to that passed by a nonsorbable reference (front mark-

er) that is not excluded from pores [6] (see figure):

$$R'_f = (R_f)_i/(R_f)_M = X_i/X_M,$$

where X_M is the migration distance and $(R_f)_M$ is the R_f value for the marker of the actual mobile phase front, i.e., for a nonvolatile nonretainable low-molecular-weight compound to which all the adsorbent pores are accessible. Such compounds are analogs of free volume markers in column chromatography. Note that there are no versatile compounds suitable for all adsorbents and all mobile phases. The main requirement is the solubility of the reference compound in the mobile phase, absence of adsorption (i.e., zero k' value), and absence of exclusion. Finding such substances in TLC is more difficult than in column chromatography, because they should not vaporize or sublime after a chromatographic run in the course of mobile phase evaporation.

The retention factor determined relative to the front marker corresponds to the thermodynamic value:

$$R'_f = 1/(1 + k').$$

Thus, determination of the true values of the retention factors in TLC and in liquid column chromatography is closely related to determination of the free volume. Furthermore, all the concomitant problems appear to be similar [5]. It should be noted that previously many authors suggested to correct R_f using arbitrarily chosen reference compounds [7–9]. In so doing, the only criterion for choosing the references was that the R_f values for the reference and test compounds should be close. Geiss [3] considers in detail and critically discusses methods for evaluating TLC results and for correcting R_f values. Taking into account the definition of R'_f, let us present the expressions for k' and K_d. It can be readily shown from the aforesaid that

$$k' = 1/R'_f - 1 = X_M/X_i - 1. \quad (5)$$

According to Skvortsov [10],

$$k' = (K - 1)V_p/V_0. \quad (6)$$

Taking into account expressions (10) and (11) and assuming that $V_0 = V_i + V_p$,

$$K_d = (1/R'_f - 1)(V_0/V_p) + 1 = (X_M/X_i - 1)(V_0/V_p) + 1. \quad (7)$$

As will be shown below, for Sorbfil plates used in this study $V_0/V_p = 2.08$. Hence, for Sorbfil plates

$$K_d = (2.08/R'_f - 1.08) = 2.08(X_M/X_i) - 1.08. \quad (8)$$

EXPERIMENTAL

The solvents (Reaktiv, St. Petersburg): carbon tetrachloride (pure grade), diethyl ether (pure grade), toluene (analytically pure grade), were purified by distillation. Cyclohexane (Merck, Darmstadt, Germany) of spectroscopic grade was freshly distilled. Tetrahydrofuran (THF, Reaktiv) was distilled from KOH just before use. Fullerene C_{60} (Fullerene Technologies, St. Petersburg), *meso*-tetraphenylporphyrin (TPP, Aldrich, USA), phenacetin (97%), acetanilide (sublimed), antracene (scintillation grade), and dyes (Sudan I, Cytochrome C, Anthraquinone Green (Reakhim, Shostka, Ukraine) were used without additional purification.

Thin-layer chromatography was performed on Sorbfil plates (Sorbpolimer, Krasnodar, Russia, produced before 2003) PTSKh-AF-V-UF of size 10×10 cm^2. After activation of plates by heating at 120°C for 40 min, solutions of test compounds (1.0 mg ml^{-1}, 1 μl) (anthracene in cyclohexane, dyes in CCl_4, phenacetin and acetanilide in THF) were applied onto the plate with a microsyringe (Hamilton Company, Reno, Nevada, USA) at a distance of 1 cm from the lower edge of the plate. Ascending chromatography to a height of 8 cm was performed at 20°C in an unsaturated S-chamber, a saturated N-chamber, or an unsaturated N-chamber containing 10 ml of one of the solvents (toluene, diethyl ether, THF–cyclohexane, or toluene–THF).

After a chromatographic run, the spots of the dyes and TPP were visible owing to their natural color, and the spots of the colorless compounds were visualized under a UV_{254} lamp. The quantities R_f and R'_f were determined as arithmetic mean from three runs. The determination error (relative standard deviation) under the given conditions did not exceed 5%.

The ratio V_p/V_0 was determined by impregnating the plates with water [2, 3]. From the difference in the plate weights before and after impregnation, we found the sum of the pore volume V_p and volume of interparticle space V_i per gram of the adsorbent (the plate was placed for weighing in a plastic container). The silica gel pore volume was 0.76 cm^3 g^{-1} (determined on an Auto-Pore 9200 mercury porosimeter, Coultronics, France).

To confirm experimentally the necessity of using

free volume markers in TLC, we obtained chromatograms of dyes, phenacetin, and acetanilide in one-component and mixed mobile phases. The results of the chromatography of the dyes in toluene and in THF–cyclohexane (17 : 83 v/v) are diven in Tables 1 and 2. The results of the chromatography of phenacetin and acetanilide in diethyl ether and in THF–toluene (54 : 46 v/v) are given in Tables 3 and 4. The quantities R_f and R'_f were calculated taking into account both the observed and actual (found with a marker) positions of the front. As markers we used anthracene, fullerene C_{60}, and TPP. It should be noted that acetanilide and phenacetin can also be used as markers of the actual position of the front for more polar mobile phases.

It follows from Tables 1–3 that the maximal R_f values are observed in the unsaturated N-chamber, and the minimal values, in the saturated N-chamber. As the differences in R_f range from 50 to 100%, the observed position of the mobile phase front cannot, apparently, be considered as the reference point in estimation of the mobility of chromatographic spots. It could be expected that the R'_f values obtained in different types of chromatographic chambers would coincide. However, the R'_f values obtained in saturated and unsaturated N-chambers noticeably differ.

$s/\bar{x} \times 100$		0.8	3	3.8	2.3	3.9	2.8	2.9

The lowest values of R'_f were obtained in a saturated N-chamber, and the highest values, in an unsaturated N-chamber. The probable cause is the large contribution of the mobile phase evaporation from the wetted area of the sorbent layer in an unsaturated N-chamber. Taking into account the experimental error (relative standard deviation ≤5%), the R'_f values in the S- and saturated N-chambers can be considered identical. Let us compare the reproducibility of the R_f and R'_f values of phenacetin and acetanilide, obtained in a saturated N-chamber (mobile phase toluene–THF, Table 4). As can be seen, replacement of R_f by R'_f has no effect on the standard deviation of the arithmetic mean s and on the standard error s_m.

Similarly to column chromatography, in TLC the R'_f values calculated using different markers do not coincide (Table 1). Nevertheless, the practical use of R'_f values allows the influence of conditions on the TLC retention characteristics to be largely eliminated.

CONCLUSIONS

(1) A new TLC retention characteristic, ratio of the migration distance of the sorbate to that of a front marker, a low-molecular-weight nonretainable reference compound to which all adsorbent pores are accessible, was suggested.

(2) With the aim to determine the thermodynamic parameters by thin-layer chromatography and to compare the data of thin-layer and column chromatography, formulas were suggetsted for calculating the capacity and equilibrium coefficients, involving the new retention characteristic.

(3) A formula was obtained for determining the equilibrium coefficient on Sorbfil plates.

(4) The validity of the new retention characteristic was confirmed experimentally.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Practicability of Using Partial Condensation in Distillation

A. V. Markova

St. Petersburg Academy of Pharmaceutical Chemistry, St. Petersburg, Russia

Received January 15, 2008

Abstract—A procedure for calculation of batch distillation followed by partial condensation was developed on the basis of the suggested mathematical model. A strategy for assessing the feasibility of using this method, compared to simple distillation, was suggested. The effect of the initial conditions on the economic efficiency of the installation employed was analyzed. Numerical values of working parameters are obtained and recommendations for performing the process in the optimal mode are formulated.

DOI: 10.1134/S1070427208090139

Chemical-pharmaceutical industry widely employs simple distillation and distillation with partial condensation (also termed reflux distillation) for recovery of valuable volatiles from production waste [1]. As a rule, the distillation is performed in the batch mode in a jacketed vessel (distillation still), with heating steam or hot water commonly serving as energy carrier. When distillation is performed simultaneously with partial condensation, a partial condenser is mounted at the top of the still (Fig. 1).

Compared to simple distillation, the capital expenditure for construction of the installation becomes higher because of the appearance of an additional heat exchanger; also grow the operating costs associated with the increase in the required amount of the heat-carrying agent. Apparently, this expenditure can be justified by the more complete recovery a valuable volatile, i.e., by production of a more concentrated distillate. It is of interest in this context to find out how the degree of partial condensation affects the quality of the product being obtained and the energy parameters of operation of the installation.

The aim of this study was to find conditions in which the reflux distillation is feasible and to determine the optimal process mode.

When developing a procedure for calculating the distillation with partial condensation, we made the following assumptions. The distillation still is an ideal mixing apparatus. The vapor phase leaving the distillation still is in equilibrium with the liquid it contains. The vapor and liquid phases leaving the partial condenser are also in equilibrium. The partial condenser operates at a constant R number equal to the ratio between the mass flow rate G_{x1} of the liquid returned into the still (kg s^{-1}) and the mass flow rate G_D of the distillate (kg s^{-1}): $R = G_{x1}/G_D$ (which is provided by varying the flow rate of cooling water in the partial condenser).

With account of the assumptions made, the material balance equations for the still and partial condenser are written as follows:

$$-\mathrm{d}M_\mathrm{W}/\mathrm{d}\tau = \mathrm{d}M_\mathrm{D}/\mathrm{d}\tau = G_\mathrm{D}, \quad (1)$$

$$-\mathrm{d}(M_\mathrm{W}x_\mathrm{W})/\mathrm{d}\tau = y_1(\mathrm{d}M_\mathrm{D}/\mathrm{d}\tau) = y_1G_\mathrm{D}, \quad (2)$$

where M_W and M_D are the masses of the liquid phase in the distillation still and distillate collector, respectively (kg); x_W, mass fraction of the volatile component in the liquid phase of the distillation still; y_1, mass fraction of the volatile component in the vapor phase leaving the partial condenser; and τ, time (s).

By differentiating the left-hand part of Eq. (2) with account of (1), we obtain

$$M(\mathrm{d}x_\mathrm{W}/\mathrm{d}\tau) = (x_\mathrm{W} - y_1)G_\mathrm{D}. \quad (3)$$

The relation between the running values of y_1 and x_W can be derived from the material balance equation for the partial condenser, which has in relative flow rates the form [1]:

$$R = (y_1 - y_\mathrm{W})/(y_\mathrm{W} - x_1), \quad (4)$$

where x_1 is the mass fraction of the volatile component in the liquid phase leaving the partial condenser, and y_W, the mass fraction of the volatile

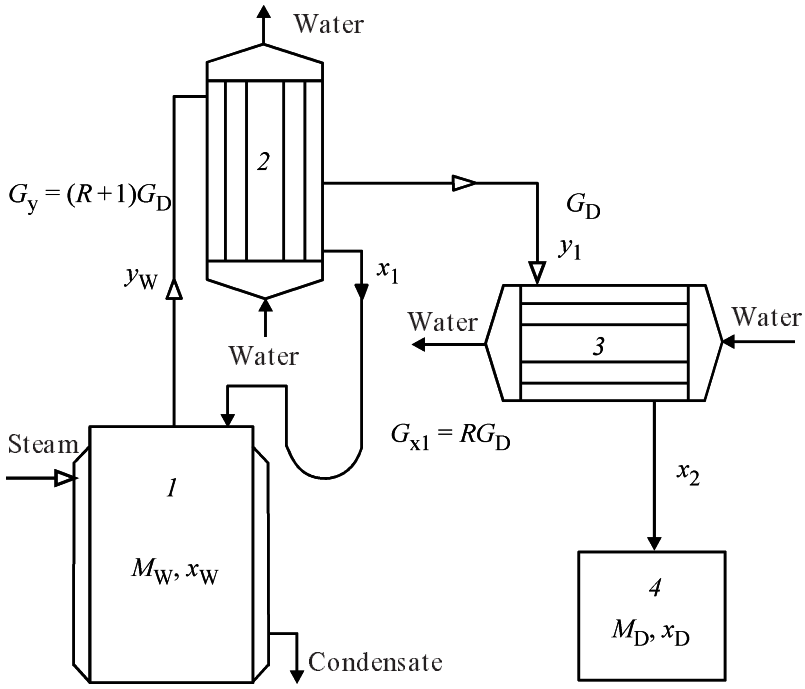

Fig. 1. Schematic of the installation for reflux distillation. (*1*) Distillation still, (*2*) partial condenser, (*3*) condenser, and (*4*) distillation collector.

component in the vapor phase leaving the still.

Using Eq. (4) and the equilibrium dependence $y_W = y^*(x_W)$, we can find, for the running value of x_W, x_1 or $y^*(x_1)$.

The heat balance equation for the still has the following form:

$$d(M_W i_W)/d\tau = q_W - G_D(R + 1)I_W + G_D R i_{x1}, \quad (5)$$

where $i_W = c_{xW}t_W$, $i_{x1} = c_{x1}t_{x1}$ are the specific enthalpies of the liquid in the still and in the liquid returned into the still after the partial condenser, respectively (kJ kg^{-1}); $I_W = c_{yW}t_W + r_{yW}$, specific enthalpy of the vapor leaving the still (kJ kg^{-1}); c_{xW}, c_{x1}, c_{yW}, specific heats of the liquid phase of composition x_W, x_1, y_W (kJ kg^{-1} K^{-1}); t_W, t_{x1}, temperatures of the liquid in the still and after the partial condenser (°C); r_{yW}, heat of vaporization of a mixture of composition y_W (kJ kg^{-1}); $q_W = KF(t_p - t_W)$, intensity of heat supply to the still (W); K, heat-transfer coefficient (W m^{-2} K^{-1}); F, heat-transfer surface area (m^2); and t_p, temperature of the heating steam (°C).

Differentiating Eq. (5) after simple rearrangements and assuming $I_W - i_{x1} \approx r_{y1}$, we can obtain the expression

$$q_W = G_D(R + 1)r_{y1} + M_W c_{xW}(dt_W/d\tau), \quad (6)$$

which can be used to estimate, with account of (3) and (4), the process duration

$$\tau = (R + 1)\int_{x_F}^{x_W} M_W r_{y1}[KF(t_p - t_W)]^{-1}(x_W - y_1)dx_W$$

$$+ \int_{t_F}^{t_W} M_W c_{x1}[KF(t_p - t_W)]^{-1}dt_W, \quad (7)$$

where the parameters with subscript F correspond to the starting mixture.

The variables in the integrands, M_W, K, r_y, and, especially, F (which is due to the decrease in the liquid level in the still), may widely vary in the course of the process and, therefore, are not taken outside the integral sign.

Equations (1), (3), (4), and (7) form the basis for calculation of the batch distillation with partial condensation. Equations (4) and (7) are solved numerically.

Preliminarily, we qualitatively analyze Eqs. (1), (3), (4), and (7) we obtained.

It follows from Eq. (4) that the composition of

the vapor phase from the partial condenser, y_1, is determined by the type of the equilibrium curve $y^*(x)$ of the binary system. Within the range x_W–x_1 the equilibrium line can be considered to be straight: $y^* = mx + b$ (b is the distribution coefficient). In this case, we obtain from (4) the following:

$$y_i = m^2(R + 1)x_W/(m + R) + b(m + mR + R)/(m + R). \quad (8)$$

Thus, at $R = 0$ (simple distillation), $y_1 = y_{1min} = mx_W + b$; at $0 < R < \infty$, Eq. (8); at $R \to \infty$, y_1 asymptotically approaches the maximum possible value: $y_1 = y_{1max} \to m^2x_W + b(1 + m)$. The quantity

$$\Delta = y_{1max}/y_{1min} = m + 1/[(m/b)x_W + 1]$$

can serve as a feasibility criterion for the method of reflux distillation. The type of the dependences $\Delta(x_W)$ for different m is shown in Fig. 2.

At low concentrations x_W, the distribution coefficient m for binary mixtures takes values $m > 1$ and the coefficient b is small. In this case, $\Delta \to m$ and the reflux distillation is efficient (Fig. 2, curves *1* and *2*).

At $m < 1$ (region of medium and high concentrations x_W), Δ approaches the line $\Delta = 1$ and even crosses it at $x_W = b/(1 - m)$. In this case, the partial condenser is inefficient and only simple distillation should be used. At other values of b, the run of the curves remains qualitatively the same.

At low concentrations of the volatile in the still, the equilibrium line can be represented as $y^* = mx$ ($m > 1$). In this case, Eqs. (1), (3), and (4) can be solved analytically. For example, the mass of the liquid in the still and its composition are related by

$$M_W = M_F x_F^c x_W^{1/c}, \quad (9)$$

and the average concentration of the final product in the distillate collector is given by

$$x_W = \frac{n^{c+1} - 1}{n^c - 1}x_W = \frac{n^{c+1} - 1}{(n^c - 1)n}x_F, \quad (10)$$

$$n = x_F/x_W.$$

In Eqs. (9) and (10), $c = (m - 1)(m + mR + R)/(m + R)$. The quantity n serves as the degree of still exhaustion. In simple distillation ($R = 0$),

$$x_{Dmin} = \frac{n^{m/(m-1)} - 1}{n^{m/(m-1)} - n}x_F.$$

In the limiting case ($R \to \infty$), the average composition of the distillate tends to the maximum value:

$$x_{Dmin} \to \frac{n^{m^2/(m^2-1)} - 1}{n^{m^2/(m^2-1)} - n}x_F.$$

The function $x_D(n)$ is plotted for the limiting cases in Fig. 3.

The region between curves *1* and *2* (Fig. 3) is that

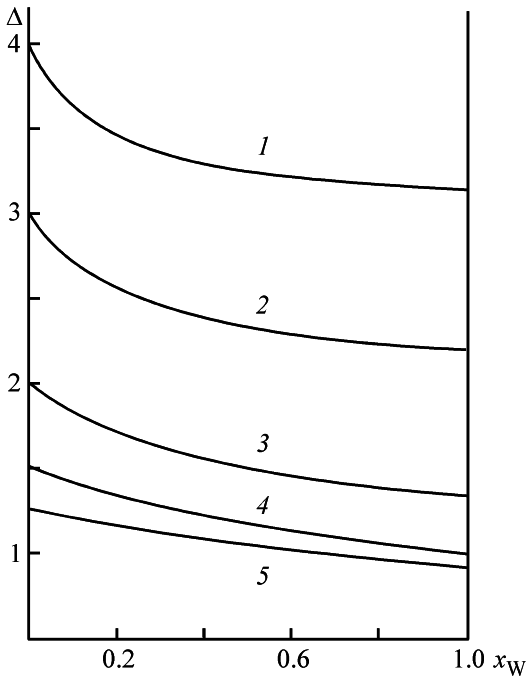

Fig. 2. Δ vs. x_W ($b = 0.5$). m: (*1*) 3, (*2*) 2, (*3*) 1, (*4*) 0.5, and (*5*) 0.25.

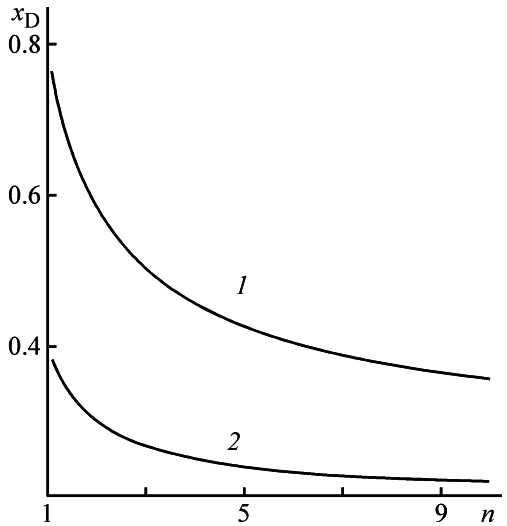

Fig. 3. Average distillate composition x_D vs. the degree n of still exhaustion ($x_F = 0.2$, $m = 2$). (*1*) $R = 0$ and (*2*) $R \to \infty$.

of working values of R. On the average, at not too strong still exhaustion, the limiting values of x_D differ by a factor of m, which confirms the feasibility of the reflux distillation at small values of x_W, characteristic of dilute solutions in the final stage of distillation. It follows from Fig. 3 that, at small n, the distillate obtained has a rather high concentration of the volatile. In further still exhaustion, the concentration of the volatile in the distillate decreases, but not so steeply as in the initial stage. This circumstance makes it possible to recover to the fullest extent the valuable component from the still at a slight deterioration of the quality of the distillate and to organize fractional collection of a distillate of high or medium quality, depending on n.

Let us consider factors determining the process duration, given by Eq. (7). The heat-exchange surface area at a variable liquid level in the still (with the surface of the partly heated bottom disregarded), $F \approx \pi Dh$, where D is the apparatus diameter (m), and h, the height of the liquid in the still (m). Taking into account that $h = 4M_W/\rho_{xW}\pi D^2$, we obtain

$$F = 4M_W/\rho_{xW}\pi D, \quad (11)$$

where ρ_{xW} is the density of the liquid in the still (kg m^{-3}).

Substituting Eq. (11) in (7), we obtain

$$\tau = (R + 1)\int_{x_F}^{x_W} D\rho_{xW}r_{y1}[4K(t_p - t_W)]^{-1}(x_W - y_1)^{-1}dx_W + \int_{t_F}^{t_W} D\rho_{xW}c_{x_W}[4K(t_p - t_W)]^{-1}dt_W. \quad (12)$$

Equation (12) gives at average values of K, t_W, and thermal parameters a simpler expression

$$\tau = (R+1)\int_{x_F}^{x_W} D\rho_{xWav}r_{y1av}[4K_{av}(t_p - t_W)_{av}]^{-1}(x_W - y_1)^{-1}dx_W + D\rho_{xWav}c_{xWav}(4K_{av})^{-1}\ln[(t_p - t_W)/(t_p - t_F)], \quad (13)$$

where the parameters with a subscript av have values averaged over the process.

Relations (12) and (13) are independent of the mass M_W of the liquid in the still. The second term in the right-hand parts of the equations, which contains the heat expended for heating the still liquid, is independent of R and is substantially smaller than the first term containing the heat of vaporization.

Calculations by Eqs. (7) and (13) show that, even at the average values K_{av}, t_{Wav}, ρ_{xWav}, c_{xWav}, and r_{y1av}, the distillation durations differ by 10–15%, with Eq. (13) yielding higher values of τ if the bottom surface is disregarded. With modern computing facilities, calculations by the more complex Eq. (7) present no difficulties, whereas Eq. (13) is well suitable for quick estimation of τ.

At small x_W, we can obtain from Eq. (13), by neglecting the second term, the following:

$$\tau = \frac{(R + 1)(m + R)}{(m - 1)(m + mR + R)}\frac{D\rho_{xWav}r_{y1av}}{4K_{av}(t_p - t_W)_{av}}\ln n. \quad (14)$$

The dependence of τ on R in Eq. (14) is virtually linear, except at very small R, and becomes less pronounced as m increases. It is also noteworthy that τ is proportional to $1/m$. Attention should also be called to the logarithmic behavior of the dependence of τ on n.

To obtain quantitative estimates, we use as input data those from an operating plant. We consider among binary mixtures the most widely occurring waste from production of extracts, aqueous–organic mixtures ethanol–water, methanol–water, and acetone–water. The mass concentration x_F of the volatile in the starting mixture was 50, 30, and 20%, and that in still bottoms, no more than 10, 5, and 2.5%, respectively. The degree of recovery of the volatile was constant (~0.9). A 5 m^3 bulk jacketed apparatus served as the distillation still. The initial charge of the starting mixture M_F = 2.6 t. The pressure of the heating steam was 2 at. The thermal properties of binary mixtures and criterion expressions for calculation of heat-transfer coefficients for jacketed apparatus were taken from [2–4].

The results of calculations made without simplifications, i.e., those by Eqs. (1), (3), (4), and (7) are presented in Figs. 4 and 5.

Figure 4 shows dependences of the concentration of the final products on the degree of partial condensation, plotted using the material balance equations (1), (3), and (4). It follows from Fig. 4 that, as expected, the efficiency of partial condensation depends on the concentration of the mixture in the still and on the separation coefficients. For example, for the system acetone–water with an initial concentration to which corresponds $m < 1$ (curve *1*), the partial condensation yields only a minor effect and is

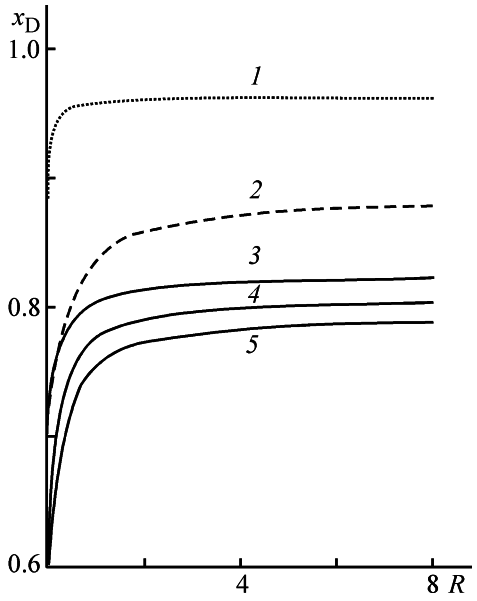

Fig. 4. Distillate concentration x_D vs. the degree of partial condensation R. (*1*) Acetone–water, x_F = 0.5; (*2*) methanol–water, x_F = 0.5; (*3*) ethanol–water, x_F = 0.5; (*4*) ethanol–water, x_F = 0.3; and (*5*) ethanol–water, x_F = 0.2; the same for Fig. 5.

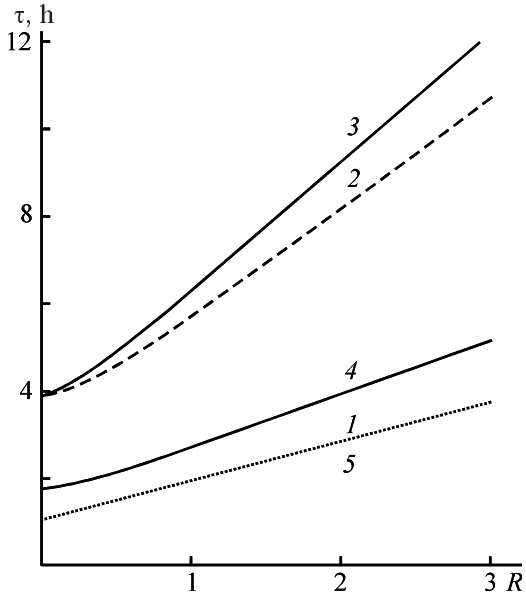

Fig. 5. Process duration τ vs. the degree of partial condensation R.

inefficient. At the same time, for the systems methanol–water (curve *2*) and ethanol–water (curve *3*) with a larger m, the partial condensation produces a certain effect. For solutions with a low initial concentration of the volatile component (curves *4*, *5*), the effect of the partial condensation is even more pronounced. In all cases, as the degree of partial condensation grows, the distillate is "saturated" with the volatile component: beginning with a certain R_{opt}, the increase in x_D is insignificant. For acetone, $R_{opt} \approx 1$ ($x_D \approx 0.96$); for methanol, $R_{opt} \approx 3$–4 ($x_D \approx 0.87$); and for ethanol, $R_{opt} \approx 2$ (x_D 0.82, 0.79, and 0.77, respectively). The expenditure for energy carriers per unit mass of the distillate is proportional to $(R + 1)$. Therefore, Fig. 4 can be interpreted as the relationship between the energy expenditure R and the distillate quality x_D.

Figure 5 shows the results obtained in calculations of the process duration. The dependences of τ on R, calculated by Eq. (7), are nearly linear. The reciprocal quantity $1/\tau$ characterizes the average output capacity of the installation.

Compared to simple distillation (R = 0), the reflux distillation of mixtures with a higher content of the volatile component in the distillation still steeply increases with R (curves *2*, *3*). In this case, it is necessary, when choosing R_{opt}, to additionally take into account the decrease in the output capacity of the installation. For mixtures with low content of the volatile in the distillation still (curves *4*, *5*), the dependence of τ on R is weaker. In this case, it is sufficient, when choosing R_{opt}, to use only material balance equations (Fig. 4). However, simple distillation should be used for separating the system acetone–water, despite the weak dependence of τ on R (Fig. 5, curve *1*).

The output capacity of the installation for reflux distillation is nearly independent of the initial mass of the feed, and other parameters (temperature of the heating steam, apparatus diameter, and thermal properties of the mixture) are related to it by a simple directly or inversely proportional dependence. Therefore, the suggested strategy for assessment of the feasibility of the reflux distillation and the procedure for choosing the optimal value of R can be regarded as general, unrelated to any particular installation.

CONCLUSIONS

(1) It is advisable to use the reflux distillation for mixtures with low concentration of a volatile component. Simple distillation should be used in the initial stage for mixtures with a high concentration. In the final stage, as the distillation still is exhausted, the partial condensation is efficient.

(2) At a degree of partial condensation $R \to \infty$,

the distillate composition asymptotically approaches the maximum limiting value.

(3) Deep exhaustion of the distillation still is not accompanied by any significant deterioration of the distillate quality.

(4) The duration of the distillation with partial condensation linearly depends on R.

(5) The choice of the optimal value of R for mixtures with low concentrations should be governed by the asymptotic nature of the $x_D(R)$ dependence; at higher concentrations, it is necessary to additionally take into account the fact that the process duration increases with R.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrical Conductivity of Lithium Chloride Solutions in the System Isopropyl Alcohol–Water

Abstract—Electrical conductivity of lithium chloride solutions in the system isopropyl alcohol–water in the temperature range 290–323 K was studied. The dependences of the specific and molar electrical conductivity of the solutions on the concentration of water and lithium chloride were determined.

DOI: 10.1134/S1070427208090140

Solutions of lower aliphatic alcohols find increasing use in technology [1–3].

The physicochemical properties of alcohols strongly depend on the concentration of dissolved water in them [3–5]. Therefore, the development of an express method for the determination of water concentration in alcohol solutions is a topical problem. One of such methods is conductometric analysis [6, 7]. To develop a conductometric method for the determination of water concentration in water–alcohol solutions, it is necessary to have data on their electrical conductivity. Data on the electrical conductivity of aqueous–organic electrolytes are available from the literature. However, the effect of water concentration on this quantity is poorly understood [5].

In this study we examined the electrical conductivity of lithium chloride solutions in the system isopropyl alcohol–water in relation to the temperature and salt concentration.

EXPERIMENTAL

The study was performed in the temperature range 17–50°C. The electrical conductivity of solutions was determined conductometrically. We used a U-shaped capillary electrochemical cell (capillary diameter 1.0 mm, length 5–7 cm). The electrodes were made of nickel. The electrical resistance of solutions at a frequency of 1 kHz was measured with an automated E7-15 ac bridge. The cell was heated at a rate of 15 deg h^{-1}. In measuring the solution resistance, heating was stopped for a short time to stabilize temperature. The temperature was measured with an accuracy of ±0.1°C.

Anhydrous LiCl and isopropyl alcohol were of chemically pure grade. To remove traces of moisture, lithium chloride was additionally dried at 200°C for 4 h, placed into a hermetic container, and stored in a desiccator.

Lithium chloride solutions in isopropyl alcohol–water mixtures were prepared by mixing a calculated amount of lithium chloride or its concentrated aqueous solution (40 wt %) with isopropyl alcohol. The concentration of lithium chloride was varied in the range 0.045–0.25 M, and the concentration of water in the mixtures, from 0 to 50 vol %. In some experiments, the concentration of lithium chloride in the solutions under study was monitored by flame emission spectrophotometry.

The experimental data were used to calculate the specific electrical conductivity χ (S cm^{-1}) of solutions under study and to obtain the temperature dependences $\chi = f(T)$ and the isotherms $\chi = f(c_{LiCl})$ at varied concentration of water in a water–alcohol solution.

The specific electrical conductivities of the solutions corresponding to various temperatures and lithium chloride concentrations at a water concentration of 5.0 and 50 vol % are given in Table 1 as example.

Table 1 shows that the specific electrical conductivity increases with the lithium chloride concentration and temperature at a constant concentration of water and with the water concentration in a solution.

A typical temperature dependence of the specific electrical conductivity at varied concentration of lithium chloride in a solution at a water concentration of 2 vol % is shown in Fig. 1.

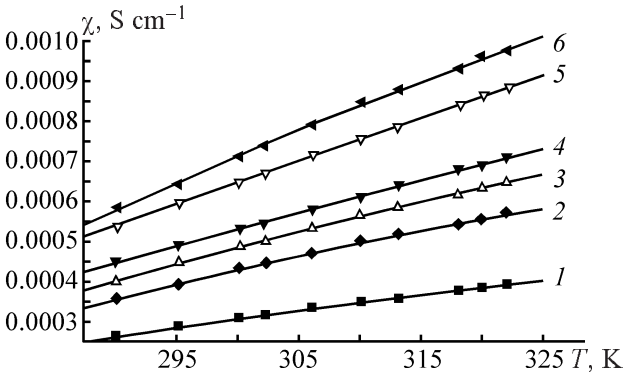

Fig. 1. Specific electrical conductivity χ vs. temperature T for lithium chloride solutions in the system isopropyl alcohol–2 vol % water at varied concentration of lithium chloride. c_{LiCl}, *M: (1)* 0.06, *(2)* 0.105, *(3)* 0.129, *(4)* 0.152, *(5)* 0.176, and *(6)* 0.228; the same for Fig. 3.

The experimental data were statistically processed by the Origin program. The correlation coefficient R and the root-mean-square deviation S were determined.

Analysis of the $\chi = f(T)$ dependences (Fig. 1) showed that, in the temperature range studied, the increase in the specific electrical conductivity with temperature is well described by a polynomial function of second degree:

$$\chi = A + B_1T + B_2T^2,$$

where A, B_1, and B_2 are constants.

The values of the polynomial coefficients are given in Table 2 for all the solutions studied.

The data of Table 2 were used to construct the isotherms of the specific electrical conductivity as a function of the lithium chloride concentration at varied concentration of water in the solutions studied. The typical $\chi = f(c_{LiCl})$ dependences corre-

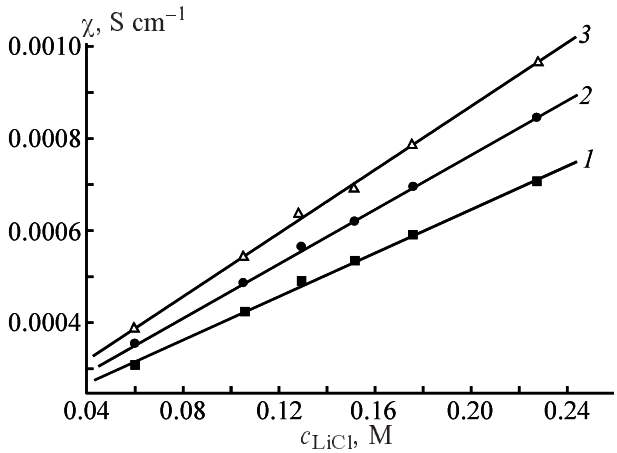

Fig. 2. Specific electrical conductivity χ of lithium chloride solutions in the system isopropyl alcohol–2 vol % water as a function of the lithium chloride concentration c_{LiCl} at various temperatures. *T*, K: (*1*) 300, (*2*) 310, and (*3*) 320; the same for Fig. 4.

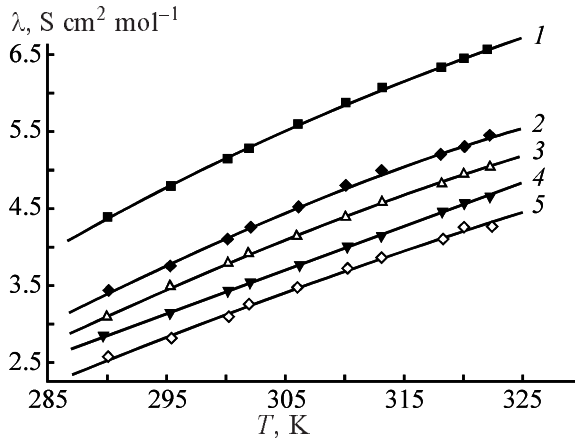

Fig. 3. Molar electrical conductivity λ vs. temperature *T* for lithium chloride solutions in the system isopropyl alcohol–2 vol % water at varied lithium chloride concentration.

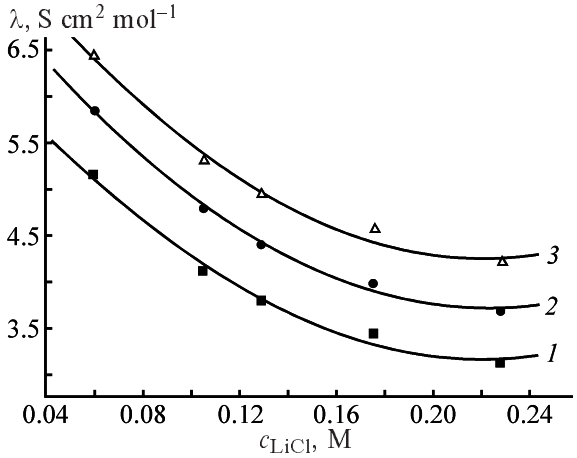

Fig. 4. Molar electrical conductivity λ of lithium chloride solutions in the system isopropyl alcohol–2 vol % water as a function of the lithium chloride concentration c_{LiCl} at various temperatures.

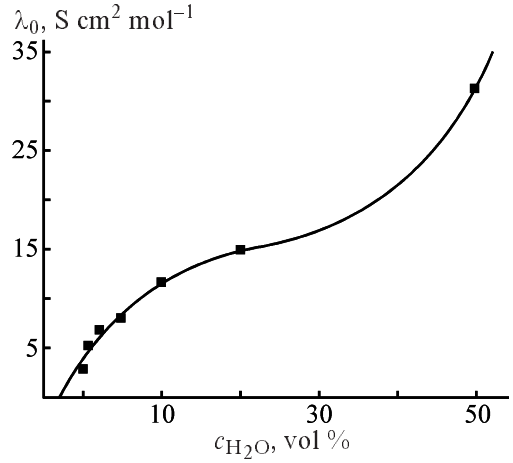

Fig. 5. Molar electrical conductivity at infinite dilution λ_0 of lithium chloride solutions in the system isopropyl alcohol–2 vol % water as a function of water concentration c_{H_2O} at 300 K.

sponding to 2 vol % water are shown in Fig. 2. We found that, for all the solutions studied, the isotherms of the specific electrical conductivity are straight lines described by the equation

$$\chi = A + Bc,$$

where c is the LiCl concentration (M), and A and B are constants.

The molar electrical conductivity of lithium chloride solutions λ was calculated and its values at infinite dilution λ_0 were determined using the values of specific electrical conductivity from Table 2.

Figure 3 shows the temperature dependences of λ, obtained at varied concentrations of lithium chloride at a water concentration of 2 vol %. The run of the $\lambda = f(T)$ curve is the same for all the solutions studied. As in the case of specific electrical conductivity, the temperature dependences for molar conductivity are nonlinear curves described by the second-degree polynomial $\lambda = A + B_1T + B_2T^2$.

Analysis of the isotherms of the molar electrical conductivity (Fig. 4) shows that, as in the case of aqueous solutions [8], in water–alcohol solutions at constant concentration of water λ decreases as the lithium chloride concentration increases. This dependence is satisfactorily described by a second-degree polynomial.

To ascertain the applicability of the Kohlrausch equation to water–alcohol solutions under study, we studied the dependence $\lambda = f(c^{1/2})$. It was found that the dependence $\lambda = f(c^{1/2})$ is linear only in solutions containing 50 vol % water. Consequently, the Kohlrausch law cannot be applied to the water–alcohol systems studied.

The dependence of λ_0 on the water concentration c_{H_2O} (vol %) in an alcohol solution at 300 K is shown in Fig. 5. As can be seen, the molar electrical conductivity at infinite dilution of lithium chloride solutions in the system isopropyl alcohol–water increases with the water concentration and is described by a third-degree polynomial:

$$\lambda_0 = 3.875 + 1.0964\,c_{H_2O} - 0.0389\,c_{H_2O}^2 + 0.00056\,c_{H_2O}^3.$$

The correlation coefficient is 0.995, and the root-mean-square deviation, 0.00057.

CONCLUSIONS

(1) The specific electrical conductivity of solution under study increases with temperature. The $\chi = f(T)$ dependence is described by a second-degree polynomial $\chi = A + B_1T + B_2T^2$.

(2) The specific electrical conductivity in the system isopropyl alcohol–water increases as the concentrations of lithium chloride and water increase. The $\chi = f(c_{LiCl})$ isotherms obtained at various concentrations of water in the solutions are linear.

(3) The molar electrical conductivity of the solutions studied was calculated. The $\lambda = f(T)$ dependence is a nonlinear curve described by a polynomial of the second degree. As the concentration of lithium chloride in the system isopropyl alcohol–water at constant concentration of water increases, the molar electrical conductivity of the solutions decreases. The isotherms $\chi = f(c_{LiCl})$ are described by a second-degree polynomial.

(4) The molar electrical conductivity of the solutions at infinite dilution λ_0 was determined. In solutions under study, λ_0 increases with water concentration, and the $\lambda = f(c_{H_2O})$ dependence is satisfactorily described by a third-degree polynomial.

Abstract—Polycrystalline and amorphous cobalt–boron coatings were electrochemically deposited. The effect of the boron content and heating temperature on the physicomechanical properties of the coatings was studied. A relationship between the composition, structure, and properties of the coatings was established.

DOI: 10.1134/S1070427208090152

The modern level of development of machine-building, radio electronics, and instrument making requires that new coatings should be produced with a set of valuable properties: high corrosion resistance and plasticity, low intermediate resistance and internal stresses, good solderability and ultrasonic weldability, and high microhardness and wear resistance. Such properties can be exhibited by metal–nonmetal coatings in which nickel, cobalt, and iron are used as a metallic matrix, and boron and phosphorus as a nonmetal. The best studied and practically used are nickel–boron and nickel–phosphorus coatings produced by chemical or electrochemical deposition from aqueous solutions [1, 2]. Cobalt–boron coatings have been studied to a considerably lesser extent, with the available information mostly related to structural properties and structural-phase transformations in these coatings under thermal treatment [3].

The aim of the present study was to examine the effect of the boron content and heating temperature on the physicomechanical properties of Co–B coatings: microhardness, wear resistance, internal stresses, and friction coefficient and to find the relationship between the composition, structure, and exhibited properties.

EXPERIMENTAL

Cobalt–boron coatings were electrochemically deposited onto copper and bronze surfaces in the galvanostatic mode (I = 2 A dm^{-2}) at 30°C from a solution of the following composition (M): cobalt chloride 0.8, boric acid 0.6, and a boron-containing compound 5.0×10^{-4}–1.2×10^{-1}, at pH 4. Sodium decahydro-*closo*-decaborate $Na_2B_{10}H_{10}$ served as the boron-containing compound. The film thicknesses were in the range 5–30 μm, depending on the requirements of an experiment. The amount of boron in the coatings was determined by potentiometric titration in the presence of mannitol [4]. The structure of freshly deposited and thermally treated coatings was subjected to X-ray diffraction analysis. X-ray diffraction patterns were measured on a DRON-2.0 diffractometer with monochromated CuK_α radiation in the scanning mode (scanning step 0.1 deg; time of pulse accumulation at a point, 15 s). Amorphous coatings were heated in air at 250–400°C, with keeping for 20 min. The chemical composition and surface structure of the coatings were studied by X-ray photoelectron spectroscopy (XPS) on a Q2000 spectrometer with an AlK_α X-ray source. The residual stresses were measured by the X-ray method in the inclined measurement mode [5]. The error in determining the residual stress was 50 MPa.

Tribotechnical tests of coating samples were performed on an ATVP tribometer equipped with an attachment for measuring the friction coefficient [6]. Tribotechnical characteristics of the coatings were measured under unlubricated friction conditions at a specific test load p_a = 1 MPa. Thermally treated U8 (45 HRC) steel was used as a counter body. The

microhardness was measured with a PMT-3 device under a load of 1 N with keeping for 10 s.

A chemical analysis of the coatings demonstrated that, upon introduction of sodium decahydro-*closo*-decaborate in the electrolyte solution, cobalt is codeposited with boron. As the $Na_2B_{10}H_{10}$ concentration in the electrolyte increases, the boron content of the coating grows to reach the maximum value of about 22 at. % (Fig. 1).

According to XPS data, Co–B coatings with the maximum boron content (22%) show two peaks corresponding to cobalt and boron, with the position of the first peak coinciding with the binding energy of Co $2p_{3/2}$ electrons in metallic cobalt, whereas the peak B 1*s* with a binding energy of 188.0 eV is shifted to higher energies as compared to the binding energy of electrons in elemental boron (187.3–187.5 eV [7]), which indicates that a cobalt–boron alloy is formed.

An X-ray diffraction analysis demonstrated that, in electrochemical deposition, cobalt crystallizes in the hexagonal α-modification of the metal, with unit cell parameters a = 2.5052 Å and c = 4.065 Å (reference data: a = 2.5031 Å and c = 4.0605 Å). The codeposition of cobalt and boron at boron concentrations of 4 and 6 at. % leads to an increase in the parameter c and a decrease in a (Table 1). Such a behavior of the crystal lattice constants of the cobalt coating with increasing boron concentration is presumably due to formation of an interstitial-substitutional solid solution. In this case, the decrease in the unit cell constant a is due to substitution of cobalt atoms having a large atomic radius (r_{Co} = 1.25 Å) by boron atoms with a smaller atomic radius (r_B = 0.97 Å), and the increase in c is due to accommodation of a part of boron atoms within octahedral pores of the hexagonal closest packing (hcp) of the crystal lattice. It should be noted that a large part of boron atoms substitute cobalt atoms, which is indicated by the decrease in the unit cell volume V, recorded for Co–B alloys as the boron concentration increases (Table 1). The formation of a solid solution of boron in the cobalt lattice can indirectly indicate that boron is codeposited in the elemental form. An increase in the boron content of a coating leads to strong distortions of the crystal lattice of α-Co and is accompanied by a rise in the physical broadening β of diffraction lines (Fig. 2). X-ray structural data indicate that the physical broadening is proportional to the tangent of the scattering angle. This points to the existence in the coating of long-range fields of atomic displacements,

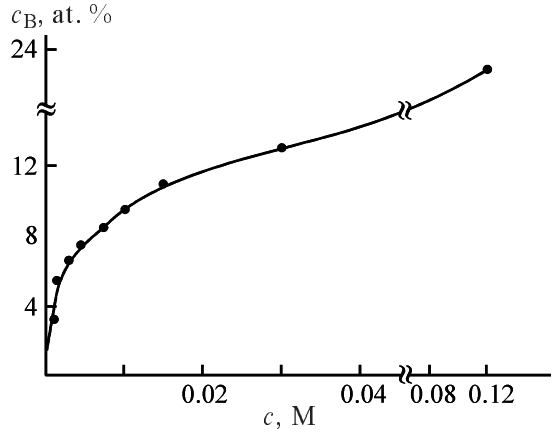

Fig. 1. Boron content c_B of the Co–B coating vs. the $Na_2B_{10}H_{10}$ concentration c in solution.

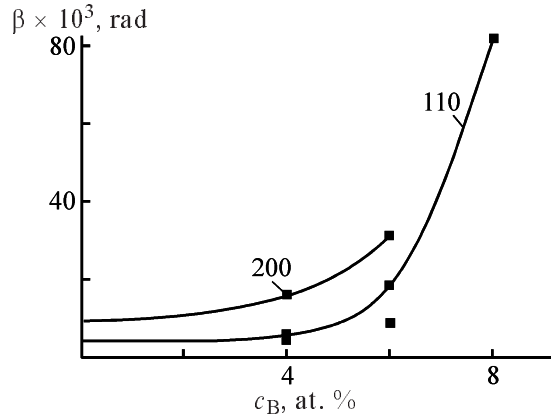

Fig. 2. Physical broadening β of the diffraction lines (110) and (200) vs. the boron content c_B of the Co–B coating.

associated with crystal lattice defects (dislocations, vacancies, impurity atoms). In this case, the strongest increase in β is observed at boron contents exceeding 6 at. %, which is presumably due to a steep rise in the density of crystal lattice defects in a Co–B coating at such concentrations of the nonmetal.

Further increase in the boron concentration in coatings from 8 to 13 at. % results in that an intermediate amorphous-crystalline structure is formed. In this case, separate broadened low-intensity dif-

fraction lines are recorded in the diffraction patterns and a strong diffraction peak is formed at small scattering angles (Fig. 3b). Still further increase in the boron content of the coatings (to ≥15 at. %) yields an amorphous structure: broadened peaks characteristic of diffraction from amorphous materials [5] are recorded in X-ray diffraction patterns (Fig. 3c). The position of the diffraction peaks enables estimation of the interatomic distance R_1 for the first coordination sphere. R_1 was found by the Ehrenfest formula [5]

$$R_1 = 0.615\lambda/\sin\theta_{1max},$$

where λ is the wavelength of the X-ray radiation, and θ_{1max}, angular position of the first broadened diffraction peak.

The estimated values of R_1 for amorphous Co–B alloys are listed in Table 2. It can be seen that, for coatings with an amorphous-crystalline structure (boron content of 8 to 13 at. %), the shortest interatomic distance R_1 = 2.494–2.496 Å. For amorphous Co–B coatings with 15 and 20 at. % B, R_1 decreases to 2.455 and 2.446 Å, respectively. It should be noted that the interatomic distance R_1 decreases as the boron content of a coating grows (Table 2).

The results of the study demonstrate that amorphous Co–B coatings have a sufficiently high thermal stability. On their heating at 250–300°C, the diffraction pattern remains nearly unchanged and retains the type characteristic of the amorphous state of the coating (Figs. 3c, 3d). Raising the heating temperature to 350°C results in that α-Co crystals with an hcp crystal lattice (Fig. 3e) are formed in the coating. It should be noted that the 002 diffraction line has the highest intensity. This points to a preferential growth of 001 planes in the course of crystallization of an amorphous coating. The lattice constants of the crystalline phase, a = 2.511 Å and c = 4.075 Å, are close to reference data for the α-Co lattice. At the same time, the increased values of a and c indicate that boron atoms are present in octahedral voids of the α-Co lattice and distort the crystal structure. Raising the heating temperature to 400°C leads to an increase in the intensity of the diffraction lines associated with the crystalline phase, which points to further crystallization (Fig. 3f). The lattice constant c remains at about 4.072 Å, and a approaches the reference value and equals 2.506 Å.

As a rule, point defects of the crystal structure, vacancies and interstitial atoms, are responsible for macroscopic stresses in electrolytic deposits. The

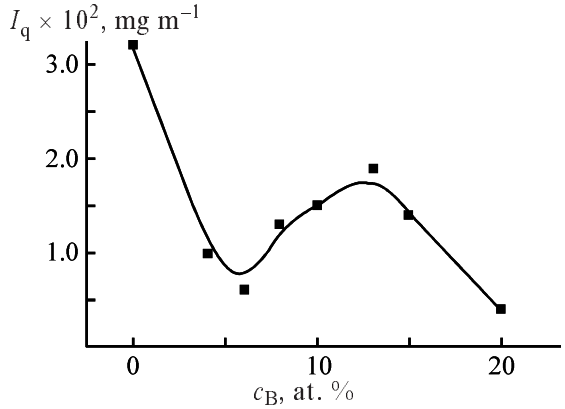

Fig. 4. Wear intensity I_q of Co–B coatings vs. their boron content c_B.

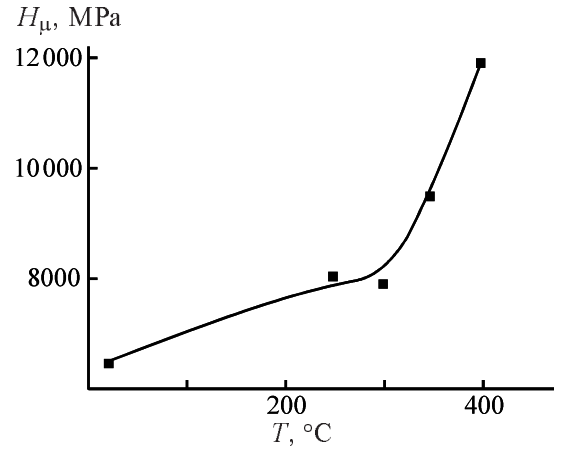

Fig. 5. Microhardness H_μ of amorphous Co–B coatings vs. the heating temperature T.

prevalent type of defects in the structure of the deposit determines the sign of these stresses. Introduction of interstitial atoms leads to a higher density of deposits and gives rise to compression stresses [8]. The estimated macroscopic stress for a Co–B alloy (6 at. % boron) is σ_ϕ = –570 MPa (compression stress), which confirms the suggestion that boron is intercalated into the α-Co crystal lattice.

The microhardness of Co–B coatings depends on their boron content in a complicated way (Table 2). Presumably, the initial rise in the microhardness, observed as the boron content of the coating increases from 4 to 8 at. %, can be understood as follows. Boron at sites of the crystal lattice of cobalt and in interstitial positions distorts its crystal lattice and makes lower the dislocation mobility, which favors strengthening of the electrochemical deposits. The substantial decrease in the microhardness for Co–B coatings with 10 at. % boron is probably due to their transition from the crystalline to amorphous–crystalline state, which is accompanied by loss of certain elements of symmetry. Steadily high values of microhardness (6100–6500 MPa) are observed for X-ray amorphous coatings.

The results of tribotechnical tests demonstrated that alloying of cobalt coatings with boron improves their wear resistance. However, the dependence of the wear intensity on the boron content is rather complicated (Fig. 4). As the boron content increases to 4 and 6 at. %, the coating wear intensity decreases by factors of 3 and 5 (Fig. 4), and the friction coefficient grows from 0.6 to 0.8–0.9 (Table 2). The high wear resistance and increased values of the friction coefficient point to a high specific work of coating wear. With an increase in the boron content in the range 8–13 at. %, the wear resistance of the coatings decreases and the intensity of their wear grows to $I_q = 1.9 \times 10^{-2}$ mg m^{-1} (Fig. 4). The friction coefficient f also decreases and reaches values of 0.3–0.4 (Table 2). As the boron content of coatings increases to 15 and 20 at. %, their wear resistance again noticeably grows and the wear intensity decreases to 0.4×10^{-2} mg m^{-1} for coatings containing 20 at. % boron (Fig. 4). The friction coefficient f = 1.0–1.1 (Table 2). Thus, the wear resistance of Co–B coatings is the lowest at boron concentrations of 10–13 at. % (Fig. 4). However, these values are higher by a factor of approximately 2 than the wear resistance of cobalt coatings. To these same boron concentrations correspond the lowest values of the friction coefficient.

As amorphous Co–B coatings are heated in the temperature range 250–300°C, their microhardness gradually grows from 6500 to 8000 MPa (Fig. 5), which indicates that crystallization nuclei are formed. Raising the heating temperature from 300 to 400°C leads to a steep rise in the microhardness, which reaches the maximum value of 12000 MPa (hardness of chromium).

As a rule, an increase in the boron content of amorphous coatings improves their thermal stability. At the same time, it is known that crystallization of amorphous materials can be caused not only by thermal heating, but also by their plastic deformation, named mechanical crystallization [9]. It can be assumed that mechanical crystallization of local parts will occur at the surface of the amorphous layer in the friction interaction (without a lubricant) of the amorphous coating with a counter body in regions of a strong plastic deformation and warming-up. The formation of crystalline regions on an amorphous substrate in friction will give rise to considerable tensile stresses at the phase boundary

because of the substantial difference between the specific atomic volumes of the amorphous and crystalline phases. It is known that the interphase deformation can make substantially lower the stability of materials against disintegration in the course of a friction interaction [10]. Therefore, the formation of crystalline regions on an amorphous substrate in the course of friction will impair the wear resistance of materials of this kind. By contrast, a higher stability of amorphous structures must lead to a better wear resistance. Thus, the lowest wear resistance in an adhesion interaction in unlubricated friction should be observed for layers with a metastable amorphous-crystalline structure with enhanced susceptibility to mechanical crystallization. This conclusion is fully confirmed by the results obtained in this study. In particular, as the threshold boron concentration leading to loss of the long-range order in the atomic arrangement is reached in alloys, the wear resistance of the coatings starts to decrease. An increase in the content of boron stabilizing the amorphous state of the materials and raising their resistance to mechanical crystallization is accompanied by a rise in the wear resistance of amorphous alloys.

CONCLUSIONS

(1) The structural-phase composition of Co–B coatings containing 4 to 22 at. % boron was studied. At a boron content lower than 8 at. %, coatings are composed of a substitutional-interstitial solid solution of boron in hexagonal α-Co; alloys with 8–13 at. % boron have an amorphous–crystalline structure; and deposits with a boron content of 15 at. % and more are X-ray amorphous.

(2) Co–B coatings with a boron concentration preceding the onset of amorphization have the optimal physicomechanical properties.

(3) Crystallization of amorphous Co–B coatings, occurring at heating temperatures of 350°C and more, improves their physicomechanical properties.

Abstract—Effect of liquid and dry extracts of rice, buckwheat, and sunflower husks on the corrosion of St.3 steel in water-salt and acid media was studied by gravimetric and potentiodynamic methods. The action of the extracts on the surface morphology of St.3 steel samples was examined by electron microscopy and electron microprobe analysis.

DOI: 10.1134/S1070427208090164

A search for environmentally safe complex inhibitors for corrosion protection of steels is a topical task. A promising source of raw materials for production of inhibitors of this kind are renewable wastes of annual plants, whose resources in agriculture constitute hundreds of thousands of tons annually. There is published evidence that by-products of processing of sugarcane [1], cotton plant [2], wood [3], Black sea laver [4], prickly pear [5], and wastes from food industry [6] can inhibit the corrosion of various alloys. It has also been found that the steel corrosion is decelerated by aqueous and alkaline extracts from vegetable wastes produced in processing of grain crops [7]. Inhibitors of this kind have complex and diverse chemical compositions and the mechanism of their action has practically not been studied at all.

The present study continues analysis of the integrated processing of vegetable wastes [7–14] and is concerned with the inhibiting effect of liquid and dry extracts from rice (RH), buckwheat (BH), and sunflower husks (SH) on the corrosion of St.3 low-carbon steel.

EXPERIMENTAL

We studied as inhibitor additives liquid water and acid extracts from rice, buckwheat, and sunflower husks, produced by treating weighed portions of a raw material with water or 0.1 N solution of hydrochloric acid (s : l = 1 : 10 by volume) under heating to 90°C for 1 h, with the subsequent separation of undissolved raw materials similarly to [11, 13, 14], and their dry extracts formed by evaporation of the liquid extracts on a water bath or by freeze drying [13].

The content of soluble substances in rice, buckwheat, and sunflower husks depends on the type of a raw material (Table 1). The chemical composition of water and acid extracts from RH, BH, and SH has been studied previously [8–14]. According to the data obtained, extracts from rice, buckwheat, and sunflower husks contain both organic and inorganic substances whose composition and concen-

Raw material	Medium*	$K \pm \Delta S$,** g m^{-2} h^{-1}	Z, %
RH	NaCl + WE	0.0305 ± 0.002	54.0
	HCl + AE	0.1317 ± 0.041	94.9
BH	NaCl + WE	0.0256 ± 0.001	61.4
	HCl + AE	0.4365 ± 0.023	83.2
SH	NaCl + AE	0.0175 ± 0.005	73.6
	HCl + AE	2.5088 ± 0.062	3.5
	NaCl	0.0663 ± 0.011	
	HCl	2.5998 ± 0.051	

* WE and AE denote water and acid extracts, respectively.
** ΔS is standard deviation.

tration are determined by the type of a raw material. The main organic fractions extracted into solution in treatment of husks with water or the acid are polysaccharides, flavonoids, and organophosphorus and other substances possessing a set of various functional groups. The best studied for the time being are only the monosaccharide composition of polysaccharides in extracts from RH [10], BH [9], and SH [12] and the content of inositolhexaphosphoric acid in SH [8]. The inorganic components are represented in these solutions by ions of more than 20 metals, among which ions of potassium, calcium, magnesium, sodium, iron, zinc, and manganese predominate [8, 9, 13].

The effect of liquid extracts, whose concentration was 500 ml l^{-1}, which corresponded to a dry substance content of the extract equal to 1.2 g l^{-1}, on the corrosion rate of St.3 low-carbon steel was studied in 3% NaCl and 0.1 N HCl solutions by the gravimetric method. St.3 samples (40 × 20 × 2 mm) were preliminarily ground, degreased with acetone, and weighed on an analytical balance.

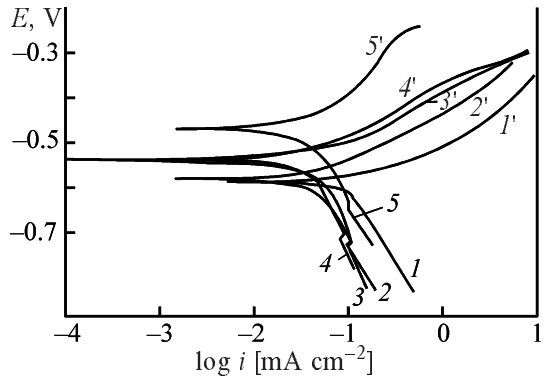

Fig. 1. (*1'–5'*) Anodic and (*1–5*) cathodic polarization curves for St.3 steel in a 3% NaCl solution containing various dry extract additives. (*E*) Potential and (*i*) current density; the same for Fig. 2. (*1, 1'*) no additive; additive: (*2, 2'*) BH, (*3, 3'*) RH, (*4, 4'*) SH, and (*5, 5'*) Diesel Guard inhibitor.

The corrosion rate K (g m^{-2} h^{-1}) was calculated by the formula

$$K = \frac{m_1 - m_2}{St}, \quad (1)$$

where m_1 and m_2 are the sample masses before and after tests (g); S, sample area (m^2); and t, time (h).

The degree of protection by vegetable extracts, Z (%), was determined by the formula

$$Z = \frac{K - K_e}{K} \times 100, \quad (2)$$

where K and K_e are the corrosion rates of St.3 steel without an additive and with addition of an extract, respectively.

Table 2 lists the results of the gravimetric studies. It can be seen that all the extracts make lower the corrosion rate. The most effective in a NaCl solution (pH 7.0) was the water extract of sunflower husks. A substantial protective effect was also produced by a water extract of buckwheat husks. However, the highest protective efficiency of all the extracts except the SH extract was manifested in an acid medium at pH 1.0. Under these conditions, the protective effect of the RH extract is as high as 94%, and that of BH extract, 83%.

A more detailed study of the inhibiting effect of the extracts was performed by measuring potentiodynamic curves with an IPC-PRO potentiostat with intellectual control (Moscow). The electrochemical measurements were made in a glass cell with an EVL-1M1 silver chloride reference electrode and a platinum auxiliary electrode. The slopes of the Tafel portions of the anodic and cathodic polarization curves, b_a and b_c, and the corrosion current density I_{cor} were calculated in the automatic mode. The hindrance coefficients of the cathodic ($\gamma_c = i_c/i_c^*$) and anodic ($\gamma_a = i_a/i_a^*$) reactions occurring in corrosion of St.3 steel were found from the polarization curves (i_c, i_a and i_c^*, i_a^* are the cathodic and anodic current densities in a medium without and with addition of an extract, respectively). The concentrations of dry extract additives and standard inhibitors was

0.67 g l^{-1}. Diesel Guard inhibitor, which is manufactured by Unitor (Norway) and is a mixture of organic substances on the nitrate–borate base, was used in a water–salt medium, and hexamethylenetetramine, which is an effective inhibitor of acid corrosion, in an acid medium.

The results of our potentiodynamic study of the behavior of steel in 3% NaCl and 0.1 N HCl solutions with addition of dry extracts from RH, BH, and SH confirm the gravimetric data. As follows from Fig. 1, addition of dry extracts from rice, buckwheat, and sunflower husks to a sodium chloride solution makes the overvoltage of the anodic and cathodic processes larger and the corrosion current density two times smaller (Table 3). The hindrance coefficients of the anodic and cathodic reactions point to preferential hindrance of the anodic reaction of the corrosion process.

The results obtained show (Table 3) that the protective effect of the RH, BH, and SH extracts is comparable with, and even somewhat exceeds that of the standard inhibitor Diesel Guard with respect to St.3 steel.

According to potentiometric data, additions of dry extracts also effectively diminish the corrosion rate of steel in an acid medium with pH 1.0 (Fig. 2). It should be noted here that introduction of the extracts under study into an HCl solution leads to the same hindrance of both anodic and cathodic reactions: values of the coefficients γ_a and γ_c differ only slightly (Table 3). A consequence of the identical effects of the extracts on the rate of the anodic and cathodic reactions is that there is no shift of the corrosion potential. The protective effect of the extracts in a 0.1 N HCl solution (and, especially, that of the BH extract) is weaker than that of hexamethylenetetramine (Table 3). It should be taken into account, however, that dry extracts are a mixture of organic and inorganic substances, not all of which are involved in diminishing the corrosion rate, and the concentration of the main component of the inhibitor "responsible" for the protective effect in solutions with extracts will be lower than that in a solution of pure hexamethylenetetramine in HCl.

Analysis of the data in Tables 1 and 2 shows that

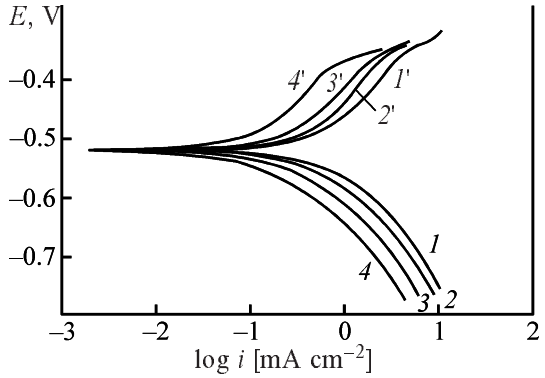

Fig. 2. (*1'–4'*) Anodic and (*1–4*) cathodic polarization curves for St.3 steel in a 0.1 N HCl solution with various extract additions. Additive: (*2, 2'*) BH, (*3, 3'*) RH, and (*4, 4'*) hexamethylenetetramine.

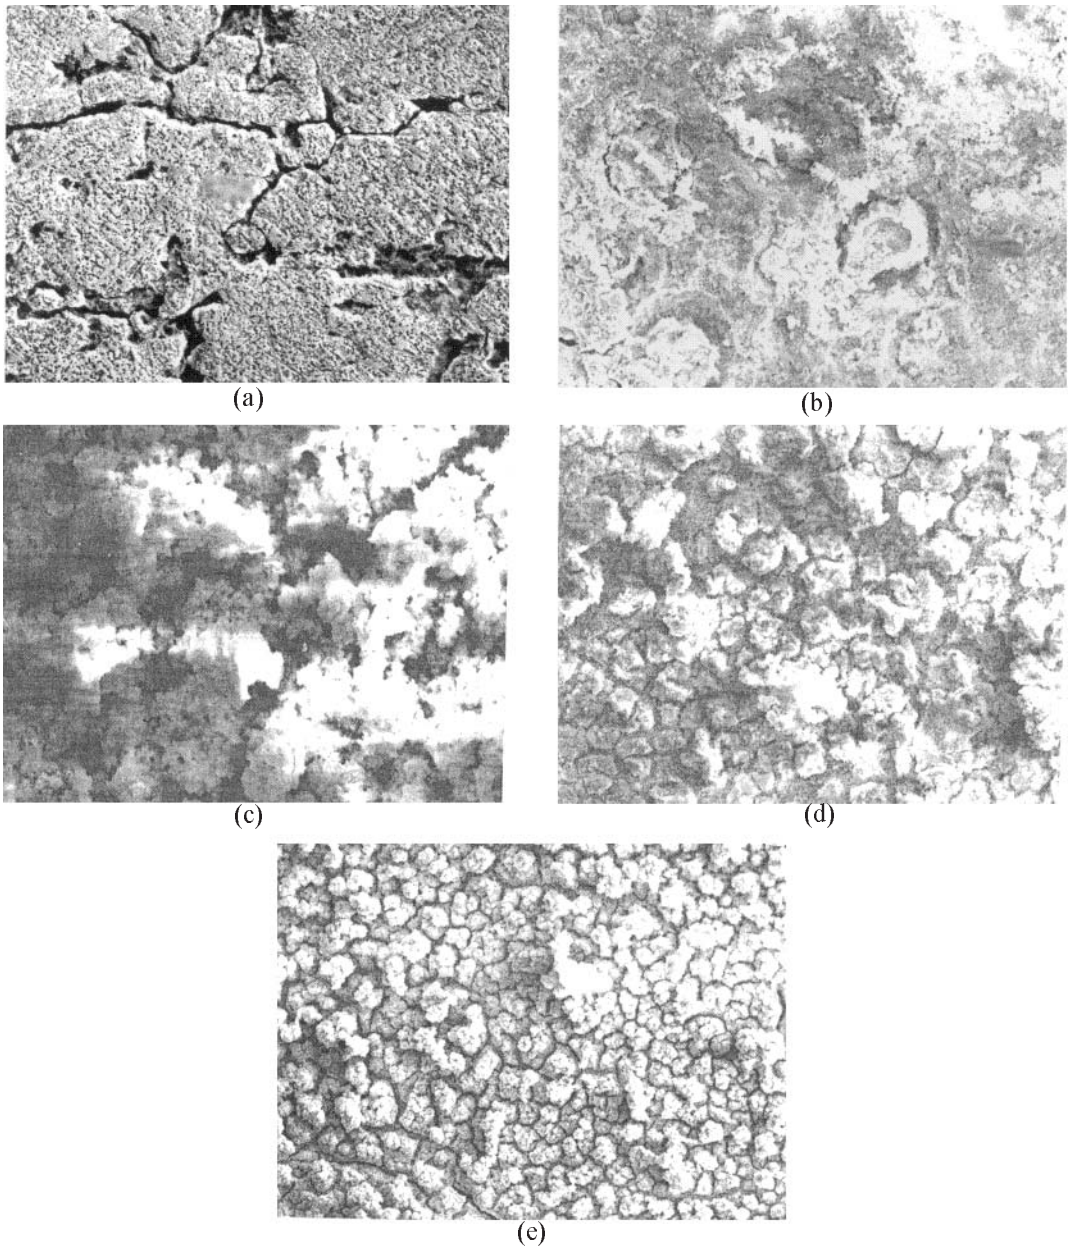

Fig. 3. Micrographs of (a) initial surface of St.3 steel and (b–e) that after corrosion tests in 3% NaCl solutions with various extract additives. (b) No additive; additive: (c) RH, (d) BH, and (e) SH.

the magnitudes Z of the protective effect, obtained using the gravimetric and potentiometric methods, are different, with the former being, as a rule, larger than the latter. This occurs because the gravimetric method determines the average corrosion rate over the entire test period, and the electrochemical method, the corrosion rate at the instant of measurement. However, the tendency toward an increase in the protective effect in water–salt and acid solutions with the extracts under study, determined by two methods, is the same: in a sodium chloride solution, the protective effect grows in the following order of water-soluble substances extracted from husks: RH < BH < SH, whereas in an HCl solution at pH 1.0, Z increases in the order SH < BH < RH.

It is known that, in the initial stage of corrosion inhibition, adsorbed films are formed on the metal surface, and, therefore, the surface morphology of St.3 steel samples was analyzed. Figure 3 shows micrographs of the St.3 steel surface before and after corrosion tests in a water–salt solution with dry

Table 4. Content of elements in corrosion products formed on the steel surface after corrosion tests in 3% NaCl solutions with dry extract additives

Solution	Content, wt %									
	Fe	O	Na	Cl	Mn	S	Si	P	Ca	Cr

extract additives. The surface morphology was studied using an EVO-50 XPV scanning electron microscope (LEO, Germany), and an electron microprobe analysis was made with JXA-8100 X-ray fluorescence microanalyzer (JEOL, Japan) with three wave spectrometers, additionally equipped with an INCA-250 (Oxford, UK) energy-dispersive spectrometer. St.3 samples ($10 \times 10 \times 0.4$ mm) were preliminarily ground, chemically etched, washed with water, and degreased with acetone. Then the samples were submerged in a NaCl solution with dry extract additives and kept there for four weeks.

As can be seen in the micrographs, a film composed of aggregates of various sizes is formed on the steel surface after four weeks of sample tests in solutions containing RH, BH, and SH extract additives (Figs. 3c–3e). It should also be noted that the visually densest film is formed on the steel surface in a sodium chloride solution with addition of an extract from sunflower husks. According to Table 2, the most pronounced decrease in the corrosion rate of St.3 steel is observed in the same solution. In a solution with RH additive, for which Z has the smallest value, a loose film is formed.

Corrosion pits 50–100 μm in size are formed on the surface of steel samples exposed to sodium chloride solutions without extract additives (Fig. 3b).

According to the results of X-ray fluorescence microanalysis, the films formed on the surface of steel samples after corrosion tests in a NaCl solution with dry extract additives contain a large amount of Fe and O (Table 4). In addition, the film formed on the steel surface in a NaCl solution with RH additive contains an increased amount of phosphorus (2.2 to 6.5%). Possibly, this is due to the presence of inositolhexaphosphoric acid in rice husks [8]. The elemental composition of the protective films formed on the steel surface from NaCl solutions with SH and BH is more diverse: the X-ray spectra contain, in addition to the peaks indicating that Fe, O, and Na are present in the film, peaks characteristic of S, P, Cr (for the solution with BH) and Ca, P, Si (for the solution with SH). The presence of these elements in the starting raw materials was noted in [14, 15]. The increased content of Fe and O in the films indicates that there occur corrosion processes to give corrosion products, probably in the form of Fe hydroxides and oxides. Because the corrosion process is decelerated in solutions containing extract additives, it can be assumed that extract solutions contain substances (with so far unidentified composition) that form poorly soluble complexes with Fe ions and hinder further dissolution of steel.

CONCLUSIONS

(1) A study of the corrosion of St.3 steel in 3% NaCl and 0.1 N HCl solutions containing additions of liquid and dry extracts from rice, buckwheat, and sunflower husks demonstrated that extracts produced from fruit husks of these plants behave as corrosion inhibitors.

(2) The protective effect in a sodium chloride solution (pH 7.0) with extracts from husks increases in the following order: rice husk < buckwheat husk < sunflower husk, and in a HCl solution at pH 1.0, the protective effect increases in the order: sunflower husks < buckwheat husks < rice husks.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anodic Dissolution of Gallium in Solution of LiCl in Anhydrous Acetic Acid

Z. G. Gasanly and T. L. Guseinzade

Institute of Chemical Problems, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received June 5, 2007

Abstract—Kinetics and mechanism of the anodic dissolution of gallium in an anhydrous acetic acid medium was studied. The results obtained can be used for choosing the optimum conditions for the electrolytic refining of gallium from acetic acid solutions.

DOI: 10.1134/S1070427208090176

Study of the kinetics and mechanism of anodic dissolution of gallium is of certain interest, because low-valence ions formed in the process are the main intermediate products of gallium refining.

The study was aimed to obtain additional data on the processes occurring in the course of electrochemical oxidation of metallic gallium. The anodic dissolution of metallic gallium was studied with a rotating disc–ring electrode (RDRE) in anhydrous acetic acid, because ions of a low-valence gallium in 100% CH_3COOH are stable. The electrode (ring and disc) was made of platinum. Prior to each run, a 2-mm-thick gallium film was electrodeposited onto the disc from a gallate solution. The rotation rate of the electrode was 500 rpm, and the temperature, 25°C. Acetic acid was dehydrated by additional distillation in the presence of acetic anhydride, and lithium chloride was dried in a flow of hydrogen chloride at 150–200°C and calcined at 500°C prior to use.

The mechanism of the anodic dissolution of gallium was studied in a 0.5 M LiCl solution in 100% CH_3COOH. The results obtained are shown in Fig. 1.

As can be seen, in the course of anodic polarization of a gallium disc electrode with currents of up to $i_d \le 4.0$ mA, the anode currents i_r are observed on the ring, due to the oxidation

$$Ga^+ \rightarrow Ga^{3+} + 2e \quad (1)$$

of Ga^+ ions formed at a disc electrode by the reaction

$$Ga^0 \rightarrow Ga^+ + e. \quad (2)$$

As the ring potential E is shifted toward positive values from 300 to 900 mV, the current i_r increases and attains a limiting value at 600 mV. It follows from the anodic polarization curves obtained on a disc–ring electrode (Fig. 1) that Ga dissolution proceeds with a slight polarization and without retardation (curve *9*). The oxidation potential for Ga^+ ions at a ring electrode is attained by shifting the potential E_r by 450 mV with respect to initial

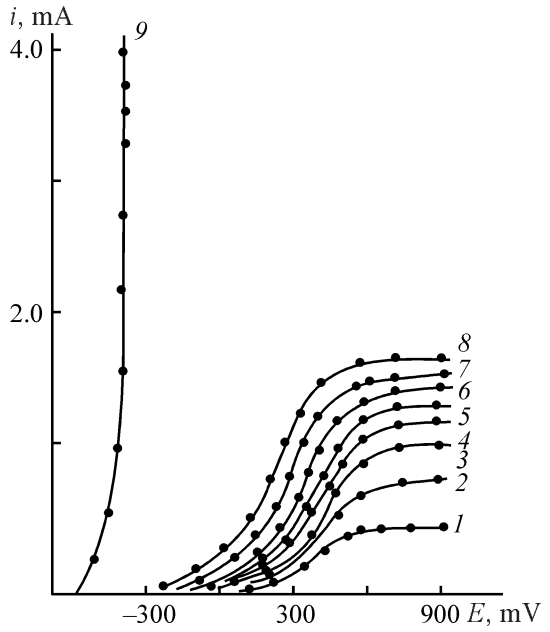

Fig. 1. Anodic polarization curves obtained at (*1*–*8*) a ring electrode and (*9*) a disc in a 0.5 N solution of LiCl in 100% CH_3COOH at varied disc current. i_d, mA: (*1*) 0.5, (*2*) 1.0, (*3*) 1.5, (*4*) 2.0, (*5*) 2.5, (*6*) 3.0, (*7*) 3.5, and (*8*) 4.0. Table 1. Results of calculation and measurements on RDRE in a 0.5 M solution of LiCl in 100% CH_3COOH

I_d	i_r	i_l	i_{kin}	k_s
mA				
0.5	0.32	0.37	0.13	0.74
1.0	0.76	0.85	0.15	0.85
1.5	0.98	1.15	0.35	0.76
2.0	1.21	1.48	0.52	0.74
2.5	1.46	1.76	0.74	0.70
3.0	1.54	2.05	0.95	0.68
3.5	1.62	1.92	1.58	0.54
4.0	1.74	2.13	1.87	0.53

Table 2. Effect of temperature on the kinetic parameters of gallium ionization at RDRE in a 0.5 M solution of LiCl in 100% CH_3COOH. i_d = 2.0 mA, ω = 500 rpm

T, °C	i_r	i_l	i_{kin}	k_s
	mA			
20	1.20	1.10	0.90	0.55
25	1.24	1.23	0.77	0.62
30	1.30	1.31	0.69	0.65
35	1.40	1.36	0.64	0.68
40	1.34	1.32	0.68	0.66
45	1.26	1.28	0.72	0.64
50	1.10	1.14	0.86	0.57

value, and the limiting current is attained by shifting it by 900 mV. The results obtained show that univalent gallium cannot be electrolytically oxidized on the disc, which is in line with the data of [1–4].

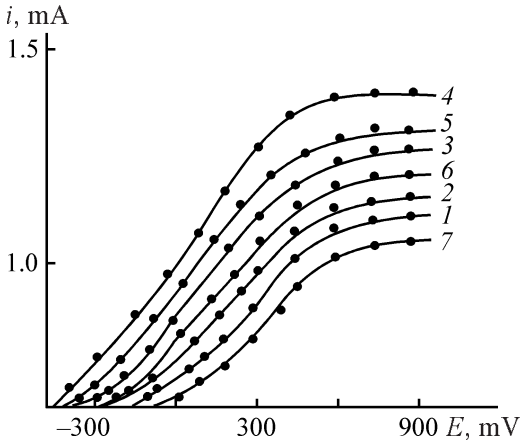

Fig. 2. Anodic polarization curves obtained at a ring electrode in a 0.5 M solution of LiCl in anhydrous acetic acid at varied temperature. T, °C: (*1*) 20, (*2*) 35, (*3*) 30, (*4*) 35, (*5*) 40, (*6*) 45, (*6*) 45, and (*7*) 50. i_d = 2.0 mA; ω = 500 rpm; the same for Fig. 3.

The kinetic parameters of the electrochemical process (i_l, i_{kin}, and k_s) of the anodic dissolution of gallium were calculated by the formulas [5]

$$i_l = n_d i_r / n_r N, \quad (3)$$

$$i_{kin} = i_d - i_l, \quad (4)$$

$$k_s = i_l / i_d, \quad (5)$$

where i_l is the current determined by the contribution of the flow of Ga^+ ions from the disc surface in the solution; i_{kin} is the current determined by the flow of Ga^+ ions spent for the disproportionation; k_s is the stability coefficient of Ga^+ ions; N is the efficiency coefficient of the rotating disc–ring electrode (0.418 in the given case); n_d and n_r are the numbers of electrons involved in the processes at disc and ring electrodes, respectively; and i_d is the disc current.

The results of the calculation are given in Table 1.

As seen from Table 1, the current i_l increases with the disc current i_d. As a result, i_{kin} increases owing to an increase in the concentration of Ga^+ ions in the bulk of the solution. The k_s values in the range of disc currents 0.0–4.0 mA do not exceed 0.85. This means that, under the given conditions, approximately 40% of univalent gallium ions do not reach the ring owing to the disproportionation

$$3Ga^+ \rightarrow 2Ga^0 + Ga^{3+}, \quad (6)$$

Reaction (6) is exothermic. With increasing temperature, its equilibrium will be shifted to the left toward the formation of Ga^+ ions. Therefore, in this study we examined the gallium ionization (i_d = 2.0 mA) in a 0.5 M LiCl solution in 100% CH_3COOH at 20, 25, 30, 35, 40, 45, and 50°C. The results obtained are given in Table 2 and Figs. 2 and 3.

The polarization curves presented in Fig. 2 show that the limiting current of the disc electrode in the temperature range 20–50°C increases (curves *1–4*). The current of the first stage, formation of Ga^+ ions, increases, reaching a maximum of 1.36 mA at 35°C, i.e., it is close to the disc current, i_{kin} = 0.64 mA, and k_s approaches 0.68 (Table 2, Fig. 3).

Consequently, at 35°C the anodic dissolution of gallium in a 0.5 M solution of LiCl in 100% CH_3COOH goes solely to the univalent state, and the Ga^+ ions are the final product of the electrode

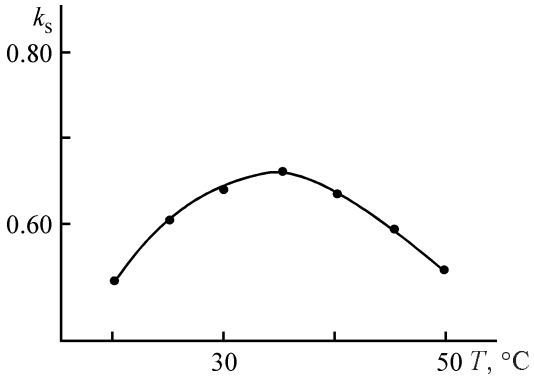

Fig. 3. Stability coefficient k_s of Ga^+ ions vs. temperature T.

reaction. In accordance with [6, 7], a decrease in the limiting current of the oxidation of Ga^+ ions and in k_s (Figs. 2, 3) at 45 and 50°C is apparently due to the increase in the rate of Ga^+ oxidation with hydrogen ions:

$$Ga^+ + 2H^+ \rightarrow Ga^{3+} + H_2. \quad (7)$$

The Ga^+ ions are unstable toward the hydrogen ions, because the standard potential of the Ga^0/Ga^{3+} couple is –0.62 V [8]. Thus, it was established that, in the course of anodic dissolution of gallium, the electrochemical ionization of gallium to Ga^+ is accompanied by subsequent disproportionation (6) with the formation of gallium ions of the highest valence and metallic gallium.

CONCLUSIONS

(1) By taking the polarization curves in a solution of LiCl in anhydrous acetic acid at a rotating disc–ring electrode, it was found that the anodic dissolution of gallium yields Ga^+ ions, which are not oxidized on the gallium disc and can be detected by the oxidation at the ring electrode.

(2) The anodic dissolution of gallium proceeds in two steps: electrochemical process and chemical disproportionation in the bulk of the electrolyte.

Received November 26, 2007

Abstract—The kinetics of oxidation of CH_4 to formaldehyde on the catalytic system $Na_4[PFeMo_{11}O_{40}]/SiO_2$ were studied, and a significant role of the redox potential of the CH_4–O_2 system with respect to the catalyst was shown. The density of centers participating in the reaction was determined, and dissociative competitive adsorption of methane and oxygen was established. The equation was deduced in the framework of the Langmuir–Hinshelwood theory taking into account the side conversion of formaldehyde. Possible participation of lattice oxygen in the reaction was suggested.

DOI: 10.1134/S1070427208090188

It was shown previously [1, 2] that, in oxidation of methane-containing gases with atmospheric oxygen in the presence of heteropoly compounds of the 12th series containing two ambivalent metals, it is possible to increase the conversion of methane by a factor of 2, the yield of formaldehyde by a factor of 3, and the catalyst performance by a factor of 40 in comparison with the known results.

Proceeding with studies on partial oxidation of methane, we examined the kinetics and mechanism of reaction on the $Na_4[PFeMo_{11}O_{40}]/SiO_2$ catalyst.

Oxidation was performed at 650°C in a batch reactor operating under conditions of quasiequilibrium kinetics when the methane conversion in single pass did not exceed 0.1%. In practice. the chosen operation mode means that the reactor operates under conditions of pseudozero conversion of methane. To avoid any kinetic restrictions that could be imposed by a high conversion of oxygen, we took into account the degree of methane conversion at oxygen conversion less than 20%.

The data obtained (Table 1) allow us to make the following conclusions: (1) An increase in the partial pressure of the reactants results in an increase in the reaction rate; however, the effect of methane pressure P_{CH_4} is stronger; (2) variation of P_{CH_4}/P_{O_2} does not significantly affect the selectivity of formaldehyde formation (71–77%), which depends in this case on formation of by-products, CO and CO_2 [3].

It is well known [4] that the activity of the catalysts for partial oxidation of methane is directly related to their ability to stabilize the reduced surface centers, which act as oxygen promoters in the redox cycle under the conditions of a dynamic equilibrium.

To estimate the dynamic equilibrium at the catalyst surface, we studied oxygen uptake by the surface at 650°C by the procedure described in [5] (Table 2). To analyze the data, let us introduce several designations for the catalyst surface: μ (nmol g^{-1}), number of physically reduced centers; μ_0 (nmol g^{-1}), total number of centers capable of reduction; and θ_{red}, density (fraction) of reduced centers at the surface.

Our data show that the absolute values of the partial pressure of the reactants do not affect μ, but this quantity is affected by the ratio of these parameters. For example, the number of physically reduced centers varies from 15 to 65 for P_{CH_4}/P_{O_2} ratios equal to 0.5 and 8.0, respectively, whereas in the absence of oxygen μ_0 is equal to 350 nmol g^{-1}.

To elucidate the influence of reactants on reduction of the catalyst centers, we constructed a logarithmic dependence $\ln\theta_{red} = f(\ln P)$ (Fig. 1) on the basis of data presented in Table 2.

The slopes of the curves having opposite trends show that the reaction order with respect to oxygen and methane is close to 0.5, with the order with respect to oxygen being negative. These dependences

0.40	0.02	20.0	2.1	2.1	75	20	5

indicate that the redox potential of the CH_4–O_2 system relative to the catalyst plays a significant role. In other words, both reactants interact with the contact surface by the redox mechanism, and the influence of the partial pressure of the reactants on the reaction rate is caused by inhibition of desorption. It is evident that the dynamic equilibrium at the catalyst surface is reached in the point of intersection of the pressure dependences of the reduced center concentration and corresponds to $\ln P = -2$ (Fig. 1).

Thus, half-order dependence of θ_{red} on P_{CH_4}/P_{O_2} evidently suggests the dissociative competitive activation of methane and oxygen molecules at the surface centers of the catalyst, and its algebraic form is as follows: $\theta_{red} = (P_{CH_4}/P_{O_2})^{0.5}$ This means that two active centers can participate in chemisorption of each reactant.

In the latter case, at inhibited desorption, the following reactions can occur at the catalyst surface:

$$CH_4 + 2\mu_1 \rightarrow CH_2O + 2\mu_2, \quad (1)$$

$$O_2 + 2\mu_2 \rightarrow 2\mu_1, \quad (2)$$

where μ_1 is the number of oxidized centers and μ_2 is the number of reduced centers.

Under the conditions of dynamic equilibrium,

$$[\mu_1] + [\mu_2] = [\mu_0]. \quad (3)$$

Then, the rate of formation of reduced centers r_{red} can be written in the form

Table 2. Influence of the partial pressure of reactants on absolute μ and fractional θ_{red} densities of reduced centers on the catalyst surface

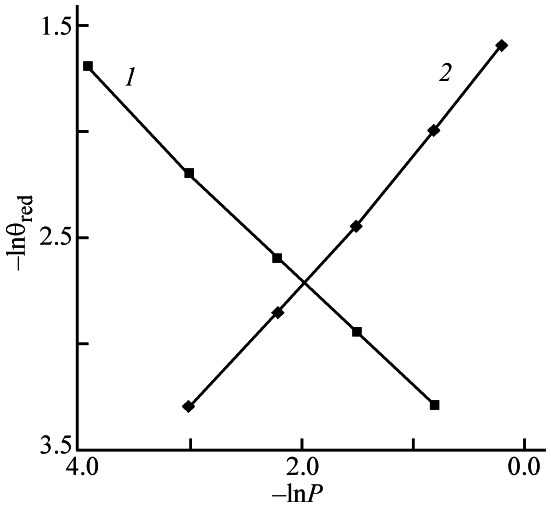

Fig. 1. Density of centers reduced at the surface θ_{red} as a function of (*1*) air and (*2*) methane pressure (log–log plots).

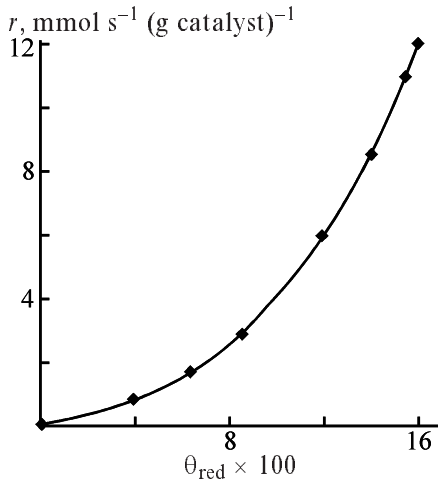

Fig. 2. Rate of methane oxidation r as a function of the fraction of centers reduced at the surface θ_{red}.

$$r_{red} = k_{red}P_{CH_4}(\mu_0 - \mu)^2. \quad (4)$$

It is well known [6] that the rate of surface diffusion of lattice oxygen ions in the SiO_2 support is negligible under the conditions of methane oxidation; however, the rate of their diffusion in phosphorus–iron–molybdenum catalyst is unknown. Based on some indirect data, it can be assumed that the catalyst fragment Mo=O donates its oxygen atom to the methyl radical to form surface methoxyl transforming into formaldehyde and methanol at elevated temperatures. At least, iron–molybdenum catalyst for oxidation of methanol into formaldehyde operates in such a way [7]. The released lattice oxygen is compensated by oxygen from the medium. However, at such a low conversion of methane (below 5%), the possible role of lattice oxygen cannot be neglected in deducing the rate equation. At the same time, the oxygen source cannot affect the rate equation since the inner balance with respect to oxygen is kept due to the compensating mechanism of its transformation. Then we assume that, under dynamic equilibrium, the rate of disappearance of reduced centers practically coincides with the rate of catalyst oxidation r_{ox}:

$$r_{ox} = k_{ox}P_{O_2}\mu^2. \quad (5)$$

Taking into account that $\theta_{red} = \mu/\mu_0$ and θ_{red} is limited by the condition $0 < \theta_{red} < 1$, the rates of reduction and oxidation of centers under dynamic equilibrium can be expressed as

$$k_{ox}P_{O_2}\mu^2\theta_{red} = k_{red}P_{CH_4}\mu_0^2(1 - \theta_{red})^2. \quad (6)$$

Solving Eq. (6) relative to θ_{red}, we obtain the following equation for the fraction (density) of reduced centers:

$$\theta_{red} = \frac{(k_{ox}/k_{red})^{0.5}(P_{CH_4}/P_{O_2})^{0.5}}{1 + (k_{ox}/k_{red})^{0.5}(P_{CH_4}/P_{O_2})^{0.5}}. \quad (7)$$

This expression corresponds to the experimental dependence $\theta_{red} = (P_{CH_4}/P_{O_2})^{0.5}$ under the condition that $k_{red}P_{CH_4}/k_{ox}P_{O_2} \ll 1$.

Treatment of data listed in Table 2 by the nonlinear regression analysis using Eq. (7) allowed estimation of k_{red}/k_{ox} at 4.5×10^{-3}. The value obtained suggests that the rate of catalyst oxidation is significantly higher than the rate of its reduction.

Since reactions (1) and (2) are irreversible, the rate of methane conversion r_{CH_4} under dynamic equilibrium should be equal to the rate of these two stages: $r_{CH_4} = r_{ox} = r_{red}$. Then, the oxidation rate can be expressed through Eqs. (4) and (5):

$$r_{CH_4} = k_{ox}P_{O_2}\mu_0^2\theta_{red}^2 = k_{red}P_{CH_4}\mu_0^2(1 - \theta_{red})^2. \quad (8)$$

The resulting dependence of the rate of methane oxidation is mathematically identical to the expression for second-order equation where one of the functions is θ_{red}. Indeed, this conclusion is confirmed by the experimental dependence shown in Fig. 2.

Substituting θ_{red} from Eq. (7) into Eq. (8) and solving these equations with respect to the oxidation rate, we obtain the following expression:

$$r_{CH_4} = \mu_0^2\frac{k_{red}P_{CH_4}}{[1 + (k_{red}P_{CH_4}/k_{ox}P_{O_2})^{0.5}]^2}. \quad (9)$$

Analyzing expression (9) from the mathematical standpoint, we can note that, at the ratio $P_{CH_4}/P_{O_2} \to \infty$, the model predicts zero reaction rate. Further, from the equation it follows that the reaction order with respect to P_{CH_4} is fractional, especially at high P_{CH_4}/P_{O_2} ratios, since with increasing methane content the degree of reduction of the catalyst surface increases. This naturally results in decreasing concentration of oxidized centers responsible for activation of methane.

The reliability of the kinetic model was confirmed by comparing the experimental and theoretical data. Nonlinear regression analysis of the curve presented

in Fig. 2 gives k_{red} and k_{ox} equal to 9×10^{7} and 4.5×10^{-3} mol s^{-1} atm^{-1}; in this case, k_{red}/k_{ox} is equal to 4.5×10^{-3}. Good agreement between the calculated and experimental data supports our kinetic model.

However, it is necessary to consider one more aspect of this problem, namely, oxygen consumption for secondary transformations of formaldehyde (to carbon oxide and carbon dioxide). According to published data [8], oxidation of CO to CO_2 proceeds at a significantly lower rate than conversion of formaldehyde to carbon oxide; therefore, we took into account one more reaction pathway:

$$CH_2O + \rho_1 \rightarrow CO + H_2O + \rho_2. \quad (10)$$

In the total rate of oxygen consumption, we considered two pathways: major and secondary, which can be described mathematically in the following way:

$$r_{O_2} = r_{CH_4}(1 + S_{CO}\alpha), \quad (11)$$

where α is the stoichiometric coefficient in reaction (10).

Continuing mathematical transformations and substitutions, we can obtain from Eq. (7) the following expression:

$$\theta_{red} = \frac{[(1+n)(k_{ox}/k_{red})]^{0.5}(P_{CH_4}/P_{O_2})^{0.5}}{1+[(1+n)(k_{ox}/k_{red})]^{0.5}(P_{CH_4}/P_{O_2})^{0.5}}, \quad (12)$$

where $n = S_{CO}\alpha$.

Substituting complete expression for θ_{red} (12) in Eq. (8), we obtain the following equation for rate of methane oxidation:

$$r_{CH_4} = \rho_2^0 \frac{k_{red}P_{CH_4}}{\{1+[(1+n)(k_{ox}/k_{red})]^{0.5}(P_{CH_4}/P_{O_2})^{0.5}\}^2}. \quad (13)$$

This expression shows not only the dependence of the reaction rate on the partial pressures of reactants but also inverse dependence of the reaction selectivity: the larger the amount of CO formed, the deeper the reduction of the catalyst surface, which results in decreased rate of the main reaction. It should be noted that the very low k_{red}/k_{ox} ratio in the examined range of P_{CH_4}/P_{O_2} is not a significant factor, since higher value of k_{ox} does not noticeably affect the reaction rate due to pseudo-first order of the reaction rate with respect to methane. On the contrary, at high P_{CH_4}/P_{O_2} ratios, the reaction rate should increase and its dependence on P_{O_2} should be insignificant. In practice this means that the concentration of sorbed methane, rather than the concentration of the oxidizing agent, becomes important. This is quite logical since the rupture of the CH_3–H bond in chemisorption of methane is the limiting stage. In addition, in formation of CH_3O the source of oxygen is presumably lattice oxygen.

Thus, it can be concluded that oxidation of methane to formaldehyde at the surface of $Na_4\cdot[PFeMo_{11}O_{40}]/SiO_2$ catalyst proceeds by a concerted mechanism involving activation of gas-phase oxygen at the surface of reduced catalyst centers and subsequent its addition to activated molecule of methane. Compensation of lattice oxygen with molecular oxygen is equally probable, especially because this process on heteropoly compounds proceeds instantaneously [9]. The latter factor suggests that the role of lattice oxygen is more significant than it was believed previously. Since completion of the lattice with oxygen is not the activated stage of the process [10], experimental consideration of its role without using special methods is difficult. In this case, one could rely on the published data [11, 12] obtained using an isotopic label. Unfortunately, these results are ambiguous because they do not allow determination of the nature of the oxygen source. In addition, based on these data, we might prefer the version of "intercalation" of molecular oxygen. However, this conclusion is not well-founded, since the content of ^{18}O in the catalyst was not determined after the reaction completion.

The only confirmation of the participation of lattice oxygen in the process is the experiment in which oxygen-free methane was passed through a catalyst bed with increased content of acting base (up to 10%). Among reaction products, traces of formaldehyde were found and the reaction quickly ceased. However, after contact of the catalyst with atmospheric oxygen, the contact activity was restored and formaldehyde was found among the reaction products again.

These data suggest that oxidation of methane can proceed, at least partially, due to participation of lattice oxygen whose consumption is compensated by oxygen from the reaction medium.

CONCLUSIONS

(1) In studying the kinetics of methane oxidation to formaldehyde, it was found that the redox poten-

tial of the CH_4–O_2 system relative to the catalyst plays a significant role, and the dissociative competitive adsorption of methane and oxygen was suggested.

(2) The reaction rate depends on the partial pressure of methane and is inversibly proportional to the reaction selectivity, due to deep reduction of the surface with carbon monoxide formed as by-product.

(3) The experimental data and especially the features of the behavior of all heteropoly compounds suggest that lattice oxygen of the heteropoly compound participates in the reaction; the vacancy formed is filled with oxygen of the reaction medium.

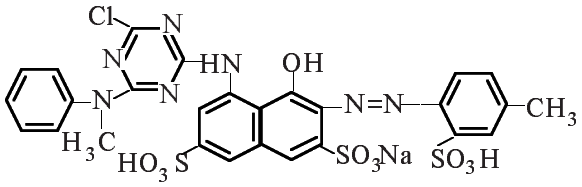
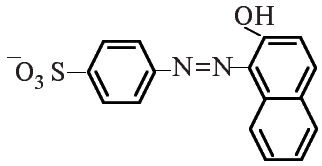
Abstract—Degradation of Direct Red 23, Rective Red 45, and Orange II azo dyes with hydrogen peroxide and hydroperite in the presence of cationic surfactants alkyldimethylbenzylammonium chloride (Katamin AB) and cetyltrimethylammonium chloride and without them was studied by spectrophotometry. The reactivity of the azo dyes was correlated with their chemical structure.



DOI: 10.1134/S107042720809019X

Azo dyes occupy the leading place in the total volume of commercially produced synthetic dyes and are widely used in various branches of industry. On the one hand, azo dyes should be resistant to various oxidants (e.g., under laundering conditions), and on the other hand, their degradation in industrial wastewater treatment is an urgent problem [1]. Also, studies of the behavior of azo dyes in redox processes in the presence of surfactants are topical [2, 3].



In this study we examined oxidation of commercial azo dyes Direct Red 23, Reactive Red 45, and Orange II with hydrogen peroxide and urea peroxide (hydroperite) in the presence of cationic surfactants alkyldimethylbenzylammonium chloride (Katamin AB) and cetyltrimethylammonium chloride (CTAC) and without them.

C.I. Direct Red 23 **(I)**

C.I. Reactive Red 45 **(II)**

Orange II, Aldrich **(III)**

EXPERIMENTAL

The dyes were purified by recrystallization from ethanol to constant extinction coefficient. At pH 5.9, ε was as follows ($l\,mol^{-1}\,cm^{-1}$): for dye **I**, 34300 (λ_{max} = 496 nm); for dye **II**, 24700 (λ_{max} = 542 nm); and for dye **III**, 22000 (λ_{max} = 484 nm).

Hydrogen peroxide (40% solution) was of chemically pure grade. Hydroperite was synthesized by the procedure described in [4] without adding stabilizers. The hydrogen peroxide content in hydroperite, determined by permanganatometric titration [5], was 35.2%, which corresponded to 97.2% content of $(NH_2)CO\cdot H_2O_2$. The concentrations of peroxides

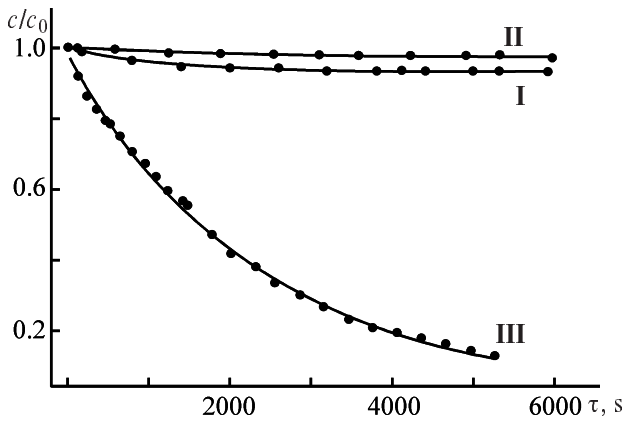

Fig. 2. Kinetic curves of oxidation of azo dyes with hydrogen peroxide. $[H_2O_2]$ = 0.05 M, 298 K, pH 11.0, initial dye concentration 3.3×10^{-5} M. (τ) Time.

are given in terms of H_2O_2.

The concentrations of Katamin AB and CTAC were determined by two-phase titration [6]. The critical micelle concentration (CMC) was determined by the maximal bubble pressure method [5] on a Rebinder installation. For both surfactants, CMC was 9.1×10^{-4} M, in agreement with the published data [7]. All surfactant solutions at the examined temperatures and concentrations were transparent, without apparent turbidity. The metal content of the detergents used, determined by atomic absorption spectroscopy on a Saturn-2 device, was as follows (%): Fe <0.00016, Cu <0.0002, and Ni <0.0002.

The absorption spectra were recorded on KFK-2 and Specord M40 devices. The concentration of the dyes was varied within $(1.6–5) \times 10^{-5}$ M.

Experiments on oxidation of Direct Red 23, Reactive Red 45, and Orange II azo dyes were performed at wavelengths of 490, 540, and 490 nm, respectively. Kinetic curves were analyzed with the OriginPro 6.0 software. The pK values of the azo dyes were determined by the standard procedure of spectrophotometric titration [8]. For azo dyes **I** and **II**, a hypsochromic shift of the electronic spectra in going from neutral to both acidic and alkaline solutions was observed (Fig. 1). For dye **I**, pK_1 3.58±0.15 and pK_2 12.30±0.12; for dye **II**, pK_1 3.81±0.09 and pK_2 8.02±0.21. For dye **III**, pK 11.22±0.11, in agreement with published data [2, 9]. In alkaline solutions, hydroxy and sulfo groups undergo ionization, and in acid solutions, amino and carbonyl groups are protonated [10, 11].

The kinetic curves of the oxidation of azo dyes with hydrogen peroxide are shown in Fig. 2. For all the three azo dyes, the reaction is first-order with respect to the dye. The reaction order with respect to hydrogen peroxide for Orange II dye is also first [12]. Figure 2 shows that the reaction rate is strongly affected by the structure of the azo dye: dye **III** is oxidized fairly readily, whereas dyes **I** and **II** under the reaction conditions are resistant to hydrogen peroxide. This trend was observed in the entire examined pH range (9.5–12.0).

Different resistance of the dyes to hydrogen peroxide is accounted for by their structural state in solution. It is known that dye **III** in aqueous solutions mainly occurs in the hydrazone form [9] and has a quinoid structure. The aromaticity of the quinoid ring is distorted, and this ring is less resistant to oxidants. Azo dye **III** is oxidized especially readily in the deprotonated form in which it occurs in alkaline solutions. It was shown previously that the pH dependence of the rate constant has a pronounced maximum at about 11.2, due to close pK values of hydrogen peroxide and the dye. Dyes **I** and **II** contain a bulky sulfo group in the *o*-position to the azo group. In these compounds, the planarity of the dye molecule is distorted and formation of the quinone hydrazone structure is hindered [10, 11].

In addition, the reaction of dyes **I** and **II** with HO_2^- is hindered by the larger, compared to **III**, number of negatively charged substituents.

Axo dyes **I** and **II** are also very resistant to such a strong oxidant as peracetic acid (PAA). Figure 3 shows the experimental kinetic curves of the oxidation of the dyes with hydrogen peroxide and PAA under similar conditions. Complete decolorization of dye solutions with peracetic acid was attained

only in 5 days. The higher reactivity of dye **I** compared to **II** is due to the presence in **I** of two carbonyl groups decreasing the mobility of the hydrogen atoms of the electron-donor NH_2 and OH groups. As a result, the dye molecule becomes more nucleophilic and more reactive toward PAA as electrophilic agent.

In industry, redox systems with azo dyes often also contain surfactants. Therefore, we examined the influence of surfactants on the behavior of azo dyes in aqueous solutions of various acidities. Experiments were performed in the presence of cationic surfactants Katamin AB and CTAC. It was shown previously that anionic and nonionic surfactants do not affect the oxidation of azo dyes [2].

Additions of Katamin AB in concentrations of $(2–2.5) \times 10^{-4}$ M to Orange II azo dye [$(2–3.5) \times 10^{-5}$ M] at pH 6.0–12.8 lead to aggregation of the dye particles. The resulting suspension of particles gradually settles, and the solution decolorizes. At pH 9.2, the aggregation and sedimentation are slow: In 3 h, the optical density decreased by 10%, and in 24 h, by 40% of the initial level. With an increase in the basicity of the medium and especially in strongly alkaline solutions, the association was faster: At pH 12.7, the optical density decreased by almost 20% in 40 min. At other concentrations of Katamin AB (above and below this interval), in the entire range of pH, aggregation and precipitation of the dye were not observed even in 100–120-h period; with CTAC, they were not observed either.

With dyes **I** and **II**, additions of Katamin AB (1×10^{-4}–2.5×10^{-3} M) in the pH range 8.0–12.5 cause formation of floccules which do not pass into the solution on stirring. The optical density of the dye solutions decreased in 40 min by 7–17% on the average, depending on the surfactant concentration and pH. With an increase in pH of solutions, the aggregation accelerated, probably owing to an increase in the concentration of the deprotonated dye species. Further experiments on the effect of surfactants on the redox processes were performed only with Orange II dye.

We found that the Bouguer–Beer law was observed in the entire examined ranges of pH and surfactant concentrations. The cationic surfactants used exert essentially equal effect on the kinetic parameters of the reaction. The reaction orders with respect to the oxidant (hydroperite) and azo dyes were the same as in the reaction without surfactant. In the presence of a surfactant, the reaction rate

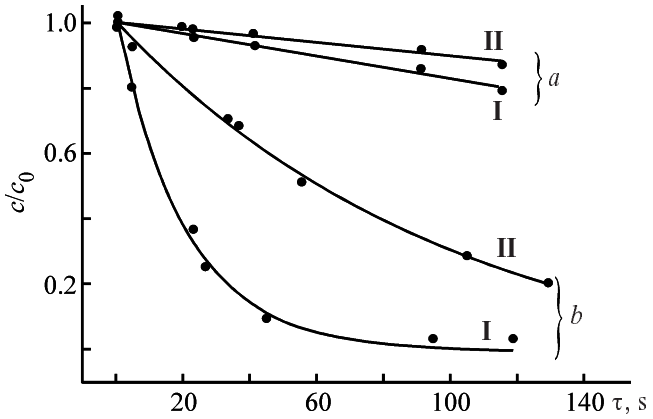

Fig. 3. Kinetic curves of oxidation of dyes **I** and **II** with (*a*) hydrogen peroxide and (*b*) peracetic acid. $[H_2O_2]$ = 0.1 M, $[CH_3COOOH]$ = 0.1 M, 298 K, pH 1.0; solvent 50% acetic acid; initial dye concentration 3.3×10^{-5} M. (τ) Time.

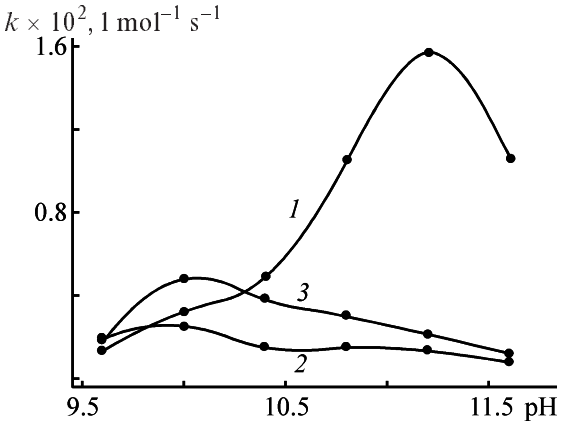

Fig. 4. pH dependence of the rate constant k of oxidation of Orange II azo dye with hydroperite at 298 K. Concentration, M: dye 2×10^{-5} and hydroperide 0.05. Surfactant (1×10^{-3} M): (*1*) none, (*2*) CTAC, and (*3*) Katamin AB.

maximum shifted to pH 10.0, and in the presence of Katamin AB the oxidation rate was slightly higher than without it (Fig. 4).

We found that the surfactant additions did not affect the reactivity of hydroperite: The concentration loss in an alkaline solution (pH 11.2) at room temperature in the presence of 1×10^{-3} M surfactant in 3 h did not exceed 5%. Hence, it can be assumed that the effect of a surfactant on the kinetics of the redox reaction is fully due to its interaction with the dye (Fig. 5). From the electronic absorption spectra of the dye in the presence of a surfactant, we calculated pK_{app} of Orange II dye (see table).

Surfactant additions alter the acid–base properties of the dye owing to formation of a dye–cationic surfactant complex. The apparent constant of for-

Influence of cationic surfactant concentration c on pK_{app} of Orange II dye

mation of the micellar complex can be determined by the equation [13]

$$K_H^{app} = K_H(1 + K_2[M])/(1 + K_1[M]),$$

where $K_H = [HA]/[H^+][A^-]$ (quantity reciprocal to the dye dissociation constant; [HA] and $[A^-]$ are the concentrations of the protonated (acidic) and deprotonated (basic) forms of the dye; M is a surfactant micelle; $K_1 = [M–A^-][M]^{-1}[A^-]^{-1}$; $K_2 = [M–HA] \times [M]^{-1}[HA]^{-1}$; $[M–A^-]$ is the concentration of the micellar complex of a surfactant with the deprotonated form of the dye, and [M–HA] is that of the micellar complex of a surfactant with the protonated form of the dye.

The relationship between K_H^{app} and K_H depends on K_1 and K_2. Cationic surfactants are characterized by high K_a values. With an increase in the cationic surfactant concentration and hence in [M], K_H^{app} increases, and since $K_{app} = 1/K_H^{app}$, pK_{app} decreases, as also does the oxidation rate. This is characteristic of strongly alkaline solutions in which the concentration of the deprotonated form of the dye is high. In more acidic solutions (pH ≤ 10), the reaction rate, on the contrary, slightly increases owing to a decrease in the concentration of the deprotonated dye species interacting with the cationic surfactant.

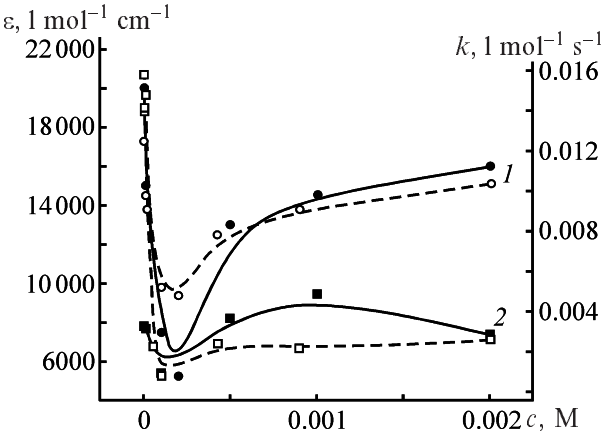

Fig. 5. (*1*) Molar extinction coefficient at λ = 490 nm ε_{490} of Orange II dye and (*2*) rate constant k of the reaction of the azo dye with hydroperite as functions of the Katamin AB concentration c at pH 10 (solid line) and 11.2 (dashed line); hydroperite concentration 0.05 M, 293 K.

CONCLUSIONS

(1) The pK values of Direct Red 23 and Reactive Red 45 azo dyes were determined.

(2) The reactivity of azo dyes in redox processes depends on their chemical structure. Bulky substituents in the *o*-position to the azo group make the dyes resistant to oxidative degradation.

(3) Addition of cationic surfactants leads to the formation of micellar complexes with Orange II dye, to a decrease in its pK_{app}, and, correspondingly, to a decrease in the rate of the dye oxidation in the presence of surfactants in strongly alkaline solutions.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Rheological Properties of a Peat–Polymer Paste Used to Obtain High-Strength Granulated Activated Carbons

Received January 16, 2008

Abstract—Rheological properties of a peat–polymer paste used for fabrication of high-strength granulated activated carbons were studied. A Tolstoi device was used to obtain dependences of the shear strain of a paste sample on the time of application and removal of a load at shear stresses of 2–60 kPa. These dependences make it possible to choose parameters of the rheological model of the paste and to evaluate its structural-mechanical properties.

DOI: 10.1134/S1070427208090206

Peat-based granulated activated carbons are effective in numerous sorption processes used in environment protection [1]. The most popular in the Russian market are domestic peat-based activated carbons of the SKT brand and activated carbons manufactured by NORIT company (Netherlands). Development of new peat-based activated carbons is a rather promising area in the technology of carbon adsorbents [2].

Peat is a widely occurring, readily available, and inexpensive raw material having the form of a multicomponent system with a complex colloid-chemical composition. It interacts with widely diverse organic and inorganic substances to give structures with pronounced plastic properties [3] which enable effective granulation [4]. An important quality parameter of activated carbons is their wear resistance: technologically, it determines the loss of a sorbent and its service life, and ecologically, affects the environment contamination by dustlike fractions of the sorbent, which commonly contain a wide variety of toxicants. At the same time, the strength characteristics of most of peat-based activated carbons are far from being perfect [4–7].

The technique developed for manufacture of high-strength activated carbons with a developed porous structure uses a formulation produced by mixing a viscous binder (waste thermoplastic polymer) with powdered raw materials of vegetable origin or peat. The formulation is produced in a screw apparatus [8]. The cylindrical grains of activated carbons produced by this technique (diameter 1–5 mm) are characterized at a 30–40% combustion loss by a wear resistance exceeding 95%, total porosity for water of 0.6–0.8 $cm^3 g^{-1}$, and sorption pore volume for benzene of 0.45–0.7 $cm^3 g^{-1}$ [8].

Generally speaking, the term "paste" is not strict. It can be used to name any viscous-elastoplastic (pasty) bodies, irrespective of their structure, composition, and use [9]. Reliable construction of a phenomenological model of the rheological behavior of the paste (macroscopic rheological model) requires a detailed evidence about the structure of the paste and processes occurring therein. At the same time, a knowledge of the macroscopic model of the rheological behavior of a paste can give insight into the type of its structure and processes occurring in it [10]. Phenomenological models of the rheological behavior, developed for numerous materials, make it possible to determine, using various instruments and, in particular, plastometers and viscometers, the optimal conditions of paste molding [10–14]. The molding conditions largely determine the strength properties of granulated activated carbons [6].

The mass fraction of peat in the resulting formulation [8] is many times that of the binder. Such a substance more likely belongs to peat pastes, rather than to filled polymers. The rheological properties of peat are closely related to its chemical composition, its moisture content, and presence of plasticizing additives [3, 14, 15]. Medium-watered peat (of vari-

ous brands) behaves as a Bingham liquid [14], whereas the behavior of peat with lowered moisture content is characterized, until the appearance of plastic deformations, by existence of elastic deformations. Peat with lowered moisture content mostly exhibits elastic and viscoelastic deformations. Peat with a high degree of decomposition tends to manifest plastic deformations to a greater extent than does the high-moor little-decomposed peat [3, 14].

The structure of the peat paste used to produce high-strength activated carbons in the technique suggested in [8] is apparently considerably more complex than that of the known peat pastes not only because both the binder and dispersed phase are multicomponent and the dispersed phase (peat) is a capillary-porous material, but also due to the occurrence of chemical reactions in the paste [8]. Thus, evaluation of the rheological properties of the paste under consideration is exceedingly important both for developing approaches to analysis of its structure and for determining the molding conditions. This evaluation was done using a Tolstoi device [16].

EXPERIMENTAL

Samples of freshly prepared pastes ($50 \times 20 \times 4.8$–5.5 mm) were tested on a Tolstoi plastometer with an IPG-10 mechanical plate shift indicator. A stopwatch served to measure time. The normal component of the load was zero. The tangential stresses in the course of a run were maintained within the range from 2 to 60 kPa. The time of paste keeping under a load was 900 s. The reverse deformations (after removing the load) were also measured during 900 s.

Time dependences of the relative shear strain are shown in Fig. 1. Each dependence is a generalized result of three parallel runs at a relative error of 0.7–0.85%. The general forward (under a constant load) and reverse (after removing the load) runs of the curves indicate that there are reversible and irreversible deformations of the pastes. The reverse deformations are wholly elastic-aftereffect strains (highly elastic strains) obeying the Kelvin model:

$$\Delta\gamma_{rev}(t) = \tau G_{hel}^{-1} \exp[(t_{for} - t)/\theta],$$

where $\Delta\gamma_{rev} = \gamma_0 - \gamma(t)$ is the change in the reverse-run strain; γ_0, maximum strain reached in the course of an experiment under a constant load; $\gamma(t)$, strain by instant of time t; τ, tangential stress; G_{hel}, elastic shear modulus (elasticity modulus in a Kelvin body); θ, delay time. $\theta = \mu/G_{hel}$; μ, viscosity of

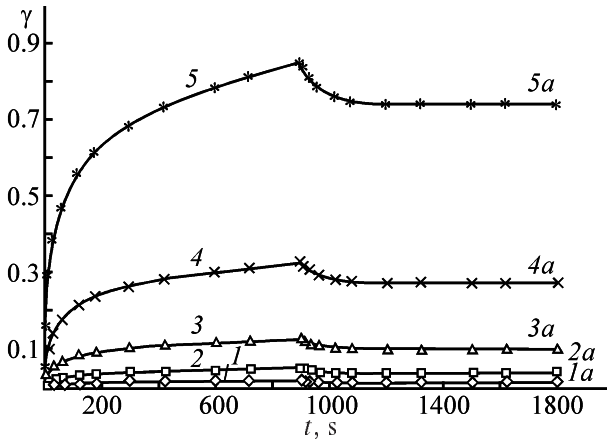

Fig. 1. Shear strain γ vs. time t. Shear stress, Pa: (*1*) 2453, (*1a*) after relieving 2453, (*2*) 4905, (*2a*) after relieving 4905, (*3*) 9810, (*3a*) after relieving 9810, (*4*) 19620, (*4a*) after relieving 19620, (*5*) 39240, and (*5a*) after relieving 39240.

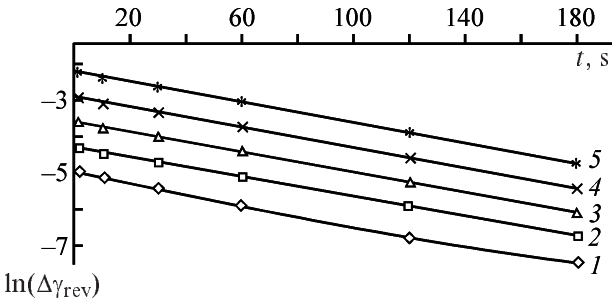

Fig. 2. Dependence of the reverse shear strain γ_{rev} on time t elapsed after relieving the load, plotted in semilog coordinates. Initial shear stress, Pa: (*1*) 2453, (*2*) 4905, (*3*) 9810, (*4*) 19620, and (*5*) 39240.

a Newton element in a Kelvin body (viscosity of the elastic aftereffect); and t_{for}, time of the forward run of a curve (time of paste exposure to a load).

This follows from Fig. 2 which shows dependences of the logarithm of reverse strains, $\ln(\Delta\gamma_{rev})$, on the time elapsed after relieving a constant load. The dependences in Fig. 2 are linear (the corresponding regression equations are given in the table). According to the data in the table, the average values of G_{hel}, θ, and μ are 362650 Pa, 69 s, and 25022920 Pa s, respectively. With account of the data obtained, the contribution of elastic strains $\gamma_{hel}(t)$ under a load can be evaluated by the formula

$$\gamma_{hel}(t) = \tau(362650)^{-1}[1 - \exp(-t/69)].$$

Figure 3 shows time dependences of the forward-run irreversible strains of the pastes, obtained in accordance with the Boltzmann superposition principle [18] by subtracting the forward-run strain of

Regression characteristics of highly elastic and irreversible strains of the paste under study [17]. Equations of the macroscopic rheological model $\ln \Delta\gamma_{rev}(t) = \ln(\tau G_{hel}^{-1}) + (900 - t)/\theta]$, $\ln \Delta\gamma_{irr}(t) = \ln C + \beta \ln \tau + n \ln t$

Shear stress, Pa	Regression equations	Correlation coefficient
2453	$\ln[\Delta\gamma_{rev}(t)] = -0.0145 \ln(900 - t) - 5.0358$	0.9959
4905	$\ln[\Delta\gamma_{rev}(t)] = -0.0140 \ln(900 - t) - 4.3129$	0.9999
9810	$\ln[\Delta\gamma_{rev}(t)] = -0.0144 \ln(900 - t) - 3.6078$	0.9997
19620	$\ln[\Delta\gamma_{rev}(t)] = -0.0145 \ln(900 - t) - 2.9088$	1
39240	$\ln[\Delta\gamma_{rev}(t)] = -0.0146 \ln(900 - t) - 2.2189$	0.9999
2453	$\ln[\Delta\gamma_{irr}(t)] = 0.2190 \ln t - 5.7807$	0.9976
4905	$\ln[\Delta\gamma_{irr}(t)] = 0.2188 \ln t - 4.7915$	0.9995
9810	$\ln[\Delta\gamma_{irr}(t)] = 0.2223 \ln t - 3.8112$	1
19620	$\ln[\Delta\gamma_{irr}(t)] = 0.2219 \ln t - 2.8120$	1
39240	$\ln[\Delta\gamma_{irr}(t)] = 0.2119 \ln t - 1.8140$	1

the Kelvin body from the total strain:

$$\gamma_{irr} = \gamma(t) - \gamma_{hel}(t),$$

where $\gamma_{irr}(t)$ is the irreversible strain by instant of time t, and $\gamma_{hel}(t) = (\tau/G_{vel})[1 - \exp(-t/\theta)]$. It can be seen that the final portions of the forward run of the flow curves are lines with a nearly constant slope.

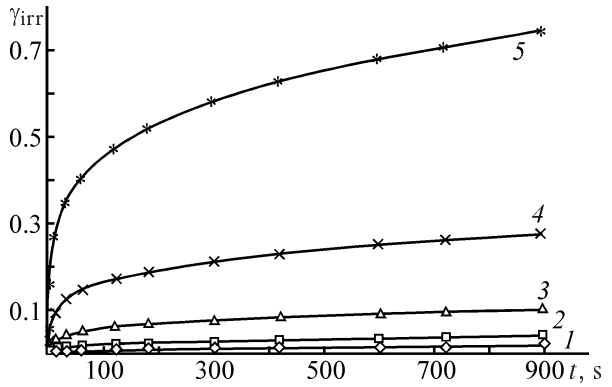

Fig. 3. Irreversible strains γ_{irr} vs. time t. Shear stress (Pa): (*1*) 2453, (*2*) 4905, (*3*) 9810, (*4*) 19620, and (*5*) 39240; the same for Fig. 4.

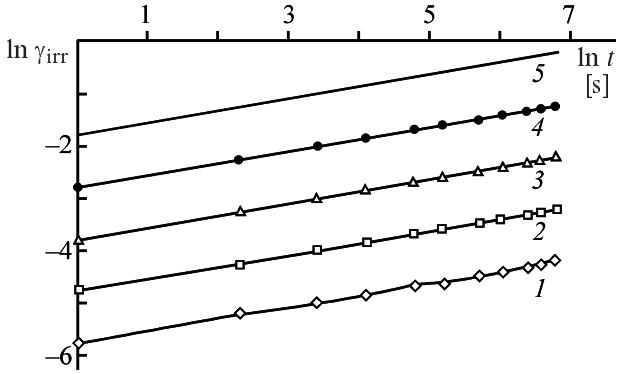

Fig. 4. Dependence of the irreversible strains γ_{irr} on time t, plotted in log–log coordinates.

However, there is no linear relationship between the slope of these portions and the applied load, and the intercepts made on the ordinate axis by straight lines coinciding with the final portions of the flow curves are smaller than the total irreversible strain at any load. Therefore, the irreversible strains are not Newtonian. At a constant load, the curves in Fig. 3 are linearized in logarithmic coordinates (Fig. 4). The corresponding regression equations $\ln[\gamma_{irr}(t)] = n \ln t + b$ are presented in the table.

The ordinate b at zero abscissa is expressed by the formula

$$b = \ln C + \beta \ln \tau$$

where $C = 4.38 \times 10^{-8}$ and $\beta = 1.43$.

The dependence obtained is in agreement with concepts of the creep theory [18, 19], and the creep function of the material under study, $\Phi(\tau, t)$, has the form corresponding to the empirical Nutting equation $\psi(\tau, t) = C\tau^{\beta} t^{p}$ [19–21], which describes the behavior of numerous polymers in the range between the brittle and vitrification points. Thus,

$$\gamma_{hel}(t) = \tau(362\,650)^{-1}[1 - \exp(-t/69)],$$

$$\gamma_{irr}(t) = \psi(\tau, t) = 4.38 \times 10^{-8} \tau^{1.43} t^{0.22}.$$

To estimate the total shear strain of a freshly prepared paste by instant of time t under the action of a constant stress τ, the following equation can be recommended:

$$\gamma(t) = \tau(362\,650)^{-1}[1 - \exp(-t/69)] + 4.38 \times 10^{-8} \tau^{1.43} t^{0.22}.$$

The resulting model of the deformation behavior of pastes enables important practical comparisons and evaluation of the structural-mechanical proper-

ties of the paste. According to the data of [3], the total shear strain γ of water–peat pastes at a tangential stress τ is equal to the sum of the initial (conditionally instantaneous) strain γ_0, elastic-aftereffect strain

$$\gamma_{hel} = \gamma_0 K \log(1 + t),$$

and irreversible plastic strain

$$\gamma_{irr} = (\tau - \tau_s)t/\mu_0,$$

where K is a constant; τ_s, limiting shear stress; and μ_0, plastic viscosity. That is,

$$\gamma = \gamma_0[1 + K\log(1 + t)] + (\tau - \tau_s)t/\mu_0.$$

The model of the rheological behavior of the peat–polymer paste, obtained in the same range of loads, differs from the model of rheological behavior of water–peat pastes in its physical essence and in the contribution of strains of each kind to the total strain. At $\tau < \tau_s = 2000–3000$ Pa, peat behaves as a elastic-viscoelastic body [3] and the paste under study manifests even at these stresses high creep strains whose contribution to the total strain is about 70–80%. At $\tau > \tau_s = 2–3$ kPa, peat flows at a constant viscosity ($\mu_0 = 10^4–10^5$ Pa s), whereas nearly instantaneous pronounced irreversible strains appear ($\Delta\gamma_{irr} = 0.1–0.3$) in the paste under study. Their buildup rate decreases to $(1–2.5) \times 10^{-4}$ s^{-1} during several tens of seconds, and the effective viscosity reaches values of $(1.6–1.9) \times 10^8$ Pa s 50–150 s after the load is applied. The calculated parameter exceeds by 3–4 orders of magnitude the plastic viscosity of peat, is 1–2 orders of magnitude lower than that of molding ceramic masses, and is at about the same level as the viscosity of melts of such polymers as polyethylene, polypropylene, and polystyrene [13]. The elastic modulus G_{hel} is smaller than the same parameter for the ceramic raw material and is the closest to the high-elasticity modulus of polymers within the range between the vitrification and flow points (nearly equal to that of polystyrene at 110–120°C) [13] or to the elasticity modulus of bakery dough [10]. The delay time θ is of the same order of magnitude as that of molding ceramic masses. The experimental plasticity index $p = 0.222$ is almost equal to the same parameter of bitumen–mineral formulations [21].

The deformation behavior of pastes under an external macroscopic load applied to a sample is based on numerous internal physical and colloid-chemical microscopic processes involving separate particles or aggregates of particles in the paste, accompanied by energy accumulation or dissipation [22]. In these two limiting cases of motion of microscopic particles, the plasticity index will be zero and unity, respectively. In the first case, the work of external forces is expended for elastic deformation leading to reversible macroscopic strains. In the second, it is expended for overcoming the internal friction in motion of separate molecules, causing irreversible macroscopic strains. The elastoplastic flow of a number of homogeneous materials (composed of identical particles) is regarded as an intermediate kind of particle motion, and the plasticity index p (power to which time is raised in the Nutting equation) corresponds to the fraction of particles executing the required displacements. The stress can be formally divided into two components causing elastic and plastic deformations. Using this approach, Rudenskii and Rudenskaya [21] suggest the following expressions for evaluating the instantaneous plastic and elastic strains:

$$\gamma_{pl}(t) = t[d\gamma(t)/dt] = p\gamma(t),$$

$$\gamma_{el}(t) = \gamma(t) - t[d\gamma(t)/dt] = (1 - p)\gamma(t).$$

According to Nechiporenko [11], the structural-mechanical type of a paste is determined by the contribution of elastic, viscoelastic, and plastic deformations developed in the paste by the instant of time $t = 1000$ s at a shear stress $\tau = 2 \times 10^6$ Pa. Estimating the contributions of elastic, viscoelastic, and plastic strains under the specified loading conditions yields relative values $\gamma_{el} = 76\%$, $\gamma_{vel} = 2.6\%$, and $\gamma_{pl} = 21.4\%$, and the paste can be attributed on these grounds to the third structural-mechanical type.

Thus, the peat–polymer paste with the above-mentioned rheological properties, intended for production of activated carbons, has, according to [8], a good moldability. In practice, with the process performed in a screw extruder with a torsion moment of 100 N m and rotation rate of 15 rpm, the paste under study can be molded at room temperature to give grains 2–6 mm in diameter. At the same time, molding of grains of about the same size from a paste in manufacture of the SKT carbon requires temperatures exceeding 60°C [23].

CONCLUSIONS

(1) The paste under study is a complex polydisperse system with interacting components; its defor-

mation properties strongly differ from those of the constituent peat and polymer. Concepts of the creep theory can be used to describe the behavior of the paste under static loads.

(2) The suggested rheological model of the paste behavior is a sum of the Kelvin and Nutting equations. The parameters of this model were determined: high-elasticity modulus 3.63×10^5 Pa; delay time 69 s; elastic-aftereffect viscosity 2.50×10^7 Pa s; and Nutting equation constants $C = 4.38 \times 10^{-8}$, $\beta = 1.43$, and $p = 0.222$.

(3) At shear stresses lower than 2–3 kPa, mostly creep deformations are observed in the paste, whereas at higher stresses, substantial irreversible deformations appear and develop with decreasing rate. The dependences of the irreversible strains on the applied stress point to a non-Newtonian type of paste flow with an effective viscosity of $(1.6–1.9) \times 10^8$ Pa s, comparable with that of polymer melts.

(4) The whole set of rheological properties of the paste under study enables its more effective molding, compared with ordinary peat pastes used in the technology of activated carbons.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thermodynamic Parameters of the Single-Stage Dehydrogenation of Isopentane to Isoprene

Abstract—From the results of experiments with platinum-containing catalysts operating in the steady mode, adiabatic changes in temperature in the course of 2-metylbutane dehydrogenation to monoolefins and isoprene were calculated. Dehydrogenation of 2-methylbutane and its mixtures with methylbutenes in the 500–600°C temperature range was simulated with varying the concentrations of 2-methylbutane, methylbutenes, hydrogen, and water, the conversion, and the selectivities with respect to both isoprene and methylbutenes. The most suitable reactor designs with intermediate heating of the reaction mixture were suggested.

DOI: 10.1134/S1070427208090218

The development of high-performance catalysts for dehydrogenation of isoalkanes is a priority research field today, because production of synthetic rubbers (including isoprene rubbers) is the most developed branch of petrochemical industry in Russia and other countries [1].

Single-step dehydrogenation of isoalkanes at atmospheric pressure in the presence of bimetallic platinum-containing catalysts is a promising and economically efficient process. This process surpasses in efficiency such existing processes as two-step method of isoprene preparation, one-step procedure of vacuum dehydrogenation of 2-methylbutane, and formaldehyde synthesis of isoprene [2–5]. Significant simplification of the flowsheet due to performing the process in one-step at atmospheric pressure (i.e., without any vacuum installations) is an advantage of this procedure. The catalyst is used in a fixed bed; in so doing, its high selectivity and activity are preserved. Elimination from the process scheme of the first step of dehydrogenation with a highly toxic chromium-containing catalyst will improve the working conditions and reduce the environmental hazard. Up to now, despite a number of advantages, one-stage dehydrogenation at atmospheric pressure using bimetallic catalysts is not used in commercial production. From our viewpoint, this is due to the fact that the one-step process, owing to high endothermic effect, requires supply of significant amount of heat to the reaction zone, which is unfeasible with modern installations.

The aim of this study was to calculate the thermodynamic characteristics of one-stage dehydrogenation of 2-methylbutane to methylbutenes and isoprene and to determine the type of reactor that can be used in this case.

Data on the theoretical yields of dienes in dehydrogenation of paraffin–olefin mixtures at various pressures were presented previously in [6, 7]. However, under the real experimental conditions, the catalyzate composition can strongly differ from the theoretical data for both operation (reactor type, procedures of the reagents and heat-carrier supply, etc.) and chemical (side cracking reactions, isomerization, diene transformations, etc.) reasons. To accomplish the goal of this study, we simulated on the basis of experimental data the dehydrogenation of 2-methylbutane and its mixtures with methylbutenes in a reactor with a fixed bed of platinum–aluminum–zinc catalyst.

The composition of the contact gas from dehydrogenation of isopentane in an isothermal laboratory reactor with a fixed bed of the catalyst that attained the steady operation mode is listed in Table 1. As can be seen, in one cycle of the single-stage dehydrogenation of 2-methylbutane using platinum–aluminum catalyst the yields of isoprene

Table 1. Composition of the contact gas and characteristics of the catalytic activity of bimetallic platinum–aluminum catalyst. Feed: 2-methylbutane, 98.57 wt %

Composition of contact gas and activity characteristics	Dehydrogenation temperature, °C			
	530	560	580	600
Composition, wt %:				
total C_2	0.24	0.53	0.62	0.97
CO_2 (recalculated to carbon)	0.65	1.89	2.51	4.23
total C_3	0.29	0.93	1.29	2.2
total C_4	2.03	4.32	4.91	6.03
2-methylbutane	40.95	31.62	30.91	33.67
n-pentane	1.01	0.13	0.07	0.01
methylbutenes	44.08	45.78	38.55	29.11
n-pentenes	0.82	0.95	0.6	0.28
isoprene	7.88	11.71	16.44	18.64
piperylene	0.45	0.85	1.34	1.31
cyclopentadiene	1.6	1.29	2.76	3.55
Catalytic parameter, wt %:				
yield of isoprene based on starting compound	7.99	11.88	16.68	18.91
yield of isoprene based on converted starting compound	13.68	17.49	24.30	28.72
yield of methylbutenes based on starting compound	44.62	46.34	39.01	29.66
yield of methylbutenes based on converted starting compound	76.33	68.23	56.83	54.66
conversion	58.46	67.92	68.64	65.84

and methylbutenes reach 18 and 40 wt % with the selectivity to unsaturated hydrocarbons of up to 91%.

The choice of the reactor with the fixed catalyst bed is primarily governed by the character of the occurring chemical reactions, determining adiabatic changes in temperature on passing of the feed through the catalyst bed. In this connection, we calculated adiabatic changes in temperature in the reactor for vapor-phase dehydrogenation of 2-methylbutane and its mixtures with methylbutenes.

In the general form, the adiabatic changes in temperature owing to changes in the reaction heat ΔT are determined by the following expression:

$$\Delta T_{ad} = T_{out} - T_{in} = \Sigma \Delta H_i / \Sigma (C_p)_j, \quad (I)$$

where $\Sigma \Delta H_i$ is the sum of thermal effects of chemical reactions occurring in the system (taking into account conversion of the reagent and selectivity to the final products) (kJ mol^{-1}); $\Sigma (C_p)_j$ is the sum of the heat capacities of the components (taking into account conversion of the reagent, selectivity to the final products, and heat capacity of the inert heat carrier fed to the system) (kJ mol^{-1} K^{-1}).

The following reactions occur in the system in the course of isopentane dehydrogenation.

(1) Dehydrogenation of 2-methylbutane to methylbutenes, without taking into account isomerism of the monoolefins:

$$i\text{-}C_5H_{12} \rightarrow i\text{-}C_5H_{10} + H_2. \quad (1)$$

(2) Dehydrogenation of methylbutenes (i-C_5H_{10}) to isoprene, without taking into account isomerism of the monoolefins:

$$i\text{-}C_5H_{10} \rightarrow i\text{-}C_5H_8 + H_2. \quad (2)$$

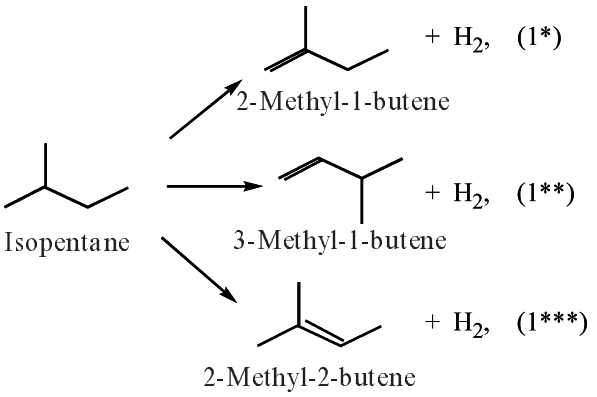
(3) Dehydrogenation of 2-methylbutane (i-C_5H_{12}) to isoprene:

$$i\text{-}C_5H_{12} \rightarrow i\text{-}C_5H_8 \text{ (isoprene)} + 2H_2. \quad (3)$$

As for thermal calculations the mechanism of a chemical reaction is of no significance, chemical transformation of 2-methylbutane into isoprene can be presented as a combination of reactions (1) and (2) with 2-methylbutane as the starting reactant.

In this case, setting certain values of the total conversion of isopentane $\alpha_{isopentane}$, selectivity of 2-methylbutane dehydrogenation to monoolefins $S_{pentene}$, and selectivity of 2-methylbutane dehydro-

Table 2. Thermodynamic characteristics of components at various temperatures



Component	Enthalpy of formation, kJ mol^{-1}	Heat capacity, J mol^{-1} K^{-1}
2-Methylbutane	$6.777\times10^{-5}T^2 - 1.345\times10^{-1}T - 1.206\times10^{2}$	$-1.756\times10^{-7}T^2 + 4.54710^{-4}T - 1.054\times10^{-3}$
2-Methyl-2-butene	$5.242\times10^{-5}T^2 - 1.126\times10^{-1}T - 1.389\times10$	$-1.410\times10^{-7}T^2 + 3.800\times10^{-4}T + 4.248\times10^{-3}$
2-Methyl-1-butene	$5.120\times10^{-5}T^2 - 1.063\times10^{-1}T - 9.285$	–
3-Methyl-1-butene	$4.475\times10^{-5}T^2 - 9.328\times10^{-2}T - 5.188$	–
Isoprene	$3.320\times10^{-5}T^2 - 6.917\times10^{-2}T + 9.326\times10$	$-1.639\times10^{-7}T^2 + 3.707\times10^{-4}T + 9.934\times10^{-3}$
Hydrogen	–	$33.066178 - 11.363417T\times10^{-3} + 11.432816(T\times10^{-3})^2 - 2.772874(T\times10^{-3})^3 - 0.158558(T\times10^{-3})^{-2}$
Water	–	$30.092 + 6.832514T\times10^{-3} + 6.793435(T\times10^{-3})^2 - 2.53448(T\times10^{-3})^3 + 0.082139(T\times10^{-3})^{-2}$

genation to isoprene $S_{isoprene}$, the amount of heat consumed in the course of the chemical reaction can be presented as follows:

$$\Delta H_{rea} = \Delta H_1\alpha_{isopentane}S_{pentene} + \Delta H_3\alpha_{isopentane}S_{isoprene},$$

where ΔH_1 and ΔH_3 are the thrmal effects of reactions (1) and (3) (kJ mol^{-1}), $\alpha_{isopentane}$ is the conversion of 2-methylbutane (fraction of unity), and $S_{pentene}$ and $S_{isoprene}$ are the molar selectivities of 2-methylbutane dehydrogenation to methylbutenes and isoprene (fraction of unity).

Since dehydrogenation of 2-methylbutane yields three major isomers of monoolefins, reaction (1) can be presented as three parallel reactions:

Now, we can identify the thermal effect of the corresponding reactions of 2-methybutane dehydrogenation to monoolefins as ΔH_1^*, ΔH_1^{**}, and ΔH_1^{***} and the selectivity of formation of the corresponding olefins as S_1^*, S_1^{**}, and S_1^{***}, after which we can transform the expression for the amount of heat consumed in dehydrogenation of 2-methylbutane to monoolefins as follows:

$$\Delta H_1^*\alpha_{isopentane}S_{pentene} = \Delta H_1^*\alpha_{isopentane}S_{pentene}S_1^* + \Delta H_1^{**}\alpha_{isopentane}S_{pentene}S_1^{**} + \Delta H_1^{***}\alpha_{isopentane}S_{pentene}S_1^{***}.$$

It should be noted the $S_1^* + S_1^{**} + S_1^{***} = 1$.

Thus, the final expression for calculation of the heat consumed in the course of chemical reactions proceeding in the system can be presented as follows:

$$\Delta H_{rea} = \Delta H_1^*\alpha_{isopentane}S_{pentene}S_1^* + \Delta H_1^{**}\alpha_{isopentane} \times S_{pentene}S_1^{***} + \Delta H_1^{***}\alpha_{isopentane}S_{pentene}S_1^{***} + \Delta H_3\alpha_{isopentane}S_{isoprene}. \quad (II)$$

It should be noted that, in our calculations of the thermal effect of dehydrogenation of methylbutenes to isoprene, we should take into account the thermal effect of isomerization of 2-methyl-2-butene to 2-methyl-1-butene and 3-methyl-1-butene.

Approximation of the second-order equations using the discrete values of the corresponding thermodynamic functions, performed in [8], allowed evaluation of the polynomial dependences of the enthalpies of formation and heat capacities of the system components, which were used in further calculations.

In the case of water and hydrogen, we used higher-order polynomial dependences published on the site of the National Institute of Standards and Technology (NIST, USA) [9], which are listed in Table 2.

Based on the given reaction conditions, a certain amount of water is added into the system to decrease the partial pressure of hydrocarbons and to compensate the endothermic effect of chemical reactions. Taking this fact into account, the heat capacity

Table 3. Thermodynamic characteristics of the system components in one-step dehydrogenation of 2-methybutane to isoprene at 600°C

Characteristic	Value

isoprene	58.18
Heat capacity, kJ mol^{-1} K^{-1}:	
2-methylbutane	0.262
2-methyl-2-butene	0.229
isoprene	0.209
hydrogen	0.0298
water	0.0397
Thermal effect of dehydrogenation to indicated compound, kJ mol^{-1}:	
2-methyl-2-butene	114.1
2-methyl-1-butene	123.3
3-methyl-1-butene	133.9
isoprene	244.6

of the flow at the reactor inlet is an additive quantity comprised of the heat capacities of the reactant (2-methylbutane or its mixture with methylbutenes), water, and excess hydrogen. Since the amount of the heat carrier is often taken as its molar excess with respect to the reagent, the specific heat capacity will be given hereinafter not on the gravimetric but on the molar scale. In this case, the heat capacity of the mixture at the reactor inlet, calculated per mole of 2-methylbutane introduced, can be presented by the expression:

$$(C_p)_{\text{inlet}} = (C_p)_{\text{isopentane}} + K_1(C_p)_{\text{water}} + K_2(C_p)_{\text{hydrogen}},$$

where $(C_p)_{\text{isopentane}}$, $(C_p)_{\text{water}}$, and $(C_p)_{\text{hydrogen}}$ are the molar heat capacities of 2-methylbutane, water, and hydrogen at the working temperature and pressure at the reactor inlet (kJ mol^{-1} K^{-1}), and K_1 and K_2 are the molar excesses of water and hydrogen with respect to 2-methylbutane at the reactor inlet (mole per mole of 2-methylbutane).

The heat capacity at the reactor outlet (or at the outlet from any reactor section) is constituted by the heat capacities of unchanged 2-methylbutane, reaction products (isomeric monoolefins, isoprene, and released hydrogen), and also water and hydrogen added to the system (heat carriers).

Thus, the heat capacity at the reactor outlet (or at the outlet from any reactor section) recalculated per mole of 2-methylbutane introduced can be presented as follows:

$$(C_p)_{\text{outlet}} = (C_p)_{\text{isopentane}}\alpha_{\text{isopentane}} + (C_p)_1^{*}\alpha_{\text{isopentane}} \times S_{\text{pentene}}S_1^{*} + (C_p)_1^{**}\alpha_{\text{isopentane}}S_{\text{pentene}}S_1^{**} + (C_p)_1^{***}\alpha_{\text{isopentane}}S_{\text{pentene}}S_1^{***} + (C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}} \times S_{\text{pentene}}S_1^{*} + (C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}}S_{\text{pentene}}S_1^{**} + (C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}}S_{\text{pentene}}S_1^{***} + (C_p)_{\text{isoprene}} \times \alpha_{\text{isopentane}}S_{\text{isoprene}} + 2(C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}}S_{\text{isoprene}} + K_1(C_p)_{\text{water}} + K_2(C_p)_{\text{hydrogen}}, \quad \text{(III)}$$

where $(C_p)_{\text{isopentane}}$, $(C_p)_1^{*}$, $(C_p)_1^{**}$, $(C_p)_1^{***}$, $(C_p)_{\text{isoprene}}$, $(C_p)_{\text{water}}$, and $(C_p)_{\text{hydrogen}}$ are the molar heat capacities of 2-methylbutane, 2-methyl-1-butene, 3-methyl-1-butene, 2-methyl-2-butene, isoprene, water, and hydrogen at working temperature and pressure at the reaction outlet (kJ mol^{-1} K^{-1}) and K_1 and K_2 are the molar excesses of water and hydrogen with respect to 2-methylbutane at the reactor inlet (mole per mole of 2-methylbutane).

Since the heat capacities of isomeric monoolefins differ insignificantly (within 1%), we used not three but only one value of the heat capacity of 2-methyl-2-butene (major isomer). In this case, expression (III) can be simplified as follows:

$$(C_p)_{\text{outlet}} = (C_p)_{\text{isopentane}}\alpha_{\text{isopentane}} + (C_p)_1^{***}\alpha_{\text{isopentane}} \times S_{\text{pentene}} + (C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}}S_{\text{pentene}} + (C_p)_{\text{isoprene}} \times \alpha_{\text{isopentane}}S_{\text{isoprene}} + 2(C_p)_{\text{hydrogen}}\alpha_{\text{isopentane}}S_{\text{isoprene}} + K_1(C_p)_{\text{water}} + K_2(C_p)_{\text{hydrogen}} = (C_p)_{\text{isopentane}}\alpha_{\text{isopentane}} + (C_p)_1^{***}\alpha_{\text{isopentane}}S_{\text{pentene}} + (C_p)_{\text{isoprene}}\alpha_{\text{isopentane}}S_{\text{isoprene}} + K_1(C_p)_{\text{water}} + (C_p)_{\text{hydrogen}}(\alpha_{\text{isopentane}}S_{\text{pentene}} + 2\alpha_{\text{isopentane}}S_{\text{isoprene}} + K_2). \quad \text{(IV)}$$

The thermodynamic characteristics of the system components at 600°C, determined using the above equations, are listed in Table 3. As seen from these data, the reactions of dehydrogenation of 2-methylbutane to methylbutenes and to isoprene are strongly endothermic are require supply of heat into the reaction zone to maintain the process parameters.

Taking into account the actual experimental

results and the above theoretical reasoning, we simulated the one-step dehydrogenation of isopentane to isoprene in a reactor with a fixed catalyst bed. The dependences of adiabatic changes in temperature in the reactor is shown in Fig. 1 in relation to the dilution with steam and hydrogen under the following reaction conditions: temperature at the reactor inlet 600°C, starting reactant 2-methylbutane, 50% conversion of 2-methylbutane, and 85 and 15% selectivity to monoolefins and isoprene, respectively. The dependences of temperature changes on the dilution of the starting reactant with the heat carrier are described by a sixth-degree polynomial. As seen from Fig. 1, in the absence of the inert heat carriers (such as water and hydrogen), the adiabatic decrease in the temperature at the reaction outlet was 268°C. Water having higher heat capacity as compared to hydrogen is a more efficient heat carrier, which is confirmed by smaller adiabatic cooling at equal reactant : heat carrier ratio in the case of water.

It should be noted that, in dehydrogenation of 2-methylbutane using aluminum–platinum catalysts promoted with tin compounds, addition of hydrogen is necessary for reducing the active component. Under the laboratory conditions, the starting reactant was diluted with hydrogen to 1 : 1 ratio. The calculated data on the adiabatic changes in temperature in dehydrogenation of 2-methylbutane in relation to the water supply at the reactant : hydrogen molar ratio from 1 to 10 are plotted in Fig. 2 using data from Table 3. Under the given conditions (temperature at the reactor inlet 600°C, 50% conversion of 2-methylbutane, and 85 and 15% selectivity to monoolefins and isoprene, respectively), the calculated thermal effect was 845.45 kJ kg^{-1} reactant.

As seen from Table 4, under the laboratory conditions (temperature 600°C, reactant : hydrogen : water molar ratio 1 : 1 : 10, weight ratio 1 : 0.03 : 2.5), the adiabatic decrease in temperature was 89°C. The decrease in temperature within 20°C range (580–600°C is the optimal range for the reaction) can be attained only at dilution of the reactant with steam to 1 : 80 molar ratio (or 1 : 20 weight ratio). Such consumption of steam increases the production cost and decreases the process efficiency. Thus, in this case the use of an adiabatic vessel of the contact type is inappropriate.

One of the ways to solve the problem of strong adiabatic decrease in temperature in the reactor can be recycling, when after separation of isoprene the

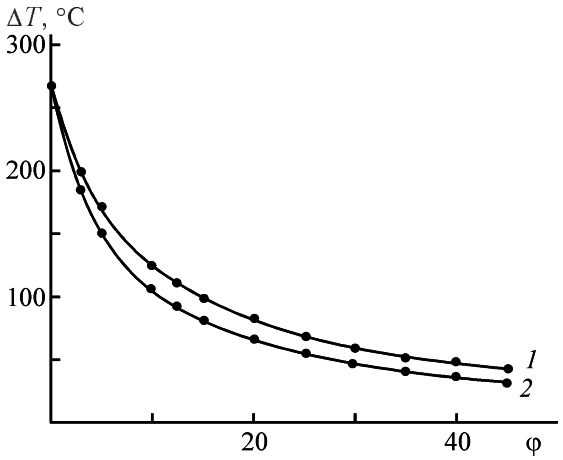

Fig. 1. Adiabatic changes in temperature in the reactor for dehydrogenation of 2-methylbutane to isoprene vs. (*1*) hydrogen : reactant and (*2*) water : reactant ratio. (ΔT) Difference between the temperatures at the reactor inlet and outlet; (φ) component ratio; the same for Fig. 2.

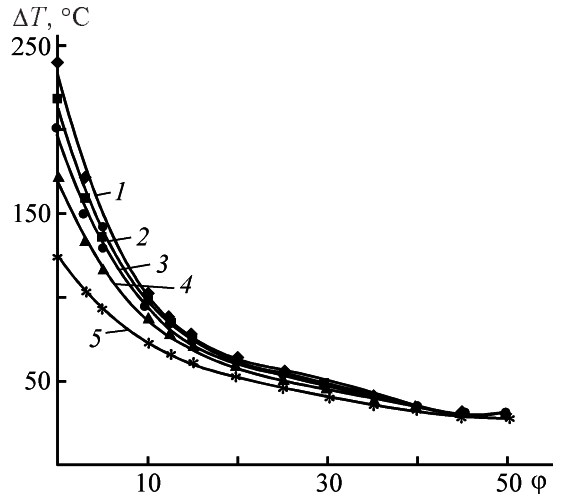

Fig. 2. Adiabatic changes in temperature in the course of 2-methylbutane dehydrogenation as function of the water supply. Reactant : hydrogen ratio: (*1*) 1 : 1, (*2*) 1 : 2, (*3*) 1 : 3, (*4*) 1 : 5, and (*5*) 1 : 10.

contact gas containing 2-methylbutane and methylbutenes is returned to the reactor. In this case, the integral thermal effect can be decreased owing to the conversion of methylbutenes. Simulation of dehydrogenation of mixtures of 2-methylbutane and methylbutenes at various selectivities to isoprene (Table 5) showed that the dilution of 2-methylbutane with methylbutenes decreases the total thermal effect and thus the difference between the temperatures at the reactor inlet and outlet.

As seen from Table 5, the selectivity of the reaction to isoprene also strongly affects the adiabatic

decrease in the temperature in the reactor. However, it should be noted that the data given in Table 5 were calculated on the assumption that the degree of conversion of 2-methylbutane and methylbutenes are constant and equal to 50 and 30%, respectively. Thus, the total conversion of the mixture of 2-methylbutane and methylbutenes is 80%. At the same time, the real conversions attained in the experiments do not exceed 50%.

The experiments with catalysts that attained the

steady operation mode showed that, with the supply of methylbutenes, the conversion was about 30%; in this case, the yield of isoprene reached 25–28% (based on the passed reactant), at the selectivity of about 80%. With the mixed reactants (2-methylbutane and methylbutenes), the yield of isoprene (based on the passed reactants) increased by 2–4% as compared to the 2-methylbutane and reached 18 wt %, with the total conversion of 40–50%. Since both 2-methylbutane and methylbutenes participate in the dehydrogenation, the conversion of each component considered separately is indefinite. The calculated thermodynamic characteristics, assuming that conversions of 2-methylbutane and methylbutenes are interrelated, are listed in Table 6. The total conversion of the reactants was taken as 50%, and the conversions of 2-methylbutane and methylbutenes were taken as x and $50 - x$, respectively.

As seen from Table 6, the integral thermal effects of the reactions decrease owing to the dehydrogenation of methylbutenes. As a result, the difference between the temperatures at the reactor inlet and outlet decreases. However, the experimental data show that, despite an increase in the isoprene yield, with increasing content of methylbutenes in the mixture the conversion and selectivity (owing to thermodynamic factors) decrease. Taking into account this fact, it should be noted that in the case of recycling it is advisable to dilute 2-methylbutane with methylbutenes up to 80 : 20–70 : 30 ratio. In this case, the adiabatic decrease in temperature varies within the 20–73°C range depending on the conversion of 2-methylbutane and methylbutenes. The catalytic experiments performed with a mixture containing 70 wt % 2-methylbutane and 30 wt % methylbutenes showed that the content of methylbutenes in the contact gas decreased by 10–12%. Hence, if we consider that the conversion of methylbutenes is 10%, then adiabatic decrease in reactor temperature will be 63 and 52°C for the mixtures containing 2-methylbutane and methylbutenes in the 80 : 20 and 60 : 40 ratios, respectively.

One of the solutions of the problem in hand is the use of a two- or three-reactor system with intermediate heating. These reactors are filled with a catalyst. The starting reactants heated to 450–500°C are fed, along with superheated steam and hydrogen in a certain ratio, to reactor 1, where dehydrogenation proceeds at 580–600°C and the conversion of 2-methylbutane is controlled so that the adiabatic decrease in the temperature in the reactor does not exceed 20–25°C. Then the contact gas from reactor 1 is transferred into a heater, where it is heated to the reaction temperature and then is fed to reactor 2.

The thermodynamic characteristics of 2-methylbutane dehydrogenation depending on the conversion are listed in Table 7. As can be seen, a less than 25°C decrease in temperature can be attained at the conversion of about 15%. Hence, to attain the total conversion of 45–50%, the dehydrogenation should be performed using at least three reactors.

CONCLUSIONS

(1) The calculated adiabatic changes in temperature in the course of dehydrogenation of 2-methylbutane to monoolefins and then to isoprene under the set conditions show that, in the optimal reaction mode, the adiabatic decrease in the reactor temperature is 89°C. The decrease in the temperature within 20–25°C range can be attained only on dilution of the starting reactants with steam to 1 : 80 molar ratio (1 : 20 weight ratio). The consumption of such amount of steam increases the product cost and decreases the process efficiency. Thus, the use of an adiabatic vessel of the contact type is not appropriate in this case.

(2) Simulation of dehydrogenation of a mixture of 2-methylbutane and methylbutenes at various selectivity to both isoprene and methylbutenes showed that the dilution of 2-methylbutane with methylbutenes decreases the total thermal effect and correspondingly the difference in temperatures at the reactor inlet and outlet. Taking into account the real conditions of operation of the aluminum–platinum catalyst, the thermodynamic parameters of the one-step dehydrogenation were evaluated. It was found that, in dehydrogenation of a mixture containing 2-methylbutane (80%) and isopentenes (20%), the adiabatic decrease in the reactor temperature should be 63°C, and for 60 : 40 isopentane : isopentenes mixture this decrease comprises 52°C. Thus, our calculations showed that one of the solutions of the problem of a strong adiabatic decrease in the reactor temperature is recycling, when after separation of isoprene the contact gas containing significant amounts of methylbutenes is returned to the reactor.

(3) A reactor with intermediate heating of the reaction mixture was suggested as the optimal solution. The thermodynamic calculations of the isopentane dehydrogenation at varied degree of conversion showed that the adiabatic decrease in temperature within 25°C can be attained at conversion of about 15% and, thus, to attain the total conversion of 45–50%, the dehydrogenation should be performed using at least three reactors.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Kinetics of Thermolysis of Sterically Hindered Phenols Used as Polymeric Material Stabilizers

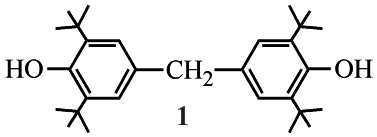
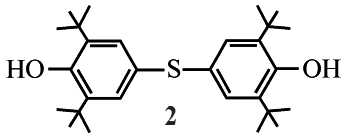
Abstract—The thermolysis kinetics of a series of sterically hindered phenols was studied.

DOI: 10.1134/S107042720809022X



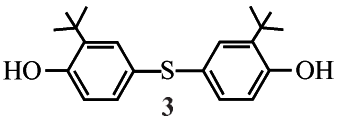
Numerous sterically hindered phenols (SHPs) have been synthesized by now. Many of them exhibit antioxidant properties and are used as additives to polymers to improve their service characteristics.

A theoretical approach to studying the performance of phenolic antioxidants consists in estimating the energy of the homolytic cleavage of the ArO–H bond [1]. These data allow conclusions on the performance of compounds used to prolong the service life of organic materials. For another important field of applied chemistry, reprocessing of stabilized polymeric materials at elevated temperatures, the decisive characeristic is their thermal oxidative degradation. The performance of thermal stabilizers for polymers is usually evaluated empirically or semiempirically [2]. In this case, the major factor is the thermal stability of the potential thermal stabilizers themselves, as it determines the temperature boundary of their applicability to stabilization of specific polymers processed in a definite temperature range.



This study continues our previous kinetic studies of thermolysis of SHPs using thermal gravimetric analysis [3–5]. Here we compare the decomposition kinetics studied previously for a series of phenolic antioxidants with the data obtained for certain new compounds, to assess the performance of the new antioxidants relative to those used commercially. To solve the problem of thermal stabilization of polymers on the basis of kinetic data on SHP thermolysis, we examined in succession the following factors: stabilizer structure–thermolysis mechanism–thermal stability of the stabilizer–conditions under which this stabilizer would be the most efficient for thermal stabilization of polymer compounds.

EXPERIMENTAL



Experiments were performed with a series of compounds in which the alkyl substituents in *o*-positions of phenols, number of sulfur atoms, and structure of acid fragments of esters were varied, but the carbon core was the same (see table and structural formulas below).

4,4'-Methylenebis(2,6-diphenylphenol) (**12**)	195	208	39	5.2×10^{16}

Some of the compounds are already used in industry as thermal stabilizers. Particular attention was given to known unique thermal stabilizers, Fenozans (Irganoxes) (see table, compounds **10** and **11**) prepared from methyl 3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propionate (Methylox). These compounds have been successfully used for more than 30 years in thermal reprocessing of polypropylene and for stabilization of shockproof polystyrene and other polymer compounds [6]. The compounds were prepared at the Novosibirsk Institute of Organic Chemistry, Siberian Branch, Russian Academy of Sciences [3] and were characterized by NMR, elemental analysis, and liquid chromatography. The main substance content was no less than 99%.

The experiment was performed on an STA 409 PC Luxx synchronous thermal analyzer (Netzsch) allowing simultaneous recording of the sample weight change and determination of characteristic temperatures and heats of phase transitions. To study the SHP thermolysis kinetics, samples of approximately equal weight (4.0±0.2 mg) were heated in a 85-μl platinum crucible with a lid from 35 to 600°C at heating rates of 3, 5, 10, 15, and 20 deg min^{-1} in a helium atmosphere.

The sample weight loss in the course of heating can be caused by its volatilization (without changes in the chemical structure) or its decomposition into volatile fragments. As shown in [7], those phenolic stabilizers are, as a rule, volatile which have the molecular weight of 400 and lower. Low-volatile 2,6-di-*tert*-butylphenol derivatives at 280–300°C undergo rapid weight loss [3] due to thermal degradation, namely, to de-*tert*-butylation [8, 9] or deeper degradation (breakdown of the carbon core), in accordance with data for related compounds [10–12].

Correlation between the activation energy E and logarithm of the preexponential factor $\ln Z$ for compounds **1**–**12**.

To determine the kinetic parameters of thermolysis of the compounds, we used the known equation for the reaction rate constant [13]

$$k = Z\exp(-E/RT)$$

or

$$\ln k = \ln Z - E/RT,$$

where k is the reaction rate constant (mol min^{-1}); E, apparent activation energy (J mol^{-1}); Z, preexponential factor; T, temperature (K); and R, gas constant (J mol^{-1} K^{-1}).

The kinetic characteristics were calculated from the experimental thermal analysis data. We used the differential method based on the shift of the inflection point of the gravimetric curve at varied heating rate [14]. The activation energies E of the examined compounds and preexponential factors Z, calculated from the experimental data, are given in the table.

With respect to the kinetic parameters E and $\ln Z$, the compounds can be subdivided into two groups forming two straight lines in the plot of E vs. $\ln Z$ (see figure). Such results suggest the occurrence of the so-called compensation effect [15–17]:

$$\ln Z = aE + b.$$

This effect is attributed to analogies in the mechanisms of chemical processes occurring in the course of the experiment with the examined compounds [1, 18]. Subdivision of the stabilizers into two groups with respect to the kinetic characteristics suggests that the mechanisms of the thermal decomposition are similar for the compounds falling on the same straight line but essentially different for compounds of different groups [19, 20].

The products of thermal decomposition of some representatives of these two groups (e.g., compounds **1** and **7**, see table) were examined previously by gas chromatography–mass spectrometry [12, 21]. In thermolysis of compounds **1**–**6** belonging to the first group (see table and figure), initially the limiting step of the decomposition process is de-*tert*-butylation with preservation of the carbon core of the molecule [8, 9]. It is not improbable that the primary event of the process is homolytic cleavage of the ArO–OH bond [1].

The second group includes compounds **7**–**12** (see table and figure) decomposing in thermolysis into coarse reactive fragments. In the course of thermolysis in the bulk of a polymer (at high temperature), these fragments apparently enter into a chemical reaction with polymers, causing the observed significant changes in their physicochemical properties. As a rule, this leads to improvement of the service characteristics of the polymer [22–25]. Such modifying additives after introduction into a polymer and its subsequent heat treatment cannot be recovered from the polymer by extraction [26]. Since there is no principal temperature limit for the use of stabilizers, they can be used in a wide temperature range, 140–350°C. Articles fabricated from a polymer with these stabilizing modifiers have two times longer service life under a deformation load [25].

It should be noted that the assignment of a sample to the first or second group of stabilizers cannot be made solely on the basis of the molecular structure of the SHP and of the temperature at which it starts to decompose in the course of heating.

The results of the studies allow a conclusion that the kinetic characteristics of SHP thermolysis are decisive when the stabilizers are used as additives to polymers. The stabilizers characterized by E = 100–150 kJ mol^{-1} and $Z = 1\times10^{10}$–1×10^{12} s^{-1} can be used as stabilizing additives to organic substances that are not subject to large thermal loads. Stabilizers characterized by high values of the activation energy (>155 kJ mol^{-1}) and preexponential factor (~1×10^{14} s^{-1} and more, see table and figure) can be used both as stabilizing additives and stabilizing modifiers. Their new modifying property is manifested under the conditions of polymer compound reprocessing under harsh conditions. Determination of the applicability fields for each of the new phenolic antioxidants is apparently associated with elucidation of the mechanism of their thermal degradation, because determination of the thermal stability limit

for each antioxidant will allow the proper choice of the temperature and method of processing of a polymer compound with the given stabilizer. For example, in processing of polymeric materials at temperatures below 200°C, for their stabilization and modification it is appropriate to use modifiers with a low thermolysis energy [22, 23]. If higher processing temperatures are required, any modifiers can be chosen [25].

A kinetic study of the thermolysis of methylenequinone **8** and vinylphenol **9** (see table) appeared to be a connecting link between structural studies of oxidation and thermolysis products of (3,5-di-*tert*-butyl-4-hydroxyphenyl)propionic acid esters, on the one hand [10], and of a polymer stabilized with these esters, on the other hand [27]. These studies have the same goal: elucidation of the causes of extremely high performance of Irganoxes (Fenozans) used for stabilizing polypropylene against thermal oxidative degradation when it is processed at very high temperatures (240–270°C). The structure of the modified polypropylene obtained after such heat treatment contains methylenequinone fragments [28]. It became evident that the modification of polypropylene under the heat treatment conditions with Irganox-1035 stabilizer, initially introduced as additive, involves the step of transformation of Irganox-1035 from an additive into a modifier, methylenequinone. The latter, in turn, in the course of thermal decomposition generates radicals [11] reacting with compounds containing double bonds [10], which is confirmed by identification of the products of their reaction with polypropylene [28]. In the course of processing of polyethylene, polystyrene, and rubbers, Irganoxes behave as common stabilizing additives.

The absence of migration of an additive from a polymer into the environment is the decisive property in the choice of a stabilizer for polymeric compounds whose surface is subjected to the action of moisture, light, and heat. Methylenequinone **8** and vinylphenol **9** (see table and figure) showed high performance as additives for protection of polyethylene films from heat and light [28]. The results of commercial tests under the conditions of combined action of heat and seawater on polymer compounds modified with 4,4'-bis(2-*tert*-butyl-4-hydroxyphenyl) disulfide demonstrate high stability of the service properties of the article and absence of migration of the additive from the polymer [23].

CONCLUSIONS

(1) The sterically hindered phenols and their derivatives examined in this study can be subdivided into two groups with respect to the kinetic characteristics. Each group is characterized by a common thermolysis mechanism. Stabilizers with a low activation energy ($\leq$150 kJ mol^{-1}) are widely used as stabilizing additives to polymers. Their thermal degradation starts with de-*tert*-butylation. Stabilizers with the activation energy higher than 155 kJ mol^{-1} act as both stabilizing additives and modifiers. Their modifying properties are manifested only at a definite thermal action on the polymer compound and are associated with the activation energy for each stabilizing modifier.

(2) The group of modifiers consists of phenol derivatives containing chains of sulfur atoms, fragments of 1,2-diphenylethane and 2,3-diphenylsuccinic acid, and, in the case of 2,6-diphenylphenol derivatives, a methylene link. In the course of thermolysis, such compounds decompose into free radicals reacting with each other or with the polymer and thus modify and improve the service properties of the polymer.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Determination of Organic Odor-Producing Substances in a Gas Mixture Using a Multisensor System

Abstract—A multisensor system based on an array of weakly selective sensors was used to determine organic odor-producing substances in gas mixture. As modifiers of electrodes of mass-metric piezoelectric resonators served polyethylene glycol esters (succinate, phthalate), tris(hydroxymethyl)aminomethane, *N*-methyl-2-pyrrolidone, polyphenyl ether, sodium nitroprusside, sulfosalicylic and ribonucleic acids, and diphenylcarbazide. For the example of a biotechnological object, true milk solution, visual "patterns" of odor-producing components were constructed. Their type is determined by the sensitivity of the sensors and is independent of the concentration of the substances under study.

DOI: 10.1134/S1070427208090231

A topical practical task of biotechnology, medicine, ecology, and security services consists in identification of odor-producing components of a gas mixture of complex composition. The odor parameters prevail in the general assessment of organoleptic characteristics.

Odor-producing substances, taken separately or in various combinations, form a characteristic odor even when present in minor amounts. The perception of this odor is due to olfactory signals caused by stimulation of nose receptors. Strong olfactory signals are produced by compounds containing the following functional groups: –OH, –CHO, –COOR, –CN, $-NR_2$, –CCl, –CBr, –SR, and –SH; the odor intensity decreases as their number in the composition of an odor-producing substance increases [1].

Lower aliphatic ketones and dicarbonyl compounds are liquids with a pungent odor. When present in small concentrations, acetylmethylcarbinol and diacetyl have a pleasant odor and are important aroma components. Carboxylic acids present in large amounts impart a forage, cheese, and rancid odors, and ethanol gives a characteristic alcoholic odor [1].

Detector devices intended for obtaining information about the qualitative and quantitative composition of an odor are known. At the same time, despite the successful solution of numerous application problems by various physicochemical methods, the only alternative are, frequently, organoleptic determinations based on subjective human perceptions [2].

In this context, an extensive work is being conducted on development of electronic sensors for odor identification [3]. The operation of these devices is based on applying a set of nonselective sensors, with the subsequent processing of their signals by methods employing modern concepts of artificial intelligence. To these methods belong the technique of substance identification by characteristic visual representations ("patterns") [4] specific to a mixture of vapors and that of multiparameter calibrations [5, 6]. In this regard, the promise shown by the method of artificial neuron networks should be noted [7, 8]. Just this approach underlies the present-day development of sensors and new detecting devices, e.g., the "electronic nose." The system is intended for odor recognition [3], its development is stimulated by the desire to simulate and, occasionally, even replace the human olfactory organ [5, 9]. First works aimed to develop a system for odor recognition were carried out in the 1960s; the concept of the "electronic nose" as an intelligent multisensor system was suggested in 1982 and became commonly accepted by the early 1990s [5].

EXPERIMENTAL

The study was carried out in order to identify individual organic odor-producing substances of

Table 1. Determination of odor-producing acids in a true milk solution (according to the chromatogram in Fig. 1a)

Acid	Retention time	Peak area, mV s^{-1}	Peak height, mV	Content, wt %
Acetic	9 min 50 s	2735	228	18.2
Butyric	11 min 32 s	11760	981	78.2
Lactic	14 min 55 s	547	23	3.6
	Σ	15042	1232	100

a biotechnological object, true milk solution obtained by ultrafiltration separation of the curd whey [10].

The main odor-producing components of the true milk solution were identified by high-performance liquid chromatography. The chromatographic conditions were as follows: 300 × 7.8 mm column, Carbo-H + 4 × 3.0 mm protective column, isocratic separation mode, 0.0025 M sulfuric acid as the mobile phase with a flow rate of 0.6 ml min^{-1}, column temperature 60°C, sample volume 20 μl.

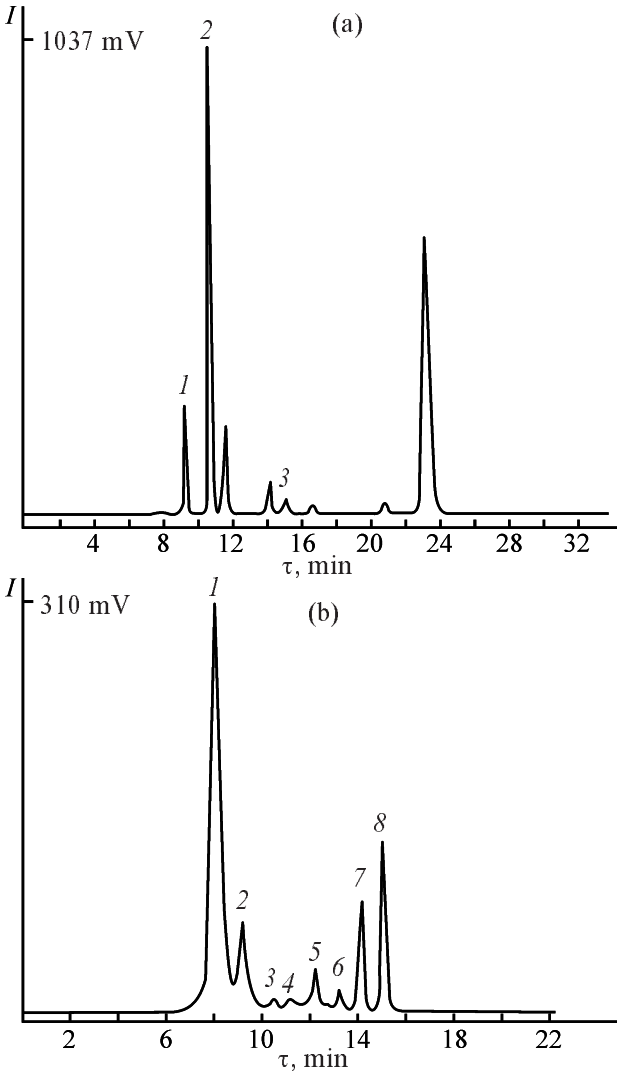

Fig. 1. Chromatogram of a true milk solution. (*I*) Signal intensity and (τ) time. Identified peaks: (a) (*1*) acetic, (*2*) butyric, and (*3*) lactic acids; (b) (*1*) ethanol, (*2*) formaldehyde, (*3*) acetaldehyde, (*4*) methyl acetate, (*5*) diacetyl, (*6*) acetylmethylcarbinol, (*7*) ethyl acetate, and (*8*) ethylal.

Substances of varied nature were identified in the gas phase of a true milk solution: acids (including volatile acetic, butyric, and lactic acids) (Fig. 1a), aldehydes (formaldehyde, acetaldehyde, ethylal), ketones (acetylmethylcarbinol, diacetyl), esters (methyl acetate, ethyl acetate), and ethanol (Fig. 1b). The identified components were quantitatively determined using the internal normalization method (Tables 1, 2).

The multisensor determination of the identified organic substances was performed under static conditions with nine piezoelectric quartz resonators. A system of the non-blow-through type provided that the results obtained were independent of the flow velocity of a sample within the cell. A multisensor detection cell fabricated from stainless steel in the form of a cylindrical vessel with a hermetically screwed cover (with panels for nine sensors circularly arranged) and a replaceable base was used. The cell casing is equipped with three pipes: (i) for sample introduction, (ii) for input of a carrier gas (air) in sorbent regeneration (bringing the sensors to the working state, removing trace amounts of substances remaining after preceding measurements), and (iii) for discharge of the carrier gas. The pipes were hermetically closed with polyurethane gaskets and pressed plugs with threaded junctions. The sensor signals were measured and processed with a nine-channel digital measuring system. The time intervals between recording of the sensor signals were 1 s. The device was connected to a computer via an RS-232 C serial interface.

Of fundamental importance is the choice of a modifier for electrodes of the mass-metric piezoelectric resonator and the optimization of the sorption conditions [11, 12]. As modifiers were studied

Table 2. Determination of odor-producing components in a true milk solution (according to the chromatogram in Fig. 1b)

Acid	Retention time	Peak area, mV s^{-1}	Peak height, mV	Content, wt %
Ethanol	8 min 31 s	6461	269	48.9
Formaldehyde	9 min 18 s	1078	645	8.2
Acetaldehyde	10 min 48 s	49	4	0.4
Methyl acetate	11 min 16 s	49	4	0.4
Diacetyl	12 min 07 s	588	25	4.4
Acetylmethylcarbinol	13 min 44 s	293	12	2.2
Ethyl acetate	14 min 11 s	1762	73	13.3
Ethylal	15 min 13 s	2938	122	22.2
	Σ	13 218	1154	100

the following substances: (1) tris(hydroxymethyl)-aminomethane, (2) *N*-methyl-2-pyrrolidone, (3) polyphenyl ether, (4) sodium nitroprusside, (5) sulfosalicylic acid, (6) ribonucleic acid, (7) diphenylcarbazide, (8) polyethylene glycol succinate, and (9) polyethylene glycol phthalate (digits in parentheses indicate the order of sensor positions in the detecting cell, Fig. 2).

The modifiers studied form thin and thickness-uniform films on the surface of electrodes of a piezoelectric resonator. These films are stable in air (are not oxidized and do not decompose) and are characterized by low volatility, considerable affinity for the sorbate, and mechanical stability (can be used for a large number of measurements on the same film). With these films, low acoustic loss is introduced into the resonant system of the sensor, which is due to use of materials that can form thickness-uniform films with a large elastic modulus on the surface of electrodes of the piezoelectric quartz resonator [10].

The optimal masses of the modifiers providing a significant signal and the minimum determination error are 10–20 μg [13, 14]. At a modifier mass smaller than 10 mg, the response of the modified piezoelectric quartz resonator is at the noise level. If the modifier mass exceeds 20 μg, the damping of oscillations in the modifier film makes lower the signal of the piezoelectric quartz resonator and leads to an increase in the determination error (Table 3).

The sorbent solvents (acetone and water) satisfied the following requirements: chemical inertness toward the sorption phases, absence of stable solvates, volatility, and high solvency.

Prior to measurements, the stability of sensor operation was checked. The stability criterion is a shift of the oscillation frequency by no more than 5 Hz in 1 min. A certain volume of vapors of the equilibrium gas phase of an odor-producing substance was injected into the multisensor detecting cell. The oscillation frequency of the sensors was recorded at intervals of 1 s by the digital measuring system and displayed on the monitor screen. Then the cell and the modifier film was regenerated by purging the system with dried laboratory air.

Substances producing a certain odor are sorbed by the modifier film, and, as a result, the frequency of characteristic oscillations of the modified piezoelectric quartz resonator changes. The analytical signal depends on the affinity of the sorbate and sorbent (determined by their nature), film mass, sorption temperature, and individual parameter of the oscillating system (resonance frequency of quartz, electrode area).

In the static conditions, the sorption of the vapor of the organic substances under study is determined by two main factors: diffusion toward the film surface and interaction with the sorbent [15]. To provide the operation speed, reversibility of sorption–desorption processes, and reproducibility of the analytical signal from the modified piezoelectric quartz resonator, only low-energy intermolecular interactions of the dipole–dipole type or donor–acceptor bonds (including hydrogen bonds) should occur in the sorbate–sorbent system. Polar molecules containing moieties with lone electron pairs (e.g., oxygen in –COOH and –CHO groups), molecules with dipole functional groups (oxygen in ethers, esters, and ketones) in their peripheral parts, and compounds with functional groups in which the electron density is concentrated on one center and is lower on another (alcohols) can exhibit, together

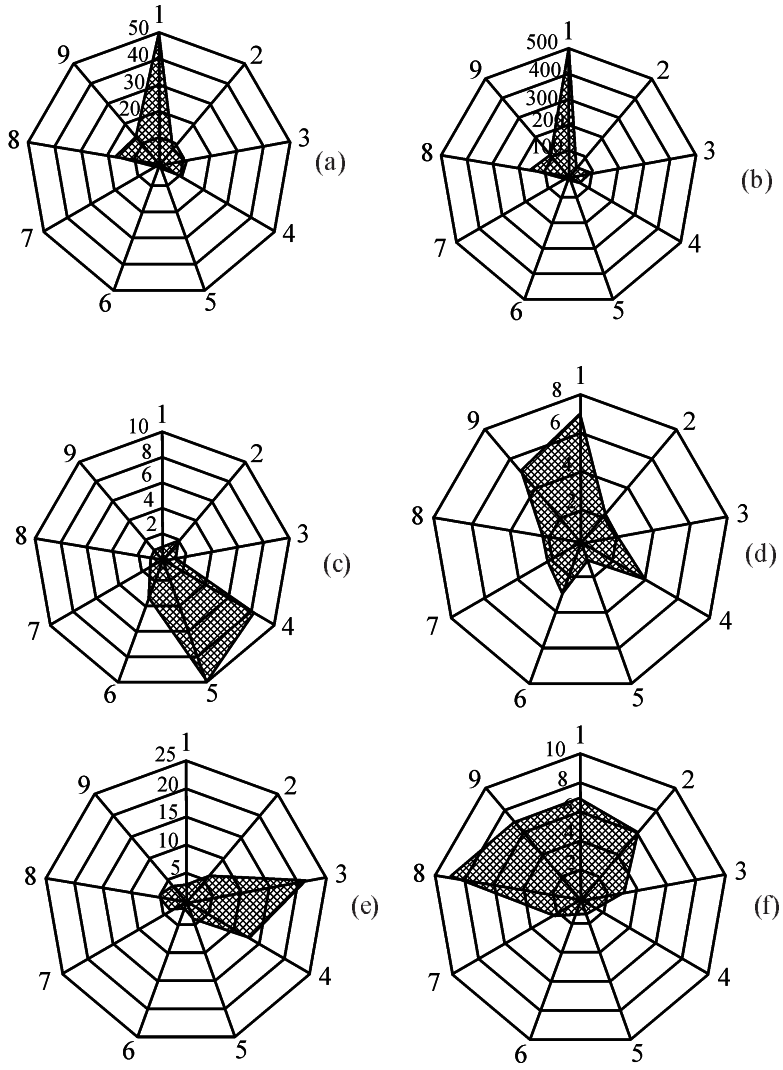

Fig. 2. "Visual patterns" of (a) butyric acid, (b) acetic acid, (c) lactic acid, (d) formaldehyde, (e) ethyl acetate, and (f) ethanol. Circularly arranged digits correspond to the order of sensor positions in the detecting cell.

Table 3. Modifiers of the electrodes of a piezoelectric quartz resonator

Sorbent	Film mass, μg
Tris(hydroxymethyl)aminomethane	9.20
Sodium nitroprusside	9.50
Sulfosalicylic acid	9.89
N-Methyl-2-pyrrolidone	10.01
Polyphenyl ether	11.27
Ribonucleic acid	12.57
Polyethylene glycol succinate	12.61
Diphenylcarbazide	12.96
Polyethylene glycol phthalate	13.55

with universal (nonspecific) intermolecular interactions, also those of directed (specific) type. The contribution of the specific interactions depends on the chemical and geometric structure of the sorbate molecule and sorbent surface and on temperature [16].

Each sensor in the multisystem is low-selective and shows cross sensitivity and selectivity in interaction with odor-producing substances toward which the sensor characteristics are different and linearly independent.

The results of multisensor determination of the odor-producing components of a true milk solution were used to construct "visual patterns" [4], lobe

diagrams of the equilibrium gas phases of individual organic odor-producing substances (Fig. 2). The shape of "visual patterns" is determined by the sensitivity of separate sensors of the multisensor system to organic odor-producing compounds and is independent of the concentration of an individual component.

Separate sensors exposed to vapors of the equilibrium gas phase exhibit the maximum response (analytical signal ΔF, Hz) in the following cases: with tris(hydroxymethyl)aminomethane and polyethylene glycol phthalate for formaldehyde; with tris(hydroxymethyl)aminomethane and polyethylene glycol esters for the alcohols studied; with tris(hydroxymethyl)aminomethane, polyphenyl ether, *N*-methyl-2-pyrroidone, and polyethylene glycol esters for acetic acid; and with polyphenyl ether and sodium nitroprusside for ethyl acetate.

If the mixture simultaneously contains formaldehyde and butyric acid, alcohols studied, or ketones, selective determination of each component is impossible.

The responses of the multisensor system were statistically processed using the method of artificial neuron networks [17, 18].

CONCLUSIONS

The shape of the visual patterns is determined by the sensitivity of separate sensors of the multisensor system toward organic odor-producing substances and is independent of the concentration of an individual component. The axis of the circular diagram corresponds to one of the nine channels of the multisensor system. In the course of sorption, the configuration of the visual pattern varies in accordance with changes in the signals of modified piezoelectric quartz resonators.

Received November 26, 2007

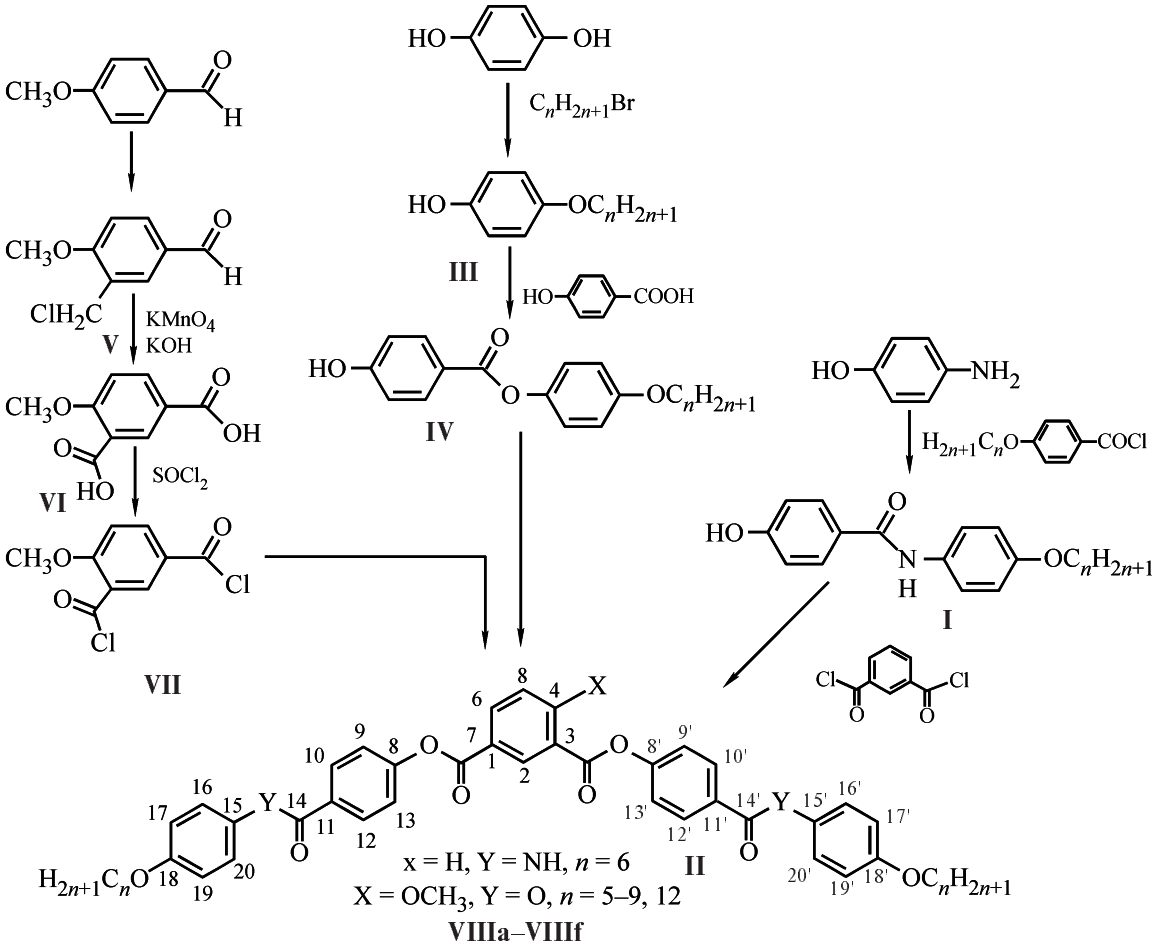
Abstract—4-Methoxy-1,3-benzenedicarboxylic acid esters and 4-(4-hexyloxybenzoylamino)phenyl 1,3-benzenedicarboxylate, each containing five aromatic rings, were synthesized. The influence of the structure of the synthesized banana-like compounds on their mesogenic activity was examined.

DOI: 10.1134/S1070427208090243

Much attention in chemistry of liquid crystals is given to synthesis of molecules having a bent shape, so-called banana-like molecules [1]. Such compounds can form a mesophase with ferroelectric properties and find use as components for liquid crystal displays, increasing their speed. Therefore, revealing a correlation between their structure and mesomorphic properties is a topical problem.

The central fragment of banana-like compounds is most frequently 1,3-disubstituted benzene containing the same or different functional groups. The side fragments include four to six aromatic or heteroaromatic rings linked by bridging groups (ester, azomethine, azoxy, double, or triple bond). Data on preparation of liquid crystal banana-like compounds with the amide linking group are lacking, whereas rodlike mesomorphic aromatic acid amides forming nematic and smectic phases have been reported [2]. There are data on rodlike and discotic liquid crystals forming complexes with lanthanides, e.g., on substituted Schiff bases [3, 4], β-aminovinyl ketones [5, 6], substituted diaza-18-crown-6 ethers [7]; some of such complexes exhibit luminescence properties. Complexes of lanthanides with banana-like liquid crystals have not been studied. The banana-like esters of 1,3-benzenedicarboxylic and 4-bromo-1,3-benzenedicarboxylic acids, described in the literature [8], have the structure that does not allow any complexing activity to be expected.

The goal of this study was to prepare 1,3-benzenedicarboxylic acid esters containing an amide group as the second linking fragment and 4-methoxy-1,3-benzenedicarboxylic acid esters, to examine their mesomorphism, and to evaluate their complexing power toward lanthanides.



1,3-Benzendicarboxylic and 4-methoxy-1,3-benzenedicarboxylic acid derivatives were prepared by the scheme shown below.

Chlorides of 1,3-benzenedicarboxylic and alkoxybenzoic acids were prepared by the standard procedure [9] in thionyl chloride in the presence of DMF. *N*-(4-Hydroxyphenyl)-4-hexyloxybenzamide **I** was prepared by the modified procedure from [10]. Its structure was proved by mass spectrometry and IR spectroscopy ($\nu_{C=O}$ = 1680 cm^{-1}). 1,3-Bis[4-(4-hexyloxybenzoylamino)phenoxycarbonyl]benzene **II** was prepared in absolute acetone in the presence of triethylamine from isophthaloyl chloride and appropriate phenol **I**. Compound **II** shows no mesomorphic properties, has high melting point, and is very difficultly soluble in the majority of solvents.

Thus, introduction of an amide group as linker into side fragments of bent molecules negatively affects all the characteristics, including the mesogenic power. Therefore, we prepared 4-methoxy-1,3-benzenedicarboxylic acid derivatives containing exclusively ester groups in side fragments.

The starting 4-alkoxyphenols **III** were prepared by the procedure given in [11]. 4-(4-Alkoxyphenoxycarbonyl)phenols **IV** were prepared by esterification in the presence of sulfuric acid in anhydrous benzene [12]. The structures of phenols **IV** were confirmed by IR spectroscopy and mass spectrometry (Table 1).

4-Methoxy-1,3-bis[4-(4-alkoxyphenoxycarbonyl)-phenylene]benzenes **VIII** were prepared from the

corresponding phenols **IV** and 4-methoxy-1,3-benzenedicarbonyl chloride **VII** in absolute benzene in the presence of triethylamine at room temperature. The purity of compounds **VIIIa**–**VIIIf** was proved by thin-layer chromatography, and the structure, by ^{1}H NMR spectroscopy. The mesomorphic properties of the compounds were studied by polarization microscopy. The spectral and mesomorphic characteristics of 4-methoxy-1,3-benzenedicarboxylic acid diesters **VIIIa**–**VIIIf** are given in Table 2.

According to Table 2, compounds **VIIa** and **VIIIb** with short terminal alkoxy groups (n = 5, 6) and the highest homolog (**VIIIf**, n = 12) are nonmesomorphic; with the terminal heptyloxy group (compound **VIIIc**), a monotropic mesophase appears, which becomes enantiotropic for the next homologs **VIIId** and **VIIIe**.

To determine the kind of mesomorphism, along with studying the textures by polarization micros-

* (*Cr*) Solid crystal, (*I*) isotropic liquid, and (B_x) "banana" mesophase.

copy (these textures for **VIIId** resemble a chiral smectic C* phase), we performed an X-ray diffraction study of the liquid crystal phase and differential thermal analysis [13].

In accordance with the X-ray diffraction data, the liquid crystal phase of **VIIId** is smectic, with the interlayer distance decreasing from 45.3 to 43.7 Å on cooling; the inclination angle of molecules relative

to the layer surface reaches 12°–15°.

The thermogram of **VIIId** in the heating and cooling mode is shown in Fig. 1.

The heat of the crystal → mesophase transition (first peak in the heating mode) is 30.2 J g^{-1}, and the heat of the subsequent transition to the isotropic liquid is 12.6 J g^{-1}, which is typical of ordered smectic–isotropic liquid transitions. In the course of cooling, the isotrope → mesophase transition occurs at 159.0°C (17.2 J g^{-1}), and the crystallization (with supercooling), at 141.1°C (33.4 J g^{-1}). The data obtained suggest formation of a "banana" mesophase of modification B_1 or B_2.

We found experimentally that the reaction of a terbium salt with 4-methoxy-1,3-bis[4-(4-dodecyloxyphenoxycarbonyl)phenoxycarbonyl]benzene **VIIIf** yields a complex compound with the luminescence characteristic of Tb(III) ions. The reaction was performed by mixing a solution of terbium trichloride in methanol with a solution of the ligand in benzene. The complex exhibits fairly strong *f–f* luminescence caused by transitions in the Tb(III) ion from the excited $^5D_4$ level to sublevels of the ground ^7F_j level ($j \leq 6$).

Figure 2 shows the luminescence spectrum of the Tb(III) complex with **VIIIf** in which the lanthanide ion, most probably, is coordinated by oxygen atoms of the carbonyl and methoxy groups. The spectrum shows that the most intense luminescence of the Tb(III) ions in its complex with banana-like compound **VIIIf**, as in the majority of other Tb(III) complexes, is observed at 545 nm and is due to the $^5D_4$–$^7F_5$ hypersensitive transition.

EXPERIMENTAL

The ^{1}H NMR spectra of 5–10% solutions of the compounds were recorded on a Varian VXR-300 spectrometer operating at 300 MHz. The mass spectra were taken on an MKh-1321 spectrometer using the direct inlet system at an ionizing electron energy of 70 eV and ionization chamber temperature of 220°C. The IR spectra were recorded on a Specord IR-75 spectrophotometer in $CHCl_3$ solutions and KBr pellets. The luminescence spectra were measured on an SDL-1 spectrometer. The luminescence was excited with a DRSh-250 mercury quartz lamp. The radiation with wavelengths of 313 and 365 nm was cut out with light filters. The purity of the compounds prepared was evaluated by TLC on Silufol UV-254 plates in the 5 : 2 chloroform–acetone sys-

tem. The spots were visualized by treatment with potassium ferricyanide and iron(III) chloride solutions. The phase transition temperatures of the compounds were determined by polarization microscopy on POLAM P-312 and Mettler TOLEDO FP 82HT microscopes (heating rate 3 deg min^{-1}).

4-Methoxy-1,3-benzenedicarboxylic acid was prepared in accordance with the procedures described in the literature; mp 270°C; published data [14, 15]: mp 270–271°C. The synthesis procedure and constants of chlorides of *p*-alkoxybenzoic and 1,3-benzenedicarboxylic acids are given in [16, 17]. 4-Dimethoxy-1,3-benzenedicarbonyl chloride (mp 79°C) was prepared in 68.7% yield by the standard procedure [9].

4-Hexyloxybenzoic acid 4-hydroxyanilide I. To a solution of 1.85 g (0.017 mol) of *p*-aminophenol in dimethylformamide (15 ml), 4 g (0.017 mol) of *p*-hexyloxybenzoyl chloride was added dropwise at room temperature. The mixture was left overnight. Then the mixture was poured into water (150 ml). The resulting crystalline precipitate was filtered off and washed with a large amount of cold alcohol. Yield 62%, mp 200–202°C. IR spectrum: $\nu_{C=O}$ 1680 cm^{-1}. Mass spectrum: M^+ 313.

Found, %: C 72.61, H 7.54, N 4.30.

Calculated, %: C 72.84, H 7.35. N 4.47.

1,3-Bis[4-(4-hexyloxybenzoylamino)phenoxycarbonyl]benzene II. To a solution of 0.812 g (0.004 mol) of isophthaloyl chloride in 8 ml of absolute acetone, we added simultaneously in portions 1.7 g (0.017 mol) of triethylamine and 2.6 g (0.0083 mol) of **I**. The mixture was refluxed for 4 h. The precipitate was filtered off, washed with water, and dried; mp 235°C. The compound is insoluble (even on heating) in alcohol, ether, chloroform, and 1 : 1 toluene–heptane mixture. The compound was refluxed in 1 : 1 acetonitrile–chloroform mixture, filtered off while hot, and dried; mp 243°C, yield 89%. IR spectrum, $\nu_{C=O}$, cm^{-1}: 1680, 1700.

Found, %: C 73.27, H 6.51, N 3.57.

Calculated, %: C 73.01, H 6.35, N 3.70.

4-Methoxybis-1,3-[4-(4-alkoxyphenoxycarbonyl)-phenoxycarbonyl]benzenes VIII. To a suspension of 0.0036 mol of phenol **IV** in 8 ml of absolute benzene, we added 0.8 ml of absolute triethylamine, after which we added dropwise a solution of 0.42 g (0.0018 mol) of chloride **VII** at 15°C and left at room temperature for 12 h. After the reaction completion (TLC monitoring), the suspension was poured onto a water (25 ml)–ice (25 g) mixture, carefully acidified with hydrochloric acid, and extracted first with ether (3 × 20 ml) and then with chloroform (3 × 20 ml). The extracts were washed with water to pH 7 and dried with anhydrous magnesium sulfate and calcium chloride. The solvents were removed under reduced pressure. The ether extract contained unchanged starting phenol **IV**. The residue after removing chloroform was recrystallized two times from a 4 : 1 alcohol–benzene mixture.

CONCLUSIONS

(1) Introduction of an amide group into side fragments of banana-like 1,3-benzenedicarboxylic acid esters leads to compounds showing no mesomorphism.

(2) Banana-like mesomorphic esters of 4-methoxy-1,3-benzenedicarboxylic acid were prepared. Their mesomorphic properties depend on the length of the terminal substituent, with the trend being similar to that observed for rodlike liquid crystals. Disappearance of the mesomorphism in the highest homolog with the terminal dodecyloxy group is due to twisting of the alkyl chain, which favors ordered packing of the molecules in a layer.

(3) The banana-like 4-methoxy-1,3-benzenedicarboxylic acid esters can be used as ligands for preparing a luminescent complex with the Tb(III) ion.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of the Molecular Weight and Structural Organization of Cationic Polyelectrolytes on Protein Flocculation

Abstract—A complex on-line procedure based on combined use of integral (spectroturbidimetry) and differential (nephelometry) light scattering methods was applied to studying the size and formation kinetics of dispersed particles in solutions containing a protein and synthetic cationic soluble polymers. The influence of pH of the medium and of the molecular weight and structural organization of polymers on the floccule size and flocculation kinetics was evaluated.

DOI: 10.1134/S1070427208090255

Native solutions of target biologically active substances (BASs) obtained after separation of mycelium from the culture broth are complex systems containing dissolved organic and inorganic impurities, colloidal particles, and suspended matter. Therefore, preparation of target products of a microbiological synthesis involves preconcentration and purification of native solutions. The extraction procedures used for this purposes involve large volumes of organic solvents (acetone, methylene chloride, butyl acetate), which makes them environmentally hazardous and leads to considerable loss of the target products [1].

Today the stability of biological liquids is controlled with water-soluble polymers of various structures, whose very small additions strongly affect the stability. Most frequently, the flocculation method is used [2]. The development of efficient flocculation procedures for biotechnology requires the development of synthetic procedures and study of properties of new soluble polymers, and also examination of molecular mechanisms of their interaction with BAS.

In this study we examined how the molecular weight and structural organization of new cationic soluble polyelectrolytes based on poly-*N,N,N,N*-trimethylmethacryloyloxyethylammonium methyl sulfate (SMS) on the floccule size and flocculation kinetics of a protein (bovine serum albumin, BSA, MW 65000 Da, pI 4.8). BSA was used as a model of impurity proteins present in native solutions of target BASs. This choice is governed by the fact that the majority of impurity proteins present in native solutions of antitumor and antibacterial antibiotics have molecular weights M 25000 Da and isoelectric points pI $\leq$ 5.5 [3].

EXPERIMENTAL

As flocculants we used cationic water-soluble polymers of various molecular weights and structural organizations, synthesized at the Institute of Macromolecular Compounds, Russian Academy of Sciences (see table). BSA was purchased from Biokhimreaktiv (now Biolar, Olaine, Latvia).

Five concentrations of flocculants (0.5, 1, 2.5, 5, 6 mg l^{-1}) were used. The BSA concentration was 1 mg ml^{-1} in all the experiments. Studies were performed in a 0.3 M ammonium acetate solution, which is an adequate model of the inorganic composition of native solutions of antibiotics.

After mixing solutions of the protein and polymer and vigorous stirring, the system became more turbid, and then the resulting insoluble complex precipitated and the solution became colorless.

The optical density of the solutions was measured on an SF-46 spectrophotometer. From the spectroturbidimetric data we calculated the wave exponent by the formula

$$n = -\partial \log \tau / \partial \log \lambda, \quad (1)$$

where n is the wave exponent; τ, turbidity of the system; and λ, incident light wavelength.

Characteristics of cationic polymers

Sample no.	Polymeric unit (polymer type)	$M \times 10^{-6}$, Da	Cationic charge, mg-equiv g^{-1}
1	Homopolymer of *N,N,N,N*-trimethylmethacryloyloxyethylammonium methyl sulfate (SMS linear)	25.5	3.5
2	Homopolymer of *N,N,N,N*-trimethylmethacryloyloxyethylammonium methyl sulfate (SMS linear)	3.1	3.5
3	Homopolymer of *N,N,N,N*-trimethylmethacryloyloxyethylammonium methyl sulfate (SMS branched)	14.0	3.5

The wave exponent is a parameter characterizing variation of the particle size. A decrease in n is indicative of an increase in the size of dispersed particles in the system [4–6]. Preliminary experiments showed that, in the visible wavelength range, the log–log plot of the optical density vs. wavelength is linear (Fig. 1). Therefore, the contribution of absorption to the light attenuation was neglected.

The kinetics of variation of the particle size was characterized by the quantity

$$A_t = n_t/n_0, \quad (2)$$

where n_t is the wave exponent at time t and n_0, wave exponent at the initial moment of time.

To measure the scattering indicatrix, we used a nephelometer allowing measurements in the angle range from 69° to 120°. As a source of linearly polarized radiation we used a He–Ne laser (λ = 632.8 nm). The polarization plane of the incident light was arranged perpendicular to the plane of recording of scattered radiation intensity. In this case, the observed scattering intensity (we measured the light scattering intensities at angles of 60° and 90°) is maximal.

In the course of experiments, we measured the quantity

$$B_t = [I(60°)/I(90°)]_t/[I(60°)/I(90°)]_0, \quad (3)$$

where $[I(60°)/I(90°)]_t$ is the ratio of light scattering intensities by particles at angles of 60° and 90° at time moment t, and $[I(60°)/I(90°)]_0$ is the ratio of the same light scattering intensities at the initial moment.

To determine the floccule size and study the flocculation kinetics, we used a complex procedure for measuring the parameters of the forming particles in liquids. In the course of developing this procedure, we found that, because of insufficient sensitivity, separate use of one of the optical methods is not informative [7]. Therefore, in this study we calculated an empirical coefficient allowing the sensitivity of each method to be enhanced:

$$C_t = B_t/A_t, \quad (4)$$

The mean effective equivalent diameter of particles at time moment t was found as follows:

$$d_{t\,\mathrm{eff}} = C_t/d_{0\,\mathrm{eff}}, \quad (5)$$

where $d_{0\,\mathrm{eff}}$ is the mean equivalent effective diameter of particles at the initial time moment [4].

It should be noted that the mean effective particle diameter is a relative quantity characterizing the kinetics of formation of the polyelectrolyte–protein dispersed phase.

Comparative analysis of the use of a single method (spectroturbidimetry) and the complex procedure showed that the complex procedure is 1.5–2.0 times more sensitive in determination of changes in the particle size with time [8].

Experimental data on flocculation of BSA with cationic polyelectrolytes at pH 3.56 (under the conditions when the ionization of carboxy groups of the

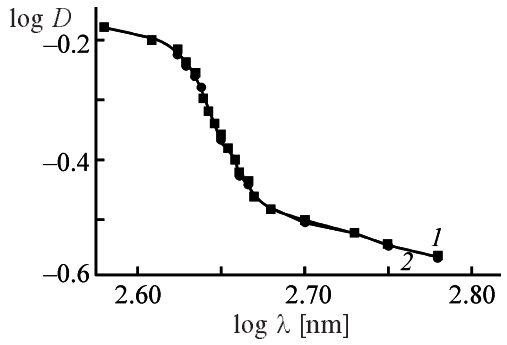

Fig. 1. log–log plot of the optical density D vs. wavelength λ.

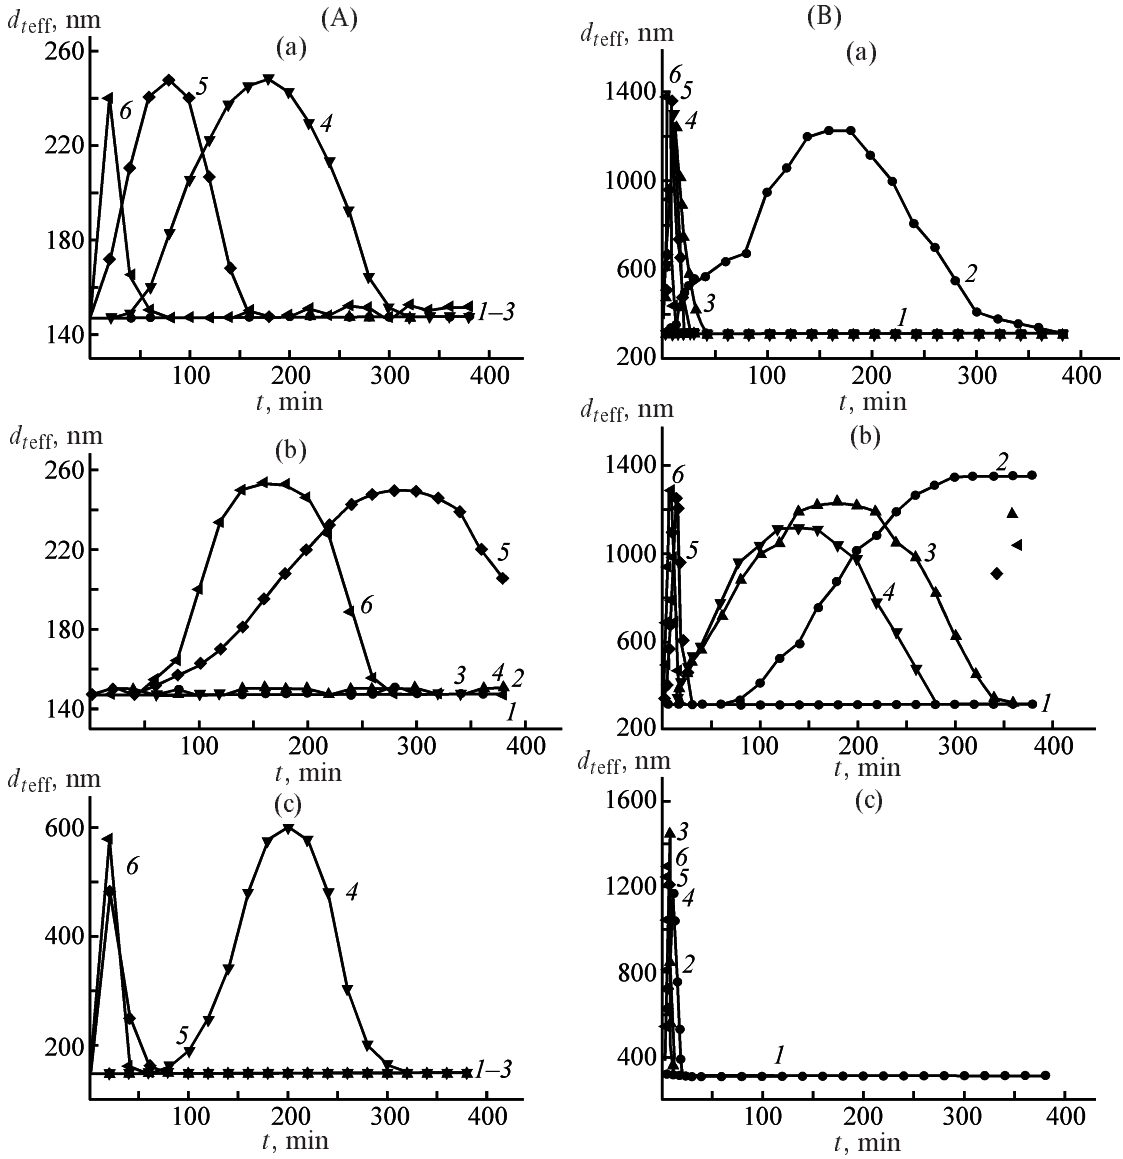

Fig. 2. Effective particle diameter d_{teff} as a function of the experiment time t at pH (A) 6.9 and (B) 9.18. Solution: (a) (*1*) BSA and (*2–6*) BSA + polymer no. 1, (b) (*1*) BSA and (*2–6*) BSA + polymer no. 2, and (c) (*1*) BSA and (*2–6*) BSA + polymer no. 3. Polymer concentration, mg l^{-1}: (*2*) 0.5, (*3*) 1, (*4*) 2.5, (*5*) 5, and (*6*) 6.

protein is suppressed and the BSA molecule bears a positive charge) showed that, for all the polymers studied, the effective particle size of the dispersed system particles was constant, about 310 nm. No floccule formation was observed. Hence, the ion–ion repulsion of positively charged amino groups of the polyelectrolytes and positively charged BSA prevented formation and growth of dispersed particles.

This conclusion is confirmed by data obtained at pH 6.9, when the degree of dissociation of carboxy groups of BSA molecules increased and the protein became negatively charged, whereas amino groups of the polyelectrolyte were still positively charged (Fig. 2A).

At this pH value, linear SMS samples of molecular weight 25.5×10^6 Da caused flocculation of dispersed particles even in concentrations of 2.5 and 5 mg l^{-1} (Fig. 2Aa). To attain the similar effect with samples of a lower molecular weight, concentrations of 5 and 6 mg l^{-1} are required (Fig. 2Ab). Furthermore, the higher-molecular-weight sample is characterized by faster flocculation kinetics. The maximal floccule size was 240–250 nm in both cases. This fact shows that the molecular weight of the linear

polyelectrolyte does not affect the size of the forming dispersed particles.

The branched SMS polymer of molecular weight 14.0×10^6 Da caused aggregation of the particles starting from a concentration of 2.5 mg l^{-1}. The effective floccule size reached 490–600 nm, and the time range of solution destabilization was 40–200 min (Fig. 2Ac). An increase in the polymer concentration to 5 and 6 mg l^{-1} led to acceleration of the flocculation.

It should be noted that the initial effective diameter of dispersed BSA micelles at pH 6.9 decreased and was about 147 nm. This may be due to the fact that, at 8.0 > pH > 4.3, the subunits of BSA molecules are in the N form and have a compact structure due to hydrophobic interactions, salt bridges, and hydrogen bonds. However, at pH < 4.3 and pH > 8.0, the N form of albumin undergoes conformational rearrangement (N–F1 in the acid range and N–B in the alkaline range). As a result, in these pH intervals the effective diameter of dispersed particles increased owing to break of interactions between their subunits [9].

Thus, the higher the molecular weight of a linear cationic polyelectrolyte, the lower concentration of this polymer is required for inducing flocculation. Apparently, the higher the molecular weight of a cationic polyelectrolyte, the higher the probability of contact of peripheral units of an adsorbed macromolecule with adjacent dispersed particles.

At the same time, the structural organization of polyelectrolytes determines the size of the dispersed particles formed and the flocculation kinetics. The linear macromolecule can simultaneously add to two particles, linking them via polymer bridges, because it has two addition sites. The branched macromolecule having several branches can add to several particles simultanepously. This fact accounts for the large effective diameter of floccules, onset of flocculation at lower concentrations, and faster flocculation kinetics with the branched polymer.

Experimental data obtained at pH 9.18 (Fig. 2B) confirm the pattern described above. The effective diameter of dispersed particles increased to 1300–1500 nm owing to unfolding of dispersed BSA micelles to the B conformation and still stronger ion–ion interaction of ionized carboxy groups of the protein and ammonium groups of cationic polyelectrolytes.

The results obtained in this study form a basis for the development of effective methods for pretreatment of native solutions of target BASs to remove impurity proteins.

CONCLUSIONS

(1) In interaction of cationic polyelectrolytes with a protein, the major driving force of floccule formation is ion–ion attraction of ionized carboxy groups of the protein and ammonium groups of polymers.

(2) An increase in the molecular weight of a linear polyelectrolyte makes lower the polymer concentration required to initiate the protein flocculation.

(3) An increase in the number of contacts of a polymeric macromolecule with a protein leads to a decrease in the time required to attain the equilibrium state in the dispersed system.

(4) At a constant pH value, the effective diameter of the forming floccules is determined by the degree of branching of the polyelectrolyte and is independent of the molecular weight of linear polymers.

Abstract—Directional action on the activity of macromolecule propagation centers and their typical set in synthesis of stereoregular polydienes in the presence of polycentered Ziegler–Natta catalytic systems allows control over the molecular characteristics of the polymers obtained and over the service characteristics of products thereof.

DOI: 10.1134/S1070427208090267

One of the main problems of chemical kinetics is the development of a theory for calculating the kinetic parameters characterizing the specific features of a process and the possibility of its control [1]. In turn, among key parameters of diene polymerization on Ziegler–Natta catalysts is the catalytic activity of macromolecule propagation centers (ACs), numerically equal to the product of the rate constant of polymer chain propagation k_p by the AC concentration c_a.

The presently existing theoretical concepts of polymerization on Ziegler–Natta catalysts are based on the idea of polycentered nature of catalysts. In the catalytic system, there are different types of ACs differing in the chain propagation rate constants and in the probability of polymer chain termination [2, 3]. This is manifested in the presence of peak in the curve of AC distribution with respect to kinetic activity, $\psi(\ln\beta)$ (β is the probability of continuation of the polymer chain propagation) and in broad molecular-weight distribution (MWD).

The total catalytic activity in the process is determined as the sum of activities of each AC. To estimate this quantity, it is necessary to have data on the kinetics of the polymerization as a whole (concentration of active centers, degree of conversion of the monomer, rate constant of the polymer chain propagation) and the results of numerical solution of the inverse problem of MWD formation, in particular, calculation of the areas of all peaks (approximated by the Gaussian function) in the $\psi(\ln\beta)$ curve [4, 5].

At the same time, the polycentered character of Ziegler–Natta catalytic systems in polymerization of dienes makes a significant contribution to the process kinetics and molecular characteristics of polymers. This, first of all, makes necessary the calculation of the optimal set of kinetic parameters R^j_{opt} (a^j, c^j_a, k^j_p, k^j_t), where a^j is the catalytic activity of propagation centers of jth type; c^j_a, k^j_p, and k^j_t are the AC concentration, rate constant of polymer chain propagation, and rate constant of polymer chain termination on jth type of ACs, respectively. The array of such sets gives the solution of the inverse kinetic problem and allows fairly accurate determination of both conversion dependences and variation of the statistical moments of MWD in time, taking into account the presence of kinetically nonuniform centers in the system.

It should be emphasized that accurately determined and fixed value of the kinetic activity appreciably decreases the error in calculating the other kinetic parameters. Apparently, an increase in the elements constituting the set R_{opt} will lead to more detailed consideration of the polymerization process with the aim to develop procedures for control of molecular chartacteristics of polymers under industrial conditions.

Here we consider an alternative approach to calculating the total kinetic activity from the conversion

dependences of the stereospecific polymerization of butadiene and a dynamic model providing fairly accurate description of the initial portion of the kinetic curve for the case of AC formation directly in the presence of the monomer.

Polymerization was performed in toluene under the conditions excluding ingress of moisture and impurities that deactivate the catalyst. The catalyst was prepared by two procedures. In the first procedure, after mixing the solutions of a transition metal salt and an organoaluminum component, the catalytic complex was kept for 30 min at 273 K ("separate" procedure). In the second procedure, the catalyst was formed directly in the reaction mixture (in situ), i.e., an organoaluminum compound and a transition metal salt were introduced into the monomer solution in succession. The polymerization was performed with continuous stirring. The degree of conversion of the monomer was determined gravimetrically with a relative error of ≤2%.

A typical experimental dependence of the degree of the monomer conversion U on the polymerization time t in synthesis of polybutadiene in the presence of separately prepared $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ is shown in Fig. 1. In the case of in situ formation of the titanium catalytic complex for butadiene polymerization, the conversion dependence becomes S-shaped with an inflection in the initial period of the process (Fig. 2). This pattern is due to the fact that the formation of Ziegler-type ACs in the course of catalyst preparation in situ occurs more slowly than with preliminary exposure of the catalyst when optimal conditions are created for the occurrence of fast alkylation processes [6, 7].

To calculate the total kinetic activity from the functional dependence of the polymer yield on the polymerization time, $U(t)$, let us present an equation for the running monomer concentration in the form

$$-dM/dt = aM, \quad (1)$$

where M is the monomer concentration and $a = \Sigma k_p^j c_a^j$ is the total activity of the catalyst.

Equation (1) is valid on the assumption that the monomer is mainly consumed in elementary chain propagation reactions and participation of the monomer in chain transfer reactions can be neglected.

By integrating Eq. (1) taking into account the initial conditions, we obtain

$$M = M_0 \exp(-at), \quad (2)$$

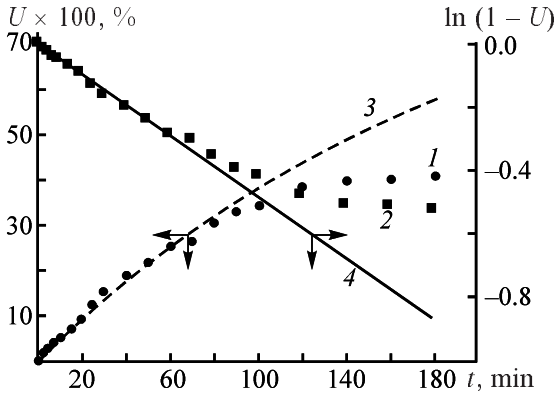

Fig. 1. Yield of polybutadiene U as a function of polymerization time t, plotted in (*1*) normal and (*2*) $\ln(1 - U)$–t coordinates. Toluene, separate procedure, [Ti] = 3 mM, M_0 = 1.5 M, Al/Ti molar ratio 1.8. (*3*, *4*) Calculated by Eqs. (4) and (5), respectively.

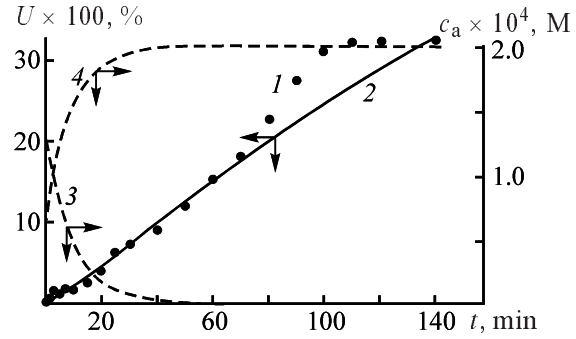

Fig. 2. Butadiene polymerization in the presence of $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ (in situ procedure). Toluene, [Ti] = 3 mM, M_0 = 1.5 M, Al/Ti molar ratio 1.8. (U) Conversion. (*1*) Experimental data and (*2*) calculated by Eq. (9); (*3*, *4*) concentration of active centers c_a of the first and second types, respectively, as a function of polymerization time t.

where M_0 is the initial monomer concentration.

As the conversion, by definition, is equal to

$$U = (M_0 - M)/M_0, \quad (3)$$

from formula (2), taking into account (3), we obtain

$$U(t) = 1 - \exp(-at). \quad (4)$$

Equation (4) is the functional dependence of the conversion on time. It includes the total kinetic activity, and the total kinetic activity of macromolecule propagation centers remains constant in time. After linearization of Eq. (4),

$$\ln(1 - U) = -at, \quad (5)$$

Table 1. Activities a of the separately prepared catalytic system $TiCl_4$–OAC in polymerization of butadiene and isoprene, calculated by Eq. (5) (correlation coefficient R = 0.989–0.999)

OAC	[Ti], mM	a	a*
		min^{-1}	
Butadiene			
$Al(i\text{-}C_4H_9)_3$	3	$(4.84 \pm 0.09) \times 10^{-3}$	5×10^{-3}
	5	$(8.32 \pm 0.02) \times 10^{-3}$	8.0×10^{-3}
$Al(i\text{-}C_4H_9)_2Cl$	5	$(4.51 \pm 0.09) \times 10^{-3}$	4.1×10^{-3}
Isoprene			
$Al(i\text{-}C_4H_9)_3$	5	$(1.28 \pm 0.03) \times 10^{-2}$	1.19×10^{-2}

* Activity calculated from the polycentered model of the catalytic system [5, 11].

the kinetic activity can be found by the least-squares technique from the slope of the straight line for the initial period of the polymerization.

Equation (4) adequately describes the experimental conversion dependence of the butadiene polymerization on a separately prepared catalytic complex up to the reaction time of 60 min (25% conversion) (Fig. 1). For longer polymerization times, formula (4) gives overestimated values of conversion compared to those observed experimentally. This is apparently due to the fact that, when deducing Eqs. (4) and (5), we did not take into account the mass transfer processes decreasing the polymerization rate.

With the progress of polymerization, the solution viscosity increases and a polymer film is formed on the surface of the microheterogeneous catalyst, which considerably decreases the rate of the mass transfer of the monomer from the bulk of the reaction mixture to active centers. Stirring with a magnetic stirrer does not ensure the turbulent mode and does not efficiently lift the diffusion hindrance. At the same time, adequate description by Eq. (4) of the conversion dependence up to relatively high monomer conversion is indicative of significant contribution of the mass transfer to the reaction rate.

Also, a decrease in the observed polymerization rate due to the monomer consumption in chain transfer reactions cannot be ruled out. At the beginning of the process, the probability of the chain transfer to the monomer is high because of a large amount of unchanged butadiene. Therefore, this process should be taken into account starting from short polymerization times (low molecular weights). However, the chain trasnfer rate constant is lower by more than three orders of magnitude than the chain propagation rate constant [8]. Apparently, the influence of the monomer consumption in chain transfer reactions on the extent of deviation of the experimental conversion dependence from that calculated by Eqs. (4) and (5) is insignificant.

From the initial portions of the semilog plots, the total kinetic activity for the separately prepared catalytic complex can be determined fairly accurately (Fig. 1). By least-squares approximation of the experimental dependence $\ln(1 - U)$–t, we calculated the total kinetic activity of the propagation centers in the catalytic systems $TiCl_4$–OAC [OAC is organoaluminum compound $Al(i\text{-}C_4H_9)_3$ or $Al(i\text{-}C_4H_9)_2Cl$] in the polymerization of butadiene and isoprene (Table 1). The activity of centers of the polymer chain propagation are strongly affected by the nature of the cocatalyst (as a component of the complex catalyst) and monomer. For example, at comparable catalyst concentations, replacement of triisobutylaluminum by diisobutylaluminum chloride leads to a decrease in the activity of the catalytic system, and in the polymerization of isoprene in the presence of $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ the activity of the centers is higher by an order of magnitude than in the polymerization of butadiene.

Application of Eq. (4) to describing the conversion dependence for the butadiene polymerization on a titanium catalyst prepared in situ showed that this functional dependence did not describe adequately the initial portion of the kinetic curve. To attain better agreement between the experimental and calculated data, it is appropriate to modify Eq. (4) on the basis of the simplified dynamic two-center model of the catalytic system.

Substantiation of this model for describing the initial portion of the conversion curve consists in analysis of the MWD of the polybutadiene synthesized with various procedures of catalyst formation. In the initial period of polymerization, the MWD of polybutadiene synthesized with in situ prepared catalyst is bimodal with a peak at low molecular weights (Fig. 3). With an increase in the monomer conversion, the characteristic low-molecular-weight peak disappears. Furthermore, in this case polybutadiene samples contain large amounts of the insoluble gel fraction. For example, in the interval of polymerization times of up to 30 min, the gel content is 22–26% on the average, whereas the gel fraction content in the polybutadiene synthesized with the separately

prepared catalyst is as low as 2–5%. A typical feature of cationic polymerization is the chain transfer to the polymer, resulting in cross linking and, as a consequence, in increased content of the gel fraction in the polymer [9]. These facts suggest the possibility of simultaneous occurrence of cationic (under the action of $TiCl_4$) and anionic–coordination polymerization of butadiene in the initial period of the synthesis with the titanium catalytic complex formed in situ.

It is well known [10] that $TiCl_4$ in the first step of the reaction with OAC is alkylated by the scheme typical of many Ziegler–Natta-type catalytic systems. The organotitanium compounds or their complexes formed in the process subsequently decompose with the formation of a $TiCl_3$ precipitate which, in turn, also undergoes alkylation with the formation of a bimetallic catalytic complex:

$$TiCl_4 + AlR_3 \rightarrow [TiCl_4 \cdot AlR_3] \rightarrow TiCl_3R \cdot AlR_2Cl,$$

$$TiCl_3R \cdot AlRCl_2 \rightarrow TiCl_3 \cdot AlR_2Cl + 0.5R_{-H} + 0.5R_{+H},$$

$$TiCl_3 + AlR_3 \rightarrow RTiCl_2 \cdot AlR_2Cl.$$

As $TiCl_4$ is cation-active in diene polymerization, in the initial period of the polymerization with the in situ prepared catalyst it can form an active center. With the progress of formation of the bimetallic ion–coordination polymerization catalyst, $TiCl_4$ irreversibly transforms into a catalyst–cocatalyst complex. This is indicated by an increase in the activity and stereospecificity of titanium catalysts after their exposure for 20–40 min [6, 7].

Therefore, it is appropriate to consider the transformation of a cationic AC into a coordination-type polymerization center containing a definite number of alkyl radicals, neglecting the chain termination reactions with the aim to simplify the calculations and save the computer time. For this purpose, it is necessary to solve an inverse problem of finding the AC distribution function with respect to kinetic activity from the MWD curves [3]. Figure 3 shows the result of numerical solution of the inverse problem in the form of the distribution function $\psi(\ln\beta)$ for two procedures of catalytic complex preparation. Each maximum in the $\psi(\ln\beta)$ dependence corresponds to, at least, one type of ACs. The formation of the microheterogeneous titanium catalyst in the medium of the monomer in situ leads to appearance of an AC type generating the low-molecular-weight polybutadiene fraction with the most probable molecular weight $\ln M$ = 7.1–7.8, which is not observed in preliminary exposure of the catalytic complex. Furthermore, the separately prepared catalytic system is characterized by the presence of chain propagation centers producing polybutadiene of the maximal molecular weight ($\ln M$ = 14.6–14.8) even at low conversions. Without preliminary storage of the catalyst, such centers appear only at the monomer conversion exceeding 15%.

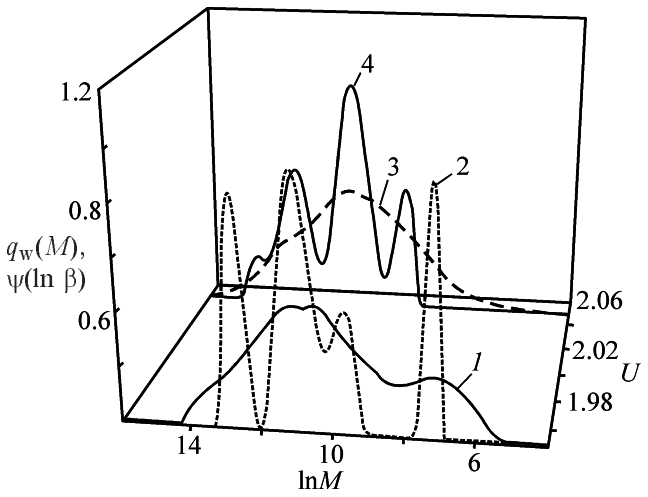

Fig. 3. (*1*, *3*) MWD–$q_w(M)$ curves and (*2*, *4*) distribution function of active centers with respect to kinetic activity $\psi(\ln\beta)$ for the (*1*, *2*) in situ and (*3*, *4*) separately prepared catalyst based on $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ in polymerization of butadiene. (*U*) Conversion and (*M*) molecular weight.

Approximation of the experimental conversion dependences for the butadiene polymerization on the titanium catalyst prepared in situ, taking into account transformation of cationic ACs into coordination-type propagation centers, consists in solution of the direct kinetic problem.

In this case, the total activity of the catalytic system varies in the course of the polymerization, and Eq. (4) takes the form

$$U = 1 - \exp\left[\int_0^t a(t)\mathrm{d}t\right]. \quad (6)$$

Assuming k_p to be constant, let us relate the variation of the total activity exclusively to variation of the concentration of the transforming centers:

$$a = k_{p,1}c_{a,1}(t) + k_{p,2}c_{a,2}(t) + \delta. \quad (7)$$

Equation (7) describes the transformation of AC of the first type into that of the second type, with

Table 2. Kinetic parameters of active centers participating in the one-way transition (k = 0.1 min^{-1})

ln M	k_p	k_p^*	$c_a^0 \times 10^4$	$c_a^0 \times 10^4$*
	l mol^{-1} min^{-1}		M	
7.1–7.8	3	5.6	1.2	1.8
9.4–9.9	15	19	0.8	0.73

* Values calculated according to [5, 11].

the activities of the other types of centers being constant (δ = const). According to the concepts of formal kinetics, the differential equations describing the variation of the concentrations of ACs of the first and second types will have the form

$$\begin{aligned} dc_{a,1}/dt &= -kc_{a,1}, \\ dc_{a,2}/dt &= kc_{a,1}, \end{aligned} \tag{8}$$

where k is the rate constant of mutual transformation of propagation centers of different types.

By solving Eqs. (6)–(8) with the initial conditions that, at $t = 0$, $c_{a,1} = c_{a,1}^0$, $c_{a,2} = c_{a,2}^0$, we obtain

$$U = 1 - \exp\{c_{a,1}^0(k_{a,2} - k_{a,1})k^{-1}[1 - \exp(-kt)] - (c_{a,1}^0 + c_{a,2}^0)k_{p,2}t\}. \tag{9}$$

Equation (9) allows correct description of the initial portion of the kinetic curve with the titanium catalyst prepared in situ (Fig. 2). In so doing, we assume that, with the reaction progress, cationic centers transform into ion–coordination ACs catalyzing the stereospecific polymerization of butadiene.

Expression (9) contains a large number of unknown kinetic parameters, which leads to the instability of the solution found. To decrease the error in determining the numerical values of kinetic constants, we developed an optimization algorithm for searching for these constants in the space of five variables, consisting in minimization of the functional

$$F(x) = \Sigma[U_1^{calc} - U_1^{exp}]^2, \qquad x(c_a, k, k_{p,1}, k_{p,2}). \tag{10}$$

As a result, we found the kinetic parameters characterizing the two-center model of the catalytic system (Table 2). To check the adequacy of the model, we calculated the concentrations of the ACs participating in the transition and the corresponding propagation rate constants by the procedure based on solution of the inverse problem of MWD formation [5, 11] in which the solution is sought for using the statistical moments of MWD and the function ψ(ln β). It can be seen that the results of direct and inverse simulation of the butadiene polymerization on the titanium catalyst prepared in situ are in good agreement (Table 2). The calculations showed that the region of inflection in the kinetic curve (onset of polymerization acceleration) corresponds to flattening-out of the concentration of second-type ACs and maximal decrease in the content of first-type ACs characterized by low rate constant of the polymer chain propagation (Fig. 2).

As the polymerization is performed under the conditions excluding ingress of moisture and impurities into the reaction system, the low activity of ACs of the first (cationic) type is apparently due to the absence of the required cocatalyst (the catalyst is an aprotic acid). Furthermore, the correlation of the acidity and cationic activity of Friedel–Crafts catalysts in polymerization processes shows that $TiCl_4$ is less reactive than the $TiCl_4$–Al(i-C_4H_9)$_3$ complex, as demonstrated in [12] by the example of polymerization of 1,3-pentadiene.

Thus, in the case of separate preparation of the catalyst, the conversion dependence is well described by expression (1) to 30–40% conversions. In the process, the total catalytic activity remains constant and can be fairly accurately determined from the semilog plot. With the titanium catalyst prepared in situ, the conversion dependence is S-shaped, which may be due to transformation of cationic active centers into coordination centers with the progress of the monomer conversion.

The data we obtained indicate that it is necessary to evaluate and take into account the rate constant of the one-way transition between different types of ACs. This allows us to choose the optimal set of kinetic parameters of the reaction with the aim to develop procedures for decreasing the probability of formation of active centers initiating the cationic processes in the course of diene polymerization in the presence of Ziegler–Natta catalysts. The formation of catalytic systems in situ favors the formation of active centers producing the polymer fraction with a low molecular weight and a high content of the insoluble gel fraction. Thus, the analytical dependences given in this paper allow control of the origination of "impurity" active centers of stereospecific polymerization when the catalyst is formed in situ. As the observed process deceleration with the catalysts formed in situ is also characteristic of the

other system for ion–coordination polymerization, the suggested physicochemical interpretation of the model of active center formation seems to be the most realistic.

CONCLUSIONS

(1) Preparation of a microheterogeneous titanium catalyst in situ for butadiene polymerization favors formation of undesirable active centers initiating cationic processes, with deceleration of the rate of the ion–coordination polymerization of dienes, and producing the polymer fraction with a low molecular weight, a broad molecular-weight distribution, and a high content of the insoluble gel fraction.

(2) The suggested analytical expression allows prediction of the appearance in the reaction mixture of macromolecule propagation centers of the cationic type and estimation of the kinetic parameters of their transformation into ion–coordination-type active centers. In large-tonnage rubber production, this will allow control of the product quality by directional variation of the set of different active centers.

Abstract—Influence of fullerene C_{60} on the structure and mechanical properties of low-density polyethylene samples cast from a melt and a solution was studied.

DOI: 10.1134/S1070427208090279

Previously we examined the influence of fullerene C_{60} additions on the mechanical properties (strength, Young's modulus, breaking elongation) of thin (10–12 μm) films of atactic poly(methyl methacrylate) (PMMA).

The choice of poly(methyl methacrylate) as the matrix was governed by the fact that its supramolecular structure is simple and uniform. The intensity of small-angle X-ray patterns of uniform inorganic and organic glasses is usually constant in the whole measurable range of scattering angles [2, 3]. Certain insignificant monotonic increase in the intensity in going to the primary beam is clearly caused by density fluctuations. Introduction of 1–5% fullerene C_{60} into PMMA films by casting from a solution containing PMMA and C_{60} had no noticeable effect on small- and wide-angle X-ray patterns. This fact suggests more or less uniform distribution of fullerene in the polymer matrix.

Introduction of fullerene into the polymer should result in formation of strong nanocomposites owing to uniform distribution of the fullerene in the matrix, the uniform size distribution of fullerene molecules, and electron-acceptor properties of fullerenes which can be considered as free radicals traps [5]. Indeed, even at 1% content of fullerene in the films, their strength increases by a factor of approximately 5.

The aim of this study was to examine the influence of small (1–10%) additions of fullerene C_{60} on the mechanical properties of the most commonly used thermoplastic, polyethylene (PE). Although the chemical composition of PE is simple, this polymer is amorphous–crystalline and has a developed morphology. Polyethylene is chemically inert and should not react with fullerene in the course of crystallization from melts and solutions. Thus, fullerene will be most likely localized in the amorphous regions of PE.

EXPERIMENTAL

Samples of low-density polyethylene [LDPE, GOST (State Standard) 16 337–77] were prepared by casting from (1) melts and (2) solutions in different solvents. The fullerene concentration was varied in the range 0–10 wt %.

In the first case, dry LDPE and C_{60} were mixed, placed in a hydraulic mold, and heated at 150°C and a pressure of 50 atm. The samples were obtained in the form of 0.2–0.3-mm plates.

In the second case, 5% solutions of LDPE in toluene and 1,2-dichlorobenzene (DCB) were prepared by heating on a water bath at 80–90°C. Then aliquots of C_{60} solutions in the same solvent were added and the mixture was stirred for a short time. The films were cast on a dry glass support heated at 80°C. The film thickness ranged from 20 to 80 μm.

To study the mechanical properties, samples in the form of a double shovel 2 or 4 mm wide, with 22-mm working part, were cut out from the films or plates. The mechanical tests were performed at 20°C on PM-1 tensile-testing machine at a moving clamp velocity of 12 mm min^{-1}. The tensile strength σ_t, breaking elongation ε_e, and initial Young's modulus E_0 were determined from the strain curves.

X-ray diffraction study of the samples was performed on DRON-2 and KRM-1 diffractometers using nickel-filtered copper radiation. The intensity of wide-angle scattering was measured on a DRON-2 diffractometer with a slit collimator. The half-width of the primary beam was 36 min. The intensity of small-angle scattering was measured on KRM-1 diffractometer with slit collimation of the primary beam. The half-width of the beam was 2.5 min. To correct the line width of the sample, the width of primary beam is usually used instead of the line width of a reference [6]. However, in this study, the width of the primary beam was not corrected since our aim was only to estimate the crystallite size. No collimation corrections were introduced for the same reason.

The measurements were performed in the transmission mode: a sample was fixed at the center of goniometer at a right angle to the primary beam. The $I_s(2\theta)$ scattering pattern was recorded. Then the sample was placed in front of the first slit and the scattering pattern of the primary beam was recorded taking into account its absorption in the sample $I_a(2\theta)$. Since the $I_a(2\theta)$ curves of all samples were similar within the limits of the experimental error, the primary beam was not normalized to the same intensity. The $I_a(2\theta)$ curve was subtracted from the $I_s(2\theta)$ curve. The experimental diffraction patterns were constructed in the form of difference curves $I(s)$ or $I(2\theta)$, where $s = 4\pi\sin\theta/\lambda$, $\varphi = 2\theta$ is scattering angle, and λ is the X-ray radiation wavelength. For small scattering angles, $s \approx 2\pi\varphi/\lambda$.

In the course of small-angle measurements, the goniometer was rotated manually. The intensity of scattered radiation at each fixed angle was measured at 1000 pulses. The relative determination error of the intensity was 3–4%.

The melting point was measured on a DSC 204F2 Netzsch calorimeter at a heating rate of 50 deg min^{-1}. The sample weight was 2–4 mg.

Representative wide-angle X-ray patterns of the initial (curve *1*) and fullerene-containing LDPE formed from a melt (curve *2*) and from a DCB solution (curve *3*) are shown in Fig. 1. As can be seen, the X-ray patterns of the initial LDPE samples are similar to those of the samples prepared from the melt and DCB solution. These patterns contain strong (110) and (200) reflections of orthorhombic lattice of PE (Fig. 1, curve *1*).

Sharp reflections of C_{60} crystallites at 2θ 10.5° and 28°–36° are observed along with (110) and (200)

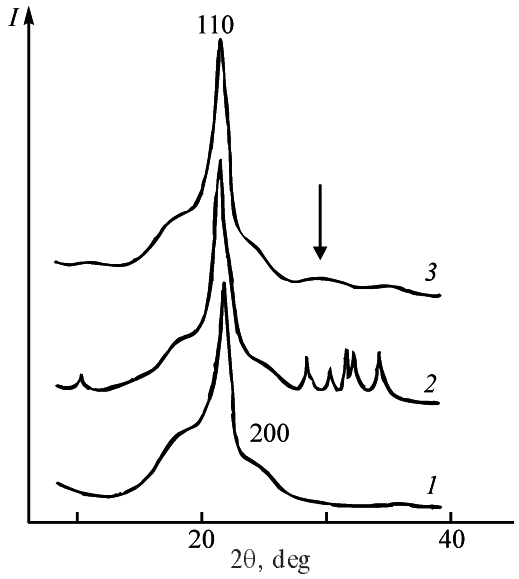

Fig. 1. Wide-angle X-ray diffraction patterns of (*1*) initial LDPE, (*2*) LDPE + 10 wt % C_{60} prepared from melt, and (*3*) LDPE + 10 wt % C_{60} prepared from DCB solution. The appearing reflection of the C_{60} lattice is indicated with an arrow. (*I*) Intensity and (2θ) Bragg angle.

reflections of LDPE on wide-angle patterns of the LDPE-C_{60} system at a fullerene concentration c = 1 wt %, prepared from the melt. At higher fullerene concentrations, the intensity of the reflections of C_{60} crystallites increases, with their radial width and location remaining the same. The intensity of the main (110) and (200) reflections of the PE matrix and their location and radial width do not change. The size of PE and C_{60} crystallites determined by the Scherrer equation [6] is 5–6 and 20–25 nm, respectively. The wide-angle X-ray diffraction patterns show that the components of the polymer compound form individual phases and C_{60} molecules are not incorporated in the crystal lattice of the matrix.

The wide-angle X-ray diffraction patterns of LDPE + C_{60} samples prepared from solutions in toluene and DCB do not change noticeably with increasing C_{60} concentration from 0 to 5 wt %. Only at c = 10 wt %, weak blurred reflections of C_{60} appear on the background of LDPE reflections (Fig. 1, curve *3*). Therefore, no ordered C_{60} aggregates are formed. According to our previous estimations [4], weak and broad C_{60} reflections are due to aggregates of no more than 100 C_{60} molecules (4–5 molecules in each direction).

Small-angle X-ray diffraction patterns of LDPE + C_{60} samples prepared from DCB solutions (samples prepared from toluene solutions are similar) are

Mechanical properties at uniaxial stretching of LDPE samples

1	0	16	300	70	3.2	300	80	30	300	460
2	1	11.5	170	110	5.7	75	80	30	250	660
3	3	8.5	135	190	6.2	45	160	32	200	660
4	5	8.5	115	230	6.9	25	160	32	120	910
5	10	7.5	105	280	7.3	21	400	25	80	1600

shown in Fig. 2. The small-angle patterns of the samples prepared from melts are essentially similar. A common feature of small-angle patterns of all the samples is the presence of separate reflections corresponding to large spacings (16–20 nm). The intensity of the reflections at the maximum I_m changes by 20–30% with increasing fullerene concentration. Analysis of I_m changes within the framework of the two-phase model (as it was done, e.g., in [7, 8]) shows that only ~10% of fullerene penetrates in interlayer amorphous regions responsible for formation of large interplanar spacings, and the majority of fullerene molecules are concentrated in the amorphous part.

The fact that the wide-angle patterns of all polyethylene matrices are similar is consistent with similar melting points of all LDPE crystallites (106–107°C).

The results of mechanical tests of LDPE samples

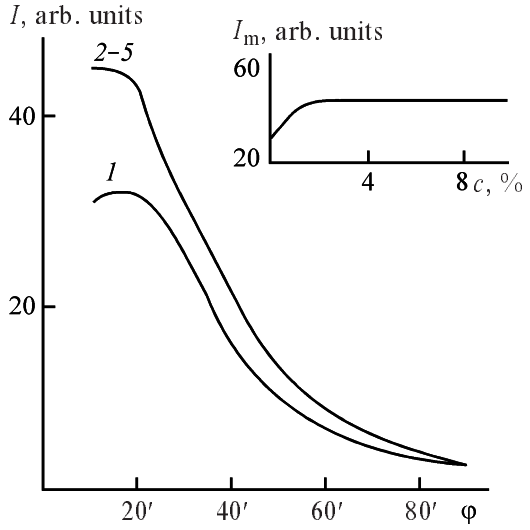

Fig. 2. Small-angle X-ray diffraction patterns of LDPE + C_{60} prepared from DCB solutions. (*I*) Intensity, (*c*) concentration, and (φ) angle. C_{60}, %: (*1*) 0, (*2*) 1, (*3*) 3, (*4*) 5, and (*5*) 10.

are presented in the table. As can be seen, the elasticity of the samples decreases (ε_b decreases) and Young's modulus E monotonically increases with increasing C_{60} concentration. The tensile strength depends on the sample type. It should be noted, however, that the mechanical properties of LDPE + C_{60} samples prepared from DCB solutions are significantly better than those of the other samples. This is probably due to high solubility of C_{60} in DCB [9] and, therefore, high uniformity of fullerene distribution in the PE matrix and dispersion of the fullerene to separate molecules and small aggregates. With an increase in the fullerene concentration, the relatively high strength (~30 MPa) of these samples is preserved, their elasticity slightly decreases, but the elastic modulus increases by a factor of more than 2.

Thus, the structure and mechanical properties of the fullerene-containing composite significantly depend on the preparation procedure and the fullerene content in the polymer matrix.

CONCLUSIONS

(1) The fullerene does not enter into low-density polyethylene crystallites and is accumulated in the amorphous parts of the matrix.

(2) Fullerene in the samples prepared from low-density polyethylene melt forms 25–30-nm crystallites, whereas in the samples prepared from solutions it is dispersed to separate molecules or small conglomerates.

(3) At uniaxial stretching of all samples, the breaking elongation decreases and the elastic modulus increases with increasing C_{60} concentration.

(4) The best mechanical properties are exhibited by the samples prepared from 1,2-dichlorobenzene solutions. With increasing fullerene concentration, their elastic modulus increases by a factor of more

than 2, with their strength preserved and elasticity slightly decreased.

Abstract—The conditions of preparation of mixed cellulose ethers containing carboxymethyl and amide groups by reaction with urea were examined with samples of commercial carboxymethyl cellulose and that prepared from flax cellulose as examples. The water solubility of the resulting products and their sorption activity toward copper ions were examined in relation to the amount of amide groups introduced.

DOI: 10.1134/S1070427208090280

Water-soluble cellulose compounds are widely used in various branches of engineering and also in food industry, perfumery manufacture, and medicine. Sodium salt of carboxymethyl cellulose (NaCMC) and methyl cellulose (MC) are the most widely applied cellulose compounds. They are used in oil extraction, paper, textile, and food industries, as well as in manufacture of paints and varnishes, dry building mixtures, adhesives, etc. These cellulose ethers are utilized primarily as aqueous solutions.

The application field for carboxymethyl cellulose (CMC) can be extended by its compounding with other polymers or by chemical modification.

Chemical modification of partly substituted cellulose ethers is effected either by introduction of new functional groups at free hydroxy groups of the polymer in anhydroglucose moieties or by selective modification of the already existing substituents.

Carboxymethyl cellulose amides (CMCAs) are prepared by reactions of amines with CMC chlorides [1–3] or with CMC in the H form [4]. We described previously [5] the conditions of preparation of amides of CMC based on flax and cotton cellulose by the reaction with chloroacetamide.

Cellulose compounds are produced mostly from wood and cotton cellulose. An alternative raw material can be found in large-capacity waste from flax production: short flax fibers and lignified part of pedicels (boon).

The physicochemical properties of new cellulose compounds are affected by the following factors: nature of the initial polymer, molecular weight, chemical composition, presence of concomitant substances, structural uniformity, fiber morphology, etc.

This study was aimed to elucidate the conditions of synthesis of cellulose ethers by the reaction of CMC prepared from flax and cotton fibers with urea. Vali et al. [6] and Goikhman et al. [7] described the conditions of preparation of cellulose carbamates by reaction with urea. These conditions differ from those for other cellulose compounds.

Urea can be introduced into the reaction mixture by various procedures [7]: using ammonia (introduction of biuret and urea into liquid ammonia) and without using ammonia: by impregnation of cellulose with an alkaline solution of urea, by introduction of urea in a buffer high-boiling substance where urea melts and gets uniformly spread over the surface of cellulose fibers, or by impregnation of cellulose with a solution of urea or biuret in water, DMSO, DMAA, and DMF.

Depending on the conditions, the reaction between CMC in the acid form (HCMC) and amines can yield cross-linked systems [8, 9] and mixed cellulose ethers containing amide and catboxymethyl groups [10]. Polysaccharides (starches, CMC) and urea can also be used to prepare composite materials that can be processed as a melt [11]. Such composites are obtained using an oxidizing agent (hydrogen peroxide) and a catalyst (iron chloride).

We elucidated here the conditions of synthesis of mixed cellulose ethers without oxidizing agents and

Table 1. Characteristics of the polymers used

Sample	DP_η	DS_{Na}	Water solubility, %
Purified commercial carboxymethyl cellulose NaCMC	460	0.57	99
Short flax fibers	4230	–	–
NaCMC (flax)	900	0.52	89
Repeated carboxymethylation of NaCMC (flax)	500	0.80	92

catalyst. The reaction of urea with CMC can presumably occur at carboxymethyl and hydroxy groups of the polymer and can be affected by the molecular characteristics of the polymers, the uniformity of distribution of the substituents (carboxymethyl groups), and morphological features of the cotton and flax fibers.

EXPERIMENTAL

For comparative assessment of the reactivities of the cellulose ethers we used commercial NaCMC sample obtained from cotton cellulose. For synthesis of mixed ethers of flax cellulose we synthesized in advance NaCMC samples by the technique described in [12] (Table 1). The NaCMC samples washed to remove NaOH and Cl^- were vacuum-dried at 60°C. The degree of substitution at carboxy groups was calculated using the expression [13]

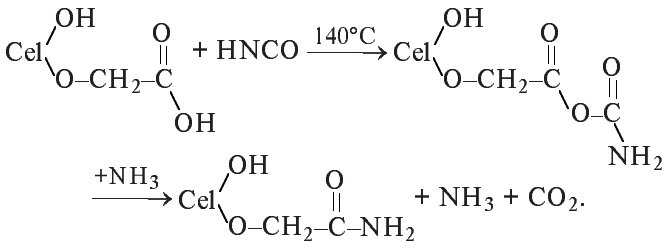
$$DS_{Na} = 162n/(23 \times 100 - 80n), \quad (1)$$

where n is the Na content of the polymer, wt %; 162, molecular weight of the elementary unit of cellulose; 23, atomic weight of sodium; and 80, increment of the molecular weight of the elementary unit of cellulose upon introduction of one CH_2COONa substituent.

The Na amount was determined by conductometric back-titration of the NaCMC samples. The solubility of NaCMC and of the ethers synthesized was determined as recalculated for 1% solutions by the technique described in [14].

The initial short flax fibers contain a significant amount of concomitant polymers and mineral substances affecting the reactivity of cellulose and uniformity of distribution of substituents in the polysaccharide molecules in flax fibers. For this reason, the flax fibers were pretreated under laboratory conditions with a cooking mixture ($NaOH : Na_2S_2O_3 : H_2O$) in a nitrogen flow [15]. Such treatment removes most of the concomitant substances (hemicelluloses, lignin, pectins) from flax fibers; it causes an insignificant decrease in DP_η of the polymer and a substantial increase in the proportion of cellulose.

Table 1 shows that the degree of polymerization DP_η of NaCMC prepared from flax fibers is much higher, while DS_{Na}, lower than those of commercial NaCMC (the DP_η parameters were calculated from the viscometrically determined molecular weights).



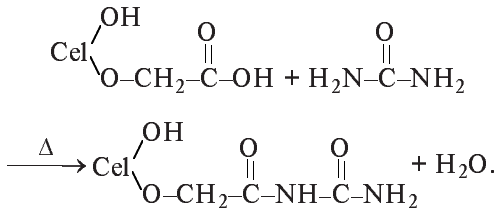
Sodium carboxymethyl cellulose was prepared by the standard technique [12], which suggests that, to increase DS_{Na} of the flax cellulose ether and its water solubility, the already synthesized NaCMC sample requires repeated carboxymethylation, which increases both its DS_{Na} and solubility in water, but simultaneously decreases DP_η of the polymer. Elucidation of the conditions of one-step synthesis of NaCMC with a higher DP requires additional research efforts [16], which is beyond the scope of this study.

Sodium carboxymethyl cellulose was converted in advance to the H form (by treating a weighed portion with 20% aqueous solution of HCl in ethanol, pH 2.0–2.5), after which the sample was washed to remove Cl^- ions to pH 7.0 and dried. The reaction was run in *o*-xylene at 140°C. The choice of *o*-xylene for the high-boiling buffer solvent was dictated by the facts that its boiling point (144.4°C) exceeds the urea decomposition temperature and that *o*-xylene is inert toward both cellulose and urea.

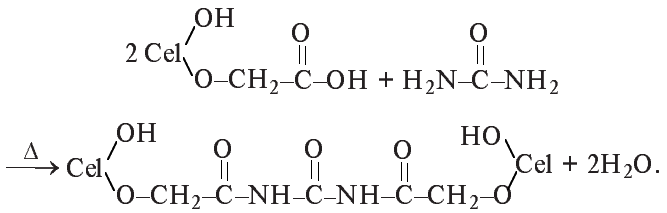
At 132.7°C, urea decomposes into isocyanic acid:

$$H_2N\text{–}C(O)\text{–}NH_2 \xrightarrow{140^\circ C} HN{=}C{=}O + NH_3.$$

The resulting isocyanic acid reacts with carboxymethyl goups of HCMC to form a CMC amide:



Under identical conditions (at 140°C), CMC amides were obtained by the reaction of HCMC with decylamine [10].



Isocyanic acid can also react with unsubstituted hydroxy groups at 140°C (preparation of cellulose carbamates) [17]:

$$Cel(OH)_3 + HN{=}C{=}O \xrightarrow{140^\circ C} Cel(OH)_{3-x}[-O-C(O)-NH_2]_x.$$

The decomposition of urea takes some time, which suggests that undecomposed urea can enter into the reaction yielding amides with elimination of water, as in the reaction of HCMC with amines (at carboxy groups) [10]:

Also possible is the reaction of urea at its two amino groups, yielding cross-linked polysaccharide macromolecules:

The necessary amount of urea was mixed with the HCMC samples at different mole fractions on a multidisperser. All the samples were mixed and ground for 30 min and then poured over with *o*-xylene. The synthesis was carried out in a glass flask at 140°C on an oil bath for different periods. The temperature was controlled with a contact thermometer. The liquor ratio in all the reactions was 13.

The resulting samples were twice washed with ethanol to remove xylene. The unchanged urea was removed by washing the samples with warm water (twice), after which they were moistened with ethanol and vacuum-dried at 40°C. A part of each sample was left in the H form, and another part was converted to the Na form (by treating with 1% NaOH solution in ethanol at 50°C for 45 min). The amount of the amide groups ($CONH_2$) in the ethers synthesized was characterized by the amount of bound nitrogen. The nitrogen content was determined by the Kjeldahl method [18]. Tables 2 and 3 present the synthesis conditions for the mixed cellulose ethers based on commercial NaCMC and that synthesized from flax fibers.

We showed previously [4] that, with increasing amount of the preliminarily introduced amine (per mole of carboxy groups) and reaction time, the proportion of bound nitrogen in the polymer tends to increase. A similar trend can be seen from Tables 2 and 3, but there are some distinctions as well. Table 2 shows that, at the 1 : 1 molar ratio and the reaction time of 2 h (experiment no. 3), the amount of bound nitrogen is at a maximum. With decreasing amount of urea preliminarily introduced into the HCMC fibers, the amount of bound nitrogen tends to decrease as a whole. At the same time, the reaction time exerts an opposite effect. For example, at the reaction time of 2 h (experiment no. 6), the amount of bound nitrogen is at a minimum. The HCMC obtained from flax fibers is also characterized by the minimal amount of bound nitrogen at the reaction time of 2 h (Table 3, run no. 5). Apparently, the reason for the observed scatter of the amounts of bound nitrogen in the mixed cellulose compounds is nonuniform distribution of urea in the fibers when the polymer was subjected to dry grinding jointly with urea and a product nonuniformly substituted over the bulk of the fibers was obtained.

Conversion of AHCMC to the Na form (needed to determine DS_{Na} and the water solubility of the samples, since HCMC is water-insoluble) by treating HCMC with an aqueous NaOH solution in ethanol causes intensive hydrolysis of the amide bonds with formation of carboxy groups [7], which results in a decrease in the amount of bound nitrogen.

It should also be noted that, with increasing amount of preliminarily introduced urea (increasing molar ratio), the amount of bound nitrogen increases to levels exceeding the theoretically possible values. For example, in the case of the reaction of isocyanic acid with carboxy groups in the CMC sample with DS_{Na} of 0.57, the theoretically possible amount of bound nitrogen is 4.3%. Table 2 shows that, for two samples (experiment nos. 2 and 3), the content of nitrogen exceeds the calculated level, which suggests that, in parallel, another reaction can also proceed, in particular, that of isocyanic acid with hydroxy groups to yield cellulose carbamates. This hypothesis will be confirmed below.

In synthesis of mixed cellulose ethers based on flax CMC (Table 3), the amount of urea introduced into the fibers and the reaction time affect the content of bound nitrogen in a similar manner, except for the fact that the experimentally determined nitrogen content does not exceed the calculated value (for CMC with DS_{Na} of 0.52, the content of bound nitrogen arising from the reaction of isocyanic acid with carboxy groups is 3.79%). It is also seen that the content of bound nitrogen in AHCMC and ANaCMC is lower than that in the similar samples obtained with commercial CMC (cotton linter). The

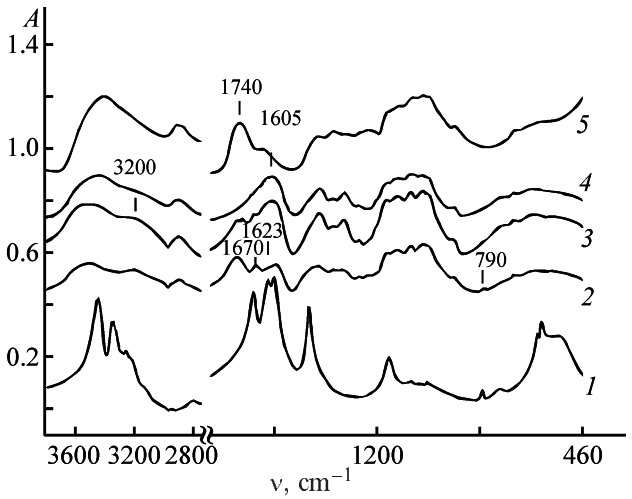

Fig. 1. IR Fourier spectra of (*1*) urea, (*2*) AHCMC, (*3*) ANaCMC, (*4*) NaCMC, and (*5*) HCMC derived from commercial CMC. (*A*) Absorption and (ν) wavenumber; the same for Fig. 2.

difference in the amount of bound nitrogen is associated with the above-mentioned presence in the initial flax fibers of other concomitant substances and the specific morphological features of the flax fibers. Presumably, the amidation in flax HCMC fibers proceeds nonuniformly and at a lower rate.

The results of chemical analysis (the amounts of bound nitrogen and carboxy groups or $DS_{Na)}$ were confirmed by IR Fourier spectroscopy. The IR absorption spectra of samples were measured on a Bruker FS-88 IR Fourier spectrometer using KBr pellets.

Figure 1 shows the IR spectra of urea, AHCMC, and ANaCMC, as well as of the initial NaCMC and HCMC. The absorption bands characteristic of purified cotton cellulose include a broad band at 3000–3700 cm^{-1} for free and hydrogen-bonded (via intra- and intermolecular hydrogen bonds) OH groups of the polymer; absorption near 2900 cm^{-1} is associated with CH_2 and CH groups of the polymers (the band at 2900 cm^{-1} of pure cellulose has approximately symmetrical shape [19]). The IR spectrum of NaCMC contains a band at 1597–1605 cm^{-1}, assigned to antisymmetric vibrations of the ionized carboxy groups COO^- [19]. Upon conversion of NaCMC to the H form, an absorption band of the COOH groups appears at 1740 cm^{-1}, as well as a shoulder at 1647 cm^{-1} [4].

Primary amides are characterized by the absorption band of the CO group at 1650–1670 cm^{-1} (amide I) and a band at 1620–1650 cm^{-1} (amide II), associated with bending vibrations of the NH_2 groups [20]. In our case, the spectrum of AHCMC contains absorption bands at 1670 and 1623 cm^{-1}. Also, an absorption band belonging to the hydrogen-bonded NH groups of the primary amide is observed at 3200 cm^{-1}. Upon conversion of AHCMC to ANaCMC, the absorption band at 1623 cm^{-1} cannot be observed because it is close to that of COO^- groups (at 1605 cm^{-1}), and the absorption band at 1670 cm^{-1} is manifested as a shoulder.

The IR spectra of cellulose carbamates contain a weak absorption band of the C=O groups at 790 cm^{-1} (bending vibrations) [7]. A stronger absorption band of the C=O groups (stretching vibrations) of cellulose carbamate at 1710–1720 cm^{-1} cannot be observed because it is obscured by the strong absorption band of the COOH groups at 1740 cm^{-1}.

Analysis of the IR spectra shows that the spectra of AHCMC contain characteristic absorption bands of amides and also an absorption band at 790 cm^{-1}. The latter confirms the above-made assumption that the hydroxy groups are also substituted, i.e., a cellulose carbamate is formed. The conversion of AHCMC to ANaCMC involves hydrolysis of the amide groups, which is responsible for the fact that the absorption band at 1670 cm^{-1} decreases in intensity. It should be noted that, during hydrolysis, the absorption band at 790 cm^{-1} virtually fully disappears. Presumably, the carbamate groups (substitution at hydroxy groups) in the samples synthesized are much less in number than the amide groups (substitution at carboxy groups).

Thus, the IR Fourier-spectroscopic results confirm the chemical and physicochemical data for the mixed cellulose ethers synthesized, which suggest the presence of carboxymethyl and amide groups in the samples. The amide groups are covalently bound to the carboxymethyl and hydroxy groups of the polymer.

Tables 2 and 3 show that the mixed cellulose ethers are only partially soluble in water. To elucidate the factors responsible for the partial solubility of ANaCMC, a sample of the mixed ether with DS_{Na} of 0.22 (Na 2.76%) and the amount of bound nitrogen N of 1.43% (Table 2, run no. 12) was preliminarily dissolved in water, and the resulting solution was filtered through a glass frit. The precipitate formed was washed with ethanol and dried, and a film was cast from the solution by the dry forming method. Figure 2 shows the IR spectra of the film and the precipitate. It is seen that these spectra differ only in the intensity of the absorption bands at 1710

and 790 cm^{-1}, which are the characteristic absorption bands of cellulose carbamates. The water-insoluble precipitate contains a large amount of carbamate groups. As known, cellulose carbamates are water-insoluble; they are well soluble in aqueous alkali solutions. Presumably, the mixed cellulose ether fraction that contains an increased amount of carbamate groups is water-insoluble.

Considering the fact that NaCMC is widely applied as aqueous solutions, we carried out comparative examination of the rheological properties of moderately concentrated (1 wt %) aqueous solutions of commercial NaCMC and of that obtained from short flax fibers (Fig. 3). The flow curves of all the systems examined are partial flow curves of non-Newtonian fluids. Based on the temperature dependences of the viscosity, we calculated the heats of activation of viscous flow E_a of the solutions, specifically for temperatures within 20–40°C. The E_a parameter for the solution of commercial NaCMC was estimated at 20.0, and for the sample based on flax fibers, at 35.0 kJ mol^{-1}. Figure 3 shows the flow curve for the solution of NaCMC that was subjected to repeated carboxymethylation to increase the DS of the cellulose ether and improve its water solubility. It is seen that the viscosity of the solution of NaCMC based on flax fibers substantially exceeds that of the solution of commercial NaCMC. The differences in the viscosity of the solutions are due to those in the molecular weight of the initial polymers.

As known, NaCMC can react with heavy metal ions [8] via carboxy groups. For example, copper, lead, zirconium, and silver salts cause precipitation of NaCMC from solution. Presumably, the appearance in the polysaccharide macromolecules of additional amide substituents containing the primary amino groups will cause an increase in the sorption activity toward polyvalent metal ions. To test this assumption, we examined the sorption activity of the mixed cellulose ethers toward Cu^{2+} ions. Figure 4 presents the kinetic curves of sorption of the copper ions with samples of commercial HCMC, AHCMC obtained thereof, and AHCMC prepared from flax (pH of the sorbate 6.3). It is seen that the maximal amount of the sorbed ions is achieved upon 30-min interaction of the polymers with the solutions of the ions. The appearance in the CMC macromolecules of amide groups (primary amino groups) causes an increase in the amount of the copper ions sorbed.

The sorption kinetic data were used for calculating the initial sorption rate and the total exchange

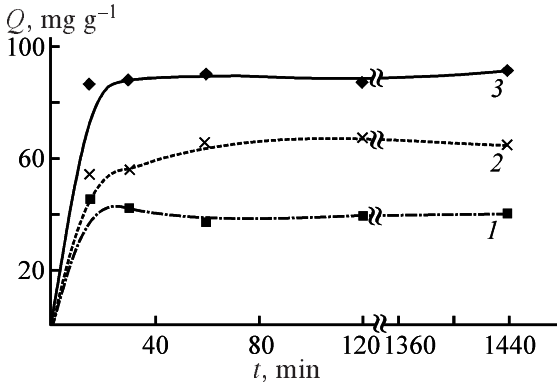

Fig. 4. Kinetic curves of sorption of the Cu^{2+} ions with (*1*) HCMC (commercial), (*2*) AHCMC (based on commercial HCMC), and (*3*) AHCMC (based on flax fibers) samples. (*Q*) Amount of copper ions sorbed and (*t*) sorption time.

Table 4. Total exchange capacity of the synthesized samples toward copper ions

Sample	Initial sorption rate, mg g^{-1} min^{-1}	TEC, meg-equiv g^{-1}
HCMC, DS_{COOH} 0.57	2.62	1.18
Commercial AHCMC, N 4.3%	3.23	2.02
Flax, AHCMC N 3.09%	5.23	2.85

capacity (TEC). The results are presented in Table 4.

It is seen that the maximal TEC is exhibited by the sample synthesized from short flax fibers. It should be noted that sorption of the Cu^{2+} ions can involve the reaction of the metal ions with carboxy groups, formation of chelate complexes, and adsorption of the ions on the fiber surface (molecular sorption via hydrogen bonding). Presumably, a higher TEC for the AHCMC sample obtained from flax is due also to adsorption on the fiber surface, which, in turn, is associated with a larger specific surface area of the flax fibers compared to the cotton fibers (0.35 for $HCMC_{cotton}$ against 0.475 cm^3 g^{-1} for $HCMC_{flax}$).

Thus, by properly choosing CMCs with different DS values and treating them with urea, it is possible to prepare carboxymethyl cellulose amides with different degrees of amidation and modified physicochemical properties. The cellulose ethers synthesized are suitable as biodegradable thickeners for various spheres of human activity, as well as sorbents for heavy metal ions.

CONCLUSIONS

(1) Mixed cellulose ethers were synthesized from commercial carboxymethyl cellulose and that obtained under laboratory conditions from flax fibers, by the reaction with urea.

(2) The cellulose compounds synthesized contain carboxymethyl and amide functional groups.

(3) The flax cellulose ethers exceed in viscosity the solutions of commercial Na salt of carboxymethyl cellulose.

(4) Introduction of amide groups into the macromolecules causes the sorption power of the mixed ethers toward copper ions to increase.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Catalytic Degradation of Polyethylene in the Presence of Synthetic Aluminosilicates

Abstract—Degradation of polyethylene in the presence of synthetic amorphous aluminosilicates as catalysts to form petroleum-like hydrocarbons was studied.

DOI: 10.1134/S1070427208090292

The amount of difficultly degradable industrial and domestic wastes steadily increases. Large-tonnage wastes from polyethylene packing materials are incinerated or disposed of. However, they can be a valuable secondary raw material for chemical industry.

It is known that thermolysis of polyethylene yields lower olefins [1]. A wide range of products which are frequently characterized as petroleum-like hydrocarbons can be obtained by catalytic degradation of polyethylene. This process can be catalyzed by aluminosilicates of different compositions. Among them, zeolites are used most frequently [2–4].

Natural aluminosilicates, clays, were proposed to produce liquid hydrocarbons from polyethylene [5].

The aim of this study was to determine the features of this process in the presence of model catalysts, synthetic aluminosilicates.

It is believed that the reactive components of a clay catalyst of polyethylene thermolysis are aluminosilicates. Their catalytic activity depends on the acidity of the samples. The aluminosilicate acidity is caused by the presence of aluminum. Therefore, the catalytic activity of aluminosilicates of similar structure in polyethylene degradation should correlate with the aluminum content of the catalysts.

EXPERIMENTAL

Eight aluminosilicates with different aluminum contents and hydrated silica sample were prepared. Since the acidity of aluminosilicates increases with increasing aluminum content to 13–17 wt %, we studied the catalysts with the aluminum content in the range including this interval.

Catalysts were prepared by coprecipitation from solution. An ethanol solution of tetraethoxysilane (tetraethoxysilane : ethanol weight ratio 1 : 1) was mixed with a 6% aqueous solution of aluminum nitrate. An ammonium hydroxide solution was added to pH 9. The mixture was stirred for 1 h with a magnetic stirrer and allowed to stand for 24 h to complete precipitation. The precipitate was filtered off and calcined in a muffle furnace at 600°C. The composition and some properties of the catalysts are presented in Table 1.

The powder X-ray diffraction patterns of the catalyst samples were recorded on DRON-3 diffractometer using CuK_α radiation.

Table 1. Properties of catalysts

Sample no.	Aluminum content, wt %	Specific surface area, $m^2\ g^{-1}$	Total pore volume, $cm^3\ g^{-1}$
1	0	149	0.6
2	1.6	167	1.0
3	2.4	110	0.5
4	5.8	208	0.9
5	8.1	129	0.6
6	12.0	324	0.8
7	12.9	184	0.9
8	16.3	183	0.9
9	22.9	216	0.8

The specific surface area, pore volume, and pore size distribution were determined by low-temperature adsorption and thermal desorption of nitrogen on an ASAP-2010 unit.

The sample morphology was studied by scanning electron microscopy on a Quanta 200 3D microscope. To estimate the sample uniformity, the aluminum content of the samples was determined by energy-dispersive X-ray spectroscopy (EDX) on a spectrometer attached to the microscope. It is known that EDX allows nondestructive determination of the local composition of a sample. Three measurements in different points of the surface were performed for each sample. The results are presented in Table 2.

The surface acidity of aluminosilicate samples were estimated by the Hammett procedure.

Catalytic degradation of polyethylene was studied on a flow unit in an argon flow. The reaction mixture was prepared as follows. A weighed portion of powdered catalyst was added to heated *m*-xylene. The mixture was vigorously stirred and allowed to stand to complete evaporation of the solvent. The polyethylene : catalyst weight ratio was 3 : 1 or 5 : 1. Polyethylene films crushed to 2–3-mm particles were loaded in a quartz reactor and heated in an argon flow to 400°C. The liquid products were collected in a receiving flask.

The degree of polyethylene degradation was estimated by the gravimetric yield of liquid and solid hydrocarbons. Gaseous thermolysis products were not collected and identified.

The liquid products were analyzed by chromatography–mass spectrometry on Saturn 200 chromatograph–mass spectrometer (Varian) with an ion trap. The mixtures were separated on a 30-m quartz capillary column 0.25 mm in diameter coated with CP-Sil 8 CB stationary phase.

Our results showed that the composition and yield of polyethylene thermolysis product significantly depend on the catalyst composition. Aluminosilicates with a low aluminum content (>3 wt %) catalyzed polyethylene degradation only to solid waxy products. In this case, no liquid products are formed at both polyethylene : catalyst ratios. Liquid products are formed in the presence of aluminosilicates containing more than 5.8 wt % aluminum. It should be noted that only liquid products were observed at a polyethylene : catalyst ratio of 3 : 1. At a polyethylene : catalyst ratio of 5 : 1, polyethylene degrades to form a mixture of liquid and solid hydrocarbons. The yield of the liquid products in the presence of almost all the examined catalysts at a polyethylene : catalyst ratio of 3 : 1 is higher than that at a ratio of 5 : 1 (Table 3).

Table 2. Comparative results of chemical and energy-dispersive X-ray (EDX) analysis of the samples

Aluminum content, wt %			
chemical analysis	EDX data		
5.8	5.8	6.8	6.2
12.0	12.3	14.3	15.0
12.9	15.3	13.2	12.9
16.3	15.9	15.8	15.7
22.9	23.5	23.4	22.8

Table 3. Yield of polyethylene thermolysis products depending on the aluminum content of the catalyst

Al content, wt %	Yield of liquid products, wt %, at indicated polyethylene : catalyst ratio	
	3 : 1	5 : 1
0	0	0
1.6	0	0
2.4	0	0
5.8	69	51
8.0	48	43
12.0	50	44
12.9	57	56
16.3	69	52
22.9	49	56

The liquid products contain linear and branched isomers of C_5–C_{26} alkanes and alkenes and aromatic hydrocarbons. For example, the fraction of low-boiling C_4–C_{10} hydrocarbons (bp < 200°C) in the products obtained in the presence of aluminosilicate with 5.8 wt % aluminum content reaches 77 wt %. The olefin content in this fraction is higher by a factor of approximately 2 than that of paraffin hydrocarbons. The content of cyclic and aromatic hydrocarbon is 9 and 19 wt %, respectively. It should be noted that this fraction contains significant amounts of linear and branched heptenes (11 wt %) and xylenes (17 wt %). Among C_{11}–C_{26} hydrocarbons, paraffins prevail and virtually no olefins are detected. High content of low-boiling hydrocarbons in the liquid products makes these fractions promising as raw materials for production of gasolines and solvents.

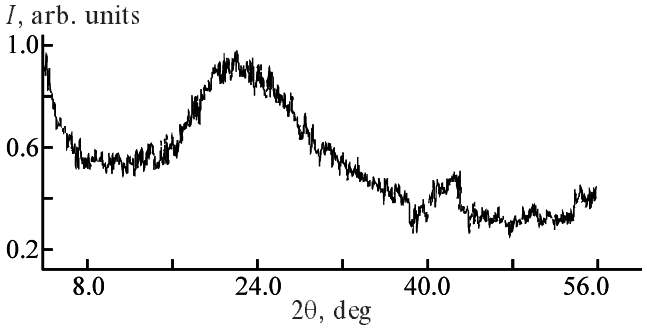

Fig. 1. X-ray diffraction pattern of aluminosilicate with 5.8 wt % aluminum content. (I) Intensity and (2θ) Bragg angle.

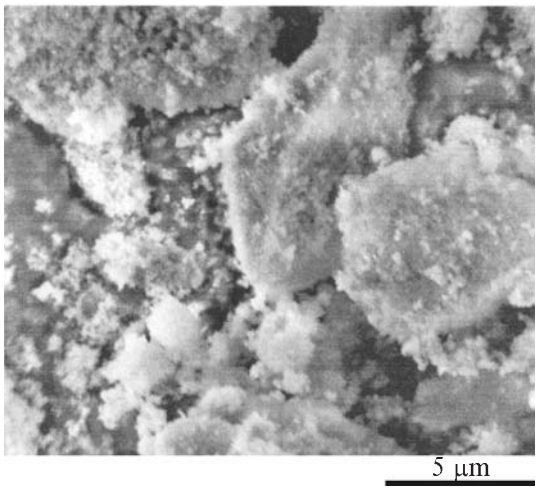

Fig. 2. Electrom micrograph of aluminosilicate with 5.8 wt % aluminum content.

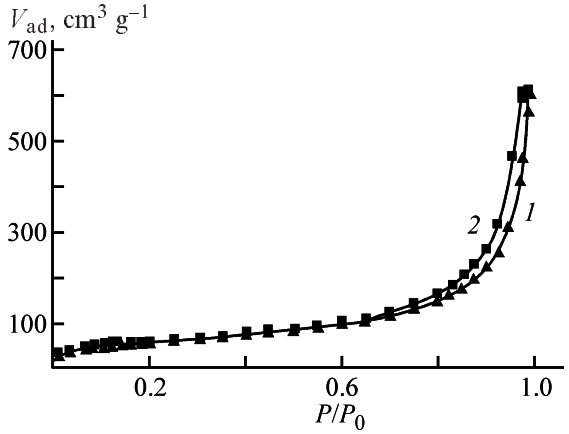

Fig. 3. Nitrogen (1) adsorption and (2) desorption isotherms on aluminosilicate with 5.8 wt % aluminum content. (V_{ad}) Adsorbed volume and (P/P_0) relative nitrogen pressure.

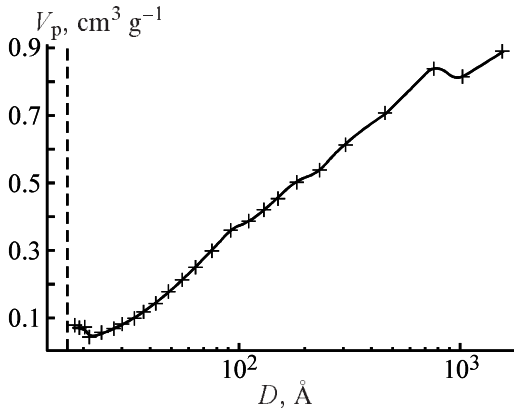

Fig. 4. Pore size distribution of aluminosilicate with 5.8 wt % aluminum content. (V_p) pore volume and (D) pore diameter.

X-ray diffraction analysis showed that all samples were X-ray amorphous. The X-ray diffraction patterns of all the samples are similar (Fig. 1). As seen from electron micrographs (magnification ×15000), the samples are characterized by a broad particle size distribution (Fig. 2).

The low-temperature nitrogen adsorption and thermal desorption isotherms for all samples are also similar (Fig. 3) and are of type IV [6]. These isotherms suggest mesoporous structure of the samples. The system in question is characterized by capillary condensation. The hysteresis loops are of type A and are typical of uniformly packed agglomerates and globules of similar size.

The pore size distribution of the aluminosilicates is rather broad. The pore size distribution of one of the examined samples is shown in Fig. 4. All samples contain significant amount of macropores.

The sample acidity was determined using appropriate indicators. All samples have acid sites affecting the color of indicators with $3.46 < pK_a < 5.0$. At the same time, only aluminosilicates that catalyze polyethylene degradation to liquid products also contain acid sites changing the color of indicators with pK_a 6.40. These sites are absent in aluminosilicates with a low aluminum content, which are inactive in polyethylene conversion to liquid products. Apparently, the behavior of aluminosilicates in polyethylene degradation depends on not only the number but also the strength of the acid sites.

CONCLUSIONS

(1) Amorphous aluminosilicates with the aluminum content exceeding 5.8 wt % are effective cata-

lysts of degradation of polyethylene waste into liquid hydrocarbons.

(2) The catalytic activity depends on not only the aluminum content but also the uniformity of aluminum distribution and the strength of acid sites of the catalyst surface.

Abstract—Properties of polymer–asphalt compounds containing 1,2-polybutadienes differing in the molecular weight and structure of macromolecules were examined. Introduction of syndiotactic 1,2-polybutadiene in combination with a plasticizing additive noticeably improves the main service properties of asphalts.

DOI: 10.1134/S1070427208090309

A promising way to improve the quality of road pavements is the use of asphalts in combination with various polymers. Polymer–asphalt binders (PABs), compared to common road asphalts, provide higher quality of road pavement and its longer service life.

The most widely used agents for modifying asphalts are butadiene–styrene block copolymers [1–3] which are thermoelastoplastics, i.e., they combine high elasticity with the capability to pass into a viscous-flow state at elevated temperatures, similarly to thermoplastics.

1,2-Polybutadiene produced by stereospecific polymerization of butadiene in solution is also a thermoelastoplastic [4, 5]. Its production is now being commercialized by the Russian chemical industry.

In this study we examined the effect of 1,2-polydiene on the physicomechanical properties of road asphalts.

EXPERIMENTAL

We used 1,2-polybutadienes differing in the molecular weight and structure of macromolecules: (1) high-molecular-weight syndiotactic 1,2-polybutadiene (SPB), M_n 52.6 × 10^3, degree of syndiotacticity 53%, melting point T_m 105°C, glass transition point T_g –18°C, degree of crystallinity 18%; (2) low-molecular-weight atactic 1,2-polybutadiene (LPB), M_n 8.35 × 10^3, degree of polydispersity 1.98, content of 1,2 units in macromolecules 70.5%, viscous resinous product, dropping point 54°C.

To prepare polymer–asphalt compounds, we used BND-90/130 road asphalt produced by Kichui Oil Refinery and Ufaneftekhim Joint-Stock Company. Polymer–asphalt binders were prepared by mixing the components at 140–150°C [6]. The physicomechanical properties of asphalts and polymer–asphalt binders were determined by standard procedures. As reference we used Kraton D-1101 butadiene–styrene thermoplastic widely used as PAB component in road paving.

Introduction of 2 wt % SPB into asphalt leads to a noticeable (by 14–19%) decrease in the needle penetration depth at 25 and 0°C (Table 1, Fig. 1), char-

acterizing the viscosity of the asphalt compound. The penetration also decreases on asphalt modification with Kraton polymeric product (Table 1). An increase in the viscosity of the asphalt compound in the presence of the above polymeric products is apparently due to formation of a three-dimensional polymer network in the asphalt structure.

On introducing low-molecular-weight 1,2-polybutadiene into the asphalt, the penetration index of the asphalt compounds remains essentially unchanged (Table 1). In this case, the influence of the polymeric additive on the properties of the asphalt compound is largely determined by the plasticizing effect of the polydiene.

Introduction of polymeric additives into asphalt compounds affects their softening point T_s. Introduction of 2 wt % polymeric products into asphalt increases T_s from 43.4 to 45.1–48.0°C. The increase in T_s is more significant with SPB and Kraton additives (Table 1). It should be noted that, as the SPB content in the asphalt compound is increased to 3 wt %, the softening point of PAB increases to 53.3°C, i.e., by approximately 10°C relative to the initial asphalt (Table 2, Fig. 1).

Another important parameter used for estimating the heat resistance of an asphalt compound is the dropping point T_d. As the content of 1,2-polybutadienes in asphalt is increased from 1 to 5 wt %, T_d

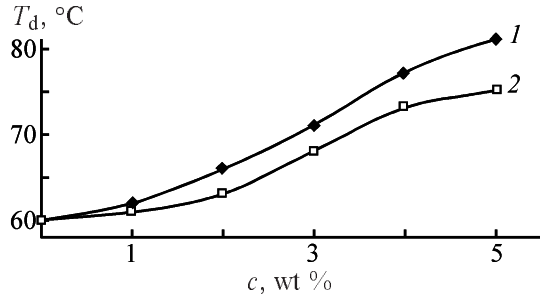

Fig. 2. Dropping point T_d of asphalt compounds as a function of the 1,2-polybutadiene content c in the asphalt. (*1*) SPB and (*2*) LPB.

regularly increases (Fig. 2). The dropping point of asphalt is affected more strongly by high-molecular-weight SPB: On adding it in an amount of 3 wt %, T_d increases by 12°C, whereas with the same amount of LPB it increases by only 7°C (Fig. 2).

On introducing polymeric additives into asphalt, the brittle point T_b characterizing the frost resistance of asphalt compound decreases by 1–3°C (Tables 1, 2).

Asphalt is a thermoplastic product showing virtually no hyperelastic properties in the service temperature range. One of parameters characterizing the plasticity of an asphalt, the extent of its structurization, is extensibility (ductility). Experiments show that the extensibility of polymer-modified asphalt compounds decreases (by a factor of 1.7–3.6 at 25°C) relative to the initial asphalt, with the effect being more significant with high-molecular-weight modifiers: SPB and Kraton (Table 1). At 0°C, binders with these polymers are also characterized by low extensibility, whereas asphalt compounds containing LPB are more ductile than the initial asphalt (Table 1).

The observed decrease in the plasticity of asphalt compounds on introducing high-molecular-weight polymeric additives should be attributed to a change in their viscoelastic properties due to formation of a three-dimensional macromolecular network and the resulting increase in the extent of asphalt structurization.

The resistance of a road pavement to dynamic loads is largely determined by elastic properties of an asphalt compound and by its resistance to reversible strains [2]. An asphalt compound can be classed with elastomers if its elasticity parameter defined as the degree of reversible tensile deformation at 0°C is no less than 70% [6]. It is important that, in contrast to the initial asphalt showing no elasticity, polymer–asphalt compounds prepared with 1,2-polybutadienes have the elasticity parameter no less than 70% (Table 1), i.e., are characterized by significant reversible deformations and hence can be classed with elastomeric products.

Thus, introduction of polymeric modifiers into SPB and LPB leads to a decrease in the plasticity characteristic of unmodified asphalt and to appearance of elasticity characteristic of amorphous polymers, which is important for making a road pavement resistant to dynamic loads.

Such parameters of asphalt compounds as the flash point, changes in the weight and softening point after heating, and penetration differ from those of the initial asphalt insignificantly and meet the requirements of the standard (Table 1).

The experimental results show that the main properties of the modified asphalt compound prepared with SPB are close to those of the asphalt compound containing Kraton D-1101 butadiene–styrene thermoelastoplastic. Introduction into the asphalt of LPB affects the properties of the asphalt compound to a lesser extent than does introduction of SPB. Nevertheless, LPB imparts to the compound certain elastic properties. The properties of asphalt compounds modified with 1,2-polybutadienes meet the requirements to PABs with butadiene–styrene block copolymers (Kraton, DST) except the penetration and extensibility at 0°C and the softening point.

Introduction into asphalts of relatively small (2–3 wt %) amounts of polybutadienes SPB and LPB yields asphalt compounds exhibiting the required elastic properties and broader, compared to the initial asphalt, set of service characteristics necessary to ensure high quality of a road pavement. To modify asphalts, it is appropriate to use high-molecular-weight syndiotactic 1,2-polybutadiene (SPB), because PABs with this additives show better characteristics than PABs with LPB.

One of the ways to improbe PAB properties, in particular, the extensibility and brittle point, is introduction into an asphalt compound of low-molecular-weight plasticizers: hydrocarbon solvents and oils [2].

We examined the effect of PN-6 aromatic solvent [TU (Technical Specification) 38.101 121 7–89] and O-40A industrial oil [GOST (State Standard) 20 799–88] on the properties of PAB containing 3 wt % SPB. Introduction of these hydrocarbons (6 wt % based on asphalt) leads to appreciable changes in the characteristics of the polymer–asphalt compound (Table 2, Fig. 1). From the viewpoint of improvement of the service properties of PAB, I-40A indus-

trial oil showed better performance as plasticizer. Introduction of I-40A oil into the polymer–asphalt compound containing SPB increased the penetration by a factor of 2.2 (at 0°C). Furthermore, the extensibility at 25 and 0°C increased by 30 and 62%, respectively, and the brittle point of PAB decreased by 8.1°C (Table 2, Fig. 1). The effect is apparently due to weakening of intermolecular interaction in the polymer–asphalt system under the action of nonpolar hydrocarbon molecules of the industrial oil.

Combined use of SPB and I-40A oil not only decreases the brittle point but also simultaneously increases the softening point of the asphalt compound (Table 2). Therefore, the service temperature range of the asphalt binder (interval between the softening and brittle points) increases by more than 20°C relative to the initial asphalt (Fig. 2) and reaches 92°C.

CONCLUSIONS

(1) The service properties of pavement bitumens can be appreciably improved by introducing high-molecular-weight syndiotactic 1,2-polybutadiene.

(2) Combined use in PAB of syndiotactic 1,2-polybutadiene and I-40A industrial oil makes its service temperature interval wider by more than 20°C compared to the initial asphalt.

(3) Polymer–asphalt compounds based on syndiotactic 1,2-polybutadiene can be recommended for practical use in road building.

Abstract—The possibility of preparing copolymers of butyl acrylate with vinyl butyl and vinyl isobutyl ethers with various ratios of monomeric units by radical polymerization was examined.

DOI: 10.1134/S1070427208090310

Macromolecular compounds are widely used as depressor and thickening additives to oils [1, 2]. Well-known additives based on polyalkyl methacrylates often exhibit thickening and depressor properties simultaneously [3–6]. However, the use of alkyl acrylates, in particular, polybutyl acrylate, for this purpose is restricted by their limited solubility in oils [7].

In this study, as thickeners for dioctyl sebacate (DOS), which is the base of synthetic oils [8], we suggest copolymers of butyl acrylate (BA) with vinyl isobutyl (ViBE) and vinyl butyl (VnBE) ethers. We examined the synthesis features and properties of these copolymers.

EXPERIMENTAL

We used freshly distilled ViBE and VnBE (83–84°C fraction) [9].

Butyl acrylate was purified by the procedure described in [7, 10]. The physicochemical constants of BA are in agreement with published data [10].

Azobis(isobutyronitrile) (AIBN) was purified by recrystallization from methanol [11].

The polymerization was performed at 50°C in evacuated ampules in the bulk of the monomer. The ampule was charged with a definite weighed portion of AIBN and with the comonomers: ViBE (or VnBE) and BA. The mixture was degassed by repeated freezing–pumping–thawing (~10^{-2} mm Hg).

Polymer samples were purified by reprecipitation from acetone into ethanol and then dried at reduced pressure to constant weight. The conversion was estimated gravimetrically by the dry residue [12].

The content of BA units in ViBE–BA and VnBE–BA copolymers was determined by IR spectroscopy. The composition of ViBE–BA and VnBE–BA copolymers was determined from the BA content. Studies were performed on an Infrolyum-FN-801 IR spectrometer in KBr cells (layer thickness 0.51 mm). The content of BA in the copolymer was determined with a calibration plot from the areas of the characteristic vibration band of the carbonyl group at 1727 cm^{-1}.

The molecular-weight characteristics were determined by gel permeation chromatography (GPC) on a Knauer liquid chromatography (Germany) with a Linear-2 linear column (Phenomenex, USA). An RI Detector K-2301 differential refractometer was used as detector, and chloroform was an eluent. The eluent flow rate was 1 ml min^{-1}, and the temperature, 25°C. For the calibration we used close-cut polystyrene references [13].

The kinematic viscosity of solutions of the polymers in DOS was determined with a VPZh-4 viscometer by the standard procedure [14]. The viscosity index was calculated by the procedure described in [15].

The well-known feature of butyl acrylate polymer at >30% conversion is low solubility in organic solvents, inculding oils, due to formation of the cross-linked polymer [16, 17]. To obtain an oil-soluble additive based on polybutyl acrylate, into BA polymer we introduced units of readily oil-soluble vinyl

Table 1. Results of copolymerization of BA with ViBE and VnBE, initiated with AIBN (0.15 mol %), in the bulk at 50°C

alkyl ethers (ViBE, VnBE) whose polymeric derivatives are also used as viscosity additives to mineral and synthetic oils [3, 4].

Copolymers of various compositions were prepared from BA–ViBE and BA–VnBE monomer mixtures at varied monomer ratio in the presence of AIBN as initiator. The results we obtained show (Table 1) that the copolymerization of BA with vinyl alkyl ethers decelerates in proportion to an increase in the ether content in the starting mixture. This is quite expectable, because it is well known that introduction of a second monomer forming a more stable radical (ether in our case) decelerates the polymerization. It is known that radical polymerization of vinyl alkyl ethers occurs difficultly, and not all compounds of this class can be involved in the process [18]. Data on homopolymerization of ViBE and VnBE and on their copolymerization with other vinyl monomers are scarce and contradictory [19–21]. Nevertheless, approximately zero relative activities of VnBE in copolymerization with BA (0, according to [21]) and relative activities of BA and ViBE in their copolymerization performed to ≤10% conversion ($r_{BA} = 5.2 \pm 1.5$, $r_{VnBE} \approx 0$, respectively), calculated by the Kelen–Tudos method [22] from the composition curve (Fig. 1) plotted on the basis of the IR data, suggest that the major fraction of both VnBE and ViBE units are incorporated in the polymer chain at deep conversions, which results in sharp deceleration of the copolymerization.

To estimate the molecular-weight characteristics, solubility, and thickening properties of copolymers, they were isolated at a conversion at which the polymerization rate starts to drastically decrease. The copolymer composition determined by IR spectroscopy appreciably differs from the composition of the monomer mixture (Table 2), which is due to different reactivities of the comonomers.

The molecular-weight characteristics indicate that, for copolymers containing up to 65% acrylate units (45 and 63%, Fig. 2, curves *1* and *2*, respectively), the molecular-weight distribution (MWD) curves are unimodal. With an increase in the content of BA units to 65%, the MWD curves tend to become bimodal (curve *3*). The bimodality is obvious in the case of the copolymer with 73% content of acrylate units (curve *4*). This fact is apparently associated with the formation of BA homopolymer along with the copolymer.

To test copolymers as additives, samples isolated at limiting conversions were dissolved in AU mineral

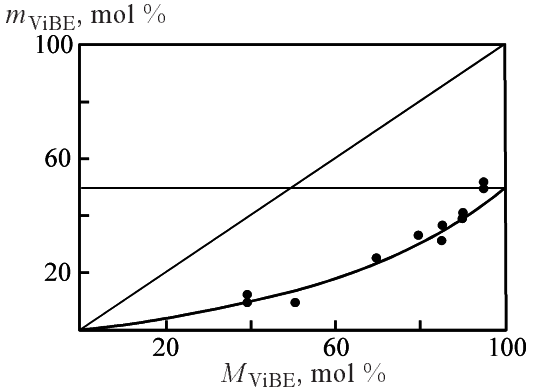

Fig. 1. Composition curve for BA–ViBE copolymer: (m_{ViBE}) content of ViBE units in the copolymer and (M_{ViBE}) content of ViBE in the monomer mixture.

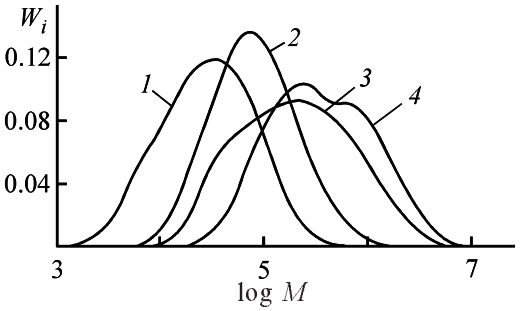

Fig. 2. Molecular-weight distribution curves for samples of BA–ViBE copolymers of compositions (mol %): (*1*) 45 : 55, (*2*) 63 : 37, (*3*) 65 : 35, and (*4*) 73 : 27. (W_i) Fraction of macromolecules with given M.

oil [8, 23] and in dioctyl sebacate (DOS), the base for synthetic oils. When added in an amount of 0.1% to the mineral base, the polymers did not dissolve even with vigorous stirring and heating. In DOS, the samples (0.1%) dissolved on heating and formed stable solutions. The viscosity of 0.1% DOS solutions of the polymers that had been isolated from monomer mixtures of various compositions was measured at 40 and 100°C in comparison with the copolymer-free sample (Table 3). For comparison, we obtained solutions of polyvinyl isobutyl ether in DOS of viscosity 3.6 cSt, attained at ~0.8% concentration of the polymer in DOS. These data indicate that ViBE–BA copolymers show a good thickening power. From the kinematic viscosities we calculated the viscosity index [14, 15]. The results are given in Table 3. As seen from the results obtained, the kinematic viscosity of solutions and viscosity indices increase in proportion with the BA content in the copolymer.

Table 3. Kinematic viscosity of 0.1 wt % solutions of VnBE (ViBE)–BA copolymers in DOS

Copolymer composition, mol %			Kinematic viscosity, cSt		Viscosity index
BA	ViBE	VnBE	40°C	100°C	
–	–	–	11.48	3.27	166
63	–	37	12.23	3.44	170
65	–	35	12.55	3.56	180
73	–	27	12.94	3.64	181
81	–	19	13.51	3.80	188
47	53	–	13.50	3.65	166
52	48	–	13.64	3.71	182
53	47	–	13.66	3.71	182
64	36	–	13.70	3.80	183

As the congealing point of DOS is very low [8], the depressor properties of the copolymers were not studied. It was shown, however, that the copolymers did not cause an increase in the congealing point.

CONCLUSIONS

(1) Copolymers of butyl acrylate with vinyl butyl and vinyl isobutyl ethers with various ratios of monomer units were prepared, and the relative activities of butyl acrylate and vinyl isobutyl ether were calculated.

(2) Copolymers of butyl acrylate and vinyl butyl or vinyl isobutyl ether are thickening additives to the base of synthetic oils, dioctyl sebacate. The effect is determined by the copolymer composition.

BRIEF COMMUNICATIONS

Coalescence of the Low-Boiling Dispersed Phase in a Turbulent Flow of a Cooling Emulsion

A. K. Rozentsvaig and Ch. S. Strashinskii

Kama State Engineering-Economical Academy, Naberezhnye Chelny, Tatarstan, Russia

Received May 16, 2008

Abstract—A nonlinear system of three differential equations is suggested as a model of the bubble boiling of drops of the dispersed phase. A qualitative analysis of the nature of the process of joint boiling and coalescence of drops of the dispersed phase in the overheated emulsion was made with certain simplifying assumptions.

DOI: 10.1134/S1070427208090322

Boiling of liquids is used in chemical technology both directly for heat-transfer purposes and as distillation or evaporation. There exist different concepts about the mechanism of heat transfer in boiling of a liquid. Theoretical description of the heat transfer in boiling of even homogeneous liquids is a rather complicated task [1]. This problem becomes considerably more complicated if heat transfer occurs in heterogeneous dispersed systems.

Experimental and theoretical studies of emulsions with a low-boiling dispersed phase demonstrated that they can substantially intensify the heat-transfer process as compared to any homogeneous liquid contained in an emulsion. For example, emulsions of organosilicon liquids with an aqueous dispersed phase are widely used for cooling of cutting tools and thermal treatment of metals [2, 3]. In these studies, it was found on the basis of experimental data that the emulsion is strongly overheated and the effect of boiling onset delay, $\Delta T_b = T_l - T_{sat}$, was examined [2].

The mechanism of this effects of boiling onset delay was found [3] to be related in many regards to the hydrodynamic characteristics and behavior of the dispersed phase of an emulsion. In particular, an important role in a turbulent flow can be played by the frequency of drop collision and coalescence under the action of pulsation of the continuous medium velocity. For a qualitative analysis and quantitative explanation of the heat transfer in unstable emulsions, it is necessary to consider the model of boiling of dispersed phase drops with account of their coarsening [4].

An overheated emulsion with a low-boiling dispersed phase is considered in terms of a monodisperse model approximation with a drop diameter assumed to be δ. The concentration W of the dispersed phase is low, not more than 0.5–1.5 vol %, and the overheating is sufficient for its full evaporation, which makes it possible to neglect, to a first approximation, the nature of heat-transfer processes. The influence exerted by the vapor phase formed in the boiling zone is disregarded. It is also assumed that the drops boil-up by the prescribed nucleation mechanism characterized by a constant frequency J of formation of vapor phase nuclei in a unit volume of the drops [5].

The total number N of drops of the dispersed phase in a unit volume of the emulsion decreases by the number n of boiled-up drops and by the number of drops coarsened in collisions of the $N - n$ drops remaining in the emulsion volume:

$$N = N + (dN/dt)\Delta t + 0.5\vartheta(N - n)\Delta t - (dn/dt)\Delta t, \quad (1)$$

where ϑ is the coalescence frequency of drops of the dispersed phase.

The change in the volume of the dispersed phase on passing of the boiling-up drops into the vapor phase can be written as follows:

$$N\pi\delta^3/6 = [N + (dN/dt)\Delta t][\delta + (d\delta/dt)\Delta t]^3\pi/6 - (dn/dt)(\pi/6)[\delta + (d\delta/dt)\Delta t]^3. \quad (2)$$

The number of evaporating drops in a unit volume of the overheated emulsion is determined by

the number $N - n$ of drops that had not enough time to boil-up and by the frequency J of nucleation in the unit volume of these drops, equal to v:

$$n = n + (dn/dt)\Delta t + Jv(N - n)\Delta t. \quad (3)$$

Retaining in Eqs. (1)–(3) terms containing the small quantity raised to first power, we obtain the following nonlinear system of first-order differential equations:

$$\left.\begin{aligned} d\delta/dt &= -(\delta/3N)[d(N - n)/dt], \\ d(N - n)/dt &= 0.5\vartheta(N - n), \\ dn/dt &= \vartheta v(N - n). \end{aligned}\right\} \quad (4)$$

For numerical integration of the system of equations (4), it is necessary to specify mechanisms of coalescence and nucleation, whose nature is not fully clear and requires a separate consideration under conditions of various transfer processes [6].

In order to qualitatively analyze the nature of the joint boiling and coalescence of drops of the low-boiling dispersed phase in an overheated emulsion, let us consider some analytical solutions to system (4) under certain simplifying assumptions. The frequency J at which nuclei of the vapor phase are formed in the bulk of drops of the dispersed phase is assumed to have a lower order of magnitude than the frequency ϑ of their coalescence. Accordingly, the number n of boiling-up drops is also assumed to be of a lower order of magnitude than the number N of drops of the dispersed phase. This makes it possible to reduce solution of the system of nonlinear differential equations to finding approximate solutions to each equation in the analytical form.

Integration of the second equation in system (4) on the condition $N >> n$ gives an expression for the decrease in the initial number N_0 of drops of the dispersed phase via their coalescence in collisions in a flow of the continuous phase of the emulsion under the action of a turbulent agitation [6]:

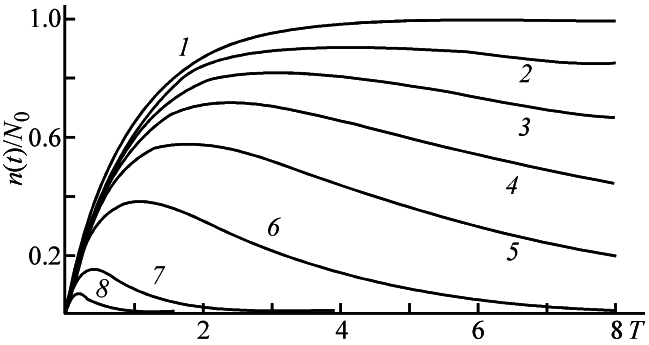
$$N(t) = N_0 \exp(-0.5\vartheta t). \quad (5)$$

The third equation can be integrated, on being represented in the form

$$(dn/dt) + nJv = NJv, \quad (6)$$

on the same assumption. Its solution was obtained on the condition that the rate dn/dt at which the number of boiling-up drops varies substantially exceeds that at which the initial number N of drops decreases:

$$n(t) = N[1 - \exp(-Jvt)]. \quad (7)$$



Taking into account the decrease via coalescence of drops of the dispersed phase in accordance with expression (5), we obtain the number of boiling-up drops:

$$n(t) = N_0 \exp(-0.5\vartheta t)[1 - \exp(-Jvt)]. \quad (8)$$

Multiplying both parts of the first equation of system (4) by δ^2, we can pass from drop diameters δ to drop volumes v. On substituting $d(N - n)/dt$ from the second equation of the system and taking into account the simplifying assumption, we obtain the following expression for the variation of the drop volume:

$$v(t) = v_0 \exp(-0.5\vartheta t). \quad (9)$$

This expression was not used to replace the drop volume v in formula (8) because it is preceded in this expression by the frequency J of spontaneous nucleation, whose small value is one of the basic assumptions made in this study for qualitative analysis. Their effect can be determined by numerical solution of the nonlinear system (4) of differential equations, but this requires that the mechanisms of coalescence and nucleation of drops of the dispersed phase in a turbulent flow of the emulsion should be preliminarily specified.

Relative number of boiled-up drops, $n(t)/N_0$, vs. the dimensionless time $T = Jvt$ at various values of the parameter $\lambda = \vartheta/(2Jv)$, which is the ratio between the rate of coalescence of drops of the dispersed phase and that of vapor phase nucleation in these drops. λ: (*1*) 0, (*2*) 0.02, (*3*) 0.05, (*4*) 0.1, (*5*) 0.2, (*6*) 0.5, (*7*) 2.0, and (*8*) 5.0.

The figure presents curves that show how the relative number of boiled-up drops, n/N_0, varies with

the dimensionless time $T = J\nu t$ at various ratios between the rate of coalescence and that of spontaneous formation of vapor phase nuclei, $\lambda = \vartheta/(2J\nu)$. In the absence of coalescence ($\vartheta = 0$), the number of boiled-up drops steadily increases from zero to N_0, initial number of drops of the dispersed phase. Coalescence leads to a decrease in the number of drops of the dispersed phase, involved in the boiling process, and, therefore, curves *2–8* cease to be monotonic at $\vartheta \neq 0$. As a result, the number of boiled-up drops increases to a maximum value and then steadily falls because of the decrease in the number of initial drops via coalescence.

Thus, the model expression (8) for the number of boiling-up drops indicates that there exist optimal conditions under which the maximum cooling by an emulsion via boiling of the dispersed phase can be achieved. To determine these conditions, it is necessary to find $(n/N_0)_{max}$ and $T_{max} = J\nu t_{max}$ by equating to zero the derivative of the expression in the right-hand part of formula (8). The result can be written as

$$T_{max} = \ln(1 + 1/\lambda),\ n_{max}/N_0 = (1 + \lambda)^{-1}(1 + 1/\lambda)^{-\lambda}. \quad (10)$$

This specific feature of model curves means that generalization of the drop boiling model (8), earlier derived in the study in the form of (7), gives a fuller notion of the heat exchange in emulsions with a low-boiling dispersed phase. In addition, it is in agreement with the experimentally found [2, 3] influence of the average size of drops of the dispersed phase on parameters of the heat exchange between an emulsion and a surface being cooled.

Qualitative analysis of the approximate solution of the nonlinear system (4) of differential equations shows how the coalescence of drops of the dispersed phase can account for the results obtained in experimental studies of the boiling of drops of the dispersed phase in the bulk of a high-boiling liquid [3]. This, in particular, refers to understanding of the heat-exchange mechanisms in the case of boiling delay determining the limits of the region in which the bubble mode of boiling is the most efficient.

CONCLUSIONS

(1) The model of the bubble mode of boiling of drops of the dispersed phase in a flow of a cooling emulsion, constructed with account of drop coalescence, makes substantially wider the number of factors that strongly affect the boiling onset delay and the heat-transfer efficiency.

(2) The existence of the optimal boiling conditions that can account for the boiling onset delay under conditions of coarsening of finely dispersed drops indicates that the suggested model [system of equations (4)] of the overheated emulsion with a low-boiling dispersed phase is adequate.

Kinetics of Immobilization of 1,2,5-Trimethyl-4-dimethylphosphonopiperid-4-ol with Maleic Anhydride–Styrene Copolymer

R. F. Mukhamedova

Satpaev Kazakh National Technical University, Almaty, Kazakhstan

Received January 21, 2008

Abstract—The kinetics of interaction of biologically active piperidol with maleic anhydride–styrene copolymer was studied, and the apparent thermodynamic functions of activation of the process were determined.

DOI: 10.1134/S1070427208090334

The main pathway of intensifying the agrotechnics of cultivation of various practically important crops is the use of agents based on biologically active components immobilized on a polymeric carrier. Such polymeric forms of regulators of plant growth and development are considered today as the most promising type of new preparations. The active components of such bioadditives can be plant growth stimulants, both natural and synthetic. A series of maleic anhydride copolymers whose properties can be controlled by varying the structure of the second comonomer are widely used as polymeric carriers [1, 2].

Previously we examined systematically the synthesis and biological activity of polymers prepared by immobilization of various piperidol derivatives on maleic anhydride copolymers [3–6]. In this study we examined the kinetic features of formation of such systems.

EXPERIMENTAL

Experiments were performed with commercial maleic anhydride–styrene copolymer (Styromal) which was purified first by sublimation to remove the monomer and then by reprecipitation from cyclohexane into petroleum ether. The content of anhydride groups was 44.7%, M = 40000. As biologically active component we used 1,2,5-trimethyl-4-dimethylphosphonopiperid-4-ol (ASA, Phospinol) prepared at the Institute of Chemical Sciences, Ministry of Education and Science of the Kazakhstan Republic [7]. The compound was used without additional purification.

Dimethyl sulfoxide (DMSO) was purified by keeping for 24 h over calcium hydride, followed by double distillation under reduced pressure (100°C at 15 mm Hg), n_D^{20} 1.4766 [8]. Dimethylformamide (DMF) was purified by keeping over calcium hydride, bp 153°C, n_D^{20} 1.4269 [8].

To determine the amount of anhydride groups [9], a weighed portion of the copolymer (0.05 g) was dissolved in 10 ml of DMSO. A 0.1 N solution of morpholine in DMSO (10 ml) was added to this solution, and the mixture was allowed to stand for 2 h. A blank sample with 10 ml of DMSO and 10 ml of a 0.1 N morpholine solution in DMSO was prepared simultaneously. After 2 h, both samples were titrated with a 0.05 N solution of HCl in DMSO with an EV-74 universal pH meter.

Synthesis of polymeric esters. A three-necked flask equipped with a stirrer and a reflux condenser was charged with 0.003 mol of styrene–maleic anhydride copolymer and 10.06 ml of DMSO. After the copolymer dissolved completely (80°C), 0.003 mol of 1,2,5-trimethyl-4-dimethylphosphonopiperid-4-ol was added (reaction mixture concentration 15%). The reaction was performed at 90°C for 3 h. After the reaction completion, the polymer was precipitated into a 3 : 1 mixture of acetone and isopropyl alcohol. The precipitate was filtered off and washed with isopropyl alcohol and acetone and dried to constant weight at 50°C in a vacuum. The content of the immobilized biologically active substance (BAS) was determined by nonaqueous titration in DMSO [10].

It was noted previously [11, 12] that the use of

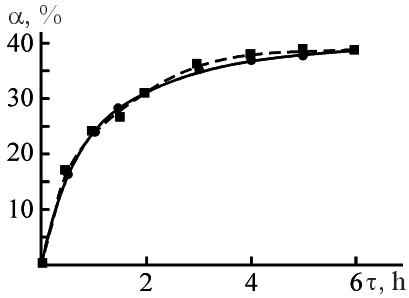

Fig. 1. Degree of completeness α of the reaction of Phospinol with Styromal as a function of reaction time τ.

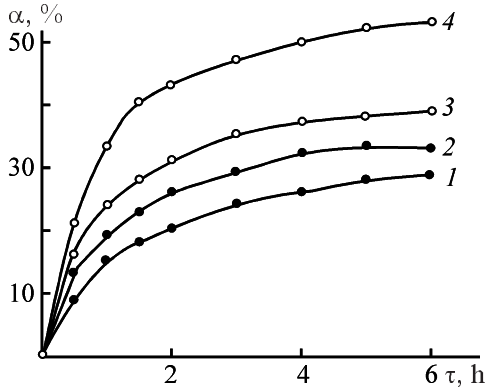

Fig. 2. Degree of completeness α of the reaction of Phospinol with Styromal as a function of reaction time τ at various temperatures. *T*, K: (*1*) 343, (*2*) 353, (*3*) 363, and (*4*) 373; the same for Fig. 3.

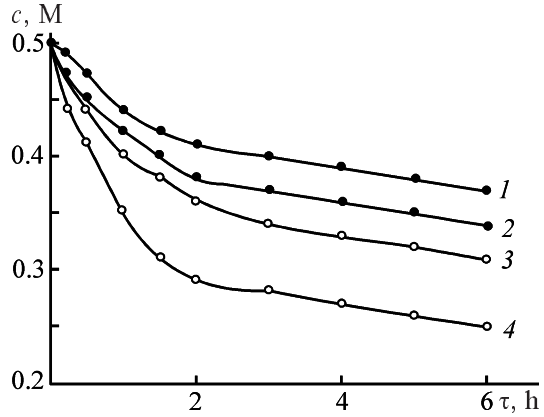

Fig. 3. Kinetic curves of Phospinol consumption in its reaction with maleic anhydride–styrene copolymer. (*c*) Phospinol concentration and (τ) time.

copolymers containing maleic anhydride with the aim of binding biologically active acids can be a very convenient and accessible procedure for preparing polymer systems exhibiting prolonged phytoactive effect. Therefore, it becomes very important to know the mechanism and kinetic features of processes by which these systems are formed. In the course of studying the reaction of the examined biologically active substances with maleic anhydride copolymers, we noted that, at certain steps of the reaction, it decelerates, and introduction of a large amount of a low-molecular-weight substance into the system does not lead to a noticeable increase in the degree of immobilization. To reveal the causes of this effect, we examined the kinetic features of the reaction.

Kinetic parameters* of the immobilization of 1,2,5-trimethyl-4-dimethylphosphonopiperid-4-ol on maleic anhydride–styrene copolymer

T, K	$k_{app} \times 10^4$, $l\,mol^{-1}\,s^{-1}$
343	1.6
353	3.1
363	5.2
373	7.6

* E_a = 63709 J mol^{-1}, $\Delta H^{\neq}$ = 60733 J mol^{-1}, $\Delta S^{\neq}$ = –34.06 J mol^{-1} K^{-1}, $\Delta G^{\neq}$ = 48000 J mol^{-1}.

For the kinetic studies we chose the temperature interval 343–373 K in which the influence of temperature on the degree of immobilization is the most noticeable.

The degree of reaction completeness was determined in parallel by two procedures: (1) from the amount of titrated unchanged anhydride groups in samples taken directly from the reaction mixture, we calculated the degree of reaction completeness and plotted it vs. reaction time (Fig. 1, solid line); (2) from the concentration of the unchanged low-molecular-weight BAS, determined by UV spectroscopy in samples taken at the same intervals as in the first case, we calculated the degree of reaction completeness and plotted it vs. reaction time (Fig. 1, dashed line).

As seen from Fig. 1, both methods gave the same degree of reaction completeness. Therefore, in the subsequent experiments were determined the degree of reaction completeness only by titration of unchanged anhydride groups.

Typical kinetic curves are shown in Figs. 2 and 3. The curves were processed by the first-, second-, and third-order equations. The kinetic curves could be linearized only in the coordinates of the second-order equation. The rate constants obtained from the slopes are given in the table.

The activation energy was determined from the Arrhenius plot $\log k$–$1/T$ (*T*, K) (Fig. 4). The result is given in the table.

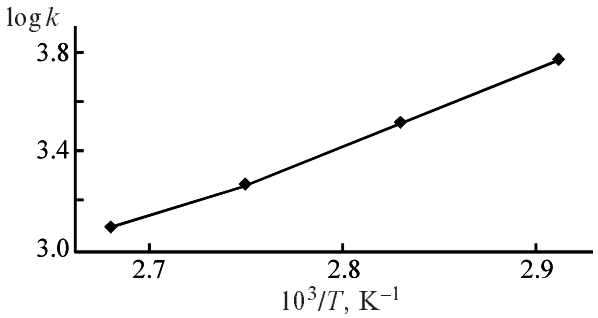

Fig. 4. Rate constant k as a function of temperature T in Arrhenius coordinates.

From the activation energy and rate constants, we determined the effective thermodynamic functions of activation of the process: enthalpy $\Delta H^{\neq}$, entropy $\Delta S^{\neq}$, and Gibbs free energy $\Delta G^{\neq}$, by the formulas $\Delta H^{\neq} = E - RT$, $\Delta G^{\neq} = H^{\neq} - TS^{\neq}$, $\Delta S^{\neq} = 4.576\log(A/T) - 49.21$.

CONCLUSION

The kinetics of immobilization of biologically active piperidol on a polymeric matrix is determined by the reaction of 1,2,5-trimethyl-4-dimethylphosphonopiperid-4-ol (Phospinol) with maleic anhydride–styrene copolymer. The activation energy and rate constants for this reaction were determined.

Abstract—The behavior of hydrogels based on sodium acrylate cross-linked to different extents with *N,N'*-methylenebis(acrylamide) was examined in aqueous solutions of copper sulfate of concentrations within 0.1–0.001 M.

DOI: 10.1134/S1070427208090346

Unique physicochemical properties of polyelectrolyte hydrogels, especially the ability to substantially change their size in response to minor changes in the external conditions, attract huge researchers' interest [1–4]. High-swelling polymeric hydrogels find application in medicine, as well as in food and cosmetic industries [5–8]. The effects arising in hydrogels under the action of low-molecular-weight salts can underlie purifying and enrichment technologies.

We examined here the swelling/compression kinetics and adsorption of bivalent metal ions for sodium acrylate hydrogel contacting copper sulfate solutions in relation to the cross-linking density of the polymeric network of the hydrogel.

EXPERIMENTAL

The hydrogels were synthesized by the procedure described in [6], by radical copolymerization of completely neutralized acrylic acid with *N,N'*-methylenebis(acrylamide). The monomers were neutralized with NaOH. The concentration of the monomers in the initial solution was 25%. The cross-linking density was controlled by the amount of the cross-linking agent introduced into the copolymerization reaction (Table 1).

In the experiments we used sodium acrylate hydrogels with different cross-linking densities (1 cross-link per 100, 200, and 300 monomer units), designated as N_{100}, N_{200}, and N_{300}, respectively.

A weighed portion of the gel (~0.02 g), dried to constant weight, was placed into aqueous $CuSO_4$ solutions of different concentrations ranging from 0.001 to 0.1 M and into distilled water. The weight of the solution was 1500 times that of the gel. The degree of swelling of the gel Q was determined gravimetrically from the ratio of the weight of the swollen hydrogel to the initial weight of the dry sample. The amount of the salt bound to the hydrogel was determined on a Specord M 40 spectrophotometer by measuring the salt content in the initial solutions and in the solutions after their contact with the hydrogel.

We obtained the dependences of the degree of swelling for the hydrogels with different cross-linking densities on the $CuSO_4$ solution concentration. Also, we determined the amount of the copper ions bound to the hydrogel during its contact with the salt solution.

Figure 1 presents the kinetic curve of swelling of

Table 1. Amounts of the chemicals used in synthesis of the gel

Compound	Weight, g	Concentration, g mol^{-1}	Content relative to monomer, mol %
Acrylic acid	5.0	6.94×10^{-2}	100
Sodium hydroxide	2.08	5.20×10^{-2}	74.94
Methylenebis(acrylamide), cross-linking agent	0.04; 0.05; 0.10	2.32×10^{-4}	0.33; 0.50; 0.98
Tetramethylethylenediamine, inhibitor	0.0081	6.97×10^{-5}	0.10
Ammonium persulfate, initiator	0.0158	6.92×10^{-5}	0.01
Distilled water	15.0	8.32×10^{-1}	300.0

the N_{300} gel [sample] in water, which served as the basic characteristic in our experiments. It is seen that the equilibrium swelling is achieved within 100 min.

The swelling of the hydrogels was examined in copper sulfate solutions with concentrations ranging from 0.1 to 0.001 M. The equilibrium in the hydrogel–salt solution systems is achieved within 100 min as well. Figure 2 presents the measured equilibrium degrees of swelling Q in relation to the concentration of the $CuSO_4$ solution after its 120-min contact with the gel. It is seen that, with increasing salt concentration (at $c < 0.025$ M), the degree of swelling of all the hydrogels tends to sharply decrease and changes insignificantly with further increase in the salt content. As expected, the maximal Q values were observed for the hydrogel sample N_{300} (with the smallest number of cross-links). It should be noted that the degrees of swelling of the hydrogel samples with different cross-linking densities differ only for dilute salt solutions ($c <$ 0.025 M). At these concentrations, the molar ratio of the gel to salt component is 0.0002 : 0.00075. In calculation of the hydrogel concentration we took into account the total volume of the hydrogel and solution. In the actual case, the nature of the swelling process is identical to that of the hydrogel in water. The aqueous solution of copper sulfate has a dark blue color, which makes it possible to monitor its penetration inside the hydrogel. During swelling of the gel in the $CuSO_4$ solution, the copper ions penetrate inside the gel and form additional cross-links. Budtova and Navard [9] examined previously the swelling of the hydrogel based on polyacrylic acid–sodium polyacrylate system (molar ratio 0.25 : 0.75) in aqueous solutions of copper sulfate and showed that, at low salt concentrations, the metal ions diffuse into the swollen gel, which results in its more or less uniform "cross-linking" over the bulk.

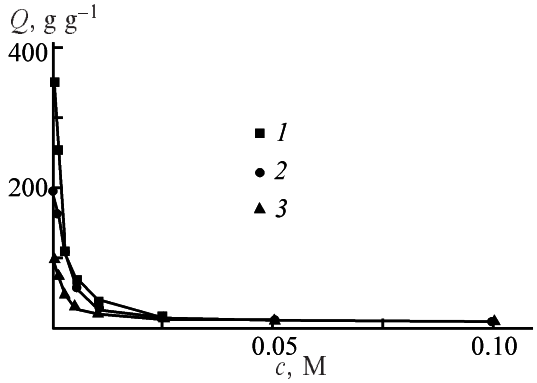

Fig. 2. Equilibrium degree of swelling Q of sodium acrylate hydrogel vs. concentration c of the $CuSO_4$ solution after 2-h contact with the gel. Sample: (*1*) N_{300}, (*2*) N_{200}, and (*3*) N_{100}.

When the gel is immersed in a salt solution of concentration $c > 0.025$ M, the degree of swelling is independent of the cross-linking density. The gel adsorbs a small amount of the solvent, whereupon its size remains unchanged. The copper ions do not fill the entire volume of the gel, since immediately after immersion of the gel into the solution, a layer preventing further penetration of the solvent inside the gel particle is formed on the surface. Hence, at high salt concentrations, the degrees of swelling for all the gel samples are approximately identical and depend only on the area of the surface contacting with the salt solution. Table 2 lists the equilibrium

Table 2. Equilibrium degrees of swelling Q of the sodium polyacrylate hydrogels with different cross-linking densities in water and copper sulfate solutions of different concentrations c_s

Cross-linking density	Q, g g^{-1}, at indicated c_s, M		
	0	0.001	0.1
N_{300}	350	250	7
N_{200}	196	163	7
N_{100}	94	71	8

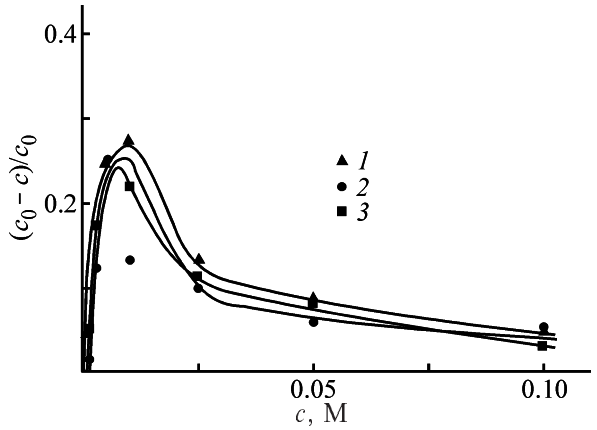

Fig. 3. Amount of copper ions sorbed by the sodium acrylate hydrogels with different cross-linking densities vs. concentration c of the $CuSO_4$ solution. (c_0, c) Copper sulfate concentrations in solution before and after the 2-h contact with the hydrogel, respectively.

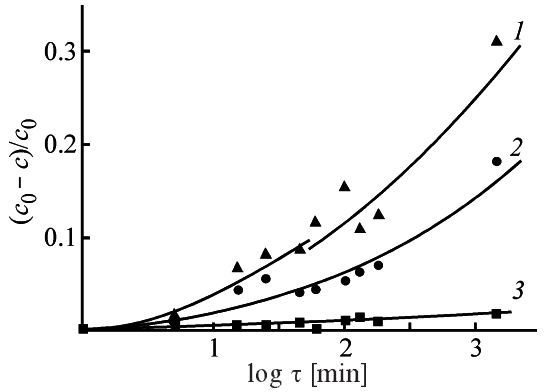

Fig. 4. Kinetic curves of sorption of copper ions with the N_{300} sodium acrylate hydrogel in copper sulfate solutions of different concentrations. (c_0, c) Copper sulfate concentrations in the solution before and after the 2-h contact with the hydrogel, respectively, and (τ) time. c, M: (*1*) 0.005, (*2*) 0.01, and (*3*) 0.1.

degrees of swelling of the sodium acrylate hydrogels with different cross-linking densities for the gel in contact with copper sulfate solutions of the maximal and minimal concentrations.

Figure 3 shows how the amounts of copper ions $(c_0 - c)/c_0$ (c_0 and c are the $CuSO_4$ concentrations in solution before and after contact with the hydrogel, respectively) sorbed by the gel samples with different cross-linking densities vary with the $CuSO_4$ solution concentration (2-h gel–solution contact) after these samples reached the equilibrium swelling. It is seen that, at the salt concentrations $c < 0.025$ M, the amount of the bound copper ions tends to increase with increasing salt concentration. With a further increase in the salt concentration in the solution, the amount of the bound ions tends to monotonically decrease. These results are fully consistent with our data on the swelling of the hydrogels (Fig. 2).

Our experiments showed that the amounts of the copper ions bound by the hydrogel are virtually identical for all the samples and independent of the cross-linking density. Presumably, the size of the insoluble copper acrylate skeleton formed on the hydrogel surface is proportional to the number of the surface carboxy groups that entered into the reaction and depends only on the area of the gel particle in contact with the salt solution. The resulting water-insoluble copper acrylate prevents further penetration of water and the ions deep inside the samples.

Figure 4 presents the kinetic curves of sorption of the ions with the hydrogel from copper sulfate solutions of different concentrations. It is seen that the rate of sorption of the ions is the higher, the lower the concentration of the solution surrounding the gel. We also found that, throughout the salt concentration range examined, the copper ions are sorbed by the hydrogel also after the equilibrium swelling was achieved.

CONCLUSIONS

(1) The degree of swelling of the hydrogels depends on the number of the cross-links only at concentrations $c < 0.025$ M, while at $c > 0.025$ M it is virtually identical for all the samples examined.

(2) When contacting the solution, the hydrogel absorbs the copper ions irrespective of the cross-linking density throughout the salt concentration range examined.

(3) The hydrogel contacting the solution absorbs the copper ions after attainment of the equilibrium swelling as well. This process is decelerated with increasing initial concentration of the copper sulfate solutions.

(4) The penetration of the copper ions inside the gel is responsible for the appearance of additional cross-links and formation on the gel surface of insoluble copper acrylate.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Selective Dimerization, Oligomerization, Homopolymerization and Copolymerization of Olefins with Complex Organometallic Catalysts

G. P. Belov

Institute of Chemical Physics Problems, Russian Academy of Sciences, Chernogolovka, Russia
e-mail: gbelov@cat.icp.ac.ru

Received October 10, 2007

Abstract—Review embarrasses the problems of low molecular weight olefins (ethylene and propylene) selective oligomerization to butene-1, hexene-1, octene-1, 4-methylpentene-1; selective polymerization of olefins to obtain polymers with a given molecular mass, molecular mass distribution, branching (for the polyethylene), chain structure [atactic, iso-, syndio-, gemiisotactic, stereoblock type and containing terminal vinyl and vinylidene bonds (for polypropylene)]; "live" homo- and copolymerization of olefins, and alternating copolymerization of olefins in the presence of complex organometallic catalysts.

DOI: 10.1134/S107042720809036X

Current situation issues a challenge for the scientists in academic and industrial institutes of producing monomeric, oligomeric and polymeric products with a predefined complex of physico-chemical, reological and endurance properties. For solving the problems it is necessary to know molecular mass and chain structure of the products and dependence of these parameters on the kinetic parameters of the process of their production. That is, the problem of obtaining products with predefined properties required complex approach to its solving. This in turn implies necessity of development of scientific base of creation and practical realization of highly selective processes. As the selectivity we assume, in line with the definition proposed by academician N.M. Emanuel [1], for simple reactions (in our case to the reactions of dimerization and oligomerization), "a fraction of initial substance converted into the targeted substace II," and for the reaction of polymerization, "obtaining the product with given molecular mass, molecular mass distribution and structure of the chain: concentration and character of location in the polymeric chain of side groups, content of terminal C=C groups, degree of alternation of comonomers."

Olefins (ethylene and propylene mainly) and oigomers and polymers based on them are the most large-tonnage products of petrochemical and chemical industries. The problem of effective use of olefins in the processes of di-, oligo- and polymerization at the catalysis with organometallic complex catalysts now becomes more and more significant. The main parameter defining efficiency of these processes from the viewpoint of rational using of the monomers is selectivity of oligo- and polymerization reactions_

DI- AND OLIGOMERIZATION OF OLEFINS

Ethylene dimerization. Dimerization of olefin has been initiated in the classical works by A.M. Butlerov who was first to carry out dimerization of isobutylene at the action of sulfuric acid [2]. However, till 50th of last century this method was used for the manufacturing of liquid propylene and butanes oligomers, that are applied for producing motor fuel, lubricant oil and synthetic washing means [3, 4]. Discovery by Natta and Zigler in the middle of 50th of new catalysts showing high activity and selectivity allowed in certain cases to obtain the olefins dimers and polymers with the structure that could not be achievable with the earlier known catalysts. A good example is the reaction of selective ethylene dimerization into butene-1, which has been introduced to chemical industry of Russia and some of leading countries [5–7].

Generally, reaction of ethylene dimerization can be represented as follows:

$$n C_2H_4 \rightarrow \text{butene-1} + \textit{cis-, trans-}\ (\text{butenes, hexenes, octenes}) + \text{polymer.}$$

The complex organometallic catalysts known to the moment commonly are bicomponent catalytic systems consisting of alkyl or halo derivative of a transition metal and organoaluminum compound. The most active and selective is the catalytic system of $Ti(OC_4H_9)_4$–$Al(C_3H_5)_3$ [8–14]. After modification with electron-donor compounds this system allows to perform the process of ethylene dimerization into butene-1 with the selectivity up to 98 %. As the side products are formed about 2 wt% of α-hexenes (3-methylpentene-1, 2-ethylbutene-1 and hexene-1), one tenth part of a procent of octenes and some of polymer (less than 0.01 wt%). Another feature of this process is the absence of formation in the step of the synthesis of β-olefins always formed at ethylene dimerization and oligomerization with other so far known complex organometallic catalysts.

A complex of research and development including pilot plant processing has been performed in the Division of polymers and composite materials and Laboratory of technological processes of the Institute of Physical Chemistry, Academy of Sciences of USSR, on the development of scientific base of industrial process of selective dimerization of ethylene into butene-1 at the action of catalytic system $Ti(OC_4H_9)_4$–AlR_3. These researches are protected by about 40 of Inventor Certificates within USSR and by international patents. In the Soviet Union in the beginning of 80-th first in the world were actuated two industrial installations for producing butene-1 with polymerization grade purity ("Orgsintez" in Kazan' and Budyenovsk, and "Stavropolpolymer" in Stavropol'), which provided with butene-1 two big plants in USSR and in Europe producing high density and medium density polyethylene.

Owing to increased demand for such α-olefins as butene-1, hexene-1, octene-1, and decene-1 used as copolymers at producing new sorts of polyethylene and polypropylene, it became actual development of simultaneous producing these olefins from ethylene in one process. At a first view seems that the best approach to solving this problem is improvement of the process of selective oligomerization of ethylene in the processes of ethylene tri-, tetra- and pentamerization [15–17]. Therewith, two problems should be solved in respect of the process of ethylene oligomerization:

– Narrowing the spectrum of α-olefins formed (to C_4–C_{12} instead of C_4–C_{30})

– Depressing the side reaction of isomerization of α-olefins into β-olefins.

Presence of β-olefins in the α-olefin passed to the reactor for ethylene or propylene polymerization even in micro amounts leads to substantial inhibition of polymerization, increases consumption of catalyst and generates problems of obtaining modified polyolefin with required reoligical and strength properties. Probably the problem can be solved on this pathway by application of transition metal complexes with bulky ligands [18, 19] for homogenous catalysis and gel-immobilized [20–23] or, in a general case, fixed on a support catalysts in the case of heterogenous catalysis.

Ethylene oligomerization (tri- and tetramerization of ethylene). To non-selective oligomerization of ethylene are denoted many communications and reviews (here we refer to only a small part of them) [24–29], in this communication we will consider only the problem of selective oligomerization of ethylene, namely, tri- and tetramerization of ethylene with formation of hexene-1 and octene-1, respectively.

In relatively large amount (over 1 wt%) the higher α-olefins butene-1, hexene-1 (in the ratio C_6-1 : C_4-1 = 25 : 1), octene-1, decene-1 and a series of branched decenes were detected at polymerization of ethylene with the catalytic system Cr(2-ethylhexanoate)$_3$ – polyisobutylalumoxane [30].

Accounting for a great interest to the synthesis of linear polyethylene of low density which can be obtained by copolymerization of ethylene with high α-olefins (butene-1, hexene-1, octene-1 and other), in the middle 70th researches began search for catalysts for selective oligomerization of ethylene with formation of these α-olefins. The main direction in search and development of the catalysts for selective oligomerization of ethylene to hexene-1 were and remain now as a rule the systems containing three or more components that include compounds with trivalent chromium, mono- (e.g., pyrrole and its alkyl derivatives, cyclopentadienyl compounds and other) and multidentate (e.g., triazacyclooctane, trispyrazolylmethane, diphosphazene, diphosphine, bis-diphosphine and bis-sulfanylamino derivatives) ligands and organoaluminum compounds. Recent results in the area of ethylene trimerization are considered in review

[31]. The first industrial process of producing hexene-1 by trimerization of ethylene was effected in Katar in 2003 along the join technology of Shevron and Phillips companies.

Since beginning and in particular since middle 90th of last century the search for effective catalysts for trimerization of ethylene to hexene-1 (since middle 80th these investigations were performed systematically by Phillips) began other advanced firms: in USA Amoco Co., in Japan Mitsubishi Chem. Co, Sumitomo Chem. Co., Idemitsu Kosau Co., Albemarle Co., Showa Denko Chem. Co., Mitsui Chem. Inc., and Japan Polyolefin Chem. Co. Since 2000 the number of firms that perform research and development of new catalysts for the synthesis of hexene-1 was extended.

Among effective researches we can notify the catalyst of Mitsubishi Chem. Co. based on Cr(2-ethylhexanoate)$_3$, 2,5-dimethylpyrrol, hexachloroethane and triethylaluminum at molar ratio of these components 1:6:4:40. At the temperature 105°C and ethylene pressure 50 atm was achieved catalytic activity up to 3780 kg/g_{Cr} h (at maintaining hexene-1 – ethylene molar ratio in the reactor equal to 0.5). This afforded 99.96 wt% of liquid oligomers containing up to 95.4 wt% of hexene-1 [32]. To the moment in the world patent literature were published more than 120 patents on the problem of producing hexene-1 by selective oligomerization of ethylene, predominantly by trimerization of ethylene to hexene-1.

Among the countries acquiring more than 40 patents the leading ones are USA and Japan. The countries acquiring 20 to 1 patents include SAR, Netherlands, Italy, France, Britain, Germany, China and Saudi Arabia.

The first example of effective trimerization of ethylene to hexene-1 in the presence of other transition metals is described in the communication of Pellecchia and co-authors [33] on the catalyst based on titanocene. In the presence of catalyst $CpCMe_2PhTiCl_3$ – methylalumoxane (1 : 1000) at 30 °C and ethylene pressure 0.2 MPa the rate of formation of hexene-1 achieved 22.35 kg/g_{Ti} h with selectivity on hexene-1 up to 83 wt%. Simultaneously 2.6 wt% of polyethylene was formed. Higher rate was achieved with titanocen trimethyl derivative [34].

A possibility of selective synthesis of octene-1 from ethylene was first reported by Kuhlmann and co-authors [35], who applied diphosphineamine chromium(III) complex in conjunction with β compounds of methylalumoxane. At the temperature 65°C and ethylene pressure 3 MPa was achieved the reaction rate 272.4 kg/g_{Cr} h with selectivity on octene-1 up to 70.3 wt%. More recently with the similar chromium complexes was studied effect of alkyl substituent at the nitrogen atom [36] and of organoaluminum co-catalyst both in the absence [37] and in the presence [38] of borates. It was found that polar solvent (chlorobenzene instead of toluene) increases activity and stability of catalyst, but simultaneously increases yield of decenes. For the catalytic system $Cr(C_5H_7O_2)_3$ – bis(diphosph ino)isopropylamine – methylalumoxane was shown that increase in the reaction temperature from 35 to 45°C decreases selectivity on octene-1 [39]. In [40] were applied various carbonyl chromium complexes with bis(diphosphno)amine ligands for the synthesis of cationic aluminate chromium(I) complex and was shown that it can be used as effective catalyst in the reaction of ethylene trimerization to octene-1.

Thus, we can note that there is certain success in the area of selective oligomerization of ethylene to hexene-1 and octene-1, while for the selective oligomerization of ethylene to higher α-olefins (decene-1, dodecene-1 and other) this is not achieved yet.

Propylene dimerization. Commonly, propylene dimer (4-methylpentene-1) is synthesized with heterogenous catalysts based on alkali metals. The synthesis of 4-methylpentene-1 on the complex organometalic catalysts based on decamethylmetallocene complexes $[Cp_2MCH_3(CH_8S)]^+BPh_4^-$, where M= Zr, Hf was first reported in 1990 by Teuben and coauthors [41, 42]. Besides 4-methylpentene-1 is formed also 4,6-dimethyl-1-heptene.

In 1991 Yamazaki and coauthors [43] using Cp_2MCl_2 (where M= Zr, Hf) in conjunction with methylamoxane synthesized 4-methylpentene-1 with a substantial amount of higher oligomers (C_{10} and higher). More selective propylene dimerization to 4-methylpentene-1 (up to 62 wt%) was achieved with $(\eta^5\text{-}C_5Me_4R^1)(\eta^5\text{-}C_5Me_4R^2)HfCl_2$ complex in the presence of methylalumoxane or mixture of *i*-Bu_3Al /$[Ph_3C][B(C_6F_5)_4]$ [44]. Selectivity on 4-methylpentene-1 up to 30 wt% was obtained at the propylene dimerization on the $NiBr_2$ calixarene complexes [45].

Undoubtedly interesting is selective dimerization of propylene not to branched dimer (as shown above) but to linear 1-hexene.

The table collects comparative data on activity and selectivity of transition metal complexes in the reactions of olefin di- and oligomerization.

Comparative characteristics of activity and selectivity of transition metal complexes in the reaction of dimerization and oligomerization of olefins

HOMO- AND COPOLYMERIZATION OF OLEFINS

Physico-mechqanical and reological properties of polymers generally and polyolefins in particular depend on the following basic parameters:

- Molecular mass (MM)
- Molecular mass distribution (MMD)
- Degree and type of branching (B)
- crystallicity
- crystal structure
- degree of orientation, etc.

Five first parameters (MM, MMD, B, crystallicity and crystal structure) are defined by the conditions of the synthesis, while the remaining is connected with the conditions of producing certain commodity. Unfortunately, up to now have been published little works generalizing effect of all these parameters on the properties of polyolefins. The most successful attempts of consideration interconnection of these characteristics with physico-mechanical properties of amorphous, semicrystalline and crystalline polymers were made in the reviews [46, 47].

At the synthesis of polyolefins commonly not arise problem of control over MM and B. Much more difficult is solving the problem of control over MMD. MMD is the polymer characteristics which, on the one hand, reflects mechanism of polymerization, and, on the other hand, in much defines physico-mechanical and reological properties of the polymer.

The data published in literature including patent data on the control over MMD of polyolefins are extremely poor. This information commonly is an object of know-how of the firms producing polyolefins. Therefore there is no possibility to formulate any general statements on the effect of conditions on the polyolefin polydispersion. All is defined by the certain catalytic system applied in the process of polymerization, and often change in one parameter, e.g., duration of the polymerization or temperature leads to opposite results at the application of different catalytic systems.

Below are presented our attempts of generalization of the published data concerning effect of some parameters on diminishing polyethylene M_w/M_n ratio:

– decrease in concentration of the catalyst components in the system:

$(C_5H_5)_2TiCl_2$-$Al(C_2H_5)_2Cl$ [48], $(C_5H_5)_2TiCl_2$–$Al(CH_3)_2Cl$ [49];

– decrease in polymerization temperature {for the system of $(C_5H_5)_2TiCl_2$–$Al(C_2H_5)_2Cl$ in the ethyl chloride medium [48]};

– increase in polymerization temperature {for the system of $(C_5H_5)_2TiCl_2$–$Al(CH_3)_2$ in the medium of benzene [49], $TiCl_4$-$Al(C_2H_5)_2Cl$ [50], supported catalysts $TiCl_4$ on MgO [51]};

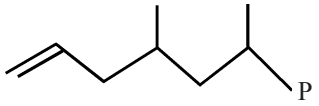
– decrease in ethylene concentration [48];

– increase in polymerization duration {for the systems of $TiCl_4$–$Al(C_2H_5)_3$ [52], $TiCl_3$–$Al(C_2H_5)_2Cl$ [53]};

– decrease in polymerization duration {for the system of $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ [49, 54]};

– introducing of various additives {$(Ti(OC_4H_9)_4$ [55], $(C_6H_5)_2Mg$ [56], dienes [57]} to the system of $TiCl_4$–$Al(C_2H_5)_2Cl$.

In details was studied effect of various conditions of the polyethylene synthesis with the system of $(C_5H_5)_2TiCl_2$–$Al(C_2H_5)_2Cl$ on MMD of the product [58–67], and on basic reological and durable properties of the polymer in a wide range of MM keeping $M_w/M_n \approx 2$. Probably this is only one published example of such a systematic research.



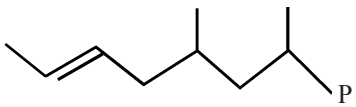
In the recent years, in principle, extended potential possibility of acquisition and detailed study of reological and durability of polyethylene, polypropylene, polybutene-1, ethylene and propylene copolymers with other α-olefins (at M_w/M_n in the range 2–3) due to application of Kaminskii catalysts [68, 69] and so-called "live" polymerization of olefins on the complex organometallic catalysts.

"Live" polymerization. Strictly controlled synthesis resulted in a given MM and narrow MMD ($M_w/M_n \sim 1.0$–1.3) can be achieved by means of "live" polymerization at anionic [70], cationic [71,72] and radical polymerization [73, 74]. A possibility of "live" polymerization of olefins (ethylene and propylene) at the action of complex organometallic catalysts has been demonstrated in the middle 80th of 20th century using vanadium catalysts [75].

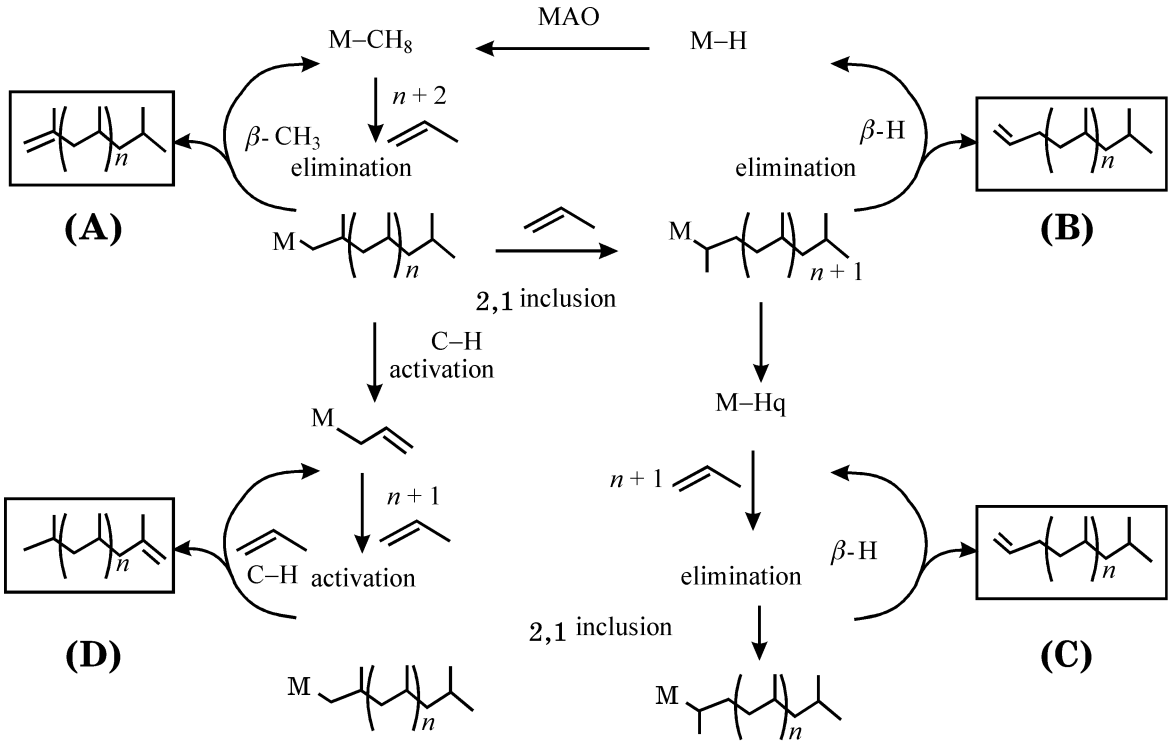
To the moment, a large cycle of research on "live" polymerization of olefin has been carried out, which is considered in two reviews [76, 77]. They describe results in this area at the polymerization of ethylene and propylene as well as of norbornene, non-conjugated dienes, statistical and block-copolymerization of norbornene or cyclopentene with ethylene, propylene, dienes and polar monomers.

As is known, together with MM and MMD the polyolefin properties are defined by such a parameter as chain structure (content and type of side groups, concentration and type of terminal C=C groups). At producing polyolefins, content and type of side groups and their concentration can be commonly controlled by the conditions of the synthesis: type and concentration of co-monomer and applied catalyst. The type and concentration of C=C groups (vinyl and vinylidene) depend on the mechanism of the polymer chain termination.

Formation of terminal vinyl structures. The possibility of producing polypropylene (oligomeric, atactic) containing 92–98% of terminal vinyl structures was reported by Resconi [78]



at application of the catalytic system $(CH_3C_5H_4)MCl_2$ – methylalumoxane, where M=Zr, Hf. More recently, Repo [79] informed abut the synthesis of polypropylene containing up to 90% of terminal vinyl structures in the presence of metallocenes with acetonaphthyl cyclopentadienyl substituents. The authors of this work suggest that formation of such structures is a result of β-elimination of methyl group at the chain propagation.



In [80] synthesis of atactic polypropylene with MM=12000-30000 and MMD≈2, containing up to 60–80% of terminal vinyl groups and with stereoregularity (mmmm pentades) up to 95% was carried out in the presence of *rac*-dimethylsilanodiyl(2-methyl-4-phenylindenyl)$ZrCl_2$ and *rac*-dimethylsilanodiyl-bis(indenyl)$Hf(CH_3)_2$ at 95–120°C. The possible pathways of formation of the terminal vinyl structures are shown in the Scheme; the pathway A is suggested as defining one.

The polymers with vinyl terminal groups can be considered as macromonomers for the reactions of binary or ternary copolymerization and also as precursors for the further functionaliztion of the macromonomer.

At the polymerization of olefins with complex organometallic catalysts, in particular with those based on metallocenes, the principal mechanism of the chain termination is β-eliminating of hydrogen leading to formation of vinylidene structures [81–83]. This mechanism leads to formation of polymer chain with vinylidene structure at the polymerization of propylene. In [84–86] was described synthesis of atactic and isotactic polypropylene containing, together with vinyl terminal groups also up to 50% of vinylidene groups.

Polymerization of α-olefins (propylene, butene-1 and other) can afford polymers with various structure of

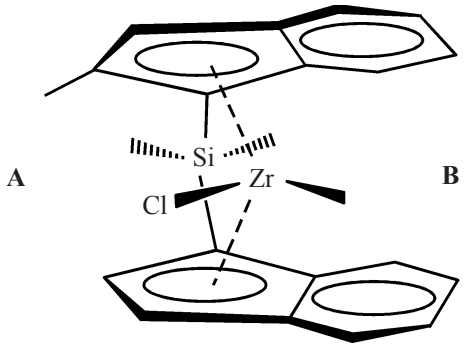
Scheme. Formation of terminal vinyl bonds at the polymerization of α-olefins.

chain, where alkyl side groups (methyl at polymerization of propylene and ethyl at polymerization of butene-1) can occupy various positions relatively to to each other and to the main chain. Also, polymerization of α-olefins can lead to the polymer with gemiisotactic, stereoblock and atactic structures. Below we consider some of recent results on the example of propylene polymerization providing certain structure of the polypropylene formed.

Isotactic polypropylene. At the synthesis of isotactic polypropylene under the action of metallocene catalysts commonly is used *rac*-form of metallocene with C_2 sym-metry. Spaleck and coauthors [87] obtained with bis-indenyl cyrconocenes a polypropylene with M_n up to 7.3×10^5, containing 95% of isotactic pentades [mmmm] 95%, with melting point157°C. This polymer by its properties is close by its properties to the polypropylene produced by industry with heterogenous catalysts features by a narrow MM range. Mechanism of formation of isotactic polypropylene on the metallocenes with C_1 simmetry is discussed in [88].

SyndiOtactic polypropylene. At the synthesis of syndiOtactic polypropylene are applied *ansa*-metallocenes of C_s symmetry [89]. SyndiOtactic polypropylene was also synthesized on the circonium fluorenyl complexes [90, 91].

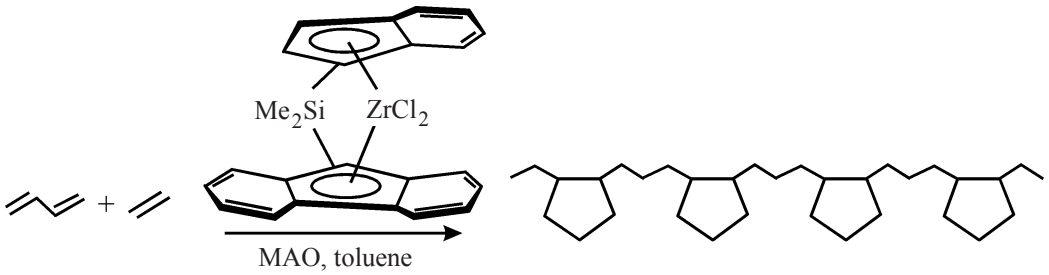
Gemiisotactic polypropylene. This type polypropylene has unusual structure with each even (or odd) CH_3 group located at one side of carbon chain while intermediate CH_3 groups are distributed statistically. Synthesis of such polypropylene is carried out in the presence of circonocenes with C_1 symmetry [88, 92].



Stereoblock polypropylene. Stereoblock polypropylene was isolated by Natta by fractionation of the polypropylene obtained on the system of $TiCl_4$–AlR_3. Such polymer contains in its chain alternating isotactic and atactic blocks and has properties typical of elastomers. Commonly as the catalyst for the synthesis of stereoblock polypropylene are used so-called oscillating metallocenes, e.g., non-bridgehead bis-indenyl circonocenes with phenyl substituents in 2 position [93–97]. At the propagation of the polymer chain occurs multiple isomerization of the complex from isospecific *rac*-form into non-specific *meso*-form. Introducing of propylene molecule in the period of existence of active center in *rac*-form leqads to formation of an isotactic block. Introducing of propylene at the *meso*-form of the active center leads to an atactic block. Thus, the polymer chain growing on the oscillating active center has stereoblock structure. In the recent time appeared publications on the synthesis of stereoblock polypropylene by the method of "live" polymerization [98].

Atactic polypropylene. As compared with isotactic polypropylene, it has lower durability characteristics and lower melting point. It is well soluble in non-polar solvents, highly hydrophobic and chemically resistant. Low molecular atactic polypropylene has been synthesized on achiral and symmetrical metallocenes [99], high molecular atactic polypropylene with perfect elastomeric properties has been synthesized on a circonocene of C_{2v} symmetry $Me_2Si(Flu)_2ZrCl_2$ [100, 101] , and on phenoxyimine metallocene [102].

Polybutene-1. Isotactic polybutene-1 was first synthesized on a heterogenous catalyst $TiCl_3$, its structure was studied by D. Natta [103]. However, industrial process with this catalyst was not developed due to certain technological problems. To the moment the principal patent owner on the process of manufacturing isotactic polybutene-1 on the metallocene catalysts is Basell Polyolefine GMBE [104–107]. In Netherlands this company has facility for producing polybutene-1 with productivity 60 thousands ton per year. It is suggested that this company can be a licensiar of polybutene-1 production in the Open join stock company "Nizhnekamskneftekhim" with productivity 30-40 thousands ton per year. Isotactic polybutene-1 of different isotacticity can be produced on circonocenes of C_1 and C_2 symmetry. On the circonocenes of C_1 symmetry with indenyl ligands is formed polybutene-1 with high MM (up to 400 000). The degree of isotacticity depends on the type of substituent at the indenyl ligand [108, 109].



Alternating copolymerization of olefins. Synthesis of alternating copolymers as a rule is possible when the rate of homopolymerization of one of monomers is much higher than that of another, and increase in the reaction zone of concentration of less active co-monomer leads to increase in degree of alternation of the copolymers in the synthesized product. However, obtaining strictly alternating ethylene copolymers with other olefins still failed. Nevertheless, a high degree of alternation of copolymers has been achieved, at the copolymerization of ethylene with propylene [110–113] on circonium catalysts of C_1 and C_2 symmetry Et(Ind)(Flu)$ZrCl_2$, *i*-Pr(3-MeCp)Flu)$ZrMl_2$, *i*-Pr(3,4-Me_2Cp)(Flu)$ZrMe_2$; also with norbornene [114–121], octene-1 [122–125], isobutylene [126], butene-2 [127], cyclopentene [128–130], butadiene-1,3 [131] and butadiene-1,4 [132–135].

The proposed mechanism of alternation at the copolymerization of ethylene with octene-1 on the circonocene of C_1 symmetry *meso*-Me_2Si(2-MeInd)$_2ZrCl_2$ assumes [122] that the active center has two different coordination sites. One site is sterically less available (A) than another (B). Therefore one can expect that more bulky co-monomer octene-1 coordinates at the center A, while ethylene at the center B if there is significant difference in concentrations, [octene-1] >> [ethylene]

Alternating ethylene copolymer with cyclopentene with mp ~184°C has been discovered by Natta [129] in the insoluble in octane fraction of this copolymer obtained on the catalysts $VOCl_3$–$AlEt_3$, $V(acac)_3$–$AlEt_3$. More recently [130] with application of bis-phenoxyimine containing titanium catalyst were obtained atactic (Fig. 1) and sindiOtactic ethylene – cyclopentene copolymers. Fig. 2 depicts experimentally determined dependence of glass transition temperature T_g of ethylene – cyclopentene copolymers on the cyclopentene content in the copolymer.

For first time was shown a possibility of cyclocopolymerization of 1,3-butadiene with ethylene in the presence of catalytic system of Me_2Si(1-Ind)(Flu)$ZrCl_2$+ methylalumoxane in the medium of toluene at 25°C with a high degree of alternation of ethylene and cyclopentane (>90% of *trans*-1,2-cyclopentane links) [131].

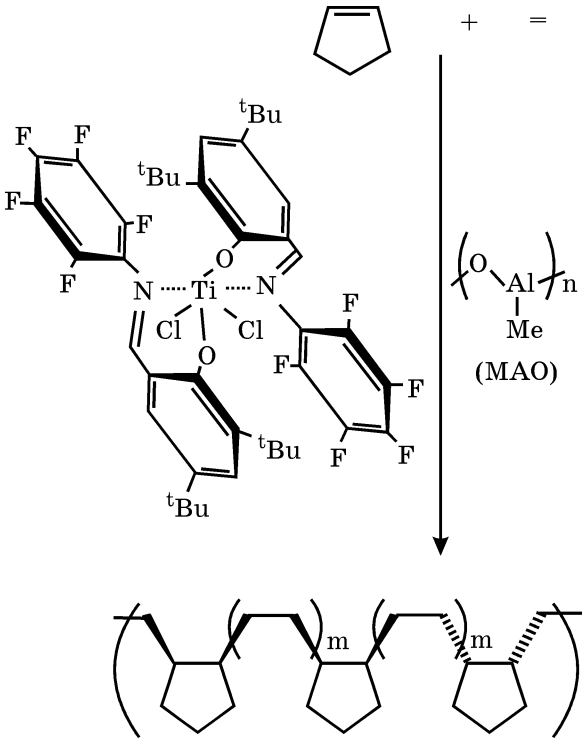


Fig. 1. Synthesis of alternating atactic cyclopentene–ethylene copolymer.

The synthesis of ethylene – 1,4-butadiene copolymers containing a fraction of alternating copolymer has been reported in [132–135].

Strictly alternating copolymers of olefins with such unusual co-monomer as carbonmonooxide wre first obtained in the middle of 80-th of the preceding century practically simultaneously by Shell firm and in the Institute of the Problems of Chemical Physics, Russian Academy of Sciences, in the presence of catalytic systems based on palladium carboxylates, mono- and bidentate phosphorus and nitrogen-containing ligands and an acid with pK <2 [136, 137]. These copolymers called polyketones represent a new generation of functional copolymers and are of certain practical significance because presence of CO group in a strict sequence after another monomeric link in the copolymer chain leads to the following:

– Increases ability of the polymer to photo- and biodestruction,

– Infinitely extends ability of modification of the copolymers by means of reactions in the polymer chain and thus obtaining new oligomeric and polymeric products with a new complex of properties,

– Admits to the polymers and compositions based on them high adhesion properties.

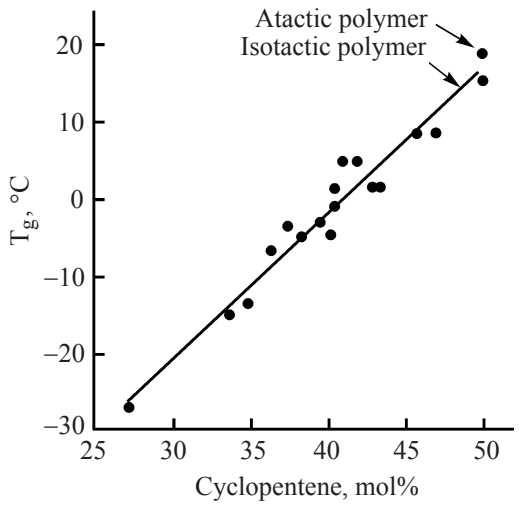

Fig. 2. Plot of glass transfer temperature T_g of cyclopentene–ethylene copolymer on the cyclopentene content in the copolymer.

The copolymer of ethylene with CO has high melting point (265°C) and can be considered as engineeric plastic. To the moment there are 16 reviews denoted to this polymer [138–153].

Analysis of the data published in patent and research literature shows that for the 50 years since discovery of complex organometallic catalysts (the Zigler – Natta catalysts and further generations) and their application in the reactions of olefins oligo- and polymerization was achieved certain success:

– in the area of selective ethylene oligomerization to butene-1, hexene-1 and octene-1 (selectivity over 70–98%) industrial processes of the synthesis of butene-1 and hexene-1 with polymerization grade purity are created,

– in the area of selective homo- and copolymerization of ethylene in the industry conditions is obtained polyethylene not only of required molecular mass (MM), branching (B) degree and type (methyl, ethyl, butyl groups), but also with a given by wideness and type (uni- and bimodal) molecular mass distribution (MMD),

– in the area of selective polymerization of propyl-ene and butene-1 are realized in the industry the processes of synthesis of isotactic and syndiotactic polypropylene, of isotactic polybutene-1,

– in the area of "live" polymerization and alternating copolymerization of olefin there are significant achievements, however, it was not yet realized in the industry, except alternating copolymerization of ethylene with carbon monoxide.

TECHNOLOGY OF ORGANIC AND INORGANIC CHEMISTRY

Technology for Manufacturing Fertilizer "Superfos" Containing Nitrogen, Phosphorus, Sulfur and Calcium

B. B. Sadykov, N. N. Volynskova, Sh. S. Namazov and B. M. Beglov

Institute of General and Inorganic Chemistry, Academy of Sciences of Republic Uzbekistan, Open Join Stock Company "Ammofos", Almalyk, Uzbekistan

Received April 2, 2008

Abstract—Technology for manufacturing a new concentrated highly effective fertilizer implemented in Join stock company "Ammofos" (Almalyk, Uzbekistan) based on the facility for the manufacturing Ammofos fertilizer is described. The technology essence is conversion of gypsum using diammonium phosphate to afford dicalcium phosphate and ammonium sulfate.

DOI: 10.1134/S1070427208090371

Until recently, the assortment of fertilizers in Uzbekistan consisted by 95% of Ammophos and by 5% of ordinary ammonized superphosphate [1]. Ammofos is produced by Almalyk join stock company "Ammofos" and by Samarkand chemical plant. This is the most concentrated nitrogen–phosphoric fertilizer (10% of N and 46% of P_2O_5) and it was applicable for all agricultural plants on the soil of any type [2]. However, its manufacturing is disadvantageous due to formation in a high scale of a side product phospho-gypsum which is pushed aside and accumulated. Producing of 1 ton of P_2O_5 as extraction phosphoric acid leads to formation of about 7 ton of phospho-gypsum [3]. Around Almalyk and Samarkand plants is accumulated 100 millions tons of this waste material.

Therefore we made efforts for utilization of this material or at least for reducing considerably its amount by means of developing conversion of gypsum in the phosphoric acid pulp into ammonium sulfate and calcium hydrogen phosphate. A possibility of such conversion follows from the data published in [4, 5]. The process essence in this case can be described by the following reaction equation

$$CaSO_4 + H_3PO_4 + 2NH_3 = CaHPO_4 + (NH_4)_2SO_4$$

In [5] was studied reaction of phospho-gypsum with ammonized solutions of diluted phosphoric acid using reagent in amounts corresponding to stoichiometry according to the above equation, under the following conditions: temperature range from 25 to 80°C, pH 6.5–9.0, reaction duration 30 to 120 min. Under the optimal conditions of the process (25°C, pH 7–8, solid–liquid ratio 1 : 2–3, duration 1 h) the phospho-gypsum conversion was 70–75%. In that study the ammonium sulfate solution was filtered, and remaining solid phase consisted of a mixture containing 75% of $CaHPO_4 \cdot 2H_2O$ and 25% of $CaSO_4 \cdot 2H_2O$.

Using pure salts, we investigated interaction of components in the systems $NH_4H_2PO_4$–$CaSO_4 \cdot 2H_2O$–H_2O, $NH_4H_2PO_4$–$(NH_4)_2HPO_4$–$CaSO_4 \cdot 2H_2O$–H_2O and $(NH_4)_2HPO_4$–$CaSO_4 \cdot 2H_2O$–H_2O as a dependence on molar ratio of the components, temperature and process duration. The lowest conversion (3.91 to 5.95%) was achieved in the system of monoammonium phosphate–gypsum dihydrate–water at the equimolar ratio of the components. The highest conversion, 93.26 and 98.33%, was achieved at 60 min interaction in the system of diammonium phosphate–gypsum dihydrate–water at the mole ratio of the components 1 : 1 and 2 : 1, respectively. We also studied the process of conversion of gypsum in real industrial phosphoric acid–gypsum pulp obtained at decomposition of washed and dried thermoconcentrate of Central Kyzylkum phosphorite with sulfuric acid in dehydrating regime [6–11]. The parent washed and dried thermoconcentrate was of the following composition (wt%): 27.26 P_2O_5; 53.36 CaO; 1.30 AI_2O_3; 0.51 Fe_2O_3; 0.61 MgO; 2.91 F 2.41 CO_2; 0.04 CI; 2.5 SO_3; 5.6 SiO_2. The sulfuric acid used was of 93% concentration. The commercial extraction phosphoric acid contained 20% of

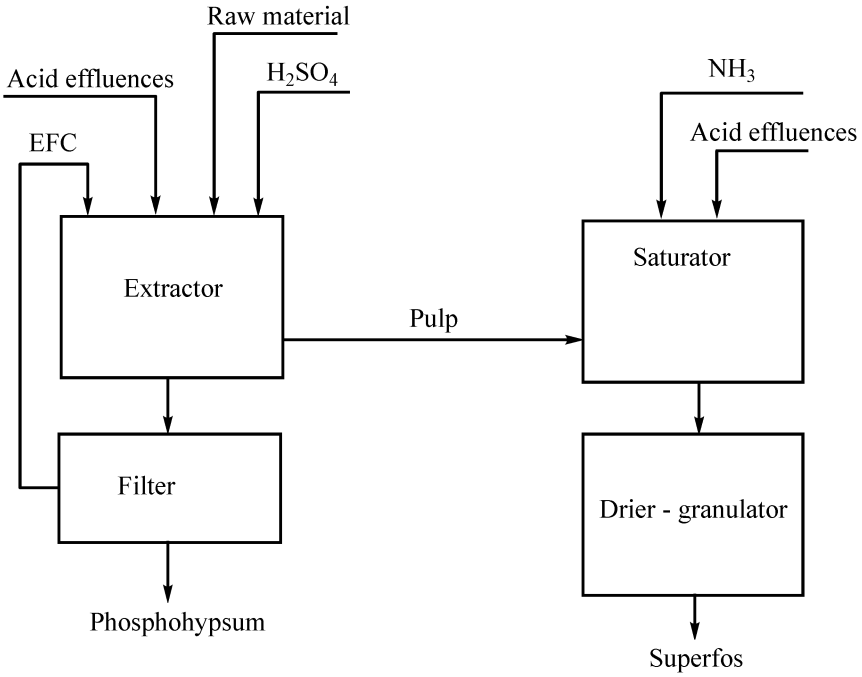
P_2O_5, 1.9 g of SO_3 per 100 cm^3, its density was 1.23 g/cm^3. The pulp composition was controlled proceeding from the phosphorus content by adding extraction phosphoric acid. The necessity of such control is defined by the following situation. Decomposition of phosphate raw material with sulfuric acid is described by the equation:

$$Ca_5F(PO_4)_3 + 5H_2SO_4 = 5CaSO_4 + 3H_3PO_4 + HF$$

This means that the pulp contains 3 mol of phosphoric acid per 5 mol of gypsum. However, complete conversion of gypsum according to above reaction equation requires the ratio 1 : 1.

Basing on the laboratory and pilot plant research, we elaborated Specification (Technical Requirements) on the Superfos, Tsh 6.6-27:2004. The quality of Superfos four sorts should respond to those listed in Table 1.

Tables 2–9 list contents of the pulps ammonized to various pH values and of dried products for all four sorts of Superfos. Analysis was carried out according to commonly used procedures [12]. As seen from the Tables, at the ammonization of phosphoric acid–gypsum pulp to pH 8.0 the gypsum conversion at the manufacturing the product of sort A is 99.48%, sort B 92.43%, sort C 79.60% and sort D 86.12%.



Superfos is a complex mixed fertilizer containing in its composition up to 45% of precipitate (valuable phosphoric fertilizer containing assimilable form of calcium), up to 35% of ammonium sulfate that contains 21% of nitrogen in ammonium form, 10% of mobile and

Table 1. Specification of four sorts of Superfos

No.	Characteristics	Sorts			
		A	B	C	D
1	Content of active component, not less than, %	75	67	65	60
2	Mass fraction of general phosphates, %	24 ± 1	20 ± 1	22 ± 1	20 ± 1
3	Mass fraction of water soluble phosphates in the general phosphates, ni more, %	25	25	25	25
4	Mass fraction of ammonium nitrogen, %	12 ± 1	15 ± 1	8 ± 1	10 ± 1

Principal technological scheme of manufacturing Superfos.

easily assimilable by plants sulfur, and 10–15% of mono- and diammonium phosphate.

Principal technological scheme of manufacturing is shown in the figure.

Phosphoric acid–gypsum pulp from the extraction section is passed to a saturator. The pulp has following characteristics: density 1.41–1.44 g/cm^3, density of liquid phase 1.22–1.24 g/cm^3, content of P_2O_5 in the liquid phase 20%, content of SO_3 in the liquid phase 1.6–2.2 g per 100 cm^3, ratio liquid–solid 2.3–2.8. The saturator with the volume 430 m^3 is equipped with four stirrers. The saturator is feed also with acid effluences of 1.05–1.10 g/sm^3 density and the pulp is diluted to the density 1.35–1.37 g/cm^3. After dissolving, feed with ammnium is switched on. Neutralization is carried out to achieving pH 7.5–8.0, at vigorous stirring. To exclude ejection of ammonium due to high temperature of exothermal neutralization reactions, the process of ammonization is carried out stepwise to maintain temperature below 90°C. For stabilization the process of producing ammonized pulp, and for avoiding possible oversaturation with the dozing components and providing the reaction proceeding under mild regime, the neutralization is carried out on the background of mother liquor. For this purpose is provided circulation of the pulp in the saturator. From saturator the pulp is passed to a drier - granulator. The process of granulation and drying, classification and cooling the final product, purification of exhaust gas, storage and

shipping the product are carried out along the technology of manufacturing of Ammofos [2].

Reorientation of the sections of extraction phosphoric acid and of Ammofos in Almalyk join stock company "Ammofos" for manufacturing Superfos allowed:

– extension of assortment of produced fertilizers;

– increasing overall producing of mineral fertilizers with simultaneous increase of overall producing of nitrogen fertilizers based on the industrial side products;

– returning to manufacture 60% of sulfuric acid used for decomposition of phosphoric raw material, owing to conversion of phospho-gypsum;

– decreasing the norm of consumption of phosphate raw material and sulfuric acid in the step of extraction

Abstract—A review of publications on the effect of various inorganic additives (metals oxides, hydroxides, chlorides and carbonates) on the process of dehydrochlorination and pyrolysis at the thermal processing of polyvinylchloride (PVC). A decrease in temperature of the PVC dehydrochlorination step is noted at processing in the presence of chromium, iron, cobalt, copper and molybdenum oxides. Aluminum, titanium, circonium, cerium and lead oxides do not change temperature of beginning of PVC destruction. No effect noted of the oxides at the second step of PVC destruction.

DOI: 10.1134/S1070427208090383

Demand for plastics grows continuously due to their wide application and relatively low cost; respectively, their manufacturing and amount of side products grow. Polyvinylchloride (PVC) plays key role in the plastics industry for 40 years and remains to be the basic polymer and a source of huge amount of wastes. For example, in West Europe the amount of PVC in municipal wastes is estimated as 2 million tons per year [1].

Combustion of municipal wastes became an alternative to the technology of their concealment at the waste dump. In Japan in 2004 appeared more than 10 million ton of wastes, and approximately 40% of this amount was either concealed or combusted [2]. However, combustion leads to the liberation of substances that can bring more harm to environment than concealment or radioactive wastes. The processes of combustion whole and not controlled combustion of wastes in particular leads to formation of hazard substances, e.g., soot, smoke, benzene, dioxins, acid gases, heavy metals, aliphatic and aromatic compounds [3–6].

For the processing of wastes of synthetic polymer materials the most often is used the method of pyrolysis. However, thermal pyrolysis of PVC wastes liberates hydrogen chloride and chlorine-containing organic compounds are formed, therefore appears a problem of corrosion at the use of chlorine-contaning plastics as raw material for blast and coke furnaces at steel manufacturing [7, 8]. Chlorinated hydrocarbons can be precursors of even more toxic substances such as polychlorinated dibenzodioxines, dibenzofurans and polychlorobiphenyls [9].

Behavior of PVC at thermal decomposition has been widely studied basing on the composition of the products and kinetics of destruction [10–16]. All explorers suggest that thermal decomposition of PVC proceeds in two steps, starting with the splitting hydrogen chloride off. This process is propagated along the polymer chain and leads to formation of polyenes that are responsible for the color of the destructed polymer. In the first step, at 200–360°C, is liberated hydrogen chloride and approximately 15% of the formed therewith polyene is converted into benzene and other aromatic compounds [17, 18] via intramolecular cyclization of the polyene segments [19] with formation of cyclohexene and cyclohexadiene remaining in this step introduced to aliphatic matrix. The hydrogen chloride liberated in the first step works as a catalyst for the further reactions of decomposition [15]. In the second step, at 360–500°C, the polyene frame exerts structural decomposition leading to formation of alkylaromatic and fused aromatic compounds (toluene, naphthalene, indene, anthracene, *o*-xylene and various chlorobenzenes) together with a small amount of hydrogen chloride and benzene [17]. During this step the polymer net formed at the condensation of polyene is damaged, that promotes aromatization of cyclohexene and cyclohexadiene rings. The main reactions in the second step are *cis-trans* isomerization, aromatization and stitching [20].

Liberation of dioxins at combustion or roasting of industrial wastes belongs to the most important social problems owing to their high and various toxicity. At the combustion of PVC the amount of the forming dioxins can be diminished by maintaining combustion temperature above 800°C [21]. However, this method can be applied in the large scale installations for combusting wastes. Many studies are denoted to diminishing formation of dioxins in the process of combustion or in the systems for afterburning. Some explorers noted an effect of precursors (chlorophenol) at the formation of polychlorinated dibenzodioxins (PCDD) and polychlorinated dibenzofurans (PCDF). It has been reported that the sources of dioxin formation can be organic and inorganic chlorides (NaCl, HCl, $FeCl_3$) [22, 23]. This allows a suggestion that by removing of HCl liberated at combustion the formation of dioxins can be depressed.

To decrease amount of halogen liberated at PVC combustion two methods are known. The first one consists in diminishing of chlorine content in the recipes including PVC, by using its mixtures with other components or as copolymers not containing halogen [24].

Another method assumes application of fillers in small amounts that can bind HCl effectively. In the patent [25] has been noted that lithium-contaning compounds (LiOH and Li_2CO_3) are more effective than $CaCO_3$ for binding the formed HCl. However, LiOH is hygroscopic and is a strong base, that restricts its application as a filler for PVC. Li_2CO_3 is enough stable in air and can be used with a high content.

Also, have been patented the methods of processing the halogen-containing compounds, including solid polymer materials containing halogen, by heating them in disintegrated state and mixed with oxides or hydroxides of calcium, magnesium, or barium, that leads to formation of respective halides and carbonates [26, 27].

In the industry of plastics for long time were used various inorganic compounds for extension of functional versatility of polymers such as flash and smoke suppression. For example, metal carbonates are used as fillers at producing PVC for reducing cost of the product. Also they are used for improving resistance to aging, electric and dielectric properties, stability at saving, decrease in planting, allow to decrease content of stabilizers and increase ultimate strength of the PVC material [28–30].

At the same time, it is found that metal oxides affect composition of PVC destruction products due to formation of metal chlorides [31, 32]. Therewith, the chlorides formed from acidic oxides of transition metals accelerate thermal decomposition of PVC, in contrast to the chlorides formed from the metal oxides with basic properties [31]. The metal oxides also affect kinetics of PVC destruction decreasing or increasing liberation of hydrogen chloride [33].

In this review embarrassing publications of recent 15–20 years we attempted to reveal effect of various inorganic substances on the processes of dehydrochlorination and pyrolysis at the thermal processing of polyvinylchloride.

DERIVATIVES OF D-METALS

Investigations performed by Li [34–37] allowed to reveal effective decrease in smoke formation at the liberation of HCl by PVC in the presence of Cu_2O, MoO_3, Cu_2O/MoO_3, CuO and Fe_2O_3. At adding of these oxides in amount 4 moles of a metal per 100 moles of chlorine in PVC the smoke formation decreases by 25.1–52.0%. Copper oxides are more effective than MoO_3 and Fe_2O_3. It was established that transition metal oxides affect the process of thermal decomposition of PVC leading to decrease in mass loss and the rate of PVC mass loss, and stimulates formation of residue in the final step of combustion. Copper(I), copper(II) and iron (III) oxides show catalytic effect for the chlorine splitting off from PVC, while MoO_3 stabilizes PVC. It was concluded that transition metal oxides accelerate the process of PVC cross-linking and stabilize carbon backbone. In addition, the presence of oxides leads to changes in the composition of volatile components at combustion of PVC in a flame. The last effect was shown in [38] at the study of copper- and molybdenum-containing substances as flame- and smoke-depressors at combustion of PVC. At the dehydrochlorination of PVC at 200°C, presence of Cu_2O, CuO, $CuCl_2$, copper powder and MoO_3, but not CuCl, leads to significant acceleration of 3-chloropentane formation. 3-Chloropentane is known to alkylate benzene at 200°C in the presence of MoO_3 to form 2- and 3-pentyl isomers of benzene, but no alkylation occurs at the replacement of MoO_3 by $CuCl_2$. At the same time, $CuCl_2$ slowly chlorinates double bond of *cis*-2-pentene at 200°C. These observations confirm reliability of the mechanism with involvement of Lewis acids for the explanation of the effect of MoO_3 on the process of PVC combustion and attest the same effect of addition of copper derivatives that can play the same role. However,

in respect of application to the polymeric system there is a considerable difference in the mechanisms of the effects of MoO_3 and copper derivatives.

At the study of thermal decomposition and carbonization of PVC, PVC/Cu_2O and PVC/Cu_2O/MoO_3 in condesed phase by the method of photoemission spectroscopy [39, 40] the authors showed that the most important role at destruction and carbonization of PVC plays early cross-linking, in part, in the presence of Cu_2O catalyst. Interaction of PVC and Cu_2O along the scheme: $Cu_2O > CuCl > Cu > Cu_2O$ at elevating temperature from 20 to 500°C is confirmed experimentally.

Studies [41-44] are denoted to elucidation of the role of FeO(OH) for the depression of smoke formation at the combustion of mixtures of polymers. Study of effect of temperature in the range 500–700°C on the formation of carbon by the mixtures of polymers containing PVC showed that in the presence and in absence of FeO(OH) occurs linear dependence between the carbon yield and the temperature of carbon formation [41]. Increase in amount of chlorine and FeO(OH) in the mixtures leads to increase in the yield of carbon in the whole temperature range, but the most important factor affecting yield of carbon is actual total chlorine content in the mixtures both containing and not containing iron. A detailed study of the products of pyrolysis in air of PVC containing mixtures that include FeO(OH) as a smoke depressor was conducted [42]. Presence of iron(III) derivatives decreases considerably the concentration of aromatic and polyciclic compounds of aromatic series that are precursors in the process of smoke formation. The mechanism of smoke depression by FeO(OH) is explained by retarding reactions leading to formation of aromatic compounds. The basic iron oxide shows also stabilizing effect at the thermal decomposition of mixture of polymers [43]. It was also established that the active compound that stimulates formation of carbon by these polymer systems is iron(III) chlorooxide FeOCl [44].

Sakata and co-workers [45] at the study of catalytic action of some compounds on the destruction of a polymeric mixture containing PVC found that sorbents based on the iron oxide bind well hydrogen chloride liberated at the pyrolysis of PVC but do not affect splitting of polymers.

At the pyrolysis of PVC in the presence of cadmium and zinc chlorides was observed formation of stable complex at the double bonds of the polyene with $CdCl_2$ [46] and $H^+ZnCl_3^-$ [47].

Effect of certain metals (Fe, Zn), related oxides (Ti, Cu, Fe) and carboxylates (Zn) on the process of thermal decomposition of PVC was studied in [48]. Metals and metal oxides with large enough metal ion radius decrease temperature of beginning of hydrogen chloride splitting off probably by binding chlorine and weakening C–Cl bonds in PVC. When formation of chlorides is possible (Fe, Zn, Ca/Zn carboxylates, CuO, TiO_2) formation of HCl and benzene is dimimnished. Formation of benzene occurred in the presence of TiO_2 is a result of ease hydrogen exchange on the oxide surface that is needed for the benzene splitting off from the dehydrochlorinated PVC segment. In the presence of the studied metals and oxides the second step of thermal decomposition of PVC proceeds at lower temperature that is explainable by ease splitting of polyene chain at the contact with the metal surface or transition metal ion.

Iron oxide and its mixture with carbon that are stable toward hydrogen chloride were proposed as additives for the process of dehydrochlorination of organochlorine compounds at the obtaining of useful substances from the municipal plastic wastes containing PVC [49]. Derivatives of Fe(II) combined with Portland cement are effective at reductive dehydrochlorination of chlorine-containing organic compounds and can be applied at decomposition of pollutants [50].

Pyrolysis of PVC in the presence of Zn, Ba and Cu chlorides was studied in [51]. It was shown that metal chlorides, in particular $ZnCl_2$ and $BaCl_2$, accelerate reaction of splitting off hydrogen chloride in PVC at pyrolysis and decelerate ($ZnCl_2$ and $CuCl_2$) second step of PVC destruction occurred for pure PVC in a significant degree at 400°C. Therefore the samples containing metal chlorides as additives are characterized by a significant mass loss in the temperature range 400–500°C, therewith amount of solid residue is larger while amount of hydrocarbons with large molecular mass (over 200), condensed aromatic hydrocarbons in particular, is much less. Thus, metal chlorides can depress reaction of aromatization.

Investigation of temperature and amount of copper(II) chloride effect on the type and amount of toxic effluents at combustion of polyvinylchloride [52] showed that at combustion of pure PVC besides a significant amount of polyciclic aromatic hydrocarbons (PAH) are formed in small amounts PCDD and PCDF. Copper(II) chloride promotes formation of two latter but inhibites formation of PAH. Thus, by the opinion of the authors of [52], metal chlorides constitute one of most important factors of

increase in amount of PCDD/PCDF formed at combustion of polyvinylchloride.

Minsker and co-workers [53] at the study of oxidative destruction of PVC in the presence of metal chlorides showed that rate of this process is defined by the presence of plasticizers in the polymer. Some chlorides ($CdCl_2$, $CoCl_2$) are relatively indifferent in the reaction of PVC dehydrochlorination, other ($MnCl_2$, CuCl) activate weakly decomposition of the polymer, while $CuCl_2$, $ZnCl_2$, and $FeCl_3$ accelerate considerably thermooxidative dehydrochlorination of PVC. This effect the authors explain by changes in the kinetics of oxidation of plasticizer under the action of the metal chlorides and strengthening or weakening of catalytic effect of the chlorides on the PVC destruction.

Effect of copper, copper(II) oxide and copper(II) chloride on the thermal decomposition of PVC was studied in [54]. In the presence of copper or its derivatives, particularly of copper(II) oxide, decomposition of PVC occurs at the higher temperature and leads to the change in the nature and concentration of gaseous products. These changes are defined by the ability of copper compounds to induce cross-linking of the polymer molecules, the maximal linking occurs in the presence of copper(II) oxide. The process of linking leads to decrease in amount of aromatic hydrocarbons like benzene and increase in amount of aliphatic compounds at high temperature. In the PVC–CuO system, e.g., in the temperature range 300–600°C the total amound of liberated chlorine falls by 40% in air and by 20% in nitrogen, formation of benzene falls by more than 90% in air and in nitrogen, amount of other aromatic and chloroaromatic compounds also falls down. Increase in formation of hydrocarbons of aliphatic series together with decrease in content of aromatic hydrocarbons leads to decrease by more than 50% of amount of carbon black formed at the pyrolysis, in particular, in the PVC–CuO system, that attests more effective oxidation of the PVC carbon.

In [55] was studied effect of adding copper compounds in the mass ratio to polymer 1 : 10 on the depression of smoke formation and flame extinguishing at the pyrolysis of PVC. These additives showed good ability to depressing the smoke formation and flame extinguishing at the combustion of solid and plasticized samples of PVC. Mixed copper oxides are found more effective. At 190°C the process of PVC cross-linking is accelerated in the presence of most of additives showing no obvious dependence on their composition or on degree of copper oxidation. For the $Cu_3(MoO_4)_2(OH)_2$–$CuSnO_3$ mixture in plasticized PVC is notes synergism of these properties.

The role of various metal oxides in the thermal decomposition of polymers (PVC and PVA) and their mixtures was studied in [56]. It was shown that some oxides (Co_3O_4, Cr_2O_3, CuO, Fe_2O_3, MoO_3) decrease temperature of the first step (liberation of HCl) of destruction while the presence of other oxides (Al_2O_3, CeO_2, PbO_2, TiO_2, ZrO_2) does not affect considerably the temperature of beginning destruction. Effect of oxides in the second step of destruction (breaking of olefins) is practically absent because the difference in the temperature of breaking the olefin bonds is only ±5°C. But it was found that destruction of polymers is affected considerably by the presence of metal chlorides. Thus, the effect of metal oxides on the destruction of polymers can be explained by the formation of chlorides. The oxides containing strong Lewis acids as cations more promotes splitting off hydrogen halide. Good enough correlation occurs between the temperature of beginning of the polymer thermal decomposition stimulated by halo compound with a cation possessing Lewis acidity. This result is consistent with the earlier investigations on the destruction of vinylidene chloride polymer [57]. The reason for these phenomena consists in the fact that acidity of metal halo derivative reflects ability of its cation to the formation of complex with the polymer chlorine atoms and thus to promote the thermal decomposition. Also was noted that carbon–carbon backbones formed after first step of PVC and PVA destruction are of similar structure and that olefinic bonds remain relatively intact in the presence of oxides .

In [58] was carried out quantitative analysis of the products of pyrolysis (gaseous, liquid and residue after pyrolysis) of PVC mixed with various metal oxides including ZnO, Fe_2O_3, rare earth oxides, CaO, PbO and Al_2O_3. For the revealing ability of utilization of PVA wastes was used higher concentration of metal oxides (PVC : oxide = 2 : 1 mol/mol, one mol of PVC corresponds to one C_2H_3Cl fragment) as compared with the study of the effect of additives on the PVC flame extinguishing [59]. From this viewpoint the authors of [58] also considered binding of chlorine by oxides at the pyrolysis of the PVC–metal oxide mixtures. It was shown that ability of the used oxides to bind chlorine differ considerably in the series. Adding of ZnO leads to increase in the amoumt of the formed carbon and to decrease in amount of liquid products. A possible explanation is formation of $ZnCl_2$ which is known

as a strong Lewis acid. On the other hand, $ZnCl_2$ has high vapor pressure and therefore should be taken into account the kinetics of the chloride evaporation that is accompanied by formation of carbon. In respect of this viewpoint should be mentioned a publication [60] on the pyrolysis of mixtures of PVC with metal oxides directly in a mass-spectrometer where observed simultaneous formation of $ZnCl_2$ and benzene. The authors suggest that presence of zinc chloride affects decrease in formation of liquid products. Thus, for the PVC-ZnO system at 400°C a precursor of carbon (possibly, cross-linked hydrocarbons) is formed simultaneously with zinc chloride at the temperature below 400°C. Deceleration in the formation of liquid substances by ZnO additive points to the possibility of zinc oxide to behave as a Lewis acid.

In the case of iron(III) oxide dominates the process of its reduction and hence chlorine is liberated from PVC basically as HCl. On the other hand, at the adding Fe_2O_3 grows significantly the amount of chlorobenzene. The authors of [58] assume that formation of the latter proceeds by chlorination of benzene with involvement of $FeCl_3$ as a Lewis acid. Probably a part of the parent PVC chlorine can form iron chloride or any intermediate Cl–Fe compound on the interphase surface between melted PVC and Fe_2O_3 which promotes formation of chlorobenzene.

The authors of [61] studied a method of dechlorination of wastes containing a mixture of high density polyethylene, polypropylene, polystyrene and PVC, consisted of a series experiments with coal tar (side product at producing coke) and convertor dust (side product at producing steel consisting mainly of Fe_2O_3) in a melt and treatment with hot water. The results obtained showed that iron oxide reacts with chlorine liberated from the wastes and form water soluble iron chloride in the melt. Chlorine is dissolved in the coal tar melt that resulted in diminishing liberation of chlorine containing gas. Besides, this stimulates pyrolysis of the side products. It was shown that ca. 98% of chlorine react with Fe_2O_3 to form iron chloride which can be extracted with hot water and ca. 58% of iron chloride is bound with the melt components to form insoluble in water compound. After conducting these processes the chlorine containing plastic wastes can be used in furnace because they contain 5000 ppm or less of chlorine. Notable that for achieving such results on dehydrochlorination the Fe_2O_3/PVC ratio should be equal to 10 times or more over the stoichiometry of formation of iron chloride.

Using thermogravimetric analysis were determined parameters of the splitting off hydrogen chloride kinetics at the destruction of PVC and of PVC mixed with $ZnCl_2$ in varied ratio [62]. The values obtained are compared with those obtained by UV spectroscopic analysis in the visible region at the heating PVC film containing $ZnCl_2$. The values of apparent activation energy of the process fall with increase in the amount of $ZnCl_2$.

Horikawa and co-workers [63] while studied a possibility of regeneration of chlorine liberated at the pyrolysis of PVA used metal oxides for absorption of hydrogen chloride at 260-400°C with formation of corresponding metal chlorides. The chlorides were then roasted at 350-450°C under oxygen flow for regeneration of gaseous chlorine and oxides. Cobalt(III) oxide was found the most effective for both absorption and removing chloride ions. At the secondary application of Co_2O_3 for absorption of HCl at 300°C followed by removing Cl_2 at 400°C the amount of chloride ions bound with the cobalt oxide powder diminished to one fifth part of the amount bound with fresh oxide, that is explained by the authors by diminishing in the area of cobalt oxide surface at the repeated application.

In [64, 65] was studied composition of the product of destruction of a mixture of plastics contaned PVC and ability of chlorine removing from the products using appropriate sorbents. It was shown that at the destruction of polypropylene/PVC mixture the additives FeO(OH) and Fe_3O_4 decrease content of chlorine in the melt, and liberated chlorine becomes bound by iron compounds to form chloride. In the presence of iron(III) oxide and carbon–oxide compositions as catalysts [66] the latter is deactivated at the absorption of HCl. Therewith, iron oxide is chlorinated to form $FeCl_2$.

Sakata and co-workers studied effect of iron oxide and of composite iron oxide–carbon (Fe_2O_3–C) on the thermal and catalytic decomposition of the mixture of municipal wastes and gas oil to obtain power station fuel [67, 68]. In the process of stepwise pyrolysis at 430°C, iron(III) oxide was used as a catalyst of dechlorination. Besides was studied destruction in the presence and in the absence of alumo-silicon catalyst SiA1 at 430°C followed by dechlorination in a reactor with steady layer at 350°C. In both these processes the iron(III) showed efficiency at the sorption of both inorganic and organic chlorine-containing substances and stability toward HCl. Chlorine content in liquid products in the presence of iron(III) decreased by the factor of 12.5. A highly selective and stable catalytic system $FeCl_2/SiO_2$ was

developed for splitting off hydrogen chloride from various organochlorine compounds contained in the power station fuel obtained from plastic wastes containing PVC [69].

The catalyst Fe_2O_3–C was also applied for decomposition of brominated (9.59 wt% of Br) flame retarding composition for acrylonitrile–butadiene–styrene copolymer (the waste at the producing electric and electronic apparatuses) mixed with polypropylene, at 450°C [70] and were obtained containing no bromine liquid products that could be used as power station fuel or as initial material in oil processing.

It was shown that introducing of TiO_2 to polymer matrix leads to acceleration of photocatalytic destruction as compared with pure PVC. Therewith this additive increases amount of liberated CO_2 and H_2O, while chlorine concentration falls [71].

COMPOUNDS CONTAINING *s*- AND *p*-ELEMENTS

Aluminum oxide does not exert chlorination or reducion at the pyrolysis of PVC [58]. Catalytic action of Al_2O_3 as proposed in [48] consists in acceleration of formation and decomposition of intermediately formed cyclohexadiene that results in formation of benzene. Decrease in the presence of Al_2O_3 in liberation of gaseous products was noted. Addition of calcium oxide reduces amount of residue at the pyrolysis. This observation indicates that cross-linking of polyene chains is in a certain extent restricted. Lead oxide and oxides of rare earth elements do not affect considerably yield of liquid and gaseous products that is explainable by lower activity of these oxides in the reaction of decomposition of cyclohexadiene structures and formation of carbon. During the pyrolysis these structures are reduced or chlorinated. For example, in the presence of lead oxide, 50 to 70% of chlorine is bound to form volatile $PbCl_2$.

With the compositions containing CaO almost a half of chlorine is bound to form mixed compounds of the type of CaClOH. Lanthane oxide can bind up to 95% chlorine contained in PVC to form lanthane chlorooxide LaOCl. Taking into account a very low solubility of LaOCl in water the authors of [58] suggest that use of La_2O_3 is more reasonable for binding chlorine than CaO to form solid chlorooxide, that prevents contamination of soil. Moreover, this chlorooxide can be converted back to respective oxide and HCl by hydrolysis at high temperature that makes reasonable to use chlorine for treatment wastes containing oxides of rare earth elements with regeneration of chlorine [72, 73].

Catalytic decomposition and dechlorination of PVC mixed with polypropylene, polyethylene and polystyrene in the presence of mixed Al–Zn and Al–Mg oxide catalysts was studied by the authors of [74, 75]. At the catalytic decomposition yield of gaseous products falls sharply while amount of residue increases as compared with thermal decomposition. Such catalysts showed ability of binding HCl and increasing chlorine content in liquid products. At the application of Al–Mg catalyst the content of chlorine in the pyrolysate oil falls 4–5.6-fold depending on the mixture composition, as compared with thermal decomposition. It is established that 91–93 wt.% of chlorine is bound by the catalyst and contained in the residue, while at thermal decomposition 71–96 wt.% of chlorine contained in the sample is liberated as HCl. Application of Al–Zn catalyst reduces this value to 88-92 and 88-96 wt.%, respectively [74]. Presence of the catalyst leads to significant increase in the rate of formation of oil from wastes therewith each mixture containing PVC gives more volatile products while amount of heavy products falls that deeper catalytic decomposition. For revealing active component responsible for cracking and ability to dechlorination, the catalytic decomposition of mixtures was carried out separately with γ-Al_2O_3 and MgO prepared under the same conditions as the catalyst [75]. As shown, magnesium oxide reveals certain dechlorination action but content of liquid products remains the same, hence MgO does not show catalytic action. On the contrary, γ-Al_2O_3 showed catalytic action at the decomposition but was almost not actve in the reaction of dechlorination. Thus, the catalyst is advantageous over separate application of MgO and Al_2O_3 both for dechlorination and cracking. Study of phase composition of fresh and used catalysts showed presence of MgO and spinel $MgAl_2O_4$, while aluminum is distributed in the catalyst uniformly without formation of Al_2O_3 phase. The authors of [76] concluded the same. In the process of PVC decomposition with magnesium oxide the amount of MgO falls and increases amount of $MgCl_2$, pointing to interation of a part of MgO with the absorbed HCl. Thus, the catalyst has both acid and basic properties. Besides, it has large specific surface and higher heat capacity than MgO [76]. These results explain dual effect of the catalyst in respect of both cracking and dechlorination than MgO. Ability to promote dechlorination of Al–Zn catalyst is also much higher than of zinc and aluminum oxides separately [74].

In [77, 78] was studied sorption of hydrogen chloride by carbon-containing composite materials based on

calcium carbonate ($CaCO_3$–C), iron oxide and potassium carbonate. The sorbent $CaCO_3$–C which reacts with hydrogen chloride absorbing HCl completely during 12 h. Under optimal conditions (gas linear rate 0.18 m/sec; HCl concentration at inlet 1820 ppm; amount of sorbent 2 g; particles size 0.25 mm; gas flow 535 cm^3/min, temperature 350°C) approximately 63% of theoretical capacity of the sorbent is used. The sorbent $CaCO_3$–C was successfuls applied also for dechlorination and debromination at the pyrolysis of mixed chlorine and bromine containing plastic wastes at 430°C with formation of liquid products not containing halides.

Interaction of MgO with hydrogen chloride liberated from organochlorine compounds at the pyrolysis of PVC-containing municipal wastes was noted in [68].

At searching effective additives for increasing thermal stability of PVC, attention of investigators attracted laminated dual hydroxides (LDH) [79–82]. LDH form a group of anion-exchange substances containing laminated metal hydroxides like brusite $Mg(OH)_2$. In such compounds commonly up to one third bivalent cations (M^{2+}: Mg, Zn, Ni, Co, Fe, etc.) can be substituted by trivalent cations (M^{3+}: Al, Fe, Cr, etc.) [83–85]. Positive charges on the hydroxide layers formed at such substitution are balanced with exchanging anions in the space of intermediate layers where commonly there is some water molecules that are connected by hydrogen bonds with anions and (or) hydroxyl groups. The LDH composition can be described by a general formula $[M^{2+}_{1-x}\,M^{3+}_{x}(OH)_2]^{x+}[(A^{m-})_{x/m}\cdot nH_2O]^{x-}$, where A^{m-} is exchanged anion of CO_3^{2-}, Cl^-, SO_4^{2-} type and various organic carboxylates, sulfates and sulfonates. Fisher and co-workers [80] found that hydrogen chloride can be substantially absorbed by Mg_3ZnAl_2–LDH and they affect thermal stabilization of PVC. The authors of [81, 82] reported on significant increase in thermal stability of PVC at including MgAl–LDH–CO_3 into PVC matrix together with other organic salts such as calcium, zinc and tin stearate.

Effect of Zn, Al laminar dual hydroxides on the thermal decomposition of PVC was studied in [86]. It was found that 4 wt% LDH additive promotes the process of dehydrochlorination proceeding in the temperature range 260–300°C. The authors explain this fact by catalytic action of chlorides formed in the reaction with the liberated hydrogen chloride, as has been noted earlier [79, 80]. With zinc and aluminum chlorides the decomposition becomes autocatalytic process: they stimulate splitting hydrogen chloride off just after initiation, decrease temperature of beginning and induce reaction proceeding in narrow temperature range. This result is consistent with the data of [51] showed that introducing to the PVC matrix of 1 mol% $ZnCl_2$ increases mass loss at 250°C from 4 to 26%. As established in [59], $ZnCl_2$ catalyzes the process of splitting off chloride ion from PVC with formation of carbenium ion. The latter decomposes into alkene affording proton that couples with $ZnCl_3^-$ to afford HCl and regenerate $ZnCl_2$. Authors of [86] suggest that freshly formed $AlCl_3$ plays a role of catalyst like $ZnCl_2$ and promotes splitting hydrogen chloride off from PVC. At the same time, in the presence of LDH or products of its conversion, the chlorine occasionally isolated in polyene links or at aromatic nuclei remains intact in a significant amount as compared with pure PVC, and its splitting proceeds difficultly.

In pure PVC just after dehydrochlorination proceeds dehydrocarbonation leading to formation of various volatile hydrocarbons [51] therewith binding and cracking of the formed linear polyenes with liberation of volatile aromatic and various solid products is possible [87–89]. Cross-linking prevails in the temperature range 370–430°C, at higher temperature prevails cracking with formation of volatile aromatic compounds. It was shown that under nitrogen atmosphere the dehydrocarbonation is diminished when 4 wt% of LDH is introduced to the PVC matrix, which by opinion of the authors of [86] is connected with the catalytic effect of LDH or its products promotoing binding into dense aromatic complexes. At the use of Zn-LDH that bears function like $ZnCl_2$ [51, 59], carbonation depresses cracking, and less volatile hydrocarbons are formed. In air, in the presence of LDH at 400–550°C formation of carbonized residue becomes easier, at higher temperature occurs thermooxidation of the latter.

In the recent time are widely explored polymer–clay nanocompositese characterized by certain unique properties as compared with pure polymers and composites containing other inorganic substances [90–97]: excellent mechanical properties, high temperature of thermal deformation and thermostability, low gas penetrability, etc. Study of properties of the polymer–clay nanocomposites opens new approaches to manufacturing highly effective composites based on PVC. In [98] were studied mechanical properties and the process of stabilization of nanocomposites with montmorillonit (MMT) as an additive for obtaining PVC/MMT nanocomposite with partially intercalated structure. Wang and co-workers [99–101] synthesized

the PVC/MMT nanocomposites with non-mixied and intercalated structures and studied their thermal and mechanical properties. Results of some studies show that adding of clay particles can improve thermal stability of polymer/MMT nanocomposites, e.g., when polymeric matrix is polystyrene [102] or polymethylmetacrylate [103, 104]. Presence of MMT promotes formation of carbon and retards diffusion of volatile products of decomposition in the nanocomposites. In [105] were studied thermal properties of PVC/MMT nanocomposites synthesized by intercalative polymerization. As compared with pure PVC, the nanocomposites have slightly higher temperature of vitrification. Adding of MMT to the PVC matrix increases temperature of maximal rate of decomposition and temperature of beginning decomposition. On the nanocomposite surface is formed structure of compact carbon with the rich by carbon MMT that diminishes thermal decomposition of polymer matrix at the high temperature. Nanocomposites accelerate formation of residue and improve properties of polymer matrix. Presence of quarternary nitrogen in the nanocomposites leads to acceleration of the polymer decomposition in the initial step. It is known that thermal destruction of ammonium salt can proceed along the Hoffman mechanism [106] with formation of some H^+ and HCl catalyzing reaction of splitting off hydrogen chloride from the PVC chain. Therefore introducing of ammonium salt at the modification of PVC matrix with MMT accelerates the process of the polymer dehydrochlorination and diminishes temperature of beginning of its decomposition.

Magnesium hydroxide is used at high-temperature decomposition and as flame retarding additive to polymer materials. For improving its dispersion and compatibility with the polymer matrix it is subjected to ultrafine grinding ant treatment of its surface. The superfine magnesium hydroxide powder improves flameproof and mechanical properties of polymeric materials, but its dispergation in the polymer matrix is problematic [107, 108]. In [109] was shown that laminar dual hydroxide modified by organic compounds acts as a disperser and promotes uniform distribution of magnesium hydroxide particles throughout the PVA matrix that results in the increase by 5–18°C of thermal decomposition temperature of the nanocomposite flameproof agent.

Effect of $CaCO_3$ and Li_2CO_3 on the liberation of HCl at combustion of PVC was studied in [110]. It was found that number and size of the filler sample affect not only HCl liberation, but also capacity of absorption. Liberation of HCl can be ever more diminished at simultaneous application of $CaCO_3$ and Li_2CO_3.

In [111] was shown that adding of $CaCO_3$ to PVC at roasting diminishes considerably concentration of liberated HCl resulting in decrease of content of dioxins in the effluent gas. At the same time, high absorption capacity of $CaCO_3$ in respect of chlorine-containing aromatic compounds leads to increase in the content of PCDD and PCDF in ash. However, since beginning of application of TiO_2-photocatalyst for decomposition of dioxins and dioxin-like compounds at UV radiation or sun light [112], the dioxins contained in the ash after combustion of a material should not create problems in respect of environment saving.

Study of reaction of PVC with calcium and magnesium oxides and hydroxides [113–116] showed that the processes of thermooxidative destruction of PVC and of reactions of products of its conversion with these compounds proceeds stepwise in the temperature range 200-500°C and includes PVC dehydrochlorination followed by the reaction of hydrogen chloride formed with the metal oxide (hydroxide) and oxide (hydroxide) carbonization. Behavior of PVC mixed with calcium or magnesium derivatives differ considerably. After the step of PVC dehydrochlorination and further reaction of hydrogen chloride with calcium oxide the sample mass increases. This feature is observed at processing both in air and inert gas that allowed the authors to suggest that at this step of reaction of the products of PVC decomposition with calcium oxide are formed calcium hydroxide and carbonate. Above 500°C proceed reactions of $Ca(OH)_2$ dehydration and $CaCO_3$ decarbonization. Increase in the sample mass at the reaction of $Ca(OH)_2$ with PVC is connected with formation of calcium carbonate in this step.

Kinetics of the reaction of metal chlorides formation in the temperature range 270–350°C at mass ratio oxide(hydroxide)–PVC 2 and 3 was studied in [115, 116]. The plot of chlorine in the polymer binding has S-shape that attests acceleration of reaction of metal chloride formation in the initial period defined by autoacceleration of the process of PVC dehydrochlorination. At higher oxide(hydroxide)–PVC mass ratio the degree of binding chlorine increases, therewith the degree of chlorine in PVC binding in the mixture with CaO is higher than for PVC–MgO under any conditions.

For the period before fall in the reaction rate were calculated specific rates of formation of metal chlorides per 1 g of initial amount of PVC in the mixture.

Increase in temperature leads to increase in the rate of formation of metal chloride, therewith specific rate of chloride formation is higher for calcium chloride than for magnesium chloride. At the degree of PVC chlorine binding 20% the values of effective activation energy of the reactions of calcium and magnesium chlorides formation are respectively 92.7 ± 6.8 and 42.5 ± 1.6 kJ mol^{-1} and practically are independent of the oxide–PVC mass ratio.

The conditions of chlorine in the polymer binding into ecologically safe products were optimized. At the temperature 290–300°C, oxide(hydroxide)–PVC mass ratio equal to 3, contact duration of the forming hydrogen chloride with the solid phase particles 6 min the chlorine in PVC at the reaction with CaO and $Ca(OH)_2$ becomes bound by 99% into calcium chloride.

Effect of fillers based on calcium carbonate and aluminum hydroxide on the destruction of plasticized PVC was studied in [117]. It was found that under argon atmosphere these compounds practically do not affect destruction of rigid PVC, although they bind differently the hydrogen chloride liberated in the process of destruction of the polymer. Intensity of the oxidative destruction of the filled PVC plastics is defined mainly by the resistance of the plasticizer to oxidation. It was noted that increase in the rate of HCl elimination at the destruction of plastics mixed with aluminum hydroxide is defined in the presence of the plasticizer by increase in the catalytic action on the thermodestruction of the polymer of aluminum chloride formed at the reaction of HCl with the filler.

Effect $CaCO_3$ and dolomite on the thermal decomposition of PVC was studied in [118]. The process of PVC dehydrochlorination in the presence of metal carbonates is decelerated due to consumption of HCl with formation of chlorides. Calcium and magnesium chlorides show almost no effect on the PVC destruction. Presence of alkali earth carbonates leads to decrease in the apparent activation energy of the step of dehydrochlorination and to increase in activation energy of the second step of PVC destruction that can change the mechanism of hydrogen chloride splitting off, e.g., via formation of fused hydrocarbon structures rather than polyene in the step of dehydrochlorination. Formation of benzene is depressed by adding inorganic compounds.

To conclusion, we can note the works [119–121] denoted to the study of PVC stabilization by phosphorus and sulfur compound. In [119] was forund that reatment with phosphorus trichloride vapor increases thermooxidative stability of PVC. Reaction of PCl_3 vapor with PVC proceeds at the formed carbonyl centers with formation of phosphoroxychloride groups grafted to the polymer surface. Increase in the phosphorus concentration on the polymer surface leads to acceleration of the process of coke formation and cross-linking in the narrower temperature range.

In [120, 121] was shown that sulfur is an effective inhibitor of the process of thermooxidative dehydrochlorination of PVC and its copolymers, and under the conditions of the PVC thermal destruction shows a weak accelerating effect on the cross-linking of macromolecules. The high antioxidative power of sulfur at the destruction of plasticized polymers is defined by the significant decrease in the rate of accumulation of hydroperoxides owing totheir heterolytic decomposition at the reaction with sulfur.

CONCLUSION

Oxides. Some of oxides: Co_3O_4, Cr_2O_3, CuO, Fe_2O_3 and MoO_3 decreases temperature of the step of dehydrochlorination at the destruction of PVC, while the presence of other oxides such as Al_2O_3, CeO_2, PbO_2, TiO_2, and ZrO_2 does not affect considerably the destruction temperature. The second step of destruction (cleavage of C–C bonds in olefins) is practically not affected by oxides.

Amount of liquid products falls at the adding of metal oxides, in particular of Fe_2O_3 and ZnO. There is a correlation between the amount of liquid products and organochlorine compounds. Effect of iron(III) oxide is in line with halogenation of benzene by the Friedel–Krafts mechanism stimulated by Lewis acids of $FeCl_3$ type.

Thermal decomposition of PVC in the presence of copper or its compounds, copper(II) oxide in particular, occurs at higher temperatures with wide varied concentration of components in the gaseous products, that follows from the ability of the copper compounds to induce cross-linking of the polymer macromolecules. The process of cross-linking at high temperature leads to decrease in amount of aromatic hydrocarbons like benzene and to increase in amount of aliphatic compounds. Copper and its compounds promote effective oxidation of the PVC carbon, in particular in the case of PVC–CuO, with removing chlorine at the pyrolysis to inorganic phase.

Ability of rare earth metal oxides to bind chlorine is changed in the series $La_2O_3 > Nd_2O_3 > CeO_2$. In the presence of CeO_2 grows formation of chlorobenzene.

Mixed Al–Mg and Al–Zn oxide catalysts increase rate of PVC decomposition and amount of light hydrocarbons in liquid products, and decrease substantially content of chlorine in the latter.

Experimental results show that the oxides containing cations that are strong Lewis acids promote considerably liberation of hydrogen halide. Good enough correlation for the temperature of beginning of the polymer thermal decomposition stimulated by halo compound with the Lewis acidity of the cation of halo compound is obtained. This is explained by the fact that acidity of halo compound of a metal reflects ability of its cation to the complex formation with chlorine atoms in the polymer and thus to promote thermal decomposition.

Hydroxides. Adding of hydroxides to PVC facilitates splitting hydrogen chloride off at the temperature 270-300°C but reduces degree of the further conversion of PVC that results in high chlorine content at the polyene backbone at decomposition either in air or in an inert gas. At higher temperature, hydroxides promote formation of carbon containing substances and decrease formation of volatile hydrocarbons.

Carbonates. In the presence of carbonates the maximal temperature of hydrogen chloride splitting off at the thermal decomposition of PVC increases and the rate of mass loss decreases. Inclusion of $CaCO_3$ into PVC composition decreases considerably amount of the forming polychlorinated dibenzodioxins.

Chlorides. Adding of metal chlorides, in particular of $ZnCl_2$ and $BaCl_2$, accelerates reaction of splitting off hydrogen chloride at the pyrolysis of PVC and decreases amount of high-molecular substances. In the presence of H_2, further destruction of polyenes at high temperature is facilitated that leads to decrease in amount of solid residue. Analysis of the content of PVC pyrolysis products at different temperatures shows that regeneration of HC1 and benzene is possible when the pyrolysis temperature is below 350°C. However, copper chloride can promote formation of polychlorinated dibenzosioxins and dibenzofurans.

Thus, investigations directed to the study of catalytic role of inorganic compounds, metal oxides first of all, in the process of thermal decomposition of PVC and their effect on the content of the products of pyrolysis with systematic consideration of their acidity should be continued. Noteworthy that still no correlation was found between the amounts of certain products forming at PVC conversion and physical characteristics of inorganic additives.

Abstract—Generation of droplets on a surface of the water thin film at upflow and down flow is considered. Expressions for computation of splash type mass transfer were developed.

DOI: 10.1134/S1070427208090395

Presence of droplets in gas-liquid flow at dispersion-annular stream affects heat and mass transfer parameters of a film apparatus. Despate variety of works devoted to an investigation of tear out and carry-over of the droplets from the film calculations according to the known relations give contradicting results requiring an additional analysis.

An amount of liquid entrained from the surface film at upflow in pipes with diameters ranging from 13.5 to 20 mm and with length ranging from 100 to 860 mm at gas velocity from 15 to 55 m/s and at sprinkle density from 0.3 to 3.2 m²/h computed by equation (1)

$$E = Au_g^{1.44}\Gamma^{m} l^{k} d\left(\frac{\mu}{\sigma}\right)^{0.3}, \quad (1)$$

where E is overall splash entrainment, kg /s; q is a volume density of the sprinkle, m²/h; A, m, k are coefficients depending on the volume density of the sprinkle and a channel length L: A=(17.037…20.924) × 10⁻³; m = 2.1 at q < 1.1 m²/h, m = 1.4 at q > 1.1 m²/h; k = 0.8 at L < 0.6 m, k = 0.5 at 0.6 m < L < 2.5 m, k = 0.3 at L > 2.5 m.

At deriving equation (1) the experimental data obtainrd for short pipes is used, however, that requires verifying of the value E for a dynamical equation section.

Known relation [2] for definition of the value of the splash type entrainment at upflow written as equation (2) shows that value E decreases with a gas flow rise that occurs only in a transition region of the stream:

$$E = \left[534 \log\left(\frac{\mu}{\sigma}\frac{\sigma_w}{\mu_w}\right) + 117\right] \mathrm{Re}_g^{-0.35}\, \mathrm{Re}^{\left[0.3 - 0.04\left(\frac{\mu}{\sigma}\frac{\sigma_w}{\mu_w}\right)\right]}, \quad (2)$$

E is part of the entrainment fwith respect to the total liquid flow; μ, μ_w are dynamic viscosity of the studied liquid and water, respectively, s Pa; σ, σ_w are surface tension of the studied liquid and water, respectively, N/m; $Re_g = u_g d/\nu_g$ and Re = q/ν_l – Reynolds criterion of gas and liquid; u_g is air velocity, cm/s; d is the channel diameter, cm; ν_g, ν_l are kinematic viscosity coefficient of gas and liquid, cm.

Equation (3) is used for calculation the splash-type mass transfer at the flowdown

$$E_0 = A\,\mathrm{Re}^{a}\,\mathrm{Re}_{go}^{b}, \quad (3)$$

where Re and Re_{go} is Reynolds number of liquid film and relative Reynolds number of gas, respectively, A, a, b are empirical constants depending on stream regimes of gas and film, also on a pipe diameter: A = (1.52…40) × 10⁻⁷, a = 0.29…0.97), b = 0.71…1.48. However, equation (3) can be used for computation the splash entrainment only in pipes of diameter of 25 mm.

Application of equation (4) suggested in [4] for computation of equilibrium amount of the splash entrainment on the interval of a steady stream at the upflow and the downflow is difficult because of complexity of definition of tangential stresses value depending on a dispersed phase concentration in a gas−liquid flow:

$$E_0 = 1.8\times10^{-5}\,\mathrm{Re}^{-0.26}\,\mathrm{Re}_{go}^{1.48}\,\frac{\delta}{d}\left(\frac{\tau_i}{\tau_1}\right)^{0.4}. \quad (4)$$

Here d is an internal diameter of the pipe, m; δ is average thickness of the film, m; τ_i is the tangential stress

on the interface, N/m^2 ; τ_l is a tangential stress on a pipe wall, N/m^2.

Investigation of splash entrainment in hydraulically smooth pipes made of stainless steal with the internal diameter d of 27 and 51 mm and with operation length l about 2.5 m were carried out for generalization of the known data and obtaining relation for computation of the splash type mass transfer. Air flow was ranged about 180 m^3/h at temperature from 15 to 60°C. A liquid film generation was realized with a gas jet that forms with an internal surface of the pipe an annular gap of 0.5−1.5 mm. Amount of the disperse phase on the gas flow was measured by probing like a Pitot tube [5] with an internal channel diameter 3 mm. As a boundary between continuous and disperse phases was assumed a height of regular waves that was 3 mm and overall liquid outside this boundary was assumed as the disperse phase. The probed liquid amount related to an area of the Pitot tube channel section. A summary average amount of the disperse phase over the pipe section was defined by an integration of distribution curves (Figs. 1 and 2).

The splash entertainment was computed by equation (5)

$$E_0 = G_d/G_s, \quad (5)$$

where G_d is the liquid flow in droplets, kg/s; G_s is the liquid flow input to spraying, kg/*s*.

The measuring results of the splash type mass transfer at the downflow and the upflow and the known data exhibited (Fig. 3) that value E_0 at the upflow (Fig. 3, dashed lines) was higher in comparison with the downflow.

It is caused by higher tangential stress on the interface at the upflow (τ_i/τ_l = 0.5–6) in comparison with the downflow (τ_i/τ_l = 0.1–0.9) that separates liquid from a ridges of large waves and from waves disturbing the films. There are two region of the splash type mass transfer in dependence of the gas flow. First region occurs in the transition hydrodynamic regime where the gas flow increase does not result in the considerable change of E_0 [2, 5–10]. In this case a start of the splash entertainment can be estimated [7] by Weber number analyzing thin film flows and the formation of droplets and bubbles (Fig. 3, a dotted line, for the pipe of d = 27 mm). Because of a wave structure formation on the film surface in the transition regime with the gas flow rise a height of large wave ridges decreases that results in the steady splash entrainment.

An onset of the formation of the second region of the droplet entrainment at the downflow and the upflow coincides with the transition border in the disperse–annular regime of the stream (Fig.3, the dotted lines). In this region E_0 is about $Re_{go}^{1.48}$ at the downflow, and $E_0 \sim Re_{go}^{0.6}$ at the upflow. Distinction in the values of exponent of Re_{go} is caused by laminarization of the gas−fluid flow. High concentration of the droplets at the upflow results in more suppression of a gas turbulence [11] in comparison with the downflow.

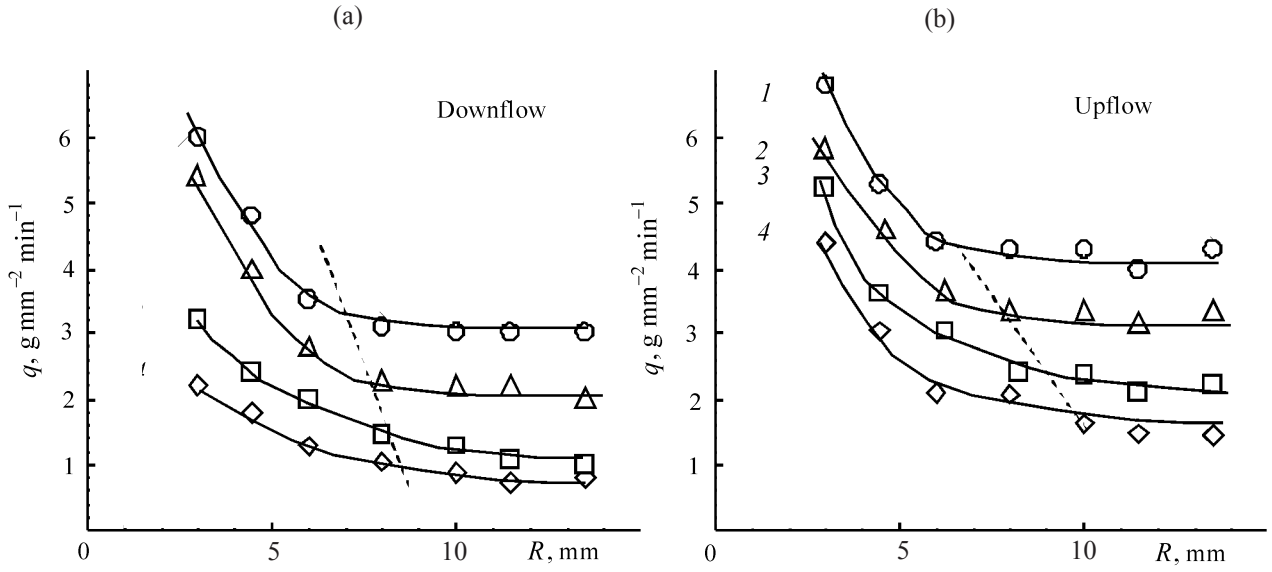

Fig. 1. Distribution of the disperse phase over the pipe section at the downflow (a) and upflow (b) of air and water at the difference Reynolds number of gas (Γ = 4.4 × 10^{-3} m^2/s, d = 27 mm, l = 1.68 m): (a) the experimental points (*1–4*) at ν_l =0.6 × 10^{-6} m^2/s: (*1*) Re_g = 42000, (*2*) 37000, (*3*) 30000, (*4*) 21000; (b) the experimental points (*1–4*) at ν_l = 1.3 × 10^{-6} m^2/s: (*1*) Re_g = 42000. (*2*) 36000, (*3*) 30000, (*4*) 21000.

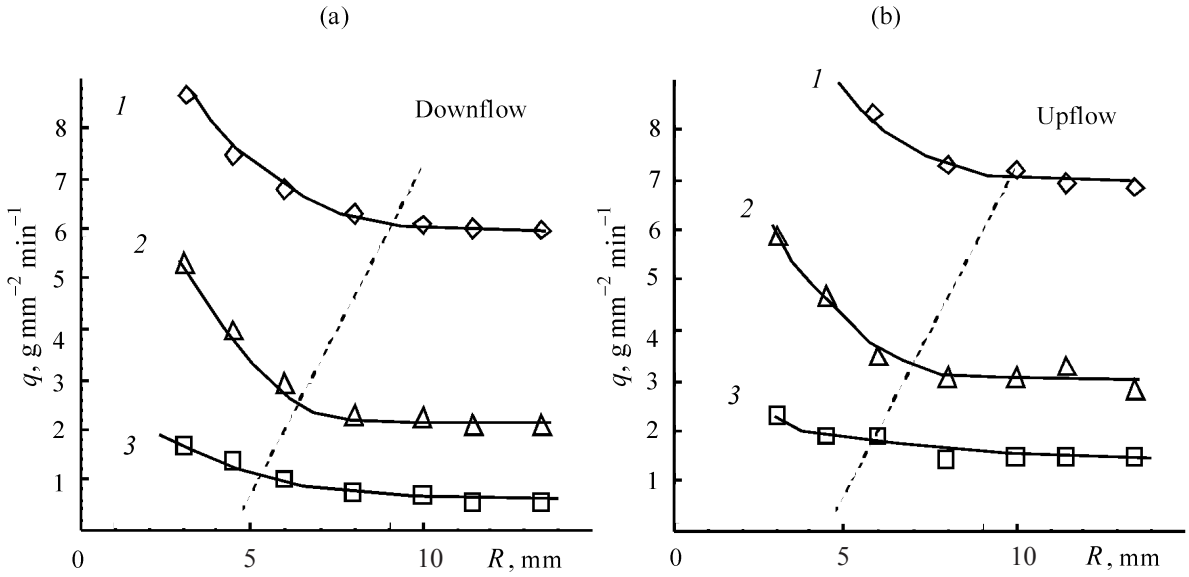

Fig. 2. Distribution of the disperse phase over the pipe section at the downflow (a) and upflow (b) of air and water at the difference spray density at $Re_g = 38000$, $d = 27$ mm, $l = 1.68$ m: (a) the experimental points (*1–3*) at $\nu_l = 0.6 \times 10^{-6}$ m²/s: (*1*) $\Gamma = 8.5 \times 10^{-3}$ m²/s, (*2*) 4.4×10^{-3}, (*3*) 2.5×10^{-3}; (b) experimental points (1–3) at $\nu_l = 1.3 \times 10^{-6}$ m²/s: (*1*) $\Gamma = 8.5 \times 10^{-3}$ m²/s, (*2*) 4.4×10^{-3}, (*3*) 2.5×10^{-3}

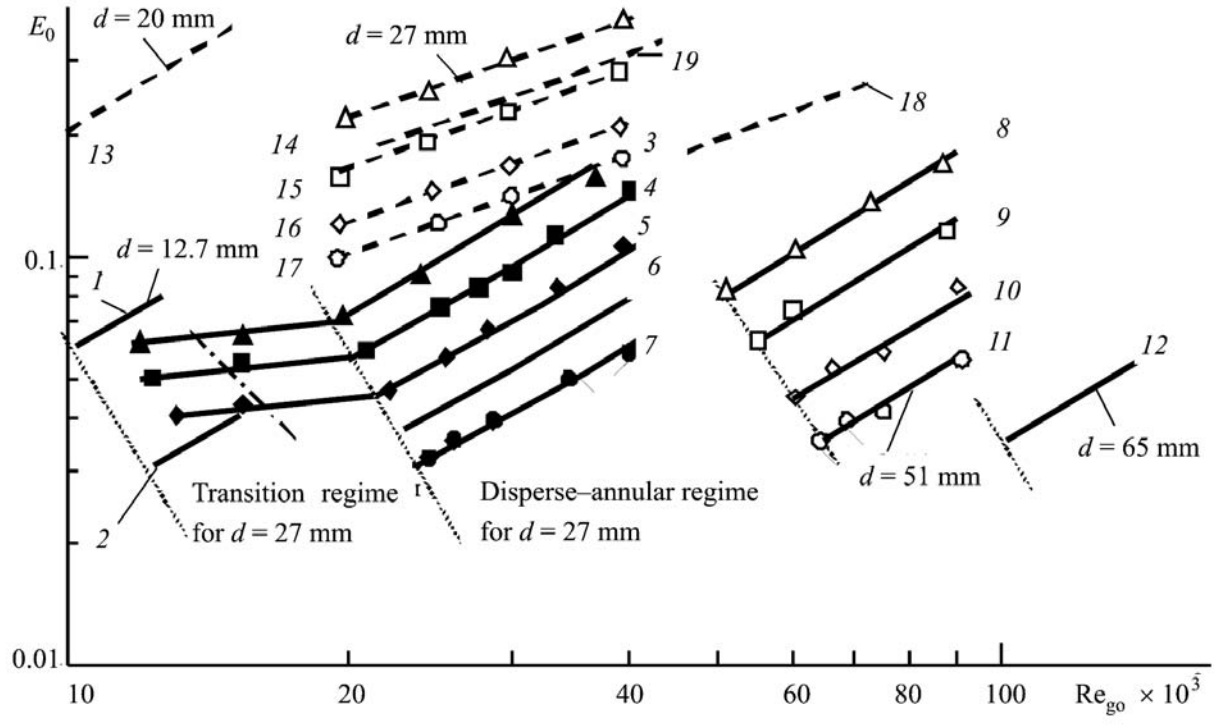

Fig. 3. Dependence of equilibrium part of E_0 on the relative Reynolds number of gas at upflow and downflow of water film and of air ($l = 1.5$–2 m), $\nu_l = (0.7$–$1.3) \times 10^{-6}$ m²/s . (*1–12*) Downflow: (*1*) Re = 8000, $d = 12.7$ mm; (*2*) 2140, $d = 12.7$, Data of [5] derived to the length 1.5 m; (*3*) 15700, $d = 27$; (*4*) 8140, $d = 27$; (*5*) 4625, $d = 27$; (*6*) 2100, $d = 25$, [3]; (*7*) 2100, $d = 27$; (*8*) 22100, $d = 51$; (*9*) 9700, $d = 51$; (*10*) 4600, $d = 51$; (*11*) 2100, $d = 51$; (*12*) 2100, $d = 65$. Computation according to equation (7): (*13–18*) Upflow (*13*) Re = 10000, $d = 20$ mm, [1]; (*14*) 10000, $d = 27$ mm; (*15*) 7200, $d = 27$; (*16*) 3700, $d = 27$; (*17*) 2100, $d = 27$; (*18*) 2020, $d = 31.75$, [8] at $l = 6.1$ m; (*19*) 2100, $d = 12.7$ mm, [5]. Points are the results of experiments performed by the authors.

Values of the coefficient C_i

The downflow					
d, mm	12.7	25	27	51	65
C_i	0.7×10^{-9}	0.28×10^{-9}	0.24×10^{-9}	0.57×10^{-10}	0.3×10^{-10}
The upflow					
d, mm	12.7	20	27	31	–
C_i	11.0×10^{-5}	0.86×10^{-5}	0.6×10^{-5}	$0.56\cdot\times10^{-5}$	–

Analysis of the experimental data in the coordination $E_0\,\mathrm{Re}_{go}^{-1.48} = f(\mathrm{Re}_l)$ at the downflow and $E_0\,\mathrm{Re}_{go}^{-0.6} = f(\mathrm{Re}_l)$ at the upflow enabled us to define an exponent of Re_l^n that have amounted $n = 0.5$ where Re_l was Reynolds number of the film on the region of the dynamic equilibrium.

$$\mathrm{Re}_l = \frac{4\mathrm{G}_n(1-E_0)}{\pi d\nu_l} \tag{6}$$

The relations for calculation of equilibrium entrainment at the disperse-annular regime are written as:

for the downflow

$$E_0 = C_i\,\mathrm{Re}^{0.5}\mathrm{Re}_{go}^{1.48}, \tag{7}$$

for upflow

$$E_0 = C_i\,\mathrm{Re}^{0.5}\mathrm{Re}_{go}^{0.6}, \tag{8}$$

where Re_{go} $(u_g - u_s)\,d/\nu_g$ is relative Reynolds number of gas; u_s is a superficial film velocity, m/s; u_g is the average gas flow, m/s.

For simplification of the computations in equations (7) and (8) Reynolds number of the liquid film can be calculated by the start the liquid flow G_s without taking into account the liquid entrainment. Analysis showed that at such data treatment $E_0 \sim \mathrm{Re}^{0.5}$.

Taking into account that on the transition border in the disperse-annular regime of the stream the value E_0 is practically the same at the constant liquid flow the values of a coefficient Ci (see the table) are defined for the pipes of different diameters.

The splash entrainment E on the start part can be calculated according to equation (9) [4] of the pipe

$$E = E_0\left[1 - \exp\left(-\frac{\mu}{u_g E_0}l\right)\right], \tag{9}$$

where an intensity of droplet entrainment from the film surface μ for obtaining experimental data was amounted to (1–20) s^{-1} and was computed by equation (10) [4]

$$\mu = c\frac{u_g}{d}E_0, \tag{10}$$

where ($c \approx 0.092$ for the downflow, $C \approx 0.055$ for the upflow).

The value μ rises with increase of Reynolds number for gas and for liquid and seems higher in 1.2–1.5 times for the upflow in comparison with the downflow.

The work is executed at a financial support of the Russian Foundation of Basas Research, the project 05-08-01367-a "Fundamental Bases of Engineering Sciences", the Ministries of Education and Sciences of the Russian Federation and the American Foundation of Civil Research and Development (CRDF) (grant P1MO002 and programs of integration researches of the Siberian Branch of the Russian Academy of Science (the project 24).

DOI: 10.1134/S1070427208090401

In hole channels various hydrodynamic regimes with precise boundaries take place at gas and fluid flows within. At Reynolds number related to the channel diameter $Re_D < 2300$ viscous forces prevailed and a pressure drop ΔP is entirely defined by a channel wall friction of the flow (here $Re_D = W_0 D/\nu$, where W_0 is the flow, m/s; D is the channel diameter, m; ν is a coefficient of kinematic viscosity, m^2/s). At Reynolds number $Re_D > 10000$ the value ΔP is characterized by inertial forces. A range of $Re_D = 2300–10000$ is transition.

Analogous hydrodynamic conditions are resulted at gas flow in channels filled by granular material or by a nozzle. However herein in distinction from the hole channels the boundaries of regimes are defined by the other values of Reynolds number and the boundaries are more diffuse.

A flow movement through the granular or nozzle layer is better to consider as the movement between the bodies filling an apparatus in many narrow curved parallel channels of variable section and form (internal problem) [1]. As a result a transfer from one hydrodynamic regime to other can not occur simultaneously within all these channels at one concrete Reynolds number [2, 3]. Thus an equivalent diameter D_{equiv} equaled to a quadrupled hydraulic radius should be accepted as characteristic linear size:

$$D_{equiv} = 4\Gamma = \frac{4F_c}{\Pi} \quad (1)$$

where: F_c is free apparatus section filled by the nozzle, m^2; Π is a perimeter of the channels in this section, m. In the nozzle layer the free section of the apparatus with the nozzle is equaled to a sumary area of the section of the channels F_c. A product F_cH gives a free volume part ε, m^3/m^3, and ΠH a specific surface S, m^2/m^3. Equation (1) is written as

$$D_{equiv} = \frac{4F_c}{\Pi} = \frac{4F_cH}{\Pi H} = \frac{4\varepsilon}{S}, \quad (2)$$

and Reynolds number that is computed with an actual gas velocity (related to a free section F: $W = V_g/F_c$) by equation (3):

$$Re_{equiv} = \frac{WD_{equiv}}{\nu} = \frac{W4\varepsilon}{\nu S} = \frac{W_0\ 4\varepsilon}{\varepsilon\ \nu\ S} = \frac{4W_0}{\nu S}, \quad (3)$$

where H is a height of the nozzle layer, m; V_g an amount of the gas, m^3/s; $W_0 = W_\varepsilon = V_g/F$ is a fictitious gas velocity (related to a total apparatus section that is not filled by nozzles: F, μ^2).

Based on experimental data [4, 5] we established that a range of Reynolds number $Re_{equiv} = 40…60$ is an upper limit of viscous flow in the apparatus filled by the nozzles of various form and $Re_{equiv} = 1200…6000$ a bottom limit of the flow regimes with the prevailing inertial forces.

We assumed that $\Delta P = f(S)$ for the nozzles since as we noted above the value ΔP is defined in the flow regime with the prevailing viscous forces by the channel wall friction of the flow.

In [6] an equation for calculation $S = f(\Delta P)$ of the granular materials of irregular shape was derived using the established relation $\varepsilon u_m = f(Re_{equiv})$. Here Euler number is $\varepsilon u_m = \Delta P \varepsilon g/HS\gamma W_0^2$; ΔP, kg/m^2; γ is the specific gas weight, kg/m^3. Ability to calculate the value S by ΔP is quite important since an exact definition of the

specific geometric surface S for the bodies of irregular shape is nontrivial.

A relation between the pressure drop and the specific surface of polymeric nozzles is considered in [7].

We attempted to establish a general relation between ΔP and the specific geometric surface of the nozzles of various shape and size at the gas flow through their layer.

A countercurrent flow of gas and fluid occurs in the nozzle layers as distinct from the granular materials where gas flows through an adsorbent or catalyst layer. Therefore now the pressure drop at two-phase movement through the nozzle is usually studied for obtaining the data required for engineering computation of a nozzle apparatus. Simultaneously the pressure drop ΔP of a not sprinkled (dry) nozzle is studied because this data contains some information about the nozzle properties.

For obtaining the target general relation data of [4, 8–23] was employed. Experimental data about the pressure drop of the dry nozzle with smooth surface of annular, semi-annular, and saddle shapes of a various construction at a value of a gas load $F_f = W_0 \gamma^{1/2} = 2.0$ were presented in Table 1. Noted value of F_f was selected because it virtually denotes the upper limit of the gas load in the nozzle apparatus. The value $F_\tau = 2.0$ for the majority annular nozzles of 50 mm size corresponds to $Re_{equiv} \sim 1600$. Also some characteristics of nozzles including the part of free volume ε and the specific geometric surface S are presented in the Table 1. Constructions of the considered nozzles are showed on the Fig. 1.

We obtained the pressure drop ΔP studying the dry nozzle for Pall ring and GIAP nozzles of 3 sizes [16–18, 23] with use of air in columns of (1) $D = 500$ m and at the height of the nozzle layer $H = 2400$ mm and (2) $D = 900$ mm at $H = 3000$ mm. Simultaneously we examined the sprinkled nozzles in the column of the same sizes for the air-water system at atmospheric pressure. Due to special techniques we provided steady start distribution of the streams: grades and wires at the input of gas flow to the nozzle layer, and multipoint spreader of liquid. Results of a hydrodynamic research of metal Pall rings of 50 mm size are presented in Fig. 3.

Results of the generalization are showed on Fig. 2. For the generalization relative values of the pressure drop were applied. On Y-axis we can see relation of hydraulic resistance of the nozzle to hydraulic resistance of metal

Experimental and calculated characteristics of the nozzles of the ring and saddle shape of the various constructions with smooth surface [4, 8–23]

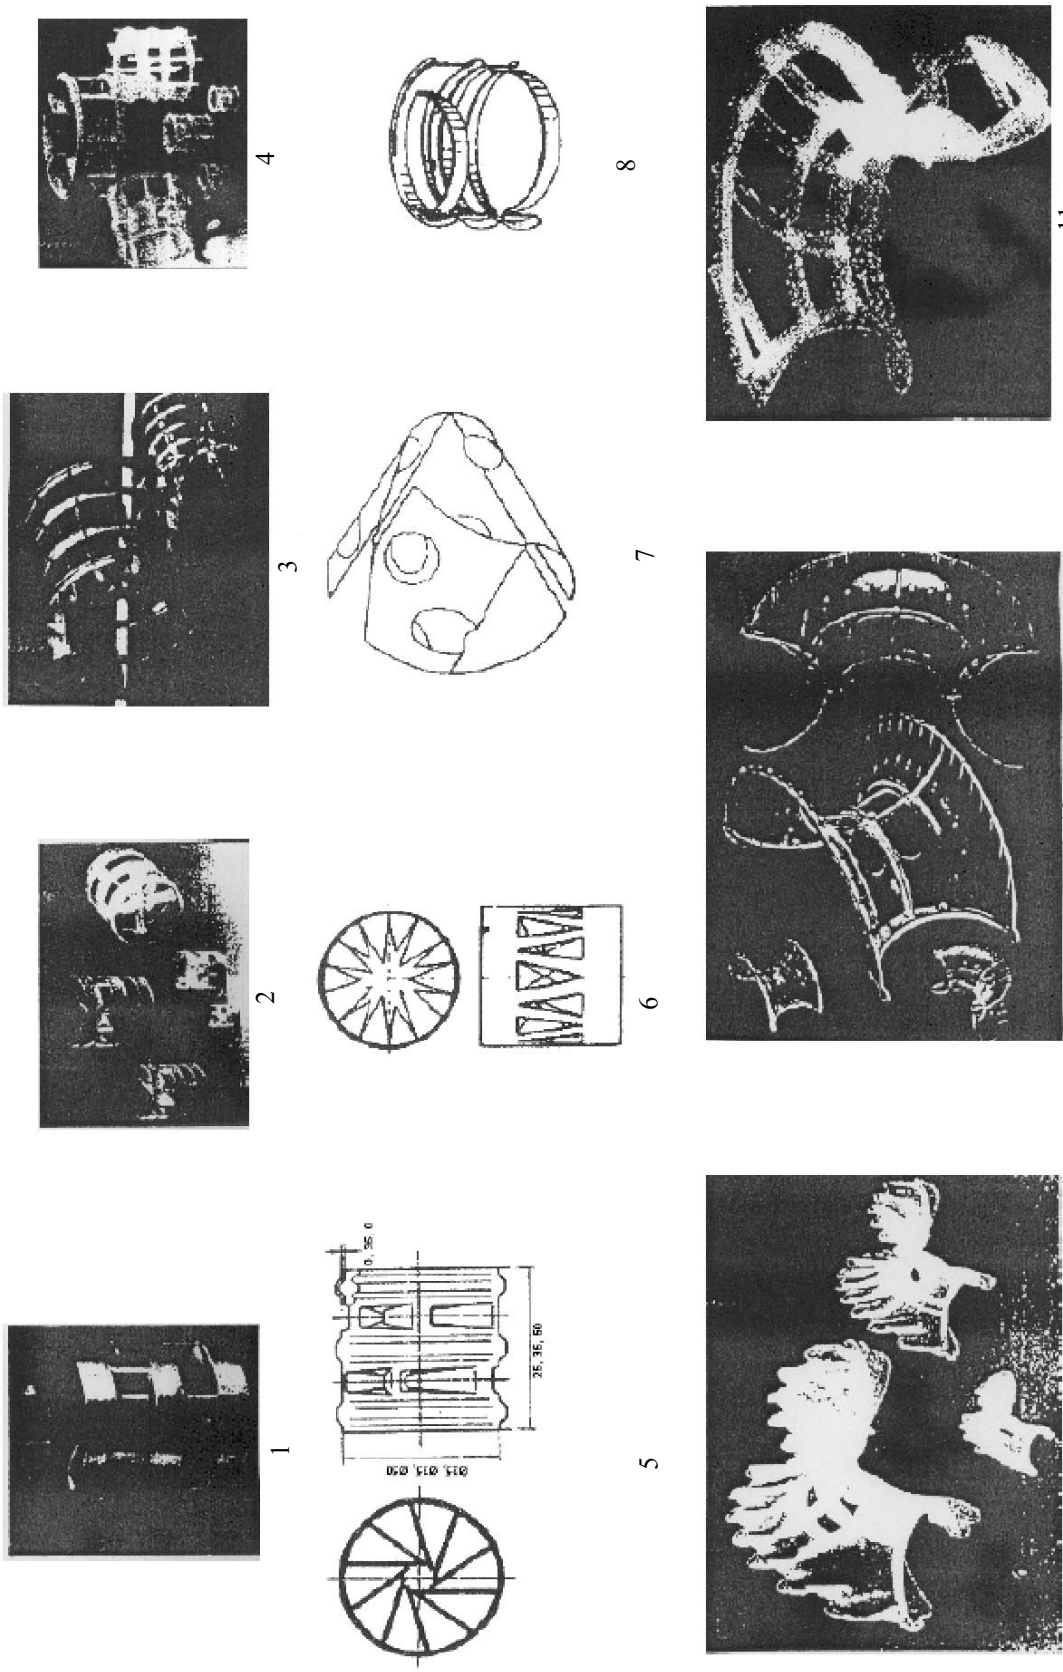

Fig. 1. Mass Transfer Nozzles: Metal: (a) ring: (1) Pall, (5) Germania, (6) Beletskii; (b) semi ring: (7) GIAP, (8) Hutter. Polymeric: (a) ring: (2) Pall, (3) Ralu, (4) Hiflow; (c) saddle: (9) Supertorus, (10) Flexisaddle, (11) Hiflow.

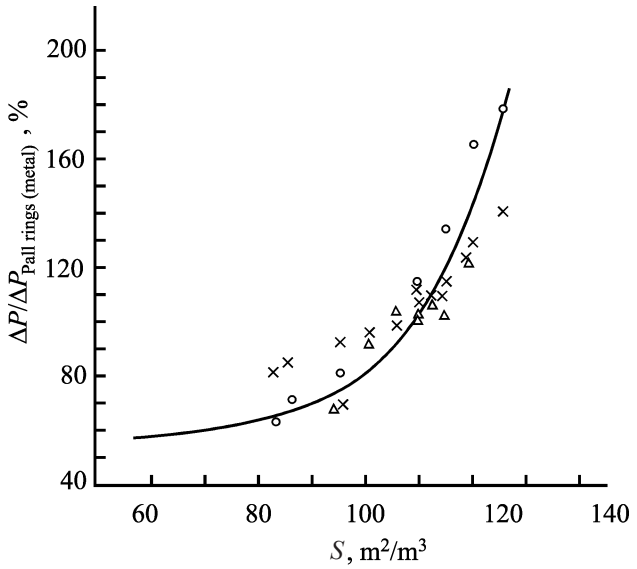

Fig. 2. A generalized dependence of the relative pressure drop $\Delta P/\ \Delta P_{\text{Pall rings}}$ on the specific surface of the smooth nozzles of various shape and size: (Δ) metal nozzles; (O) polymeruc nozzles (experimentral data); (x) calculated values according with equation (5).

Pall rings: $\Delta P/\Delta P_{\text{Pall ring}}$, %. Thus the hydraulic resistance of the metal nozzle made of Pall ring of 50 mm size as the most often on world industry was assumed as base resistance for comparison. And on the X-axis there is specific geometric surface.

Majority of the experimental points is generalized by a curve with an error no more ±12%. It reveals that at Re_e belonging to $F_f = 2$ the viscous forces prevail to a significant degree and an effect of the nozzle shape and their design features enabling stream turbulization to ΔP is not large. The curve on Fig. 3 is described by equation (4)

$$\frac{\Delta P}{\Delta P_{\text{Pall rings}}} 100 = 0.009\ S^{2.0}, \qquad (4)$$

that can be used in the range of the specific surface S = 80…125 m²/m³.

For computation of the specific surface of the granular materials by the measured pressure drop ΔP in the dry granular layer we transformed an equation suggested in [6] relative to ΔP with reference to the nozzle layers:

$$\Delta P = \frac{\left[\left(S + 18\times10^{3}\ \frac{W_0}{\nu}\right)^2 - 324\times10^{-6}\ \frac{W_0^2}{\nu}\right]\nu H\gamma W_0.}{0.09\ g\ \varepsilon^3} \qquad (5)$$

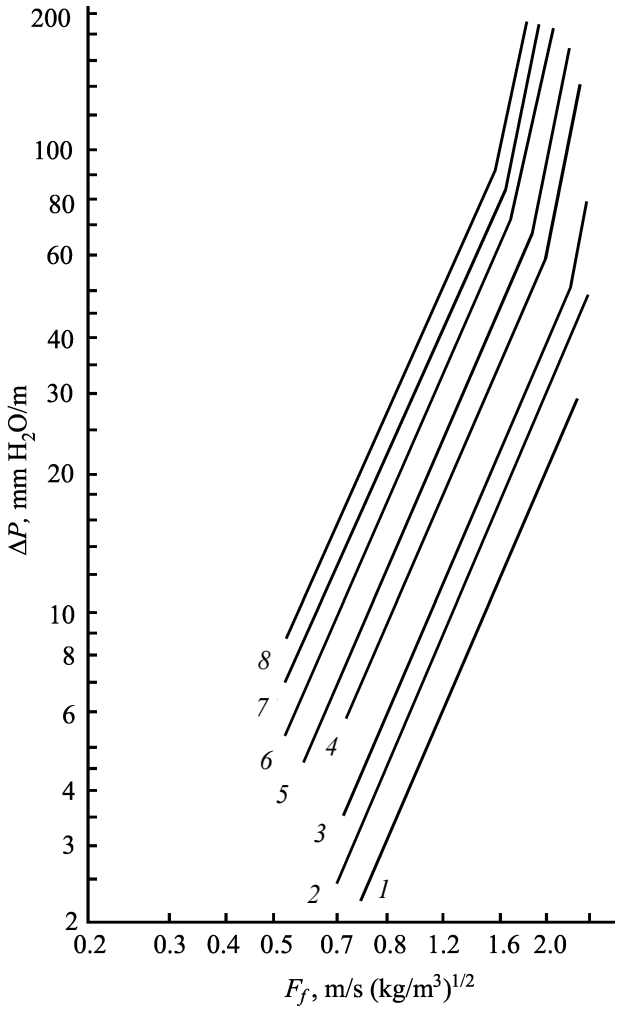

Fig. 3. Hydraulic resistance of Pall rings of 50 mm made of metal: (*1*) dry nozzle, (*2*) L_{Op} = 20 m³ m⁻² h⁻¹; (*3*) L_{Op} = 40 m³ m⁻² h⁻¹; (*4*) L_{Op} = 60 m³ m⁻² h⁻¹; (*5*) L_{Op} = 80 m³ m⁻² h⁻¹, (*6*) L_{Op} = 100 m³ m⁻² h⁻¹ (*7*) L_{Op} = 120 m³ m⁻² h⁻¹; (*8*) L_{Op} = 135 m³ m⁻² h⁻¹.

The results of computation of ΔP according to equation (5) presented in Table 1 and on Fig. 2 reveal that the experimental and calculation values of ΔP are correlated on range of ±20%. This range can be explained by errors at measurements of S and ε by various authors for the nozzles of a comlex configuration.

In [24] an analogous way is suggested for computation S of the nozzle on the base of equation $S = f(\Delta P)$ [6].

As we noted above we applied for generalization the experimental data obtained at the load $F_f = 2.0$. However the calculation exhibited that at operation with the relative hydraulic resistance, e.g. $\Delta P/\Delta P_{\text{Pall rings}}$, the curve (Fig. 2) sufficiently well describes the experimental data obtained at other loads in the range of $F_\tau = 0.5…2.0$, i.e.,

virtually in the overall range of the gas loads which are typical for industrial packed columns. Since the relation $\Delta P/\ \Delta P_{\text{Pall rings}} = f\,(S)$ sufficiently fairly correlated data about the nozzles of the various shape and size it can be suggested that this relation is universal for the nozzles of various shape. Evidently application of suggested relation $\Delta P/\Delta P_{\text{Pall rings}} = f(S)$ is of interest first for estimation of ΔP of the nozzles for which experimental data are absent due to various causes. That is in the first place the newly derived nozzles for which only the specific surface is known. Using an information about their geometric surface by the suggested curve it can be obtain a comparative estimation with Pall rings and if it is required using then the curve *1* on the Fig. 3 also a numeral value of ΔP of the dry nozzle.

The relation of hydraulic resistance of non-sprinkle nozzle made of the metal Pall rings of 50 mm size $\Delta P = f(F_f)$ is described by equation (6):

$$\Delta P = 4.9\ F_{\tau}^{2.0}\ . \qquad (6)$$

After substitution $\Delta P_{\text{Pall rings}}$ from equation (6) in (4) and then solving equation (4) relative to ΔP we obtain the relation for computing the value ΔP of any nozzle if its specific surface is known:

$$\Delta P = 4.4 \times 10^{-4}\ S^2\ W_c^2 \gamma. \qquad (7)$$

A dimension of ΔP in equations (4), (6) and (7) is mm H_2O.

Since as a rule the resistance of the dry nozzles is higher the higher is ΔP of the sprinkled nozzle the curves *2* and *3* can be used for preliminary qualitative estimation of ΔP of new nozzle at its sprinkling.

Thus, the obtained general relation enables us to execute the comparative preliminary estimation of new and known industrial nozzles on the basis of their specific surface avoiding the performance of experiments and also a search, and a comparison of experimental data obtained in various environments at different loads, temperatures, pressures etc. are quiet difficult.

A computed estimation of an effect of the nozzle design parameters: equivalent diameter, mass transfer coefficient in gas β_g and liquid phase β_*, according to equations of various authors by the example of Raschig rings is presented in [25]. From computed estimation of the effect of D_{equiv} on the β_g and β_* [25] giving contradicting results of Laptev et al. [25] included that available equations enable calculation of the transfer coefficients in the packed column at a film regime exclusively by results of the hydraulic experiments. We suggest general relation for computed estimation of ΔP and for an increase of the following accuracy of the calculation of the mass transfer coefficients in the packed columns avoiding the additional hydraulic experiments.

Received October 10, 2007

Abstract—Some water treatment way of industrial water on the local plants are presented herein. An application of the suggested ways allows the treated water to reuse and to optimize operating costs.

DOI: 10.1134/S1070427208090413

Agitation is extensively used in a chemical and a related branches of industry for preparation of emulsions, suspensions, homogeneous systems, and also for enhancing the chemical, heat, and diffusive processes.

Let us consider the agitation as a way for enhancing the chemical, heat, and diffusive processes in the homo- and heterogeneous systems. These processes are applied to absorption, evaporation, extraction, and other chemical technologies because a good mixing of components provides optimum conditions for feeding the substances to a reaction area, an interphase boundary or a heat exchange surface. The enhancing of exchange processes is performed primarily due to [1]:

– increase of phase contact area;

– increase in the speed of relative movement of phases;

– use of nonsteady regimes of an interphase exchange that provide reaching high instantaneous values of mass transfer coefficients;

– executing the mass exchange in hydrodynamically unstationary conditions of the interphase surface.

Ways and selection of devices for agitation are determined by a target of agitation and an aggregate state of mixed materials. The agitation in the liquid media is extensively used in chemical industry [2].

Direct flow mixing of components for concentration equalizing on a cross sectional area normal to a velocity vector is one of the agitation ways in the fluid media. For estimation of an operation efficiency of such devices analogously to mechanic agitators the following characteristic features can be marked:

– energy loss;
– intensity or degree of the agitation;
– agitation efficiency.

ENERGY LOSS

The energy loss of a mechanical agitators is expressed by the driver power consumption that reveals the amount of spent energy for an overcoming the friction force of the agitator blades against a liquid.

In a case of the direct flow agitation a pressure drop on the agitation section of the device including the feed area, the agitator, and an area of stabilizing movement can be assumed as parameter defining the energy loss.

At the agitation of the liquid components in a pipe of the constant cross section the pressure dropped owing to hydrostatic constituent and therefore the energy loss is characterized only by the pressure drop.

THE INTENSITY OF THE AGITATION

Usually the intensity of the agitation is defined by time of reaching the given technological result or at the mechanical mixing by the speed of the agitator at a given duration of the process. The agitation intensity is the higher the smaller is the time spent for reaching of the given agitation result. The enhancing of the agitation results in the decrease of the designing devices and in an output rise. It is required from the economic point of view that the target agitation is reached in the shortest time.

A quantitative estimation of the agitation intensities of the direct flow agitators should be related to the

the given agitation result. The enhancing of the agitation results in the decrease of the designing devices and in an output rise. It is required from the economic point of view that the target agitation is reached in the shortest time.

A quantitative estimation of the agitation intensities of the direct flow agitators should be related to the geometric size of the device. Thus in the pipe of round cross section the agitation intensities can be described by a relation if the pipe diameter to the length of the mixing device section.

THE AGITATION EFFICIENCY

The agitation efficiency of the device expresses the quality of the mixing operation.

For estimation of the agitation efficiency in the general case a dispersion of concentration that is equaled to standard mean square deviation of concentration from an average concentration should be determined [1]:

$$\sigma(t) = \frac{1}{V}\int_V \sqrt{(C(t) - C_{av})^2}\,dV, \qquad (1)$$

where the average concentration is calculated in accordance with:

$$C_{av} = \frac{1}{V}\int_V C\,dV. \qquad (2)$$

For the direct flow agitators the efficiency of the mixing described by the concentration dispersion in an area normal to the velocity vector after the mixing section S:

$$\sigma(x) = \frac{1}{S}\int_S \sqrt{(C - C_{av})^2}\,dS, \qquad (3)$$

where the average concentration is calculated according to:

$$C_{av} = \frac{1}{S}\int_S C\,dS. \qquad (4)$$

A criterion of a nonuniformity in the concentration field for such devices is computed by equation (5)

$$\eta = \frac{\sigma(x)}{\sigma_{max}}, \qquad (5)$$

where

$$\sigma_{max} = \frac{|C_1 - C_{av}|Q_2 + |C_2 - C_{av}|Q_1}{Q_1 + Q_2}. \qquad (6)$$

Deriving the general criterion for the estimation of the efficiency of the direct flow agitator is complicated by considerable distinctions in physicochemical properties of the mixed components and in the requirements to the agitation efficiency for the optimum process operation. The simplest way to compare various devices is to determine a relation of the agitation efficiency to the energy loss for each device at the satisfaction of the requirements of the process to the intensity and efficiency of the agitation.

Thus selection of the apparatus that appropriates to process execution in the optimum way can be made by comparison of the basis parameters describing the direct flow agitator.

USED DESIGNATIONS

σ is the dispersion of concentration;
t is the time, s;
C is concentration in the considered point;
C_{av} is the average concentration;
V is the volume of the mixing section, m^3;
S is the cross sectional area of the apparatus, m^2;
x is the longitudinal coordinate, m;
Q_1, Q_2 are the volume flow, m^3/s.

INTRODUCTION

The devices for the gas scrubbing from solid and liquid mechanic inclusions are important designing technological devices in chemical, gas and related branches of industry.
